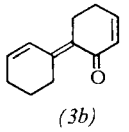
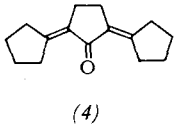
[a] Isolated.

[*] Dr. W. Fenzl and Doz. Dr. R. Köster
Max-Planck-Institut für Kohlenforschung
433 Mülheim/Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

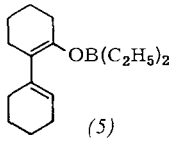


When heated to 50—70 °C in the presence of diethylboryl pivalate, triethylborane and diethyl ketone form *trans*-3-diethylboryloxy-2-pentene *(2a)*; 98% of ethane and only 2% of ethylene are evolved during the reaction (see Table).

Cycloketones having seven or more ring members also react with triethylborane under catalytic conditions to give diethylboryl cycloenolates and hardly any reduction products. Cyclododecanone affords exclusively a mixture of the two *cis/trans* isomers of diethylboryloxycyclododecene. Cycloheptanone, however, gives only 70% of diethylboryloxy-*cis*-cycloheptene alongside 30% of a $C_{14}H_{22}O$ ketone, a condensation product of two ketone molecules.



Methyl ketones and particularly acetone, as well as cyclic ketones having five- and six-membered rings (cyclopentanone, cyclohexanone, 2-cyclohexenone), react with triethylborane in the presence of diethylboryl pivalate to give only aldol condensation products. In contrast to the base-catalyzed aldol condensation[3] the yields can be as high as 95%. Compounds that are sensitive to air or to alkalis, *e.g.* the 6-(2-cyclohexenylidene)-2-cyclohexenones *(3a)* and *(3b)*, are also readily obtained. The condensations of cyclopentanone and cyclohexanone proceed particularly rapidly. The dimeric or trimeric condensation products,



(3a)

(3b)

(4)

(5)

formed according to the molar ratio ketone/triethylborane, are obtained free from boron [*e.g. (4)*] or as diethylboryl enolates [*e.g. (5)*].

(3a) and *(3b)*, as well as, *e.g.*, *(4)*, can also be diethylborylated at 80 °C. Methanolysis quantitatively regenerates the intact boron-free starting materials.

3-Diethylboryloxy-2-pentene (2a):

3-Pentanone (43 g, 0.5 mol) is added dropwise over 80 min 40—60 °C to boiling triethylborane (49 g, 0.5 mol) to which diethylboryl pivalate (2 ml) has been added. Evolution of gas occurs. The reaction mixture is then heated to about 100 °C for about 15 h and 12 l of gas containing (GC) 98% of C_2H_6 and 2% of C_2H_4 is collected. Vacuum distillation gives, after 9 g of fore-run up to 44 °C/15 torr, compound *(2a)* (61 g, 82%), b.p. 57—59 °C/15 torr, containing no other isomer; hardly any residue is left in the distillation flask. IR spectrum (neat liquid): 1680 cm^{-1} ($\nu_{C=C}$); ^{1}H-NMR spectrum (neat liquid): $\tau=5.41$ (vinylic H).

6-(2-Cyclohexylidene)-2-cyclohexenone (3a) and (3b):

2-Cyclohexenone (96 g, 1 mol) is added dropwise at 75 °C over about 6 h to triethylborane (123 g, 1.25 mol) to which diethylboryl pivalate has been added. 28 l of gas comprised of 98% C_2H_6 and 2% of C_2H_4 is liberated. After initial distillation of about 100 g of a mixture (triethyl-

borane and tetraethyl diboroxide) up to 42 °C/14 torr, a yellow liquid (83 g) of b. p. 71—80 °C/0.08 torr is obtained. Methanol (50 ml) is added and all volatile components (bath temperature up to 100 °C, pressure down to 14 torr) are distilled off to yield 74 g (85%) of a pale yellow equimolar mixture of *(3a)* and *(3b)* (GC, ^{1}H-NMR spectrum) of b. p. 73—74 °C/0.09 torr.

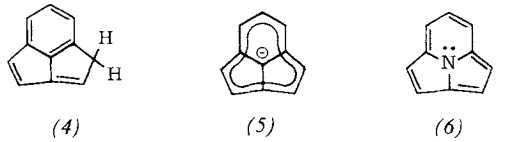
Synthesis of 1*H*-Cyclopent[*cd*]indene and its Anion[**]

By *Peter Eilbracht* and *Klaus Hafner*[*]

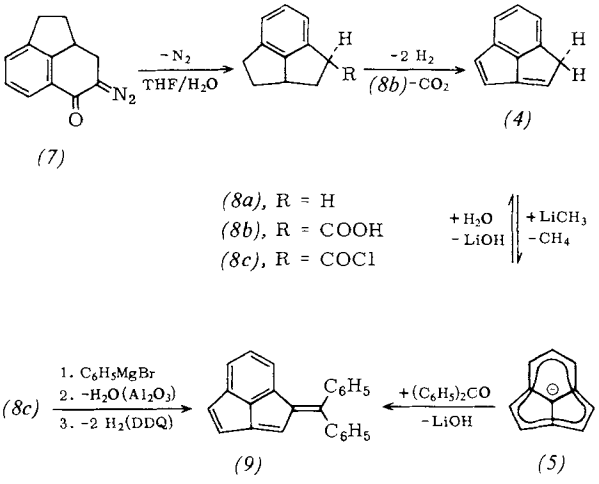


Dedicated to Professor Walter Franke on the occasion of his 65th birthday

In connection with studies of 2*H*-benz[*cd*]azulene *(1)*[1] and the strongly acidic fluoradene *(2)*[2] particular interest[2-6] attaches to the parent system of the latter, 2a*H*-cyclopent[*cd*]indene *(3)* and its 1*H*-isomer *(4)* as well as to their anion *(5)* which is isoelectronic with [3.2.2]cyclazine *(6)*[3].

According to quantum-chemical calculations by *Zahradník et al.*[4], the anion *(5)* containing twelve π-electrons should be electronically more stable than the corresponding cation. *Rapoport et al.*[2] and *Streitwieser Jr.*[6] postulated

(1) *(2)* *(3)*



(4) *(5)* *(6)*

that the acidity of 2a*H*-cyclopent[*cd*]indene *(3)* should be comparable with that of phenols. The 1*H*-tautomer *(4)* was not taken into account in these considerations.

In order to test these predictions experimentally we synthesized the lithium salt of *(5)*. *Rapoport et al.*[7] prepared the strained 2,2a,3,4-tetrahydrocyclopent[*cd*]indene *(8a)* and several of its derivatives by Pb salt distillation of 7-carboxy-1-indanacetic acid, but all attempts to introduce double bonds into *(8)* were unsuccessful.

By photolysis of 4-diazo-3,4-dihydro-5(2a*H*)acenaphthenone *(7)*[8] in tetrahydrofuran/water (5:1) with a Hg high-pressure lamp (Q 81, Quarzlampen-Gesellschaft Hanau) we prepared 2,2a,3,4-tetrahydrocyclopent[*cd*]indene-1-carboxylic acid *(8b)*[9] in 36% yield [colorless needles, m. p. 114 °C; UV spectrum (in *n*-hexane): λ_{max} = 217 (3.97), 269 (2.92), 276 (2.90) nm (log ε); NMR spectrum (in CCl_4): τ = −2.42 (1 H/s), 2.30—2.80 (3 H/m), 5.50 (1 H/dd, J = 5 Hz and J = 11 Hz), 6.30—8.50 (7 H/m)].

The acid *(8b)* can be dehydrogenated, with simultaneous decarboxylation, in the gas phase by 10% palladized charcoal at 480 °C in a high vacuum; the hydrocarbon *(4)* produced was isolated at −70 °C and, after chromatography on Al_2O_3 (activity 3, neutral) at −10 °C, was

obtained in 40% yield as a pale yellow oil that solidified at 0 °C and was very sensitive to autoxidation. The UV spectrum of *(4)* in *n*-hexane [λ_{max} = 251 (4.11), 254 (4.11), 273 (3.65), 309 (3.54), 316 (3.64), 330 (3.60) nm (log ε)] is similar to that of 1-isopropylideneindene[10]. The NMR spectrum of *(4)* (in CCl_4) contains, besides a resolved doublet (J = 1.5 Hz) centered at τ = 6.07 for the methylene protons at position 1, two multiplets centered at τ = 3.38 (2 H) and τ = 2.80 (4 H) due to the six further protons. The exclusive formation of *(4)* by the dehydrogenation of *(8b)*—the tautomer *(3)* could not be observed in the product—shows that the fulvenoid hydrocarbon *(4)* has an energy content lower than that of its tautomer 2a*H*-cyclopent[*cd*]indene *(3)*. Attempts to prepare the 1-carboxylic acid of *(4)* directly by *Wolff* rearrangement of 4-diazo-5(4*H*)-acenaphthylenone[11] have so far been unsuccessful.

Contrary to expectation, 1*H*-cyclopent[*cd*]indene *(4)* cannot be converted into its anion *(5)* either by methanolic NaOH or by sodium methoxide in methanol. However, treating *(4)* with methyllithium in tetrahydrofuran/ether (2:1) at −30 °C afforded the lithium salt of *(5)* as a thermally not very stable, red-orange compound, sensitive to autoxidation and hydrolysis, which was precipitated in crystalline form by *n*-hexane. The position and intensity of the long-wave band in the UV spectrum of the Li salt of *(5)* [in THF/ether (20:1) at −30 °C[12], λ_{max} = 338 (3.58), 346 (3.58), 354 (3.60), 458 (2.88) nm (log ε)] are in good agreement with SCF—CI calculations[14]. The NMR

Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Schlossgartenstrasse 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

spectrum (in THF at −55°C) shows, besides the two doublets of the two AB systems of the five-ring protons at $\tau = 3.15$ (H-2, H-3) and 3.65 (H-1, H-4) ($J = 4.0$ Hz), also a multiplet centered at $\tau = 2.70$ for the three six-ring protons. Hydrolysis of *(5)*, which regenerates *(4)*, also confirms the theoretical expectations[4], according to which position 1 or 4 should have a high electron density. In agreement therewith, reaction of *(5)* with benzophenone leads to thermally stable 1-(diphenylmethylene)cyclopent[*cd*]indene *(9)* [yellowish-orange prisms, m. p. 125°C (dec); UV spectrum (in *n*-hexane), $\lambda_{max} = 255$ (4.34), 310 (4.35), 352 (4.28) nm (log ε); NMR spectrum (in CCl_4), $\tau = 2.62$ (6 H/s), 2.66 (3 H/s), 2.70—3.70 (7 H/m)], which can also be obtained from *(8c)*[13] and phenylmagnesium bromide after subsequent dehydration and by dehydrogenation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in 30% yield.

Like the formation of *(4)* from *(8b)*, the hydrolysis of the Li salt of *(5)* which leads to *(4)* shows that *(4)* is energetically favored over *(3)*. Correspondingly, a higher total π electron energy was found by SCF—CI calculations[14] for the 1*H*-tautomer *(4)* than for the 2a*H*-tautomer *(3)*[15]. The unexpectedly low acidity of *(4)*, comparable with that of indene, probably represents a considerable difference of 1*H*-cyclopent[*cd*]indene *(4)* from its 2a*H*-tautomer *(3)* for which a p*K* value of 11 has been calculated[6]. This can probably be ascribed to a considerably lower gain of energy on conversion of the fulvenoid tricycle *(4)* into its anion *(5)* than in the corresponding deprotonation of the indene-like hydrocarbon. Also, the correlation obtained by *Streitwieser*'s method between acidity and the π-electron energy difference of anion and hydrocarbon leads to an appreciably lower p*K* value for *(4)* than for *(3)*. Attempts to convert the hydrocarbon *(4)* into its cation and radical are in progress.

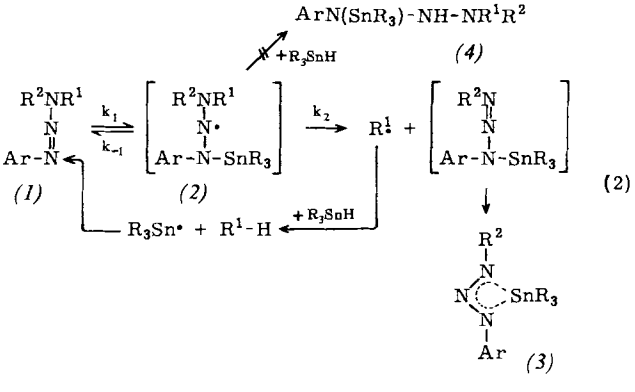
Free-Radical $S_H2\gamma$ Diplacement in the Triazene System[**]

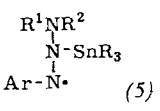


By *Jochen Hollaender* and *Wilhelm P. Neumann*[*]

The action of stannyl radicals $R_3Sn^{\bullet}$ on 1-aryl-3-alkyltriazenes *(1a)—(1c)* resulted in replacement of the arylazo group on N^3 by the stannyl group [eq. (1) and Table]. This $S_H2\alpha$ reaction corresponds to known types of displacement by free radicals[2–5].

(1)

Surprisingly, 1,3-displacement ($S_H2\gamma$) also occurs and predominates or becomes almost the only reaction when at least one of the groups R^1 and R^2 on N^3 forms a stable



(2)

free radical, *i. e.* when the dissociation energy of its bond to N^3 is lowered. Examples include R^1 = benzyl, triphenylmethyl, or trialkylstannyl [see *(1d)—(1i)*, eq. (2), and Table]. The stannyl radical attacks at N^1. The intermediate

[*] Dipl.-Chem. J. Hollaender [1] and Prof. Dr. W. P. Neumann

radical *(2)* rapidly undergoes the reverse reaction (k_{-1}) or elimination (k_2) to give pentacoordinated[6] *N*-stannyltriazene *(3)*. In any case, no stabilization products *(4)*, which could be formed from *(2)* through H-abstraction from the powerful radical scavenger present (organotin hydride), were detected. Attack on N^2 would lead to the intermediate

(5)

radical *(5)*, but no reaction products of this species were observed.

Initial attack by the stannyl radical on N^3 with subsequent 1,1-displacement of R^1 ($S_H2\alpha$) can also be ruled out since

Table. $S_H2\alpha$ and $S_H2\gamma$ reactions of aryltriazenes *(1)* (0.4 M in cumene at 80 °C) with $(C_2H_5)_3SnH$, molar ratio 1:4. Results after six hours' reaction. Catalyst: azoisobutyronitrile.

	(1) Ar	R^1	R^2	Yield (mol.-%) based on reacted *(1)* Ar—H eq. (1)	R^1—H eq. (2)
(a)	C_6H_5	C_2H_5	C_2H_5	100	0
(b)	C_6H_5	$-(CH_2)_5-$		100	0
(c)	p-$CH_3C_6H_4$	CH_3	C_6H_5	100	0
(d)	C_6H_5	$CH_2C_6H_5$	C_6H_5	13	87
(e)	C_6H_5	$CH_2C_6H_5$	$CH_2C_6H_5$	10	90
(f)	C_6H_5	$Sn(CH_3)_3$	$CH_2C_6H_5$	7	91 [a] / $2R^2H$
(g) [b]	C_6H_5	$C(C_6H_5)_3$	C_6H_5	7 [c]	93
(h)	C_6H_5	$Sn(CH_3)_3$	C_6H_5	2	98 [a]
(i) [d]	C_6H_5	NH_2	C_6H_5	61	[e]

[a] R^1—H is in equilibrium with *(1f)* or *(1h)* respectively.
[b] At 60 °C without catalyst.
[c] Benzene (Ar—H) is formed here from spontaneous decomposition of *(1g)*.
[d] In toluene at 20 °C without catalyst.
[e] NH_3 is formed. A quantitative determination has yet to be performed.

benzylaniline, diphenylbenzylamine, or *N*-benzylimidazole gives no toluene under the above conditions. Moreover, such an attack is unlikely in the case of the triphenylmethyl derivative *(1g)* for steric reasons.

It may be assumed that attack of the π system of the azo group also occurs as a competing reaction in the case of eq. (1) but remains very much in the background owing to a lack of readily replaceable groups R. This behavior of the N=N group would correspond to that of internal C=C groups[7].

The reactions depicted in eq. (1) and eq. (2) are greatly accelerated, or in some cases even made possible, at 80 °C by free radicals from azoisobutyronitrile or at 28 °C by UV irradiation (λ_{max} 254 nm).

The triazene system behaves here as a triaza analog of the allyl system and it is likely that the $S_H2\gamma$ reaction described above is possible with all allyl analogs, as we have actually observed with the allyl system itself[8]. A number of allyl displacement reactions proceed by the same mechanistic route[9], while various other free radical reactions[10] correspond to an $S_H2\beta$ mechanism.

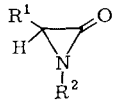
An α-Lactam Derived from 2-Adamantylamine[**]

By *Erach R. Talaty, James P. Madden*, and *Louis H. Stekoll*[*]

Several α-lactams having a *tertiary*-alkyl group attached to the nitrogen atom are known[1]. Attempts to prepare α-lactams with other types of alkyl substituents on nitrogen have been made, but such α-lactams have been reported to be either not formed or too reactive to be isolated[2]. We now report the isolation of an α-lactam, 1-(2-adamantyl)-3-(1-adamantyl)aziridin-2-one *(2a)*, which has a *secondary*-alkyl group attached to position 1, and is remarkably stable. Compounds of this type could also have potential applications in medicinal chemistry, since 1-adamantylamine and its derivatives have been reported to have antiviral activity[3].

R^1—CHR^2—CO—R^3 *(1)*
(a), R^1 = 1-adamantyl, R^2 = H, R^3 = Cl
(b), R^1 = 1-adamantyl, R^2 = Br, R^3 = Cl
(c), R^1 = 1-adamantyl, R^2 = Br, R^3 = NH-2-adamantyl



The acid chloride *(1a)* was treated with bromine in boiling carbon tetrachloride until conversion into *(1b)* was complete, and the crude reaction mixture was allowed to react with 2-adamantylamine to afford, in 71% over-all yield, the bromo-amide *(1c)*, m.p. 237.5—240.0 °C (decomp.) [NMR ($CDCl_3$, 60 MHz, δ-value in ppm relative to TMS): 6.60 (N—H/broad d, J = 8 Hz), 4.08 (1 H/s), 4.08 (1 H/broad d, J = 8 Hz), 2.26—1.44 (29 H/m); mass spectrum: *m/e* 407/405 (M^+), 326 (M^+—Br)]. Reaction of *(1c)* with potassium *tert*-butoxide in ether at 0 °C effected ring closure to the desired α-lactam *(2a)*, m.p. ≈225 °C (decomp.). However, in contrast with the preparation of α-lactams such as *(2b)*[4], where the ring-closure could be

[**] This work was supported by the Wichita State University Research Committee.

driven to completion by the use of an excess of base without the concomitant formation of other products, the present reaction required very careful control of the reagents and experimental conditions in order to achieve optimum conversions. The isolation of *(2a)* was accomplished only after fractional crystallization at low temperatures. The structure of *(2a)* is supported by spectral data [IR (CCl_4): $\nu \approx 1850\,cm^{-1}$; NMR ($CDCl_3$, 60 MHz, δ-value in ppm relative to TMS): 2.53 (H^3/s), 3.16 (1 H/broad s), *ca.* 2.4—1.4 (29 H/m); mass spectrum: *m/e* 325 (M^+)].

(2)

(a), R^1 = 1-adamantyl, R^2 = 2-adamantyl
(b), $R^1 = R^2$ = 1-adamantyl
(c), $R^1 = C_6H_5$, $R^2 = C(CH_3)_3$
(d), $R^1 = R^2$ = *tert*-alkyl

The thermal stability of the novel α-lactam *(2a)* is illustrated by the observation that its complete decomposition in boiling xylene (138 °C) at a concentration of 0.4 mmol/6 ml requires 1 h, whereas the complete decomposition of *(2b)* under the same conditions requires 3.5 h. The chemical stability of *(2a)* is equally remarkable: its complete decomposition in boiling methanol at a concentration of 1.5 mmol/10 ml occurs only after 1.75 h. By comparison, *(2b)* requires 30 h for complete decomposition under identical conditions, and *(2c)* is reported to decompose in methanol at 5 °C within 20 minutes[5]. Thus, the stability of *(2a)* is superior to that of *(2c)*[6] and approaches that of *(2d)*, the most stable class of α-lactams known so far.

CONFERENCE REPORTS

Reactions of Adamantanes and Their Derivatives in Sulfuric Acid

By *J. Schlatmann*[*]

Under suitable conditions 1-adamantanol can be converted into adamantanone in concentrated sulfuric acid. The key reaction is the reversible isomerization of 1- to 2-adamantanol; the equilibrium is much in favor of the 1-isomer. It has been proved that this isomerization occurs intermolecularly. The 2-adamantanol present in the reaction mixture is transformed into adamantanone by a hydride shift, the hydride acceptor being either the adamantanyl cation (yielding adamantane as a by-product) or the sulfuric acid. Adamantane is reconverted into 1-adamantanol by sulfuric acid; thus the synthesis of adamantanone can also be carried out from adamantane (yield *ca.* 50%).

Besides adamantanone, adamantanediols are formed from 1-adamantanol in sulfuric acid, presumably also in hydride shift reactions, with either the adamantanyl cation or the sulfuric acid as hydride acceptor. Although these are unimportant side products when the reactions are performed in concentrated sulfuric acid, conditions can be found in which the diol formation will be enhanced and the adamantanone formation suppressed because all these reactions are influenced differently by the concentration of the sulfuric acid. Thus in 20% fuming sulfuric acid the formation of the 1,3-, 1,4- and 2,6-adamantanediols predominates. After oxidation with chromic acid the components of the reaction mixture can be separated and 5-hydroxyadamantanone (yield *ca.* 50%) and 2,6-adamantanedione can be isolated in pure form.

Mechanism of Cyanation of Tertiary Amines[**]

By *Gabor Fodor* and *Shiow-yueh Abidi*[*]

We have been able to show that the von Braun cyanogen bromide degradation of tertiary amines proceeds by two successive steps:

[*] Prof. Dr. G. Fodor and Dr. Sh. Abidi
West Virginia University
Department of Chemistry
Morgantown, West Virginia 26506 (USA)

[**] This work is being supported by National Science Foundation, Grant GP-26558.

1. Electrophilic addition of a cyano group to nitrogen, giving an *N*-cyano ammonium salt in a reaction that is immeasurably fast even at −60 °C.

2. Attack by the bromide ion on a carbon atom attached to nitrogen, giving a cyanamide and RBr in a reaction whose rate is measurable between −30 and −9 °C.

NMR measurements on 1-cyano-*trans*-decahydro-1-methylquinolinium bromide show the second stage to be a reaction of the first order; it occurs ten times faster in $CDCl_3$ than in CD_3CN. The activation energy of decomposition amounts to 18 kcal/mol. On replacement of the bromide by a less nucleophilic (or non-nucleophilic) anion, *e.g.*, hexachloroantimonate, methanesulfonate, *p*-toluenesulfonate, or tetrafluoroborate, stable quaternary *N*-cyano ammonium salts can be isolated for the first time, analyzed, and subjected to examination of their chemical behavior.

Recently also we have been able to trap the adduct formed from methyl chloroformate and *trans*-decahydro-1-methylquinoline at low temperature and to stabilize it as fluoroborate.

To determine the stereochemistry of the *N*-isomeric products obtained we have separated them as fluoroborates and are presently studying (a) their nuclear Overhauser effect at 250 MHz and at 100 MHz, (b) their ^{13}C-NMR spectra, and (c) the structure of the major product by X-ray methods.

Lectures at Darmstadt on May 26, 1971, München on June 4, 1971, and at Erlangen on June 7, 1971 [VB 310 IE]
German version: Angew. Chem. *83*, 732 (1971)

Synthesis and Structure of Haloamines

By *Jochen Jander, Klaus Knuth, Rolf Minkwitz*, and *Werner Renz*[*]

The lecture concerned, *inter alia*, the synthesis and solid-state FIR-spectroscopic study of the structure of $NI_3 \cdot 3NH_3$ *(1)*, the so-called $NH_2I \cdot NH_3$ *(2)*, the so-called NH_2I *(3)* [better formulated, in view of the results below, as $NI_3 \cdot \sim 5NH_3$ *(2)* and $NI_3 \cdot \sim 2NH_3$ *(3)*, respectively] as well as of the *N*-iodomethylamines $CH_3NI_2 \cdot CH_3NH_2$ *(4)*, $CH_3NI_2 \cdot Py$ *(5)*, $CH_3NI_2 \cdot (CH_3)_3N$ *(6)*, CH_3NI_2 *(7)*, and $(CH_3)_2NI$ *(8)*. The NI_3 adducts were obtained by treatment of ICl or I_2 with NH_3 in aqueous solution or with liquid NH_3; $(NI_3 \cdot NH_3)_n$ can be used as iodinating agent, as well as ICl or I_2, for preparation of the *N*-iodomethylamines[1]. Because of their sensitivity, compounds *(1)*—*(4)* and *(7)*—*(8)* can be studied only at low temperatures; this was possible by use of a new low-temperature measurement technique.

The glittering green *(1)*, the pale red *(2)*, and the black *(3)* contain the same polymeric structure as $(NI_3 \cdot NH_3)_n$ consisting of NI_4 tetrahedra joined by common iodine atoms[2–4]; differences were found as follows:

[*] Prof. Dr. J. Jander and Dr. K. Knuth
Anorganisch-Chemisches Institut der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)
Dr. R. Minkwitz
Institut für Anorganische Chemie der Freien Universität
1 Berlin 33, Fabeckstrasse 34–36 (Germany)
Dr. W. Renz
Farbwerke Hoechst AG.,
8261 Gendorf/Obb. (Germany)

(1) and *(2)* bind more NH_3 than $(NI_3 \cdot NH_3)_n$ and, because the contact sites are occupied by NH_3, they contain no I—I contacts between the tetrahedron chains as $(NI_3 \cdot NH_3)_n$ does; *(2)* and *(3)*[5] are amorphous to X-rays and thus contain only ill-developed and possibly shorter tetrahedron chains than $(NI_3 \cdot NH_3)_n$.

The reddish-yellow *(4)*, the brick-red *(5)*, the orange *(6)*, and the reddish-brown *(7)* are also polymeric and consist of NI_3C tetrahedron chains which either, as in *(7)*, use the iodine atoms that are not part of the chain for binding by I—I contacts or, as in *(4)*—*(6)*, for binding the nitrogen base. This result has been confirmed for *(5)* by X-ray investigations.

The yellow *(8)* is probably monomeric; two very long-wave FIR bands $< 100\ cm^{-1}$ can be interpreted either as lattice vibrations or as very weak intermolecular N—I contacts, *i.e.* as a precursor of a stable tetrahedron chain.

Lecture at Aachen on June 8, 1971 [VB 311 IE]

Molten Salts at High Pressures and High Temperatures

By *Klaus Tödheide*[*]

The macroscopic properties of molten salts cannot yet be calculated from the properties of the ions and molecules by means of statistical mechanics. Thus models for molten salts have been developed in order to enable interpretations of experimental results as well as predictions, where experimental information is missing. For the purpose of testing the capability of these models to describe the density dependence of macroscopic properties of molten salts correctly, experiments at high pressures are necessary. It is only in recent years that the first investigations of this type have been performed.

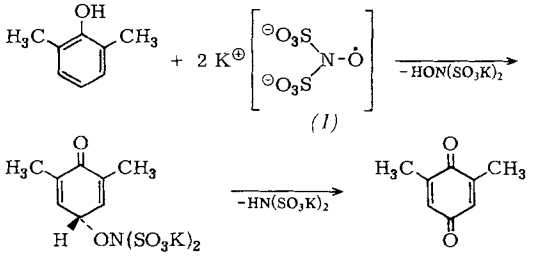
The specific conductivity of the molten alkali metal nitrates has been measured up to 60 kbar. In the region of low and medium pressures (for $NaNO_3$ up to about 20 kbar) straight lines were obtained for the logarithm of the specific conductivity as a function of pressure and as a function of the reciprocal absolute temperature. From the slopes of these lines, and from experimentally determined PVT data, the activation volumes and activation energies for the equivalent conductivity have been calculated. The activation volume increases from $0.7\ cm^3/mol$ for $LiNO_3$ to $8.0\ cm^3/mol$ for $CsNO_3$, while the isochoric activation energy decreases from 3.5 to 1.4 kcal/mol. The ratio of the isochoric to the isobaric activation energy decreases from 0.97 for $LiNO_3$ to 0.36 for $CsNO_3$. This result indicates

[*] Dr. K. Tödheide
Institut für Physikalische Chemie und Elektrochemie
der Universität
75 Karlsruhe, Postfach 6380 (Germany)

that for the charge transport process at constant pressure very little energy is required for the volume expansion in $LiNO_3$, whereas with $CsNO_3$ almost two thirds of the total isobaric activation energy is needed for this purpose.

The experimental results cannot be interpreted quantitatively in terms of any of the molten salt models. They are, however, in qualitative agreement with the "density fluctuation hole" model developed by *Fürth*. In this model the formation of holes of about the size of the ions by density fluctuations has a dominating influence on the rate determining step of the charge transport process.

If the molten alkali metal nitrates are compressed to densities higher than that of the corresponding solid phase, the activation volume decreases over a small pressure range to half its original value, whilst the activation energy increases considerably. The transition occurs at about 22 kbar for $NaNO_3$ and as low as at about 14 kbar for KNO_3, but was not observed in the whole pressure range covered for $LiNO_3$ with its relatively small cation. This result also agrees with the "hole" model, since at such high densities no holes are formed which are sufficiently large for the bigger ions.



For glass-forming molten salts the models of *Cohen* and *Turnbull* and of *Adam* and *Gibbs* are better suited to describe the pressure and temperature dependence of the electrical conductivity, especially in the low temperature range.

At supercritical temperatures, where the density can continuously be varied from that of a dilute gas to that of a liquid, the transition from a non-conducting vapor to an ionically conducting dense fluid phase may be investigated as a function of the average distance between the particles at constant temperature. This has been done by measuring the specific conductivity and the density as functions of pressure and temperature. Measurements on $BiCl_3$, whose critical temperature is 905 °C, demonstrated that the molar conductivity increases with density by four to five orders of magnitude mostly within a narrow interval around the critical density.

Lecture at Göttingen (Germany) on June 10, 1971 [VB 312 IE]
German version: Angew. Chem. *83*, 768 (1971)

SELECTED ABSTRACTS

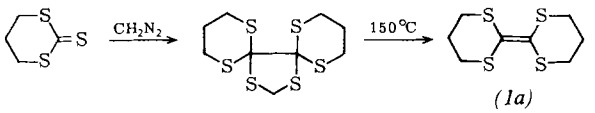
Oxidations with potassium nitrosodisulfonate (*Fremy*'s radical) *(1)* are summarized by *H. Zimmer, D. C. Lankin,* and *S. W. Horagen. (1)* is a specific oxidizing agent that converts phenols and secondary amines into quinones. With more complicated structures such as indole and carbazole derivatives, quinone formation is accompanied

by dehydration and coupling. [Oxidations with Potassium Nitrosodisulfonate (*Fremy*'s Radical). The Teuber Reaction. Chem. Rev. *71*, 229—246 (1971); 84 references, 11 tables, numerous formulas]

[Rd 386 IE -M]

Direct liquid-phase fluorination of organic compounds is reviewed, with particular reference to the author's own studies, by *V. Grakauskas.* A discussion of experimental technique is followed by examples of fluorination of organic nitrogen compounds (ureas, carbamates, guanidine derivatives, amides), alkali metal salts, aliphatic nitro compounds, primary nitramines, and carboxylic acids in aqueous solution and aromatic hydrocarbons. [Direct Liquid Phase Fluorination of Organic Compounds. Intra-Science Chem. Reports *5*, 85—104 (1971); 94 references, numerous formulas]

[Rd 387 IE -M]



Properties and uses of trifluoroacetic anhydride constitute the subject matter of an article by *R. E. A. Dear.* Space is devoted to physical and chemical properties such as esterification, trifluoroacetylation, electrophilic substitution of aromatic compounds, as well as acylation of aliphatic compounds with trifluoroacetic anhydride, rearrangements promoted by trifluoroacetic anhydride, and a number of other reactions of trifluoro- and chlorodifluoroacetic anhydride. The report closes with safety measures recommended for handling the reagent and toxicity data. [Trifluoroacetic Anhydride: Properties and Uses. Intra-Science Chem. Reports *5*, 37—53 (1971); 118 references, numerous formulas]

[Rd 388 IE -M]

New syntheses of organic sulfur compounds suitable for industrial use are considered by *F. Becke* in a review article. Particular attention is devoted to the reactions of sulfur with organic halo compounds: Reactions with hexachlorocyclohexane; mechanism of the "sulfur reaction"; reactions with aliphatic chlorides, with phosphorus-nitrogen compounds, and with benzisothiazoles; formation of heterocyclic compounds containing no sulfur is also mentioned. [New Syntheses of Organic Sulfur Compounds which Are Suitable for Industrial Purposes. Internat. J. Sulfur Chem. *6*, 77—83 (1971); 19 references, formulas]

[Rd 389 IE -M]

Synthetic routes to tetrathioethylenes *(1)*, and especially the highly effective new technique of orthothiooxalate pyrolysis, represent the body of a review by *D. L. Coffen, J. Q. Chambers, D. R. Williams, P. E. Garret,* and *N. D. Canfield.* The electrochemical properties of characteristic tetrathioethylenes were also studied. The UV spectra of these compounds can be explained by EHT calculations

(1a)

including 3d orbitals of the sulfur. The chemistry of *(1)* deviates from that of "electron-rich olfins". Syntheses *via* carbenes are also successful. [Tetrathioethylenes. J. Amer. Chem. Soc. *93*, 2258—2268 (1971); 70 references, numerous formulas]

[Rd 390 IE -M]

Kinetic data for abstraction of hydrogen and deuterium by methyl and trifluoromethyl radicals in the gaseous phase have been collected by *P. Gray, A. A. Herod,* and *A. Jones.* The reaction can be represented formally by

$$R + XH \longrightarrow RH + X$$
$$R + XD \longrightarrow RD + X$$

R = methyl, trifluoromethyl; X = free radical or atom

The review encompasses: Experimental methods and elementary theoretical considerations; abstraction from H_2, HD, D_2, from CH and CD, NH and ND, OH and OD, and SH and SD bonds, as well as from members of isoelectronic series; attack by free radicals at specific positions of the molecule; comparison of reactivity of methyl and trifluoromethyl radicals; and isotope effects in abstraction reactions. [Kinetic Data for Hydrogen and Deuterium Atom Abstraction by Methyl and Trifluoromethyl Radicals in the Gaseous Phase. Chem. Rev. *71*, 247—294 (1971); 230 references, 48 tables, numerous formulas]

[Rd 392 IE -M]

Photoelectron spectroscopy in chemistry is the subject of a report by *S. D. Worley.* This new technique is based upon measurement of the energies of photoelectrons emitted by molecules on irradiation with ultraviolet light. A review of theoretical principles is followed by a discussion of the photoelectron spectra of many polyatomic molecules. Examples include alkanes, alkenes, alkynes, cyclic hydrocarbons, azabenzenes and azanaphthalenes, metal carbonyl compounds, furans, pyrroles, thiophenes, amines, hydrazines, alcohols, aldehydes, ketones, acids, ethers, and oxides, as well as compounds containing B, P, As, and S. [Photoelectron Spectroscopy in Chemistry. Chem. Rev. *71*, 295—314 (1971); 187 references, 2 tables, numerous formulas]

[Rd 393 IE -M]

Syntheses and chemical properties of heterocyclic systems bearing phosphorus substituents are summarized by *Derek Redmore* in a review covering the topic up to September 1970. The compounds considered contain phosphorus bonded to a C atom of the heterocyclic system. In the light of general synthetic methods, the author discusses nucleophilic displacements on the phosphorus by heterocyclic organometallic compounds, nucleophilic displacements by phosphorus nucleophiles, nucleophilic addition reactions, cycloaddition reactions, condensation reactions, free-radical reactions, as well as electrophilic substitution by phosphorus. [Heterocyclic Systems bearing Phosphorus Substituents. Synthesis and Chemistry. Chem. Rev. *71*, 315—337 (1971); 154 references, 12 tables, numerous formulas]

[Rd 394 IE -M]

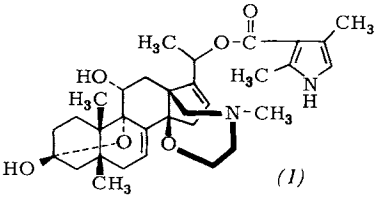
Reaction of carboxylic esters with sodium in presence of trimethylchlorosilane *(1)* in inert solvents is reviewed by *K. Rühlmann.* Compound *(1)* traps all basic products of Bouveault-Blanc condensation so that the reaction mixture remains neutral and base-catalyzed side reactions (β-elimination, Claisen and Dieckmann condensation) no longer occur. The bis(siloxy)alkenes *(2)* formed by C—C linkage can be isolated, converted into acyloins by acid hydrolysis or alcoholysis, or used *in situ* for further reactions. Alkoxysilanes such as *(3)* occur as minor products.

$$2\ R^1\text{-}COOR^2 + 4\ Na + 4\ Cl\text{-}SiMe_3 \longrightarrow$$
(1)

$$R^1\text{-}C(\text{=}C\text{-}OSiMe_3)\text{-}R^1 + 2\ R^2\text{-}OSiMe_3 + 4\ NaCl$$
(2) *(3)*

Dicarboxylic esters afford 1,2-bis(siloxy)-1-cycloalkanes instead of *(2)*. [Die Umsetzung von Carbonsäureestern mit Natrium in Gegenwart von Trimethylchlorsilan. Synthesis *1971*, 236—253; 125 references, 14 tables, numerous formulas]

[Rd 395 IE -M]



Chemistry of optically active sulfur compounds having S as active center are dealt with in a review by *A. Nudelman.* The article embraces sulfoxides (stereospecific synthesis, resolution, racemization, spectral studies, reactions, steroidal and penicillin sulfoxides), sulfinates, sulfonium salts, sulfonium ylides, oxosulfonium methylides, complex sulfonium salts, sulfinamides, sulfilimines, sulfoximines, sulfites, thiosulfinates, sulfinimidoates, sulfinimide amides, sulfonimide amides, [^{16}O, ^{17}O]sulfones and -sulfonates, as well as sulfinic acids. [The Chemistry of Optically Active Sulfur Compounds. Internat. J. Sulfur Chem. *6*, 1—39 (1971); 234 references, numerous formulas]

[Rd 396 IE -M]

Stereochemistry of organic sulfur compounds is reviewed by *K. K. Anderson.* Since the S atom can accommodate up to six ligands and 12 electrons in its valence shell, the possible structures are legion. Examples of tricoordinate S^{IV} compounds include sulfonium salts, sulfoxides, and sulfilimines. Representatives of tetracoordinate S^{VI} compounds are sulfones and sulfoximines. [Stereochemistry of Organic Sulfur Compounds. Internat. J. Sulfur Chem. *6*, 69—76 (1971); 56 references, numerous formulas]

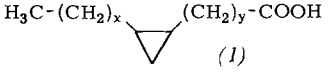
[Rd 397 IE -M]

Chemistry and pharmacology of batrachotoxin *(1)*, a steroidal alkaloid from the poison arrow frog *Phyllobates aurotaenia,* is reviewed by *E. X. Albuquerque, J. W. Daly,* and *B. Witkop.* Compound *(1)* exerts novel, selective effects on electrogenic membranes. In many cases the action can be explained in terms of an irreversible increase in permeability to Na^+ ions. The subsequent reactions promoted by *(1)* can be blocked reversibly by tetrodo-

(1)

toxin. [Batrachotoxin: Chemistry and Pharmacology. Science *172*, 995—1002 (1971); 33 references, 3 tables, 9 figures]

[Rd 398 IE –M]



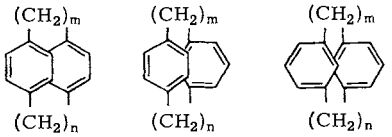
Monosubstituted diazenes (diimides) R—N=NH are considered by *E. M. Kosower*, particular attention being paid to the author's own studies. The chemical possibilities presented by monosubstituted diazenes will become clear in further work. Diazenes are reactive, readily accessible intermediates that can decompose, *inter alia*, *via* free radicals or carbanions. The article embraces: Synthesis (by fragmentation, decarboxylation, ester elimination, aldehyde elimination, oxidation, reduction); physical and chemical properties; bimolecular reactions; chemical and biological significance of diazenes. [Monosubstituted Diazenes (Diimides). Surprising Intermediates. Accounts Chem. Res. *4*, 193—198 (1971); 44 references, 3 tables, numerous formulas, 1 figure]

[Rd 399 IE –M]

Comparative pharmacology of indole alkaloids and their derivatives, which act upon the cerebral blood circulation and the metabolism of nervous tissues, is surveyed by *M. Aurousseau*. The compounds are of considerable importance in the treatment of the steadily increasing number of cases of damage to cerebral blood vessels. The author deals with the following groups of compounds: Rauwolfia alkaloids (reserpine group, ajmalicine group); ergot alkaloids; *Vinca minor* alkaloids (vincamine). [Pharmacologie comparée des alcaloides indoliques et de leur dérivés agissant sur la circulation cérébrale et le métabolime de tissu nerveux. Chimia therapeutica *6*, 221—234 (1971); 104 references, 16 tables and figures]

[Rd 400 IE –M]

Biosynthesis of cyclopropane rings is summarized by *J. H. Law*. Naturally occurring fatty acids *(1)*, amino acids, terpenes, and sterols containing cyclopropane rings have all become known. The CH_2 unit which forms the three-membered ring with a C=C double bond comes from *S*-adenosylmethionine. Cyclopropane synthetase from *Clostridium butyricum* catalyzes the biosynthesis of fatty acids



(1)

having cyclopropane rings; a phosphatidylethanolamine was found to be a good substrate. [Biosynthesis of Cyclopropane Rings. Accounts Chem. Res. *4*, 199—203 (1971); 45 references, 2 tables, selected formulas]

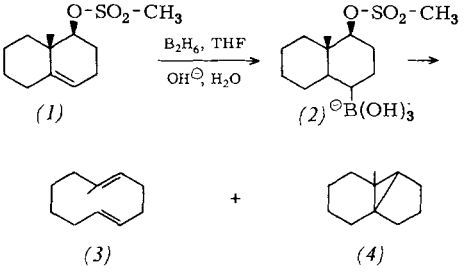
[Rd 401 IE –M]

Recent studies on [*m.n*]cyclophanes are discussed by *D. J. Cram* and *J. M. Cram*, particular emphasis being placed on systems having m and $n \leq 3$. These compounds *(1)*—*(3)* (para-, metapara-, and metacyclophane) differ considerably from their open-chain analogs. Bent benzene rings and abnormally small ring-ring distances number among the

(1) *(2)* *(3)*

characteristic features of these highly strained molecules. The consequences of this structure include sterically hindered rotation of the rings, transannular effects, and unexpected chemical reactions. [Cyclophane Chemistry: Bent and Battered Benzene Rings. Accounts Chem. Res. *4*, 204—213 (1971); 41 references, numerous formulas]

[Rd 402 IE –M]



Paramagnetic probes for NMR relaxation studies of phosphoryl transfer enzymes are reported by *M. Cohn* and *J. Reuben*. The technique is made possible by the fact that enzymatic reactions of nucleoside triphosphates of the type

$$ATP^{4-} + XH \rightleftharpoons ADP^{3-} + XPO_3^{2-} + H^+$$

require divalent metal ions that can be replaced, *e.g.*, by the paramagnetic Mn^{2+} ion. NMR relaxation and ESR studies of this kind reveal quantitative information about configuration and dynamics of the active site of an enzymatic system in solution which could not be obtained otherwise. [Paramagnetic Probes in Magnetic Resonance Studies of Phosphoryl Transfer Enzymes. Accounts Chem. Res. *4*, 214—222 (1971); 54 references, 5 figures, 1 table]

[Rd 403 IE –E]

The synthesis of 1,5-dienes and 1,5- and 1,6-cyclodecadienes by solvolytic cleavage of intermediate borinic acid derivatives such as *(2)* is reviewed by *J. A. Marshall*. Particular attention is devoted to 1,5-dienes that participate, *e.g.*, in

(1) *(2)* *(3)* *(4)*

the biosynthesis of terpenes. Conversion of the sulfonate *(1)* by diborane into the product *(2)*, which is subsequently subjected to alkaline solyolysis to give 1-methyl-1,5-cyclodecadiene *(3)* and the tricyclic compound *(4)* (97:3), represent a typical example. [Diene Synthesis *via* Boronate Fragmentation. Synthesis *1971*, 229—235; 31 references, 1 table, numerous formulas]

[Rd 405 IE –L]

Electroorganic synthesis is the topic of a review by *S. Wawzonek*. Anions, radical anions, radicals, radical cations, and carbonium ions can be produced from organic compounds by direct electron transfer; these species can then react with one another, with the solvent, with the electrodes, or with added compounds to form isolable products. A brief introduction to theory and a description of equipment are followed by numerous examples of applications supplemented by experimental procedures. [Electroorganic Syntheses. Synthesis *1971*, 285—301; 137 references, 5 figures, 1 table, numerous formulas]

[Rd 406 IE –L]

The spectra of simple molecular ions in the gaseous phase are surveyed by *G. Herzberg*. Spectra of this kind permit an insight into the electronic structure, and thus into the bonding, of the corresponding neutral molecules. Experimental methods for production of molecular ions are considered first, and their emission, absorption, photoelectron, and fluorescence spectra are then discussed. Molecular ions have also been detected in planetary atmospheres and in interstellar gas. [Spectra and Structure of Molecular Ions. Quart. Rev. Chem. Soc. *25*, 201—222 (1971); 52 references, 23 figures]

[Rd 407 IE–K]

NMR studies of molecular relaxation processes in solid polymers are described by *D. W. McCall*. A discussion of theoretical principles is followed by a wealth of examples of applications. Thus the method can be used to follow the movements of several different side chains, special movements of the main chain in crystalline polymers, and processes occurring near the glass transition temperature. [Nuclear Magnetic Resonance Studies of Molecular Relaxation Mechanisms in Polymers. Accounts Chem. Res. *4*, 223—232 (1971); 46 references, 17 figures]

[Rd 404 IE–E]

BOOK REVIEWS

Catalytic Processes and Proven Catalysts. By *C. L. Thomas*. Academic Press, New York—London 1970. xiii, 284 pp., 19 tab., bound, $ 12.50.

Thanks to his long years of service as a scientific advisor to the Sun Oil Company, the author has a wealth of experience in the operation of commercial catalytic processes. He has now done us the service of setting this experience down in book form, for the first time making publicly available proprietary information which in many cases was previously jealously guarded.

The book includes descriptions of a large number of catalytic reactions, arranged by reaction type. They include oxidation, hydrogenation, dehydrogenation, dehydration, alkylation, isomerization, cracking and reforming, polymerization, ammonia and methanol synthesis, synthesis gas and hydrogen production, and gas purification processes. Proven catalysts are described for each reaction, and their advantages and disadvantages are discussed; commercial catalysts are also described, but only those from American manufacturers. In addition, the book contains data on the most favorable operating conditions, particularly temperature and concentrations, the space-velocity, and the catalyst lifetime. There is also information on the various types of reactors, the handling of catalysts, catalyst poisons, and the regeneration (especially by eliminating carbon deposits) of inactivated catalysts. In conclusion, there is a section on carriers.

The book is not intended as a textbook, but it can be used as a guide or collection of formulations, which should be particularly pleasing to practising chemists and chemical engineers, who will find it a valuable aid in the solution of catalyst problems.

E.-G. Schlosser [NB 989 IE]

Catalyst Handbook. Wolfe Scientific Books, London 1970. 1st ed., 231 pp., 81 figs., 16 tab., £ 3.15.

This book, specifically concerned with unit processes encountered in the manufacture of ammonia and hydrogen, deserves attention for two reasons. In the first place, it contains a number of full yet concise explanations of the fundamentals of heterogeneous catalysis, which justifies its description as a "handbook". But secondly, and what is more important, it aims to provide the catalyst user with a wealth of important practical information, all of which was specifically obtained on the range of catalysts distributed by ICI.

Many well-known scientists, including *S. P. S. Andrew*, *G. W. Bridger*, *J. S. Campbell*, *G. C. Chinchen*, *P. Craven*, *D. A. Dowden*, *D. R. Goodman*, *J. J. Phillipson*, *C. B. Snowdon*, *W. Spendley*, and *P. W. Young*, have collaborated in the preparation of this book. The questions of catalyst activity, selectivity, and lifetime, of decisive importance in all processes, are dealt with thoroughly by all the authors, and run as an underlying theme throughout the book. The specific reactions described are the desulfurization of hydrocarbons, hydrocarbon-reforming, removal of carbon monoxide, and ammonia synthesis. In each case the various methods used, the selection of catalyst, the reaction mechanism, and the kinetics are described; mention is also made of problems concerned with the need to use certain feedstock blends and to control catalyst poisons. One section is devoted to the testing and another to the practical handling of catalysts. In addition, computer programs for converter calculations are included. An extensive tabular appendix contains data on ICI catalysts, substance properties, and gas-phase equilibrium constants, together with examples of calculations.

This book is an important reference work for the plant designer and chemical engineer and is highly recommended.

E.-G. Schlosser [NB 988 IE]

Technique of Organic Chemistry. Edited by *A. Weissberger*. Vol. IX/Part 2: Microwave Molecular Spectra. By *W. Gordy* and *R. L. Cook*. Interscience, New York 1970, 2nd Edit., 747 pp., bound, *ca.* DM 139.—[1].

In recent years, microwave spectroscopy has progressed in measuring technique, theory, and evaluation technique to such a degree that this method is applicable to a series of problems that face the chemist. It provides the most precise geometrical data on molecules, allows the study of conformation equilibria, rearrangements, and short-lived intermediates, is suitable for qualitative and quantitative analyses, and provides information about the electronic structure. Microwave spectroscopy was formerly

[1] Cf. Angew. Chem. internat. Edit. *6*, 1092 (1967).

discussed in "Weissberger" in short chapters (*Gordy*, 1956; *Dailey*, 1960); an entire volume is now devoted to this method. It is a revised version of a book by *Gordy*, *Smith*, and *Trambarulo*, which was published by Wiley in 1953.

Contents: Introduction, Theoretical Aspects of Molecular Rotation; Microwave Transitions – Line Intensities and Shapes; Diatomic Molecules; Linear Polyatomic Molecules; Symmetric-Top Molecules, Asymmetric-Top Molecules; Centrifugal Distortion; Nuclear Hyperfine Structure in Molecular Rotational Spectra; Effects of Applied Electric Fields; Effects of Applied Magnetic Fields; Internal Rotation; Derivation of Molecular Structures; Quadrupole Couplings, Dipole Moments, and the Chemical Bond. The mathematical methods that are important to interpretation are described and physical data are given in ten appendices covering 92 pages; special mention should be made of the table of molecular structure data established up to 1969.

The fundamental principles of all microwave transitions (nuclear magnetic resonances, electron spin resonances) are discussed; the application examples are concerned mainly with the rotational spectra of gaseous molecules. Instruments and measuring techniques are not described. The intention of the authors was to write a textbook *and* handbook for chemists, in which the theory is developed "from the simplest approach consistent with essential correctness and applicability". They have succeeded well in this aim. The printing and presentation are also outstanding.

Bernhard Schrader [NB 975 IE]

Elements of Chemical Kinetics. By *M. Prettre* and *B. Claudel*. Documents on Chemistry, Vol. 1. Gordon and Breach, Scientific Publishers, London 1970. 1st ed., xvi, 184 pp., bound, $ 18.—.

The purpose of this new series, "Documents on Chemistry", is to bring together the various aspects of chemistry that are often widely separated in more conventional presentations. Since it is intended to publish extensive original papers and specific seminars for advanced students in both French and English, the widest possible circle of readers should be reached. The first volume is concerned with elementary chemical kinetics and is mainly limited to reactions connected with the conversion of covalent bonds in simple molecules. In the first 93 pages concepts such as the rate and order of a reaction, activation energy, activated complexes, photochemical reactions, and chain reactions are explained by means of examples. The authors use a minimum of formal mathematics, but are also rather sparing with their illustrations. The second part contains descriptions of catalytic reactions, including acid-base catalysis, adsorption of molecules on solid surfaces, and the related contact catalysis, and there is even a very brief look at the *Michaelis-Menten* enzyme catalysis. Finally, the significance of kinetic problems in the optimization of syntheses under both laboratory and industrial conditions is discussed. At the end of each chapter there are simple numerical exercises and a few literature references, mostly of historical interest.

The book can be used as a first introduction to the problems and terminology of chemical kinetics, and is rather more detailed and less general than the corresponding sections in most of the physical chemistry textbooks. The few printing errors in the English edition are not a serious drawback. However, the phenomenological presentation and the selection of the material (and the price) are hardly likely to arouse any particular enthusiasm in chemistry students for this subject.

F. M. Pohl [NB 985 IE]

Carbenes, Nitrenes and Arynes. By *T. L. Gilchrist* and *C. W. Rees*. Thomas Nelson and Sons Ltd., London 1969. 1st ed., 131 pp., bound, $ 21.—.

A number of review articles and monographs have appeared in recent years on carbenes, nitrenes, and arynes. The present book is the first attempt to give a comprehensive picture of a field of research in which so much work has been done.

Chapter 1 indicates the relationships between carbenes, nitrenes, and arynes. Chapters 2—4 deal with the preparation and Chapters 5—8 with the reactions of these compounds. Finally, Chapter 9 shows their preparative applications.

In their introduction the authors express their intentions of taking the fullest possible account of recent work (the literature is covered up to 1968) and of providing a general survey rather than an exhaustive treatment. These intentions have certainly been realized, but they require a rigid selection of the individual reactions, so that many of them are given very brief treatment. This is particularly true of the Wolff rearrangement, described on p. 77. For example, the occurrence of ketocarbenes is stated to be improbable, and yet recent work suggests that they are found at any rate in photolytic reactions. Chapter 9 on the range of uses of carbenes, nitrenes, and arynes in syntheses could also be expanded a little. The book contains very few factual errors (pp. 11, 61, 62, 63, 106, and 108) and is practically free from printing errors.

The text is written in a very clear and understandable style. Most of the chapters contain references to the most important literature on the individual reactions. All in all, it is well worth the money, and can be recommended both to advanced students and to anyone who wants to become acquainted rapidly with the field concerned.

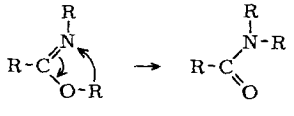
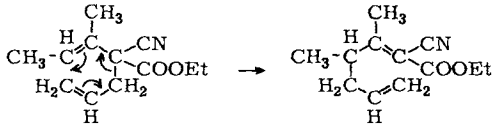
Aromaticity and Pericyclic Reactions



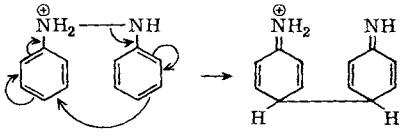
By Michael J. S. Dewar[*]

Pericyclic reactions formally resemble the conversion of one Kekulé structure into another; the transition state may be "aromatic", "nonaromatic", or "antiaromatic". Thermally induced pericyclic reactions proceed preferentially via aromatic transition states whereas their photochemical counterparts lead to products that are formed via antiaromatic transition states.



1. Introduction

For half a century organic chemists have recognized the possibility that certain reactions and molecular rearrangements might take place by a mechanism involving the concerted cyclic permutation of bonds round a ring of atoms. In the era of the classical electronic theory of *Lapworth* and *Robinson*[1] and *Ingold*[2], such mechanisms were proposed for a number of reactions using the current curved arrow symbolism to represent the displacement of electron pair bonds. The following are typical examples, involving rings of various sizes:



The isoamide-amide rearrangement[3]

The Cope rearrangement[4]

The benzidine rearrangement[5]

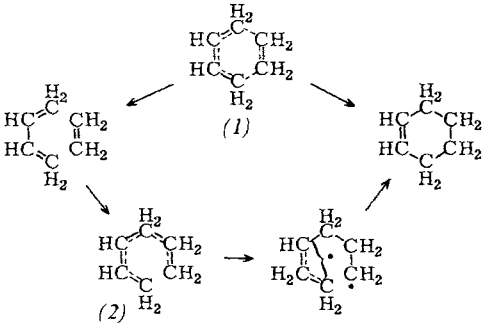
However, although the possibility of such processes, which *Woodward* and *Hoffmann*[6] have termed *pericyclic*, was recognized at an early date, it is only in the last ten years that they have become a matter of major concern to organic chemists. There are three reasons for this.

First, reactions of this type present very difficult mechanistic problems, so much so that *Doering*[7] suggested the term "no mechanism reaction" for them. It is only recently that suitable experimental techniques (*e.g.* the analysis of secondary isotope effects) have been developed for their study.

Secondly, the earlier examples were rather featureless and limited in scope; the development of modern analytical techniques, in particular GLC and NMR spectroscopy, has suddenly opened up a field (*i.e.* nonionic thermal rearrangements) in which interesting pericyclic mechanisms abound.

Thirdly, under the stimulus of this new information, *Woodward* and *Hoffmann* formulated a set of rules[6] which systematized it in a very satisfactory manner.



There can be no question concerning the value of the contribution by *Woodward* and *Hoffmann* in the formulation and application of these rules. Their work has brought order into a new and active field and has also led to the discovery of many interesting new reactions. Rules of this kind can of course be of value regardless of their origin; resonance theory provides a good example, the corresponding rules having been used successfully for many years by organic chemists with little understanding of their theoretical basis. On the other hand the analogy of resonance theory also shows the dangers inherent in this course; the literature is full of errors arising from the uninformed use of resonance theory.

Resonance theory also illustrates a third point; the success of a rule is no justification for the particular theoretical approach used to deduce it in the first place. Thus the original derivation of resonance theory by *Pauling* proved incorrect; a valid interpretation was given[8] only after the theory had been in general use for many years.

The purpose of this article is to review critically the various theoretical derivations that have been given for the Woodward-Hoffmann rules. It will appear that the best and simplest of these derives from an early treatment of pericyclic reactions which has for various reasons been largely overlooked.

2. Pericyclic Transition States as Aromatic Systems; Evans' Principle

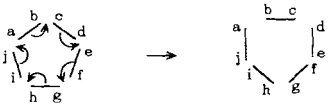
Thirty-five years ago the mechanism of the Diels-Alder reaction was still uncertain, the possibilities being a one-step process involving a cyclic transition state *(1)*, and a two-step process involving an intermediate biradical or zwitterion, produced *via* the linear transition state *(2)*.

During the reaction each carbon atom remains attached to three other atoms; it is reasonable to suppose that three of its valence AOs are used throughout to form localized σ bonds to them. The dotted lines in *(1)* and *(2)* then denote MOs formed by interaction of the six remaining carbon AOs, and containing all together six electrons.

The formation of multicenter MOs by mutual interaction of AOs depends on the latter overlapping in space but it does not depend on the geometry of overlap. In *(1)*, six AOs overlap in a ring, each AO with AOs of the two neighboring atoms; the situation is topologically equivalent to the overlapping of the six carbon 2p AOs in benzene to form cyclic π MOs. Likewise the overlap in *(2)* is topologically equivalent to that in 1,3,5-hexatriene. In other words, the delocalized electrons in *(1)* are topologically equivalent to, or isoconjugate with, the π MOs in benzene, and those in *(2)* to the MOs of hexatriene. The same factors that make benzene more stable than hexatriene, *i.e. aromatic*, should likewise make *(1)* more stable than *(2)*. On this basis we would therefore expect the one-step mechanism *via (1)* to be favored because the corresponding transition state is *aromatic*.

This argument was put forward by *M. G. Evans* in 1939[9, 10]. *Evans* and *Polanyi* had just published[11] their well known extension of the Eyring-Polanyi semiempirical method; *Evans* and *Warhurst*[9] set out to test this by applying it to the Diels-Alder reaction. In this treatment the transition state is first approximated as the crossing point of the potential curves for bond breaking and bond forming processes; the value so found for its energy is then corrected for resonance between the bond-broken and bond-formed structures. *Evans* and *Warhurst* pointed out the analogy noted above between the delocalized electrons in the transition state for the reaction between butadiene and ethylene and the π electrons of benzene and they accordingly calculated the resonance energy of this transition state by the same valence bond (VB) method that *Pauling* had used in his classical study of benzene. They estimated the resonance energy of the transition state to be 18 kcal/mole, about half *Pauling*'s value for benzene, and they estimated the overall activation energy for the reaction to be 18 kcal/mole, a value which was too low but of the right order. They also pointed out that the resonance energy for the transition state for the analogous dimerization of ethylene

should be small (because the valence bond method predicts cyclobutadiene to be nonaromatic); since the other terms in the expression for the activation energy seemed to be similar for both reactions, the activation energy of the Diels-Alder reaction should be less than that of ethylene dimerization by *ca.* 18 kcal/mole.



In the following year *Evans*[10] published a more detailed study of these reactions, using the Hückel MO method to calculate the resonance energies of the transition states. He also included calculations for the two-step reaction of butadiene with ethylene *via* the linear transition state *(2)*. He explicitly stated the analogy between the transition state *(1)* and benzene, and between the linear transition state *(2)* and 1,3,5-hexatriene, the resonance energies of *(1)* and of benzene being greater than those of *(2)* and hexatriene respectively.

There can therefore be no doubt that *Evans* fully recognized the role played by delocalization in the transition state of the Diels-Alder reaction and the analogy between the delocalized systems of the cyclic and linear transition states and the π systems of benzene and hexatriene respectively. He also recognized the difference between the Diels-Alder reaction with its six-membered transition state (analogous to benzene and so highly resonance stabilized) and the ethylene dimerization where the transition state should be stabilized to a much lesser degree, if at all. He also clearly stated that the additional resonance energy of the cyclic transition state *(1)* over the linear transition state *(2)* should be a factor in favoring the one-step reaction and he even gave quantitative estimates of the various resonance energies by the admittedly somewhat primitive theoretical methods then available.

This account of *Evans*' work seems necessary in view of recent attempts to belittle it and also because it seems to have been overlooked elsewhere, possibly because it was published just before the outbreak of World War II[12]. It is quite clear from his papers that he fully recognized the special features controlling the course of pericyclic reactions

and the basic ideas used to interpret π cycloaddition reactions can be applied equally well to other pericyclic processes.

A pericyclic reaction by definition involves a cyclic interchange of bonds around a ring of atoms, *e.g.*

Such a process is formally analogous to the conversion of one Kekulé structure for a cyclic polyene into the other. The transition state for the pericyclic reaction is therefore precisely analogous to the hybrid of classical structures in an intermediate "aromatic" structure for the polyene. If the polyene is aromatic, the intermediate structure is more stable than either classical structure and the reaction can proceed smoothly; if the polyene is antiaromatic, the conversion of one classical structure into the other involves an unfavorable intermediate. We can therefore relate the facility of a pericyclic reaction to the stability of the cyclic transition state relative to an open chain analog; by analogy with cyclic polyenes, we can then describe the cyclic transition state as being aromatic, nonaromatic, or antiaromatic, according to whether it is more stable than, as stable as, or less stable than the open chain analog. This obvious generalization of *Evans*' work leads to a simple rule for predicting the facility of pericyclic processes, a rule which should clearly be named for him and has accordingly been termed[13] *Evans' Principle*:

Thermal pericyclic reactions take place preferentially via aromatic transition states.

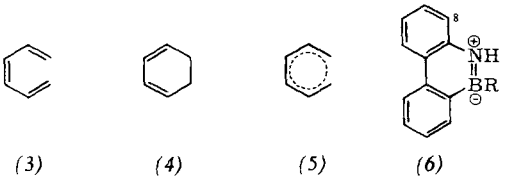
The problem of pericyclic reactions is thus identical in principle with that of aromaticity; any theory of aromaticity is *ipso facto* a theory of pericyclic reactions. The utility of this approach from the point of view of the practicing organic chemist then depends on the facility with which he can predict whether or not a given pericyclic transition state is aromatic.

In 1939 there was no satisfactory theory of aromaticity; indeed, no one had clearly recognized the possibility that cyclic conjugated systems might be antiaromatic, *i.e.* less stable than open chain analogs. Such a theory, and indeed the term "antiaromatic", was proposed in 1952[14] on the basis of a simple extension of the Hückel MO method, using perturbation theory. As we shall see presently, this treatment, which is a clear sequel to *Evans*' 1939 paper[10], provides a complete and simple account of pericyclic reactions of all kinds.

The paper by *Evans* and *Warhurst*[9] has had a similar sequel. *Mulder* and *Oosterhof*[15] have recently used an analogous valence bond treatment to explain the course of electrocyclic ring opening reactions and this approach could also be extended to other pericyclic processes. While it is satisfactory that their elegant treatment leads to conclusions similar to those given by the MO method, it suffers from several disadvantages by comparison. First, the MO method has proved generally superior to the VB method for the interpretation of organic chemistry. Secondly, as a result of this, few chemists now are familiar with the VB method. Thirdly, the procedure used by *Mulder* and *Oosterhof* can be applied only to simple monocyclic systems and so is less general than the MO approach.

3. The Frontier Orbital Method

A third approach that has been used to estimate the energies of pericyclic transition states is based on the Frontier Orbital (FO) method of *Fukui*[16]. In this the transition state for a bimolecular reaction is regarded as a perturbation of the reactants, the corresponding activation energy being given by second order perturbation theory. Since the only terms that survive[14, 17] are those involving interactions between a filled orbital of one component and an empty orbital of the other, and since the magnitude of the interaction between two orbitals varies inversely as the difference in energy between them, the main contributions arise from interactions between the highest occupied MO (HOMO) or *frontier* orbital of one component and the lowest unoccupied MO (LUMO) of the other. *Fukui* assumes that these terms dominate the situation so that all others can be neglected.



The original discussion[18] of electrocyclic reactions by *Woodward* and *Hoffmann* was formulated in terms of the FO method and *Fukui*[19] has recently extended it to the whole range of pericyclic processes. While superficially attractive, this approach suffers from several obvious limitations.

First, in order to use the FO method one needs to know the shapes of frontier orbitals. In simple cases these are determined by symmetry but in general they have to be calculated by procedures requiring the use of digital computers. Moreover, the form of the orbitals is not invariant to the procedure used to calculate them; the MOs given by different methods, or with different parameters, can vary very significantly.

Secondly, the FO method cannot in general be applied to unimolecular pericyclic processes because in this case first order perturbations are involved and these are of comparable magnitude for all the MOs. Consider, for example, the cyclization of 1,3,5-hexatriene *(3)* to 1,3-cyclohexadiene *(4) via* the pericyclic transition state *(5)*. The change in energy (δE_μ) of the MO ψ_μ on passing from *(3)* to *(5)* is given[14, 17] to a first approximation by

$$\delta E_\mu = a_{\mu 1} a_{\mu 6} \beta_{16}$$

where $a_{\mu 1}$ and $a_{\mu 6}$ are the coefficients in ψ_μ of the AOs of the terminal carbon atoms in *(3)* and β_{16} is the 1,6 resonance integral in *(5)*. The total difference in energy between *(3)* and *(5)* is a sum of the contributions δE_μ. There

(3) *(4)* *(5)* *(6)*

is no reason why that of the HOMO should dominate and in general it will not; the total energy difference is in fact given[14, 17] approximately by $2p_{16}\beta_{16}$ where p_{16} is the 1,6 bond order in *(3)*.

Thirdly, the FO method often leads to incorrect predictions, particularly in the case of molecules containing heteroatoms. A good example is provided[20] by derivatives of 10-bora-9-azaphenanthrene *(6)* which undergo electrophilic substitution most readily at the 8-position. All the MO treatments we have tried predict this position to lie almost on a node of the frontier orbital, the frontier orbital density being less there than at any other position in the molecule.

Fukui[19] avoids the first difficulty by confining attention to simple hydrocarbons where the general form of the HOMOs and LUMOs is determined by symmetry. The second difficulty is circumvented by the rather cavalier procedure of dissecting the π electron system into two parts so that the usual bimolecular procedure can be applied; thus the conversion of *(3)* to *(4)* is regarded as an internal Diels-Alder reaction between ethylene and butadiene moieties. Having established that the Woodward-Hoffmann rules hold for these special cases, it is then assumed that they will hold generally.

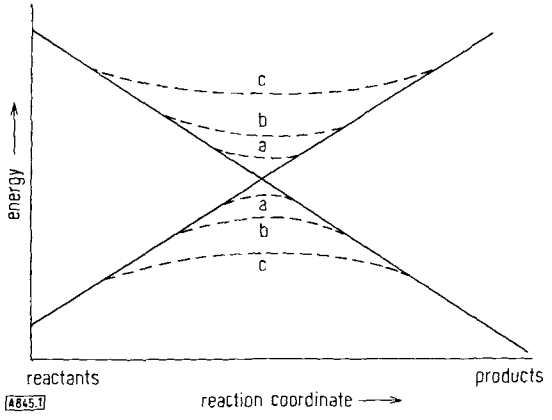
This kind of approach is of course useful as a guide in the search for generalizations; indeed, *Woodward* and *Hoffmann*[18] were originally so guided by a FO study of simple pericyclic reactions. However, such an argument is necessarily limited to the specific area where it is applicable, in this case to reactions of simple hydrocarbons. Consequently the use of the Woodward-Hoffmann rules in other connections has no real support from the FO method.

4. Conservation of State and Orbital Symmetry

An entirely different and very ingenious approach was suggested by *Longuet-Higgins* and *Abrahamson*[21], based on certain well known properties of molecular wave functions. If a molecule has some element of symmetry, the molecular wave function must conform[17] to that symmetry; thus in the case of a two-fold symmetry, *e.g.* a plane or center of symmetry, the wave function must be either symmetric, or antisymmetric, with respect to that symmetry operation. Any change in such a system which takes place with retention of symmetry must leave the symmetry of the wave function unchanged; if the wave function is initially symmetric, it must remain symmetric, and if initially antisymmetric, it must remain antisymmetric. Thus if the reactants in a reaction have a plane of symmetry, and if that symmetry is retained throughout the reaction, then the wave function must remain throughout either symmetric or antisymmetric.

One can on this basis correlate the states of the reactants with those of the products, plotting the energy of each state against a suitable reaction coordinate. If then the ground state of the reactants correlates with an excited state of the product, one can be sure that the reaction will be extremely unfavorable energetically because it will be impossible for the products to be formed in their ground state.

If the ground state of the reactants correlates with an excited state of the products, then of course the ground state of the products must correlate with an excited state of the reactants. The two lines on the correlation diagram (Figure 1) must cross. Such a crossing is normally forbidden; it occurs here only because the states have different symmetries. Any deviation from perfect symmetry will lead to a mixing of states in the crossover zone so that now the ground states of reactants and products correlate. This situation is indicated in Figure 1 for increasing loss of symmetry by the dotted lines a—c. It is, however, clear that the correlation plot will still tend to show a maximum which one would intuitively expect to be greater than for an analogous process in a system where symmetry is retained but where the ground states correlate with each other. In systems which are almost symmetric, the same qualitative distinction between "allowed" and "forbidden" reactions should therefore still hold as in cases where symmetry is rigorously maintained.



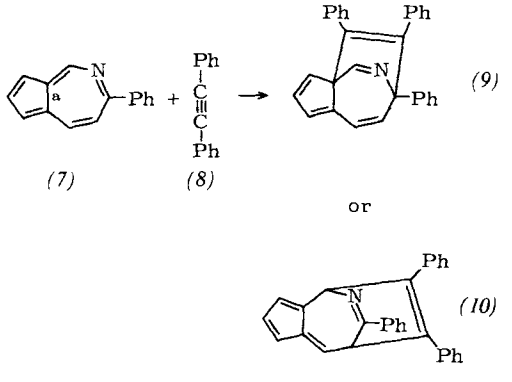


Fig. 1. Plot of energies of states *vs.* reaction coordinate for a process where symmetry is retained (—) and the effect (- - - -; a, b, c) of progressively removing the symmetry.

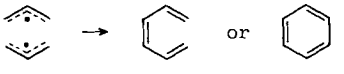
In the orbital approximation, the symmetry restrictions that apply to the total wave function also hold for the individual orbitals[17]. Individual MOs of the reactants can thus be correlated with MOs of the products and one can deduce the symmetry of the overall wave function of a given state from the symmetries of the MOs occupied in it. *Longuet-Higgins* and *Abrahamson*[21] applied this treatment to several simple pericyclic reactions of symmetrical molecules, assuming symmetry to be retained throughout, and showed that the reactions were "allowed" or "forbidden" in accordance with the predictions of the Woodward-Hoffmann rules.

A simpler version of this treatment has been adopted[6] by *Woodward* and *Hoffmann* as their preferred procedure for explaining pericyclic processes. Consider a reaction in which some element of symmetry is retained. Since the energies of the MOs must change continuously throughout, we can correlate MOs of the reactants with MOs of the products. The correlations can be represented on a diagram similar to Figure 1. In the ground states of the reactants and products, certain MOs are filled and the rest empty. If the filled MOs of reactants and products correlate with one

another, it is clear that the ground states must likewise correlate; the reaction is then "allowed". If, however, a filled MO of the reactants correlates with an empty MO of the product, and if the corresponding correlation of an empty MO of the reactants with a filled MO of the products (cf. Figure 1) involves a MO of different symmetry to the first, then the ground state of the reactants correlates with an excited state of the products and the reaction is consequently "forbidden". In this way one can base the distinction between "allowed" and "forbidden" reactions on correlations of orbital symmetry rather than of symmetry of states.

This approach is clearly superior to the FO method because it does apply quite rigorously to systems where symmetry is retained. The FO method is based on the assumption that one term in the expression for the second order perturbation dominates, an assumption which may be true in practice but for which there is no rigorous theoretical basis. However, both treatments suffer from the same basic defect of being inapplicable to systems where symmetry is not present. It is true that the present argument should also hold for systems where symmetry is "almost retained", but what do we mean by "almost"? Even small disturbances of symmetry can have far-reaching effects. Thus the strong absorption band of benzene at 208 nm ($\varepsilon \approx 10^4$) is due to a transition that would be forbidden were it not for small disturbances of the molecule from D_{6h} symmetry by molecular vibrations. Besides, we have to consider reactions where there is no semblance of symmetry involved, a good example being the π-cycloaddition reactions[22] of *(7)* and *(8)* to form *(9)* or *(10)* (see Section 6.2).

A further difficulty is the apparent disregard of symmetry shown by pericyclic reactions. If their course were controlled by conservation, or near conservation, of symmetry, the control should certainly become progressively less effective as the symmetry of the system is progressively destroyed. The experimental evidence[6] shows no indication of this. The Woodward-Hoffmann rules hold just as rigorously in systems totally lacking in symmetry as they do in symmetric ones. The rules are much more powerful—and much more useful—than they would be if this were not the case.



Although therefore this approach, like the FO one, has been of historical importance in leading to the original formulation of the Woodward-Hoffmann rules, it cannot be regarded as a satisfactory basis for them.

5. The PMO Theory of Aromaticity

In order to make use of Evans' Principle, one must have some simple procedure for telling whether or not a given system is aromatic; such a procedure was first developed in 1952[14].

The majority of chemical problems involve differences in energy between closely related structures; *Coulson* and *Longuet-Higgins*[23] first pointed out that these should logically be found by using perturbation theory and they were thus able to account for a number of phenomena in a simple way. However such differences in energy usually involve second order perturbations which cannot be estimated without a detailed knowledge of the MOs of the unperturbed species; these in turn can be found only by massive calculations. The breakthrough came with the discovery[14] of subterfuges by which first order perturbation theory could be used instead, under conditions where the first order perturbations can be estimated very simply; this led to a general "pencil and paper" theory of organic chemistry[17] which included a simple general theory of aromaticity.

The treatment[13, 14, 17] of aromaticity involves two steps. First one compares the energy of a given conjugated system with that of an isoconjugate hydrocarbon, *i.e.* one with the same number of π electrons and with all the heteroatoms replaced by carbon; one finds that the rules for aromaticity are the same for both. In the second, one compares the energy of the cyclic conjugated hydrocarbon with that of an open chain analog by relating both systems to open chain radicals or ions; thus benzene can be related to hexatriene by constructing both molecules by "union" of a pair of allyl radicals.

The unpaired electrons in such radicals occupy nonbonding MOs (NBMOs) that all have the same energy. The change in energy during union is consequently dominated by the first order perturbation involving the NBMOs. Moreover, the NBMO in such a radical can be found extremely simply by a method due to *Longuet-Higgins*[24] which involves a trivial calculation using pencil and paper; one can therefore predict very easily whether a given cyclic conjugated hydrocarbon will be more or less stable than the open chain analog, *i.e.* aromatic or nonaromatic. This approach is of course quite independent of symmetry and it can moreover be extended to individual rings in polycyclic systems; it therefore provides exactly the basis needed for the effective use of Evans' Principle.

In the case of a normal conjugated molecule, the π MOs are written as linear combinations of p AOs of the atoms. The two lobes of a p AO have opposite signs but the choice of absolute signs or *phases* is quite arbitrary. The resulting MOs are independent of this choice. For convenience one usually tries to choose the phases so that wherever two AOs overlap, they overlap in phase, *i.e.* positive with positive or negative with negative. In a normal conjugated

molecule one can of course satisfy this condition throughout (Figure 2a).

In 1959 *Craig*[25] pointed out that if one of the p AOs in a conjugated ring is replaced by a d AO, this condition can no longer be met; there will be a *phase dislocation* at some point in the ring (Figure 2b). Another example was pointed out by *Heilbronner*[26] in 1964; if we take a conjugated chain, twist it through 180°, and then join up the ends into a ring, the resulting π system will have a phase dislocation (Figure 2c). Here the π MOS, instead of forming rings above and below the nodal plane, form a continuous ring with the topology of a Möbius strip.

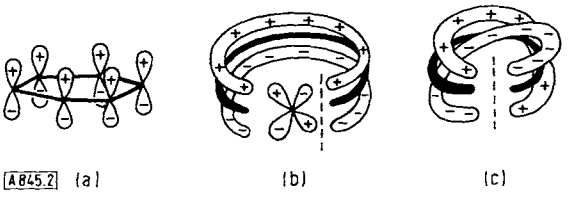


Fig. 2. (a) Normal Hückel conjugated system; (b), (c) phase dislocations (- - -) in antiHückel systems.

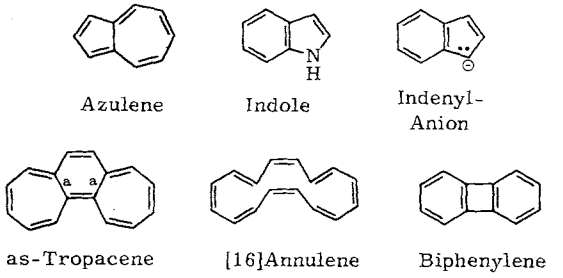
There are therefore two topologically distinct types of conjugated systems, normal *Hückel systems* in which the AOs can be chosen so that they all overlap in phase, and *antiHückel systems* where there will always be at least one phase dislocation, no matter how the phases of the AOs are chosen. There are only two possibilities in the case of a given ring because the number of phase dislocations can be increased or decreased two at a time by changing the phases of individual AOs; thus a ring is of Hückel type if the number of phase dislocations in it is even, of anti-Hückel type if the number is odd.

The PMO method can be applied equally well to anti-Hückel systems; in this way one can arrive at a set of general rules for aromaticity[13, 17], *viz.*:

a) Replace all heteroatoms by carbon atoms with an equivalent number of p (π) electrons; thus the nitrogen atom in pyridine (which contributes one p or π electron) is replaced by neutral C while the nitrogen atom in pyrrole, or the oxygen atom in furan (each of which contributes two p or π electrons) is replaced by $:C^-$.

b) Delete all essential single and double bonds, *i.e.* bonds that are respectively single or double in all possible classical (unexcited resonance) structures for the molecule. A good example is the central bond in azulene, whose π system is consequently equivalent to that of [10]annulene.



c) The aromaticity of each remaining ring is indicated in Table 1.

Table 1. Rules for aromaticity. + denotes aromatic character, − antiaromatic.

Type of conjugated system	Even-numbered rings [a]		Odd-numbered rings [b]			
	$4n$ atoms	$(4n+2)$ atoms	$(4n+1)$ atoms cations	$(4n+1)$ atoms anions	$(4n+3)$ atoms cations	$(4n+3)$ atoms anions
Hückel	−	+	−	+	+	−
antiHückel	+	−	+	−	−	+

[a] Neutral rings only.
[b] Radicals are nonaromatic (*i.e.* have predicted resonance energies similar to those of open-chain analogs).

It should be emphasized that the distinction between Hückel and antiHückel systems is a very profound one, depending on the phase relationships between the basis set AOs and quite independent of the MOs constructed from them. A topological distinction of this kind is obviously much more fundamental than one based on considerations of symmetry or molecular geometry. It should be noted that the signs attached to AOs here refer to the basis set AOs, not to MOs constructed from them; since an apparently similar notation has often been used (*e.g.* by *Woodward* and *Hoffmann*[6]) to indicate the symmetries of MOs, it is important that the two usages should not be confused.

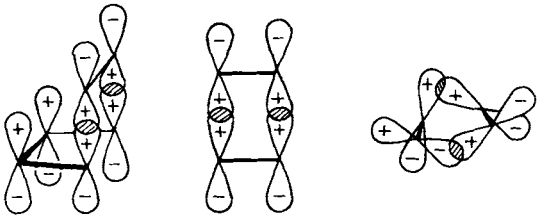
Some examples of the rules for aromaticity follow:

Indole is isoconjugate with the indenyl anion; both rings are aromatic, Hückel-type systems, one ring being neutral with $(4n+2)$ atoms and the other an anion with $(4n+1)$ atoms.

Deletion of essential single bonds in as-tropacene leaves an antiaromatic [16]annulene ring having 16, *i.e.* $4n$ atoms (see Section 6.2).

In biphenylene, the central ring is antiaromatic ($4n$ atoms) and the terminal rings aromatic [$(4n+2)$ atoms].

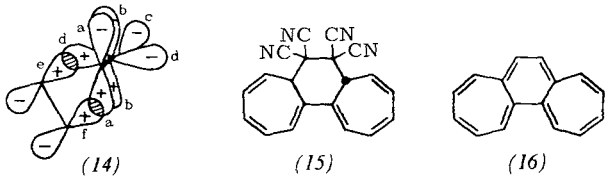
6. The Use of Evans' Principle



6.1. Introduction

Evans' Principle, together with the PMO treatment of aromaticity and the concept of antiHückel systems, provides in effect a simple theory of pericyclic reactions[13]. This could be regarded either as providing a satisfactory theoretical basis for the Woodward-Hoffmann rules or as a satisfactory alternative to them. The latter possibility will now be illustrated by a brief survey of pericyclic reactions in such terms.

6.2. Cycloaddition Reactions

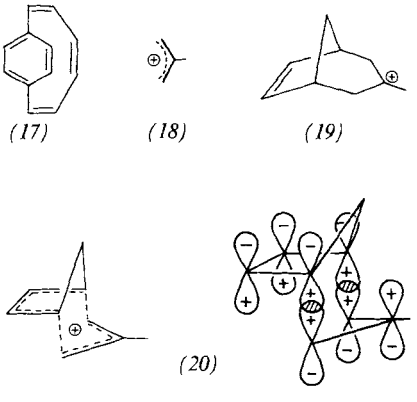


The Diels-Alder reaction has already been considered; it is easily seen from examination of the AOs involved [see *(11)*] that their phases can be chosen so that they all overlap in phase. The transition state is therefore of Hückel type and so isoconjugate with normal Hückel benzene, as *Evans* first pointed out[7]. The Diels-Alder reaction is, as predicted, a one-step pericyclic process[27]. On the other hand an analogous concerted combination of two olefins

to a cyclobutane, by *cis-cis* addition, would involve a transition state *(12)* isoconjugate with Hückel cyclobutadiene which is antiaromatic; here a two-step process *via* a biradical should be favored, as indeed appears to be the case[28]. A concerted addition of two olefins should, however, be possible if one of them undergoes *trans* addition, a feasible process if the reaction involves strained cyclic olefins where the double bond is twisted[29]; the corresponding transition state *(13)* involves a phase dislocation and so is isoconjugate with antiHückel cyclobutadiene which is aromatic. Such an addition has been observed in the dimerization of a *trans* cycloolefin[30] and the resulting dimer had the predicted *cis-trans* geometry.

(11) *(12)* *(13)*

Another interesting concerted reaction involving formation of four-membered rings occurs with ketenes[31]. This can be explained in terms of a transition state *(14)* in which the p AOs of the approaching olefin overlap with p AOs of the methylene and central carbon atom of the ketene, belonging to different π systems. In the transition state, the symmetry of the ketene is lost; the oxygen p AOs can then couple the π systems together. This is indicated in *(14)*, where a p AO (c) of oxygen (at the back) is represented as overlapping with both p AOs (b and d) of the central carbon atom. There is now an unbroken chain of overlap along the AOs a, b, c, d, and a and d overlap with the AOs (e and f) of the olefin. The resulting transition state is then isoconjugate with that in the Diels-Alder reaction. On this basis one would expect allene to show similar concerted 1,2 cycloadditions with suitable dienophiles, allene playing the role of the diene in a Diels-Alder reaction; reactions of this type are known but it has not yet been established that any of them involve concerted cycloaddition.



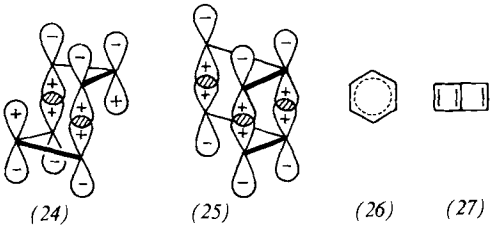
(14) *(15)* *(16)*

If the phases of the AOs are chosen so as to avoid phase dislocations inside each of the reacting molecules, *cis* addition takes place at lobes with the same phase and *trans* addition at lobes with opposite phase. The transition states for *cis-cis* or *trans-trans* addition are therefore of Hückel type, since the phases of the AOs can be chosen to avoid any phase dislocation, while the *cis-trans* addition involves an antiHückel transition state. It should be obvious that all the other cycloaddition reactions cited by *Woodward* and *Hoffmann*[6] can be explained immediately in these terms. Thus the transition state for the cycloaddition of tetracyanoethylene to heptafulvalene to form[32] *(15)* is isoconjugate with the tricyclic system *(16)*; since the transannular bonds here are essential single bonds, this is effectively the [16]annulene which is aromatic only in the antiHückel series. The reaction should therefore involve *cis-trans* addition; examination of models shows that it must be the heptafulvalene that adds *trans*, as indeed is the case[32], the adduct having, as predicted, the geometry indicated in *(15)*.

The π cycloaddition[22] of *(7)* to *(8)* noted above can be explained at once in these terms. The bond marked a in *(7)* remains an essential single bond throughout; disregarding it, the transition states for formation of *(9)* or *(10)* are seen to be isoconjugate with *(17)* which contains two fused aromatic rings (one with six, one with ten atoms). Note that the fact that *(17)* would be highly strained is irrelevant; any strain in such a system is due entirely to distortions of σ bonds and is irrelevant to the question of its aromaticity. Bonds of pπ:pπ type show no directional properties since p AOs are axially symmetric.

Similar arguments can obviously be applied to cycloadditions isoconjugate with ions. Thus the cycloaddition[33] of 2-methylallyl cation *(18)* to cyclopentadiene to form *(19)* involves a transition state *(20)* which is isoconjugate with the (aromatic) tropylium ion, while the numerous dipolar additions reported by *Huisgen et al.*[34] involve additions to olefins of compounds isoconjugate with allyl anion (*e.g.* $C_6H_5-C\equiv\overset{\oplus}{N}-\overset{\ominus}{O}$) and so have transition states isoconjugate with the aromatic cyclopentadienate anion.

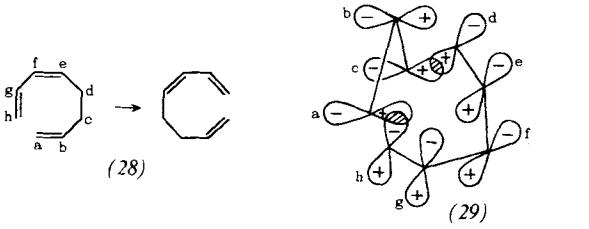
(17) *(18)* *(19)*



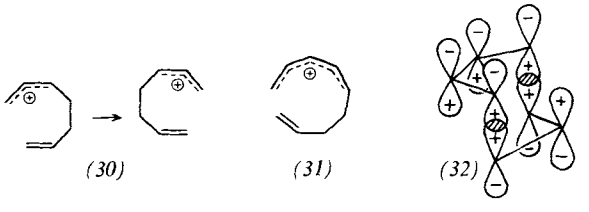
(20)

6.3. Claisen, Cope, *etc.* Rearrangements

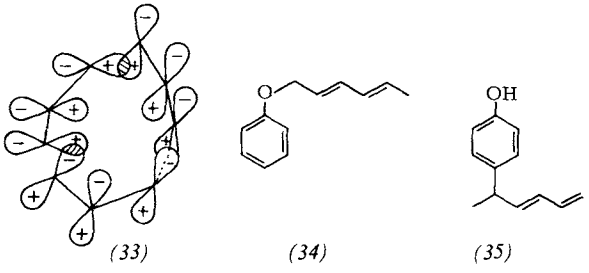
The Cope rearrangement of a biallyl *(21)* to the isomer *(23)* is a concerted pericyclic process involving the transition state *(22)*. As *Doering* and *Roth* pointed out[35], this can exist in two distinct configurations *(24)* and *(25)* analogous to the "chair" and "boat" forms of cyclohexane. As indicated in *(24)* and *(25)*, the orbital overlap in them is equivalent to the π overlap in benzene *(26)* and bicyclohexatriene *(27)* respectively. Since the latter contains two antiaromatic cyclobutadiene rings, it is clearly less aromatic than *(26)*; we can therefore predict that the reaction should take place *via* the "chair" transition state *(24)*, as indeed it does[35].



(21) (22) (23)



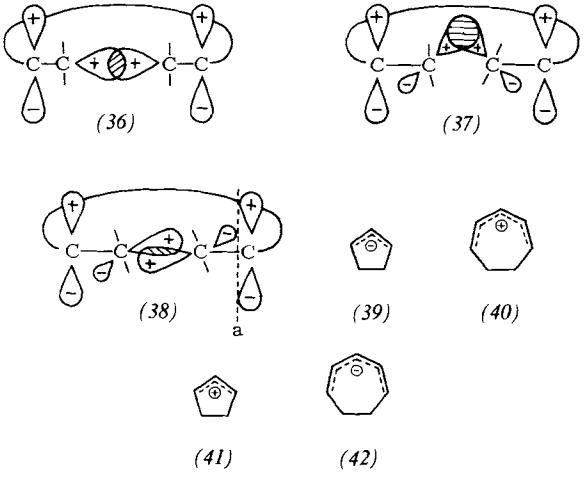
(24) (25) (26) (27)



Exactly similar considerations should apply to other analogous rearrangements of structures isoconjugate with biallyl, *e.g.* the Claisen rearrangement which also[36] takes place *via* a "chair" transition state. One can obviously also envisage analogous rearrangements involving larger even-numbered rings and ions. In the case of $(4n+2)$-membered rings, the rearrangements should take place *via cis* transition states analogous to *(24)*. In the case of $4n$ membered rings, *e.g. (28)*, the rearrangement should occur only if the transition state has one phase dislocation; this is possible if the rearrangement involves a *trans* combination of the ends of the conjugated system [cf. *(29)*]. In rearrangements of ions the same principles apply; in the case of ions which are aromatic in the Hückel series, the rearrangements should be *cis*, in the case of those that are aromatic in the antiHückel series, *trans*. Possible examples might be the rearrangements of *(30)* and *(31)*, the former taking place *via* the *cis* transition state *(32)*, the latter *via* the *trans* one *(33)*.

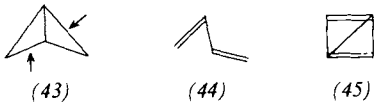
(28) (29)

(30) (31) (32)



(33) (34) (35)

An interesting point is raised by the rearrangement of *(34)* to *(35)*, recently reported by *Fráter* and *Schmid*[37]. Here the transition state is again isoconjugate with *(17)*.



6.4. Electrocyclic Reactions[6]

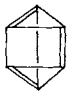
The thermal conversion of cyclobutenes into butadienes, and of 1,3,5-hexatrienes into cyclohexadienes, are stereospecific processes which were among the first pericyclic reactions studied by *Woodward* and *Hoffmann*[6]. These processes are represented schematically below, *(36)* being the ring closed product and *(37)* and *(38)* the transition states involving reactions of respectively disrotatory[6] and conrotatory[6] stereochemistry. It is immediately obvious, as *Zimmerman*[38] has pointed out, that the disrotatory transition state *(37)* involves no phase dislocations and so is of Hückel type, whereas the conrotatory one involves a single phase dislocation [a in *(38)*] and so is of antiHückel type. Which of the two will be favored can be deduced at once from Table 1. Thus if the reaction involves rupture or formation of an even-numbered ring, the disrotatory path should be favored if the ring contains $(4n+2)$ atoms (as in cyclohexadiene) but conrotatory if it contains $4n$ (as in cyclobutene). In the case of odd-numbered ions, the disrotatory path should be favored in anions with $(4n+1)$ atoms [*e.g. (39)*] or cations with $(4n+3)$ atoms [*e.g. (40)*] and the conrotatory path in cations with $(4n+1)$ atoms [*e.g. (41)*] or anions with $(4n+3)$ [*e.g. (42)*]. These predictions of course agree with those of *Woodward* and *Hoffmann*[6] and have been confirmed for neutral rings with four or six atoms[6], for cations with three[39] or five[40], and for anions with five[41].

(36) (37) (38) (39) (40) (41) (42)

The present approach can also be applied to polycyclic systems. A good example is provided by bicyclobutane *(43)* which undergoes a thermal ring opening, by breaking of the bonds indicated by arrows, to butadiene *(44)*. The transition state is isoconjugate with bicyclobutadiene *(45)*; since the transannular bond is an essential single bond, this is equivalent to cyclobutadiene and so antiaromatic in the Hückel series. The transition state must therefore involve just *one* phase dislocation, so one of the bonds in

(43) (44) (45)

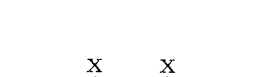
(43) must undergo disrotatory rupture, the other conrotatory, a prediction in agreement with experiment[42].



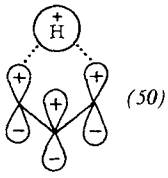
Other examples are provided by the benzene isomers, benzvalene *(46)* and prismane *(47)*. Although the conversion of either into benzene involves a huge decrease in energy[43,44], derivatives of them are surprisingly stable[44]. This can be understood at once in terms of the present treatment. Thus the conversion of *(46)* to benzene involves the same type of bond rupture as does the conversion of *(43)* to *(44)*. However the ethylene bridge in *(46)* makes it imperative that both bonds undergo disrotatory fission, or both conrotatory fission; steric considerations make it impossible for one to break by a disrotatory, the other by conrotatory, process. The conversion of *(46)* to benzene therefore involves an antiaromatic transition state. A similar situation arises in the case of prismane where the transition state for direct conversion to benzene is isoconjugate with the bridged benzene analog *(48)*; this, like the analogous boat transition state for the Cope rearrangement (see Section 6.3), is antiaromatic.

(46)

(47)

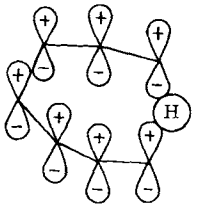


(48)



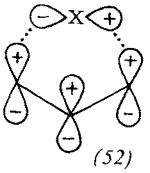
One might add that much of the current theorizing concerning possible types of pericyclic reaction seems to have ignored one of the fundamental principles of reaction theory. In a reaction where one bond is broken and another formed, activation is usually necessary since the new bond does not begin to form until the old one has been severely weakened. A reaction involving rupture of two bonds will require correspondingly more activation and one involving rupture of three bonds more again. For this reason the majority of organic reactions involve rupture and/or formation of just one bond and hardly any involve rupture of three. Reactions involving rupture of two or more bonds normally occur only if they are strongly exothermic and if the transition state is also highly resonance-stabilized (*i.e.* aromatic). It has, of course, been known for many years, from the theory of potential surfaces of *Evans*, *Polanyi*, and *Bell*[17,45], that the more exothermic a reaction, the smaller in general its activation energy (cf. [46]); however, exothermicity alone is not sufficient to enable a reaction involving multiple bond fission to take place under normal conditions. The conversion of *(47)* to benzene may well be a stepwise process.

6.5. Sigmatropic Rearrangements

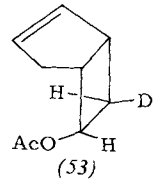


This term was introduced by *Woodward* and *Hoffmann*[6] to describe rearrangements of the type symbolized in *(49)*. A classic example is the migration of allylic hydrogen to an adjacent conjugated chain of atoms. If the hydrogen atom remains on the same side of the plane of conjugated atoms (*suprafacial* rearrangement[6]), it is obvious that the transition state will be of Hückel type [cf. *(50)*]. Such reactions should occur only if the transition state contains a $(4n+2)$-membered ring, *i.e.* by 1,5 or 1,9 migration, not 1,3 or 1,7. This is now well known to be the case[47]. Conversely, an antarafacial[6] rearrangement, in which hydrogen migrates to the other side of the nodal plane of the π system, involves a transition state of antiHückel type [see *(51)*]; this geometry should be favored in 1,3, 1,7, *etc.*, rearrangements.

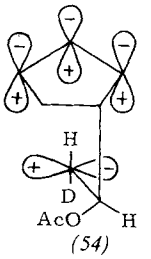
(49)



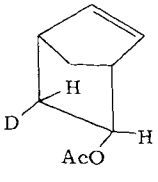
(50)



(51)



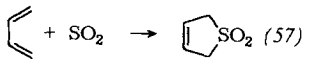
In cases where the migrating group uses a p AO for bonding, the rules for antarafacial and suprafacial reactions can be inverted. Thus the transition state *(52)* for 1,3 migration is clearly of antiHückel type and so aromatic. Intramolecular allylic migrations of halogen have been known for some time and probably involve this mechanism; the classic example, however, is that of *Berson* and *Nelson*[48]. Thermal rearrangement of *(53)* gives *(55)*, *via* the transition state *(54)*.



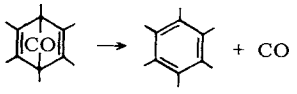
(52)

(53)

(54)



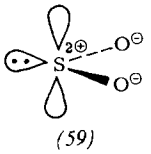
(55)



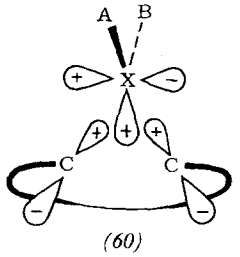
6.6. Chelotropic Reactions

Chelotropic is the appropriate term devised by *Woodward* and *Hoffmann*[6] to describe reactions in which an odd-numbered ring is formed by insertion of an atom between the ends of a linear polyene, or the converse regeneration of the polyene from the cyclic adduct. The formation of sulfone *(57)* from butadiene and sulfur dioxide, and the pyrolysis of Diels-Alder adducts *(58)* to carbon monoxide and benzene derivatives are good examples. *Woodward* and *Hoffmann*[6] also include in this category cycloadditions to simple olefins, *e.g.* the addition of carbenes to olefins to form cyclopropanes; for reasons indicated below it seems

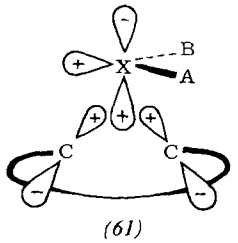
better to classify reactions of this type separately, chelotropic processes being taken to involve reactions in which polyenes are involved (see Section 6.7).



(56) (57)



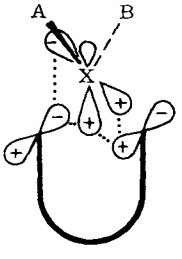
(58)



Since the reagent forms two new bonds in the reaction, it must have two free AOs. These moreover must contain just two electrons in order that the reaction take place with no net transfer of charge. Typically, the reagent has, or can be written as having, a filled hybrid AO and an empty p AO, the hybrid AO being filled since hybrid AOs are lower in energy. Thus one can write such a structure *(59)* for SO_2.

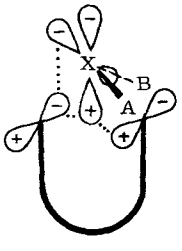
(59)

(60)



(61)

The terminal methylene groups of the polyene undergo rotations out of coplanarity during the reaction, analogous to those undergone by the terminal methylene groups in an electrocyclic process; chelotropic reactions can therefore be subdivided into disrotatory and conrotatory types. In the transition state, the two AOs of the reagent interact with the p AOs of the terminal methylenes to form two cyclic conjugated systems each with an odd number of atoms. That involving the filled hybrid AO will have one more electron than there are atoms in the ring and so will be isoconjugate with an odd cyclic hydrocarbon anion while that involving the empty p AO of the reagent will likewise be isoconjugate with an odd hydrocarbon cation.



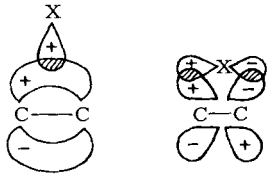
In a disrotatory process, the best overlap between the AOs of the reagent and the terminal p AOs of the olefin should occur in the geometry indicated in *(60)* where the reagent approaches in a direction perpendicular to the polyene. the hybrid AO undergoing σ-type overlap, and the p AO π-type overlap, with the terminal p AOs. This approach will be superior to one in which the role of the AOs is inverted [see *(61)*] for two reasons. First, the σ-type overlap in *(61)* is inferior since half the p AO is wasted; secondly the π overlap is also inferior since only the p component of the hybrid AO can take part.

The σ-type overlap leads to a Hückel cyclic system, the π-type overlap to an antiHückel one [see *(60)*]. If the polyene contains $4n$ atoms, the Hückel type system is isoconjugate with a Hückel $(4n+1)$-membered cyclic hydrocarbon anion and so is aromatic, while the antiHückel system is isoconjugate with an antiHückel $(4n-1)$, *i.e.* $(4n'+3)$-membered cyclic hydrocarbon cation and so is also aromatic. The transition state for such a process is thus doubly aromatic, while that for reaction of a polyene containing $(4n+2)$ atoms will be doubly antiaromatic. This type of addition should therefore be favored in the case of polyenes with $4n$ atoms, *e.g.* butadiene; the formation of butadiene sulfone, and related processes, are disrotatory[6]. It is easily seen that the rules are inverted for the other mode of approach *(61)*; here the transition state is aromatic for polyenes with $(4n+2)$ atoms and antiaromatic for those with $4n$. Disrotatory addition is therefore always possible though more favorable in the case of $4n$-membered polyenes.

In a conrotatory process, it is equally clear that the best mode of addition of the reagent will be in the plane of the polyene as indicated in *(62)*. Again, the best overlap will be attained if the reagent approaches so that its hybrid AO overlaps in σ-type fashion, and its p AO in π-type fashion, with the terminal p AOs of the olefin *(62)*. In this case, however, the cyclic conjugated system arising from the σ-type overlap is of antiHückel type, that from π-type overlap of Hückel type; the transition state will therefore be aromatic if the polyene contains $(4n+2)$ atoms and antiaromatic if it contains $4n$. Again, one can envisage an alternative less favorable mode of approach *(63)* [cf. *(61)*] in which the roles of the hybrid and p AOs of the reagent are interchanged and where the transition state is now aromatic if the polyene contains $4n$ atoms and antiaromatic with $(4n+2)$.

(62)

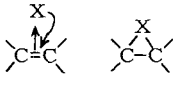
(63)



Either mode of approach is therefore possible with polyenes of either type [$4n$ or $(4n+2)$ atoms]; since the disrotatory and conrotatory transition states involve different types of overlap, it is impossible to predict on the basis of any qualitative theory whether one of them may be favored to the extent that one of the less satisfactory modes of reaction [*(61)* or *(63)*] may on balance prove superior to the more satisfactory mode [*(60)* or *(62)*] of opposite type. The experimental evidence suggests that the two most favorable modes of reaction are in fact *(60)* and *(62)*,

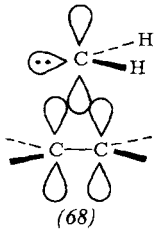
polyenes with $4n$ atoms reacting by the disrotatory path[6] and those with $(4n+2)$ atoms by the conrotatory one[49].

Woodward and *Hoffmann*[6] did not consider the geometry of approach indicated in *(60)* and *(61)*; however their arguments can be extended in an obvious manner to this case.



6.7. π-Complex Reactions

It has long been recognized[50] that olefins can behave as Lewis bases, forming *π complexes* with acceptors by donation of their π electrons *(64)*; the majority of electrophilic reactions of olefins involve processes of this kind[17, 50, 51]. In cases where the acceptor has a filled p, π, or d orbital, the π complex can be further stabilized by back-coordination *(65)* into the empty antibonding π MO of the olefin; as the present author first pointed out[50], the structure of olefin-transition metal complexes can be explained in such terms. In a complex of this type, there is in effect a double bond between the olefin and the acceptor; the resulting structure can be represented either in terms of two opposed dative bonds *(66)* or in terms of a three-membered ring *(67)*, the two descriptions being equivalent[50].

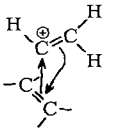


(64)

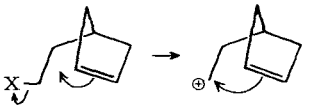
(65)

(66)

(67)



(68)



Reagents of suitable type should therefore be able to add to olefins to form products containing three-membered rings, a process which bears obvious analogies to the chelotropic reactions discussed above and has been classified accordingly by *Woodward* and *Hoffmann*[6]. However, the back-coordination of the reagent to the olefin in such a reaction is a side issue; it serves only to facilitate the primary acid-base interaction of the olefin behaving as a Lewis base with the reagent acting as a Lewis acid. The resulting π complexes occur as intermediates in many reactions where the reagent is incapable of back-coordination[51]; many of these moreover are molecular rearrangements quite unrelated to chelotropic processes.

Reactions of this type leading to three-membered rings include the epoxidation of olefins by formal addition of oxygen atoms and the addition of singlet carbenes to olefins to form cyclopropanes. In the case of carbene addition the stereochemistry of approach must of course be that indicated in *(68)*, as *Skell*[52] has remarked, in order that the empty p AO of the carbene should overlap with the filled bonding π MO of the olefin. In this case back-coordination involves a pseudo-π interaction of the filled hybrid AO of the carbene with the empty antibonding π MO of the olefin [cf. *(61)* and *(63)*].

A further reaction falling into this category is the addition of vinyl cations to olefins to form cyclobutyl or cyclopropylmethyl derivatives. The π complex *(69)* formed by addition is identical with the "non-classical" carbonium ion or π complex that appears[51] to be an intermediate in the solvolysis of certain cyclobutyl or cyclopropylmethyl esters.

(69)

(70) *(71)*

Woodward and *Hoffmann*[6] classify this process as a $[{}_2\pi_s + {}_2\pi_a]$ cycloaddition; however, there is no reason to suppose that it does not involve a simple one-center attack on the carbonium ion by the olefin analogous to the corresponding reactions of alkyl cations, *e.g.* the formation[51] of norbornyl cation by the π route *(70)* → *(71)*.

6.8. Photochemical Pericyclic Processes

A number of pericyclic reactions take place photochemically, usually with consequences different from those of analogous thermal reactions[6]. Light must therefore play some role other than that of merely providing energy to overcome an activation barrier. Moreover the reactions almost certainly involve a direct conversion of the excited reactants into products in their ground state because the conversion of excited reactants into excited products is in many cases energetically impossible[53]. Such processes must involve a breakdown in the Born-Oppenheimer approximation, the product being formed in a vibronically excited form of its ground state.

At some point in the reaction, the molecule must therefore pass from an electronically excited, vibronically unexcited configuration to one than is electronically unexcited but vibronically excited. It is well established that processes of this kind occur more easily, the smaller the degree of vibronic excitation involved; places where the potential surfaces for the excited and ground states approach one another therefore act as weak points in the former where the photochemically excited reactant can leak through to the ground state.

As *Dougherty*[54] has pointed out, one can on this basis derive an extension of Evans' Principle to cover photochemical pericyclic reactions. According to the PMO theory, there is a close connection[55] between the excitation energies of conjugated systems and their aromaticity. The relative stabilities of analogous aromatic, nonaromatic, and antiaromatic alternant[17] hydrocarbons are determined mainly by the energies of the highest occupied MOs. The electrons in these are more tightly bound in aromatic

systems, and less tightly in antiaromatic systems, than in nonaromatic ones (Figure 3); from the pairing theorem[17], the energies of the lowest unoccupied MOs vary in a mirror image manner (Figure 3). The first excitation energies of aromatic compounds should therefore be greater, and those of antiaromatic compounds less, than those of analogous nonaromatic compounds; this certainly appears to be the case. Thus the first absorption band of naphthalene is at much shorter wavelengths than that of a corresponding open chain polyene while the reverse is true for heptalene whose absorption extends into the infrared[56].

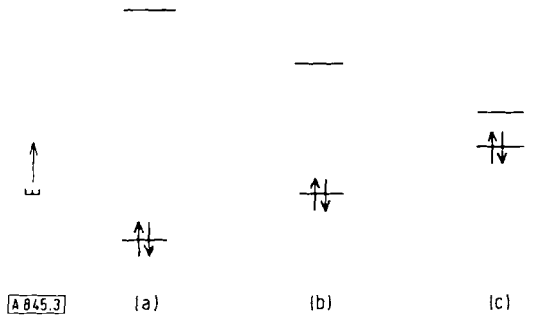


Fig. 3. Highest occupied and lowest unoccupied MOs of analogous aromatic (a), nonaromatic (b), and antiaromatic (c) hydrocarbons.

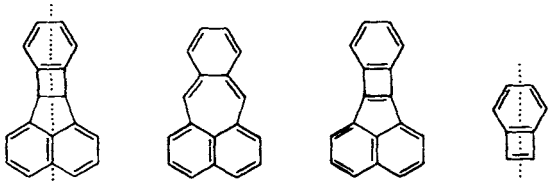


In the case of a pericyclic reaction, the potential surfaces for the ground state and the first excited state should therefore come particularly close together for geometries corresponding to antiaromatic transition states of thermal reactions. These should therefore be the regions where the Born-Oppenheimer approximation should be most prone to fail and where deexcitation of the photoexcited system should consequently be most probable. The photochemical reaction should therefore tend to lead to the conversion of the reactants into the antiaromatic transition states that correspond to "forbidden" thermal pericyclic reactions and so lead to the corresponding products. This argument provides an extension of Evans' Principle to such processes:

Photochemical pericyclic reactions lead preferentially to the products that would be formed thermally via antiaromatic transition states.

In other words the rules for photochemical pericyclic reactions should be exactly opposite to those for corresponding thermal ones, a generalization that was proposed[13] on the basis of a less rigorous PMO argument by the present author and which forms a logical extension of the original MO approach by *Evans*[10]. The same conclusion has also been reached by *van der Lugt* and *Oosterhof*[53] on the basis of a valence bond treatment that represents an analogous extension of the original study by *Evans* and *Warhurst*[9].

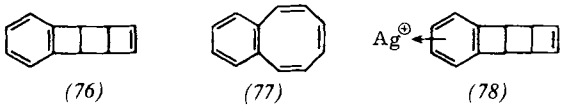
The experimental evidence seems to be entirely consistent with this generalization[6]. Thus the *cis-cis* dimerization of olefins to cyclobutanes takes place very readily under the influence of light while the Diels-Alder reaction remains unaffected; likewise the stereochemistry of electrocyclic and chelotropic processes is inverted in the case of photochemical reactions.

One recent apparent exception[57] to this generalization serves in fact as further support for it. The photochemical conversion of *(72)* to *(73)* does not involve the lowest excited state. The reason for this is that the chromophores in *(72)* are uncoupled and the first absorption band corresponds to excitation of the naphthalene moiety; such excitation should be ineffective for converting *(72)* into *(73)*. The transition state for this process is isoconjugate with *(74)* in which the naphthalene and cyclobutabenzene moieties are isolated from one another by essential single bonds. For photoinduced disrotatory ring opening to occur, the excitation energy must be located in the benzene. Excitation of the naphthalene moiety could then lead to reaction only if the excitation energy could be transferred to the nascent cyclobutabenzene system. However both *(72)* and cyclobutabenzene *(75)* have planes of symmetry (···); their wave functions must be symmetric or antisymmetric for reflection in those planes. Since the lowest excited state of *(72)* is, like the ground state, symmetric while that of *(74)* is antisymmetric, transfer of energy from the naphthalene to the nascent benzocyclobutadiene system in *(72)* is forbidden.

(72) *(73)* *(74)* *(75)*

6.9. Catalysis by Transition Metals

A number of cases are now known where pericyclic reactions are catalyzed by transition metals. Some of these involve direct chemical reaction of the metal with the reagent to form organometallic species that undergo further conversions[58]; such processes, while interesting and important, are unrelated to normal pericyclic processes. There is, however, reason to believe that in certain cases transition metals can influence the course of pericyclic reactions solely by coordinating with unsaturated or aromatic systems in the reactants; such a process would be an example of true metal catalysis of a pericyclic reaction.

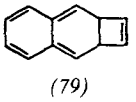


The π complex theory[50] of metal-olefin complexes attributes their stability to back-coordination of d electrons of the metal into an antibonding π MO of the olefin; this argument suggests that antiaromatic hydrocarbons should form particularly strong metal complexes since they have a pair of electrons in an MO of very high energy (Figure 3), very suitable for donation to the metal, and at the same time an empty MO of very low energy (Figure 3), ideal for back-coordination. Cyclobutadiene does indeed form exceptionally stable complexes of this type[59], while cyclooctatetraene can apparently form analogous ones with metals containing electrons in AOs of the correct symmetry (*i.e.* f) for back-coordination (uranocene[60]).

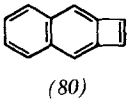
The analogy between the delocalized electrons of pericyclic transition states and the π MOs of aromatic and antiaromatic conjugated molecules leads one to suppose

that antiaromatic transition states should likewise form very stable complexes to transition metals of suitable type, *i.e.* ones towards the end of each transition series where d electrons are available for back-coordination. If then the the reactants are aromatic, or non-aromatic, coordination to such a transition metal should facilitate a reaction involving an antiaromatic transition state; for the coordination energy of the metal to the latter should be greater than to the reactants. It is of course impossible to predict on the basis of qualitative arguments such as this whether or not such catalysis will be sufficient to overcome the inherent barrier to reaction due to the antiaromaticity of the transition state; one can, however, predict with some confidence that if catalysis by transition metals of pericyclic reactions is observed, it will be confined to processes which are normally "forbidden" because the transition states are antiaromatic. One could state this conclusion in the form of a second amendment to Evans' rule:

Transition metals may catalyze pericyclic reactions if, and only if, they involve antiaromatic transition states.

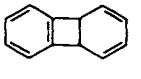


A probable example of such catalysis is that observed by *Pettit* and his collaborators[61]. The codimer *(76)* of cyclobutadiene and cyclobutabenzene is thermally quite stable because opening of either cyclobutene ring, to form ultimately benzocyclooctatetraene *(77)*, would involve an antiaromatic transition state (disrotatory ring opening of a cyclobutene ring, conrotatory opening being stereochemically impossible). Conversion of *(76)* to *(77)* does take place on heating but requires 3 hours at 150 °C to go to completion. If, however, a silver salt is added to a solution of *(76)* at room temperature, the conversion is complete in less than 10 seconds. Silver is known to form very strong complexes with benzene rings; in the complex *(78)* opening of the cyclobutene ring adjacent to benzene is catalyzed by coordination of Ag^+ to the latter. The product *(79)* undergoes further reaction to *(77)* very readily; for here the starting material is nonaromatic whereas the transition state for disrotatory ring opening is isoconjugate with cyclobuta[*b*]naphthalene *(80)* which is on balance aromatic, containing two aromatic rings and one antiaromatic one. A further nice touch is that treatment of *(76)* with platinum salts leads[61] to an equally facile conversion into *(81)*. Platinum coordinates much more strongly to olefins than to benzene rings so the catalytically active species is presumably *(82)*; here platinum catalyzes disrotatory ring opening to *(81)* which is now stable

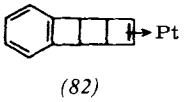


(76)

(77)



(78)



(79)

(80)

(81)

(82)

because, unlike *(79)*, it contains an aromatic ring. The transition state for disrotatory ring opening of *(81)* will again be isoconjugate with *(80)* and so contain on balance one aromatic ring; conversion of *(81)* into this transition state is therefore much less favorable than conversion of *(79)* into the corresponding one because *(79)*, unlike *(81)*, is nonaromatic.

7. Results of Recent MO Calculations

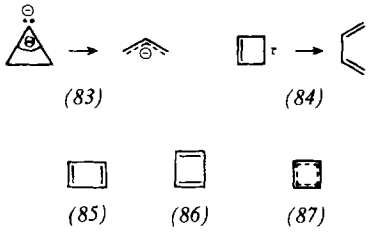
The treatments of pericyclic reactions in terms of the FO method, of conservation of symmetry of states, or of Evans' Principle, are all essentially qualitative; while one can consequently predict from them that conrotatory opening of cyclobutene should be favored, one cannot give any numerical estimate of the difference in activation energy, and so of rate, between the conrotatory and disrotatory paths. *Woodward* and *Hoffmann*[6] have expressed the belief that the factors opposing "forbidden" pericyclic reactions are so great that no exceptions to the Woodward-Hoffmann rules are possible; they consider that apparent exceptions, such as the thermal conversion of *(76)* into *(77)*, must take place by non-concerted mechanisms. On the other hand *Evans* and *Warhurst*[9] using an admittedly very crude VB treatment, estimated the difference in activation energy between the Diels-Alder reaction of butadiene with ethylene, and the corresponding "forbidden" dimerization of ethylene to cyclobutane, to be 18 kcal/mole, a difference that could easily be countered by steric effects. Thus the relief of ring strain in the initial conversion of *(76)* into *(79)* or *(81)* must be greater than 50 kcal/mole, amply adequate to permit the observation of "forbidden" disrotatory ring opening if the difference between the "allowed" and "forbidden" paths is of the order of 20 kcal/mole.

The parallel between the delocalized MOs of pericyclic transition states and the π MOs of cyclic conjugated molecules suggests that the differences between aromatic and antiaromatic systems should be comparable for both. In the case of conjugated hydrocarbons, techniques have been developed[62–64], based on the Hückel σ, π approximation and the use of semiempirical SCF MO methods for the π electrons, that enable their heats of atomization, and hence their resonance energies[62,63], to be estimated with high precision. The resonance energy of benzene on this basis is[62,63] *ca.* +20 kcal/mole, that of cyclobutadiene, assuming a symmetrical square geometry, −34 kcal/mole[65], and the corresponding resonance energies of both the aromatic and the antiaromatic series decrease with increasing ring size. The difference in resonance energy between the aromatic and antiaromatic series is therefore *ca.* 50 kcal/mole for small rings and decreases with ring size. The difference is furthermore reduced by bond alternation; the most stable form of cyclobutadiene, with a rectangular geometry, is predicted[65] to have a resonance energy of −18 kcal/mole. Since the overlap of AOs in pericyclic transition states is likely to be less than in π systems, and since bond alternation can occur very easily in antiaromatic transition states, one would expect the effects embodied in the Woodward-Hoffmann rules, and described by Evans'

Principle, to produce a maximum variation in activation energies of *ca.* 30 kcal/mole.

In order to proceed further, one must include all the valence electrons in one's calculation so that one can estimate directly the effect of delocalization in transition states. One must also be able to calculate the properties of molecules, in particular their heats of atomization and geometries, with "chemical" accuracy. Recently a semiempirical SCF MO procedure (MINDO/2[66, 67]) has been developed which comes close to meeting these requirements and calculations have been carried out for several pericyclic reactions with results that seem relevant to the present discussion.

First, the difference in activation energy between the disrotatory and conrotatory paths for several simple electrocyclic reactions, *i.e.* the ring opening of cyclopropyl radical, anion, and cation to corresponding allyl derivatives, was found to be *ca.* 30 kcal/mole, in agreement with the estimate above[68].



Secondly, the difference in activation energy between the two paths for the Cope rearrangement, *via* the "chair" *(24)* and "boat" *(25)* transition states, was correctly predicted[67, 69] and it was shown that the "boat" transition state is disfavored because of the antibonding interaction indicated in *(25)* and *(27)*. In confirmation, the calculated activation energies for a number of Cope rearrangements, in particular those of bullvalene, barbaralane, and semibullvalene, reproduced closely the observed variation in rates[70].

Thirdly, a remarkable and unexpected feature was encountered in carrying out calculations for the electrocyclic ring opening of cyclopropyl to allyl, or cyclobutene to butadiene[68].

In a "normal" reaction, one can represent the reaction path as a plot of energy *versus* a reaction coordinate, the latter being any dimension in the system (*e.g.* a bond length or bond angle) that varies monotonically during the reaction. This can be done if there is a single valley leading from the reactants to the products; if one then minimizes the energy with respect to all other variables for each value of the reaction coordinate, one arrives at a series of points at the bottom of the valley separating reactants from products. The plot of energy *versus* the reaction coordinate is then a section across the potential surface, along the bottom of the valley in question.

When, however, calculations were carried out for the "forbidden" electrocyclic ring opening of cyclobutene and cyclopropyl anion by disrotatory paths, or of cyclopropyl cation by a conrotatory one, using the apical angle θ [in *(83)*] or the bond length r [in *(84)*] as reaction coordinates, this standard technique failed. In each case there were two distinct minima in the potential surface for each value of θ or r. Further investigation showed that the potential surface is as indicated in Figure 4 which shows a two dimensional contour map of energy as a function of θ (or r) and ϕ, ϕ being the angle of twist of the methylene groups that undergo disrotatory or conrotatory rotation during the reaction. For any value of θ (or r) there are two stable geometries, one corresponding to the arrangement of bonds in the reactants and one to that in the products, while intermediate configurations have a higher energy.

As we have seen, a pericyclic reaction involves a cyclic permutation of bonds round a ring of atoms. The reaction

(83) *(84)*

(85) *(86)* *(87)*

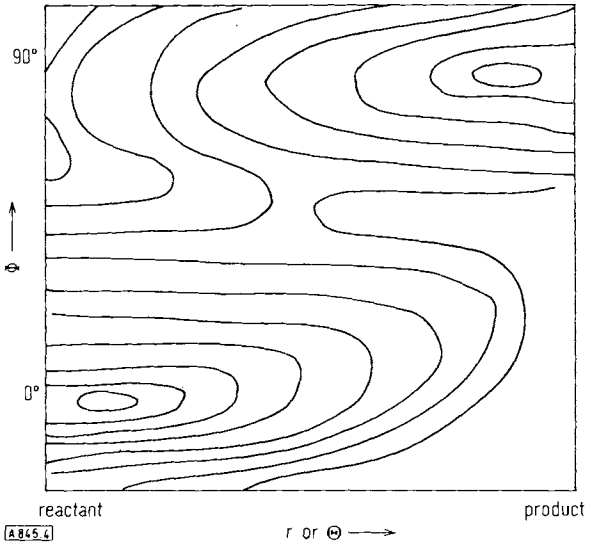


Fig. 4. Potential surface for "forbidden" electrocyclic reactions; ϕ is the angle of twist of the methylene groups from reactants ($\phi = 0$) to product ($\phi = 90°$).

can formally be regarded as the conversion of one Kekulé-like structure into another. In the transition state the system must have an intermediate geometry. If the transition state is aromatic, this intermediate structure has a lower energy than either of the "classical" structures corresponding to reactant or product; there will then be just *one* minimum in the potential surface for each value of a given reaction coordinate and consequently a single valley, leading from reactants to products, in the potential surface. This situation indeed held for the analogous "allowed" reactions, *e.g.* the conrotatory opening of cyclobutene.

If, however, the transition state is antiaromatic, the intermediate structure has a *higher* energy than either "classical" structure. The situation is analogous to that in cyclobutadiene where the classical structures *(85)* and *(86)* are more stable than the intermediate *(87)*. There are consequently *two* distinct valleys in the potential surface, corresponding to the reactant and product; the transition state is now the low point in the ridge separating the two valleys.

According to this argument, the same situation should arise in any reaction proceeding *via* an antiaromatic transition state; we have already found this to be the case for the "forbidden" *cis, cis* dimerization of ethylene to cyclobutane.

These calculations thus confirm in a rather dramatic and unexpected way the picture on which Evans' Principle is based. They also suggest that the energy factor favoring reactions with aromatic transition states are by no means overwhelming. On this basis the terms "allowed" and "forbidden" seem unfortunate in view of the connotations they carry from molecular spectroscopy. Resonance stabilization or destabilization of the transition state is only one of the factors affecting the rate of a pericyclic reaction and one that is by no means necessarily dominant. It would seem more appropriate to refer to the two types of pericyclic process as *aromatic* and *antiaromatic*, emphasizing that the antiaromatic reactions are no less possible than the existence of antiaromatic conjugated systems.

In this connection it should be pointed out that *Zimmerman*[38] and others have used the term Möbius system for those termed here antiaromatic. The term Möbius seems unsatisfactory for two reasons. First, the MOs of many antiaromatic transition states [*e.g. (38)*] do not have the topology of a Möbius strip; secondly, the topological distinction between aromatic and antiaromatic systems was first pointed out by *Craig*[25] on a different basis.

I am grateful to Professor R. Pettit and Professor I. K. Ugi for helpful criticisms and to Professor J. Halpern for a valuable discussion concerning the role of Evans. This work was supported by the Air Force Office of Scientific Research through Contract F 44620-70-C-0121.

Vanadium and Chromium Catalysts for Polymerization of Ethylene

By G. Henrici-Olivé and S. Olivé[*]

In the present progress report literature data concerning homogeneous catalyst systems based on vanadium and chromium are reviewed and complemented by a combined study of the magnetic properties and the polymerization activity of such systems. The results show that vanadium forms active species as V(III) and as V(II), but chromium only as Cr(II); models are suggested for the polymerization process.—A comparison with heterogeneous systems (Phillips catalyst) allows the establishment of some general principles concerning the activity of the catalyst and the properties of the polymers.

1. Introduction

The catalysts used for the industrial production of linear polyethylene are based essentially on either of two transition metals: titanium or chromium. Whereas the former is one of the components of the classical Ziegler systems[1], the latter represents the fundamental constituent of the Phillips catalyst[2]. Vanadium, situated between these two metals in the Periodic System, should be expected to have comparable catalytic activity. In fact there are numerous papers and patents referring to vanadium based catalyst systems for the polymerization of ethylene. However, none has reached commercial importance, perhaps due to the high molecular weights of the products. The specific use of vanadium-based systems appears to be for the copolymerization of ethylene and propylene[3,4]. Furthermore the name of vanadium will be coupled for ever with the first case of a stereospecific polymerization of an α-olefin with a homogeneous catalyst (syndiotactic polypropylene[5,6]).

The mechanism of the polymerization of ethylene on commercial, titanium based heterogeneous catalysts has lost a great part of its mystery as a consequence of a deeper knowledge obtained in the study of homogeneous systems[7,8]. It is now generally agreed that the active center is an alkylated titanium species with one vacant site in its coordination sphere, where the monomer can be coordinately bonded to the transition metal. The propagation step consists in the insertion of the olefin into the titanium-carbon bond [eq. (1)].

$$\begin{array}{l} H_2C{=}CH_2 \\ \quad\downarrow \\ (L_x)\text{-}Ti\text{-}R \longrightarrow (L_x)\text{-}Ti\text{-}CH_2\text{-}CH_2\text{-}R \end{array} \qquad (1)$$

The electron-donor-acceptor properties of the other ligands (L_x) of the titanium center have to be such that the Ti-carbon bond is stable in the absence of coordinated ethylene, and acquires just sufficient destabilization on coordination to permit the insertion reaction. It appears that Ti(IV), Ti(III), and Ti(II) are active valence states, each of them, however, having different requirements concerning the ligands L_x for suitable activity. (See recent reviews on the mechanistic aspects of the polymerization of ethylene with titanium based catalysts[9,10].)

How far has our knowledge advanced in the case of vanadium and chromium based catalysts? The valence states of V(IV), V(III), and V(II), as well as of Cr(V), Cr(III), and Cr(II) have been claimed for the active species *(vide infra)*. Although, after the experience gained with Ti, various valence states might be expected to be active, a look at the organometallic chemistry and the work carried out to synthesize and stabilize metal-carbon bonds of vanadium[11,12] and chromium[13,14] casts some doubt on the existence of alkyl groups or growing chains attached to V(IV), Cr(V), and to some extent (at $T > 0\,^{\circ}C$) also to Cr(III).

In the following a study of the present state of knowledge, concerning homogeneous as well as heterogeneous systems, will be supplemented by recent results obtained by the authors using homogeneous vanadium and chromium catalysts, with the aim of reaching some general conclusions concerning valence state, structure of the active species, and ligand requirements in the case of these two transition metals.

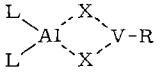
2. Homogeneous Systems



2.1. Present State

The first soluble vanadium catalyst for the polymerization of ethylene was reported in 1958 by *Carrick*[15]. Vanadium tetrachloride, aluminum bromide, and triphenyl- or triisobutylaluminum in cyclohexane constitute a system able to polymerize ethylene at 60 °C.

Extraction of the catalytic solution with sulfuric acid and polarographic analysis showed the vanadium to be exclusively divalent. The reduction of the original V(IV) was accomplished in less than one minute, but no further reduction to V(I) or V(0) was observed.

On the other hand, VCl_2 and VBr_2 are not soluble in cyclohexane, nor are they catalytically active. They can, however, be solubilized by complex formation with $AlBr_3$. Addition of an aluminum alkyl to these solutions then also provides an active catalyst.

From these facts *Carrick* concluded that the active species in the VCl_4 system is also a V(II)-Al complex, and in analogy to bridge-bonded Ti—Al complexes[16] structure *(1)* was suggested (L = alkyl or halogen, X = halogen, R = alkyl or growing chain).

(1)

The aluminum alkyl was later replaced by tetraphenyltin[17], and it was shown that the first process to occur in the system is the formation of an aluminum alkyl[17, 18]. *Van der Kerk et al.*[19] demonstrated that the combination of $AlBr_3$ and the organometallic compound $[(C_6H_5)_4Sn$ or $(C_6H_5)_3Al]$ could be replaced by $(C_2H_5)AlCl_2$, leading to a catalyst of comparable activity. The same authors[20] deduced from a spectroscopic investigation of the system VCl_4 (or $VOCl_3$) with $(C_2H_5)AlCl_2$ in cyclohexane at room temperature that the catalyst precursor is a V(II) species complexed to an aluminum alkyl. It is assumed that the active species forms only under the influence of trace amounts of oxygen (compare also *Carrick et al.*[21]), the valence state of the vanadium in the active species is said to be uncertain.

In 1962, *Bier et al.*[22] reported evidence for V(III) in the active species of the system $VOCl_3/(C_2H_5)_3Al_2Cl_3$ in heptane when used as catalyst for the copolymerization of ethylene with propylene (20 °C). They found a certain catalyst depletion with time, accompanied by a decrease of the concentration of V(III) in the solution. Both phenomena followed approximately the same rate law. The authors concluded that the active species consists of a V(III)-Al complex which is deactivated on reduction V(III) → V(II).

Natta et al.[23] also found V(III) to be the active valence in systems consisting of VCl_4 or $V(acac)_3$ (acac = 2,4-pentanedionate) with aluminum alkyls when used at −78 °C as catalyst for the syndiotactic polymerization of propene. The authors stated that a necessary condition for catalytic activity is the presence of at least one halogen ligand at either of the two components. The catalytic solutions are stable only at low temperature; on heating to room temperature inactive solid VCl_2 precipitates.

The system $V(acac)_3/(C_2H_5)_2AlCl$ shows the same catalytic behavior as the VCl_4 catalyst, thus eliminating V(IV) as the active valence. From the observation of constant polymerization rate (with the VCl_4 system), and the fact that only a small amount of the vanadium is active, it is deduced that the active species is continuously formed and destroyed to guarantee a steady state concentration. The catalyst is assumed to be VCl_2R complexed with the aluminum alkyl. The following mechanism is proposed for its formation and destruction:

$$VCl_4 \xrightarrow{R_2AlCl} VCl_2R_2$$
$$VCl_2R_2 \longrightarrow VCl_2R + R^*$$
$$VCl_2R + \text{monomer} \longrightarrow VCl_2P$$
$$VCl_2P \longrightarrow VCl_2 + P^*$$

P = polymer chain and P* = polymer radical

i.e. a dialkylated V(IV) species is proposed as the catalyst precursor.

Lehr et al.[24], however, discovered, with the same catalyst system and by ESR measurements (cf. Section 2.2), that after a few minutes at −78 °C practically all V(IV) is reduced, presumably to V(III), thus eliminating V(IV) species as possible catalyst precursor. A non-alkylated V(III) compound is suggested instead, which on alkylation becomes the catalyst. This opinion has been opposed recently by *Sváb*[25] who deduced, from an oxidimetric investigation of the systems VCl_4 (or $VOCl_2$) with several aluminum alkyls at varying temperatures, that at −78 °C the active species is $(C_2H_5)VCl_3$.

Thus there is agreement among different workers concerning certain points: the active species is a complex containing vanadium as well as aluminum; one of the catalyst components must contain at least one halogen ligand; no valence lower than V(II) is active. Disagreement has been found concerning the mechanism of the formation of the active species (pathways *via* dialkylated V(IV) and *via* non-alkylated V(III) species have been proposed), and concerning the valence state of the transition metal (V(IV), V(III), and V(II)).

On the other hand, homogeneous chromium based catalyst systems for the polymerization of ethylene have rarely been reported. A few literature references (including patents)[26–28] are not particularly clear about the physical state of the catalysts used. The only declaredly homogeneous system appears to be tris(π-allyl)chromium(III) as described by *Wilke et al.*[29] in a report on the conversion of ethylene at room temperature to high molecular weight polymer with an IR spectrum essentially coincident with that of Ziegler polyethylene, but with poor solubility, presumably due to crosslinking. Mechanism and valence state of the Cr in the active species have not been investigated.

2.2. Magnetic Measurements

An early ESR study with vanadium catalysts was carried out by *Natta et al.*[23] with the systems mentioned in the previous section (*e.g.* $VCl_4/(C_2H_5)_2AlCl$). Whereas the

active catalyst solution did not exhibit any ESR signal at $-78\,^{\circ}C$, the loss of activity on heating to room temperature was accompanied by the appearance of a broad one-line signal, identified as belonging to solid VCl_2.

Lehr[24] used ESR in an ingenious way to prove his hypothesis that VCl_4 is reduced immediately by $(C_2H_5)_2AlCl$ at $-78\,^{\circ}C$, and therefore could not be the precursor of the active species. V(IV) in solutions of VCl_4 is not detectable by ESR at temperatures above $9\,^{\circ}K$[30]. But VCl_4 can easily and quantitatively be converted into the VO^{2+} ion by quenching with ethanol. Since the vanadyl ion has a strong and well characterized ESR signal, the disappearance of V(IV) could easily be monitored. It was found that less than 0.07% of V(IV) remained after five minutes.

2.2.1. Choice of Suitable Systems

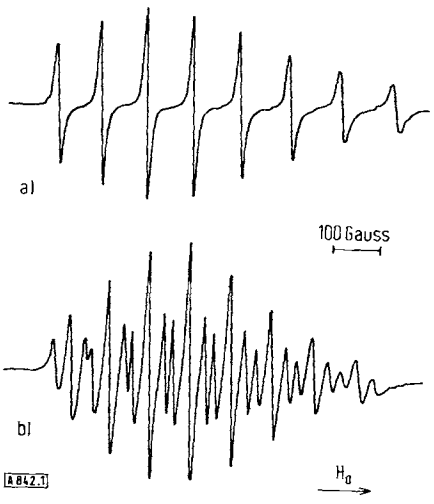
For a combined study of magnetic properties and polymerization activity we chose vanadyl bis(2,4-pentanedionate), $VO(acac)_2$, and chromium tris(2,4-pentanedionate), $Cr(acac)_3$, as transition metal components. Both are crystalline compounds which can be obtained in high purity. They are soluble in hydrocarbon solvents, stable enough in air for weighing operations, and quite stable under dry argon. Because of these properties the chosen compounds compare favorably with, *e.g.*, VCl_4 or $VOCl_3$, which are extremely air sensitive liquids, and with $VOCl_2$, which is insoluble in hydrocarbons and highly deliquescent.

Both $VO(acac)_2$ and $Cr(acac)_3$ form homogeneous catalyst solutions with $(C_2H_5)_2AlCl$. The stability of these solutions depends to some extent on the ratio of Al/M (M = transition metal). At low ratios, *i.e.* low Al content, the solutions tend to become turbid after some minutes, but this can be overcome by addition of phosphanes or phosphites. The measurements described below were therefore carried out in the presence of these stabilizing ligands.

2.2.2. Magnetic Measurements with Vanadium Systems

A recent ESR investigation[31] of the reaction of $VO(acac)_2$ with alkylaluminum chloride revealed that the acac ligands are replaced rapidly by chlorine. The evidence is as follows: $VO(acac)_2$ dissolved in toluene presents the typical eight-line signal of the free VO^{2+} ion (Fig. 1a). This signal does not change in the presence of triethyl phosphite. However, if ethylaluminum dichloride is added to a solution containing the phosphite, a new signal appears almost immediately (Fig. 1b). Each of the eight vanadium lines of the pure vanadyl spectrum is now split into a 1:2:1 triplet, indicating the interaction of the unpaired electron of the vanadium with two equivalent phosphorus nuclei.

The complex giving the signal in Fig. 1b can be decomposed by the addition of tetrahydrofuran. A vanadyl signal similar to that of Fig. 1a, but not identical, is then obtained. The spectra of $VO(acac)_2$ and $VOCl_2$ show a small but significant difference in the vanadium hyperfine splitting constant a_V (300 ± 2 and 287 ± 2 MHz, respectively), which allows the conclusion that the vanadyl center now bears chlorine ligands instead of the original acac ligands. The latter are assumed to be now bonded to aluminum which



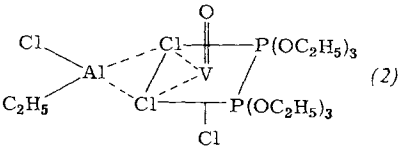


Fig. 1. ESR signals of vanadyl compounds in toluene. a) $VO(acac)_2$ alone, b) $VO(acac)_2/(C_2H_5O)_3P/(C_2H_5)AlCl_2$, V:P:Al = 1:6:10.

does not form part of the complex. The ligand exchange appears to be very rapid.

If the decomposition of the complex with THF is made a few minutes after the addition of the aluminum alkyl, essentially all vanadium is recovered as VO^{2+}, *i.e.* in this short time interval no reduction has taken place. On the other hand, $VOCl_2$ in the presence of triethylphosphite gives the triplet signal (Fig. 1b) only if aluminum alkyl is added[31]. Thus, in order to obtain the signal it is not sufficient only to replace the acac ligands by chlorine, but complex formation with the aluminum alkyl must also be possible. Presumably a bridge-bond is formed which completes an octahedral configuration as shown in *(2)*.

(2)

After longer time intervals the intensity of the signal in Fig. 1b decreases somewhat, indicating a slow reduction, presumably to V(III). With $(C_2H_5)_2AlCl$ instead of $C_2H_5AlCl_2$ the same ESR signal is observed, but the reduction rate is considerably higher. At a ratio of Al/V > 5 the V(IV) disappears so rapidly that no ESR signal can be detected, not even immediately after mixing of the components. With $(C_2H_5)_3Al$ the acac ligands also disappear, but the reduction goes through to V(0) which is stabilized as its bis-toluene complex, identified by the ESR signal reproduced in Fig. 2[32]. Each of the eight vanadium lines is split by the ten ring protons of two toluene molecules.

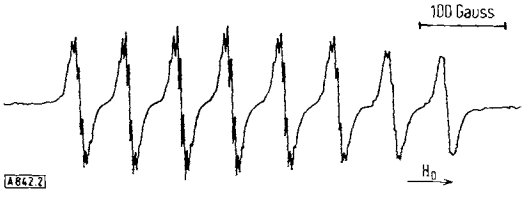

Fig. 2. ESR signal of bis-toluene-V(0) [32].

(This signal was erroneously attributed by *Shiulydin et al.*[33] to a complex containing one V(II) and two aluminum alkyls.)

The reduction reactions occurring in the V/Al catalyst systems are best investigated by magnetic susceptibility measurements. We determined the effective magnetic moment, μ_{eff}, of the vanadium in the system $VO(acac)_2/(C_2H_5)_2AlCl$ in benzene at different ratios of Al/V, in the presence and absence of stabilizing phosphanes and phosphites. From these data the average number of unpaired electrons per vanadium was calculated, making use of the spin-only formula, which is a good approximation for vanadium in its different valence states[34].

The results of the magnetic measurements are shown in Fig. 3. The data are obtained five minutes after mixing the components, the solutions then being completely homogeneous. At Al/V < 100, there is a tendency for the solution to become turbid after some 20—60 minutes, especially in the absence of stabilizing phosphorus compounds. At Al/V > 100 the solutions are stable and the magnetic data do not change with time.

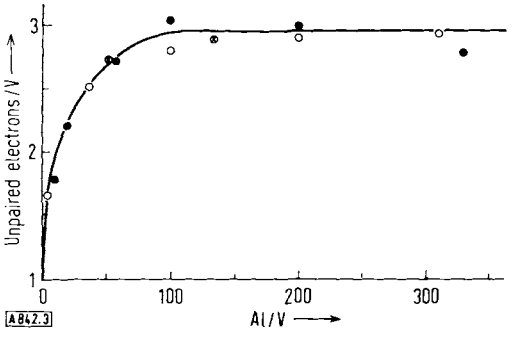

Fig. 3. Average number of unpaired electrons per vanadium center in the system $VO(acac)_2/(C_2H_5)_2AlCl$. ●: without stabilizer; ⊗: with $(C_6H_5)_3P$; ○: with $(C_2H_5O)_3P$. P/V = 6; $T = 20°C$.

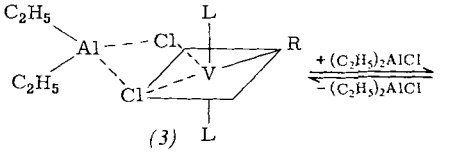

Fig. 3 shows a steady increase from one to three unpaired electrons per vanadium center in the range of Al/V from 0 to 100, the limiting values corresponding to V(IV) and V(II) respectively. At Al/V = 100 practically pure V(II) is reached. No further reduction takes place, not even at Al/V > 300. The presence of phosphorus compounds does not essentially affect the reduction process.

Table 1 gives the valence distribution at different ratios of Al/V. These numbers are computed from the data of Fig. 3. Since it has been proved by ESR that no V(IV) is detectable at Al/V > 5 immediately after mixing the components, the magnetic effect must be distributed between V(III) and V(II). The fraction of 6% of V(III) at Al/V ≥ 100 is probably not real, but is due to a small deviation of the true values of the molar susceptibility, χ_{mol}, from those calculated with the spin-only formula for V(II) and V(III) (6330×10^{-6} and 3370×10^{-6} e.m.u., respectively).

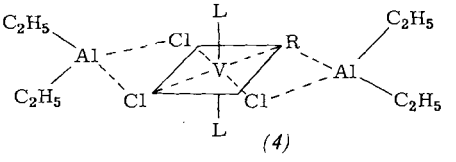

Table 1. Fractions of V(III) and V(II) after the reaction of $VO(acac)_2$ with $(C_2H_5)_2AlCl$. (Computed from the data of Fig. 3.)

Al/V	Unpaired electrons	$\chi_{mol} \times 10^6$ (e.m.u)	V(III) (%)	V(II) (%)
20	2.3	4110	75	25
50	2.7	5360	33	67
100	2.95	6150	6	94
300	2.95	6150	6	94

From the ESR experiments cited above we know that the acac ligands do not form part of the reduced vanadium complex. On the other hand it should be noted that with $(C_2H_5)_2AlCl$ it is not possible to obtain the bis-benzene-V(0) complex which is formed with $(C_2H_5)_3Al$. Presumably the presence of chlorine ligands at the vanadium center permits the formation of a bridge complex with one or two aluminum alkyl molecules which stabilizes the vanadium in the valence state V(II). Thus, the final stable V(II) complex may well be an equilibrium mixture of structures *(3)*

(3)

(4)

and *(4)* (R = ethyl or chlorine). The ligands L completing the octahedral structure might be solvent, phosphane, phosphite, or aluminum alkyl (cf. Section 2.3.2).

2.2.3. Magnetic Measurements with Chromium Systems

The chromium in $Cr(acac)_3$ is paramagnetic ($3d^3$). From the magnetic susceptibility of a benzene solution the magnetic moment $\mu_{eff} = 3.84$ BM can be obtained which, with the spin-only formula, corresponds to 2.96 unpaired electrons per chromium center.

The addition of $(C_2H_5)_2AlCl$ to the solution at ratios of Al/Cr < 200 results in the immediate appearance of turbidity and, after some minutes, the formation of a precipitate. In the presence of triethyl phosphite, however, the solution remains homogeneous. At ratios of Al/Cr ≥ 200, no precipitation is observed even in the absence of phosphite.

We measured the magnetic susceptibility of the homogeneous solutions at different ratios of Al/Cr, and calculated the average number of unpaired electrons per Cr center. These data are represented in Fig. 4.

In the range of Al/Cr from 0 to 20 the number of unpaired electrons decreases from three to about two. At higher ratios this number starts to increase; it again reaches a value of three at Al/Cr ≈ 70, and apparently tends asymptotically to four at Al/Cr > 400. The data given in Fig. 4 were recorded five minutes after mixing the components. There is still some variation with time which is shown in Table 2. In the absence of phosphite and at Al/Cr = 300 the final value of four unpaired electrons is almost reached after one hour (run 2). With $(C_2H_5)AlCl_2$ the process indicated by the change from two to four unpaired electrons appears to be slower than with $(C_2H_5)_2AlCl$ (run 3).

Our interpretation of the experimental findings given in Fig. 4 and Table 2 is as follows:

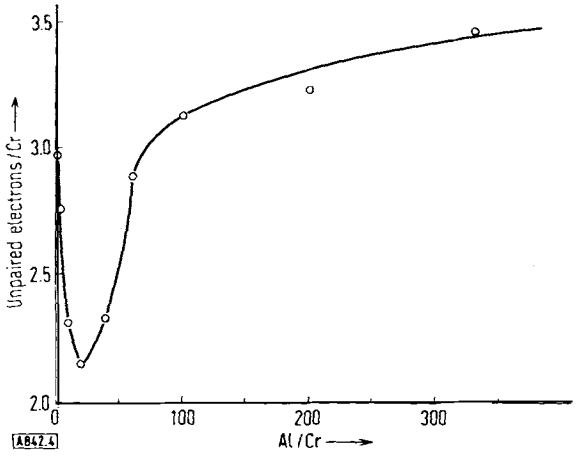

Fig. 4. Average number of unpaired electrons per chromium center in the system $Cr(acac)_3/(C_2H_5)_2AlCl/(C_2H_5O)_3P$; P/Cr = 6; T = 20 °C.

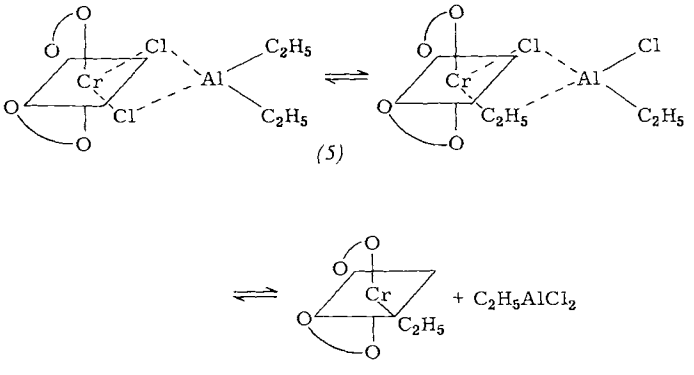
Table 2. Average number of unpaired electrons per chromium center as a function of time. $[Cr(acac)_3]_0 = 20 \times 10^{-3}$ mol/l, Al/Cr = 330, benzene, 20 °C.

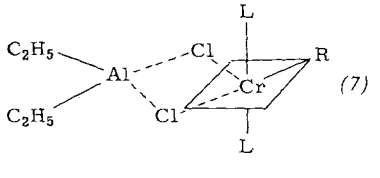


Run	Al-alkyl	$(C_2H_5O)_3P/Cr$	t (min)	Unpaired electrons per Cr
1	$(C_2H_5)_2AlCl$	6	5	3.42
			60	3.71
			120	3.73
2	$(C_2H_5)_2AlCl$	0	5	3.73
			60	3.88
			120	3.88
3	$(C_2H_5)AlCl_2$	0	5	2.89
			60	3.68
			120	3.72

Cr(II) ($3d^4$) complexes are, with very few exceptions, octahedral[35]. In this symmetry two arrangements are possible for the four 3d-electrons, depending on the energy differences between the t_{2g} orbitals (d_{xy}, d_{xz}, d_{yz}) and the e_g orbitals ($d_{x^2-y^2}$, d_{z^2})[34]. In a strong ligand field this separation, Δ, is large. In this case it is energetically more favorable that all four electrons stay in the lower lying t_{2g} orbitals, although pairing energy has to be expended. On the other hand, in a weak ligand field Δ is relatively small, and the promotion of one electron to the e_g level is favored. Consequently, Cr(II) is expected to have two unpaired electrons in a strong ligand field, and four in a weak field.

Thus the course of the curve in Fig. 4 represents the reduction Cr(III)→Cr(II) (low spin) in the region of Al/Cr ≤ 20. At higher ratios of Al/Cr we observe the transition from low spin to high spin configuration. A reasonable explanation for this behavior is a ligand exchange without variation of the symmetry of the complex. The acac ligands are known to be strong field ligands[36, 37]. We suggest that in the region of Al/Cr > 20 acac ligands are replaced by ligands producing a weaker field, presumably chlorine. In the case of vanadium this kind of exchange was demonstrated by ESR measurements (preceding section). However, in the case of $Cr(acac)_3$ too, a substitution of acac ligands by other ligands has already been observed on several occasions. *Hein*[38] reported the formation of phenylchromium compounds during the reaction of $Cr(acac)_3$ with phenylmagnesium bromide in ether. The reaction with triethylaluminum has also been described[39], including the formation of C—O—Al bonds and the evolution of ethane and ethylene. Presumably the alkylchromium compounds originating from the substitution of the acac ligands by ethyl groups are completely unstable in the absence of stabilizing ligands. If this latter reaction is carried out in aromatic solvents, zerovalent and low-valent chromium can be stabilized as bis-arene complexes, as evidenced by the ESR signal of bis-arene-Cr(I)[32].

Summarizing the magnetic measurements in the case of chromium, it can be said that the reaction of $Cr(acac)_3$ with aluminum alkyls leads to ligand exchange and reduction. If chlorine ligands are available, Cr(II) is stabilized, and no further reduction takes place even at very high ratios of Al/Cr. In the special case of $(C_2H_5)_2AlCl$ we propose the following reaction path:



Exchange of the first acac with Cl leaves one coordination site free, where an aluminum bridge bond can establish [cf. titanium[8, 9] and vanadium (Section 2.2.2) systems].

If this bridge bond opens again, leaving an ethyl group at the metal center, the very unstable Cr(III)-carbon bond cleaves, resulting in a Cr(II) species *(6)* that is probably stabilized by phosphite ligands L (precipitation occurs in the absence of phosphite).

$$2(acac)_2Cr(III)C_2H_5 \longrightarrow \underset{(6)}{2(acac)_2Cr(II)L_2} + C_2H_4 + C_2H_6$$

Further exchange of the acac ligands for Cl or C_2H_5 may then lead to a species *(7)* similar to that formulated above

for the case of vanadium, perhaps also in equilibrium with a complex having two bridges.

2.3. Polymerization of Ethylene

2.3.1. Polymerization with Vanadium Systems

Fig. 5 shows the ethylene uptake in solutions of the $VO(acac)_2/(C_2H_5)_2AlCl$ catalyst at 20°C in the presence of a phosphane and at different ratios of Al/V. (For experimental methods see Reference [8].) At Al/V < 20, essentially no uptake is observed. The polymerization rate has a maximum at Al/V = 50, and then decreases steadily to Al/V = 500.

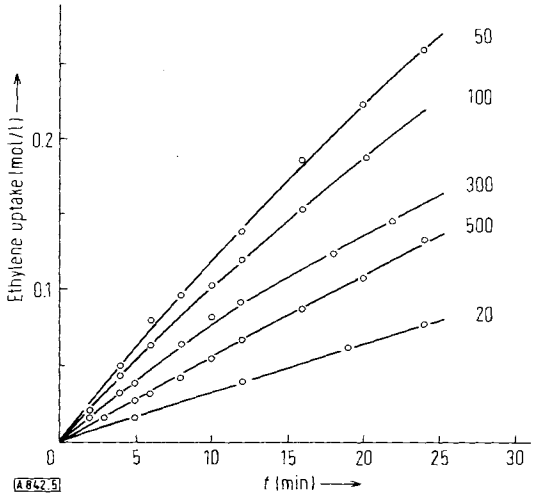


Fig. 5. Polymerization of ethylene with $VO(acac)_2/(C_2H_5)_2AlCl$ in the presence of $(C_6H_5)_3P$, at different ratios Al/V (numbers next to curves). $[V] = 1 \times 10^{-4}$ mol/l; P/V = 6; toluene, 20°C, ethylene pressure = 700 torr.

A look at Table 1 does not provide an immediate explanation for this behavior. The discussion is easier at the higher end of the Al/V scale. From Al/V = 100 upwards there is essentially only V(II) present, which must be the catalyst. In this range the initial rate of polymerization decreases linearly with the ratio Al/V, as shown in Fig. 6. This decrease is best interpreted as a blocking of coordination sites by aluminum alkyl, as depicted in formula *(2)* (Section 2.2.2).

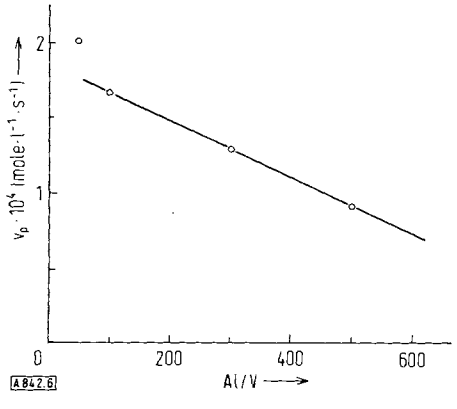

Fig. 6. Initial rate of polymerization V_p as a function of Al/V (taken from Fig. 5).

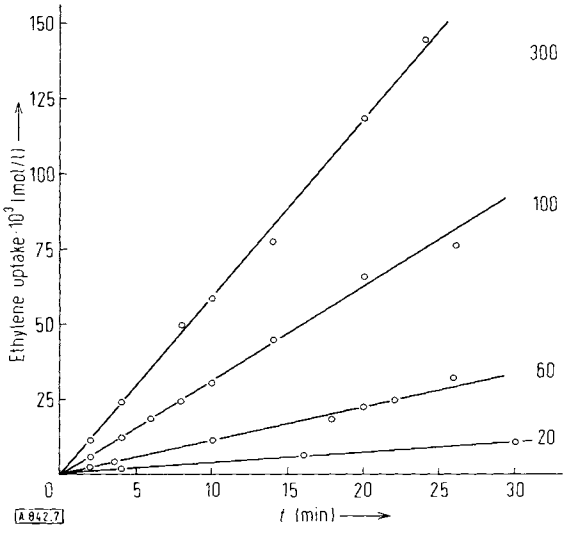
At Al/V = 50, the rate is higher than could be expected from the linear relationship, although under these conditions only 67% of the vanadium is present as V(II) (Table 1). We may deduce that V(III) is also a catalyst, and even more active than the V(II) species. Why then do we observe such a low polymerization rate at Al/V = 20, where, according to Table 1, we have most of the vanadium present as V(III)? We suggest that the active V(III) species is also a complex with the aluminum alkyl, and that this complex must be formed in an equilibrium reaction. At this relatively low ratio of Al/V there is just not enough aluminum alkyl present to displace the equilibrium sufficiently in favor of the complex.

We may summarize our knowledge concerning the vanadium catalysts as follows: Both V(III) and V(II) species are able to form, with aluminum alkyl, a catalyst for the polymerization of ethylene. V(III) based catalysts are probably more reactive, but less stable at room temperature.

2.3.2. Polymerization with Chromium Systems

A set of polymerization data with the homogeneous system $Cr(acac)_3/(C_2H_5)_2AlCl$ in the presence of $(C_2H_5O)_3P$ and at different ratios of Al/Cr is represented in Fig. 7.



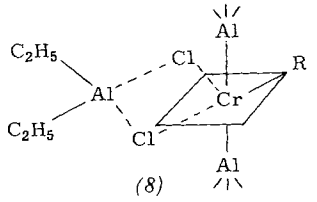


Fig. 7. Polymerization of ethylene with $Cr(acac)_3/(C_2H_5)_2AlCl$ in the presence of $(C_2H_5O)_3P$ at different ratios Al/Cr (numbers next to curves). $[Cr] = 2 \times 10^{-4}$ mol/l; P/Cr = 6; toluene, 20°C; ethylene pressure = 700 torr.

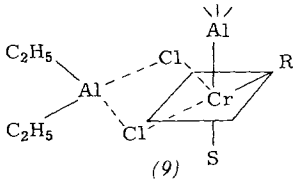

The same system has been investigated magnetically (Fig. 4). A comparison of the two sets of data indicates clearly that the active species is the high spin Cr(II) complex *(7)*, whereas the low spin Cr(II) complex *(6)* predominantly present at Al/Cr = 20 is inactive. It is evident that the acac ligands must be replaced by C_2H_5 and Cl in order to obtain the active species. This exchange not only makes a site available for the coordination of the monomer, but also provides a chlorine "pier" for the activating aluminum bridge (compare the case of titanium[8]).

As mentioned already in connection with the magnetic measurements, the high spin Cr(II) is also soluble in the absence of phosphite at Al/Cr > 200. The rate of polymerization of ethylene, obtained with such a phosphorus-free catalyst under otherwise identical conditions is about

three times higher than with the system containing $(C_2H_5O)_3P$. (Compare Fig. 8, upper curve, with Fig. 7, curve for Al/Cr = 300.) This indicates that different ligands are effective in the two cases. In the presence of phosphite, the two ligands L of the octahedral complex *(7)* are probably $(C_2H_5O)_3P$. Since in the absence of this compound the solubility of the Cr(II) species can be achieved only at very high ratios of Al/Cr, we may conclude that one or two further aluminum alkyl molecules have entered into the coordination sphere of the chromium to maintain it in solution, *e.g.* as *(8)* or *(9)* (with ≥Al = aluminum alkyl, S = solvent, and R = C_2H_5 or growing chain).

(8)

(9)

Since no more Cl ligands are available as piers for bridge bonds, we have to consider direct Al—Cr interaction. (A similar suggestion was put forward by *Wilke et al.*[29] for Al—Ni during the reaction of bis(π-allyl)Ni with $(C_2H_5)_2AlH$.)

Polymerization with phosphite-free systems was further investigated with $(C_2H_5)_2AlCl$ as well as with $C_2H_5AlCl_2$. Three runs are represented in Fig. 8 and described in Table 3. The polymers A and B differ only in the degree of conversion. The polymers have been analyzed by gel permeation chromatography; the molecular weight distributions obtained from these data are given in Figs. 9 and 10.

Polymerization with $(C_2H_5)_2AlCl$ proceeds at a considerably higher rate, and at comparable conversion also gives a higher molecular weight than that observed on polymerization with $C_2H_5AlCl_2$ (see Table 3). This parallels the experience with titanium catalysts[8, 9], and corroborates the assumption that the aluminum alkyl forms part of the catalytic complex. The donor ligand C_2H_5 destabi-

Table 3. Conversion and molecular weights of polymers prepared with $Cr(acac)_3$ catalyst systems in the absence of phosphite. $[Cr] = 2 \times 10^{-4}$ mol/l, Al/Cr = 300, T = 20 °C, ethylene pressure = 700 torr.

Polymer	Al-alkyl	t (min)	Conversion (mol/l)	$M_n \times 10^{-3}$ [a]	$M_w \times 10^{-3}$ [a]	Polymer molecules per Cr
A	$(C_2H_5)_2AlCl$	15	0.29	41.1	635	0.98
B	$(C_2H_5)_2AlCl$	33	0.56	62.5	776	1.23

lizes the metal carbon bond Cr—R (with $R=C_2H_5$ or growing chain) *via* the bridge bond[9], and here perhaps additionally *via* the direct Al—Cr bond [see *(8)* and *(9)*], and thus increases the polymerization rate. The acceptor ligand Cl, on the other hand, withdraws electron density from the transition metal, and in this way increases its ability to abstract β-hydrogen from the growing chain[9b]:

$$\begin{aligned} &Cr{-}CH_2{-}CH_2{-}P \longrightarrow Cr{-}H + CH_2{=}CH{-}P \\ &Cr{-}H + C_2H_4 \longrightarrow Cr{-}CH_2{-}CH_3 \end{aligned}$$

This chain transfer reaction obviously reduces the molecular weight.

Roughly one polymer molecule has grown per chromium center in the systems containing $(C_2H_5)_2AlCl$ (see last column in Table 3), indicating that in these cases the polymerization process proceeds, at least predominantly, *via* a "living polymer" mechanism. That means that neither chain transfer nor termination reactions occur, and the Cr-polymer bond is broken only when the reaction solution is quenched with methanol at the end of the reaction. The increase of the number average molecular weight M_n with growing conversion confirms this view. With $(C_2H_5)AlCl_2$, on the other hand, 2.4 polymer molecules have grown, on average, at every Cr center, confirming the chain transfer process previously mentioned.

The polymers have an extremely broad molecular weight distribution, recalling those normally obtained with heterogeneous catalysts (M_w/M_n: 15.4 for A, 12.4 for B, and 6.4 for C). The gel permeation chromatography diagrams give some additional information concerning this point. In the case of the systems with $(C_2H_5)_2AlCl$ (Fig. 9), the molecular weight distribution curves show (at least) two maxima. The abscissa value of the lower maximum increases roughly proportionally with the conversion, as is usual for living polymers. Although this low molecular weight fraction constitutes only 1—2% of the total weight of the polymer, it contains more than 90% of the polymer molecules. (It was calculated from the GPC data that more than 90% of the molecules of polymers A und B have a molecular weight $<10^5$.) The bulk of the polymer thus consists of relatively few extremely large molecules, which must have grown at different catalyst centers, having a much greater rate constant of chain growth than the centers producing the low molecular weight part.

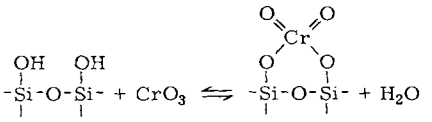
If one wishes to speculate about the configuration of the two different growth centers, one might suggest structures *(8)* and *(9)*, or perhaps a complex with two solvent ligands as a third possibility. Since aluminum alkyls presumably act as electron acceptors with respect to Cr(II), and the aromatic solvent, on the other hand, as a donor, the solvent-containing structure should be responsible for the high molecular weight part, due to more effective activation of the Cr-carbon bond. Alternatively, one of the structures might sterically (or electronically) hinder the coordination of the ethylene, thus giving rise to a much slower reaction rate.

In the case of the system with $(C_2H_5)AlCl_2$ (Fig. 10), the situation is different. The low molecular weight maximum is much more prominent, and has an approximately "normal distribution", as expected for molecules terminated by chain transfer. (The dotted curve in this figure has been calculated for a normal distribution with the average molecular weight equal to the abscissa value of the low molecular weight maximum of the curve[40].) However, there is also a high molecular weight part which must have grown at different centers.

The experiments with homogeneous chromium systems have shown that the catalyst center is an octahedral Cr(II) species in a weak ligand field (high spin) with a bridge-bonded aluminum alkyl.

The Lewis acidity of these Cr(II) centers, particularly of those prepared with $(C_2H_5)_2AlCl$, is not high enough to cause sufficient chain transfer to control the molecular weight, so that living polymers are obtained, *i.e.* the molecular weight increases with growing degree of conversion.

At least two different catalyst centers are present, the rate constants of which differ by at least an order of magnitude.



3. Heterogeneous Catalysis

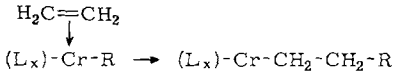
The most important heterogeneous chromium catalyst is that of the Phillips process[2], *i.e.* supported chromium oxide, which works at low ethylene pressure (even at subatmospheric) and temperature (in special cases as low as −40°C). The process was discovered in 1951. In the ensuing years it has been used worldwide and is the dominant commercial process for linear polyethylene. For example, it presently accounts for about two thirds of USA capacity, the remaining third being of the Ziegler type[41].

Perhaps the most impressive description of the discovery of this process is the report of one of the inventors[42]: "Some years ago *W. C. Lanning, J. P. Hogan, R. C. Banks* and I *(A. Clark)* were studying the polymerization of ethylene from refinery stack gases to liquid polymers over nickel oxide supported on silica-alumina, a catalyst discovered earlier at Phillips by *J. A. Reid* and *G. C. Bailey*. We were trying to make motor fuel. But the process made a lot of butylene, giving a total product which was too volatile for motor fuel. Many catalyst modifications were tried in an effort to reduce the volatility. One day chromium oxide was added to the catalyst, and all the ethylene reacted to form high polymer. That solved the volatility problem! It was quickly shown that high polymers could be made without nickel oxide. Then began a gratifying and hectic period when ideas and nature seemed to be cooperating".

The elucidation of the catalytic characteristics and the mechanism of this process has been the subject of numerous papers[43-48]. The catalyst is generally prepared by impregnation of silica or silica-alumina with an aqueous solution of CrO_3. After drying, the finely divided catalyst is activated by fluidizing in dry air at 500—1000°C for several hours. It is then stored in dry air or nitrogen. A recent careful study by one of the inventors[48] has revealed that the chromium trioxide forms a chromate *(10)* with the silanol groups of the carrier surface.

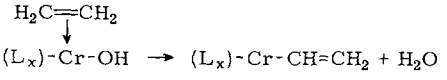
During the activation process (500—1000 °C, streaming dry air) the equilibrium is shifted to the right and water is removed. The formation of surface chromate accounts for

(10)



the ability of silica to stabilize Cr(VI) far above the decomposition temperature of CrO_3. Thus, more than 90% of the chromium can be present as Cr(VI) after the activation period (provided overloading with Cr has been avoided). If ethylene is then brought in contact with the catalyst the Cr(VI) behaves in the usual way as a strong oxidizing agent. In a redox reaction the true catalyst species is produced in form of a low-valent chromium center and the hydrocarbon undergoes oxidation. The oxidation products poison the catalyst centers. As a consequence, polymerization starts with an induction period. In time, however, ethylene displaces the poisoning substances and the final polymerization rate is reached. The induction period can be avoided if the catalyst is reduced with H_2 or CO at 250—400 °C before the admission of ethylene. CO treatment is preferable, since with H_2 water is formed which decomposes the chromate bonds in *(10)*; the free CrO_3 then decomposes to inactive Cr_2O_3. After reduction with CO, the catalyst must be flushed with N_2 at 300—400 °C in order to eliminate excess CO which would otherwise block all coordination sites.

The actual valence state of the reduced chromium in the active center has been the object of conflicting views. Cr(III) has been proposed with the argument that valences intermediate between Cr(VI) and Cr(III) are unstable and have defied attempts at separation[44]. It can be seen from the work with homogeneous catalysts reported in the last section that this reasoning is not sufficient [Cr(II) being the active species there].



Other workers favored Cr(V) in view of an ESR signal at $g = 1.97$ exhibited by the solid catalyst and ascribed to Cr(V)[43,45]. The polymerization activity was found to be proportional to the intensity of this signal[43]. This correlation was established with the ESR signal given by the catalyst before the polymerization reaction has started. Later on, however, it was discovered that the signal declines appreciably during the polymerization process while the activity appears to be sustained[46]. Thus the ESR signal could be, at best, due to a precursor of the active site.

Finally, *Krauss* and *Stach*[47] reported recently that the average oxidation state of the chromium in a CO reduced catalyst may well approach the value of two under optimal conditions, and that the polymerization rate increases with the fraction of Cr(II) for catalysts with average oxidation state between two and three (20 °C, 1 atm.). They also proved the presence of Cr(II) by a characteristic absorption in the reflection spectrum at 725 nm, and this not only in CO-reduced, but also in ethylene-treated catalysts. Thus it was reasonably concluded that Cr(II) is the essential part of the active centers.

For the initiation of polymerization it appears necessary that this Cr(II) center has a ligand R able to attack the first coordinated ethylene molecule:

Under the usual conditions of reduction of the chromium, with ethylene itself or with H_2 or CO, R might well be a hydrogen or an OH group. It has also been proposed that the first step might be an elimination of water from an OH group and hydrogen from ethylene:

No effort has been reported to clarify this open question by analysis of low conversion material.

Heterogeneous vanadium systems have considerably less importance. Patent literature is abundant, but no detailed mechanistic study of the polymerization process has come to our attention. Perhaps a recent reference concerning vanadium oxide as a highly active catalyst for the polymerization of ethylene[49] will turn out to be important in the future.

4. Comparison between Homogeneous and Heterogeneous Catalysts

Although Cr(II) appears to be the active valence state in homogeneous as well as in heterogeneous catalysts, there are considerable differences between these two kinds of systems which require further discussion.

Primarily, no aluminum alkyl is necessary in the Phillips catalyst to reduce the chromium and to stabilize the active valence state. Furthermore, the heterogeneous catalyst is far more reactive (considerably more monomer is converted per active site and unit time, see Table 4). Finally, a great number of polymer molecules grows per minute on each active site of a Phillips catalyst, indicating a strong chain transfer reaction, confirmed by the fact that each polymer molecule has one vinyl and one methyl end group[48]. In the homogeneous systems, on the other hand, no essential chain transfer but living polymers were found.

The heterogeneous and homogeneous systems are compared in Table 4. To make the data comparable, the polymerization rate and the rate of chain transfer are given per active site and per minute.

Although the data of Table 4 are obtained at different temperatures, the higher activity of the Phillips catalyst, for both growth and chain transfer, is obvious.

If we admit that the active species in the heterogeneous and the homogeneous catalysts both contain Cr(II), we must make the ligand environment of the Cr(II) centers responsible for the differences.

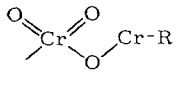


Table 4. Comparison of heterogeneous and homogeneous Cr catalyst. Ethylene pressure roughly 1 atm.

T (°C)	Catalyst system	Polymerization rate [a]	Chain transfer rate [b]	Ref.
95	Phillips (1% Cr on SiO_2)	1.2×10^5	168	[48]
20	$Cr(acac)_3$/ $(C_2H_5)_2AlCl$	100	$\simeq 0$	Polymer A, Table 3
20	$Cr(acac)_3$/ $C_2H_5AlCl_2$	15	2.3×10^{-2}	Polymer C, Table 3

[a] Monomer units grown per active site per minute.
[b] Chain transfer steps per active site per minute.

The rate-determining step for chain growth appears to be the coordination of the ethylene to the metal center. A Cr(II) center at a heterogeneous catalyst surface is presumably coordinately unsaturated. This has been deduced by *Hogan*[48], who reported that the Phillips catalyst trimerizes acetylene to benzene at a high rate, indicating space for the simultaneous coordination of three acetylene molecules around a single Cr site. The homogeneous center, on the other hand, can achieve the preferred hexacoordination in a variety of ways (aluminum alkyls, solvent). Presumably, the "free coordination site" [see formulas *(7)*, *(8)*, and *(9)*] is not really free on average, but one weakly bonded ligand has to be replaced by ethylene in an equilibrium reaction. This would explain the large differences in polymerization rate.

The ability to cause chain transfer (β-hydrogen abstraction) is governed by the electron affinity of the metal center. (This has been shown experimentally in the case of titanium catalysts[9a].) In the homogeneous systems the aluminum alkyl ligands have not sufficiently strong Lewis acid character to increase the electron affinity of the Cr(II) center to such an extent as to cause considerable chain transfer, although a significant difference is to be noted in the electron-withdrawing effect of the two aluminum alkyls ($C_2H_5AlCl_2 > (C_2H_5)_2AlCl$, see Tables 3 and 4). For the Phillips catalyst, however, we have to look for an environment much more electron withdrawing than that provided by the aluminum alkyls. The choice is not very broad: either part of the chromium has survived the reduction process in a higher valence state and forms oxygen bridged surface compounds with the Cr(II) centers, *e.g.*

or the supporting material acts in some way or other as a strong Lewis acid, withdrawing electron density from the Cr(II) centers. Unfortunately, no systematic data are available which would correlate the number average molecular weight of the polymer, under otherwise identical conditions, with the average oxidation state of the chromium (*e.g.* after different times of CO treatment) and with the acidity of the support. Thus the question of the environmental conditions favoring the β-hydrogen transfer reaction in the Phillips catalyst must also remain open.

In conclusion we wish to express our hope that the present paper may help to emphasize the basic similarities of homogeneous and heterogeneous polymerization reactions. We feel that, as in the case of titanium, the study of soluble systems can also help to provide a better understanding of the heterogeneous catalysts, allowing the establishment of general principles of common application.

Thanks are due to Dr. R. A. Mendelson and Dr. E. E. Drott, Monsanto Company, Texas City, for the GPC measurements, and to Miss E. Arnold for careful and conscientious experimental help.

Synthesis of Naturally Occurring Polypeptides, Problems of Current Research[**]

By Erich Wünsch[*]

The synthesis of naturally occurring polypeptides has recently again become a center of interest. It therefore seems appropriate to make a critical appraisal of the present state of research, and at the same time to try to eliminate much of the element of chance from the solution of the problems that face us. An attempt will be made to group the preparation methods commonly used in the past into four strategies, to point out their advantages, and to uncover their disadvantages. The ultimate aim in the synthesis of naturally occurring peptides must always be a true, clean synthesis.

1. Introduction

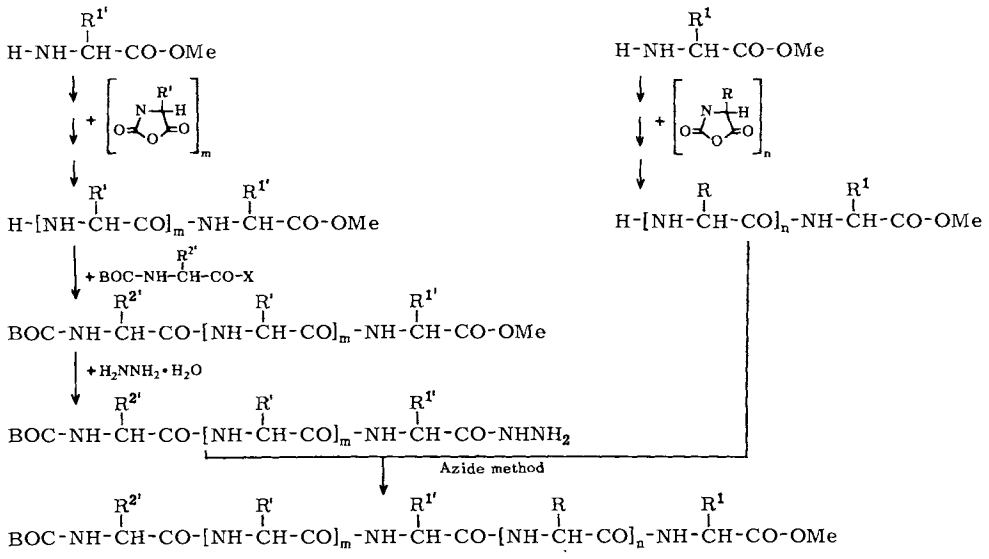
After its beginning with the synthetic preparation of oxytocin[1], the synthesis of naturally occurring polypeptides rose to a peak, and also came to a temporary halt, with the synthesis of ACTH (adrenocorticotropic hormone) by *Schwyzer et al.*[2]. The rapid further progress since that time has taken four directions:

Strategy I, the conventional synthesis with maximum masking of the side-chain functions of polyfunctional amino acids (referred to hereafter as third functions), by which the total syntheses of glucagon[3,4] and of calcitonin[5,6] were achieved. In the synthesis of glucagon, all the third functions were masked except the ω-amide groupings of aminodicarboxylic acids. *Akabori*[7], *Weygand*[8], *Chillemi*[9], and more recently *Geiger*[10] and their coworkers have carried out syntheses in which this ω-amide function was also protected.

Strategy II, the conventional synthesis with minimum masking of the third functions of polyfunctional amino acids. It is based on systematically controlled linkage with the aid of *N*-carboxylic acid anhydrides. *Denkewalter, Hirschmann et al.*[11,12] have shown that only the ω-amino and mercapto functions must be blocked.

Any intermediate stage (as far as masking of the third functions is concerned) between the two extremes of the conventional peptide synthesis is naturally possible; the work of *K. Hofmann*[13] on the ribonuclease synthesis is characterized in particular by relatively slight masking of the third functions.

Features common to both conventional synthesis strategies, except in a few cases, are:



1. The initial construction of large peptide fragments,
2. the subsequent linkage of these fragments to form larger units. In view of the technique used, this is possible only by the azide method in strategy II (Scheme 1).

Strategy III, the "solid-phase synthesis", which was launched by *Merrifield*[14,15], and of which there are a number of variants. In all solid-phase syntheses (except the methods used by *Letsinger*[16] and more recently by *Merrifield*[17][*]), the C-terminal amino acid of the peptide is masked by attachment to a polymer. The peptide sequence was originally built up in steps in all the solid-phase methods. The obvious aim of both the older "Merrifield method"

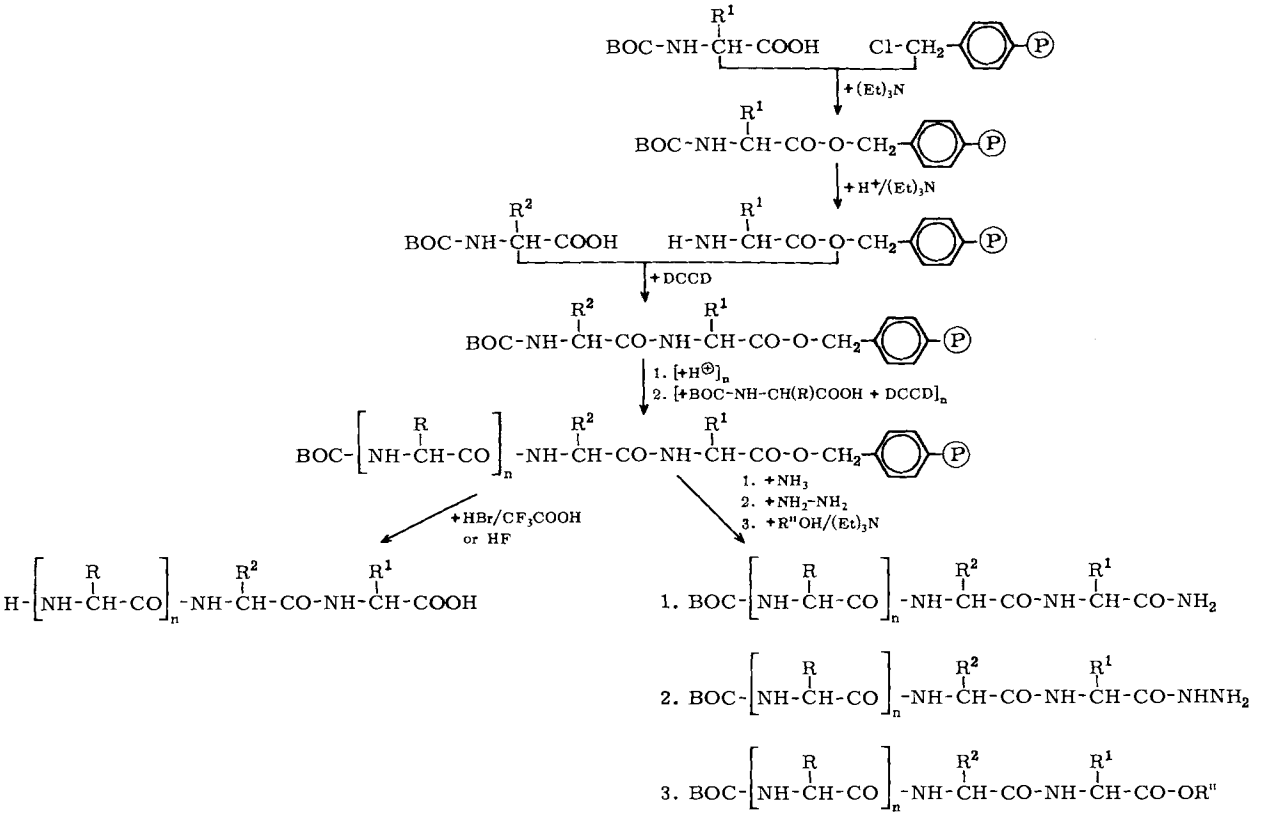
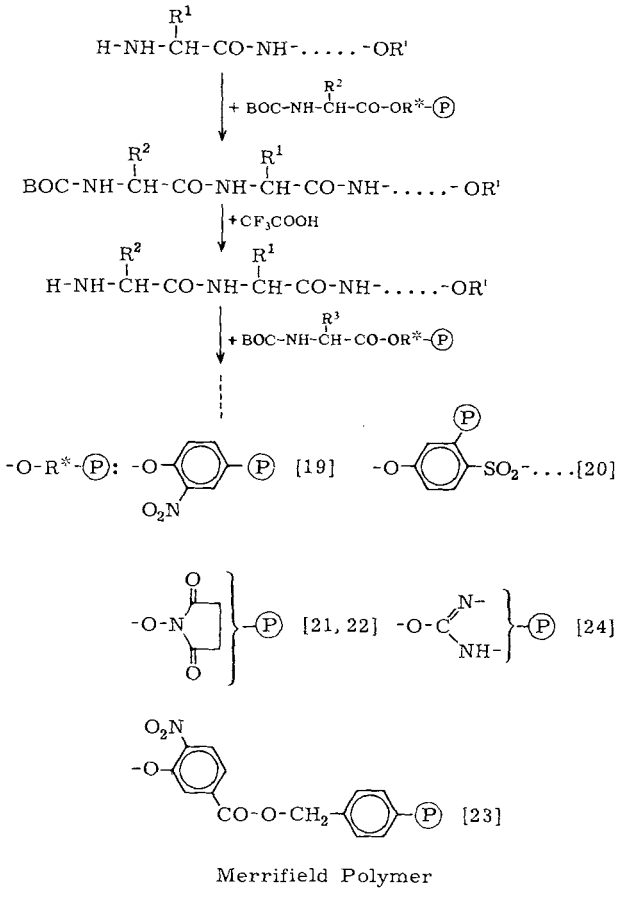
[**] Based on a lecture to the 8th International Congress of Biochemistry, Interlaken, Sept. 1970; Abstracts, edited by *J. G. Gregory*, p. 72.



[*] In these methods [16, 17], the N-terminal amino acid is attached to the polymer.

Scheme 1. Strategy II using the *N*-carboxylic acid anhydride method. Me = methyl, BOC = *tert*-butyloxycarbonyl, X = succinimidyl. Side-chain protection for lysine: N_ε-benzyloxycarbonyl; side chain protection for cysteine: *S*-acetamidomethyl.



and the "Shemyakin method"[18] is the synthesis of the complete sequence (Scheme 2).

Strategy IV, the "polymer reagent synthesis", which was introduced by *Katchalsky*[19] and *Wieland*[20] on the basis of polymer nitrophenyl esters and polymer sulfonylphenyl esters, and was recently carried on by *Blout*[21] and *Fridkin*[22] with polymer hydroxysuccinimide esters, by *Panse* and *Laufer*[23] with modified polymer nitrophenyl esters, and (even earlier than these authors) indirectly by *Frankel*[21] with the use of polymer carbodiimides. The feature common to all these syntheses is the conversion of acylamino acids or peptides into polymer-activated carboxyl

Scheme 2. *Merrifield*'s solid-phase synthesis. All third functions except the ω-amide function must be masked. (P) = polymer, DCCD = dicyclohexylcarbodiimide, Et = ethyl, BOC = *tert*-butyloxycarbonyl.

derivatives and their linkage to amine components of various types and sizes (Scheme 3).

Scheme 3. Strategy IV. Bottom: examples of the group —O—R*—(P). (P) = polymer, BOC = *tert*-butyloxycarbonyl.

2. Critical Discussion of the Four Synthesis Strategies

2.1. Strategy I

The conventional synthesis with maximum use of protective groups allows the synthesis of peptide fragments, and recently also the successive linkage of these fragments to form the complete unit, with almost total avoidance of by-products; since the problem of linkage without racemization may now be regarded as having been largely solved[25,26], this principle appears to merit the comment "very good" for the synthesis of peptide sequences containing up to 30 amino acid residues. For longer sequences, the solubility of the peptide chain presents considerable difficulties in strategy I; depending on the nature of the peptide sequence to be synthesized, therefore, the maximum sequence length that may be expected by this method at present is in the region of 30—50 amino acid residues.

2.2. Strategy II

The conventional synthesis with minimum masking of the third functions is not reliable as regards freedom from by-products in the synthesis of the first partial sequences; one is therefore more or less forced to interrupt the stepwise synthesis of the peptide fragments with *N*-carboxyamino acid anhydrides at intervals to purify a partial sequence. For the further synthesis the fragments, which are obtained as *N*-acylpeptide esters, must, with the exception of the C-terminal fragment, be converted into *N*-acylpeptide hydrazides[27–29]; it remains to be seen whether the technique developed for this purpose by *Denkewalter, Hirschmann, et al.*[11] generally proceeds without side reactions. These *N*-acylpeptide hydrazides are then linked successively to the C-terminal fragment by the azide technique[27–29] (cf. Scheme 1). This restriction to the azide method for the linkage of the fragments must be seen as a distinct disadvantage of strategy II; it has been known for a long time that the azide method is not all that one might wish as far as yield is concerned, and that it is subject to side reactions as a result of an azide-isocyanate rearrangement. Above all, it is practically impossible to separate urea derivatives formed in these reactions from the "correctly linked" peptide sequences.

This method has undisputable advantages in three respects: the ease and cheapness of preparation of the linking materials (*N*-carboxyamino acid anhydrides);

the very high reactivity of the *N*-carboxyamino acid anhydrides, and hence the relatively fast linkage;

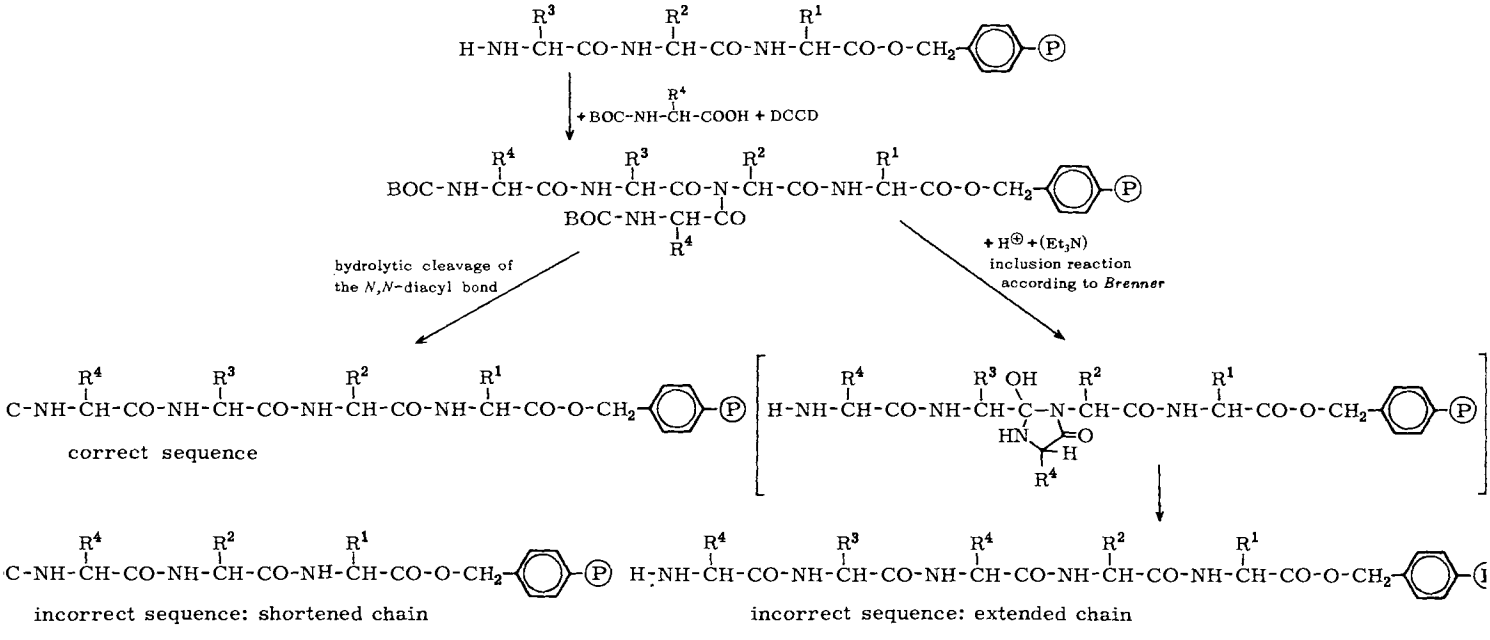
the better solubility properties of the fragments prepared by this principle (as compared with those of the fragments prepared by strategy I).

2.3. Strategy III

The most surprising features of the solid-phase synthesis in its many variations are the idea itself, its simplicity, and finally the possibility of the automation or mechanization of peptide syntheses. On closer examination, however, the solid-phase synthesis exhibits "inborn defects", in the build-up technique on the one hand, and in the present inadequacy of analytical methods on the other.

1. In the stepwise addition of *N*-acylamino acids ("head components") to the amino component, which is attached by its carboxyl function to a suitable polymer, the desired *N*-acylaminoacylation can be achieved quantitatively only with an excess of active head component (5 moles or more of the head component are often used). This technique, particularly when "anhydride-like" activation stages are used, presents considerable danger of *N*-acylaminoacylation of peptide linkages[30], with all the possible consequences of this "diacylamine formation", such as chain shortening[31] and chain lengthening[32] (cf. Scheme 4).

2. As was indicated under 1, the solid-phase synthesis is based on a quantitative reaction of the amino component, and hence on 100% unmasking of the *N*-acylpeptide derivatives formed. Definite quantitative information on these two reaction steps is at present possible only after removal of the peptide chain from the polymer (cf. 4), and with an uncertainty of ±2% by the analytical methods that are currently available. This uncertainty is too great for the assessment of solid-phase syntheses of peptides containing more than 15 amino acid residues; it should



be of the order of $\pm 0.1\%$. The time required for such a determination nevertheless remains the same; this considerably detracts from the simplicity of the solid-phase synthesis.

Interesting direct determinations of unreacted *N*-α-amino groups in the reaction mixture have been described. However, both the normal Edman degradation followed by mass-spectrometric dilution analysis[33] or scintillation analysis using radioactively labeled isothiocyanates[34] and has been random, a consequence of the preparation method. This means:

inevitable differences in swellability and pore size between individual charges of support material;

a danger of steric hindrance effects as the peptide synthesis progresses when the "loading density" is too high;

doubtful applicability of "equivalent analysis" for the determination of the peptide-chemical conversion in accordance with 2.

Scheme 4. Strategy III: Undesirable *N*-aminoacylation of a peptide linkage and subsequent reactions. (P) = polymer, DCCD = dicyclohexylcarbodiimide, Et = ethyl, BOC = *tert*-butyloxycarbonyl.

the well-known spectrophotometric analysis of a 2-hydroxy-1-naphthaldehyde reaction[35] are based primarily on chemical reactions of these residual free amino groups without definite knowledge of the proportion that has reacted. These determination methods are therefore fundamentally subject to the same "uncertainty" as the reaction to be determined.

3. The solid-phase synthesis also depends on the swellability or solubility of the amino component-polymer with or in solvents. As a physical constant, the swellability or solubility must initially be a property of the polymer. During the growth of the high molecular weight peptide chains, however, this physical constant will be increasingly influenced by the peptide chain; from experience in conventional syntheses with maximum use of protective groups (strategy I), it may be expected that the swellability or solubility of the complex will be determined by the peptide, and not by the polymer, at a chain length of 30—50 amino acid residues. It will obviously then be necessary to take the "loading" of the polymer into account as an additional factor.

(The diffusion of the head component, which is closely connected with the swellability of the peptide-polymer, is discussed in Section 2.4.)

4. The particle sizes of the polymers used in all the solid-phase syntheses carried out so far have been relatively arbitrary, and the distribution of the attached groupings

The "inborn defects" mentioned under 1 to 4 must be eliminated at all costs if the solid-phase synthesis is to become an ideal method, particularly for the synthesis of naturally occurring peptides.

2.4. Merrifield Technique

The much-mentioned "Merrifield technique" (cf. Scheme 2) as described by *Merrifield*, *Stewart*, and *Jernberg*[36,37] is a special variant of the solid-phase synthesis; it therefore possesses the "general inborn defects" mentioned above. However, it also has other peculiarities that require critical examination, simply because the "Merrifield technique", particularly in its automated or mechanized form, has become more widely used than other methods in many laboratories in view of the speed, extreme simplicity, and complete mechanizability that are ascribed to it. The main features of the "Merrifield technique" are:

1. The attachment of the C-terminal amino acid to a polymer with formation of a benzyl ester. Except in a few cases, this is achieved by reaction of *N*-BOC-amino acids with a chloromethylated phenyl polymer (polystyrene copolymer with 2% of divinylbenzene) in the usual manner.

2. After removal of the N-protective group, *N*-BOC-amino acids are incorporated stepwise into the amino component-polymer by the carbodiimide method or the nitrophenyl

ester method[38]. (Masking of the third function is necessary in polyfunctional amino acids.) This stepwise incorporation is carried out at fixed time intervals (*e.g.* 2 or 4 hours) and without purity checks on the intermediates.

3. The "unchecked" synthesis of the peptide chain is followed by removal from the support material by proton solvolysis of the benzyl ester linkage *e.g.* with hydrogen bromide/trifluoroacetic acid or anhydrous liquid hydrogen fluoride[39,40]; benzyl-based third function masking groups, with the exception of the N^{im}-benzyl grouping, are removed at the same time (N^{im} = N-1 in the imidazole part of histidine).

Removal from the solid support can also be achieved by ammonolysis[38] or hydrazinolysis[41] with simultaneous peptide amide or peptide hydrazide formation or with transesterification by base-catalyzed alcoholysis (racemization?), which leads to *e.g.* peptide methyl esters[42], though success is assured only if the sequence synthesized contains no aminodicarboxylic acid or aminodicarboxylic acid ω-amide residues or peptide linkages that can be broken by these procedures. The cleavage of the benzyl ester linkage of the polymer by hydrogenolysis or by alkaline hydrolysis is probably of little significance.

This synthesis method has several sources of error:

Regarding 1: The reaction of the benzyl groups of the polymer is incomplete; residual benzyl chloride or benzylammonium groupings are quite likely to cause side reactions in the course of the synthesis.

Loffet[43] has recently suggested the use of tetramethylammonium hydroxide as the base to avoid the formation of quaternary salts on the polymer.

should generally be given to this method for the preparation of the amino component-polymer[38,44].)

Regarding 2: The stepwise incorporation of *N*-BOC-amino acids at fixed time intervals is probably one of the main sources of error in the "Merrifield technique". Apart from the above-mentioned possibility of diacylation of the peptide linkages, limitation of the time available for the linkage step, even with a large excess of the head component, is unsuitable for quantitative formation of the peptide linkage.

Prediction of the reaction rates is impossible at present, and almost certainly will not become possible in the near future, since these depend not only on the two amino acids being linked but also (particularly in the solid-phase synthesis) on the size and nature of the amino component polymer, *i.e.* the conformation of the peptide chain including the solid support[34], as well as on the rate of diffusion of the head component (and possibly also of dicyclohexylcarbodiimide) in the swollen amino component-polymer.

Klostermeyer[45] had the following to say regarding the latter phenomenon: "This possibility was surprisingly never considered during the development of the method, as Professor *Merrifield* confirmed in a personal discourse at the IXth European Peptide Symposium at Orsay in April 1968.

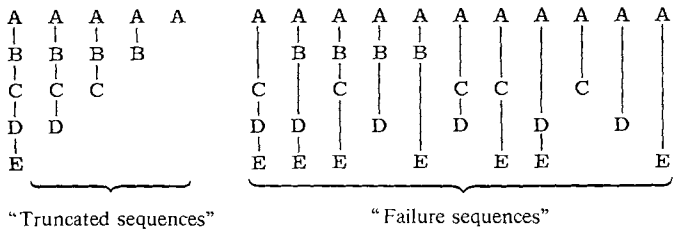
The diffusion effect naturally has a considerable bearing on the usefulness of the Merrifield synthesis, which does not satisfy the claim that it is universally applicable and mechanizable. This would be possible only if each reaction step proceeded quantitatively under standardized conditions.

Table 1. Determination of free amino groups during the synthesis of $(Leu\text{-}Ala)_6$ [48].

Amino acid sequence	Ala	Leu	Ala	Leu	Ala	Leu	Ala	Leu	Ala	Leu	Ala	Leu
Coupling step	1	2	3	4	5	6	7	8	9	10	11	
Free amino groups after cleavage of protecting group (2 mmol = 100%)	2.05	1.96	2.05	2.04	1.92	1.85	1.85	1.52	1.55	1.08	1.01	
Free amino groups after the 1st reaction in mmol	0.01	0.08	0.08	0.08	0.48	0.09	0.77	0.137	0.79	0.29	0.535	
in %	0.5%	4%	4%	4%	25%	5%	42%	9%	51%	27%	53%	
Free amino groups after the 2nd reaction in mmol	0	0	0.01	0.01	0.08	0.037	0.388	0.076	0.543	0.26	0.23	
in %	0%	0%	0.5%	0.5%	4%	2%	21%	5%	35%	24%	23%	
Free amino groups after the 3rd reaction [a] in mmol							0.388			0.26	0.21	
in %							21%			24%	21%	
Free amino groups after the 1st acetylation in mmol					0.388		0.037		0.052	0.19		
in %					0.8%		2%		3.5%	17.5%		
Free amino groups after the 2nd acetylation in mmol										0.104		
in %										9.6%		

[a] Reaction time 8 hours.

Methionine- and N^{im}-benzylhistidine-benzyl ester polymers are obtainable *only* by esterification with the hydroxymethyl solids, residual free hydroxyl groups then being "neutralized" by esterification with acetic anhydride. (Preference



However, a diffusion-controlled reaction depends *inter alia* on the pore size of the support, which not only differs from charge to charge of the starting material but also varies from step to step during the synthesis. It is therefore funda-

mentally impossible to program the various steps of a large synthesis in advance in such a way that the outcome is certain. To make the scope of the method more general, it would be necessary to use a true automatic synthesis system with built-in monitoring of the individual steps, the analytical requirements for which cannot be satisfied."

For these reasons the reaction rates must be determined afresh for each individual case[33,46,47]. This is shown by an investigation by *Hagenmaier*[48] (cf. Table 1):

In the synthesis of the dodecapeptide $(Leu\text{-}Ala)_6$, the linkages of BOC-alanine and BOC-leucine in positions 7 and 10 proceed in yields of only 79 and 76%[*] respectively, even after repetition of the reaction three times with a total reaction time of 12 hours (according to *Weygand*[33], this is more likely to give maximum yields than a single reaction for longer periods).

This necessarily leads to truncated sequences if no further reaction occurs on the unreacted amino groups, while failure sequences[**] are formed if these groups react in the later stages of the synthesis (cf. Scheme 5).

Scheme 5. Synthesis of the pentapeptide A-B-C-D-E; unwanted sequences.

The order of magnitude of the failure-sequence component has been demonstrated by *E. Bayer et al.*[50] *e.g.* for a relatively simple solid-phase synthesis of $(Ala\text{-}Phe)_6$. At least 9.3% of phenylalanylphenylalanine was found as a failure sequence by the partial hydrolysis technique.

Regarding 3: The use of hydrogen bromide/trifluoroacetic acid for removal of the synthesized peptide chain is a relatively severe treatment, which *e.g.* the indole system in tryptophan does not survive without extensive damage. Moreover, the pronounced accumulation of benzyl cations during this operation may lead to benzylation reactions, which cannot always be suppressed by "cation interceptors" if certain steric requirements are satisfied. Benzyl-based third function masking groups, *i.e.* protective groups for the ω-carboxyl, ω-amino, and hydroxyl functions, are simultaneously removed, and this usually rules out any intended "part-sequence synthesis". However, the other third function masking groups used in the "Merrifield technique", *i.e.* the nitro or tosyl group on the guanido function of arginine, the *S*-benzyl masking of cysteine, and the N^{im}-benzyl protective group in histidine are not attacked. The removal of the last two masking groups from cysteine and histidine (and of the N_ω-tosyl protective group from arginine) with sodium in liquid ammonia is not very successful[51–54]; it is unsatisfactory from the standpoint of the method.

Other *S* and N^{im} derivatives of the two amino acids have been adopted from the conventional synthesis, according to the various authors[55–58], sometimes successfully and sometimes unsuccessfully. The prospects are probably best for the *S* and N^{im} protective groups that are stable under the conditions of the removal of the peptide chain from the supporting resin[59–61].

The removal of the peptide chain from the support with liquid hydrogen fluoride at 0 °C, though more promising, is "very expensive" according to *Weber*[56]. In addition to the rupture of the polymer benzyl ester linkage and the removal of all benzyl-based and *tert*-butyl-based *N* and *O* protective groups, the nitroguanido and *S*-methoxybenzyl masking groups are also removed[39]. N^{im}-Benzyl, N^{im}-dinitrophenyl, 4-nitrobenzyl ester, and *S*-alkylthio groupings are reported to be resistant to hydrogen fluoride; the indole system of tryptophan also appears to be unaffected[62].

To summarize the situation, therefore, the "Merrifield technique" in its present form is unsuitable for the satisfactory synthesis of higher natural peptides (with more than 15 amino acid residues). The product isolated, even after purification operations, is always a mixture of peptides, and cannot satisfy the purity criteria of a successful synthesis. The low biological activities of higher naturally occurring polypeptides synthesized so far by this technique[63,64] even make it doubtful whether the technique can be used to confirm a proposed structure.

The question whether the synthesis of peptide fragments containing 10—15 amino acid residues in accordance with the existing principles of the "Merrifield technique" is possible from case to case will be left unanswered for the present.

2.5. Strategy IV

There is little information available at present regarding the use of the polymer reagent synthesis for the preparation of naturally occurring polypeptides[65]; no final judgment can therefore be made as yet.

It must be pointed out in a critical examination that the use of polymer derivatives to activate the carboxyl compound is probably limited by steric problems. This may be of decisive importance in the synthesis of naturally occurring polypeptides.

3. Outlook

It would be unjust to criticize the four principles for the synthesis of naturally occurring polypeptides without offering suggestions as to how the disadvantages could be overcome and how the advantages might be developed further.

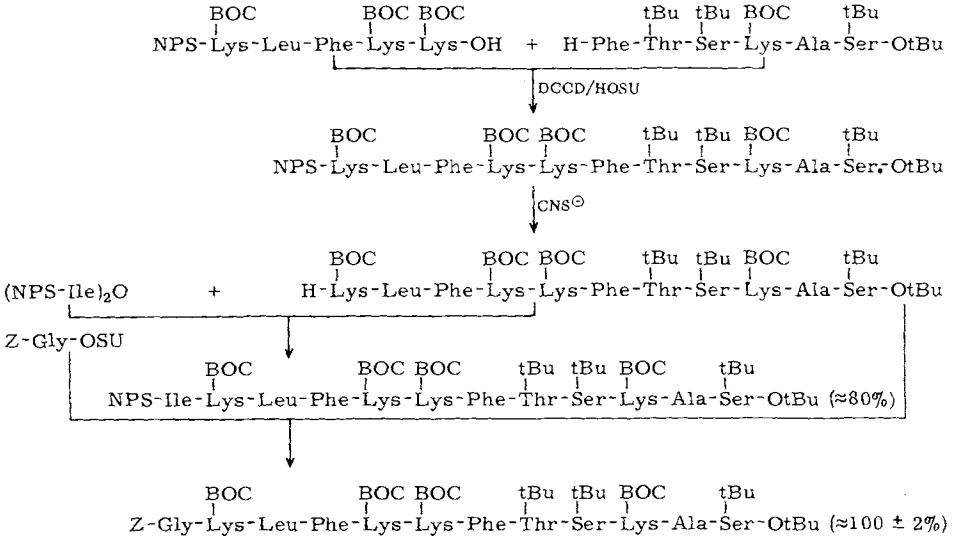
[*] According to indirect determination of free amino groups (*Dorman* [49]), the reliability of which may be doubtful. However, the conversions of 19 and 14.4% on acetylation with acetic anhydride confirm a high content of unreacted material (cf. Table 1).

[**] These failure sequences may naturally also result from "diacylamine formation", cf. Section 2.3 and Scheme 3.

3.1. Suggestions for Strategy I

The conventional synthesis with maximum use of protective groups will allow the preparation of naturally occurring polypeptides with more than 50 amino acid residues only if *e.g.* the solubility of the peptide chains synthesized can be considerably improved.

Our investigations on glucagon had shown that the presence of arginine residues protected by protonation considerably increases the solubility of the synthesized fragments in the common solvents[66]. It has now been found in a recent secretin synthesis that the solubility of the secretin fragment 12—27 is influenced to such a degree by the presence of four protonated arginine residues that specific purification of the hexadecapeptide amide derivative L-arginyl-(hydrobromide)-L-leucyl-L-arginyl(hydrobromide)-L-aspa-raginyl(β-*tert*-butyl ester)-*O*-*tert*-butyl-L-seryl-L-alanyl-L-arginyl(hydrobromide)-L-leucyl-L-glutaminyl-L-arginyl(hydrobromide)-L-leucyl-L-leucyl-L-leucyl-L-glutaminyl-glycyl-L-leucyl-L-valinamide hydrobromide is possible by gel filtration on Sephadex G-15 in aqueous media, and that the reaction of this peptide with carboxyl components is possible *e.g.* in dimethylformamide[67].



This result led us to hope for a considerable improvement in the solubility of synthesized peptide chains through the use of "bifunctional" protective groups; for example, one line of investigation will be the attempted provision of "artificial" arginine functions in the peptide, with the ultimate aim of achieving a synthesis analogous to the secretin synthesis mentioned.

fd coat protein monomer (49 amino acids) indicate that this is quite feasible. A tridecapeptide derivative of the sequence 37—49, swollen in dichloromethane, was successfully made to react with head components in accordance with the principle of the solid-phase synthesis; the reaction proceeded almost quantitatively with benzyloxycarbonyl-glycine hydroxysuccinimide ester, whereas only about 80% reaction was achieved with the symmetrical anhydride of nitrophenylsulfenylisoleucine, though there were still free, *e.g.* acylatable, amino groups present (cf. Scheme 6)[68].

3.2. Suggestions for Strategy II

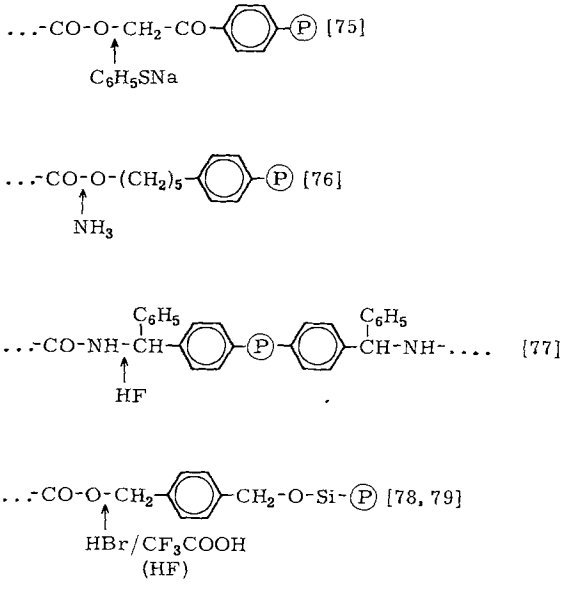
The conventional synthesis with minimum masking of third functions has so far been used only by *Hirschmann et al.*[27-29,69,70] in experiments on the synthesis of ribonuclease S, or more precisely the S-protein; this lack of general experience makes a critical evaluation difficult. Two possibilities should, however, be considered for the further development of this synthetic principle:

The synthesis of fragments by the acyl hydrazide method described by *K. Hofmann*[71], which avoids a subsequent hydrazinolysis, and the replacement of the azide method for the combination of the fragments by other linkage methods that proceed without racemization[72]. However, a compromise would then undoubtedly be necessary between masking and nonmasking of the third functions. This would mean there is only one conventional synthesis principle, of which strategies I and II are limiting cases.

Scheme 6. Synthesis of the sequence 38—49 of phage fd coat protein. BOC = *tert*-butyloxycarbonyl, NPS = *p*-nitrophenylsulfenyl, tBu = *tert*-butyl, HOSU = hydroxysuccinimide, Z = benzyloxycarbonyl, DCCD = dicyclohexylcarbodiimide.

A second possibility would be to make use of the substantial insolubility of synthesized peptide fragments of the C-terminal sequence by using these insoluble fragments as their own supports for a solid-phase synthesis. Two synthetic principles would thus be combined. Experiments carried out in my laboratories on the synthesis of the phage

3.3. Suggestions for Strategy III



The recognition of the shortcomings and undesirable phenomena associated with the solid-phase synthesis has led to a search for improvements both of the principles of the method and of the analytical determination methods:

1. variation of the "attachment grouping" with a view to obtaining improved removal of the peptide chain from the support and shorter reaction times, which depend on diffusion;

2. modification of the reaction procedure to achieve improvement of the nucleophilic reaction step or correction of the first reaction;

3. extension of the analytical determination methods for the various stages of the synthesis to ensure an uncertainty of $\pm 0.1\%$.

Regarding 1: The relative ease of nucleophilic cleavage of the peptide phenacyl ester linkage[73,74] was used by *Weygand*[75] for a new solid-phase technique (cf. Scheme 7); this favorable separation from the resin also allows both fast isolation of the synthesized fragments for purity checks and the preparation of peptide intermediates whose side chains are still protected. Moreover, a peptide chain that has been removed can be attached again to the polymer. *E. Bayer*[76] and *Merrifield*[77] have offered useful suggestions for the removal of the peptide chain from the polymer with simultaneous amide formation; whereas *Bayer* obtains a suitable resin by attachment of long-chain aliphatic alcohol residues to the phenyl groups of polystyrene[*], *Merrifield* suggests the use of polymeric diphenylmethane as the support material. The removal of the synthesized peptide chain with hydrogen fluoride leads directly to the peptide amide in the latter case (cf. Scheme 7).

Scheme 7. New types of solid supports. (P) = polymer.

Felix and *Merrifield*[17] have recently tried an improvement of the polymer-benzyloxycarbonyl method described by *Letsinger*[16], in which the linkage step is carried out by the azide method using intermediate BOC hydrazides. According to *E. Bayer et al.*, the dependence on "deceptive" diffusion effects is greatly reduced by the use of "pellicular" solids. The authors use glass beads about 100 nm in diameter, coated with a thin film of Merrifield polymer[50], or porous glass beads, quartz spheres, or silica gel with their surface silanol groups covalently bonded to *p*-bis(hydroxymethyl)benzene to form the monoether, so that a benzyl alcohol grouping remains free for the attachment of the first amino acid by formation of the benzyl ester[76,78,79] (cf. Scheme 7). According to the authors, this technique allows a solid-phase synthesis in a column process, and can be automated. As a result of the shorter reaction times due to the fast diffusion of the head components, not only is the yield improved, but the proportion of failure sequences can also be reduced.

Regarding 2: On the basis of progress in the technique of linkage without racemization, *Weygand et al.*[80] have also tried fragment linkage for the solid-phase synthesis. Despite the expected increase in the reaction times, which was in fact observed, this reaction technique was successful; above all, one has always the choice of forming the peptide linkage for which the most favorable reaction is to be expected on the basis of empirical results. The obvious advantage of fragment linkage over step-by-step synthesis is the substantial limitation of the proportion of failure sequences[81].

The "Mukaiyama technique"[82][**] is regarded by *Merrifield*[83] as an advance in linkage technique, though it still involves stepwise synthesis. It remains to be seen whether this method is also suitable for the linking of fragments.

Correction of the first reaction in a conventional stepwise synthesis is nearly always regarded as the avoidance of residual free amino groups. If *Hagenmaier*'s observations[48] are correct, however, it seems that it is not always quantitatively possible even by carefully thought-out acylation reactions *e.g.* with 3-nitrophthalic anhydride[84] or with the intramolecular anhydride of 3-sulfopropionic acid[85]. The amino functions that escape amino-acylation probably owe this largely to the prevailing steric situation. The possibility of nucleophilic opening of acylating reagents from the molecular dimensions of acetic anhydride upward is accordingly limited.

It remains to be seen whether the prospects of success are better with deamination reactions. In this connection, mention should be made of deamination experiments with difluoroamine[86]. This difficult preparative possibility, the technique of which has not yet been fully developed, would certainly overcome the steric problem. The HNF_2 molecule should be small enough to reach any residual free amine function.

Regarding 3: Analytical methods for the fast determination of the percentage reaction (linkage and deacylation step) have not progressed very far, despite various approaches. The use of ^{14}C-labeled BOC-amino acids[***] is too expensive in the long-term view[87]. All other methods make use of "equivalent analysis", which is unsuitable for the solid supports used so far, color reactions[88] with an excessively wide error margin, or chemical reactions that are associated with the same uncertainty as the reaction to be determined (see Section 2.3).

[*] Aminolysis of the ester linkage in liquid ammonia/dimethylformamide.

[**] Formation of the peptide linkage from the components with triphenylphosphane and dipyridyl disulfide.

[***] Obtained in the usual manner from ^{14}C-BOC azide.

4. Conclusion

This critical consideration of the present situation with regard to the synthesis of peptides should end with the following remark. There is little probability that a single "synthesis strategy" will provide a general solution to the problems that face us in the synthesis of natural proteins. The best method will vary with the sequence in question, and it seems quite possible that the best prospects are to be found in a rational combination of various features of the strategies mentioned.

Bifunctional Reagents for the Crosslinking of Proteins

By Hugo Fasold, Jürgen Klappenberger, Christa Meyer, and Heinz Remold[*]

Proteins can be crosslinked by chemical compounds without any accompanying change in the complicated three-dimensional structure. Many bifunctional reagents that can react with functional groups in the side chains of the amino acids are now known. Not only can the distance between the linked amino acid residues be deduced from the known length of the bridge introduced, but information can also be obtained concerning changes in conformation during other reactions and concerning the arrangement of the components of a quaternary structure.

1. Introduction

The repeated combination of α-amino acids *via* their α-amino and α-carboxyl groups to form peptide linkages leads to the formation of the backbone of a protein molecule, *i. e.* the *main chain* or *peptide chain*. The characteristic residues attached to the α-C atoms of the amino acids branch off from the main chain as side chains. The conformation of the main chains and side chains is evidently determined at the site of the protein biosynthesis by the genetically determined sequence of the amino acids. Interactions between the side chains force the entire molecule into a rigid, three-dimensional structure that is capable only of slight movement in small regions.

The *sequence* of the amino acids is known as the *primary structure*. The conformation of the main chain and all its side chains is called the tertiary structure; characteristic subunits such as helices can be distinguished as a secondary structure (see also Fig. 1). Several main chains are sometimes covalently linked by disulfide bridges to form a tertiary structure (see Fig. 3). If several tertiary structures combine in a little dissociated aggregate, without covalent links between them, to form one molecule, this is referred to as a *quaternary structure*.

In the tertiary structures that have been established so far, most of the hydrophobic side chains are packed tightly together in the interior of the molecule with exclusion of water, while the ionizable and polar side chains are situated on the surface of the molecule in contact with the surrounding water. This second group can undergo chemical substitutions; examples are the acylation of the ε amino group of lysine, the alkylation of the SH group of cysteine, and the nitration of the phenolic side chain of tyrosine with tetranitromethane. *Zahn*[1-3] has suggested the introduction of artificial crosslinks into the protein by carrying out such reactions with bifunctional bridging reagents.

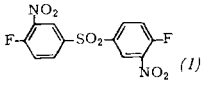
2. Possible Applications

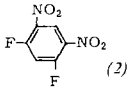
The crosslinking method has so far been proposed for three types of problems:

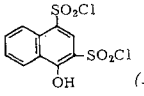
1. To allow the determination of the distance between two functional groups in a protein molecule, these groups must be linked by a rigid bifunctional reagent. After enzymatic degradation of the crosslinked protein, it is then necessary to identify the partial sequences in the primary structure of the protein to which the two ends of the bridge are attached. Many polar side chains on the protein surface possess a limited mobility; the distance found from the crosslinking reaction is therefore a value lying between upper and lower limits (see Table 1).

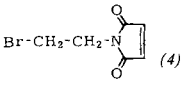
2. Some proteins undergo characteristic and physiologically significant changes in conformation. Allosteric enzymes, for example, are rearranged by a low molecular weight product of metabolism with a specific point of attachment on the protein in such a way that their enzymatic activity increases or decreases on attachment of this ligand. One can try to block this change in conformation by crosslinking in order to obtain information about the mechanism of the rearrangement from the position of the bridges introduced. Moreover, some types of crosslink may be formed in only

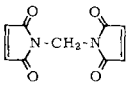
[*] Prof. Dr. H. Fasold, Dr. J. Klappenberger, Ch. Meyer, and Dr. H. Remold
Institut für Biochemie der Universität
6 Frankfurt/Main-Sachsenhausen, Sandhofstrasse (Germany)

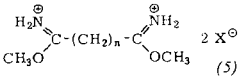


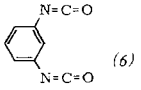


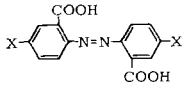


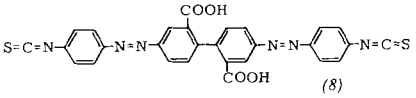


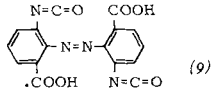


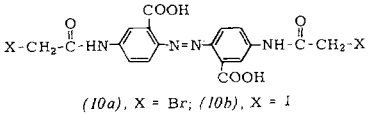


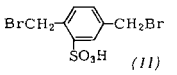












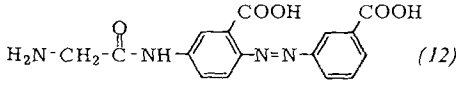
one of the conformers. It is then possible to establish the part of the molecule that is mainly affected by the rearrangement.

3. Crosslinks between two protein molecules should help to establish the positions and the contact areas of the individual proteins in multienzyme complexes, membrane preparations, or other protein aggregates. It is becoming increasingly clear from the investigations on the known enzymes with quaternary structures and on membrane enzymes how strongly the catalytic activity of the subunits of such systems can be regulated by contact with their neighbors.

3. Reagents and Interpretation of the Experiments

Table 1 shows a few members of each class of substances synthesized for the purpose of crosslinking. Azo dye reagents, in addition to their rigid structure, have the advantage that cleavage is possible in a mild reaction with dithionite. After enzymatic degradation of a protein crosslinked with azo dyes, therefore, the two bridgehead peptides can be isolated separately from the azo-peptides. Moreover, a link between two different protein molecules can be broken again without damage to peptide bonds.

Table 1. Reagents for crosslinking in proteins.



Formula	Side chains linked	Length of link in main chain (Å)	Ref.
 (1)	Lysines (Cysteines, Tyrosines, Histidines)	6—18	[1]
 (2)	Lysines (Cysteines, Tyrosines, Histidines)	3—12	[1]
 (3)	Lysines (Cysteines, Tyrosines, Histidines, Serines)	3—12	[4]
 (4)	Cysteines (Histidines, Lysines)	4—14	[5, 6]
 (4a)	Cysteines (Histidines, Lysines)	4—14	[5, 6]
 (5)	Lysines	dependent on *n*	[7]
 (6)	Lysines (Cysteines, Tyrosines, Serines, Histidines)	4—14	[8]
 (7a), X = N=C=O; (7b), X = N=C=S	Lysines (Cysteines, Tyrosines, Serines, Histidines)	6—24	[9]
 (8)	Lysines (Cysteines, Tyrosines, Serines, Histidines)	16—34	[11]
 (9)	Lysines (Cysteines, Tyrosines, Serines, Histidines)	3—10	[11]
 (10a), X = Br; (10b), X = I	Cysteines (Histidines, Lysines)	6—22	[10]
 (11)	Cysteines (Histidines, Lysines)	4—16	[12]

The first step in the interpretation of crosslinking experiments for the determination of distances is always the detection of the bridges incorporated by the "fingerprint method". The proteins must first be broken down by enzymes that, like trypsin, reproducibly hydrolyze the peptide linkages only at a few points in the sequence. The peptides in the resulting mixture are separated by a two-dimensional combination of high-voltage paper electrophoresis and paper chromatography. A characteristic peptide pattern is thus obtained for any protein. The pattern of the new bridge peptides that appear in the case of crosslinked proteins allows the characterization of the tertiary structure of the protein. The three-dimensional structures of related sequences can thus be compared. An example of the application of this method is given for the digestive enzyme chymotrypsin and its precursor chymotrypsinogen[11].

4. Sources of Error and Interfering Factors

The coupling of the predominantly hydrophobic reagents to the protein may upset the natural folding of the molecules. After crosslinking, therefore, it is necessary to verify that the three-dimensional structure has not been affected, *e.g.* by enzyme-kinetic measurements, determination of the accessibility of various families of side chains to chemical modifications, or measurement of the rotatory dispersion and of the molecular volume[13].

A proportion of the reagent molecules will react by only one of their functional groups with the protein, since the second functional group will not always find a reaction site at a suitable distance. Spurious crosslinks are therefore formed during further treatment. It was necessary in some cases to stop crosslinking *e.g.* with the dye *(12)*.

(12)

Undesirable crosslinking of the bifunctional reagent with two protein molecules to form false dimer molecules can be easily avoided.

5. Examples

5.1. Insulin

The first identification of a crosslink was achieved by *Zahn* in insulin[4]; it was formed by the reagent *(2)* between the N-terminal groups of the two peptide chains of the molecule, which are linked by disulfide bridges. This result was confirmed by the recently completed X-ray structural analysis of insulin crystals. Experiments with the same reagent also led to the first crosslinkage (between an N-terminal group and a lysine side chain) of two protein molecules. This was taken as evidence that the molecules are parallel in the stable aggregates of insulin, which are not dissociated in solution.

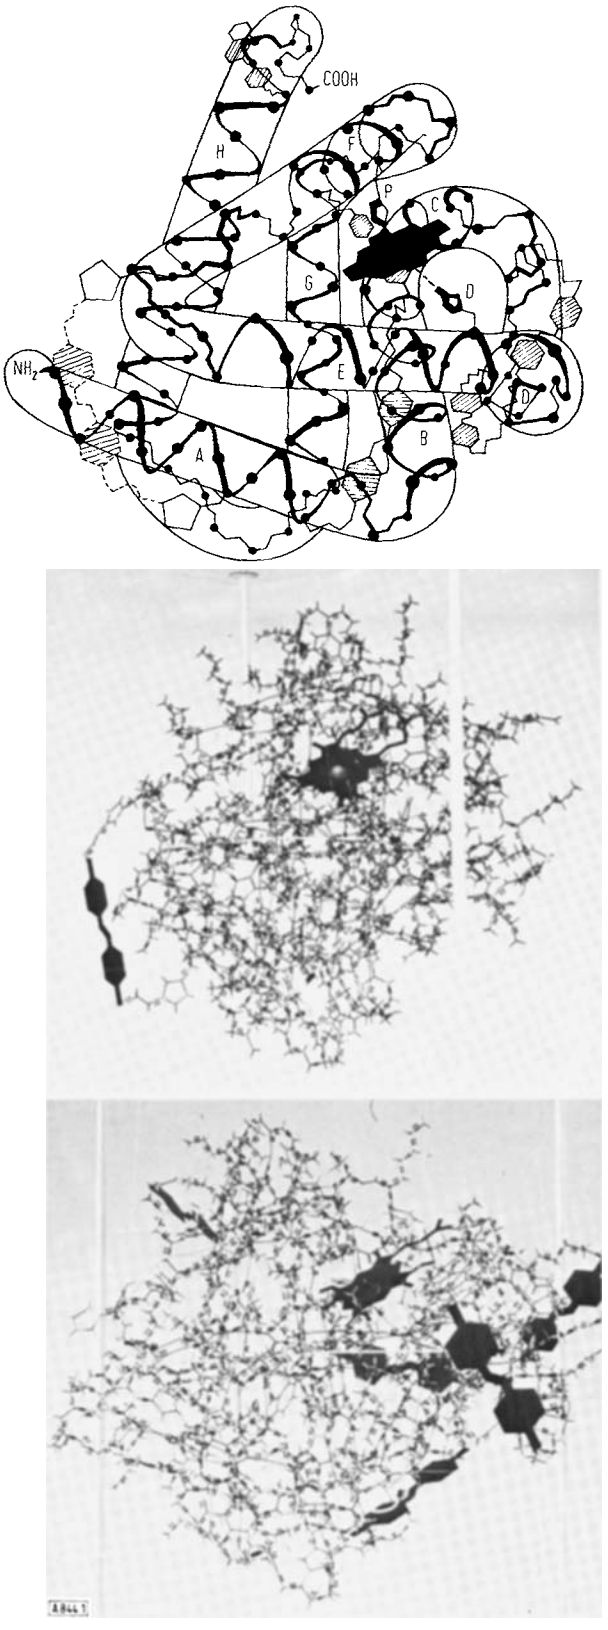


Fig. 1. Top: Conformation of the peptide main chain of whale myoglobin (according to *R. E. Dickerson*). NH_2, COOH: amino and carboxyl ends respectively of the chain. The helical regions of the main chain, which are situated in the linear parts of the structure, are labeled with the letters A, B, C, *etc.* from the amino end. The black area shows the outline of the porphyrin ring. Two histidine side chains (P and D) from the F helix (proximal) and from the E helix (distal) respectively are drawn toward this ring. The oxygen molecule is attached to the iron complex on the same side as the distal histidine. The five crosslinks formed with the reagents *(7a)* and *(7b)* between lysines (continuous lines) and the crosslink formed with the reagent *(10a)* between two histidine side chains (broken line) are shown. Center: Rod model of whale myoglobin with crosslinks inserted between histidine side chains [reagent *(10a)*]. Bottom: Same model with crosslinks between lysine side chains [reagents *(7a)* and *(7b)*].

5.2. Whale Myoglobin

The known tertiary structure of whale myoglobin was used as a subject for the measurement of intramolecular distances with a series of azo dye reagents of the type *(7)—(10)*. The crosslinks found all agreed with possible distances based on the model of the molecule (Fig. 1). Partial denaturation was detected only on introduction of six azo dye bridges per molecule. This was particularly easy to recognize in the heme-containing protein by the change in the absorption spectrum; the accessibility of the imidazole ring of histidine was also measured[11, 13, 14].

5.3. Ribonuclease

In bovine pancreas ribonuclease, which can cleave phosphoric acid diester linkages in ribonucleic acids at pyrimidine bases, two lysine side chains (positions 7 and 41) can be linked by the reagent *(2)*. The change in the enzymatic activity showed that the crosslink must be situated in the immediate vicinity of the active center (Fig. 2)[15].

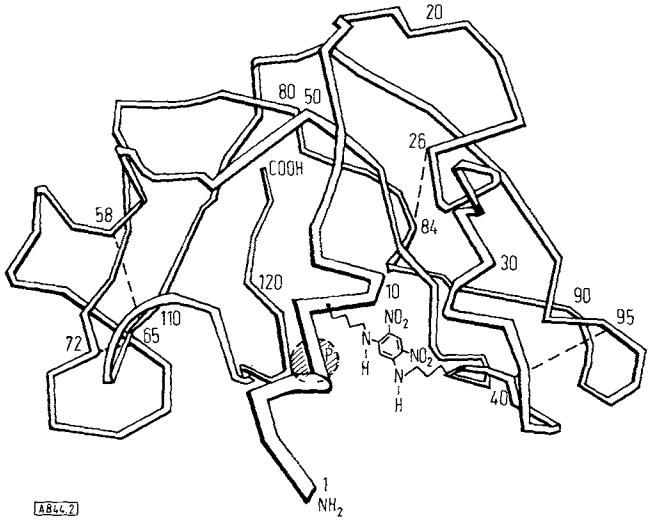

Fig. 2. Conformation of the peptide main chain of bovine pancreas ribonuclease (after [17, 18]). NH_2, COOH: amino and carboxyl ends respectively of the chain. The numbers indicate the positions of the amino acids in the sequence of the molecule. Broken lines: disulfide bridges. P: point of attachment of the substrate to the enzyme molecule. The crosslink formed between two lysine side chains by the reagent *(2)* (positions 7 and 41) is shown (after [15]).

The determination of the peptide sequence in the vicinity of the bridge, together with the results of stepwise blocking experiments on histidine side chains, helped to elucidate the mode of action of the enzyme. It was found that the two imidazole rings of the side chains 12 and 119 are involved together in the essential steps of the catalysis[16]. This hypothesis has been impressively confirmed by the results of the X-ray structural analysis.

5.4. Chymotrypsin and Chymotrypsinogen

The inactive precursor chymotrypsinogen, which is synthesized in the pancreas, loses two dipeptides in the intestine to form the active digestive enzyme chymotrypsin (see Fig. 3). The main chain of the proenzyme is thus broken down into three partial chains, which are linked by disulfide bridges. Two amino acid side chains in the active center of the molecule, *i.e.* histidine in position 57 and serine in position 195, are thus brought into close proximity with each other; the activation of the proenzyme therefore leads to a rearrangement of the tertiary structure. Reproducible fingerprints of the azo bridge peptides were obtained for chymotrypsinogen and chymotrypsin after crosslinking with the reagents *(7a)* and *(7b)*. The fingerprints were almost identical. This led to the conclusion that the rearrangement of the tertiary structure on activation of chymotrypsinogen must affect only a limited part of the folded molecule. The blueprint of the peptide main chain must be almost identical in the two proteins, since any pronounced change would strongly affect the crosslinking pattern. Three of the azopeptides were isolated from crosslinked chymotrypsinogen and identified. These are shown in Figure 3 in the tertiary structure of chymotrypsin, which

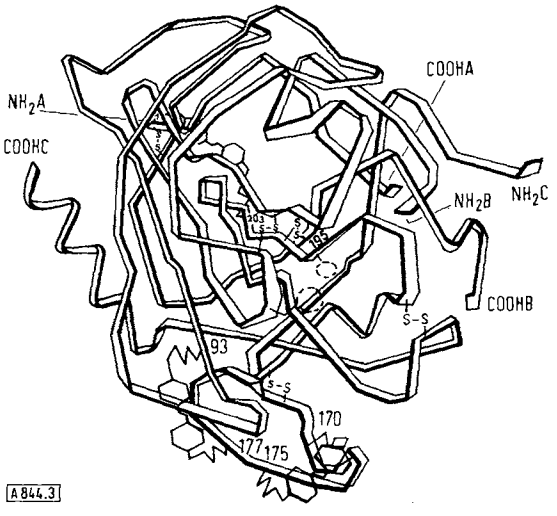

Fig. 3. Conformation of the peptide main chain of bovine pancreas chymotrypsin (after [19]). By elimination of two dipeptides (positions 14—15 and 147—148) from the peptide chain of the inactive precursor chymotrypsinogen on activation in the intestine, the three individual chains A, B, and C, which are linked by disulfide bridges, are formed. NH_2A, COOHC: amino and carboxyl ends respectively of the original peptide main chain of chymotrypsinogen. NH_2B, COOHA: new amino and carboxyl ends formed by elimination of the dipeptide in positions 14—15 of the chymotrypsinogen chain. NH_2C, COOHB: new amino and carboxyl ends formed by elimination of the dipeptide 147—148 from the chymotrypsinogen chain. Dotted circles: schematically indicated locations of the two side chains in the active center, histidine (position 57) and serine (position 195). The three crosslinks identified in chymotrypsinogen with the reagents *(7a)* and *(7b)* are shown (after [11]). —S—S—: natural disulfide bridges. The numbers indicate the positions of the amino acids in the sequence of chymotrypsinogen.

has now been elucidated by X-ray structural analysis[19]. This observation has been confirmed in the meantime by the comparative X-ray structural analysis of chymotrypsinogen.

5.5. Hemoglobin

Several groups of workers have set out to form crosslinks in hemoglobin and to identify their positions. In hemoglobin, four tertiary structures are combined to form a

quaternary structure. The four tertiary structures consist of two identical pairs, which are known as the α and β chains. The X-ray structural analysis carried out by *M. F. Perutz* and co-workers first gave the three-dimensional arrangement of the four chains with respect to one another (see also Fig. 5), and have progressed now to the precise localization of the atoms in this three-dimensional structure[20].

It was recognized at an early date that the quaternary structure changes on combination with or release of oxygen. This rearrangement is the result of the mutual effects of the four chains, which can also be seen in the characteristic oxygen saturation curve of the protein (Fig. 4). In contrast

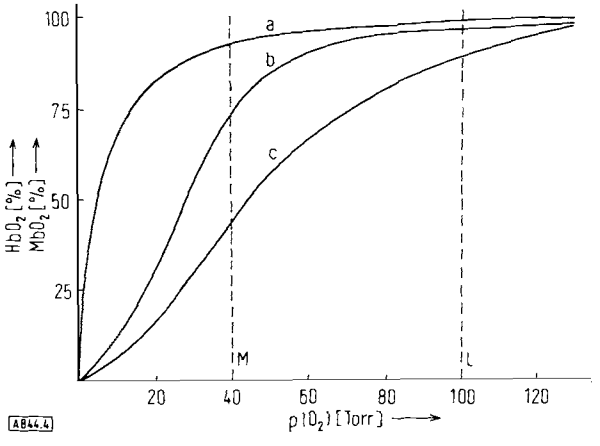

Fig. 4. Course of the oxygen-binding curves of myoglobin (a) and hemoglobin at pH = 7.4 (b) and at pH = 6.8 (c). Broken lines: oxygen partial pressure in the peripheral tissue, *e.g.* in muscle tissue (M), and in the lungs (L).

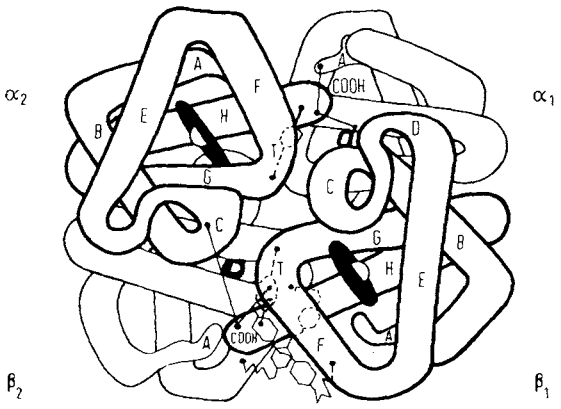
with the curve of the monomeric heme protein myoglobin, the curve for hemoglobin follows a distinct sigmoid course, since the bonding of the oxygen molecule to one or more subunits increases the affinity of the others for the substrate. This property is necessary for optimum O_2 uptake in the lungs and optimum release of O_2 in the peripheral tissue (Fig. 4). A second characteristic of the interaction is seen in the alkaline Bohr effect: on release of oxygen, the p*K* value of several functional groups increases; in the physiological pH range of blood, the protein takes up 0.8 proton per subunit, which it releases again in the lungs during uptake of oxygen. This buffering action allows the transport of carbon dioxide away from the tissue.

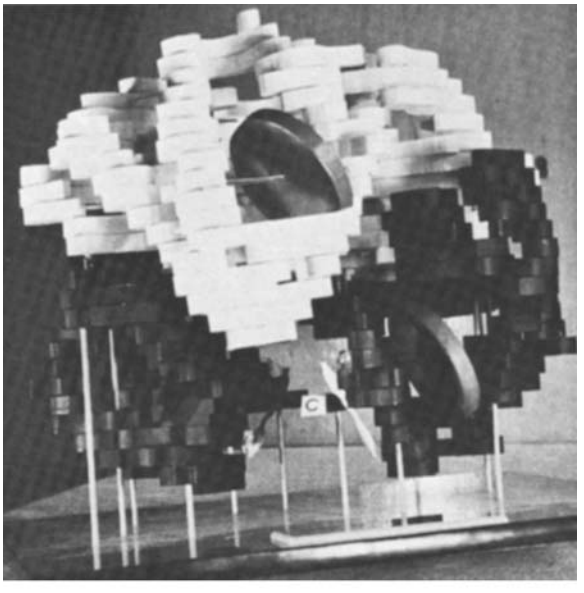
The tertiary structures of myoglobin and of the hemoglobin chains are almost identical. They change only slightly on uptake or release of oxygen. The displacements of individual atoms in the neighborhood of the heme during these processes are less than 1 Å. The rearrangement of the quaternary structure, on the other hand, involves displacements of up to 8 Å.

The oxygen affinity of deoxyhemoglobin, and hence that of the subunits, is less than that of the oxy form. It is not yet certain at what point in the oxygenation of the molecule the affinities, the quaternary structures, and the p*K* values (Bohr effect) change. Until recently, it was also unknown how the mutual interaction at the interfaces between the four subunits arises.

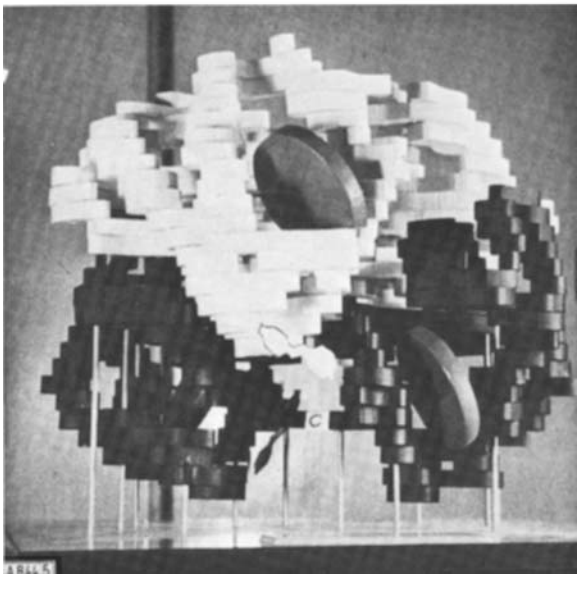
Crosslinking reactions were helpful in finding a hypothesis in this case. Crosslinks firmly fixed in the interior of the tertiary structures should influence the oxygen-binding capacity of the molecule as a whole if they are situated close to a region of the interfaces that is particularly important to the interactions between the subunits. Attempts were made in particular to form bridges between different subunits. The idea was that this should show how the binding of oxygen is affected by hindrance of the change in the quaternary structure. The reagents *(4)*, *(4a)*, and *(10b)* were used, since it was necessary for these to react first with the two SH groups of the cysteines in position 93 of the β chains, which lie on the surface of the molecule. The two reagents derived from maleimide formed crosslinks within the β chains [*(4)* to histidine 97 and *(4a)* to the amino end group of the β chains][6]. In the crosslinking reaction with *(10b)*, it was possible to isolate two hemoglobin derivatives, the structures of which are shown in Figure 5. All these derivatives changed the sigmoid O_2 binding curve to the hyperbolic shape of the curve for monomeric myoglobin, *i.e.* the interactions of the subunits had been eliminated (Fig. 4).



The three crosslinks within the two β chains of the molecule, when fitted into the detailed model of hemoglobin[21], show the same effect on the molecular structure. The carboxyl end groups of the β chains are displaced by several Å from their normal positions.



The displacement depended on the covalent bonding of both functional groups of the reagent; the corresponding monofunctional reagents caused only a slight change in the oxygen binding after attachment to cysteine β 93.



The carboxyl end groups of all four chains are freely mobile in oxyhemoglobin. In deoxyhemoglobin, on the other hand, each of these four amino acids is firmly anchored by two salt bridges (Fig. 5). The carboxyl groups of the arginines in the α chains are linked to the amino end groups of the valines in the opposite α chains, whereas their guanido groups are joined to the carboxyl groups of the aspartic acid in position 126 (helix H) of the opposite α chain. Similarly, the carboxyl groups of the histidines at the ends of the β chains are linked to the ε-amino groups of the lysines in position 40 (helix C) of the neighboring α chain (*e.g.* β_1 with α_2), while the imidazole ring is linked to the carboxyl group of the aspartic acid in position 94 of the same β chain.

Together with this anchoring of the carboxyl end groups on transition from oxyhemoglobin to deoxyhemoglobin, the side chains of the tyrosines in the penultimate positions of all four chains are linked in the interior of the four tertiary structures (see Fig. 5). As a result of the fixation of the carboxyl end groups, they are inserted in recesses between the helices F and H, where they are held partly by van der Waals forces and partly by the hydrogen bonds shown in Figure 5 between their hydroxyl groups and the carbonyl groups of the peptide linkage of valine at the junction between the F and G helices. The tyrosines cannot emerge from these recesses without simultaneous rupture

of the salt bridges of the carboxyl end groups. The crosslinking reactions carried out and characterized in the oxy form with the reagents *(4)*, *(4a)*, and *(10a)* (Fig. 5) in any case prevent the formation of the expected bonds of the carboxyl ends and the tyrosines on transition to the deoxy form, and thus fix the two β chains in the oxy form.

The course of the rearrangement of hemoglobin on oxygen uptake, which was recently published by *M. F. Perutz*[23], is based, among other observations, on the blockage of the transition in typical deoxy structures when the molecule contains crosslinks of this type. The X-ray structural analysis of hemoglobin crystals has shown that on oxygenation of the individual chains, the iron atoms, which project about 0.8 Å from the plane of the porphyrin rings toward the F helices in the deoxy form, are withdrawn into this plane. It is not known how the pull that moves the imidazole group of the histidine from the F helix (see Fig. 1) by at least 0.2 Å toward the porphyrin ring is translated into a change in the tertiary structure in the region of the E, F, and H helices. The two α chains probably first react with oxygen molecules, since they have room both in the oxy form and in the deoxy form for the addition to the sixth coordination site of the iron. In any case, it can be shown that the F helices move slightly toward the H helices, as a result of which the linkage of the tyrosine side chains mentioned apparently becomes impossible. If the bonds in the two α chains are broken, the terminal arginines must also give up their salt bridges. Since these lead to other chains, the quaternary structure is then loosened to such a degree that it can change into the oxy form. At the same time, a proportion of the protons becomes free and causes the Bohr effect. However, the salt bridges between the carboxyl ends of the β chains and the adjacent α subunits are broken by the rearrangement, so that only the two salt bridges within the β chains remain intact. This is evidently enough to facilitate greatly the addition of oxygen with liberation of the carboxyl end, whereupon the remaining "Bohr effect protons" become free. These processes cannot take place in the crosslinked derivatives, since the attachment of the tyrosines and carboxyl end groups on release of oxygen from the two β chains is prevented, and the quaternary structure therefore remains in the oxy form.

The second component crosslinked with the reagent *(10b)* (Fig. 5) has the same crosslinking in a β chain as the symmetrical derivative. The accessible SH group of the other β chain is linked to the imidazole ring of the histidine 46 of the adjacent α chain. It is known from other experiments[24]

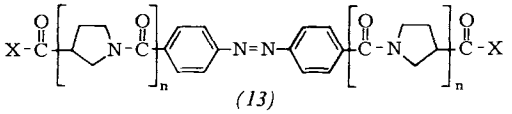


Fig. 5. Top: Conformation of the four peptide main chains of the hemoglobin molecule as in Fig. 1. The letters A—H denote helical regions as indicated in Fig. 1, A being at the amino ends of the individual chains and at the beginning of the A helix. COOH: carboxyl ends of the chains. The black areas with white spheres incorporated denote the porphyrin rings with iron atoms. The two salt bridges of the terminal histidines and arginines at the carboxyl ends of the β_1 and α_2 chains in the foreground are indicated schematically as lines. The incorporation of the side chains of the tyrosines (T) in the penultimate position into the tertiary structure by hydrogen bonds to the peptide linkage in the region of the F—G transition is also shown for these chains (see text). The two crosslinks formed with the reagent *(10b)* within the two β chains are also shown. Center: Hemoglobin models with crosslinks introduced by the reagent *(10b)*. C: carboxyl ends of one of the two β chains (black). The crosslinks within the two β chains run from cysteine in position 93 to lysine in position 82 in the vicinity of the carboxyl end. Bottom: Same model with crosslinking within a β chain (in the background, as in center illustration) and interchain crosslinking of cysteine in position 93 of the β_1 chain to histidine 45 of the neighboring α_2 chain (in the foreground) [22].

that the modification of only one β chain is not enough to block the interaction of the molecule as a whole with oxygen. Since this derivative also exhibits the myoglobin type of oxygen-binding curve, the interchain crosslinking, *i.e.* the fixation of the quaternary structure of the protein according to the model, can hinder the rearrangement from the deoxy form into the oxy form as effectively as the blockage of the terminal histidines of the β chains. The change in the quaternary structure, according to these experiments, is then a necessary condition for the transition between the oxy and deoxy forms of the tertiary structures.

6. Outlook

Apart from the experiments on insulin and hemoglobin mentioned, very few linkages of two tertiary structures or protein molecules with bifunctional reagents have been achieved[25]. Most of the reagents used so far are too short; longer reagents are too hydrophobic, and cause denaturization or unfolding of the protein even on introduction of one to two molecules per tertiary structure.

Reagents having the formula *(13)* were synthesized especially for crosslinking. Oligoproline has the structure of an

(13)

X = Cl, -O- 

elongated, rigid helix beyond $n=5$[26]. The molecule is hydrophilic, and the denaturing effect on proteins is very small. Since the oligoprotein component may be made as long as one wishes, reagents of this kind can be used for the investigation of numerous biological protein associates.

Allyldihydropentalenylene Complexes of Transition Metals

By *Akihisa Miyake* and *Atsuo Kanai*[*]

Reaction of allylnickel chloride with dihydropentalenylenedilithium *(1)*[1] yields diallyldihydropentalenylenedinickel *(2)*[3] as deep green crystals.

(1) *(2)*

Compound *(2)* is stable at room temperature (sintering above 145 °C with decomposition) and is monomeric in benzene. Hydrogenation of *(2)* gives propane and *cis*-bicyclo[3.3.0]octane. The ^{1}H-NMR spectrum (in C_6D_6) exhibits two signals for the dihydropentalenylene protons at $\tau=3.97$ (2 H/t, $J=2.4$ Hz) and 4.81 (4 H/d, $J=2.4$ Hz), as well as three signals for the π-allyl protons at $\tau=5.11$ (2 H/septet, $J=6.0$ Hz), 6.93 (4 H/d, $J=6.0$ Hz), and 8.49 (4 H/d, $J=12.0$ Hz).

X-ray structure analysis[2] showed the molecule to possess a center of symmetry and to have the two nickel atoms *trans* to each other (see Figure; Ni—Ni distance 4.31 Å).

Basic Research Laboratories, Toray Industries, Inc.
Kamakura (Japan)

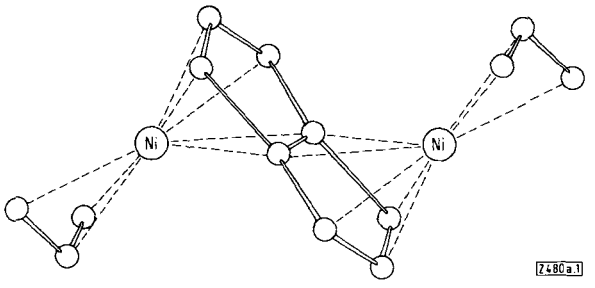

Fig. Structure of diallyldihydropentalenylenedinickel *(2)*.

In similar reactions we have prepared tetraallyldihydropentalenylenedichromium *(3)*[3] as reddish brown crystals which decompose above −20 °C and hexaallyldihydropentalenylenedizirconium[3] as reddish violet crystals which decompose above −10 °C. Compound *(3)* is paramagnetic. The temperature dependence of the ESR signal intensity[4] follows the Curie law, thus indicating that the unpaired electrons of both chromium atoms are mutually independent, *i.e.*, that the chromium atoms in *(3)* are also *trans* to each other.

Diallyldihydropentalenylenedinickel (2):

A solution of *(1)* (3.0 g) in THF (150 ml), which is cooled to −78 °C, is slowly added dropwise to a stirred solution of allylnickel chloride (4.9 g) in THF (100 ml) at −30 to −40 °C. After 16 hours' stirring at −20 °C the THF is evaporated off at room temperature. The residue is extracted with ether (100 ml) and then extracted continuously with a 200-ml volume of ether for 20 h. The extract is diluted with ether, filtered, and evaporated to 250 ml. The deep green crystals that precipitate at −78 °C are recrystallized from ether (600 ml) at −78 °C; yield 2.5 g (46% based on C_3H_5NiCl).

Catalytic Formation of Macrocyclic Polyenes from Butadiene

By *Akihisa Miyake, Hisao Kondo*, and *Masaki Nishino*[*]

Cyclodimerization[1] and cyclotrimerization[2] of butadiene are known to occur on nickel catalysts. We have found that cyclotetramerization, cyclopentamerization, and cyclohexamerization, as well as higher cyclooligomerization, of butadiene are also possible by using certain nickel catalysts.

Butadiene is converted into a viscous liquid at room temperature in the presence of a catalyst system comprising bis(π-allyl)nickel and π-allylnickel chloride. Apart from cyclic dimers and trimers, the product also contains a high boiling fraction (b. p. 70—260 °C/1 torr) and a waxy residue in a total yield of about 70% (based on reacted butadiene). The high boiling fraction contains cyclopolyenes of structure *(1)*, $n=1$—6, lesser amounts of vinylcyclopolyenes of structure *(2)*, $n=1$—6, and small

(1) *(2)*

amounts of open chain oligomers. All the compounds of type *(1)* and *(2)* could be separated by fractional distillation. Proof of the structure is provided by elemental analysis, molecular weight determination, mass, IR, and NMR spectra, hydrogenation, and ozonolysis. The IR spectra indicate that *(1)* and *(2)* contain only *trans* double bonds. Whereas silver nitrate gives crystalline complexes with all-*trans*-1,5,9,13-cyclohexadecatetraene *(1)*, $n=1$, (m. p. 167—169 °C), and all-*trans*-1,5,9,13,17,21-cyclotetracosahexaene *(1)*, $n=3$, (m. p. 141—143 °C), all-*trans*-1,5,9,13,17-cycloeicosapentaene *(1)*, $n=2$, forms only an oily complex.—IR and NMR spectra of the waxy residue closely resemble those of the high boiling fraction. It is undoubtedly a mixture of higher cyclic oligomers or polymers (Tables 1 and 2).

It is an established fact that bis(π-allyl)nickel catalyzes the cyclotrimerization of butadiene[3] and π-allylnickel chloride the 1,4-polymerization of butadiene[4]. The specific activity of our catalyst must therefore be due to interaction of the two components. We assume that the growth of the butadiene oligomer chain takes place on the associated system

Table 1. Properties of the cyclooligomers of type *(1)* and *(2)*. IR spectrum: *(1)*: 960 cm^{-1}; *(2)*: 990, 960, 910 cm^{-1}.

(1), n = 1

(3) and that ring closure occurs on the dissociated "naked" nickel as in *(4)*. Accordingly, π-allylnickel chloride should be replaceable by other Lewis acids; experiments designed to test whether this is the case are currently in progress.

Procedure:

A solution of bis(π-allyl)nickel (0.85 g) and π-allylnickel chloride (0.57 g) in toluene (20 ml) is added to liquid butadiene (125 g) in a glass autoclave. The deep red reaction mixture is stirred magnetically for 85 h at room temperature. Unreacted butadiene is blown off. Acetone is added to the residue in the presence of air, precipitated polymer is separated off, and the filtrate is distilled (see Table 2). 58.2% of the butadiene reacted. Conversions of more than 90% without significant changes in the products can be achieved with prolonged reaction times.

This synthesis of *(1)* can be conducted on any scale. The molar ratio of the two catalyst components is not critical. No significant change in activity is recorded for a molar ratio of Ni:NiCl ranging between 0.7:0.3 and 0.4:0.6. A readily accessible system composed of nickel pentanedionate, triethylaluminum, and allyl chloride can also be used instead of bis(π-allyl)nickel and π-allylnickel chloride.

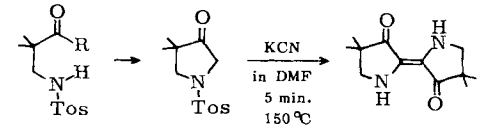
4,4,4′,4′-Tetramethyl-$\Delta^{2,2'}$-bipyrrolidine-3,3′-dione, a Compound having the Basic Chromophore System of Indigo[1]

By *Eike Wille* and *Wolfgang Lüttke*[*]

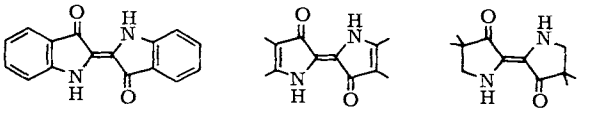


HMO and PPP calculations[2-4] have indicated that the grouping *(1)* is to be regarded as the basic chromophore of indigo. Preparation of compound *(2)* with X=S in grouping *(1)* provided experimental support for the correctness of the theoretical considerations[6, 7]. In order to make a direct comparison with indigo, however, it was necessary to synthesize a compound whose electron donor and acceptor groups resembled those of indigo in nature, configuration, and conformation [*(1)* with X=NH].

(1) *(2)*

We have now accomplished this aim by the synthesis of 4,4,4′,4′-tetramethyl-$\Delta^{2,2'}$-bipyrrolidine-3,3′-dione *(7)* in the following manner:

N-Tosylaminopivalic acid *(3)*, prepared from the alkaline-hydrolysis product of ethyl aminopivalate[8], was converted into the acid chloride *(4)* and thence, by reaction with diazomethane, into the diazo ketone *(5)*. Acidolytic decomposition of the diazo ketone *(5)* in glacial acetic acid gave *N*-tosyl-4,4-dimethylpyrrolidin-3-one *(6)* which yielded the desired product *(7)* (m.p. 159°C) on reaction with potassium cyanide in dimethylformamide.



(3), R = OH
(4), R = Cl
(5), R = $CH{=}N_2$

(6) KCN, in DMF, 5 min., 150°C (53%) *(7)*

The structure of *(7)* is established by satisfactory elemental analyses and spectroscopic data: IR (KBr): $\tilde{\nu}$(NH) = 3377, $\tilde{\nu}$(C=O) = 1665; IR (C_2Cl_4): $\tilde{\nu}$(NH) = 3395, $\tilde{\nu}$(C=O) = 1674 cm^{-1}. UV/visible (cyclohexane): λ_{max} = 473 nm (log ε = 4.05), 204 (3.98); (benzene): 483 (4.05); (solid in KBr): 488. NMR ($CDCl_3$): τ = 8.81 (12 H/s, 4 CH_3), 6.63 (4 H/s, 2 N—CH_2), 4.45 (about 2 H/s, 2 NH). Mass spectrum: (*m/e*) 222 (100%) and 207 (42%).

The appearance of *only one* $\tilde{\nu}_{as}$(C=O) and *no* $\tilde{\nu}$(C=C) band indicates that only the *trans* configuration of *(7)* is present.

With the synthesis of *(7)* and the preparation of *(8)* recently reported by *Bauer*[9] there now exists the complete series from indigo *(9)* to the basic chromophore *(7)* with

(9) *(8)* *(7)*

NH as electron donor group. It should therefore prove possible to test the theoretical concept[2-4] of the nature of the basic chromophore system of indigo dyes, which has been the subject of much discussion.

The following points can be deduced from the data presented in Tables 1 and 2:

1. Compound *(7)* exhibits not only the long-wave light absorption but also the gradation of λ_{max} along the series *(9)* → *(8)* → *(7)* required by theory.

[*] Dipl.-Chem. E. Wille and Prof. Dr. W. Lüttke
Organisch-Chemisches Institut der Universität

[b] Not determined.

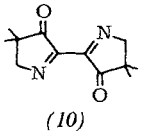

Table 2. Characteristic π-bond orders p(C=O), p(C=C) and charge densities $q(O)_{C=O}$, $q(C)_{C=O}$, q(N) calculated by the PPP method.

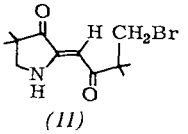
	Ground state			First excited state		
	(9)	*(8)*	*(7)*	*(9)*	*(8)*	*(7)*
p(C=O)	0.752	0.735	0.808	0.671	0.667	0.659
p(C=C) central	0.683	0.692	0.668	0.477	0.497	0.437
$q(O)_{C=O}$	1.496	1.502	1.473	1.538	1.503	1.565
$q(C)_{C=O}$	0.740	0.756	0.700	0.843	0.852	0.914
q(N)	1.629	1.605	1.777	1.497	1.491	1.567



2. The $\tilde{\nu}$(C=O) frequencies observed for *(9)*, *(8)*, and *(7)* are in good agreement with the calculated carbonyl bond orders.

3. The $\tilde{\nu}$(NH) band of *(7)* as a solid is about 100 cm^{-1} higher than the $\tilde{\nu}$(NH) bands of *(8)* and *(9)*; moreover, the $\tilde{\nu}$(NH) frequency of *(7)* increases only slightly (by 18 cm^{-1}) on transition to C_2Cl_4 solution whereas the $\tilde{\nu}$(NH) frequency of *(9)* increases by 137 cm^{-1}. The $\tilde{\nu}$(C=O) band behaves analogously. This would indicate that the molecules of *(8)* and *(9)*, but not those of *(7)*, are connected *via* intermolecular hydrogen bonds in the crystals. The ready sublimation [above 100 °C in high vacuum as against 220 °C for *(9)* and *(8)*] and solubility of *(7)* in polar solvents stem from the same cause.

4. The ease of oxidation of *(7)* is remarkable: The dehydro compound *(10)* was isolated from a benzene solution of *(7)* that had been exposed to atmospheric oxygen for 12 h.

(10)

(11)

A correct elemental analysis and spectroscopic data prove the structure of *(10)* (m.p. 118—119 °C): NMR ($CDCl_3$): τ = 8.78 (12 H/s, 4 CH_3), 5.63 (4 H/s, 2 N—CH_2). IR (KBr): 1742 ($\tilde{\nu}$(C=O)), in C_2Cl_4 1750 cm^{-1}. UV/visible (cyclohexane): λ_{max} = 387 nm (log ε = 2.37), 252.5 (2.91), 215 (3.79).

As a further characteristic of indigo, $\tilde{\nu}$(C=O) and the light absorption of *(7)* (1665 cm^{-1}, 487 nm) and of *(10)* (1750 cm^{-1}, 387 nm) show a gradation which is analogous to that observed for the redox pair indigo *(9)* (1626 cm^{-1}, 605 nm)—dehydroindigo (1736 cm^{-1}, 443 nm).

Reduction of *(7)* leads to a mixture of colorless products.

5. According to the PPP calculations, the charge density on the nitrogen atom of *(7)* is greater than in the compounds *(8)* and *(9)*. The resulting enhanced basicity can actually be observed: In formic acid compound *(7)* is completely monoprotonated at the nitrogen [λ_{max} = 366 nm (log ε = 4.07)], in propionic acid the free and monoprotonated forms of *(7)* can both be detected [λ_{max} = 460 nm (log ε = 2.89) and 368 nm (log ε = 3.94)]. Even in aqueous tartrate buffer of pH 5.4 only a vanishingly small proportion of the neutral form is present [λ_{max} = 368 nm (log ε = 4.03) and $\approx$ 470 nm (log $\varepsilon \approx$ 2.3)]. *N*-Protonation can be deduced from a comparison of the longest wave absorption of *(7)* in acid solution with that of 4,4-dimethyl-2-(4-bromo-3,3-dimethyl-*n*-butan-2-on-1-ylidene)pyrrolidin-3-one *(11)* (prepared by *Fitjer*[12]) whose chromophore structure resembles *(1)* except for a missing amino group [λ_{max} = 365 nm (log ε = 4.09) in ethanol].—Unlike *(7)*, compound *(2)* exhibits a bathochromic shift of the longest wave absorption maximum on addition of acids; however, this effect is observable only with very strong acids.

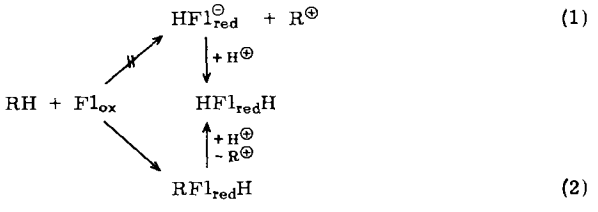
Novel Photoalkylation Reactions on the Flavin Nucleus



By *Martin Brüstlein*, *W.-R. Knappe*, and *Peter Hemmerich*[*]

Flavin(Vitamin B_2) dependent hydrogen transfer has remained up to the present day as one of those biological reactions for which no formulation in terms of molecular structure has been found. *Wallenfels* and *Gellrich*[1] and

[*] Dr. M. Brüstlein, Dipl.-Chem. W.-R. Knappe, and Prof. Dr. P. Hemmerich
Fachbereich Biologie der Universität
775 Konstanz, Postfach 733 (Germany)

Suelter and *Metzler*[2] were the first to observe that the flavin-dependent activation of C—H bonds in dihydro nicotinamides is not a radical reaction despite the known stability of flavosemiquinone. In agreement with this, radicals of C—H activating flavoproteins can only be generated artificially, *e.g.* with dithionite, and not by reduction with natural substrates[3].

On the basis of these findings the mechanism of the reaction has been considered as a direct "hydride-transfer" in accordance with Eq. (1). We would suggest, however, that the reaction involves a "group transfer" in accordance with Eq. (2) followed by a protolytic elimination of the residue R^+, the ease of which depends on the nature of R^+.

The following reactions suggest the second of these two possibilities as being the more likely one:

The flavin dependent photodehydrogenation of the cycloolefins given in Fig. 1 in acetonitrile with large excess of substrate proceeds in the order of a few seconds (for experi-

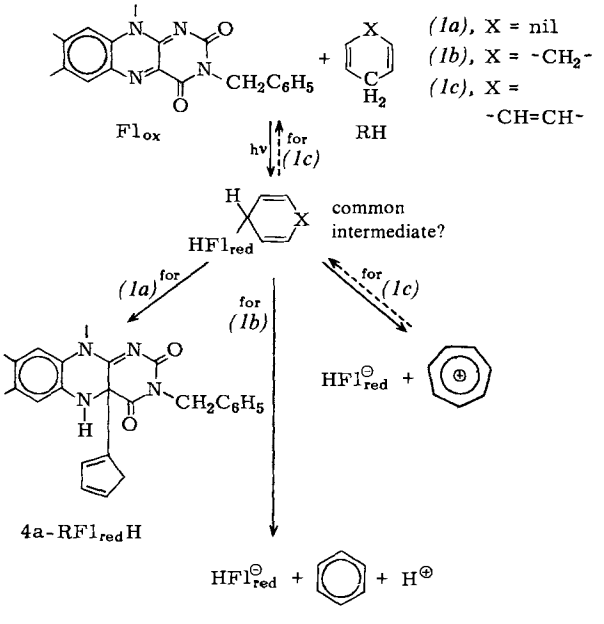


Fig. 1. Photodehydrogenation of cyclopentadiene *(1a)*, 1,4-cyclohexadiene *(1b)*, and cycloheptatriene *(1c)* with 3-benzyllumiflavin in acetonitrile in the absence of oxygen ($\lambda = 445$ nm, bandwidth 16 nm).

mental conditions see Table 1). The reaction course and nature of products depend on the properties of the leaving group R^+.

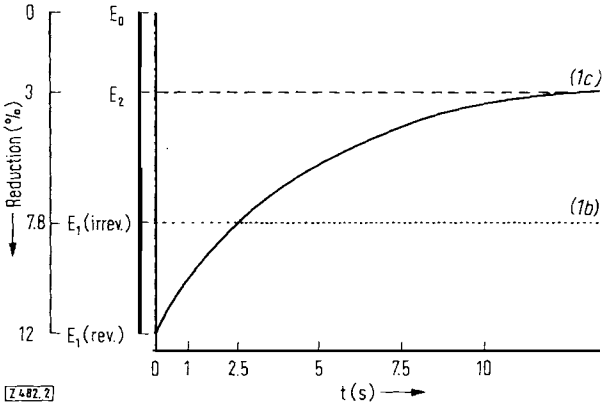
In the case of the cyclopentadiene *(1a)* a quantitative yield of 4a-(1-cyclopentadienyl)-4a,5-dihydrolumiflavin (4a-$RFl_{red}H$) is obtained. Decomposition of the molecule is energetically unfavorable since the leaving group $R^+ = C_5H_5^+$ is antiaromatic. In fact a decomposition of this covalent "flavin-substrate complex" is only possible by prolonged exposure to a strong oxidizing agent (NO^+).

Table 1. Anaerobic photoreaction of flavin with organic sulfides (acetonitrile, 0.73×10^{-4} mol/l 3-benzyllumiflavin, 0.067 mol/l sulfide, under argon. 250 W/24 V tungsten-halogen lamp with 300—800 nm transparent filter- and lens system).

Substrate	$t_{1/2}$ (s)	Reversibility [%] [a] [b]	[c]	[d]	Main product (λ_{max})
Dimethyl sulfide	150	5	10	76	Adduct (340 nm)
Diethyl sulfide	180	70	81	100	1,5-Dihydroflavin
Methyl *tert*-butyl sulfide	60	21	28	75	Adduct (340 nm)
Ethyl *tert*-butyl sulfide	110	35	75	100	1,5-Dihydroflavin
Methyl phenyl sulfide	55	41	67	83	Adduct (343 nm)
Ethyl phenyl sulfide	120	60	100	—	1,5-Dihydroflavin
Thiolane	50	15	26	88	Adduct (335 nm)
Thiane	110	42	70	93	1,5-Dihydroflavin

[a] Quoted as reoxidation [%] on treatment with the oxidizing agents in [b]—[d].
[b] 1 min air in the dark.
[c] 10 min air in the dark.
[d] 1 min boiling with 50% aqueous acetic acid and sodium nitrite.

Reaction of the flavin with 1,4-cyclohexadiene *(1b)* is completely different: here, no stable intermediate $RFl_{red}H$ can be detected since it decomposes spontaneously and irreversibly to benzene and free dihydroflavin. Cycloheptatriene *(1c)* also behaves in a characteristically different fashion: similarly, no intermediate $RFl_{red}H$ can be observed since the leaving group R^+ (= tropylium ion) is resonance stabilized and only slow secondary decomposition reactions occur. Consequently, in this case the photoreduction of the flavin is reversed in the dark from an initial 12% to a final 3% (Fig. 2). This back reaction can be considered as a recombination of dihydroflavin anion $HFl^{\ominus}_{red}$ and tropylium ion, followed by liberation of the starting substrate cycloheptatriene. The occurrence of this back reaction is confirmed by the fact that 1,5-dihydrolumiflavin $HFl_{red}H$ [generated photochemically as given for *(1b)* in Fig. 1] is reoxidized anaerobically to flavoquinone Fl_{ox} by addition of tropylium bromide. The question as to whether the back reaction leads, at least in part—in analogy to the electrochemical reduction of the tropylium ion[4]—to formation of bitropyl has not been investigated.



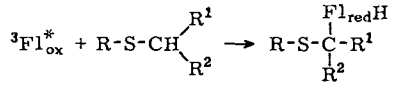


Fig. 2. Photoreaction between 1,4-cyclohexadiene *(1b)* or cycloheptatriene *(1c)* and 3-benzyllumiflavin under anaerobic conditions with subsequent reversing dark reaction in the case of *(1c)*. For experimental conditions see Table 1. The extinction (E) serves as a measure of the reduction of 3-benzyllumiflavin.

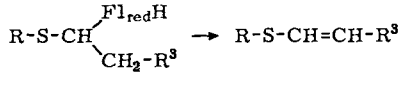
The residues R in $RFl_{red}H$ can be fixed, like the C_5H_5-$Fl_{red}H$ described above and like the adduct C_4H_7S-$Fl_{red}H$ *(2)*, previously prepared by us[5], to C-4a or to N-5 of the flavin

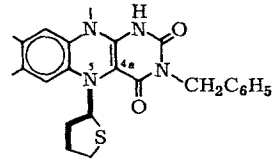
nucleus. When R = benzyl, even a mixture of both isomers occurs[6], the 5-$RFl_{red}H$ being rearranged thermally into 4a-$RFl_{red}H$[6].

This rearrangement can be reversed by light in the presence of oxidized flavin as sensitizer[7]. However, it is very difficult to decide whether the migration of such a residue R in the flavin nucleus takes place in the dihydro state or in the radical state[8]. A general tendency for the adduct $RFl_{red}H$ to undergo homolytic cleavage into $R^{\cdot}$ and $\dot{F}lH$ can, however, be ruled out.



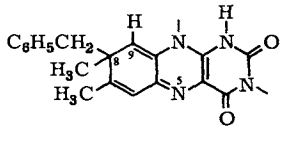
It follows from Table 1 that organic sulfides are dehydrogenated by triplet flavin ($^3Fl^*_{ox}$) in the α-position with formation of an adduct in accordance with Eq. (3).

(3)



The stability of this adduct depends on the nature and spatial configuration of the leaving group, $R^1R^2CH^+$:

When $R^1 = R^2 = H$, the adduct does not decompose in the absence of oxygen and does so only slowly in its presence. If, however, R^1 = alkyl and R^2 = H or alkyl, then decomposition by elimination [Eq. (4)] is possible and preferred with anaerobic liberation of unsubstituted dihydroflavin that reacts very rapidly with oxygen.



(4)

This elimination is subject to strict steric requirements: The groups to be eliminated must be conformationally in the *anti*-position, and not in an eclipsed or even skewed position to each other[9]. Hence, the ethyl sulfides and thiane (Table 1) react "reversibly", while thiolane forms a stable adduct *(2)* since in this case a *trans* elimination is not possible.

C_4H_7S-$Fl_{red}H$ *(2)*

Further, we presume that the "flavin-dependent C—H activation" under discussion does not—or in any case does not always—lead directly to an adduct bound *via* N-5 or C-4a. In the case of the flavin dependent photodecarboxylation of phenylacetate we can prove this:

(3)

As mentioned in an earlier report[10], in neutral to alkaline solution a primary product is formed the structure of which we suggest in formula *(3)* on the basis of the following findings:

1. In the ^{1}H-NMR spectrum the methyl group on C-8 of the flavin appears in the region of the aliphatic methyl groups ($\delta = 1.05$ ppm). This assignment is substantiated by comparison with the analogous 8-CD_3 derivative[11].

2. When the reaction is carried out in deuterium oxide, a selective (partial) exchange of hydrogen on C-9 is observed, as is required for a 7-alkylidene-7,8-dihydropteridin[12].

3. Structure *(3)* is also in accord with previously reported absorption spectra [λ_{max} ($CHCl_3$) = 332, 333, and ≈460 nm, longwave end absorption up to 600 nm] and the acid- and heat-catalyzed rearrangement[13]

as a cyclohexadienone-phenol rearrangement[14]; furthermore, it could explain the observation of red, diamagnetic flavin-substrate complexes in flavoproteins[15].

4. Structure *(3)* explains the "action p*K*" of the order of 5 (which is characteristic for the flavin photoreduction and which could not previously be assigned[16]) as deprotonation on N-1. With these results, we hope to make some progress towards a (stereo)chemical understanding of flavin-dependent biological dehydrogenations.

For discussions, suggestions, and communication of data we are indebted to Dr. *G. Blankenhorn* and Dipl.-Chem. *W. Haas*, Konstanz, Dr. *V. Massey*, University of Michigan, and Drs. *G. Radda* and *J. A. T. Taylor*, University of Oxford.

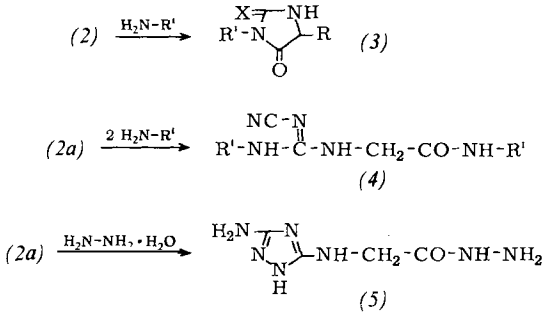
New Amino Acid Derivatives from Cyanamide and Cyanacetamide

By *Joachim Gante* and *Günther Mohr*[*]

Six to eight hours' refluxing of dimethyl cyanimidodithiocarbonate *(1a)*[1] and dimethyl (α-cyanocarbamoylmethylene)dithiocarbonate *(1b)*[2] with glycine ethyl ester or DL-methionine ethyl ester hydrochloride, respectively, and sodium ethoxide (molar ratio 1:1:1) in anhydrous ethanol afforded the hitherto unknown amino acid derivatives *(2a)* (yield 50%, m.p. 98—99 °C) and *(2b)* (yield 91%, oil).

(1) *(2)*



(a), X = =N-CN, R = H

(b), X = =C(CN)-CO-NH$_2$, R = CH$_2$-CH$_2$-SCH$_3$ (DL-Form)

On refluxing for several hours with equimolar amounts of primary amines in ethanol or with an excess of concentrated ammonia/ethanol (2:1), *(2a)* and *(2b)* were converted into the respective hydantoin analogs *(3)* (see Table).

Cpd.	R	R'	X	Yield (%)	M.p. (°C)

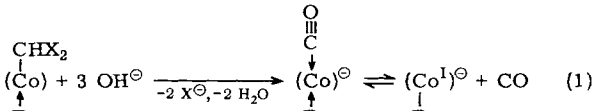
Novel Degradation Reactions of Halomethyl Derivatives of Bis(diacetyldioximato)cobalt[**]

By *Gerhard N. Schrauzer*, *Anthony Ribeiro*, *Lian P. Lee*, and *Raymond K. Y. Ho*[*]

Unsubstituted alkylcobaloximes[1] *(1)* with, *e.g.*, R = CH$_3$, which are of interest as model compounds of organocobalt derivatives of vitamin B$_{12}$, generally exhibit a high resistance to attack by alkali. In contrast, studies on halomethyl-

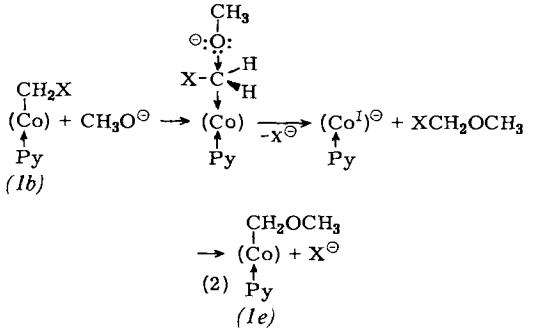


(1)

(1a), R = CHX$_2$ (X=Cl, Br, I)
(1b), R = CH$_2$X (X=Cl, Br, I)
(1c), R = CX$_3$ (X=Cl, Br, I)
(1d), R = CF$_3$
(1e), R = CH$_2$OCH$_3$
(1f), R = COOCH$_3$

cobaloximes *(1a)*—*(1c)* revealed evidence for a surprisingly high alkali sensitivity. Nucleophilic attack of the cobalt-bonded halomethyl group by OH$^\ominus$ ion causes initial Co—C bond cleavage to give halomethanols and cobaloxime(I). The interesting reactions that ensue are reported in the present communication.

In 0.1 N NaOH dihalomethylcobaloximes *(1a)*[2] undergo rapid, quantitative decomposition (no isolable intermediate) into carbonylcobaloxime(I), the carbon monoxide complex of cobaloxime(I), which is at equilibrium with free CO and cobaloxime(I) [eq. (1)].



(1a) (1)

[**] This work was supported by the US Department of Health, Education and Welfare, Grant 1-RO 1 ES 00325-01.

In principle, equation (1) corresponds to a conversion of trihalomethanes into carbon monoxide catalyzed by the nucleophilic cobaloxime(I) since dihalomethylcobaloximes *(1a)* can be prepared from cobaloxime(I) and trihalomethanes[2].

Monohalomethylcobaloximes *(1b)*[2] are cleaved by $NaOCH_3$ in anhydrous CH_3OH with intermediate formation of cobaloxime(I) and halomethyl methyl ethers. Subsequent reaction of the products in absence of air gives methoxymethylcobaloxime *(1e)* which was isolated in 40% yield. The Co—C bond in *(1b)* is ruptured in this case by nucleophilic attack of $CH_3O^{\ominus}$ ion [eq. (2)]:

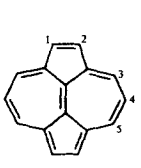
(1b)

(2)

(1e)

Decomposition of *(1b)* by aqueous alkali also proceeds initially as shown in eq. (2). The resulting halomethanol reacts with the cobaloxime(I), but it proved impossible to isolate hydroxymethylcobaloxime. Instead a complicated series of reactions ensues giving rise to cobaloxime(III) and methane, as well as to traces of methanol and formaldehyde as the final products.

Trihalomethylcobaloximes[4] *(1c)*, and *(1d)* too, also undergo degradation with Co—C bond cleavage on treatment with alkali. Heating of *(1d)* in 2 N NaOH furnishes cobaloxim(I), carbonate and fluoride ion. The complexes *(1c)* are by far the most alkali-labile. Treatment of *(1c)*, X = Cl, with $NaOCH_3$ in anhydrous CH_3OH gives methoxycarbonylcobaloxime *(1f)* in 23% yield.



The halomethyl derivatives of vitamin B_{12}[5] are generally more alkali-stable than the corresponding derivatives of cobaloximes; however, they also decompose with Co—C bond cleavage on heating in 1 N NaOH. The reactions observed are possible prototypes for detoxification processes involving the dehalogenation of halohydrocarbons with biogenic metal complexes as catalysts.

Simple Synthesis of Pyraceheptylene and Benzo[*a*]pyraceheptylene[**]

By *Christian Jutz* and *Erich Schweiger*[*]

Of the three nonbenzenoid (nonalternant) pyrene isomers made up only of five- and seven-membered rings and exhibiting an "aromatic" $4n+2$ Hückel perimeter—pentaleno[2.1.6-*def*]heptalene[1] ($R_E = 5.9495\ \beta$), dipleiapentalene ($R_E = 6.0297\ \beta$), and pyraceheptylene *(1)* ($R_E = 6.0515\ \beta$)—compound *(1)* appears, according to simple HMO calculations[2], to have the greatest resonance energy (R_E). R_E for pyrene is 6.5055 β.

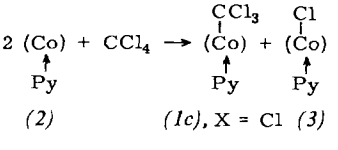
(1)

(2)

A brief account of the preparation of *(1)* has been given by *Anderson*[3]. We have now been able to prepare *(1)* and *(2)* after the manner of a Ziegler-Hafner azulene synthesis[4].

If equimolar amounts of the pentamethine salt *(3)*[5] and the 6-dimethylaminovinylfulvene *(4)*[6] are refluxed together under N_2 for 24 h in pyridine after addition of $NaOCH_3$, the pyridine distilled off in a stream of N_2, and heating to 230 °C in quinoline continued until liberation of dimethylamine ceases, the residue left when the quinoline is distilled off *in vacuo* yields pure pyraceheptylene *(1)* in 5% yield on chromatography, first in methylene chloride and then in hexane, on Al_2O_3 (activity grade III, neutral). Compound *(1)* was isolated as bronze-colored platelets (hexane), m. p. 257—259 °C; UV (CH_2Cl_2): $\lambda_{max} = 484$ nm ($\log\varepsilon = 4.21$); 471 (3.50); 461 (3.21); 454 (3.27); 444 (3.17); 432 sh (2.75); 423 (2.75); 410 (2.89); 358 (3.64); 344 (4.26); 334 (4.14); 299 (4.30); 285 (4.46); 267 (4.99); 254 (4.70).

Under the same conditions we found 2-dimethylamino-1-dimethylaminopropenylidene-3-dimethylimmoniopropenylindene perchlorate *(6)* and cyclopentadiene to give benzo[*a*]pyraceheptylene *(2)* in 2.5% yield. *(2)*, blackish brown needles (hexane), m. p. 198—200 °C; UV (CH_2Cl_2): $\lambda_{max} = 498$ nm ($\log\varepsilon = 3.84$); 485 (3.98); 464 (3.66); 453 (3.54); 422 (3.09); 387 (4.28); 369 (3.94); 348 (4.06); 342 sh (4.02); 300 (4.82); 291 sh (4.75); 286 sh (4.74); 272 sh (4.78); 263 (4.88); 253 (4.87); 237 (4.81).



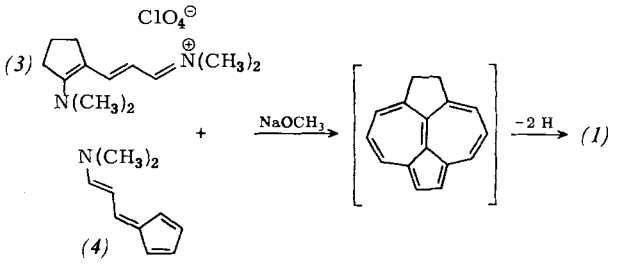
---

[1] Cobaloximes are bis(diacetyldioximato)cobalt complexes; cf. *G. N. Schrauzer*, Accounts Chem. Res. *1*, 97 (1968).

[2] The halomethylcobaloximes *(1a)*, *(1b)*, and *(1d)* can be prepared by the known method [3] of reaction of di- and trihalomethanes or CF_3I with cobaloximes(I): The sole limitation is that the reaction medium should not be too strongly alkaline, cf. Inorg. Syntheses *11*, 61 (1968).

[3] *G. N. Schrauzer, J. H. Weber*, and *T. M. Beckham*, J. Amer. Chem. Soc. *92*, 7078 (1970).

[4] Trihalomethylcobaloximes *(1c)* are not accessible by the method given in Ref. [2]; they are formed, however, from cobaloximes(II) [3] and tetrahalomethanes in CH_2Cl_2 as solvent. To prepare, *e.g. (1c)*, X = Cl, compound *(2)* (10 g) is suspended in CH_2Cl_2 (50 ml) with exclusion of air and the stoichiometric amount of CCl_4 is added slowly. After 25 min the reaction mixture is poured into *n*-hexane (200 ml) and the precipitate is filtered off. In order to isolate compound *(3)*, formed according to



(2) *(1c)*, X = Cl *(3)*

the reaction mixture is washed with water; the insoluble residue is recrystallized from CH_2Cl_2 by addition of *n*-hexane. Compounds *(1c)* decompose gradually on storage and in some cases explode on heating to 120—180 °C. The composition of all the new cobaloximes is established by elemental analysis and NMR spectra.

The mass spectra of *(1)* and *(2)* exhibit very intense molecular ion peaks at *m/e* 202 and 252.

As a preliminary to synthesizing the salt *(6)* we first prepared 1-dimethylaminopropenylidene-2-dimethylimmonioindane perchlorate *(5)*. Compound *(5)*, orange-red needles (acetonitrile), m.p. 245 °C, λ_{max} (CH_3CN) = 474 nm ($\log \varepsilon = 4.84$), is formed in 85% yield from equimolar amounts of 2-dimethylaminoindene[7] and $(CH_3)_2SO_4$-dimethylaminoacrolein adduct in anhydrous ethanol at room temperature.

The ethanol is removed under vacuum after 3 h, the residue dissolved in water, and compound *(5)* precipitated by addition of $NaClO_4$.

Compound *(6)*, black needles (acetonitrile), m.p. 236 to 237 °C, λ_{max} (CH_2Cl_2) = 543 nm ($\log \varepsilon = 4.96$), is obtained from *(5)* in 66% yield on heating with an excess of dimethylaminoacrolein diethylacetal[8] in acetonitrile[***].

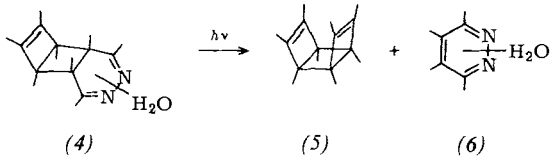
Direct Proof of Existence of Tetramethylcyclobutadiene[1][**]

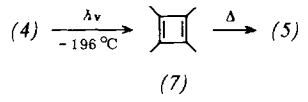


By *Günther Maier* and *Manfred Schneider*[*]

Photocleavage of alkylated cyclobutenedicarboxylic anhydrides in a matrix at −196 °C is accompanied by a yellow coloration which disappears on thawing as soon as the organic glass begins to soften[2]. The long-wave absorption of the matrix (λ_{max} = 410 nm) observed on low-temperature irradiation of 3,4-di-*tert*-butylcyclobutenedicarboxylic anhydride[2] cannot arise only from frozen 3,4-di-*tert*-butylcyclopentadienone *(1)*, which has an absorption maximum at 365 nm, but must be mainly due to another species. The conclusion that this species must be di-*tert*-butylcyclobutadiene *(2)* is compelling, assuming that *(3)*, a positional isomer of *(1)* which has not been isolated but must also be present in the matrix, absorbs below 400 nm like *(1)*.

This assumption has recently been questioned since the cyclopentadienones (2,3,4- and 2,3,5-tri-*tert*-butyl derivatives) formed on photolysis of 2,3,4-tri-*tert*-butylcyclobutenedicarboxylic anhydride[3] exhibit maxima at 415 and 418 nm, respectively. Accordingly, the long-wave absorption found in the di-*tert*-butyl series might possibly also be due to the dienone *(3)*.

Unequivocal spectroscopic proof that the cyclobutadiene system can exist under the above conditions and can be identified by a characteristic UV absorption band is therefore possible only if an independent route is available for the photochemical production of cyclobutadienes. Such a route must avoid cyclopentadienones as reaction products.



A possible method consists in the photolysis of the tricyclic compound *(4)* [m.p. 172 °C (decomp.); prepared from the parent diacetyl compound[4] with hydrazine; spectra, *e.g.* NMR (CH_2Cl_2): τ = 8.03, 8.33, 8.89, 9.11 (each 6H/s), elemental analysis, and molecular weight are consistent with the proposed structure]. Irradiation of a methylene chloride suspension of *anti (4)* with a low pressure mercury arc lamp proceeded almost quantitatively to give the *syn* tricyclic compound *(5)*[5] and tetramethylpyridazine *(6)* [m.p. 69 °C (decomp.); NMR (CCl_4): τ = 7.52, 7.87 (each 6H/s)].

If *(4)* is irradiated in an EPA matrix (ether, isopentane, ethanol) at −196 °C, a yellow color is also seen which is

[*] Prof. Dr. G. Maier and Dipl.-Chem. M. Schneider

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

again stable only under these extreme conditions and disappears immediately on removal of the liquid nitrogen coolant. Irradiation products are the hydrocarbon *(5)* and the pyridazine *(6)* (yield >90%). Since *(6)* absorbs at 258.5 nm (in ether) and a charge-transfer complex with tetramethylcyclobutadiene *(7)* is unlikely, the maximum at 375 nm observed on low-temperature irradiation of *(4)* must be assigned to "free" tetramethylcyclobutadiene *(7)*.

(7)

Irradiation of tetramethylcyclobutenedicarboxylic anhydride under the same conditions leads to a broad absorption band (350—600 nm) having a maximum at 425 nm. The reason for the differing electronic spectra—depending upon whether one starts from *(4)* or from the corresponding anhydride—is presumably to be sought in the predominant formation of tetramethylcyclopentadienone on photocleavage of the anhydride, the tetramethylcyclobutadiene being hidden in the short-wave branch of the curve. Alternatively, a donor-acceptor complex between the two compounds may possibly be present in this case.

The exclusive formation of the *syn* tricyclic compound *(5)* on photolysis of *(4)* indicates that tetramethylcyclobutadiene has a singlet ground state. Additional evidence is provided by the low extinction coefficient of the band in the electronic spectrum—we estimate a value of about 200. According to calculations by *Allinger*[6], only two forbidden transitions in the long-wave region are to be expected for singlet cyclobutadiene, while the triplet state should be characterized by a very intense absorption band. In our opinion, the above constitutes the first direct spectroscopic proof of the existence of a "free" alkyl-substituted cyclobutadiene.

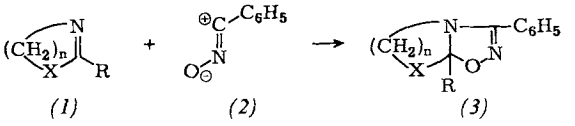
1,3-Dipolar Cycloaddition of Nitrile Oxides to Cyclic Imidic Esters and Amidines



By *Karl-Heinz Magosch* and *Roland Feinauer*[*]

Dedicated to Professor Karl Hamann on the occasion of his 65th birthday

Nitrile oxides undergo 1,3-dipolar cycloaddition to numerous unsaturated systems to give derivatives of 1,2-oxazole[1]. Cycloadditions of cyclic imidic esters and amidines with, *e.g.*, epoxides are also known[2].

[*] Dr. K.-H. Magosch and Dr. R. Feinauer
Forschungslaboratorien der Chemische Werke Hüls AG
437 Marl (Germany)

We have studied the reaction of nitrile oxides with cyclic imidic esters and amidines and found that novel bicyclic 1,2,4-oxadiazole derivatives *(3)* result from benzonitrile oxide and oxazol-2-ines, 5,6-dihydro-4*H*-1,3-oxazines, imidazol-2-ines, and 1,4,5,6-tetrahydropyrimidines.

(1) *(2)* *(3)*

n	X	R	yield (%) [a]	*(3)* m. p. (°C)
2	O	CH_3	87	64
3	O	CH_3	26	87
3	N—CH_3	CH_3	32	100
3	N—C_2H_5	CH_3	41	95
3	N-*n*-C_4H_9	CH_3	31	37

[a] Yields not optimized.

Benzohydroxamoyl chloride can be used as starting material instead of benzonitrile oxide *(2)* and converted into the latter immediately prior to reaction with *(1)* by treatment with triethylamine[1].

In order to produce the compounds *(3)*, the reactants *(1)* and *(2)* are allowed to react at 0°C (5 h) in a suitable solvent, *e.g.* diethyl ether; the resulting hetero bicyclic compounds *(3)* are subsequently isolated by evaporation and crystallization. The colorless compounds *(3)*, which readily crystallize, are easily hydrolyzed by aqueous acids and aqueous alkali. Their structure is established by elemental analysis and IR and NMR spectra.

Perfluoroalkanesulfinic Acids

By *Herbert W. Roesky*[*]

Perfluoroalkanesulfinic acids have not previously been isolated.

We have now found that perfluoroalkanesulfonyl fluorides *(1)* are reduced by hydrazine and that hydrazinium salts *(2)* are formed[1] which contain sulfur having an oxidation number of +4.

$$2R{-}SO_2{-}F + 5N_2H_4 \rightarrow 2R{-}S(O)O[N_2H_5] + N_2 + 2[N_2H_5]F$$

(1) *(2a)*, R = CF_3; *(2b)*, R = *n*-C_4F_9

Compounds *(2)* are soluble in diethyl ether and can thus be separated from hydrazinium fluoride. On reaction with

[*] Prof. Dr. H. W. Roesky
Chemische Institute der Universität
6 Frankfurt, Robert-Mayer-Strasse 7—9 (Germany)

an excess of concentrated sulfuric acid they yield the corresponding perfluoroalkanesulfinic acids. For $CF_3S(O)OH$, the ^{1}H-NMR and ^{19}F-NMR spectra provided the following data: $\delta_H = -11.0$ ppm (singlet, external standard $(CH_3)_4Si$), $\delta_F = 78.0$ ppm (singlet, external standard $CFCl_3$). The most striking difference from the already well-known perfluoroalkanesulfonic acids[1] is in the IR spectra: on comparing the spectra, the expected absence of an asymmetric (S=O) stretching vibration[2] is observed in the case of sulfinic acids. The spectrum of $CF_3S(O)OH$ shows bands at 2900 (vs), 2450 (s), 1700 (s), 1185 (vs) with shoulder at 1160, 1095 (vs), 850 (s), 750 (w), 635 (w), 587 (m), 480 (m), and 440 (s) cm^{-1}. The perfluoroalkanesulfinic acids investigated ($CF_3S(O)OH$, b.p. 26—28 °C/0.1 torr) could be characterized by elemental analysis. They are water-clear liquids that do not react with glass and can be vacuum distilled without decomposition.

Preparation of n-$C_4F_9S(O)OH$

Diethyl ether (1400 ml) and anhydrous hydrazine (22 g) are transferred to a three-necked flask fitted with KPG stirrer, dropping funnel, and reflux condenser (with drying tube). n-$C_4F_9SO_2F$[3,4] (60 g) is added dropwise to the stirred mixture at room temperature. A white precipitate is formed and nitrogen is evolved. The ethereal phase is separated from the precipitate and evaporated under vacuum. 12 g of compound *(2b)* remains. Concentrated sulfuric acid (30 ml) is added to *(2b)* (10 g) and the resulting sulfinic acid is distilled off under vacuum (oil-pump; flask temperature 60 °C): b.p. 40—42 °C at 0.05 torr; yield: 7.5 g.

A New Route to Dewar-Benzenes

By *Robert Weiss* and *Clemens Schlierf*[*]

The thermal rearrangement of bicyclopropenyls *(1)* to benzene derivatives discovered by *Breslow*[1,2] is of considerable mechanistic and preparative interest. We have investigated whether this reaction can be catalyzed by transition metals.

(1) *(2)* *(3)*

[*] Dr. R. Weiss and C. Schlierf
Organisch-chemisches Institut der Universität
8 München 2, Karlstrasse 23 (Germany)

If a solution of equimolar amounts of *(1)* and $AgClO_4$ in anhydrous acetonitrile is heated to boiling, the occurrence of the rearrangement *(1)*→*(2)*→*(3)* can be established by ^{1}H-NMR spectroscopy. After one hour's reaction the singlet of the bridgehead protons of *(1)* at $\tau = 7.60$ has been completely replaced by a sharp singlet at $\tau = 5.78$, which we assign to the hitherto unknown 2,3,5,6-tetraphenyl-Dewar-benzene *(2)*[3]. The reaction can also be followed in an NMR sample tube and proceeds quantitatively within the limits of detection of NMR; in particular, no evidence is found for the formation of the intermediates tetraphenylprismane and 1,2,3,4-tetraphenyl-Dewar-benzene assumed by *Breslow*[1].

The class of rearrangements Dewar-benzene→benzene is known to be catalyzed by transition metals[5]; accordingly, compound *(2)* rearranges to *(3)* under the above conditions. The NMR spectrum indicates that *(2)* is accompanied by 25% of *(3)*. This finding also shows that the rearrangement *(1)*→*(2)* proceeds more rapidly than *(2)*→*(3)*.

(2) could be isolated pure by column chromatography on basic Al_2O_3 (yield 45%) and characterized: ^{1}H-NMR: $\tau = 2.3$—2.8 (20 H/m); $\tau = 5.78$ (2 H/s); UV: $\lambda_{max}(CH_3CN) = 292$ nm ($\log\varepsilon = 4.38$). For comparison: *cis*-stilbene has $\lambda_{max}(C_2H_5OH) = 290$ nm ($\log\varepsilon = 4.0$)[6]; m.p. 156 °C (Kofler bench); on melting it is converted into 1,2,4,5-tetraphenylbenzene *(3)* of m.p. 268 °C (identical with authentic sample)[7]; $t_{1/2}$ for the thermal rearrangement *(2)*→*(3)* in boiling $CDCl_3 = 15.5$ h.

Preliminary experiments with various substituted bicyclopropenyls suggest that the new rearrangements is of a general nature. Mechanistic details are currently under study.

New Method of Polypeptide Synthesis

By *Manfred Mutter*, *Hanspaul Hagenmaier*, and *Ernst Bayer*[*]

The use of insoluble, polymeric carriers has simplified peptide synthesis since the soluble reagents present in excess can be removed by filtration[1]. However, the coupling reactions do not usually proceed quantitatively, thus giving rise to failure sequences which can be separated from the final product only with difficulty, if at all[2,3]. Moreover, synthesis on an insoluble carrier permits less

[*] Dipl.-Chem. M. Mutter, Doz. Dr. H. Hagenmaier, and Prof. Dr. E. Bayer
Lehrstuhl für Organische Chemie der Universität
74 Tübingen, Wilhelmstrasse 33 (Germany)

freedom regarding choice of solvents, protective groups, and coupling method than peptide synthesis in solution. Even the use of solid carriers having ordered surfaces ("brush carriers")[4, 5] or uncrosslinked polystyrenes[6–8] cannot avoid these difficulties entirely.

We have now developed a synthesis in homogeneous phases which permits a definite and simple separation of reagents from the growing peptide chain. A solubilizing protective group is bound to the C-terminal amino acid where it remains for the duration of the synthesis. Polymeric protective groups can be chosen which make the molecule soluble in the desired solvents. In practice, polyethylene glycol residues which can form an ester-type bond with the C-terminal acid have proved particularly effective. The first amino acid as well as the following ones can be linked in homogeneous solution.

The decisive second step of the process, the separation of the low-molecular-weight reagents from the growing peptide chain, which has polymeric character right from the start owing to the protective group, is carried out by ultrafiltration (membrane filtration)[9].

The synthesis has the following advantages: Synthesis and removal of excess reagents in a homogeneous phase can be carried out without the time-consuming separations of "classical" peptide syntheses and the repeated washings of the solid phase method; higher yields than when working in heterogeneous phases; possibility of removing incomplete sequences after each unsatisfactory coupling step; easy assessment of the coupling yield in aliquot amounts (^{19}F-NMR[10] and radioactivity measurements especially suitable); possibility of repeating a coupling step by any other desired method if yields prove unsatisfactory; possibility of condensing larger peptides bearing the macromolecular protective group[11]; possibility of automation, including yield monitoring.

The technique will be explained on the basis of two syntheses of the tetrapeptide H-Ile-Ala-Val-Gly-OH.

1. *Synthesis with tert-butyloxycarbonyl-protected amino acids by the anhydride method*[2]:

Esterification with the soluble carrier: Polyethylene glycol (M. W. 20000) was used as soluble polymer. Esterification is carried out with BOC-protected glycine and with 1,1'-carbonyldiimidazole as coupling reagent[13].

Synthetic cycle: a) Preparation of the mixed anhydride of isobutyl chloroformate and the BOC-protected amino acid with addition of *N*-methylmorpholine[12]. b) Addition of a three-fold excess of the mixed anhydride to the amino component (polymer-peptide). c) After coupling: Removal of protecting group by 4 N HCl in dioxane. d) Removal of solvent by distillation and dissolution in water. e) Ultrafiltration to remove excess components and distillation to remove water.

Conversion test: Aliquots of the reaction mixture are taken during coupling and analyzed by the ninhydrin method[14]. The coupling steps give yields in excess of 98%. The coupling of alanine to valine, which is possible in yields of only about 80% by the solid phase method, also gives a yield of over 95%.

Cleavage from carrier and isolation: The tetrapeptide is split off in the homogeneous phase by 0.05 N NaOH[15] and isolated by ion-exchange chromatography on Dowex X-50.

Ultrafiltration: The substance is dissolved in about 50 ml of water (*ca.* 2% solution) and diafiltrated[16]. The ultrafiltrate is tested for amino acids with ninhydrin until no positive reaction occurs. Hitherto, no membranes have been used that are stable to organic solvents[16].

2. *Synthesis in aqueous solution with benzyloxycarbonyl-protected amino acids and a water-soluble carbodiimide:*

Esterification with polyethylene glycol as described for the anhydride method.

Synthetic cycle: a) The amino component is dissolved in a small volume of water and coupled with a Z-protected amino acid. A water-soluble carbodiimide, *N*-[2-(cyclohexyliminomethyleneimino)ethyl]-*N*-methylmorpholinium *p*-toluenesulfonate[17], is used as coupling reagent. Coupling component and Z-amino acid are used in threefold excess. b) After coupling, an equal volume of methanol is added to the aqueous solution and the protective group removed by hydrogenation (Pd/activated charcoal). c) Ultrafiltration as well as cleavage and isolation of the tetrapeptide are carried out as described for the anhydride method.

The new method combines the advantages of the Merrifield solid phase synthesis and "classical" peptide synthesis. The effect of macromolecular C-terminal protecting groups on solubility and coupling opens up new preparative possibilities extending beyond the bounds of this method.

$(CH_3As)_2S_2N_4$—A Novel Arsenic-Sulfur-Nitrogen Heterocycle

By *Otto J. Scherer* and *Reinhard Wies*[*]

Formally, 3,7-dimethyl-1,5,2,4,6,8,3,7-dithia(IV)tetrazadiarsocine *(1)* can be visualized as tetrasulfur tetranitride (S_4N_4)

[*] Prof. Dr. O. J. Scherer and Dipl.-Chem. R. Wies
Universität Trier–Kaiserslautern and
Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)

in which two sulfur atoms have been replaced by CH_3As groups. It is formed in 76% yield by cleavage of the Si—N bonds[1] of *N,N'*-bis(trimethylsilyl)sulfur diimide by CH_3AsCl_2.

(1)

(1) is a red liquid (glass-like solid at low temperature), which is sensitive to hydrolysis, is very soluble in ether, benzene, and carbon tetrachloride, and moderately soluble in hexane; it can be distilled without decomposition at b. p. 84—86 °C/0.05 torr. Prolonged heating at 110—120 °C leads to slight decomposition[2].

Reaction of *(1)* with SCl_2 in molar concentrations of 1:2 affords, in addition to CH_3AsCl_2, about 40% S_4N_4.

Compound *(1)* was characterized by means of complete elemental analysis, cryoscopic molecular weight determination (in benzene; found: 294; calc.: 300) and by ^{1}H-NMR, IR, UV, and mass spectroscopy.

^{1}H-NMR (60 MHz; 10% CCl_4 solution; TMS int.): singlet at $\delta(CH_3As) = -106$ Hz. Mass spectrum (16 eV)[3]: *m/e* 300, molecular ion (100); 285, $CH_3As_2N_4S_2$ (92); 136, CH_3AsNS (8). None of the additional fragments has a relative intensity >1. IR (capillary film between KBr plates): The bands at 1043, 1066, and 1190 cm^{-1} have tentatively been assigned to the NSN system. UV (in hexane): λ_{max}(nm) 242 ($\varepsilon = 15400$), 302 (2300), 405 (419).

Experimental

Methyldichloroarsane (5.5 g, 34 mmol) is added dropwise in an atmosphere of nitrogen into a rapidly stirred solution of *N,N'*-bis(trimethylsilyl)sulfur diimide[4] (7.0 g, 34 mmol) in ether (50 ml). As reaction proceeds, the yellow solution gradually turns orange and a small amount of yellow precipitate separates out. After filtration through a G3 frit, solvent and trimethylchlorosilane are sucked off under vacuum (water pump). The residue is then fractionally distilled under vacuum (oil pump). Yield 3.9 g (76%).

Preparation of *N,N,N',N'*-Tetraaminopiperazinium Salts[**][1]

By *Karl-Heinz Linke* and *Ralf Turley*[*]

Although the onium salts of triazane, N_3H_6X, are extraordinarily unstable[2], the triazanium salts with organic substituents exhibit a relatively high stability[3-5]. We have been able to prepare *N,N,N',N'*-tetraaminopiperazinium sulfate *(3)* by exhaustive amination of *N,N'*-diaminopiperazine *(1)* with the sodium salt of hydroxylamido-*O*-sulfuric acid *(2)*. This is the first reported synthesis of a bis(triazanium)salt.

The chloride *(4)* and the azide *(5)* could be prepared by reaction of *(3)* with barium chloride and barium azide, respectively, in aqueous medium. The salts *(3)*, *(4)*, and *(5)* are colorless and crystalline: *(3)*, m. p. 144 °C (dec.); *(4)*, m. p. 156 °C (dec.); *(5)*, m. p. 128 °C (dec.). They are

(1) *(2)* *(3)*

only very slightly soluble in the usual organic solvents and moderately soluble in neutral aqueous solutions. They can be stored indefinetely in the solid state or in neutral aqueous solution.

Characterization of the compounds follows from IR spectroscopic analysis (see Table) and elemental analysis.

Table. Most intense IR bands of cations in the salts *(3)*, *(4)*, and *(5)*.

Vibrational mode	IR (cm^{-1}) *(3)*	*(4)*	*(5)*
ν_{as} NH_2	3230	3205	3230
ν_s NH_2	3110	3110	3110
δ NH_2	1630, 1610	1635, 1595	1630, 1610
γ NH_2	1150	1150	1150
ν NN	910	910	910
ν NNH_2	715	730	730

Proof of the given structure of the cation is afforded by the mode of reaction, since the aminating reagent always attacks at the most basic nitrogen atom. Further evidence is provided by the absence of the $\equiv\overset{\oplus}{N}H$-, $=\overset{\oplus}{N}H_2$-, or $-\overset{\oplus}{N}H_3$ bands, which one would expect[4] to find in the IR spectra between 2200 and 2700 cm^{-1} in the case of the other three theoretically possible structures for the triazine groups:

N,N,N',N'-Tetraaminopiperazinium sulfate (3)

An ice-cold solution of *(2)*, prepared by careful neutralization of an aqueous solution of hydroxylamido-*O*-sulfuric acid [11.3 g (0.1 mol) in 50 ml H_2O] with aqueous sodium hydroxide [4.0 g (0.1 mol) in 50 ml H_2O], is added dropwise over 10 mins with vigorous stirring to a warm (80 °C) aqueous solution of *(1)* [5.8 g (0.05 mol) in 300 ml H_2O]. The reaction mixture is evaporated down to 80 ml under reduced pressure and the crystals which precipitate are

Intermolecular Interactions in the Crystal Structure of the Hydrogen-Bond-Free Barbiturate Sodium Metharbital

By *Bernhard Berking*[*]

In the crystal structures of barbiturates and their derivatives that have been investigated so far, the packing of the molecules in the unit cell is established by one or more of the following intermolecular interactions: effective packing of alkyl groups, coordination of cations, dipole-dipole interaction, and, predominantly, by extended systems of hydrogen bonds. If in the latter case, the hydrogen atoms on C(5) are substituted, the imino nitrogen atoms in the pyrimidine ring usually serve as donors and the exocyclic oxygen atoms as acceptors—as, for example, in the barbital I and II structures[1].

The crystal structure of sodium 1-methyl-5,5-diethylbarbiturate (also called sodium metharbital or sodium

gemonil) was determined since in this case N(1) is methylated and N(3) deprotonated; consequently, hydrogen bonding is, *a priori*, not possible and the other types of bonding become effective.

As in the sodium[2] and calcium[3] salts of barbital (5,5-diethylbarbiturates) the deprotonation of the trioxopyrimidine ring at the imino nitrogen atom N(3) causes a shortening of the endocyclic C—N(3) bonds and a stretching of the adjacent exocyclic C=O bonds:

N(3)—C(2)	1.339 Å	C(2)—O(2)	1.240 Å
N(3)—C(4)	1.342 Å	C(4)—O(4)	1.233 Å
N(1)—C(2)	1.417 Å	C(6)—O(6)	1.225 Å
N(1)—C(6)	1.362 Å		

Comparable values in free barbituric acid are 1.37 Å for C—N bonds and 1.21 Å for C=O bonds (mean values)[1]. It can therefore be concluded that there is a redistribution of the formal negative charge over the anion—namely to the oxygen atoms, particularly the two oxygen atoms adjacent to N(3). Of special interest, therefore, is the remaining electronegativity of the deprotonated nitrogen atom and its ability to coordinate the sodium ion.

Figure 1 shows the packing of the molecules in the unit cell. All the ethyl groups lie in hydrophobic channels; the

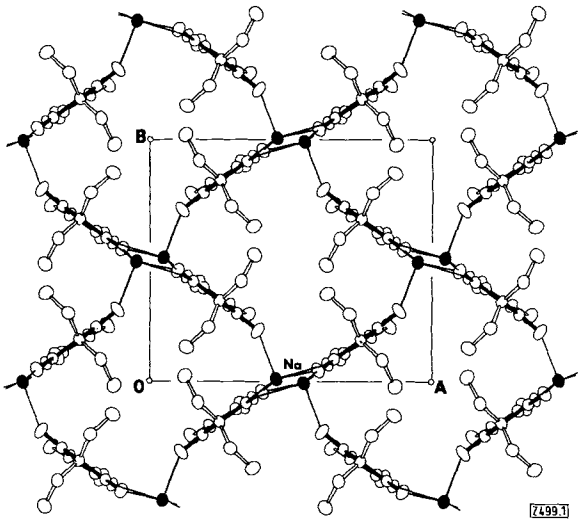

Fig. 1. Packing of sodium metharbital molecules in the unit cell.

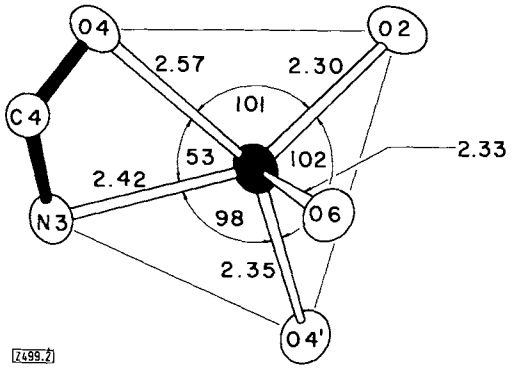

Fig. 2. Coordination of the sodium ion (black) in the sodium metharbital lattice [bond lengths Å, angles (°)].

van der Waals interactions are weak: no intermolecular distance is less than 2.45 Å, eight are smaller than 2.70 Å. All the oxygen atoms are situated in hydrophilic regions together with the sodium ion.

As can be seen in Figure 2, the sodium ion is fivefold coordinated: three oxygen atoms and the deprotonated nitrogen atom form the base and oxygen atom O(6) the apex of a pyramid which is surrounding the sodium ion. The coordination polyhedron can also be described as a tetrahedron with one corner replaced by the rigid intramolecular group N(3)—C(4)=O(4). The polyhedra are linked by sharing corners. Three of the Na—O distances have expected values, *i.e.* in the range 2.30—2.35 Å, but one (Na—O(4)) with a value of 2.57 Å is exceptionally large. A Na—N distance of only 2.42 Å has not been reported so far.

Na ions are preferably coordinated by oxygen atoms and not by nitrogen atoms. Thus, *e.g.*, in the structure of sodium barbital[2] the Na^+ ion is surrounded by an almost regular tetrahedron (d_{Na-O} = 2.31—2.35 Å) while the deprotonated nitrogen atom (d_{Na-N} = 2.80 Å) does not take part in intermolecular interactions.

In the few cases of coordination by nitrogen, no Na—N distance of less than 2.5 Å has been found, even in structures such as NaN_3[4, 5] and $NaCl \cdot 5^1/_7\ NH_3$[6] in which com-

[*] Dr. B. Berking
Crystallography Department, University of Pittsburgh
Pittsburgh, Pa. 15213 (USA)

peting oxygen atoms are absent. These structures exhibit comparably short bond lengths of 2.44 and 2.37 Å, respectively, only in other modifications at low temperatures.

The short Na—N and the extra long Na—O(4) distances in sodium metharbital suggest that the Na—N interaction is not a result of rigid intermolecular grouping N(3)—C(4)=O(4), in which coordination is actually by O(4), but that the electronegativity of the deprotonated nitrogen atom is itself not inferior to that of the oxygen atoms.

Sodium metharbital crystallizes in the orthorhombic space group $Pna2_1$ with $a=12.670$, $b=10.796$, $c=7.802$ Å, $Z=4$, and $D_m=1.369$ g/cm³. 962 X-ray reflections were recorded on an automatic diffractomer. The structure was solved by direct methods, and the refinement converged at $R=0.023$ with a standard deviation of 0.002 Å for the quoted bond lengths.

N-(Nitridofluorosulfur)sulfur imide difluoride

By *Oskar Glemser* and *Rainer Höfer*[*]

Bis(N-trimethylsilylimido)sulfur difluoride *(1)*[1], which is formed in the reaction of sulfur nitride trifluoride NSF_3 with lithium bis(trimethylsilyl)amide, reacts with sulfur tetrafluoride in an autoclave to give *(2)* in accordance with the following equation:

(2) is the first sulfur-nitrogen compound to be prepared containing SN single, double, and triple bonds. It reacts vigorously with water and readily decomposes at room temperature. The composition of *(2)* was established by elemental analysis and its structure has been confirmed by NMR, IR, and Raman spectroscopy.

^{19}F-NMR (ext. $CFCl_3$): $\delta(-N{=}SF_2)=-37.2$ ppm (triplet); $\delta(N{\equiv}SF_2-)=-101.5$ ppm (triplet) at -25 °C; $^4J_{FF}=4.2$ Hz. IR (cm^{-1}): 1470 (s) ($\nu_{S\equiv N}$), 1222 (vs) ($\nu_{S=N}$), 1085 (w), 1008 (w), 868 (m), 815 (m), 779 (vs), 659 (m), 587 (w), 445 (w), 414 (m). Raman (cm^{-1}): 1475 p ($\nu_{S\equiv N}$), 1203 p ($\nu_{S=N}$), 1043 dp, 829 p, 726 dp, 662 p, 590 p, 414 p, 381 dp, 273 dp. Mass spectrum (rel. intensity): molecular ion NSF_2—NSF_2^+ (90), NSF_2NSF^+ (2), NSF_2NS^+ (3), NSF_2^+ (50), SF_2^+ (100), NSF^+ (30), SF^+ (70), NS^+ (92).

Two weak signals (quintet and triplet) in the ^{19}F-NMR spectrum and additional fragments in the mass spectrum (SF_4—NSF_2^+, SF_2—NSF_2^+, and SF_3^+) suggest the existence of a further compound, which probably is to be formulated as $F_2S{=}N{-}SF_4{-}N{=}SF_2$; it is present in the reaction mixture to the extent of about 1%.

Experimental

SF_4 (18.0 g, 0.167 mol) is carefully condensed (liq. air) in an autoclave containing *(1)* (16.1 g), (0.066 mol). After thawing-out, the reaction mixture is stirred for 24 h at room temperature and finally fractionally distilled under high vacuum. Yield of *(2)*: 6 g (56%); m.p. -25 °C.

CONFERENCE REPORTS

Reactivity and Conformation in the Heterocyclic Series.—The Gear Effect

By *Jacques Metzger*[*]

The influence of conformation on chemical reactivity and NMR spectra was described for the case of Δ4-thiazolin-2-thiones. With 3,4-dialkyl-Δ4-thiazolin-2-thiones *(1a)*, which are accessible from α-halogenated ketones and *N*-alkyldithiocarbamates, dealkylation is observed from the nitrogen atom if N-3 carries a *tert*-butyl group and C-4 a methyl or larger alkyl group.

A simple calculation of the van der Waals interaction energy by *Westheimer*'s method affords a good correlation between this energy and the anomalous reaction.

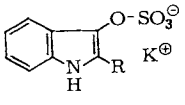
(1a), $R^1 = R^2 =$ Alkyl, $R^3 =$ H
(1b), $R^1 =$ Isopropyl, $R^2 =$ Alkyl, $R^3 =$ H
(1c), $R^1 = R^2 =$ Alkyl, $R^3 =$ Methyl

For 4-alkyl-3-isopropyl-Δ4-thiazolin-2-thiones *(1b)* the shape of the NMR signal of the methyl protons of the isopropyl group depends on the substituent at C-4: if $R^2=H$,

[*] Prof. Dr. J. Metzger
Département de Chimie Organique
Marseille 13 (France)

CH_3, C_2H_5, $(CH_3)_2CH$, or $(CH_3)_3C$, a sharp doublet, a broad doublet, an unresolved broad signal, two poorly resolved doublets, and a very sharp doublet are observed at room temperature. This result can be simply explained on the basis of the calculated relative energies of the possible conformations of the molecule.

Introducing a methyl group at C-5 [compound *(1c)*] greatly alters the ratio of the conformers that differ in arrangement around N-3. We call such an indirect conformational interaction a "gear" effect. In general, this effect is found when the ratio of the conformers differing in arrangement at atom 'a' is altered by the substituents on atom 'c', the effect operating through and beyond atom 'b'. It may well contribute to an understanding of several hitherto unsolved conformational problems.



Lecture at Hamburg (Germany) on June 11, 1971 [VB 313 IE]

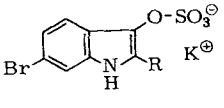
Biological Precursors and Genesis of Tyrian-Purple

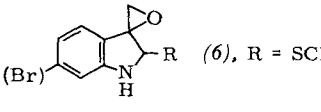


By *Herbert Fouquet* and *Hans-Joachim Bielig* (Lecturer)[*]

It has been known for some time that indigo[1] and 6,6'-dibromo indigo[2] are major constituents of the ancient dye Tyrian purple (red = purpura blatta, blue = purpura hyacinthina, and violet-red = purpura dibapha) from gastropod mulluscs (Murex, Purpura, and other species). Living gastropod mulluscs contain no indigoid dyes however. They are formed, as previously assumed, by the action of atmospheric oxygen and light on the autolyzed hypobranchial glands. An enzyme (purpurase) also plays an important role in this transformation[3,4]. *Letellier*'s attempts at isolating chromogens from *Purpura lapillus* Lam. (Atlantic)[5] yielded two photolabile components (water-soluble leuco- and ether-soluble chlorolapillin), which afford dyes at different rates, in addition to photostable alkali-soluble xantholapillin. The analog of leucolapillin obtained from the hypobranchial glands of *Murex brandaris* or *M. trunculus* L. (Mediterranean) can be separated into one or two prochromogens which on acid hydrolysis afford sulfate, or sulfate and a thiol, as well as indigoid and bromoindigoid dyes[6].

We[7] have now been able to establish that four chromogens are always present (average total 1.2 mg/gland, in the ratio *(1)*:*(2)*:*(3)*:*(4)* ≈ 4.5:0.5:3:2) in methanol extracts of *Murex trunculus* and usually only one of these (up to 0.6 mg (4)/gland) in extracts of *M. brandis*, *M. erinaceus*, and *P. haemastoma*. The colorless water-soluble crystallates of the chromogens were isolated in pure form by combination of gel chromatography and thin-layer chromatography.

(1), R = H
(2), R = SCH_3



(3), R = H

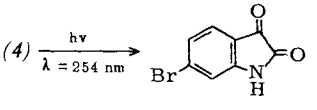
(5), R = SCH_3

[*] Dr. H. Fouquet and Prof. Dr. H.-J. Bielig
Institut für Biochemie der Universität
66 Saarbrücken 11



Their structures, *(1)* to *(4)*, were established by elemental analysis, and UV, mass, and NMR spectroscopy. Compound *(5)*, which is missing in this series, was discovered independently in *Dicathais orbita* (Pacific Ocean)[8].

On treatment with Raney nickel in ethanol, compounds *(2)* and *(4)* are converted into *(1)* either directly or *via (3)*. Hydrolysis with hydrochloric acid affords sulfate [like *(1)* and *(3)*] and methanethiol (detected as Hg thiolate by gas chromatography) corresponding to the cleavage observed with phalloidin and α-amanitin[9]. Besides indigo and 6,6'-dibromoindigo, the analogous indirubins and other known red 2,3'-coupled indigoid dyes are formed.

The chromogens *(1)* and *(3)* react anaerobically in the dark at pH = 7.4 with the purpurase recognized as aryl sulfatase to give indoxyl and 6-bromoindoxyl (as indolinones) respectively, which afford aerobically in the dark only indigo and 6,6'-dibromindigo taking up 1 mol O_2/mol dye. The chromogens *(2)* and *(4)*, on the other hand, react aerobically with aryl sulfatase in the dark to give the green ether-soluble quinhydrones (corresponding to *Letellier*'s chlorolapillin) of 2-methylthioindole and 2-methanesulfonyl-6-bromo-indoxyl and their oxidation products (indolenineinones). The last-named can be precipitated as the epoxide-type compounds *(5)* by treatment with diazomethane. In daylight, the green intermediates undergo photolytic cleavage of the *S*-components (to dimethyl sulfide or secondary methanethiols) to give exclusively the same dyes as *(1)* and *(3)*. A total of only 0.5 mol O_2/mol dye is consumed in this combined dark- and light-reaction. If conversion of the chromogens is carried out in the presence of isatin or 6-bromoisatin [*(7)*, *Latellier*'s xantholapillin] also found in purpura glands, formation of the corresponding indirubins additionally takes place. When the chromogen *(4)* is irradiated in the solid phase with 254-nm light it undergoes quantitative photooxidation to compound *(7)*, whereas the chromogen *(2)* is not affected.

(6), R = SCH_3, SO_2CH_3

(7)

It can be concluded from the above findings that the ancient dye purpura blatta originates predominantly from the chromogen *(4)*, *i.e.* from purpura gastropod molluscs of

Modes of Action of Antibiotics

By *Josef Schmidt-Thomé*[*]

In the lecture five important groups of antibiotics, classed according to mode of action, were discussed:

1. Antibiotics which inhibit synthesis of the cell wall. The first and foremost of this group are the penicillins and cephalosporins, which specifically hinder the synthesis of the murein of the cell wall by inhibition of a D-alanyl transpeptidase. Other antibiotics, such as cycloserin, bacitracin, novobiocin, vancomycin, and ristocetin also interfere with the murein synthesis, but in a different manner.

2. Antibiotics which influence the permeability of the cell membrane and thus increase the exit and entry of ions and important cell components. For example, the tyrocidins, polymyxins, polyene antibiotics, alkali metal ionophores such as valinomycin, and the nonactins *etc.* belong to this group.

3. Antibiotics that inhibit the synthesis of important cell components in the interior of the cell, *e.g.* azaserin and diazooxonorleucin, which interfere with purine biosynthesis; also belonging to this group are a series of purine antibiotics such as psicofuranin, angustmycin and cordycepin.

4. Antibiotics which inhibit the synthesis of DNA and RNA. Rifamycins, streptovaricins, and tolypomycin specifically inhibit the DNA-dependent RNA polymerases. A large number of antibiotics react with the DNA template and thus interfere with or inhibit activity of the RNA or DNA polymerases, *e.g.* actinomycins, chromomycins, anthracyclin antibiotics such as rhodomycin, cinerubins, pyrromycins, mitomycins, and porfiromycin *etc.*

5. Antibiotics which inhibit protein biosynthesis. The interaction of mRNA and tRNA with the ribosomes and the enzymes taking part in protein biosynthesis can be disturbed and inhibited at various points by antibiotics. Several antibiotics, some of which are currently being used in therapy, interfere with these complicated processes, *e.g.* tetracyclins, macrolides, chloramphenicol, and aminoglycosides such as streptomycin *etc.*

The lecture concluded with a report on some of the work being carried out at Farbwerke Hoechst on the mode of action of moenomycin and on the application of *in vitro* systems of protein synthesis to specificity investigations of tetracyclin derivatives and other antibiotics.—A knowledge of the effect of antibiotics on vitally important processes in the cell opens up new prospects for future cancer and virus therapy.

Polarographic Trace Analysis of Inorganic Substances in Non-Aqueous Solvents (Example: Phosphorus and Silicon)

By *Friedel Pottkamp* and *Fritz Umland* (Lecturer)[*]

Phosphorus and silicon can be selectively extracted as the dodecamolybdato acids (abbreviated PMo and SiMo) with butyl acetate[1]. The acids are polarographically active in the organic phase after addition of ethanolic LiCl solution as supporting electrolyte. In the ppm range (*ca.* 10^{-4} mol/l) two groups of three polarographic waves are obtained which are best resolved by AC rapid polarography; position in volts versus the Ag/AgCl electrode in 1 N ethanolic LiCl solution: 1. −0.14, 2. −0.46, 3. −0.65, 4. −1.29, 5. −1.50, 6. −1.85.

The AC peaks No. 1 and No. 2 correspond to the H^+-dependent waves also occurring in aqueous solution and can be rendered by the following reduction process:

$$H_3[PMo_{12}O_{40}] + nH^{\oplus} + ne^{\ominus} = H_3[PMo_{12}O_{40-n}(OH)_n]$$

where $n=2$ and $n=4$. The signals of the two isomeric forms of dodecamolybdato-silicic acid appear at considerably different positions: 1. α-SiMo: −0.13 V; 2. β-SiMo: −0.30 V. The electrode process responsible for peak 3 is not yet clear; however, it can be stated with certainty that it is not due to reduction of an isopolymolybdic acid, which accompanies the PMo signal in aqueous solution.

In the case of the more negative group of three peaks, a diffusion controlled wave (peak No. 5) occurs at higher LiCl concentrations (*ca.* 4 mol/l) which is flanked by two adsorption controlled waves. These disappear with decreasing LiCl concentration and increasing H^+ concentration. With decreasing LiCl concentration, the wave No. 5 converts to a kinetically controlled limiting current. In the case of PMo it is a matter of a catalytic H^+ reduction, which permits an accurate determination of P in the ppb range ($3\sigma = 2 \times 10^{-11}$ mol/l).

The catalytic H^+ discharge at a substantially more positive potential than the discharge of stronger acids resembles the H^+ discharge catalyzed by organic ammonium ions that was reported by Nürnberg[2].

As distinguished from the ammonium depolarizers, however, the H^+ reduction catalyzed by PMo is dependent not only on the K_s value but also on other properties of the acid. Thus, the catalytic wave is obtained with PMo + acetic acid but not with PMo + chloroacetic acid.

Consequently, a complex associate or solvate of (reduced) PMo and acetic acid occurring as oxonium ion must be assumed to act as depolarizer.

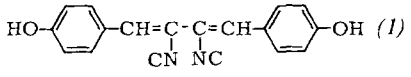
General Meeting of the Gesellschaft Deutscher Chemiker 1971



This year's General Meeting was held at Karlsruhe (Germany) from 13th to 18th September. A selection of abstracts of the lectures and discussions that took place on this occasion is given below. Only work that has not been published or presented for publication is included. The abstracts are listed in the alphabetical order of authors names.

From the lectures:

Studies of the Biogenesis of Xanthocillin

By *Hans Achenbach* (Lecturer) and *Franz König*[*]

Xanthocillin *(1)* is characterized by a symmetrical 1,4-diarylbutadiene skeleton to which two isocyano groups are attached at positions 2 and 3.

(1)

Tracer experiments with doubly labeled tyrosine showed that this amino acid can be incorporated into *(1)* as an intact C_6—C_2—N unit. Mass-spectrometric isotopic analysis of *(1)* after addition of [^{15}N]tyrosine led to a surprising result: only one of the nitrogen atoms in the two isocyano groups arises from tyrosine.

This and other experimental results contradict the biogenetic equivalence of the two symmetrical halves of the xanthocillin molecule. They suggest that some other amino acid is concerned in the formation of the isocyano groups.

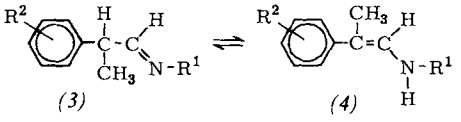
Relation of Imine-Enamine Tautomerism to Structure



By *Hubertus Ahlbrecht*[*]

The condensation products of primary aromatic and aliphatic amines *(1)* with hydratropaldehydes *(2)* that are substituted in the benzene nucleus tautomerize in solution to mixtures of imine *(3)* and enamine *(4)*.

The position of the equilibrium is dependent on the solvent and the temperature. It is also strongly influenced by substituents on the nitrogen (R^1) and in the β-benzene ring (R^2). Study of the dependence on substituents showed that any structural change that tends to remove electrons from the enamine system leads to stabilization of the enamine form. The influence of a substituent in the β-benzene nucleus is thus described very nicely by the Hammett σ value. This is no longer true for substituents on an *N*-phenyl group; with *para*-substitution direct resonance interactions occur. The latter can be recognized from enthalpy/entropy diagrams. The values of the enthalpy and entropy changes were determined from the temperature-dependence of the equilibria; they showed that in the systems studied the enamine formation is in general exothermic and involves loss of entropy and that the equilibrium is enthalpy-controlled.

Fluorescence and Fluorescence Thermochromism of Copper(I) Compounds

By *Heinz D. de Ahna* (Lecturer) and *H.-D. Hardt*[*]

Reduction of copper(II) acetate in acetonitrile/acetic acid by hydrazine hydrate with exclusion of oxygen leads to solutions of copper(I) acetate, from which very pure microcrystalline copper(I) halides are precipitated on addition of an acetyl halide (=AcX):

$$Cu(OOC{-}CH_3)_2 \xrightarrow[CH_3CN/CH_3COOH]{\Delta,\ N_2H_5OH} CuOOC{-}CH_3 \xrightarrow{AcX} CuX$$

On treatment with pyridine or alkylpyridines (=L) these halides form yellow to greenish-yellow compounds of composition $Cu(L)_3X$.

From these can be obtained, by controlled thermal decomposition, colorless compounds of composition Cu(L)X. All these compounds show an intense fluorescence of the most varied colors.

Some compounds of the composition Cu(L)X change their fluorescence color reversibly at low temperature, *e.g.*, Cu(2-picoline)Br from red to blue. The term "fluorescence-thermochromism" is proposed for this phenomenon.

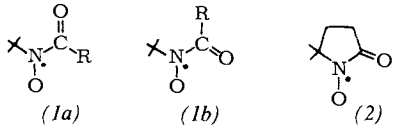
Crystallo-Chemical Aspects of the Gas-Phase Synthesis of Icosahedral Boro- and Boride-Structures

By *Eberhard Amberger*[*]

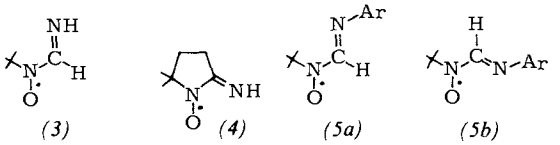
When the pyrolysis of pure borohalides and H_2 is carried out at a temperature in the range in which crystal growth is dependent on the kinetics (900—1500 °C), separation of elemental boron takes place: besides glassy-amorphous boron, only two lattices of the long series of lattices described in the literature as "boron modifications" are formed, namely the α-rhombohedral and the II-tetragonal lattices. Since all lattices of boron and boron-



[*] Prof. Dr. E. Amberger
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1 (Germany)

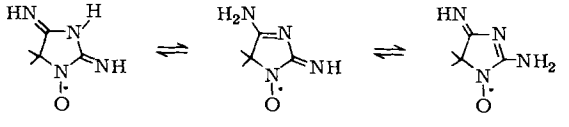
rich borides contain B_{12} icosahedra as structural units, space-filling is slight. On addition of small amounts of foreign gases ($AlBr_3$, CH_4, $SiBr_4$, N_2, PBr_3) to the synthesis gas individual foreign atoms occupy holes in the lattice. When incorporated in very small amounts, the atoms Al, C, Si, N, and P induce formation of a β-rhombohedral lattice. Incorporation of slightly larger amounts of foreign atoms leads to formation of the I-tetragonal lattice [*e.g.* $(B_{12})_4B_2C$, $(B_{12})_4B_2C_2$, $(B_{12})_4C_3$, $(B_{12})_4B_2N_{1-2}$]. If still larger amounts of foreign atoms are incorporated the rhombohedral angle of the α-rhombohedral cell expands to the "$B_{13}C_2$" cell ("borocarbide structure"; *e.g.* $B_{12}BC_3$, $B_{12}B_{2.45}P_{0.55}$, $B_{12}P_{1.5}$).

ESR Spectroscopic Investigations of Acyl and Azomethine Nitroxides



By *Hans G. Aurich* (Lecturer), *Jürgen Trösken*, and *Helmut Forster*[*]

In the ESR spectra of the radicals *(1)*, R = CH_3, C_2H_5, $(CH_3)_2CH$, and $(CH_3)_3C$, the nitrogen coupling constants are substantially unchanged as the size of the group R is increased. It may therefore be assumed that these radicals adopt the *E* conformation *(1a)* and not the *Z* conformation *(1b)*.



(1a) *(1b)* *(2)*

For *(1)*, R = CH_3, and the nitroxides *(2)*—*(4)* in aprotic solvents the nitrogen coupling constants are found to increase with increasing polarity of the solvent (correlation with E_T values). In protic solvents, however, the expected increase in coupling constants does not occur; this is attributed to preferred formation of hydrogen bonds to the carbonyl or imino group.

(3) *(4)* *(5a)* *(5b)*

However, the ESR spectra of *(5)* in strongly polar solvents show two radical species, from which it can be concluded that both conformations *(5a)* and *(5b)* are present.

(6a) *(6b)* *(6c)*

For the porphyrexide *(6)*, which can exist as *(6a)*—*(6c)*, it was shown by deuteration and labeling of the nitrogen at position 2 by ^{15}N that the forms *(6a)* and/or *(6b)*, with the exocyclic 2-imino group, preponderate in a series of aprotic solvents.

Conformational Analysis of Organometallic Lanthanoid and Actinoid Complexes by Means of the Paramagnetically Induced Shifts in Their ^{1}H-NMR Spectra

By *Reinhard von Ammon* (Lecturer), *R. Dieter Fischer*, and *Basil Kanellakopulos*[*]

The organometallic complexes $(C_5H_5)_3PrCNC_6H_{11}$ *(1)*, $(C_5H_5)_3UOC_6H_{11}$ *(2)*, and $(C_5H_5)_3UO$-cholesteryl *(3)* show ^{1}H-NMR spectra extended over a wide frequency range. The positive and negative paramagnetic shifts are due to the central metal whose electron relaxation is particularly favorable for NMR investigations because of the f^2 configuration (Pr^{3+}, $4f^2$; U^{4+}, $5f^2$).

In the spectra of *(1)*, *(2)*, and *(3)* all the protons of the cyclohexyl group can be seen and can be assigned by correlation with their geometric factors because the paramagnetic shift can be related exclusively to the pseudo-contact interaction. The sole exception is the α-proton of *(2)* and *(3)*, whose shift contains a considerable contribution from Fermi contact interactions. The ΔG value for ring inversion of *(1)* can be obtained directly from intensity measurements at low temperatures. Structural information can also be obtained.

Determination of the Relative Electron Density at the Be Nucleus in Various Chemical Compounds, Measured as the Change in the EC Half Life of ^{7}Be

By *D. C. Aumann* (lecturer), *H. W. Johlige*, and *H.-J. Born*[*]

The change in the EC decay constant of ^{7}Be in various chemical compounds was measured with a differential ionization chamber. The results are

$$\lambda(BeO) - \lambda(BeF_2)_{amorph} = (1.130 \pm 0.058) \times 10^{-3}\lambda(Be)$$
$$\lambda(BeO) - \lambda(Be_4O(CH_3COO_6) = (-0.724 \pm 0.057) \times 10^{-3}\lambda(Be)$$
$$\lambda(BeO) - \lambda(BeBr_2) = (1.472 \pm 0.063) \times 10^{-3}\lambda(Be)$$
$$\lambda(Be_4O(CH_3COO)_6) - \lambda(BeF_2)_{amorph} = (1.852 \pm 0.082) \times 10^{-3}\lambda(Be)$$
$$\lambda(BeO) - \lambda(Be(C_5H_5)_2) = (0.795 \pm 0.074) \times 10^{-3}\lambda(Be)$$
$$\lambda(BeO) - \lambda(Be^{2+}(OH_2)_4) = (-0.374 \pm 0.077) \times 10^{-3}\lambda(Be)$$
$$\lambda(Be(C_5H_5)_2) - \lambda(Be^{2+}(OH_2)_4) = (-1.169 \pm 0.106) \times 10^{-3}\lambda(Be)$$

The decay constant of ^{7}Be is proportional to the electron density at the Be nucleus. These results can therefore be used to construct a scale of relative electron densities at the Be nucleus in various chemical compounds.

Transformation of Flavonols by an Enzyme from *Cicer arietinum*

By *Wolfgang Barz* (Lecturer) and *Wolfgang Hösel*[*]

By experiments involving pulse labeling we have shown that the flavonols kaempferol, quercetin, and isorhamnetin

[*] Doz. Dr. W. Barz and Apotheker W. Hösel
Biologisches Institut II der Universität
78 Freiburg, Schänzlestrasse 9—11 (Germany)

are metabolically active constituents of *Cicer arietinum*. We have now isolated an enzyme preparation that transforms specifically flavonol aglycones in an oxygen-dependent reaction. The very labile product of the enzyme reaction, which can be purified by paper and column chromatography (Sephadex LH 20), consists, according to its UV, IR, and nuclear magnetic resonance spectra, of a flavonoid with a modified γ-pyrone ring. Because of the great similarity of the substance to dihydroflavonols, the electrophoretic and spectroscopic properties, and the ready acid-catalyzed regeneration of flavonols, we conclude that it has the structure of a 2,3-dihydroxyflavanone.

This enzyme, which is so far the only known plant enzyme transforming flavonols, could be shown to be present in a large number of plants. In *C. arietinum* its presence is confined to the root, hypocotyl, cotyledons, and stem.

Possible Reactions in Organic Electrochemistry

By *Fritz Beck*[*]

Electrode reactions of organic molecules X lead primarily to radical ions, which in follow-up reactions with nucleophilic ($\mathcal{N}$) or electrophilic ($\mathcal{E}$) reactants afford the products (P):

Cathodic:

$$X \xrightarrow{\ominus} X.^{\ominus} \xrightarrow{\mathcal{E}} e, c \ldots . P$$

Anodic:

$$X: \xrightarrow{-\ominus} X.^{\oplus} \xrightarrow{\mathcal{N}} e, c \ldots . P$$

Although much information is available from electrochemical measurements about the primary reaction, particularly in aprotic solvents, little is known about the kinetics of the subsequent reactions, *i. e.* the chemistry of the radical ions.

The possible reactions in organic electrochemistry can be divided into two groups:

1. X is not identical with $\mathcal{E}, \mathcal{N}$

These include hydrogenations, oxidations, substitutions, and mixed dimerizations. Elimination reactions can also be assigned to this group.

$\mathcal{E} = H^{\oplus}, CO_2, CO, SO_3, SO_2$;
$\mathcal{N} = Cl^{\ominus}, F^{\ominus}, OH^{\ominus}, OCH_3^{\ominus}, CH_3COO^{\ominus}, NO_2^{\ominus}$, *etc.*

2. X is identical with $\mathcal{E}, \mathcal{N}$

These embrace dimerizations and polymerizations. The mode of reaction is favored by high substrate concentration, high dielectric constant, and shielding of the charge of the radical ion.

A selection of the preparatively and industrially interesting reactions was discussed. Organic electrosynthesis is without competitors above all when the specific conditions at the interface through which the current flows (high, controllable electric field strength, adsorption, concentration profile in the diffusion layer, structure of the electrochemical double layer) are particularly favorable for the desired reaction course. The environmental advantages of electrochemical reactions are also obtaining increasing recognition.

Badische Anilin- & Soda-Fabrik AG, Hauptlaboratorium
67 Ludwigshafen (Germany)

The Crystal Structure of $EuBr_2$

By *H. P. Beck* (Lecturer) and *H. Bärnighausen*[*]

Using three-dimensional single-crystal X-ray data (Mo-K_α radiation) the crystal structure of $EuBr_2$ has been determined by interpretation of Patterson syntheses and least squares refinement (see Table).

Table. Crystal data, positional parameters, and Debye-Waller factors of $EuBr_2$ (tetragonal; $a = 11.567$, $c = 7.094$ Å; space group P4/n (No 85); $Z = 10$).

Atom	Position	x	y	z	B(Å^2)
Eu(1)	8 (g)	0.1030	0.5871	0.2489	1.52
Eu(2)	2 (c)	0.25	0.25	0.8555	1.39
Br(1)	8 (g)	0.1554	0.4605	0.6256	2.02
Br(2)	8 (g)	0.3390	0.4576	0.1025	1.59
Br(3)	2 (a)	0.25	0.75	0.0	1.38
Br(4)	2 (b)	0.25	0.75	0.5	1.46

In the crystal structure of $EuBr_2$, both Eu(1) and Eu(2) are surrounded by 8 Br^- ions in a square antiprismatic arrangement [however, this idealized geometry is considerably distorted in the case of the cation Eu(1)]. The arrangement of the Eu coordination polyhedra can be compared with that of cubic close packed spheres, so that it is tempting to draw a parallel with the fluorite type. In both structures the cations are eight-fold coordinated, and the geometric arrangements of the coordination polyhedra are also the same. The only difference lies in the geometry of the polyhedra, in that the square antiprism of $EuBr_2$ contrasts with the cubic coordination of the fluorite type.

As expected, $EuBr_2$ and $SrBr_2$ are strictly isostructural. The statistical distribution of the Sr(2) cations over two different positions discussed in the literature as a possibility can now be ruled out conclusively since the original hypothesis can be assigned to faulty interpretation of the powder diagram.

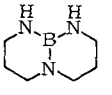
Institut für Anorganische Chemie der Universität
75 Karlsruhe 1, Postfach 6380 (Germany)

Photoelectron Spectra of Organometallic Compounds

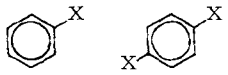
By *Hans Bock*[*]



Photoelectron spectroscopy is a molecular probe for σ- and π-interactions, which provides information on the electronic structure of molecules up to now inaccessible.

Topics discussed were:

1. π-systems and geometry of aminoboranes.



$(R_2N)_nBX_{3-n}$ n = 1,2,3; X = H, CH_3, F, Cl, Br

2. Substituent effects from the perturbation of the benzene π-system.

[*] Prof. Dr. H. Bock
Chemische Institute der Universität
6 Frankfurt (Main), Ludwig-Rehn-Strasse 14 (Germany)

X = NR_2, PR_2, OR, SR

3. Acceptor properties of silyl groups towards electron pairs and π-systems.

$X(SiH_3)$, X = Br or OR $\pi(SiH_3)$, π = C_2H_3 or C_6H_5

4. σ-electron delocalization in polysilane chains and rings.

$R(SiR_2)_nR$, n = 1,2,3,4,5 $(SiR_2)_m$, m = 5,6

Coupling Products of Diazotized Anthranilic Acid and *p*-Alkylphenols for Separation, Enrichment, and Determination of Beryllium

By *Ewald Blasius* (Lecturer), *Horst-Joachim Finkenauer*, and *Klaus-Peter Janzen*[*]

o-Hydroxy-*o'*-carboxy-disubstituted azo dyes are selective complexing agents for Be(II).

Coupling products of diazotized anthranilic acid with poly-4-hydroxystyrene or *p*-dodecylphenol are used for separation and enrichment of traces of Be(II) as solid or liquid chelate exchangers, respectively.

o-(2-Hydroxy-5-methylphenylazo)benzoic acid, as a coupling product analogous to that of *p*-cresol, makes possible the synergic extraction of Be(II) from water/methanol mixtures that contain Al(III) and Fe(III).

The Be(II) complex can be detected polarographically to a limiting concentration of 10^{-9} mol/ml in presence of Al(III), Fe(III), Co(II), Ni(II), or Cu(II). The complex can also be determined by inverse voltammetry or photometry at concentrations of, respectively, 10^{-10} mol/ml and 10^{-9} mol/ml.

Influence of Electrocatalytic Properties of Tungsten Carbide on Anodic Oxidation of Hydrogen

By *Harald Böhm* (Lecturer) and *Wolfgang Diemer*[*]

The anodic oxidation of hydrogen on smooth tungsten carbide electrodes and on rotating tungsten carbide disk electrodes has been studied. The kinetics of the overall reaction were determined by the adsorption of the hydrogen on tungsten carbide. The exchange current density of the hydrogen reaction depends on the mode of preparation of the tungsten carbide; values between 4×10^{-7} and 8×10^{-5} A/cm² were found for i_0. The catalytic activity of the tungsten carbide and thus i_0 are influenced by the carbon and oxygen contents of the sample. Thus the highest activity is found at a carbon content of about 5.9% and not at the content of 6.12% that is calculated for pure WC. The current density of anodic oxidation of hydrogen can be increased by a factor of 2 by partial oxidation of the tungsten carbide surface.

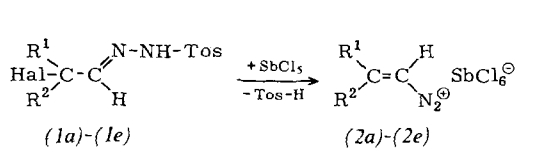
Preparation and Properties of Oligomeric Polynuclear Phenolic Compounds Containing Nitrophenol Components

By *Volker Böhmer* (Lecturer) and *Hermann Kämmerer*[*]



Molecularly homogeneous phenolic polynuclear compounds containing nitro groups cannot be prepared by nitration of preformed polynuclear compounds. Nevertheless, compounds with up to four phenolic units per molecule each carrying at least one nitro group can be prepared either by condensation of nitrophenols with formaldehyde in the presence of sulfuric acid or by condensation of chloromethylated nitrophenols with other nitrophenols in the presence of zinc chloride. On condensation of chloromethylated nitrophenols with methylphenols, however, substitution occurs not only in the *ortho*- but also in the *meta*-position to the phenolic OH group. With binuclear compounds the two isomeric products can be isolated and identified by NMR spectroscopy. New compounds can then be obtained from such "mixed" polynuclear compounds by hydroxymethylation and further condensation. The UV spectra of the oligomers obtained can in some cases be explained over the whole spectral region by addition of "increments" for the individual units.

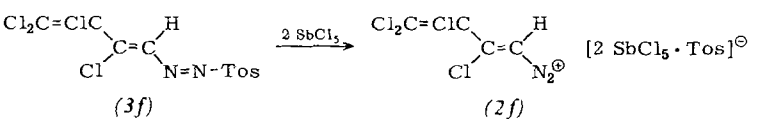
Synthesis and Properties of Ethylenediazonium Salts



By *Kaspar Bott*[*]

The action of Lewis acids such as antimony pentachloride, aluminum chloride, and stannic tetrachloride on *p*-toluenesulfonylhydrazones *(1a)—(1e)* of α-halogenated aldehydes in chlorohydrocarbons affords, in some cases in high yield, substituted ethylenediazonium salts that, with the exception of *(2d)*, can be isolated as well-crystalline hexachloroantimonates *(2a)—(2e)*. By using *(3f)* and *(3g)* as examples it was shown that the azosulfones postulated as intermediates can be isolated and then converted by antimony pentachloride or a mixture thereof with hydrogen chloride into a diazonium chlorosulfinatoantimonate *(2f)* or hexachloroantimonate *(2g)*, respectively. The compound *(2b)* is also accessible by reaction of nitrosyl hexachloroantimonate with 2,2-dichlorovinyl isocyanate. In all the reactions of ethylenediazonium salts with "basic" reagents the azo coupling is repressed in favor of attack on the β-carbon atom; the particularly reactive *(2b)* substitutes the *p*-hydrogen of anisole even below room tem-

perature, but the second halogen atom of the resulting 2-chloro-2-(*p*-methoxyphenyl)ethylenediazonium hexachloroantimonate *(2h)* is replaceable only by the more strongly basic methanol. Finally, an α,β-diaryl-substituted

ethylenediazonium salt was also synthesized, namely, the deep green *(2j)*, which with its reactive double bond and its relatively long-wavelength N≡N stretching band (as a measure of the resonance stabilization) fits well into the series of substances *(2a)*—*(2i)*.

A Contribution to the Mode of Reaction of Anthrahydroquinones with Formaldehyde

By *Karl Bredereck* (Lecturer) and *Lothar Banzhaf*[*]

The mode of reaction of substituted anthrahydroquinones with formaldehyde in aqueous ethanol in the pH region 7—14 has been investigated. Direct-current polarographic measurements showed that anthrahydroquinones that are amenable to enol-keto rearrangement undergo, in the presence of formaldehyde, a reversible equilibration affording 10-hydroxy-10-(hydroxymethyl)-9-anthrones. In individual cases it was possible to isolate these very labile compounds and prove their structure. Further, amino- and hydroxy-anthrahydroquinones and formaldehyde can form ring-methylated anthraquinones; this reaction (the Marschalk reaction) was also studied polarographically; the formation of (hydroxymethyl)anthrahydroquinones as intermediates could be proved.

It was also found that nucleofugal leaving groups in the 2-position of 1-aminoanthraquinones were replaced smoothly by hydroxymethyl or aminomethyl groups on reaction with, respectively, formaldehyde or formaldehyde/amines and sodium dithionite as reducing agent.

Gaseous Carbonium Ions from the Decay of Tritiated Molecules

By *Fulvio Cacace*[*]

When a T atom covalently bound to carbon undergoes β decay, the daughter ^3He is rapidly lost as a neutral atom, and a carbonium ion is formed[1], *e.g.*:

$$CH_3T \xrightarrow{\text{beta decay}} CH_3^{\oplus} + {}^3He + \beta^- \quad (1)$$

If the original molecule contains at least two radioactive atoms, a *labeled* carbonium ion is formed, whose reactions can be conveniently followed and the final products identified. In recent years, the decay of tritiated precursors has been extensively used as a convenient tool to investigate the stability and the reactions of carbonium ions of precisely defined structure in gases at atmospheric pressure[2]. Among the many systems investigated, a few representative ones are briefly discussed. The $CT_3^{\oplus}$ ions from the decay of CT_4 were shown to react rapidly with CH_4 at 760 torr, yielding ethyl ions that are unreactive towards methane. Both methyl and ethyl ions, on the other hand, readily abstract a hydride ion from higher alkanes to yield, respectively, CT_3H and tritiated ethane. As a whole, these results show a significant analogy with those obtained in $HFSO_3/SbF_5$ solutions[3]. The cyclopentyl cation obtained from the decay of $C_5H_8T_2$ was found to retain its cyclic structure, undergoing rearrangement to the linear pentenyl cation only to a limited extent:

(2)

The decay of molecular tritium yields an exceedingly strong *Brønsted* acid, the helium tritide ion, whose reactions with organic substrates represent another convenient route to gaseous carbonium ions:

$$T_2 \rightarrow {}^3HeT^{\oplus} + \beta^- \quad (3)$$

$$HeT^{\oplus} + RH \rightarrow RHT^{\oplus} + He \quad (4)$$

The tritiation of the appropriate gaseous substrates by the $HeT^{\oplus}$ reagent provided the first direct evidence for the long postulated occurrence of cycloalkanium ions as stable gaseous species. In particular, the intervention of protonated cyclopropanes was unambiguously established by the gas-phase tritiation of cyclopropane and *cis*- and *trans*-dimethyl cyclopropane at pressure of several hundred torr[4]. Reaction (4) proved particularly useful for the study of the gas-phase electrophilic substitutions of aromatic substrates, including benzene, toluene, *tert*-butylbenzene, the halobenzenes, benzonitrile, anisole and α-trifluorotoluene. The contrast between the very low substrate selectivity and the measurable positional selectivity, represents a distinctive feature of the gas-phase reactions, as shown by the study of related gaseous reagents, and suggests that their reaction mechanism must significantly differ from those postulated for the corresponding processes occurring in solution.

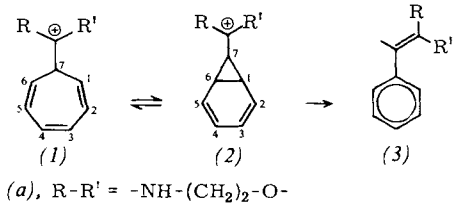
Aligned Composites Prepared by Solid State Transformations

By *F. M. A. Carpay*[*]



By using the same experimental techniques as in directed eutectic solidification we have effected eutectoidal decomposition and cellular precipitation under directed control. Under unidirectional cooling conditions—for example, by mechanical movement through a temperature gradient—the transformation proceeds in a directed manner. The resulting lamellar structure is illustrated by examples: the eutectoids Co_3Si, β-Cu-In, β-Ni-In, β-Cu-Al, and the separation of Sn in Pb. High rates of movement give undirected structures. The distances between lamellae which occur on discontinuous solid-state transformations are found to be on the average smaller by a factor of 10 than those obtained on directed eutectic solidification with comparable rates of movement. The interlamellar spacings are of the order of 0.1 to 1 μm. Further, the relation between lamellar spacing λ and rate of movement R is not the same as for eutectics; for the eutectoids Co_3Si and β-Ni-In we found experimentally: $\lambda^4 R$ = a constant. This relation was explained in detail.

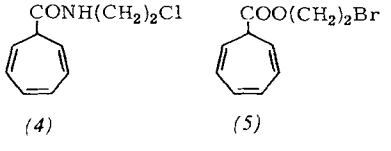
Properties and Reactions of Stable 7-Cycloheptatrienyl Carbonium Ions



By *Jörg Daub* (Lecturer) and *Werner Betz*[*]

Cations that are stabilized by heteroatoms make it possible to study in greater detail the course of the known rearrangement of intermediate 7-cycloheptatrienyl carbonium ions *(1)* into styrene derivatives *(3)*.

(1) *(2)* *(3)*

(a), R-R' = -NH-$(CH_2)_2$-O-
(b), R-R' = -O-$(CH_2)_2$-O-

(4) *(5)*

Reaction of *(4)* with silver tetrafluoroborate yields *(1a)* for which existence of a dynamic equilibrium between cycloheptatriene and norcaradiene structures has been established by ^{1}H-NMR spectroscopy (temperature-dependence of chemical shifts). Above 100 °C, *(1a)* isomerizes with ring contraction to the benzene derivative. From *(5)* and $AgBr_4$ the benzene derivative is formed directly at room temperature.

These results agree with theoretical considerations: as a stronger electron-acceptor, the positive charge in *(1b)*, gives better stabilization of the norcaradiene structure, thus weakening the bonds between C-7 and C-1, and C-7 and C-6.

Cyclization of Cyanoethylated Aliphatic Ketones

By *Martin Cherubim* (Lecturer) and *Faisal Abo Dagga*[*]

Ketones containing CH groups in α-position to the carbonyl group can be cyanoethylated in presence of suitable catalysts, yielding mono- or poly-substituted ketone derivatives. 3-Pentanone affords mainly a monocyanoethylated and two dicyanoethylated ketone derivatives, these two being position isomers. Under suitable conditions, one of the position isomers, namely 2,2-bis(2-cyanoethyl)-3-pentanone, is cyclized to 3-amino-6-(2-cyanoethyl)-2,6-dimethyl-2-cyclohexenone. Similar cyclizations were effected also with other cyanoethylated ketones that had free CH_2 or CH_3 groups near the carbonyl group, *e.g.*, with 2-(2-cyanoethyl)-3-pentanone, 3,3-bis(2-cyanoethyl)-2-butanone, and 1,1,1-tris(2-cyanoethyl)-2-propanone. Further, a bicyclic compound was obtained from 3,3-bis(2-cyanoethyl)-2-butanone.

A tautomeric equilibrium exists between the isomers with ketimine and enamine structure. Cyclization of monocyanoethylated ketones and hydrolysis of the enamines affords dihydroresorcinol or derivatives thereof.

3-(4-Hydroxy-1,3-dimethyl-2-oxo-3-cyclohexenyl)propionic acid is obtained by hydrolysis of 3-amino-6-(2-cyanoethyl)-2,6-dimethyl-2-cyclohexenone or analogously by alkali treatment of 2,2-bis(2-cyanoethyl)-3-pentanone. Other cyanoethylated ketones and their cyclization products react similarly.

Determination of the Molecular Weight Distribution in Nylon 6 by Solution Fractionation

By *Hans Craubner*[*]

The use of a new solution fractionation apparatus for the determination of the molecular weight distribution in nylon 6 was described.

The poly-ε-caprolactam was fractionated by extraction with solvents of increasing solvent strengths, including concentrated formic acid, between 20 and 90 °C. The molecular weight distribution was determined from the weight fractions and the viscometric molecular weights. The number average and the weight average molecular weights of the sample as a whole are $\bar{M}_n = 14800$ and $\bar{M}_w = 24600$. The nonuniformity is $U = (\bar{M}_w/\bar{M}_n) - 1 = 0.66$.

The statistical analysis shows a three-component mixed distribution. This is explained by the preparation of the polymer (polymerization, granulation, extraction with hot water, drying). The linear nylon 6 with an extremely narrow distribution accounts for more than 98 wt. %. It is preceded by a small oligomer fraction (<1%). The tail of the distribution is formed by a small high molecular weight component consisting of weakly crosslinked material

[*] Dr. H. Craubner
Max-Planck-Institut für Züchtungsforschung
5 Köln 30 (Germany)

(<1%). The mean properties calculated from the distribution, such as, for example, the intrinsic viscosity ($[\eta] = 104\ cm^3/g$), agree quantitatively with the measurements on the starting material.

The narrow nylon 6 distribution found by solution fractionation is confirmed by fast turbidimetric titration according to dynamic volume pulse techniques.

Charge Distribution in the Chain 132 from the Fission of Uranium-235 and Uranium-233 by Thermal Neutrons

By *H. O. Denschlag* (Lecturer), *R. Naeumann*, and *H. Folger*[*]

The fractional independent and cumulative fission yields of the three principal chain members of mass 132—tin, antimony, and tellurium—obtained from the fission of U-235 and U-233 by thermal neutrons have been measured. For this purpose the elements concerned were rapidly separated from one another as hydrides. The following yields (in percentages) were found for the fission of U-235 [U-233]:

Sn-132: 13.7 ± 0.8 [2.5 ± 0.5] (cumulative),
Sb-132: 48.7 ± 1.0 [27.1 ± 3.0] (independent), and
Te-132: 37.6 ± 1.5 [64.4 ± 4.0] (independent)

These afford the following Z_p values for the two fission reactions:

$$51.28\ ^{+\ 0.10}_{-\ 0.30}\left[51.75\ ^{+\ 0.10}_{-\ 0.15}\right]$$

The deviation of the most probable nuclear charge in the chain 132 from the value calculated with the assumption that the charge density is unchanged from that of the compound nucleus follows with $\Delta Z = -0.37^{+0.10}_{-0.30}$ for the fission of U-235 and $\Delta Z = -0.34^{+0.10}_{-0.15}$ for the fission of U-233. No local effect of the closed shells of 50 protons and 82 neutrons in $^{132}_{50}Sn^{82}$ on the charge distribution was observed.

Gel Adsorption Chromatography

By *Helmut Determann* (Lecturer) and *Klaus Lampert*[*]

The retardation of dissolved (mostly low-molecular) substances by interaction with a gel matrix was originally regarded as a source of interference in normal gel-chromatographic separation. Meanwhile it has been shown in various schools that very effective separations can be achieved by using selective retardation, outside the gel filtration scheme. The effects may be caused by van der Waals forces, hydrogen bonding, and hydrophobic interaction, whose influences naturally overlap. Nevertheless the contributions of, in particular, hydrogen bonding and hydrophobic interaction can largely be studied separately by variation of the test substances, gel materials, solvent, and temperature. It is now possible, given a knowledge of the rules of gel adsorption chromatography, to define conditions that will afford optimal separation in actual cases.

Solvolysis of Polyepoxides of Unbranched Polybutadienes

By *Walter Dittmann* (Lecturer) and *Karl Hamann*[*]

An anomaly is found in the mode of reaction of linear polybutadiene epoxides with ring-cleaving agents such as water, methanol, or hydrogen chloride. By the application of statistical methods to the experimental findings, it has been shown that sequences of epoxide groups in a 1,5 position with respect to one another react by addition of the solvolytic agent across the "ends", with intramolecular ether formation within the sequences. This anomalous reaction explains why the epoxide values found by chemical methods are too low. It agrees with the conformation proposed for unbranched polybutadienes on the basis of the UV spectrum, and rules out the indirect formation of head-to-head polymers, *e.g.* head-to-head polyvinyl alcohol, by hydrolysis of polybutadiene epoxides.

Investigation of the Furnace Black Process in a Model Reactor

By *Gerhard Kühner* and *Gunther Dittrich* (Lecturer)[*]

Experiments with a pilot-scale furnace carbon black plant are described that enable the observed relations between yield of carbon black and throughputs of raw materials (benzene; illuminating gas as heating gas; air) to be interpreted quantitatively. For this purpose the furnace black reaction

$$a C_6H_6 + b O_2 + 4b N_2 \rightarrow 4b N_2 + c C_{black} + d CO + e CO_2 + f H_2O + g H_2$$

is broken down into cleavage and various possible combustion reactions, *e.g.*:

$$C_6H_6 + 0.0\ O_2 \rightarrow 6\ C + 3\ H_2;$$
$$\cdots$$
$$C_6H_6 + 1.5\ O_2 \rightarrow 6\ C + 3\ H_2O;$$
$$\cdots$$
$$C_6H_6 + 6\ O_2 \rightleftharpoons 6\ CO_2 + 3\ H_2;$$
$$\cdots$$

[*] Dr. G. Kühner and Dr. G. Dittrich
Degussa, Forschung Chemie
6450 Hanau, Postfach 602 (Germany)

By linear combination of the equations the yield of carbon black is obtained as

$$A = 100 - \frac{V \times 100}{6} \times \frac{S}{B}(\%)$$

S and B are the amounts of oxygen and benzene, respectively, in mol, and V is a factor that depends on S and the positions of the Boudouard and water-gas equilibria.

A similar equation is obtained for the presence of heating gas. Further, relations are derived between the exit gas composition and the yield of black and between the mean reactor temperature and the molar ratio benzene/air.

Preparation of Multicomponent Oxide Glasses by Polycondensation

By *Helmut Dislich*[*]

Alcoholates of different metals react with one another to give alkoxo complexes that can be converted into homogeneous multicomponent oxides by hydrolysis and polycondensation reactions involving loss of alcohol and water. Multicomponent oxide glasses can thus be obtained without passage through a molten phase.

Thus glass—the "oldest thermoplast"—is accessible by a route that is customary in macromolecular chemistry and in particular in organosilicon chemistry. The method is suitable especially for preparation of thin layers on substrates to withstand a temperature around 500 °C. Several of these layers delay the flaking of iron and the tarnishing and corrosion of brass and protect sensitive glasses from climatic effects.

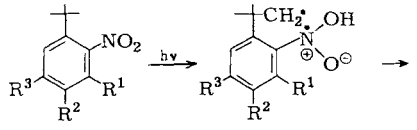
The Influence of Apparative Gas-Chromatographic Parameters on the Detector Response of Thermocouple Detectors

By *H. W. Dürbeck*[*]

To obtain reproducible results with standard deviations of about 1% in quantitative gas-chromatographic analysis with thermocouple detectors it is necessary to have a fundamental knowledge of the influencing effects caused by systematic or occasional changes of apparative parameters, *i.e.* bridge current, type of carrier gas and its rate of flow, oven temperature and block temperature of the thermocouple detector.

The following are the principal results of investigations carried out in a systematic study.

1. The stability of bridge current and carrier gas velocity is of fundamental importance.
2. Changes in block temperature of the thermocouple detector are less important but depend on the nature of sample or carrier gas as regards the mathematical sign.
3. The oven temperature of the gas chromatograph usually has no effect.
4. The nature of the carrier gas mainly influences the sensitivity and dynamic behavior of the thermocouple detector.



Quantitative correlations were given.

Bicyclohexenols as Benzvalene Derivatives, and Their Photochemical Reactions

By *Heinz Dürr* (Lecturer), *Peter Heitkämper*, and *Peter Herbst*[*]

On irradiation by Hg high-pressure lamps, tetrasubstituted *exo*- and *endo*-bicyclo[3.1.0]hex-3-enols *(1)* undergo a stereospecific reaction that gives good yields of tetrasubstituted cyclopentenes *(3)* together with phenanthrene *(4)* and benzene derivatives *(5)* as by-products. Thermolysis of *(1)* affords β,γ-unsaturated cyclopentenecarbaldehydes *(2)*, which also fragment to *(3)*. Further, *(2)* can be shown to be intermediate in the photolysis of *(1)*. The intramolecular course of the photoreaction was demonstrated by isotopic labeling (deuterium). The multiplicity of individual steps was clarified by sensitization studies, and the quantum yields were determined by use of radioactive isotopes (tritium). The reaction mechanism of the photoreactions thus determined was discussed.

Determination of the Distribution of Radii of Polymer Dispersions on Macroporous Silica Gels

By *Winfried Wunderlich*, *Karl-Friedrich Krebs*, and *Friedhelm Eisenbeiss* (Lecturer)[*]

The carriers required for gel-chromatographic separation of particles such as dispersed polymers, cell constituents, viruses, and the like must have extremely large pores corresponding to the size of the particles to be separated and they must be mechanically stable. We have prepared such materials, on the basis of silica gels, with pore diameters up to 25000 Å and with a narrow distribution of pore size[1].

Several polymer dispersions whose mean particle radius was determined by electron microscopy and light scattering measurements to be between 150 and 2500 Å were placed on such silica gels, and the elution volumes of the bands were measured.

Plotting the mean particle radii against the corresponding elution volumes gave relations such as can be found in gel permeation chromatography of polymers (log M against V_e). In this way the mean radii and particle size distribution of "unknown" dispersions can be determined from gel-chromatographic data for the system. The experiments were carried out in the apparatus customarily used for gel chromatography.

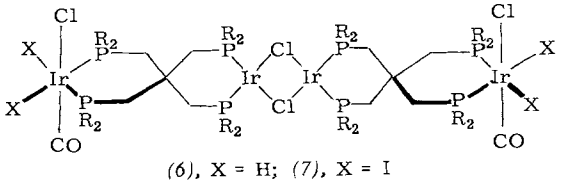
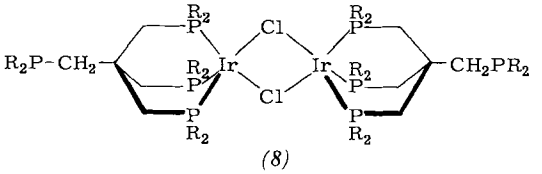
Carbonylhalogenohydrido-, Carbonylhalogeno-, and Halogeno-iridium Complexes Involving a Tetradentate Phosphane

By *Jochen Ellermann* (Lecturer), *Rainer Gerbeth*[*], and *Kurt Geibel*[**]



The square planar *trans*-iridium(I) complex $[Ir\langle(CO)Cl\rangle\langle(PR_3)_2\rangle]$ $(R = C_6H_5)$ *(1)* is formed in the system $PR_3/IrCl_3(H_2O)_3$ *(2)* in presence of $CH_3O(CH_2)_2O(CH_2)_2OH$ *(3)* as solvent and carbonylating and reducing agent[1]. It is of interest as a model for biochemical O_2 fixation. This fixation is irreversible if the Cl is replaced by I. It is not yet known whether iridium(I) complexes analogous to *(1)* but with *cis*-organophosphorus groups exist and whether they also fix oxygen.

[*] Priv.-Doz. Dr. J. Ellermann and R. Gerbeth
Institut für Anorganische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Fahrstrasse 17 (Germany)
[**] Priv.-Doz. Dr. K. Geibel
Institut für Organische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Henkestr. 42 (Germany)



If *(2)* (2 mol) is treated with $C(CH_2PR_2)_4$ ($R=C_6H_5$) *(4)* (1 mol), which because of its geminal system can react as a bidentate ligand only with *cis*-coordination, the expected spirocyclic complex *(5)* is not obtained but instead the hydrido complex *(6)* [^{1}H-NMR: $\tau=20.1$ ppm, $^2J_{trans H,P}=$ 100 Hz (doublet), proof by spin decoupling of ^{31}P; IR: ν(CO) and ν(IrH) = 2055, 1973 sh, 1965, δ(IrH) = 795, 781 cm^{-1}]. With CH_3I, *(6)* forms the iodo complex *(7)* [IR: ν(CO) = 2055 cm^{-1}] with elimination of CH_4.

(5)

(6), X = H; *(7)*, X = I

(8)

When a 1:1 molar ratio is used under the same conditions, *(2)* and *(4)* yield *(8)*, which is methylated by CH_3I on both terminal PR_2 groups.

These experiments show that the reactions undergone by iridium are completely changed by two *cis*-coordinated phosphane groups. O_2-fixing iridium complexes with such coordination are thus not immediately accessible.

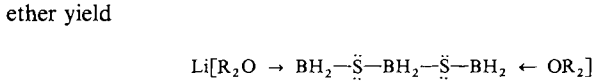
Cleavage of Diborane(6) by Alkali Metal Sulfides and Polysulfides



By *Hans-Herbert Friese* and *Udo Engelhardt* (Lecturer)[*]

Diborane(6) and sodium sulfide in tetrahydrofuran at room temperature react with unsymmetrical cleavage to sodium tetrahydridoborate and a compound of composition $Na[B_4H_9S_2\cdot 2R_2O]$, whose method of formation, molecular weight, ^{11}B-NMR spectrum, and IR data indicate a tautomeric structure in solution:

Use of an anhydrous sulfide of higher sulfur content, *e.g.*, potassium tetrasulfide, leads to evolution of hydrogen and formation of the above products together with glassy polymers or oligomers of composition $[S(BH_2)_2\cdot xR_2O]_n$. Elemental sulfur does not react with diborane(6) even under more drastic conditions, but octasulfur and lithium tetrahydridoborate afford, besides lithium sulfide, salts of varying composition which with diborane(6) in diethyl ether yield

as main product.

Kinetics and Mechanism of the Degradation of Vinyl Polymers in the Solid State

By *D. H. Everett*[*]

This paper is concerned with a study of the kinetics and mechanism of thermal decomposition of polyvinylidene chloride and its co-polymer (Saran) with polyvinyl chloride in the solid state. The work reported is aimed at elucidating the mechanism by which hydrogen chloride is formed, and the changes which take place in the internal structure of the polymers during degradation. It is found that the rate of decomposition, besides being dependent on temperature, is markedly influenced by pre-irradiation with UV or γ-rays and by the chemical nature of the gas phase in which it is in contact. The kinetics are also influenced by morphological factors. Possible mechanisms for the decomposition process are discussed and related to the observed kinetics. The physical properties of the carbon which results from the decomposition are strongly dependent on the conditions under which the degradation occurs, and an attempt is made to correlate various factors which influence the carbon structure.

Migration of Additives from Plastic Films into Edible Fats and Fat Simulants

By *Karl Figge*[*]

In order to assess the toxicological harmlessness of plastic packagings used for storing edible fats, the migration of ^{14}C-labeled additives from packaging films into fats or fat simulants was investigated. The additives used were di-*n*-hexyl [1-^{14}C]di-*n*-octyltin bis(2-ethylthioglycolate), [^{14}C]-1,3,5-tris(3,5-di-*tert*-butyl-4-hydroxybenzyl)-2,4,6-trimethyl benzene (Ionox-330-^{14}C), [1-^{14}C]stearamide or [1-^{14}C]-*n*-butyl stearate.

The films used were of rigid polyvinyl chloride (PVC), polystyrene (PS), high-density polyethylene (HD-PE), and low-density polyethylene (LD-PE).

Results to date: The passage of an additive from a plastic film into various edible fats such as 'Biskin' (a partially hardened ground-nut oil product), margarine, butter, sunflower oil, and olive oil is similar, but passage from different types of plastic films into an edible fat varies widely.

[*] Dr. K. Figge
Unilever Forschungsgesellschaft mbH
2000 Hamburg 50, Behringstrasse 154 (Germany)

The substances shown in Table 1 are suitable as fat simulants.

Table 1. Fat simulants.

Type of plastics	Under conditions of migration (20 °C/60 d)	extraction (65 °C/5 h)
HD- and LD-PE	MCT [a]	—
PS	MCT, paraffin oil, methanol	coconut fat
PVC	tricaprin, HCFA-T [b]	paraffin oil, *n*-heptane

[a] Mixture of medium-chain triglycerides.
[b] Mixture of hydrogenated, cyclic fatty acid triglycerides.

The PVC simulants listed in Table 1, under extraction, give values which are too high for both types of polyethylene. The same is valid for *n*-heptane in the case of PS and for diethyl ether in the case of all four plastics respectively. The amounts of ^{14}C-labeled additive that migrated into triglycerides, and the increase in weight of the films tested, pass through a maximum when plotted against the length of the acyl group; this maximum being particularly steep for PVC and PS.

On the basis of these results a fat simulant has been prepared that contains triglycerides with acyl groups of various lengths. This mixture is suitable as standard fat for all types of plastics, as is shown, *e.g.*, by the comparative migration values of two additives from PS into edible fat and into the fat simulant (Table 2).

Table 2. Comparison of the migration of additives from PS into edible fats and the fat simulant.

Additive	Amount (%) of migrated additive 'Biskin'	butter	coconut fat	fat simulant
Ionox-330-^{14}C	2.1	3.1	2.5	3.1
[1-^{14}C]-Stearamide	5.2	7.1	5.6	7.6

Carbonylrhodium-Tertiary Amine Complexes as Catalysts for the Hydroformylation Reaction

By *Bernhard Fell* (lecturer), *Antoin Geurts*, and *Edwin Müller*[*]

In studies on the Reppe alcohol synthesis from olefins, carbon monoxide, and water with catalysis by carbonyliron-tertiary amine complexes, it was found that this reaction can be extremely favorably influenced by very small quantities of cocatalytically active rhodium compounds. The successful application of the synthesis to olefins having higher molecular weights becomes possible only with this rhodium-modified catalyst system. The results with the Reppe alcohol synthesis led to further systematic experiments with carbonylrhodium-tertiary amine complex catalysts in the hydroformylation and other reactions of olefins. Thus with hydridocarbonyltris(tribenzylamine)-rhodium(I) as the catalyst, just as with the corresponding carbonylrhodium-tertiary phosphane complexes described by *Wilkinson et al.*, the hydroformylation of an olefin can be achieved at a water gas pressure of 1 atm and at normal temperature. With other carbonylrhodium-tertiary amine complexes, a direct one-step oxoalcohol synthesis is possible even at 70—80 °C. After exposure to hydrogen gas for one hour and addition of 5 wt.-% tribenzylamine *N*-oxide a solution of the hydridocarbonyltris(tribenzylamine)rhodium(I) in benzene becomes an active catalyst for the selective isomerization of 1-olefins to the 2-isomers.

Reactions of Trichloromethyl Isocyanide Dichloride

By *Kurt Findeisen*[*]

Trichloromethyl isocyanide dichloride is synthesized by chlorination of dimethylcarbamoyl chloride. Reactions in which a hydroxyl group or a carbonyl or anhydride oxygen atom is replaced by halogen can often be effected better with trichloromethyl isocyanide dichloride than with thionyl chloride, phosphorus pentachloride, *etc.* The compound can often find use in place of the usual dehydrating reagents.

Trichloromethyl isocyanide dichloride is an interesting component for synthesis of heterocycles: the structural unit Cl—C—N=C—Cl remains intact in formation of *s*-triazines, 1,2,4-triazoles, 2,4,6-trichloropyrimidines, 2,4-dichloroquinazolines, and 1,2,4-oxadiazoles.

The Existence of 3-Bromo-L-tyrosine in Blood Serum

By *Günter Firnau* (Lecturer) and *Klaus Fritze*[*]

The binding of bromine to the serum proteins of blood[1–3] was investigated. By a tracer study, using ^{82}Br, it is demonstrated that bromine is bound to serum proteins *in vivo*. $K^{82}Br$ of high specific activity (7.5 mg, 40 mCi) was injected into rabbits and serum removed one day later. Approximately 0.5% of the total ^{82}Br in the serum was found to be protein-bound at this stage. The application of various separation methods (electrophoresis, bromide exchange, denaturation followed by desalting on a gel column) showed that one-third of the protein-bound bromine is loosely attached whereas two-thirds are firmly bound.

To elucidate the nature of this firmly bound bromine the serum proteins were completely hydrolyzed[4] and the amino acids were separated on a Dowex-50-X8 column[5]. The radioactivity eluted from the column was associated with 3-bromo-L-tyrosine. No bromine could be detected in thyroxine.

Neutron Spectra in the Decay of Some Fission Products

By *H. Franz* (Lecturer), *J.-V. Kratz*, and *Günter Herrmann*[*]

The spectra of delayed neutrons in the thermal neutron induced fission of ^{235}U were measured with a ^{3}He-spectrometer up to energies of 1.5 MeV. In the spectra of the unseparated fission products a number of neutron peaks could be observed. Some of these peaks can be directly assigned to 55-s ^{87}Br because of their half-life. The other peaks are attributed to 24-s ^{137}I and/or 16-s ^{88}Br.

By a rapid chemical separation, arsenic was isolated from the fission products as a volatile hydride. The neutron spectrum of the delayed-neutron precursor 2.05-s ^{85}As was measured. Four prominent neutron peaks could be observed besides some weaker lines. In addition, γ-spectra of the arsenic isotopes were measured with a Ge(Li)-diode. A 2-s component in the decay-curves of the 1455.1 keV and 667.1 keV γ-lines of the 5.4-s ^{84}As proves that excited levels of ^{84}Se are fed by the delayed neutron emission of ^{85}As.

Mössbauer Effect Measurements on Neptunium Compounds

By *Klaus Fröhlich* (Lecturer), *Philipp Gütlich*, and *Cornelius Keller*[*]

By means of the Mössbauer effect it has been proved that neptunium has the oxidation state +7 in the following compounds: Li_5NpO_6, $[Co(en)_3]NpO_5 \cdot xH_2O$, $Ba_3(NpO_5)_2 \cdot xH_2O$, and $Ca_3(NpO_5)_2 \cdot xH_2O$.

Radiolysis effects were studied for Li_5NpO_6, but no decomposition was oberved after storage of the compound for several months. Mössbauer measurements indicate conclusively that Li_5NpO_6 does not have O_h symmetry, but that the $[NpO_6]^{5-}$ ion is compressed, presumably in the z-direction (neptunyl group) and rhombically distorted in the xy plane.

The neptunium-containing anion of the other compounds studied presumably contains a tetragonal-bipyramidal configuration with the neptunyl group oriented in the z-direction and two oxygen atoms as well as two OH-groups, both in *trans* position, in the xy plane. The neptunyl group is more pronounced than in Li_5NpO_6.

Kinetics and Mechanism of the Specific Binding of Ions by Cyclodepsipeptide Antibiotics

By *Theodor Funck*, *Frieder Eggers*, and *Ernst Grell* (Lecturer)[*]

Studies on specific complex formation of alkali-metal ions with cyclodepsipeptides such as valinomycin and enniatin B in homogeneous solution are important for the understanding of selective transport of cations through membranes mediated by these antibiotics.

Thermodynamic data were determined for the cation complexes in methanol. The remarkable differences in the stabilities of the various cation complexes can be correlated with the ligand conformation in the complexes as characterized by spectroscopic techniques. Kinetic studies by relaxation methods led to the elucidation of the reaction mechanism. Complexation of cations is due to a multistep reaction, the rate of complexation being remarkably slow and corresponding to the rate of the slowest conformational change of the uncomplexed antibiotic. Differences in the rates of complex formation of the antibiotics with different cations are significant for the mechanism of ion selectivity.

Preparation and Spectroscopic and Magnetic Investigations of Inorganic Complex Azides

By *Harald P. Fritzer* (Lecturer), *Karl Torkar*, and *Fritz Lunzer*[*]

Complex azides have been prepared in crystalline form from potassium azide, cesium azide, and transition-metal hydroxides or carbonates of zinc, nickel, and cobalt. Analytical investigations yielded the formulas $K_2Zn(N_3)_4$, $Cs_2Zn(N_3)_4$, $K_4Ni(N_3)_6$, and $KCo(N_3)_3$. The Co compound is highly explosive and must be handled with extreme care! The compounds deflagrate strongly in a flame and some are sensitive to shock.

Both electronic diffuse reflection spectra and the magnetic susceptibilities[1] were analyzed by the model of the extended crystal field theory. The aims of these investigations which will be extended also to other complex azides are the determination of the microsymmetry of the transition-metal ion in each azide lattice, determination of optical and magnetic parameters, and, with the aid of some intrinsic properties of the N_3^- ion, characterization of covalent contributions to the metal-ion/azide bond[2].

Conformational Analysis and Kinetics of the Conformational Rearrangements of Cyclodepsipeptide Antibiotics

By *Ernst Grell*, *Frieder Eggers*, and *Theodor Funck* (Lecturer)[*]

Conformational transitions of membrane-active antibiotics such as valinomycin and enniatin B have been studied as a function of solvent polarity by ultrasonic absorption measurements. The results provide information about the number of occupied conformational states as well as the rates of interconversion between conformers.

Even in solvents of low polarity at least three conformational states have to be considered for both depsipeptides. The interpretation of the results is confirmed by spectroscopic

[*] E. Grell, F. Eggers, and Th. Funck
Max-Planck-Institut für biophysikalische Chemie
34 Göttingen-Nikolausberg (Germany)

studies. For valinomycin and enniatin B the kinetic measurements show, in addition to relatively rapid processes in the frequency range of 10—100 MHz, slower conformational transitions which are closely related to conformational rearrangements of these ligands during complex formation with cations. The observed conformational changes of valinomycin are due to a stepwise opening of a structure that is stabilized by intramolecular hydrogen bonds whereas the conformational changes of enniatin B are induced by specific solvent effects.

Analysis of Mixtures of Metallic Nickel and Oxide Hydrates of Bivalent and Higher-Valency Nickel

By *Werner Gann*[*]

The quantitative determination of metallic nickel and the effective valency of the nickel present as hydroxides or oxide hydrates in various valency stages in samples moistened with alkali obtained from positive electrodes of alkaline accumulators presents difficulties, since higher-valency Ni compounds decompose spontaneously, and the system does not consist of phases thermodynamically coexistent.

Taking these facts into account, it is possible to find the effective valency to within ± 0.02 valency units and also to determine the metallic component in samples of 50 to 200 mg by the following scheme:

Reduction of the sample, which has been dried with Na_2CO_3 and ground in a mortar, with a large excess of arsenate(III) solution, filtration and reaction of As(V) (formed in an equivalent quantity) with KI setting free elementary, photometrically determinable iodine, extraction of the Ni compounds present in the residue with dilute H_2SO_4, dissolution of the remaining metallic Ni in $H_2SO_4+H_2O_2$, and photometric determination of the Ni solutions as EDTA complex. The results agreed well with those obtained electrochemically.

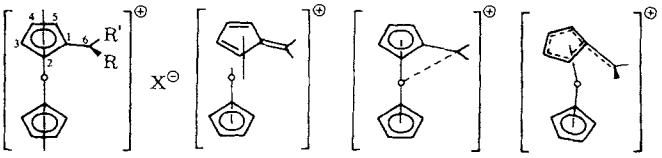
Study of the Sorption Behavior of Fruit Powders with a New Type of Automatic Apparatus

By *Heinrich Drexler* and *Karlheinz Gierschner* (Lecturer)[*]

Determination of their sorption isotherms is important for evaluation of fruit powders and other dry foods. Most methods of determining sorption isotherms require a long time, which may result in spoiling of the samples and thus uselessness of the result. Often only a few points of the sorption isotherms can be measured, so that the exact course of the curve cannot be decided.



In work with fruit powder a method has been developed for automatic determination of the sorption isotherms. By a special arrangement the vapor pressure (the relative humidity) in the sorption space is altered as soon as the weight of the sample has remained constant for a definite time. With this apparatus as many points as desired on the sorption isotherm can be determined over a large temperature range within 2—3 days.

Experiments on the Halogenation of 1,3-Dibromo-1,3-dimethylcyclobutane

By *Karl Griesbaum* (Lecturer), *Mahmud El Borai*, and *Yingli Chu*[*]

The title compound is readily obtained from allene and/or methylacetylene and HBr, and the objective of these experiments was its selective chlorination to afford 1,3-dibromo-2,4-dichloro-1,3-dimethylcyclobutane. Treatment with chlorine or *tert*-butyl hypochlorite gave, however, monochlorides (1,2-dibromo-3-chloro-1,3-dimethylcyclobutanes) in which the entering chlorine substituent replaced one of the bromine atoms already present in the starting material while the bromine atom appeared at one of the previously unsubstituted methylene groups. The migration of the bromine substituent was accompanied by substantial inversion at the tertiary C atom at which the chlorine-bromine exchange occurred.

The structures of the resulting stereoisomeric monochlorides—in particular the position of the chlorine substituents in the molecule—were established in independent syntheses by addition of bromine to 1-chloro-1,3-dimethylcyclobutene. The stereochemical result of this chlorination is indicative of a concerted reaction course, possibly *via* bridged radical intermediates.

Bromination of the title compound also proceeded with partial, but distinctly less, inversion at one of the tertiary C atoms and yielded two isomeric 1,2,3-tribromo-1,3-dimethylcyclobutanes.

Influence of Microorganisms on the Oxidative Deterioration of Fats

By *Werner Grosch* (Lecturer), *Friedrich Senser*, and *Klaus Fischer*[*]

36 Psychrophilic strains of microorganism that metabolize linoleic acid were isolated from fresh herrings. A preliminary experiment (growth on sunflower oil emulsion) showed that: None of these strains had prooxidative action, but a number of them delayed the autoxidation. Eleven of the latter were cultivated on linoleic acid hydroperoxides (LOOH). Two (F 25 and 29) degraded the hydroperoxy group rapidly and the diene system slowly; the other eight (including F 75) reacted only slowly with LOOH. F 29 can consume LOOH, primarily reducing the 13- and 9-hydroperoxy acid to the hydroxy acid. F 75 (*Pseudomonas fluorescens* sp.), however, reduces the hydroperoxy group more slowly, giving the hydroxy acids which it then consumes; but unlike F 29 it does not multiply in the process.

Analytical Determination of Phase Equilibration Behavior of Multicomponent Systems in Distillation Columns

By *Helmut Günzler*[*]

Several graphical and algebraic methods of calculation have been described for determination of the number of theoretical plates n_t required for a given distillation operation. The McCabe-Thiele method, which is very simple to use for two-component mixtures, is most often employed, but all the graphical methods fail for mixtures of more than three components. With highly sophisticated programs for large electronic computers it is now possible to handle also very complex mixtures with a close approximation to reality.

All reliable methods of calculation require preknowledge of all the binary phase equilibrium relations of the components of the mixture. Approximate procedures require a knowledge of at least the vapor pressure curves.

In practice it is often the case that not all the equilibrium relations are known or even that the identity of individual materials is uncertain, and this is often the cause for deviation of the calculated from the experimental distillation behavior of a mixture. A test procedure that can be carried out with laboratory columns was described for practical determination of the number of plates required for a separation as well as for checking of the calculations. Continuously operating bubble plate columns made of glass are fitted with side arms for removal of samples so that the concentration profile in the column can be established by analysis for the steady state under various conditions. The predictive power and reliability of the procedure was demonstrated for a model example.

Theoretical Conditions for Conjugation Involving d Orbitals

By *Günter Häfelinger*[*]

HMO π-electron models are used to examine the stability of the ground state and the reactivity of cyclic π-conjugation systems with various ring sizes in which one or more p_π orbitals are replaced by atoms that contribute outer or inner d orbitals to the π system.

Taking into account the special symmetry behavior of the d orbitals, the extent of $(pd)_\pi$ overlap, and the inductive effect of the hetero atom, it is found that no unusual energy stabilization, comparable *e. g.* with that found in the systems of aromatic hydrocarbons, is to be expected, though cyclic delocalization with participation of the d orbitals is possible. Transition metal chelates with aliphatic 1,2-diimine ligands are considered as special examples.

Procedure for Stereospecific Hydrogen-Labeling of Prochiral Centers on a Preparative Scale

By *Helmut Günther* (Lecturer), *Miguel Alizade*, *Florian Biller*, *Max Kellner*, *Hans Jürgen La Roche*, and *Helmut Simon*[*]

Stereospecifically hydrogen-labeled compounds of the type $CH\overset{*}{H}ab$ are interesting for a whole series of reasons. Hitherto only a few such compounds have been obtained on a preparative scale. Chemical synthesis by stereospecific replacement of X in a chiral compound by $\overset{*}{H}$ requires sterically pure starting material, and the quality of the products depends on the stereospecificity of the reactions $CHXab \rightarrow\rightarrow CH\overset{*}{H}ab$. Stereochemically pure forms are

[*] Dr. H. Günther, M. Alizade, F. Biller, M. Kellner, H. J. La Roche, and Prof. Dr. H. Simon
Chemisches Institut Weihenstephan der Technischen Hochschule München
8050 Freising-Weihenstephan (Germany)

generally obtained by enzymatic reactions. According to our findings, microorganisms often catalyze hydrogen exchange in their metabolic prochiral end products. Such exchange reactions can also be effected by coupled enzyme reactions. In such work either CHHab is incubated in D_2O or H_2O/HTO, or CHHab is incubated in H_2O. In this way we obtained:

The (1*R*)- and (1*S*)-forms of [1-H]-ethanol, -propanol, and -butanol, as well as the (2*R*,3*R*)-forms of [2,3-H]-butyric, -valeric, -octanoic, -4-bromobutyric, -2-bromobutyric, and other acids.

Clostridium kluyveri ferments crotonate to acetate and butyrate. Preparative amounts of [2,3-^{2}H]-(2*R*,3*R*)butyrate can be prepared in D_2O. Similar results can be obtained with other α,β-unsaturated acids.

Synthesis and Chemistry of *N*-Chlorocarbonyl Isocyanate

By *Hermann Hagemann*[*]

ClCONCO (colorless liquid, b.p. = 64 °C) is obtained in a yield of 90% by partial hydrolysis of *N*-chlorocarbonyl isocyanide dichloride[1], the addition product of phosgene and cyanogen chloride.

This simple and very reactive iminodicarboxylic acid derivative can be used for the preparation of many compounds of this series. Both the acyl chloride group and the isocyanate group can undergo selective reactions. One outcome is a simple method for the preparation of isocyanates from alcohols, phenols, thiols, and thiophenols[2].

The combination of the two functional groups and their peculiar symmetry, which becomes clear *e.g.* in the HCl adduct, also enable *N*-chlorocarbonyl isocyanate to enter into cyclizations under particularly mild conditions.

Sigmatropic 1,3-Phenyl Shift in Photoexcited Phenyl Trityl Ketones

By *H.-G. Heine*[*]

On irradiation (Philips HPK 125 W, $\lambda > 300$ nm) in solution, phenyl trityl ketone *(1)* undergoes a novel photoisomerization, in which the enol phenyl ether *(2)* is formed by a phenyl shift. α-Cleavage occurs to a small extent. In the presence of triplet quenchers (*e.g.* piperylene), only the isomerization *(1)*→*(2)* is observed.

(1) *(2)*

[*] Dr. H.-G. Heine
Farbenfabriken Bayer AG,
Wissenschaftliches Hauptlaboratorium
415 Krefeld-Uerdingen (Germany)

It is shown by the use of substituted derivatives of *(1)* that the photoisomerization proceeds with retention of the arrangement of the substituents in the migrating phenyl residue as a 1,3-(C_{sp^3}→0) shift, and not as a double 1,2-phenyl shift, which is also conceivable. The photoisomerization is formulated as a synchronous process, in agreement with the selection rules for sigmatropic reactions.

Ion-Pair Formation—Sources of Error in the Determination of Equilibrium Constants in Aqueous Solution

By *Ludwig Heck*[*]

Spectrophotometric investigations and solubility determinations on hexamminecobalt(III) salts have shown that the perchlorate ion, like all monovalent anions, forms ion pairs even in dilute aqueous solution:

$$[Co(NH_3)_6]^{3+} + ClO_4^- \rightleftharpoons [Co(NH_3)_6]^{3+}\ x\ ClO_4^-$$

By fast precipitation of hexammineplatinum(IV) chloride, carbonate, or sulfate from 0.02 M hexammineplatinum(IV) perchlorate solutions, up to 40 mole % of perchlorate ion pairs are coprecipitated.

Addition of perchlorate in the determination of the equilibrium in the system hexamminecobalt(III) ion—chloride considerably influences the constant, even if the ionic strength is kept strictly constant. This provides a simple explanation for conflicting literature data.

If a cationic species has acid properties, as *e.g.* the hexammineplatinum(IV)-complex which is easily deprotonated to its conjugate base, amidopentammineplatinum(IV)-ion, the perchlorate ion tends to associate primarily with the higher charged acid ion. Lowering the equilibrium concentration of the hexammine complex by ion-pair formation results in a decrease of its acid strength.

A Contribution to the Investigation of Fossil Amino Acids and Peptides from Black Shales

By *Wolfgang Heller*[*]

The investigations were carried out on samples of the Upper Devonian black shales of Meschede, the Triassic bituminous shales of Monte San Giorgio (Ticino, Switzerland), and the Posidonomya shales (Lias epsilon) of Schwaben. The material was ground to a fineness suitable for analysis, and was then extracted under mild conditions. The resulting extracts were examined for free amino acids and peptides.

In the examination of a large number of samples both from Monte San Giorgio and from the Posidonomya shales of Schwaben for protein degradation products, it was found that the content of amino acids often varies very considerably in one and the same zone, even when the sampling points are only 50 cm apart. A considerable accumulation of amino acids always occurs in particular in the vicinity of

[*] Prof. Dr. W. Heller
Chirurgische Universitätsklinik, Laboratorium
74 Tübingen, Calwer Strasse 7 (Germany)

ammonite shells with retention of the living chambers or of saurian skeletons, especially those with skin retention. It can therefore be seen that these amino acids are degradation products of animal protein.

In the vicinity of ammonite shells with retention of the living chambers and of saurian skeletons, the amino acids are separated according to their R_f values. The clay minerals have acted here as a natural partition chromatography system during the breakdown of the proteins. The migration of the amino acids is also closely related to the content of organic matter in the sediment.

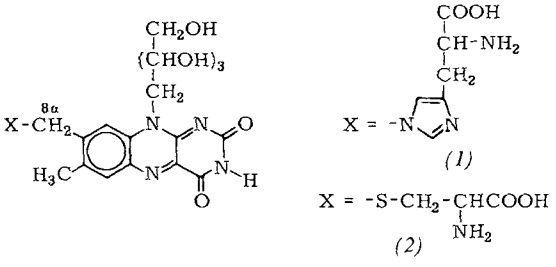
So far we have detected 14 free amino acids, three tripeptides having been found in the bituminous shales of Monte San Giorgio and in the Posidonomya shales. The results obtained so far indicate that the black shales of Meschede contain only free amino acids.

Electrochemistry of Corrosion and of Corrosion Prevention

By *Ewald Heitz*[*]

The corrosion of metals in liquid media is an electrochemical process in which the corroding metal is the anode and an oxidizing agent is reduced at cathodic sites. The individual steps of the reaction can be established by the methods of electrochemical kinetics and thermodynamics. As in any heterogeneous chemical reaction, the steps consist of transport processes and reactions at phase boundaries. The reactions at phase boundaries may be electrochemical transfer reactions. However, adsorption and chemisorption processes also can be rate determining as well as preceeding and subsequent homogeneous and heterogeneous reactions. For example, the reaction course is largely known for the systems iron/nonoxidizing acids, alloyed steel/sea water, and copper/oxidizing acids.

The electrochemical mechanism of corrosion provides the basis of a series of test methods which are based in principle on the evaluation of the current-voltage curve for the metal and the solution in question. Such methods give either the instantaneous corrosion rate or the potential susceptibility of passive metals to certain types of corrosion.



The electrolytic mechanism also provides the basis of a series of corrosion prevention methods. These include the methods of cathodic protection by the use of impressed current, active anodes, and cathodically active coatings. Mention should also be made of inhibitors, which reduce the reaction rate at both anodic and cathodic sites on the surface.

New Flavocoenzymes

By *Sandro Ghisla, Peter Hemmerich* (Lecturer), *E. B. Kearney, T. P. Singer*, and *W. H. Walker*[*]

It is known from earlier investigations that the flavocoenzymes of succinate dehydrogenase ("SD flavin")[1] and of monoamine oxidase ("MAO flavin")[2] are flavin-adenine dinucleotide derivatives attached to the protein by covalent bonds. These flavocoenzymes have been characterized by absorption, fluorescence, and ESR spectra that differ from those of the "normal" unsubstituted flavocoenzymes. It is found in this way that the protein is bonded to the heteroaromatic flavin ring in position 8α[3]. This has been demonstrated by synthesis of 8α-substituted lumiflavin models[4], which exhibit the same spectral behavior. In work carried out in collaboration with Dr. *T. P. Singer*'s research team, the structure of these flavocoenzymes was established and it was shown that the natural products and the synthetic compounds are identical. In the case of "SD flavin" *(1)*, the linkage is formed between position 8α and the imidazole ring of a histidine, while in "MAO flavin" *(2)*, a covalent bond is similarly formed with the sulfur of a cysteine.

(1)

(2)

The course of the synthesis *via* 8α-bromoflavins and the influence of the 8α substituent on the ESR, fluorescence, and absorption spectra were discussed. Other new flavocoenzymes whose structures are still unknown are being studied at present by teams working with Dr. *Decker* (Universität Freiburg) and Dr. *Massey* (University of Michigan).

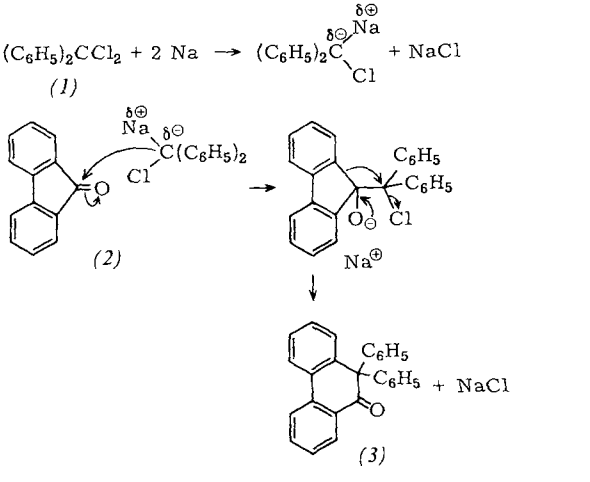
Reversible Photodehydrogenation of Diduroquinone to the Aroxyl Radical with Optically Excited Carbonyl Compounds such as Quinones, Ketones, and Xanthene Dyes

By *G. O. Schenck* and *H. Hermann* (Lecturer)[*]

The photodimer of duroquinone, the phenolic chroman *(1)*, serves as a model for the structurally related α-tocopherol [vitamin E *(2)*]. Both have characteristic inhibitor effects. On photodehydrogenation with the carbonyl compounds *(3)* duroquinone, 2,3-dimethylnaphthoquinone, 2-phenylnaphthoquinone, chloranil, benzophenone, rose bengale, and eosin, *(1)* forms the short lived aroxyl radical *(4)* and the monohydrocarbonyl compound *(3-H)*. Both radicals are reconverted by different routes into the starting materials to complete the chemical quenching cycles. The reverse reactions of *(4)* depend on the photodehydrogenating *(3)* used. The different kinetics of the back reactions of the various systems are explained by the involvement of

[*] Prof. Dr. G. O. Schenck and Dr. H. Hermann
Max-Planck-Institut für Kohlenforschung, Abt. Strahlenchemie
433 Mülheim-Ruhr, Stiftstrasse 34—36 (Germany)

H-bonded radicals and H-bonded radical pair complexes. In the photochemical reaction of *(1)* with benzophenone *(3a)* the radicals are synchronously regenerated in part



from the primary H-bonded radical pair complex, the dissociation of which is followed by further reverse reactions.—The results of flash-photolytic studies on duroquinone, 2,3-dimethylnaphthoquinone, 2-phenylnaphthoquinone and chloranil in benzene, ethanol and cyclohexane are described.

Rearrangement Induced by Nucleophilic Addition of an α-Haloorganometallic Compound

By *B. J. Herold* (Lecturer) and *J. J. R. P. Queiroga*[*]

When a solution of equimolar quantities of dichlorodiphenylmethane *(1)* and fluorenone *(2)* in diethyl ether is allowed to react with two equivalents of sodium, 10,10-diphenyl-9-phenanthrone *(3)* is formed[1]. To elucidate

the reaction, it is necessary to establish whether the metal reacts first with fluorenone (in which case the dianion would be formed) or whether it reacts first with *(1)* to form the α-haloorganometallic compound. It has been possible to rule out the first of these two possibilities. A reaction course has been proposed in which α-chlorobenzhydrylsodium adds as a nucleophile to fluorenone, and the addition product undergoes a rearrangement that may be regarded as an otherwise unknown base-catalyzed analog of the Tiffeneau rearrangement.

Spallogenic ^{53}Mn ($T \approx 2 \times 10^6$ a) and the Measurement of a Depth Effect in a Material Exposed to Cosmic Radiation

By *Wilfrid Herr* (Lecturer), *Ulrich Herpers*, and *Robert Wölfle*[*]

Accurate determinations of long-lived spallation nuclides, *e.g.* of ^{53}Mn ($T \approx 2 \times 10^6$ a), are currently of interest for the determination of "radiation ages" and the detection of possible variations of the cosmic flux. An extremely economical analytical method has been developed for the investigation of meteorites and lunar samples. Spallogenic ^{53}Mn, a K emitter, is difficult to count directly; however, the nucleus has a high neutron cross section. By long term exposure in a nuclear reactor for 42 days ($\Phi_{therm} = 8 \times 10^{12}$ n/cm^2·s), it is possible to convert the nuclide into ^{54}Mn, which can be easily detected because of its characteristic 0.84 MeV γ radiation. The influence of the interfering $^{54}Fe(n,p)^{54}Mn$ and $^{55}Mn(n,2n)^{54}Mn$ reactions has been investigated in detail. A practically "carrier-free" ^{52}Mn carrier prepared by the reaction $^{52}Cr(p,n)^{52}Mn$ was used to allow control of the chemical yield of manganese. In a rock from the Sea of Tranquillity a ^{53}Mn depth profile was found which can be attributed to the interaction and overlapping of "solar wind" and primary cosmic radiation.

Isotopic Effects of Calcium in Heterogeneous Exchange Equilibria

By *K. G. Heumann* (Lecturer) and *K. H. Lieser*[*]

Several heterogeneous exchange reactions have been examined for isotope fractionations.

The isotopic ratio of calcium was determined by means of a mass spectrometer with a thermal ion source.

In the systems $CaCO_{3(solid)} / Ca^{2+}_{(dissolved)}$ and GBHA-$Ca_{(solid)} / Ca^{2+}_{(dissolved)}$ (GBHA = glyoxal bis(2-hydroxyanil)), it was possible to show by multi-stage experiments that the elementary effect is less than 0.5 ‰ per mass unit. It follows that no isotope fractionation is to be expected in precipitations or crystallizations of calcium salts.

In the case of the exchange equilibrium between calcium on a cation exchanger and Ca^{2+} ions in solution, the elementary effect could be determined directly only when Dowex A1 was used. This led to 20.5 ‰ enrichment of ^{48}Ca in the solution. Enrichment of ^{48}Ca in the solution was also found with Dowex 50 by multiplication of the elementary effect. The isotopic effect was found to depend on the concentration of the hydrochloric acid used as the eluent.

The Elastic State of High Polymers

By *Martin Hoffmann*[*]

In a lecture surveying the highly elastic deformation of polymers, experimental findings were compared with the predictions of the existing theory of rubbery elasticity. The differences are large, but can be quantitatively traced to entanglement.

Twenty vulcanizates of a random butadiene-acrylonitrile-(18) copolymer with different degrees of crosslinking were swollen in several solvents. They were then stretched at different speeds or examined at various elongations for stress relaxation before removal of the load and for specimen length relaxation after removal of the load. The elastic elongation can be calculated from the length of the stretched specimen only 0.1 s after the start of loading (or on elongation at $d\lambda/dt = 1\ [s^{-1}]$) and the initial length. However, the same elongation law is obtained if the length of the specimen after prolonged loading is divided by the length found 0.1 s after the removal of the load: The entangled filament molecules form a network with exchangeable bonds.

This gives an elongation law that is completely free from arbitrariness. It can be approximately evaluated according to *Mooney* for the partial moduli $2C_1$ and $2C_2$. The former describes the effect of principal-valence crosslinks, and the latter the effect of entanglements. On swelling, $2C_2$ decreases with the square of the polymer concentration, and $2C_1$ only with the cube root. The sum of $2C_1$ and $2C_2$ is independent of $2C_1$ for unswollen, moderately strongly crosslinked specimens, since the entanglements are replaced by crosslinks. The elongation law for entangled chains is different from that for crosslinked chains. The number of effective entanglements depends not only on the time under load, but also (on geometric grounds) on the elongation. The causes are discussed and yield a quantitative formulation of the actual elongation process.

Finally, it is pointed out that to be of industrial interest, an elastomer must be easy to process and to vulcanize, as well as having good properties in the vulcanized state.

Reaction of Recoil Products with Free Radicals

By *Peter Hoffmann, Knut Bächmann* (Lecturer), *Helmut Klenk, Werner Bögl*, and *K. H. Lieser*[*]

We investigated the reaction of recoil products of Ra-224 with alkyl radicals formed by thermal decomposition of tetraalkyllead. The Ra-224 was deposited on a gold foil by evaporation of a 0.2 N HCl solution or by vapor deposition. The products of the free-radical reaction were transported through a distillation system to the measuring point and identified by γ spectrometry. The chemical yields were 65—90% for Pb-212, 95—100% for Bi-212, and 45—85% for Tl-208, based on the recoil yields, which were determined separately. It was possible to compare these experiments with inert gas experiments, in which hydrogen, nitrogen, helium, argon, acetone, diethyl ketone, and undecomposed tetraalkyllead compounds were led over the source and used for the transport of Rn-220.

Reaction of Allyl Alcohols with Acetoacetic Acid Derivatives (Carroll Reactions)

By *Werner Hoffmann*[*]

Carroll found that allyl alcohols react with acetoacetic esters at 160 to 200 °C with elimination of alcohol and carbon dioxide to form γ,δ-unsaturated ketones[1]. These reactions have become very important in terpene chemistry. They are used *e.g.* for the preparation of intermediates for industrial vitamin A and vitamin E syntheses.

The relation between constitution and reactivity of the starting materials is shown for this type of reaction by variation of the substituents in the alcohol and ester components and kinetic investigation of the reactions.

R = alkyl
R^1 = H or alkyl
R^2 = H, Cl, alkyl, COO-alkyl, or —CH=CH—CO-alkyl
R^3 = H, alkyl, or O-alkyl

The reactivity of the acetoacetic ester derivatives can be increased by introduction of electron-attracting substituents or by increased enolization of the hydrogen on the methine group. In the allyl alcohols, the reactivity decreases from the tertiary *via* the secondary to the β-substituted primary compounds. Some syntheses of terpenoid substances from the products of these reactions are illustrated.

The Decomposition of Organolead Halides $R_{4-n}PbX_n$ and Attempts to Prepare Organolead Halides that Occur as Intermediates

By *Friedo Huber* (Lecturer), *J. Gmehling, H.-J. Haupt*, and *H. Lindemann*[*]

$Alkyl_2PbX_2$ decomposes in aqueous solution in the presence or in the absence of foreign salts MX in accordance with the overall equation (1), which is the result of a primary disproportionation (2) and a subsequent decomposition (3) (alkyl = CH_3).

$$2\,(CH_3)_2PbX_2 \rightarrow (CH_3)_3PbX + PbX_2 + CH_3X \quad (1)$$
$$2\,(CH_3)_2PbX_2 \rightarrow CH_3PbX_3 + (CH_3)_3PbX \quad (2)$$
$$CH_3PbX_3 \rightarrow PbX_2 + CH_3X \quad (3)$$

(1) is first order, irrespective of the concentration of MX. The reaction rate increases considerably with increasing

[*] Prof. Dr. F. Huber, Dipl.-Chem. J. Gmehling, Dr. H.-J. Haupt, and Dipl.-Chem. H. Lindemann
Lehrstuhl für Anorganische Chemie der Universität
46 Dortmund, August-Schmidt-Strasse (Germany)

polarizability of the anion. (2) is the rate-determining step, and proceeds as a ligand-exchange reaction. Higher temperatures are required for the decomposition of $Alkyl_3PbX$. Attempts to prepare the unstable intermediates $RPbX_3$ ($X \neq$ carboxylate) led to the first preparation of complexes of phenyllead trihalides, *e.g.* $[pyH]_2[C_6H_5PbCl_5]$, $[(C_6H_5)_4As][C_6H_5PbCl_4]$, $[(C_6H_5)_4P][C_6H_5PbBr_4]$ and of $C_6H_5PbCl_3$ as ether adduct and as the py-adduct $C_6H_5PbCl_3 \cdot 2py$.

Synthetic Resins in Elastomer Adhesives

By *Kurt Hultzsch*[*]

Synthetic resins can fulfil important functions in elastomer adhesives. The physical and chemical interactions between resins and elastomers and their causes are discussed and presented as a synopsis. The resins act as a sort of solid solvent, and increase the tackiness of the elastomers. They may also increase the cohesion and hence the heat resistance of adhesives by a kind of reinforcing effect. In the case of polychloroprene, there is also a possibility of an irreversible increase in cohesion as a result of self-crosslinking of the elastomer with ZnO and MgO. It was shown by vulcametric experiments that added resin, as a diluent, inhibits this process on the one hand. On the other, "base-reactive" resins favor vulcanization after their reaction with the metal oxides, presumably because the basic reactants are now present in a homogeneously dissolved form. No resin vulcanization has been detected. The aging behavior of the adhesives may also be affected by resins.

Recent Developments in Chromatography: Column Liquid- and Supercritical Fluid Chromatography

By *J. K. F. Huber*[*]

In the past few years new forms of chromatography have been developed in which gases under high pressure or supercritical fluids have been employed as the mobile phase. A continuous transition between gas- and liquid-chromatography has thus been accomplished. The non-ideality of the carrier gas increases with increasing pressure; the partition coefficient becomes a function of the pressure and type of carrier gas. At the same time, the diffusion coefficient decreases. Beyond the critical point, large changes in the partition coefficient occur and its temperature dependence is reversed.

Results of a series of investigations have shown that the partition coefficient can be reduced by about two orders of magnitude by working with supercritical phases. Hence, low volatile compounds such as polycyclic aromatic hydrocarbons or dialkylphthalates can be analyzed by this technique.

The oldest chromatographic method, column liquid chromatography, is at present experiencing a second renaissance. This is due, on the one hand, to a more complete knowledge of the theory of the chromatographic process and, on the other hand, to the fact that the limitations of other chromatographic methods are becoming more clearly defined. Advances made on the theoretical side have made it possible to describe all forms of elution chromatography. The verification of theory for the case of column liquid chromatography demonstrates the influence of the various process variables. From the practical point of view it can be concluded that columns should be used which are packed with very fine-grain material and through which eluent flows relatively rapidly; thus, a high inlet pressure is required. Data for the optimization of separation referred to speed or dilution of sample can be derived theoretically and confirmed by experiment.

Most useful are methods by which the partition coefficients can be predicted. Promising results have been obtained for steroids in ternary liquid-liquid systems.

The performance of modernized column liquid chromatography is illustrated *e.g.* by the rapid separation of steroids, biocides, and non-ionic surfactants as well as by the residue analysis and trace determination of steroids in urine and blood plasma.

Chromium Dioxide Pigments. Dependence of Some Properties (Particularly Magnetic) on the Particle Size

By *Franz Hund*[*]

The economic development of magnetic recording with γ-Fe_2O_3 pigments is first discussed. γ-Fe_2O_3 and CrO_2 pigments are then compared with regard to suitability for use as magnetic recording substrates. The CrO_2 pigments can be prepared by thermal decomposition of pure chromyl chloride, pure chromium trioxide, or chromium trioxide in the presence of foreign or intrinsic modifiers that control the particle size. The coercive force and the signal-to-noise ratio depend on the particle size of the chromium dioxide pigments prepared by the hydrothermal two-step process[1]. When chromium dioxide is used as the catalyst in the air oxidation of SO_2 and HCl, the yield increases with decreasing particle size.

Rapid and Simple Enrichment of Trace Elements in High-Purity Zinc by Partial Dissolution of the Matrix in the Presence of Mercury

By *Ewald Jackwerth* (Lecturer) and *Eva Döring*[*]

During the dissolution of zinc in hydrochloric acid, a definite accumulation of traces of metallic impurities is observed on the surface of the residue. Though the phenomenon is of little value in this form, its effectiveness and reproducibility are decisively improved if the zinc is coated with a thin layer of mercury before dissolution. The trace elements Bi, Cu, Cd, Pb, Co, Ni, Sn, Tl, In, Ag, Au, and Pd that are present as impurities then remain almost quantitatively in the residue. The addition of 1—2% of mercury

[*] Priv.-Doz. Dr. E. Jackwerth and E. Döring
Institut für Spektrochemie und angewandte Spektroskopie
46 Dortmund, Bunsen-Kirchhoff-Strasse 11 (Germany)

based on the zinc is sufficient for the amalgamation, and has practically no effect on the rate of dissolution.

For analysis of the concentrated trace metals, mercury spheres that still contain about 50—100 mg of Zn are dissolved in nitric acid. The concentrated elements are determined photometrically and polarographically after separation of the mercury. The correctness of the analyses has been checked on spectrochemically analyzed material.

The Loose Connection between Electron Configuration and Chemical Behavior of the Transuranics

By *Christian Klixbüll Jørgensen*[*]

According to the "Aufbau Principle" of the Periodic System, the electrons successively fill n l-shells, each fully-occupied shell containing at most $(4l+2)$ electrons. Seen from a quantum-mechanical point of view[1] the angular functions are homogeneous polynomials of degree l in the Cartesian coordinates, and high l values (such as 3 for f electrons) go along with unusually large amounts of angular kinetic energy, much larger than the ionization energy in rare earths. The competition between different shells often depends on the ionic charge. Thus, there are fourteen lanthanides between lanthanum ($Z=57$) and lutetium ($Z=71$) yet eleven of them have only two valence electrons (6s) in the neutral atom. *Klemm* showed from the physical properties of the metals that they have as many 4 f electrons as their trivalent ions; only europium and ytterbium are bivalent.

Goldschmidt suggested that thorium ($Z=90$) started a new, mainly quadrivalent 5 f series, and *Ephraim* has pointed out that uranium(IV) compounds have narrow absorption bands due to transitions between the energy levels of two 5 f electrons. When neptunium and plutonium were first produced it was thought for a while that they were the first members of a predominantly hexavalent 5 f series. On the basis of the properties of the succeeding elements, Seaborg developed the "actinide hypothesis" which states that the 5 f shell is filled in all chemical systems containing more than 86 electrons. With exception of the metallic elements and alloys, this hypothesis has been confirmed by spectroscopic studies.

However, there is not necessarily a connection between exclusive trivalency and presence of f electrons. In fact, only about six transplutonium elements are predominantly trivalent; the word "actinide" is rather an unfortunate choice. Mendelevium ($Z=101$) and nobelium ($Z=102$) are usually bivalent. A closer theoretical analysis[2,3] shows that this variation is connected with a parameter $(E-A)$ and the hydration or Madelung energy which represents the chemical influences. Elements containing shells with small average radii such as 3 d, 4 f, and 5 g have a low and rather constant oxidation state, whereas the elements with other shells such as 4d, 5d, and 5f have higher and more variable oxidation states at the beginning of electron-filling (cf. Nb, Mo, Tc, Ru with V, Cr, Mn, Fe) but lower oxidation states as the shells become fully occupied (cf. Ag with Cu).

A few atoms with $Z=103$, 104, and 105 have been made in California and in Russia, and perhaps a few with $Z=112$ at CERN in Geneva; these elements, like element 114, should be normal post-transition elements, whereas the elements between, which probably can be prepared according to the nucleonic shell model of *Maria Goeppert-Mayer* and *Hans Jensen* belong to transition groups. The element with $Z=126$, with its four 5 g electrons, is exclusively tetravalent. Dwi-lead ($Z=164$) is palladium-like and has eight 7 d electrons (and two 8 s and two 8 p electrons, which are highly stabilized for relativistic reasons). The element with $Z=184$ should be a super-rhenium with oxidation states between 4 and 12 and eight to zero 6 g electrons with large average radii[3].

New Methods for the Solid-Phase Synthesis and for the Analysis of Polypeptides

By *Günther Jung* (Lecturer), *Eberhard Breitmaier*, *Wolfgang Voelter*, and *Ernst Bayer*[*]

Difficulties that arise with certain combinations of protective groups can be avoided by the use of alkyl-substituted supports based on polystyrene. The number of incorrect and incomplete sequences that are frequently formed in solid-phase syntheses and the synthesis time can be reduced in some cases by a column process using a silicate support. This new type of support, which contains covalent Si—O—C and Si—C bonds, can be modified in any desired way on the surface, and can be used not only for the synthesis of biopolymers but also in preparative and analytical chromatographic procedures.

Pulse Fourier transform ^{13}C-NMR spectroscopy is particularly suitable for the determination of the redox and dissociation equilibria of cysteinyl peptides. The enantiomeric purity of amino acids can be determined independently of other methods from the ^{19}F-NMR spectra of derivatives with chiral sensors containing fluorine. This purity can also be determined by gas-chromatography on chiral dipeptide phases.

The Aminoisoxazole-Pyrazolone and Retro-Aminoisoxazole Rearrangements

By *Hans Junek*[*]

Examination of the products obtained from benzohydroxamoyl chlorides or nitrile oxides with cyanoacetic acid derivatives shows that they are not the expected 5-amino-3-phenylisoxazole-4-carbonitriles, but the isomeric pyrazolones. This can be demonstrated by acylation experiments, degradation, and rearrangement, as well as by comparative IR and NMR spectroscopy. A mechanism based on a rearrangement of the initially formed unstable isoxazoles is proposed for the formation of the pyrazolones. This aminoisoxazole-pyrazolone rearrangement is due to

[*] Prof. Dr. H. Junek
Institut für Organische Chemie der Universität
A-8010 Graz, Heinrichstrasse 28 (Austria)

a specific influence of the nitrile group. This effect is eliminated by hydrolysis of the nitrile group, and a retro-amino-isoxazole rearrangement can then occur.

The Decay of the Isomers of Rhenium-190

By *Norbert Kaffrell* (Lecturer) and *Norbert Trautmann*[*]

The β and γ radiation of 2.8 min ^{190g}Re and 2.8 h ^{190m}Re have been investigated with scintillation and semiconductor detectors. Two Ge(Li) diodes and a matrix of 1000 × 1000 channels were available for γ-γ coincidence measurements. Both isomers were prepared by irradiation of natural osmium with 14 MeV neutrons followed by chemical separation of the rhenium fraction. The 2.8 min isomer was also obtained by activation of enriched ^{192}Os with bremsstrahlung.

Spin and parity of $J^{\pi}=2^-$ and the configuration pn[402↑]—[505↓] have been assumed for the 2.8 min ground state. The β^- decay feeds almost exclusively the $J^{\pi}=3^-$ level of ^{190}Os at 1387 keV. This level is assigned the configuration pp[402↑]—[505↑], since according to the log ft value of the β transition it must be an allowed, unhindered transition. The 2.8 h activity decays mainly by an isomeric transition into the ground state of ^{190}Re. A smaller component feeds levels in ^{190}Os by direct β decay. The ground state rotational and γ-vibrational bands are excited up to spins of $J=8$. A decay scheme for both isomers was proposed and discussed.

(2)

A 9-sila-anthracene is found only under mass-spectrometric conditions. Bulky ligands R and R′ in the 9-chloro-9R-10R′-9,10-dihydro-9-sila-anthracene system have a decisive effect on the elimination of HCl.

Significance of Chemical Surface Reactions in Electrode Processes

By *Bertel Kastening*[*]

Many electrode processes are coupled with chemical reactions that precede or follow the charge transfers. Processes of this type can proceed as homogeneous or as heterogeneous reactions. The conditions for the reaction in the latter case are different from those for pure homogeneous reactions.

If strong interaction with the electrode is present, charge transfer, chemical reactions, and change of solvation may take place as concerted reactions rather than as individual steps and may be looked at as potential-dependent adsorption/desorption phenomena.

In the case of weak interaction (adsorption resulting from the lyophobic character of the substrate), the following particular conditions must be considered:

1. The rate depends on the surface concentration and hence on the adsorptivity.
2. The reaction proceeds in an environment that differs from the bulk of the solution, and under the influence of a very strong electric field, both effects resulting in a change of charge distribution within the molecule and in a particular orientation sometimes effecting stereospecific reactions.
3. The reaction takes place directly at the electrode. It may, therefore, proceed unidirectionally towards an unfavored species, if the latter is immediately displaced by a secondary charge transfer.

Valuable information has been obtained by investigations in the presence of surface-active substances not involved in the process but hindering surface reactions by replacing the substrate and reducing its adsorptivity. By this means the author has shown that a heterogeneous proton transfer reaction (*i.e.* $O_2^- + H_2O \rightarrow HO_2 + OH^-$) is responsible for the reversible character of the O_2/HO_2^- couple in aqueous alkaline solutions. Because they ignored heterogeneous reactions, other authors reached incorrect conclusions concerning the mechanism and the thermodynamic and kinetic parameters in this case.

Radiation-Induced Crosslinking in Polyisoprene

By *Hans Katzer* (Lecturer) and *Helmut Heusinger*[*]

Polyisoprene was prepared by the living-polymer method. This leads mainly to 1,2 and 3,4 addition. The radiation-induced crosslinking was investigated in the pregel and gel region. The G values for crosslinking calculated from the gel contents and the corresponding molecular weights range from 13.5 to 38, and depend on the molecular weight. Our experimental results can be described quantitatively if one assumes that the crosslinking, as in the case of the unsaturated polyesters investigated by *Charlesby*, proceeds by a chain reaction with consumption of double bonds. The decrease in the content of double bonds during irradiation was followed by IR spectroscopy. However, the G value for the decrease in the content of double bonds was found to be greater by a factor of 13 than the G value for crosslinking. We assume that a cationic chain reaction occurs on irradiation, and that this leads in an intramolecular reaction to cyclized units and in an intermolecular reaction to crosslinking.

Formation of Hydrocarbons on Heating of Saturated Fatty Acids and their Methyl Esters

By *H.-J. Kleinau*[*]

In oxidation experiments with saturated fatty acids and their methyl esters, numerous reaction products had already been identified. However, unknown substances were also recorded on gas chromatography. More recent investigations showed that these included hydrocarbons. Hydrocarbons have also been detected when the material under investigation was heated in the absence of oxygen. Their formation can therefore be attributed to thermal decomposition of the fatty acids.

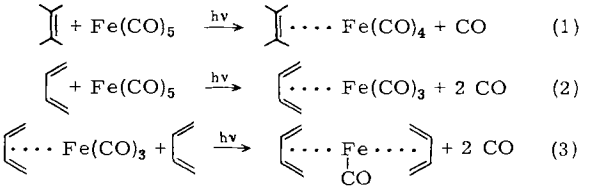
Aldol Condensation of Trihaloacetaldehydes with Aliphatic Ketones

By *Eberhard Kiehlmann*[*]

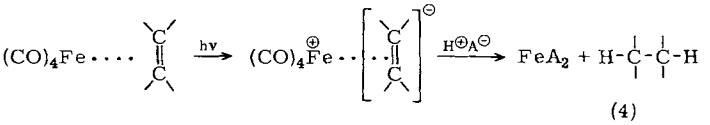
Fluoral and chloral react with aliphatic ketones in glacial acetic acid to form 1,1,1-trihalo-2-hydroxy-4-alkanones, whereas bromal does not. With diethyl ketone and cyclohexanone, two chromatographically separable diastereoisomeric ketols, which epimerize in reactions on the preparative scale, are obtained. The rate constant for the epimerization was measured. Methyl ethyl ketone condenses both in the α-CH_2 group and in the α-CH_3 group to form three isomeric ketols, the former condensation predominating. Methyl isobutyl ketone reacts with chloral exclusively in the α-methyl group, whereas fluoral also adds to the methylene group. Higher methyl alkyl ketones also react mainly on the α-methyl group, on steric grounds.

[*] Prof. Dr. E. Kiehlmann
Simon Fraser University, Department of Chemistry
Burnaby 2, British Columbia (Canada)
Present address:
Institut für Organische Chemie der Universität
5 Köln, Zülpicher Str. 47 (Germany)

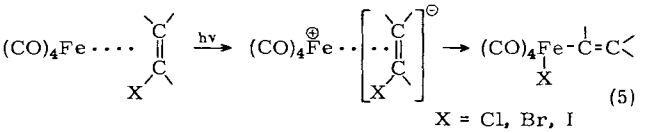


The orientation in the aldol condensation of trihaloacetaldehydes with unsymmetrical aliphatic ketones is kinetically controlled; no α,β-unsaturated ketones are formed.

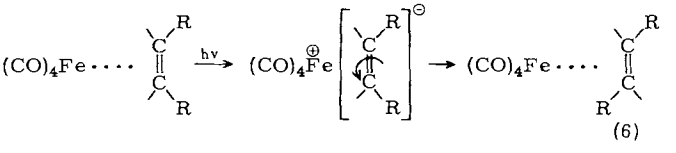
Comparison of the above results with the rate constants for the exchange of hydrogen atoms in the α positions of the corresponding ketones against deuterium shows that the addition of the enol form of the ketone to the carbonyl group of the aldehyde molecule is the rate-determining step.



Photochemical Synthesis and Transformation of Olefin-Carbonyliron Compounds



By *Ernst Koerner von Gustorf* (Lecturer), *Friedrich-Wilhelm Grevels*, *Mrinal K. Das*, *Jürgen Buchkremer*, and *Zorka Pfajfer*[*]



The photochemical reactions (1)—(3) represent preparatively useful routes for the preparation of monoolefin-, diene-, and bis(diene)-carbonyliron compounds.

The individual steps of the successive substitution of CO can be attributed to the intramolecular or intermolecular attack of a π system on charge-transfer ($d_{Fe}\rightarrow\pi^*_{C=C}$) excited molecules. The direction of the charge transfer is shown by reactions (4)—(6).

Phosphorylides as Polymerization Initiators

By *Heinz Klippert* (Lecturer) and *Helmut Ringsdorf*[*]

Phosphorylides $R_3P{=}CH{-}X$ and $R_3P{=}CH_2\cdot LiBr$ (R = alkyl and aryl, X = H, $Si(CH_3)_3$, and CO—R), as basic compounds, can initiate the anionic polymerization of vinyl monomers. In the cases of methacrylonitrile and

[*] Dipl.-Chem. H. Klippert and Prof. Dr. H. Ringsdorf
Organisch-Chemisches Institut III der Universität
65 Mainz, Johann-Joachim-Becker-Weg 18—20

methyl methacrylate, the ylides are incorporated into the polymers as end groups, as has been shown by analysis and by IR and mass spectroscopy.

$$R_3P{=}CH_2 + CH_2{=}CHR' \rightarrow R_3\overset{\oplus}{P}{-}CH_2{-}CH_2{-}\overset{\ominus}{C}HR'$$

For the salt-free ylides, the ability to act as initiators depends on the basicity of the ylide carbanion; however, the structure of these ylides has no measurable effect on the molecular weight of the resulting polymers or on the stereocontrol of the reaction. On initiation with ylides containing salts, on the other hand, the tacticity and the polymer growth rate depend on the substituents on the hetero atom of the ylide.

Determination of Charge Distribution in Mass Chains in the Region of the Closed 50-Neutron Shell in the Thermal-Neutron Induced Fission of ^{235}U

By *J.-V. Kratz* (Lecturer) and *Günter Herrmann*[*]

By fast chemical separation of arsenic and selenium as volatile hydrides from the mixture of fission products, arsenic nuclides with half-lives down to 0.3 s and selenium nuclides with half-lives down to 1.4 s were identified and their mass assignment verified by milking of daughter and grand-daughter activities. ^{87}Se, ^{88}Se, ^{84}As, ^{85}As, and ^{86}As were detected as delayed-neutron precursors. Isomeric states were observed in ^{82}As and ^{84}As. Fractional cumulative yields of arsenic and selenium isotopes were measured in the mass chains 83, 84, 87, and 88, taking into account the half-lives and branching ratios found, and were used to determine the most probable nuclear charge and the width of the Gaussian dispersion curves. The results show that in the thermal-neutron induced fission of ^{235}U, fission products with mass numbers 84 ± 1 are formed preferentially with a charge density that deviates from that of neighboring mass chains. This observation could correspond to a shell effect on the charge distribution of primary fission fragments. However, calculations show that the effect can also be explained by a shell-dependent evaporation of prompt neutrons.

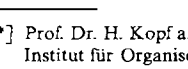
The Base-Catalyzed Reaction of Organic Hydroperoxides with Electron-Poor Olefins



By *Heinz Kropf* (Lecturer) and *Michael Ball*[*]

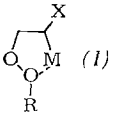
Organic hydroperoxides react with electron-poor olefins in the presence of basic catalysts either to form the dialkyl peroxides[1,2] or to form epoxides[3-5] in a reaction analogous with the epoxidation of α,β-unsaturated ketones with H_2O_2 as found by *Weitz* and *Scheffer*[3].

$$RO_2H + OH^{\ominus} \rightleftharpoons RO_2^{\ominus} + H_2O \quad (1)$$

$$RO_2^{\ominus} + CH_2{=}CH{-}X \rightleftharpoons RO_2{-}CH_2{-}\overset{\ominus}{C}H{-}X \quad (2)$$

$$RO_2{-}CH_2{-}\overset{\ominus}{C}H{-}X + H_2O \rightleftharpoons RO_2{-}CH_2{-}CH_2{-}XOH^{\ominus} \quad (3)$$

$$+ RO^{\ominus} \quad (4)$$



[*] Prof. Dr. H. Kopf and Dipl.-Chem. M. Ball
Institut für Organische Chemie und Biochemie der Universität
2 Hamburg 13, Papendamm 6 (Germany)

On the basis of our results[2], particularly with esters of vinylsulfonic acid and divinyl sulfone, it does not seem possible to distinguish these two reaction directions on the basis of the thermodynamic acidity series

$$-NO_2 > -SO_3R > -SO_2R > -CHO > -COR > -COOR > -CN > \approx$$
$$\approx CONH_2 > -CO_2^{\ominus}$$

(the epoxides should be obtained with strongly acidifying substituents[4]).

On the other hand, a relationship is found with the lifetime of the intermediate carbanion, *i.e.* the rate of protonation as the ratio of the kinetic and thermodynamic acidities of the peroxides obtained, as is also shown by the dependence of the yields of dialkyl peroxide on the concentration of alkali and solvent. The influence of the nature of the alkali (peroxide yields increasing in the order KOH < NaOH < LiOH) suggests that the elimination to form the epoxide proceeds *via* a cyclic transition complex *(1)*. This view is also supported by the fact that the reactions with H_2O_2 lead almost exclusively to the epoxides.

Molecular and Crystal Structures of Some Ni(0) Complexes

By *Carl Krüger* (Lecturer), *B. L. Barnett*, and *Y.-H. Tsay*[*]

Elementary nitrogen is fixed by bis(tricyclohexylphosphane)nickel as bis[bis(tricyclohexylphosphane)nickel]dinitrogen *(1)*[1], $[(C_6H_{11})_3P]_2NiN_2Ni[P(C_6H_{11})_3]_2$. X-ray structure analysis of *(1)* shows a linear Ni—N—N—Ni system (Ni—N: 1.78 Å, N—N: 1.12 Å). The P_2Ni groupings are twisted through 105° with respect to each other, with the result that an inclusion effect is produced with regard to the nitrogen by four of the cyclohexyl groups. A similar twisting has also been observed in the case of bis[1,3-bis(dicyclohexylphosphino)propanenickel hydride] $\{[(C_6H_{11})_2P(CH_2)_3P(C_6H_{11})_2]NiH\}_2$.

Comparative studies on several compounds containing σ-Ni—C bonds are also described. The X-ray structural analysis of tricyclohexylidenephosphoranetricarbonylnickel $(C_6H_{11})_3PCH(CH_3)Ni(CO)_3$ shows a comparatively elongated bond (2.097 Å) between the tetrahedrally hybridized carbon of the ethylidene group and nickel. The corresponding Ni—C distance in the square-planar compound tricyclohexylphosphanemethylnickel pentanedionate $(C_6H_{11})_3PNiCH_3C_5H_7O_2$ is 1.94 Å.

Electrophilic Nitrosation with Nitrosyl Tetrafluoroborate

By *Richard Kreher* (Lecturer), *Hans Hennige*, and *Manfred Schmidt*[*]

The complexing of azides with Lewis acids has been systematically studied by us as a method for the production of *N*-diazonium ions[1]. A logical extension of this work is the nitrosation of organic azides *(1)* with nitrosyl tetrafluoroborate[2]. An independent route to *N*-diazonium salts, which are of interest as precursors of nitrenium ions[3], should also be provided by the reactions of 2-tetrazenes *(3)*, of acylated hydrazines *(4)*, and of *N,N'*-sulfonyldihydrazines *(5)* with the same electrophile.

According to our findings, 1-acyl-3-aryltriazenes *(6)* and substituted iminophosphoranes *(7)* with a nucleophilic nitrogen atom can be nitrosated with the reactive nitrosyl tetrafluoroborate under mild conditions[4]. These reactions provide an elegant route to reactive nitroso compounds, which cannot generally be isolated, and which enter into fragmentation reactions that are of interest from the mechanistic standpoint. The universal importance of these secondary reactions in connection with the production of reactive cationic intermediates was discussed.

New Impetus for Food Research Under the Auspices of the Federal Ministry for Food, Agriculture, and Forestry (BML)

By *Felix Krusen*[*]

Of the 16 Federal Research Institutes under the BML, eight are concerned exclusively with food research (meat, fish, milk, fats, cereals, food preservation, quality of plant products, domestic science). As a result of reorganization of BML research, three special departments have been created with senates of leading scientists, the staff of each department comprising 25% scientific personnel. The department "Food Research and Food Technology", which covers the eight institutes mentioned above, has grouped the research programs of the different institutes under five headings: maintenance and improvement of food quality, progress in food technology, consumer-oriented research, economic problems, and fishery research. There are also three main objectives: control of residues, protein production, and improvement of fat quality. The aim is to increase cooperation and to promote joint research among the institutes, in the hope of improving efficiency.

The Relationship of Trichloromethanesulfenyl Chloride and Related Compounds to Carbonic Acid Chemistry

By *Engelbert Kühle*[*]

An attempt is made to fit trichloromethanesulfenyl chloride ("perchloromethyl mercaptan") $Cl_3C—SCl$, which may be regarded as orthocarbonic acid trichloride sulfenyl chloride, and the sulfenyl chlorides derived from it, such as chlorocarbonylsulfenyl chloride, chlorothiocarbonylsulfenyl chloride, iminochloromethanesulfenyl chloride, and dichloromethanebis(sulfenyl chloride), into a general scheme of carbonic acid chemistry. The relationship of these sulfenyl chlorides with carbonic acid derivatives was examined on the basis of a number of reactions.

Organolead Compounds $(Y\text{-}C_6H_4)_nPbX_{4-n}$ with Reactive Substituents Y

By *Friedo Huber* and *Eberhard Kunze* (Lecturer)[*]

Compounds R_nPbX_{4-n} (n=4,3,2,1) with R=m-$O_2N—C_6H_4$ were prepared and investigated as model substances for R′=Y—C_6H_4 with Y as a reactive electron-withdrawing substituent. R_4Pb, which cannot be obtained by direct nitration of $(C_6H_5)_4Pb$, can be prepared by introduction of the nitro group into $(C_6H_5)_2Pb(NO_3)$ by treatment with concentrated sulfuric acid [the same method can be used for $(Z_m—C_6H_{5-m})_2Pb(NO_3)_2$ with Z=4-CH_3, 3-CH_3, m=1 and Z=3,5-CH_3, m=2], conversion of the resulting $R_2PbSO_4 \cdot xH_2O$ into R_2PbX_2 (X=Cl, Br) and symmetrization with hydrazine. Mild degradation with bromine leads to R_3PbBr. $RPb(OCO—CH_3)_3$ is prepared by reaction of $Hg(OCO—CH_3)_2$ with $R_2Pb(OCO—CH_3)_2$.

$R_2Pb(OCO—CH_3)_2$ reacts with HBr and $(C_6H_5)_4PBr$ in glacial acetic acid to give $[(C_6H_5)_4P]_2(R_2PbBr_4)$, and with HCl and $(C_6H_5)_4PCl$ in acetone/methanol to give $[(C_6H_5)_4P](R_2PbCl_3)$. The introduction of the nitro groups renders electrophilic attack on the aryl-lead bond more difficult, and the solubilities are considerably altered in some cases.

Anion-Exchange Behavior of Protactinium and Other Elements in Mixtures of HNO_3, HF, and Organic Solvents

By *H. W. Lagally* (Lecturer), *J. I. Kim*, and *H.-J. Born*[*]

The anion-exchange behavior of protactinium was investigated in several water-miscible organic solvents containing HNO_3 and HF as complexing agents. Solvents with low to high dielectric constants were chosen. The adsorption of uranium, thorium, and other elements in these solutions was also investigated. By variation of the solvent and its concentration in the acid mixture, it is possible to increase the adsorption of the anions in question on the ion exchange resin to the desired degree. The effects of the dielectric constant, the dipole moment, the ionic strength of the solution, *etc.* on the adsorption are discussed. On the basis of these results, possibilities are shown for the separation of protactinium from the other elements, the protactinium remaining stable in the mixtures containing HF.

Reaction of Silicon Nitride with Oxygen

By *I. Fränz* and *W. Langheinrich* (Lecturer)[*]

When thin layers of vitreous silicon nitride, such as can be deposited *e. g.* on silicon by reaction of silane with ammonia, are heated in oxygen, silicon dioxide is formed as a thin vitreous layer with a sharp boundary between the two phases in accordance with the equation

$$Si_3N_4 + 3\,O_2 \rightarrow 3\,SiO_2 + 2\,N_2$$

For greater thickness of the SiO_2 layers formed, *i. e.* when the growth process has become stationary, a parabolic law of the form

$$x^2 = B \cdot t$$

where x is the thickness of the SiO_2 layer formed, t is the oxidation time, and B is a temperature-dependent constant, is valid for heating in dry as well as in moist oxygen.

The formation of SiO_2 from silicon nitride is much slower than the thermal oxidation of silicon, which also follows a parabolic law for large layer thicknesses. This is probably due to the fact that the equilibrium concentration of the oxidant in the oxide is influenced by nitrogen which is produced in the interface reaction and which diffuses to the surface.

Detection of Staphylococcus Enterotoxins with the Aid of a New "Micro-Slide Kit" for Immune Diffusion

By *H. J. Langner*[*]

There is a need for increasing sensitivity of detection methods in analytical chemistry. This also applies to the detection of macromolecular natural products such as proteins. If such substances can be isolated in a highly purified form and used for the preparation of antiserums, immune diffusion offers an extremely sensitive and specific method of detection and determination. In immune diffusion on the micro scale, however, all the important analytical parameters must be accurately standardized. On the other hand, nearly every laboratory has its own individual procedures for this method. A complete outfit[**], including reagents, for "micro-slide immune diffusion", in which all the parts are rigorously standardized, and which allows the very simple execution of both qualitative and quantitative protein determinations, *e. g.* detection of staphylococcus enterotoxins, milk protein, soybean protein, and egg protein in other foods, in microbiological nutrient solutions, or in human examination material, is proposed in this lecture.

Separation of Fission Inert Gases from Combustion Waste Gases from High-Temperature Fuel Elements by Washing with Liquid Carbon Dioxide

By *Manfred Laser* (Lecturer) and *Holger Beaujean*[*]

The separation by washing and subsequent rectification is carried out in a compact apparatus designed for a combustion gas throughput of 1 Nm^3/h. The columns have the following dimensions:

Wash column: height 2500 mm, diameter 43 mm, packing: wire mesh rings with web 6 × 6 mm.

Rectifying column: total height 1200 mm, of which the rectifying section accounts for 450 mm and the stripping section for 750 mm; packing: wire helices, 4 × 4 mm.

Measurements on the equilibrium between Kr and CO_2 showed that the solubility is better than the calculated value at Kr contents ≤ 1000 ppm. This leads to the relatively favorable gas/solvent ratio of 80 in the wash column and facilitates the concentration of krypton in the rectifying section of the rectifying column.

The solubility coefficient for Kr is 0.00715 at 25 °C.

Possibilities in Preparative Organometallic Electrochemistry

By *Herbert Lehmkuhl* (Lecturer), *Wolfgang Leuchte, Edo Janssen, Klaus Mehler, Siegfried Kintopf*, and *Wilhelm Eisenbach*[*]

Organometallic complex compounds of main group metals (Al) and transition metals with aromatic, olefinic, or cycloolefinic hydrocarbons as ligands can be synthesized by electrochemical reduction of suitable, readily obtainable metal compounds (chlorides, acetylacetonates, alkyls, *etc.*) in the presence of the ligands. The electrochemical systems consist of the two components of the desired complex, an organic, usually aprotic solvent (pyridine, THF, DMF, dimethoxyethane), and a suitable conducting salt (lithium halide, tetraalkylammonium halide, alkali metal tetraalkylaluminate, *etc.*). Depending on the anode process coupled with the reduction at the cathode, one thus achieves an electrochemical synthesis from compact metal (anode) and ligand:

$$M\,(\text{Anode}) + \text{Lig} \rightarrow [M \ldots . \text{Lig}]$$

This synthesis has been achieved for cyclooctatetraenenickel(0), bis-cyclooctatetraenenickel(0), and bis-cyclooctatetraeneiron(0).

If the complex formed at the cathode is oxidized more readily than the anode metal, the electrode compartments must be separated by diaphragms, or a more readily oxidizable metal may be used as the anode. Aluminum has proved particularly suitable for this purpose. The overall electrochemical reaction is then given by:

$$M^{\oplus} + M'\,(\text{Anode}) + \text{Lig} \rightarrow M'^{\oplus} + [M \ldots . \text{Lig}]$$

$$M' = \tfrac{1}{3}\,Al$$

Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

This general case has been verified in the syntheses of cyclooctatetraenetitanium chloride, bis-cyclooctatetraenezirconium dichloride, π-cyclooctenylcobalt-1,5-cyclooctadiene, bis-1,5-cyclooctadienenickel, and 1,5,9-cyclododecatrienenickel.

4-Bromo-5-cyclohexene-1,2,3-triol as a Specific Inactivator for the α-Glucosidases of Yeast (Saccharomyces cerevisiae)

By *Günter Legler* (Lecturer) and *Wolfgang Lotz*[*]

The reaction of α-glucosidases with all-*trans*-4-bromo-5-cyclohexene-1,2,3-triol (bromoconduritol) leads to irreversible inhibition. Investigation of the inactivation reaction with an enzyme isolated in pure form from brewers' yeast showed second order kinetics at concentrations around 10^{-6} mole/l ($k = 8.8 \times 10^4$ $mole^{-1}$ l min^{-1} at 25 °C and pH = 6.0). Substrate or competitive inhibitors reduce the reaction rate, pointing to an attack on the active center. The enzyme has two SH groups, one of which is essential. After inactivation with bromoconduritol, only 0.5 SH/mole was detectable; however, the SH groups become fully accessible again on denaturation. Reaction with a histidine residue is assumed from the amino acid analysis. The pH dependence of the inactivation reaction and the behavior of the epoxide obtained from bromoconduritol indicate that the bromoconduritol is converted into the epoxide on the enzyme before the reaction.

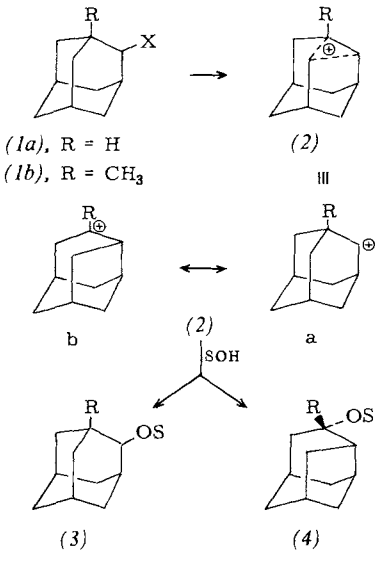
The Solvolysis of 1-Methyl-2-adamantyl Compounds (Influence of β-Methyl Substitution on the Solvolysis of Secondary Compounds)



By *Dieter Lenoir* (Lecturer) and *Paul v. R. Schleyer*[*]

The solvolysis of unsubstituted 2-adamantyl compounds *(1)*, R = H, X = tosyloxy or bromine, was chosen as a model for a limiting solvolysis mechanism (k_c mechanism) of secondary substrates. Whereas solvent assistance (k_s mechanism) could be ruled out, the question of the magnitude of a possible anchimeric component (k_Δ) was particularly interesting.

The effect of a carbonium ion-stabilizing methyl group on C-1 on the nature of the secondary ion (2) was therefore investigated. The rate of solvolysis of the substituted compounds *(1)*, R = CH_3, X = tosyloxy or bromine, is 35 times that of the unsubstituted compounds *(1)*, R = H, X = tosyloxy or bromine at 25 °C. Whereas only 0.4% of the rearrangement product *(4)* with R = H, OS = acetate is formed in the kinetically controlled solvolysis of the unsubstituted compound *(1a)*, X = tosyloxy, in glacial acetic acid, the component of the rearrangement product *(4)* with R = CH_3, OS = OH is increased to 30% in the solvolysis of *(1b)* in 60% acetone.

It is clear from these kinetic findings, particularly the formation of the rearrangement product with a uniform

Princeton, New Jersey 08540 (USA)

(1a), R = H
(1b), R = CH_3

(2)

(3)

(4)

4-*exo*-protoadamantane structure, that the ion *(2)* with R = H is only very weakly bridged, whereas the ion *(2)* with R = CH_3 has a considerable proportion of bridged character. The difference between the energies of the two canonical forms a and b is reduced as a result of compensation of electronic effects by strain effects only in the substituted ion.

The special stability of the ion *(2)* with R = CH_3 is also confirmed by the result of the solvolysis of the 4-epimeric 4-methylprotoadamantyl 3,5-dinitrobenzoate in 60% acetone; with kinetic control, both substrates give a product ratio similar to that obtained from *(1b)*, so that the ion *(2)* is a common intermediate for all three substrates.

The application of the linear free energy relation shows that the protoadamantane system is richer in energy by about 11 kcal/mole than the adamantane system; this value agrees satisfactorily with the results calculated from conformational analysis.

Ternary Chromium Sulfides

By *H. D. Lutz* (lecturer), *K.-H. Bertram*, *R.-A. Becker*, and *W. Becker*[*]

In the reaction (950°C) of CrS (NiAs defect structure) with transition metal sulfides having the formula MS (M = Mn, Fe, Co, Ni, Cu, and Zn), the very strong reducing power of "chromium(II) sulfide" leads to the formation of higher sulfides of chromium ($FeCr_2S_4$ cubic or monoclinic, $CoCr_2S_4$ cubic, $Ni_xCr_{3-x}S_4$ monoclinic). The sulfides used are thus reduced to the metals (Fe, Co, Ni) or subsulfides (Ni_3S_2). No reduction is observed in the systems CuS—CrS (formation of rhombohedral $CuCrS_2$), MnS—CrS, and ZnS—CrS. The desired stabilization of a chromium sulfide that crystallizes in the undistorted NiAs type by solid solution formation with NiS, CoS, or FeS could not be achieved.

To clarify the conditions for the transformation of the spinel lattice of the ternary chromium sulfides MCr_2S_4 (M = Mn, Fe, Co, Cu, and Zn) into the monoclinic NiAs defect structure of $NiCr_2S_4$, the mutual miscibility was investigated in the systems $CoCr_2S_4$—$NiCr_2S_4$ (spinel → $Co_{0.81}Ni_{0.19}Cr_2S_4$) and $CuCr_2S_4$—$NiCr_2S_4$ (spinel → $Cu_{0.74}Ni_{0.26}Cr_2S_4$). In the system $CoCr_2S_4$—$CuCr_2S_4$, solid solution formation was observed between the metallically conducting copper chrome thio-spinel and the semiconducting cobalt compound in all proportions. However, the Vegard rule is not satisfied.

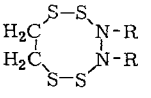
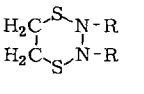
Sulfane Derivatives of Hydrazine

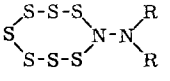


By *Karl-Heinz Linke* (lecturer), *Herbert Lingmann*, *Rudolf Bimczok*, *Hans Jürgen Göhausen*, and *Dietmar Skupin*[*]

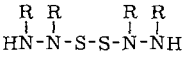
Whereas hydrazine is oxidized to nitrogen by chlorosulfanes, a series of cyclic and open-chain sulfane derivatives of hydrazine have been synthesized by reaction of esters of hydrazinedicarboxylic acid or dimethylhydrazine with chlorosulfanes:



(1a)-(1c)

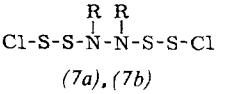


(2a), *(2b)*



(3a)

(4a)



(5a)

(6a), *(6b)*

(*a*), R = $CO_2C_2H_5$
(*b*), R = $CO_2C(CH_3)_3$
(*c*), R = CH_3

(7a), *(7b)*

(6a) is also formed in high yields by addition of disulfane to diethyl azodicarboxylate.

Attempts to remove the ester groups from the heterocyclic compounds *(1b)* and *(2b)* by acidolysis or pyrolysis failed to lead to the isolation of unsubstituted sulfur-nitrogen rings containing nitrogen-nitrogen bonds.

Thermodynamic and Kinetic Aspects of the Synthesis of New Forms of Carbon

By *H. Lydtin*[*]

The novel forms of elementary carbon, such as "highly oriented pyrographite" and "vitreous carbon", are products of special preparation methods. In these methods, the carbon formation is forced to occur either by condensation of carbon from the gas phase on substrate surfaces or by pyrolysis of suitable organic substances in the solid state.

[*] Dr. H. Lydtin
Philips Forschungslaboratorium
51 Aachen, Postfach 1980 (Germany)

Both methods are based on the thermal instability of organic carbon compounds. Apart from hydrocarbons, which are the most commonly used materials in practice, other systems that may be considered on thermodynamic grounds for the deposition of carbon from the gas phase include C/S, C/Cl, and C/O.

The molecular mechanisms of carbon formation differ in the two methods. In the gas-phase deposition, the desired deposition of carbon takes place either by direct condensation of atomic carbon or by the decomposition of molecules containing carbon on the surface. Depending on the temperature and pressure, complications can arise from cluster formation in the gas phase or from inadequate thermal accommodation on the surface of the solid. In the pyrolysis of solids, the carbon formation depends on simultaneous decomposition and diffusion processes in the initial and intermediate stages of the material used. The structure of the final product depends not only on the starting materials but also on the competition between production (decomposition) and elimination (diffusion) of the cleavage products.

By suitable choice of the starting material, the preparation method, and the preparation conditions, it is possible to adjust a number of properties in the final product over wide ranges. This fact, together with good chemical and thermal stability, is the basis of the wide range of possible applications and uses of these modern materials.

The Binding of Volatile Carbonyl Compounds to Food Components

By *H. G. Maier*[*]

The adsorption and desorption of the vapors of aldehydes (C_3 and C_6 alkanals and alkenals, some aromatic) and ketones (C_3—C_5 alkanones, biacetyl, camphor) to food components that are poor in water at room temperature has been investigated by IR-spectroscopic and gas-chromatographic methods. Ketones are adsorbed only in small quantities in the absence of water, while adsorption by macromolecular substances improves with increasing water content. Rapid drying then leads to the formation of nonstoichiometric inclusion compounds. The quantities adsorbed decrease with the molecular size. Aldehydes are usually bound in a similar manner and in similar quantities. The physical adsorption on water-free solids is often greater. Chemical reaction occurs with some low molecular weight solids, and leads *e.g.* in the case of cysteine and urea to bonding that is reversible in the presence of water.

Enumeration, Identification, and Significance of Staphylococci in Dried Soups and Their Raw Materials

By *R. S. Moussa* and *J. C. de Man* (lecturer)[*]

Of all the culture media suggested for the enumeration and identification of pathogenic staphylococci, that most commonly used in food laboratories is the Baird-Parker medium. The advantages and some limitations of this medium were discussed, and the results obtained with other culture media were compared with those obtained with the Baird-Parker medium. When Baird-Parker culture medium is used for the enumeration of *Staphylococcus aureus* in dried soups and their raw materials, a large number of the colonies that develop must be tested for coagulase and/or deoxyribonuclease-production, and occasionally for ability to produce enterotoxin.

Influence of Conformation on the Stereochemical Course of Hot Substitution Reactions in Diastereomeric Haloalkanes

By *H. J. Machulla* (lecturer), *L. Vasaros*, and *Gerhard Stöcklin*[*]

The question of the mechanism of hot substitution reactions with high translational energies (eV range) was reinvestigated for diastereomeric 1,2-dichloro-1,2-difluoroethanes and 2,3-dihalobutanes in the light of conformational analysis. In the liquid phase, the replacement of hydrogen by recoil tritium, and to a greater degree the replacement of halogen by recoil halogen atoms, can also take place with inversion of configuration under favorable steric conditions. By comparative IR-spectroscopic conformational analysis and radiochemical yield determination in solvents of different dielectric constants, it was possible to show that the stereochemical course is strongly dependent on the conformation of the rotational isomers, and can be varied within a wide range (*e.g.* 30 to 85% retention of configuration in the case of recoil chlorine in 2,3-dichlorobutane) by changing of the equilibrium concentration of the conformers.

This conformational effect exhibits a new characteristic feature of hot one-step substitution and indicates that these reactions may also proceed as concerted processes *via* a collision complex that is long-lived as compared to molecular vibration periods.

Search for "Solar Wind" Rhenium in Moon Samples

By *U. Herpers*, *R. Michel* (lecturer), and *W. Herr*[*]

Since the natural β-radioactive ^{187}Re ($E_\beta \approx 2$ keV) in the interior of the sun possibly suffers a faster "bound-state" β^--decay—as was predicted some years ago—one would expect this nuclide to be deficient in the "solar wind". The composition of the latter shows that all elements are present with almost cosmic abundances. Since lunar materials was available we had the chance to study the composition of the captured "solar wind" rhenium. Therefore, we measured the isotopic abundance of ^{185}Re and ^{187}Re by neutron activation techniques.

After an intense neutron bombardment suitable preparations were subjected to γ spectroscopy with a 20 cm^3

[*] Dr. U. Herpers, Dipl.-Phys. R. Michel, and Prof. Dr. W. Herr
Institut für Kernchemie der Universität
5 Köln, Zülpicher Strasse 47 (Germany)

Ge(Li)-detector. The isotope ratio was checked by comparing the 137 keV γ line of ^{186}Re with the 155 keV γ line of ^{188}Re. Lunar rocks gave Re contents between 0.2×10^{-10} and 0.9×10^{-10} g/g, which roughly correspond to those of achondritic meteorites. The soil samples were found to be considerably richer (70×10^{-10} to 110×10^{-10} g/g for Apollo 11 regolith and 6×10^{-10} g/g for Apollo 12 regolith). In rocks Re was found—contrary to expectation—to be slightly enriched in ^{187}Re.

This effect is believed to be due to the neutron capture reaction $^{186}W(n,\gamma)^{187}W \xrightarrow{\beta^-} {}^{187}Re$. The possibility of deriving thermal and epithermal neutron fluxes on the lunar surface by the Re-isotope anomaly was discussed.

Fast-Drying Binder Based on Dehydrated, Epoxidized Linseed Oil in Theory and Practice

By *J. D. von Mikusch-Buchberg* (lecturer, Part I) and *E. W. Trautschold* (lecturer, Part II)[*]

Varnish and paint binders that dry rapidly to hard films are obtained from linseed oil by (a) partial epoxidation, (b) complete esterification of the epoxy oil with unsaturated fatty acids, and (c) thermal cleavage of the estolide with formation of new double bonds. Since the removal of the fatty acids is incomplete, the stand oil-like product has an increased functionality. Drying proceeds with the typical characteristics of conjugated unsaturated oils, but completely tack-free films are formed. A detailed discussion of the individual process steps (Part I) was followed by a report on the results of outdoor weathering and other practical tests (Part II).

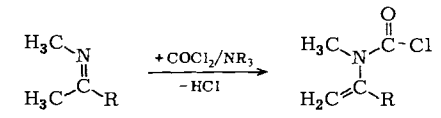
Chemical Consequences of the $^{185}Re(n,\gamma)^{186}Re$ Nuclear Process in the Double Salt $K_2ReF_6 \cdot KCl$

By *Horst Müller* (lecturer)[*] and *Siegfried Abberger*[**]

The hitherto unknown double salt $K_2ReF_6 \cdot KCl$ can be obtained from a solution of the components. It crystallizes tetragonally with $a = 12.009$ and $c = 11.847$ Å. Model considerations suggest that its structure is very similar to that of $(NH_4)_3[SiF_6]F$. It should thus be built up from a succession of ReF_6^{2-} and Cl^- in the c direction, with K^+ scattered between the layers.



The ^{186}Re recoil atoms formed as a result of neutron capture, which have a recoil energy of about 70 eV, react in the lattice to give mixed chlorofluororhenates(IV) $^{186}ReCl_nF_{6-n}^{2-}$. The two forms $^{186}ReCl_3F_3^{2-}$ and $^{186}ReCl_4F_2^{2-}$ are formed only in very small quantities, and the two forms $^{186}ReCl_5F^{2-}$ and $^{186}ReCl_6^{2-}$ are totally absent. The possibility of using these results as a basis for conclusions regarding the degree of distortion of the lattice as a result of the recoil process was discussed.

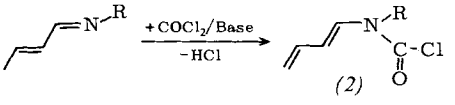
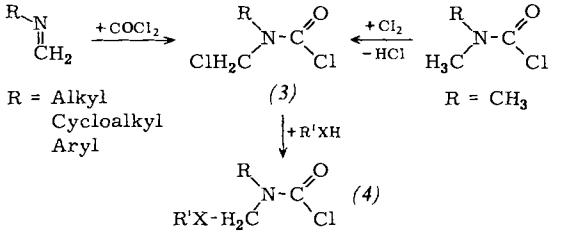
New Carbamoyl Chlorides by Phosgenation of Lactim Ethers, Imido Esters, and Schiff Bases and by Chlorination of *N,N*-Dimethylcarbamoyl Chloride



By *Albrecht Müller* (lecturer), *Hans Kiefer*, *Karl-Heinz König*, *Horst Pommer*, and *Bernd Zeeh*[*]

The reaction of azomethines, lactim ethers, and imido esters with phosgene in the presence of tertiary amines leads in good yields to hitherto unobtainable α,β-unsaturated carbamoyl chlorides, *e.g. (1)*. These reactions are based on a general synthetic principle that can also be applied to other reactive acylating agents, such as chloroacetyl chloride and acetyl chloride.



R = H, OCH_3 *(1)*

α,β-Unsaturated azomethines can be converted in the same way into the corresponding butadienylcarbamoyl chlorides *(2)*:

(2)

In the absence of bases, it is possible to isolate the α-chloroalkylcarbamoyl chlorides, which tend to undergo dehydrochlorination. Azomethines of formaldehyde, on the other hand, yield stable chloromethylcarbamoyl chlorides, which are also obtainable *e.g.* by chlorination of *N,N*-dimethylcarbamoyl chloride:

R = Alkyl, Cycloalkyl, Aryl *(3)* $R = CH_3$ *(4)*

The selective substitution of *(3)* with various nucleophiles R'XH (X = O, S, OAc, SAc) with formation of *(4)* was described.

Thermal Aldol Reactions Between Ketones and Aldehydes

By *Herbert Müller* (lecturer), *Georg Klotmann*, and *Hermann Overwien*[*]

Little attention has been paid so far to thermally initiated aldol condensations between ketones and aldehydes. In many cases, however, these reactions proceed much

[*] Dr. H. Müller, Dr. G. Klotmann and Dr. H. Overwien
Badische Anilin- & Soda-Fabrik AG, Hauptlaboratorium
67 Ludwigshafen (Germany)

more selectively than the catalytic reactions, provided that the correct reaction conditions are strictly maintained.

The reaction products obtained are identical with those of the catalytic condensation. The primary products are keto alcohols, which may be dehydrated to form unsaturated ketones under the drastic reaction conditions.

The synthesis proceeds surprisingly smoothly with aldehydes substituted in the α position by alkyl or aryl groups and with formaldehyde. The structure of the ketones, on the other hand, has little effect on the course of the reaction.

The reaction temperatures required are mainly determined by the aldehydes. For simple adehydes they are between 200 and 300 °C. They can be reduced by 100 °C by the use of aldehydes with electron-attracting groups in the α position. An example of this is the condensation of glyoxylic acid with acetone, which gives acetylacrylic acid in high yields.

Inverse-Voltammetric Determination of Traces of Antimony after Separation of the Matrix by Various Methods

By *Hans Monien* (lecturer), *Doris Bohn* and *Peter Jacob*[*]

For the determination of approximately 0.5 to 5 ppm of antimony in metallic iron, copper, and bismuth, the matrix is separated by extraction, by column chromatography, and by potentiostatic electrolysis. With the extraction of iron or copper, the complete analysis takes one hour. The antimony content of the iron is 0.54 ppm, the relative standard deviation of the results being 0.12. The copper analyzed contains 3.8 ppm of antimony (relative standard deviation 0.03). The separation of iron or copper by column chromatography takes two hours. The results of the analyses agree with those given above. The relative standard deviation in this determination is 0.06. With separation of copper by potentiostatic electrolysis, an analysis takes 90 minutes.

In all three separation methods, for sample weights of between 0.2 and 1 g, only a few minutes are required for the dissolution process and the preparation of the solution for separation of the matrix. About half of the time indicated is taken up by the separation, and the remainder by the preparation of the solution for the voltammetric determination. Direct determination of 2.0 ppm of antimony is possible only in bismuth. The antimony determinations are carried out with a carbon paste electrode by the addition method.

Investigations on Neutron-Induced Radiation Damage in KCl Single Crystals

By *M. Müller*[*]

The mobility of argon that can be formed by the (n,p) nuclear reaction, which is very strongly dependent on the irradiation defect concentration[1], was used as an indicator of radiation damage. An activation energy of $\Delta H = 1.9$ eV was found for the annealing of the radiation damage, which occurred preferentially on the surface of the single crystals. It was therefore concluded that the neutron irradiation probably leads to the formation of small vacancy clusters, which are broken down at the surface on heating.

The extent to which an interpretation of the gas release kinetics is still possible was investigated[2]. A homogeneous defect concentration has been assumed in the past, but this is no longer present because of the healing. It was found that the diffusion coefficients must be discussed as a function of position and time.

Volatilization of Fission-Product Chlorides from Solid UCl_4

By *Bernd Neidhart* (lecturer), *Knut Bächmann*, *Silke Kubny*, *K. H. Lieser*, and *Elke Stoll*[*]

For the development of targets for on-line experiments on nuclear reactors, UCl_4 and mixtures of $^{235}UCl_4$ with KCl, $SrCl_2$, and YCl_3 were irradiated in the reactor, and the volatilization of chlorides of the fission products Zr, Nb, Mo, Tc, and Te was investigated as a function of the temperature and of the matrix. Between 30% (Zr) and 80% (Tc) of the fission products formed can be volatilized from UCl_4 as the chlorides at about 400 °C. The delay times in the target are 15 to 40 s. Only a slight improvement results when the temperature is raised to 600 °C (m.p. of UCl_4). A clean separation of the products cannot be achieved by variation of the temperature. When $^{235}UCl_4$ is mixed *e.g.* with $SrCl_2$ in a ratio of 1:30, Tc leaves the target at 550 °C and Te at 680 °C, while the other elements are retained up to 800 °C. KCl and YCl_3 show similar effects. With a suitable choice of the matrix and of the temperature, Tc and Te can be separated from the other fission products, and Tc can even be separated from Te.

Gallium Arsenide Whisker Growth by the VLS Mechanism

By *W. Just*, *J. J. Nickl* (lecturer), and *H.-J. Kaiser*[*]

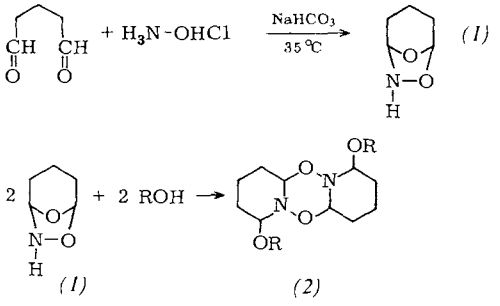
The growth of gallium arsenide crystals in the system $Ga—AsCl_3—H_2$ was investigated with quartz and GaAs substrates coated with liquid gallium to induce whisker growth by the VLS mechanism. The morphology of the GaAs crystals is largely determined by the temperature. Whisker growth was observed between 550 and 680 °C. In the lower temperature range (< 640 °C), only ⟨111⟩-oriented needles twinned perpendicular to the growth direction were found. Only ⟨112⟩ blades twinned parallel to the growth direction grew in a higher temperature range (> 640 °C).

[*] Dipl.-Phys. W. Just, Dr. J. J. Nickl, and Dr. H.-J. Kaiser
Forschungslaboratorium für Festkörperchemie der Universität
8 München 23, Leopoldstrasse 175 (Germany)

A new type of whisker, rosette whiskers, was found in the region of needle growth.

The same temperature dependence of the whisker morphology is observed when the gallium is replaced in the reaction system by CH_3GaCl_2 or $GaCl_3$.

The temperature dependence of the electric properties of the GaAs whiskers is comparable with that of epitaxially deposited GaAs layers produced under similar conditions.



New Reaction Products from Glutaraldehyde, Hydroxylamine, and Alcohols

By *Gerd Eikelmann, Werner Heimberger, Gerhard Nonnenmacher* (lecturer), and *Wolfgang Weigert*[*]

A uniform reaction product is obtained from glutaraldehyde and 1 mole of hydroxylammonium chloride only under certain conditions. If a molar solution of hydroxylammonium chloride is added dropwise to an aqueous solution of glutaraldehyde at 35 °C over a period of 60 min, the acid liberated being intercepted by acid acceptors, a colorless product, m.p. = 169—171 °C, is obtained in more than 80% yield; on the basis of the element analysis, and the IR and mass spectra, this product is assumed to have the structure *(1)*. The product *(1)* can be converted into the dioxime by reaction with further hydroxylamine.

If *(1)* is heated for a short time with methanol or allowed to stand for a few hours at room temperature in suspension in methanol, thorough drying and repeated recrystallization from CH_2Cl_2 leads to more than 80% yield of a substance having m.p. = 155—160 °C, whose IR, NMR, and mass spectra indicate the structure *(2)*. In a similar way the reaction of *(1)* with ethanol leads to an ethoxy compound of structure *(2)*.

Unlike *(1)*, which is insoluble in water and in the common organic solvents, *(2)* dissolves readily in all lipophilic solvents.

A Vector Scheme for Separation Processes

By *Holm Pauschmann*[*]

All processes for the separation of matter on the basis of differences in migration velocities are traced back to combinations of three elements:

1. migrations in which the individual types of particles move with different velocities,

2. displacements that influence all types of particles to the same extent,

3. gradients that modify migrations or displacements.

Because of their direction in space, these elements are vectors, from which it is possible to develop a theoretical "building block system" that can be used for the interpretation of existing separation processes and for the development of new processes. Some examples of new or possible processes were described, and the conclusions collected into fundamental rules.

Dependence of the Enzyme Mechanism on Allosteric Effectors in the Case of Isocitrate Dehydrogenase

By *Dieter Palm* (lecturer) and *H. Katzendobler*[*]

The dependence of the isotope effect of *threo*-D_s-[2-^{3}H]-isocitrate and of the activation energies on the substrate concentrations and the presence of the effector 5'-AMP in the reaction of isocitrate dehydrogenase from yeast indicated a dependence of the enzyme mechanism on the ligands. A "random order rapid equilibrium mechanism" at low NAD concentrations is replaced by a "compulsory ordered mechanism" at high NAD concentrations or in the presence of 5'-AMP. This showed that pure allosteric K systems (classification of *Monod, Wyman*, and *Changeux* —different affinity for different enzyme states) probably do not exist. As in the example described, a conformation of the binding site(s) that leads to a different affinity also influences the kinetic behavior of the enzyme.

Electron Spin Resonance of ^{99}Tc(IV) in $K_2[PtF_6]$ and SnO_2

By *H. H. Pieper* (lecturer), *W. Krasser*, and *K. Schwochau*[*]

The ESR hyperfine structure spectra of ^{99}Tc(IV) in $K_2[PtF_6]$ and SnO_2 single crystals were measured in the Q band at 77 °K and 4.2 °K resp., and depending on the crystal orientation. The spectrum of the fluoro complex with 10 HFS lines corresponding to the nuclear spin 9/2 ħ of Tc-99, shows strong anisotropy in agreement with results of vibrational spectroscopy, which is, to a first approximation, attributable to a trigonal distortion of the octahedral ligand field.

The line-rich, orientation-dependent SHFS spectrum of doped SnO_2 single crystals can be explained by the interaction of the Tc(IV) with the adjacent Sn atoms. The term splitting of the Tc(IV) is due to the nearly octahedral ligand field of the oxygen atoms and the adjacent Sn atoms.

Both spectra were described with suitable spin-Hamilton operators, and the constants were calculated.

Binary Compounds of Boron with Main Group V Elements with Retention of Basic Icosahedral Frameworks: Tetragonal Boron Nitride and Rhombohedral Boron Phosphide

By *Klaus Ploog* (lecturer), *Peter Rauh*, *Wolfgang Stoeger*, and *Herbert Schmidt*[*]

In an experimental apparatus of new design, we were able to prepare a tetragonal boron nitride having the composition $B_{53}N$ to $B_{28}N$ by pyrolysis of BBr_3—H_2-mixtures and additional N_2 on BN-substrates at 1150 to 1500 °C. With rising preparation temperature, the content of nitrogen in the grown material increases from 2.40 to 4.50 wt.%; the densities increase in the same order from 2.404 to 2.460 g/cm³, and the lattice constants a from 8.79 to 9.02 Å and c from 5.08 to 5.26 Å. The structure of this compound is derived from the lattice of the so called I-tetragonal boron: The basic I-tetragonal framework with four B_{12}-icosahedra and two single B-atoms is preserved, and the N-atoms occupy one or two of the larger tetrahedral holes.

In a similar manner we obtained a rhombohedral boron phosphide having the composition $B_{48}P$ to B_9P by pyrolysis of BBr_3—PBr_3—H_2-mixtures on tantalum wires at 1150 °C. Despite their wide range of compositions, the products are derived from the same basic framework: As in boron carbide $B_{13}C_2$, rhombohedrally linked B_{12}-icosahedra form large elongated cavities in the [111]-direction, in which theoretically five sites per unit cell can be occupied by single B- and/or P-atoms. With rising phosphorus content a three-dimensional lattice expansion is oberved; a increases from 5.83 to 5.99 Å and c from 11.71 to 11.98 Å (rhombohedral: a from 5.15 to 5.29 Å and α from 68.9 to 69.8 Å). The hexagonal a to c ratio remains nearly constant. The question which of the available sites along [111] are occupied by B- or P-atoms depends very strongly on the preparation conditions.

Low-Yield Nuclear Reactions Induced by Fast Neutrons, Particularly (n,t) Reactions

By *S. M. Qaim* (lecturer), *Robert Wölfle*, and *Gerhard Stöcklin*[*]

Little is known as yet about the systematics of low-yield nuclear reactions induced by fast neutrons, particularly (n,t) processes. However, an accurate knowledge of these reactions is of practical interest in connection with the evaluation of undesirable production of tritium in high-flux reactors and for the planning of future fusion reactors. Using radiochemical methods in conjunction with γ-spectrometric, γ,γ-coincidence, and low-level measuring techniques, the cross sections for (n,t) reactions were determined for ^{89}Y and ^{204}Pb with very fast reactor neutrons (> 10 MeV), for ^{50}Cr, ^{54}Fe, ^{64}Zn, ^{92}Mo, ^{139}La, and ^{197}Au with 14.7 MeV neutrons, and for ^{24}Mg, ^{50}Cr, ^{56}Fe, ^{58}Ni, ^{90}Zr, ^{112}Sn, ^{120}Te, ^{133}Cs, ^{197}Au, and ^{204}Pb with approximately 25 MeV neutrons. In addition to the product nuclei, tritium was also separated and measured in some cases. The dependence of the $\sigma(n,t)$ values on the nuclear charge Z of the target for $Z > 10$ shows a maximum at about $Z = 26$, as in the case of the (n,p) reactions. The expected dependence on the relative neutron excess $(N-Z/A)$ is observed for the elements with $Z > 22$, with no indication of shell effects.

Photochemical Intermediates in Organic Synthesis

By *Horst Prinzbach*[*]

Norbornadienes and 7-methylene, 7-oxa, or 7-aza derivatives are converted into the tetracycles by a (very probably two-step) cycloaddition on *direct* photoexcitation. The high energy content of these photoproducts, which are mostly kinetically very stable, can be utilized for numerous valuable reactions. Isomerizations of the type $2\sigma \rightarrow 2\pi$ and $3\sigma \rightarrow 3\pi$ are often quantitative, and yield *e.g.* specifically substituted heterotropilidenes; additional isomerization pathways are opened up by metal catalysts. Ionic additions to the σ skeleton are largely stereoselective. Reactions with a series of "bishomodienophilic" reagents result in generally stereospecific cycloadditions in positions 1,5 2,4 or 1,4. The behavior of the norbornadienes and of the 7-hetero analogs on *sensitized* photolysis is not uniform. Nevertheless, 6-hydroxyfulvenes and 6-aminofulvenes can be obtained in reasonable yields in this way.

Intramolecular photochemical $[2\pi+2\sigma]$ cycloadditions in substrates such as cyclopropanorbornene, monohomobarrelenes, and bishomobarrelenes, as well as in additionally bridged systems, proceed with preparatively satisfactory results when the steric conditions are suitable. Photoisomerizations of this type can occasionally also be achieved on replacement of the cyclopropane ring by an oxirane or aziridine ring. The *cis, cis, cis-* and *cis, cis, trans*-trishomobenzene products and the bridged systems of the "mitrane" type are particularly interesting here.

The Pesticide Problem in Water Pollution

By *K.-E. Quentin*[*]

About 40% of the water requirements in the German Federal Republic is supplied directly or indirectly from surface water (rivers, lakes, dams), which is contaminated to a greater or lesser degree by its environment. One of the current pollution problems is concerned with the occurrence, behavior, and removal of pesticides. The small quantities of pesticide present in water contaminated with a wide variety of substances require special methods of sampling and quantitative determination, which were briefly described. Methods that rapidly indicate any danger to water are becoming increasingly important. Pesticide studies in this connection have been concerned with the determination of total contents of insecticidal esters of phosphoric acid and carbamates by enzymatic test methods, as well as with the adsorption of chlorinated

[*] Prof. Dr. K.-E. Quentin
Institut für Wasserchemie und Chemische Balneologie der Technischen Universität
8 München 55, Marchioninistrasse 17 (Germany)

hydrocarbons on plastic films suspended in the water. Investigations on the kinetics of the adsorption process have led to new approaches to the simplification and acceleration of pesticide checks.

As far as the behavior of pesticides is concerned, studies have been carried out on the changes undergone by insecticidal esters of phosphoric acid in water, *e.g.* on the rate of hydrolysis of parathion under natural conditions and on its microbiological conversion into aminoparathion. The investigations on the relations between pesticides dissolved in water and those bound to solid material suspended in the water are significant in view of the persistence of chlorinated hydrocarbons and their accumulation in the biological chain. Since the various harmful substances do not occur singly in water, it is difficult to estimate a danger situation. A model was therefore developed for the representation of the toxic summation effect of the harmful substances present; the experimental checking of this model is an important task for the future.

The presence of pesticides in water must also be taken into account in the various processes for the preparation of drinking water. Results of investigations on the ozonization of water under waterworks conditions and on the effect of this measure on pesticides of the chlorinated hydrocarbon group were finally reported.

Possibilities of Fast Liquid Chromatography

By *Dieter Randau*[*]

The aim of fast liquid chromatography is the column-chromatographic separation of a mixture of substances and the simultaneous acquisition of quantitative information about the composition. Instruments with high-pressure pumps and sensitive detectors, as well as injection systems with very low dead volumes, are necessary for this purpose.

Silica gels, glass spheres coated with silica gel, and gels are generally used as chromatographic supports. The separation is strongly influenced by the manner in which the column is packed, by the particle size, by the speed of the mobile phase, by the activity of the support, and by eluent exchange. The possibilities of fast liquid chromatography that exists when these parameters are taken into account were demonstrated.

Polymer Melts as Viscoelastic Liquids

By *Falko Ramsteiner*[*]

Polymer melts are viscoelastic liquids, the study of which is important to many fields. For example, the chemist can draw conclusions concerning certain molecular parameters of polymers from the rheological data for molten polymers, the physicist can carry on the development of the nonlinear viscoelasticity theory by rheological studies on polymer melts, and the engineer must take the viscoelastic properties into account in the design of processing machineries and in the assessment of the service characteristics of plastic end products.

[*] Dr. F. Ramsteiner
Badische Anilin- & Soda-Fabrik AG
67 Ludwigshafen (Germany)

At low shear rates, most molten polymers exhibit linear viscoelastic behavior as described by the theory of linear viscoelastic bodies. In this theory, quantitative relations exist between the relaxation, stressing, oscillation, and creep behavior (under both shearing and tensile stresses), which are illustrated by some practical examples. The time-temperature behavior is that of a thermo-rheologically simple body. The elastic and viscous properties reflect the molecular weight and the molecular weight distribution.

At high loading rates, the deformation behavior of molten polymers is strongly nonlinear, as is shown by a strong dependence of the viscosity and elasticity on the nature of the load and the occurrence of normal stresses. Finally, some consequences of this nonlinear behavior with regard to processing were mentioned (melt fracture, secondary flow).

The Acid Metabolism in Grapes

By *Adolf Rapp* (lecturer), *Heinz Steffan*, *Gerhard Kupfer*, and *Herbert Ullemeyer*[*]

The acid content of grapes increases during the growth of the berries, reaches a maximum 5—9 weeks after flowering, and then decreases during the ripening of the berries. The start of the incorporation of sugar into the berries coincides with the time of the maximum acid content.

The individual acids differ in their behavior. The malic acid concentration increases gradually after flowering, passes through a maximum, and decreases again during ripening of the berries. The tartaric acid content, on the other hand, reaches a maximum only 4—7 weeks after flowering, and then remains substantially constant during further development of the berries.

By the use of radioactively labeled malic acid, we were able to show that about 60% of the malic acid was consumed in respiration within 15 hours before the acid maximum (30 °C, dark experiment), and more than 90% after the acid maximum. This high activity in the respiratory CO_2 shows the large extent to which malic acid is used as a respiration substrate in ripening berries. The biological half-life of malic acid is between 8 and 13 hours, depending on the stage of growth or ripening of the berries.

The distribution of the radioactivity in the berries shows that acids, amino acids, and sugars are synthesized from the C structure of malic acid during the entire growth and ripening phase. Tartaric acid, on the other hand, is used only to a small extent in respiration, and the quantity used shows no temperature dependence.

The Glass State of High Polymers

By *Günther Rehage*[*]

The nature of the glass state of high polymers was discussed. The results of recent volume, specific heat, torsion modulus, thermal conductivity, and NMR measurements were dis-

[*] Prof. Dr. G. Rehage
Physikalisch-Chemisches Institut der Technischen Universität Clausthal
3392 Clausthal-Zellerfeld, Adolf-Römer-Strasse 2A (Germany)

cussed in this connection. The measurements were carried out over a wide temperature range in the region of the glass transition temperature. Compressibility measurements were also carried out as a function of pressure up to about 10000 atm. It is concluded from the results of the measurements that the vitrification is a freezing-in process. It is not a second order transition, as is often claimed in the literature. Consequently, the Ehrenfest equations for a second order transition are inapplicable. There is also no indication that a second order transition takes place below the glass temperature, as has been suggested by various authors.

The Importance of Microorganisms in the Production of Foods

By *H. J. Rehm*[*]

For thousands of years, there have been foods that are produced with the aid of microorganisms. There has been a steady increase in the number of such foods as a result of modern technical advances. Microorganisms are involved in the production of a number of conventional foods, particularly leavened bread, wheaten breads, alcoholic beverages, various kinds of sausages, numerous milk products, and a number of pure substances such as acetic acid, lactic acid, citric acid, and vitamin C.

Though the production of the above foods is well known, new microbiological technologies have led to several further developments in the production processes.

In addition to these conventional foods, new foods or new substances used in the food industry are produced microbiologically. These include many enzymes, microbiological proteins from various carbon sources, including protein from algae and mushrooms grown by submerged culture, amino acids, and 5'-nucleotides.

As in the USA, attempts will undoubtedly also be made in the German Federal Republic to introduce microbial foods that are already well known in other parts of the world, *e.g.* in Eastern Asia. These include soybean products such as miso and shoyu, fish products, and many others. Examples are nata, sufu, tempeh, prahoc and gari.

Novel Trinuclear Polymethinecyanine and Polymethinemerocyanine Dyes

By *Christian Reichardt* (lecturer) and *Werner Mormann*[*]

The three aldehyde groups of formylmalonaldehyde $CH(CHO)_3$, which has recently become obtainable, can be made to react in succession, under suitable reaction conditions, with the heterocyclic *N*-alkylimmonium salts that are common in cyanine chemistry in the sense of a base-catalyzed aldol condensation.

Reaction of formylmalonaldehyde with *N*-alkylimmonium salts in equimolar quantities yields novel, negatively solvatochromic γ-formyltetramethinemerocyanine dyes; the same reaction in a molar ratio of 1:2 leads to the hitherto unknown γ-formylpentamethinecyanine dyes. Symmetrical, trinuclear [2.2.2]heptamethinecyanine dyes are obtainable for the first time by condensation of the two reaction partners in a molar ratio of 1:3. The isolation of the monocondensation and dicondensation products of formylmalonaldehyde also allows the preparation of unsymmetrical, trinuclear [2.2.2]heptamethinecyanine dyes.

These trinuclear cyanine dyes may be regarded as vinylogous, or more generally methine-homologous, guanidinium ions, by analogy with the phenylogous guanidinium ions (aminotriphenylmethane dyes).

The spectral properties of the new dyes were described as a function of structure and solvent together with the results of simple HMO calculations.

Chemical Determination of Amino End Groups in Polyamide Fibers

By *Volker Rossbach*[*]

The reaction of nylon 6 and nylon 6,6 with 2,4-dinitro-1-fluorobenzene[1] in the homogeneous phase (trifluoroethanol) leads to a polymer whose amino groups are *completely* dinitrophenylated. With dinitrophenyl-oligomers as calibration substances, the reaction is used as a specific photometric method for the determination of amino end groups. Its reproducibility is similar to that of the potentiometric method. UV spectroscopic studies on model substances (dinitrophenylamines) and on the methylated polymer show that the new analytical method also allows the differentiation of primary and secondary amino groups and their determination in the presence of each other. A related topic is the detection of heat damage in polyamides. Heat treatment leads to the formation of basic groups, which are detected spectroscopically as the dinitrophenyl derivatives. Another application of the dinitrophenyl method is the difference analysis of fibers dyed with reactive dyes. Thus for Remazol Brilliant Blue R® (vinyl sulfone dye), it is found that about 50% of the amino end groups have reacted.

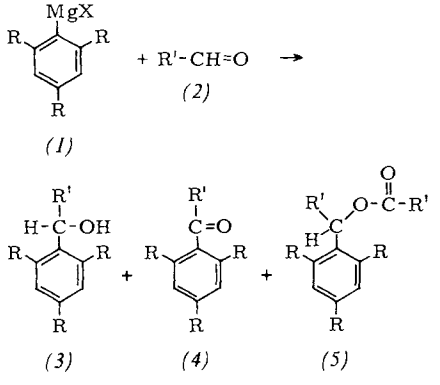
Pulse Radiolysis in the Gas Phase: the Formation of the Azide Radical in Pure Nitrogen and in Nitrogen Containing Additives

By *E. P. Röth* (lecturer), *J. W. Dreyer*, and *D. Perner*[*]

On irradiation of nitrogen at a pressure of 1—3 atm with fast electrons (600 kV), the azide radical is formed as an intermediate. The yield and formation of N_3 in the electronic ground state $^2\Pi_g$ was measured by kinetic absorption spectroscopy.

In pure nitrogen, the formation of the azide radical can be described by the rate constants of two consecutive reac-

[*] Dipl.-Phys. E. P. Röth, Dipl.-Phys. J. W. Dreyer, and Dr. D. Perner
Institut für Physikalische Chemie der Kernforschungsanlage Jülich
517 Jülich, Postfach 365 (Germany)



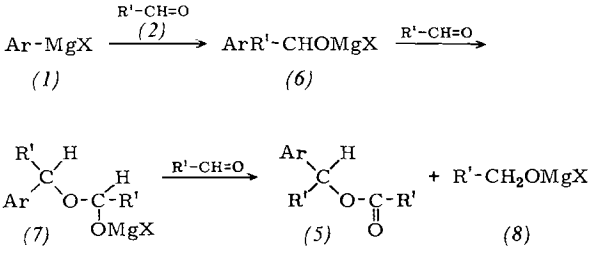
tions. The 100 eV yield increases with the nitrogen pressure, and is approximately 0.2 at 3 atm. The presence of small quantities of, for example, ammonia or cyclopropane leads to much faster formation of N_3. The 100 eV yield is 1.1 in a mixture of 7 torr of cyclopropane in 3 atm of nitrogen.

The formation of N_3 in pure nitrogen is attributed to a reaction of excited neutral particles, whereas on addition of NH_3 or cyclopropane, the N_3 is formed by a complicated ion-molecule mechanism.

Esters of Carboxylic Acids from Aldehydes and Grignard Compounds

By *Anton Rieker* and *Yasuo Butsugan*[*]

Sterically hindered aromatic Grignard compounds *(1)* react with aldehydes *(2)* to form alcohols *(3)*, and under some conditions also to form ketones *(4)* or esters *(5)*:



(1) *(2)* *(3)* *(4)* *(5)*

R	R'	*(1)*:*(2)* Mol.-ratio	Yield (%) *(3)*	*(4)*	*(5)*
CH_3	C_6H_5	1:3	trace	27	42
		1:2	17	34	10
$CH(CH_3)_2$	C_6H_5	1:3	—	[a]	52
$C(CH_3)_3$	C_6H_5	1:3	—	—	55
		1:1	60	—	—
$C(CH_3)_3$	CH_3	1:3	24	—	—
$C(CH_3)_3$	H	1:3	5 [b]	—	29 [b]

[a] Detected, but not isolated.
[b] Total yield of *(3)* + *(5)* before separation: 71%.

In every case, *(1)* and *(2)* first give the magnesium compound *(6)* of the alcohol *(3)*. If "oxidizing" aldehydes ($R'=H, C_6H_5$) are used in excess, *(6)* is either dehydrogenated by the aldehyde in a sort of Oppenauer reaction to form the ketone *(4)*, or first adds on the aldehyde to form *(7)*, which is then oxidized to *(5)*. This is accompanied by the simultaneous formation of *(8)*:

(1) *(6)* *(7)* *(5)* *(8)*

[*] Doz. Dr. A. Rieker and Dr. Y. Butsugan
Chemisches Institut der Universität
74 Tübingen, Wilhelmstrasse 33 (Germany)

The highest yields of *(5)* are thus obtained when the oxidizing aldehyde *(2)*, $R'=H, C_6H_5$, is present in a 3 M excess. The alcohol to be expected from hydrolysis of *(8)* is found for $R'=C_6H_5$. With "nonoxidizing" acetaldehyde *(2)*, $R'=CH_3$, no ester formation was detected. The yield of *(5)* increases with increasing bulk of the residue R in *(1)* (for R = H: 0%). It appears that the direct Oppenauer oxidation of *(6)* to *(4)* becomes increasingly difficult in this order for steric reasons, with the result that the addition of *(6)* to *(2)* to form *(7)* with subsequent dehydrogenation to give *(5)* predominates.

Maximum Column Inlet Pressure—An Optimum Parameter for Gas-Chromatographic Separations

By *Lutz Rohrschneider*[*]

After a survey of the rules known at present for the optimization of gas-chromatographic separations, the importance of the column inlet pressure for fast analyses with high separation efficiencies is discussed. Practically all the separations investigated that are not carried out with maximum column pressure can be carried out in a shorter time with the same separation efficiency or in the same time with a higher separation efficiency.

Practical examples are described to show that the maximum resolution in a given time for a given column packing is achieved at the maximum pressure with a column length that depends on the column temperature.

Mechanism of Solid-State Reactions in Hexahalorhenates

By *K. Rössler* (lecturer) and *J. Otterbach*[*]

The thermal annealing of nuclear recoil halide ions in crystalline hexahalorhenates(IV) can be largely attributed to two processes: a solid state exchange *via* ligand vacancies throughout the crystal[1], and combination processes within the disturbed zone produced by the recoil atom. The latter exhibit considerable field effects. In $K_2[ReCl_6]$ and $K_2[ReBr_6]$, electric fields (3—5 kV/cm) inhibit the annealing of recoil halide, whereas the ligand exchange in the corresponding doped systems is not affected. The inhibition decreases with increasing annealing temperature and, in the case of alternating fields, with the frequency. No further inhibition is found at about 200 cycles in the system $^{38}Cl^-/K_2[ReCl_6]$ and at about 110 cycles in the system $^{82}Br^-/K_2[ReBr_6]$.

The rapid hot reactions occurring during irradiation have been studied in $K_2[ReCl_6]/K_2[ReBr_6]$ mixed crystals of varying compositions. The formation of the ^{38}Cl- and ^{82}Br-labeled products can be explained by mechanisms involving zero (primary retention), first (direct substitution) and second order reactions (multi-step process *via* ligand exchange).

Medium-Sized Rings of the Peptide Type

By *Manfred Rothe* (lecturer), *Wolfgang Schindler*, *Rainer Pudill*, *Michael Kostrzewa*, and *Rainer Theysohn*[*]

The formation tendency of medium-sized rings of the peptide type on cyclization of linear active peptide derivatives and on incorporation of aminoacyl residues into amide linkages of lactams and diketopiperazines was reported.

Cyclotripeptides, *e.g.* *c*-Sar-Pro-Pro, can be obtained only in exceptional cases from *N*-alkylamino acid peptides and on incorporation of β-amino acids. The ring closure of tripoline is examined as a function of the solvent; high yields of *c*-$(Pro)_3$ are obtained if a chain conformation with *cis*-peptide linkages is stabilized, *e.g.* in pyridine.

N-(mono-β-alanyl)glycine anhydride, *N*-(mono-β-alanyl)-glycine-sarcosine anhydride, and *N*-(mono-β-alanyl)-glycine-L-proline anhydride form ten-membered cyclic tripeptides on aminoacyl incorporation, with intermediate cyclol formation. Similarly, the cyclic tetrapeptide *c*-Pro-Gly-Pro-Gly is formed from *N*,*N'*-bis-(L-prolyl)glycine anhydride. Unstable cyclotripeptides undergo transannular reactions with formation of bicyclic cyclols, anhydrocyclols, and acylamidines.

Gas-Chromatographic Determination of Arsenic

By *Harald Rüssel* (lecturer) and *Georg Schwedt*[*]

The investigation of some organic arsenic derivatives for quantitative formation, vaporizability, and determinability with the flame ionization detector showed that triphenylarsane is particularly suitable for the gas-chromatographic determination of arsenic. A fast method was developed for forensic purposes. The organ material is dried and burnt in a Schöniger flask. The arsenic in hydrochloric acid solution is extracted as the dithiocarbamate, which is treated with diphenylmagnesium to obtain triphenylarsane and determined by gas chromatography. As little as 1 μg of As/g can be determined in 100 mg of organ; the operation takes $1\frac{1}{2}$—2 hours. Other metals that can be extracted as dithiocarbamates are partly also converted into phenyl compounds, but these are separated gas-chromatographically.

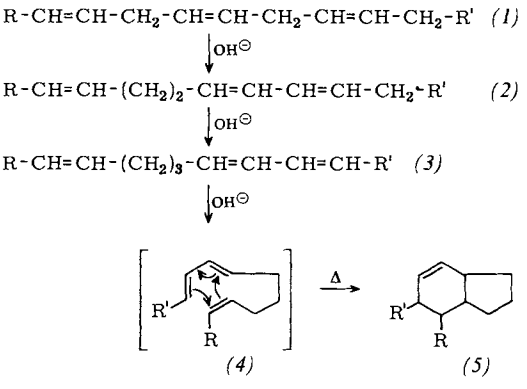
3 Hannover, Bischofsholer Damm 15 (Germany)

Potassium Intercalation Compounds in Carbon Fibers

By *W. Ruland*[*]



The incorporation of potassium into carbon fibers is investigated by thermogravimetric, electric, and mechanical measurements and by X-ray diffraction (small-angle and large-angle scattering). It is found that despite the absence of discrete absorption stages below the saturation value, defined intercalation compounds of the first stage (insertion between every pair of carbon layers, C_8K) and of the second stage (insertion between every second pair of carbon layers, $C_{16}K$ to $C_{24}K$) are formed. The preferred orientation and the pore structure of the fibers are not affected by the incorporation; the color, as in the case of graphite intercalation compounds, is bronze-brown for the first stage and steel blue to black-blue for the second stage. The X-ray studies show that the potassium layers both in the first and in the second stage are hexagonally close-packed. The transition from the composition $C_{16}K$ to $C_{24}K$ in the second stage is the result of an increase in the concentration of randomly distributed vacancies in the two-dimensional potassium lattice with progressive desorption.

Synthesis of Indanyl Derivatives from Linear Unsaturated Compounds

By *A. N. Sagredos* (lecturer), *J. D. von Mikusch-Buchberg*, and *Viktor Wolf*[*]

On cyclization of 9,12,15-octadecatrienoic acid *(1a, 1b)* with alkali, the formation of bicyclic carboxylic acids having an indan structure was observed. The following reaction course was proposed:

(a), R = C_2H_5, R' = $(CH_2)_6$-COOH
(b), R = $(CH_2)_7$-COOH, R' = CH_3
(c), R, R' = H, Alkyl

The correctness of this course has been confirmed by synthesis of the postulated intermediates *(2a)* and *(3a)* and their conversion into the indan *(5a)*.

Directionally Solidified Alloys for High-Temperature Applications

By *P. R. Sahm*[*]

Directional solidification represents a method in which the heat flow at the growth front is regulated by the solidification rate and the temperature gradient. This method has proved valuable in the production of high-

[*] P. R. Sahm
Brown Boveri Research Center
CH-5401 Baden (Switzerland)

temperature alloys, particularly what concerns eutectic and the conventional superalloys based on cobalt and nickel, since it brings a remarkable improvement of the mechanical properties. The improvement of properties is mainly due to the unilateral alignment or the complete absence of grain boundaries. Grain boundaries are normally starting points for crack formation, preferred loci for plastic deformation, and areas of increased diffusion. Their absence thus increases the time-dependent creep and the fatigue strength as well as the corrosion resistance. The incorporation of directionally oriented highly elastic phases in one-dimensional, two-dimensional, and three-dimensional forms will, in addition, considerably favor the mechanical properties (yield point and tensile strength) in certain directions. They will be useful wherever anisotropic stress applications are required. Alloys of this type obtained by directional solidification are therefore likely to become the next generation of superalloys.

Adsorbed Layers on Platinum Electrocatalysts

By *Horst Binder, Alfons Köhling,* and *Gerd Sandstede* (lecturer)[*]

Even below their reduction potential and above their oxidation potential, substances are stable in various electrolytes if they are present as monoatomic surface layers. We have investigated the adsorption of elements of the sixth main group on platinum electrodes by the non steady state voltammetric method. Smooth platinum (platinum gauze) and porous platinum (Raney platinum) behave in fundamentally the same way. We have also measured the influence of partial monatomic layers of adsorbed elements on the chemisorption of carbon monoxide, carbon dioxide, formic acid, formaldehyde, and methanol. Potentiodynamic current-voltage curves show that the chemisorption strength of the carbonaceous products changes only when the major part of the platinum surface is covered with the adsorbed element. The adsorbed elements accelerate the anodic oxidation of some substances and retard that of others.

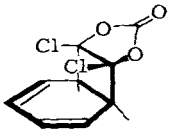
The Influence of Dispersion on the Coloristic Properties and Fastness Properties of Molybdate Red Pigments

By *Hugo Schäfer*[*]

The color shift of molybdate red pigments toward yellower hues with increasing dispersion time increases with increasing particle size of the pigment under identical external conditions. On the basis of colorimetric investigations, thin-layer electron micrographs, and X-ray diffraction diagrams, it is shown that this color shift is mainly due, not to a simple decrease in the size of the crystals, but to a change in the crystal modification.



The stabilization-dependent fastness properties, such as light fastness and SO_2 resistance, decrease in molybdate red pigments with increasing dispersion time. This decrease in fastness is partly due to mechanical damage to the stabilizing oxide layer on the pigment grain. Moreover, free, unstabilized fracture surfaces are produced as a result of splitting of the crystals, particularly in the case of large-particle pigments. The observed loss of fastness is therefore greater for large-particle than for small-particle pigments under the same conditions.

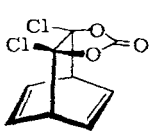
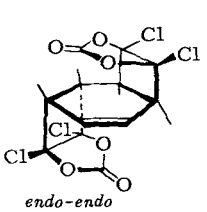
623 Frankfurt/Main 80 (Germany)

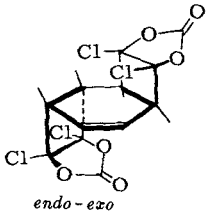


Photosensitized Cycloaddition of Dichlorovinylene Carbonate to Benzene

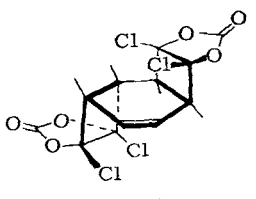
By *Hans-Dieter Scharf* (lecturer) and *Reinhard Klar*[*]



The photochemical cycloaddition of dichlorovinylene carbonate (DCVC) to benzene with acetophenone or acetone as a sensitizer leads to the 1:1 cycloadducts *(1)* and *(2)* and the three stereoisomeric 2:1 cycloadducts *(3a)—(3c)*.



(1) m.p. 147 °C



(2) m.p. 194 °C

endo-endo
(3a) m.p. 231 °C

endo-exo
(3b) m.p. 200 °C

exo-exo
(3c) m.p. 244 °C

The structures of these compounds have been verified, and their formation pathways have been investigated. The reaction is based on a triplet mechanism.

The initially formed cycloadduct *(1)* reacts further in the following ways:

1. photosensitized rearrangement into *(2)*, 2. retrocleavage into benzene and DCVC, 3. dimerization to form 2:2 cycloadducts, and 4. formation of the 2:1 cycloadducts *(3b)* and *(3c)* by addition of a further molecule of DCVC.

The existence of *(3a)*, exclusively formed in the reaction mixture of benzene and DCVC, indicates the intermediate occurrence of the *endo*-isomer of *(1)*, which, however, cannot be isolated. An alternative formation path for *(3a)* *via* a charge-transfer complex can be excluded.

Use of Gel Permeation Chromatography in the Analysis of Fats

By *Harry Scharmann* (lecturer) and *Manfred Unbehend*[*]

Gel permeation chromatography is a suitable method for the assessment of chemical changes in plant and

[*] Dr. H. Scharmann and Dr. M. Unbehend
Unilever Forschungsgesellschaft mbH
2 Hamburg 50, Behringstrasse 154 (Germany)

animal fats as a result of thermal oxidation during deep-fat frying.

A series of examples are described to show that in addition to partial breakdown of the triglycerides, linkage of the triglycerides to form dimeric and higher molecular weight compounds also occurs. The formation of dimeric triglycerides is confirmed by gas-chromatographic and mass-spectrometric investigations on fractions isolated from a used frying fat by preparative gel permeation chromatography.

Additional information about the formation of oxidized triglycerides is obtained by liquid chromatography on analytical silica gel columns using the Pye liquid chromatography detector.

Investigation of the Reactions of CN-Radicals by Kinetic Spectroscopy

By *M. F. Kamat, D. Perner,* and *R. N. Schindler* (lecturer)[*]

CN-radicals were produced by pulsing gaseous samples of CH_3CN, CCl_3CN, BrCN and $(CN)_2$ respectively in the presence of up to 6 atm argon with 16 nsec pulses of fast electrons. CN formation is attributed to energy transfer from the pressure gas argon to the substrate molecules. In BrCN also the electron capture process contributes to CN-production:

$$BrCN + e^{\ominus} \rightarrow CN + Br^{\ominus}$$

From the rate of decay of the CN-absorption in the presence of additives, absolute rate constants were obtained for the abstraction from molecules like H_2, CH_4, C_2H_6, C_3H_8, $COCl_2$, CCl_4, H_2S, COS, O_2, *etc.* Besides the disappearance of CN, the formation of new absorptions was observed in a number of systems; *e.g.* with O_2 present, the radical NCO was detected; NCS absorption arises in systems containing COS and/or CS_2.

Rate constants were given and the mechanism of the processes was discussed.

Shift Reagents Without Heavy Metals for NMR Spectroscopy

By *G. P. Schiemenz*[*]

The use of lanthanide complexes as NMR shift reagents is limited to relatively few classes of compounds and solvents. For example, they cannot be used to resolve overlapping signals of phosphonium salts. If the onium center is chosen as the coordination site instead of an electron pair, and an aromatic ring current for the signal shift instead of the metal, one arrives at a valuable alternative which supplements the earlier method. Phosphonium ions form short-lived contact ion pairs, *e.g.* in methylene chloride, with aromatic anions. The center of negative charge is situated close to the phosphorus; α protons, and to a smaller extent β and γ protons, of the cation are sited over an aryl group of the anion, and their signals are displaced to higher fields. For α protons, the effect of the tetraphenylborate anion is usually greater than 1 ppm, and up to about 3 ppm in favorable cases, whereas the effect for β and γ protons is about 20% of the α value. The tris(2,2'-biphenylylene)phosphate ion is even more effective. For example, the signals of the methine protons in the benzhydryltriphenylphosphonium and fluorenyltriphenylphosphonium ions are completely separated from the aromatic signal. The ring current effect differs from the usual anion effect in (a) the magnitude, (b) the direction of the signal shift for β and γ protons, (c) the relative influence on methyl and benzyl protons, (d) the influence on the anisochrony of diastereotopic methylene protons in chiral cations, and (e) the influence on the rotational barrier of phosphonium-substituted dimethylbenzamides. The tetraphenylborates need not be prepared as such, but may be produced by the technique of exchange experiments in the measuring tubes. Salt mixtures give complete averaging, so that the signals can be placed at any desired position between the extreme values. The method can be applied to compounds with acidic functional groups.

Microbiological Problems of the Preservation of Foodstuffs

By *W. Schmidt-Lorenz*[*]

Like all biosynthetically formed organic material, the foods required for human nourishment are broken down and ultimately mineralized by the microorganisms that occur everywhere in nature. It is becoming increasingly important to improve the keeping qualities not only of the basic foodstuffs but also of the industrially prepared, ready-to-eat meals, which are much more susceptible to attack by microorganisms. The most important requirement is the greatest possible certainty that the foodstuffs are free from food-poisoning and pathogenic microorganisms.

There are fundamentally two methods of eliminating microorganisms and preventing microbial decay:

1. The partial or complete destruction or inactivation of the microorganisms in the food (pasteurization or sterilization) by physical methods, particularly heating or treatment with gases, and more recently treatment with ionizing radiation or chemical preservatives, or the mechanical removal of microorganisms from the substrate (by filtration).

2. Technological modification of the foodstuffs such that the conditions required for the growth of the microorganisms are no longer satisfied (drying, salting, acidification, candying, curing, cooling, and deep freezing).

The general requirements for maximum retention of food value and minimum modification of the food with simultaneous improvement of keeping qualities can probably be achieved only by production and processing of the raw materials under conditions that are as nearly sterile as possible and by a carefully selected combination of preservation means in accurately measured proportions. However, this will depend on a much better knowledge of the microorganisms that occur in the various foods and of their properties.

The C—H Acidity of Organic Nitriles

By *Wolffram Schröer* (lecturer) and *Ernst Lippert*[*]

With the interaction of the strong base hexamethylphosphoric triamide (HMPT) with a nitrile, *e.g.* acrylonitrile, in an inert solvent (CCl_4, cyclohexane) as an example, high-resolution nuclear magnetic resonance is used to examine the extent to which the complexes formed already have the structure postulated for the transition state of nucleophilic reactions. The proton and ^{13}C shifts and the coupling constants are obtained with LAOCOON III from the ABC or ABCX spectra and used for the calculation of the association constants and of the association energy.

An association constant of $K_x = 4.4$ and an association enthalpy of $\Delta H = -0.63$ kcal/mole are obtained for the association of the base with the α proton at 18 °C in CCl_4, while the values for the β-*trans* proton are $K_x = 9.1$ and $\Delta H = -1.1$ kcal/mole. The proton shifts are 1.013 and 0.305 ppm respectively toward lower fields, and the ^{13}C shifts are 0.49 and 2.99 ppm respectively toward lower fields. The experimental values are explained with the aid of results from CNDO calculations, taking into account the magnetic and electronic anisotropy.

Syntheses and Reactions of *N*-Chloropolyamides

By *Herman Schuttenberg* (lecturer) and *Rolf C. Schulz*[*]

Nylon 66, nylon 6, nylon 3, poly-*N*-benzylacrylamide, and other polyamides were chlorinated by various methods. The chlorinating agents used were (a) *tert*-butyl hypochlorite, (b) aqueous potassium hypochlorite solution, (c) chlorine dissolved in chloroform, and (d) chlorine oxide.

In accordance with equation *(1)*, for example, nylon 66 *(1)* gives *N*-chloro-nylon *(2)* with 70—100% of the calculated chlorine content (determined iodometrically).

(1) *(2)* (1)

Molecular weight determinations showed that only slight chain degradation occurs with *tert*-butyl hypochlorite. *(2)* is soluble in benzene, chloroform, or dioxane; the IR spectra lack the NH bands at 3300 and 3080 and the amide band at 1530 cm^{-1}.

(2) dissolved in benzene in the presence of pyridine oxidizes secondary alcohols to ketones at 35 °C (molar ratio of *(2)* : alcohol : pyridine = 1.1 : 1 : 1). The yields after 24 hours are 82—95% (determined by gas chromatography), and are higher in some cases than in comparison experiments with *N*-bromohydantoin and *N*-bromoacetamide. The oxidizing capacity decreases on heating or on UV irradiation of *(2)* (in solution or as a film), and the NH and amide bands reappear in the IR spectrum.

Use of Polymers as Packing Material in Gas Chromatography

By *Hans Schnecko*[*]

The use of three types of polymers for the preparation of efficient separating columns for gas chromatography was described.

1. Liquid ethylene-propylene copolymers can be used as the stationary phase on solid support materials. The separating efficiency for hydrocarbons, aromatic compounds, and other apolar substances is good. The columns are characterized by a remarkable thermal stability, and can be temperature-programmed up to 350 °C.

2. Liquid polyenes with functional end groups (*e.g.* bifunctional polybutadienes and polyisoprenes containing OH, SH, COOH, or Br) form excellent stationary phases for numerous classes of polar and apolar substances; the liquids can be fixed on the support, so that no bleeding from the column is possible.

3. Elastic and thermoplastic foams can be used as column packings in gas-solid chromatography. The products are best prepared by pregrinding. These columns are particularly suitable for the separation of polar components, which then exhibit little or no tailing. The glass transition points of the materials can be determined by *Guillet's* method, and the results agree with those obtained by other methods.

Measurement of Electron Capture Cross Sections

By *K. G. Mothes, E. Schultes* (lecturer), and *R. N. Schindler*[*]

The secondary electrons formed in an irradiated medium dissipate their excess energy in ionization and excitation processes. When their kinetic energy finally falls below the lowest excitation potential of the molecules surrounding them, the electrons are thermalized and disappear in reactions with electron scavengers and/or in neutralization processes.

Absolute rate constants for the capture of thermal electrons by suitable scavengers can be determined by electron cyclotron resonance. This new method is based on the measurement of the ECR signal in a rapidly flowing gas. It is shown that the integral over the absorption signal $\chi''(H)$ is a direct measure of the number of free electrons per unit volume. Effective cross sections can be determined from the change in the signal magnitude on addition of a scavenger.

The method was described and the influence of the experimental parameters discussed. Measurements on the best-known electron scavengers were reported.

Determination of the Wetting Behavior of Pigments

By *P.-J. Sell*[*]

In a number of industrial processes, it is very important to know the wetting behavior of powders and pigments. Methods of measurement have been described in which quantities connected with the surface energy (*e.g.* surface or interfacial tensions, contact angles) can be determined on planar surfaces, fibers, and acicular single crystals or on powders and pigments. An example is given to show that the results obtained by the three measurement methods agree. Heats of wetting can be determined from the temperature dependence of the adhesion tension.

Polarographic and Coulometric Reduction of Actinide(IV)Chlorides in Dimethyl Sulfoxide

By *Ludwig Astheimer* and *Klaus Schwochau* (lecturer)[*]

In order to determine the reduction behavior of the actinides in nonaqueous solvents and to detect their lower oxidation states the chlorides of tetravalent Th, Pa, U and Np were investigated in dimethyl sulfoxide by means of DC and AC polarography as well as potential-controlled coulometry. Two reduction waves were observed for $NpCl_4$ and UCl_4. According to coulometric analysis the first wave with $E_{1/2} = -0.47$ V and $E_{1/2} = -1.22$ V respectively (*vs.* S.C.E.) can be assigned to the reduction to the trivalent state, whereas the second wave with $E_{1/2} = -2.19$ V and $E_{1/2} = -2.16$ V respectively should correspond to the reduction to the metal. At $E_{1/2} = -1.49$ V $PaCl_4$ was also reduced to the metal but the desired trivalent state was omitted. $ThCl_4$ showed a diffusion controlled wave at $E_{1/2} = -1.64$ V which apparently leads to Th(II).

Mechanism of the Self-Adhesion of Macromolecular Films

By *Peter O. Seidler*[*]

The cause of the adhesion of adhesives, lacquers, metallic coatings, *etc.*, is of a complex nature. The adhesion consequently cannot be traced to a simple principle that could be used as a basis for predicting the possibility of obtaining a satisfactory bond in practice. The situation is simpler in the case of the adhesion of macromolecular films having the same composition (self-adhesion). In this case the physics of solids and of liquids, *i.e.* cohesion, microbrownian movement, diffusion, rheology, *etc.*, can be used to find an explanation, and together with the molecular structure they allow certain predictions regarding the conditions for optimum adhesion.

The microbrownian motion of macromolecule segments is of decisive importance to self-adhesion. This mobility is absent in the vitreous state; self-adhesion can occur only when there is adequate microbrownian motion of sufficiently large segments of macromolecules (ideal limiting case: liquid state). Polyethylene and polytetrafluoroethylene, which are not adhesive at room temperature, are therefore adhesives at higher temperatures. It can therefore be stated that when macromolecular substances are heated, they may pass through not only the states of a glass, a plastic mass, a rubber, and a liquid, but also an adhesive state, which differs from that of the liquid.

Gram-Scale Preparation of Americium

By *J. Cl. Spirlet* (lecturer) and *W. Müller*[*]

The complete reduction of americium oxide by molten lanthanum or ultrapure hydrogen necessitates shifting of the reduction equilibrium by either distillation of the americium metal[1] or formation of an intermetallic compound[2]. The americium can be separated from the condensed phases and purified by distillation or sublimation.

Several grams of ^{241}Am were prepared by lanthanum reduction of purified oxide or thermal dissociation of Pt_5Am. Repeated distillation and condensation of the metal vapor on tantalum yielded americium with 200 ppm O and 100 ppm N, respectively. By condensation on quartz, americium foils were obtained which could be shaped into electrodes. The samples are being used for the investigation of physico-chemical properties, *viz.*, metallography, crystal structure, heat of dissolution, electrochemical behavior in molten salts.

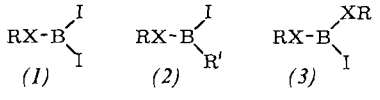
The Importance of Physico-Chemical Parameters to the Understanding of Drug Action and to the Rational Development of New Drugs

By *J. K. Seydel*[*]

Many theories, some of them successful, on the relation between biological effects and physico-chemical parameters of a drug molecule have been developed during recent years. The first investigations of this kind, which became the starting point for a new type of drug research, were carried out by *Richet* (1893), *Overton* (1897), *Meyer* (1899), and *Traube* (1903). The reason for looking for structure-activity relations and if possible to predict them is to recognize the qualitative and quantitative significance of the chemical, physico-chemical, and biological properties of a chemotherapeutic agent. This can lead to suggestions for the synthesis of new substances and for substances with special pharmacokinetic properties, or it may be possible to find the most effective compound within a homologous series more quickly. Two kinds of conditions necessary for a biological effect can be differentiated:

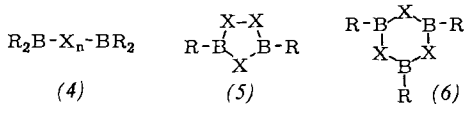
[*] Priv.-Doz. Dr. J. K. Seydel
Forschungsinstitut Borstel, Institut für experimentelle Biologie und Medizin
2061 Borstel (Germany)

1. chemical properties, which initiate a physico-chemical or chemical reaction at the site of action,



2. physico-chemical properties, which initiate a certain pharmacokinetic behavior, such as absorption, partition, metabolism, and elimination rate in the biological system in question.

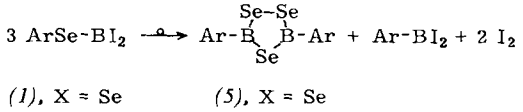
An optimum of the parameters of the first condition do not necessarily mean that the parameters of the second condition will also be optimal. However, the parameters that influence the pharmacokinetics frequently have a greater degree of variability. The parameters that are useful for structure-activity relations can be divided into two groups, *i.e.* parameters that predominantly describe the physico-chemical properties and parameters that are more closely related with the chemical reactivity. These parameters may be correlated with the biological data singly or in a multiparameter correlation *(Hansch)*. The correlation of electronic data with the antibacterial effect and of partition coefficients and pK_a values with the binding to serum albumins and the elimination rate is shown in the example of the sulfonamides. The interplay of conditions 1 and 2 for an optimum drug effect is demonstrated.



Synthesis and Properties of Selenoboranes

By *Walter Siebert* (lecturer), *Antonio Ospici*, and *Friedrich Riegel*[*]

A comparative study of the stability of the chalcogen-substituted boranes *(1)*—*(6)* (X = S, Se) shows that the selenoboranes rearrange more readily than the corresponding thioboranes. Arylthioboranes having the formulas *(1)* and *(3)* tend only to undergo symmetrization, whereas a 1,2-aryl shift takes place in the selenium compounds,



(1) *(2)* *(3)*

(4) *(5)* *(6)*

leading in the case of *(1)* to the formation of triselenadiborolane *(5)*, aryldiiodoborane, and iodine:

(1), X = Se *(5)*, X = Se

The compounds *(1)* and *(2)* with $R = R' = CH_3$; X = S, Se achieve stability by trimerization, a process that fails to occur in *(2)* for steric and electronic reasons when an X atom is inserted into the B—R' bond or when $R' = C_6H_5$ is introduced.

Diboryldisulfanes are relatively stable; *(4)* with $R = CH_3$, $n = 2$ decomposes above 130 °C into *(5)*, BR_3, and S_8. The corresponding selenoborane behaves similarly.

[*] Dr. W. Siebert, Dr. A. Ospici, and cand. rer. nat. F. Riegel
Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)

(1), *(2)*, *(3)* and *(5)* can be prepared by redox reactions between iodoboranes and diselenanes or selenium. The compounds *(4)*, $n = 2$ or $n = 1$ are obtained from R_2BI and Cp_2TiSe_5 or $(R_2SnSe)_3$; the product with $n = 1$ readily forms polymeric *(6)*.

Extraction Chromatography with High-Porosity Polymers

By *Markus Stoeppler* (lecturer), *Ivan Havezov* and *Safa Äl-Murab*[*]

Styrene-divinylbenzene copolymers (SDVB) were examined for use as support materials in extraction chromatography.

The large specific surface area (up to 850 m^2/g) leads to the uptake even of relatively low-boiling solvents, and this leads to a distinct analogy with the processes that occur in liquid extraction. Matrix effects that are frequently observed also affect the capacity.

In kinetic studies, the diffusion within the SDVB grains was found to be the rate-determining step. The HETP values attainable (≤ 0.6 mm) are independent of the flow rate over a wide range.

The versatility of these materials is illustrated by a number of very selective separations for the elements iodine, tellurium, gold, uranium, and neptunium.

Metabolism of Carcinogenic Purine *N*-Oxides

By *Gerhard Stöhrer* (lecturer) and *George B. Brown*[*]

The chemical carcinogens 3-hydroxyxanthine and guanine 3-oxide are converted *in vivo* into reactive metabolites. Rats treated with 3-hydroxyxanthine excrete 8-chloroxanthine and 8-methylthioxanthine. These metabolites are products of the 8-substitution reaction of 3-acyloxypurines, which can be studied with synthetic 3-acetoxyxanthine. A protein fraction from rat liver catalyzes this reaction by the intermediate formation of sulfates and phosphates of the *N*-hydroxypurines. A noncarcinogenic derivative, 7-methyl-3-hydroxyxanthine, does not react in this way, and does not lead to 8-substituted metabolites.

The reactions of 3-acetoxyxanthine with biological molecules were finally described.

Unidirectional Solidification of Pseudobinary Eutectics in Ternary Systems with Copper as the Matrix

By *Heinz Sprenger* (lecturer) and *Julius Nickl*[*]

In ternary systems containing copper, eutectics suitable for unidirectional solidification have been found on pseudobinary sections between copper (matrix) and the E phases MCuSi and MCuGe (M = Ti, Zr, Hf). The investigations were carried out with the system Cu/ZrCuSi

[*] H. Sprenger and Dr. J. Nickl
Forschungslaboratorium für Festkörperchemie der Universität
8 München 23, Leopoldstrasse 175 (Germany)

as a model. The samples produced at solidification rates of 1 to 20 mm/min show a fibrous morphology, with the ZrCuSi fibers of 1—5 μm in diameter and 100—500 μm in length lying more or less parallel to one another in the copper matrix.

The degree of alignment and the morphology of the eutectic depends on the temperature gradient and the solidification rate. The crystallographic orientation in the growth direction was found by rotating-crystal photographs to be $[001]_{Cu} \| [001]_{ZrCuSi}$.

A tensile strength of about 40 kg/mm^2 was found on measurement of the mechanical properties. The high electrical conductivity of the eutectic (10—20% lower than that of copper) is due to the low solubility of Zr and Si in the copper matrix.

Information and Documentation in Food Science

By *Berend Strahlmann*[*]

Since the beginning of the 19th century, when *J. H. Becker* listed 7276 titles from the literature known to him in the field of "nutrition science", the number of publications on food science has multiplied every year, particularly since the handbooks and scientific periodicals started to distinguish food science as a new discipline. Abstracting systems that soon appeared found themselves in difficult situations, not only because the food field is also covered by other scientific fields with their own abstracting services, with the result that some of the publications are abstracted twice while others are not abstracted at all, but also because the existing documentation systems can no longer cope with the information explosion. One way out of this dilemma is offered by conversion to electronic data processing and international cooperation, such as has been achieved *e.g.* by the International Food Information Service (IFIS) and with a still wider scope in a neighboring field by the International Nuclear Information System (INIS).

Formation and Properties of 2,3-Bis(1,4-naphthoquinone-2-yl)butanes

By *Winfried Storck* (lecturer) and *Georg Manecke*[*]

No 2-vinylnaphthoquinone is obtained on alkaline hydrolysis of 1,4-diacetoxy-2-vinylnaphthalene and subsequent oxidation in an acidic medium. Instead, three dimerization products derived from the rearranged semiquinone *(1c)* or *(1d)* were found; these products are *meso*- and *rac.*-2,3-bis(1,4-naphthoquinone-2-yl)butane and 6,13-dimethyl-6,13-dihydro-5,14;7,12-pentacenediquinone.

The 2,3-bis(naphthoquinonyl)butanes, which are of interest as models for polymeric redox systems, were therefore prepared independently by Wurtz reaction from 2-(1-haloethyl)- and 2-methyl-3-(1-haloethyl)-1,4-naphthoquinones. All the isomeric dimerization products of the radicals *(1c)* and *(1d)* were isolated.

Attempts to Detect Monomeric Hexadecylketene on Thermal Decomposition of Isopropenyl Stearate

By *H. J. Strauss* (lecturer) and *J. D. von Mikusch-Buchberg*[*]

NH or OH groups that are difficult to acylate are converted into the corresponding *N*- and *O*-acyl compounds by isopropenyl stearate under acid catalysis with elimination of acetone.

The active acylating agent in this reaction is thought to be free hexadecylketene, which is also thought to be formed when isopropenyl stearate is heated alone in inert hydrocarbons.

IR spectroscopic studies on such thermolysis products and their reactions with *tert*-butanol and cyclopentadiene gave no indication of free monomeric ketene. A tetrameric hexadecylketene is formed as a stable reaction product.

Hydroxyalkylation of Dialkylamides of Carboxylic Acids with Epoxides

By *Wolfgang Sucrow* (lecturer), *Marion Slopianka*, and *Dieter Winkler*[*]

N,N-Dialkylcarboxamides (*e.g.* dimethylacetamide, dimethylpropionamide, dimethylphenylacetamide, or *N*-methylpyrrolidone) are deprotonated with sodamide in liquid ammonia to form the α-carbanions, which can be alkylated with epoxides (*e.g.* ethylene oxide, 1,2-butylene oxide, isobutylene oxide, or styrene oxide) in moderate to satisfactory yields to obtain the amides of γ-hydroxy acids. *trans*-2,3-Butylene oxide does not react, whereas the *cis* form reacts with dimethylacetamide to form a small quantity of 2-methyl-3-hydroxyvaleric dimethylamide. The formation of by-products (lactones and glycol ethers) is discussed.

[*] Prof. Dr. W. Sucrow, M. Slopianka, and Dipl.-Ing. D. Winkler
Organisch-Chemisches Institut der Technischen Universität
1 Berlin 12, Strasse des 17. Juni Nr. 115 (Germany)

Some of the dialkylamides of γ-hydroxy acids are reduced by $LiAlH_4$ to the amines, which give 3-buten-1-ols on oxidation with hydrogen peroxide and Cope degradation. The naturally occurring isopentenol *(1)* is obtained in this way from ethylene oxide and dimethylpropionamide:

(1)

Temperature Dependence of the Hydrolysis of Esters by Trypsin and Chymotrypsin

By *Gerhard Talsky* (lecturer) and *Christian Gramsch*[*]

The investigation of the temperature dependence of the hydrolysis of esters, amides, and proteins by trypsin and chymotrypsin in small temperature intervals has shown that these enzyme-substrate systems do not give a continuous straight line when log v_{br} is plotted against $1/T$. It is necessary to distinguish between linear regions and wave-like regions. This behavior can be explained by changed reaction conditions resulting from small temperature-induced changes in the conformation of the enzyme.

Effects of the pH value, of salts and urea, and of thermal denaturation indicate only an *indirect* connection between the activity and the anomalies.

The separate investigation of the overall reaction, the acylation step, and the deacylation step in the hydrolysis of cinnamoylimidazole by trypsin led to the conclusion that the elementary step in which the anomalies occur takes place before the formation of the acylenzyme. If one also considers the experiments with inhibitors, the reason for the anomalies seems to lie in the modified bonding of the substrate.

New Determination of the ^{238}U(sp.f.)Decay Constant *via* Fission Tracks in an Antique U-Stained Glass of Known Age

By *Klaus Thiel* (lecturer) and *Wilfrid Herr*[*]

A new determination of the decay constant for the spontaneous fission of ^{238}U was carried out by means of an artificial U-glass from the middle of the last century with engraved dedication and carrying the date "1844".

The beaker was very probably made in the same year. From the number of spontaneous fission tracks recorded until now and the fission tracks induced by irradiation with an accurately known dose of thermal neutrons, it was calculated that the fission constant of ^{238}U is $\lambda_{sp.f.} = (8.57 \pm 0.42) \times 10^{-17} a^{-1}$. The neutron dose was measured by the gold foil technique, the absolute value of the ^{198}Au activity being determined by β-γ coincidences.

By counting sufficiently large areas, it was possible to reduce the simple statistical error of the spontaneous fission tracks to less than 1.66%, and that of the induced fission tracks to less than 0.35%.

Gas-Chromatographic Determination of Residues from Pesticides (Carbamates, Ureas, Amides) in Plant Material

By *Hans-Peter Thier*[*]

The residue analysis of herbicidal ureas and amides and of carbamates used as insecticides or germination inhibitors was described. The plant material is treated in the same way as for the determination of chlorinated hydrocarbons and organophosphates. Thus the diluted acetonitrile extract is extracted with petroleum ether and dichloromethane (8:2), and the organic phase is purified by passage through a Florisil column. The purified extracts are first examined for chlorinated hydrocarbons and organophosphates by gas chromatography, and are then treated with a mixture of bromine (5% iodine) and water or with a solution of bromine (5% iodine) in glacial acetic acid. This leads to the formation of bromine derivatives of the carbamates, ureas, and amides, which are then determined gas-chromatographically with the electron capture detector under the same conditions as in the determination of chlorinated hydrocarbons and organophosphates.

Aberystwyth, SY 23 1 NE (Wales)

Mechanism of Formation of Polywolframates and -molybdates in Aqueous Solution

By *Karl-Heinz Tytko*[*]

The elongation of the M—O bond resulting on protonation of the MO_4^{2-} ion (M = W, Mo) creates a situation in which the tetrahedral coordination sphere of the M atom can be expanded into an octahedral one by simple *addition* involving an overall gain in energy. In this a non-protonated MO_4^{2-} ion, a further HMO_4^- ion (or if present

[*] Dr. K. H. Tytko
Anorganisch-Chemisches Institut der Universität
34 Göttingen, Hospitalstrasse 8—9 (Germany)

a H_2MO_4 molecule), or an addition product already formed and having MO_6 octahedra can act as bidentate ligand. As confirmed by experimental results, such a simple addition reaction can proceed very rapidly. Of the many possible aggregates that can be formed according to this principle, those ring-shaped aggregates built up exclusively of octahedra which result from participation of an *intra*molecular addition step command particular attention: Their structures are the kinetically most stable that can be formed by this addition principle since removal of a WO_4 unit entails simultaneous destruction of at least two octahedra. For statistical reasons and in agreement with experimental results only four-membered "rings" as the smallest possible rings are to be expected.

Consideration of the acid/base properties of the aggregates affords additional information about the mechanism of aggregation. The basicity of the base function of the HMO_4^- ions in the aggregate depends upon the number of terminal O atoms present in the octahedron made up of HMO_4^- ion. (The H atom of the HMO_4^- ion, however, does not correspond to an acid function.) Aggregation therefore proceeds in such a manner that formation of the energetically favorable base function MO_n^- having large n is promoted. One particular consequence is that the H atoms occupy predominantly bridging O positions. Also to be considered is that, in the pH range in which significant aggregation takes place ($pH < 8$), the base functions MO^- (octahedra with one terminal O atom) and $M—O^- \cdots M$ (octahedra having no terminal O atom) can only exist in the protonated form. This additional protonation for octahedra having just one terminal O atom or none at all is the main regulatory principle in the aggregation process when there is a lack of H^+ ions (initial ratio $H^+/MO_4^{2-} \lessapprox 1$): On the one hand these H^+ ions could be used for protonation of additional MO_4^{2-} ions and the HMO_4^- ions for the building of more octahedra (energy gain); on the other hand the higher protonation of the polyanion reduces the electrostatic repulsion energy between the negative charges.

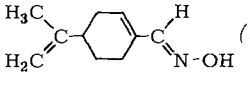
If the partitioning of a structure and of the related reaction pathway is carried out far enough, the free energy of reaction ΔG_r for the case in question can be visualized as being made up of increments for the different units. Thus ΔG_r is given by the sum over the products of frequency and ΔG_r increment of the structural units. Because of the scarcity of H^+ ions in the acidification range $\lessapprox 1$, a comparison of the many different structures that are possible according to the addition principle requires a standardization of the frequency of the structural units with reference to the use of a given number of H^+ ions. It then becomes apparent that, in terms of the limiting values for *relative* values of the ΔG_r increments estimated within adequate safety factors, the planar four-membered "ring" is not only the kinetically most stable but also by far the energetically most favorable polymetalate species according to the addition principle.

Similar arguments regarding the subsequent course of aggregation lead, in the case of a scarcity of H^+ ions, to a hexawolframate ion $[W_6O_{19}(OH)_3]^{5-}$ (parawolframate A) formed by 7 H^+ and 6 WO_4^{2-} for the H^+/WO_4^{2-} system, which is in agreement with experimental findings, and to a heptamolybdate ion $Mo_7O_{24}^{6-}$ formed by 8 H^+ and 7 MoO_4^{2-} for the H^+/MoO_4^{2-} system, also in accord with experiment, as the thermodynamically most stable species formed by a *condensation* mechanism. The difference between the two systems arises from the reduced tendency of the $HMoO_4^-$ ion to undergo aggregation and the resulting participation of H_2MoO_4 in the aggregation.

High Pressure Column Liquid Chromatography with Modified Porous Silica as Stationary Phase Material

By *Klaus Unger* (lecturer) and *Peter Ringe*[*]

High pressure column liquid chromatography has been developed in recent years as a new chromatographic method. High separation efficiencies are not only influenced by the elution rate, the nature of the mobile phase, and the column dimensions but also by the properties of the porous particles used as stationary phase. These properties include the shape and the diameter of the particles, the parameters of the pore structure, and the chemical composition of the surface.



Porous silica is particularly suitable as stationary phase material for high pressure column liquid chromatography. It can be produced in the form of spherical particles and in form of porous layers on nonporous particles. Its pore structure and the polarity of its surface can be varied within wide limits. The influence of these properties on the chromatographic separation was investigated and discussed for examples from adsorption, partition, and gel permeation chromatography.

Synthetic Sweeteners from Oximes

By *Bernard Unterhalt* (lecturer) and *Lothar Böschemeyer*[*]

Isomeric oximes can have different physiological effects. For example, according to our experience, (*E*)-*p*-methoxybenzaldehyde oxime and (*E*)-*p*-methylbenzaldehyde oxime taste sweet, while the (*Z*) isomers do not. Contrary to earlier reports, perillaldehyde oxime *(1)*, as an α-alkyl-α,β-unsaturated oxime, for steric reasons occurs only in the (*E*) form, which has a sweetening factor of 1400—2000. This behavior was confirmed for the basic structure by the investigation of 1-cyclopentenecarbaldehyde oxime and 1-cyclohexenecarbaldehyde oxime.

(1)

The reduction of oximes leads *inter alia* to amines, which react with chlorosulfonic acid to form the salts of the corresponding sulfamic acids. These were tested for their sweetening properties in analogy with cyclamate. The investigations led to a series of alkylsulfamates and cycloalkylsulfamates having sweetening properties comparable with those of cyclamate; toxicity tests are currently being carried out on these products.

The Use of Silylation Reactions in Foodstuff Analysis

By *Werner Untze*[*]

The introduction of the trimethylsilyl group into compounds having replaceable hydrogen atoms has become important both in preparative and in analytical chemistry[1].

Silylation products are characterized by greater ease of volatilization and by a greater stability in the vapor phase. Thus phenolic compounds (*e. g.* antioxidants, preservatives), amino acids, carboxylic acids, steroids, and some carbohydrates can be silylated with suitable silylating agents (*e. g.* *N,O*-bis(trimethylsilyl)trifluoroacetamide, hexamethyldisilazane, trimethylchlorosilane, *N*-trimethylsilylimidazole), and can then be separated and determined by gas chromatography[2]. Polyhydroxy compounds containing water may be allowed to react, after partial drying, with *N*-trimethylsilylimidazole or with *N,O*-bis(trimethylsilyl)trifluoroacetamide and determined gas-chromatographically[3]. Free fatty acids and in some cases hydroxy acids have been detected and determined with the aid of a suitable silylation reaction.

The Mechanism of Alkylation with *O*-Alkyl-*N,N'*-Dicyclohexylisoureas

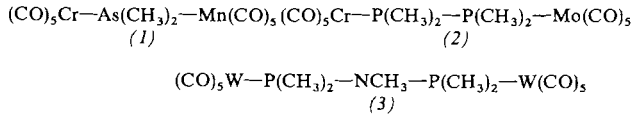
By *Erich Vowinkel* (lecturer) and *Rolf Jaeger*[*]

O-(2-Octyl)-*N,N'*-dicyclohexylisourea reacts with acetic acid or phenol in a four-step process. The reaction rate is determined by two successive steps, one of which is bimolecular and the other unimolecular. The bond cleavage precedes the formation of the new bond. The intermediate 2-octyl cation can react to form 1-octene or 2-octene instead of the ester *(1a)* or the ether *(1b)*; its occurrence is verified by the detection of the products resulting from hydride shifts and by interception reactions.

The reaction to form 2-octyl acetate proceeds in cyclohexane or acetonitrile with 100% inversion. This observation, which is surprising for an S_N1 reaction, is explained by ion-pair participation.

(1)

(a), R = CH_3CO; *(b)*, R = C_6H_5



The ether formation is also associated with inversion; the stereospecificity is 99.3%. The ring alkylation that occurs simultaneously in a side reaction also proceeds stereospecifically.

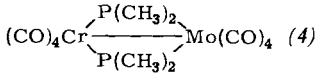
Base-Bridged Dinuclear Carbonylmetal Complexes

By *Heinrich Vahrenkamp* (lecturer) and *Winfried Ehrl*[*]



Three kinds of dinuclear transition metal complexes, in which the two metal atoms were bridged by one, two, or three basic atoms, were prepared. Examples of these complexes, in which nitrogen, phosphorus, arsenic, oxygen, and sulfur act as the basic atoms, are *(1)*, *(2)*, and *(3)*:

(1) *(2)*

(3)

The complexes were examined for their ability to act as precursors of more highly aggregated metal-metal linked clusters. On thermolysis and photolysis, however, the types *(1)* and *(3)* undergo disproportionation to form mononuclear complexes. The type *(2)*, on the other hand, loses CO when heated, with formation of compounds such as *(4)*.

Application of ^{13}C Resonance to Stereochemical Problems in Carbohydrates

By *Wolfgang Voelter* (lecturer), *Eberhard Breitmaier*, and *Günther Jung*[*]

The CAT method has been used in the past for the routine recording of ^{13}C resonance spectra; this method has the disadvantages of long recording times and high stability requirements with regard to the NMR equipment. By accumulation of pulse spectra and Fourier transformation[1-5] of the interferograms, on the other hand, useful ^{13}C resonance spectra can be recorded in a short time. According to our investigations, it is advantageous, as in proton resonance spectroscopy, to use tetramethylsilane as the standard, since the frequently used carbon disulfide gives a ^{13}C signal that may overlap with that of carbonyl carbon atoms.

A definite signal assignment is possible for many open-chain polyalcohols even without the use of "off-resonance" decoupling[1]. The ^{13}C signals of the CH_3 or CH_2 groups of deoxypolyols occur at highest field, the C atoms of primary alcohol groups are more strongly shielded than

[*] Univ.-Doz. Dr. W. Voelter, Univ.-Doz. Dr. E. Breitmaier, and Priv.-Doz. Dr. G. Jung
Chemisches Institut der Universität
74 Tübingen, Wilhelmstrasse 33 (Germany)

those of secondary alcohol groups, and "identical" C atoms in symmetrical polyols give signals of stronger intensity. The methylglycosides are particularly suitable for the systematic investigation of the conformation of carbohydrates by means of ^{13}C resonance, since they exhibit no mutarotation[6]. The signals of the glycoside C atoms of the pyranose ring appear at the lowest fields. The resonances of the hydroxymethylene C atoms are most strongly shielded in hexoses. In pentoses the ring methylene C atom signals appear at highest field. C atoms with axial substituents generally give signals at higher fields than comparable C atoms with equatorial substituents. This rule allows the determination of the conformation of a sugar. Thus D-arabinose, unlike most other sugars, has the 1C conformation[7].

The Photochemical *cis-trans* Isomerization of *n*-Octenes in the Presence of Organoaluminum Compounds

By *Siegfried Warwel* (lecturer) and *Heinz-Peter Hemmerich*[*]

The *n*-octenes with nonterminal double bonds undergo *cis-trans* isomerization on irradiation with UV light or γ rays even at room temperature whenever molar quantities of an organoaluminum compound ($HAlR_2$ or AlR_3) are present. This configurational isomerization, which does not occur under otherwise identical conditions without irradiation or in the absence of $HAlR_2$ or AlR_3, proceeds without the slightest shift of the C=C double bond in the olefin molecule, and leads with all octenes, irrespective of the configuration, to the thermodynamically stable equilibrium mixture of the *cis-trans* isomers. A distinct dependence of the isomerization on the temperature and on the organoaluminum species is observed, particularly when UV light is used. On replacement of AlR_3 by tetraalkyltin, a pure *cis-trans* isomerization of the monoolefin used is also observed under analogous conditions.

Sources of Information for the Determination of the Effectiveness of Corrosion Prevention with Thermosets

By *Josef Wagner*[*]

The change in effectiveness with time is of special industrial and economic importance in every field of corrosion prevention. In cases of metallurgical corrosion prevention, the behavior toward a given medium can usually be accurately determined. On the other hand, conclusive information on the effect of a thin protective surface coating, *e. g.* in passive corrosion prevention with thermosets, is much less commonly available, the main reason for this being lack of coordination of practice with analytical test methods. This shortcoming can also be seen from the lack of suitable standards.

In view of the worldwide importance of the protection of industrial installations against corrosion, it is desirable to build up an information system that shows as accurately as possible, and with specific reference to practical conditions, how long effective protection can be expected by a given means against a specified medium, *i. e.* the number of years of maintenance-free protection provided.

Information sources of this type that were mentioned in the lecture are technological punched cards, resistance lists, and simulated practical tests for laboratory use in individual corrosion-prevention cases. The results of testing experience covering a period of ten years are summarized in this work.

Rapid Radiochemical Separations by Electrolytic Removal

By *Max Weber* (lecturer), *Alfred Stelter,* and *Günter Herrmann*[*]

The release of 3.1 min ^{208}Tl from cathodic layers of its parent substance 60 min ^{212}Bi in aqueous media was investigated. It is shown that release occurs within seconds even for layers several mg/cm^2 thick. The α-recoil of the ^{208}Tl plays an essential part here. On the one hand, it results in the loss of 50% of the ^{208}Tl for the removal, while on the other hand, it overcomes an adsorption of small amounts of thallium that depends on the electrical potential of the cathode. Consequently, the behavior of ^{208}Tl differs considerably from that of thallium that does not originate from recoil processes. Applications of the release technique in the study of shortlived nuclides and also of electrochemical processes are discussed.

Photophysical Primary Processes

By *Albert Weller*[*]

On absorption of a light quantum, the energy content of the absorbing molecule is increased and its electron density distribution is changed. This leads to characteristic changes in the dipole moment, the acid and base strength, the ability to associate, and the electrochemical potential. The reactions that are possible in the excited state as a result of these changes can be investigated by luminescence and flash spectroscopic methods, and their half-lives can be determined by comparison of the lives of the excited reactants as found by intramolecular (radiative and radiationless) deactivation processes.

Of the bimolecular processes studied,

1. proton transfer (dissociation of acids, hydrolysis of bases, acid-base reactions)

[*] Prof. Dr. A. Weller
Max-Planck-Institut für biophysikalische Chemie
34 Göttingen-Nikolausberg, Postfach 968 (Germany)

2. complex formation (excimer and hetero-excimer formation)
3. electron transfer (univalent redox processes)
4. H-atom transfer ("simultaneous" proton and electron transfer),

all of which are reversible, *i.e.* revert rapidly to the original ground state configuration and are not therefore usually regarded as photochemical reactions, 1 and 2 lead to fluorescence transformation (*i.e.* the excited state persists), while the fluorescence is quenched in 3 and 4.

As is shown by the rate constants found, the reactions are all diffusion-controlled, and the actual reaction step that occurs in the encounter complex has frequencies of the order of $10^{11}\ s^{-1}$.

Some Recent Results from the Chemistry of Borazine-Metal Complexes

By *Helmut Werner* (lecturer), *Edith Deckelmann*, and *Karl Deckelmann*[*]

In the search for reactive starting compounds for the synthesis of the complexes $R_3B_3N_3R'_3M(CO)_3$ [M = Cr, Mo, W; R = R' = alkyl], a series of new nitrile complexes of the type *cis*-$(RCN)_3M(CO)_3$ were prepared, and their chemical and physical properties were studied. These investigations led to the first preparation of the hexaalkylborazine-molybdenum complexes $Me_3B_3N_3Et_3Mo(CO)_3$ and $Et_3B_3N_3Me_3Mo(CO)_3$, with a maximum yield of 5%, by three different reaction paths:

1. reaction of *cis*-$(MeCN)_3Mo(CO)_3$ or *cis*-$(PhCN)_3Mo(CO)_3$ with $R_3B_3N_3R'_3$ under rigorously controlled conditions in a high vacuum;
2. the action of $R_3B_3N_3R'_3$ on the addition compound $[(MeCN)_3Mo(CO)_3]_2 \cdot C_4H_8O_2$, which is obtained from *cis*-$(MeCN)_3Mo(CO)_3$ and dioxane, in a high vacuum;
3. photochemical reaction of $Mo(CO)_6$ with $R_3B_3N_3R'_3$ at ≈ 20 torr.

Intermediate compounds having the composition $R_3B_3N_3R'_3Mo(CO)_5$, which are stable in solution at room temperature, are formed.

The hexaalkylborazine-metal complexes $R_3B_3N_3R'_3M(CO)_3$ [M = Cr, Mo] are kinetically labile, and react very rapidly even with weak nucleophiles. The extreme reactivity is closely related to the bonding, which is discussed on the basis of IR, NMR, and X-ray structural investigations.

The Occurrence of Various Trypsin and Chymotrypsin Inhibitors in Peas

By *Jürgen Weder*[*]

Preliminary investigations showed that eight inhibitors that are active against trypsin and chymotrypsin are present in peas (*Pisum sativum* L.). The inhibitors were extracted from crushed peas with 0.25 N H_2SO_4, concentrated by fractional precipitation with ammonium sulfate (20—80% saturation), and freed from inactive proteins by filtration through a trypsin-resin column. Five electrophoretically homogeneous inhibitors have been isolated from this mixture by preparative polyacrylamide gel electrophoresis (system: glycine/tris pH = 8.3; 6 M in urea, anodic) in two stages (concentration followed by purification).

The specific activities are different. 1 mg of the inhibitors provides 100% inhibition of 0.84—3.1 mg of trypsin and 1.0—2.4 mg of α-chymotrypsin. The amino acid analysis shows the absence of methionine in all the inhibitors, and with one exception, the absence also of cysteine. The molecular weights (averages from the amino acid analysis, specific activity against trypsin and α-chymotrypsin, and polyacrylamide gel electrophoresis by the Na dodecyl sulfate method) are between 10000 and 12000.

Crosslinking of Polyethylene in the Presence of Additives

By *Rudolf Wiedenmann* (lecturer) and *Helmut Markert*[*]

Peroxides that seem suitable for the crosslinking of polyethylene were decomposed in paraffinic hydrocarbons (models for PE) at 150—180 °C, and the liberation of gas and the composition of the reaction gases were investigated as a function of the peroxide concentration and of the decomposition temperature. In the case of dicumyl peroxide (Di-Cup) and 1,3-bis(*tert*-butylperoxyisopropyl)benzene (m-P14), the other decomposition products were also determined, and the rate constants, half-lives, and activation energies were determined by measurement of the gas volumes instead of by the usual back-determination of the peroxide concentration.

With Di-Cup and m-P14, methane is the only gaseous reaction product formed, apart from traces of other gases. The reaction gas in the case of m-P14 also contains the volatile cleavage products acetone and *tert*-butanol. The formation of methane can be considerably reduced if additives such as selected polymethines or special aromatic compounds are introduced to intercept the methane-forming methyl radicals that are formed as secondary cleavage products of the peroxide as a function of the crosslinking temperature. The influence of these additives on the decomposition mechanism of the peroxides and on the degree of crosslinking of crosslinked films was investigated.

Erythrocuprein

By *Ulrich Weser*[*]

Erythrocuprein, a greenish-blue Cu protein with a molecular weight of 32 600, was isolated from bovine erythrocytes. It was prepared using chloroform-ethanol extraction extended by DEAE chromatography and additional gel filtration steps[1]. As in the case of erythrocuprein from human erythrocytes[2], two additional atoms of Zn per molecule were detected here. Thus, bovine erythrocuprein can also be considered to be a Cu—Zn protein[1, 3]. Spectroscopic studies at 77 °K show a fivefold increase in the inten-

[*] Doz. Dr. U. Weser
Physiologisch-chemisches Institut der Universität
74 Tübingen, Hoppe-Seyler-Strasse 1 (Germany)

sity of the Cu absorption band at 670 nm and the shoulder at 430 nm is more distinct. It can be concluded from ESR measurements that Cu^{2+} is bonded to several nitrogen atoms[1,4]. On titration of erythrocuprein with dithionite under argon, the metalloprotein takes up two electrons, *i.e.* one electron per Cu^{2+}. CD and MCD measurements indicate a small helical portion in the protein residue. After incubation of erythrocuprein in 1% sodium dodecyl sulfate and 4M urea, monomeric and tetrameric units, which can be separated by electrophoresis, are formed. The erythrocuprein obtained by the usual preparative methods is dimeric. Apart from a dismutase reaction[5], *i.e.* the disproportionation

$$O_2^{-\bullet} + O_2^{-\bullet} + 2H^+ \rightleftharpoons O_2 + H_2O_2$$

no biochemical reaction of this metalloprotein could be detected.

Thermal Decomposition of Azosilanes

By *Nils Wiberg* (lecturer) and *Wilfried Uhlenbrock*[*]

The thermolysis of azo compounds X—N=N—Y can proceed with decomposition [eq. (1)], disproportionation [eq. (2)], and, as we have also found, dimerization [eq. (3)]:

Whereas azoalkanes (X, Y = H, alkyl) undergo "decomposition" and "disproportionation"[1,2], the azosilanes (X, Y = H, silyl) undergo "disproportionation" and "dimerization". The products of the thermolysis of $Me_3Si—N=N—SiMe_3$ or reaction of $Me_3Si—N=N—SiMe_3$ with $Me_3Si—N=N—H$ are accordingly $(Me_3Si)_2N—N(SiMe_3)_2$ or $(Me_3Si)_2N—NH(SiMe_3)$ (free radical formation) and $(Me_3Si)_2N—N=N—N(SiMe_3)_2$ or $(Me_3Si)NH—N=N—NH(SiMe_3)$ (non-radical formation)[3]. Since silylated tetrazenes, as we have found, can decompose in accordance with eq. (4) and hydrazoic acid reacts with azosilanes in accordance with eq. (5), azides, amines, and nitrogen are found under "special" reaction conditions as the end products of a dimerization reaction.

Thus a mixture of $Me_3Si—N=N—SiMe_3$ and LiMe (intermediate formation of $Me_3Si—N=N—Li$) gives LiN_3 and $LiN(SiMe_3)_2$ in a molar ratio of 1:1, while a mixture of $Me_3Si—N=N—SiMe_3$ and hydrochloric acid (intermediate formation of H—N=N—H) gives, *inter alia*, NH_3 and nitrogen in a molar ratio of 1:1.

Polymers from Succinonitrile

By *Dieter Wöhrle*[*]

We investigated the catalytic reaction of succinonitrile *(1)* to form polymers, which always contain (—C=N—) bonds.

In the cationic polymerization, *(1)* was allowed to react *e.g.* with metal halides such as $ZnCl_2$ at 180—300 °C. Dark-colored polymers having the crosslinked structure *(2)* were obtained. The investigation of the semiconductor properties showed specific electrical conductivities of $\sigma_{300°K} \leq 1.5 \times 10^{-5}$ ohm^{-1} cm^{-1}. Anionic polymerization could be achieved by reaction of *(1)* in solution *e.g.* in methanol in the presence of $NaOCH_3$ [polymers having the structure *(3)*]. The conductivities are $\sigma_{300°K} \leq 8.5 \times 10^{-8}$ ohm^{-1} cm^{-1}. The bulk polymerization of *(1)* in the presence of potassium *tert*-butoxide, on the other hand, leads to polymers having the structure *(4)* with $\sigma_{300°K} \leq 6.7 \times 10^{-14}$ ohm^{-1} cm^{-1}. In the reaction of *(1)* with Ziegler catalysts such as $TiCl_4/Al(C_2H_5)_2Cl$, dark-colored polymers having the structure *(3)* and with $\sigma_{300°K} \leq 2.7 \times 10^{-9}$ ohm^{-1} cm^{-1} were obtained.

Molecular weight determinations by vapor-pressure osmometry in DMSO gave values of 600—5000 for some

polymers. It was possible to use mass-spectroscopic sequence analysis for the elucidation of the structures of the polymers. Some of the polymers are stable up to 800 °C under N_2. Polymers having the structure *(3)* could also be prepared by polycondensation from succinimidine *(5)* and 5-chloro-2-imino-α-pyrroline *(6)*.

Preparation and Absolute Configuration of *cis*-Pheophorbides

By *Herbert Wolf* (lecturer) and *Hugo Scheer*[*]

The chiroptic properties of pheophorbides with the *trans* configuration on C-7/C-8 (macrocyclic basic skeleton of chlorophylls a and b) have been investigated in detail[1]. Optically active pheophorbides with the *cis* configuration were not obtainable until now, since the isomerization[2] of natural pheophorbides and the synthesis[3] yielded only the thermodynamically more stable *trans* compounds.

(2a)	Ethyl	$COOCH_3$	OCH_3	—	—	*S*
(2b)	Ethyl	H	H	—	—	—

We succeeded in preparing the *cis*-pheophorbides *(1b)*, *(1c)* and *(1e)*, *(1f)* by "HI isomerization"[4] of the *trans*-pheophorbides *(1a)* and *(1d)* into the pheophorphyrins, whose Zn complexes *(2a)* and *(2b)* were rehydrogenated photochemically to the *cis*-pheophorbides (ethanol/ascorbic acid, 1,4-diazabicyclo[2.2.2]octane, white light). The diastereoisomers *(1b)* and *(1c)* obtained from *(2a)* were separated by thin layer chromatography. The relative configurations were determined from the NMR spectra (proton signals of the pyrrolenine ring), mass spectra (intensity of the $(M-2)^+$ signal resulting from dehydrogenation), and absorption spectra (red shift of the "chlorine band").

The absolute configuration of *(1b)* and *(1c)* on C-7 and C-8 was determined by spectral polarimetry (CE curves at 225, 400, and 535 nm), with reference to the third chirality center C-10, the absolute configuration of which is known[1]. The racemate *(1e)*/*(1f)* obtained from *(2b)* was partly resolved by chromatography on cellulose $2^1/_2$-acetate, and the absolute configuration of *(1e)* and *(1f)* was determined by spectral-polarimetric correlation with *(1b)* and *(1c)*.

ESR Spectra, Radical Complexes, and Electron Transfer in the Quenching of Photoexcited Rose Bengale by Quinones

By *G. O. Schenck* and *Rudolf Wolgast* (lecturer)[*]

H-bonded radical complexes of substituted hydroxymethyl radicals determine the reaction course *e.g.* of the photoreduction of benzophenone, in which they can be investigated directly by ESR spectroscopy. The quenching of photoexcited dye molecules by quinones which can be detected by the inhibition of the photoreactions of the dye, also occurs *via* radical pair complexes which can be recognized by characteristic reactions and ESR spectra. Thus rose bengale is oxidized in light by oxygen in the presence of duroquinone. The ESR signals from excited rose bengale with duroquinone and 2,3-dimethyl-3-chloroquinone arise only in the absence of oxygen in a predominantly reversible reaction, and differ in their chemical and kinetic behavior, and sometimes also in their hyperfine structure, from the signals of "free" semiquinones.

The Crystalline State of High Polymers

By *H. G. Zachmann*[*]

Unlike low molecular weight substances, high polymers do not crystallize completely, but consist of a mixture of crystalline and noncrystalline regions, irrespective of the duration of the crystallization process. These regions often form more extensively ordered units (spherulites).

On the basis of a simple two-phase model, it is possible to determine the crystalline content of the samples by various methods, *e.g.* by X-ray studies or from the density. X-ray small-angle scattering gives the mean distance, and hence the size of the crystallites. It is found that the crystalline component and the crystallite size increase with rising crystallization temperature. This clearly shows that the incomplete crystallization is due to kinetic inhibition, which is strongly dependent on the internal mobility and hence on the chemical structure of the chain molecules.

In recent times, interest has been directed mainly at the investigation of the arrangement of the chains in the noncrystalline regions and of the structure of the crystallites.

[*] Prof. Dr. H. G. Zachmann
Institut für Physikalische Chemie der Universität
65 Mainz, Jakob-Welder-Weg 15 (Germany)

Folding of the chains is found on preparation of crystals from the solution. It cannot be definitely established whether the noncrystalline regions of the material crystallizing from the melt also consist of chain folds or loops projecting from the crystallites. It is only known from measurements of the absolute intensity of the small-angle scattering that both the noncrystalline regions and the crystals in many cases do not have the density that they should have in the ideal case. The deviations depend on the chemical structure and on the previous heat treatment. Details on the structure of the crystallites are obtained by evaluation of the intensity and width of the X-ray crystal reflections with the aid of the paracrystal theory. One finds a large number of structural imperfections that, like *e.g.* kinks, are characteristic of high polymers.

Interesting behavior is also observed when high polymers are heated. Instead of a sharp melting point, one observes a melting range, recrystallization processes, or even superheating phenomena, depending on the crystallization conditions. All these results can be readily explained on the basis of a statistical thermodynamics developed specially for chain molecules.

Identification of Amines: Thin Layer Chromatography and Mass Spectrometry of 4-Dimethylamino-3,5-dinitrobenzoyl Derivatives (DADB Amines)

By *Alfred Zeman* (lecturer) and *I. P. G. Wirotama*[*]

For separation and identification, amines were converted into their 4-dimethylamino-3,5-dinitrobenzoyl derivatives (DADB amines). The separation was carried out on silica gel G/Carbowax 400 with the solvent hexane/ethyl acetate (7:3). DADB amines are intensely yellow; compared with the DNP amines[1], which are also deep yellow, they have the advantage of stability to light.

The components separated by thin layer chromatography were identified by mass spectrometry. In the mass spectra of the DADB amines, the molecule-ions and the ions M—ÖH are observed with very high intensity; this provides rapid preliminary information on the molecular weight of the amine. The fragmentation in the case of lower aliphatic amines takes place preferentially in the 4-dimethylamino-3,5-dinitrobenzoyl residue of the molecule; even here, however, the structure of an unknown amine can be largely determined by mass spectrometry. In some cases, *e.g.* for some DADB-iso-alkylamines and DADB-*n*-alkylamines, NMR measurements are also useful. The mass-spectrometric fragmentation of the DADB amines is discussed on the basis of the spectra of numerous derivatives.

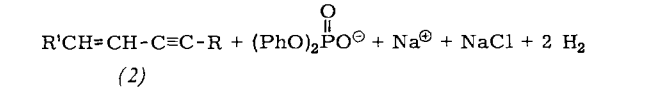
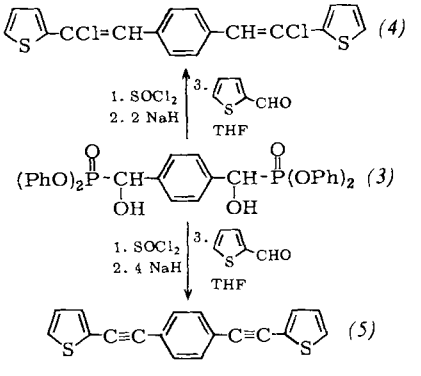
Syntheses of Enynes and Polyacetylenes *via* α-Heterosubstituted Phosphonate Carbanions

By *Hans Zimmer* and *Kenneth R. Hickey*[*]



The usefulness of α-heterosubstituted phosphonate esters of type *(1)* as easily accessible starting materials for the synthesis of α-heterosubstituted olefins, enynes, and polyacetylenes *via* a Wittig-Horner-type reaction was demonstrated. The synthesis of the enynes *(2)* is carried out according to Eq. (1).

$$(PhO)_2\overset{O}{\overset{\|}{P}}H + RCHO \longrightarrow (PhO)_2\overset{O}{\overset{\|}{P}}-\underset{OH}{\underset{|}{CHR}} \xrightarrow{SOCl_2} \underset{(1)}{(PhO)_2\overset{O}{\overset{\|}{P}}-\underset{Cl}{\underset{|}{CHR}}}$$



$$(1) + R'CH{=}CH{-}CHO + 2\ NaH \xrightarrow{THF} \qquad (1)$$

$$R'CH{=}CH{-}C{\equiv}C{-}R + (PhO)_2\overset{O}{\overset{\|}{P}}O^{\ominus} + Na^{\oplus} + NaCl + 2\ H_2$$

$$(2)$$

If in this sequence R = *p*-formylphenyl the reaction proceeds *via* the bis(phosphonate) ester *(3)*. In Eq. (2) the reaction with 2-thiophenecarbaldehyde to give the dialkyne *(5)* and the dichlorodialkene *(4)* is given as example.

(2)

The synthesis of several such heterocyclic substituted acetylenes was dealt with. Also, the preparation of an enyne-system-containing natural product was discussed. A mechanism for this reaction was suggested.

Recent topics of petroleum genesis are reported by *A. Shimoyama* and *W. D. Johns*. Clay minerals catalyze the decarboxylation of fatty acids and cracking of the resulting *n*-paraffins. For example, *n*-$C_{21}H_{43}COOH$ and Ca-montmorillonite yielded, besides a kerogen-like main product, all *n*-paraffins C_{16} through C_{28} (other paraffins could not be detected with the analytical procedure used). A crude kinetic analysis of the experiments showed that in geological time this reaction can yield petroleum-like products. [Catalytic Conversion of Fatty Acids to Petroleum-like Paraffins and Their Maturation. Nature Phys. Sci. *232*, 140—144 (1971); 15 references, 3 tables, 4 figures.]

[Rd 408 IE –H]

A brief review of new applications of the Faraday effect in chemistry is given by *A. J. McCaffery*. By Faraday effect (magnetic circular dichroism, MCD) is meant the difference in absorbance of left and right circularly polarized light under the influence of a longitudinal magnetic field. The genesis of MCD is illustrated with simple examples, and a brief account of its theory is given. The measurement of MCD is especially helpful in assignment of absorption bands to certain electronic transitions. Additional applications performed presently and developments possible in the future are considered. [New Applications for Magnetic Circular Dichroism. Nature Phys. Sci. *232*, 137—140 (1971); 35 references, 2 figures.]

[Rd 409 IE –H]

A modern method for the calculation of lattice energies of salts containing complex ions is reported by *H. D. B. Jenkins* and *T. C. Waddington*. A model is used which considers each atom or ion in the crystal as a point charge; the distances are taken from crystal structure data. The charge on the atoms constituting the complex ion appears as a parameter in the calculation. Assuming that the charge distribution in a complex ion does not depend on the details of crystal structure one can eliminate the charge parameter by comparison of polymorphic salts or of series of complex salts with different counterions. Thus, the charge distribution in complex ions can be calculated. [Lattice energies, charge distributions and thermochemical data for salts containing complex ions. Nature Phys. Sci. *232*, 5—7 (1971); 19 references, 2 figures.]

[Rd 410 IE –H]

An account of the stereochemistry of five-coordinate nickel(II) and cobalt(II) complexes is given by *P. L. Orioli*. The relative stabilities of the two ideal configurations (trigonal bipyramid and square pyramid) in different environments are discussed and some factors are mentioned which can effect departures from these ideal geometries. A list is then given of the known complexes of nickel(II) and cobalt(II) with coordination number 5, separated according to their high-spin or low-spin character. [The Stereochemistry of Five-coordinate Nickel(II) and Cobalt(II) Complexes. Coord. Chem. Rev. *6*, 285—308 (1971); 76 references, 7 figures, 13 projection formulas, partly with distances and angles, 6 tables.]

[Rd 411 IE –H]

The assessment and interpretation of properties of transition metal compounds by means of MO calculations is reviewed by *D. R. Davies* and *G. A. Webb*. One chapter deals with the principles of the calculation methods, the models they are based upon, and the different degrees to which they rely on empirical results. Calculations of electronic energy levels in transition metal compounds of different symmetries are then shown; the review concludes with a brief account of the more or less covalent aspects of metal-ligand bonds. [Molecular Orbital Calculations on Transition Metal Compounds. Coord. Chem. Rev. *6*, 95—146 (1971); 267 references, 10 figures, 10 tables.]

[Rd 412 IE –H]

The chemistry of allyl and crotyl Grignard reagents has been reviewed by *R. B. Benkeser*. The author compares the different reaction behavior of these two types of extraordinarily reactive organometallic compounds. Allyl- and crotylmagnesium halides permit introduction of unsaturated C_3- and C_4-chains.

$H_2C{=}CH{-}CH_2{-}MgX$ *(1)* $\qquad$ $H_3C{-}CH{=}CH{-}CH_2{-}MgX$ *(2)*

Steric hindrance of the reaction partner seldom influences the course of the reaction. The review includes: preparation of allyl and crotyl Grignard reagents *(1)* and *(2)*; structure of *(2)*; reactions of *(1)* and *(2)* with carbonyl compounds; exchange reactions; and also addition of *(1)* to azomethines and of *(2)* to olefins. [Synthesis *1971*, 347—358; 93 references, 8 tables, many formulas].

Methods for the synthesis of polyaminomonosaccharides (di-, tri-, and tetraaminosugars) are reviewed in a paper by *F. J. M. Rajabalee*. The amino functions are usually introduced by N-containing nucleophiles, either directly or *via* cyclic intermediates (epoxides, aziridines, 1,3-oxazolines, 1,3-oxazolones). In many cases nitrosugars are suitable precursors for polyaminosaccharides. [Synthesis *1971*, 359 to 366; 70 references, numerous formulas.]

[Rd 416 IE –M]

Principles of Mass Spectrometry and Negative Ions. By *Charles E. Melton.* Marcel Dekker Inc., New York 1970. 1st ed., v, 313 pp., bound $ 17.75.

A series of books on mass spectrometry have so far been published dealing either with special applications (particularly in organic chemistry) or (insofar as the authors attempt to cover the entire field) presenting the physical fundamentals and the principles of the equipment together with a survey of the various fields of use.

The present book, unlike those that have preceded it, is predominantly of the character of a textbook. The author presents a mathematically immaculate description of the physical principles that are required for an understanding of the function and use of mass spectrometers. Knowledge of vector analysis and of the manipulation of differential equations is necessary for an understanding of the subject matter.

The history of mass spectrometry and the wide field of uses are described briefly, but with many references, in the introductory chapter. Chapters 2 to 8 contain the mathematical description of the physical principles of the following fields: 2. movement of charged particles in electric and magnetic fields, 3. formation of ions, 4. mass separation (analysis), 5. detection of ions, 6. positive ions, 7. negative ions, and 8. secondary reactions. No references for further studies are given in Chapters 2 to 5.

Because of the author's evident delight in the handling of the methods of theoretical physics, the application of the quantum theory in the chapters on positive ions, negative ions, and secondary reactions, *e.g.* in the calculation of effective cross sections for collision phenomena and in pair formation, is not too brief. The appendix contains tables of appearance potentials from investigations with negative ions, secondary reactions of negative ions, and electron affinities of atoms and molecules.

The book should be a useful aid to advanced students of physics and chemistry and to physicists and chemists who wish to familiarize themselves with the field of mass spectrometry. However, it should also find a place in the laboratories of pure and applied specialists.

Karl Heinz Maurer [NB 991 IE]

Carboranes. By *R. N. Grimes.* Academic Press, New York–London 1970. 1st ed., xiv, 272 pp., numerous formulas and tables, bound $ 14.00.

The chemistry of carboranes, which were first reported in 1953, has developed very rapidly during the past 12 years. It now occupies an independent place alongside polyborane chemistry. As in the case of the boranes, the syntheses, the diverse structures, and the bonding (three-center bonds, metal π bonds) in this class of compounds are of interest to the inorganic chemist, the organometallic chemist, and the organic chemist alike. The present book appears at a time when a survey of what has been achieved is of great value.

Following the examination of the most important steric structures and the bonding in the various types of carboranes and of the latest nomenclature, *nido* and *closo* carboranes with small and medium numbers of atoms are discussed.

The treatment concentrates on the preparative field. Most of the book is occupied by the description of preparations and transformations of the three isomeric $C_2B_{10}H_{12}$ carboranes and their derivatives and of the properties of carborane polymers. The alternate conversions of the $C_2B_{10}H_{12}$ isomers into dicarbollides $C_2B_9H_{11}^{2-}$ and the preparation of monocarbapolyborates are then discussed. A section is devoted to the degraded $C_2B_{10}H_{12}$ carboranes with integrated main-group elements (Be, Al, Ga, Ge, Sn, P, As, Sb), and a comprehensive chapter deals with the π complexes of the various carborane anions (dicarbollides $C_2B_9H_{11}^{2-}$, dicarbacanastides $C_2B_8H_{10}^{4-}$, dicarbazapides $C_2B_7H_9^{2-}$) with transition metals.

The up-to-date survey is supplemented by well-chosen literature (472 references). A comprehensive author index and an adequately detailed subject index are added. The author's wish "to summarize the existing literature of carborane chemistry, and to introduce the field to organic chemists and others with little previous knowledge of the boranes" is fulfilled.

Roland Köster [NB 992 IE]

Selective Organic Transformations, Vol. 1. By *B. S. Thyagarajan.* John Wiley and Sons, New York–London–Toronto 1970. 1st ed., 400 pp., numerous formulas, bound £ 9.50.

The first volume of the new series "Selective Organic Transformations", which will appear periodically, has now been published. This series is to present reviews on chemical transformations in which the formation of one of many, usually isomeric reaction products predominates. It is intended to place the description of a plausible reaction mechanism alongside a pure list of preparative and kinetic data.

B. S. Thyagarajan has managed to have the eight reviews in the first volume written by authoritative investigators. More than 150 of the 400 pages are taken up by the nucleophilic addition to acetylene *(S. J. Miller* and *R. Tanaka)* and the stereoselective addition to allenes *(M. C. Caseirio)*. These reactions have only been intensively studied during the last few years; with careful choice of the reactants, they allow the synthesis of olefin derivatives that are otherwise unobtainable.

Two other articles deal with the asymmetric induction in the reduction of carbonyl compounds with hydrides *(S. Yamada* and *K. Koga)* and the asymmetric selection by elimination from cycloalkyl derivatives *(S. Goldberg)*. Both reactions yield the stereoisomers in unequal amounts, since the enantiomer mixtures give transition states having different free energies. The optical induction on addition of hydrides to dissymmetric carbonyl compounds is sufficiently well known through Cram's rule. On the other hand, a new chapter is opened up in asymmetric synthesis by elimination. The reactions involved here are mainly the pyrolyses of sulfoxides, amine oxides, phosphine oxides, and esters in which the loss of a chiral group leads to two "diastereoisomeric" transition states with different energies.

A. T. Bottini discusses the stereoselectivity in the quaternization of tertiary amines, and *R. A. Moss* describes the cycloaddition of carbenes to olefins and subsequent reac-

tions. The last two articles deal with the decomposition of triazolines to form aziridines and imines *(P. Scheiner)*, which is of great interest from the mechanistic standpoint, and oxidation with selenium dioxide, *(R. A. Jerussi)*, which is of immense preparative importance.

It is clear from the diversity of the reaction types discussed that the title of this new series is to be understood in a very broad sense. However, this does not detract from the value of the clearly and comprehensively written individual reviews, and the continuation of the series will be eagerly awaited.

Bernd Giese [NB 993 IE]

Physikalische Grundlagen der Verfahrenstechnik (Physical Fundamentals of Process Engineering). By *P. Grassmann*, Verlag Sauerländer, Aarau and Frankfurt 1970. 2nd ed., 960 pp., figures, bound, DM 128.—.

Ten years ago "Physical Fundamentals of Chemical Engineering" appeared as the first volume of the excellent "Fundamentals of Chemical Technology" series published by Verlag Sauerländer. Now, the second edition has appeared, under a slightly different title. The factual material is presented in twelve main chapters, starting from the fundamentals typical for process engineering from the fields of thermodynamics, physical chemistry, mechanics, fluid dynamics of single-phase and multiphase systems, heat and mass transfer, and mathematics.

Continual use of the work shows that the author has been highly successful not only in his selection of the material but also in combining it into an organic whole. Its relation to the fundamentals has resulted in a pretentious work for scientifically oriented readers, but the author supports his material by careful and readily comprehensible presentation and also by his unambiguous and clear method of writing equations, by graphic illustrations, and by careful cross-indexing and literature references. The reviewer personally found the author's individual style of writing a particular attraction of the book.

The author has not spared himself the trouble of re-formulating a considerable number of chapters in the new edition in order to take into account new developments in those fields. In particular, the sections on "Momentum, heat, and mass transfer" and on "Multiphase flow" have profited from this treatment.

A large number of literature references, have been added, some as recent as 1970, contributing toward the up-to-date nature of the work. The book can be recommended to engineers, physicists, and chemists in the various specialist fields connected with process engineering, as an ever-handy source of advice. In my experience it is also suitable for advanced students as a textbook which can show the relationship between the basic sciences (which otherwise seem isolated) in their application to process engineering problems.

Eckhart Blass [NB 994 IE]

Atomic Absorption Spectroscopy. By *R. J. Reynolds* and *K. Aldous*. With a chapter by *K. C. Thompson*. Charles Griffen & Co. Ltd., London 1970. 1st ed., xii, 201 pp., 29 figures and 6 tables, bound £ 4.50.

This book provides the kind of introduction to the experimental techniques of atomic absorption that an analyst who wanted a quick guide to the essential information for analytical applications would require. Following a very short presentation of the fundamentals, the technical data needed for analysis are given, possible interferences are noted, the selection of suitable flames is discussed, and an attempt is made to clarify essential concepts such as sensitivity, detection limits, precision, *etc.*

The most extensive chapter summarizes the essential data for the atomic absorption determination of 49 elements and the rare earth metals (taken together), in alphabetical order of the elements. The subsequent bibliography contains 74 references, also arranged by elements. In another chapter are given examples of applications: the analysis of biological materials and organic substances, clinical and metallurgical analyses, silicate analyses, *etc.* This is also followed by a suitably arranged bibliography. The book ends with chapters on the characterization of standard equipment, new atomic absorption techniques, and the chapter by *K. C. Thompson* which gives a clear and readily understandable picture of the theoretical foundations. Each chapter is followed by a bibliography. A subject index simplifies the location of specific information. The book will provide the practising analyst with the necessary analytical data in a readily acceptable form, but it also gives the chemical and physical foundations necessary for an understanding of the method.

Methods of Asymmetric Synthesis—Enantioselective Catalytic Hydrogenation

By Yoshiharu Izumi[*]

It is proposed that asymmetric syntheses be divided into enantioselective and diastereoselective syntheses. The enantioselective hydrogenations discussed in the present progress report were catalyzed by Raney nickel that had previously been treated with solutions of optically active compounds. Relationships exist between the enantioselectivity of the catalyst and the structure of the chiral compound used to modify it.

1. Introduction

"Asymmetric synthesis" is still one of the most undeveloped fields of organic chemistry, though most natural products are asymmetric and the enantiomer that occurs in nature is in many cases the only one that acts as a drug, nutrient, or flavoring agent. The development of asymmetric syntheses is of particular interest to branches of industry that produce synthetic natural products such as amino acids.

Studies on asymmetric syntheses are of great importance not only scientifically but also preparatively. They may even help, for example, to elucidate the mode of action of enzymes. Improved knowledge of asymmetric syntheses should also provide an insight into unsolved problems in connection with the origin of life, as well as an answer *e.g.* to the question why all proteins that are important to life consist exclusively of L-amino acids.

We have been concerned in recent years with catalysts for asymmetric hydrogenation. The results are reported briefly in the present article. However, let us first examine the term "asymmetric synthesis".

2. Definitions

The description "asymmetric" is used in two ways. On the one hand, "asymmetric synthesis", is understood to be a reaction in which the enantiomers of a chiral molecule are formed in unequal quantities. On the other, a molecule is described as "asymmetric" if it lacks symmetry elements at least of the second kind.

Nakazaki[1] has referred to the need for a new definition of "asymmetric reactions" based on the concept of chirality[2]. Together with *Nakazaki*, therefore, the present author proposes that "asymmetric syntheses" be divided into enantioselective syntheses and diastereoselective syntheses. In this new classification, most "inductive asymmetric syntheses" are diastereoselective syntheses, while "asymmetric catalytic syntheses", "absolute asymmetric syntheses", and most enzymatic syntheses should be classified as enantioselective syntheses.

2.1. Diastereoselective Synthesis

If a molecule contains a center of chirality and a center of prochirality, the molecule can be divided by a plane in such a way that the parts on either side of the plane are diastereotopically related to each other. If a reaction results in the conversion of the center of prochirality into a new center of chirality, the reagent may attack from either side of this plane, with the result that diastereoisomers are formed[3]. The formation of the diastereoisomers in unequal quantities in such a reaction may be due to differences in the strength with which a catalyst is adsorbed on the two sides of the "diastereotopically reacting" plane of the substrate or to differences in the rate at which a reactant attacks on the two sides of the plane.

We shall refer to reactions of this type as diastereoselective syntheses. For example, in the hydrogenation of 3-ethyl-6-benzylidene-3-methyl-2,5-dioxopiperazine *(1)*[4], a cata-

[*] Prof. Dr. Yoshiharu Izumi
Institute for Protein Research, Osaka University,
Kita-ku, Osaka (Japan)

lyst is adsorbed less strongly on the side of the dioxopiperazine ring (O) on which the ethyl group projects (reverse side in Fig. 1) than on the other side. Hydrogenation thus leads mainly to the product in which the ethyl and benzyl groups lie on the same side of the piperazine ring *(1)* (*cis*-configuration).

A "diastereotopic reaction plane" (P) can also be drawn in the reaction of phenylglyoxyl ester *(2)*, which is shown in Figure 2 in the preferred conformation, with methylmagnesium iodide[5]. In the reaction, the Grignard reagent will preferentially attack the phenylglyoxyl ester from the side opposite the largest substituent L, with preferential formation of the product in which L and the methyl group lie on opposite sides of the plane (P) (*trans*-conformation).

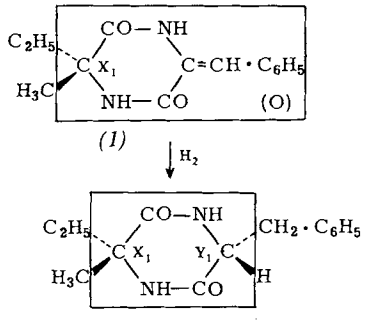

Fig. 1. Diastereoselective hydrogenation on the side of the diastereotopic plane (O) favored by the configuration. x_1 = existing center of chirality, y_1 = induced center of chirality.

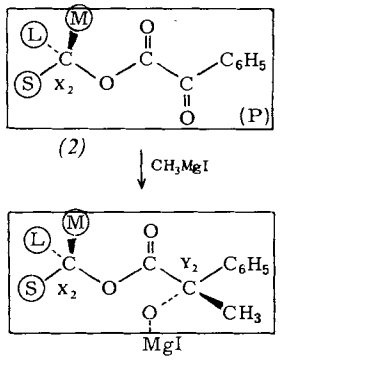

Fig. 2. Diastereoselective synthesis on the side of the diastereotopic plane (P) favored by the conformation. (L), (M) and (S) denote the largest, middle, and smallest substituents respectively. x_2 = existing center of chirality, y_2 = induced center of chirality.

In this type of reaction, the inequality of the quantities of the *cis*- and *trans*-compounds in the product is proportional to the diastereoselectivity of the catalyst or of the reagent. With racemic starting materials, neither a catalyst nor a reactant can induce the preferential formation of one enantiomeric form of the new center of chirality. This can be achieved, however, if optically active substrates are used. If the ligands on the existing centers of chirality x_1 and x_2 are constant, the degree to which x_1 and x_2 influence the stereochemistry of the new centers of chirality y_1 and y_2 depends only on the diastereoselectivity of the catalyst or of the reagent[6]. "Inductive asymmetric synthesis" is thus a special case of diastereoselective synthesis.

2.2. Enantioselective Synthesis

Achiral molecules containing a center of prochirality can be divided by a plane in such a way that the two sides of the plane are enantiotopically related to each other. The attack of a reactant from one side leads to the *S* enantiomer of the new chiral molecule, while attack from the other side leads to the *R* enantiomer[3]. An achiral reactant or an achiral catalyst approaches both sides of the "enantiotopic plane" at the same rate and so yields the racemate. An enantioselective reactant or an enantioselective catalyst, on the other hand, can differentiate between the two sides of the "enantiotopic plane"; the rates of attack on the two sides of the plane are different, and the *R* and *S* compounds are formed in unequal quantities. The difference between the quantities of enantiomers formed depends on the enantioselectivity of the reagent or of the catalyst. A synthesis carried out with an enantioselective reagent or catalyst will be referred to as an "enantioselective synthesis".

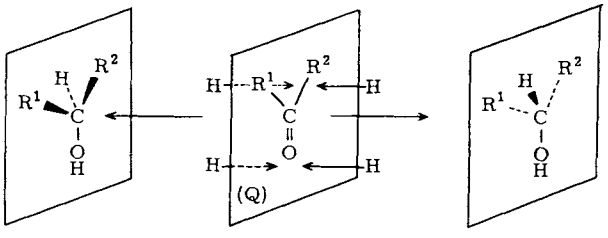

Fig. 3. Enantioselective hydrogenation on the enantiotopic plane (Q).

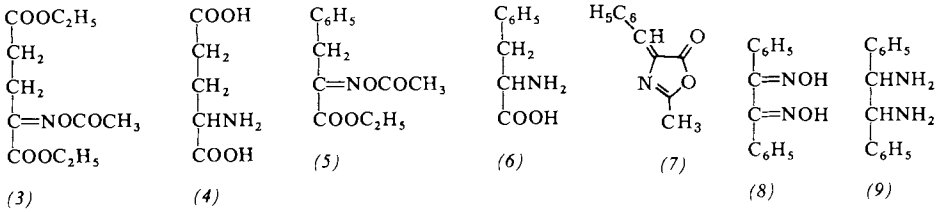
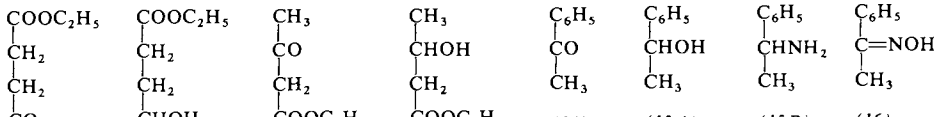


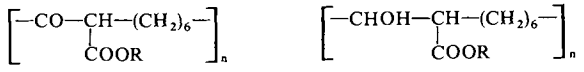
In enantioselective synthesis, the enantioselective action of the catalyst or of the reagent causes the new center of chirality to be formed mainly in the *R* or in the *S* form. Examples of such reactions are the enantioselective hydrogenation described in the present progress report and reactions with chiral Grignard reagents[7].

For example, the enantioselective, modified Raney nickel catalyst (see Section 4 *et seq.*) has two functions; firstly, it catalyzes hydrogenations in the same way as ordinary Raney nickel, and secondly it distinguishes between the two sides of the enantiotopic plane of the substrate. The hydrogenation is due to the metal of the catalyst, and the differentiation between the two sides to the chiral compound adsorbed on the catalyst.



3. Survey

The first enantioselective synthesis with a heterogeneous catalyst was achieved by our research group in 1956 with a silk-palladium catalyst[8–10]. This catalyst enantioselectively hydrogenated derivatives of oximes and oxazolones (Table 1, Part 1).



During our investigations on the silk-palladium catalyst and the modified Raney nickel catalyst, *Isoda et al.*[11,12] published a report on enantioselective hydrogenations with Raney nickel. They investigated the hydrogenation of oxazolone and α-oxoglutaric acid derivatives with Raney nickel that had been treated with amino acids (Table 1, Part 2).

After the investigation of silk-noble metal catalysts[13–18], we turned in 1963 to the enantioselective hydrogenation of methyl acetoacetate with modified Raney nickel. Since then, we have continued our systematic studies on this catalyst[19–40].

In 1964, *Padgett et al.*[41] reported the enantioselectivity of a palladium catalyst on a specially prepared silica gel support (Table 2). The silica gel had been precipitated from sodium silicate with hydrogen chloride in the presence of optically active alkaloids. *Beamer et al.*[42–44] investigated the similar enantioselective hydrogenation of α-methylcinnamic acid and α-acetaminocinnamic acid with palladium catalysts on polyamino acid supports.

The mechanism proposed by *Beamer et al.* for the enantioselective hydrogenation is based on the idea that the catalyst has two kinds of adsorption sites, which differ in their affinity for the two sides of the enantiotopic plane of the substrate. The chiral structure of the polyamino acid used as the support causes the two types of adsorption sites to be formed on the surface of the catalyst in unequal quantities. According to *Beamer*'s view, the enantioselectivity of the catalyst is due to the surface structure of the silica gel, which has been modified in such a way by the precipitation in the presence of optically active alkaloids that the silica gel, like the polyamino acids, can now act as an optically active support for the metal. Ion affinity, dipole interaction, hydrogen bonding, and van der Waals forces are named as playing an important part in the adsorption of the substrate on the catalyst (Fig. 4).

Table 2. Enantioselectivity of a palladium catalyst on an optically active support. α-Methylcinnamic acid is reduced to α-methylphenylpropionic acid, and α-acetylaminocinnamic acid to phenylalanine.

[b] Palladium was deposited on silica gel that had been precipitated in the presence of a sulfate of an organic base (0.5 g of salt based on 42 g of sodium silicate solution). QN = quinine sulfate, QND = quinidine sulfate, CN = cinchonine sulfate, CDN = cinchonidine sulfate.
[c] Palladium was deposited on the polyamino acid indicated.

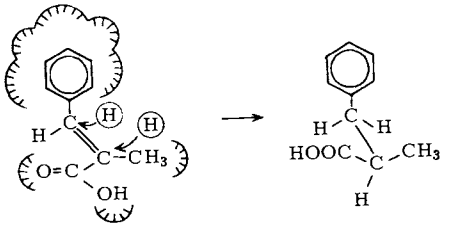

Fig. 4. Course of the enantioselective hydrogenation of α-methylcinnamic acid with palladium on poly-(*S*)-leucine as the catalyst (after a suggestion by *Beamer et al.*) [42—44].

Petrov et al. also investigated modified Raney nickel catalysts (Table 1, Part 3)[45]. *Plate et al.*[46] recently reported the enantioselectivity of modified Raney nickel in the hydrogenation of poly-β-oxo esters and poly-β-diketones (Table 1, Part 4).

Soviet chemists explained the steric effect of a reagent that allows the asymmetric hydrogenation of the substrate on the basis of *Balandin*'s presentation of the multiplet theory of the catalyst[47]. They assume further that the modifying reagent and the substrate are combined in the form of a chelate.

Klabnovskii and *Petrov* suggested that enantioselective hydrogenation on modified Raney nickel proceeds as shown in Figure 5[48]. They assume that the adsorption of the substrate is determined by the stability of the catalyst-

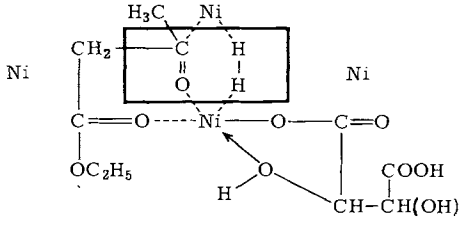

Fig. 5. Enantioselective hydrogenation of ethyl acetoacetate with modified Raney nickel as the catalyst (after a suggestion by *Klabnovskii*) [48].

substrate bond; this bond will be influenced by the chiral structure of the modifying reagent. According to *Plate et al.*[46], the same processes underlie the enantioselective hydrogenation of poly-β-oxo esters or poly-β-diketones.

4. Development of the Modified Raney Nickel Catalyst

In our investigations on enantioselective catalysts, we started by considering the course of enzymatic reactions. We simply assumed at first that the enantioselectivity of enzymatic reactions was due to the asymmetric environment of the protein molecule, and that the chiral product was formed in a "chiral mould" just as a waffle is formed in a waffle iron.

Silk fibroin has a rigid structure, contains no amino acid residues containing sulfur, and can coordinate metal irons. If silk fibroin is boiled with aqueous palladium chloride solution and the silk-palladium complex subsequently hydrogenated, one obtains a palladium catalyst in which the metal is embedded in an asymmetric environment. We achieved the first enantioselective hydrogenation with this catalyst (see Section 3, Table 1). Unfortunately, it was found after a few months that the enantioselectivity of the silk-palladium catalyst is very strongly dependent on the type of silk, and that the results were accordingly not reproducible.

While investigating the reproducibility of the enantioselectivity of the silk-palladium catalyst, we found that the hydrogenation activities of silk-palladium, silk-platinum, and silk-rhodium catalysts are much weaker for the C=O double bond than for other double bonds. To establish whether this behavior was attributable to the silk protein, Raney nickel was treated with aqueous gelatin solution, and the activity of the resulting catalyst for the carbonyl group was tested[49]. It can be seen from Table 3 that the hydrogenation activity of the catalyst for the carbonyl group, as expected, was greatly decreased by this treatment.

At that time we assumed that the active sites on the hydrogenation catalyst behaved differently toward C=O, NO_2, C=C, *etc.* To explain this behavior (see Table 3), the concept of competitive inhibition was applied to these reactions. We assumed that the sites of the catalyst that are active toward the carbonyl group lose their activity when occupied by the carbonyl group of the modifying reagent, which evidently has a greater affinity for these active sites than the carbonyl group of the substrate.

The hydrogenation activities of Raney nickel catalysts modified with amino acids and with chelating agents were also tested on carbonyl, nitro, and C=C double bonds. The results are shown in Tables 3 and 4.

Below 10 °C, the carbonyl group undergoes practically no hydrogenation in the presence of the modified Raney nickel, and the uptake of hydrogen begins only above 60 °C. The hydrogenation activity towards other double bonds, on the other hand, remains unchanged or is even improved by the modification of the catalyst.

Table 3. Hydrogenation activity of modified Raney nickel [49].

Modifying reagent	Hydrogenation activity [a] compared to 2-Butanone at 10 °C	2-Butanone at 60 °C	Allyl alcohol at 10 °C	Nitrobenzene at 10 °C	Nitrobenzene at 40 °C
—	2.0	55	34	9	16

[b] Reduction at 80 °C.
[c] Taken up in 3 min.
[d] Taken up in 4 min.
[e] The CO losses in the products were 11% and 3% respectively.

From the above results, we expected that the chirality of an amino acid must take effect if a Raney nickel modified with this amino acid is used as a catalyst in hydrogenations above 60 °C. The Raney nickel catalyst with which the first enantioselective hydrogenation was achieved had been modified with an aqueous solution of (*S*)-glutamic acid.

We have developed the following view on the active sites in modified Raney nickel catalysts. The hydrogenation can take place at any site on the catalyst on which the substrate is adsorbed. The active sites are not specific for the various functional groups such as C=O, NO_2, or C=C. In our view, the active sites on the catalyst surface, *e.g.* dislocations, are capable of functioning even before contact with hydrogen; they initiate the activation of the hydrogen like initiators in a chain reaction.

The position of the modifying reagent on the catalyst surface is determined by the affinity of the reagent for the catalyst on the one hand and the repulsive forces between the reagent molecules on the other. The poisoning of the catalyst can be explained as a special case of modification, *i.e.* poisoning is observed when the repulsive forces between the modifying reagent and the substrate are stronger than the affinity of the substrate for the catalyst.

Since modification of a catalyst often promotes the hydrogenation of one substrate and inhibits the hydrogenation of another (see Tables 3 and 4), the term "modification", is more apt than "poisoning".

5. Preparation of Modified Raney Nickel Catalysts and Determination of the Enantioselectivity

For the investigations discussed here, we prepared Raney nickel from an alloy containing 40% of Ni and 60% of Al. An aqueous solution of the modifying reagent was adjusted

to a predetermined pH value and a predetermined temperature. The freshly prepared Raney nickel was then added, and the mixture was allowed to stand at the same temperature for 1.5 h with occasional shaking. The modifying solution was decanted off, and the catalyst was washed once with water and twice with methanol.

To determine the enantioselectivity of the catalyst, 17 g of methyl acetoacetate was hydrogenated in the presence of the modified Raney nickel catalyst obtained from 1.5 g of alloy. The reaction was allowed to proceed in a shaking autoclave at 60 °C under an initial hydrogen pressure of 80—100 kg/cm^2. After distillation under reduced pressure (b. p. 61—62 °C/12 torr), the optical rotation of the undiluted methyl 3-hydroxybutyrate was measured. The result was taken as the specific rotation, since the specific gravity of the product is approximately 1.0. According to *Levene* and *Haller*[50], $[\alpha]_D^{20}$ of methyl (*R*)-(−)-3-hydroxybutyrate is −20.9°.

The reliability of the results of the enantioselective synthesis improves with increasing purification of the product and with increasing care in the measurement of the optical rotation. Methyl acetoacetate was used as the substrate in most cases, since its hydrogenation product has the following advantages. It can be distilled (with no change in the optical purity); impurities can be easily detected by gas chromatography; its optical rotation is high (see above), and can be measured without dilution of the liquid.

6. Dependence of the Enantioselectivity of the Catalyst on the Modification Conditions

The enantioselectivity of the catalyst is strongly dependent on the temperature and the pH value of the modifying solution. The optimum pH value is 5.0 in the case of acidic modifying reagents and the isoelectric point in the case of monoamino acids (Fig. 6):

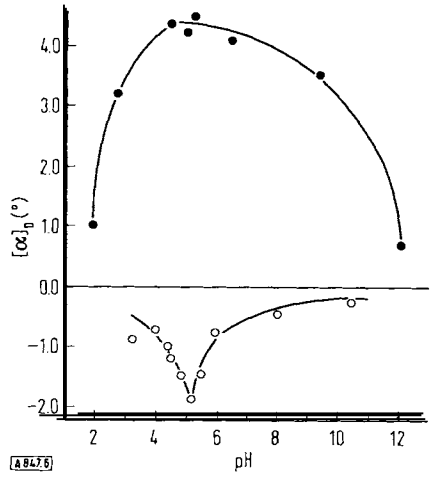

Fig. 6. Enantioselectivity of Raney nickel modified with (*S*)-malic acid and (*S*)-aspartic acid [36] as a function of the pH value of the modifying solution. Substrate: methyl acetoacetate; product: methyl 3-hydroxybutyrate.
–○–○– (*S*)-malic acid
–●–●– (*S*)-aspartic acid

On modification with hydroxy acids, the enantioselectivity of the catalyst increases with rising temperature. The temperature dependence is more complicated, however, when the catalyst is modified with amino acids (Fig. 7).

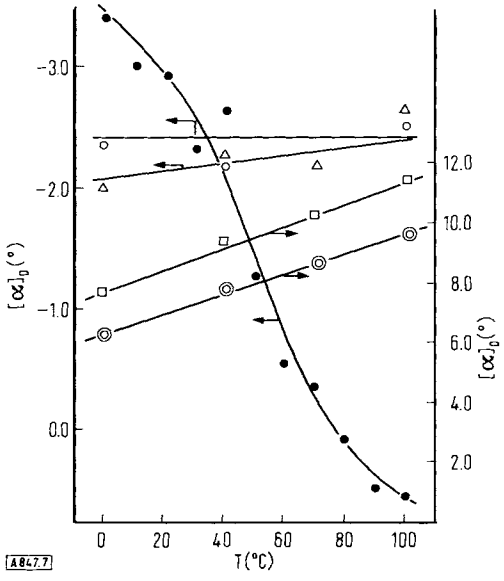

Fig. 7. Enantioselectivity of modified Raney nickel as a function of the temperature of the modifying solution. Substrate: methyl acetoacetate; product: methyl 3-hydroxybutyrate. The right-hand ordinate is valid for the following reagents:
–□–□– (+)-*erythro*-2-methyltartaric acid [27] (modified at pH = 5.0 to 5.2)
–◎–◎– (2*S*,3*S*)-tartaric acid [27] (modified at pH = 5.0—5.2)
The left-hand ordinate is valid for the following reagents:
–△–△– (+)-2-methylglutamic acid [29] (modified at pH = 5.2)
–○–○– (*S*)-valine [20] (modified at pH value of the isoelectric point)
–●–●– (*S*)-glutamic acid [23] (modified at pH = 5.2)

On modification of the catalyst with amino acids such as glutamic acid and leucine, the enantioselectivity changes direction[51] with rising temperature (cf. also Table 6).

7. Conditions for an Enantioselective Modifying Reagent

To give useful enantioselectivity, the modifying reagent must satisfy the following conditions:

1. The modifying reagent must be an optically active compound. Experiments with mixtures of (2*R*, 3*R*)- and (2*S*, 3*S*)-tartaric acid showed that the enantioselectivity of the catalyst varies linearly with the mixing ratio of the modifying reagents[27].

2. If the molecule contains several centers of chirality, it is desirable that their enantioselective effects do not cancel one another out. Part 1 of Table 5 shows the enantioselectivities of some Raney nickel catalysts modified with reagents containing two centers of chirality. (For further examples see [10, 24, 26, 39].)

3. It is desirable that the center of chirality carry one carboxyl group and one amino or hydroxyl group. Part 2 of Table 5 shows the enantioselectivity of Raney nickel catalysts modified with α-substituted succinic acids. A hydroxyl group or an amino group attached to the asymmetric carbon atom gives the catalyst a higher selectivity than a methyl group. As can be seen in Part 3 of Table 5, the amino acids make the catalyst more strongly enantioselective than the corresponding amino alcohols.

Table 5. Examples of enantioselective hydrogenations with Raney nickel modified with compounds of the type R—CR′ X—R″ at 0 °C and at the pH indicated. Substrate: methyl acetoacetate; product: methyl 3-hydroxybutyrate.

[d] Dextrorotatory form.

Part 4 of Table 5 shows that substituents on the amino, hydroxyl, or carboxyl group of the modifying reagent reduce the enantioselectivity of the catalyst.

4. A hydrogen atom on the asymmetric carbon atom is essential for the success of the modification. If this hydrogen atom is replaced by other residues, the enantioselectivity of the catalyst decreases (Table 5, Part 5).

8. Relation Between the Structure of the Modifying α-Substituted Acids and the Enantioselectivity of the Catalyst

8.1. Factors that Determine the Direction of the Enantioselectivity

The direction of the enantioselectivity of the catalyst is determined by the absolute configuration of the center of asymmetry C_α of the modifying reagent, which has the general structure RCHX—COOH. The substituent X also

influences the direction of the enantioselectivity. Table 5 contains examples in which the direction of the enantioselectivity is reversed when the amino group is replaced by the hydroxyl group. With catalysts modified with L-hydroxy acids, methyl acetoacetate is hydrogenated to methyl (*S*)-(+)-3-hydroxybutyrate; this is not the case on modification with a number of β-substituted hydroxy acids. On the other hand, catalysts modified with L-amino acids generally lead to the (*R*)-(−)-ester (see Table 6).

8.2. Factors that Influence the Degree of Enantioselectivity

The degree of enantioselectivity of the catalyst is determined by the structure of the substituent R. Our investigations on this effect of R lead to the following picture:

1. As described in Section 7 under paragraph 2, a second center of chirality in the substituent has a strong influence of the enantioselectivity of the catalyst. The absolute configuration on the β-carbon atom of an α-hydroxy acid is often of greater importance to the enantioselectivity of the catalyst than the absolute configuration on the α-carbon atom.

2. As can be seen from Figure 8, with amino acids as the modifying reagents, the enantioselectivity of the catalyst increases with increasing chain length. On modification with hydroxy acids, the enantioselectivity of the catalyst decreases with increasing chain length. Figure 9 shows that secondary or tertiary alkyl groups in the modifying reagent influence the selectivity of the catalyst more strongly than primary alkyl groups having the same number of carbon atoms.

3. As is shown in Table 7, hydroxyl, carboxyl, and thiol groups on the β-carbon atom of the modifying reagent strongly influence the enantioselectivity of the catalyst. If the reagent is an amino acid, the substituents not only reduce the selectivity but often reverse its direction, as can be seen, *e.g.* in the examples of modification with serine, threonine, and cysteine. On the other hand, a catalyst treated with α-hydroxy acids substituted in this way exhibits stronger selectivity. From these observations, to-

Glycyl-(*S*)-aspartic acid	—	−1.47

gether with results mentioned in Section 7 under paragraph 2, it is understandable that the strongest enantioselectivity is obtained by modification with *threo*-tartaric acid [(2*S*, 3*S*)].

4. If the amino acid or α-hydroxy acid with which the catalyst is modified contains a sulfonic acid group, the enantioselectivity is decreased (Table 7).

5. If dipeptides are used instead of amino acids for modification of the catalyst, the relation between structure and enantioselectivity becomes more complicated. As can be seen from Table 8, the direction of the enantioselectivity is generally determined by the center of chirality of the C-terminal amino acid.

9. Durability of the Catalyst

The modified Raney nickel retains its enantioselectivity for a very long time[27]. In a series of experiments, freshly prepared modified catalyst was used for the hydrogenation of methyl acetoacetate, recovered, and used again. The $[\alpha]_D$ values of the methyl 3-hydroxybutyrates obtained in experiments with fresh catalysts and with catalysts that had been recovered once, twice, three times, four times, and five times were −6.22, −6.30, −6.09, −6.01, −6.25, and −6.19° respectively. The modifying reagent was (2*S*,3*S*)-tartaric acid.

10. Substrates for Hydrogenations with Modified Raney Nickel

The best substrates for modified Raney nickel are β-oxo esters and β-diketones. Monoketones are also enantioselectively hydrogenated to secondary alcohols, but the optical yields are low, as can be seen from Table 9.

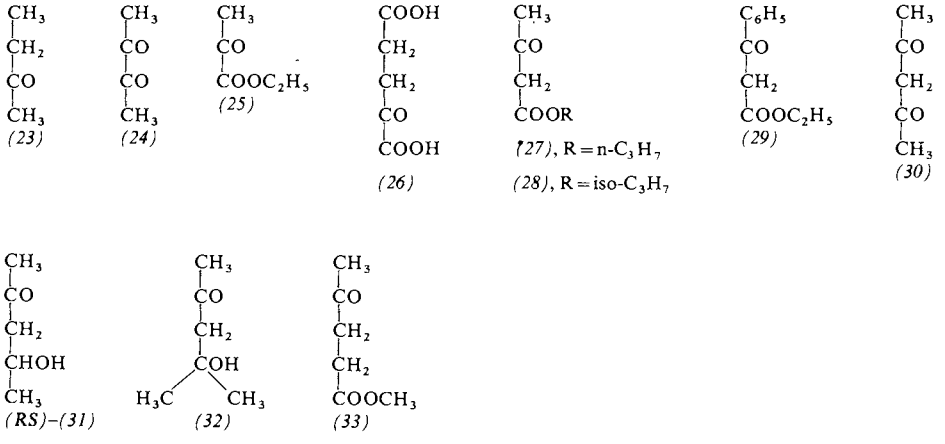

Table 9. Examples of enantioselective hydrogenations with modified Raney nickel. The italicized numbers in brackets in the "substrate" column refer to the formulas reproduced above, or, in the case of numbers lower than *(23)*, to the formulas given with Table 1 [30].

11. Dependence of Enantioselectivity of Catalyst on Hydrogenation Conditions

The hydrogenation temperature has no influence on the enantioselectivity of the catalyst above 60 °C. Below 60 °C, however, the catalysts exhibit practically no hydrogenation activity and practically no enantioselectivity.

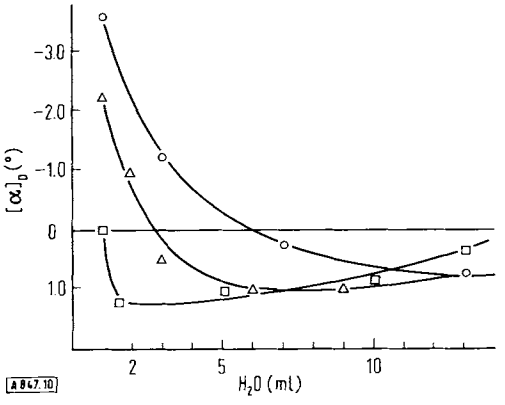

Fig. 10. Effect of water on the enantioselectivity of a modified Raney nickel catalyst. The quantities of water are based on 17 g of the substrate methyl acetoacetate [40a].
-○-○- (*S*)-glutamic acid (modified at pH = 5 and 0 °C)
-△-△- (*S*)-valine
-□-□- (*S*)-alanine (both modified at the pH of the isoelectric point and 0 °C)

Any trace of impurities, particularly carboxylic acids, either in the substrate or in the solvent, affects the enantioselectivity of the catalyst[40]. This effect is more pronounced with amino acids as the modifying reagents than with hydroxy acids. In the former case, as can be seen from Figure 10, the direction of the selectivity may even be reversed in the presence of water.

12. Hypothesis on the Course of the Enantioselective Hydrogenation

As was mentioned in Section 2.2, the enantioselective hydrogenation is made possible by a preceding enantioselective adsorption of the substrate on the catalyst surface. To explain the enantioselective adsorption, the adsorption process is broken down into three steps, as shown in Figure 11. From the fact that β-diketones and β-oxo esters give the best results in enantioselective hydrogenation with modified Raney nickel, it can be concluded that adsorption of the carbonyl groups on the catalyst surface to form a chelate structure plays an important part in the hydrogenation. Thus the Raney nickel catalyst itself has the ability to adsorb carbonyl compounds selectively in the direction of the C=O axis.

The modification of the catalyst with an optically active compound decides whether the catalyst attacks the substrate from the re side or the si side[3]. Since the z axis of the substrate is fixed by the catalyst surface, the modification of the catalyst must produce the selectivity for the x and y axes of the substrate. There are two possible explanations for the production of the enantioselectivity on modification: 1. As proposed by *Beamer*[44], there are two types of

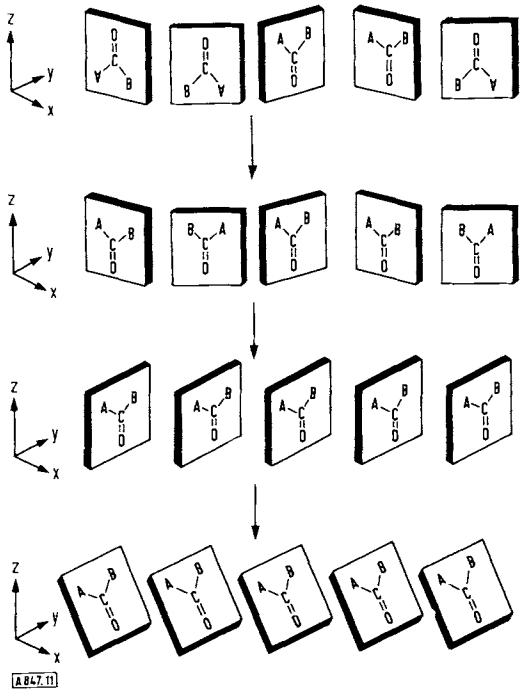

Fig. 11. Enantioselective adsorption of a ketone on the surface of a modified Raney nickel catalyst (schematic). The z axis is perpendicular to the surface of the catalyst.

sites on the untreated catalyst, one of which produces the *S*-form and the other the *R*-form, and one type is blocked or poisoned as a result of the modification, 2. The enantioselective site is formed by the combined effect of the catalyst surface and the modifying reagent.

Experimental results support the second possibility. If the enantioselectivity of the catalyst were due to the first process, a double modification, first with (*S*)- and then with (*R*)- or first with (*R*)- and then with (*S*)-glutamic acid, should deactivate both types of enantioselective sites on the catalyst. However, the enantioselectivity of the catalyst depends only on the last modifying reagent used[19].

It is clear from the facts described above that the selectivity is produced by the modifying reagent adsorbed on the catalyst. The adsorbed reagent is in adsorption equilibrium with its solution.

In the present review, it has been possible to describe only the most important results obtained with Raney nickel catalysts, mainly modified at pH = 5 and 0 °C. For further results and detailed discussions, the reader is referred to the original literature.

We are grateful to Dr. S. Akabori for his valuable suggestions, and we would also like to thank Professor M. Nakazaki of the Faculty of Engineering Science, Osaka University, for discussions on the new classification of "asymmetric synthesis". We also thank our many colleagues for their constant efforts and their assistance.

[51] Note on the concept of enantioselectivity. In the discussion of enantioselectivity, two factors must be considered: (i) the numerical value of the optical rotation of the enantioselectively hydrogenated product and (ii) the sign + or − associated with the absolute configuration of the product. Whereas the first factor is important in the discussion of the optical yield, the second factor indicates the "direction of the enantioselectivity".

Active Transport of Na^+ and K^+ through Animal Cell Membranes[**]

By Wilhelm Schoner[*]

The transport of Na^+ out of the cell and K^+ into the cell against a concentration gradient is catalyzed by a ($Na^+ + K^+$)-activated ATPase. The way in which the cations pass through the cell membrane has not yet been elucidated. Studies on the ATP hydrolysis revealed a Na^+-dependent phosphorylation of the enzyme protein; the conformation of the enzyme also appears to change. The energy required for transport of the cations against their concentration gradients is probably provided by K^+-dependent hydrolysis of the enzyme-bound phosphate. The enzyme can synthesize ATP from inorganic phosphate and ADP on reversal of the cation concentration gradient. By keeping the enzyme in a particular conformation, the cardiac glycoside ouabain specifically inhibits the Na^+ pump.

1. Introduction

The distributions of the monovalent cations sodium and potassium inside and outside living cells are usually different[1]. The potassium concentration is generally high and the sodium concentration low inside cells, while the situation is reversed outside the cells[1-3]. If the cell dies, or if its metabolism is blocked by cell poisons or by supercooling, the distributions become the same[4-7].

1.1. Action of Sodium and Potassium Ions on Metabolism[2, 3]

Potassium ions increase, among other things, the respiration in muscle, kidney, adipose tissue, and erythrocytes[8-13], glycolysis and lipolysis[14-19], protein synthesis[20], and acetylcholine synthesis[21]. Sodium ions have an inhibitory effect on the same metabolic processes.

The reason for the antagonistic effects of these two cations has been found in some cases to be an activating effect of potassium ions and an inhibitory effect of sodium ions on enzymes[19, 22-24]. Since the cell membrane is permeable to both cations[25, 26], K^+ must be pumped into the cell and Na^+ out of the cell ("Na^+ pump") in order to maintain a metabolism in the cell that is largely independent of the composition of the extracellular electrolytes.

1.2. Physiological Importance of the Active Transport of Na^+ and K^+

By establishing a difference in the distributions of sodium and of potassium ions between the interior and the exterior of the cell, the Na^+ pump also provides the conditions through which the stimulation of nerve and muscle is possible[27-31]. It can be assumed from investigations on the syndrome of hereditary spherocytosis of the erythrocytes[32-34] that the osmotic pressure of the cells is probably kept constant by active transport of Na^+ and K^+, *i.e.* transport against the concentration gradient. The active transport of Na^+ and K^+ is also the driving force for the movement of NaCl and water in the reabsorption of primary urine in the tubular cells of the kidney[35, 36] and in the secretion of saliva and of pancreatic juice[37]. An active Na^+ pump is also essential to the absorption of glucose and amino acids through the mucous cells of the small intestine and the tubular cells of the kidney (general reviews in[5, 28, 30, 34, 38-42]).

2. Properties of the Na^+ Pump

Detailed information about the properties of the Na^+ pump has been obtained in particular from studies with isolated perfused squid giant axons and with erythrocytes loaded by reversible hemolysis[43]. As was shown by these investigations, the energy for the transport of cations against the concentration gradient is obtained by hydrolysis of adenosine triphosphate (ATP)[44-52]. The binding site of ATP is located on the inside of the cell membrane, where the reaction products adenosine diphosphate (ADP) and inorganic phosphate (P_i) are also liberated[51, 53, 54].

The active transport of sodium into the extracellular space is coupled with the transport of potassium into the intracellular space[44, 55-57]. Sodium ions can be taken up by the pump only on the inside of the membrane[58-60]; on the outside of the membrane, they act as antagonists of the potassium ions that are necessary for their transport[32, 60-62]. However, this function of the potassium ions on the outside of the membrane can also be taken over by other alkali metal ions[57-63].

Cardiac glycosides specifically inhibit the Na^+ pump on the outside of the cell membrane[51, 64-66], whereas they have no effect on the inside[67].

These observations can be combined in a kinetic model of the active transport of Na^+ and K^+ developed by *Shaw*[55] (Fig. 1). Na^+ on the inside of the cell membrane is bound to a carrier, and migrates with the latter through the cell membrane. On the outside of the membrane the carrier

34 Göttingen, Humboldtallee 7 (Germany)

[**] The author's own work in this field was generously supported by the Deutsche Forschungsgemeinschaft (SFB 33).

gives up Na^+ and becomes the K^+ carrier. The K^+ carrier charged with K^+ passes to the inside of the cell membrane, where it gives up K^+. The K^+ carrier is then converted back into an Na^+ carrier by an ATP-dependent reaction.

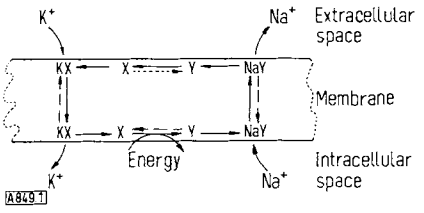

Fig. 1. Kinetic model of the coupled transport of Na^+ and K^+ in opposite directions through the cell membrane (after *Shaw* [55]). X = potassium carrier, Y = sodium carrier.

In agreement with this model, it was shown for the squid giant axon that the transport of sodium ions out of the cell is linked with the absorption of an equal number of potassium ions into the cell. According to *Baker* and *Shaw*[68,69], approximately three sodium ions are transported out of the cell and three potassium ions into the cell per mole of ATP hydrolyzed. However, *Garrahan* and *Glynn*[70] and *Post et al.*[54,56,71] found a ratio of only $3\,Na^+/2\,K^+$ per mole of ATP hydrolyzed for human erythrocytes. Evidently the Na^+ transport can be partially uncoupled from the K^+ transport. Investigations carried out in recent years have shown that uncoupling occurs when the intracellular ATP/ADP or ATP/P_i ratios are low[72-74].

2.1. ATP Synthesis by Reversal of the Na^+ Pump

The coupling of the active transport of Na^+ with the K^+ transport and the dependence of this process on the hydrolysis of ATP raises the question whether reversal of the Na^+ pump can lead to an ATP synthesis. This question has been largely answered by investigations on human erythrocytes. The Na^+ pump was reversed by incubating red blood cells, which had been preloaded with ATP, ADP, inorganic [^{32}P]phosphate and K^+, in Ringer's solution containing no K^+ but Na^+ in high concentrations. Under these conditions radioactive phosphate is incorporated into ATP[75-82]. This process is inhibited by ouabain, the specific inhibitor of the Na^+ pump. The possibility that the labeling of the ATP with $^{32}P_i$ took place *via* the substrate chain phosphorylation in the glycolysis, and is thus independent of the reversal of the Na^+ pump, was ruled out[75,76]. The synthesis of ATP by reversal of the Na^+ pump was found to be favored by steep concentration gradients of Na^+ and K^+ and by low $[ATP]/([ADP]\cdot[P_i])$ ratios[78-85]. Preliminary stoichiometric studies have shown that one molecule of energy-rich phosphate is formed for the efflux of two to three potassium ions[77,80]. The intracellular ATP synthesis by reversal of the Na^+ pump stops when the potassium concentration in the extracellular space and the sodium concentration in the cell rise above 10 mmole/l[78,79,83].

3. ($Na^+ + K^+$)-Activated ATPase and the Na^+ Pump

The cell membranes and microsomes of cells with an active Na^+ pump contain an ATP-hydrolyzing enzyme system, which is activated by the simultaneous presence of sodium and potassium ions. An ($Na^+ + K^+$)-activated ATPase found in the cell membranes of crab nerve was first described in 1957 by *Skou*[86]. The enzyme has now been detected in all the tissues in which active transport of Na^+ and K^+ occurs that can be inhibited by ouabain[34,36,38-40,87,88]. *Bonting et al.*[88], in particular, investigated the relation between the active Na^+ pump and ($Na^+ + K^+$)-activated ATPase. Though the pump activities may differ very widely in some cases, a constant ratio of cation flux/($Na^+ + K^+$)-ATPase activity, based on a membrane area of 1 cm^2, is found in all tissues. These findings show that the ($Na^+ + K^+$)-activated ATPase corresponds to at least a part of the Na^+ pump.

3.1. Properties of ($Na^+ + K^+$)-Activated ATPase

($Na^+ + K^+$)-activated ATPase is a structure-bound enzyme. Attempts to separate the enzyme from the cell membrane with proteases[89,90] or phospholipase[89,91-93] or by physical treatment[89] were unsuccessful. The enzyme has, however, been converted into a pseudo-solution by treatment of the cell membranes with detergents[94,95]. Purification of the enzyme from inactive accompanying proteins and from a soluble ATPase that is dependent only on Mg^{2+} can be achieved by differential centrifugation to obtain the cell membranes, treatment with salts and detergents, and aging[34,38,89].

For optimum activity, the ($Na^+ + K^+$)-activated ATPase requires the *simultaneous* presence of Mg^{2+}, Na^+, and K^+. With magnesium ions alone, the enzyme exhibits only weak activity. The additional presence of one of the monovalent

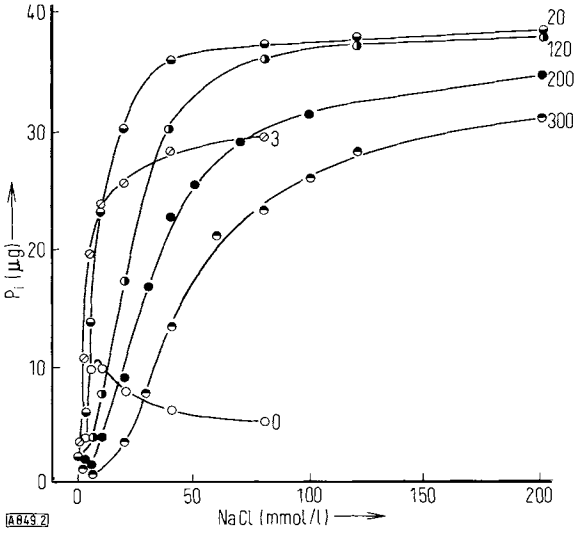

Fig. 2. Na^+ dependence of the activation of the ($Na^+ + K^+$)-activated ATPase of crab nerve at various K^+ concentrations; Mg^{2+} concentration: 6 mmole/l (from *Skou* [86]). Ordinate: relative rate of liberation of phosphate from ATP, expressed as µg of P_i per unit time. The figures by the curves are the K^+ concentrations in mmole/l.

cations Na^+, K^+, Rb^+, Cs^+, Li^+, and NH_4^+ increases the hydrolysis of ATP[86]. A considerable further activation is observed when sodium ions are added to the reaction mixture that already contains magnesium and potassium ions (Fig. 2). Sodium ions are absolutely essential for this additional activating effect, and cannot be replaced by other monovalent cations. Potassium ions, on the other hand, can be replaced by other alkali metal or ammonium ions.

The optimum enzyme activity of the $(Na^+ + K^+)$-activated ATPase is determined by the Na^+/K^+ ratio, and is usually reached at a concentration of 100 mmole/l of Na^+ and 20 mmole/l of K^+ (+6 mmole/l of Mg^{2+}) (Fig. 2). In contrast with the Na^+ pump, however, the enzyme system exhibits no pronounced adenine-specificity[89, 96, 97]; besides ATP, other nucleoside triphosphates also slowly undergo $(Na^+ + K^+)$-dependent cleavage[98]. The use of other nucleoside triphosphates as energy sources for the Na^+ pump cannot be detected with certainty in the models used for transport studies; the test systems are probably not sensitive enough. The membrane-bound enzyme, like the Na^+ pump, is inhibited by ouabain, oligomycin, and fluoride and calcium ions[99–101]. The molecular weight of the $(Na^+ + K^+)$-activated ATPase has been calculated from the inactivation of the enzyme by X-rays on the basis of the "target theory" to be $2.5 \times 10^5 - 5.0 \times 10^5$[102, 103].

3.2. Course of ATP Hydrolysis

When the $(Na^+ + K^+)$-activated ATPase is incubated with terminally labeled [^{32}P]-ATP, $(Mg^{2+} + Na^+)$-dependent incorporation of radioactive phosphate is detected in the denatured enzyme obtained by precipitation with acid[96, 98, 104–113]. On addition of potassium ions to the *native* enzyme that has already been phosphorylated in the presence of magnesium + sodium ions, the incorporated radioactivity is rapidly lost (Fig. 3). This observation suggests that the $(Na^+ + K^+)$-activated hydrolysis of ATP proceeds in at least two steps [equations (1) and (2), E = enzyme]:

$$ATP + E \xrightleftharpoons{Mg^{2+},\,Na^+} E \sim P + ADP \qquad (1)$$

$$E \sim P + H_2O \xrightarrow{K^+} E + P_i \qquad (2)$$

The function of the sodium ions in the phosphorylation reaction cannot be taken over by other cations. The activating effect of the potassium ions on the liberation of phosphate, on the other hand, is also exhibited by other alkali metal ions and by ammonium ions[105].

The degree of phosphorylation of the membrane-bound enzyme protein is determined by the specific enzyme activity of the $(Na^+ + K^+)$-activated ATPase preparation, the Na^+ concentration, the concentrations of Mg^{2+} and ATP, and their ratio[98, 105, 110, 111]. Other nucleoside phosphates besides ATP can act as phosphate donors in the phosphorylation reaction (Fig. 3)[87, 98, 110, 114].

The Na^+-dependent phosphorylation reaction has been found in all membrane preparations with an $(Na^+ + K^+)$-activated ATPase[112, 113]. This is significant in that the preparations of this membrane-bound enzyme obtained so far are still relatively impure. The results of comparative kinetic studies on the rates of the $(Na^+ + K^+)$-activated hydrolysis of ATP and of the Na^+-dependent phosphorylation reaction agree with the assumption that the concentration of a phosphorylated intermediate determines the rate of liberation of phosphate[105, 108–110].

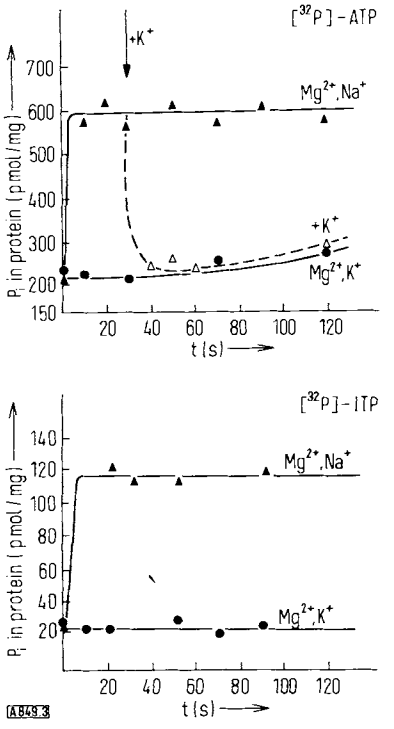

Fig. 3. Kinetics of the Na^+-dependent uptake and release of phosphate by the $(Na^+ + K^+)$-activated ATPase on incubation with [^{32}P]-ATP (top) and [^{32}P]-ITP (bottom). 30 seconds after the start of phosphorylation (arrow), 5 µmole of KCl were added to the native enzyme (after *Schoner et al.* [98]).

Corresponding to the assumption that the $(Na^+ + K^+)$-activated hydrolysis of ATP consists of an Na^+-dependent phosphorylation reaction [eq. (1)] and a K^+-dependent phosphatase reaction [eq. (2)], an *Na^+-dependent ATP-ADP transphosphorylation reaction* has been demonstrated in the enzyme preparations[115–120]. This reaction becomes noticeable only after a soluble enzyme has been separated out that catalyzes a Mg^{2+}-dependent ATP-ADP transphosphorylation[118]. This adenine-unspecific ATP-ADP transphosphorylation reaction does not take part in the $(Na^+ + K^+)$-activated hydrolysis of ATP[118]. The Na^+-dependent ATP-ADP transphosphorylation most probably participates in $(Na^+ + K^+)$-activated ATP hydrolysis. This reaction has a Mg^{2+} optimum of 0.1 to 0.2 mmole/l[115–119], thus contrasting with the Na^+-dependent phosphorylation reaction and the $(Na^+ + K^+)$-activated hydrolysis of ATP, which reach their optimum rate at Mg^{2+} concentrations of 3 mmole/l. However, the optimum Mg^{2+} concentration for the Na^+-dependent ATP-ADP transphosphorylation reaction is shifted towards higher values (3 mmole/l)[104] if the second step [eq. (2)], *i.e.* the K^+-dependent liberation of protein-bound phosphate, is blocked by pretreatment of the ATPase with *N*-ethylmaleimide (NEM) or by the addition of ouabain or oligomycin[95, 105, 110]. Simultaneously the

Na^+-dependent [^{14}C]-ADP-ATP exchange activity increases[115,116]. Both the Na^+-dependent phosphorylation and the Na^+-dependent ATP-ADP transphosphorylation exhibit half-maximal activation by sodium ions at the same concentration[116,117]. Calcium ions inhibit the Na^+ pump[49], the $(Na^+ + K^+)$-activated ATPase[99-101], the Na^+-dependent phosphorylation[105], and the Na^+-dependent ATP-ADP transphosphorylation[115].

On the basis of these similarities, it is assumed that the Na^+-dependent ATP-ADP transphosphorylating enzyme is part of the $(Na^+ + K^+)$-activated ATPase. However, the question of the nucleotide specificity still remains to be answered. In contrast with the $(Na^+ + K^+)$-activated hydrolysis of ATP and the Na^+-dependent phosphorylation[87,98,110], the Na^+-dependent ATP-ADP transphosphorylation is adenine-specific[115,116,119].

The enzyme that catalyzes this last reaction has recently been brought into solution[121]. This agrees with the assumption that $(Na^+ + K^+)$-activated ATPase is a multienzyme complex, the Na^+-dependent phosphorylation being catalyzed by a different enzyme unit from that involved in the K^+-dependent phosphatase step[122].

No P_i-ATP exchange has so far been observed with the $(Na^+ + K^+)$-ATPase preparations[97,115]. This exchange should be detectable, since an incorporation of radioactive phosphate into ATP that could be inhibited by ouabain was demonstrated for erythrocytes under conditions which lead to a reversal of the Na^+ pump[75-80,82]. The failure to detect a P_i-ATP exchange is probably due to the fact that no cation concentration gradient can be built up between the inside and the outside of the membrane fragments in the enzyme suspensions.

Two states of the phosphorylated intermediate were postulated by *Fahn et al.*[114,115] on the basis of the difference in the Mg^{2+} optima of the Na^+-dependent ATP-ADP transphosphorylation on the one hand and for the Na^+-dependent phosphorylation and the overall reaction of the $(Na^+ + K^+)$-activated ATPase on the other. *Post et al.*[123,124] were able to confirm this assumption further by kinetic studies on the reactivity of the phosphorylated intermediate toward ADP and K^+. Thus the following steps are involved in the $(Na^+ + K^+)$-activated hydrolysis of ATP (Fig. 4)[123]. Sodium ions are bound by the enzyme in the conformation E_1 in which it has a high affinity for Na^+[117]. The portion of the enzyme to which Na^+ is bound can be phosphorylated (step I). This reaction corresponds to the Na^+-dependent ATP-ADP transphosphorylation detected for the native enzyme at low Mg^{2+} concentrations (0.1 mmole/l)[115]. At higher Mg^{2+} concentrations (3 mmole/l), the phosphorylated enzyme passes from the conformation E_1-P into the state E_2-P (step II). This leads to inhibition of the Na^+-dependent ATP-ADP transphosphorylation; the phosphorylated intermediate can no longer react with ADP[115,123]. If the transition from E_1-P to E_2-P is inhibited by oligomycin, *N*-ethylmaleimide (NEM), or BAL arsenite[96,105,110], the Na^+-dependent ATP-ADP transphosphorylation is accelerated and can now also be detected at an Mg^{2+} concentration of 3 mmole/l[116,117]. On inhibition of the $(Na^+ + K^+)$-activated ATPase by oligomycin and NEM, the enzyme is no longer dephosphorylated on addition of K^+, though dephosphorylation does occur on addition of unlabeled ADP[123,124]. If the native enzyme is phosphorylated at high Mg^{2+} concentrations so that the formation of E_2-P is favored, the phosphate can be liberated only by addition of K^+ (step III), but not by addition of ADP[123].

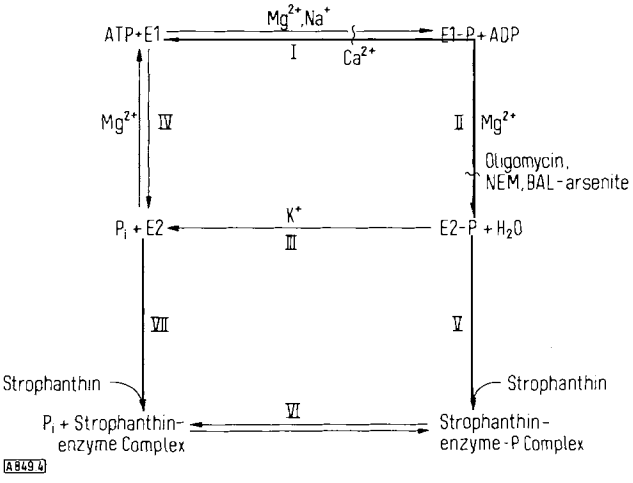

Fig. 4. Reaction steps in the $(Na^+ + K^+)$-activated hydrolysis of ATP (numbered I to VII, E = enzyme). Wavy lines show the points of attack of inhibitors. BAL arsenite = 2,3-dimercaptopropanol + arsenite in equimolar amounts (strophanthin = ouabain).

The phosphorylated enzyme seems to be converted into another modification in the presence of the specific inhibitor ouabain (strophanthin) (step V). *Post et al.*[123,124] showed that the phosphorylation of the enzyme with [^{32}P]-ATP in the presence of strophanthin leads to a phosphorylated product that can no longer be hydrolyzed by the addition of K^+. The formation of this modified form of the phosphorylated enzyme is prevented if the ATPase is pretreated with NEM. On addition of ouabain and magnesium ions to the unphosphorylated enzyme, it can no longer undergo Na^+-dependent phosphorylation with ATP[123]; however, the enzyme now exhibits incorporation of radioactive phosphate[123-127], which is not found with the enzyme that has not been treated with ouabain[105]. All the criteria available at present indicate that the phosphorylation with inorganic phosphate yields the same enzyme phosphate as the phosphorylation with ATP (step IV)[124,126,127]. To explain these observations, it is assumed that the enzyme is converted into a ouabain-enzyme complex (steps VI and VII).

3.3. Chemical Nature of the Phosphorylated Intermediate

The intermediate obtained from the ouabain-treated ATPase by phosphorylation with [^{32}P]-phosphate and the intermediate obtained from the untreated enzyme by Na^+-dependent phosphorylation with terminally labeled [^{32}P]-ATP exhibit chemically identical behavior according to all the investigation methods known at present[124,126,127]. Both products migrate at the same rate on electrophoresis; they are rapidly hydrolyzed in alkaline media and in the presence of molybdate and Hg^{2+}[106,124-128]. It has been shown that the phosphoryl-

ated intermediates are not phosphatidic acids or protein-bound serylphosphate[128-130].

Evidence in favor of an acylphosphate as the intermediate of the $(Na^+ + K^+)$-activated ATPase is the fact that the enzyme-bound phosphate is liberated as inorganic phosphate on incubation with the purified acylphosphatase or hydroxylamine [eq. (3)][106, 107, 128]:

$$E{-}COPO_3H_2 + NH_2OH \longrightarrow E{-}CONHOH + H_3PO_4 \quad (3)$$

Kahlenberg et al. assume that the phosphate acceptor group in the Na^+-dependent phosphorylation with ATP is the γ-carboxyl group of a glutamate residue[131, 132]. After incubation of the acid-denatured phosphorylated enzyme with ^3H-labeled *N*-propylhydroxylamine, the authors were able to isolate a ^3H-labeled peptide, which gave a homogeneous radioactive product on digestion with pronase and electrophoretic and chromatographic separation. In five out of seven electrophoretic and chromatographic systems, this radioactive product behaved in the same way as authentic glutamyl-*N*-propylhydroxamate.

With the native enzyme, hydroxylamine has no effect on the $(Na^+ + K^+)$-activated hydrolysis of ATP[133, 134]. This is in conflict with the assumption of an acylphosphate intermediate. Since the phosphate acceptor group is irreversibly blocked by conversion of an acylphosphate into the hydroxamic acid [eq. (3)], at least partial inactivation should be expected. However, *Chignell* and *Titus*[135] were able to show that the hydroxylamine does not reach the active center. ATP and Na^+, which must always be present in the phosphorylation reaction [eq. (1)] probably prevent the NH_2OH from approaching the acylphosphate in the active center. A protective action of ATP, Na^+, and K^+ has been detected in inactivation experiments with dicyclohexylcarbodiimide, a substance that reacts with carboxyl groups[136].

Doubt has recently been cast on the intermediate formation of an acylphosphate on thermodynamic grounds. The formation of an acylphosphate from inorganic phosphate is difficult to imagine, unless the inorganic phosphate breaks an energy-rich bond that is formed by the preincubation with ouabain.

3.4. Relationship between $(Na^+ + K^+)$-Activated ATPase and K^+-Activated Phosphatase

The membrane fractions with $(Na^+ + K^+)$-activated ATPase regularly contain a phosphatase that can be activated with potassium ions. The enzyme is also inhibited by ouabain[136-152]. The substrates of the enzyme are carbamylphosphate, acetylphosphate, and *p*-nitrophenylphosphate[140]; K^+ can be replaced by other alkali metal ions and by ammonium ions[137, 139]. Sodium ions and nucleoside diphosphates and triphosphates inhibit the enzyme activity[137, 138, 148]. Incubation of the membranes with [^{32}P]-acetylphosphate leads to the formation of a phosphorylated enzyme, which has the same properties as the phosphorylated enzyme obtained in the Na^+-dependent phosphorylation with [^{32}P]-ATP[138, 143]. All these properties and the detection of the increase in the specific activity of the K^+-activated phosphatase together with the $(Na^+ + K^+)$-activated ATPase indicate that the K^+-activated phosphatase catalyzes the K^+-dependent reaction step of the $(Na^+ + K^+)$-activated ATPase [eq. (2)][137, 140].

3.5. Kinetic Studies on the Process of Cation Activation

The investigations on the behavior of the phosphorylated intermediate toward ADP and K^+ at various Mg^{2+} concentrations suggest that the $(Na^+ + K^+)$-activated ATPase undergoes a change in conformation during the transport of cations. Further evidence in favor of this assumption can be obtained from kinetic studies on the activation of the enzyme by Na^+ and K^+. Thus *Squires*[153] and *Robinson*[154, 155] found a homotropic cooperative effect of both cations on the enzyme. Variation of the concentrations of both cations leads to changes in the cooperativity of the enzyme (compare *n* values in Table) and its affinity for the other cation (compare $K_{0.5}$ values in Table). The affinity of the enzyme for ATP is also controlled by the Na^+ and K^+ concentrations. With increasing K^+ concentration, the affinity of the enzyme for ATP decreases. A change in the ATP concentration, on the other hand, influences the concentrations of both cations that are required for half-maximal activation of the enzyme[154].

Table. Variation of the kinetic parameters of the $(Na^+ + K^+)$-activated ATPase for Na^+ and for K^+ with the concentration of the other cation (after *Robinson* [155]).
n = Hill coefficient, $K_{0.5}$ = activation constant of cation, rel. V_{max} = maximal velocity of ATP hydrolysis.

Activator	NaCl (mmole/l)	KCl (mmole/l)	*n*	$K_{0.5}$ (mmole/l)	V_{max}
NaCl	—	0.8	1.57±0.05	1.7±0.3	0.69±0.02
	—	2.0	1.35±0.06	2.8±0.6	0.91±0.04
	—	10.0	1.17±0.03	5.0±0.7	1.03±0.02
	—	30.0	1.22±0.08	6.3±1.3	1.08±0.05
KCl	3	—	0.75±0.06	0.18±0.04	0.53±0.04
	5	—	1.08±0.11	0.15±0.01	0.63±0.02
	10	—	1.28±0.09	0.19±0.03	0.74±0.05
	90	—	1.41±0.04	0.75±0.11	1.03±0.02

The change in the activation constants $K_{0.5}$, *i.e.* the concentrations of the cations that are required for half-maximal activation, was evident even in the first description of the enzyme by *Skou*[86] (see Fig. 2). *Skou* assumed that this displacement of $K_{0.5}$ values was due to competition of the K^+ for the Na^+ binding sites and of the Na^+ for the K^+ binding sites, a view that was also shared by other authors[50, 86, 97, 156]. Kinetic studies yielded no definite information about the number of binding sites for Na^+ and K^+. *Ahmed et al.*[157] postulated two Na^+ binding sites per K^+ binding site, whereas *Robinson*[155] assumes several binding sites for Na^+ and K^+, which can be occupied simultaneously or successively.

3.6. Studies for the Detection of Na^+ and K^+ Binding Sites

The direct detection of Na^+ and K^+ binding sites on the enzyme has not yet been possible because of the impurity

of the enzyme preparations. An ATP-dependent binding of Na^+ on rat brain microsomes has been described by *Järnefelt* and *von Stedingk*[158]. In their studies, half-maximal saturation of the microsomes by Na^+ was found at a concentration of 0.1 mole/l. However, $(Na^+ + K^+)$-activated ATPase is activated half-maximally by Na^+ at much lower concentrations Fig. 2[86, 155]. From this comparison it is evident that the Na^+ binding site found by *Järnefelt* and *von Stedingk* is not involved in the active Na^+ transport. In addition, *Ahmed* and *Judah*[159] could show that the ability of the microsomes to bind Na^+ is increased to a much greater extent by EDTA than by ATP. The authors therefore concluded that Mg^{2+} completes with Na^+ for the acceptor site. Nonspecific binding of Na^+ to the cell membrane is also indicated by the fact that equal quantities of H^+/mg of protein are released on addition of NaCl, KCl, or LiCl in a concentration of 0.1 mole/l to microsomes.

The phosphorylation experiments with terminally labeled [^{32}P]-ATP[96, 98, 104–113] could give the impression that ATP is necessary for the cation-specificity of the enzyme. On the basis of inhibition experiments with diisopropyl fluorophosphate[160], *N*-ethylmaleimide (NEM)[161], and $BeCl_2$[162], however, it must be assumed that Na^+ and K^+ react specifically with the enzyme even in the absence of ATP[162]. Thus in the absence of ATP, sodium ions protect the $(Na^+ + K^+)$-activated ATPase against inactivation by $BeCl_2$, while K^+ strengthens the inactivation[162, 163]. The protective and inactivating effects of the cations occur at concentrations that lie in the physiological range.

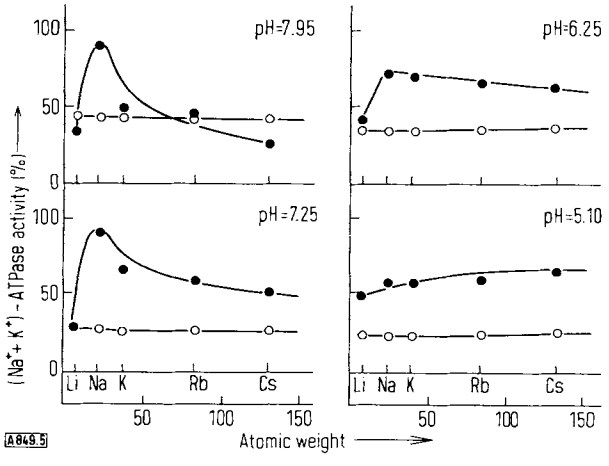

Fig. 5. Protective action of alkali metal ions against the inactivation of $(Na^+ + K^+)$-activated ATPase by dicyclohexylcarbodiimide (DCCD) as a function of the pH value (after *Schoner* [165]). Ordinate: ATPase activity after incubation for 6 min with DCCD with reference to the control without DCCD (in percent). ● = cation concentration 60 mmole/l; ○ = control without cation.

In our own investigations, we observed a pH-dependent change in the protective effect of alkali metal ions against the inactivation of the $(Na^+ + K^+)$-activated ATPase by dicyclohexylcarbodiimide (Fig. 5)[164, 165]. This result suggests that the cation specificity changes with changing dissociation of an acidic group of the enzyme. This is in agreement with the observed displacement of the pH optimum of the $(Na^+ + K^+)$-activated ATPase with the Na^+/K^+ ratio in the test medium[165–167].

3.7. Mode of Action of Cardiac Glycosides

Cardiac glycosides specifically inhibit the active transport of Na^+ and K^+ and the $(Na^+ + K^+)$-activated ATPase[66, 168]. Further information about the processes involved in the transport of Na^+ and K^+ should therefore be obtainable by the investigation of the mode of action of these inhibitors. The inhibitory action of the cardiac glycoside ouabain is a time- and temperature-dependent process. The onset of action is strongly accelerated by the simultaneous presence of Mg^{2+}, Na^+, and ATP[125]. This suggests that ouabain reacts with the phosphorylated enzyme[169, 170]. In agreement with this assumption, it has been shown that the simultaneous presence of Mg^{2+}, Na^+, and ATP is necessary for the binding of ^{3}H-labeled cardiac glycosides[125, 171, 172]. Ouabain reacts in stoichiometric quantities with the enzyme (one molecule of ouabain per two phosphorylation sites)[125, 173].

The phosphorylated enzyme can be obtained not only under physiological conditions (step I in Fig. 4) but also by incubation of the enzyme with ouabain, inorganic phosphate, and Mg^{2+} (steps IV, VII, and VI in Fig. 4)[125–127]. The phosphorylated enzyme obtained in this way also binds more [^{3}H]-ouabain than the native enzyme[172].

The quantity of [^{3}H]-ouabain bound to the enzyme under these last conditions decreases strongly in the presence of Na^+[172], whereas an Na^+-dependent increase in the uptake of [^{3}H]-ouabain is observed in the presence of Mg^{2+} and ATP[125, 171, 172]. The *Na^+-dependent increase* in the binding of ouabain to the $(Na^+ + K^+)$-activated ATPase in the presence of Mg^{2+} + ATP and the *Na^+-dependent inhibition* of the binding of ouabain in the presence of Mg^{2+} + inorganic phosphate (P_i) show that "the conformational state of the enzyme is probably of primary significance in glycoside binding[173]".

According to *Tobin* and *Sen*[172], the equilibrium between the two assumed conformations of ATPase, *i.e.* E_1 and E_2, is displaced in favor of E_2 by Mg^{2+} and P_i (step IV in Fig. 4). In this form, which is equivalent to E_2-P, ouabain can be bound to the enzyme. Ouabain holds the enzyme in the E_2 conformation. The affinity of Na^+ for the enzyme is also lower in this conformation. The equilibrium between E_1 and E_2 is displaced in favor of E_1 in the presence of Mg^{2+} and P_i if Na^+ is present in higher concentrations. Under these conditions, ouabain cannot be bound. E_1 should thus be sensitive to Na^+ in its phosphorylated and in its unphosphorylated forms.

This assumption is supported by the detection of a specific protective action of Na^+ against the inactivation of the $(Na^+ + K^+)$-activated ATPase by $BeCl_2$[162, 163] and the antagonistic action of K^+ on the non-phosphorylated enzyme.

3.8. Properties of the Enzyme-Bound Cardiac Glycoside

The enzyme-bound radioactive steroid does not exchange its radioactivity with unlabeled cardiac glycosides. However, it is released from the enzyme at higher temperatures and in acidic media below pH 5, and can be extracted with

methanol[125, 174]. On the basis of the extractability and the observation that the time required for the inhibitory effect of the steroids to appear is inversely proportional to the number of hydroxyl groups and of sugar substituents, *Albers et al.*[125], in agreement with assumptions made by *Portius* and *Repke*[170], concluded that the cardiac glycosides enter into hydrophobic interactions with hydrophobic regions of the enzyme. However, this assumption is opposed by investigations carried out by *Yoda* and *Hokin*[175], which showed that the inhibitory action of the aglycones of the cardenolides is more readily reversible than that of the glycosides.

4. Outlook

The detection of Na^+-specific protective effects against inactivating agents in the absence of ATP[162–165] indicates that cation-specific acceptor groups are present on the enzyme. The phosphorylated intermediate does not therefore appear to be involved in the occurrence of the cation specificity, but probably takes part in the transport of the cations through the cell membrane. This process is probably associated with a change in the conformation of the enzyme[114, 115, 123, 124, 171–173]. It is uncertain whether carriers are involved in the transport of the cations. It is to be hoped that the answer to this question will be provided by further investigations on the mode of action of the $(Na^+ + K^+)$-activated ATPase.

Ternary Fission[**]

By Reinhard Brandt[*]

In this review paper, ternary fission is defined as the break-up of heavy nuclei into three fragments of approximately equal mass. This relatively new type of nuclear decay has been investigated intensively during the last decade. Muga has studied ternary fission induced by thermal neutrons in uranium. The results of his experiments are discussed in detail. Ternary fission can definitely be observed and studied in the interaction of heavy target elements with 39 MeV alpha particles, 20 GeV protons, and 300—400 MeV argon ions. The ratio of binary-to-binary fission for uranium is approximately 10^{-4}: 100 in the interaction of 39 MeV alpha particles, approximately 0.1 : 100 for 20 GeV protons, and 3 : 100 for 400 MeV argon ions. A theoretical model for the interpretation of ternary fission, the "cascade model", is described. The paper concludes with a discussion of the possible connection of ternary fission with the production and decay of still undiscovered superheavy elements ($Z = 114$).

1. Introduction

Binary fission was discovered in 1938. The "liquid drop" model of the nucleus was used from the beginning to interpret this new phenomenon. Using this model *Present*[1] pointed out as early as 1941, that the disintegration of nuclei into three particles of equal mass should be possible. Such a nuclear disintegration will be defined in this paper as ternary fission; fission yielding two heavy particles and one light particle (usually an alpha particle) will not be dealt with here. Later, *Swiatecki*[2] studied the application of the liquid drop model for the interpretation of fission. In this model it is assumed that the nucleus is an ideal, electrically charged, spherical liquid drop. Such a liquid drop has a surface tension of $E_s^{(o)}$ and a Coulomb energy of $E_c^{(o)}$. It is common practice to express the ability of such a drop for fission in terms of a *fissionability parameter*, X, defined as follows:

$$X = \frac{E_c^{(o)}}{2 \cdot E_s^{(o)}} \tag{1}$$

It is possible to calculate $E_c^{(o)}$ and $E_s^{(o)}$ for nuclei carrying a nuclear charge Z and mass A. When rather simple semi-empirical parameters are chosen, X is[3]:

$$X = \frac{Z^2/A}{(Z^2/A)_{crit.}} \qquad (Z^2/A)_{crit.} = 50.1 \tag{2}$$

The decay energy for fission of a nucleus into n equally sized fragments, and its dependence on the fissionability parameter X, has been calculated by *Swiatecki*[2] for several values of n. The results, which are shown in Figure 1, allow the following conclusions to be drawn:

1. Fission of light nuclei is only exothermic when $Z^2/A > 17$. Binary fission is energetically more favorable than ternary fission.

2. The range of $30.5 < Z^2/A < 43.3$ covers the elements from $_{83}$Bi up to $_{100}$Fm. These elements are the targets most commonly used in fission studies. For these nuclei, the decay energy for ternary fission is larger than for binary fission. Based on this simple consideration, many attempts were made to observe ternary fission. All of them were without success until 1966.

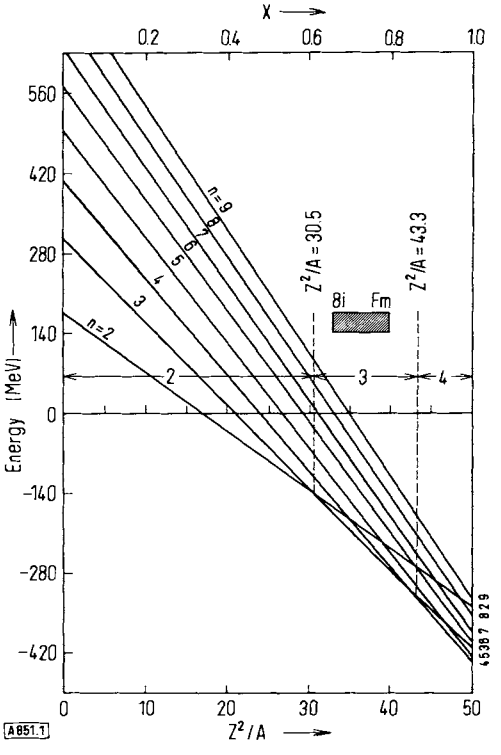

Fig. 1. Decay energy of an ideal, electrically charged liquid drop as a function of the fissionability parameter X and of the value Z^2/A. The parameter n gives the number of equally sized fission fragments obtained in the decay process [2]. Fission into two fragments is energetically favored for $Z^2/A < 30.5$, ternary fission is energetically most favorable for $30.5 < Z^2/A < 43.3$. Fission into four fragments gives the largest amount of kinetic energy for $Z^2/A > 43.3$.

[*] Professor Dr. Reinhard Brandt
Institut für Kernchemie der Universität

[**] A condensed version of an invited paper given at the "Heavy Ion Seminar on Nuclear Fission and Superheavy Elements", The Technical University, Darmstadt, 1970. The seminar was arranged by the "Gesellschaft für Schwerionenforschung, GSI", Darmstadt.

3. Stable nuclei are unknown for $Z^2/A > 43.3$. However, for undiscovered elements, multiple fission should become more and more probable.

4. The biggest possible value of Z^2/A for the target system should be chosen when investigating ternary fission.

Experiments for the study of ternary fission will be described in the following section. These investigations are interesting in two respects: Firstly, this new type of nuclear decay was predicted theoretically. Secondly, there is reason to believe that the production and decay of possibly stable elements around $Z = 114$ might be connected with ternary fission. This rather speculative working hypothesis will be discussed at the very end of this review paper.

2. Experimental Investigation of Ternary Fission

2.1. The Fission of Uranium and Plutonium with Thermal Neutrons

2.1.1. Counter experiments by *Muga et al.*

For several years, *Muga* and his co-workers have been investigating ternary fission of uranium and plutonium induced by thermal neutrons[4-8]. They use three fission-fragment detectors, employed in the coincidence mode. Figure 2 shows the geometrical arrangement of the target (U or Pu on a thin backing) and the three fission-fragment detectors in a vacuum chamber. This chamber is exposed to the thermal neutrons of a reactor. Further, since it is assumed that the three fission fragments separate at angles of approximately 120°, the detectors are arranged correspondingly. The three fission fragments reach the detector

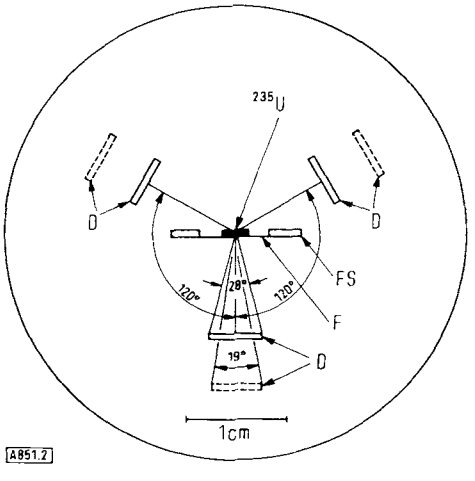

Fig. 2. Experimental arrangement for ternary fission studies of ^{235}U with thermal neutrons. D: fission fragment detectors, F: foil to hold the ^{235}U-target, FS: target holder [5].

within a time interval of 20 ns. Their kinetic energy E is then measured and registered electronically. Further details of the electronic apparatus and the method of data handling are not given here, but may be found in References [4]—[8].

The determination of the ratio of ternary fission $\sigma(T)$ to binary fission $\sigma(B)$ is an essential result of these studies[*]:

$\sigma(T):\sigma(B) \approx 10^{-4}:100$
Reaction: $^{239,241}Pu + n_{th} \longrightarrow$ ternary fission (3)
Method: counter experiment

Proof of the existence of ternary fission (TF) is obtained in an indirect rather than in a direct manner. Figure 3 shows, for example, the distribution of the lightest fragments in the ternary fission of ^{239}Pu and ^{241}Pu induced by thermal neutrons. The two distributions differ significantly from each other. For *Muga*, this statistically significant difference was proof that he had observed ternary fission and not a scattering phenomena or an electronic malfunction. *Muga* can not explain the reason for this difference; however, this is irrelevent here.

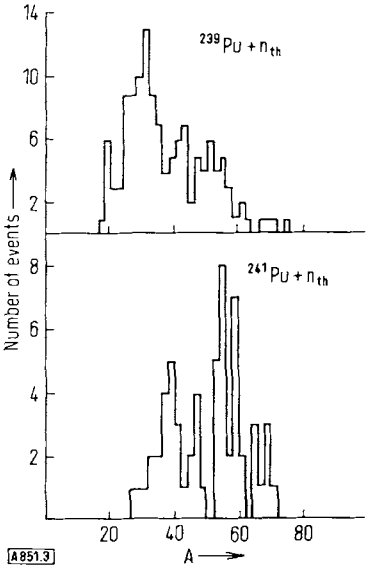

Fig. 3. Mass-distribution for the lightest fragment in ternary fission of ^{239}Pu and ^{241}Pu with thermal neutrons [8].

The most surprising result, which can be drawn from Figure 3, is the existence of fragments in the mass range $25 < A < 70$. Due to the experimental technique employed, it is not known whether these light fragments are beta-stable or not, that is, whether or not they can be detected by radiochemical methods.

Muga's experimental results have not been generally accepted. Recently, *Steinberg*[9] *et al.* showed that *Muga*'s results can be explained to a large extent as scattering phenomena. It is the opinion of the author of this review, that this issue has not been completely settled, as experiments using advanced time-of-flight techniques for mass determinations, have not been conducted and published.

2.1.2. Radiochemical Experiments

The mass distribution of the lightest fission fragment in ternary fission, as shown in Figure 3, has induced a number

[*] The cross-section σ is a quantitative measure for nuclear reaction probabilities. Its unit is 1 barn ($1\ b = 10^{-24}\ m^2$). Further details may be found in many textbooks on nuclear chemistry, for example, *M. Lefort*: "Nuclear Chemistry", Van Nostrand Company, New York.

of radiochemists to search for radioactive products in the mass-range of $20 < A < 60$[10–12]. These investigations have been necessarily restricted to sufficiently long-lived radioactive nuclides such as ^{28}Mg, ^{38}S, ^{37}Ar, ^{39}Ar, ^{41}Ar, ^{42}Ar, ^{48}Sc, ^{51}Cr, ^{54}Mn, ^{56}Co, ^{57}Co, ^{58}Co, ^{60}Co, and ^{59}Fe. However, as no such radioactive products could be found, one can give a lower limit for ternary fission:

$\sigma(T):\sigma(B) \leq (10^{-6}—10^{-8}):100$
Reaction: $^{235}U + n_{th} \longrightarrow$ ternary fission (4)
Method: radiochemical experiment

As already mentioned, this negative result does not necessarily exclude the correctness of *Muga*'s work[4–8], since non-radioactive light fission fragments are also observed with the latter technique.

2.2. Experiments at Medium Bombarding Energies (10—50 MeV)

Initial research in this field has been reviewed elsewhere by *Hyde*[3] and therefore shall not be repeated here. Likewise, the experiments carried out by *Benisz et al.*[13] and *Medveczky et al.*[14] shall be mentioned only briefly here.

A particularly elegant proof for the existence of ternary fission was given by *Iyer* and *Cobble*[15, 16], who irradiated uranium with alpha particles and determined the cross-section for light fragments such as ^{24}Na, ^{28}Mg, and ^{38}S

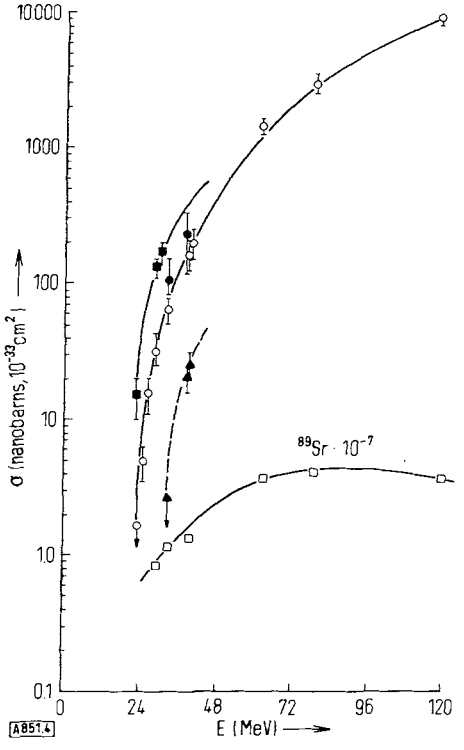

Fig. 4. Excitation function of some radioactive products produced by ^{3}He-induced fission of ^{238}U [16]. σ: cross-section, E: bombarding energy.

□: ^{238}U (^{4}He, f$_b$) ^{89}Sr

by radiochemical methods. The excitation function[*] for the production of these nuclides is shown in Figure 4. The measured cross-sections were extremely small, being in the order of $\sigma \approx 10^{-32}$ cm^2. The nuclides searched for had to be separated from a 10^7-fold excess of common binary

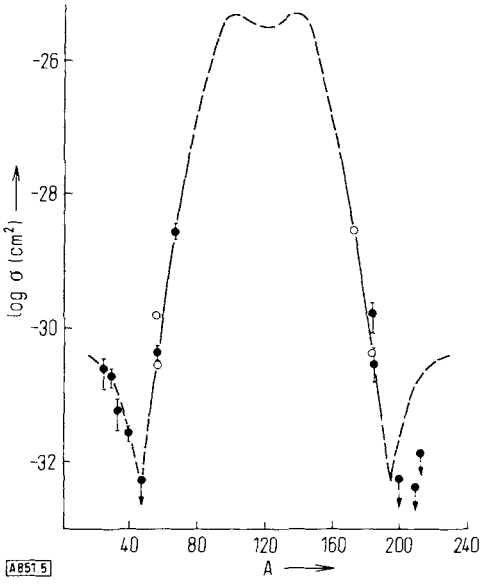

Fig. 5. Mass yield curve for fission of ^{238}U induced by 39 MeV ^{4}He [16]. Closed points are directly measured, open points are reflected.

fission products. The isolated samples showed counting rates of 1 to 100 counts-per-minute. However, the identity of an isolated chemical isotope was assured by the chemical separation technique and by the determination of the radioactive half-life. In order to exclude the possibility that light fragments were not created in a very asymmetric binary fission process, *Iyer* and *Cobble* searched for the complimentary heavy fragment in the mass-range $A \approx 190$. Such heavy fission fragments could not, however, be detected. The measured mass-yield curve is shown in Figure 5. The very light fragments with $20 < A < 60$ were formed in a considerably higher yield than very heavy fragments with $A \approx 190$. This shows conclusively that light fragments such as ^{28}Mg are formed by a ternary fission process when ^{238}U is bombarded with 39 MeV alpha-particles.

2.3. Ternary Fission Induced by 20 GeV Protons

Modern high-energy accelerators, such as at CERN, Geneva, provide proton beams of considerable energy, usually of about 28 GeV (1 GeV = 10^9 eV). In the interaction of high energy protons with complex heavy nuclei, such as ^{238}U, a variety of nuclear reactions are observed. These reactions can be understood only partially on the basis of present theoretical models[3, 17]. Nevertheless, nuclear reactions yielding two or three "heavy" fragments are also classified as binary or ternary fission. The definition of "heavy" depends again on the kind of experiment to be carried out.

[*] The "excitation function" is defined as the dependence of the cross-section σ of a particular nuclear reaction product on the energy of the bombarding particle.

The dependence of the total fission cross-section of heavy elements on the proton energy has been studied using the mica-sandwich technique. Mica is a widely used detector for fission fragments having a mass $A \geq 30$. The fission fragment tracks are etched with hydrofluoric acid and can be observed directly with an optical microscope (see Fig. 6)[18, 19]. High energy protons can not be detected with mica[20]. Further experimental details are described in References [22] to [26].

The tracks made by the fission fragments are clearly seen under an optical microscope. One can observe correlated pairs of tracks (B), obviously originating from binary fission. The point of origin of such correlated pairs of tracks is not visible, since the decaying uranium atom (target) is placed between the mica plates (sandwiched).

The cross-section for binary fission $\sigma(B)$ is determined from the number of pairs of correlated tracks in the sandwich[21, 23, 24]. Sometimes, single, uncorrelated tracks (S) can be seen, as is also shown in Figure 6. Their origin is not completely clear; however, it has been shown that they originate to a large extent from binary fission events with one fragment being absorbed within the target and thus not yielding an etchable track[21, 22, 25].

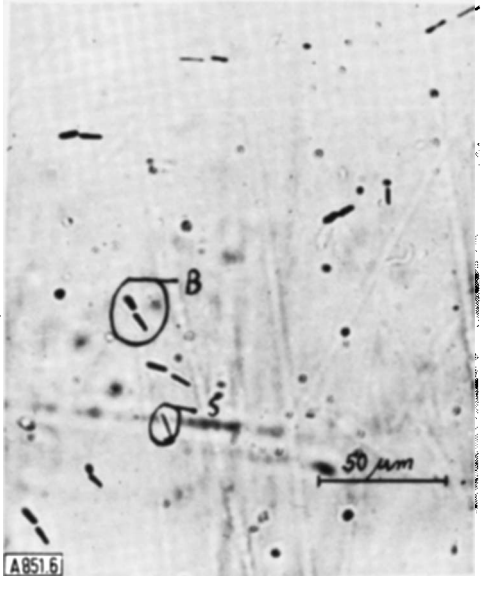

Fig. 6. Photomicrography of typical examples of correlated pairs of fission fragments (B) as well as single tracks (S). The two inner surfaces of the mica sandwich are simultaneously in focus. Reaction: $^{238}U + 20$ GeV protons.

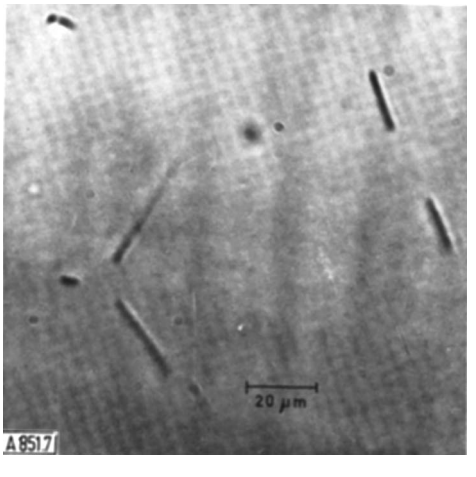

Fig. 7. Photomicrography of a possible example of ternary fission in the reaction $^{238}U + 20$ GeV protons.

In relatively few instances one can observe three correlated tracks (T) as shown in Figure 7. Such an event can have a twofold origin: either it is an accidental overlap of a binary track (B) and a single track (S), or it is a genuine ternary fission. The largest angle α between two tracks in the plane of observation is measured for all ternary events in order to distinguish between the two alternative interpretations. The observed distribution of α is shown in Figure 8. Quite often the angle α is approximately 140°. The corresponding distribution of angles for binary fission is also measured; here practically all angles are approximately 180°[26]. One can now calculate the expected distribution of the largest angle α for an accidental overlap of binary (B) and single (S) tracks. This is also shown in Figure 8.

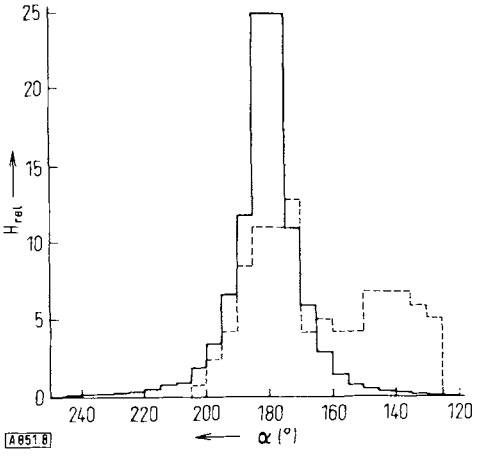

Fig. 8. Distribution of the largest angle α in the mica plane for all possible examples of ternary fission. H_{rel} = relative probability; – – –: observed distribution, ——: expected distribution for *no* ternary fission. $\chi^2 = 585$ ($\gamma = 2$), $P(\chi^2) \ll 1\,‰$.

The two distributions shown in Figure 8 differ considerably, and are statistically significant (χ^2-test). This is proof for the observation of ternary fission in the interaction of uranium with 20 GeV protons, provided that the possibility of this being a scattering phenomena is excluded. This can be done by comparing the ratio of $\sigma(T):\sigma(B)$ as a function of the irradiation energy, as shown in Table 1. An increase in the ratio of $\sigma(T):\sigma(B)$ with irradiation energy demonstrates that this is not a scattering of fission fragments giving rise to false ternary fission events (Fig. 7). Additional independent methods of proving the existence of ternary fission have also been published[26, 27]. In all, about 200 events of the kind shown in Fig. 7 have been observed.

Table 1. Dependence of $\sigma(T):\sigma(B)$ for uranium on the bombarding energy using the mica sandwich technique [27].

Energy and particle	$\sigma(T):\sigma(B)$	$\sigma(T)$ (mb)
thermal neutrons	$\leq 1.3 \cdot 10^{-2}:100$	—
600-MeV-protons	$(0.2 \pm 0.1):100$	2.0 ± 1.5
18-GeV-protons	$(0.18 \pm 0.06):100$	1.5 ± 1.1
23-GeV-protons	$(0.48 \pm 0.16):100$	3.5 ± 1.2

Further characteristics of ternary fission are difficult to determine using the sandwich technique. The measurement of the direction of an etched track in space is rather inaccurate[27]. (The direction of a track in space can be determined about as accurately as can that of the direction of a pointing finger.) With these reservations in mind, one

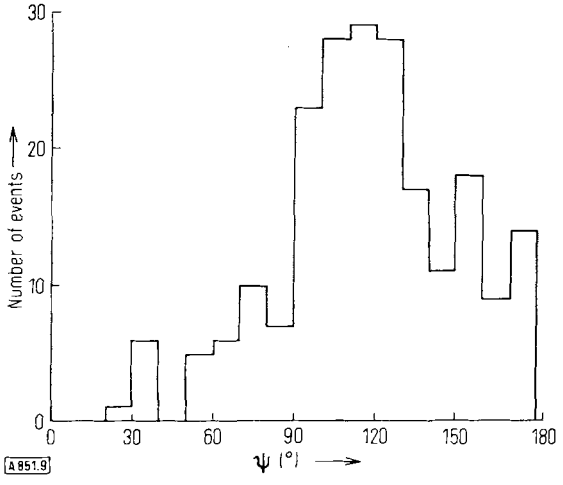

Fig. 9. Distribution of angles between fission fragments in ternary fission of ^{238}U with 20 GeV protons (simplified figure after Ref. [27]). ψ = angle between fission fragments.

can determine the angle in space between tracks of ternary fission events (see Fig. 9)[27]. It is usually about 120°, indicating that ternary fission is a planar and symmetrical decay process in the laboratory system. However, it must be pointed out that the mica sandwich technique does not allow the evaluation of mass-distributions in ternary fission.

Two other groups of research-workers have also observed ternary fission under similar conditions. *Hudis* and *Katcoff*[23] determined the excitation function of ternary fission for uranium-, bismuth-, and gold-targets in the GeV region. *Debeauvais et al.*[28,29] carried out similar studies, using a more sensitive detector, called "Macrophol", which registered all particles with mass $A \geq 14$.

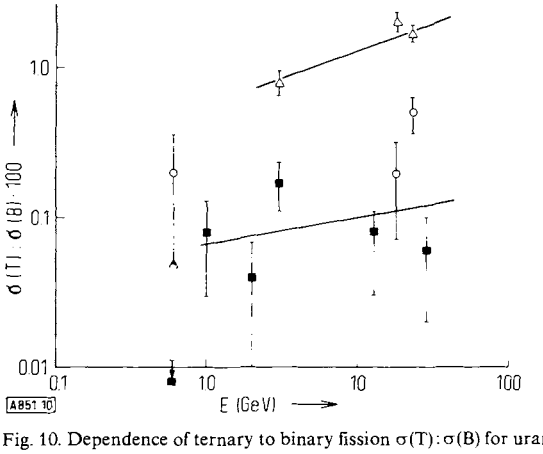

Fig. 10. Dependence of ternary to binary fission $\sigma(T):\sigma(B)$ for uranium on the proton bombarding energy.
△: Results obtained with macrophol detectors ($A \geq 14$) at Strasbourg [29].
○: Results obtained with mica detectors ($A \geq 30$) at Geneva [27].
■: Results obtained with mica detectors ($A \geq 30$) at Brookhaven [23].

Obviously, a considerably greater number of ternary fissions is observed with this more sensitive detector (the ratio $\sigma(T):\sigma(B) \approx 1:100$). The excitation function of ternary fission for uranium obtained by different techniques is summarized in Figure 10[23,27,29].

Finally, it should be mentioned that ternary fission in the reaction U + 20 GeV protons was observed by a further independent experimental technique. This technique,

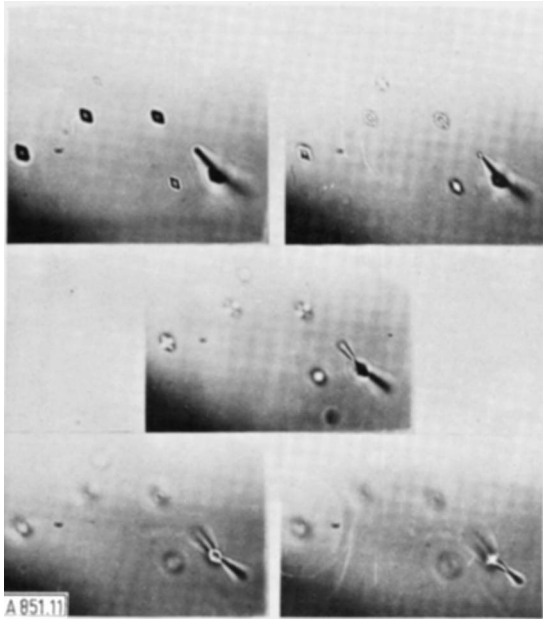

Fig. 11. Hole detector in mica, after *Starke*. In this sequence of photomicrographs only the focal plane of observation is subsequently lowered from picture to picture; thus a binary fission event in one hole can be observed. Nuclear reaction: ^{238}U + 20 GeV protons [30].

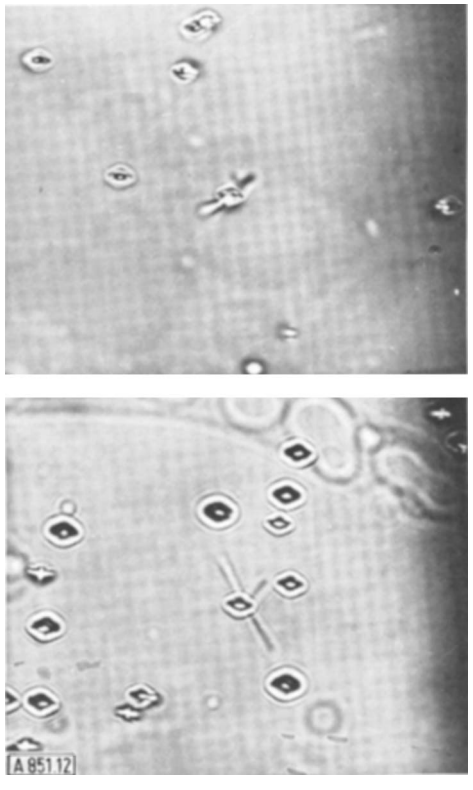

Fig. 12. Two possible examples of ternary fission in the reaction of ^{238}U with 20 GeV protons, as observed in the hole detector, after *Starke*.

known as the "hole-detector" method, was introduced by *Starke*[30]. Fine holes are produced in mica by etching fission fragment tracks on the surface and are partially filled with uranium. The mica is then irradiated with 20 GeV protons and then re-etched with hydrofluoric acid. A sequence of photomicrographs of a binary fission event in such a hole is shown in Figure 11. (Only the focal plane was changed for each picture.) Two possible examples of ternary fission observed in these holes are shown in Figure 12. However, the potentialities of this method have not as yet been worked out.

2.4. Ternary Fission Induced by Heavy Ions

Heavy ions such as neon or argon can be accelerated in "heavy ion accelerators" to such energies as to render them capable of inducing nuclear reactions. These heavy ions usually induce nuclear fission in heavy target elements. In this case it can be assumed that target nuclei and projectile fuse together and form a so-called "compound nucleus". This compound nucleus has a well-defined and rather high Z^2/A, as well as a well-determined excitation energy E_{ex}. (This is in contrast with high-energy proton induced reactions, where Z^2/A and E_{ex} for the fissioning nuclei are practically unknown.) As mentioned in the introduction, according to *Swiatecki*'s arguments it is plausible to search for and investigate ternary fission with heavy ions. One theoretical model for the interpretation of ternary fission induced by heavy ions does exist. This is discussed further on in Section 3.1. Unfortunately, there have been only a limited number of investigations in this field; most of these have been carried out with the heavy ion accelerators at Berkeley (USA) and at Dubna (USSR).

These experiments will be described according to the experimental method used for investigation. Hence, the work of *Fleischer*, *Price*, *Walker*, and *Hubbard*[31] will unfortunately be mentioned last, despite the fact that they were the first to prove the existence of ternary fission in the interaction of 414 MeV-Ar with Th in $ThSiO_4$-crystals. They still hold the "world record" for having found the largest ratio for $\sigma(T):\sigma(B)=(3.3\pm0.3):100$.

2.4.1. Electronic Counter Experiments

In this field only two papers have been published[32, 33]. Figure 13 shows schematically the experimental arrangement for such electronic counter experiments. The arrangement is similar to that used by *Muga* (see Section 2.1.1); however, the fission fragment detectors are not placed in one plane, but rather are placed so as to account for the momentum of the incoming particle. The registration of ternary fission is restricted to events in which the angle between the fragments is $(120\pm8)°$ in the center-of-mass system. The energy of the fission fragments is measured with semiconductor detectors and is then registered electronically. The measured distribution of kinetic energies for two different reactions is shown in Figure 14. The mean total kinetic energy ("combined spectrum") increases with increasing Z of the projectile. Such a result can be predicted from knowledge of the general behavior of fission[3]. The ratio $\sigma(T):\sigma(B)$ can be obtained by measuring the ratio of threefold coincidences to the number of measured fission events (Table 2).

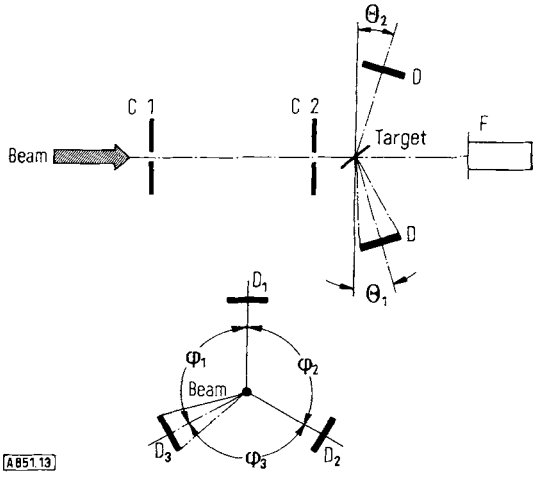

Fig. 13. The experimental arrangement for studying ternary fission induced by heavy ions [33]. C: collimator, D: fission fragment detector, F: Faraday cup.

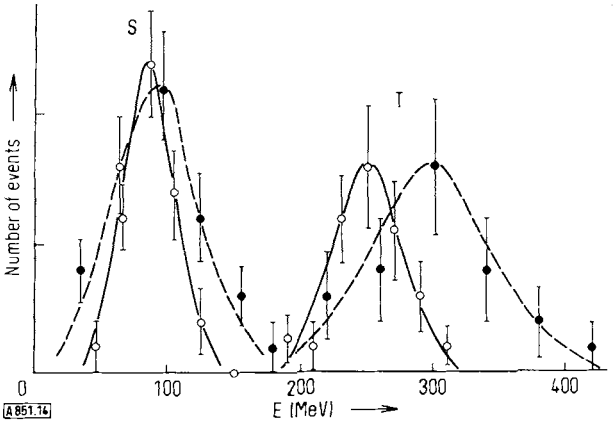

Fig. 14. Spectra of measured kinetic energies of fission fragments in ternary fission. S: spectrum of single fragments, T: spectrum of the sum of three fission fragment energies [32].
○: $^{238}U+185$ MeV Ne
●: $^{238}U+270$ MeV Ar

Two conclusions which may be drawn from Table 2 are:

1. The probability of ternary fission increases with increasing Z^2/A of the compound nuclei. However, one has to use rather heavy ions such as Ne or Ar in order to obtain rates of ternary fission high enough to be observed experimentally. In comparison to the values given in Table 2, *Muga*'s results appear to be rather high.

Table 2. The ratio of $\sigma(T):\sigma(B)$ for heavy ion induced ternary fission [32, 33].

Reaction	Heavy ion energy (MeV)	Z^2/A of compound nucleus	$\sigma(T):\sigma(B)$
$^{197}Au+^{22}Ne$	185	36	$7\times10^{-4}:100$
$^{238}U+^{22}Ne$	185	40	$(7.0\pm1.5)\times10^{-3}:100$
$^{209}Bi+^{40}Ar$	310	41	$(1.0\pm0.4)\times10^{-2}:100$
$^{238}U+^{40}Ar$	270	43.4	$(2\pm1)\times10^{-2}:100$
$^{238}U+^{40}Ar$	310	43.4	$(1.3\pm0.3)\times10^{-1}:100$

2. The probability of ternary fission increases drastically with the increasing excitation energy of the compound nucleus, as can be seen on the last two lines of Table 2.

In summary, the counting experiments establish the order of magnitude for the probability of ternary fission and yield information on the kinetic energy of the fission fragments. Little is known, however, about the angular distribution of fission fragments in ternary fission. This will be discussed in the next section.

2.4.2. Mica experiments

As was shown earlier (Section 2.3), the mica-sandwich technique yielded valuable information on ternary fission induced by 20 GeV protons. Unfortunately, the same technique did not work properly in 300 MeV Argon ion induced fission (see Reference [34]). Therefore, initial experiments were carried out using the so-called "2π-geometry" method. In this method uranium is evaporated onto a mica sheet, irradiated with argon ions, and then treated in such a way so as to reveal fission tracks[*]. Only those tracks which move forward in the laboratory system, and which are thus intercepted by the mica, are registered. When only one fission fragment moves forward, a single track (S) is seen, when two tracks move forward, a binary track (B) is seen. Sometimes three tracks move forward. An example of such an event has been photographed and is shown in Figure 15. This event is defined as ternary fission. The center of the fissioning nucleus is still outside

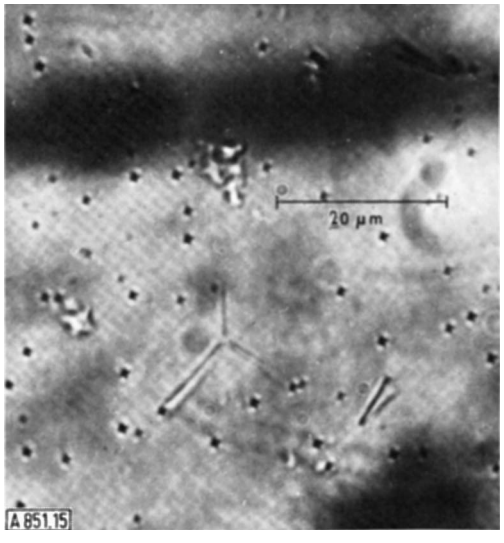

Fig. 15. Photomicrography of a ternary fission event of ^{238}U induced by 305 MeV ^{40}Ar and observed with 2π-geometry in mica [35].

the mica, but is restricted to a much smaller area than that seen in Figure 7. Therefore, an explicit proof of the existence of ternary fission is omitted in this part of the investigation.

It is now possible to count the binary (B) and ternary (T) fission events (as defined above) and to calculate the ratio $\sigma(T):\sigma(B)$ for this "2π-geometry" method. The results are shown in Figure 16.

[*] The proper treatment includes 6 hours' annealing of the argon-ion tracks at 430 °C, followed by etching with hydrofluoric acid [36].

1. The ratio $\sigma(T):\sigma(B)$ increases again with the increasing energy of the argon ion.

2. For a constant Ar-ion energy, the ratio $\sigma(T):\sigma(B)$ increases with the increasing Z^2/A of the compound nucleus.

3. The compound nucleus system has the same value for Z^2/A in the system $^{232}Th+Ar$ as in the system $^{238}U+Ar$. Therefore the ratio $\sigma(T):\sigma(B)$ is the same for both systems.

4. If the two values determined at 414 MeV argon energy using the 4π-geometry method (see Section 2.4.3) are compared with those values determined using the 2π-geometry method, it will be seen that the 2π-geometry method gives ratios of about a factor of 2 smaller.

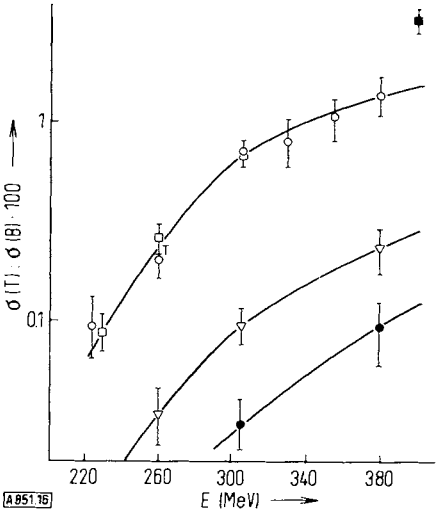

Fig. 16. Dependence of the ratio of ternary to binary fission $\sigma(T):\sigma(B)$ on the argon-ion energy, as measured with 2π- and 4π-geometry [35]. Details are given in the text. ○: U, □: Th; ▽: Bi, ●: Au with 2π-geometry; ■: Th; ▼: Pb with 4π-geometry.

The ratio for $\sigma(T):\sigma(B)$, as shown in Figure 16, is about a factor of ten larger when compared to the results shown in Table 2 (counter experiments). This is quite plausible, since the latter technique selects only events in which all angles in the center-of-mass system between the three fragments are $(120\pm8)°$. The "2π-geometry" method does not take these restrictions into account. Furthermore, a quantitative comparison between the two methods is difficult, since the registration threshholds also differ in each method.

The distribution of angles between fission tracks in ternary fission has been determined for a number of different compound nuclei and excitation energies[35]. It suffices, here, to show the angular distribution between the tracks in ternary fission for the reaction: U + 300 MeV Ar (Fig. 17). The angle with the highest probability is $\varepsilon_M \simeq 110°$; however, there is a wide distribution around this angle. The events with $\varepsilon < 100°$ and $\varepsilon > 120°$ are those which were not detected in the counting experiments described in Section 2.4.1. The distribution of the sum of three angles in ternary fission ($\varphi = \varepsilon_1 + \varepsilon_2 + \varepsilon_3$) is shown in Figure 17a. The most probable value is $\varphi_M = 320°$. This implies that the observed ternary fission events were rather "flat" events. However, this might also be due to the special detector arrangement used in the "2π-geometry" method. The values marked "model" were calculated theoretically on the assumption

that ^{238}U and ^{40}Ar form a compound nucleus and decay symmetrically into three fragments in a center-of-mass plane perpendicular to the direction of the beam. Furthermore, a kinetic energy of 100 MeV per fragment was used

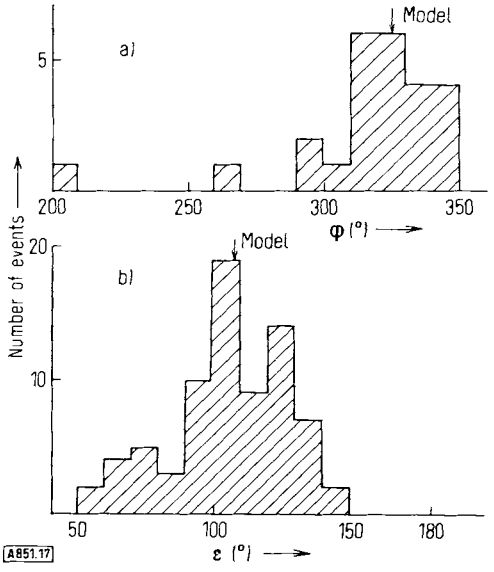

Fig. 17. a) Distribution of the sum $\varphi = \Sigma\varepsilon_i$ of the three angles in ternary fission in the interaction of ^{238}U with 300 MeV ^{40}Ar [35]. b) Distribution of the angle ε between two fragments in ternary fission for the same reaction. The "model" is explained in the text (for further details see [35]).

in the calculations. The calculated angles of the "model" agree with the maximum of the observed distributions, thus indicating that the assumptions were reasonable.

2.4.3. Investigations Using the 4π-Geometry Method with $ThSiO_4$-Crystals

An ideal system for the investigation of ternary fission is one in which the target atoms are distributed as finely as possible within the fragment detector matrix. Such a system is realized in synthetic $ThSiO_4$-crystals. Thorium serves as the target atom, and fission fragment tracks can be made visible within the crystal by etching it at 220 °C with phosphoric acid. Binary (B) and ternary (T) fission events are visible under an optical microscope after this etching, which is done when at least one fission fragment has penetrated the crystal surface (Fig. 18). In this case it is obvious that all the tracks of a fission event originate from one point. Due to conservation of momentum binary fission events cannot be colinear.

The first investigations using $ThSiO_4$ were carried out by *Fleischer*, *Price*, *Walker*, and *Hubbard*, using 414 MeV argon ions. They proved that events such as those shown in Figure 18 are genuine examples of ternary fission. They also determined the ratio for $\sigma(T):\sigma(B)=(3.3\pm0.3):100$ (Table 3). Furthermore, they calculated the angular distribution of fission tracks in the center-of-mass system, from the observed angular distribution of tracks (assuming that all ternary fission fragments have a mass of $A=89$). This is shown in Figure 19. The distribution is symmetrical around the angle of 90°—a consequence of compound nuclei formation. The most surprising result which can be drawn

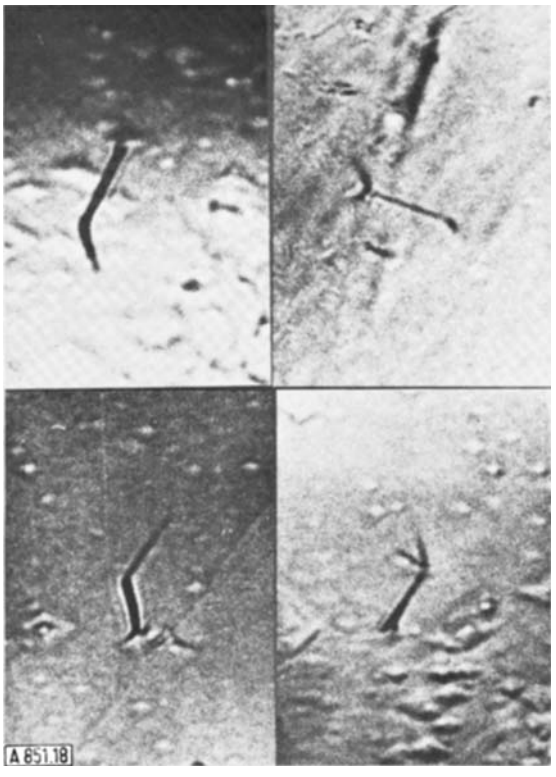

Fig. 18. Photomicrography of binary and ternary fission in thorium induced by 305 MeV Ar ions and registered in $ThSiO_4$ crystals.

from Figure 19, however, is that many tracks go either in the direction of the incoming argon ion or exactly in the opposite direction.

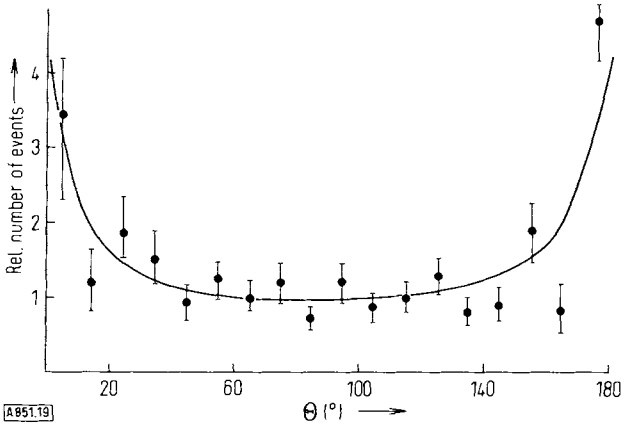

Fig. 19. Distribution of angles θ between fission fragments and the direction of the incoming Ar ions in the centre-of-mass system for the reaction Th + 414 MeV Ar [31].

The exciting results obtained by *Fleischer et al.* proved to be reproducible and are listed in Table 3[37, 38]. The angular distribution shown in Figure 19 could also be reproduced[38].

A small sample of $ThSiO_4$-crystal was irradiated in a test experiment with 300 MeV Ca-ions. One ternary and 116 binary fission events were observed[38], thus showing that such studies are feasible with Ca-ions also.

Unfortunately, it has not been possible to find other heavy-metal crystals displaying comparable properties to those

Table 3. Ratio of $\sigma(T):\sigma(B)$ in the reaction $^{232}Th + ^{40}Ar$, using $ThSiO_4$-crystals.

Ar-ion energy (MeV)	$\sigma(T):\sigma(B)$	Ref.
414	$(3.3\pm0.3):100$	[31]
300	$(2.0\pm0.5):100$	[37]
300	$(0.7\pm0.4):100$	[38]

of $ThSiO_4$. A further aim in this field is the development of target-systems which can be irradiated with heavy ions such as Kr or Xe obtained from recently completed accelerators. One such detector might be Cd-doped AgCl-crystals[39].

3. Theory and Outlook

3.1. Direct Ternary Fission and Cascade Fission

The phenomenon of ternary fission has not been studied systematically from a theoretical point of view. To date, only *Muzychka et al.*[40] have suggested a reasonably plausible model. Figure 20 illustrates the two decay modes proposed for ternary fission, namely:

1. *Direct ternary fission:* Target and projectile form a compound nucleus which decays in *one* step into three fragments of approximately equal size. *Muzychka et al.*[40] have not developed a model for the calculation of this decay channel. Only one paper, written by *Greiner* and co-workers[41], is known to have been published regarding such a model. These authors claim that the compound nucleus oscillates into many possible forms, some of which are oblate. It is feasible that such oblate forms may decay more naturally into three particles than do prolate forms.

2. *Cascade fission:* The first step of this kind of fission is the asymmetrical decay of the compound nucleus into one light and one very heavy fragment with $A \simeq 200$. When this heavy fragment has a sufficiently high excitation energy, it may decay once more into two fragments, within a period of $\tau \simeq 10^{-21}$ seconds. Such a total decay process would yield three fragments in two steps.

The probability of this last step can be calculated if some fairly reasonable assumptions are made. The details are described in Reference [40]. However, two facts must be kept in mind, before these results can be discussed:

1. When *Muzychka et al.*[40] carried out their calculations in 1967, the mass-yield curves for only two heavy ion induced fission reactions were known experimentally ($U + ^{22}Ne$ and $Au + ^{12}C$). Obviously, the heavy branch of the mass-yield curve ($A > 190$) enters substantially into the calculations. However, the calculated ternary fission cross-section turned out to be too small for this reaction:

Reaction: ^{238}U + 185 MeV $^{22}Ne \longrightarrow$ fission

$\sigma(T):\sigma(B) = 10^{-4}:100$ (theory) (5)

$\sigma(T):\sigma(B) = (7.0\pm1.5)\cdot10^{-3}:100$ (experimental) (6)

2. In 1967 the mass-yield curve for argon-ion induced fission was unknown. *Muzychka et al.* estimated the yields for heavy fragments and then calculated a satisfactory agreement between theory and experiment for the reactions U + 270 MeV Ar, U + 310 MeV Ar, and Th + 414 MeV Ar[31,33]. Some years later, the mass-yield curves were determined experimentally for these same fission reactions[42–44]. As it turned out, *Muzychka et al.* had considerably underestimated the yield of heavy fragments; thus their agreement was to some extent fortuitous. It is hoped that future work will improve our understanding of ternary fission.

In this context it might be interesting to show the mass-yield curve for heavy ion induced fission reactions, as shown in Figure 21. Binary fission leads to a symmetry of the mass-yield curve around the mass $A_f = {}^1/_2$ [A (target) + A (projectile) − X neutrons]. This symmetry will necessarily be lost when ternary fission contributes appreciably to the

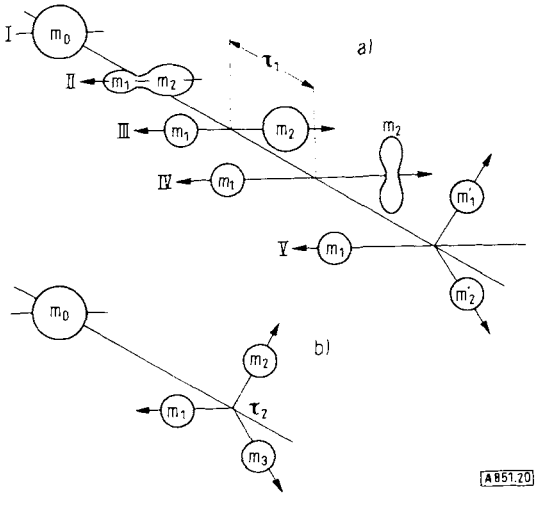

Fig. 20. Schematic representation of (a) cascade-type ternary fission [40] and (b) direct ternary fission [40].

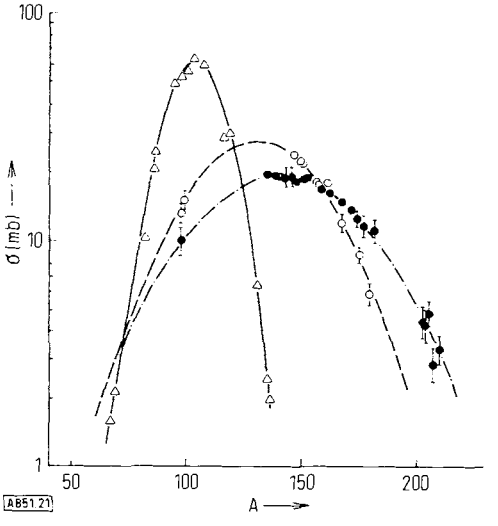

Fig. 21. Mass yield curve for various types of heavy-ion induced fission reactions. The experimental points were obtained by radiochemical methods and fitted to Gaussian-type distributions [44].
△: $Au + ^{12}C$; ○: $U + ^{20}Ne$; ●: $U + ^{40}Ar$.

total fission cross-section, giving a relative increase of light fragments as compared with heavy fragments. The experimentally known curves (Fig. 21) are, however, not determined accurately enough in order to show any such asymmetry. On the contrary, *Oganesyan* and co-workers were able to fit these curves to Gaussian distributions[43, 44].

3.2. The Production of Superheavy Elements ($Z \approx 114$) and the Phenomenon of Ternary Fission

A particular nuclear stability of the elements with $110 \leq Z \leq 120$ ("superheavy elements") has been predicted by a number of physicists during the last few years[45–48]. On the basis of these predictions, it is conceivable that superheavy elements might be so stable that they can be synthesized in a laboratory. It is also feasible that they exist in nature. However, for the production of superheavy elements in the laboratory, powerful new accelerators are needed which can accelerate ions as heavy as those of uranium up to such energies as to be able to induce nuclear reactions. Several such accelerators are under construction or have recently been completed. In the Federal Republic of Germany such an accelerator, called "UNILAC", is under construction by the "Gesellschaft für Schwerionenforschung, m. b. H.", near Darmstadt.

Several methods of producing superheavy elements have been discussed[49–53]. One such method, the fusion-fission method will be described here in some detail[53]. *Karamyan* and *Oganesyan*[53] assume that compound nuclei are formed in the interaction of uranium with uranium or xenon ions. The cross-section for such a complete fusion reaction is optimistically estimated to be 10^{-26}—10^{-25} cm^2 or 1—10% of the geometrical cross-section. These compound nuclei decay within approximately 10^{-21} sec by fission. *Karamyan et al.*[53] assume further that only two fragments are formed in fission. On the basis of the known fusion-fission mass-yield curves, as shown in Figure 21, the authors estimated the corresponding mass-yield curves for the reactions (U + U) and (U + Xe). It is plausible that one can expect very heavy fission fragments with $290 \leq A \leq 310$. Furthermore, one can estimate the upper limit for the production of a typical superheavy nuclide $^{A}Z = {}^{294}110$ as follows:

$$\sigma(^{294}110) \leq 10^{(30+1)}\ \text{cm}^2.$$

The production path can be summarized as follows:

$$^{238}\text{U} + {}^{238}\text{U} \rightarrow {}^{476}184 \qquad \text{(fusion to compound nucleus)} \quad (1)$$

$$^{476}184 \rightarrow {}^{294}110 + \text{(partners)} \qquad \text{(decay of compound nucleus)} \quad (2)$$

The limit for the ability to detect superheavy elements in such reactions will be approximately $10^{-(38\pm2)}$ cm^2, provided their half-lives are in the range of 10^{-9} sec $\leq \tau_{1/2} \leq 10^3$ a.

According to the calculations of *Karamyan* and *Oganesyan*, it should be possible to produce and detect superheavy nuclei. Unfortunately, these authors can only give an upper limit for the production cross-section, not a lower limit. This is connected in a twofold way with ternary fission:

1. The direct ternary fission process, as shown in Figure 20, has not been considered as a decay channel for the compound nucleus formed by fusion of uranium with uranium. Presently, it is impossible to estimate the relative importance of this decay channel as compared to others. But it cannot be excluded at all that, due to this factor, the production cross-section of superheavy elements will be decreased considerably.

2. The cascade fission process is also shown in Figure 20. It is quite feasible that the heavy fragment after the decay of the compound nucleus (Fig. 20, position III) is not spherical and unexcited but deformed and highly excited. *Karamyan* and *Oganesyan* assume that this heavy fragment de-excites itself essentially only by neutron and gamma emission, not by further fission. But this is not at all certain. *Swiatecki*[54] pointed out that the stability of superheavy nuclei against fission is restricted to spherical shapes and fairly low excitation energies. There exists a reasonable chance, therefore, that heavy fragments of the first binary fission process of the compound nucleus fission once more, thus giving rise to ternary fission and not to the production of superheavy nuclei. These considerations are presently the basis for extensive theoretical calculations. One example for calculations of the accesibility of superheavy nuclei is given by *Moretto et al.*[56]. Unfortunately, one cannot exclude the possibility that superheavy nuclei cannot be produced at all by fusion-fission reactions.

Nevertheless, all scientists associated with the problem of detecting superheavy elements *hope* that these elements can be produced with the new (and expensive) heavy-ion accelerators.

3.3. A Speculation on the Decay of Superheavy Elements and Possible Applications

It has been stated in this paper that, so far, superheavy elements have not been found anywhere and it is not clear whether they will be found in the future at all. Nevertheless, in conclusion it is worth speculating on possible radioactive decay modes for these undiscovered elements and on possible applications of them.

The alpha- and beta-decay of superheavy elements are not expected to exhibit any new and surprising characteristics. However, one expects some exciting features for spontaneous fission and neutron-induced fission of superheavy elements. The kinetic energy in spontaneous fission of superheavy nuclei will be approximately twice as large as for fission of uranium nuclei, but particularly important is the expectation that approximately 10—11 neutrons might be emitted per fission as compared with 2.5 neutrons in the fission of uranium nuclei[55]. In the case of ternary fission of superheavy elements, the number of neutrons per fission can be roughly estimated to be as high as 15.

It is well known that the critical mass of a nuclear assembly depends, very sensitively, on the number of neutrons per fission. The ratio of binary to ternary fission of superheavy elements will determine the average number of neutrons per fission and thus the critical size. A mixture of ^{235}U and sufficiently long-lived superheavy elements will then allow

the construction of any critical size within the limits given by the two pure components. A discussion of the technical and social consequences of this possible new application will not be entered into here.

The support of the author's own experiments on ternary fission by Professor Starke (Marburg) is gratefully acknowledged, as is also the financial support given by the "Bundesministerium für Bildung und Wissenschaft" and the "Fonds der chemischen Industrie".

Application of Ligand Field Spectroscopy to Problems of Chemical Bonding in Solids[**]

By Dirk Reinen[*]

Selected examples (d^n systems) are presented to illustrate the interpretation of ligand field spectra (remission spectra) of solid inorganic compounds. In particular, this article demonstrates possible means for the investigation of weak cooperative interactions between transition metal coordination polyhedra and for the determination of the cation distribution in crystal lattices. The information value of the spectroscopic method to the chemist is critically discussed.

1. Introductory Considerations

If a free atom or ion is brought into a chemical environment of ligands, its energy levels undergo characteristic changes, which depend on the symmetry and strength of the "ligand field"[1,2]. The symmetry effect leads to splitting of some of these energy levels, while the strength of the electronic interaction between the central atom and its environment determines the degree of this splitting and of term shifts. In this progress report, we shall be concerned with transition metal coordination polyhedra, *i.e.* d^n systems. If one considers *e.g.* $3d^n$ cations in a ligand field of cubic symmetry, the five-fold degenerate d level splits into two, with energy differences Δ that very often correspond to absorption bands in the visible region of the spectrum. The optical d—d transitions that thus become possible are frequently the reason for the wide range of colors exhibited by the transition metal compounds. The cations of the elements of the lanthanum series are much less sensitive to environmental influences, owing to the much stronger shielding of the 4f electrons, while the available experimental data on 5f systems are scanty; moreover, the situation is more complicated, since the f level is split into three even in chemical environments of cubic symmetry, so that two ligand field parameters are required to describe these systems.

The MO scheme of a $3d^n$ cation in an octahedral environment of ligands that can form dative π bonds (*e.g.* F^-, O^{2-}) is shown in Figure 1. The orbitals of the central ion χ are shown on the left, while the linear combinations of the ligand orbitals φ, classified according to the symmetry of the octahedron O_h (symmetry-adapted), are shown on the right. For simplicity, sp_z hybridization of the ligand orbitals in the bond directions has been assumed, so that six functions lie on the sides of the ligands remote from the central ion, and may be disregarded as nonbonding. The electrostatic interaction of the central ion with its environment (Coulomb component C') and the overlap of the orbitals of the central atom with the appropriate linear combinations of the ligand orbitals (exchange component A') lead

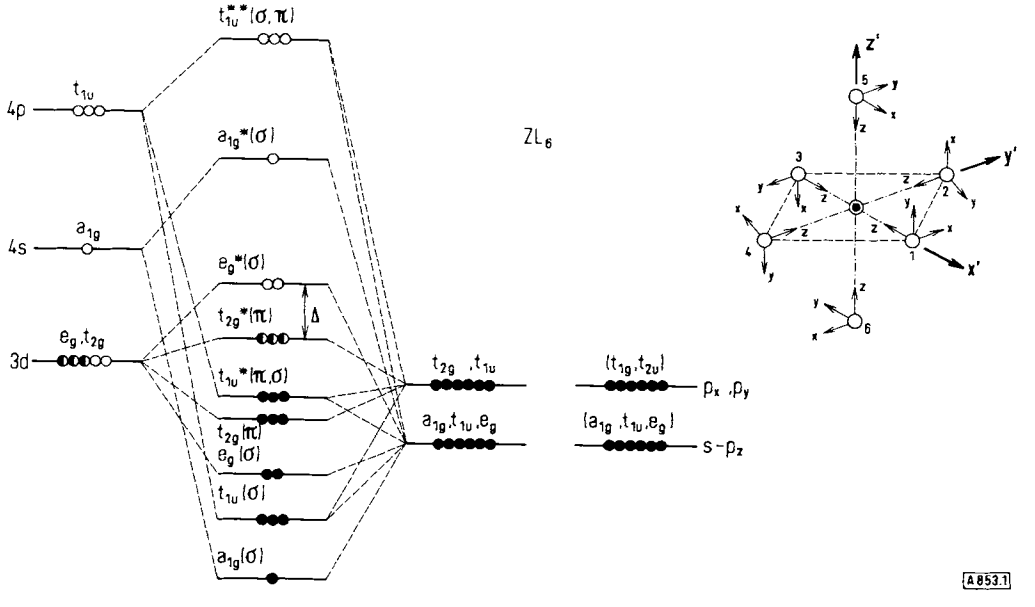

Fig. 1. Qualitative MO scheme of an octahedral transition metal complex ZL_6 (electron occupation corresponding to that of a CrF_6^{3-} octahedron). One of the three wave functions of the t_{2g}^{*} level ([eq. (2)]), for example, on the basis of the indicated coordinate systems is of the form: $\psi_t = \gamma d_{xy} - \delta(p_x^1 + p_y^2 + p_y^3 + p_x^4)$.

[**] Based on a lecture to the Solid State Chemistry Group of the GDCh on October 1, 1970, in Bonn.

to the bonding, nonbonding, and antibonding molecular orbitals indicated; we are particularly interested in the e_g^* and t_{2g}^* levels. If the wave functions describing these two MOs are[3]:

$$\psi_e = \alpha\chi_e^{(n)} - \beta\varphi_e^{(m)}; \quad \chi_e^{1,2}: d_{x^2-y^2}, d_{z^2} \tag{1}$$

$$\psi_t = \alpha\chi_t^{(m)} - \delta\varphi_t^{(m)}; \quad \chi_t^{1,2,3}: d_{xy}, d_{xz}, d_{yz} \tag{2}$$

then, to a rough approximation, Δ is given by[4]:

$$\Delta \approx [\int \chi_e H_L \chi_e d\tau - \int \chi_t H_L \chi_t d\tau] - [\beta \int \chi_e H_L \varphi_e d\tau - \delta \int \chi_t H_L \varphi_t d\tau] \tag{3}$$

where H_L is the energy operator characterizing the chemical environment and $d\tau$ is the infinitesimal volume element. Quantitative calculations[4] have shown that the Coulomb expression C' corresponding to the classical crystal field energy in the first set of brackets in eq. (3) is negative, and thus predicts that the e_g^* level will lie below the t_{2g}^* level, contrary to experimental findings. It is only with the "covalent" expression A' in the second set of brackets (negative), which gives the energy associated with the overlap between the orbitals of the central atom and of the ligands, that this effect is "overcompensated" so that the ligand field parameter Δ becomes positive (Fig. 2). It is clear from this greatly simplified consideration that electrostatic effects make only a minor contribution to the splitting of the d orbitals by a ligand field.

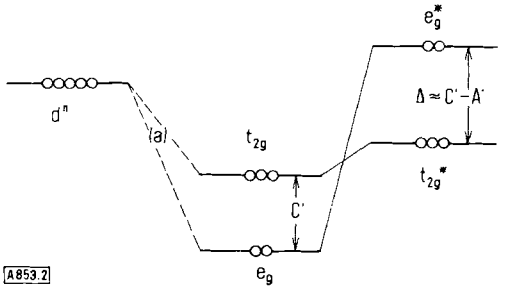

Fig. 2. Relative magnitudes of the "electrostatic" (Coulomb component C') and "covalent" (exchange component A') components of the parameter Δ that describes the splitting of the five-fold degenerate d state in an octahedral ligand field (qualitative picture—one-electron scheme).
(a) Coulomb interaction energy between d^n cation and ligands (spherically symmetrical and d-specific component).

The parameter Δ can be easily determined experimentally from the ligand field transitions between the e_g^* and t_{2g}^* levels. It further follows from the foregoing discussion that Δ is a measure of the strength of the interaction between the central atom and the ligands, or more precisely of the component of this interaction that is due to the d electrons of the central atom. It increases with the strength of the σ bond and, in the case of dative π bonds from the ligand to the central atom, with decreasing strength of the π bond component; Δ can therefore yield information on the bonding. In the spectrochemical series, the ligands are arranged in order of their "Δ effect"[1,2]. C and N always induce very large Δ parameters, whereas Br and I give quite small Δ parameters.

We have so far remained within the one-electron model, *i.e.* the electrostatic interactions between the d or the e_g^* and t_{2g}^* electrons were not considered. This "interelectronic interaction" can be described by additional energy quantities; in the case of d electrons, this is usually done by the Racah parameters B and C[1,2,5]. Figure 3 shows the spectra of the Ni^{2+} and Co^{2+} ions in an octahedral oxygen environment, together with the theoretical (electrostatic "crystal field model") band positions. As is immediately evident, the additional consideration of the interelectronic repulsion not only increases the number of terms, and hence also the number of possible transitions, but also

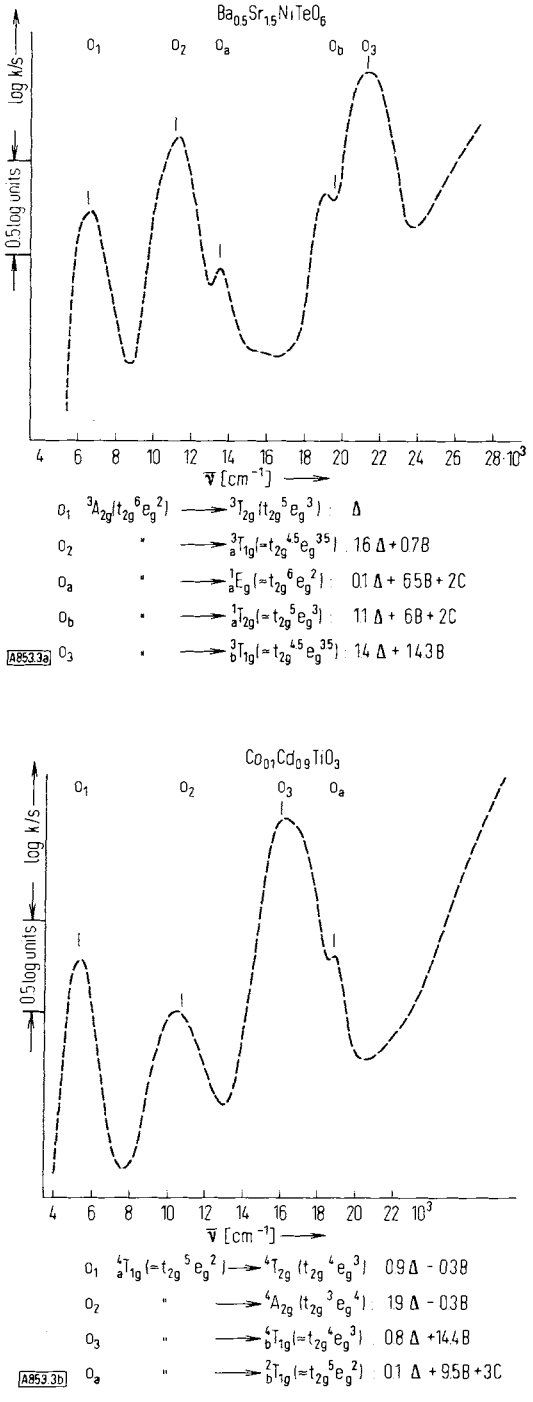

Fig. 3. Remission spectra of the Ni^{2+} ion (a) in a perovskite ordered in the octahedral sites $(Ba_{0.5}Sr_{1.5})^{(12)}(NiTe^{VI})^{(6)}O_6$ (band positions matched with $\Delta = 6500\ cm^{-1}$; $B = 860\ cm^{-1}$; $C/B = 4.2$; "nephelauxetic ratio" $B/B_0 = 0.83$) and of the Co^{2+} ion (b) in a host lattice of the ilmenite type $(Co_{0.1}Cd_{0.9}Ti)^{(6)}O_3$ ($\Delta = 5500\ cm^{-1}$; $B = 770\ cm^{-1}$; $C/B = 4.5$; $B/B_0 = 0.79$), together with the theoretical band positions (for $\Delta/B \approx 7.5$); octahedral coordination in each case [6].

causes mixing of one-electron states, so that configurations $t_{2g}^m e_g^n$ with non-integral m and n result.

For Ni^{2+}, for example, there are only two possible electron jumps in which the electron spin ($S=1$) is retained (triplet-triplet transitions): $t_{2g}(\uparrow\downarrow\ \uparrow\downarrow\ \uparrow\downarrow)\, e_g(\uparrow\ \uparrow) \rightarrow t_{2g}(\uparrow\downarrow\ \uparrow\downarrow\ \uparrow)\, e_g(\uparrow\downarrow\ \uparrow)$ or $t_{2g}(\uparrow\downarrow\ \uparrow\ \uparrow)\, e_g(\uparrow\downarrow\ \uparrow\downarrow)$; on the other hand, three principal bands o_1, o_2, and o_3 are observed. Moreover, the excited states to be correlated with the bands o_2 and o_3 are pronounced mixtures of one-electron functions with $m \approx 4.5$ and $n \approx 3.5$ (Fig. 3). The additional weak transitions (spin forbidden) o_a and o_b proceed with a change in the spin quantum number (triplet-singlet bands), and can be described approximately by: $t_{2g}(\uparrow\downarrow\ \uparrow\downarrow\ \uparrow\downarrow)\, e_g(\uparrow\ \uparrow) \rightarrow t_{2g}(\uparrow\downarrow\ \uparrow\downarrow\ \uparrow\downarrow)\, e_g(\uparrow\downarrow)$ and $t_{2g}(\uparrow\downarrow\ \uparrow\downarrow\ \uparrow)\, e_g(\uparrow\downarrow\ \uparrow)$.

It is now found that the parameters B and C calculated from the matching of the theoretical (crystal field model) band positions to the experimental positions are distinctly smaller than the values B_0 and C_0 found for the free d^n cations without a chemical environment. This depression should be due to covalent bonding, which has not yet been taken into account, and can be attributed partly to the extension of the electron cloud of the central atom towards the ligands on entry into a chemical bond and partly to the fact that the d electrons participate in the antibonding MOs with the fractions α and γ[7] [eq. (1), (2)][1,2] only. B and C should therefore decrease with increasing delocalization of the d electrons, *i. e.* with increasing "covalent character" of the bond in its d components. A rough idea of this effect is given by the "nephelauxetic series"[1,2], in which ligands are arranged according to the strength of their effect on B (and C).

The question now arises how far the theory outlined, which relates to individual complex units, is applicable to solids, in which the individual coordination polyhedra may be joined to one another by shared corners, edges, or even faces, and what deductions are possible in such cases. Compounds of the low-charge transition metal ions with ligands consisting of lighter atoms fortunately behave as if they consisted of *largely independent* complex units (cf. Fig. 3). The usual ligand field spectra are observed, though often with certain modifications, which are due to weak electronic effects extending beyond the individual coordination polyhedra. Weak "cooperative interactions" of this type are the subject of the following section. When we come to compounds such as FeS, NiSe, and NiAs, however, the d electrons are already extensively delocalized over the entire lattice. The electronic interactions between the individual coordination polyhedra have broadened the MOs of Figure 1 into bands, which fact usually leads to a total obliteration of the ligand field spectrum. Another important use of the ligand field spectroscopy of solid compounds is discussed in Section 3.

2. Influence of Weak Cooperative Effects on Ligand Field Spectra

Figure 4 shows the remission spectra of some compounds of the corundum type containing Cr^{3+}, in which the cations are octahedrally coordinated by oxygen, together with the theoretical band positions (crystal field treatment again) in multiples of Δ and B. First of all, it is clear that Δ, as measured by the position of the first band, decreases as the lattice is expanded. It is of no consequence here whether the expansion is due to Cr^{3+} or to Ga^{3+}, which are almost equal in size (α-$Cr_{0.1}Al_{1.9}O_3 \rightarrow Cr_2O_3$ or α-$Cr_{0.1}Ga_{1.9}O_3$). If, on the other hand, one considers the position of the second principal band, which is partly determined by the parameter B, distinct differences are found between Cr_2O_3 and α-Ga_2O_3 doped with Cr^{3+}. Whereas the B values of the latter compound and of α-Al_2O_3 containing Cr^{3+} are practically the same, B is much smaller in the case of Cr_2O_3[8]. The paramagnetic Cr^{3+} ions of different coordination polyhedra evidently "see" one another, *i. e.* delocalization effects of the d electrons—as indicated by the extremely low B-value—are operative beyond the individual CrO_6 polyhedra. This is in agreement with the antiferromagnetism of Cr_2O_3 as a result of spin-spin interaction between the Cr^{3+} ions of adjacent octahedra through shared faces.

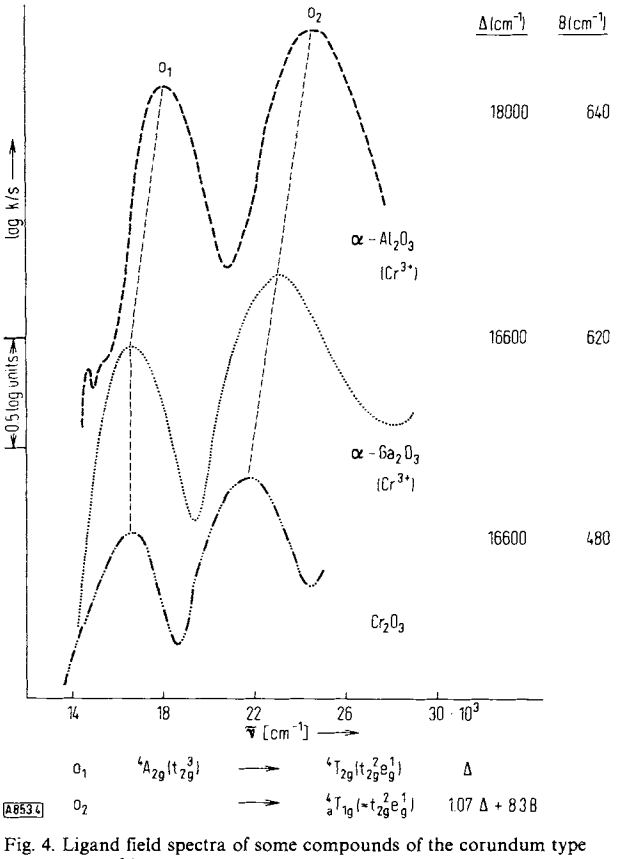

Fig. 4. Ligand field spectra of some compounds of the corundum type containing Cr^{3+} ($Cr_{0.1}Al_{1.9}O_3$, $Cr_{0.1}Ga_{1.9}O_3$, Cr_2O_3) and theoretical band positions (for $\Delta/B \approx 30$; only two of the three spin-allowed transitions are shown); octahedral coordination in each case.

A similar though weaker depression of the B values is found for the solid solution series $Ni_xMg_{1-x}O$[9] with NiO, which is also antiferromagnetic, as the final member. However, this series points to a further interesting effect. The spectra of the compounds with small values of x show the usual picture, with three strong bands (o_1, o_2, o_3), which correspond to triplet-triplet transitions, and a few triplet-singlet transitions (o_a, o_b, o_c), which are spin forbidden and therefore weak (Figs. 3a and 5). These latter transitions become stronger with increasing Ni^{2+} concentration,

until finally their intensities become at least comparable to those of the first three bands mentioned (Fig. 5). The antiferromagnetic interactions between the (S = 1) ground states of the Ni^{2+} ions of different octahedra evidently lead to a new "cooperative" singlet ground state, so that the previously spin-forbidden bands are now allowed (Fig. 6).

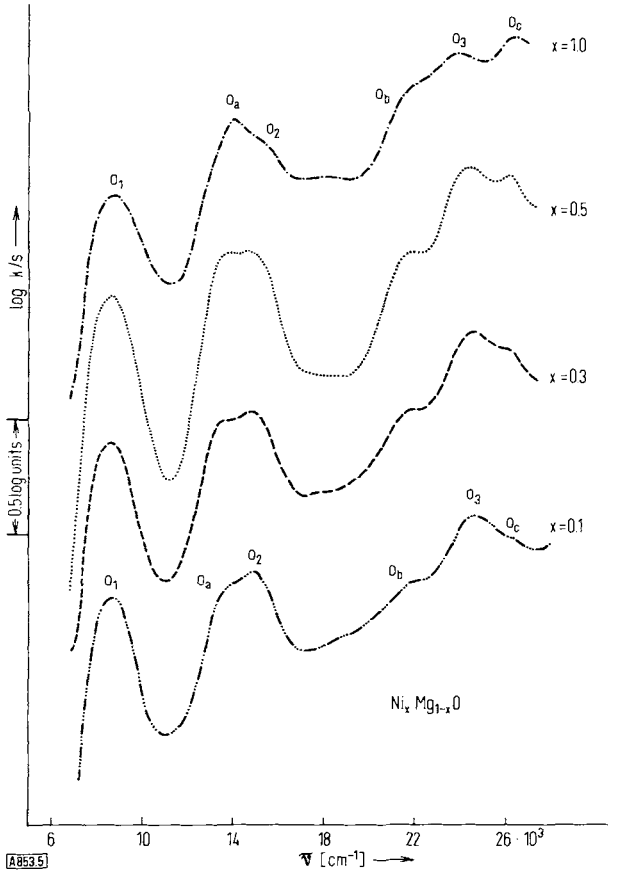

Fig. 5. Remission spectra of solid solutions $Ni_xMg_{1-x}O$ (NaCl structure).

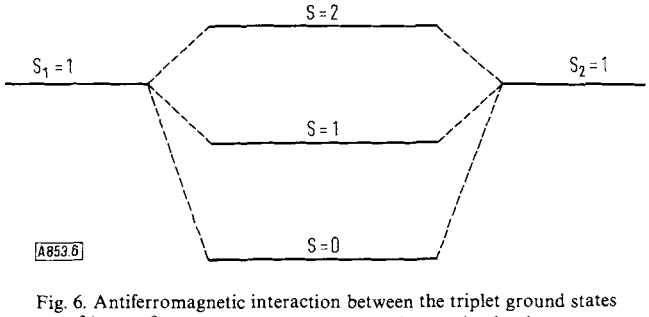

Fig. 6. Antiferromagnetic interaction between the triplet ground states of Ni^{2+} ions ($^3A_{2g}$) for the case of only two interacting levels.

A different kind of example of the effect of the cationic environment on the bonding in a transition metal coordination polyhedron is provided by perovskites which are ordered in the octahedral sites (elpasolite type) and have the structure and composition shown in Figure 7. Each Ni^{2+} ion is surrounded *via* its six oxygen neighbors by six M^{VI} cations. If M^{VI} is an ion having an inert gas configuration, such as W^{VI}, the ligand field parameters are about 25% higher ($\Delta = 8500\ cm^{-1}$) than for M^{VI} being an ion with a d^{10} configuration, such as Te^{VI} ($\Delta = 6600\ cm^{-1}$)[10]. Single crystal X-ray investigations have shown that the Ni—O distances are practically the same in both compounds, so that ionic size effects can be largely ruled out as a cause[11]. Since the *B* value (860 cm^{-1}), and hence the d covalence of the Ni—O bonds, is also the same in both cases, the σ and π components of the bonds are presumably different. W^{VI} should have a stronger π-polarizing effect and a weaker σ-polarizing effect on the linking oxygen ligands than Te^{VI}, which has little tendency to form π bonds because of its filled d shell. The result of this bond polarization would thus be stronger σ components and weaker π components of the Ni—O bonds, and hence a greater Δ for the tungsten perovskite. Similar investigations can also be carried out with other cations and for other host lattice structures[8, 10].

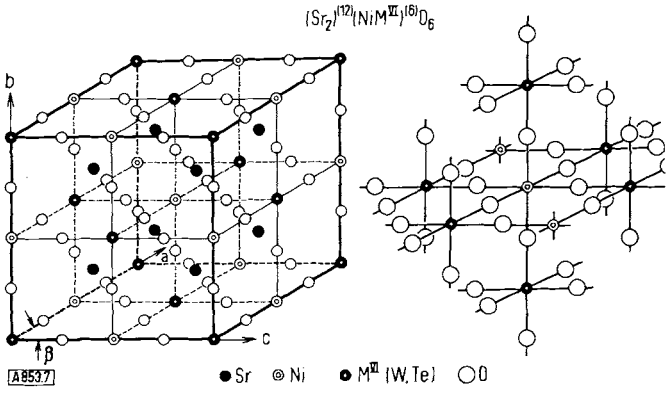

Fig. 7. Lattice structure (left) of perovskites ordered in the octahedral sites $(Sr_2)^{(12)}(NiM^{VI})^{(6)}O_6$ (idealized) and nearest cationic M^{VI} neighbors (right) of the Ni^{2+} ions in this lattice (elpasolite type).

Interesting aspects are also offered by the numerous compounds in which *one* transition element is present in *different* oxidation states. While the spectra of such mixed valence compounds are often simply the sums of the spectra of the constituent complex units, new bands frequently also appear, as in the case of the complex $Fe^{II}-Fe^{III}$ cyanides (*e.g.* Prussian blue and Turnbull's blue). It was uncertain for a long time whether Fe^{2+} and Fe^{3+} occupy fixed positions in these lattices or whether a rapid valence change occurs by transfer of an electron. It was shown with the aid of Mössbauer and ligand field spectroscopy[12] and from the results of magnetic measurements that almost total "charge localization" with octahedral $Fe^{II}C_6$ and $Fe^{III}N_6$ polyhedra must be assumed in all compounds of this type, Fe^{2+} having a low-spin configuration (t_{2g}^6) and Fe^{3+} a high-spin configuration ($t_{2g}^3e_g^2$). Thus the structure of "soluble Prussian blue" $KFe^{III}Fe^{II}(CN)_6$ can be described in the same way as the perovskites ordered in the octahedral sites (Fig. 7), with alternating occupation of the octahedral sites by Fe^{2+} and Fe^{3+} ions, which are linearly linked to one another *via* CN^- groups. The two "additional" bands in the spectrum of this compound can be interpreted as transitions of an electron from the $Fe^{II}C_6$ to the $Fe^{III}N_6$ term system. These transitions are the cause of the blue color, which is not characteristic of the two component polyhedra; appreciable electronic coupling between them may therefore be assumed. The two bands at

about 15000 and 25000 cm^{-1} can be approximately characterized as follows:

$$Fe^{II}\,t_{2g}^6\,(C) - Fe^{III}\,t_{2g}^3\,e_g^2\,(N) \quad (a)$$
$$\longrightarrow Fe^{III}\,t_{2g}^5\,(C) - Fe^{II}\,t_{2g}^4\,e_g^2\,(N) \quad (b)$$
$$\text{and} \longrightarrow Fe^{III}\,t_{2g}^5\,(C) - Fe^{II}\,t_{2g}^3\,e_g^3\,(N) \quad (c)$$

The energy difference ($\approx 10000\ cm^{-1}$), in agreement with the assignment made, corresponds to the position of the band found in the spectrum of octahedral $Fe^{II}N_6$ complexes for the transition: $t_{2g}^4 e_g^2 \rightarrow t_{2g}^3 e_g^3$. Finally, intensity calculations show that the ground state of the Fe ions in soluble Prussian blue is determined by *(a)* to an extent of 99%, while the contribution of the configuration *(b)* is only $\approx 1\%$, *i.e.* almost complete charge localization may in fact be assumed in the lattice.

The next example illustrates a further advantage of spectroscopic methods, *viz.* the possibility of specifically determining the symmetry of the environment of a transition metal cation that is present only in a very low concentration in a host lattice. It is well known that the ^2E_g ground state of the d^9 cation Cu^{2+} has a very high Jahn-Teller instability in octahedral coordination[13, 14]. As is illustrated by Figure 8, this level can be split by distortion of the coordination octahedron (tetragonal in the simplest case), and electronic energy thus be obtained (energetic aspect of the Jahn-Teller effect).

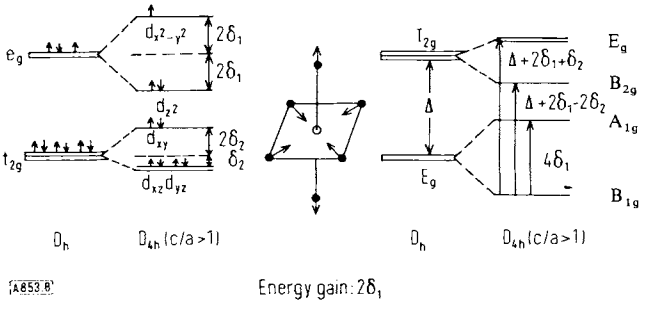

Fig. 8. Demonstration of the Jahn-Teller effect for Cu^{2+} (d^9) in an octahedral environment (moderately strong tetragonal ligand field component—expansion in two and compression in four directions). Left: one-electron scheme, right: many-electron scheme.

The extent of this splitting $4\delta_1$ will increase with the magnitude of the tetragonal ligand field component, and hence with the distortion of the CuL_6 octahedron. Even if the distortion of the octahedron is of a symmetry lower than tetragonal, the tetragonal component normally dominates, and nearly always corresponds to an elongation in two Cu—L directions and a compression in the plane perpendicular to these, as is assumed in Figure 8. If Cu^{2+} ions are incorporated isomorphously into host lattice structures, *e.g.* instead of Zn^{2+} (Zn being adjacent to Cu in the periodic table), the ligand field spectrum is "tetragonal" even at low Cu^{2+} concentrations. It is characterized by three bands instead of the single transition expected for O_h symmetry (Fig. 8), even when there is not yet any macroscopic effect (decrease in the symmetry of the host lattice) to be observed (Figs. 10 and 11)[15]. The distortion of *e.g.* CuO_6 polyhedra indicated by the ligand field spectrum at very low Cu^{2+} concentration is "dynamic"[14, 16], *i.e.* the long, preferred axis of the octahedron changes between the three possible directions (Fig. 9), so that, in a time average an undistorted octahedron results (ESR spectroscopic result). When a certain limiting concentration of Cu^{2+} ions is

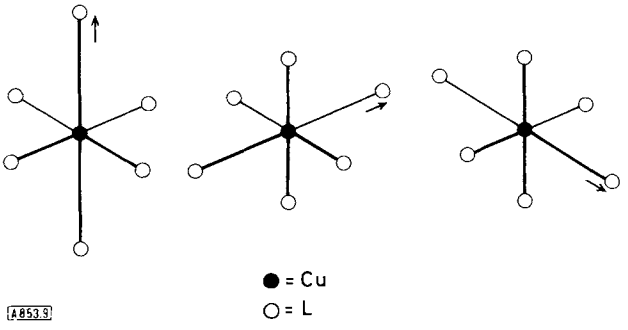

Fig. 9. Dynamic Jahn-Teller effect of "tetragonally elongated" CuL_6 octahedra (directions of axes time dependent).

reached, cooperative elastic interactions between the individual CuO_6 polyhedra in the lattice lead to a fixation and energetically favorable orientation of the long axes of the CuO_6 units in relation to one another (static Jahn-Teller effect), and hence to a macroscopic symmetry effect of the host lattice structure (X-ray result). While these last data cannot be obtained from the ligand field spectrum, this nevertheless provides other information. If Cu^{2+} ions are incorporated into host lattice structures characterized by a layer structure as shown in Figure 10[17], one observes tetragonal distortions of the CuO_6 coordination poly-

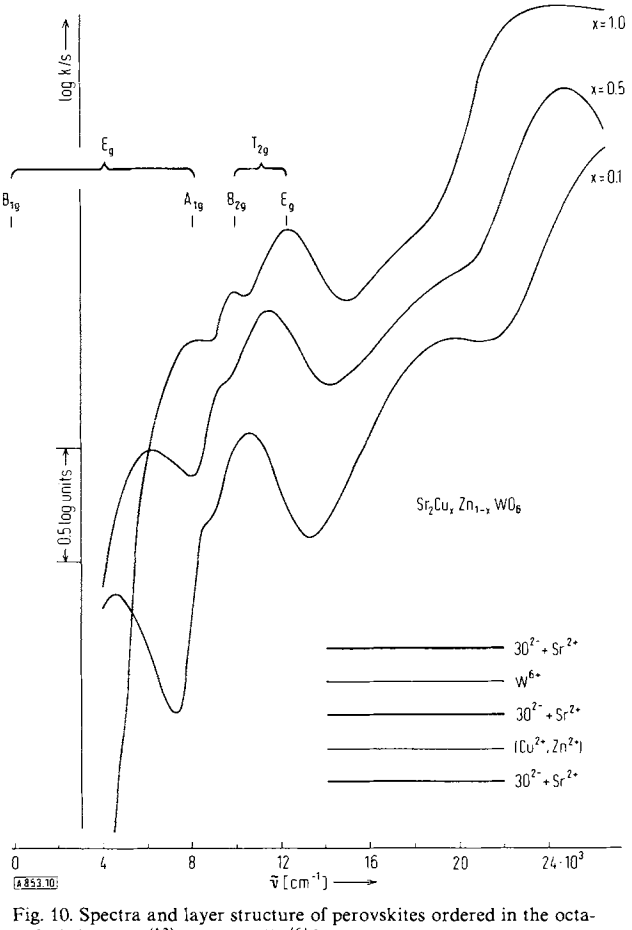

Fig. 10. Spectra and layer structure of perovskites ordered in the octahedral sites $(Sr_2)^{(12)}(Zn_{1-x}Cu_xW)^{(6)}O_6$.

hedra, which increase with increasing Cu^{2+} concentration as is indicated by the measured E_g splitting (position of the lowest-energy ligand field band)[15]. The spectroscopic result seems understandable, since on the one hand the layers consisting *exclusively* of bivalent cations possess great geometric flexibility, while on the other hand the tetragonal distortion of the CuO_6 octahedra should increase with decreasing number of ZnO_6 octahedra which occupy equivalent lattice sites and hence must also be distorted. If, however, bivalent cations and cations of higher charge are mixed in the same layer, as in the trirutile lattice, the splitting of the E_g ground state is independent of the Cu^{2+} concentration, and remains small (Fig. 11)[15]. The highly charged, and hence strongly structure-determining, Sb^{5+} ions evidently oppose any distortion of their environment, so that the geometric conditions in this case are unfavorable for a maximum Jahn-Teller deformation.

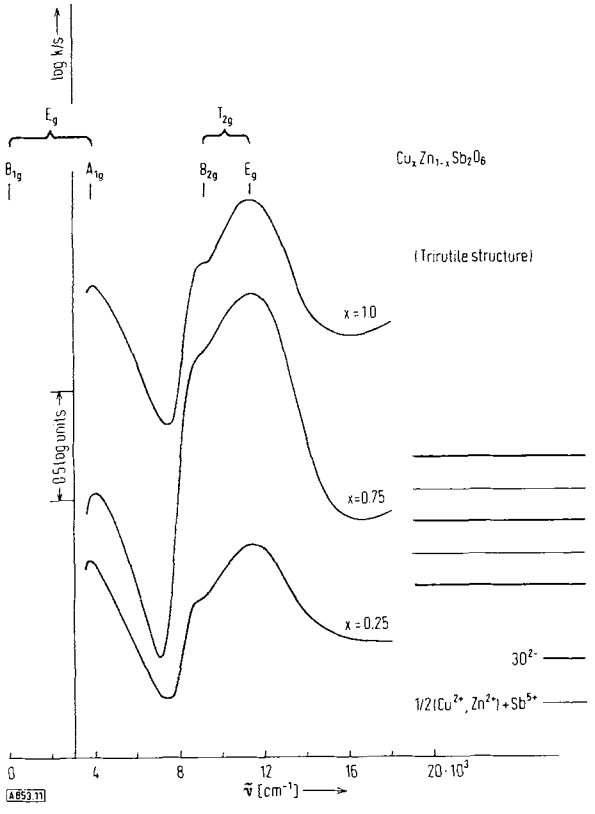

Fig. 11. Spectra and layer structure (highly idealized) of trirutile phases $(Zn_{1-x}Cu_xSb_2)^{(6)}O_6$.

Let us now briefly consider the question of the geometric patterns in which distorted CuL_6 octahedra are arranged with respect to one another within a lattice for a few simple cases. In the case of the spinel structure, for example, in which the Jahn-Teller distorted coordination octahedra are joined to one another exclusively by shared edges, the elastic interactions between these polyhedra should proceed *via* these shared edges. The energetically most favorable geometric arrangement for this case is the pattern of Figure 12, corresponding to tetragonal distortion of the lattice with $c/a>1$[18, 19]. In the perovskite structure ABL_3, on the other hand, there are only corner-linked octahedra, and the energetically most favorable interactions lead to a tetragonal deformation with $c/a<1$ (Fig. 13)[19]. In this arrangement, long and short Cu-ligand distances alternate in two lattice directions, while the third direction has only short distances. If the $M^{VI}O_6$ unit in the ordered perovskite structure (Fig. 7) is now regarded as *one* extended ligand L, the lattice may be regarded as consisting of edge-linked and corner-linked CuL_6 octahedra. As expected, the interaction *via* the edges, which is determined by the shorter distances, dominates here, and this leads, for compounds having the composition $Sr_2(CuM^{VI})O_6$, to tetragonal lattices with $c/a>1$[15, 21]. Compounds $A^I_2[M^{II}Cu](NO_2)_6$ [A^I: K^+, Tl^+, Rb^+, Cs^+; M^{II}: Ca^{2+}, Sr^{2+}, Ba^{2+}], whose structures can be described in almost the same way[20, 23], also crystallize tetragonally with $c/a>1$. If however the alkaline earth metal ions M^{II} are replaced by Pb^{2+}, cubic structures determined by a dynamic Jahn-Teller effect are observed at higher temperatures[20, 22], which change very

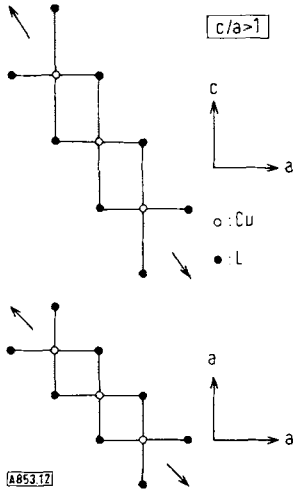

Fig. 12. Elastic interactions between "tetragonally elongated" CuL_6 octahedra with common edges leading to a tetragonal lattice distortion with $c/a>1$.

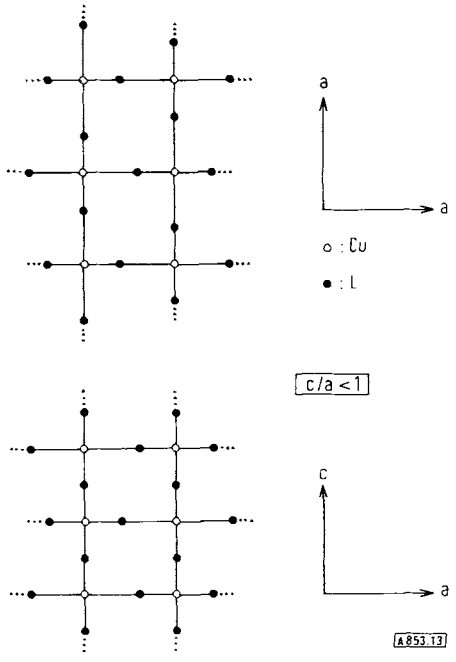

Fig. 13. Elastic interactions between corner-linked "tetragonally elongated" CuL_6 octahedra leading to a tetragonal lattice distortion with $c/a<1$.

soon into tetragonal lattices with $c/a<1$ when the temperature is lowered (high and low temperature Guinier techniques)[20, 24]. It is possible that the substitution of the M^{II} ions with inert gas configurations by the covalent Pb^{2+} ion with a $d^{10}s^2$ configuration increases the elastic-cooperative interactions *via* the corners of the octahedra (more precisely *via* the linear $NO_2—M^{II}—O_2N$ bridges) to such a degree that the mechanism of Figure 13 predominates over that of Figure 12. This last example has also marked a limit for the information value and sensitivity of the ligand field spectra. Whereas the charge transfer spectra[22, 25] as well as the ESR spectra[20] of the alkaline earth metal and Pb^{II} compounds show distinct differences, the ligand field spectra do not record the alteration of the M^{II} ion and hence the difference in the cooperative Jahn-Teller order[20]. Finally, this example shows that cooperative phenomena in solids should not be investigated by a single method, but require the use of a number of mutually complementary methods if useful information is to be obtained.

3. Ligand Field Spectroscopy and Cation Distribution in Solids[6]

Another very important use of ligand field spectroscopy is the qualitative to semiquantitative determination of the cation distribution in crystal lattices. If a transition metal ion can occupy sites of different coordination numbers in a host lattice (*e.g.* spinel or garnet structure), the ligand field spectrum rapidly provides information on how this possibility has been utilized. The cation distribution can also be analyzed with the aid of ligand field spectra in the case of lattice sites having the same coordination number but sufficiently different Δ values (*e.g.* olivine and enstatite structures). The following discussion will be confined to cases in which *octahedrally* and *tetrahedrally* coordinated lattice sites compete with one another. Figure 14 shows sections of the MO schemes for octahedrally and tetrahedrally coordinated d^n cations with the partly occupied antibonding levels which we are interested in. The energy positions of the t_2^* and e^* orbitals are inverted for the tetrahedron compared to the octahedron, and the ligand field parameter Δ_t (for the same ligands) is only about half as great as Δ_o[26]. The spectrum of a tetrahedrally coordinated d^n cation thus mostly appears at longer wavelengths than that of the octahedrally coordinated cation. For example, if a transition metal ion occupies octahedral as well as tetrahedral sites in the spinel lattice $A^{(4)}B_2^{(6)}O_4$, Fe^{2+} spectra show octahedral and tetrahedral bands clearly separated from each other, whereas these transitions partly overlap for the Ni^{2+} ion[27] (Figs. 15 and 16).

Interesting further information on the cation distribution is provided by estimates of the "ligand field stabilization energies" produced by the particular d^n occupation (one-electron model without consideration of the interelectronic repulsion—"high-spin configuration")[6, 28, 29]. If the t_{2g}^* and e^* levels (Fig. 14) are taken as arbitrary zero energy levels, we find the values given in Table 1 for the relative destabilizations for octahedral and tetrahedral coordination as a function of n[6, 29]. These specific d-electron contributions are responsible *e.g.* for the fact that the lattice energies of fluorides MF_2 ($M=3d^n$ cation) do not exhibit the expected linearity as a function of n[1]. The differences between the octahedral and tetrahedral stabilization energies with $\Delta_o \simeq 2\Delta_t$ should be a *relative measure* of the preference of an octahedral to a tetrahedral environment or *vice versa* for a d^n cation (Table 1). They should be the deciding factor for the site preference when one considers a sequence of cations that differ only very slightly, if at all, in all the parameters that influence bonding (principal quantum number, ionic charge and size, *etc.*) except in

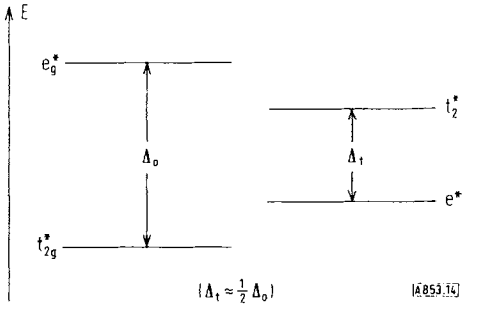

Fig. 14. The antibonding MOs for octahedral and tetrahedral ligand fields which are largely determined by the d orbitals of the central atom (sections from the corresponding MO schemes).

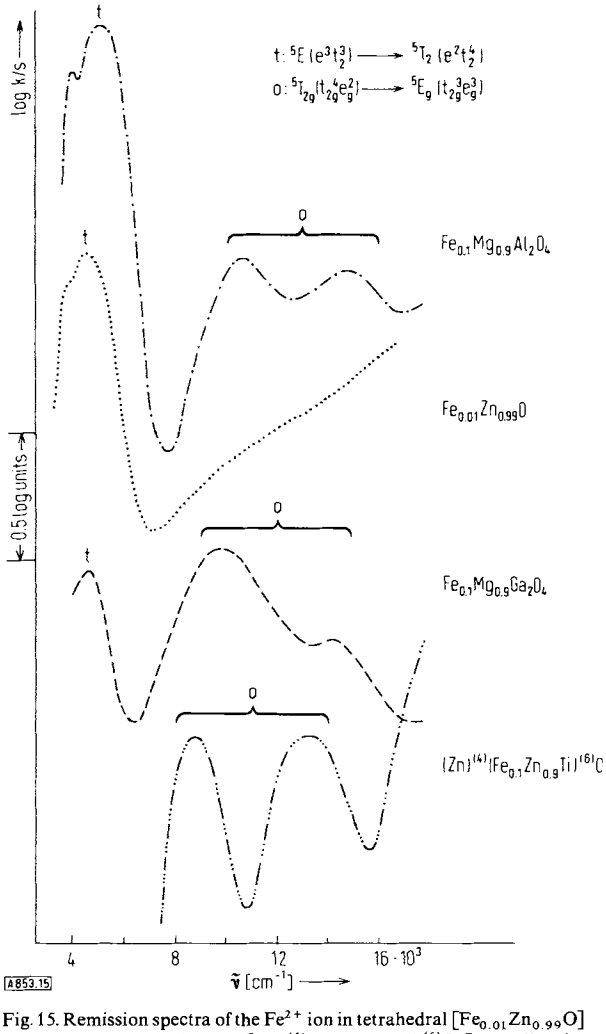

Fig. 15. Remission spectra of the Fe^{2+} ion in tetrahedral $[Fe_{0.01}Zn_{0.99}O]$ and octahedral coordination $[(Zn)^{(4)}(Fe_{0.1}Zn_{0.9}Ti)^{(6)}O_4]$ as well as for cases of a distribution over tetrahedral and octahedral lattice sites (arbitrary intensity scale—wurtzite and spinel structures).

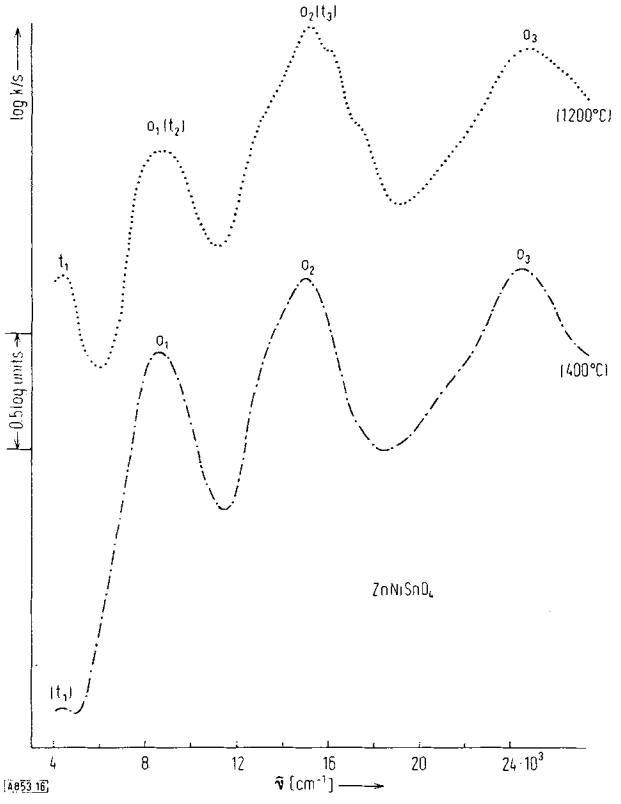

Fig. 16. Remission spectra of the Ni^{2+} ion in the spinel $ZnNiSnO_4$ at different equilibrium temperatures.

the number of d electrons (provided, naturally, that the ligands are the same). These "site preference energies" are energetically relative, since the zero energy levels chosen for the octahedral and tetrahedral stabilization energies (Fig. 14) are different. Even if π bonds are negligible, as may be assumed for the spinel lattice[6], the Coulomb energies are not the same[30]. However, a considerable amount of information can be obtained from these relative "site preference energies". Thus cations having a d^{10} configuration should favor the tetrahedral configuration, while d^3 cations should favor the octahedral configuration. $Ni^{(4)}Cr_2^{(6)}O_4$ is in fact a normal spinel with exclusively octahedral coordination of the Cr^{3+} ions, while $NiGa_2O_4$ has the inverted cation distribution $Ga^{(4)}(NiGa)^{(6)}O_4$, the Ni^{2+} ions evidently being totally displaced into the octahedral sites of the lattice by Ga^{3+}. These distributions can be established quantitatively from the ligand field spectra, since only tetrahedral Ni^{2+} bands are found in the former case and only octahedral bands in the case of $NiGa_2O_4$. Another example is provided by the spectra of Figure 15. The replacement of the Al^{3+} ions in the spinel $Fe_{0.1}Mg_{0.9}Al_2O_4$ by Ga^{3+} leads to a very pronounced decrease in the intensity of the tetrahedral Fe^{2+} absorption in relation to the octahedral absorption, since the d^{10} Ga^{3+} ions, as expected, displace Fe^{2+} ions from tetrahedral into octahedral sites. Nevertheless, a considerable concentration of tetrahedrally coordinated Fe^{2+} ions remains. Ga^{3+} evidently does not block the tetrahedral holes to Fe^{2+} as extensively as to Ni^{2+}, again in agreement with the δ energies of Table 1, which hint at a stronger preference for octahedral coordination in the case of d^8 cations than for d^6 cations.

Table 1. Ligand field stabilization energies of d^n cations (high-spin configuration) for octahedral (E_o) and tetrahedral coordination (E_t) as well as relative site preference energies ($E_o - E_t = \delta$, with $\Delta_o \approx 2\Delta_t$). (One-electron energies without consideration of interelectronic repulsion.)

n		E_o			E_t	δ
1, 2	$t_{2g}^{1,2}$	0	$e^{1,2}$		0	0
3	t_{2g}^3	0	e^2	t_2^1	$-\Delta_t$	$+\frac{1}{2}\Delta_o$
4	t_{2g}^3 e_g^1	$-\Delta_o$	e^2	t_2^2	$-2\Delta_t$	0
5, 6, 7	$t_{2g}^{3,4,5}$ e_g^2	$-2\Delta_o$	$e^{2,3,4}$	t_2^3	$-3\Delta_t$	$-\frac{1}{2}\Delta_o$
8	t_{2g}^6 e_g^2	$-2\Delta_o$	e^4	t_2^4	$-4\Delta_t$	0
9	t_{2g}^6 e_g^3	$-3\Delta_o$	e^4	t_2^5	$-5\Delta_t$	$-\frac{1}{2}\Delta_o$
10	t_{2g}^6 e_g^4	$-4\Delta_o$	e^4	t_2^6	$-6\Delta_t$	$-\Delta_o$

Finally, the temperature dependence of cation distributions can also be followed spectroscopically. Whereas the spinel $ZnNiSnO_4$ has a practically normal cation distribution $Zn^{(4)}(NiSn)^{(6)}O_4$ at low temperatures, as can be seen from Figure 16, a higher equilibrium temperature leads to a migration of the Zn^{2+} ions (d^{10}) from tetrahedral to octahedral sites and of Ni^{2+} ions (d^8) in the opposite direction. This can be deduced from the increase in intensity of the tetrahedral band t_1 in the spectrum (Fig. 16) for example, and corresponds to the tendency of the d^n cations to migrate into the energetically less favored coordination when energy is supplied[26]. This completes our discussion of questions of cation distribution. Further examples, also with different host lattice structures, may be found in [6].

Concluding, it is to be stated that ligand field spectra of single crystals naturally provide more extensive information than those of crystalline powders, particularly in connection with intensity problems or low symmetry effects. However, the information value of remission spectra to the chemist should not be underestimated, particularly when one considers the ease with which such spectra are obtainable.

[23] The NO_2 ligand taking the place of oxygen is bonded by the nitrogen to Cu^{2+} and by the oxygen to M^{II} (cf. Fig. 7): *N. W. Isaacs* and *C. H. L. Kennard*, J. Chem. Soc. *A 1969*, 386.

[24] Whereas the K and Tl compounds are still cubic at 298 °K, the Rb and Cs compounds crystallize tetragonally with $c/a<1$ at this temperature already [20].

[25] Charge transfer bands correspond to transitions from nonbonding or bonding MOs to the t_{2g}^* or e_g^* levels (Fig. 1), and usually occur at shorter wavelengths than the ligand field bands.

[26] It should also be mentioned that the intensity of the "tetrahedral absorption" is greater by approximately one order of magnitude than that of the "octahedral absorption"; changes in the occupation density of tetrahedral lattice sites are therefore recorded more sensitively by the ligand field spectrum than changes in the occupation of octahedral positions.

[27] This is a consequence of the fact that the positions of the principal bands in the case of Ni^{2+}, unlike in the case of Fe^{2+}, are determined not only by Δ but also by the Racah parameter B (Fig. 3), which has practically the same value for octahedral as for tetrahedral coordination.

[30] The electrostatic stabilization of an octahedrally coordinated ion in a crystal lattice (Madelung energy) is generally greater than that of a tetrahedrally coordinated ion, so that the site preference energies (δ in Table 1) would become more positive as a result of a correction in this sense, in agreement with the structural observation that among the oxides VO, MnO, FeO, CoO, NiO, and ZnO, only the last crystallizes with tetrahedral MO_4 units.

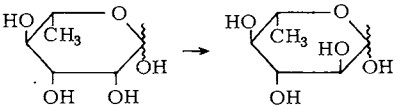
Epimerization of Carbohydrates Catalyzed by Molybdate Ions

By *Vojtech Bilik*, *Wolfgang Voelter*, and *Ernst Bayer*[*]

All aldopyranoses having free hydroxyl groups on C-1 to C-3 react with molybdate ions[1]. The resulting sugar-molybdate complexes have hitherto been used in configurational and conformational analysis of carbohydrates by circular dichroism measurements. We have now found a new sugar synthesis involving these complexes as intermediates. Heating of, *e.g.* D-glucose with molybdic acid in aqueous solution for several hours affords D-mannose in 25% yield. This epimerization can be explained in terms of formation of a glucose-molybdate complex of structure *(1)*.



(1)

Our studies have shown that epimerization of L-rhamnose *(2)* with molybdic acid gives 60% of L-chinovose *(3)* *via* the L-rhamnose-molybdate complex.

This sugar was previously prepared only in poor yield by multistep syntheses[2]. Other rare sugars, *e.g.* D-talose from D-galactose[3], also become readily accessible in good yields by this epimerization.

(2) *(3)*

L-*Chinovose (3)*:

A mixture of L-rhamnose *(2)* (100 g), molybdic acid (1 g), and water (500 ml) is heated to 95 °C for 3 h. Filtration is followed by deionization with a basic ion exchanger and subsequent evaporation under reduced pressure to give a syrup, which is dissolved in anhydrous ethanol and again evaporated to dryness. The syrup is dissolved in anhydrous ethanol (100 ml) and treated in the warm with ethyl acetate (200 ml). L-Chinovose *(3)* (33 g) crystallizes at room temperature. The filtrate is concentrated and again epimerized as described above to give a further yield of *(3)* (20 g). By reaction of the second filtrate obtained it was possible to isolate a further 13 g of *(3)*. The sugar is recrystallized from anhydrous ethanol (m.p. 151 °C, $[\alpha]_D^{24} = -64°$ (5 min)→ −48° (10 min)→ −30° (2 h); $c = 2.0$, H_2O).

Fixation of Trimethylsilylnitrene as μ_3-Trimethylsilylimido(decacarbonyltriiron)

By *Ernst Koerner von Gustorf* and *Rosemarie Wagner*[*]

Trimethylsilyl azide[1] *(1)* exhibits a remarkably higher degree of thermal stability (b.p.$_{760}$ = 95 °C) than organic azides, due to $d_\pi - p_\pi$ interactions[2] between silicon and nitrogen. A similar stabilization is to be expected for trimethylsilylnitrene *(2)* formed from *(1)* by N_2 elimination. Very little has been reported hitherto about the chemistry of *(2)*[3]. In connection with investigations on the stabilization of labile intermediates in transition metal complexes[4] we have tried to trap *(2)* as a carbonyliron complex during the decomposition of *(1)*.

Like organic azides[5], *(1)* already decomposes at room temperature in the presence of $Fe_2(CO)_9$; $(CH_3)_3SiN[Fe_3(CO)_{10}]$ *(3)* is formed as brownish-red needles which decompose without melting at 110 °C. The mass spectrum of *(3)* shows, in addition to the molecular ion, fragments which correspond to successive loss of 10 CO groups. The ^{1}H-NMR spectrum (in benzene) contains a singlet due to a $(CH_3)_3Si$ group at 9.57 τ, which is shifted only slightly downfield compared to that of *(1)* (9.89 τ). In the IR spectrum (in *n*-hexane), which contains relatively few bands, five stretching vibrations of terminal CO groups are to be found (in order of decreasing intensity) at 2048, 2019.5, 2014, 1993, and 2088 cm^{-1}. An intense band at 1743 cm^{-1} is due to bridging CO[6, 7]. The symmetrical CH_3 bending vibration of the $(CH_3)_3Si$ group in *(3)*, like that in *(1)*, appears at 1255 cm^{-1} (in CCl_4).

The data obtained for *(3)* are consistent with formulation as a trimethylsilylnitrene-$[Fe_3(CO)_{10}]$ complex. Comparison with the known organonitrene complexes of similar configuration, $(CH_3N)_2[Fe_3(CO)_9]$[8] and $C_4H_9N[\pi\text{-}C_5H_5Ni]_3$[9] suggests *(3)* as having the structure proposed below. The trimethylsilylnitrene functions as a 4-electron donor, giving a "closed shell" complex.

(3)

X-ray structural analysis[10] confirms the almost perfect symmetrical arrangement of the $(CH_3)_3SiN$ group in *(3)* and shows that the axial CO group is triply bridging, in analogy to $[Fe_4(CO)_{13}]^{2-}$[11].

Hitherto it has not been possible to obtain *(3)* by photochemical reaction of $Fe(CO)_5$ with *(1)*. We are currently investigating the protolytic cleavage of the $(CH_3)_3Si$ group, which should lead to a complex of the imine.

Experimental:

A mixture of *(1)* (0.087 mol) and $Fe_2(CO)_9$ (0.028 mol) in benzene (70 ml) is mechanically stirred under argon for 24 h at 20 °C. Approximately 0.01 mol of gas is evolved. Unchanged $Fe_2(CO)_9$ is filtered off. The residue remaining after removal of solvent by evaporation is extracted with pentane. On cooling the extract to −78 °C, *(3)* crystallizes out; repeated recrystallization from pentane affords 0.8 mmol of analytically pure *(3)*[12].

μ_3-Trimethylsilylimido-μ_3-carbonyltris-(tricarbonyliron)—Crystal and Molecular Structure

By *Bobby L. Barnett* and *Carl Krüger*[*]

μ_3-Trimethylsilylimido-μ_3-carbonyltris(tricarbonyliron) *(1)*, a product obtained on reaction of $(CH_3)_3SiN_3$ with $Fe_2(CO)_9$[1], crystallizes from pentane in the acentric space group $Pca2_1$ along [001] of the orthorhombic system. The unit cell ($a = 12.853$, $b = 13.316$, $c = 11.488$ Å), with a calculated density of 1.807 g/cm^3, contains four molecules of the title compound.

The molecular structure was determined from 1639 diffraction data by the heavy atom method. The positions of the iron atoms were deduced from a sharpened three-dimensional Patterson function; the light-atom positions were obtained by subsequent Fourier synthesis. Anisotropic least-squares refinement, in which the anomalous scattering of the Fe and Si atoms was included[2], gave a final $R = 4.3\%$.

The structure of *(1)* (Fig. 1) can be described by a pseudo-C_3 symmetry of the molecular skeleton including a triply coordinated carbonyl group on the iron cluster as well as a trimethylsilylimino group. The coordination of the equidistant Fe atoms is characterized by distorted octahedra in which three carbonyl groups (C_2,C_5,C_8) are slightly twisted out of the plane of the Fe atoms (see Fig. 2). The average Fe—C and C—O bond lengths are 1.798 and 1.141 Å, respectively, and correspond to analogous carbonyl-iron clusters; the same is true of the average Fe—Fe bond lengths of 2.535 ± 0.002 Å. The linearity of the carbonyl groups should be noted.

The bond lengths and angles in the symmetrically bound, triply bridging carbonyl groups C_{10}—O_{10} (see Fig. 3)

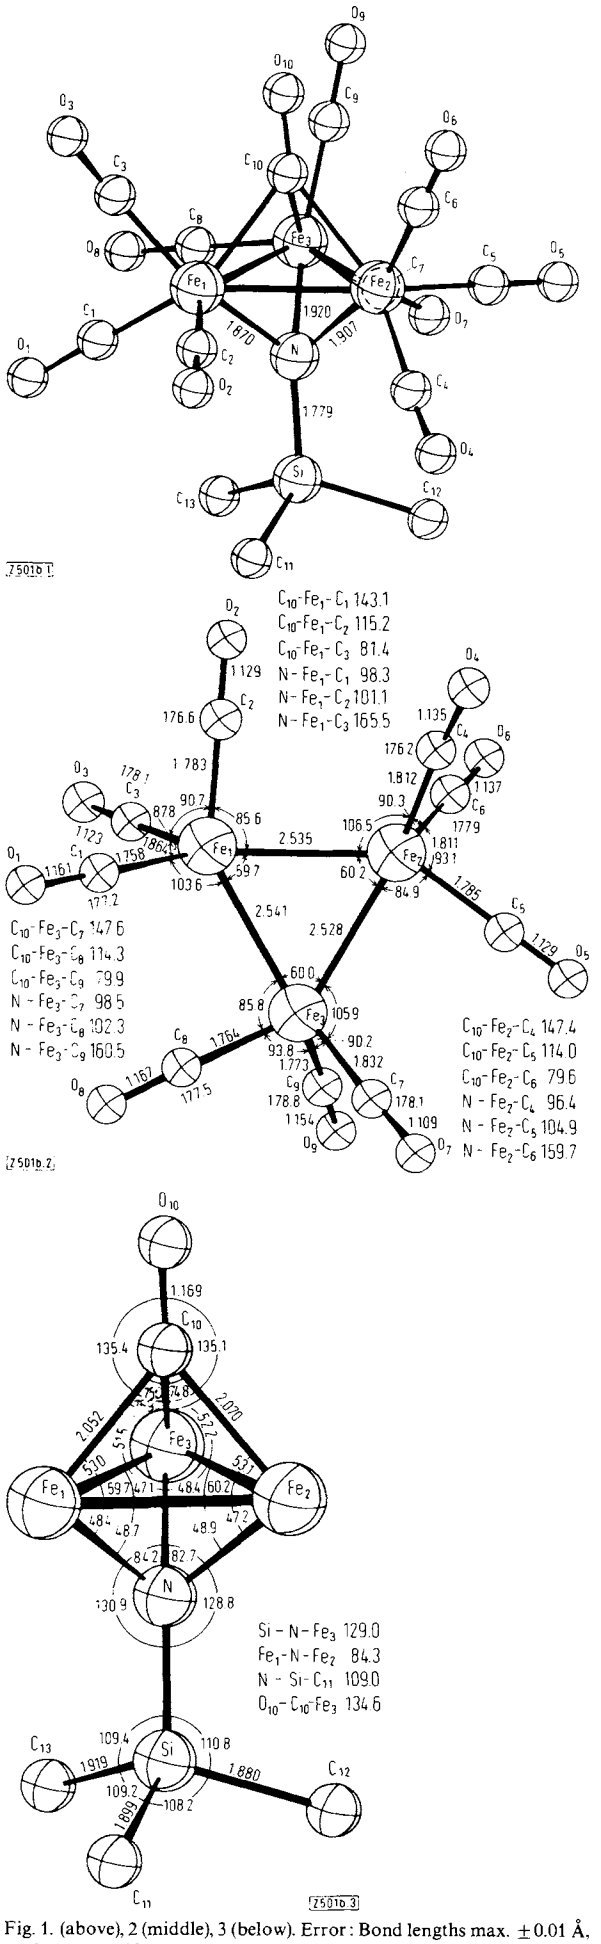

Fig. 1. (above), 2 (middle), 3 (below). Error: Bond lengths max. ±0.01 Å, angles max. ±1°.

correspond to those in the $[Fe_4(CO)_{13}]^{2-}$ grouping[3]. The vertical distance of the carbonyl C atoms from the Fe_1—Fe_2—Fe_3 plane is 1.466 Å, that of the N atoms 1.209 Å. The N—Fe bond lengths (see Fig. 1) are not identical and thus reflect a slight asymmetry of the molecule. The average Fe—N bond length (1.899 Å) is shorter than that in doubly bridged imidoiron compounds (1.94 to 2.00 Å)[4]; the angles at the N atoms, however, are on average 4° greater and approximate ideal tetrahedral angles. The value found for the Si—N bond length can readily be explained as due to decreased (p→d) π interaction causing some lengthening of the bond.

Electrocyclic Reactions of Radicals[**]

By *Gernot Boche* and *Günter Szeimies*[*]

We have found that the avoidance of crossing resulting from loss of symmetry allows the electrocyclic reaction of radicals to proceed *via* a "symmetry-controlled" activation barrier to the ground state of the product.

The first treatment of electrocyclic radical reactions from the standpoint of conservation of orbital symmetry[1] is due to *Woodward* and *Hoffmann*[2]. Their frontier orbital approach predicts that the stereochemical course of these reactions should be controlled by the symmetry of the highest singly occupied molecular orbital of the polyene reactant.

Shortly afterwards, *Longuet-Higgins* and *Abrahamson*[3] published orbital and state correlation diagrams for the interconversion of cyclopropyl and allyl radical which showed this isomerization to be symmetry-forbidden, whether by a disrotatory or a conrotatory process; the ground states of the reactants and products both belong to different symmetry classes and in order to conserve orbital symmetry the thermal reaction would thus always have to give an electronically excited state of the product. These authors therefore expected a "much higher activation energy" for thermal ring opening of the cyclopropyl radical than for isomerization of the cyclopropyl cation or anion.

The above argument should be capable of generalization: This would mean that all thermal electrocyclic reactions of radicals, radical cations, and radical anions are "symmetry forbidden" and require a large activation energy (Figs. 1 and 2).

This prediction cannot be confirmed experimentally. On the contrary, the activation energy of cyclopropyl radical ring opening in the gas phase is about 20—22 kcal/mol[4] and for some substituted cyclopropyl radicals[5] it is

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

lowered to such an extent that, even in cumene, ring opening competes successfully with H abstraction[6].

Disrotatory ring opening to give the homocyclooctatetraene radical anion on reaction of *cis*-bicyclo[6.1.0]nona-2,4,6-triene with alkali metals, although apparently symmetry-forbidden too[1], actually occurs at as low a temperature as $-80\,^{\circ}C$[7].

Judging by the relatively low activation energies, it seems extremely unlikely that these radical reactions should lead to an electronically excited state of the product.

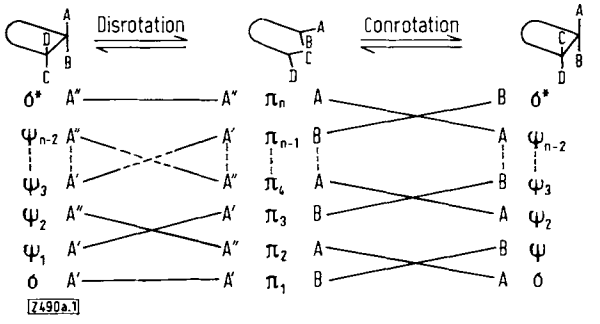

Fig. 1. Orbital correlation diagram for the disrotatory and the conrotatory ring closure of a linear conjugated π-electron system.

Perturbation by substitution, non-symmetrical molecular vibrations, or not fully concerted changes in the geometrical parameters during reaction can lead to a lowering or to a complete anullment of the symmetry of a reacting molecule. This should have no significant effect, however, on the validity of the rules for the conservation of orbital symmetry[1] for closed shell systems.

A different situation prevails in electrocyclic interconversions of radicals. The destruction of the symmetry elements common to reactants and products, C_2 (conrotation) and σ_v (disrotation), leads in the course of the reaction to an increasing interaction between the configurations A and B, or A′ and A″, of the unperturbed molecule[8], shown as crossing in Figure 2. The magnitude of this interaction will

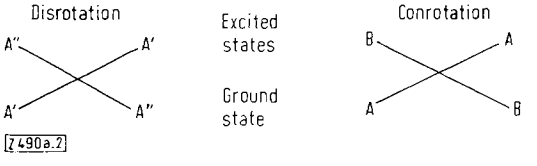

Fig. 2. State correlation diagram for the disrotatory and for the conrotatory electrocyclic radical reaction with conservation of orbital symmetry (in general form).

depend upon the degree of perturbation and the energy difference between the two states[9]. Since the energies of the two states approach each other very closely along the reaction coordinate, even a slight distortion of the reacting system suffices for a significant interaction, which in turn obviates the need for crossing (noncrossing rule) and affects the correlation between the ground states.

The electrocyclic reaction of radicals thus leads, owing to the crossing which is laid down at the start of the reaction but later avoided by loss of symmetry, *via* a "symmetry-controlled" activation energy barrier[10] to the ground state of the product (Fig. 3).

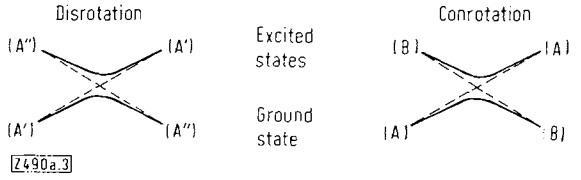

Fig. 3. Realistic course (——) of the correlation lines in electrocyclic radical reactions (in general form).

The activation energy of a disrotatory or conrotatory electrocyclic radical reaction is therefore difficult to estimate even qualitatively[11]. It should depend upon the energy of the electronic ground state and the excited states of the reacting system and also upon the degree of symmetry perturbation along the reaction coordinate. A quantitative treatment of the cyclopropyl-allyl radical interconversion with the aid of semiempirical SCF MO methods is given in the following communication[12].

Electrocyclic Transformation of Cyclopropyl Radical into Allyl Radical: A Semiempirical SCF MO Study[**]

By *Günter Szeimies* and *Gernot Boche*[*]

All electrocyclic rearrangements of radicals should pass over a symmetry-controlled activation barrier[1]. Since qualitative considerations permit no unequivocal predictions to be made concerning the chemically interesting

Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We also wish to thank Dr. *H. U. Wagner* for valuable discussions.

problem of the activation energies of the disrotatory and the conrotatory ring opening process[1] we have performed semiempirical SCF MO calculations on the cyclopropyl-allyl radical rearrangement by the CNDO/2[2] and MINDO/2 techniques[3].

The geometry of the cyclopropyl radical was taken to correspond to that of cyclopropane[4] and we assumed a unidimensional reaction coordinate for the ring opening, *i.e.* all geometric parameters involved in the transformation were transformed continuously into those of the allyl system[5]. C—H bond lengths remained unchanged. Energies were calculated for the cyclopropyl and allyl radicals as well as nine geometric intermediates, corresponding to an opening of the $C^2C^1C^3$ angle from 60° to 120° in steps of 6°.

Since the cyclopropyl radical probably has an inversion barrier at the radical center[6], the tricovalent carbon atom thus assuming a pyramidal structure, two disrotatory ring opening modes are possible. H^1 and H^3 (see Fig. 1) can either approach (disrotation 1) or move away from each other (disrotation 2). There is only one possible conrotatory mode.

The reaction course assumed has the C_2 axis or the σ_v plane as symmetry element along the reaction coordinate[***]. The computation methods chosen take account only of the ground state configuration; the increase or decrease in energy takes place on correlation pathways of different state symmetry (A′ and A″ for disrotation, and A and B for conrotation). The point of intersection characterizes the activated complex and thus allows the calculation of the activation energy. This model reaction is "symmetry forbidden", as is also apparent from the results of the calculation. The CNDO/2 bond indices[7] of the C—C bonds exhibit sharp discontinuities in the region of the activated complex.

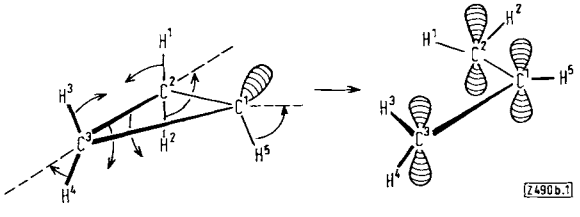

Fig. 1. Movement of the H atoms during disrotation 1.

We have already pointed out[1] that a perturbation of the symmetry along the reaction coordinate could energetically favor the reaction as a result of configurational interaction. With this in mind, our calculations can be seen to give an upper limit for the activation energy of the cyclopropyl-allyl radical transformation (Table 1). Figure 2 shows the variation in energy along the reaction coordinate for the MINDO/2 case.

CNDO/2 and MINDO/2 give very similar results. However, we regard the MINDO/2 values as more reliable since the underestimation of ring strain effects is less serious than by CNDO/2.

The value of 20—22 kcal/mol[9] determined by *Grey* and *Thynne* for the ring opening of the cyclopropyl radical is in good agreement with the calculated figures. That the activation energy can be even lower for suitably substituted cyclopropyl radicals is clear from the successful competition of ring opening with H abstraction[10], whose activation energy is only 7—8 kcal/mol[11].

[***] Strictly speaking this applies to the conrotation only when the reaction is made to start with a trigonal radical center.

Table 1. Calculated activation energies (kcal/mol) for the ring opening of cyclopropyl radical to give allyl radical. In the case of MINDO/2 the ring strain in the parametrization used is estimated as about 12 kcal/mol too low [3, 8]. The values in parentheses take this into consideration.

Method	Disrotation 1	Disrotation 2	Conrotation
CNDO/2	31.8	42.5	40.7
MINDO/2	30.1	46.6	37.5
	(18.1)	(34.6)	(25.5)

[13] The observation that reaction of *syn*-9-chloro(or methoxy)-*cis*-bicyclo[6.1.0]nona-2,4,6-triene with alkali metal leads to all-*cis*-cyclononatetraenyl anion by disrotatory ring opening, could be regarded as an example. The corresponding *anti* compounds, on the other hand, give mainly *trans,cis,cis,cis*-cyclononatetraenyl anion; *G. Boche* and *D. Martens*, unpublished; *G. Boche, D. Martens*, and *W. Danzer*, Angew. Chem. *87*, 1003 (1969); Angew. Chem. internat. Edit. *8*, 984 (1969).

[14] *M. S. Gordon*, J. Amer. Chem. Soc. *91*, 3122 (1969).

Both CNDO/2 and MINDO/2 indicate a definite preference among the possible modes of ring opening: Contrary to earlier qualitative predictions[12], our results show that disrotation 1 should require the lowest activation energy[13].

Why is this reaction path more favorable than the others? The calculated total energies can be resolved into interpretable energy components[14]. Analysis of these CNDO partial energies shows that the differences in the activation energies lie almost exclusively in the term that is decisive for covalent bonding ($\sum\sum_{A<B} E^1_{AB}$, for notation see ref. [14]). Further dissection of the summation term indicates that the activation energy difference is due mainly to the contributions of the three C—C bonds. In the case of disrotation 1 the carbon centers in the transition state exhibit more pronounced mutual covalent bonding than in conrotation or disrotation 2.

Representation of Chemical Systems and Interconversions by *be* Matrices and Their Transformation Properties[1]

By *Ivar Ugi* and *Paul Gillespie*[*]

Isoelectronic chemical entities that contain the same atomic nuclei are described by the same Schrödinger equation. These include not only families of isomeric molecules but *families of isomeric ensembles of molecules* (FIEM) as well.

The latter concept arises as an extension of the isomerism equivalence relation[2] of individual molecules to ensembles of molecules (EM). EM belonging to the same FIEM originate from the same set $\boldsymbol{A}$ of atoms.

The C_3H_8O FIEM contains, *e.g.*, $EM_0=\{3C+8H+2O\}$,
$EM_1=\{CH_3—CHOH—CH_2OH\}$,
$EM_2=\{CH_3—CH_2—CHO+H_2O\}$,
$EM_3=\{CH_3CHO+CH_3OH\}$,
$EM_4=\{CH_2O+CH_3—CH_2OH\}$,
$EM_5=\{CH_3—CH{=}CH_2+H_2O_2\}$, and
$EM_6=\{CH_3—CH_2—CH_3+O_2\}$, *etc.*

Distinguishable IEM of a FIEM (we treat stereoisomers as being equivalent here) can be represented by a family of *be* matrices $\boldsymbol{F}=(\boldsymbol{M}_0,\boldsymbol{M}_1,\ldots,\boldsymbol{M}_\phi,\ldots\boldsymbol{M}_f)$. In general the number $f\leqslant(2N)!/2^T\,(2N-T)!$ or $f\leqslant N!/(N-T/2)!$, if no EM with unpaired electrons are considered. N is the sum of the AO's and LCAO's occupied in the ground states of the IEM by the $T=T_0$ valence electrons of $\boldsymbol{A}$. The *be* matrix $\boldsymbol{M}_\phi$ of an EM_ϕ consisting of a set $\boldsymbol{A}$ containing n atoms, $\boldsymbol{A}=\{A_1,A_2,\ldots A_n\}$ is an $n\times n$ matrix (eq. (1))[3].

$$\boldsymbol{M}_\phi=\begin{bmatrix} e_1 & i_{12} & i_{13} & i_{14}\cdots i_{1n} \\ b_{21} & e_2 & i_{23} & i_{24}\cdots i_{2n} \\ b_{31} & b_{32} & e_3 & i_{34}\cdots i_{3n} \\ b_{41} & b_{42} & b_{43} & e_4\cdots i_{4n} \\ \vdots & \vdots & \vdots & \vdots \\ b_{n1} & b_{n2} & \cdots & e_n \end{bmatrix} \quad (1)$$

[*] Prof. Dr. I. Ugi and Dr. P. Gillespie
Department of Chemistry
University of Southern California
Los Angeles Calif. 90007 (USA)

The entries $b_{\mu\nu}$ of the *b*-region (lower triangle) where $\mu>\nu$ are the formal bond orders of the bonds between pairs of atoms A_μ and A_ν. Off diagonal matrix elements $b_{\mu\nu}$ may be simply interpreted as follows:

$b_{\mu\nu}=0$: no formal bond between A_μ and A_ν
$b_{\mu\nu}=1$: $A_\mu-A_\nu$ (= single bond)
$b_{\mu\nu}=2$: $A_\mu=A_\nu$ (= double bond)
$b_{\mu\nu}=3$: $A_\mu\equiv A_\nu$ (= triple bond)

Fractional bond orders must be employed for representations of multi-center bonds. For third and higher row elements $b_{\mu\nu}>1$ is usually avoided. Since the chemical bond is a symmetrical relation $b_{\mu\nu}=b_{\nu\mu}$, it suffices to use the *b*-region for bond information freeing the upper triangle (*i*-region, see Ref.[7]) for any form of additional information on the EM_ϕ. The matrix elements $i_{\mu\nu}$ of the *i*-region can represent any property, *e.g.*, thermodynamic, kinetic, electronic, steric[4], *etc.*, that exists between pairs of atoms A_μ and A_ν, unless a symmetrical matrix is preferred because of advantages upon transformation[**].

Diagonal matrix elements $e_{\lambda=\mu\mu=\nu\nu}$ (eq. (2)) are numerically equivalent to the number of valence electrons belonging to atom A_λ in EM_ϕ, *i.e.*, the electrons in the σ and π bonds by which A_λ is connected to other atoms and e'_λ, the "free" valence electrons of A_λ[**].

$$\bar{e}_\lambda=\sum_{\nu=1}^{\nu=\lambda-1} b_{\lambda\nu}+\sum_{\mu=\lambda+1}^{\mu=n} b_{\mu\lambda} \quad (2)$$

$$e_\lambda=e'_\lambda+\bar{e}_\lambda \quad (2a)$$

$$T=\sum_1^n e_\lambda \quad (3)$$

$$T_0=\sum_1^n e'_{0\lambda} \quad (3a)$$

$$\hat{e}_\lambda=e'_\lambda+2\bar{e}_\lambda \quad (4)$$

$$\hat{e}_\lambda=\hat{e}_{\lambda,\mathrm{opt}} \quad (4a)$$

$$\hat{e}_{\lambda,\min}\leq\hat{e}_\lambda\leq\hat{e}_{\lambda,\max} \quad (4b)$$

$$e^+_\lambda=e'_{0\lambda}-e_\lambda \quad (5)$$

The numbers $\hat{e}_\lambda$ of valence electrons that surround A_λ have preferred values, *e.g.*, 8 for B to F, or lie within an interval defined by eq. (4b), characteristic of $A_{0\lambda}$. The limits, $\hat{e}_{\lambda,\min}$ and $\hat{e}_{\lambda,\max}$ are 0 and 2 for the elements of group IA of the periodic table, 0 and 4 for group IIA, 6 and 8 for second row elements B to F and 6 and 12 for third row elements Si to Cl.

The trace T, eq. (3), of the *be* matrix $\boldsymbol{M}_\phi$ in EM_ϕ is equal to T_0, eq. (3a), the sum of all valence electrons for each of the atoms $A_1,\ldots A_m$ that belong to $\boldsymbol{A}$. The diagonal entries $e'_{0\lambda}$ of $\boldsymbol{M}_0$ are the numbers of valence electrons of the elements $A_{0\lambda}$ to which the A_λ belong; *e.g.*, ${}_He'_{0\lambda}=1$, ${}_Ce'_{0\lambda}=4$, ${}_Ne'_{0\lambda}=5$, ${}_Oe'_{0\lambda}=6$, *etc.*

The formal net electrical charge, e^+_λ, of an atom A_λ is given by eq. (5); here $e'_{0\lambda}$ represents the positive core charge.

In addition to the selection rule defined by eq. (4) further selection rules may be based upon preferred coordination numbers for the various elements within $\boldsymbol{A}$.

[**] Note added in proof: Sometimes it is advantageous to represent the EM by symmetric *be*-matrices in which the numbers of free valence electrons e'_λ are entered on the diagonal. In this case, the sums over the rows or columns correspond to the e_λ and the sums over all entries correspond to the total number $T=T_0$ of valence electrons.

Symmetries and/or permutational equivalencies[2, 5] in the EM∈FIEM may be represented by permutations of the indices λ or μ and ν, respectively.

be-Matrices which differ only by permutations of indices whose atoms belong to the same element are equivalent. Any set of equivalent ***be***-matrices contains ε! irreducible matrices. These are in block form if the represented EM contains ε disjoint molecules. Further, they are the ***be***-matrices of the individual molecules within the EM. Equivalent irreducible ***be***-matrices differ only by permutations of the blocks.

Chemical processes correspond to interconversions $EM_\phi \rightarrow EM_\psi$ of IEM (EM_ϕ and $EM_\psi \in FIEM$) and are represented by eq. (6) where R_ρ is a transformation operator.

$$M_\psi = R_\rho \cdot M_\phi \tag{6}$$

The set A_0 of free atoms $A_0 = \{A_{01}, A_{02}, \ldots A_{0n}\}$ is represented by a ***be*** matrix M_0 whose diagonal elements are $e'_{0\lambda}$, and whose *b*-region contains only zeros. Transformations R_ρ generate from M_0, according to eq. (6), the set $\boldsymbol{F}$ that corresponds to the total FIEM[6]. Cycles of such transformations form closed lines in the corresponding topological space.

Equation (6) then may be considered the consequent result of the application of logical structures[5] to chemical systems, in short, a master equation for describing the chemistry of the FIEM.

The various operators R_ρ correspond to various types of chemical processes.

It is interesting to note that eq. (6) contains any of the conservation laws one normally assumes in the solution to problems within chemical systems, *e.g.*, conservations of mass, charge, electrons, *etc.* It follows that those transformations generated as a result of the operation of R_ρ acting on some M_ϕ correspond to processes described by a time-dependent Schrödinger equation.

Potential applications of this equation include the computer assisted planning of syntheses, elucidation of reaction mechanisms and mass spectrometric patterns[7], and documentation of chemical reactions.

Matter Preserving Synthetic Pathways and Semi-Empirical Computer Assisted Planning of Syntheses[1]

By *Ivar Ugi* and *Paul Gillespie*[*]

Synthetic planning processes consist of two steps; first one looks for the pathways that lead from readily available starting materials to a target molecule ***Z***, then one decides which of these conceivable pathways is the optimum as a function of some chosen criteria. This communication deals primarily with the problem of determining the available synthetic alternatives without detailed discussion of the evaluation problem[3].

The search for a synthetic pathway is best accomplished by "working the problem backwards"[4]. A target molecular structure ***Z*** is analyzed for "seams" in order to find the set ***Y*** of precursors $\{Y_1, Y_2, \ldots, Y_y, \ldots\}$ that can be converted by one step reactions into ***Z***. A set ***X*** of compounds $\{X_1, X_2, \ldots, X_x, \ldots\}$ are then sought which can be converted in one-step reactions into the precursors $\{Y_1, Y_2, \ldots, Y_y, \ldots\}$ until a set ***A*** of convenient starting materials $\{A_1, \ldots, A_a, \ldots\}$ is achieved. Thus the mappings $A_a \rightarrow B_b \rightarrow \cdots \rightarrow Z$ yields a tree (1) of synthetic pathways.

(1)

An existing computer program[5], designed to produce this "tree", and employing empirical information concerning known synthetic reactions, is limited to the generation of those synthetic pathways which are suggested to the chemist by his knowledge of the literature.

As in all chemical processes, synthetically useful reactions including sequences of reactions (if suitably defined) proceed with a constant matter balance[6] and correspond to interconversions of IEM∈FIEM[2]. Therefore, eq. (2)[2]

$$M_\psi = R_\rho \cdot M_\phi \tag{2}$$

provides the basis for a program conceptually dependent upon fundamental principles which, in contrast to the

[1] Chemistry and Logical Structures, Part 3.—Part 2: see Ref. [2].

[3] The ***be*** matrices differ fundamentally from extended connectivity matrices, the so-called principal matrices of molecules, by being endowed with well defined transformation properties. Further, the ***be*** matrices not only refer to molecules but EM as well.

[4] The steric features of the considered systems can also be represented by additional diagonal entries referring to the local configurations of the vicinities of the individual atoms; the numbering of the atoms can serve as a sequence rule for descriptors[5]. An alternative would be to include some suitably chosen nuclear coordinates, *e.g.* cartesian or approximate cubic lattice coordinates[5].

[6] We gratefully acknowledge a valuable discussion with Prof. *J. Dugundji* (Department of Mathematics, U.S.C) during which the following evolved: The *be*-matrices of an FIEM define a finite metric space which may be properly called the EM space or the chemical topology of the FIEM. In this space the distance *d* between two points (*i.e.*, EM and EM', represented by their *be*-matrices *M* and *M'*) is given by $d = |M - M'|$. The EM space of a FIEM is a *subspace* of the *universal chemical topology* referring to the universal FIEM that contains all chemical compounds of the universe. Chemical topology, as a term, has previously been used in an attempt to represent steric features of molecules topologically[5]. It follows that a synthetic route is a pathway in the topological space of an FIEM connecting a starting material point, frequently *via* other points, with that of a product such that none of the distances between two points exceeds a specified limit (see Ref. [7]).

Los Angeles, Calif. 90007 (USA)

above empirical, analogy oriented program, generates the complete set of all conceivable synthetic routes for a given target. This includes new reactions, *i.e.*, computer invented pathways suggesting experimental discovery.

At any given moment, these synthetic pathways not only contain the characteristic intermediates $A_a, B_b, \ldots Y_y, \boldsymbol{Z}$, but all unconsumed starting materials and existing by-products that accompany the intermediates as well. The pathway $A_a \rightarrow B_b \rightarrow \cdots \boldsymbol{Z}$ shown in scheme (3) may also be

$$\begin{array}{lll} A_a + A'_a & \rightarrow & B_b + B''_b \\ B_b + B'_b & \rightarrow & C_c + C''_c \\ C_c + C'_c & \rightarrow & \cdots \\ \cdots & \rightarrow & \cdots \\ \cdots & \rightarrow & X_x + X''_x \\ X_x + X'_x & \rightarrow & Y_y + Y''_y \\ Y_y + Y'_y & \rightarrow & \boldsymbol{Z} + Z'' \end{array} \qquad (3)$$

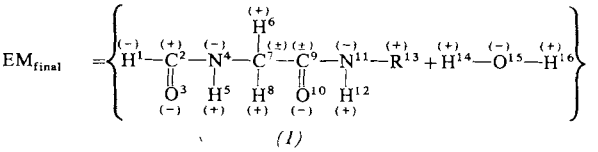
represented by the balance of matter preserving pathway $EM_{initial} \rightarrow EM_b \rightarrow \cdots EM_y \rightarrow EM_{final}$ (4), with $A_a \in EM_{initial}$, $B_b \in EM_b, \ldots, \boldsymbol{Z} \in EM_{final}$.

$$\begin{array}{lll} EM_{initial} & = & \{A_a + A'_a + B'_b + C'_c + \cdots + X'_x + Y'_y\} \\ EM_b & = & \{B_b + B''_b + B'_b + C'_c + \cdots + X'_x + Y'_y\} \\ EM_c & = & \{B_b + B''_b + C'_c + \cdots + X'_x + Y'_y\} \\ \vdots & & \vdots \\ EM_x & = & \{B''_b + C''_c + \cdots + X_x + X''_x + X'_x + Y'_y\} \\ EM_y & = & \{B''_b + C''_c + \cdots + X''_x + Y_y + Y''_y + Y'_y\} \\ EM_{final} & = & \{B''_b + C''_c + \cdots + X''_x + Y''_y + \boldsymbol{Z}_z + Z''_z\} \end{array} \qquad (4)$$

An input of M_{final} is required for the matter preserving synthetic path computer program. Additional input of $M_{initial}$, if known, reduces output as well as run time. From these inputs, *i.e.* ***be***-matrices[2], the complete set of transformations, $R_z, \ldots R_a$, for

$$M_{final} = R_z \cdot R_y \cdot, \ldots R_b \cdot R_a \cdot M_{initial} = \bar{R} \cdot M_{initial} \qquad (5)$$

is generated. Sequential application of the operators $R_a, \ldots, R_z$ on $M_{initial}$ yield the ***be*** matrices which represent the EM_ϕ encountered on the individual paths while the operators R_ρ represent the chemical processes of the synthetic steps.



If it is not possible to derive the EM_{final} directly from the formula of $\boldsymbol{Z}$, one adds, as the required complements, α molecules of A—B, equivalent to $A^\oplus + :B^\ominus$ or $A\cdot + B\cdot$, and β molecules of C=D representing unsaturated by-products (*e.g.*, $(C_6H_5)_3P{=}O$) of synthetic steps to form the $EM_{final} = \{\boldsymbol{Z} + \alpha(A{-}B) + \beta(C{=}D)\}$. From this the program yields EM_y representations containing the Y_y that can be identified, simultaneously identifying the complements A—B and C=D of $\boldsymbol{Z}$. In the next step the Y_y are subjected to an analogous treatment *etc.*, until readily available starting materials are reached.

Simplification of matrices with an attendent reduction of computer time can be gained by replacing a substituent on $\boldsymbol{Z}$ with an R$^\cdot$ ($0 \leq_R \hat{e}_\lambda \leq 2, {}_R e_{0\lambda} = 1$) symbol possessing an electron or its polyfunctional analog if this substituent appears in a starting material and no reaction sequence involves it.

In order to achieve a convenient and economical procedure the operator R_ρ must be subjected to *empirical selection rules* such that those steps can be avoided that do not proceed with practical rates or yields. The rules must provide that only those transformations are used that correspond to operations whereby one, two or in exceptional cases three connections are dissected or made, and bond orders $b_{\mu\nu}$ in M_ϕ are changed by $\Delta b_{\mu\nu} \pm 1$ with simultaneous changes in $\hat{e}_\lambda$ by $\Delta\hat{e}_\lambda = \pm 1$ (for radical reactions) or by $\Delta\hat{e}_\lambda = 0, \pm 2$ (for ionic reactions). Preferred transformations can be effected by loading the transformation invariant *i*-region of the ***be*** matrix[2] with further information regarding the system at hand, *e.g.*, kinetic or thermodynamic pair parameters. Relative "charge affinity" information in the form of an extended Evans-Lapworth Scheme may be used to indicate by the algebraic sign and values of the $i_{\mu\nu}$ which of the bonds $b_{\mu\nu}$ are preferentially subject to ionic reactions and determine which of the atoms (A_μ or A_ν) will play the nucleophilic role[7, 8]. Heats of bond formation $\Delta H_{\mu\nu}$ between A_μ and A_ν may be included as off diagonal matrix elements, $\Delta H_{\mu\nu}$, in the *i*-region of the ***be*** matrices. A summation of these $\Delta H_{\mu\nu}$ according to the *b*-region serves as an estimate of the heat of formation for the corresponding EM_ϕ. This information will allow the program to reject excessively endothermic reactions.

Subsequent selection rules based upon other known principles such as the Dewar-Evans rule[9–17] as well as general empirical or semi-empirical information on chemical reactivity can be added to the *i*-region of the ***be*** matrices. The latter include observations to the effect that in cyclic processes involving five- or six-membered rings and carbon compounds, those R_ρ are preferred that represent reactions involving multiple bonds, bonds immediate or next neighbors to multiple bonds or electrically charged or heteroatoms. If more than one of these conditions applies to one of the bonds the preference for reactions involving these bonds is enhanced.

An example of a synthetic planning process for *N*-formylglycine-*N'*-methylamide *(1)* may serve to illustrate the present method and its potential usefulness. If one looks for those syntheses of *(1)* that proceed with the loss of one mole of water, one starts with R = CH_3 and

$EM_{final} =$ 

(1)

assigns numbers to the atoms of *(1)* as indicated. Further, one can label the latter with (+) or (−) according to an Evans-Lapworth pattern[7, 8]. From these, one obtains a *bei* matrix M_{final} (6a). The *b*-region entries represent the bond system of EM_{final}; the number, $b_{32} = 2$, in the second column, third row means that in *(1)* the C-atom. 2 is connected by a double bond to the O-atom 3. Diagonal entries represent those numbers of electrons belonging to the corresponding atoms. For example, the third diagonal element from the top $e_3 = 2 + 4$ relates to the fact that six valence electrons belong to O-3 of which two are bonding and four are "free". Entries to the *i*-region[2] are relative "charge affinity" data concerning pairs of atoms in the sense of an extended Evans-Lapworth pattern; the (+) sign of $i_{24} = +2$ in (6a) indicates that C-atom 2 is electrophilic *vs.* N-atom 4, the latter being nucleophilic relative to the former. The value 2 of i_{24} represents a crude estimate of a relative charge affinity difference which does not always correspond to an electronegativity difference. Higher $i_{\mu\nu}$ values for a pair of atoms (A_μ,A_ν) indicates an increased likelihood for an ionic reaction involving bond making or bond breaking between A_μ and A_ν.

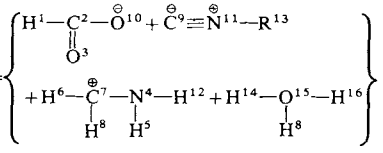
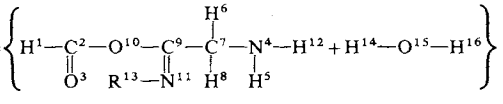
(6d) $= M_{\text{initial}}$

In (6b)—(6d), the "zeros" of the *b*-region as well as the entries of the *i*-region that correspond to those of (6a) are omitted for simplicity. Additionally, if bond enthalpy data $\Delta H_{\mu\nu}$ had been included in the *i*-region, one would find that the sequence (6a)—(6d) corresponds to a favored, strongly exothermic pathway.



One of the transformations defined by the octet rule ($\Delta e_\lambda = 0$) which is preferred according to the entries of the *i*-region leads from (6a) to $M_{\alpha\text{-add}}$ (6b) and from here one obtains, *e.g.*, analogously $M_{\text{prec.}}$ (6c) and from this M_{initial} (6d). This sequence of transformations corresponds to the matter balance preserving synthetic pathway $EM_{initial} \rightarrow EM_{precursor} \rightarrow EM_{\alpha\text{-add}} \rightarrow EM_{final}$.

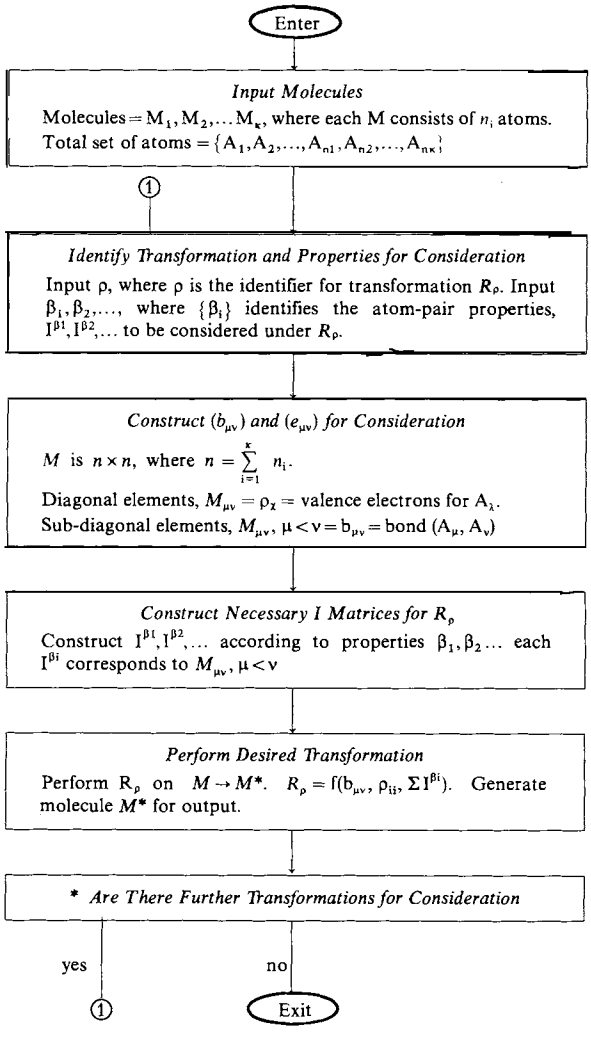
$EM_{initial}$ =



(2) (3) (4) (5)

$EM_{precursor}$ =

EM_{final} =



The above reaction is a four component condensation[18] of *(2)+(3)+(4)+(5)*. If this investigation had been carried out before 1959, then the four component condensation might have been proposed by a computer for experimental discovery.

For the prediction of conceivable mass spectrographic fragment patterns, the parent molecule or parent ion may be represented by its ***be*** matrix M_ρ. Those EM∈FIEM generated by suitably selected classes of dissecting transformation operators acting on M_ρ represent the fragments. This is in contrast to existing machine assisted mass spectral interpretation schemes that depend upon empirical data[19].

For the generation of a computer program, logical thought is transformed into algorithms. The latter are created from flow charts which represent the flow of logic and decision relative to a problem that will be solved by a computer.

An abbreviated flow chart for the program used to generate solutions to the ***be*** matrix transformations follows:

Note: If dissection is desired, transformations will be performed on successive M^*'s.

M_i molecule i
A_i atom *i*
n_i number of atoms in molecule i
ρ identifier for a transformation, *R*
R transformation identified by ρ.
β_i identifier for atom-pair property
μ, ν row, column numbers for matrix *M*.
M *be* matrix
M^* *be* matrix generated by some R_ρ on *M*.

Oxidation of $C_5H_5Mn(CO)_2N_2H_4$ to $C_5H_5Mn(CO)_2N_2$, a New Dinitrogen Complex[1]

By *Dieter Sellmann*[*]

In order to study the redox behavior of complexed hydrazine, $C_5H_5Mn(CO)_2N_2H_4$ *(1)*[2] was subjected to the action of various oxidizing agents. The two-electron oxidant H_2O_2/Cu^{2+} was found to convert *(1)* into π-cyclopentadienyldicarbonyldinitrogenmanganese(I) *(2)* in 40% yield according to:

$$C_5H_5Mn(CO)_2N_2H_4 + 2\,H_2O_2 \xrightarrow[THF/-40\,^\circ C]{Cu^{2+}/1\,h} \underset{(2)}{C_5H_5Mn(CO)_2N_2} + 4\,H_2O$$

(1)

After removal of the solvent tetrahydrofuran, *(2)* sublimed at room temperature ($\approx 10^{-3}$ torr) to give large, reddish-brown crystals that are diamagnetic and highly refractive. They are also air-stable, resublimable, melt at 60°C with evolution of gas, and dissolve in all common organic solvents. Their composition and structure were confirmed by elemental analysis, IR, ^{1}H-NMR, and mass spectroscopy[3].

The IR spectrum of the complex *(2)* in *n*-hexane shows three characteristic very strong bands of approximately equal intensity at 2169 ($\nu_{N\equiv N}$), 1980 ($\nu_{C\equiv O}$, A_1), and 1923 cm^{-1} ($\nu_{C\equiv O}$, B_1); in KBr these bands are shifted to 2163, 1965, and 1895 cm^{-1}.

The method of preparation and the extremely intense $\nu_{N\equiv N}$ band suggest "end-on" bonding of the N_2 ligand to the central metal atom.

In the ^{1}H-NMR spectrum ([D_6]-acetone) the C_5H_5 protons of *(2)* show a sharp singlet at $\tau = 5.16$, which is shifted upfield by 12 Hz compared to the signal of $C_5H_5Mn(CO)_3$ *(3)*.

[*] Dr. D. Sellmann
Anorganisch-chemisches Laboratorium
der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

In the mass spectrum (50 eV) the molecular ion occurs at *m/e* 204. The ionization-induced degradation of *(2)* resembles that of *(3)*; however, the intensity ratios of the ions at *m/e* 204, 176, and 148 exhibit characteristic differences for the two compounds.

Contrary to the prevailing opinion[4], the spectroscopic data show that the N_2 can act quite well as a stronger donor than CO if attention is paid to the sum of the σ-donor and π-acceptor strengths. The weakening of the $\nu_{C\equiv O}$ frequencies compared to *(3)*, as well as the drop in force constants k and k_i calculated according to ref. [5], which are respectively 15.61 and 0.49 mdyn/Å for *(3)* and 15.38 and 0.45 mdyn/Å for *(2)*, and the upfield shift of the C_5H_5 protons, evidence an increase in electron density on the central metal atom due to the N_2 ligand.

(2) is the first N_2-complex to have been synthesized by controlled oxidation of the corresponding hydrazine derivative. Further studies on related complexes will show whether the technique is applicable to the systematic synthesis of N_2 complexes. Preliminary experiments on *(2)* indicate a high reactivity in solution and ready substitution of the N_2 ligand by other donors.

Fluorochlorobromoiodosilane[**]

By *Friedrich Höfler* and *Walter Veigl*[*]

Halosilanes of the type SiX_3Y and SiX_2Y_2 have been known for a long time[1], but only a few investigations regarding SiX_2YZ compounds have been published in the literature[2-4]. In our investigations of halogen exchange reactions at the silicon atom[5] we have now succeeded in synthesizing the hitherto unknown fluorochlorobromoiodosilane SiFClBrI *(1)*:

$$SiBr_4 \xrightarrow{SbF_3} \underset{(2)}{SiFBr_3} + SiF\,Br_{4-n}\,(n=2\text{–}4) \qquad (1)$$

$$\underset{(2)}{SiFBr_3} \xrightarrow{SbCl_3} \underset{(3)}{SiFClBr_2} + SiFCl_nBr_{3-n}\,(n=2,3) \qquad (2)$$

$$\underset{(3)}{SiFClBr_2} + HSiI_3 \longrightarrow \underset{(1)}{SiFClBrI} + HSiBrI_2 \qquad (3)$$

By modifying the reaction conditions (slow addition of Sb-halide to boiling halosilane, rapid removal of reaction products) used by *Schumb* and *Anderson*[2,6] in reactions (1) and (2) we have been able to obtain better yields of *(2)*

[**] This work was supported by the Fonds zur Förderung der wissenschaftlichen Forschung, Vienna.

and *(3)*. On heating *(3)* with SbI_3 at 100°C for 24 hours in a sealed tube no iodination took place, whereas 12 hours' heating of *(3)* with SiI_4 at 100°C gave *(1)* in 5% yield. In each case, however, the main reaction was disproportionation of *(3)* to *(2)* and $SiFCl_2Br$ *(4)*. On the other hand, reaction of *(3)* and $HSiI_3$ at 100°C for 18 hours resulted in 50% conversion according to Eq. (3); small amounts of other products formed by progressive Br/I exchange that could be detected spectroscopically were (in order of decreasing amounts): $HSiBr_2I$ and $HSiBr_3$ (by ^{1}H-NMR), $SiFClI_2$ *(5)*, $SiFBr_2I$, $SiFBrI_2$, *(2)*, *(4)*, and $SiFI_3$ (^{19}F-NMR). *(1)* can be separated from the reaction mixture in very pure form by fractional distillation, since, with exception of *(3)* (b.p. 59.5°C), all the main components of the mixture boil at higher temperatures.

(1) is a colorless, readily hydrolyzable liquid ($b.p._{.735}$ = 85°C, $n_D^{20} = 1.507$) which turns pink in color when exposed to air or light. Its thermal stability is remarkable: the substance remains unchanged after 8 hours' heating at 100°C in an ampoule. After 33—50 hours at this temperature, 5—8% *(3)* and *(5)* could be detected in the Raman spectrum by means of their most intense lines at 361 and 316 cm^{-1}, respectively.

All fundamental vibrations of *(1)* are Raman and IR active. As expected, the Raman spectrum shows nine polarized lines (Table 1); the IR absorptions of the four stretching vibrations were also measured. The quoted assignments are derived from a vibration analysis, which, in combination with force constants and averaging methods described in Ref. [7], lead to good agreement of calculated and measured frequencies (stretching force constants: f(SiF) = 5.7, f(SiCl) = 3.0, f(SiBr) = 2.42, f(SiI) = 1.76 mdyn/Å). In addition to the relatively strong mixing of bending coordinates, the coupling of the lowest stretching vibration (νSiI) with the highest bending mode (δFSiCl) is noteworthy.

Table 1. Fundamental vibrations of SiFClBrI in the IR (1000—250 cm^{-1}) and Raman spectra.

	IR (cm^{-1})	Raman (cm^{-1})	Int.	Depol. factor	Calc. (cm^{-1})	Assignment

Effect of Non-Planarity on the Paramagnetic Ring Current in the Dianion of 1,6;8,13-Propanediylidene[14]annulene[**]

By *Fabian Gerson, Klaus Müllen*, and *Emanuel Vogel*[*]

A concept of "ring current" induced in cyclic π-electron systems[1] (perimeters) is usually invoked to account for the ^{1}H-NMR chemical shifts of ring protons in these systems[2]. Theory predicts a "diamagnetic" or "paramagnetic" ring current according to whether the perimeter has $4n+2$ or $4n$ π-electrons[3]. In a perimeter with $4n+2$ electrons, the signals of the outer and inner ring protons undergo a down-field and an up-field shift, respectively, relative to the signals of olefinic protons. The reverse is true for a perimeter with $4n$ electrons[2]. Bond alternation and deviations of the perimeter from planarity should reduce the paramagnetic ring current much more effectively than the diamagnetic one[3]. This statement has been verified by us for 1,6;8,13-propanediylidene[14]annulene *(1)*[4], a bridged fourteen-membered perimeter with $4\times3+2=14$ π-electrons, and for its dianion $(1)^{2\ominus}$ having $4\times4=16$ π-electrons. As shown by molecular models, X-ray structure[5], and other spectroscopic studies[6], the perimeter in *(1)* exhibits moderate deviations from planarity. The same geometry can be assumed for $(1)^{2\ominus}$, since the shape of the perimeter is fixed by the bridging groups.

The dianion $(1)^{2\ominus}$ has been produced by reduction of *(1)* with potassium in perdeuteriotetrahydrofuran ([D_8]-THF) or 1,2-dimethoxyethane (DME). This method has also been used for the preparation of the anthracene dianion $(2)^{2\ominus}$ from the parent neutral hydrocarbon *(2)*. The relevant proton resonance data for *(1)*, $(1)^{2\ominus}$, *(2)*, $(2)^{2\ominus}$ are listed in Table 1, along with the corresponding values for *trans*-10b,10c-dimethyl-10b,10c-dihydropyrene *(3)*[7] and its dianion $(3)^{2\ominus}$[8].

In the following brief discussion, the data for *(1)* and $(1)^{2\ominus}$ will be compared with those for *(3)* and $(3)^{2\ominus}$. Unlike *(1)* and $(1)^{2\ominus}$, the rigid fourteen-membered perimeter in both *(3)*[10] and $(3)^{2\ominus}$[8] achieves a high degree of planarity.

Comparison of the τ-values for the ring protons in the neutral compounds *(1)* and *(3)* indicates that moderate deviations of the perimeter from planarity affect the diamagnetic ring current to a small extent only. (The difference of 0.7 ppm is partially due to unequal perimeter areas in the two compounds[11].) In contrast, as shown by an analogous comparison for the ring protons in the dianions $(1)^{2\ominus}$ and $(3)^{2\ominus}$, even moderate deviations from a

coplanar arrangement have a striking effect on the paramagnetic ring current. It should be borne in mind that—on going from the neutral compounds to their dianions—an average shift of approximately $2 \times 10/14 \approx 1.4$ ppm per ring proton is expected by a mere allowance for two additional negative charges[2]; such a shift (+1.6 ppm) indeed occurs

(1)

(3)

Table 1. Centers of gravity for proton resonances of *(1)*, $(1)^{2\ominus}$, *(2)*, $(2)^{2\ominus}$, *(3)* and $(3)^{2\ominus}$. τ-values in ppm. The uncertainty in the number given for the bridge protons of $(1)^{2\ominus}$ is due to a partial masking of the pertinent signals by the resonances of the solvents (isotopic impurities in $[D_8]$-THF, wing of the CH_3 band in DME).

Species	Ring protons	Shift	Bridge protons	Shift	Solvent/ temp. (°C)	Ref.
(1)	2.4	+ 2.1	10.9	− 3.1	$CDCl_3$/+25	[4]
$(1)^{2\ominus}$	4.5		7.8 (± 0.3)	(± 0.3)	$[D_8]$-THF/−60	this work
(2)	2.2	+ 1.6	—		CS_2/+25	[9]
$(2)^{2\ominus}$	3.8		—		DME/−60	this work
(3)	1.5	+12.1	14.3	−25.3	$CDCl_3$/+25	[7, 8]
$(3)^{2\ominus}$	13.6		−11.0		$[D_8]$-THF/−65	[8]

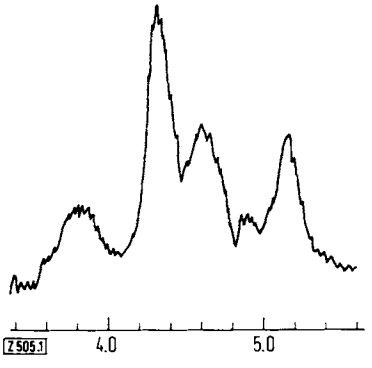

Fig. 1. Proton resonance spectrum of the dianion $(1)^{2\ominus}$ in the τ-range of 3.5−5.5 ppm; recorded for a $[D_8]$-THF solution at −60 °C and a frequency of 60 MHz.

for the conversion of anthracene *(2)* to its dianion $(2)^{2\ominus}$. The fact that the corresponding shift (+2.1 ppm) for the conversion of *(1)* to $(1)^{2\ominus}$ is only 0.5 ppm larger points to an almost complete quenching of the paramagnetic ring current in $(1)^{2\ominus}$. On the other hand, an analogous shift of more than +10 ppm is observed in the case of *(3)* and $(3)^{2\ominus}$ (Table 1).

Similar conclusions can be drawn from the shift of the bridge protons, although their different positions in the two bridged annulenes make a direct comparison more problematical than for the ring protons.

It is noteworthy that the resonance signals of the ring protons in $(1)^{2\ominus}$ extend over a range of 1.5 ppm (Figure 1), whereas the corresponding range for the neutral compound *(1)* is only 0.5 ppm[4]. This increase for $(1)^{2\ominus}$ points to larger differences in the chemical shifts. Unfortunately, an analysis of the spectrum of $(1)^{2\ominus}$ is impeded by line-broadening due to the presence of the intermediate radical anion $(1)^{\ominus}$[6].

Crystal and Molecular Structure of Bis(π-cyclopentadienyl)tetrasulfidotungsten(IV)[**]

By *Betty R. Davis, Ivan Bernal,* and *Hartmut Köpf*[*]

In 1969, *Köpf*[1] prepared the first metallocene tetrachalcogenide chelate $(\pi\text{-}C_5H_5)_2MoS_4$ and proposed from NMR studies that the cyclic MoS_4 moiety was nonplanar but nevertheless symmetrically disposed with respect to the two cyclopentadienyl rings. This conclusion was based on the evidence that the solution ^{1}H-NMR spectrum of the compound consists of a single, sharp line which showed no broadening down to −95 °C. Later, similar results were found for $(\pi\text{-}C_5H_5)_2WS_4$ *(1)*[2]. In continuation of our

[**] This work was performed under the auspices of the U. S. Atomic Energy Commission.—It is to be regarded as Part 7 of the series: Organometallic polychalcogenide chelates.—Part 6: [4]; Part 5: *H. Köpf, A. Wirl,* and *W. Kahl,* Angew. Chem. *83*, 146 (1971); Angew. Chem. internat. Edit. *10*, 137 (1971).

studies of polychalcogenides[3,4], the structure of the tungsten compound *(1)* was determined. Of additional interest was the question of the S—S bond lengths in the S_4 fragment since an alternation of bond lengths in a tetrasulfide bridge of an aromatic system analogous to paracyclophane has been previously reported[5].

Diamond-shaped, orange plates of the compound were found to crystallize in the monoclinic system, space group $P2_1/n$, with $a=11.242$ (3), $b=12.154$ (5), $c=8.790$ (2), and $\beta=92.93$ (3)°; $V=1199.34$ Å^3; $d_{exp}=2.46$ g cm^{-3} and d_{calc} ($Z=4$) $=2.44$ g cm^{-3}. Each reflection was collected twice to give a total of 5700 data ($d^*_{max}=1.20$). These data were averaged and corrected for absorption ($\mu=108.1$ cm^{-1}) to give an independent data set of 2288 reflections of which 989 were used in the present analysis. The structure was solved using conventional heavy atom techniques. To date, the tungsten and four sulfur atoms have been refined with anisotropic thermal parameters, the carbon atoms have been refined with isotropic thermal parameters, and the hydrogen atoms have been held to their idealized positions and assigned an isotropic thermal parameter of 5.0 Å^2. This refinement gives residuals of $R_1=0.049$ and $R_2=0.048$, and the error in an observation of unit weight is 1.12 electrons. A difference Fourier synthesis at this stage shows peaks as high as 2.9 electrons/Å^3 associated with ripples from the tungsten atom.

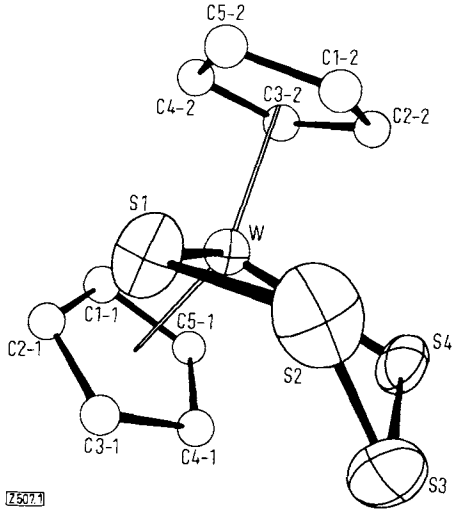

Fig. Molecular configuration of $(\pi\text{-}C_5H_5)_2WS_4$ *(1)*. The thermal ellipsoids shown for the W and four S atoms are 50% probability envelopes. The isotropic thermal parameters used for the C atoms are of an arbitrary size chosen because of representational convenience.

The molecule is shown in the Figure where it is obvious that previous conformational predictions[1,2] are verified and thus the NMR results obtained for *(1)* and related compounds are readily understood. A selection of bond lengths and angles for *(1)* are given in the Table.

A comparison of *(1)* with compounds of the type $(\pi\text{-}C_5H_5)_2W(SC_6H_5)_2M(CO)_4$ *(2)* (M = W, Mo, Cr) studied by *Cameron et al.*[6] is of interest since the latter also possess a $(\pi\text{-}C_5H_5)_2WS_2$ bonding system. The S—W—S angle in all three compounds *(2)* has an average value of 72.5° while in *(1)* this angle has opened to give a value of 89.1 (2)°. This opening is apparently responsible for the shorter W—S bond distance of 2.413 (6) Å found in *(1)*; the average W—S bond distance in the three compounds of type *(2)* is 2.49 Å. The Cp—W—Cp angle (Cp = cyclopentadienyl ring centroid) is essentially preserved since in *(2)* it is approximately 133° and in *(1)* it is 135°. Likewise, the average W—Cp distance remains almost constant [2.03 Å in *(1)* and about 2.00 Å in *(2)*]. It is interesting to note that the Cp—M—Cp angle is relatively constant for species of the type $(\pi\text{-}C_5H_5)_2MX_2$ since for $(\pi\text{-}C_5H_5)_2TiS_5$ the value is[3,4] 133.7° and for $(CH_2)_3(\pi\text{-}C_5H_4)_2TiCl_2$[7] it is 132.64°.

Distances (Å)			
W–S1	2.413(6)	S1–S2	2.105(7)
W–S4	2.413(5)	S2–S3	2.016(8)
W–Cp1 [a]	2.025	S3–S4	2.116(9)
W–Cp2 [a]	2.035		
Angles (°)			
S1–W–S4	89.1(2)	S1–S2–S3	100.3(3)
Cp1–W–Cp2	135.1	S2–S3–S4	100.1(3)
W–S1–S2	109.6(3)		
W–S4–S3	108.7(3)		

[a] Ring centroid.

There is a small but distinct variation in the three S—S bond lengths. The two outer bonds have an average value of 2.109 (9) Å which is longer than the central bond of 2.016 (8) Å; this is a reversal in the mode of the bond length alternation reported for an aromatic tetrasulfide[5]. The variation in bond lengths in the S_4 system of *(1)*, which is also observed in $(\pi\text{-}C_5H_5)_2MoS_4$[8], could be due to a perturbation of the normal S—S π interactions by $(d\rightarrow d)_\pi$ back bonding from the d^2 central atom to the adjacent sulfur atoms. This would also account for the shortening of the W—S bond length compared to compound *(2)* in which the M→S back bonding probably originates from the d^6 zerovalent carbonylmetal.

Ethoxydimethylaminocarbenepentacarbonylchromium(0)[1]

By *Ernst Otto Fischer, Eberhard Winkler, Cornelius G. Kreiter, Gottfried Huttner*, and *Bernhard Krieg*[*]

We recently reported the synthesis of the first carbonylmetal derivative of an acyclic carbene stabilized by two hetero atoms, $(CO)_5Cr—C(OC_2H_5)N(C_2H_5)_2$, and deduced the nature of the bonding in this compound from ^{1}H-NMR, IR, and MS studies[1].

[*] Prof. Dr. E. O. Fischer, Dr. E. Winkler, Dr. C. G. Kreiter, Dr. G. Huttner, and Dipl.-Chem. B. Krieg
Anorganisch-chemisches Laboratorium
der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

Since the X-ray structure analysis of this compound proved difficult because of the low melting point (29 °C), we prepared the yellow, diamagnetic compound ethoxydimethylaminocarbenepentacarbonylchromium(0), which melts at 45 °C, and elucidated its structure by spectroscopic means and also by X-ray analysis.

$$Cr(CO)_6 + LiN(CH_3)_2 \xrightarrow[0\,^\circ C]{THF} (CO)_5Cr{=}C\begin{matrix}\diagup OLi \cdot x\,THF \\ \diagdown N(CH_3)_2\end{matrix}$$

$$\xrightarrow[\substack{CH_2Cl_2\\0\,^\circ C}]{+\,[(C_2H_5)_3O]\,BF_4} (CO)_5Cr{=}C\begin{matrix}\diagup OC_2H_5 \\ \diagdown N(CH_3)_2\end{matrix} + LiBF_4 + O(C_2H_5)_2$$

The complex has a dipole moment of 5.87 ± 0.1 D at 20 °C in cyclohexane, sublimes at 30 °C, and starts to decompose at about 110 °C. Its IR spectrum (*n*-hexane; LiF optics) shows two ν_{CO} frequencies (cm^{-1}) at 2057 m (A_1) and 1928 vs (A_1, E). In view of the thus indicated minimal distortion of the $(CO)_5Cr$ system, we determined the CO force constants for the presumed C_{4v} symmetry[2]: $k_1 = 15.22$, $k_2 = 15.63$, $k_i = 0.31$ mdyn/Å; k_1 is the force constant for the CO group *trans* to the carbene and k_2 that for the *cis* one; k_i is the interaction constant of the CO groups.

In C_6D_6 [$CDCl_3$] the ^{1}H-NMR spectrum (τ values) exhibits a quartet at 5.68 (2) [5.38 (2)] for the OCH_2 protons, a triplet at 9.07 (3) [8.58 (3)] for OCH_2CH_3, a singlet at 7.85 (3) [6.94 (3)] for NCH_3 *(cis)*, and another singlet at 7.12 (3) [6.43 (3)] for NCH_3 *(trans)*.

In molten naphthalene, initial reversible broadening of the NCH_3 signals is followed on further heating by coalescence (only one NCH_3 signal) at +141 °C. This leads to an activation energy of $\Delta G^{\neq} = 20.8$ kcal/mol[3] for rotation about the $C_{carbene}$—N bond, thereby demonstrating a large π-bonding contribution to this bond. On cooling of the complex in [D_8]-toluene/carbon disulfide mixtures we were able to observe line broadening of the OC_2H_5 signals below about −80 °C but no signal splitting was to be seen, even at about −120 °C. Nevertheless, these data would suggest that the activation energy for rotation about the $C_{carbene}$—O bond must be lower than 8 kcal/mol; this bond therefore also has π character, although much less than the $C_{carbene}$—N bond.

Since a *cis*-OC_2H_5 group would involve increased steric hindrance with the *cis*-NCH_3 protons and since the small shift of the OCH_2 signals induced by [D_8]-toluene also suggests a *trans* conformation, this configuration should at least predominate in solution.

The results of a three-dimensional X-ray structure analysis ($R_1 = 0.054$; 2329 independent non-zero structure factors; space group $P\bar{1}$; $Z = 2$) show that only the sterically more favorable *trans* configuration is present in the crystal (Fig. 1).

The carbene ligand is essentially planar, its plane passing approximately through the bisector of the angle between two mutually *cis* CO groups. Despite the presence of two electron-donating substituents on the carbene carbon, the $C_{carbene}$—Cr distance (2.133 ± 0.004 Å) is not longer than those found for pentacarbonylchromium(0) complexes of monoamino-substituted carbenes (2.15 ± 0.01 Å in pentacarbonyl[cyclohexylamino-(1-methoxyvinyl)carbene]chromium(0)[4] and 2.16 ± 0.01 Å in pentacarbonyl[diethylaminomethylcarbene]chromium(0)[5]). The $C_{carbene}$-hetero atom distances are considerably shorter

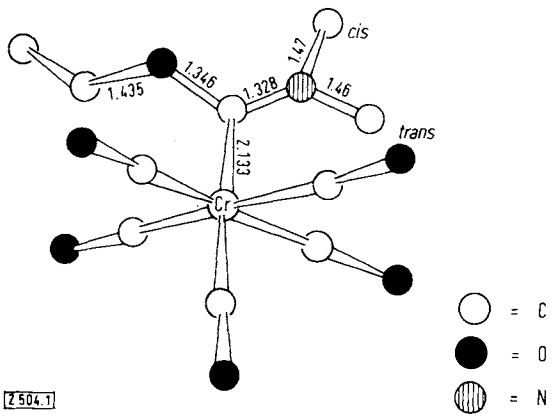

Fig. 1. Molecular structure of ethoxydimethylaminocarbenepentacarbonylchromium(0).

than the corresponding single bonds (see Fig. 1); the π-bond component of the $C_{carbene}$—N bond is significantly greater than that of the $C_{carbene}$—O bond. The carbene ligand exerts a geometrical *trans* effect: The axial Cr—C_{CO} bond (1.847 ± 0.005 Å) is significantly shorter than any of the equatorial Cr—C_{CO} bonds, for which values of 1.873 ± 0.005 to 1.897 ± 0.005 Å were found with a mean value of 1.887 ± 0.01 Å.

The mass spectrum[6] (Atlas CH4, ion source TO4, 50 eV, direct sample injection) exhibits the molecular ion (*m/e* 293) and fragments corresponding to successive loss of CO ligands $[(CO)_nCr{-}C(OC_2H_5)N(CH_3)_2]^+$ ($n = 4-0$) at *m/e* 265, 237, 209, 181, and 153. The fragment $[Cr{-}C(OC_2H_5)N(CH_3)_2]^+$ responsible for the base peak of the spectrum decomposes in a manner characteristic of metal-carbene ions, either by complete loss or by partial fragmentation of the intact carbene ligand.

Procedure

All operations must be carried out with exclusion of air in N_2-saturated solvents previously dried over $CaH_2/LiAlH_4$. A solution of $LiN(CH_3)_2$ (1.02 g, 20 mmol) in THF (100 ml) is added dropwise at 0 °C to a stirred suspension of $Cr(CO)_6$ (4.40 g, 20 mmol) in THF (100 ml). If the 1:1 adduct is to be isolated, the reddish brown solution is concentrated to a volume of about 50 ml (oil-pump vacuum) at 0 °C and the product precipitated with *n*-pentane; repeated recrystallization from ether at −50 °C gives $(CO)_5CrC(N(CH_3)_2)$-$OLi \cdot 2O(C_2H_5)_2$ as colorless needles.

To prepare the carbene complex the reaction solution is completely freed from solvent under oil-pump vacuum at 0 °C, and the residual oily adduct dissolved directly without further purification in methylene chloride (25 ml) and added dropwise, with stirring, to a solution of $[(C_2H_5)_3O]BF_4$ (3.80 g, 20 mmol) in methylene chloride (20 ml). After 10 minutes' stirring, the solvent is evaporated under vacuum and the brown, oily residue is extracted with two 20-ml portions of *n*-hexane. The combined extracts are filtered through a G 3 frit, concentrated to a volume of

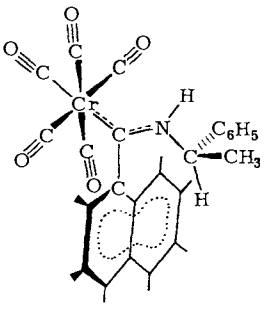
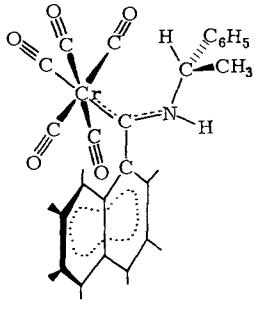
Atropisomerism of Transition Metal Carbene Complexes[1]

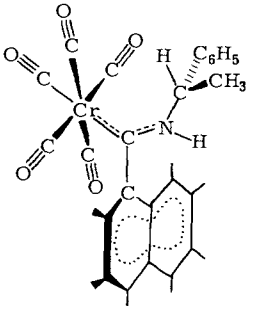


By *Henri Brunner*, *Ernst Otto Fischer*, and *Manfred Lappus*[*]

o-Substituted derivatives of biphenyl and similar compounds exist in atropisomeric forms[2]. Appropriately substituted carbene complexes of transitions metals were also expected to exhibit atropisomerism.



Reaction of (methoxy-1-naphthylcarbene)pentacarbonylchromium(0)[3] with (+)-α-phenylethylamine in diethyl ether yields [(α-phenylethylamino)-1-naphthylcarbene]-pentacarbonylchromium(0). Of the two possible *cis-trans* isomers (with regard to the C—N bond) *(1)* and *(2)*, the *cis* isomer *(1)* is formed preferentially. The barrier to free rotation between the carbene carbon and the 1-naphthyl group gives rise to a further kind of isomerism: For the



(1a)

(1b)

(2a)

(2b)

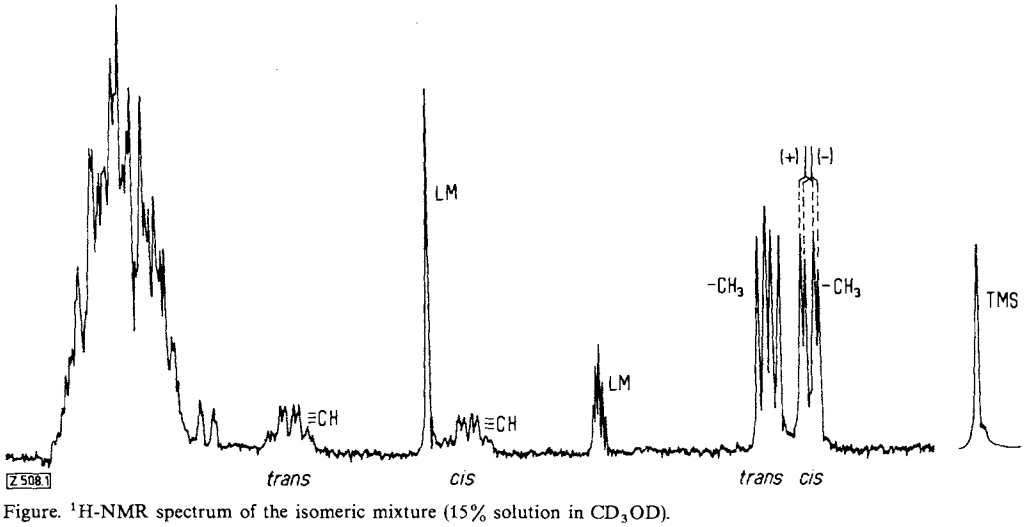


Figure. ^{1}H-NMR spectrum of the isomeric mixture (15% solution in CD_3OD).

cis and *trans* products *(1)* and *(2)* there are two atropisomers each, *viz. (1a)*, *(1b)* and *(2a)*, *(2b)*, which differ in the spatial arrangements of the 1-naphthyl group.

Nuclear magnetic resonance is particularly suitable for identification of the isomers. The ^{1}H-NMR spectrum of a 1:1 mixture of the *cis-trans* isomers *(1)* and *(2)* in CD_3OD (Fig.) exhibits four doublets for the diastereoisomers *(1a)*, *(1b)*, *(2a)*, and *(2b)* in the methyl region; the signals are grouped as two pairs each with similar chemical shifts for the *cis* and *trans* compounds. The differences between the chemical shifts of the methine protons in the *cis-trans* isomers are greater than those for the methyl protons. The low intensity and poor resolution of the methine signals, however, precludes their use in quantitative studies or for distinguishing between the atropisomers. Separation of the *cis-trans* isomers or the atropisomers on the basis of differing solubilities, however, can readily be followed with the aid of the methyl signals.

The *cis* and *trans* forms can be recognized from the change in chemical shift of the N—CH—CH_3 group on transition from acetone to chloroform solvent[4]: The signals of the *cis*-N—CH—CH_3 group display a larger upfield shift than the *trans*-N—CH—CH_3 group when the solvent is changed.

It may thus be seen from the Table that the signal systems of the methyl and methine protons at higher field are to be assigned to the *cis* compounds *(1a)* and *(1b)*, and those at lower field to the *trans* isomers *(2a)* and *(2b)*.

The *cis-trans* isomers are formed in the ratio of about 6:1 on preparation of [(α-phenylethylamino)-1-naphthylcarbene]pentacarbonylchromium(0) at room temperature.

Recrystallization of the *cis-trans* mixture from diethyl ether/pentane after chromatography on SiO_2 affords a pure sample of the more sparingly soluble *cis* compound *(1)*; in contrast, the more readily soluble *trans* isomer *(2)* has not yet been separated completely from the *cis* isomer. We therefore limited our attempts to resolve the atropisomers to the *cis* compounds *(1)*. After repeated fractional crystallization (18 ×) from diethyl ether/pentane the more sparingly soluble fraction containing the levorotatory diastereoisomer exhibited a specific rotation of $[\alpha]_{546}^{20} = -168°$. The highest rotations recorded so far for the fractions of the mother liquor enriched in the more readily soluble dextrorotatory diastereoisomers are $[\alpha]_{546}^{20} = +46°$. The rotations were measured with approximately 10^{-3} M solutions in benzene. The four doublets of the methyl groups of *(1a)*, *(1b)*, *(2a)*, and *(2b)* are retained in the ^{1}H-NMR spectrum at 70 °C in CD_3OD solution. Like the thermal interconversion of *cis* and *trans* isomeric amino carbene complexes[5], the transition between the atropisomers *(1a)*—*(1b)* and *(2a)*—*(2b)* is so slow that it cannot be determined from the temperature dependence of the ^{1}H-NMR spectrum.

Table. τ values from the ^{1}H-NMR spectrum of the isomeric mixtures in various solvents (15% solutions).

Cycloadditions with Mesomeric Pyrimidine Betaines[1]

By *Thomas Kappe* and *Wolfgang Lube*[*]

Recently, we reported on the synthesis of mesomeric pyrimidine betaines *(A)*, whose structure can only be described by a series of zwitterionic canonical formulas[2]. The distribution of charge in these compounds is best expressed in terms of formulation *(B)*. *Huisgen*'s "sextet limiting formula" *(C)*[3] suggests that such compounds are potential starting materials for 1,4-dipolar cycloadditions[3]. Since five-membered mesoionic heterocycles can, in many cases, be used for 1,3-dipolar cycloadditions[4] to give five-membered ring systems, the mesomeric six-membered ring betaines *(1)* ought to be suitable for 1,4-dipolar cycloadditions leading to six-membered heterocycles.

This is in fact shown to be the case in the reaction of *(1)* with dimethyl acetylenedicarboxylate *(2)* and maleic anhydride *(3)*[5]. Thus, *(1a)* and *(1b)* react with *(2)* with loss of phenyl isocyanate to give, respectively, the 2-pyridones *(5a)* and *(5b)* in good yields. As in the case of the analogous reactions with acetylene derivatives[4, 5] the tendency to rearomatization leads to elimination of a neutral molecule (in this case $C_6H_5N{=}C{=}O$) from the primary addition product *(4)*.

(1a), R = H; *(1b)*, R = $CH_2C_6H_5$

In the reaction of *(1b)* with maleic anhydride, however, we have been able to isolate the 1:1 adduct *(6)*[6]. The structure of *(6)* has been confirmed by mass spectrometry, molecular weight determination (528), and NMR spectroscopy (in DMSO). The NMR spectrum contains one singlet at δ = 3.70 due to the methylene protons of the benzyl group, two doublets of the *cis*-protons in positions 7 and 8 at δ = 4.32 and 5.53, $J = 9.5$ Hz, as well as signals for 20 aromatic protons at δ = 6.8—8.8. The IR spectrum (in KBr) with anhydride bands at 1860 and 1790 cm^{-1} and C=O bands at 1710 and 1670 cm^{-1}, is also in agreement with this structure.

2-Pyridones (5a) and (5b)

The solutions of *(1a)* and *(1b)* (5 mmol) in chlorobenzene (25 ml) are heated under reflux with *(2)* (1.4 ml. 10 mmol) for 16 h. The residue recovered after evaporation under vacuum is digested with petroleum ether. *(5a)*: yield 83%, colorless needles recrystallized from methanol, m. p. 168—170 °C[7]; free dicarboxylic acid (by hydrolysis with 1 N NaOH): m. p. 253—256 °C[7]. *(5b)*: yield 67%, colorless needles recrystallized from ethanol, m. p. 235—237 °C[7].

4-Benzyl-3,5-dioxo-1,2,6-triphenyl-2,6-diazabicyclo[2.2.2]-octane-7,8-dicarboxylic anhydride (6)

(1b) (1.07 g, 2.5 mmol) and *(3)* (0.25 g, 2.5 mmol) are vigorously ground together and then heated at 170 °C for

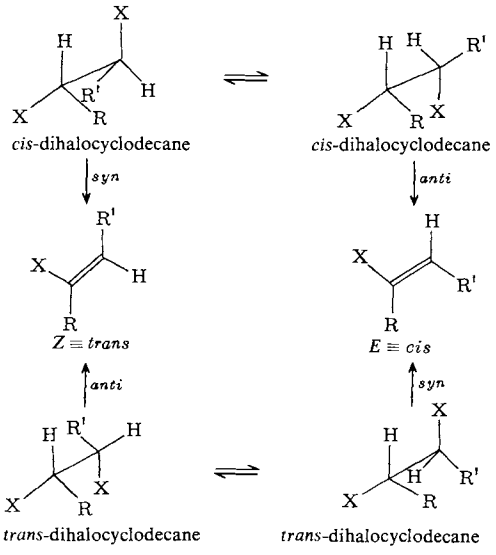
[5] Analogous reactions of the bicyclic "*anhydro*-2-hydroxyl-1-methyl-4-oxopyrido[1,2-*a*]pyrimidinium hydroxide" with acetylenedicarboxylate derivatives have been described recently by *K. T. Potts* and *M. Storm*, J. Org. Chem. *36*, 8 (1971).

[6] The reason for adducts such as *(6)* being difficult to isolate is that if R = H in compound *(1)* only "ene-addition" occurs, as observed by *Potts* [5] in the reaction of zwitterions with tetracyanoethylene or azodicarboxylate. We have found that the addition is also hindered—for electronic, and particularly steric reasons—if *(1)* contains a substituent such as C_6H_5.

[7] The structures of the products were confirmed by elemental analysis (C, H, N) and IR and NMR spectroscopy.

Preferred *syn*-Elimination from *trans*-1,2-Dichloro- and *trans*-1,2-Dibromocyclodecane[**]



By *Jiří Sicher*, *Gérald Jan*, and *Manfred Schlosser*[*]

The mechanisms of elimination of hydrogen bromide from secondary alkyl bromides and from cycloalkyl bromides of medium ring size differ significantly[1].

A detailed discussion of these divergencies is only possible if one can differentiate between the four elementary elimination processes *syn* → *cis*, *syn* → *trans*, *anti* → *cis*, and *anti* → *trans*[2]. Keeping this in mind we have extended our investigations to *vic*-dihaloalkanes[3] and 1,2-dihalocyclodecanes. Such substrates exist in two diastereoisomeric forms, for each of which two of the stereochemical pathways are blocked: 1-halo-*trans*-cyclodecene (*Z* isomer) can arise from *cis*-1,2-dihalocyclodecane only by *syn* elimination, and from the *trans* isomer by *anti* elimination. Conversely, the 1-halo-*cis*-cyclodecene (*E* isomer) must be formed from the *cis*-dihalide by *anti*-coplanar elimination and from the *trans*-dihalide by *syn*-coplanar elimination (Scheme 1).

Cyclodecane derivatives have been chosen as cyclic model compounds since their elimination behavior differs most typically from that of acyclic substrates. Furthermore, the heats of formation of the configurational isomers of 1,2-dihalocyclodecanes and especially those of the configurational isomers of 1-halocyclodecenes should be very similar, so that differences in reactivity due to differences in thermodynamic stability (Polanyi-Hammond principle!) should be negligible.

trans-1,2-Dichlorocyclodecane was readily prepared from *cis*-cyclodecene and trichloroamine[4], and *trans*-1,2-dibromocyclodecane by addition of bromine to *cis*-cyclodecene in ethanol-free carbon tetrachloride at −10 °C[5, 6]. Unfortunately, we have not yet been able to prepare the *cis*-dihalides[7]; however, the results obtained on treating the *trans* isomers with bases and observations from earlier work[8] already permit a first comparison of the dehydrohalogenation mechanisms of ten-membered cyclic dihalides with those of the corresponding acyclic substrates.

Scheme 1. Elimination pathways open to *cis*- and *trans*-1,2-dihalocyclodecanes. R,R′ = —$(CH_2)_8$—.

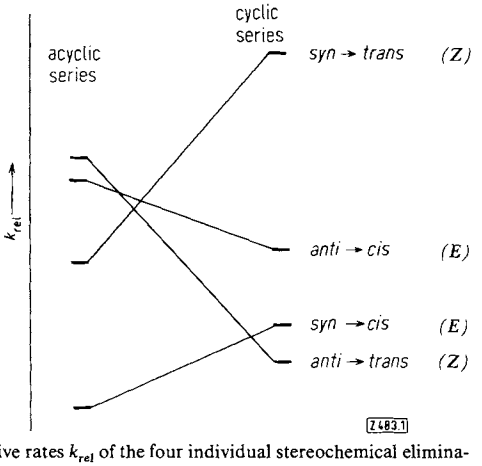


Figure. Relative rates k_{rel} of the four individual stereochemical elimination processes which can take part in the base-induced dehydrohalogenation of acyclic substrates (haloalkane → *cis*- and *trans*-alkene; *vic*-dihaloalkane → *Z*- and *E*-1-haloalkene; see left-hand side of figure) and cyclic substrates (halocyclodecane → *cis*- and *trans*-cyclodecene; *vic*-dihalocyclodecane → *Z*- and *E*-1-halocyclodecene; see right-hand side of figure). Base/solvent system: potassium butoxide in *tert*-butyl alcohol.

As can be seen from the above figure, going from the acyclic series to the cyclodecane derivative—at least in *tert*-butyl alcohol—always favors *syn*-coplanar cleavage, and particularly the *syn* → *trans* process. Evidently, the transition states profit from the reduction in transannular repulsive forces. On the other hand *anti* elimination is considerably retarded in the ten-membered ring system. In addition to steric hindrance of attack by bases[1], steric hindrance of halogen solvation may play an important role here too.

The most striking consequence of this situation is the cross-over of *syn* → *cis* and *anti* → *trans* reactivities. In the case of the ten-membered ring system, the *anti* → *trans* route, most favored with acyclic substrates, falls back to

last place behind the exceptionally enhanced *syn* → *cis* elimination. The *cis* isomer, which is the product of a *syn* elimination, always predominates (see Table).

Table. Dehydrohalogenation of *trans*-1,2-dihalocyclodecane to *cis*- and *trans*-1-halocyclodecene.

Base/solvent system	Halogen = Cl			Halogen = Br		
	cis:*trans* [a]	Reaction conditions	Yield (%) [b]	*cis*:*trans* [a]	Reaction conditions	Yield (%) [b]
Piperidine	7.7:1	48 h, 135 °C	96	5.3:1	6 h, 100 °C	100
$NaOC_2H_5/HOC_2H_5$	5.6:1	16 h, 100 °C	53	4.7:1	20 min, 80 °C [c]	97
$KOC(CH_3)_3/HOC(CH_3)_3$	10 :1	1 h, 100 °C	68	12 :1	30 min, 90 °C	95
$KOC(CH_3)_3$/Benzene	20 :1	1 h, 100 °C	95	23 :1	30 min, 90 °C	95

[a] The product ratios were determined by vapor phase chromatography (2.5 m 5% SE 30, 120 °C and 2.5 m 20% Carbowax 1540) from the peak areas (no correction was made for substance-dependent differences in detector response). For identification, the 1-halocyclodecenes were isolated, spectroscopically examined, submitted to combustion analysis, and reduced to *cis*- or *trans*-cyclodecenes with sodium in liquid ammonia. The by-products were identified by comparison of their retention times with those of independently prepared reference substances: 3-chloro-*cis*-cyclodecene, 2—25% [b] (from 2-cyclodecen-1-ol and thionyl chloride, 62%, b.p. 55—57 °C/0.2 torr); 3-bromo-*cis*-cyclodecene, 3—5% [b] (from *cis*-cyclodecene and *N*-bromosuccinimide [9], 67% b.p. 56—57 °C/0.05 torr); 8—24% [b] *cis*- and *trans*-3-ethoxycyclodecene (from 3-bromo-*cis*-cyclodecene and ethanol in the presence of sodium ethoxide, 72%, b.p. 99—101 °C/torr). On the basis of observed retention times, the remaining by-products formed could be 3-chloro-*trans*-cyclodecene (1—14% [b]) and $C_{10}H_{16}$ hydrocarbons (1—16% [b]).

[b] The yields are corrected for unchanged material (*i.e.* net yields). Under the chosen conditions, 14% (in *tert*-butyl alcohol solution)—83% (in benzene solution) of the *trans*-1,2-dichlorocyclodecane was converted and generally about 70% of the *trans*-1,2-dibromocyclodecene.

[c] 10% KOH instead of $NaOC_2H_5$ in ethanol.

The ease of conversion *via* the two possible stereochemical pathways appears to be very much less dependent on the base/solvent system than the *syn* → *trans* process in the dehydrobromination of cyclodecyl bromide[9]. Both the relative and the absolute rates of dehydrohalogenation change only slightly upon variation of the solvent.

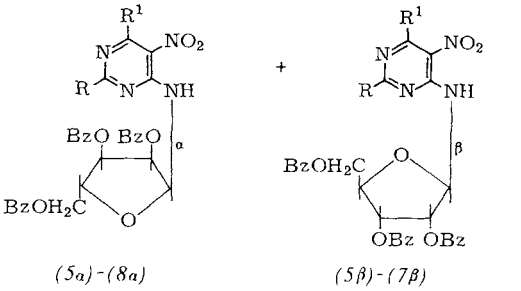
Synthesis of 8-Ribofuranosyl- and 2-Ribofuranosylamino-7-oxo-7,8-dihydropteridines[**]



By *Dieter Autenrieth, Helmut Schmid, Klaus Harzer, Manfred Ott*, and *Wolfgang Pfleiderer*[*]

We have recently shown that the fusion of 4-amino-5-nitropyrimidines with fully acylated ribofuranose derivatives[2] is a decisive step in the synthesis of pteridine *N*-8-ribofuranosides[1].

To test the scope of this method we have carried out analogous reactions on the pyrimidines *(1)*—*(3)* using various substituents in positions 2 and 6. The results showed that ribosidation of the 4-amino group with simultaneous formation of the anomeric 5-nitro-4α- and -4β-ribofuranosylaminopyrimidines *(5)*—*(7)* takes place, as expected, in the presence of aprotic substituents such as halogen, alkoxy, alkylthio, or dialkylamino. The anomeric mixture

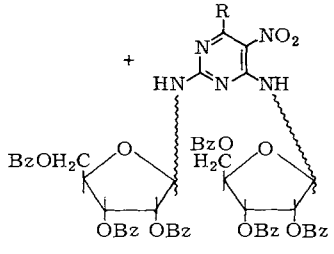
[(7), 29% yield] obtained from 4-amino-6-dimethylamino-2-methylthio-5-nitropyrimidine (3) was resolved into its components by preparative layer chromatography; the α/β ratio proved to be 2:1, the same as in previous investigations[2].

Absence of a substituent in position 2 is to be avoided since this usually leads to lower yields; thus reaction of 4-amino-2-dimethylamino-5-nitropyrimidine (4) and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose gives a reaction product in 10% yield only. Interestingly, according to NMR investigations the product is exclusively pure α-riboside (8).



Conversion into the corresponding 7-oxo-7,8-dihydropteridine *N*-8-riboside was accompanied by the usual difficulties; relatively good yields of the desired product, after reduction of the nitro group and subsequent cyclization by condensation with glyoxylate hemiacetal, were obtained only in the conversions of (6)—(8) into (9) to (11) (23, 13, and 20% resp.). The isolated products were exclusively β-ribosides, irrespective of the nature of the glycosidic linkage of the starting material. The isolation and identification of 6-dimethylamino-9-β-D-ribofuranosylpurine (12)[3], which is formed alongside (11) probably by nucleophilic addition of the 4-amino function to the azomethine grouping of the initially-formed Schiff base and subsequent hydrolysis, decarboxylation and dehydrogenation, threw some light on the possible side reactions that take place. On fusion of 2,4-diamino-5-nitropyrimidines (13) and (14) with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose reaction occurs almost exclusively at the 2-amino group and affords the chromatographically separable anomeric mixtures (15) and (16), respectively, as main products. Small amounts of the corresponding 2,4-bis(ribosylamino) derivatives (17) and (18), which also usually occur as mixtures of the four possible pairs of anomers (2α, 4α; 2α 4β; 2β 4α; 2β 4β), are formed as side products. In the case of 2,4-bis(2,3,5-tri-*O*-benzoyl-D-ribofuranosylamino)-6-dimethylamino-5-nitropyrimidine (17) we were able to separate the four components by very carefully planned layer chromatography; the structure and configuration of the anomers were then determined by NMR, and ORD and CD spectroscopy.

(15α) → (20α) + (20β)
(15β) → (20α) + (20β)
(16) → (19) → (21) → (22)

Reduction with Raney nickel/H_2 and subsequent condensation with glyoxylate in methanol led, both in the case of pure (15α) as well as (15β), to partial anomerization of the glycosidic linkage, since the two anomeric 2-ribosylamino-7-oxo-7,8-dihydropteridine derivatives (20α) and (20β) were obtained in different amounts in each case [from (15α), 11% (20α) and 22% (20β); from (15β), 3.5% (20α) and 1.5% (20β)]. Sodium dithionite reduction proves to be very satisfactory in the case of the anomeric mixture (16) since the 5-amino base (19) can be isolated. Condensation with glyoxylate to the Schiff base and alkoxide-catalyzed cyclization leads, with simultaneous deacylation, to the α, β mixture (21) (25% yield), which is just as difficult to separate into pure components as its acetylation mixture (22% yield).

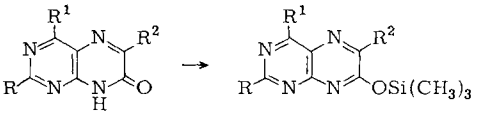
General Synthesis of Pteridine *N*-8-Glycosides[**]

By *Wolfgang Pfleiderer*, *Dieter Autenrieth*, and *Margarete Schranner*[*]



The relatively difficult accessibility of pteridine *N*-8-glycosides *via* 4-glycosylamino-5-nitropyrimidines[1] induced us to attempt direct *N*-glycosidation of the pteridine system by the same method as has been used with success in the case of 2-oxo-1,2-dihydroquinoxalines[2]. This is based on the Birkofer variant[3] of the Hilbert-Johnson synthesis[4] which recently has been used with great success, partic-

ularly in the pyrimidine nucleoside series[5, 6] and in related nitrogen heterocycles[7].

The 7-oxo-7,8-dihydropteridines *(1)*—*(4)* were used as starting materials; these were first silylated with hexamethyldisilazane to the corresponding 7-trimethylsilyloxy derivatives *(5)*—*(8)* and then converted into the halogenoses *(9)*, *(10)*, and *(11)*. Here, the "Wittenburg conditions"[5]—prolonged (several hours) boiling in benzene in the presence of $HgO/HgBr_2$ (Table)—proved most satisfactory and generally applicable.

In the reactions of *(5)* with *(9)* and *(10)*, *N*-8-glycosidation takes place to give 7-oxo-7,8-pteridine *N*-8-(2,3,5-tri-*O* benzoyl-β-D-ribofuranoside) *(12)* and -*N*-8-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside) *(13)* respectively. The reaction of *(6)* and *(8)* with *(9)* are sterically controlled[8] and lead to *N*-8-β-D-ribosides *(14)* and *(15)* respectively, whereas the expected *N*-8-α,β-anomeric mixture *(16)* was obtained from *(6)* and *(11)*. With α-acetobromoglucose *(10)*, a mixture of isomers *(17)* and *(17a)* was obtained (66% yield), which could be resolved into its pure components only by very tedious layer chromatography giving low recoveries. The same difficulty in separation of components was encountered in the case of the mixture of isomers *(18)* and *(18a)* formed in an analogous fashion in 77% yield by reaction of *(7)* with *(9)*. A further, interesting reaction was observed to take place between *(8)* and *(9)* in acetonitrile in absence of catalyst at room temperature: A mixture of anomers *(19)* and *(15)* was

Synthesis of Isoxanthopterin *N*-8-β-D-Ribofuranoside—A Structural Analog of Guanosine[**]

By *Helmut Schmid, Margarete Schranner,* and *Wolfgang Pfleiderer*[*]

The successful direct *N*-8-glycosidation[1] of 7-oxo-7,8-dihydropteridines by the "silyl method" made it fitting to undertake the synthesis also of isoxanthopterin *N*-8-β-D-ribofuranoside *(29)*, a structural analog of guanosine. With this aim in mind we have investigated the behavior of the 2-amino-4-alkoxy-7,8-dihydropteridines *(1)*—*(6)* in the form of their trimethylsilyl derivatives *(8)*—*(13)* toward 1-bromo-2,3,5-tri-*O*-benzoyl-D-ribofuranose *(15)*.

The completely blocked 2-dimethylamino-4-methoxy-7-oxo-7,8-dihydropteridine *(1)* reacts with hexamethyldisilazane to give the 7-trimethylsilyloxy derivative *(8)* which, on boiling in benzene in the presence of $HgO/HgBr_2$ catalyst, affords a mixture of *N*-8-*(17)* (56%) and 7-*O*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranoside) *(17a)* (7%). The

bis(trimethylsilyl) derivatives *(9)*—*(12)* behave similarly. The isomers obtained were separated by layer- or column chromatography on silica gel (Table).

Further reaction products that can be separated are the diribosides of type *(30)*, to which we tentatively assign the given structures on the basis of the fact that they lose a ribose residue when treated with methoxide.

The "Vorbrüggen conditions"[2] can also be used in this series: thus, reaction of *(9)* with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose *(16)* in acetonitrile in the presence of $SnCl_4$ gives *(18)* in 24% yield. As in *(6)*, acylation at the 2-amino group affords protection of this function against silylation as well as against glycosidation. Compound *(22)* can be obtained from *(13)* in 10% yield.

In the silylation of the isoxanthopterin *(7)* the amine group and the two amide functions enter into reaction and the tris(trimethylsilyl) derivative *(14)*, which can be distilled under high vacuum, is formed. In the ribosidation of *(14)* a complex mixture of substances is formed which can be separated chromatographically into two clean fractions. The main fraction (54% yield) contains an extraordinarily difficultly separable mixture of *N*-8- *(23)* and 7-*O*-riboside *(23a)* and the second fraction small amounts (4%) of an isoxanthopterin tririboside whose structure is presumably that of *(24)*. Because of the alkali-lability of the *O*-glycosidic and the exocyclic *N*-glycosidic linkages, compound *(24)*

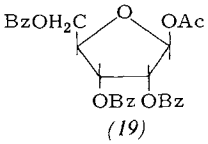
Synthesis of 4-Amino-7-oxo-7,8-dihydropteridine *N*-8-β-D-Ribosides—Structural Analogs of Adenosine[**]

By *Manfred Ott* and *Wolfgang Pfleiderer*[*]



In our studies on the direct glycosidation of 7-oxo-7,8-dihydropteridines by the "silyl method" we have established that the conditions chosen for the reaction of 7-trimethylsilyloxypteridine with halogenoses in boiling benzene in the presence of Hg salts as catalyst[1] do not generally lead to optimum yields of desired product. In particular, the absence of electron-donating substituents in position 2 leads to low yields of *N*-8-ribosides. For example, 2-dimethylamino-7-trimethylsilyloxypteridine *(17)*[2] affords the desired product in 49% yield, the isomeric 4-dimethylamino derivative *(10)*, on the other hand, in only 27%. The desired *N*-8 riboside *(21)* can be obtained using 4-amino-7-oxo-7,8-dihydropteridin *(2)* as starting material; the bis(trimethylsilyl) derivative *(11)* of *(2)* is prepared first and then subjected to the corresponding reaction conditions—a route that was previously not possible.

A satisfactory variant has proved to be the combined "Silyl-fusion" method in which the 7-trimethylsilyloxypteridines *(10)*—*(18)* are allowed to react with a fully acylated sugar [1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose *(19)*] in the presence of a Lewis acid (preferably $ZnCl_2$) at 140—170°C (see Table).

(19)

(20)-*(34)*

(35)

In this way *(11)* gives the riboside *(21)* in 18% yield, and subsequent debenzoylation converts *(21)* into the structural analog of adenosine, 4-amino-7-oxo-7,8-dihydropteridine *N*-8-β-D-ribofuranoside *(30)*. As expected, the presence of 2-alkylthio substituents favors the reaction; the mono- or bis(trimethylsilyl) derivatives *(12)*—*(16)* of the 4-amino-7-oxo-7,8-dihydropteridines *(3)*—*(7)* react smoothly and undergo preferred *N*-8-ribosidation with steric control of the glycosidic linkage of aglycon and sugar residue[3] to give the β-ribosides *(22)*—*(26)*. Interestingly,

it has also been established that reactions in acetonitrile at room temperature in presence of $SnCl_4$—under the conditions preferred by *Vorbrüggen*[4] in the pyrimidine series—offer no direct advantages; *e. g.* the yield of *(26)* from *(16)* and *(19)* is likewise 54%. The potential of the described fusion method is illustrated very well by the reaction of *(17)* with *(19)* in which ribosidation at *N*-8 takes place and *(27)* is formed in almost quantitative yield. In the reaction of *(18)* with *(19)*, difficulties were encountered in the working up; a diriboside of probable structure *(35)* was isolated (4.5%) in addition to the main product *(28)* (21%).

Synthesis of Lumazine and Isopterin *N*-1-β-D-Ribofuranosides and -(2-Deoxyribofuranosides)—Structural Analogs of Uridine, Cytidine, and Thymidine[**]

By *Götz Ritzmann, Klaus Harzer*, and *Wolfgang Pfleiderer*[*]

Amide functions in heterocyclic nitrogen ring systems are potential reaction centers for glycosidation and since *N*-8 substitution has recently proved possible in 7-oxo-7,8-dihydropteridines[1], an analogous reaction has been tried with lumazine *(1)* and isopterin *(5)* and their derivatives, particularly on use of the Hilbert-Johnson-Birkofer method[2]. To obtain the structural analogs of the pyrimidine nucleosides uridine, cytidine, and thymidine in the pteridine series, the starting substances *(1)*—*(6)* were first silylated with hexamethyldisilazane to give the compounds *(7)*—*(12)*, which were then allowed to react with the halogenoses *(13)* and *(14)* in boiling benzene in the presence of $HgO/HgBr_2$[3]. Under the chosen reaction conditions, lumazine *(1)* and isopterin *(5)* and their 6,7-dimethyl and 6,7-diphenyl derivatives undergo preferred glycosidation at *N*-1.

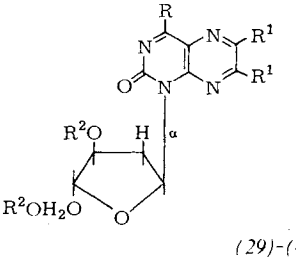
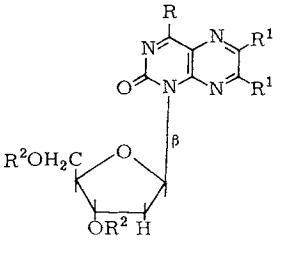
(15a)-(17a), (23a)

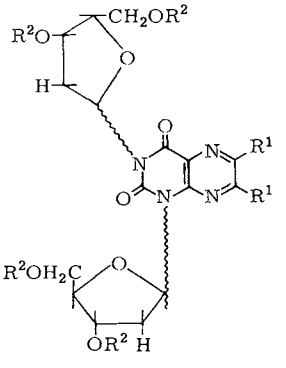


(27), (28)



in a corresponding fashion, with substitution at *N*-1 to give the compounds *(18)—(20)* (Table 1).

Reaction of *(9)* with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose in 1,2-dichloroethane at room temperature in presence of $SnCl_4$ leads to *(17)* and *(17a)*, each in 20% yield, and, as a further reaction product, lumazine *N*-3-β-D-ribofuranoside *(27)*. The free pteridine ribosides *(21)—(26)*, *(23a)*, and *(28)* were prepared *via* the well-known method of deacylation with sodium methoxide or methanolic ammonia. It was found that when the latter reagent is employed for the deacylation of *(18)* not only hydrolysis of benzoyl groups takes place but also replacement of the 4-dimethylamino group by $-NH_2$ (Table 1).



In principle, the lumazine and isopterin (2-deoxyribosides) (Table 2) can be prepared by the same method, if the silylated pteridine derivatives are treated in the usual way with 1-chloro-3,5-di-*p*-toluoyl(2-deoxy-D-ribofuranose) *(14)*. As expected, complex reaction mixtures are formed which can be resolved into their components on a preparative scale only by tedious column and layer chromatographic separations. We have also been able to establish that product distribution in this series largely depends on the reaction conditions. In almost all cases, the main fractions consist of *N*-1-(deoxyribosides) in the form of anomeric mixtures. Further separation leads to isolation of pure α- and β-anomers, the α-anomer always being the dominant component. Structural assignment can be carried out on the basis of NMR spectral findings.

In the lumazine series a 1,3-bis-(2-deoxyriboside) fraction [*(30a), (32a), (34a)*] can be separated, albeit in small amounts, as a second, more mobile reaction product, which according to chromatographic investigations might be a preparatively inseparable mixture of the four possible combinations of anomers (α,α; α,β; β,α, and β,β).

Atomic Reactions with Carbonylmetal Compounds[**]

By *Karl H. Becker* and *Maria Schürgers*[*]

Carbonylmetal compounds react rapidly in the gaseous phase at low pressure with oxygen, hydrogen, or nitrogen atoms to give electronically excited products which emit characteristic spectra.

Because of their reactivity carbonylmetal compounds play a significant role as catalysts in oxidation processes in polluted atmospheres; for example, the oxidation of NO to NO_2 is accelerated considerably if slight amounts of $Fe(CO)_5$ are present[1]. The presence of trace amounts of carbonylmetal compounds in hydrocarbon-air mixtures leads to either quenching of the hydrocarbon-air flames or, at least, to substantial reduction of their flame velocities[2]; as a consequence of this, $Fe(CO)_5$ can be employed as an antiknock agent in gasolines[3].

We have investigated the reactions of $Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$, $Fe(CO)_5$, and $Ni(CO)_4$ with oxygen, hydrogen, and nitrogen atoms. The atoms were generated in a microwave discharge and then mixed with the carbonylmetal compounds in a reaction chamber. The total pressure in the reaction chamber was a few torr, the partial pressure of the carbonylmetal compounds 10^{-6} torr at a flow rate of 3 l/s.

The chemiluminescence observed in the reactions was recorded with a spectral resolution of about $\Delta\lambda = 10$ Å by a detector arrangement consisting of a 1.5 m Czerny-Turner monochromator and an EMI-9665-B photomultiplier.

Inspection of the spectra permits the following conclusions to be drawn:

1. In reactions of carbonylmetals with oxygen atoms an apparently continuous emission occurs which must be assigned to a polyatomic emitter.
2. MO* emissions occur in all reactions of the type $M(CO)_n + O$ except $Mo(CO)_6 + O$.
3. Emissions of excited, neutral metal atoms M* are identifiable in the spectra of reactions $M(CO)_n + O$ as well as in those of the reactions $M(CO)_n + H$ and $M(CO)_n + N$.
4. In the reactions $Mo(CO)_6 + H$ and $Mo(CO)_6 + N$ an intense band system is observed at 5200 Å which is emitted by a diatomic molecule.

On the basis of reaction kinetics and spectroscopic data, the continuum can be interpreted as emission from MCO*. That the emissions occurring in all the reactions of carbonyl metals with oxygen were due to CO_2^* could be ruled out because of the different low wavelength limits between 3000 Å and 4000 Å.

MO* emissions are possibly due to direct formation of this species from oxygen atoms and metal atoms. Metal atoms are formed from carbonylmetal compounds by stepwise degradation of the CO ligand with formation of CO_2.

An explanation for the occurrence of metal atom emission lines in all the reactions is that the metals do not lose, or only partly lose, their valence energy, which they possess as central atom in the carbonylmetal compounds, and thus remain in an excited state. This assumption is supported by the fact that (i) the same M* emission lines occur in reactions of a carbonylmetal compound with different atoms, and (ii) the excitation energies of the atoms observed,

Cr*, Mo*, W*, and Fe*, are always less than the corresponding valence energy. A spectral analysis of the band system, which, in the case of reactions $Mo(CO)_6 + H$ and $Mo(CO)_6 + N$, occurs at 5200 Å, indicates the presence of a diatomic species having a very low bonding energy of about 1.5 kcal/mol; quadratic dependence of the intensity of emission on the $Mo(CO)_6$ concentration suggests that this system is to be assigned to an excited, weakly bound Mo_2^* species.

The rate constants for the overall reaction $M(CO)_n +$ atoms → products were determined in a flow tube at a linear flow velocity of 10 m/s. The intensity of chemiluminescence, which follows a first order reaction in the presence of excess atoms served as indicator. The rate constants of the light reaction $M(CO)_n + O$ were obtained by comparison with the standard reaction $NO + O \rightarrow NO_2 + h\nu$[4]. All the rate constants are listed in Table 1.

Table 1. Rate constants in [l. mol^{-1} s^{-1}]; $T = 298$ K.

$M(CO)_n$	Overall reaction			Light reaction
	H atoms	N atoms	O atoms	O atoms
$Cr(CO)_6$	—	4.0×10^{8}	4.2×10^{9}	1.5×10^{7}
$Mo(CO)_6$	3.0×10^{8}	2.9×10^{8}	1.9×10^{9}	1.9×10^{7}
$W(CO)_6$	—	5.5×10^{8}	1.7×10^{9}	3.8×10^{7}
$Fe(CO)_5$	—	—	—	5.8×10^{7}

Comparison of the rate constants of the overall reaction $M(CO)_n + O \rightarrow$ products with those of the light reaction $M(CO)_n + O$ shows that a small percentage of the overall reaction leads to formation of excited products.

Pulse Fourier Transform ^{13}C-NMR Spectroscopy of Mutarotating Sugars[**]

By *Wolfgang Voelter, Eberhard Breitmaier,* and *Günther Jung*[*]

Routine measurement of the mutarotation of sugars by ^{13}C-NMR spectroscopy has until now been hindered by fundamental and instrumental difficulties[1, 2]: Although the sensitivity of ^{13}C resonance, which is relatively very much lower than that of ^{1}H resonance, can be improved by accumulation of spectra with averaging computers (CAT method, Computer Averaged Transitions), the unusually long accumulation times required are often unacceptable. Consequently, only the spectra of mutarotated anomeric mixtures could be obtained hitherto by conventional ^{13}C-NMR spectroscopy. Development of the new, more sensitive and more rapid recording technique known as Pulse Fourier Transform (PFT) NMR spectroscopy has now made it also possible to study time-dependent phenomena such as mutarotation by means of ^{13}C resonance. Furthermore, the recording of the ^{1}H broad-band decoupling ^{13}C spectra of reducing sugars before and after mutarotation equilibrium has greatly extended the scope of the previously used methods of ^{13}C signal assignment (comparison of the resonances with those of other compounds, and off-resonance decoupling[1, 2]) in the investigation of carbohydrates.

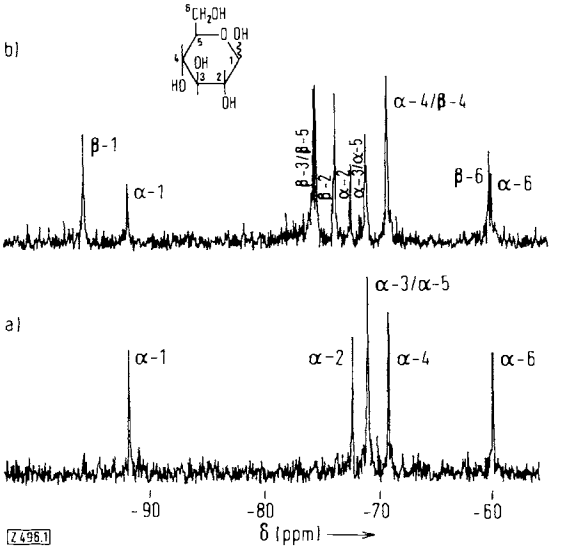

Fig. 1. PFT ^{13}C-NMR spectra of D-glucose, 0.5 M in D_2O, 512 pulses, pulse interval 0.8 s; a) immediately, b) three days after preparation of solution (ppm values negative w.r.t. TMS external = 0).

The spectrum of α-D-glucose (Fig. 1a) shows five signals. After adjustment of the mutarotation equilibrium ten signals can be recognized (Fig. 1b) ([2]: eight signals). The assignments of most signals are well known. The signal at −95.70 ppm is ascribed to C-1 of the β-anomer (equatorial hydroxyl group) on the basis of the known downfield shift[1-5] of about 4 ppm compared to that of C-1 of the α-anomer (axial hydroxyl group). The assignment of β-C-3/β-C-5[2] (Table) arises since the signals of the γ carbon atoms C-3 and C-5 are displaced to lower fields than the signal of the β carbon C-2 when the axial hydroxyl group on C-1 changes into an equatorial position. Comparison of the Figures 1a and 1b reveals that the crystalline D-glucose used by us was present as the α-anomer.

D-Trehalose is formed by glycosydic coupling of two α-D-glucose residues. The influence of the glycosidic linkage ought to be the least at C-4 and C-6; the ppm-values of the signals of these carbon atoms are almost the same as those of the corresponding carbon atoms of α-D-glucose (Table). In the disaccharide the signal of the anomeric carbon atom (C-1) is displaced downfield by about 1.15 ppm from the corresponding signal of α-D-glucose. Such downfield shifts have also been established in the comparison of signals of a free sugar with those of its methylglycoside[2-4]. Since the difference of the chemical shifts of C-2 of α-methyl-D-glucopyranoside and C-2 of α-methyl-D-glucose is less than 0.5 ppm, the C-2 (2') signal of trehalose (−72.35 ppm) can be compared with the C-2 resonance of α-D-glucose (−72.55 ppm). The signals at −70.85 and −71.90 then belong to C-3 (3') and C-5 (5').

Table. ^{13}C-shifts of D-glucose and disaccharide in D_2O (ppm-values negative w.r.t. TMS external = 0 ppm).

C-Atom	Cellobiose	Glucose [a]	Trehalose [b]	Maltose
β-6	− 59.75	−60.40	−60.35	−60.60
α-6	− 59.95	−60.60		−60.45
6′	− 60.45			−60.35
4′	− 69.25			−69.15
α-3/α-5	− 69.90	−71.25	−70.85	−69.80
α-3/α-5	− 71.05		−71.90	−71.15
α-2	− 71.20	−72.55	−72.35	−71.50
2′	− 73.00			−73.85
β-2	− 73.75	−73.90		−73.00
β-3/β-5	− 74.10	−75.55		−74.40
β-3/β-5	− 74.60	−75.70		−76.00
3′/5′	− 75.35			−72.50
3′/5′	− 75.80			−72.70
β-4	− 78.50	−69.40		−76.60
α-4	− 78.60		−69.50	−76.85
α-1	− 91.65	−91.85	−93.00	−91.65
β-1	− 95.55	−95.70		−95.60
1′	−102.40			−99.35

[a] See Fig. 1.
[b] The corresponding C atoms of both glucose residues gave the same signals (only one entered here).

The ^{13}C-spectra of the disaccharides cellobiose and maltose were assigned by comparison with the spectra of trehalose and D-glucose before and after adjustment of the mutarotation equilibrium (Table).

The signals of the coupling atoms C-4 of maltose (−76.60/76.85) and cellobiose (−78.60/78.50), as expected, appear downfield from that of the C-4 signal of D-glucose (−69.40). The signals of the carbon atoms C-2, C-3, and C-5 are assigned on the basis of the 1,3-diaxial interaction (see above) in glucose residues containing an α axial group. In the case of glucose residues having α anomeric C-atoms the signal sequence downfield is C-3/C-5, C-2 and for those with β anomeric C-atoms C-2, C-3/C-5.

Simple Synthesis of Hexafluoro Complexes of Osmium(IV), Iridium(IV), and Platinum(IV)

By *Wilhelm Preetz* and *Yukhanneh Petros*[*]

Hexafluoro complexes of the heavy tetravalent platinum metals have been known for more than fifty years[1, 2]; however, their preparation by methods previously given in the literature and in text books[3, 4] always meets with difficulties since simple complexes have to be reacted with elemental fluorine or very reactive compounds that can be obtained only by reaction with free fluorine, *e.g.* BrF_3. In such reactions hexafluoro complexes of pentavalent platinum metals are first formed which are readily reduced in alkaline solution to the corresponding complexes with a quadrivalent central atom. They can, however, be prepared directly in a KHF_2 melt without the use of aggressive reagents:

$$K_2[MX_6] + 6KHF_2 \longrightarrow K_2[MF_6] + 6KF + 6HX\uparrow$$
(M = Os, Ir, Pt; X = Cl, Br, I)

Since the heavier halogen hydrides, unlike HF, do not form stable solvates and are immediately liberated from fused salts at relatively high temperatures, complete conversion is usually achieved. $K_2[PtBr_6]$, which is very stable, reacts slowly; increased temperatures favor reaction, but simultaneous decomposition of KHF_2 takes place rapidly above 350 °C with liberation of HF and the $K_2[PtF_6]$ formed decomposes pyrolytically. This is avoided by use of $K_2[PtCl_6]$.

The yield and purity of the compound prepared is determined by the water content of the starting material: the drier the starting substance the lower the amount of by-products formed (presumably oxygen-bridged polynuclear complexes). Since hexafluoro complexes are very stable in aqueous solution they are readily purified by recrystallization. By-products formed in the preparation of osmium complexes are readily removed hydrolytically by gentle warming in alkaline solution. $K_2[IrF_6]$, which has frequently been described as a red or pink complex, can be prepared in the pure state by continuous ionophoresis[5, 6]; like other hexafluoro complexes it is only pale yellow in color. Although the red impurity normally present (maximum 2%) has a very low ionic mobility its complete removal, either by partial hydrolysis or by precipitation, has not been achieved.

The IR spectra of the pure hexagonal Cs complexes are all very similar. The new method for preparing hexafluoro complexes of the heavy platinum metals considerably simplifies the route previously described by *Seel*[7] for the purely chemical winning of free fluorine.

Experimental:

K_2MX_6 (0.5 g) is intimately mixed with very dry (heated for one week at 120 °C), finely divided KHF_2 and heated in a nickel crucible (300—400 °C) until a clear, almost colorless melt with escaping gas bubbles is obtained.

Immediately crystals start to separate out, the melt is quenched and the fine, yellow (M = Os, Pt) or red (M = Ir) cake is extracted two or three times with a few ml of cold water to remove KHF_2. The hexafluoro complex is then extracted from the residue with warm water (80 °C); on cooling the extract, the complex is obtained as hexagonal platelets in 60—80 °C yield.

Benzyloxydivinylboranetricarbonyliron—A π-Divinylborane Complex Containing a Boron—Iron Bond[**]

By *Gerhard E. Herberich* and *Horst Müller*[*]

The discovery of complexes of the aromatic borine ("borabenzene", C_5H_5B)[1-3], in which boron fully participates in the metal-ligand bond[1,4,5] led us to investigate the possible existence of complexes of analogous non-cyclic B—C ligand systems. In this paper we wish to report the first complex with a divinylborane derivative as a π-ligand.

Alkoxydivinylboranes[6] *(1)* react with $Fe_2(CO)_9$ in benzene to give labile tetracarbonyliron complexes *(2)* having one free and one complexed vinyl group. Removal of the $Fe(CO)_5$ formed and subsequent irradiation leads to alkoxydivinylboranetricarbonyliron *(3)*:

(1) *(2)* *(3)*

(a), R = n-C_4H_9; *(b)*, R = $C_6H_5CH_2$

This two-step reaction was first established in the case of the butyl series (a) using NMR and IR spectroscopy. The analogous benzyloxydivinylboranetricarbonyliron *(3b)* of the benzyl series (b) was then prepared in analytically pure form [38% yield (based on $Fe_2(CO)_9$); orange oil, very sensitive to air, crystallizable from *n*-pentane at −60 °C; soluble without decomposition in pentane, benzene, ether, and acetone].

The mass spectrum[7] (50 eV) of *(3b)* contains, in addition to the molecular ion $LFe(CO)_3^+$ [L = *(1b)*] (I_{rel} = 4), the following fragment ions: $LFe(CO)_2^+$ (5), $LFe(CO)^+$ (12), LFe^+ (63), $FeC_9H_{10}^+$ (100), $FeC_7H_8^+$ (48), $C_7H_7^+$ (50), Fe^+ (42). Successive loss of the CO groups, of CH_2=CH—BO, C_2H_2, and C_7H_8 is proved by metastable peaks at *m/e* 258.5, 230.7, 203.1, 132.8, 125.9, and 21.2.

The IR spectrum shows three sharp, very intense ν_{CO} bands (in hexane) at 2050, 1998, and 1986 cm^{-1}, as are typical for tricarbonyliron complexes with strong perturbation of the local C_{3v} symmetry of the $Fe(CO)_3$ group[8].

In the ^{1}H-NMR spectrum of *(3b)* (Table) the signals of the vinyl groups show *trans-* and *cis*-couplings of 14.5 and 12.0 Hz, while the geminal coupling can not be observed, as usual in the case of terminal methylene groups of π-ligands[9]. All the resonances can be assigned on the basis of these couplings and of the relative intensities. The large differences between the chemical shifts of $H_{(1)}$, H_{syn}, and H_{anti} should be noted. Such differences are generally observed in the case of allyl and butadiene[9], as well as pentadienyl[10] ligands. Thus, in the case of $[Fe(CO)_3(C_5H_7)]ClO_4$ the corresponding signals of H_2[11], H_{syn}, and H_{anti} occur in the same sequence and with similar shift differences; they are shifted about 2—3 ppm downfield, merely because of the charge on the cation and the different solvent. Accordingly, the ligand *(1b)* is bound to the metal as a pentadienyl and not as a non-conjugated diene[12]: the metal-to-ligand bond includes a boron-iron bond.

Table. ^{1}H-NMR spectrum of *(3b)* in C_6D_6 (60 MHz; 20 °C).

Signal	$I_{rel.}$	τ [a]	Multiplicity and coupling constants in Hz
C_6H_5	(5) [b]	3.2–3.5	m
CH_2	2	5.57	s
$H_{(1)}$	2	6.80 (3.74) [c]	dd } $\lvert J_{1,syn}\rvert$ = 12.0 (9.8)
H_{syn}	2	8.37 (6.25)	d } $\lvert J_{1,anti}\rvert$ = 14.5 (13.0)
H_{anti}	2	9.77 (7.83)	d } $\lvert J_{syn,anti}\rvert$ < 1 (3.5)

[a] Measured against external TMS; [b] partially overlapped by solvent signal; [c] in brackets, corresponding value of spectrum of $[Fe(CO)_3(C_5H_7)]ClO_4$ in SO_2, cf. [10].

Experimental:

A solution of *(1b)* in benzene (35 ml), prepared as described by *Matteson*[6] from 2,2-divinyl-1,3,2-oxazaborinane (1.5 g, 12 mmol), is stirred with $Fe_2(CO)_9$ (2.18 g, 6.0 mmol) at 35 °C, under rigorous exclusion of O_2. After one hour the reaction mixture is filtered and all volatiles are removed by evaporation (0.1 torr). The residue is then taken up in ether (50 ml) and irradiated for 7 hours [mercury vapor lamp (70 W), Duran glass vessel, cooling with water (10 °C)]. Removal of the ether and distillation under high vacuum at 65—75 °C affords an orange oil; in order to remove residual benzyl alcohol this oil is dissolved in pentane, filtered through a small amount of Al_2O_3, and redistilled. The resulting product is recrystallized three times from pentane (3 × 5 ml) at −60 °C discarding the mother liquor. Finally it is dried under vacuum at 0 °C. Yield of *(3b)*: 0.71 g.

1,3,5-Benzenetriyltris[di(*p*-biphenyl)methyl], a Radical Having a Quartet Ground State that Dimerizes by Entropy Bonding

By *Gerd Kothe, Ernst Ohmes, Jürgen Brickmann,* and *Herbert Zimmermann*[*]

Organic radicals having three unpaired electrons (three-spin systems) have only been known for a few years. Their magnetic properties are determined by dipole- and exchange interactions of the radical electrons[1-9].

In the case of weak magnetic dipole coupling three-spin systems give ESR spectra with hyperfine structure. Strong coupling, however, leads to broad unstructured ESR signals. Little is known about the magnetic properties of these radicals. In no case has a zero field splitting been observed so far. In the present communication we report the results of investigations on the hydrocarbon *(1)*, a three spin system with strong magnetic dipole coupling.

(1)

The synthesis of the reddish brown, oxygen-sensitive radical *(1)* has been described previously[4]. Preliminary molecular-weight determinations indicated that in benzene radical (1) is partly associated[4]. In order to determine the nature of this association the dependence of the average molecular weight $\bar{M}$ on the sample concentration c_0 referred to monomeric *(1)* in benzene was measured. Values of $\bar{M}$ between 1750 and 1920 ($M_{\text{monomer}} = 1030$) were found for concentrations c_0 between 3.5×10^{-3} and 3.3×10^{-2} mol/l. This finding suggests dimerization of *(1)*.

We have also established the dimerization equilibrium

$$2(1) \rightleftharpoons (1)_2$$

by ESR spectroscopy from the dependence of the molar paramagnetic susceptibility on the concentration c_0. The experimental technique employed has been described elsewhere[10]. A plot of the ratio of the measured molar paramagnetic susceptibility χ of toluene solutions referred to c_0 to the molar susceptibility χ_s of a free monoradical, which serves as standard, *versus* c_0 is shown in Figure 1. χ/χ_s falls rapidly with increasing c_0 and reaches a value corresponding to only about 15% of the susceptibility of the monoradical at the highest concentration investigated. It appears that association involves spin coupling with formation of diamagnetic dimer $(1)_2$.

The value of χ/χ_s increases sharply with falling c_0. At the lowest measureable concentrations c_0 the ratio χ/χ_s

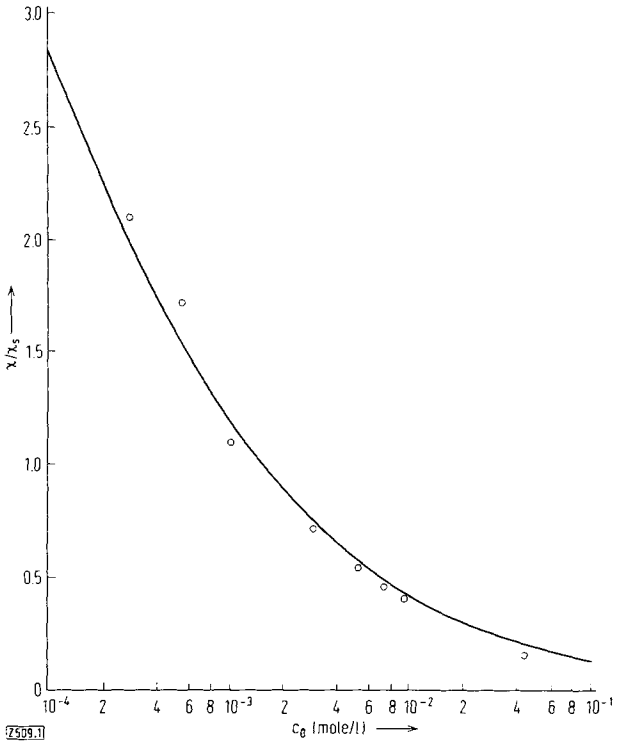

Fig. 1. Concentration dependence of the relative paramagnetic susceptibility χ/χ_s in toluene solution. χ = measured molar paramagnetic susceptibility; χ_s = molar paramagnetic susceptibility of a standard (DPPH); c_0 = concentration of sample, based on monomeric *(1)*; $T = 263$ K, o = experimental point, —— = calculated curve.

assumes values exceeding twice the susceptibility of a monoradical. Thus the three-spin system *(1)* can exist in limiting cases either as a triradical $\chi_{(1)} = 3\chi_s$, or as a quartet state, $\chi_{(1)} = 5\chi_s$. For both possible limiting forms, the association constant

$$K = \frac{c_{(1)_2}}{c_{(1)}^2} = \frac{1-(\chi/\chi_{(1)})}{2c_0(\chi/\chi_{(1)})^2} \qquad (1)$$

was calculated from the concentration dependence of the measured susceptibility χ.

The value of the equilibrium constant remains constant within the limits of experimental accuracy over the whole concentration range of two orders of magnitude only for $\chi_{(1)} = 5\chi_s$. At 263 K the value of K is $(6.7 \pm 0.3) \times 10^3$ l/mol. The curve in Figure 1 was calculated with this equilibrium constant from eq. (1). The agreement achieved is satisfactory. The radical *(1)* therefore possesses a quartet ground state and is in equilibrium with a diamagnetic dimer.

The temperature dependence of K, which can also be measured by ESR spectroscopy, permits calculation of the standard enthalpy of association ΔH^0. Figure 2 shows a plot of log K *versus* $1/T$. The slope of the curve shows that within the limits of accuracy the enthalpy of association is $\Delta H^0 = 0$. This result is surprising since association equilibria are generally temperature dependent. The equilibrium constant gives a standard free energy of association of $\Delta G^0 = -4.6$ kcal/mol and a standard entropy of association of $\Delta S^0 = +17.6$ e. u., both at 263 K.

The dimer $(1)_2$ has a singlet ground state. The simplest interpretation for this fact is an associate in which two

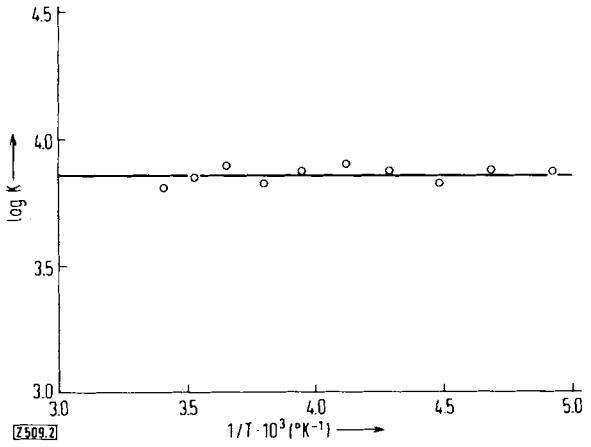

Fig. 2. Temperature dependence of the association constant K of *(1)* in toluene. $c_o = 9.9 \times 10^{-4}$ mol/l.

molecules of *(1)* are bound by way of three σ bonds with spin coupling. However, this possibility appears rather unlikely since an association *via* σ bonds is hardly compatible with a bonding enthalpy $\Delta H^0 = 0$; moreover, steric considerations also contraindicate the formation of three σ bonds in the complex. Regardless of the question of the structure of the dimer and the mechanism of the spin coupling we wish to emphasize that association occurs only as a result of an increase in the entropy of the entire system: It would appear that we are here confronted with a new kind of bonding which we wish to term "entropy bonding". Further studies on the structure and properties of the complex are currently in progress.

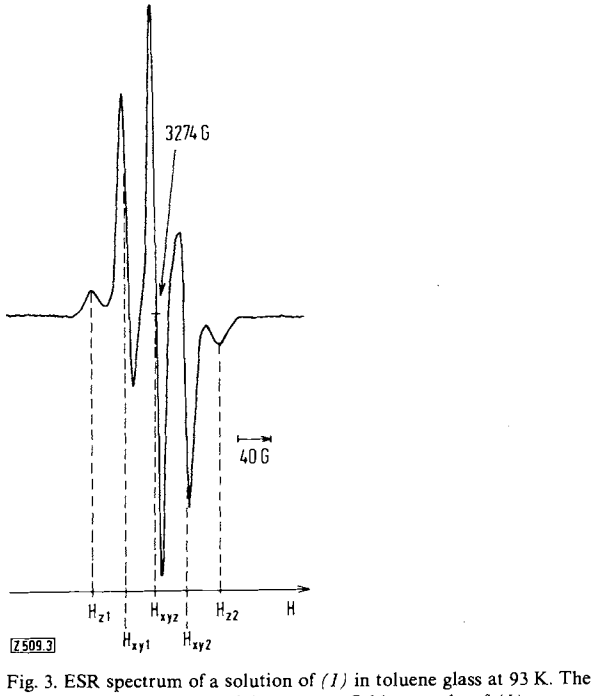

Fig. 3. ESR spectrum of a solution of *(1)* in toluene glass at 93 K. The broken lines indicate the axial resonance field strengths of *(1)*.

At room temperature a solution of the monomeric radical *(1)* in toluene gives a broad, structureless ESR signal. If the solution is cooled to 93 K the solvent solidifies to a glass and a structured ESR signal is observed (Fig. 3) which corresponds to the theoretically predicted signal for randomly oriented quartet radicals having a threefold principal axis of symmetry.

Our interpretation of the ESR spectrum of a three-spin system with magnetic dipole coupling is based on an effective spin Hamiltonian[11]:

$$\mathcal{H} = g\beta\vec{H}\vec{S} + g^2\beta^2\langle\phi|\sum_{i<j}^{3}\left\{\frac{\vec{S}_i\vec{S}_j}{r_{ij}^3} - \frac{3(\vec{r}_{ij}\vec{S}_i)(\vec{r}_{ij}\vec{S}_j)}{r_{ij}^5}\right\}|\phi\rangle \qquad (2)$$

where $\vec{S}$ = total electron spin operator of the three-spin system having the cartesian components $\vec{S} = (S_x, S_y, S_z)$; g = isotropic g tensor; β = Bohr magneton; $\vec{H}$ = external magnetic field; $\vec{S}_i$ = spin operator of electron i, in units of $\hbar$, $\vec{r}_i = (x_i, y_i, z_i)$ space coordinates of electron i; $\vec{r}_{ij} = \vec{r}_i - \vec{r}_j = (x_{ij}, y_{ij}, z_{ij})$, interelectronic vector; $\phi = \phi(\vec{r}_1, \vec{r}_2, \vec{r}_3)$ antisymmetric spatial portion of the quartet state wave function. By proper choice of a molecular coordinate system[11], the operator (2) can be written in the form

$$\mathcal{H} = g\beta\vec{H}\vec{S} + D(S_z^2 - \tfrac{5}{4}) + E(S_x^2 - S_y^2) \qquad (3)$$

with

$$D = \tfrac{3}{4}g^2\beta^2\langle\phi|\frac{r_{12}^2 - 3z_{12}^2}{r_{12}^5}|\phi\rangle$$
$$E = \tfrac{3}{4}g^2\beta^2\langle\phi|\frac{y_{12}^2 - x_{12}^2}{r_{12}^5}|\phi\rangle \qquad (4)$$

For a molecule whose z axis is a threefold axis of symmetry $E = 0$[11].

The operator *(3)* splits the degenerate quartet states. A first order perturbation treatment yields the following axial resonance field strengths:

$$\left.\begin{aligned} H_{xy1} &= H_o - D' \\ H_{xy2} &= H_o + D' \end{aligned}\right\} \quad \vec{H} \perp z$$
$$\left.\begin{aligned} H_{z1} &= H_o - 2D' \\ H_{z2} &= H_o + 2D' \end{aligned}\right\} \quad \vec{H} \parallel z \qquad (5)$$
$$H_{xyz} = H_o \quad \vec{H} \text{ any orientations with respect to } z$$

where $H_0 = h/(g\beta)$, $D' = D/(g\beta)$, and ν is the frequency of the microwave field $\vec{H}_1 \perp \vec{H}$.

If the random orientation of the molecules, the transition probabilities, and the line broadening are taken into consideration[11], an ESR spectrum is calculated which corresponds to the spectrum observed for *(1)* and whose

assignment is given in Figure 3. The zero-field parameter $D = 128$ MHz was determined from the distance of H_{z2} and H_{z1}.

Apart from the high-field part of the spectrum considered with ($\Delta m = 1$)-transitions, a half-field transition ($\Delta m = 2$) of lower intensity is also observed at 1637 G. In agreement with theory[11] its absorption maximum lies exactly at $H_0/2$.

Radical *(1)* is the first organic three-spin system for which a quartet ground state has been proved.

A Novel Phosphorus Heterocycle: 1,2,3,4-Tetraphenyl-1,2,3,4-tetraphospholane[1]

By *Marianne Baudler, Jürgen Vesper, Peter Junkes,* and *Harald Sandmann*[*]

Several carbon heterocycles containing one or two phosphorus atoms are already known and have been reported[2]. We have been able to synthesize 1,2,3,4-tetraphenyl-1,2,3,4-tetraphospholane *(1)* as the first phosphorus heterocycle of the type $(PR^1)_{n-1}CR^2_2$ ("cyclocarbaphosphanes") derived from the cyclophosphanes $(PR)_n$.

Compound *(1)* is formed in the reaction of methylene chloride with triphenylcyclotriphosphanedipotassium *(2)*[3] or 1,2,3,4-tetraphenyltetraphosphane-1,4-dipotassium *(3)*[4].

The title compound can be prepared batchwise in 73% yield by reaction of pentaphenylcyclopentaphosphane, $(PC_6H_5)_5$, in tetrahydrofuran with the requisite stoichiometric amount of potassium for formation of *(2)* or *(3)* and subsequent treatment of the potassium salt with an equimolar amount of methylene chloride. Compound *(1)* crystallizes from acetonitrile as colorless needles, m.p. 134—138 °C, which are readily soluble in benzene, toluene, and tetrahydrofuran. In the solid state, *(1)* is stable towards atmospheric oxygen for a short while but is rapidly oxidized in the presence of solvents. It could be characterized by complete elemental analysis, osmometric molecular weight determinations, and IR, UV, ^{1}H-NMR, ^{31}P-NMR, and MS spectroscopy[5].

The IR spectrum closely resembles that of pentaphenylcyclopentaphosphane; however, a few characteristic differences are observable in the range 520—300 cm^{-1} (ring-vibration region) and additional absorptions of the CH_2 group occur at 2924 and 2880 cm^{-1} and in the region of the C—H_{aliph} bending vibrations. The UV spectrum [$\lambda_{max} = 215$ nm ($\varepsilon = 37600$) in *n*-hexane] exhibits increased extinction, so additional interactions probably occur between the P atoms *via* d-hybrid functions.

The NMR spectra (solution in CS_2, 24 °C) provide unequivocal evidence of the symmetry of the ring. The ^{1}H-NMR spectrum shows two groups of signals in the intensity ratio 10:1 which can be assigned to aromatic and methylene protons. On decoupling of the ^{31}P nucleus, the multiplet of the methylene protons degenerates to a sharp line at $\tau = 6.970$ ppm, so there is obviously equivalence. The ^{31}P-NMR spectrum consists—with simultaneous proton decoupling—of one AA'BB' system centered at $\delta = -34.6$ ppm (against 85% H_3PO_4, external). These findings are compatible only with C_2 symmetry of the ring. Detailed analysis of the AA'BB' system and X-ray structural investigations are presently being carried out.

The mass spectrum (15 eV) contains a very strong signal due to the molecular ion ($m/e = 446$) alongside one for the fragment $C_6H_5^+$. With increasing electronic energy and heating, additional signals of the following transformation products occur: $(C_6H_5)_4P_2$ ($m/e = 370$), $(C_6H_5P)_3$ (324), $(C_6H_5)_3PCH_2$ (276), $(C_6H_5)_3P$ (262), $(C_6H_5)_2PCH_3$ (199), $(C_6H_5)_2PH$ (186), and $C_6H_5P_2H_3$ (142).

Experimental:

A solution of pentaphenylcyclopentaphosphane (12.5 g, 0.023 mol) in dry tetrahydrofuran (150 ml) is heated under reflux with potassium (3.0 g, 0.077 g atom) for several hours in the absence of air. The reaction mixture is vigorously stirred and reaction allowed to proceed until a clear, dark red solution of *(2)* is formed. A solution of methylene chloride (3.28 g, 0.039 mol) in tetrahydrofuran (20 ml) is then added at 0 °C over a period of 2 hours and the resulting mixture stirred for a further 10 hours. After complete removal of the solvent at reduced pressure, the residue is taken up in carbon disulfide (100 ml), filtered to remove insoluble material, and finally re-evaporated to dryness. Recrystallization of the final residue from acetonitrile (400 ml) affords *(1)* in 73% yield [9.4 g; mol. wt. (osmometric in CS_2, 25 °C): 436].

Crystal Structure of 2,4-Hexadiynediol[1]

By *Erich Hädicke, Klaus Penzien,* and *Hans W. Schnell*[*]

Numerous derivatives of diacetylene can be polymerized in the crystalline state by heat or high-energy radiation. The main contribution to the understanding of these topochemically controlled reactions[2] has hitherto been the structure determination of polymeric 2,4-hexadiynylene-bis(phenylurethane)[3,4]. We therefore tried to find an explanation for the ready polymerizability of 2,4-hexadiynediol by an X-ray structure analysis of the monomer. The monomeric crystals of 2,4-hexadiynediol, unlike those of 2,4-hexadiynylenebis(phenylurethane), are stable under the employed conditions for an X-ray structure analysis.

[*] Dr. E. Hädicke, Dr. K. Penzien, and Dr. W. Schnell
Badische Anilin- & Soda-Fabrik AG
67 Ludwigshafen (Germany)

The three-dimensional X-ray structure analysis of 2,4-hexadiynediol was carried out with monoclinic platelets obtained by crystallization from water. Crystallographic data: $a=4.08_9$, $b=15.99_1$, $c=4.76_9$ Å; $\beta=106.5_9°$; $d_{exp}=1.22\,g\,cm^{-3}$; space group $P2_1/c$. The asymmetric unit contains $^1/_2$ molecule $C_6H_6O_2$ ($d_{calc}=1.22\,g\,cm^{-3}$). The individual molecule has a center of symmetry. Owing to their sensitivity to X-rays a number of crystals had to be used in succession for intensity measurements. These measurements on our single-crystal diffractometer ($\vartheta/2\vartheta$-scan, 5-point measurement) were carried out with one crystal as long as periodically repeated measurements on reference reflections showed a statistically significant decrease in intensity. The quality of this crystal was then checked by photography. We recorded 382 reflections of 8 crystals ($Cu_{K\alpha}$ radiation, $\vartheta\leqslant 50°$); 10 of these reflections could not be observed ($I<2\sigma_I$).

Using triple product methods with symbolic addition[5], 96 signs could be determined for the 99 strongest reflections ($E\geqslant 1.0$). An E-Fourier synthesis based on these data afforded the positions of all atoms ($R=50.4\%$). By least-squares isotropic refinement (full matrix) with a scaling factor an R factor of only 25.3% could be obtained. However, simultaneous refinement of the scaling factors from the sets of data obtained from the eight crystals and of the anisotropic temperature factors lowered the R value to 9.4%. The structure of the planar single molecule is shown in Figure 1. The standard deviations of the bond lengths are 0.01 Å, those of the bond angles 0.7°. All bond lengths are in agreement with values given in the literature for similar compounds[6, 7].

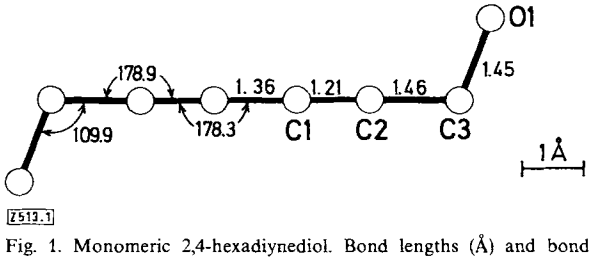

Fig. 1. Monomeric 2,4-hexadiynediol. Bond lengths (Å) and bond angles (°).

If the product in this reaction too (cf. ref. [4]) is a poly-en-yne formed by 1,4-linkage of neighboring monomer units (Fig. 2c), the carbon atoms to be bonded should not be farther apart than about 4 Å[2, 8]. The experimentally obtained intermolecular distances reveal that the monomers can polymerize either along the c axis or along the a/c diagonal. Figures 2a and 2b show the planes fixed by these two directions and the molecular axis.

It is found that the distance between the C atoms to be bound is 3.94 and 3.52 Å, respectively. We therefore assume

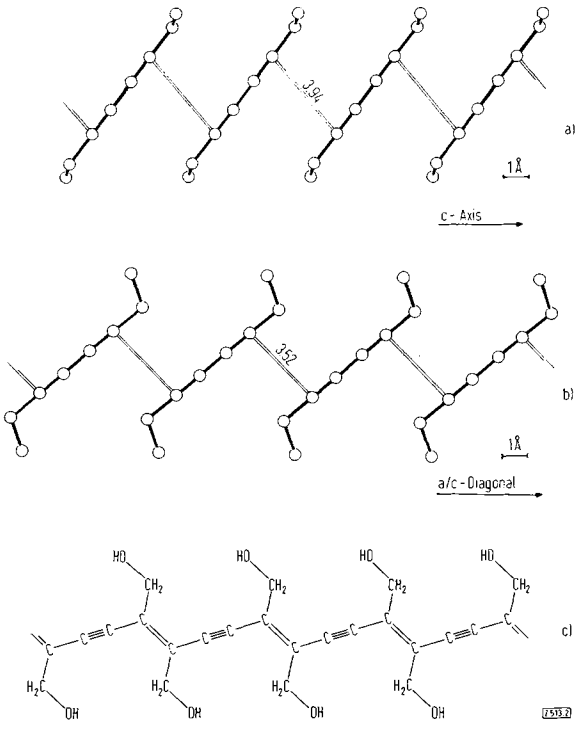

Fig. 2. Possible modes of polymerization of 2,4-hexadiynediol.

that polymerization is possible in both planes; this in turn would account for the largely amorphous character of polymeric 2,4-hexadiynediol.

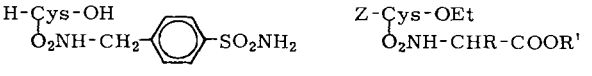
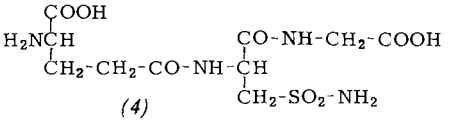
Synthesis of Modified Amino Acids and Peptides having Anticoagulant, Bactericidal, and Vitamin-K Type Action[**]



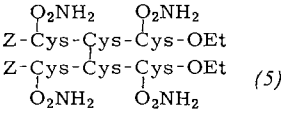
By *Boris Aleksiev*[*]

The known synthesis[1] of cysteinamide (2-amino-3-sulfamoylpropionic acid) *(1)* has been considerably improved[2]. We have been able to synthesize a number of its derivatives[3], including the bacteriostatic Marfanil



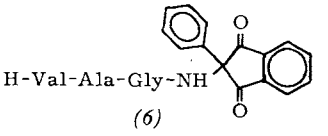
(1)

derivative *(2)*, by reaction of the sulfonyl chloride with amines. Action of amino acid esters on the protected sulfonyl chloride yields compounds *(3)* which are substituted in the sulfonamide group[4].

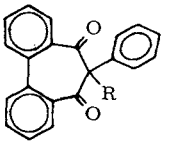


(2) *(3)*

We have also found that the azide and carbodiimide methods can be used with cysteinamide *(1)*[5]; several peptides containing this sulfonamide could be prepared. For example, the sulfonamide derivative of glutathione *(4)* and a hexapeptide of high sulfur content *(5)* were prepared for the first time.



(4)



(5)

Another series of modified amino acids and peptides was obtained from 2-amino-2-phenyl-1,3-indandione and 1,3-dioxo-2-phenyl-2-indanacetic acid. The carbodiimide method gave, *inter alia*, the modified tripeptide *(6)* in very good yield[6]. Such compounds can be expected to have an anticoagulant action. In contrast to 2-phenyl-1,3-indandione, its analog *(7)*, synthesized from phenylacetic acid and diphenic anhydride[7], and corresponding derivatives exhibit a powerful vitamin-K type action, resembling that of vitamin K_3[8]. We have prepared a variety of derivatives *(8)* (including amino acid derivatives) of this analog *via* the sulfonyl chloride[9].

(6)

(7), R = H
(8), R = SO_2NHR'

The compounds prepared are currently being tested for physiological activity.

Preparation of Dichlorovinylene Carbonate and Examples of its Use in Organic Synthesis

By *H.-D. Scharf*[*]

Treatment of tetrachloroethylene carbonate with zinc leads to dichlorovinylene carbonate *(1)*[1], which can be converted by methanolysis, firstly into methyl methoxycarbonylchloroglycolate *(2)* and subsequently into the dimethyl acetal of methyl glyoxylate *(3)*. Aminolysis with aniline gives α-(*N*-phenylcarbamoyloxy)chloroacetanilide *(4)*, a product analogous to that formed in the first step of the methanolysis[2].

The cheletropic cleavage of *(1)* into oxalyl chloride *(5)* and CO is observable only to a slight extent on prolonged heating of *(1)* under reflux[2]. The loss of CO *via* a concerted linear pathway from the ground state proves to be symmetry forbidden. Thermal [4+2]-cycloaddition of

[*] Prof. Dr. H.-D. Scharf
Institut für Organische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

(1) to anthracene and its 9,10-dimethyl derivative leads to the cycloadducts *(6)* and *(7)*, respectively, in good yield; *(6)* and *(7)* are converted by hydrolysis into the α-diketones *(8)* and *(9)* respectively. (For an account of the dienophilic reactivity of *(1)* toward 9,10-dimethylanthracene, see Ref. [3].) Acyclic dienes, such as dimethyl-1,3-butadiene, react like 1,3-cyclohexadiene to give only small amounts of the [4+2]cycloadducts *(10)* and *(12)*; with cyclopentadiene, the adduct *(11)* is formed in 65—70% yield. Hydrolysis of the bridged adducts *(11)* and *(12)* also leads to α-diketones *(14)* and *(15)*; hydrolysis of *(10)* affords 3,4-dimethylcatechol *(13)*.

The photosensitized addition of *(1)* to common olefins proceeds in the sense of a [2+2] cycloaddition with formation of the cyclobutane derivatives *(16)*, which on hydrolysis are immediately converted into the α-hydroxycyclopropanecarboxylic acids *(17)*[1,4]. Products *(17)*, which are derived from cyclic olefins, react as tosylates with expansion of the ring.

Surprisingly, *(1)* also undergoes photocycloaddition reactions with benzene[5] and naphthalene[6] to give first 1,2-cycloadducts which subsequently undergo a 1,3 shift yielding derivatives corresponding to the adducts *(6)*. (Naphthalene forms *exo* and *endo* adducts.) Hydrolysis leads to the previously unknown α-diketones.

"Selected Abstracts", a part of the journal previously containing summarized versions of primary publications of topical interest, will in future be devoted exclusively to abstracts of publications of a more comprehensive nature (reviews, progress reports, *etc.*). The editorial staff will make every effort to ensure that this modification of the "Selected Abstracts" section will provide readers of "Angewandte Chemie — International Edition" with an even more representative and up-to-date survey of current developments in each of the branches of chemistry than heretofore.

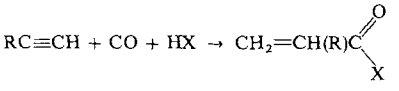
The synthesis of heterocyclic quinones is discussed by *I. Baxter* and *B. A. Davis*, only those quinones being considered that contain the hetero ring fused directly to a quinone moiety. Examples of heterocyclic systems are furan, pyrane, dioxane, thiophene, dithiane, dithiole, pyrrole, pyrazole, imidazole, triazole, pyridine, diazine, oxazole, or oxazine. A number of such compounds are used as dyes, catalysts, or drugs. Some antibiotics such as

(1)

(2)

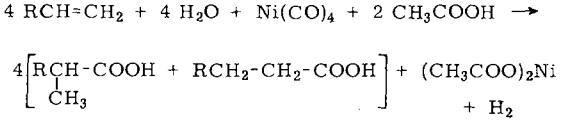
streptonigrin and the mitomycins are heterocyclic quinones. They can nearly all be prepared by oxidation of derivatives of the parent compounds carrying OH or NH_2 substituents. The syntheses of *(1)* and *(2)* can be regarded as examples of intramolecular cyclization and 1,3-dipolar addition respectively. [Synthesis of Heterocyclic Quinones. Quart. Rev. Chem. Soc. *25*, 239—263 (1971); 108 references]

[Rd 419 IE –E]

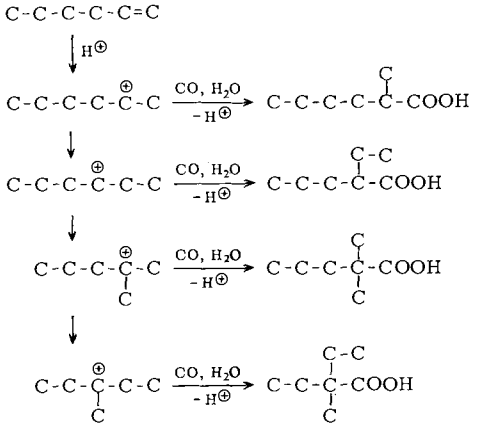


Resolution of racemates into enantiomers is summarized by *P. H. Boyle*. Reactions of racemates with chiral reagents are known to yield diastereomers which are physically separable. More recent reagents of this kind are, *e.g.*, 1-phenylethylamine, dehydroabietylamine, *threo*-1-*p*-nitrophenyl-2-aminopropane-1,3-diol, tartranilic acid, and menthylchloroformate. The kinetic methods of resolution are based on differences in reaction rates of the two enantiomers with chiral compounds. Thus reaction with diisopinocamphenylborane is suitable for the separation of alkenes having no functional groups. Other possibilities include reduction with chiral compounds or with microorganisms, chromatography and ion exchange. The most important reagent for resolution by formation of molecular complexes is 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid. Resolution by seeding of solutions is of industrial interest. [Methods of Optical Resolution. Quart. Rev. Chem. Soc. *25*, 323—341 (1971); 132 references]

[Rd 422 IE –E]



Concepts of liquid water structure are reviewed by *P. Krindel* and *I. Eliezer*. Many different models are presented, and their utility in contributing to an understanding of the known properties of liquid water is evaluated. The relevance of X-ray scattering and vibrational spectroscopy to the problem is stressed. In addition, brief accounts of "anomalous" water and of interfacial effects are included. [Water structure models. Coord. Chem. Rev. *6*, 217—246 (1971); 137 references, 12 figures, 4 tables]

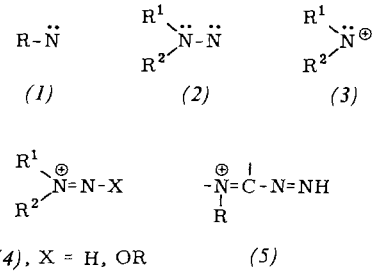


[Rd 425 IE –H]

Catalytic carbonylation of alkenes and alkynes with carbon monoxide is reviewed by *Yu. T. Eidus*, *K. V. Puzitskii*, *A. L. Lapidus*, and *K. Nefedov*. The alkynes are carbonylated in the presence of a Group VIII metal carbonyl and a compound having a mobile H atom:

stoichiometric or catalytic amounts of carbonyl are used. The carbonylation of alkenes can be carried out a) in the presence of catalysts based on Group VIII metals or

b) with acid catalysts. [Carbonylation of Mono-Olefinic and Mono-Acetylenic Hydrocarbons. Russ. Chem. Rev. *40*, 429—440 (1971); 237 references]



[Rd 426 IE –M]

Progress in use of amino acid mixtures in place of proteins for human nutrition in the past decade is discussed in a review by *V. M. Belikov* and *T. L. Babayan*. Prolonged administration of such mixtures shows that they are an

adequate substitute for nutritional proteins and that no side effects occur. Moreover, such mixtures can be used for improving second class proteins. The authors discuss the nitrogen balance and biological value of proteins, amino acids, and their mixtures, and also the reasons for variations in the degree of utilization of proteins and amino acid mixtures; in conclusion they turn their attention to amino acids in medicine, concentrating particularly on parenteral administration. [Mixtures of Amino Acids in Human Nutrition. Russ. Chem. Rev. *40*, 441—445 (1971); 164 references, 6 tables]

[Rd 428 IE -M]

The chemistry of reactive nitrogenous intermediates is the topic of an article by *S. Hünig*. The author deals mainly with the production and subsequent reactions of uncharged and cationic intermediates having a sextet of electrons on the nitrogen. Nitrenes *(1)*, 1,1-disubstituted diazenes *(2)*, nitrenium ions *(3)*, 1,1-disubstituted diazenium ions *(4)*, and phenylogous and azavinylogous diazenium ions *(5)* receive particular attention. BOOK REVIEWS

Catalyse et catalyseurs en chimie organique (Catalysis and Catalysts in Organic Chemistry). By *P. Brun*. Masson et Cie, Paris 1970, 1st ed., 241 pp., 29 figures, Fr. 70.—.

The use of catalysts in organic reactions has received comparatively scanty treatment in previous textbooks on heterogeneous catalysis. The attempt of the present book to repair this deficiency is therefore welcome. The book starts with a section on methods for the investigation of surfaces and on the underlying phenomena which play a part in catalysis; this is followed by a section on the role of individual chemical elements in catalysis. After a discussion of the properties required for technical purposes, reactions such as hydrogenation, oxidation, dehydrogenation, hydration, dehydration, rearrangements, polymerization, and also the influence on radicals and many other topics are discussed.

Although the plan of the book is good, its execution leaves much to be desired. Conciseness in presentation should not be achieved at the expense of comprehensibility, but this occurs frequently, particularly in the first chapter. On the basis of the descriptions given there no-one could understand the BET method of surface area determination or the measurement of a pore spectrum, or even carry them out. The bibliography should be just as complete as the collection of reactions; if, however, one averages out the years of appearance of the papers quoted, values prior to 1940 are obtained in some cases. It is therefore not surprising that one looks in vain for many reactions at the forefront of current interest (oxidation of ethylene on silver to ethylene oxide; oxidation of propylene to acrolein, butene to butadiene, and the ammoxidation of propylene to acrylonitrile on bismuth-molybdenum catalysts). On the other hand, it is pleasing to find the catalytic reactions of complicated organic molecules handled in previously unknown detail.

Willi Herzog [NB 995 IE]

Chemische Technologie (Chemical Technology). Edited by *K. Winnacker* and *L. Küchler*. Carl Hanser Verlag, Munich 1969. 3rd ed., Vol. 1: Anorganische Technologie I (Inorganic Technology I), xx, 729 pp., 271 figures, 137 tables, bound, DM 168.—. Vol. 2: Anorganische Technologie II (Inorganic Technology II), xxiii, 671 pp., 267 figures, 138 tables, bound, DM 168.—.

This established collective work gives in a limited space a description of the individual branches of the chemical industry. The editors' efforts to keep the size within limits can be clearly seen: despite complete rewriting, many of the articles have the same number of pages as in the previous edition. Even the bibliographies have not just been amplified by the addition of new references but have been critically reviewed, so that in places they are in fact shorter than before. Some of the articles are completely new, which has suggested a regrouping of the whole material. For this reason, although the individual volumes of the third edition have the same number of pages, or even fewer than before, the whole work will consist of seven volumes, while the previous edition consisted only of five.

Volumes 1 and 2, which have now appeared, deal only with inorganic technology, in contrast to the previous editions. The review articles on process technology and chemical reaction techniques, which previously were at the start of the entire work, will now appear in Volume 7 ("General").

Volume 1 starts with an new contribution, "Lines of development of chemical technology", by *Winnacker* and *Biener*, which provides an excellent introduction to the descriptive articles that follow. The stages of the short history of the German chemical industry are clearly shown and set in an international context. The particular problems of research are discussed, as also are those of patent technology and documentation.

In the other articles an attempt has been made to adapt the material so that related topics are brought together. Over half of the 35 principal authors are subject specialists who are new to this task. This, and the consideration of recent developments, has led to considerable changes in places.

The overall field is broken down into the following articles:

Volume 1: Lines of development of chemical technology (*Winnacker* and *Biener*, 45 pages); Water (*Greiner*, 31 pages); The potassium industry (*Autenrieth*, 85 pages); Technology of boron compounds (*Heinerth*, 12 pages); Common salt, soda, and potash (*Heuse* and *Wilsing*, 51 pages); Chlorine and its inorganic compounds (*Hund* and *Zirngiebl*, 97 pages); Fluorine and its inorganic compounds (*Weise*, 17 pages); Phosphorus and its inorganic compounds (*Harnisch* and *Saenger*, 79 pages); Carbide, calcium nitride, and silicon carbide (*Ritter* and *Krause*, 40 pages); Electrolytic graphite and artificial carbon (*Dönges* and *Vohler*, 47 pages); Peroxo compounds (*Pistor*, 81 pages); Nitrogen and its inorganic compounds (*Mundo*, 117 pages).

Volume 2: Sulfur and its inorganic compounds (*Dönges*, *Saenger* and *Wolf*, 84 pages); Chromium compounds (*Dilthey* and *Weise*, 35 pages); Manganese compounds (*Preisler*, 19 pages); Inorganic pigments (*Hund* and *Schultz*, 53 pages); Rare earths (*Greinacher*, 29 pages); Binders in building work (*Wittekindt*, 56 pages); Ceramics (*Kienow*, 60 pages); Glass (*Trier*, 65 pages); Liquefaction and separation of gases (*Baldus*, *Knapp* and *Schlatterer*, 101 pages); Materials of high surface area (*Bratzler*, 46 pages); Problems of chemical technology in nuclear technology (*Küchler*, 93 pages).

There is no need to read further than the article on water to see how favorable an influence the new treatment can exert on both form and content. However, it is surprising that waste water purification is no longer dealt with in a separate section. In this connection, the question arises whether air, which like water is used as a raw material and as a coolant and is burdened with waste materials, does not deserve a more thorough treatment than it receives in the article on gas separation.

All the articles on classical inorganic technology have been rewritten and brought up to date as far as possible. Statistical data and literature references are considered up to 1968. New developments have caused large changes, particularly in the electrochemical processes used in chlorine chemistry. The articles on graphite and on nuclear technology are new.

From the earliest days graphite electrodes have been of decisive importance in the great electrochemical and electrothermal processes of inorganic chemistry. The arrival of more and more new applications, particularly in apparatus construction, in nuclear technology, and most recently in the field of fibers, justifies the treatment of this topic as a subject in its own right.

Nuclear technology is beginning to make a significant contribution to power supplies, and it is high time that is was included in the normal realm of technology. From the production of fissionable material with the use of minimum separation factors to the performance of radiochemical reactions in chemical nuclear reactors and the processing of nuclear fuels under conditions necessitating extreme purity and safety requirements, many problems of chemical technology are involved. *Küchler* and his associates have summarized them very successfully.

It is a difficult task to cover so vast a field as that of inorganic chemistry while on the one hand presenting a comprehensive picture and on the other hand preserving the unity of the presentation by keeping it as far as possible to a limited space. The participation of a large number of authors may lead to a sharing but not a simplification of this task. The editor and publisher have overcome the problems with great success in the first two volumes of the third edition of this work. It is to be hoped that the remaining volumes will soon be published, so that the complete work can take its place in our libraries.

Ulrich Wagner [NB 997 IE]

Thermal Stability of Polymers, Vol. 1. By *R. T. Conley*. Marcel Dekker Inc., New York 1970. 1st ed., x, 644 pp., numerous figures, bound $ 44.50.

The two-volume work, which is being published in the series "Monographs in Macromolecular Chemistry", and of which this is the first volume, reviews the most important literature on heat-resistant plastics.

The opening chapters are devoted to the polymer properties and the structural characteristics that influence the thermal stability of polymers. The broad concept of the "thermal stability" of polymers is first explained and discussed with reference to general criteria such as molecular structure and crystallinity, kinetics and mechanism of the thermal depolymerization, the basic theory of random degradation processes, and fundamental problems relating to oxidation products. Separate chapters are devoted to the thermal or oxidative degradation of various important classes of substances, *e.g.* polyolefins, rubber, vinyl and vinylidene polymers, polyfluorohydrocarbons, polyamides, polyesters, polyethers, formaldehyde-based thermosets, epoxy resins, cellulose derivatives, and some heterocyclic ring systems. The last chapter deals with inorganic polymers based on boron, silicon, phosphorus, and sulfur. The possible reactions of the various classes when heated in the presence and in the absence of oxygen are discussed in detail.

Since the book draws on the specialized experience of several authors, it cannot and does not claim to be complete in its coverage of polymers and to give equal treatment to all. The present first volume unfortunately contains no table of contents for Volume 2, which is in preparation. Consequently, no final judgment can be made on this point at present.

The keyword index is regrettably not sufficiently comprehensive, since many of the facts and classes of substances treated are mentioned only superficially. For example, polysulfides are mentioned on p. 181, but do not appear in the subject index. More information on the practical use of members of the classes of substances discussed and of the effects described would have been of special interest to the industrial chemist.

A few technical shortcomings must be mentioned. Temperatures in °C and in °F are indiscriminately mixed. As a result of many errors, *e.g.* missing or displaced double and single bonds and H atoms, as well as tetravalent phosphorous or tetravalent boron, some of the formulas are almost incomprehensible.

Despite these faults, the book should be of use to any chemist who is concerned with the degradation of polymers and who requires information beyond that normally available.

Rudolf Merten [NB 1000 IE]

Fluorescence Analysis. By *C. White* and *R. J. Argauer*. Marcel Dekker Inc., New York 1970. 1st edit., x, 389 pp., numerous figures, bound, $ 18.75.

During the past two decades fluorescence analysis has become a favorite analytical technique, which has proved particularly useful in biological, biochemical, and clinical laboratories. This is due to its ability to detect a large number of substances, which either themselves fluoresce or else can be converted into fluorescing compounds by specific reactions, in astonishingly small concentrations, and at a relatively modest cost in equipment.

The present monograph is concerned with the currently available instruments and techniques. The basic phenomena of fluorescence, the currently available spectrofluorimeters, calibration methods, and fluorescence standards are all dealt with briefly but in sufficient detail for routine applications. The fluorescence properties of metal chelates are presented in great detail, since these form the foundation of the whole technique. There are further detailed chapters devoted to the fluorescence of proteins, vitamins, and steroids, and, rather outside the scope of the present book, chapters on chemiluminescence and X-ray fluorescence. Some criticism concerns the chapter on fluorescence indicators; the authors do not appear to know that the changes in a fluorescence spectrum are not necessarily governed by the pH value.

The emphasis of the book is on applications. Since it contains material reprinted from the manuals of two manufacturers it contains a large number of detailed instructions for use in a wide range of applications, particularly for clinical chemistry. The detailed nature of the presentation and the lack of theoretical padding make this book appear particularly suitable for the instruction of laboratory technicians.

Theodor Förster [NB 999 IE]

Grenzflächenaktive Substanzen (Surface Active Substances). By *H. Bueren* and *H. Grossmann*. Chemische Taschenbücher Vol. 14, edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. x, 196 pp., 64 figures, 27 tables, paperback DM 24.—

The present pocket book is an attempt by the authors to fill a gap in the technical and scientific literature with a brief survey of everything that is worth knowing about surface active substances. The subject is discussed under the following headings: historical review, scientific importance, physico-chemical principles, chemical composition of surface active substances, analysis, biological degradation, industrial use.

The book will be a valuable aid to the interested student who wishes to find out more about the field than he can learn from chemistry and technology lectures and to the practical worker in adjacent fields who wishes a quick survey. The large bibliography attached to each chapter also offers an opportunity to pursue the study further by reference to the original literature.

A number of adverse comments are also justified. Too much emphasis is sometimes placed on practical use, at the expense of chemical and industrial aspects (as in the case of nonionic surfactants). The treatment of the physico-chemical principles of surface activity is rather too general and simplified. No mention is made of some important current developments in the surfactant field, such as new classes of surfactants and the substitution of detergent phosphates. There are a number of printing errors in the text and several omissions in tables and graphs, some of which lead to distortion of meaning, and which will have to be corrected in later editions.

Apart from these points, the authors have succeeded well in their purpose of presenting a general survey of the field of surface active substances.

Horst Baumann [NB 10 IE]

Wörterbuch der Chemie und der chemischen Verfahrenstechnik (Dictionary of Chemistry and Chemical Engineering), Vol. 1 German/English. By *L. de Vries* and *H. Kolb* with the collaboration of *J. Thuss*. Verlag Chemie GmbH, Weinheim/Bergstr., and Academic Press, New York–London, 1970. viii, 708 pp., bound, DM 135.—.

The 70000 or so entries in this technical dictionary have been drawn from the whole field of chemistry and also from the vocabulary of chemical engineering, metallurgy, and the petroleum, rubber, and textile industries. The dictionary also contains terms from the fields of physics, biology, medicine, mathematics, mineralogy, and crystallography. The authors have taken particular trouble to include recently coined terms from biochemistry, physiology, molecular biology, biophysics, atomic physics, spectroscopy, stereochemistry, reactor engineering, and electronics. Chemical compounds are recorded both under their trivial and under their systematic names, although naturally only the simple compounds are included. Outmoded names still often found in the technical literature will be found, but are specially marked. At the end there is a table of the chemical elements, a table of German weights and measures, and a temperature-conversion table.

This dictionary has been used by us ever since it appeared and has rarely failed to supply an answer. There is thus no doubt that this is an extremely useful work, and not only to chemists but also to engineers and technical translators.

If we consider the sheer bulk of the material handled, it is hardly surprising that, despite the great care with which the book has been compiled there are still a few minor errors. For example, "Rotkupfererz" is only given under "Cuprit"; omissions include Widerstandszahl (drag coefficient), Schüttschicht (fixed bed), Formkern (mandrel), the synonym for film evaporation (film boiling), and under Verweilzeit the English term "residence time". Outmoded names for compounds are not always marked, *e.g.* "Zinnjodür". Neither descriptions such as "Zirkon" for Zr and "Vanadium" for V nor the spellings "Siliciumkarbid" and "Silikat" are in agreement with the principles of nomenclature, and there seems to be some confusion about the spelling of "oxid" (oxidhaltig, but oxydartig), although particular mention of this is made in the foreword. Since, however, the entire vocabulary is stored on magnetic tape, future modifications should not cause any difficulties.

It should be emphasized that these minor blemishes in no way detract from the work's usefulness, and it is hoped that this dictionary will find the widest possible circulation.

Christian Weiske [NB 9 IE]

Methoden der enzymatischen Analyse (Methods of Enzymatic Analysis). Edited by *H. U. Bergmeyer*. Verlag Chemie GmbH, Weinheim/Bergstr. 1970. 2nd Edit., lxix, 2220 pp., numerous figures, bound DM 285.—.

The second edition of this work has now appeared, and one need only look back to the reviews of the first edition[1] to see that any further praise would be superfluous. Then, as now, no comparable work existed, and all that remains for the reviewer to do is to indicate the places where this new edition (edited by *H. U. Bergmeyer* with the collaboration of 230 authors) is an improvement on the original one.

The new edition of this laboratory handbook is essentially larger and in two volumes. Despite the fact that it has almost doubled in size, the presentation is clearer, and the information provided is more precise and more markedly oriented toward practical use in clinical and biochemical laboratories. The care that has been taken in the layout of the book is one of the fundamental factors contributing toward its clarity.

The general division of the material into four sections has been retained; however, the general introduction is now followed by biochemical reactions as the second section, then come the methods for measuring enzyme activity, and finally the methods for the determination of metabolites. The general introduction has been extended to nine times its original length and has assumed an entirely new character. In addition to the description of new analytical methods, such as the enzyme isotope dilution technique, and information on the automation of analyses, the clinician will find valuable practical help in the newly added chapter "Evaluation, Checking, and Assessment of Measurements". Stability properties of substrates, enzymes, and tissue cultures are carefully described and illustrated by numerous literature references.

Biochemists who work with enzymes will note with gratitude that in the section on "Biochemical Reagents" not only are more than a hundred of the best known enzymes grouped together with their properties, but also the procedures for their activity determinations are given. In this connection it would be desirable if in future this part could also be arranged according to the rules of IUPAC nomenclature, as has already been done in the section on "Measurement of Enzyme Activities". Here account is taken of the mechanization and automation of enzyme analysis in clinical laboratories, a phenomenon that is observed more and more these days. With the determination of GOT, GPT, and LDH as examples, detailed data on automated analysis are given, and for other enzymes largely mechanized analyses are described. Analyses by electrophoretic separation, radiochemical analysis, and to a greater extent fluorometric methods are given for the first time, in addition to the traditional methods. Thus, for example, 41 pages are devoted to LDH and its isoenzymes, seven analytical methods and four methods of automatic analysis are given, and 51 literature references are provided to ensure the availability of further information. The favored subdivision into necessary reagents, solutions, method of operation, *etc.*, has been extended to include data on the precision of the method and also pipetting schemes which will lead to a dramatic simplification of the actual execution of determinations. The new edition no longer contains the chapter on histochemical methods, and in our opinion rightly so, since such methods are described in the appropriate textbooks and handbooks on histochemistry.

In both the section on the determination of enzyme activity and the final section on methods for metabolites, each determination is prefaced by a brief introduction and the sensitivity and precision of the method are given. Particular emphasis is placed on the pipetting scheme with data on the concentrations in the test. The methods given for the production of preparations of enzymes not commercially available are very useful. Finally, the tables giving the metabolite contents of animal tissues deserve particular mention, since they represent a valuable compilation of previously published values.

All things considered, this book, which has already made a name for itself, is indispensable to all practising biochemists, and is a practically inexhaustible source of information for laboratory practice. It is sure to find a wide distribution and to be highly popular.

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ACENAPHTHYLENO[5,5a,6-cd]-1,2-OXATHIOL 2,2-dioxide, 5,6-Dibromo-~ (LA) 428

Acenaphthylene, Heavy atom effect in photoreaction of ~ with maleic anhydride (SC) 272 [G.E. *83*, 291 (1971)]

Acetaldehyde, Nature of rotational barrier in ~ (LA) 524

Acetolysis, Energy surface for ~ via C_8H_9 cations from exo-tetracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]-oct-3-yl p-nitrobenzoate (SC) 559 [G.E. *83*, 581 (1971)]

Acetonitrile, N-Alkylimino acid anhydrides as intermediates in anodic oxidation of aliphatic carboxylic acids in ~ (SC) 557 [G.E. *83*, 579 (1971)]

N-tert-Butylimino-~ (LA) 79

Acetylene hydrogenation, Catalytic activity of palladium in ~ (LA) 524

Acrylonitrile, Addition to derivatives of 1,4-dihydropyridine (SC) 733 [G.E. *83*, 758 (1971)]

Formation of macrozwitterions in the anionic polymerization of vinyl monomers initiated by tertiary phosphanes (CR) 349 [G.E. *83*, 371 (1971)]

Actinide(IV) chlorides, Polarographic and coulometric reduction of ~ in dimethyl sulfoxide (CR) 857 [G.E. *83*, 932 (1971)]

Adamantanes, Reactions of ~ and their derivatives in sulfuric acid (CR) 754 [G.E. *83*, 732 (1971)]

Anomalous chlorination of adamantylideneadamantane (LA) 142

Dichloromethyl-~ (LA) 203

Proto-~ and 2,4-cyclo-~ (LA) 359

2-Adamantylamine, An α-lactam derived from ~ (SC) 753 [G.E. *83*, 848 (1971)]

2-Adamantyl compounds, Solvolysis of 1-methyl-2-~ (influence of β-methyl substitution on the solvolysis of secondary compounds) (CR) 843 [G.E. *83*, 918 (1971)]

Addition compounds, Tellurium tetrachloride-olefin ~ (SC) 73 [G.E. *83*, 81 (1971)]

X-Ray crystallographic investigations of tellurium tetrachloride-olefin adducts (SC) 74 [G.E. *83*, 81 (1971)]

Adenosine, Convenient synthesis of 2',3',5'-tri-O-acetyl-~ and -uridine (SC) 75 [G.E. *83*, 82 (1971)]

Synthesis of 4-amino-7-oxo-7,8-dihydropteridine N-8-β-D-ribosides – structural analogs of ~ (SC) 931 [G.E. *83*, 974 (1971)]

Adhesion, Mechanism of the self-~ of macromolecular films (CR) 857 [G.E. *83*, 931 (1971)]

Adhesives, Synthetic resins in elastomer ~ (CR) 836 [G.E. *83*, 910 (1971)]

Adsorption, of hydrogen halides on alkali-metal halides (LA) 283

~ (Book Review) 84

The theory of ~ and catalysis (Book Review) 431

Aldehydes, α-Allylcarb-~ (LA) 81

Conversion of alkyl bromides into ~ (LA) 81

New sensitive and specific reaction for detection of ~ (LA) 202

Aldol condensation of trihaloacetaldehydes with aliphatic ketones (CR) 839 [G.E. *83*, 913 (1971)]

Aldol reactions, Thermal ~ between ketones and aldehydes (CR) 846 [G.E. *83*, 921 (1971)]

Aliphatic nucleophilic substitution, Reexamination of the limiting mechanisms of ~ (SC) 503 [G.E. *83*, 493 (1971)]

Alkaloids, Model reactions for biosynthesis of Erythrina ~ (SC) 411 [G.E. *83*, 409 (1971)]

Comparative pharmacology of indole ~ and their derivatives (LA) 758

The ~ (Book Review) 206

Alkanes, Experimental evidence for kink formation (SC) 558 [G.E. *83*, 580 (1971)]

Photooxidation of ~ by nitrobenzene (LA) 142

Methoden der Organischen Chemie (Book Review) 432

Alkenes, Catalytic carbonylation of ~ and alkynes (LA) 944

Alkenylamines, Electrophilic alkylation of α-diazosulfones with ~ (SC) 271 [G.E. *83*, 290 (1971)]

Transamination of cyano ~ (SC) 725 [G.E. *83*, 756 (1971)]

Alkenylphenols, Isomerization of quinone methides to ~ (SC) 566 [G.E. *83*, 617 (1971)]

3-Alkoxycyclobutanones, precursors of bicyclo[1.1.0]butanes (LA) 283

Alkylation, Electrophilic ~ of α-diazosulfones with enamines (SC) 271 [G.E. *83*, 290 (1971)]

Mechanism of ~ with O-alkyl-N,N'-dicyclohexylisoureas (CR) 862 [G.E. *83*, 937 (1971)]

Alkyl bromides, Conversion into aldehydes (LA) 81

Alkyl nitrates (LA) 284

Alkyne, [1+2]Cycloadditions of isocyanides to ~-s (SC) 409 [G.E. *83*, 401 (1971)]

3,3,7,7-Tetramethylcycloheptyne, an isolable seven-membered carbocyclic ~ (SC) 509 [G.E. *83*, 540 (1971)]

Topochemical polymerization of monomers with conjugated triple bonds (CR) 355 [G.E. *83*, 368 (1971)]

Intramolecular interactions between parallel triple bonds (LA) 524

Catalytic carbonylation of alkenes and ~-s (LA) 944

Alkynylamines, Cycloadditions of keteneimines to ~ (SC) 184 [G.E. *83*, 171 (1971)]

Allenes, Detection of dipoles in cycloadditions to ~ (SC) 70 [G.E. *83*, 46 (1971)]

Catalytic mixed oligomerization with butadiene (SC) 659 [G.E. *83*, 731 (1971)]

Fluorinated ~ (LA) 80

Alloxazine, New synthesis (LA) 202

Alloys, Directionally solidified ~ for high-temperature applications (CR) 853 [G.E. *83*, 928 (1971)]

Allyl alcohols, Reaction with acetoacetic acid derivatives (Carroll reactions) (CR) 835 [G.E. *83*, 909 (1971)]

α-Allylcarbaldehydes (LA) 81

π-Allylcarbonylmetals from σ-allylorganotin compounds (SC) 339 [G.E. *83*, 360 (1971)]

Allyldihydropentalenylene complexes of transition metals (SC) 801 [G.E. *83*, 851 (1971)]

Aluminate ion, Structure (LA) 142

Aluminum compounds, Photochemical cis-trans-isomerization of n-octenes in presence of organo-~ (CR) 281 [G.E. *83*, 296 (1971)]

Gaseous mixtures of $AlCl_3/Al_2Cl_6$ and $NaAlCl_4$ are electrical conductors (LA) 582

Aluminum trichloride, Chromium trichloride-tris(~) (SC) 128 [G.E. *83*, 112 (1971)]

Americium, Gram-scale preparation (CR) 857 [G.E. *83*, 932 (1971)]

Amidines, 1,3-Dipolar cycloaddition of nitrile oxides to cyclic imidic esters and ~ (SC) 810 [G.E. *83*, 882 (1971)]

Amination, Oxidative ~ of hydroquinones 405 [G.E.]

Amines, Biochemistry and function of biogenic ~ in the central nervous system (FP) 51 [G.E. *83*, 53 (1971)]

Mechanism of cyanation of tertiary ~ (CR) 754 [G.E. *83*, 732 (1971)]

Synthesis and structure of halo-~ (CR) 755 [G.E. *83*, 767 (1971)]

Identification of ~: Thin layer chromatography and mass spectrometry of 4-dimethylamino-3,5-dinitrobenzoyl derivatives (DADB ~) (CR) 867 [G.E. *83*, 942 (1971)]

Charge-transfer bands of amine-aromatic hydrocarbon complexes (LA) 582

Ozonization of a secondary amine (LA) 143

Amino acids, Removal of chloroacetyl group from N-chloroacetyl derivatives of ~ and peptides by 1-piperidinethiocarboxamide (SC) 75 [G.E. *83*, 83 (1971)]

Higher ~ by alkylation of α-metalated isocyano-acetic or -propionic esters (SC) 331 [G.E. *83*, 357 (1971)]

Synthesis of (isothiocyanatoacyl)-~ (SC) 507 [G.E. *83*, 539 (1971)]

New amino acid derivatives from cyanamide and cyanacetamide (SC) 807 [G.E. *83*, 886 (1971)]

Contribution to the investigation of fossil ~ and peptides from black shales (CR) 832 [G.E. *83*, 906 (1971)]

Synthesis of modified ~ and peptides having anticoagulant, bactericidal, and vitamin-K type action (CR) 942 [G.E. *83*, 986 (1971)]

Improved specific enzyme electrodes for urea and ~ (LA) 143

Progress in use of amino acid mixtures (LA) 944

Amino acid anhydrides, Symmetrical BOC-~ for economical peptide syntheses on a

solid phase (SC) 336 [G.E. *83*, 333 (1971)]

β-Amino alcohols (SA) 524

Aminobenzenes, Oxidative dimerization (CR) 826 [G.E. *83*, 899 (1971)]

Aminoisoxazole, The ~-pyrazolone and retro-~ rearrangements (CR) 837 [G.E. *83*, 912 (1971)]

Amino sugar, Configuration of garosamine, a branched chain ~ (SC) 660 [G.E. *83*, 729 (1971)]

Aminyl radical, 1,3,6,8-Tetra-tert-butyl-9-carbazyl: a crystalline monomeric ~ (SC) 732 [G.E. *83*, 756 (1971)]

Ammonia synthesis, Chromium as catalyst in ~ (SC) 195 [G.E. *83*, 214 (1971)]

Ammonium salts, Extraction of transplutonium elements by alkyl-~ salts (CR) 580 [G.E. *83*, 625 (1971)]

Anilines, Reversibility of bromination of N-alkyl-~ (SC) 493 [G.E. *83*, 535 (1971)]

Simple one-step conversion into dehydrobenzene (LA) 203

Annulene, 6,11-Methanocyclobutabenzo-[1,2-a][10]-~, a biphenylene analog containing a carbocyclic 10π-electron ring (SC) 125 [G.E. *83*, 111 (1971)]

Dicarbonyl derivatives of 1,6-bridged [10]-~ (SC) 398 [G.E. *83*, 401 (1971)]

Bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione (SC) 399 [G.E. *83*, 403 (1971)]

5-Ethoxy-1,2,3-trichloropentaleno[3,2,1-cd]phenalene: A perturbed [16]-~ (SC) 576 [G.E. *83*, 623 (1971)]

Effect of non-planarity on the paramagnetic ring current in the dianion of 1,6;8,13-propanediylidene[14]-~ (SC) 920 [G.E. *83*, 1014 (1971)]

Anode material, Tungsten carbide as ~ for fuel cells (SC) 194 [G.E. *83*, 213 (1971)]

Anthracene, System with π bonds to the elements boron, silicon, and arsenic (CR) 838 [G.E. *83*, 912 (1971)]

Anthrahydroquinones, Contribution to mode of reaction with formaldehyde (CR) 822 [G.E. *83*, 895 (1971)]

9-Anthroic acid, Dynamics of the photodimerization of ~ and sodium 9-anthroate (SC) 517 [G.E. *83*, 545 (1971)]

9-Anthroxy groups for protection of hydroxy functions (LA) 81

Antibiotics, Synthesis of a biologically active gougerotin analog (SC) 334 [G.E. *83*, 331 (1971)]

Modes of action (CR) 817 [G.E. *83*, 808 (1971)]

Conformational analysis and kinetics of the conformational rearrangements of cyclodepsipeptide ~ (CR) 829 [G.E. *83*, 903 (1971)]

Kinetics and mechanism of the specific binding of ions by cyclodepsipeptide ~ (CR) 829 [G.E. *83*, 904 (1971)]

Antibiotic sugars, Synthesis (FP) 236 [G.E. *83*, 261 (1971)]

Antimony, Inverse voltammetric determination of traces of ~ after separation of the matrix by various methods (CR) 847 [G.E. *83*, 921 (1971)]

Antimony compounds, Hydrogendicarboxylate ions as hydrogen bonded chelate systems in organo-~ (SC) 136 [G.E. *83*, 149 (1971)]

Aquatic chemistry (Book Review) 588

Arabinofuranosyl-4-thiouracil, Conformation of the arabinonucleoside 1-β-D-~ (SC) 187 [G.E. *83*, 174 (1971)]

D-Arabinose, Stereospecific synthesis of optically pure quinic acid and shikimic acid from ~ (SC) 336 [G.E. *83*, 329 (1971)]

Arenology principle (SC) 743 [G.E. *83*, 798 (1971)]

Aromatic compounds, Formation from D-glucuronic acid and D-xylose (LA) 142

Aromaticity and pericyclic reactions (FP) 761 [G.E. *83*, 859 (1971)]

Aromatic substitution, Calculation of intermediates and transition state in electrophilic ~ (SC) 497 [G.E. *83*, 499 (1971)]

Arsenic compounds, Phenylarsenic(V) trichloride azide and phenylarsenic(V) chloride nitride (SC) 516 [G.E. *83*, 504 (1971)]

$(CH_3As)_2S_2N_4$ – a novel arsenic-sulfur-nitrogen heterocycle (SC) 812 [G.E. *83*, 882 (1971)]

Arsine, Trifluoro-~ as ligand for a complex (SC) 418 [G.E. *83*, 445 (1971)]

Arynes, Carbenes, nitrenes and ~ (Book Review) 760

Association behavior of atactic and stereospecific polymethyl methacrylates (CR) 346 [G.E. *83*, 375 (1971)]

Asymmetric synthesis, Methods of ~ – enantioselective catalytic hydrogenation (FP) 871 [G.E. *83*, 956 (1971)]

Atoms, Reactions of ~ (FP) 604 [G.E. *83*, 561 (1971)]

Production of F ~, H ~, and OF radicals (SC) 564 [G.E. *83*, 586 (1971)]

Atomic absorption spectroscopy (Book Review) 870

Atomic reactions with carbonylmetal compounds (SC) 934 [G.E. *83*, 888 (1971)]

Atropisomerism of transition metal carbene complexes (SC) 924 [G.E. *83*, 1022 (1971)]

2-Azaallyllithium, [1,3]-Anionic cycloaddition of ~ compounds to dienes (SC) 739 [G.E. *83*, 794 (1971)]

3-Azabicyclo[4.1.0]hept-4-en-2-ones, Synthesis and reactions of 1-hydroxy-~ (SC) 735 [G.E. *83*, 763 (1971)]

Azacyclol, Synthesis of an ~ (SC) 128 [G.E. *83*, 113 (1971)]

1,2-Aza-P^V-phosphol-1-ines, Novel type of 1,3-dipolar cycloaddition: ~ from methyleneaminophosphanes (SC) 396 [G.E. *83*, 397 (1971)]

Azides, Preparation of tertiary alkyl ~ (SC) 412 [G.E. *83*, 410 (1971)]

Phenylarsenic(V) trichloride azide and phenylarsenic(V) chloride nitride (SC) 516 [G.E. *83*, 504 (1971)]

Preparation and spectroscopic and magnetic investigations of inorganic complex ~ (CR) 829 [G.E. *83*, 902 (1971)]

Azide radical, Pulse radiolysis in the gas phase: the formation of the ~ in pure nitrogen and in nitrogen-containing additives (CR) 851 [G.E. *83*, 927 (1971)]

1-Azidophosphetane 1-oxides, Photolysis (LA) 582

Aziridine, Photochemical olefin-~ cycloaddition (SC) 273 [G.E. *83*, 292 (1971)]

Azosilanes, Thermal decomposition (CR) 865 [G.E. *83*, 940 (1971)]

Azulenes, New synthesis of hydro-~ (LA) 143

BARBITURATE, Intermolecular interactions in the crystal structure of the hydrogen-bond-free ~ sodium metharbital (SC) 814 [G.E. *83*, 889 (1971)]

Batrachotoxin, Chemistry and pharmacology (LA) 757

Benzene, Direct transformation of the second excited singlet state of ~ into Dewar-~ (SC) 745 [G.E. *83*, 803 (1971)]

Benzenesulfenyl chloride, Pentafluoro-~ (LA) 144

1,4-Benzodiazepines, Chemistry and some aspects of the structure-activity relationship (FP) 34 [G.E. *83*, 70 (1971)]

Benzofuran, Ring expansion in the ~ series (SC) 748 [G.E. *83*, 755 (1971)]

Benzofurazane, Photochemistry (LA) 583

Benzo[d]isothia(IV)-azole, 3-Oxo-~ 1-oxides (SC) 76 [G.E. *83*, 83 (1971)]

Benzo[α]pyraceheptylene, Simple synthesis of pyraceheptylene and ~ (SC) 808 [G.E. *83*, 886 (1971)]

o-Benzoquinones, Substituted ~ (CR) 281 [G.E. *83*, 297 (1971)]

1,2,4,5-Benzotetrathiepins, Synthesis (SC) 331 [G.E. *83*, 331 (1971)]

Benzylation of aromatic compounds with benzyl sulfides (LA) 144

Benzyl sulfides, Benzylation of aromatic compounds with ~ (LA) 144

Beryllium, Determination of the relative electron density on the Be nucleus in various chemical compounds, measured as the change in the EC half life of ^7Be (CR) 819 [G.E. *83*, 892 (1971)]

Coupling products of diazotized anthranilic acid and p-alkylphenols for separation, enrichment, and determination of ~ (CR) 821 [G.E. *83*, 894 (1971)]

Bicyclo[1.1.0]butanes, 3-Alkoxycyclobutanones, precursors of ~ (LA) 283

Bicyclo[2.1.1]hexene, New route to derivatives of ~ and tricyclo[3.1.0.$0^{2,6}$]hexane (SC) 263 [G.E. *83*, 251 (1971)]

Bicyclo[2.2.0]hex-1(4)-ene, Synthesis (LA) 284

Bicyclohexenols as benzvalene derivatives, and their photochemical reactions (CR) 826 [G.E. *83*, 899 (1971)]

Bicyclo[2.2.2]octadiene, Photochemical (2π + 6π)-cycloadditions. Novel 1,4-cycloaddition with formation of the ~ system (SC) 133 [G.E. *83*, 143 (1971)]

Bicyclopropenyls, A new route to ~ (SC) 811 [G.E. *83*, 887 (1971)]

Bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione (SC) 399 [G.E. *83*, 403 (1971)]

Bicyclo[4.4.1]undeca-3,6,8,10-tetraene-2,5-dione, Dicarbonyl derivatives of 1,6-bridged [10]annulenes (SC) 398 [G.E. *83*, 401 (1971)]

Binder, Fast-drying ~ based on dehydrated, epoxidized linseed oil in theory and practice (CR) 846 [G.E. *83*, 920 (1971)]

Biochemistry (Book Review) 83

Laboratory techniques in ~ and molecular biology (Book Review) 585, 586

Biodegradation, Surfactant ~ (Book Review) 286

Biogenic amines, Biochemistry and function in the central nervous system (FP) 51 [G.E. *83*, 53 (1971)]

Biological membranes (FP) 388 [G.E. *83*, 419 (1971)]

Biopolymers, Thermodynamics of the cooperative transformations of ~ in solution (CR) 345 [G.E. *83*, 367 (1971)]

Biphenyls, Nucleophilic aromatic substitution: a new synthetic route to ~ (SC) 566 [G.E. *83*, 619 (1971)]

Intramolecular charge transfer in (dialkylamino)nitro-~ (SC) 567 [G.E. *83*, 621 (1971)]

Bisacylhydrazones, Oxidation products of ~ of α,β-diketones (SC) 129 [G.E. *83*, 115 (1971)]

Bis(chlorodisulfanyl)benzenes, Synthesis of ~ and hexathia[3.3]-cyclophanes (SC) 413 [G.E. *83*, 439 (1971)]

Bis(diacetyldioximato)cobalt, Novel degradation reactions of halomethyl derivatives of bis(diacetyldioximato)-cobalt (SC) 807 [G.E. *83*, 849 (1971)]

Bis(trimethylsilyl)diimine: Preparation, structure, and reactivity (FP) 374 [G.E. *83*, 379 (1971)]

Bleaching, Chemistry of lignin-removing ~ (CR) 522 [G.E. *83*, 540 (1971)]

Blood coagulation and fibrinolysis (FP) 85 [G.E. *83*, 89 (1971)]

Bond character of β-diketone metal chelates (FP) 225 [G.E. *83*, 239 (1971)]

Bond exchange, Inhibition in cyclooctatetraenes (SC) 746 [G.E. *83*, 804 (1971)]

Bonding, Chemical ~ in solids (FP) 460 [G.E. *83*, 521 (1971)]

Application of ligand field spectroscopy to problems of chemical ~ in solids (SC) 901 [G.E. *83*, 991 (1971)]

Bond isomerism in sulfinato complexes of transition metals (SC) 193 [G.E. *83*, 213 (1971)]

Boranes, Cyclopentadienyl-~ (SC) 423 [G.E. *83*, 447 (1971)]

Diethylborylation and determination of water with activated triethylborane (SC) 748 [G.E. *83*, 805 (1971)]

Reactions of dialkyl ketones with triethylborane (SC) 750 [G.E. *83*, 750 (1971)]

Borane complex, Benzyloxydivinylborane-tricarbonyliron—a divinyl-~ containing a boron-iron linkage (SC) 937 [G.E. *83*, 1020 (1971)]

Borazine, Arguments concerning the orbital sequence in ~ (SC) 182 [G.E. *83*, 169 (1971)]

Borazine-metal complexes, Some recent results from the chemistry of ~ (CR) 864 [G.E. *83*, 939 (1971)]

Borin, Bis(perhydro~) (LA) 427

Bornadiene, Chiral ~: its synthesis and rearrangement (CR) 78 [G.E. *83*, 85 (1971)]

Boron, Combustion of elemental ~ in air: a thermodynamic study (SC) 421 [G.E. *83*, 412 (1971)]

Crystallo-chemical aspects of the gas-phase synthesis of icosahedral boro- and boride-structures (CR) 818 [G.E. *83*, 892 (1971)]

Boron compounds, Derivatives of 1,3,4,2,5-triazadiborolidine (SC) 126 [G.E. *83*, 112 (1971)]

Trisboranephosphite and tetrakisboranephosphate ions (SC) 416 [G.E. *83*, 446 (1971)]

Binary compounds of boron with main group V elements with retention of basic icosahedral frameworks: Tetragonal boron nitride and rhombohedral boron phosphide (CR) 849 [G.E. *83*, 923 (1971)]

Boron-nitrogen compounds, Structural problems in boron-nitrogen and boron-sulfur chemistry (CR) 518 [G.E. *83*, 505 (1971)]

Boron-sulfur compounds, Structural problems in boron-nitrogen and boron-sulfur chemistry (CR) 518 [G.E. *83*, 505 (1971)]

Borylation, Diethyl-~ and determination of water with activated triethylborane (SC) 748 [G.E. *83*, 805 (1971)]

Bridges, Synthesis of 2,5-piperazinediones having sulfur-containing ~ between C-3 and C-6 (SC) 130 [G.E. *83*, 114 (1971)]

Bromination, Reversibility of ~ of N-alkylanilines (SC) 493 [G.E. *83*, 535 (1971)]

~ in liquid bromine (CR) 280 [G.E. *83*, 296 (1971)]

Bromine, Existence of 3-bromo-L-tyrosine in blood serum (CR) 828 [G.E. *83*, 902 (1971)]

Bromine isocyanate (SC) 416 [G.E. *83*, 445 (1971)]

Bullvalene, Complex bonding of a vinylcyclopropane group of ~ to a transition metal via a π-allyl and a σ component (SC) 188 [G.E. *83*, 175 (1971)]

A stable bis(tricarbonyliron) complex of tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene and its dynamic behavior in solution (SC) 189 [G.E. *83*, 176 (1971)]

Iso-~-bis(tricarbonyliron) (SC) 190 [G.E. *83*, 177 (1971)]

Butadiene, Mechanism of cyclodimerization with nickel-ligand catalysts (SC) 329 [G.E. *83*, 329 (1971)]

Catalytic mixed oligomerization with allenes (SC) 659 [G.E. *83*, 731 (1971)]

Catalytic formation of macrocyclic polyenes from ~ (SC) 802 [G.E. *83*, 851 (1971)]

Binary and ternary copolymerization in the system vinyl chloride-~-maleic anhydride (CR) 353 [G.E. *83*, 370 (1971)]

Telomerization with alcohols (LA) 359

tert-Butoxycarbonylation, 4-Dimethylamino-1-tert-butoxycarbonylpyridinium chloride (LA) 429

N-tert-Butyliminoacetonitrile (LA) 79

2-Butyne, Reactions with triallylchromium(III) and with tetraallyldichromium(II) (SA) 525

Butyrolactones, New synthesis of α-methylene ~ (LA) 583

CARBAMOYLATION, Reagent for direct nucleophilic ~ (SC) 339 [G.E. *83*, 334 (1971)]

Carbamoyl chlorides, New ~ by phosgenation of lactim ethers, imido esters, and Schiff bases and by chlorination of N,N-dimethylcarbamoyl chloride (CR) 846 [G.E. *83*, 920 (1971)]

Carbanions, Energy and entropy parameters of different species of ~ from the polymerization kinetics and from conductivity measurements on polystyrylsodium in polar organic solvents (CR) 354 [G.E. *83*, 371 (1971)]

Stereochemical investigation of carbanion and carbenoid formation from conformationally rigid cycloheptatriene derivatives (CR) 357 [G.E. *83*, 336 (1971)]

Structures of ~ (LA) 81

Carbazole, Synthesis and properties of N-ethynyl-~ and poly-N-ethynyl-~ (LA) 203

9-Carbazyl, 1,3,6,8-Tetra-tert-butyl-~: a crystalline monomeric aminyl radical (SC) 732 [G.E. *83*, 756 (1971)]

Carbenes, Generation by thermal cycloelimination (FP) 529 [G.E. *83*, 595 (1971)]

Generation by photochemical cycloelimination (FP) 537 [G.E. *83*, 604 (1971)]

Alkyl/halogen substitution in ~ (carbenoids): A route to new cyclopropane derivatives (SC) 138 [G.E. *83*, 150 (1971)]

PO-substituted ~ (CR) 581 [G.E. *83*, 625 (1971)]

Methylchlorocarbene (LA) 203

Rearrangement of a thermally generated oxycarbene (LA) 524

7-Norbornenylidene, a potentially nonclassical carbene (LA) 582

~, nitrenes and arynes (Book Review) 760

Carbene complexes, Atropisomerism of transition metal ~ (SC) 924 [G.E. *83*, 1022 (1971)]

Carbenoids, Alkyl/halogen substitution in carbenes (~): A route to new cyclopropane derivatives (SC) 138 [G.E. *83*, 150 (1971)]

Stereochemical investigation of carbanion- and carbenoid formation from conformationally rigid cycloheptatriene derivatives (CR) 357 [G.E. *83*, 336 (1971)]

Carbohydrates, Synthesis of antibiotic sugars (FP) 261 [G.E. *83*, 261 (1971)]

Application of ^{13}C resonance to stereochemical problems in ~ (CR) 862 [G.E. *83*, 937 (1971)]

Epimerization of ~ catalyzed by molybdate ions (SC) 904 [G.E. *83*, 967 (1971)]

Pulse Fourier transform ^{13}C-NMR spectroscopy of mutarotating sugars (SC) 935 [G.E. *83*, 1011 (1971)]

Carbon, Reactions of atoms (FP) 604 [G.E. *83*, 561 (1971)]

Thermodynamics and kinetics of the synthesis of new forms of ~ (CR) 844 [G.E. *83*, 919 (1971)]

Potassium intercalation compounds in ~ fibers (CR) 853 [G.E. *83*, 927 (1971)]

Active ~, Manufacture, properties and applications (Book Review) 360

Carbon black, Investigation of the furnace black process in a model reactor (CR) 824 [G.E. *83*, 898 (1971)]

Carbon compounds, Rodd's chemistry of ~ (Book Review) 208

Carbonium ions, Dehalogenation of α-haloketones via α-~ to stable oxonium salts (SC) 327 [G.E. *83*, 327 (1971)]

Gaseous ~ from the decay of tritiated molecules (CR) 822 [G.E. *83*, 895 (1971)]

Stable arylalkoxy-~ (LA) 428

Carbonylation, Catalytic ~ of alkenes and alkynes (LA) 944

Carbonyl compounds, Bonding of volatile ~ to food components (CR) 845 [G.E. *83*, 919 (1971)]

Carbonylmetal complexes, Stepwise formation of bridged dinuclear ~ (SC) 513 [G.E. *83*, 501 (1971)]

Atomic reactions (SC) 934 [G.E. *83*, 888 (1971)]

Base-bridged dinuclear ~ (CR) 862 [G.E. *83*, 937 (1971)]

Carboranes, Molecular motions in crystalline o- and m-~ (LA) 142

~ (Book Review) 869

Carbosilanes, Si-Fluorinated ~ (SC) 510 [G.E. *83*, 500 (1971)]

Carboxamides, Michael addition of metalated ~ to nitrostyrenes – A simplified route to tryptamines (SC) 501 [G.E. *83*, 542 (1971)]

Carboxylic acids, N-Alkylimino acid anhydrides as intermediates in anodic oxidation of aliphatic ~ in acetonitrile (SC) 557 [G.E. *83*, 579 (1971)]

Chain lengthening of ~ by three carbon atoms via oxazol-5-one anions (SC) 655 [G.E. *83*, 727 (1971)]

Carboxylic esters, ~ from aldehydes and Grignard compounds (CR) 852 [G.E. *83*, 926 (1971)]

Reaction with sodium in presence of trimethylchlorosilane (LA) 757

Catalysis, Catalytic formation of macrocyclic polyenes from butadiene (SC) 802 [G.E. *83*, 851 (1971)]

Catalytic activity of palladium in acetylene hydrogenation (LA) 524

Catalytic carbonylation of alkenes and alkynes (LA) 944

~ by nonmetals. Rules for catalyst selection (Book Review) 82

The theory of adsorption and ~ (Book Review) 431

Catalyse et catalyseurs en chemie organique (Book Review) 945

Catalysts, Influence of ligands on the activity and specificity of soluble transition metal ~ (FP) 105 [G.E. *83*, 121 (1971)]

Mechanism of contact elimination. A contribution to understanding the function of polar ~ (FP) 172 [G.E. *83*, 185 (1971)]

Vanadium and chromium ~ for polymerization of ethylene (FP) 776 [G.E. *83*, 782 (1971)]

Chromium as catalyst in ammonia synthesis (SC) 195 [G.E. *83*, 214 (1971)]

Catalytic processes and proven ~ (Book Review) 759

Catalyst Handbook (Book Review) 759

Chain lengthening of carboxylic acids by three carbon atoms via oxazol-5-one anions (SC) 655 [G.E. *83*, 727 (1971)]

Charge transfer, Intramolecular ~ in (dialkylamino)nitrobiphenyls (SC) 567 [G.E. *83*, 621 (1971)]

Charge-transfer bands of amine-aromatic hydrocarbon complexes (LA) 582

Chelates, Bond character of β-diketone metal ~ (FP) 225 [G.E. *83*, 239 (1971)]

Pentachalcogenide ~ of vanadium (SC) 137 [G.E. *83*, 146 (1971)]

Conformational studies on enedithiolate ~ (SC) 143 [G.E. *83*, 146 (1971)]

Chelate systems, Hydrogendicarboxylate ions as hydrogen bonded ~ in organoantimony compounds (SC) 136 [G.E. *83*, 149 (1971)]

Chemiluminescence, Sensitized ~ on thermolysis of phthaloyl peroxide in presence of 9,10-diphenylanthracene (SC) 67 [G.E. *83*, 43 (1971)]

Chiral bornadiene: Its synthesis and rearrangement (CR) 78 [G.E. *83*, 85 (1971)]

Chlorination, Anomalous ~ of adamantylideneadamantane (LA) 142

Chlorine, Influence of ~ attached to the double bond of unsaturated five-membered ring carbonates and anhydrides on dienophilic activity (CR) 356 [G.E. *83*, 335 (1971)]

Chlorine isocyanate, Molecular structure of gaseous ~ (LA) 358

Chloroacetyl group, Removal from N-chloroacetyl derivatives of amino acids and peptides by 1-piperidinethiocarboxamide (SC) 75 [G.E. *83*, 83 (1971)]

Chromatography, Problems of high speed liquid ~ (SC) 423 [G.E. *83*, 411 (1971)]

Chromatographic resolution of racemates (CR) 520 [G.E. *83*, 547 (1971)]

Gel absorption ~ (CR) 824 [G.E. *83*, 897 (1971)]

Influence of apparative gas-chromatographic parameters on the detector response of thermocouple detectors (CR) 825 [G.E. *83*, 899 (1971)]

Recent developments in ~: Column liquid- and supercritical-fluid ~ (CR) 836 [G.E. *83*, 910 (1971)]

Possibilities of fast liquid ~ (CR) 850 [G.E. *83*, 925 (1971)]

Use of gel permeation ~ in the analysis of fats (CR) 854 [G.E. *83*, 929 (1971)]

Extraction ~ with high-porosity polymers (CR) 858 [G.E. *83*, 933 (1971)]

High pressure column liquid ~ with modified porous silica as stationary phase material (CR) 861 [G.E. *83*, 936 (1971)]

Chromium, Vanadium and ~ catalysts for polymerization of ethylene (FP) 776 [G.E. *83*, 782 (1971)]

~ as catalyst in ammonia synthesis (SC) 195 [G.E. *83*, 214 (1971)]

Chromium complexes, Crystal and molecular structure of tricarbonyl(hexaethylborazine)chromium(0) (SC) 512 [G.E. *83*, 541 (1971)]

Organoelementphosphanepentacarbonylchromium, -molybdenum, and -tungsten complexes (LA) 524

Reactions of triallylchromium(III) and of tetraallyldichromium(II) with 2-butyne (LA) 525

Chromium compounds, Ethoxydimethylaminocarbenepentacarbonylchromium (SC) 922 [G.E. *83*, 1021 (1971)]

Chromium dioxide pigments, Dependence of some properties (particularly magnetic) on the particle size (CR) 836 [G.E. *83*, 910 (1971)]

Chromium(II) fluorides, Structure of ternary copper(II) fluorides and ~ (SC) 413 [G.E. *83*, 440 (1971)]

Chromium sulfides, Ternary ~ (CR) 844 [G.E. *83*, 919 (1971)]

Chromium trichloride-tris(aluminum trichloride) (SC) 128 [G.E. *83*, 112 (1971)]

Chromophore, 4,4,4′,4′-Tetramethyl-$\Delta^{2,2}$-bipyrrolidine-3,3′-dione, a compound having the basic ~ system of indigo (SC) 803 [G.E. *83*, 803 (1971)]

Cobaloximes, Novel degradation reactions of halomethyl derivatives of bis(diacetyldioximato)cobalt (SC) 807 [G.E. *83*, 849 (1971)]

Cobalt complexes, Tetrakis(trimethylphosphane)cobalt(0): preparation and reactions (SC) 343 [G.E. *83*, 363 (1971)]

Molecular perchlorato complexes of iridium(I), rhodium(I), and cobalt(I) (SC) 511 [G.E. *83*, 497 (1971)]

Novel degradation reactions of halomethyl derivatives of bis(diacetyldioximato)-cobalt (SC) 807 [G.E. *83*, 849 (1971)]

Account of the stereochemistry of five-coordinate nickel(II) and cobalt(II) complexes (LA) 868

Cobalt compounds, Incorporation of olefin and nitric oxide into organo-~ (SC) 515 [G.E. *83*, 546 (1971)]

Complexes, Optical activity from asymmetric transition metal atoms (FP) 249 [G.E. *83*, 274 (1971)]

Sulfinato ~ (FP) 315 [G.E. *83*, 315 (1971)]

Trifluoroarsine as ligand for a complex (SC) 418 [G.E. 83, 445 (1971)]

Stepwise formation of bridged dinuclear carbonylmetal ~ (SC) 513 [G.E. *83*, 501 (1971)]

Electronic and molecular structure of coordination compounds of transition metals as derived from their optical properties (CR) 278 [G.E. *83*, 295 (1971)]

Metal ~ of new macrocyclic sexadentate ligands (LA) 282

Coordination compounds of 2,3-diazabicyclo[2.2.1]hept-2-ene (LA) 284

Charge-transfer bands of amine-aromatic hydrocarbon ~ (LA) 582

Composites, Aligned ~ prepared by solid state transformations (CR) 823 [G.E. *83*, 896 (1971)]

Compressibility, Surface tension and ~ of liquids (LA) 79

Computer programs for chemistry (Book Review) 431

Conformation, Conformational studies by low temperature ^{13}C-NMR spectroscopy (SC) 730 [G.E. *83*, 759 (1971)]

~ of molecules in undiluted, noncrystalline polymers (CR) 349 [G.E. *83*, 375 (1971)]

Influence of proline on the ~ of a polypeptide chain (CR) 354 [G.E. *83*, 366 1971)]

Reactivity and ~ in the heterocyclic series. – The gear effect (CR) 815 [G.E. *83*, 808 (1971)]

Conjugation, Theoretical conditions for ~ involving d orbitals (CR) 831 [G.E. *83*, 905 (1971)]

Contraception: The chemical control of fertility (Book Review) 432

Cooperative transformations, Thermodynamics of the ~ of biopolymers in solution (CR) 345 [G.E. *83*, 367 (1971)]

Coordination compounds (Book Review) 207

Copper, Unidirectional solidification of pseudobinary eutectics in ternary systems with ~ as matrix (CR) 858 [G.E. *83*, 933 (1971)]

Copper compounds, Fluorescence and fluorescence thermochromism (CR) 818 [G.E. *83*, 891 (1971)]

Copper(II) fluorides, Structure of ternary ~ and chromium(II) fluorides (SC) 413 [G.E. *83*, 440 (1971)]

Corrosion, Electrochemistry of ~ and of ~ prevention (CR) 833 [G.E. *83*, 907 (1971)]

Sources of information for determination of effectiveness of ~ prevention with thermosets (CR) 863 [G.E. *83*, 938 (1971)]

Crosslinking, Bifunctional reagents for ~ of proteins (FP) 795 [G.E. *83*, 875 (1971)]

Detection of grafting and ~ of the elastomer phase in two-phase systems (CR) 345 [G.E. *83*, 369 (1971)]

Crystal structure, ~ and molecular structure of diethyl 2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate (SC) 490 [G.E. *83*, 489 (1971)]

~ and molecular structure of tricarbonyl(hexaethylborazine)chromium(0) (SC) 512 [G.E. *83*, 541 (1971)]

~ of 2,4-hexadiynediol (SC) 940 [G.E. *83*, 1024 (1971)]

Curium, Gram-scale purification of ^{244}Cm by extraction chromatography (SC) 727 [G.E. *83*, 766 (1971)]

Cyanacetamide, New amino acid derivatives from cyanamide and ~ (SC) 807 [G.E. *83*, 886 (1971)]

Cyanamide, New amino acid derivatives from ~ and cyanacetamide (SC) 807 [G.E. *83*, 886 (1971)]

Cyanation, Mechanism of tertiary amine ~ (CR) 754 [G.E. *83*, 732 (1971)]

Cyanines, Condensation of dichloromethylenedimethylammonium chloride ("phosgene immonium chloride") with N,N-dialkylcarboxamides (SC) 574 [G.E. *83*, 615 (1971)]

Cyano enamines, Transamination (SC) 725 [G.E. *83*, 756 [1971)]

2,4-Cycloadamantane and protoadamantene (LA) 359

Cycloaddition, ~ to diethyl 2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate (SC) 68 [G.E. *83*, 45 (1971)]

Detection of dipoles in ~-s to allenes (SC) 70 [G.E. *83*, 46 (1971)]

Photochemical ($2\pi+6\pi$)- ~. Novel 1,4 -~ with formation of the bicyclo[2.2.2]octadiene system (SC) 133 [G.E. *83*, 143 (1971)]

~-s of N-methoxycarbonyl-2,3-homopyrrole (SC) 135 [G.E. *83*, 148 (1971)]

~ of keteneimines to ynamines (SC) 184 [G.E. *83*, 171 (1971)]

~-s of phosphonodithioic anhydrides; formation of dienephosphinodithioic acids (SC) 191 [G.E. *83*, 178 (1971)]

Photochemical olefin-aziridine ~ (SC) 273 [G.E. *83*, 292 (1971)]

Novel type of 1,3-dipolar ~: 1,2-aza-P-phosphol-1-ines from methyleneaminophosphanes (SC) 396 [G.E. *83*, 397 (1971)]

[1 + 2]-~-s of isocyanides to alkynes (SC) 409 [G.E. *83*, 401 (1971)]

[1,3]-Anionic ~ of 2-azaallyllithium compounds to dienes (SC) 739 [G.E. *83*, 794 (1971)]

1,3-Dipolar ~ of nitrile oxides to cyclic imidic esters and amidines (SC) 810 [G.E. *83*, 882 (1971)]

~-s with mesomeric pyrimidine betaines (SC) 925 [G.E. *83*, 967 (1971)]

Triplet biradicals in ~ (CR) 77 [G.E. *83*, 49 (1971)]

Photosensitized ~ of dichlorovinylene carbonate to benzene (CR) 854 [G.E. *83*, 929 (1971)

Cycloalkanes, Methoden der Organischen Chemie (Book Review) 432

Cycloalkylation of phenol with 1,5-hexadiene (LA) 429

Cyclobutabenzo[1,2-a][10]annulene, 6,11-Methano-~, a biphenylene analog containing a carbocyclic 10 π-electron ring (SC) 125 [G.E. *83*, 111 (1971)]

Cyclobutadiene, Addition of electrophiles to diethyl 2,4-bis(diethylamino-~-1,3-dicarboxylate (SC) 67 [G.E. *83*, 44 (1971)]

Cycloaddition to diethyl 2,4-bis(diethylamino)-~-1,3-dicarboxylate (SC) 68 [G.E. *83*, 45 (1971)]

Crystal and molecular structure of diethyl 2,4-bis(diethylamino)-~-1,3-dicarboxylate (SC) 490 [G.E. *83*, 489 (1971)]

Cyclobutanes, Stereoelectronically controlled reductive ring cleavage of cis-1,2-divinyl-~ (SC) 132 [G.E. *83*, 144 (1971)]

Experiments on the halogenation of 1,3-dibromo-1,3-dimethylcyclobutane (CR) 831 [G.E. *83*, 904 (1971)]

Cyclobutenedione, Reaction of diphenyl-~ with diazomethane (SC) 736 [G.E. *83*, 764 (1971)]

Cyclobutenone, Synthesis (LA) 583

Cyclodecadienes, The synthesis of 1,5-dienes and 1,5- and 1,6-~ (LA) 758

Cyclodecane, Preferred syn-elimination from trans-1,2-dichloro- and trans-1,2-dibromo-~ (SC) 926 [G.E. *83*, 1012 (1971)]

Cyclododecanone, Ring expansion of ~ by two and four carbon atoms (LA) 584

Cyclodimerization, Mechanism of ~ of butadiene with nickel-ligand catalysts (SC) 329 [G.E. *83*, 329 (1971)]

Cycloelimination, Generation of carbenes by thermal ~ (FP) 529 [G.E. *83*, 595 (1971)]

Generation of carbenes by photochemical ~ (FP) 537 [G.E. *83*, 604 (1971)]

1-(Cyclohepta-2',5'-dienyl)but-1-ene, Synthesis of the sex attractant of Ectocarpus siliculosus (SC) 492 [G.E. *83*, 537 (1971)]

Cycloheptatriene, New spironorcaradienes.–Demonstration of a reversible norcaradiene–~ valence-isomerization (SC) 342 [G.E. *83*, 362 (1971)]

Stereochemical investigation of carbanion and carbenoid formation from conformationally rigid ~ derivatives (CR) 357 [G.E. *83*, 336 (1971)]

Two new norcaradiene-~ equilibria (SC) 563 [G.E. *83*, 585 (1971)]

Properties and reactions of stable 7-cycloheptatrienyl carbonium ions (CR) 823 [G.E. *83*, 897 (1971)]

2,4,6-Cycloheptatrien-1-ylmethyl cations, Stable ~ (SC) 269 [G.E. *83*, 289 (1971)]

Cycloheptyne, 3,3,7,7-Tetramethyl-~, an isolable seven-membered carbocyclic alkyne (SC) 509 [G.E. *83*, 540 (1971)]

Cyclohexane, Mechanism of radiolysis of ~ (CR) 420 [G.E. *83*, 411 (1971)]

Cycloisomerization of tetraphosphorus nitride oxide derivatives: octaphenyloxazatetra-P^{V}-phosphocinium salts (SC) 131 [G.E. *83*, 142 (1971)]

Cyclooctatetraenes, Inhibition of bond exchange (SC) 746 [G.E. *83*, 804 (1971)]

Cyclopentadienylboranes (SC) 423 [G.E. *83*, 447 (1971)]

Cyclopentenes, Synthesis of 3,5-disubstituted ~ by ozonolysis of norbornadiene (LA) 203

2-Cyclopenten-1-one, Photodimerization of 3-methyl-~ (LA) 359

1H-Cyclopent[cd]indene, Synthesis of ~ and its anion (SC) 751 [G.E. *83*, 802 (1971)]

Cyclophane, An organosilicon ~ (LA) 203

Recent studies on [m,n]-~-s (LA) 758

Cyclopropane, Biosynthesis of ~ rings (LA) 758

Cyclopropane derivatives, Alkyl/halogen substitution in carbenes (carbenoids): A route to new ~ (SC) 138 [G.E. *83*, 150 (1971)]

Cyclopropanimines, a novel variant of the Favorskii reaction (SC) 651 [G.E. *83*, 728 (1971)]

Cytidines, Simple new synthesis (SC) 657 [G.E. *83*, 729 (1971)]

Synthesis of lumazine and isopterin N-1-β-D-ribofuranosides and -(2-deoxyribofuranosides) – structural analogs of uridine, cytidine, and thymidine (SC) 932 [G.E. *83*, 975 (1971)]

DECARBONYLATION, Noncheletropic photo-~ of 1,3-diphenyl-substituted 2-indanone derivatives (SC) 198 [G.E. *83*, 210 (1971)]

Decomposition reactions, Electron-induced topotactic ~ (LA) 282

Dehalogenation of α-haloketones via α-oxocarbonium ions to stable oxonium salts (SC) 327 [G.E. *83*, 327 (1971)]

Dehydrobenzene, Simple one-step conversion of aniline into ~ (LA) 203

Deoxygenation of oxaziranes by sulfur-containing nucleophiles (SC) 327 [G.E. *83*, 355 (1971)]

Desorption spectra in the adsorption system iron/nitrogen (SC) 562 [G.E. *83*, 584 (1971)]

Deuterium, Kinetic data for abstraction of hydrogen and ~ by methyl and trifluoromethyl radicals in the gaseous phase (LA) 757

Dewar-benzene, Direct transformation of the second excited singlet state of benzene into ~ (SC) 745 [G.E. *83*, 803 (1971)]

New route to ~-s (SC) 811 [G.E. *83*, 887 (1971)]

Diamond-type lattice, Preparation of larger sections (LA) 282

Diarylamine radical cations (SC) 71 [G.E. *83*, 48 (1971)]

2,3-Diazabicyclo[2.2.1]hept-2-ene, Coordination compounds of ~ (LA) 284

Diazenes, Monosubstituted ~ (diimides) (LA) 758

Diazomethane, Reaction with diphenylcyclobutenedione (SC) 736 [G.E. *83*, 764 (1971)]

Diazonium salts, Synthesis and properties of ethylene-~ (CR) 821 [G.E. *83*, 895 (1971)]

α-Diazosulfones, Electrophilic alkylation with enamines (SC) 271 [G.E. *83*, 290 (1971)]

Dibenzo[c,e]cyclononene, Anions (LA) 80

Diborane, Cleavage of ~-(6) by alkali metal sulfides and polysulfides (CR) 827 [G.E. *83*, 900 (1971)]

Di-tert-butylnitroxide, ESR spectrum (LA) 81

Dicarbonyl compounds, Interaction between the orbitals of lone pair electrons in ~ (SC) 401 [G.E. *83*, 405 (1971)]

Dichloroacetylene, Safe synthesis (LA) 80

Dichloromethyladamantanes (LA) 203

Dichloromethylenedimethylammonium chloride, ("Phosgene immonium chloride"): A versatile immonium salt (SC) 573 [G.E. *83*, 614 (1971)]

Condensation with N,N-dialkylcarboxamides (SC) 574 [G.E. *83*, 615 (1971)]

Reaction with carbonyl-activated methylene groups (SC) 575 [G.E. *83*, 616 (1971)]

N,N-Dichlorophosphoramidate, Dimethyl-~ – a warning (SC) 491 [G.E. *83*, 537 (1971)]

Dichlorovinylene carbonate, Preparation and examples of use in organic synthesis (CR) 942 [G.E. *83*, 987 (1971)]

Dictionary of chemistry and chemical engineering (Book Review) 947

Dienes, [1,3]-Anionic cycloaddition with 2-azaallyllithium compounds (SC) 739 [G.E. *83*, 794 (1971)]

Novel stereoselective synthesis of 1,3-~ from terminal alkynes (LA) 203

Synthesis of 1,5-~ and 1,5- and 1,6-cyclodeca-~ (LA) 758

Dienophilic activity, Influence of chlorine attached to the double bond of unsaturated five-membered ring carbonates and anhydrides on ~ (CR) 356 [G.E. *83*, 335 (1971)]

Diferratricyclododecatriene: An iron heterocycle showing rapid degenerate valence isomerization (SC) 560 [G.E. *83*, 583 (1971)]

1,4-Dihydropyrazine, 1,4-Bis(trimethylsilyl)-~ by reductive silylation of pyrazine (SC) 127 [G.E. *83*, 145 (1971)]

Dihydropyridine, Addition of acrylonitrile to derivatives of 1,4-~ (SC) 733 [G.E. *83*, 758 (1971)]

4,5-Dihydrothiepin 1,1-dioxide (LA) 81

Diimides, Monosubstituted diazenes (~) (LA) 758

Diimine, Bis(trimethylsilyl)-~: Preparation, structure, and reactivity (FP) 374 [G.E. *83*, 379 (1971)]

Diketone, Bond character of β-~ metal chelates (FP) 225 [G.E. *83*, 239 (1971)]

Oxidation products of bisacylhydrazones of α,β-~-s (SC) 129 [G.E. *83*, 115 (1971)]

β-Diketone metal chelates, Bond character (FP) 225 [G.E. *83*, 239 (1971)]

Dimethyl(methylene)ammonium iodide (SC) 330 [G.E. *83*, 355 (1971)]

1,2-Dinitriles, Preparation from furazanes (LA) 79

Diphenylaminyl (SC) 71 [G.E. *83*, 47 (1971)]

Dioxetanes, Formation of stable bicyclic ~ (LA) 428

9,10-Diphenylanthracene, Sensitized chemiluminescence on thermolysis of phthaloyl peroxide in presence of ~ (SC) 67 [G.E. *83*, 43 (1971)]

Dipoles, Detection in cycloadditions to allenes (SC) 70 [G.E. *83*, 46 (1971)]

Dipole moments of diatomic IV/VI molecules (LA) 79

Disilane pyrolysis, Kinetics (LA) 358

Disinfection (Book Review) 145

Distillation, Analytical determination of phase equilibration behavior of multicomponent systems in columns (CR) 831 [G. E. *83*, 905 (1971)]

1,3-Dithiolane-2,4-diones (SC) 726 [G.E. *83*, 793 (1971)]

Dithiophosphinic acids, Synthesis by nucleophilic fission of perthiophosphonic anhydrides (SC) 508 [G.E. *83*, 544 (1971)]

Dithiosylates (LA) 583

Divinylbenzene polymers, Reactivity of pendant vinyl groups in crosslinked ~ and styrene-divinylbenzene copolymers (CR) 351 [G.E. *83*, 369 (1971)]

cis-1,2-Divinylcyclobutanes, Stereoelectronically controlled reductive ring cleavage (SC) 132 [G.E. *83*, 144 (1971)]

Dosimetry, Festkörperdosimetrie ionisierender Strahlung (Book Review) 434

Double resonance, Methods and applications of nuclear magnetic ~ (FP) 472 [G.E. *83*, 470 (1971)]

Drosophila, Some aspects of chemical mutagenesis in man and in ~ (FP) 302 [G.E. *83*, 301 (1971)]

Structure of the red eye pigments of the fruit fly ~ melanogaster (SC) 414 [G.E. *83*, 440 (1971)]

Drugs, The importance of physico-chemical parameters to the understanding of drug action and to the rational development of new ~ (CR) 857 [G.E. *83*, 932 (1971)]

Dyes, Trimethylsilyl- and triphenylsilyl-substituted ~ (CR) 280 [G.E. *83*, 258 (1971)]

Chemistry of reactive ~ (CR) 580 [G.E. *83*, 624 (1971)]

Novel trinuclear polymethinecyanine and polymethinemerocyanine ~ (CR) 851 [G.E. *83*, 926 (1971)]

EINSTEIN, Albert ~/Arnold Sommerfeld: Briefwechsel (Book Review) 83

Electrical conductors, Gaseous mixtures of $AlCl_3/Al_2Cl_6$ and $NaAlCl_4$ are ~ (LA) 582

Electrochemical reactions, Adsorption of oxygen on gold and its effect on the kinetics of ~ (CR) 79 [G.E. *83*, 49 (1971)]

Electrochemistry, N-Alkylimino acid anhydrides as intermediates in anodic oxidation of aliphatic carboxylic acids in acetonitrile (SC) 557 [G.E. *83*, 579 (1971)]

Possible reactions in organic ~ (CR) 820 [G.E. *83*, 893 (1971)]

Possibilities in preparative organometallic ~ (CR) 843 [G.E. *83*, 917 (1971)]

Electrocyclic reactions, ~ of radicals (SC) 911 [G.E. *83*, 978 (1971)]

Electrocyclic transformation of cyclopropyl radical into allyl radical: a semiempirical SCF MO study (SC) 912 [G.E. *83*, 979 (1971)]

Electrolytic reduction of higher metal halides in methanol (SC) 421 [G.E. *83*, 412 (1971)]

Electrons, Interaction between the orbitals of lone pair ~ in dicarbonyl compounds (SC) 401 [G.E. *83*, 405 (1971)]

Solvated ~ in liquid and solid solutions (CR) 578 [G.E. *83*, 590 (1971)]

Electron affinities, New versatile method for the evaluation of ~ of molecules (LA) 358

Electron capture cross sections, Measurement of ~ (CR) 856 [G.E. *83*, 931 (1971)]

Electronic absorption spectroscopy, Introduction to ~ (Book Review) 590

Electron spectrometer, Imaging and analysis of surfaces with a scanning electron microscope and ~ (FP) 591 [G.E. *83*, 632 (1971)]

Electron spectroscopy, Electron spectroscopic studies of adsorbents and catalysts (CR) 860 [G.E. *83*, 935 (1971)]

Elemental analysis, Problems in determination of very small amounts of elements (CR) 661 [G.E. *83*, 733 (1971)]

Chemische Elementaranalyse mit kleinsten Proben (Book Review) 585

Elimination, The mechanism of contact ~, a contribution to understanding the function of polar catalysts (FP) 172 [G.E. *83*, 185 (1971)]

Increase in selectivity of photo-~ products on replacing the liquid phase by the crystalline phase (SC) 199 [G.E. *83*, 212 (1971)]

~ reactions of trichlorobutyl acetates (SC) 731 [G.E. *83*, 757 (1971)]

Preferred syn-~ from trans-1,2-dichloro- and trans-1,2-dibromocyclodecane (SC) 926 [G.E. *83*, 1012 (1971)]

Embrittlement of steel by hydrogen absorption (LA) 358

Emulsion polymerization, Continuous ~ (CR) 201 [G.E. *83*, 151 (1971)]

Enamines, Electrophilic alkylation of α-diazosulfones with ~ (SC) 271 [G.E. *83*, 290 (1971)]

Enantioselective hydrogenations, Methods of asymmetric synthesis—catalytic ~ (FP) 871 [G.E. *83*, 956 (1971)]

Energy reserves, Nuclear ~ and long-term energy requirements (FP) 1 [G.E. *83*, 1 (1971)]

Energy surface for acetolysis via C_8H_9 cations from exo-tetracyclo[3.3.0.0^{2,8}.0^{4,6}]-oct-3-yl p-nitrobenzoate (SC) 559 [G.E. *83*, 581 (1971)]

Entropy bonding, 1,3,5-Benzenetriyltris[di-(p-biphenyl)methyl], a radical having a quartet ground state that dimerizes by ~ (SC) 938 [G.E. *83*, 1015 (1971)]

Enzymatic analysis, Methoden der enzymatischen Analyse (Book Review) 947

Enzyme, The anomalous temperature dependence of ~-catalyzed reactions (FP) 548 [G.E. *83*, 553 (1971)]

Paramagnetic probes for NMR relaxation studies of phosphoryl transfer ~-s (LA) 758

Enzyme electrodes, Improved specific ~ for urea and amino acids (LA) 143

Epoxides, Solvolysis of poly-~ of unbranched polybutadienes (CR) 824 [G.E. *83*, 898 (1971)]

Hydroxyalkylation of dialkylamides of carboxylic acids with ~ (CR) 859 [G.E. *83*, 934 (1971)]

Erythrina alkaloids, Model reactions for biosynthesis of ~ (SC) 411 [G.E. *83*, 409 (1971)]

Erythrocuprein (CR) 864 [G.E. *83*, 939 (1971)]

ESR spectroscopy, ESR investigations of an oscillating redox system (SC) 192 [G.E. *83*, 208 (1971)]

ESR study of the oxidation of triethyl phosphite by tert-butoxy radicals (SC) 738 [G.E. *83*, 800 (1971)]

ESR spectrum of di-tert-butylnitroxide (LA) 81

Ethane, Homolysis of the ~ C-C bond: detection of tris(phenylthio)methyl by ^{13}C-labeling (SC) 500 [G.E. *83*, 534 (1971)]

Ethylene, Vanadium and chromium catalysts for polymerization of ~ (FP) 776 [G.E. *83*, 782 (1971)]

~ oligomerization (CR) 348 [G.E. *83*, 370 (1971)]

Ethylene-propylene copolymers, Determination of sequence length distributions from the pyrolysis of labeled and unlabeled ~ (CR) 346 [G.E. *83*, 372 (1971)]

N-Ethynylcarbazole, Synthesis and properties of ~ and poly-~ (LA) 203

Europium compounds, Crystal structure of $EuBr_2$ (CR) 820 [G.E. *83*, 893 (1971)]

Exchange processes, Nomenclature for intramolecular ~ (SC) 570 [G.E. *83*, 618 (1971)]

Extraction of transplutonium elements by alkylammonium salts (CR) 580 [G.E. *83*, 625 (1971)]

Extraction chromatography, Gram-scale purification of ^{244}Cm by ~ (SC) 727 [G.E. *83*, 766 (1971)]

Eye pigments, Structure of the red ~ of the fruit fly Drosophila melanogaster (SC) 414 [G.E. *83*, 440 (1971)]

FARADAY effect, Brief review of new applications in chemistry (LA) 868

Fats, Influence of microorganisms on oxidative deterioration (CR) 831 [G.E. *83*, 905 (1971)]

Fatty acids, Formation of hydrocarbons on heating of saturated ~ and their methyl esters (CR) 839 [G.E. *83*, 913 (1971)]

Favorskii reaction, Cyclopropanimines, a novel variants of the ~ (SC) 651 [G.E. *83*, 728 (1971)]

Ferrate(VI) ion, Use as a new selective oxidizing agent (LA) 427

α-Ferrocenylethyl acetate, Retentive nucleophilic substitution of (R)-~ (SC) 191 [G.E. *83*, 178 (1971)]

Ferrocenylmethyl cation, Structure (CR) 830 [G.E. *83*, 903 (1971)]

Fibrinolysis, Blood coagulation and ~ (FP) 85 [G.E. *83*, 89 (1971)]

Films, Migration of additives from plastic ~ into edible fats and fat simulants (CR) 827 [G.E. *83*, 901 (1971)]

Flavin, Novel photoalkylation reactions on the ~ nucleus (SC) 804 [G.E. *83*, 854 (1971)]

Flavocoenzymes, New ~ (CR) 833 [G.E. *83*, 907 (1971)]

Flavonols, Transformation by an enzyme from Cicer arietinum (CR) 819 [G.E. *83*, 893 (1971)]

Flow behavior, Relations between the structural elements and ~ of polymers and their solutions (SC) 425 [G.E. *83*, 449 (1971)]

Fluctuating bonds, Molecules with ~ (LA) 582

Fluorenone, Rearrangement induced by nucleophilic addition of an α-halo organometallic compound (CR) 834 [G.E. *83*, 908 (1971)]

Fluorescence analysis (Book Review) 946

Fluorides, Structure of ternary copper(II) and chromium(II)~ (SC) 413 [G.E. *83*, 440 (1971)]

N-(Nitridofluorosulfur)sulfur imide difluoride (SC) 815 [G.E. *83*, 890 (1971)]

Novel ~ of divalent palladium (LA) 584

Fluorination, Direct liquid-phase ~ of organic compounds (LA) 756

Fluorine, Production of ~ atoms, H atoms, and OF radicals (SC) 564 [G.E. *83*, 586 (1971)]

Fluorine compounds, Reactions of disulfur difluoride with fluorosulfonic acid, oleum, boron trifluoride, and arsenic pentafluoride (SC) 186 [G.E. *83*, 173 (1971)]

Si-Fluorinated carbosilanes (SC) 510 [G.E. *83*, 500 (1971)]

Fluorinated allenes (LA) 80

Flouro complexes, Simple synthesis of hexaflouro complexes of osmium(IV), iridium(IV), and platinum(IV) (SC) 936 [G.E. *83*, 1019 (1971)]

Fluorosteroids, Synthesis, chemistry, and biological properties of some novel hormonal ~ (CR) 140 [G.E. *83*, 116 (1971)]

N-Fluorosulfonyldichloroamine (SC) 265 [G.E. *83*, 252 (1971)]

Foods, New impetus for food research under the auspices of the Federal Ministry for Food, Agriculture, and Forestry (BML) (CR) 841 [G.E. *83*, 916 (1971)]

Importance of microorganisms in the production of ~ (CR) 851 [G.E. *83*, 925 (1971)]

Microbiological problems of the preservation of foodstuffs (CR) 855 [G.E. *83*, 930 (1971)]

Information and documentation in food science (CR) 859 [G.E. *83*, 934 (1971)]

Formamide, Pyrimidines from N,N-unsubstituted β-enamino carbonyl compounds and ~ (SC) 268 [G.E. *83*, 287 (1971)]

Fossils, Biogenic substances in sediments and ~ (FP) 209 [G.E. *83*, 221 (1971)]

Free-radical polymerizations, Stereochemical control (CR) 347 [G.E. *83*, 374 (1971)]

Fuel cells, Tungsten carbide as anode material (SC) 194 [G.E. *83*, 213 (1971)]

Fulminates, Oxidative addition of nitroalkanes to tetrakis(triphenylphosphane)-platinum(0): a simple route to complex metal ~ (SC) 66 [G.E. *83*, 43 (1971)]

Furazanes, Preparation of 1,2-dinitriles from ~ (LA) 79

GALLIUM arsenide whisker growth by the VLS mechanism (CR) 847 [G.E. *83*, 922 (1971)]

Garosamine, Configuration of ~, a branched chain amino sugar (SC) 660 [G.E. *83*, 729 (1971)]

Gas contents of salts from the Upper Permian formation (LA) 82

Gas chromatography, Maximum column inlet pressure – an optimum parameter for ~ separations (CR) 852 [G.E. *83*, 926 (1971)]

Gas-chromatographic determination of arsenic (CR) 853 [G.E. *83*, 928 (1971)]

Use of polymers as packing in ~ (CR) 856 [G.E. *83*, 930 (1971)]

~, principles, techniques and applications (Book Review) 586

Gas mixtures, IR analysis (LA) 525

Gear effect, Reactivity and conformation in the heterocyclic series. – The ~ (CR) 815 [G.E. *83*, 808 (1971)]

Genetic information, Translation on the ribosome (FP) 638 [G.E. *83*, 645 (1971)]

Germacycloalkanols and 1-germylallyl alcohols (SC) 267 [G.E. *83*, 286 (1971)]

Germanes, Reactions of silicon difluoride with silanes and ~ (LA) 284

Germanium compounds, Crystalline π-radicals containing ~ (SC) 499 [G.E. *83*, 538 (1971)]

1-Germylallyl alcohols and germacycloalkanols (SC) 267 [G.E. *83*, 286 (1971)]

Gesellschaft Deutscher Chemiker, General meeting (CR) 818 [G.E. *83*, 891 (1971)]

Glasses, New routes to multicomponent oxide ~ (FP) 363 [G.E. *83*, 428 (1971)]

Preparation of multicomponent oxide glasses by polycondensation (CR) 825 [G.E. *83*, 898 (1971)]

Glow discharges, Organic reactions in the plasma of ~ (SC) 422 [G.E. *83*, 413 (1971)]

α-Glucosidase, 4-Bromo-5-cyclohexene-1,2,3-triol as a specific inactivator for the ~-s of yeast (Saccharomyces cerevisiae) (CR) 843 [G.E. *83*, 917 (1971)]

D-Glucuronic acid, Formation of aromatic compounds from ~ and D-xylose (LA) 142

Glutaraldehyde, New reaction products from ~, hydroxylamine, and alcohols (CR) 848 [G.E. *83*, 922 (1971)]

Glycogen phosphorylase, Dual role of pyridoxal 5'-phosphate as chemical and conformation-determining active group in ~ (CR) 519 [G.E. *83*, 505 (1971)]

Gold, Adsorption of oxygen on ~ and its effect on the kinetics of electrochemical reactions (CR) 79 [G.E. *83*, 49 (1971)]

Gougerotin, Synthesis of a biologically active ~ analog (SC) 334 [G.E. *83*, 331 (1971)]

Grafting Detection of ~ and crosslinking of the elastomer phase in two-phase systems (CR) 345 [G.E. *83*, 369 (1971)]

Grignard compounds, Inversion of secondary cyclic ~ (SC) 270 [G.E. *83*, 288 (1971)]

Chemistry of allyl and crotyl ~ (LA) 868

Guanosine, Synthesis of isoxanthopterin N-8-β-D-ribofuranoside — a structural analog of ~ (SC) 930 [G.E. *83*, 972 (1971)]

HALIDES, Electrolytic reduction of higher metal ~ in methanol (SC) 421 [G.E. *83*, 412 (1971)]

Halide hydrates, Alkaline earth metal ~: use of IR spectra for phase analysis and determination of possible structural types (SC) 183 [G.E. *83*, 170 (1971)]

Haloamines, Synthesis and structure (CR) 755 [G.E. *83*, 767 (1971)]

Halogens, Reactions of atoms (FP) 604 [G.E. *83*, 561 (1971)]

α-Haloketones, Dehalogenation via α-oxocarbonium ions to stable oxonium salts (SC) 327 [G.E. *83*, 327 (1971)]

Handbook, Taschenbuch für Chemiker und Physiker (Book Review) 83

~of chemistry and physics (Book Review) 83

Gmelins Handbuch der anorganischen Chemie (Book Review) 204

Helix-coil transition, Dielectric measurements for the determination of aggregation and ~ in polybenzyl-L-aspartate and poly-DL-phenylalanine (CR) 352 [G.E. *83*, 367 (1971)]

Hemoglobin, Present position of ~ research (FP) 663 [G.E. *83*, 735 (1971)]

Hetarynes, Progress in the hetaryne field (FP) 20 [G.E. *83*, 21 (1971)]

Heterocycles, New synthesis by means of isocyanides (SC) 424 [G.E. *83*, 448 (1971)]

~from C_3 systems and sulfur (CR) 278 [G.E. *83*, 216 (1971)]

Synthesis of heterocyclic quinones (LA) 944

Heterocyclic steroids, Approaches to total synthesis (FP) 450 [G.E. *83*, 511 (1971)]

Heterocyclic systems, Valence isomerism in selected ~ (FP) 11 [G.E. *83*, 11 (1971)]

Hexacyclodecane, Hexacyclo[4.4.0.$0^{2,4}$.$0^{3,9}$.$0^{5,7}$.$0^{8,10}$]decane, a bridged cis-trishomobenzene (SC) 417 [G.E. *83*, 404 (1971)]

Hexadecylketene, Attempts to detect monomeric ~ on thermal decomposition of isopropenyl stearate (CR) 859 [G.E. *83*, 934 (1971)]

1,5-Hexadiene, Cycloalkylation of phenol with ~ (LA) 429

2,4-Hexadiynediol, Crystal structure (SC) 940 [G.E. *83*, 1024 (1971)]

2,4-Hexadiynylenebis(phenylurethane), Structure of polymeric ~ (SC) 266 [G.E. *83*, 253 (1971)]

Hexahalorhenates, Mechanism of solid-state reactions in ~ (CR) 852 [G.E. *83*, 927 (1971)]

Hexathia[3.3]cyclophanes, Synthesis of bis-(chlorodisulfanyl)benzenes and ~ (SC) 413 [G.E. *83*, 439 (1971)]

Homologation of cyclic ketones by isocyanomethyllithium (SC) 491 [G.E. *83*, 490 (1971)]

2,3-Homopyrrole, Synthesis and thermolysis of N-methoxycarbonyl-~ (SC) 135 [G.E. *83*, 147 (1971)]

Cycloadditions of N-methoxycarbonyl-~ (SC) 135 [G.E. *83*, 148 (1971)]

Hydration, The ~ kinetics of 2-methylbutyraldehyde (SC) 72 [G.E. *83*, 80 (1971)]

Product ratios on gas-phase ~ of propene (SC) 335 [G.E. *83*, 332 (1971)]

Hydrazines, Restricted rotation in N-silylated ~ (SC) 343 [G.E. *83*, 364 (1971)]

Hydrosilylation of a N=N double bond (SC) 408 [G.E. *83*, 437 (1971)]

Hydrazine derivatives, Preparation of some ~ containing nitrogen-sulfur bonds (SC) 407 [G.E. *83*, 437 (1971)]

Hydrazones, The oxidation products of bisacyl-~ of α,β-diketones (SC) 129 [G.E. *83*, 115 (1971)]

Hydroazulenes, A new synthesis (LA) 143

Hydrocarbon, The energetic positions of the lowest singlet and triplet state of the Schlenk and of the Müller ~ (SC) 506 [G.E. *83*, 498 (1971)]

Methoden der Organischen Chemie (Book Review) 433

Hydrogen, Reactions of atoms (FP) 604 [G.E. *83*, 561 (1971)]

Production of F atoms, ~ atoms, and OF radicals (SC) 564 [G.E. *83*, 586 (1971)]

Steel embrittlement by ~ absorption (LA) 358

Kinetic data for abstraction of ~ and deuterium by methyl and trifluoromethyl radicals in the gaseous phase (LA) 757

Hydrogenation, Methods of asymmetric synthesis — enantioselective catalytic ~ (FP) 871 [G.E. *83*, 956 (1971)]

Hydrogen atoms in UV irradiated acid aqueous solutions of indole and 3-β-hydroxyethylindole (LA) 358

Hydrogen bond, 50 Years of ~ theory (FP) 147 [G.E. *83*, 163 (1971)]

Hydrogen bridges with nitrogen as donor and acceptor (SC) 426 [G.E. *83*, 449 (1971)]

Hydrogendicarboxylate ions as hydrogen-bonded chelate systems in organoantimony compounds (SC) 136 [G.E. *83*, 149 (1971)]

Hydrogen halides, Adsorption on alkali-metal halides (LA) 283

Hydrogen labeling, Procedure for stereospecific ~ of prochiral centers on a preparative scale (CR) 831 [G.E. *83*, 905 (1971)]

Hydrogen shift, A photochemical sigmatropic 1,7-~ in a semicyclic triene (LA) 142

Skeletal rearrangement with participation of 1,5-sigmatropic ~ (LA) 282

Hydroperoxides, Base-catalyzed reaction of organic ~ with electron-poor olefins (CR) 840 [G.E. *83*, 915 (1971)]

Hydroquinones, Oxidative amination (SC) 405 [G.E. *83*, 441 (1971)]

Redox behavior of insoluble quinone/~ (SC) 514 [G.E. *83*, 502 (1971)]

Hydrosilylation of a N=N double bond (SC) 408 [G.E. *83*, 437 (1971)]

Hydroxy functions, The 9-anthroxy group is suitable for protection of ~ (LA) 81

3-Hydroxyhydantoins, a new class of cyclic diacylated hydroxylamines (LA) 202

Hypophosphorous acid, Esters (LA) 428

IMIDES, N-(Nitridofluorosulfur)sulfur imide difluoride (SC) 815 [G.E. *83*, 890 (1971)]

Imidic esters, 1,3-Dipolar cycloaddition of nitrile oxides to cyclic ~ and amidines (SC) 810 [G.E. *83*, 882 (1971)]

Imine-enamine tautomerism, Relation to structure (CR) 818 [G.E. *83*, 891 (1971)]

Imino acid anhydrides, N-Alkyl-~ as intermediates in anodic oxidation of aliphatic carboxylic acids in acetonitrile (SC) 557 [G.E. *83*, 579 (1971)]

Iminophosphorane, A novel rearrangement around the (P=N) double bond (SC) 344 [G.E. *83*, 365 (1971)]

Iminosulfur oxydifluorides, New method of preparing ~ (SC) 419 [G.E. *83*, 443 (1971)]

Immonium salts, Dichloromethylenedimethylammonium chloride ("phosgene immonium chloride"): A versatile immonium salt (SC) 573 [G.E. *83*, 614 (1971)]

Condensation of dichloromethylenedimethylammonium chloride ("phosgene immonium chloride") with N,N-dialkylcarboxamides (SC) 574 [G.E. *83*, 615 (1971)]

Reaction of dichloromethylenedimethylammonium chloride ("phosgene immonium chloride") with carbonyl-activated methylene groups (SC) 575 [G.E. *83*, 616 (1971)]

Immune diffusion, Detection of staphylococcus enterotoxins with the aid of a new "micro-slide kit" for ~ (CR) 842 [G.E. *83*, 917 (1971)]

Indan, Synthesis of indanyl derivatives from linear unsaturated compounds (CR) 853 [G.E. *83*, 928 (1971)]

1,5-Indandiones, New type of asymmetric cyclization to optically active steroid CD partial structures (SC) 496 [G.E. *83*, 492 (1971)]

2-Indanone, Non-cheletropic photodecarbonylation of 1,3-diphenyl-substituted ~ derivatives (SC) 198 [G.E. *83*, 210 (1971)]

Increase in selectivity of photoelimination products on replacing the liquid phase by the crystalline phase (SC) 199 [G.E. *83*, 212 (1971)]

Indigo, 4,4,4',4'-Tetramethyl-$\Delta^{2,2'}$-bipyrrolidine-3,3'-dione, a compound having the basic chromophore system of ~ (SC) 803 [G.E. *83*, 853 (1971)]

Biological precursors and genesis of Tyrian-purple (CR) 816 [G.E. *83*, 856 (1971)]

Indole, Hydrogen atoms in UV irradiated acid aqueous solutions of ~ and 3-β-hydroxyethyl-~ (LA) 358

The chemistry of ~-s (Book Review) 361

Indole alkaloids, Comparative pharmacology of ~ and their derivatives (LA) 758

Industry, Mensch und Arbeit im Chemiebetrieb (Book Review) 82

Inert gases, Separation of fission ~ from combustion waste gases from high temperature fuel elements by washing with liquid carbon dioxide (CR) 843 [G.E. *83*, 917 (1971)]

Infrared spectroscopy (Book Review) 434

Inorganic chemistry, Lehrbuch der anorganischen Chemie (Book Review) 146

Inorganic compounds, The synthesis and characterization of ~ (Book Review) 205

Inorganic ring systems, The chemistry of ~, Parts 1 and 2 (Book Review) 285

Insect herbicide, Myrmicacin, the first ~ (SC) 124 [G.E. *83*, 110 (1971)]

Instrumental analysis, Undergraduate ~ (Book Review) 525

Intermolecular interactions in the crystal structure of the hydrogen-bond-free barbiturate sodium metharbital (SC) 814 [G.E. *83*, 889 (1971)]

Intermolecular potentials, Improved determinations (SC) 426 [G.E. *83*, 450 (1971)]

Intramolecular interactions between parallel triple bonds (LA) 524

Inversion of secondary cyclic Grignard compounds (SC) 270 [G.E. *83*, 288 (1971)]

Iodine compounds, ^{127}I Mössbauer spectra of aromatic compounds with polyvalent iodine (LA) 283

Ions, Spectra of simple molecular ~ in the gaseous phase (LA) 759

Ion energies, Table of ~ for metastable transitions in mass spectrometry (Book Review) 145

Ionization constants of water in mixtures with organic solvents (LA) 144

Ionizing radiation, Festkörperdosimetrie ionisierender Strahlung (Book Review) 434

Ion-pair formation – sources of error in the determination of equilibrium constants in aqueous solution (CR) 832 [G.E. *83*, 906 (1971)]

Iridium complexes, Molecular perchlorato complexes of iridium(I), rhodium(I), and cobalt(I) (SC) 511 [G.E. *83*, 497 (1971)]

Synthesis of octakis(trifluorophosphane)-diiridium (SC) 725 [G.E. *83*, 725 (1971)]

Simple synthesis of hexafluoro complexes of osmium(IV), iridium(IV), and platinum(IV) (SC) 936 [G.E. *83*, 1019 (1971)]

Incorporation of S_2 and Se_2 units into rhodium complexes and ~ (LA) 428

Iron, Desorption spectra in the adsorption system ~/nitrogen (SC) 562 [G.E. *83*, 584 (1971)]

Iron complexes, Complex bonding of a vinylcyclopropane group of bullvalene to a transition metal via a π-allyl and a σ-component (SC) 188 [G.E. *83*, 175 (1971)]

A stable bis(tricarbonyliron) complex of tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene and its dynamic behavior in solution (SC) 189 [G.E. *83*, 176 (1971)]

Isobullvalenebis(tricarbonyliron) (SC) 190 [G.E. *83*, 177 (1971)]

Iron compounds, Photochemical synthesis of bis(1,3-diene)monocarbonyl-~ (SC) 260 [G.E. *83*, 249 (1971)]

Molecular and crystal structure of bis(1,3-cyclohexadiene)monocarbonyliron (SC) 261 [G.E. *83*, 250 (1971)]

Diferratricyclododecatriene: an iron heterocycle showing rapid degenerate valence isomerization (SC) 560 [G.E. *83*, 583 (1971)]

Fixation of trimethylsilylnitrene as μ_3-trimethylsilylimido(decacarbonyltriiron) (SC) 910 [G.E. *83*, 968 (1971)]

μ_3-Trimethylsilylimido-μ_3-carbonyltris-(tricarbonyliron) — crystal and molecular structure (SC) 910 [G.E. *83*, 969 (1971)]

Benzyloxydivinylboranetricarbonyliron — a divinylborane complex containing a boron-iron linkage (SC) 937 [G.E. *83*, 1020 (1971)]

Photochemical synthesis and transformation of olefin-carbonyl-~ (CR) 839 [G.E. *83*, 914 (1971)]

IR spectroscopy, Alkaline earth metal halide hydrates: use of ~ for phase analysis and determination of possible structural types (SC) 183 [G.E. *83*, 170 (1971)]

Analysis of gas mixtures (LA) 525

Isobullvalene bis(tricarbonyliron) (SC) 190 [G.E. *83*, 177 (1971)]

Isocitrate dehydrogenase, Dependence of the enzyme mechanism on allosteric effectors in the case of ~ (CR) 848 [G.E. *83*, 923 (1971)]

Isocyanates, Synthesis and chemistry of N-chlorocarbonyl isocyanate (CR) 832 [G.E. *83*, 906 (1971)]

Isocyanato compounds, Pyridine, pyrimidine, and pyrazine derivatives with an isocyanato substituent vicinal to nitrogen (SC) 402 [G.E. *83*, 406 (1971)]

Isocyanatoquinones (SC) 403 [G.E. *83*, 408 (1971)]

Isocyanato-s-triazines (SC) 403 [G.E. *83*, 407 (1971)]

Isocyanides, New preparation (SC) 132 [G.E. *83*, 143 (1971)]

2-Unsubstituted oxazoles from α-metalated ~ and acylating agents (SC) 333 [G.E. *83*, 358 (1971)]

[1+2]Cycloadditions to alkynes (SC) 409 [G.E. *83*, 401 (1971)]

New synthesis of heterocycles by means of ~ (SC) 424 [G.E. *83*, 448 (1971)]

Isocyanide complexes of thorium and uranium halides (SC) 274 [G.E. *83*, 294 (1971)]

Isocyanide dichloride, Reactions of trichloromethyl ~ (CR) 828 [G.E. *83*, 902 (1971)]

Isocyanoacetic esters, Higher amino acids by alkylation of α-metalated isocyanopropionic esters or ~ (SC) 331 [G.E. *83*, 357 (1971)]

Isocyanomethyllithium, Homologation of cyclic ketones by ~ (SC) 491 [G.E. *83*, 490 (1971)]

Isocyanopropionic esters, Higher amino acids by alkylation of α-metalated isocyanoacetic esters or ~ (SC) 331 [G.E. *83*, 357 (1971)]

Isomerization, Photochemical cis-trans ~ of n-octenes in presence of organoaluminum compounds (CR) 281 [G.E. *83*, 296 (1971)]

Photochemical cis-trans ~ of n-octenes in the presence of organoaluminum compounds (CR) 863 [G.E. *83*, 938 (1971)]

Isopterin, Synthesis of lumazine and ~ N-1-β-D-ribofuranosides and -(2-deoxyribofuranosides) — structural analogs of uridine, cytidine, and thymidine (SC) 932 [G.E. *83*, 975 (1971)]

Isosbestic point, Generalization of the ~ (SC) 195 [G.E. *83*, 214 (1971)]

(Isothiocyanatoacyl)amino acids, Synthesis (SC) 507 [G.E. *83*, 539 (1971)]

Isotopic effects of calcium in heterogeneous exchange equilibria (CR) 834 [G.E. *83*, 908 (1971)]

Isoxanthopterin, Synthesis of ~ N-8-β-D-ribofuranoside — a structural analog of guanosine (SC) 930 [G.E. *83*, 972 (1971)]

KETENIMINES, Synthesis and reactions (FP) 435 [G.E. *83*, 455 (1971)]

Cycloadditions of ~ to ynamines (SC) 184 [G.E. *83*, 171 (1971)]

Ketones, Homologation of cyclic ~ by isocyanomethyllithium (SC) 491 [G.E. *83*, 490 (1971)]

Reactions of dialkyl ~ with triethylborane (SC) 750 [G.E. *83*, 750 (1971)]

Cyclization of cyanoethylated aliphatic ~ (CR) 823 [G.E. *83*, 896 (1971)]

Methyl and n-alkyl ~ (LA) 144

Synthesis of seven-membered carbocyclic ~ and troponoid compounds (LA) 523

Kinetics, Elements of chemical ~ (Book Review) 760

Kink formation, Experimental evidence for ~ (SC) 558 [G.E. *83*, 580 (1971)]

LABORATORY techniques in biochemistry and molecular biology (Book Review) 585, 586

Lac repressor (FP) 160 [G.E. *83*, 195 (1971)]

α-Lactam, An ~ derived from 2-adamantylamine (SC) 753 [G.E. *83*, 848 (1971)]

Lactam polymerization, Mechanism and application of anionic ~ (CR) 579 [G.E. *83*, 624 (1971)]

Language barrier, Chemistry through the ~ (Book Review) 361

Lattice energies, Modern method for calculation of ~ of salts containing complex ions (LA) 868

Layers, Systems of monomolecular ~: assembling and physico-chemical behavior (FP) 620 [G.E. *83*, 672 (1971)]

Lead compounds, Decomposition of organolead halides $R_{4-n}PbX_n$ and attempts to prepare organolead halides that occur as intermediates (CR) 835 [G.E. *83*, 909 (1971)]

Organolead compounds $(YC_6H_4)_nPbX_{4-n}$ with reactive substituents Y (CR) 842 [G.E. *83*, 916 (1971)]

Learning, Chemistry of ~ (CR) 279 [G.E. *83*, 257 (1971)]

Ligand field spectroscopy, Application to problems of chemical bonding in solids (SC) 901 [G.E. *83*, 991 (1971)]

Lignin, Chemistry of ~-removing bleaching (CR) 522 [G.E. *83*, 548 (1971)]

Lipid metabolism, Comprehensive biochemistry (Book Review) 361

Liquids, Surface tension and compressibility (LA) 79

Lumazine, Synthesis of ~ and isopterin N-1-β-D-ribofuranosides and -(2-deoxyribofuranosides) — structural analogs of uridine, cytidine, and thymidine (SC) 932 [G.E. *83*, 975 (1971)]

MACROMOLECULAR colloquium (CR) 345 [G.E. *83*, 366 (1971)]

Macromolecular materials, Biologische Zerstörung der makromolekularen Werkstoffe (Book Review) 205

Macromolecules, Stereochemistry (CR) 579 [G.E. *83*, 590 (1971)]

Macrozwitterions, Formation in the anionic polymerization of vinyl monomers initiated by tertiary phosphanes (CR) 349 [G.E. *83*, 371 (1971)]

Maleic anhydride, A heavy atom effect in the photoreaction of ~ with acenaphthylene (SC) 272 [G.E. *83*, 291 (1971)]

Binary and ternary copolymerization in the system vinyl chloride-butadiene-~ (CR) 353 [G.E. *83*, 370 (1971)]

Reaction with nitrosocyclohexene (LA) 358

Manganese, Spallogenic $^{53}Mn(T \approx 2 \times 10^6 a)$ and the measurement of a depth effect in a material exposed to cosmic radiation (CR) 834 [G.E. *83*, 908 (1971)]

Manganese compounds, Oxidation of $C_5H_5Mn(CO)_2N_2H_4$ to $C_5H_5Mn(CO)_2N_2$, a new dinitrogen complex (SC) 919 [G.E. *83*, 1017 (1971)]

Tetrakis(pentacarbonylmanganese)uranium (LA) 427

Mass spectra, Influence of the complexed metal ion on the ~ of organic metal complexes (CR) 78 [G.E. *83*, 85 (1971)]

Mass spectrometry, Pyro field ion ~ (PFIMS) for determination of structure and degradation behavior of polymers and copolymers (CR) 349 [G.E. *83*, 372 (1971)]

Table of ion energies for metastable transitions in ~ (Book Review) 145

Tables for use in high-resolution mass spectroscopy (Book Review) 207

Principles (Book Review) 869

Membranes, Biological ~ (FP) 388 [G.E. *83*, 419 (1971)]

Porous plastic foils as functional models of excitable nerve ~ (CR) 420 [G.E. *83*, 410 (1971)]

Mercurinium ions, Stable ~ (LA) 429

Mercury compounds, Tetrakis(methylmercurio)phosphonium salts (CR) 555 [G.E. *83*, 577 (1971)]

Ozonolysis of organic mercurials (LA) 143

Mercury ion, A new ~ (LA) 284

Mesoionic compounds, X-Ray photoelectron spectroscopy of ~ (SC) 569 [G.E. *83*, 588 (1971)]

Metabolism, Acid ~ in grapes (CR) 850 [G.E. *83*, 925 (1971)]

Metal complexes, Influence of the complexed metal ion on the mass spectra of organic ~ (CR) 78 [G.E. *83*, 85 (1971)]

6,11-Methanocyclobutabenzo[1,2-a][10]-annulene, a biphenylene analog containing a carbocyclic 10 π-electron ring (SC) 125 [G.E. *83*, 111 (1971)]

2-Methylbutyraldehyde, Hydration kinetics (SC) 72 [G.E. *83*, 80 (1971)]

Methylchlorocarbene (LA) 203

α-Methylenebutyrolactones, New synthesis (LA) 583

Methylene compounds, Reaction of dichloromethylenedimethylammonium chloride ("phosgene immonium chloride") with carbonyl-activated methylene groups (SC) 575 [G.E. *83*, 616 (1971)]

Michael addition of metalated carboxamides to nitrostyrenes – a simplified route to tryptamines (SC) 501 [G.E. *83*, 542 (1971)]

Microscope, Imaging and analysis of surfaces with a scanning electron ~ and electron spectrometer (FP) 591 [G.E. *83*, 632 (1971)]

Molecular biology, Progress in molecular and subcellular biology (Book Review) 145

Molecules and life, An introduction to ~ (Book Review) 589

Molecular structure, Quantenmechanik und Theorie des Molekülbaues (Book Review) 145

Molecular orbitals, Sequence of highest occupied ~ in the phosphorin system (SC) 656 [G.E. *83*, 723 (1971)]

Molecular weight distribution of n-component copolymers ($n \geq 2$) in "living polymer" systems (CR) 350 [G.E. *83*, 373 (1971)]

Molten salts, at high pressure and high temperatures (CR) 755 [G.E. *83*, 768 (1971)]

~ Characterization and analysis (Book Review) 589

Molybdate ions, Epimerization of carbohydrates catalyzed by ~ (SC) 904 [G.E. *83*, 967 (1971)]

Molybdenum complexes, Organoelement-phosphanepentacarbonylchromium, -molybdenum, and -tungsten complexes (LA) 524

Molybdenum compounds, Anions derived from PH_3 complexes: deprotonation by PH_2^- (SC) 186 [G.E. *83*, 172 (1971)]

P-N cleavage in tris(dimethylamino)-phosphanecarbonyl complexes of molybdenum(0) (SC) 187 [G.E. *83*, 174 (1971)]

Monothioformic acid (SC) 415 [G.E. *83*, 444 (1971)]

Mössbauer spectroscopy, Applications to problems in solid-state chemistry (FP) 716 [G.E. *83*, 746 (1971)]
^{127}I Mössbauer spectra of aromatic compounds with polyvalent iodine (LA) 283
Müller hydrocarbon, The energetic positions of the lowest singlet and triplet state of the Schlenk hydrocarbon and of the ~ (SC) 506 [G.E. *83*, 498 (1971)]
Multiple bonds, Base-catalyzed addition of oxazol-5-ones to activated ~ (SC) 653 [G.E. *83*, 725 (1971)]
Mutagenesis, Some aspects of chemical ~ in man and in Drosophila (FP) 302 [G.E. *83*, 301 (1971)]
Myrmicacin, the first insect herbicide (SC) 124 [G.E. *83*, 110 (1971)]

1,6-NAPHTHALENEDIONES, New type of asymmetric cyclization to optically active steroid CD partial structures (SC) 496 [G.E. *83*, 492 (1971)]
1,2-Naphthalene oxide, Optically active ~ (LA) 80
Naphthoquinone, Formation and properties of 2,3-bis(1,4-~-2-yl)butanes (CR) 859 [G.E. *83*, 934 (1971)]
Narcotic, Nutmeg as a ~ (FP) 370 [G.E. *83*, 392 (1971)]
Natural products, Synthesis of naturally occurring polypeptides, problems of current research (FP) 786 [G.E. *83*, 773 (1971)]
Nematic phases, New, nonplanar trans-stilbenes exhibiting ~ at room temperature (SC) 410 [G.E. *83*, 399 (1971)]
Neptunium compounds, Measurements of the Mössbauer effect in ~ (CR) 829 [G.E. *83*, 902 (1971)]
Nerve membranes, Porous plastic foils as functional models of excitable ~ (CR) 420 [G.E. *83*, 410 (1971)]
Nervous system, Biochemistry and function of biogenic amines in the central ~ (FP) 51 [G.E. *83*, 53 (1971)]
Neurosciences, The ~: second study program (Book Review) 588
Neutron spectra in the decay of some fission products (CR) 829 [G.E. *83*, 902 (1971)]
Nickel, Analysis of mixtures of metallic ~ and oxide hydrates of bivalent and higher-valency ~ (CR) 830 [G.E. *83*, 903 (1971)]
Nickel complexes, Bis(tri-2-biphenylphosphite)nickel (SC) 77 [G.E. *83*, 84 (1971)]
Bis(olefin)nickel(0) complexes (SC) 328 [G.E. *83*, 328 (1971)]
Molecular and crystal structures of some Ni(0) complexes (CR) 841 [G.E. *83*, 915 (1971)]
Account of the stereochemistry of five-coordinate nickel(II) and cobalt(II) complexes (LA) 868
Nickel-ligand catalysts, Mechanism of the cyclodimerization of butadiene with ~ (SC) 329 [G.E. *83*, 329 (1971)]
Niobium, Gmelins Handbuch der anorganischen Chemie (Book Review) 526
Nitrene, Fixation of trimethylsilyl-~ as μ_3-trimethylsilylimido(decacarbonyltriiron) (SC) 910 [G.E. *83*, 968 (1971)]
Carbenes, ~-s and arynes (Book Review) 760
Nitric oxide, Incorporation of olefin and ~ into organocobalt compounds (SC) 515 [G.E. *83*, 546 (1971)]
Nitride, Phenylarsenic(V) trichloride azide and phenylarsenic(V) chloride ~ (SC) 516 [G.E. *83*, 504 (1971)]
N-(Nitridofluorosulfur)sulfur imide difluoride (SC) 815 [G.E. *83*, 890 (1971)]
Nitriles, C-H acidity of organic ~ (CR) 856 [G.E. *83*, 931 (1971)]
One-step preparation from carboxylic acids (LA) 427
Nitrile oxides, 1,3-Dipolar cycloaddition of ~ to cyclic imidic esters and amidines (SC) 810 [G.E. *83*, 882 (1971)]
Nitroalkanes, Oxidative addition to tetrakis(triphenylphosphane)platinum(0): a simple route to complex metal fulminates (SC) 66 [G.E. *83*, 43 (1971)]
Nitrobenzene, Photooxidation of alkanes by ~ (LA) 142
Photoconductivity of liquid ~ (LA) 143
Nitro compounds, Photoreactions of sterically hindered ~, Light-induced formation of nitrones from o-tert-butylnitrobenzenes (CR) 825 [G.E. *83*, 898 (1971)]
2-Nitrofuran, Photorearrangements of ~ and 2-nitropyrrole (LA) 142
Nitrogen, Desorption spectra in the adsorption system iron/~ (SC) 562 [G.E. *83*, 584 (1971)]
Nitrogen complexes, Oxidation of $C_5H_5Mn(CO)_2N_2H_4$ to $C_5H_5Mn(CO)_2N_2$, a new dinitrogen complex (SC) 919 [G.E. *83*, 1017 (1971)]
Nitrogen compounds, Hydrogen bridges with nitrogen as donor and acceptor (SC) 426 [G.E. *83*, 449 (1971)]
$(CH_3As)_2S_2N_4$ – a novel arsenic-sulfur-nitrogen heterocycle (SC) 812 [G.E. *83*, 882 (1971)]
Rearrangements of ~ having electronegative substituents (CR) 141 [G.E. *83*, 116 (1971)]
Chemistry of reactive nitrogenous intermediates (LA) 945
2-Nitropyrrole, Photorearrangements of 2-nitrofuran and ~ (LA) 142
Nitrosation, Electrophilic ~ with nitrosyl tetrafluoroborate (CR) 841 [G.E. *83*, 915 (1971)]
Nitrosocyclohexene, Reaction with maleic anhydride (LA) 358
Nitrosodisulfonate, Oxidations with potassium ~ (LA) 756
Nitrostyrenes, Michael addition of metalated carboxamides to ~ – a simplified route to tryptamines (SC) 501 [G.E. *83*, 542 (1971)]
α-Nitro sulfonic esters, Synthesis of aliphatic ~ (LA) 143
Nitroxide, ESR spectroscopic investigations of acyl and azomethine ~-s (CR) 819 [G.E. *83*, 892 (1971)]
ESR spectrum of di-tert-butyl-~ (LA) 81
Nitroxyl radicals, Free ~ (Book Review) 528
NMR Spectroscopy, Pulse Fourier transform ^{13}C-~, principles and applications (FP) 673 [G.E. *83*, 659 (1971)]
Conformational studies by low temperature ^{13}C-~ (SC) 730 [G.E. *83*, 759 (1971)]
Effect of non-planarity on the paramagnetic ring current in the dianion of 1,6; 8,13-propanedilylidene[14]annulene (SC) 920 [G.E. *83*, 1014 (1971)]
Pulse Fourier transform ^{13}C-~ of mutarotating sugars (SC) 935 [G.E. *83*, 1011 (1971)]
Conformational analysis of organometallic lanthanoid and actinoid complexes by means of the paramagnetically induced shifts in their ^{1}H-NMR spectra (CR) 819 [G.E. *83*, 892 (1971)]
Shift reagents without heavy metals (CR) 855 [G.E. *83*, 929 (1971)]
Paramagnetic probes for NMR relaxation studies of phosphoryl transfer enzymes (LA) 758
NMR studies of molecular relaxation processes in solid polymers (LA) 759
Nomenclature for intramolecular exchange processes (SC) 570 [G.E. *83*, 618 (1971)]
Norbornadiene, Synthesis of 3,5-disubstituted cyclopentenes by ozonolysis of ~ (LA) 203
1-Norbornene, Concerning the existence of ~ (SC) 262 [G.E. *83*, 254 (1971)]
7-Norbornenylidene, a potentially nonclassical carbene (LA) 582
Norcaradiene, New spiro-~-s. – Demonstration of a reversible ~ – cycloheptatriene valence-isomerization (SC) 342 [G.E. *83*, 362 (1971)]
Two new ~-cycloheptatriene equilibria (SC) 563 [G.E. *83*, 585 (1971)]
Nuclear energy reserves and long-term energy requirements (FP) 1 [G.E. *83*, 1 (1971)]
Nuclear fission, Ternary fission (FP) 890 [G.E. *83*, 1000 (1971)]
Nuclear magnetic double resonance, Methods and applications (FP) 472 [G.E. *83*, 470 (1971)]
Nuclear reactions, Low-yield ~ induced by fast neutrons, particularly (n,t) reactions (CR) 849 [G.E. *83*, 924 (1971)]
Nucleophilic substitution, Retentive ~ of (R)-α-ferrocenylethyl acetate (SC) 191 [G.E. *83*, 178 (1971)]
Reexamination of the limiting mechanisms of aliphatic ~ (SC) 503 [G.E. *83*, 493 (1971)]
Nucleoside, Conformation of the arabino-~ 1-β-D-arabinofuranosyl-4-thiouracil (SC) 187 [G.E. *83*, 174 (1971)]
Synthesis of polymer gels with covalently incorporated ~ residues and their use for the separation of nucleic acid structural units (CR) 354 [G.E. *83*, 367 (1971)]
Nutmeg as a narcotic (FP) 370 [G.E. *83*, 392 (1971)]
Nylon, Determination of the molecular weight distribution in ~ 6 by solution fractionation (CR) 823 [G.E. *83*, 896 (1971)]

n-OCTENES, Photochemical cis-trans isomerization of ~ in presence of organoaluminum compounds (CR) 281 [G.E. *83*, 296 (1971)]
Olefin, Tellurium tetrachloride-~ addition compounds (SC) 73 [G.E. *83*, 81 (1971)]
X-Ray crystallographic investigations of tellurium tetrachloride-~ adducts (SC) 74 [G.E. *83*, 81 (1971)]
Photochemical ~-aziridine cycloaddition (SC) 273 [G.E. *83*, 292 (1971)]
Incorporation of ~ and nitric oxide into organocobalt compounds (SC) 515 [G.E. *83*, 546 (1971)]
Novel method for ~ synthesis (LA) 80
Photocycloaddition to phenanthrene (LA) 144
Olefin polyreaction, Di-~ in the homogeneous phase (CR) 354 [G.E. *83*, 369 (1971)]
Onium salts, Preparation of N,N,N',N'-tetraaminopiperazinium salts (SC) 813 [G.E. *83*, 884 (1971)]
Optical activity from asymmetric transition metal atoms (FP) 249 [G.E. *83*, 274 (1971)]

Optical resolution, Resolution of racemates into enantiomers (LA) 944

Orbitals, Interaction between the ~ of lone pair electrons in dicarbonyl compounds (SC) 401 [G.E. *83*, 405 (1971)]

Bond-bond interaction in polysilanes (SC) 404 [G.E. *83*, 435 (1971)]

Orbital sequence, Arguments concerning the ~ in borazine (SC) 182 [G.E. *83*, 169 (1971)]

Organic chemistry, Grundlagen der Organischen Chemie (Book Review) 527

Grundpraktikum der organischen Chemie (Book Review) 662

Organic synthesis (Book Review) 589

Organic transformations, Selective ~ (Book Review) 889

Oscillating systems, ESR Investigations of an oscillating redox system (SC) 192 [G.E. *83*, 208 (1971)]

Oudenone, Structure and synthesis of ~, a novel tyrosine hydroxylase inhibitor (LA) 523

Osmium complexes, Simple synthesis of hexafluoro complexes of osmium(IV), iridium(IV), and platinum(IV) SC) 936 [G.E. *83*, 1019 (1971)]

6-Oxa-2-azabicyclo[3.1.0]hex-3-ene, Synthesis of a ~: heterocyclic 8π-systems as reactive intermediates (SC) 572 [G.E. *83*, 622 (1971)]

Oxalyl bromide, Vibrational spectra (IR and Raman) (LA) 430

Oxatriazatetra-P^V-phosphocinium salts, cycloisomerization of tetraphosphorus nitride oxide derivatives: octaphenyl-~ (SC) 131 [G.E. *83*, 142 (1971)]

1,3,5-Oxazaphosph(V)oles, Reactions of 4,5-dihydro-~ with alkynes and alkenes (SC) 728 [G.E. *83*, 761 (1971)]

Orientation of addition of unsymmetrically substituted alkynes and alkenes to 4,5-dihydro-~ (SC) 729 [G.E. *83*, 762 (1971)]

Oxaziranes, Deoxygenation of ~ by sulfur-containing nucleophiles (SC) 327 [G.E. *83*, 355 (1971)]

Oxazoles, 2-Unsubstituted ~ from α-metalated isocyanides and acylating agents (SC) 333 [G.E. *83*, 358 (1971)]

Oxazol-5-ones, Base-catalyzed addition of ~ to activated multiple bonds (SC) 653 [G.E. *83*, 725 (1971)]

4(5H)-Oxazolones, Novel synthesis (LA) 144

Oxazol-5-one anions, Chain lengthening of carboxylic acids by three carbon atoms via ~ (SC) 655 [G.E. *83*, 727 (1971)]

Oxepin, New route to the ~ system (SC) 425 [G.E. *83*, 449 (1971)]

Oxidations with potassium nitrosodisulfonate (LA) 756

Oxidative amination of hydroquinones (SC) 405 [G.E. *83*, 441 (1971)]

Oxidative phosphorylation, Model reactions for ~: sulfur compounds as carriers of the phosphoryl group (CR) 521 [G.E. *83*, 506 (1971)]

N-Oxides, New method for the synthesis of ~ of polyhalogenated N-hetero aromatics (LA) 283

Oxide glasses, New routes to multicomponent ~ (FP) 363 [G.E. *83*, 428 (1971)]

Oxidizing agent, Ferrate(VI) ion as a new selective ~ (LA) 427

Oximes, Synthesis of heterocycles from syn- and anti-amino-~ (CR) 830 [G.E. *83*, 904 (1971)]

Oxonium hydrates, Rates of formation and decomposition (LA) 144

Oxonium salts, Dehalogenation of α-haloketones via α-oxocarbonium ions to stable ~ (SC) 327 [G.E. *83*, 327 (1971)]

Oxycarbene, Rearrangement of a thermally generated ~ (LA) 524

Oxygen, Reactions of atoms (FP) 604 [G.E. *83*, 561 (1971)]

New type of reaction resulting from the action of O_2 on diarylfluoroacylphosphanes (SC) 565 [G.E. *83*, 587 (1971)]

Adsorption of ~ on gold and its effect on the kinetics of electrochemical reactions (CR) 79 [G.E. *83*, 49 (1971)]

Ozonolysis, ~ of organic mercurials (LA) 143

Synthesis of 3,5-disubstituted cyclopentenes by ~ of norbornadiene (LA) 203

Ozonization of a secondary amine (LA) 143

PAINTS, X. Fatipec-Kongressbuch (Book Review) 205

Palladium, Catalytic activity in acetylene hydrogenation (LA) 524

Palladium compounds, Novel fluorides of divalent palladium (LA) 584

Panepoxydone, Structures of ~ and some related metabolites (LA) 142

Paper, Synthetic ~ (FP) 287 [G.E. *83*, 347 (1971)]

Penicillin, Recent advances in ~ chemistry (CR) 356 [G.E. *83*, 335 (1971)]

5,6,8,8b,9-Pentaazanaphth[3,2,1-de]anthracene (LA) 429

Pentafluorobenzenesulfenyl chloride (LA) 144

Pentaleno[3,2,1-cd]-phenylene, 5-Ethoxy-1,-2,3-trichloro-~: a perturbed [16]annulene (SC) 576 [G.E. *83*, 623 (1971)]

Peptides, Synthesis of physiologically active ~ (FP) 152 [G.E. *83*, 155 (1971)]

Synthesis of naturally occurring poly-~, problems of current research (FP) 786 [G.E. *83*, 773 (1971)]

Removal of the chloroacetyl group from N-chloroacetyl derivatives of amino acids and ~ by 1-piperidinethio carboxamide (SC) 75 [G.E. *83*, 83 (1971)]

Symmetrical Boc amino acid anhydrides for economical peptide synthesis on a solid phase (SC) 336 [G.E. *83*, 333 (1971)]

New method of polypeptide synthesis (SC) 811 [G.E. *83*, 883 (1971)]

Influence of proline on the conformation of a polypeptide chain (CR) 354 [G.E. *83*, 366 (1971)]

New methods for the solid-phase synthesis and for the analysis of poly-~ (CR) 837 [G.E. *83*, 911 (1971)]

Medium-sized rings of the peptide type (CR) 853 [G.E. *83*, 927 (1971)]

Synthesis of modified amino acids and ~ having anticoagulant, bactericidal, and vitamin-K type action (CR) 942 [G.E. *83*, 986 (1971)]

Perchlorato complexes, Molecular ~ of iridium(I), rhodium(I), and cobalt(I) (SC) 511 [G.E. *83*, 497 (1971)]

Perchloric acid, Kinetics of decomposition of aqueous ~ (LA) 358

Perfluoroalkanesulfinic acids (SC) 810 [G.E. *83*, 890 (1971)]

Pericyclic reactions, Aromaticity and ~ (FP) 761 [G.E. *83*, 859 (1971)]

Peroxides, Organic ~ (Book Review) 206

Peroxosilicon compounds, Problems and results in the chemistry of peroxosulfur compounds and ~ (CR) 522 [G.E. *83* 548 (1971)]

Peroxosulfur compounds, Problems and results in the chemistry of Peroxosilicon compounds and ~ (CR) 522 [G.E. *83*, 548 (1971)]

Perthiophosphonic anhydrides, Synthesis of dithiophosphinic acids by nucleophilic fission of ~ (SC) 508 [G.E. *83*, 544 (1971)]

Pesticides, The ~ problem in water pollution (CR) 849 [G.E. *83*, 924 (1971)]

Gas-chromatographic determination of residues from ~ (carbamates, ureas, amides) in plant material (CR) 860 [G.E. *83*, 935 (1971)]

Petroleum, First identification of a steroid carboxylic acid in ~ (SC) 747 [G.E. *83*, 805 (1971)]

~, genesis (LA) 868

Pharmacology Arzneimittelwirkungen (Book Review) 588

Phase diagrams, materials science and technology (Book Review) 205, 587, 587

Phase distribution chromatography, Determination of the polydispersity of anionic polystyrenes by ~ (CR) 347 [G.E. *83*, 374 (1971)]

Phase equilibria (Book Review) 431

Phase transformations, Investigations of reactions and ~ with a novel X-ray camera (CR) 277 [G.E. *83*, 216 (1971)]

Phenanthrene, Photocycloaddition to olefins (LA) 144

Phenol, Preparation and properties of oligomeric polynuclear phenolic compounds containing nitrophenol components (CR) 821 [G.E. *83*, 894 (1971)]

Cycloalkylation with 1,5-hexadiene (LA) 429

Phenyl p-benzoquinone, Flash-vacuum thermolysis of ~ (LA) 584

Phenyl shift, Sigmatropic 1,3-~ in photoexcited phenyl trityl ketones (CR) 832 [G.E. *83*, 906 (1971)]

Pheophorbides, Preparation and absolute configuration of cis-~ (CR) 866 [G.E. *83*, 941 (1971)]

Phosphane, Tetrakis(trimethyl-~)cobalt(0): preparations and reactions (SC) 343 [G.E. *83*, 363 (1971)]

Novel type of 1,3-dipolar cycloaddition: 1,2-aza-P^V-phosphol-1-ines from methyleneamino-~-s (SC) 396 [G.E. *83*, 397 (1971)]

New type of reaction resulting from the action of O_2 on diarylfluoroacyl-~-s (SC) 565 [G.E. *83*, 587 (1971)]

Synthesis of octakis(trifluoro-~)diiridium (SC) 725 [G.E. *83*, 725 (1971)]

P,P-Diphenylethylenedi-~ (SC) 734 [G.E. *83*, 766 (1971)]

Formation of macrozwitterions in the anionic polymerization of vinyl monomers initiated by tertiary ~-s (CR) 349 [G.E. *83*, 371 (1971)]

Phosphane complexes, Anions derived from ~: deprotonation by PH_2^- (SC) 186 [G.E. *83*, 172 (1971)]

P-N cleavage in tris(dimethylamino)-phosphanecarbonyl complexes of molybdenum(0) (SC) 187 [G.E. *83*, 174 (1971)]

π-Allylpentakis(trifluorophosphane)tantalum (SC) 408 [G.E. *83*, 437 (1971)]

Carbonylhalogenohydrido-, carbonylhalogeno- and halogeno-iridium complexes

involving a tetradentate (CR) 826 [G.E. *83*, 900 (1971)]

Phosphate, Trisboranephosphite and tetrakisborane-~ ions (SC) 416 [G.E. *83*, 446 (1971)]

Phosphirane complexes, Complexes of phosphirane (SC) 125 [G.E. *83*, 111 (1971)]

Phosphite, Trisborane-~ and tetrakisboranephosphate ions (SC) 416 [G.E. *83*, 446 (1971)]

ESR study of the oxidation of triethyl ~ by tert-butoxy radicals (SC) 738 [G.E. *83*, 800 (1971)]

Phospholene oxide, An optically active ~ (SC) 498 [G.E. *83*, 496 (1971)]

Phosphonate carbanions, Syntheses of enynes and polyacetylenes via α-heterosubstituted ~ (CR) 867 [G.E. *83*, 942 (1971)]

Phosphonium salts, Tetrakis(methylmercurio)-~ (CR) 555 [G.E. *83*, 577 (1971)]

Phosphorane, Novel rearrangement around the (P=N) double bond (SC) 344 [G.E. *83*, 365 (1971)]

Optically active selenoxomethylphenylpropyl-~-s and their transformations (SC) 494 [G.E. *83*, 491 (1971)]

Diethylaminotetrafluoro-~ by fluorolytic cleavage of the P=N bond (SC) 733 [G.E. *83*, 760 (1971)]

Phosphorin, Sequence of highest occupied molecular orbitals in the ~ system (SC) 656 [G.E. *83*, 723 (1971)]

Phosphorines, 1,3,5-Triaza-~ and -di-~ from 1,3,5-triazine (SC) 397 [G.E. *83*, 398 (1971)]

Phosphorus, Polarographic trace analysis of inorganic substances in non-acqueous solvents (example: ~ and silicon) (CR) 817 [G.E. *83*, 809 (1971)]

Phosphorus acids, $H[PO_2ClF]$ and $H[PO_2BrF]$, two new dihalooxo-~ (SC) 555 [G.E. *83*, 578 (1971)]

Phosphorus compounds, Cycloisomerization of tetraphosphorus nitride oxide derivatives: octaphenyloxazatetra-P^V-phosphocinium salts (SC) 131 [G.E. *83*, 142 (1971)]

Cycloadditions of phosphonodithioic anhydrides: formation of dienephosphinodithioic acids (SC) 191 [G.E. *83*, 178 (1971)]

Dimethyl N,N-dichlorophosphoramidate — a warning (SC) 491 [G.E. *83*, 537 (1971)]

Synthesis of dithiophosphinic acids by nucleophilic fission of perthiophosphonic anhydrides (SC) 508 [G.E. *83*, 544 (1971)]

PO-substituted carbenes (CR) 581 [G.E. *83*, 625 (1971)]

Phosphorus analogs of the polychalcogenide chelates (CR) 840 [G.E. *83*, 914 (1971)]

Syntheses and chemical properties of heterocyclic systems bearing phosphorus substituents (LA) 757

Phosphorus heterocycle, A novel ~: 1,2,3,4-tetraphenyl-1,2,3,4-tetraphospholane (SC) 940 [G.E. *83*, 1019 (1971)]

Phosphorus ylides as polymerization initiators (CR) 839 [G.E. *83*, 913 (1971)]

Phosphoryl compounds, Model reactions for oxidative phosphorylation: sulfur compounds as carriers of the phosphoryl group (CR) 521 [G.E. *83*, 506 (1971)]

Photoalkylation, Novel ~ reactions on the flavin nucleus (SC) 804 [G.E. *83*, 854 (1971)]

Photochemistry, Generation of carbenes by photochemical cycloelimination (FP) 537 [G.E. *83*, 604 (1971)]

Photochemical $(2\pi+6\pi)$-cycloadditions. Novel 1,4-cycloaddition with formation of the bicyclo[2.2.2]octadiene system (SC) 133 [G.E. *83*, 143 (1971)]

Photochemical synthesis of bis(1,3-diene)-monocarbonyliron compounds (SC) 260 [G.E. *83*, 249 (1971)]

Photochemical olefin-aziridine cycloaddition (SC) 273 [G.E. *83*, 292 (1971)]

Direct proof of existence of tetramethylcyclobutadiene (SC) 809 [G.E. *83*, 885 (1971)]

New developments in the field of steroid ketone photochemistry (CR) 201 [G.E. *83*, 180 (1971)]

Photochemical cis-trans isomerization of n-octenes in presence of organoaluminum compounds (CR) 281 [G.E. *83*, 296 (1971)]

Photochemical intermediates in organic synthesis (CR) 849 [G.E. *83*, 923 (1971)]

Photophysical primary processes (CR) 863 [G.E. *83*, 939 (1971)]

ESR spectra, radical complexes, and electron transfer in the quenching of photoexcited rose bengale by quinones (CR) 866 [G.E. *83*, 942 [(1971)]

Photolysis of 1-azidophosphetane 1-oxides (LA) 582

~ of piperidinoanthraquinones (LA) 582

~ of benzofurazane (LA) 583

Photoconductivity of liquid nitrobenzene (LA) 143

Photocycloaddition, Intramolecular ~ of 7,7'-polymethylenedioxycoumarin (SC) 338 [G.E. *83*, 359 (1971)]

~ of olefins to phenanthrene (LA) 414

Photodecarbonylation, Non-cheletropic ~ of 1,3-diphenyl-substituted 2-indanone derivatives (SC) 198 [G.E. *83*, 210 (1971)]

Photodimerization, Dynamics of ~ of 9-anthroic acid and sodium 9-anthroate (SC) 517 [G.E. *83*, 545 (1971)]

~ of 3-methyl-2-cyclopenten-1-one (LA) 359

Photoelectron spectroscopy, Arguments concerning the orbital sequence in borazine (SC) 182 [G.E. *83*, 169 (1971)]

Interaction between the orbitals of lone pair electrons in dicarbonyl compounds (SC) 401 [G.E. *83*, 405 (1971)]

Bond-bond interaction in polysilanes (SC) 404 [G.E. *83*, 435 (1971)]

X-Ray ~ of mesoionic compounds (SC) 569 [G.E. *83*, 588 (1971)]

Sequence of highest occupied molecular orbitals in the phosphorin system (SC) 656 [G.E. *83*, 723 (1971)]

~ of organometallic compounds (CR) 820 [G.E. *83*, 894 (1971)]

~ in chemistry (LA) 757

Photoelimination, Increase in selectivity of ~ products on replacing the liquid phase by the crystalline phase (SC) 199 [G.E. *83*, 212 (1971)]

Photointermediates, Kinetic procedure for detection of short-lived (SC) 340 [G.E. *83*, 361 (1971)]

Photoisomerization of 1,2,4-trifluorobenzene (LA) 202

Photoluminescence, Method for the measurement of ~ quantum yields (LA) 661

Photooxidation of alkanes by nitrobenzene (LA) 142

Photoreaction, A heavy atom effect in the ~ of maleic anhydride with acenaphthylene (SC) 272 [G.E. *83*, 291 (1971)]

Photorearrangements of 2-nitrofuran and 2-nitropyrrole (LA) 142

Phthaloyl peroxide, Sensitized chemiluminescence on thermolysis of ~ in presence of 9,10-diphenylanthracene (SC) 67 [G.E. *83*, 43 (1971)]

Physical chemistry, Physikalische Chemie (Book Review) 525

~, an advanced treatise (Book Review) 587

Physics, Die Physik. Ihre Sprache und Untersuchungsmethoden (Book Review) 526

Pigments, Structure of the red eye ~ of the fruit fly Drosophila melanogaster (SC) 414 [G.E. *83*, 440 (1971)]

Influence of dispersion on the coloristic properties and fastness properties of molybdate red ~ (CR) 854 [G.E. *83*, 929 (1971)]

Determination of the wetting behavior of ~ (CR) 857 [G.E. *83*, 932 (1971)]

2,5-Piperazinediones, Synthesis of ~ having sulfur-containing bridges between C-3 and C-6 (SC) 130 [G.E. *83*, 114 (1971)]

Piperidinoanthraquinones, Photochemistry (LA) 582

1-Piperidinethiocarboxamide, Removal of the chloroacetyl group from N-chloroacetyl derivatives of amino acids and peptides by ~ (SC) 75 [G.E. *83*, 83 (1971)]

Plasma, Organic reactions in the ~ of glow discharges (SC) 422 [G.E. *83*, 413 (1971)]

Plastics, Synthetic paper (FP) 287 [G.E. *83*, 347 (1971)]

Synthesis of heterocyclic ring systems for heat-resistant ~ from polyisocyanates (FP) 294 [G.E. *83*, 339 (1971)]

Kunststoffe I und II (Book Review) 433

Plastics Analysis, Atlas der Kunststoff-Analyse (Book Review) 204

Kunststoff-Bestimmungsmöglichkeiten (Book Review) 432

Platinum complexes, Oxidative addition of nitroalkanes to tetrakis(triphenylphosphane)platinum(0): a simple route to complex metal fulminates (SC) 66 [G.E. *83*, 43 (1971)]

Simple synthesis of hexafluoro complexes of osmium(IV), iridium(IV), and platinum (IV) (SC) 936 [G.E. *83*, 1019 (1971)]

Platinum electrocatalysts, Adsorbed layers on ~ (CR) 854 [G.E. *83*, 928 (1971)]

Poly(amic acids), Influence of triethylamine on the viscosity of ~ from pyromellitic dianhydride and benzidine in dimethylacetamide (CR) 348 [G.E. *83*, 375 (1971)]

Polyamides, Syntheses and reactions of N-chloro-~ (CR) 856 [G.E. *83*, 931 (1971)]

Polyamide fibers, Chemical determination of amino end groups in ~ (CR) 851 [G.E. *83*, 926 (1971)]

Polyaminomonosaccharides, Methods for synthesis (LA) 868

Polyanions, Mechanism of formation of polywolframates and -molybdates in aqueous solution (CR) 860 [G.E. *83*, 935 (1971)]

Polybenzyl-L-aspartate, Dielectric measurements for the determination of aggregation and helix-coil transition in ~ and poly-DL-phenylalanine (CR) 352 [G.E. *83*, 367 (1971)]

Polydispersity, Determination of ~ of anionic polystyrenes by phase distribu-

tion chromatography (CR) 347 [G.E. *83*, 374 (1971)]

Polyenes, Catalytic formation of macrocyclic ~ from butadiene (SC) 802 [G.E. *83*, 851 (1971)]

Polyethylene, Crosslinking of ~ in presence of additives (CR) 864 [G.E. *83*, 940 (1971)]

Polyisocyanates, Synthesis of heterocyclic ring systems for heat-resistant plastics from ~ (FP) 294 [G.E. *83*, 339 (1971)]

Polyisoprene, Radiation-induced crosslinking in ~ (CR) 839 [G.E. *83*, 913 (1971)]

Polymers, Synthetic paper (FP) 287 [G.E. *83*, 347 (1971)]

Structure of polymeric 2,4-hexadiynylene-bis(phenylurethane) (SC) 266 [G.E. *83*, 253 (1971)]

Relations between structural elements and flow behavior of ~ and their solutions (SC) 425 [G.E. *83*, 449 (1971)]

Experimental evidence for kink formation (SC) 558 [G.E. *83*, 580 (1971)]

Investigation on the self-diffusion of small molecules in a high-molecular environment (CR) 139 [G.E. *83*, 151 (1971)]

Pyro field ion mass spectrometry (PFIMS) for determination of structure and degradation behavior of ~ and co-~ (CR) 349 [G.E. *83*, 372 (1971)]

Conformation of molecules in undiluted, noncrystalline ~ (CR) 349 [G.E. *83*, 375 (1971)]

Elastic state of high ~ (CR) 835 [G.E. *83*, 908 (1971)]

Polymer melts as viscoelastic liquids (CR) 850 [G.E. *83*, 924 (1971)]

The glass state of high ~ (CR) 850 [G.E. *83*, 925 (1971)]

The crystalline state of high ~ (CR) 866 [G.E. *83*, 941 (1971)]

NMR studies of molecular relaxation processes in solid ~ (LA) 759

Thermal stability of ~ (Book Review) 946

Polymer-analogous reactions, Sequence kinetics in ~ by Monte-Carlo simulation and NMR investigation (CR) 351 [G.E. *83*, 373 (1971)]

Polymer gels, Synthesis with covalently incorporated nucleoside residues and their use for the separation of nucleic acid structural units (CR) 354 [G.E. *83*, 367 (1971)]

Polymerization, Vanadium and chromium catalysts for ~ of ethylene (FP) 776 [G.E. *83*, 782 (1971)]

Continuous emulsion polymerization (CR) 201 [G.E. *83*, 151 (1971)]

Stereochemical control in free-radical ~ (CR) 347 [G.E. *83*, 374 (1971)]

Polymerization rate, Monomer concentration in polymers and its correlation with the ~ in heterogeneous polymerization (CR) 351 [G.E. *83*, 370 (1971)]

Polymer structure, "Molecular probes" in the study of ~ and interactions (CR) 348 [G.E. *83*, 371 (1971)]

Poly(methinimine), polynitrile (LA) 584

7,7'-Polymethylenedioxycoumarin, Intramolecular photocycloaddition (SC) 338 [G.E. *83*, 359 (1971)]

Poly(methyl methacrylates), Association behavior of atactic and stereospecific ~ (CR) 346 [G.E. *83*, 375 (1971)]

Polynitrile, Poly(methinimine), ~ (LA) 584

Poly-DL-phenylalanine, Dielectric measurements for the determination of aggregation and helix-coil transition in polybenzyl-L-aspartate and ~ (CR) 352 [G.E. *83*, 367 (1971)]

Polysilanes, Bond-bond interaction in ~ (SC) 404 [G.E. *83*, 435 (1971)]

Polystyrenes, Determination of the polydispersity of anionic ~ by phase distribution chromatography (CR) 347 [G.E. *83*, 374 (1971)]

Polystyrylsodium, Energy and entropy parameters of different species of carbanions from the polymerization kinetics and from conductivity measurements on ~ in polar organic solvents (CR) 354 [G.E. *83*, 371 (1971)]

Polyurethane, Present trends in ~ chemistry (CR) 200 [G.E. *83*, 179 (1971)]

Poly-p-xylylenes, Aromatically substituted ~ (CR) 346 [G.E. *83*, 368 (1971)]

Potassium, Active transport of Na^+ and K^+ through animal cell membranes (FP) 882 [G.E. *83*, 947 (1971)]

Potentials, Improved determinations of intermolecular ~ (SC) 426 [G.E. *83*, 450 (1971)]

Preparative organic chemistry, Neuere Methoden der präparativen organischen Chemie (Book Review) 585

Printing, Rheological and boundary layer problems (SC) 424 [G.E. *83*, 448 (1971)]

Process engineering, Physikalische Grundlagen der Verfahrenstechnik (Book Review) 870

Process technology, Fortschritte der Verfahrenstechnik (Book Review) 360

Proline, Influence on the conformation of a polypeptide chain (CR) 354 [G.E. *83*, 366 (1971)]

Propene, Product ratios on gas-phase hydration of ~ (SC) 335 [G.E. *83*, 332 (1971)]

Protactinium, Anion-exchange behavior of ~ and other elements in mixtures of HNO_3, HF, and organic solvents (CR) 842 [G.E. *83*, 916 (1971)]

Protecting group, The 9-anthroxy group is suitable for the protection of hydroxy functions (LA) 81

Novel light-sensitive ~ (LA) 143

Proteins, Synthesis of physiologically active peptides (FP) 152 [G.E. *83*, 155 (1971)]

Lac repressor (FP) 160 [G.E. *83*, 195 (1971)]

Bifunctional reagents for the crosslinking of ~ (FP) 795 [G.E. *83*, 875 (1971)]

Physical principles and techniques of protein chemistry (Book Review) 362

Protoadamantene and 2,4-cycloadamantane (LA) 359

Protophanes, Pyridino-~ with alkylene segments of various lengths (SC) 740 [G.E. *83*, 795 (1971)]

Pseudoferrocenes (LA) 282

Pseudorotation, Non-rigid molecular skeletons — Berry ~ and turnstile rotation (FP) 687 [G.E. *83*, 691 (1971)]

Pteridines, Synthesis of 8-ribofuranosyl- and 2-ribofuranosylamino-7-oxo-7,8-dihydro-~ (SC) 927 [G.E. *83*, 970 (1971)]

General synthesis of pteridine N-8-glycosides (SC) 928 [G.E. *83*, 971 (1971)]

Synthesis of 4-amino-7-oxo-7,8-dihydropteridine N-8-β-D-ribosides – structural analogs of adenosine (SC) 931 [G.E. *83*, 974 (1971)]

Purine N-oxides, Metabolism of carcinogenic ~ (CR) 858 [G.E. *83*, 933 (1971)]

Pyraceheptylene, Simple synthesis of ~ and benzo[α]-~ (SC) 808 [G.E. *83*, 886 (1971)]

Pyrazine, 1,4-Bis(trimethylsilyl)-1,4-dihydro-~ by reductive silylation of pyrazine (SC) 127 [G.E. *83*, 145 (1971)]

Pyridine, pyrimidine, and ~ derivatives with an isocyanato substituent vicinal to nitrogen (SC) 402 [G.E. *83*, 406 (1971)]

Pyridine, ~, pyrimidine, and pyrazine derivatives with an isocyanato substituent vicinal to nitrogen (SC) 402 [G.E. *83*, 406 (1971)]

1,4-Dihydro-1,4-bis(trichlorosilyl)-~ from Si_2Cl_6 and ~ (SC) 412 [G.E. *83*, 408 (1971)]

Organometallic synthesis of thiophene-~ combinations (SC) 741 [G.E. *83*, 796 (1971)]

Pyridinium chloride, 4-Dimethylamino-1-tert-butoxycarbonyl-~ (LA) 429

Pyridinoprotophanes with alkylene segments of various lengths (SC) 740 [G.E. *83*, 795 (1971)]

Pyridoxal 5'-phosphate, Dual role as chemical and conformation-determining active group in glycogen phosphorylase (CR) 519 [G.E. *83*, 505 (1971)]

Pyrimidine betaines, Cycloadditions with mesomeric ~ (SC) 925 [G.E. *83*, 967 (1971)]

Pyrimidines, ~ from N,N-unsubstituted β-enamino carbonyl compounds and formamide (SC) 268 [G.E. *83*, 287 (1971)]

Pyridine, pyrimidine, and pyrazine derivatives with an isocyanato substituent vicinal to nitrogen (SC) 402 [G.E. *83*, 406 (1971)]

A pyrimidine phototetramer (LA) 583

Pyro field ion mass spectrometry (PFIMS) for determination of structure and degradation behavior of polymers and copolymers (CR) 349 [G.E. *83*, 372 (1971)]

2H-Pyrroles, Reactions of 4,5-dihydro-1,3,5-oxazaphosph(V)oles with alkynes and alkenes (SC) 728 [G.E. *83*, 761 (1971)]

Orientation of addition of unsymmetrically substituted alkynes and alkenes to 4,5-dihydro-1,3,5-oxazaphosph(V)oles (SC) 729 [G.E. *83*, 762 (1971)]

Pyrrol-1-ines, Reactions of 4,5-dihydro-1,3,5-oxazaphosph(V)oles with alkynes and alkenes (SC) 728 [G.E. *83*, 761 (1971)]

Orientation of addition of unsymmetrically substituted alkynes and alkenes to 4,5-dihydro-1,3,5-oxazaphosph(V)oles (SC) 729 [G.E. *83*, 762 (1971)]

QUANTUM mechanics, Quantenmechanik und Theorie des Molekülbaues (Book Review) 145, 204

Quinic acid, Stereospecific synthesis of optically pure ~ and shikimic acid from D-arabinose (SC) 336 [G.E. *83*, 329 (1971)]

Stereospecific conversion of (-)-methyl tri-O-benzoylquinate to the corresponding (-)-methylshikimate (SC) 652 [G.E. *83*, 722 (1971)]

o-Quinodimethane derivatives, Kinetic spectrophotometry of relaxation systems containing 7,8-polyphenyl-substituted ~ (SC) 196 [G.E. *83*, 209 (1971)]

Quinoline, Organometallic synthesis of thiophene-~ combinations (SC) 744 [G.E. *83*, 799 (1971)]

Quinones, Isocyanato-~ (SC) 403 [G.E. *83*, 408 (1971)]

A new method of preparing heterocyclic ~ (SC) 406 [G.E. *83*, 442 (1971)]
Redox behavior of insoluble quinone/hydroquinones (SC) 514 [G.E. *83*, 502 (1971)]
Reversible photodehydrogenation of diduroquinone to the aroxyl radical with optically excited carbonyl compounds such as ~, ketones, and xanthene dyes (CR) 833 [G.E. *83*, 907 (1971)]
Quinone methides, Isomerization to alkenylphenols (SC) 566 [G.E. *83*, 617 (1971)]

RACEMATES, Chromatographic resolution (CR) 520 [G.E. *83*, 547 (1971)]
Radiation chemistry, The radiation-induced decomposition of inorganic molecular ions (Book Review) 82
Radiation damage, Investigations on neutron-induced ~ in KCl single crystals (CR) 847 [G.E. *83*, 921 (1971)]
Radiation dosimetry, Manual on ~ (Book Review) 206
Radicals, Diphenylaminyl (SC) 71 [G.E. *83*, 47 (1971)]
Crystalline π-~ containing germanium compounds (SC) 499 [G.E. *83*, 538 (1971)]
Homolysis of the ethane C-C bond: Detection of tris(phenylthio)methyl by ^{13}C-labeling (SC) 500 [G.E. *83*, 534 (1971)]
Production of F atoms, H atoms, and OF ~ (SC) 564 [G.E. *83*, 586 (1971)]
1,3,6,8-Tetra-tert-butyl-9-carbazyl: a crystalline monomeric aminyl radical (SC) 732 [G.E. *83*, 756 (1971)]
ESR study of the oxidation of triethyl phosphite by tert-butoxy ~ (SC) 738 [G.E. *83*, 800 (1971)]
Free-radical S_H2_γ diplacement in the triazene system (SC) 752 [G.E. *83*, 850 (1971)]
Electrocyclic reactions of ~ (SC) 911 [G.E. *83*, 978 (1971)]
Electrocyclic transformation of cyclopropyl radical into allyl radical: a semiempirical SCF MO study (SC) 912 [G.E. *83*, 979 (1971)]
1,3,5-Benzenetriyltris[di(p-biphenyl)methyl], a radical having a quartet ground state that dimerizes by entropy bonding SC) 938 [G.E. *83*, 1015 (1971)]
Triplet bi-~ in cycloaddition (CR) 77 [G.E. *83*, 49 (1971)]
Reaction of recoil products with free ~ (CR) 835 [G.E. *83*, 909 (1971)]
Investigation of the reactions of CN-~ by kinetic spectroscopy (CR) 855 [G.E. *83*, 930 (1971)]
Kinetic data for abstraction of hydrogen and deuterium by methyl and trifluoromethyl ~ in the gaseous phase (LA) 757
Free nitroxyl ~ (Book Review) 528
Radical anions as intermediates in organic chemistry (FP) 115 [G.E. *83*, 132 (1971)]
Radical cations, Diarylamine ~ (SC) 71 [G.E. *83*, 48 (1971)]
Radical chain reactions, Free-~ (Book Review) 207
Radical ions (Book Review) 430
Radiolysis, Mechanism of ~ of cyclohexane (CR) 420 [G.E. *83*, 411 (1971)]
Reactions, Representation of chemical systems and interconverions by be-matrices and their transformation properties (SC) 914 [G.E. *83*, 980 (1971)]
Reactive dyes, Chemistry (CR) 580 [G.E. *83*, 624 (1971)]
Rearrangements, Non-rigid molecular skeletons — Berry pseudorotation and turnstile rotation (FP) 687 [G.E. *83*, 691 (1971)]
Novel rearrangement around the (P=N) double bond (SC) 344 [G.E. *83*, 365 (1971)]
A new route to Dewar-benzenes (SC) 811 [G.E. *83*, 887 (1971)]
~ of nitrogen compounds having electronegative substituents (CR) 141 [G.E. *83*, 116 (1971)]
Skeletal rearrangement with participation of 1,5-sigmatropic hydrogen shifts (LA) 282
New organosilicon rearrangement (LA) 284
Rearrangement of a thermally generated oxycarbene (LA) 524
Redox behavior of insoluble quinone/hydroquinones (SC) 514 [G.E. *83*, 502 (1971)]
Redox system, ESR investigations of an oscillating ~ (SC) 192 [G.E. *83*, 208 (1971)]
Position of equilibrium in vinylogous two-step ~-s (SC) 275 [G.E. *83*, 293 (1971)]
Reduction, Electrolytic ~ of higher metal halides in methanol (SC) 421 [G.E. *83*, 412 (1971)]
Relaxation systems, Kinetic spectrophotometry of ~ containing 7,8-polyphenyl-substituted o-quinodimethane derivatives (SC) 196 [G.E. *83*, 209 (1971)]
Repressor, Lac ~ (FP) 160 [G.E. *83*, 195 (1971)]
Rhenium, Decay of the isomers of ~-190 (CR) 838 [G.E. *83*, 912 (1971)]
Search for "solar wind" ~ in moon samples (CR) 845 [G.E. *83*, 920 (1971)]
Chemical consequences of the ^{185}Re(n,γ)^{186}Re nuclear process in the double salt K_2ReF_6KCl (CR) 846 [G.E. *83*, 921 (1971)]
Rhodium complexes, Molecular perchlorato complexes of iridium(I), rhodium(I), and cobalt(I) (SC) 511 [G.E. *83*, 497 (1971)]
Carbonylrhodium-tertiary amine complexes as catalysts for the hydroformylation reaction (CR) 828 [G.E. *83*, 901 (1971)]
Incorporation of S_2 and Se_2 units into ~ and iridium complexes (LA) 428
Ribonucleic acids, Investigations on the influence of various ions on the radius of gyration and structure of tRNA in solution (CR) 352 [G.E. *83*, 366 (1971)]
Investigations on fragments of phenylalanine-specific tRNA (CR) 355 [G.E. *83*, 366 (1971)]
Methods of sequence analysis (LA) 661
Ribosome, Translation of genetic information on the ~ (FP) 638 [G.E. *83*, 645 (1971)]
Ring cleavage, Stereoelectronically controlled reductive ~ of cis-1,2-divinylcyclobutanes (SC) 132 [G.E. *83*, 144 (1971)]
Ring expansion, ~ in the benzofuran series (SC) 748 [G.E. *83*, 755 (1971)]
~ by two C atoms on "siloxy Cope rearrangement" (LA) 430
~of cyclododecanone by two and four carbon atoms (LA) 584
Rotation, Restricted ~ in N-silylated hydrazines (SC) 343 [G.E. *83*, 364 (1971)]
Rotational barrier, Nature of ~ in acetaldehyde (LA) 524
Ruthenium complexes, Molecular structure of bis(hexamethylbenzene)ruthenium(0) (SC) 556 [G.E. *83*, 579 (1971)]
SALTS, Gas contents of ~ from the Upper Permian formation (LA) 82
Schlenk hydrocarbon, Energetic positions of the lowest singlet and triplet state of the Müller hydrocarbon and the ~ (SC) 506 [G.E. *83*, 498 (1971)]
Sediments, Biogenic substances in ~ and fossils (FP) 209 [G.E. *83*, 221 (1971)]
Selenium compounds, Incorporation of S_2 and Se_2 units into rhodium and iridium complexes (LA) 428
Selenoboranes, Synthesis and properties (CR) 858 [G.E. *83*, 933 (1971)]
Selenoxomethylphenylpropylphosphoranes, Optically active ~ and their transformations (SC) 494 [G.E. *83*, 491 (1971)]
Self-diffusion, Investigation on ~ of small molecules in a high-molecular environment (CR) 139 [G.E. *83*, 151 (1971)]
Separation processes, Vector scheme for ~ (CR) 848 [G.E. *83*, 923 (1971)]
Sequence kinetics in polymer-analogous reactions by Monte-Carlo simulation and NMR investigation (CR) 351 [G.E. *83*, 373 (1971)]
Sequence length distributions, Determination from pyrolysis of labeled and unlabeled ethylene-propylene copolymers (CR) 346 [G.E. *83*, 372 (1971)]
Sex attractant, Synthesis of the ~ of Ectocarpus siliculosus (SC) 492 [G.E. *83*, 537 (1971)]
Shikimic acid, Stereospecific synthesis of optically pure quinic acid and ~ from D-arabinose (SC) 336 [G.E. *83*, 329 (1971)]
A stereospecific conversion of (-)-methyl tri-O-benzoylquinate to the corresponding (-)-methylshikimate (SC) 652 [G.E. *83*, 722 (1971)]
Silane, Fluorchlorobromoiodo-~ (SC) 919 [G.E. *83*, 977 (1971)]
Silanes, Bond-bond interaction in poly-~ (SC) 404 [G.E. *83*, 435 (1971)]
Reactions of silicon difluoride with ~ and germanes (LA) 284
Reaction of carboxylic esters with sodium in presence of trimethylchlorosilane (LA) 757
Silica gels, Determination of distribution of radii of polymer dispersions on macroporous ~ (CR) 826 [G.E. *83*, 900 (1971)]
Silicon, Polarographic trace analysis of inorganic substances in non-aqueous solvents (example: phosphorus and ~) (CR) 817 [G.E. *83*, 809 (1971)]
Silicon compounds, Si-Fluorinated carbosilanes (SC) 510 [G.E. *83*, 500 (1971)]
An organosilicon cyclophane (LA) 203
A new organosilicon rearrangement (LA) 284
Evidence for the existence of a "silylenoid" species (LA) 427
Organosilicon heteropolymers and heterocompounds (Book Review) 206
Silicones, Chemie und Technologie der Silicone (Book Review) 360
Silicon difluoride, Reactions with silanes and germanes (LA) 284
Silicon nitride, Reaction with oxygen (CR) 842 [G.E. *83*, 916 (1971)]
"Siloxy Cope rearrangement", Ring expansion by two C atoms on ~ (LA) 430
Silylammonium compounds (LA) 427
Silylation, 1,4-Bis(trimethylsilyl)-1,4-dihydropyrazine by reductive ~ of pyrazine (SC) 127 [G.E. *83*, 145 (1971)]
Hydro-~of a N=N double bond (SC) 408 [G.E. *83*, 437 (1971)]

Use of ~ reactions in foodstuff analysis (CR) 862 [G.E. *83*, 937 (1971)]

Silyl compounds, Bis(trimethylsilyl)diimine: preparation, structure, and reactivity (FP) 374 [G.E. *83*, 379 (1971)]

Restricted rotation in N-silylated hydrazines (SC) 343 [G.E. *83*, 364 (1971)]

1,4-Dihydro-1,4-bis(trichlorosilyl)pyridine from Si_2Cl_6 and pyridine (SC) 412 [G.E. *83*, 408 (1971)]

Trimethylsilyl- and triphenylsilyl- substituted dyes (CR) 280 [G.E. *83*, 258 (1971)]

Singlet state, Energetic positions of the lowest ~ and triplet state of the Schlenk and of the Müller hydrocarbon (SC) 506 [G.E. *83*, 498 (1971)]

Sodium, Active transport of Na^+ and K^+ through animal cell membranes (FP) 882 [G.E. *83*, 947 (1971)]

Reaction of ~ with carboxylic esters in presence of trimethylchlorosilane (LA) 757

Sodium metharbital, Intermolecular interactions in the crystal structure of the hydrogen-bond-free barbiturate ~ (SC) 814 [G.E. *83*, 889 (1971)]

Solids, Chemical bonding in ~ (FP) 460 [G.E. *83*, 521 (1971)]

Application of ligand field spectroscopy to problems of chemical bonding in ~ (SC) 901 [G.E. *83*, 991 (1971)]

Solid state chemistry, Preparative ~: the present position (FP) 43 [G.E. 83, 35 (1971)]

Applications of Mössbauer spectroscopy to problems in ~ (FP) 716 [G.E. *83*, 746 (1971)]

Solid state dosimetry, Festkörperdosimetrie ionisierender Strahlung (Book Review) 434

Solvents, Ionization constants of water in mixtures with organic ~ (LA) 144

Non aqueous ~ (Book Review) 526

Sommerfeld, Albert Einstein/Arnold ~: Briefwechsel (Book Review) 83

Sorption isotherms, Study of the sorption behavior of fruit powders with a new type of automatic apparatus (CR) 830 [G.E. *83* 903 (1971)]

Spectral analysis, Chemische Spektralanalyse (Seith-Ruthardt) (Book Review) 285

Spectroscopy, Generalization of the isosbestic point (SC) 195 [G.E. *83*, 214 (1971)]

Kinetic spectrophotometry of relaxation systems containing 7,8-polyphenyl-substituted o-quinodimethane derivatives (SC) 196 [G.E. *83*, 209 (1971)]

The spectra of simple molecular ions in the gaseous phase (LA) 759

Introduction to electronic absorption ~ (Book Review) 590

Spironorcaradiene, New ~-s. – Demonstration of a reversible norcaradiene-cycloheptatriene valence-isomerization (SC) 342 [G.E. *83*, 362 (1971)]

Staphylococci, Enumeration, identification, and significance of ~ in dried soups and their raw materials (CR) 845 [G.E. *83*, 920 (1971)]

Steel embrittlement by hydrogen absorption (LA) 358

Stereochemistry of macromolecules (CR) 579 [G.E. *83*, 590 (1971)]

Steroids, Approaches to total synthesis of heterocyclic steroidal systems (FP) 450 [G.E. *83*, 511 (1971)]

New type of asymmetric cyclization to optically active steroid CD partial structures (SC) 496 [G.E. *83*, 492 (1971)]

Synthesis, chemistry, and biological properties of some novel hormonal fluoro-~ (CR) 140 [G.E. *83*, 116 (1971)]

New developments in the field of steroid ketone photochemistry (CR) 201 [G.E. *83*, 180 (1971)]

Rodd's chemistry of carbon compounds (Book Review) 208

Steroid carboxylic acid, First identification of a ~ in petroleum (SC) 747 [G.E. *83*, 805 (1971)]

Stilbenes, New, nonplanar trans-~ exhibiting nematic phases at room temperature (SC) 410 [G.E. *83*, 399 (1971)]

Structure, Concepts of liquid water ~ (LA) 944

Styrene-divinylbenzene copolymers, Reactivity of pendant vinyl groups in cross-linked divinylbenzene polymers and ~ (CR) 351 [G.E. *83*, 369 (1971)]

Substitution, Nucleophilic aromatic ~: a new synthetic route to biphenyls (SC) 566 [G.E. *83*, 619 (1971)]

Influence of conformation on the stereochemical course of hot ~ reactions in diastereoisomeric haloalkanes (CR) 845 [G.E. *83*, 919 (1971)]

Succinonitrile, Polymers from ~ (CR) 865 [G.E. *83*, 940 (1971)]

Sulfane derivatives of hydrazine (CR) 844 [G.E. *83*, 918 (1971)]

Sulfenyl chloride, Pentafluorobenzene-~ (LA) 144

Sulfides, New ~ of metals (SC) 422 [G.E. *83*, 413 (1971)]

Sulfinato complexes (FP) 315 [G.E. *83*, 315 (1971)]

Bond isomerism in ~ of transition metals (SC) 193 [G.E. *83*, 213 (1971)]

4,4'-Sulfonyldimethylenedibenzoic acid (SC) 652 [G.E. *83*, 723 (1971)]

Sulfur, Heterocycles from C_3 systems and ~ (CR) 278 [G.E. *83*, 216 (1971)]

Sulfur compounds, Conformational studies on enedithiolate chelates (SC) 143 [G.E. *83*, 146 (1971)]

Reactions of disulfur difluoride with fluorosulfonic acid, oleum, boron trifluoride, and arsenic pentafluoride (SC) 186 [G.E. *83*, 173 (1971)]

Preparation of 1,1-dimethyl-5-oxo-4,5-dihydro-1,3,2,4,6-thia(VI)thiatriazine 3,3-dioxide from dimethyl sulfone diimine (SC) 264 [G.E. *83*, 256 (1971)]

N-Fluorosulfonyldichloroamine (SC) 265 [G.E. *83*, 252 (1971)]

3-Chloro-1,3,5,2,4,6-thiadithia(IV)triazine 1,1,3-trioxide (SC) 266 [G.E. *83*, 253 (1971)]

Deoxygenation of oxaziranes by sulfur-containing nucleophiles (SC) 327 [G.E. *83*, 355 (1971)]

Preparation of some hydrazine derivatives containing nitrogen-sulfur bonds (SC) 407 [G.E. *83*, 437 (1971)]

Synthesis of bis(chlorodisulfanyl)benzenes and hexathia[3.3]cyclophanes (SC) 413 [G.E. *83*, 439 (1971)]

New method of preparing iminosulfur oxydifluorides (SC) 419 [G.E. *83*, 443 (1971)]

$(CH_3As)_2S_2N_4$ – a novel arsenic-sulfur-nitrogen heterocycle (SC) 812 [G.E. *83*, 882 (1971)]

Reactivity, modification, and polymerization behavior of monomers containing sulfur (CR) 352 [G.E. *83*, 368 (1971)]

Model reactions for oxidative phosphorylation: ~ as carriers of the phosphoryl group (CR) 521 [G.E. *83*, 506 (1971)]

Incorporation of S_2 and Se_2 units into rhodium and iridium complexes (LA) 428

New synthesis of organic ~ (LA) 756

Stereochemistry of organic ~ (LA) 757

Sulfur dioxide, Vibrational frequencies of adsorbed ~ (LA) 79

Surfaces, Imaging and analysis of ~ with a scanning electron microscope and electron spectrometer (FP) 591 [G.E. *83*, 632 (1971)]

Surface active substances, Grenzflächenaktive Substanzen (Book Review) 947

Surface compounds, Reactions at coordinatively unsaturated ~ (CR) 520 [G.E. *83*, 507 (1971)]

Surface reactions, Significance of chemical ~ in electrode processes (CR) 838 [G.E. *83*, 912 (1971)]

Surface tension and compressibility of liquids (LA) 79

Surfactant biodegradation (Book Review) 286

Sweeteners, Synthetic ~ from oximes (CR) 861 [G.E. *83*, 936 (1971)]

Syntheses, Matter preserving synthetic pathways and semi-empirical computer assisted planning of syntheses (SC) 915 [G.E. *83*, 982 (1971)]

Synthesis, Modern reactions in organic ~ (Book Review) 82

TANTALUM complexes, π-Allylpentakis-(trifluorophosphine)tantalum (SC) 408 [G.E. *83*, 438 (1971)]

Technetium compounds, Electron spin resonance of $^{99}Tc(IV)$ in $K_2[PtF_6]$ and SnO_2 (CR) 848 [G.E. *83*, 923 (1971)]

Technology, Chemische Technologie (Book Review) 945

Tellurium compounds, Tellurium tetrachloride-olefin addition compounds (SC) 73 [G.E. *83*, 81 (1971)]

X-Ray crystallographic investigations of tellurium tetrachloride-olefin adducts (SC) 74 [G.E. *83*, 81 (1971)]

Telomerization of butadiene with alcohols (LA) 359

Technique of organic chemistry (Book Review) 759

Ternary fission (FP) 890 [G.E. *83*, 1000 (1971)]

N,N,N',N'-Tetraaminopiperazinium salts, Preparation (SC) 813 [G.E. *83*, 884 (1971)]

2,3,7,8-Tetraazahexacyclotetradeca-2,7-diene, 2,3,7,8-Tetraazahexacyclo[7.4.1.$0^{4,12}$.$0^{5,14}$.$0^{6,11}$.$0^{10,13}$]tetradeca-2,7-diene (LA) 429

Tetracyclodeca-3,8-diene, Stable bis(tricarbonyliron) complex of tetracyclo[4.4.0.-$0^{5,7}$.$0^{2,10}$]deca-3,8-diene and its dynamic behavior in solution (SC) 189 [G.E. *83*, 176 (1971)]

exo-Tetracyclooct-3-yl-p-nitrobenzoate An energy surface for acetolysis via C_8H_9 cations from exo-tetracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]-oct-3-yl p-nitrobenzoate (SC) 559 [G.E. *83*, 581 (1971)]

4,4,4',4'-Tetramethyl-$\Delta^{2,2'}$-bipyrrolidine-3,3'-dione, a compound having the basic chromophore system of indigo (SC) 803 [G.E. *83*, 853 (1971)]

Tetramethylcyclobutadiene, Direct proof of existence (SC) 809 [G.E. *83*, 885 (1971)]

3,3,7,7-Tetramethylcycloheptyne an isolable seven-membered carbocyclic alkyne (SC) 509 [G.E. *83*, 540 (1971)]

1,2,3,4-Tetraphospholane, A novel phosphorus heterocycle: 1,2,3,4-tetraphenyl-~ (SC) 940 [G.E. *83*, 1019 (1971)]

Tetrasulfur dinitride, molecular structure (LA) 283

Tetrathioethylenes, Synthetic routes to ~ (LA) 756

Thallium, Rapid radiochemical separation by electrolytic removal (CR) 863 [G.E. *83*, 939 (1971)]

Thermolysis, Flash-vacuum ~ of phenyl-p-benzoquinone (LA) 584

Thiacyclobutane, Oxidation of ~ and thiacyclopentane (LA) 430

Thiacyclopentane, Oxidation of thiacyclobutane and ~ (LA) 430

1,3,5,2,4,6-Thiadithia(IV)triazine 1,1,3-trioxide, 3-Chloro-~ (SC) 266 [G.E. *83*, 253 (1971)]

1,3,2,4,6-Thia(VI)thiatriazine 3,3-dioxide, Preparation of 1,1-dimethyl-5-oxo-4,5-dihydro-~ from dimethyl sulfone diiminc (SC) 264 [G.E. *83*, 256 (1971)]

Thiazyl cation, The ~ $[NS]^+$ (SC) 127 [G.E. *83*, 145 (1971)]

Thiepin 1,1-dioxide, 4,5-Dihydro-~ (LA) 81

2-Thiobenzopropiolactone (LA) 283

Thioformic acid, Mono-~ (SC) 415 [G.E. *83*, 444 (1971)]

Thiophene, Organometallic synthesis of ~-pyridine combinations (SC) 741 [G.E. *83*, 796 (1971)]

Organometallic synthesis of ~-quinoline combinations (SC) 744 [G.E. *83*, 799 (1971)]

Thiouracil, Conformation of the arabinonucleoside 1-β-D-arabinofuranosyl-4-~ (SC) 187 [G.E. *83*, 174 (1971)]

Thiozone, S_3 ~ (LA) 429

Thorium halides, Isocyanide complexes of ~ and uranium halides (SC) 274 [G.E. *83*, 294 (1971)]

Thymidine, Synthesis of lumazine and isopterin N-1-β-D-ribofuranosides and -(2-deoxyribofuranosides) – structural analogs of uridine, cytidine, and ~ (SC) 932 [G.E. *83*, 975 (1971)]

Tin compounds, π-Allylcarbonylmetals from σ-Allylorgano-~ (SC) 339 [G.E. *83*, 360 (1971)]

Topochemical polymerization of monomers with conjugated triple bonds (CR) 355 [G.E. *83*, 368 (1971)]

Topomerization, Nomenclature, for intramolecular exchange processes (SC) 570 G.E. *83*, 618 (1971)]

Topotactic decomposition reactions, Electron-induced ~ (LA) 282

Trace analysis, Polarographic ~ of inorganic substances in non-aqueous solvents (example: phosphorus and silicon) (CR) 817 [G.E. *83*, 809 (1971)]

Transamination of cyano enamines (SC) 725 [G.E. *83*, 756 (1971)]

Transition metals, Optical activity from asymmetric transition metal atoms (FP) 249 [G.E. *83*, 274 (1971)]

Allyldihydropentaleneylene complexes of ~ (SC) 801 [G.E. *83*, 851 (1971)]

Transition metal compounds, Assessment and interpretation of properties (LA) 868

Transition state, Calculation of the intermediates and ~ in electrophilic aromatic substitution (SC) 497 [G.E. *83*, 499 (1971)]

Transplutonium elements, Extraction by alkylammonium salts (CR) 580 [G.E. *83*, 625 (1971)]

Transport, Active ~ of Na^+ and K^+ through animal cell membranes (FP) 882 [G.E. *83*, 947 (1971)]

Transuranics, The loose connection between electron configuration and chemical behavior of the ~ (CR) 837 [G.E. *83*, 911 (1971)]

1,3,4,2,5-Triazadiborolidine, Derivatives (SC) 126 [G.E. *83*, 112 (1971)]

1,3,5-Triazaphosphorines and -diphosphorines from 1,3,5-triazine (SC) 397 [G.E. *83*, 398 (1971)]

Triazene, Free-radical S_H2_γ diplacement in the ~ system (SC) 752 [G.E. *83*, 850 (1971)]

Triazines, 1,3,5-Triazaphosphorines and -diphosphorines from 1,3,5-triazine (SC) 397 [G.E. *83*, 398 (1971)]

Isocyanato-S-~ (SC) 403 [G.E. *83*, 407 (1971)]

Tribromobenzene, The base-catalyzed halogen dance (CR) 579 [G.E. *83*, 590 (1971)]

Tricarbonyl(hexaethylborazine)chromium(0), Crystal and molecular structure (SC) 512 [G.E. *83*, 541 (1971)]

Trichlorobutyl acetates, Elimination reactions (SC) 731 [G.E. *83*, 757 (1971)]

Trichloromethanesulfenyl chloride, Relationship of ~ and related compounds to carbonic acid chemistry (CR) 842 [G.E. *83*, 916 (1971)]

Tricyclo[3.1.0.0^{2,6}]hexane, New route to derivatives of bicyclo-[2.1.1]hexene and ~ (SC) 263 [G.E. *83*, 251 (1971)]

Triethylamine, Influence on the viscosity of poly(amic acids) from pyromellitic dianhydride and benzidine in dimethylacetamide (CR) 348 [G.E. *83*, 375 (1971)]

Trifluoroacetic anhydride, Properties and uses (LA) 756

Trifluoroarsine as ligand for a complex (SC) 418 [G.E. *83*, 445 (1971)]

1,2,4-Trifluorobenzene, Photoisomerization (LA) 202

Triple bonds, Intramolecular interactions between parallel ~ (LA) 524

Triplet biradicals in cycloaddition (CR) 77 [G.E. *83*, 49 (1971)]

Triplet state, Energetic positions of the lowest singlet and ~ of the Schlenk and of the Müller hydrocarbon (SC) 506 [G.E. *83*, 498 (1971)]

Tris(chloromethyl)amine, Preparation of ~, $N(CH_2Cl)_3$ (SC) 653 [G.E. *83*, 721 (1971)]

Trishomobenzene, Hexacyclo[4.4.0.0^{2,4}.-0^{3,9}.0^{5,7}.0^{8,10}]decane, a bridged cis-~ (SC) 417 [G.E. *83*, 404 (1971)]

Tris(phenylthio)methyl, Homolysis of the ethane C-C bond: Detection of ~ by ^{13}C-labeling (SC) 500 [G.E. *83*, 534 (1971)]

Troponoid compounds, Synthesis of seven-membered carbocyclic ketones and ~ (LA) 523

Trypsin, Temperature dependence of the hydrolysis of esters by ~ and chymo-~ (CR) 860 [G.E. *83*, 935 (1971)]

Occurrence of various ~ and chymo-~ inhibitors in peas (CR) 864 [G.E. *83*, 938 (1971)]

Tryptamines, Michael additions of metalated carboxamides to nitrostryrenes – a simplified route to ~ (SC) 501 [G.E. *83*, 542 (1971)]

1,2,3,5,4,6-Trithiathia(IV)diazine, Molecular structure of tetrasulfur dinitride (LA) 283

Tricyclo[2.2.2.0^{2,6}]oct-7-enes, Preparation of substituted 5-vinylcyclohexa-1,3-dienes and ~ (SC) 276 [G.E. *83*, 285 (1971)]

Tungsten carbide, ~ as anode material for fuel cells (SC) 194 [G.E. *83*, 213 (1971)]

Influence of electrocatalytic properties on anodic oxidation of hydrogen (CR) 821 [G.E. *83*, 894 (1971)]

Tungsten compounds, Crystal and molecular structure of bis(π-cyclopentadienyl)-tetrasulfidotungsten(IV) (SC) 921 [G.E. *83*, 1018 (1971)]

Hydridobis(π-cyclopentadienyl)phenyltungsten (LA) 282

Organoelementphosphanepentacarbonylchromium, -molybdenum, and -tungsten complexes (LA) 524

Turnstile rotation, Non-rigid molecular skeletons — Berry pseudorotation and ~ (FP) 687 [G.E. *83*, 691 (1971)]

Tyrian-purple, Biological precursors and genesis (CR) 816 [G.E. *83*, 856 (1971)]

Tyrosine hydroxylase inhibitor, structure and synthesis of oudenone, a novel ~ (LA) 523

UPPER Permian, Gas contents of salts from the ~ formation (LA) 82

Uranium, Charge distribution in the chain 132 from the fission of ~-235 and ~-233 by thermal neutrons (CR) 824 [G.E. *83*, 897 (1971)]

Determination of charge distribution in mass chains in the region of the closed 50-neutron shell in the thermal-neutron induced fission of ^{235}U (CR) 840 [G.E. *83*, 914 (1971)]

New determination of the ^{238}U(sp.f.) decay constant via fission tracks in an antique U-stained glass of known age (CR) 860 [G.E. *83*, 935 (1971)]

Uranium compounds, Volatilization of fission-product chlorides from solid UCl_4 (CR) 847 [G.E. *83*, 922 (1971)]

Tetrakis(pentacarbonylmanganese)uranium (LA) 427

Uranium halides, Isocyanide complexes of thorium halides and ~ (SC) 274 [G.E. *83*, 294 (1971)]

Urea, Improved specific enzyme electrodes for ~ and amino acids (LA) 143

Uridine, A convenient synthesis of 2',3',5'-tri-O-acetyladenosine and -~ (SC) 75 [G.E. *83*, 82 (1971)]

Synthesis of lumazine and isopterin N-1-β-D-ribofuranosides and -(2-deoxyribofuranosides) – structural analogs of ~, cytidine, and thymidine (SC) 932 [G.E. *83*, 975 (1971)]

VALENCE isomerism in selected heterocyclic systems (FP) 11 [G.E. *83*, 11 (1971)]

Valence isomerization, New spironorcaradienes – demonstration of a reversible norcaradiene-cycloheptatriene ~ (SC) 342 [G.E. *83*, 362 (1971)]

Diferratricyclododecatriene: an iron heterocycle showing rapid degenerate ~ (SC) 560 [G.E. *83*, 583 (1971)]

Vanadium and chromium catalysts for polymerization of ethylene (FP) 776 [G.E. *83*, 782 (1971)]

Vanadium chelates, Pentachalcogenide chelates of vanadium (SC) 137 [G.E. *83*, 146 (1971)]

Vinyl azides, New methods for synthesis (FP) 98 [G.E. *83*, 103 (1971)]

Vinyl chloride, Binary and ternary copolymerization in the system ~/butadiene/maleic anhydride (CR) 353 [G.E. *83*, 370 (1971)]

5-Vinylcyclohexa-1,3-dienes, Preparation of substituted ~ and tricyclo[2.2.2.$0^{2,6}$]oct-7-enes (SC) 276 [G.E. *83*, 285 (1971)]

1-Vinylcyclopenta-1,3-diene, Photochemical sigmatropic 1,7-shift of hydrogen in a semicyclic triene (LA) 142

Vinylcyclopropane, Complex bonding of a ~ group of bullvalene to a transition metal via a π-allyl and a σ component (SC) 188 [G.E. *83*, 175 (1971)]

Vinyl groups, Reactivity of pendant ~ in crosslinked divinylbenzene polymers and styrene-divinylbenzene copolymers (CR) 351 [G.E. *83*, 369 (1971)]

Vinyl polymers, Kinetics and mechanism of degradation in the solid state (CR) 827 [G.E. *83*, 901 (1971)]

4-Vinylpyridinium salts, Mechanism of "spontaneous polymerization" (CR) 353 [G.E. *83*, 367 (1971)]

Viscosity, Influence of triethylamine on the ~ of poly(amic acids) from pyromellitic dianhydride and benzidine in dimethylacetamide (CR) 348 [G.E. *83*, 375 (1971)]

WATER, Diethylborylation and determination of ~ with activated triethylborane (SC) 748 [G.E. *83*, 805 (1971)]

Ionization constants of ~ in mixtures with organic solvents (LA) 144

Concepts of liquid ~ structure (LA) 944

XANTHOCILLIN, Studies of biogenesis (CR) 818 [G.E. *83*, 891 (1971)]

X-Ray analysis, X-ray crystallographic investigations of tellurium tetrachloride-olefin adducts (SC) 74 [G.E. *83*, 81 (1971)]

Molecular and crystal structure of bis(1,3-cyclohexadiene)monocarbonyliron (SC) 261 [G.E. *83*, 250 (1971)]

Structure of polymeric 2,4-hexadiynylene-bis(phenylurethane) (SC) 266 [G.E. *83*, 253 (1971)]

Molecular structure of bis(hexamethylbenzene)ruthenium(0) (SC) 556 [G.E. *83*, 579 (1971)]

X-Ray camera, Investigations of reactions and phase transformations with a novel ~ (CR) 277 [G.E. *83*, 216 (1971)]

X-Ray photoelectron spectroscopy of mesoionic compounds (SC) 569 [G.E. *83*, 588 (1971)]

D-Xylose, Formation of aromatic compounds from D-glucuronic acid and ~ (LA) 142

YNAMINES, Cycloadditions of keteneimines to ~ (SC) 184 [G.E. *83*, 171 (1971)]

ZINC, Rapid and simple enrichment of trace elements in high-purity ~ by partial dissolution of the matrix in the presence of mercury (CR) 836 [G.E. *83*, 911 (1971)]
