Photoelectron Spectra of Nonmetal Compounds and Their Interpretation by MO Models[1]

By Hans Bock and Brian G. Ramsey[*]

Dedicated to Professor Karl Winnacker on his 70th Birthday

The results of (low energy) photoelectron spectroscopy render possible a better appreciation of the "Nature of the Chemical Bond". The application of this new experimental method is demonstrated utilizing representative compounds of the nonmetal elements, and a close symbiosis delineated with molecular orbital models. In particular, general consequences are discussed concerning electron deficiency, σ- and π-interactions, electron pair delocalization, and substituent effects or geometric perturbations. Photoelectron spectroscopic ionization energies permit evaluation of parameters for specified molecular groups, allow correlation with numerous other experimental data, and are didactically valuable in the teaching of general chemistry.

Had Sisyphus not been king of Corinth, but a natural scientist, he would probably have been bound to the task of preparing a survey of a rapidly developing topic.

1. On the Interpretation of Photoelectron (PE) Spectra

The well known photoionization process of a neutral molecule M to its radical cation $\dot{M}^{\oplus}$,

$$M + h\nu \rightarrow \dot{M}^{\oplus} + e^{\ominus} \quad (1)$$

in which the photon energy $h\nu$ in excess of the ionization energy $IE_n(M)$ appears as the kinetic energy of the ejected electron,

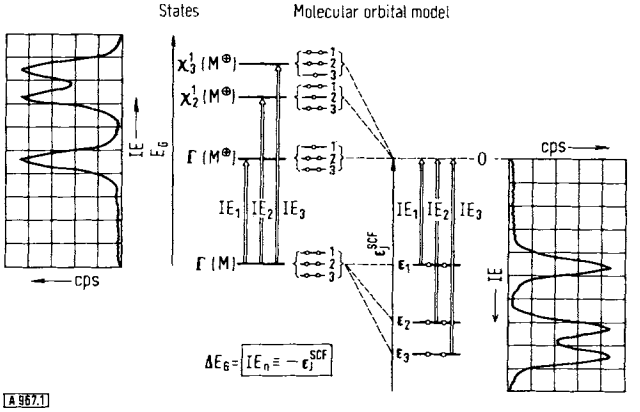
$$h\nu = IE_n(M) + E_{kin}(e^{\ominus}) \quad (2)$$

is the basis of photoelectron (PE) spectroscopy. If one chooses—as was proposed by *Turner* and co-workers[2a]—a helium(I) discharge lamp, for which $h\nu = 21.21\,eV$[**], as a monochromatic photon source and counts the emitted electrons (counts per second) of given kinetic energy, this allows (eq. 3) all vertical[**] ionization energies to be observed up to 21.21 eV:

$$IE_n(M) = 21.21\,eV - E_{kin}(e^{\ominus}) \quad (3)$$

These ionization energies correspond to energy differences, ΔE_G, between the ground state of a molecule and the different radical cation states and can be correlated—within the restriction of unchanged geometry and other assumptions—with calculated SCF orbital energies, ε_j^{SCF}, *via* use of Koopmans' theorem[2b,3] (Fig. 1).

$$(\Delta E_G =)\ IE_n(M) = -\varepsilon_j^{SCF} \quad (4)$$



A 967.1

Fig. 1. Koopmans' theorem: comparison of the measurable energy differences, $\Delta E_G = IE_n(M)$, between the molecular ground state $\Gamma(M)$ and the ground state $\Gamma(M^{\oplus})$ or excited states $\chi_n^m(M^{\oplus})$ of its radical cation with calculated SCF orbital energies, ε_j^{SCF}, (referred to the zero energy level of the removed electron) [***].

[**] The reader will find in the reviews [2] a general description of the construction and operation of photoelectron spectrometers as well as a survey of different energy sources. The observed ionization potentials are independent of the energy of the photon source. A "vertical" ionization may be described as an electron ejection process which is so fast that the nuclear coordinates of the molecular framework remain unchanged.

[***] In contrast to simple MO methods, as for example the Hückel approximation probably known to the reader, SCF calculations are carried out by an iteration process by which a part of the electron-electron repulsion can be accounted for. It is also pointed out that in the transition from the state diagram to the molecular orbital model in Figure 1, the states are represented in a simplified manner by a single configuration. However, a complete description of the radical cation states χ_n^m is possible only on inclusion of configuration interaction.
In addition it should also be mentioned that an infinite number of sets of equivalent wave functions can be constructed from occupied SCF orbitals. They all permit calculation of the total energy of a molecule. From these sets, Koopmans' theorem selects only the set of canonical SCF orbitals [3a].

Generally, the vertical excitation ends in an additionally vibrationally excited state of the radical cation $M^{\oplus}$. Different possibilities are set forth in Figure 2 for the simplest example of a diatomic molecule AB.

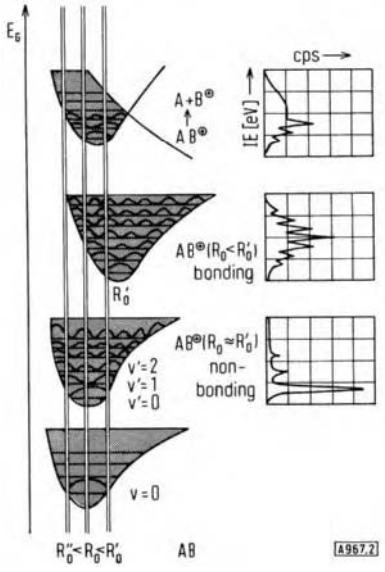

Fig. 2. Vertical [*] transitions between the vibrational ground state, $v=0$, of a diatomic neutral molecule AB and vibrational levels in different types of radical cation states $AB^{\oplus}$.

The minima of the potential energy curves (Fig. 2) represent the equilibrium bond distances R_0. These do not change significantly ($R_0 \approx R'_0$) if a "nonbonding" electron is ionized, and the vibrational frequencies remain approximately comparable ($v \approx v'$). Further, as one may gather from the overlap of the illustrated vibrational functions v and v', the transition from $v = 0$ to $v' = 0$ is the most intense, and the PE band consists of a sharp peak followed by peaks of greatly reduced intensity (Fig. 2). Normally in the ground state only $v=0$ is significantly populated. By contrast, on ionization of a bonding electron, the equilibrium bond distance increases ($R_0 < R'_0$), and the vibrational frequency decreases sharply ($v > v'$). At the same time a transition from $v=0$ to $v'>0$ is more probable and this results in a broad PE band, which may exhibit a vibrational fine structure as shown in Figure 2. From among other possible cases[2b], mention should be made of the predissociation $AB^{\oplus} \rightarrow A + B^{\oplus}$ which leads to a loss of band fine structure with increasing ionization energy (Fig. 2).

In addition to that from vibrational fine structure of PE bands, other information can be gathered from the spectrum about the radical cation state concerned. Thus, the splitting of certain PE bands through spin-orbit coupling of heavy atoms (Section 4.3) or through a Jahn-Teller distortion in degenerate radical cation states (*e. g.* allene *(8)*), often permits inferences about the nature of the electron removed by ionization. On the other hand, the intensity ratios of PE bands are not always simple to interpret[2b], and hence should only be used with caution as arguments for spectral assignments.

The assignment of PE spectra exclusively on the basis of spectroscopic data will be demonstrated with hydrogen bromide as an example. HBr contains eight valence electrons in the ground state. Of these, according to a useful rule of thumb, those with preponderant "$4s_{Br}$-character" should exhibit an ionization energy outside of the He(I) photon range of measurement, *i.e.* greater than 21.21 eV. The rest of the electrons are allocated to the two electron pairs n_{Br} and the σ_{HBr} bond.

The He(I) PE spectrum of hydrogen bromide[2a, 4] shows three bands in an approximate intensity ratio of 1 : 1 : 1 (Fig. 3). An unequivocal spectroscopic assignment succeeds

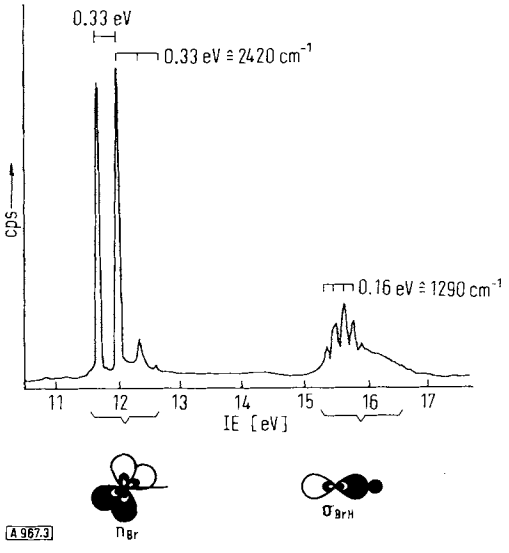

Fig. 3. He(I) PE spectrum of hydrogen bromide [2a, 4] with spectroscopic band assignments.

on the basis of: the vibrational fine structures (HBr: $2560\,cm^{-1}$; $HBr^{\oplus}$ $2420\,cm^{-1} \Rightarrow$non-bonding and $1290\,cm^{-1} \Rightarrow$bonding), the spin-orbit coupling of the bromide lone pair electron ($\Delta IE = 0.33$ eV), the wider band shape with increased bond participation, as well as the predissociative structure loss of the 15.6 eV band on the higher ionization energy side[2a] (compare Fig. 2).

In the case of molecules such as HBr, whose PE spectra allow spectroscopic assignment and which have an easily understood bonding system, one can act with Koopmans' theorem "as if orbital energies can be read directly from PE spectra". For the interpretation of the PE spectra of more complicated polyatomic molecules, one generally proceeds in a reverse manner, and the assignment will begin with qualitative, or where necessary, with the most rigorously calculable molecular orbital (MO) model. The comparison of chemically related compounds on the basis of perturbation arguments offers important aids to assignments. These combined methods will be illustrated here for the specific example of diborane[5].

Diborane, B_2H_6, contains twelve valence electrons, which in the ground state occupy pairwise six bonding molecular orbitals, and is isosteric with diprotonated ethylene $C_2H_6^{2\oplus}$. Hence, as a starting point, we selected the isoelectronic ethylene, whose six bonding molecular orbitals, as Figure 4 illustrates, may be constructed qualitatively according to the following approximate but reliable rules:

1) The energy sequence of the starting atomic orbitals is $C_{2p} > H_{1s} \gg C_{2s}$.

[*] See footnote [**] on p. 734.

2) The constructed symmetry-adapted linear combinations are ordered, each according to increasing number of nodal planes.

3) Orbitals of the same symmetry type mix and split apart, the magnitude of the splitting being directly proportional to the overlap of the orbitals and inversely proportional to their energy gap.

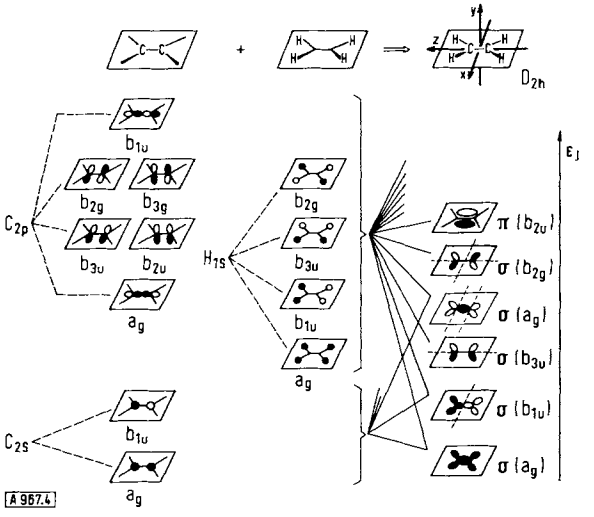

Fig. 4. Construction of qualitative symmetry-adapted linear combinations of atomic orbitals for ethylene.

An "unmixed" π MO and five σ MOs with differing CH and CC contributions result. Their energy sequence, estimated from the position of the starting orbitals as well as the increasing number and pattern of nodes, is confirmed through SCF "*ab initio*" calculations[5] (cf. Fig. 5), and is also in accord with the observable vibrational fine structure of the ethylene radical cation states in the PE spectrum[5]. The transition to diborane is made with two appropriate perturbation arguments: 1) $C_2H_4 \rightarrow B_2H_4^{2\ominus}$ (hypothetical), whereby, corresponding to the decrease in effective nuclear charge of boron as compared to carbon, a raising of all MOs is to be expected; and 2) diprotonation $B_2H_4^{2\ominus} \xrightarrow{2H^{\oplus}} B_2H_6$, in which the two additional positive hydrogen nuclei potentials, perpendicular to the σ molecular plane, should lower primarily the molecular orbital $1b_{2u}$. These plausible arguments are justified, both through the results of "*ab initio*" calculations and by the comparison of the PE spectra and their vibrational fine structure for ethylene and diborane[5] (Fig. 5).

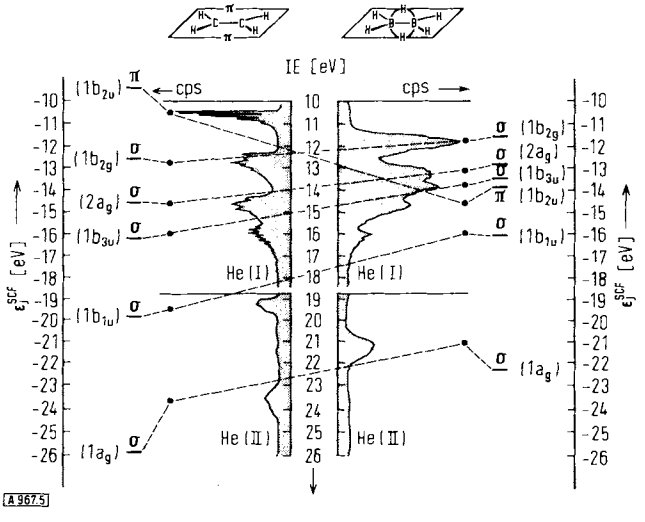

Fig. 5. Comparison of "*ab initio*" orbital energies, ε_j^{SCF} (eV) [—] and the vertical ionization energies IE_n^v (eV) [•] in the He(I)/He(II) PE spectra of ethylene and diborane [5].

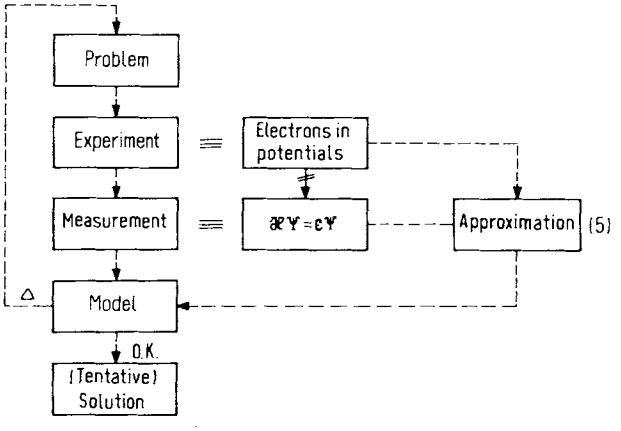
Clearly, the PE spectroscopic vertical ionization energies—the energy differences between molecular ground state and the resultant radical cation state—allow a satisfactory correlation with calculated orbital energies (cf. Fig. 1). Thus the intimate symbiosis with the new experimental methods of PE spectroscopy establishes still further the utility of MO models and increases their trustworthiness. Starting from the diborane bonding problem, the PE spectra were measured and a plausible assignment achieved by means of MO models of comparable electronic systems; this cycle is simultaneously an example of how MO models are increasingly drawn upon today in the interpretation and rationalization of measured data which taken alone would be generally uninformative (5)[6]



As "their own computer", molecules print out in the form of measured data complete solutions of the Schrödinger equation, which is not capable of closed solution for many-body systems. Approximate calculations and the models deduced from them increase in usefulness the more closely they can be directly correlated with experimental data. Photoelectron spectra, which permit *via* Koopmans' theorem a "quasi" reading off of orbital energies, are an exceptionally appropriate starting point for MO studies. These frequently lead, as should be demonstrated in the following, to a better conceptualization of "Bonding in Molecules", and with that also of other molecular properties.

2. Electron Delocalization in Boron Compounds

The PE spectrum of diborane was discussed with a qualitative MO model which, starting from ethylene, assumed a diprotonated or four centered π bond perpendicular to the molecular plane. The thus described electron delocalization, which reduces the electron deficiency at the boron center, at the same time can be drawn upon as an explana-

tion for the dimerization of monoborane BH_3. The chemist universally accepts the unoccupied virtual boron $2p_z$ orbital, whose energy in calculations is placed[7] a few electron volts above the carbon π_z orbitals, as the unifying thread through the physical properties and reactions of boron compounds of coordination number 3[8]. Besides the stabilization with an increase in coordination number through formation of multi-centered bonds as in boron hydrides or through formal octet completion as in Lewis acid/Lewis base complexes, a π type electron back bonding $>\overset{\curvearrowleft}{B}-X$, perpendicular to the molecular plane has also been discussed for filling the boron electron-hole. Numerous observations on boron compounds, such as planar molecular frameworks, unexpectedly small dipole moments or relatively high rotational barriers $>B-\overset{\curvearrowleft}{\ddot{}}-X$, find their easiest interpretation in this way[8]. What information about charge distribution and bonding in ground state trigonal planar boron compounds does PE spectroscopy furnish?

In the series of boron compounds $R_2B\dot{X}$, $RB\dot{X}_2$, $B\dot{X}_3$, in which the neighboring atom $\dot{X}$ exhibits an electron pair n_X of π symmetry an occupied bonding π_b orbital with decreasing orbital energy as well as none, one, or two occupied nonbonding orbitals respectively of equal energy are anticipated according to qualitative MO models (Fig. 6). These expectations are fully met in the photoelectron spectra[9] of the (dimethylamino)methylboranes $(H_3C)_{3-n}B[N(CH_3)_2]_n$.

From the PE spectrum of trimethylborane given for comparison, one gathers that the ionizations from the BCH framework only occur above 10.5 eV. The PE bands at lower ionization energies are to be assigned on this basis to the bonding and nonbonding π electrons. As expected, the ionization energy $IE^v(\pi_b)$ increases with increasing number n of substituents X, and the approximate intensity ratios of the bands $\pi_{nb}:\pi_b$ amount to 1:1 for $n=2$ and 2:1 for $n=3$. Especially instructive is the change from tris(dimethylamino)borane, whose BN π bonds are twisted in a propeller-like fashion by some 30° to the ring-flattened π system of triazaboradecalin because of the steric demands of the methyl groups. As a consequence of better overlap, the π delocalization becomes greater and the π_b ionization energy increases by about 0.9 eV. As expected, the π_{nb} band remains nearly constant and is broadened because the different alkyl substitution—$N(CH_2—)_2$/—$NH(CH_2—)$ removes the π_{nb} degeneracy[9].

In the general case of planar BX_3 compounds with at least local D_{3h} symmetry, the degenerate π_{nb}-orbital belongs to symmetry type e'' and the π_b orbital to a_2''. The difference ΔIE_π in the PE ionization potentials thus assigned reflects the dependence of π stabilization on the substituent X (Fig. 7).

In Fig. 7 the BX_3 molecules are arranged according to increasing π_{nb} ionization potential. An increasing π splitting is found for $S \approx O < N$ and $I < Br < Cl < F$. As a rough approximation, it is to be expected that with comparable overlap the π interaction should increase with decreasing energy gap between the electron pair n_X and the unoccupied p_B boron orbital, for example $\Delta\pi_N > \Delta\pi_O$. With a comparable energy gap between n_X and p_B, the π interaction increases with better overlap, for example $\Delta\pi_O > \Delta\pi_I$. Finally in a comparison of BCl_3 with BF_3, $\Delta\pi_{Cl}$ is smaller than $\Delta\pi_F$,

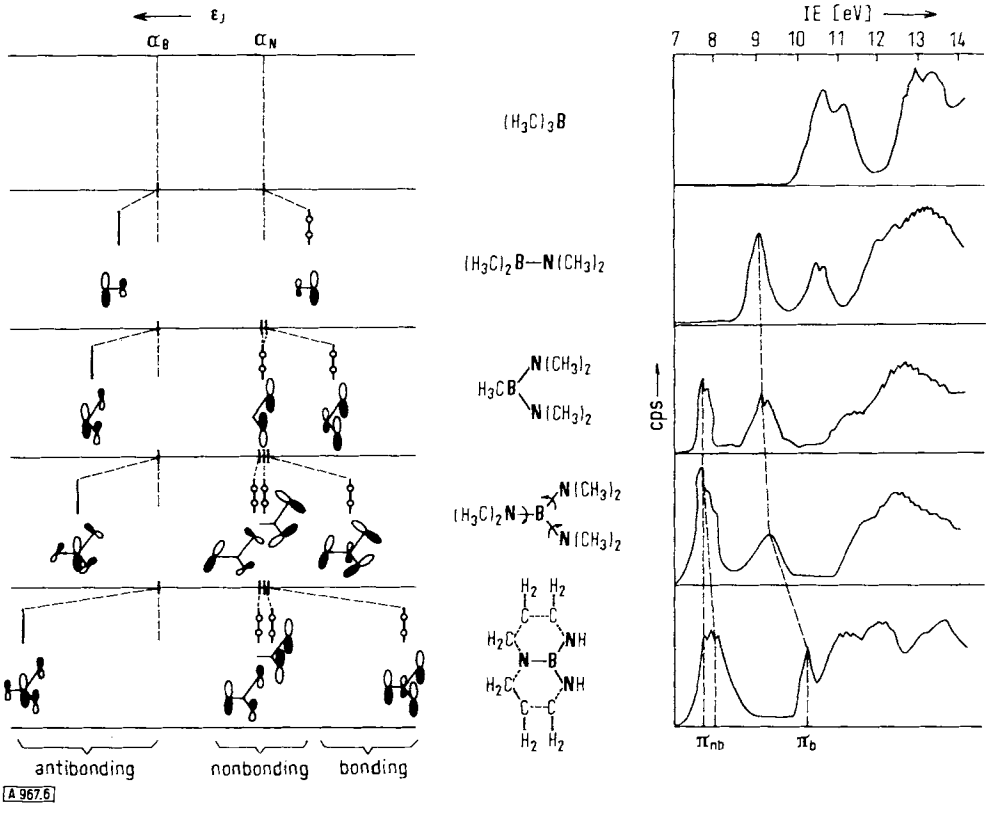


Fig. 6. Qualitative MO models for π delocalization in boron compounds $R_{3-n}BX_n$ and PE spectra in the 7—14 eV region for trimethylborane, (dimethylamino)methylboranes, as well as triazaboradecalin (2,6,10-triaza-1-borabicyclo[4.4.0]decane) [9].

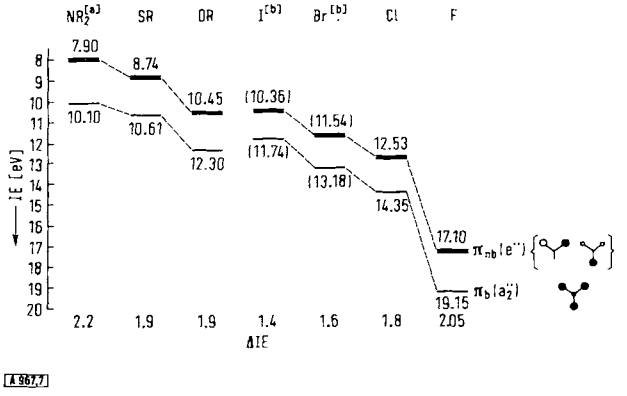
even though n_{Cl} lies more than 4 eV higher than n_F, which demonstrates the limitations of an exclusively π argument. It is known that fluorine substituents lower σ orbitals by several electron volts because of their strong σ electron withdrawing interaction, but that because of an opposing



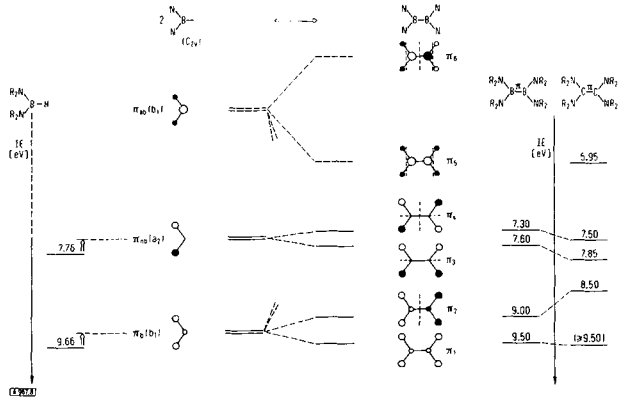
A 567.7

Fig. 7. PE ionization energies of BX_3 compounds [9—11].
[a] triazaboradecalin. [b] spin-orbit coupling.

donor interaction the π orbitals are only slightly affected. BF_3 can be regarded as a special example of this "perfluoro effect" in which the large inductive effect of three fluorines at a single center lowers the vacant boron 2p orbital sufficiently to allow strong π back bonding by n_F, $\ddot{F}\overset{\frown}{\leftarrow}B$.

The π splitting from the PE spectra of the boron trihalides (Fig. 7) permits rationalization of further molecular properties. Thus, *inter alia*, the order of decreasing Lewis acidities $BI_3 \approx BBr_3 > BCl_3 > BF_3$[7,11,12] may be the result of the loss of π stabilization energy[7,11] in the order $BI_3 < BBr_3 < BCl_3 < BF_3$ which is important in determining the position of the equilibrium:

$$X_3B + :D \rightleftharpoons X_3B{-}D$$



A 567.8

Fig. 8. Molecular orbitals of the $(R_2N)_2BH$ π system, their symmetry-adapted combination to the molecular orbitals π_1 to π_6 of $(R_2N)_2E{-}E(NR_2)_2$, and comparison of the PE ionization energy of tetrakis(dimethylamino)diborane(4) and -ethylene [13]. (All orbital diagrams as bird's-eye views.)

Next, the compounds $(R_2N)_2E{-}E(NR_2)_2$ with E = B,C should serve as another example along the way, which illustrates not only the utility of PE spectroscopy in comparison of related molecules, but also the construction of MO models through symmetry-adapted combinations of partial systems characterized by PE spectroscopy. The π system of bis(dimethylamino)boranes, $(R_2N)_2BR$, presented in Figure 7 is the point of departure. For R = H from the PE spectrum one obtains a splitting $IE_{\pi_b} - IE_{\pi_{nb}} = 9.66 - 7.76 = 1.9$ eV. Union at E—E of the $(R_2N)_2E$ building blocks yields in a transparent fashion the desired molecular orbitals of $(R_2N)_2E{-}E(NR_2)_2$, π_1 to π_6 (Fig. 8). The starting orbitals π_b and π_{nb} from $(R_2N)_2BH$ were combined in Figure 8 on the assumption that they are inductively raised on exchange of H for the two $B(NR_2)_2$ groups, and that the π_6 (b_1) interaction with the symmetry equivalent $\pi_{ab}(b_1)$ orbital produces negligible intermixing because of the large orbital separation $E\pi_{ab} - E\pi_b$. This results in orbitals of increasing nodal number with predominate or exclusive N character, the B—B contribution being minute and the resultant splitting of the pair π_1/π_2, as well as π_3/π_4, only slight. In contrast to tetrakis(dimethylamino)diborane(4), the ethylene derivative possesses two more electrons, which occupy π_5. This orbital ought to be strongly lowered due to the substantial π_{ab} splitting, in keeping with the dominant C—C character. Within our MO picture, the fine differences in the vertical ionization energies allow parametrization such that the interaction C—N is smaller than B—N and as a result the splitting of the starting orbitals π_b/π_{nb} decreases, whereas the splitting π_1/π_2 increases because the interaction C—C is greater than B—B.

The qualitative MO model for the π systems $N_2E{-}EN_2$, developed on the basis of PE spectra (Fig. 8), permits additional properties of the molecules $(R_2N)_2E{-}E(NR_2)_2$ to be understood. Thus tetraaminoethylene reacts with C—C cleavage to form metal-diaminocarbene complexes, and because of ready electron donation functions as a strong reducing agent with formation of radical cations and dications. For the diboron derivative, a dianion is predicted with a shortened B—B bond[13].

Is borazine, $B_3N_3H_6$, an "inorganic benzene"? This apparent problem, a subject of much discussion[8c], arises from the isosteric relationship between the two compounds, which can be illustrated by comparison of the PE spectra, and will at the same time close this Section on electron delocalization in boron compounds. The point of departure is the PE spectrum of benzene (Fig. 9), whose bands of lower ionization energies are assigned as specified to the five highest occupied molecular orbitals[14a]. On going to borazine, the symmetry D_{6h} is reduced to D_{3h}, whereby according to symmetry correlation tables[15], the following symmetry transformations occur:

			D_{6h}	→	D_{3h}
π:	e_{1g}	and	e_{2u}	→	e″
	b_{2g}	and	a_{2u}	→	a_2''
	e_{2g}	and	e_{1u}	→	e′

(6)

Within a qualitative MO model this means that additional splitting is to be expected for each of those molecular orbitals which then belong to the same symmetry type as a result of the symmetry lowering $D_{6h} \rightarrow D_{3h}$—compare for example the arguments pertinent to Figure 4 or 8. Thus the bonding π-orbitals 1e″ and $1a_2''$ (previously $1e_{1g}$

and $1a_{2u}$) should be depressed through the interaction with the antibonding π orbitals 2e'' and $2a_2''$ (previously $1e_{2u}$ and $1b_{2g}$). By contrast, the occupied σ orbital 4e' must remain nearly constant as a result of being bracketed by three σ bonding and 4 antibonding σ^* orbitals of equivalent symmetry type e'[16a]. As Figure 9 shows, these expectations are entirely fulfilled.

The orbital sequence $\pi/\sigma/\pi$ in borazine, as has been proposed proceeding from the isoconjugate six-membered rings on the basis of symmetry-adapted perturbation arguments[16a], finds numerous confirmations in the PE spectra: the ring vibrational fine structure[16a,b,18], the Jahn-Teller splitting[16b,18] of the states corresponding to the doubly degenerate orbitals π_2(1e'') and σ_8(4e'), and the approximate intensity ratios of 2:2:1 in the first three bands. The π splitting amounts to 2.74 eV (2.99 eV in benzene).

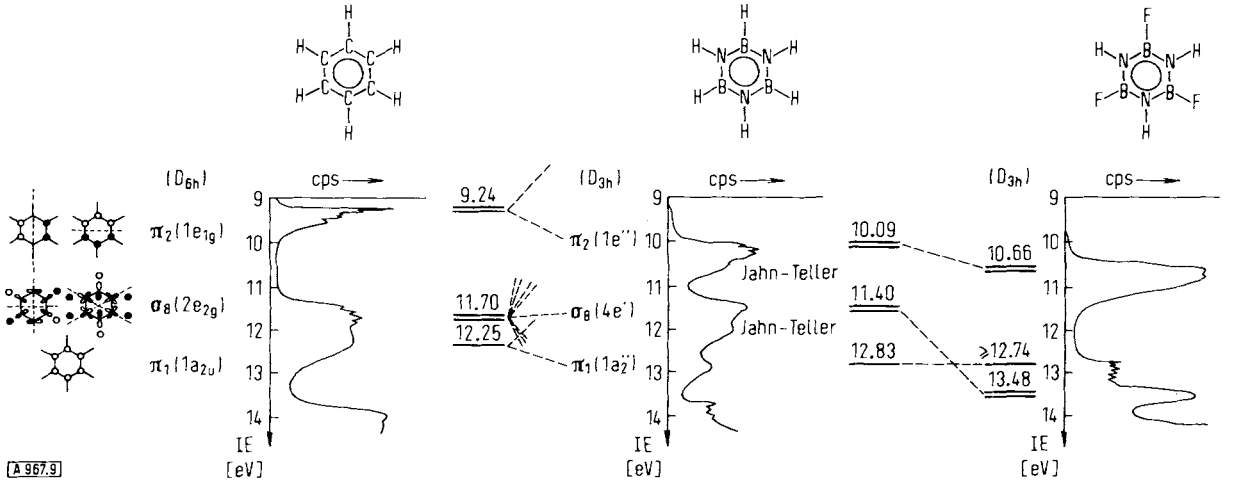


Fig. 9. PE spectra in the region 9—14 eV of benzene [14], borazine [16a], and *B*-trifluoroborazine [17a] with band assignments.

An "*ab initio*" calculation yields the same orbital sequence[17]. Comparison with the PE spectrum of *B*-trifluoroborazine furnishes additional arguments[16b,18]. As already discussed for BF_3, the fluorine substituents increase the σ ionization energies, whereas the π ionization energies remain nearly constant. A comparison of the PE spectra of borazine and its *B*-trifluoro derivative shows that the σ ionization energy increases by about 2.08 eV. At the same time the intensity ratios of the first three bands change from 2:2:1 to 2:1:2. The perfluoro effect thus confirms the orbital sequence $\pi/\sigma/\pi$ for borazine and thus also the similarity with benzene.

Looking back, Section 2 contained further examples of how connections between related molecules become visible in their PE spectra, and how this simultaneously facilitates the assignment of spectra. For these purposes, compounds with trigonal planar boron are didactically excellent, because a π system follows as a consequence of the boron electron deficiency. These π systems are satisfactorily described with MO models whose orbital energies can be correlated by Koopmans' theorem with vertical ionization energies which we measure as energy state differences. Although the discussion of boron trifluoride showed how arbitrary the model subdivision of molecules can be, in many planar molecules π and σ electrons can obviously be separated to a good approximation. Therefore, π and σ systems of selected carbon and silicon compounds will next be treated separately.

3. π and σ Interactions in Carbon and Silicon Compounds

Elements of Group IVB differ from the electron-deficient element boron in that the number of valence electrons corresponds to the number of valence orbitals. In discussions of their compounds this has lead to an overemphasis of the so-called "bond model". The bond line, as the topological symbol for the connection between atoms, has been identified with two electrons, and the molecule described in this way with localized bonds. On the other hand, for example, the bond enthalpy parameters derived from heats of formation are not strictly additive even for isomeric hydrocarbons[19a] and as might be expected cannot be correlated with mass spectroscopic dissociation energies.

3.1. PE Splitting Patterns for Ethylene π Units in Different Molecular Frameworks

The PE spectrum of planar ethylene (Fig. 5) was assigned with a molecular orbital model (Fig. 4) which established an occupied π molecular orbital with the usually accepted σ-π separation. Extending this assumption, to what extent can the PE splitting patterns of larger π systems (Fig. 10) be interpreted in terms of interactions between small π units such as these?

For a detailed discussion of the PE spectra of the hydrocarbons in Figure 10, the reader is referred to the original work largely carried out by *Heilbronner et al.* Neglecting the σ contributions (cf. Section 3.3), an attempt will be made in a simple model to clarify their π ionization energies (Fig. 10) by means of the different spatial arrangements and symmetry types of the π molecular orbitals. For a better overview, we differentiate between three groups:

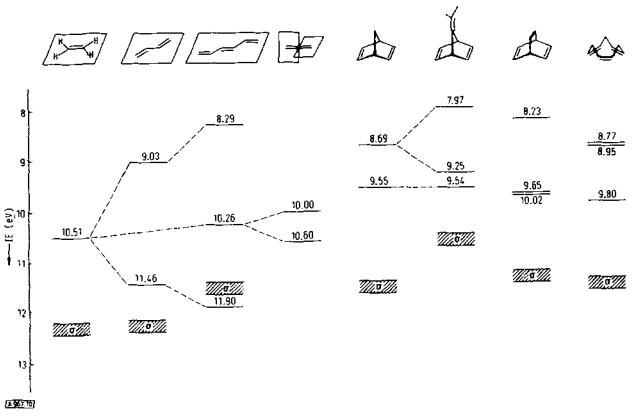

Fig. 10. Vertical π-ionization energies IE^v (eV) of ethylene [2a, 5], s-*trans*-butadiene [2b, 20], all-*trans*-hexatriene [20], allene [21, 2a], norbornadiene [22—24], 7-isopropylidenenorbornadiene [23, 24], barrelene [25], and trishomobenzene [22, 26].

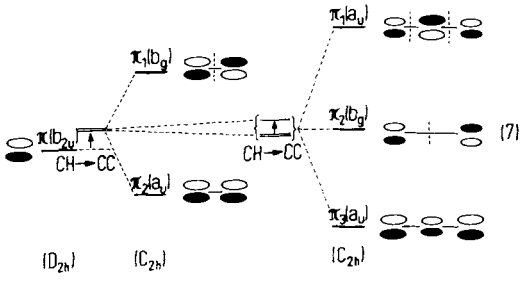
planar conjugated, linear cumulated, and nonneighboring through space interacting ethylene π systems.

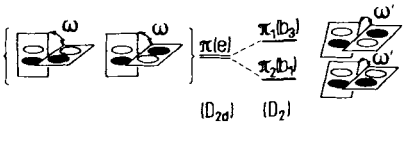
The planar alkenes $H(HC{=}CH)_nH$ exhibit a PE splitting pattern[20] (Fig. 10), which is describable in a clear fashion through a linear combination of occupied ethylene π orbitals:



(7)

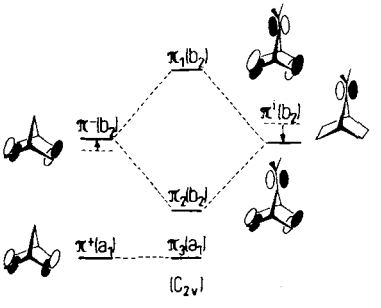
In the MO model (7) the coupling of two ethylene molecules raises the π center of gravity because of the replacement of each CH by a common C—C bond[20]. This then splits into a bonding (C_{2h}:a_u) and an antibonding (b_g) linear combination; the interaction parameter, $\beta = -1.22$ eV, follows from the PE ionization energy difference, $\Delta IE_\pi = 2.43\,\text{eV} = 2|\beta_\pi|$. In hexatriene one must proceed formally from two different ethylene π units; of these, the C—C bonded on both sides should be raised still further. After "switching on" the π interaction, the nonbonding MO $\pi_2(b_g)$, with a nodal plane through the central bond, remains unaltered, whereas the two a_u molecular orbitals show a splitting of $IE_{\pi_3} - IE_{\pi_1} = 3.61$ eV ($\beta_\pi = -1.2$ eV[20]). Notice that in the PE spectrum of hexatriene a σ orbital is inserted between π_2 and π_3 (Fig. 10).

The spectrum of linear allene with two crossed ethylene π units exhibits two PE π bands at 10.0 and 10.6 eV[2a], whose π center of gravity 10.3 eV corresponds closely to that of butadiene. The splitting $\Delta IE_\pi = 0.6$ eV results from



(8)

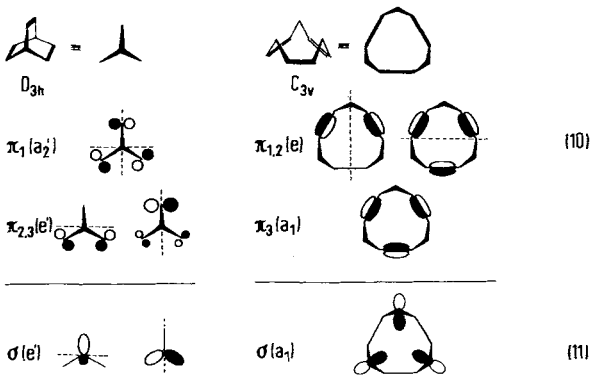
a Jahn-Teller twisting deformation of the radical cation ($D_{2d} \rightarrow D_2$)[21], which lifts the degeneracy of the MO's made up of the mutually perpendicular, noninteracting π units. In the MO model (8) the decrease[21] of the twist angle (calc. $\omega' \approx 38°$) leads to a bonding (D_2:b_1) and an antibonding (b_3) π MO. Of the corresponding radical cation states, the one with doubly occupied bonding π orbitals $(\pi_2)^2(\pi_1)^1$ is more stable than that with the occupancy $(\pi_2)^1(\pi_1)^2$. The interaction of non-neighboring ethylene π moieties through space[27,22] appears especially clear and impressive in a comparison of the PE spectra of norbornadiene[22—24] and 7-isopropylidenenorbornadiene[23,24]. Starting from the two lowest vertical ionization energies of norbornadiene, in a MO model (9) with neglect of σ mixing[26], the electrons may approximately be assigned to the linear combinations π^- and π^+ (C_{2v}: b_1 and a_1):



(9)

Proof for the sequence $IE_{\pi^-} < IE_{\pi^+}$ and, at the same time, another example of splitting between non-neighboring orbitals of the same symmetry type are provided by the ionization energies of 7-isopropylidenenorbornadiene (Fig. 10), which is discussed in a π MO scheme (9) as follows. The arrows designate modification of starting orbitals. Thus, as a result of the increase in size of the C molecular framework of norbornadiene, both the highest occupied σ orbital and the π center of gravity are raised[24,28]. At the same time, the introduction of double bonds into the C molecular framework of 7-isopropylidenenorborane lowers the orbital $\pi^i(b_2)$[24,29]. Interaction is possible only between orbitals of the same symmetry type. Thus, the MO $\pi_3(a_1)$ corresponds to the unchanged starting orbital $\pi^+(a_1)$, whereas $\pi^-(b_2)$ and $\pi^i(b_2)$ mix to form the MOs $\pi_1(b_2)$ and $\pi_2(b_2)$. The "through space" interaction parameter, $\beta_\pi = -\Delta IE_\pi/\sqrt{2} = -0.45$ eV, is comparable to that of norbornadiene[24] and, as expected, smaller than that for direct conjugation, for example in butadiene ($\beta_\pi = -1.22$ eV).

In closing, the π systems of barrelene and trishomobenzene should be compared. These contain in different molecular geometries (D_{3h} and C_{3v}, respectively) three double bonds separated from each other by a tetrahedral carbon center. Their PE spectra exhibit different splitting patterns (Fig. 10) in which the Jahn-Teller-split double maximum appears once as the second and once as the first PE band. Assuming that the through space π interaction dominates in these molecules too, the qualitative π MOs (10), ordered according to increasing number of nodes, permit rationalization of the PE spectroscopically secured sequences $\pi_1(a_2')/\pi_{2,3}(e')$ and $\pi_{1,2}(e)/\pi_3(a_1)$.



(10)

(11)

The additional σ MOs sketched out in (11) should point out here (cf. Section 3.3) that in three-dimensional molecular frameworks π and σ orbitals of the same symmetry type are generally present and will mix with each other to a greater or lesser extent an exception, for example, is π(a'2) of barrelene[25]). Apart from this, however, the π splitting in the PE spectrum of trishomobenzene is in aggreement with the concept of homoaromaticity suggested by *Winstein*[30] for rings with $2n+1$ π units of the same symmetry type and of similar energy[26], with $4n+2$ electrons in accordance with the Hückel rule. However, as is to be expected, a special homoaromaticity cannot be measured[19,26], and the homoconjugative splittings, *e. g.* in cycloactatetraene[29] with 2n π units, are of the same order or larger.

As shown in the previously discussed PE spectra of unsaturated hydrocarbons, π conjugation is consequently not limited to neighboring double bonds. π units separated by a tetrahedral carbon[30a] also conjugate in molecules of appropriate geometry. Here, a useful concept in qualitative MO models, *viz.* that only orbitals of the same symmetry can interact, becomes especially clear. Increasing C_π—C_π distance between the interacting units leads to a decrease in splitting. Examples of this are benzene ($d_{C_\pi C_\pi} = 1.4$ Å, $\Delta IE \approx 3$ eV) and trishomobenzene ($d_{C_\pi C_\pi} = 2.2$ Å, $\Delta IE \approx 0.9$ eV)[27], for which similar PE splitting patterns can be predicted from orbital symmetries, independent of the value of the π splitting (Figs. 9 and 10).

In three-dimensional molecular frameworks, such as trishomobenzene, "σ orbitals" of π symmetry[10]type can mix with π orbitals. But before a discussion of this σ-π interaction, it should be investigated first how far the MO model developed with π systems can be applied to σ systems.

over the molecular framework. Predictably, therefore, the data can be satisfactorily understood in terms of different MO models[31]. Here an approximation closely related to the discussed PE splitting pattern of π units is preferred, which considers interactions exclusively between bonding orbitals[20,27,31]. This so-called LCBO (linear combination of bond orbitals) MO model[31] proves to be especially useful[20] in interpretation of PE spectra, in spite of its inherent simplifications[27], because it may be more straightforwardly parametrized from PE spectra.

The He(II) spectrum of methane[2b] shows two bands; one between 12.6—16 eV with a center of gravity at 14.2 eV, with apparent threefold Jahn/Teller splitting[32] due to the change in molecular geometry of the radical cation ($T_d \rightarrow D_{2d}$[32]→...), and a second one near 23 eV. The molecular orbitals of the LCBO model (Fig. 11) follow from the known rule that their number of nodes increases with increasing orbital energy. The relative orbital energies can be estimated with the help of an approximate formula[*][19b,32].

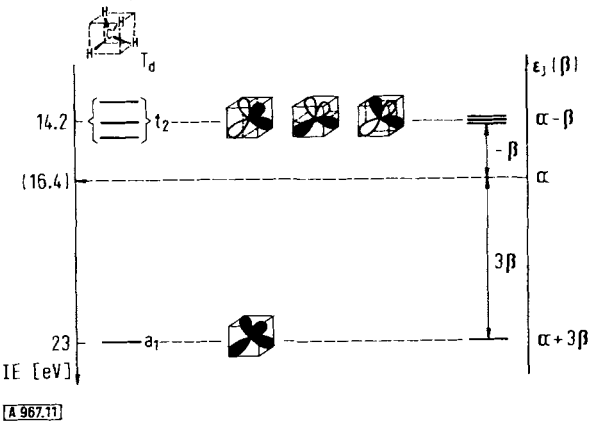


Fig. 11. PE ionization energies of methane and parametrization of a CH bond orbital model [*].

As can be seen in Figure 11, one MO without nodes at $\varepsilon_1 = \alpha + 3\beta$[*] and three degenerate MOs each with one node at $\varepsilon_{2,3,4} = \alpha - \beta$[*] result. Comparison with the PE ionization energies *via* Koopmans' theorem (4) gives an orbital center of gravity $\alpha_{CH} = -16.4$ eV and an interaction parameter $\beta_{CH} = -2.2$ eV.

Alkane	CH_4	H_3C-CH_3				C_6H_{14}		
IE_1 [eV]	13.0	11.6	11.1	10.6	10.2	10.1	10.1	10.0

(12)

3.2. Bond-Bond Interactions in Alkanes and Silanes

It has been long known that mass spectroscopic ionization potentials of alkanes decrease with increasing chain length and increasing branching[31].

This experimental result suggests that in the resultant alkyl radical cation the positive charge is significantly delocalized

[*] For systems with equivalent starting orbitals, the approximate eigenvalues $\varepsilon_j^0 = \alpha + x_j^0\beta$ (where x_j^0 is the splitting relative to the orbital center of gravity in units of β) are given by the following[19b,33]: The eigenvalue coefficient $x_j^0 = 2\left(\frac{1}{n_j}\right)(Z_{b,J} - Z_{ab,J})$ is obtained from the number of starting orbitals n_j in molecular orbital J as well as the number of bonding $Z_{b,J}$ and antibonding $Z_{ab,J}$ interactions between them. For the LCBO molecular orbital of methane one obtains, $x_1^0 = 2(\frac{1}{4})(6-0) = +3$ and $x_{2,3,4}^0 = 2(\frac{1}{4})(2-4) = 1$ (cf. Fig. 11).

The example of methane not only demonstrates how easy it is to parametrize LCBO models. It also shows that with the previously mentioned assumption of four C—H bonds containing four equal and independent bonding electron pairs important molecular properties remain unexplained. Finally, the observed[2b] band intensities $t_2:a_1=7:1$ (instead of 3:1), which would have to be explained[26,34] by a predominant C(2p) contribution with larger cross section to the t_2 orbital and predominant $C(2s_1)$ contribution to the a_1 orbital, also point out the limitations of models with isolated equivalent bonds[*].

The electron delocalization[**] in σ molecular frameworks becomes especially clear in a comparison of the PE spectra of permethylpolysilanes and their interpretation by simple MO models[35]. Hexamethyldisilane ($Me_3SiSiMe_3$) exhibits a well separated PE band at 8.69 eV in its spectrum, which can be assigned as an ionization from a predominantly Si—Si bond molecular orbital. In the region 7.5—10 eV open-chain, branched, and cyclic polysilanes (—Si—Si—) possess characteristic PE splitting patterns (Figure 12) as would be expected from the topology of the Si—Si bond framework.

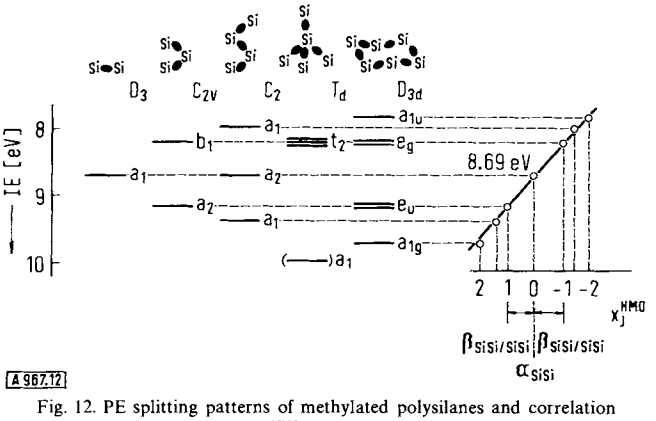

Fig. 12. PE splitting patterns of methylated polysilanes and correlation with eigenvalue coefficients x_j^{HMO}.

With the different splittings, the center of gravity of the Si—Si molecular orbitals (8.69 eV) remains approximately constant, so that the SiC and CH orbital contributions can be neglected, except in so far as they are absorbed into the hexamethyldisilane standard. For this correlation Hückel MO eigenvalues (orbital energies) $\varepsilon_j^{HMO}=\alpha+x_j^{HMO}\beta$ (cf. [**]) are used. The PE parametrization can be carried out in this case directly from the first ionization potential of hexamethyldisilane IE_1 ($Me_3SiSiMe_3$) = 8.69 eV = $-\alpha_{SiSi}$ ($x_j^{HMO}=0$); the interaction parameter $\beta_{SiSi/SiSi}=-0.5$ eV is obtained from the slope of the regression line drawn in Figure 12. In conclusion it may be noted that numerous other properties of polysilanes, such as the decreasing electronic excitation energy of open-chain derivatives $R—(SiR_2)_k—R$ with increasing chain length k, are explained with σ electron delocalization[35].

The PE spectra of polysilanes (Fig. 12) are, as a consequence of the low ionization potential of the Si—Si bond, an especially illustrative example of the utility of σ MO models. In particular for molecular frameworks of high symmetry, these models can be broadened to accommodate the general case in which mixing between different bond types cannot be neglected. Thus the PE spectrum of neopentane can be assigned on the basis of a LCBO model similar to that of Figure 11 with symmetry-adapted combinations of CC and CH bonding orbitals[36]. Returning to the starting point, it becomes understandable that the first ionization potential of linear or branched alkanes C_nH_{2n+2} must decrease[37] with increasing n, *i.e.* an increasing number of starting orbitals[19d,31].

LCBO models are frequently advantageous for the description of σ molecular skeletons, even though they neglect the possible mixing in of unoccupied orbitals, because they may be easily parametrized with the aid of PE ionization energies. At the same time, an important contribution of photoelectron spectroscopy to our knowledge of molecules becomes apparent: σ molecular skeletons are finally more accessible to measurement.

3.3. π-σ-Conjugation

In the preceding sections, π-π and σ-σ interaction models were introduced on the basis of the PE ionization energies of selected hydrocarbons and alkylsilanes. Here, it was pointed out that conjugation between π bonds is not restricted to planar systems with neighboring π centers, but that depending on molecular geometry and symmetry type of the π starting orbitals, "through space" interactions may also result. Further on in the discussion of MO models for three dimensional unsaturated molecules, it was shown that the π orbital center of gravity did not depend only on the composition of the molecules compared with each other (cf., *e. g.* (9): differing alkyl group size or increasing number of π bonds), but was significantly determined by the available "σ-orbitals" or π symmetry (cf., *e.g.*, (10) and (11)). In the following, this extension of the π conjugation concept to symmetry-allowed π-σ interactions, termed "hyperconjugation" by *Mulliken*[38] and summarized under through bond coupling effects by *Hoffmann*[27], will be explained in greater detail utilizing additional spectroscopic results.

For an example of the application of a hyperconjugation model, we can draw upon the methylacetylene PE spectrum[2a] which can be assigned, with assumption of a splitting between the degenerate π orbitals of the rotationally symmetric acetylene π system and the degenerate π orbitals of the methyl group[39] (Fig. 13).

For the starting orbitals we use the first ionization potentials of acetylene $IE_1(HC{\equiv}CH)=11.4\,eV\equiv-\alpha_{C\equiv C}$ and of methane $IE_1(CH_4)=14.2\,eV\equiv-\alpha_{CH_3}$ because three CH bonding orbitals under local C_{3v} symmetry with $\alpha_{CH}=-16.4$ eV and $\beta_{CH/CH}=-2.2$ eV should split to give the CH_3

[*] In the LCBO model of methane the three highest occupied orbitals are of symmetry t_2 and can contain only the p_C atomic orbital. The low lying a_1 molecular orbital contains only the s_C atomic orbital.

[**] In general each linear combination of a set of occupied orbitals leads to exactly equivalent calculation results [3b]. Clearly the labor and expense of the calculation decreases with a proper choice of starting orbitals. A set of occupied orbitals may readily be transformed into another without changing the total energy (see, for example, the discussion of methane in [19a]). Thus bonds may be localized or delocalized. Such equivalent MO models are differentiated only in their application to the explanation of specific molecular properties.

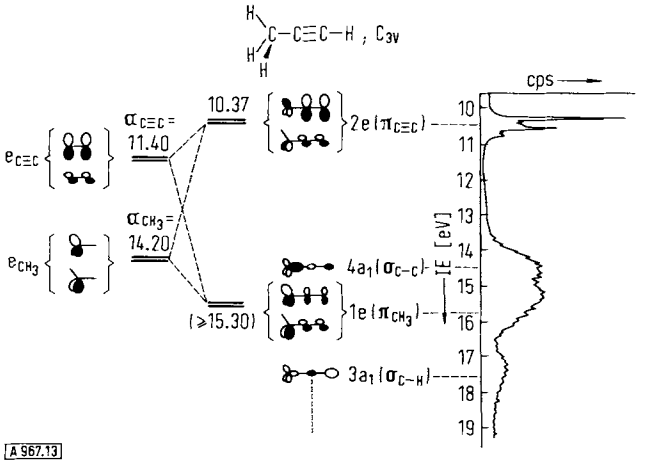

Fig. 13. Hyperconjugation model $e_{C\equiv C}/e_{CH_3}$ and PE spectrum of methylacetylene [2a].

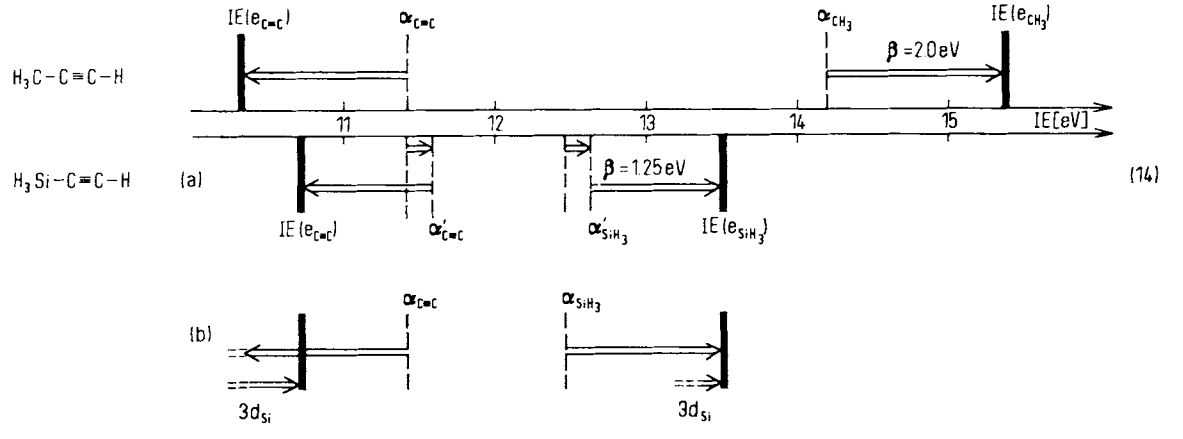
group orbitals e and a_1 at -14.2 eV and -20.8 eV (Fig. 11). The hyperconjugation parameter $\beta_{C\equiv C/CH_3}$ can be calculated as follows from the PE ionization energy[39].

$$\begin{vmatrix} \alpha_{C\equiv C}-\varepsilon & \beta_{C\equiv C/CH_3} \\ \beta_{C\equiv C/CH_3} & \alpha_{CH_3}-\varepsilon \end{vmatrix} = 0$$

$$\beta_{C\equiv C/CH_3} = -\sqrt{(IE_1^{HC\equiv CH}-IE_1^{H_3C-C\equiv CH})(IE_1^{CH_4}-IE_1^{H_3C-C\equiv CH})}$$
$$= -2.0\,\text{eV}$$

A comparison is interesting with silylacetylene $H_3SiC{\equiv}CH$[39] whose first ionization potential $IE_\pi = 10.73$ eV is some 0.4 eV greater (!) than that of the methyl derivative. Parametrization is possible with $\alpha_{SiH_3} \equiv -12.45$ eV the average ionization potential of the e_{1g} and e_{1u} orbitals of disilane[39]. After a necessary 0.16 eV correction to the π center of gravity, the relatively smaller (compared to CH_3 hyperconjugation) parameter $\beta_{C\equiv C/SiH_3} = -1.15$ eV is obtained. Diagram (14) compares the π ionization potentials (|) and the hyperconjugation parameters (:) for methyl- and silylacetylenes:



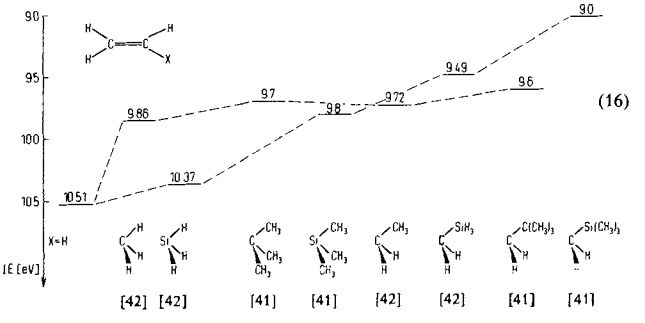
as $3d_{Si}$ or $4p_{Si}$ (14b), can only be defined in corresponding LCAO MO calculations (cf. *e. g.*[39] and particularly[40]). Nevertheless, the PE spectroscopic parameters (14) demonstrate that in spite of a smaller orbital separation $\alpha_{XH_3} - \alpha_{C\equiv C}$ in the silicon compound the net interaction β is smaller over the longer bond length in accordance with reduced overlap. Beyond this, the utility of the PE parameters (14) can be illustrated, for example, through the prediction of the three π ionization potentials of the disubstituted acetylenes[39]:

$$IE_{1,3} = \frac{\alpha_{C\equiv C}+\alpha_{CH_3}}{2} \mp \sqrt{\left(\frac{\alpha_{C\equiv C}-\alpha_{XH_3}}{2}\right)^2 + 2\,\beta^2_{C\equiv C/XH_3}}$$
$$IE_2 = \alpha_{XH_3}$$

IE_1 ($H_3CC{\equiv}CCH_3$) calc. 9.62 eV, exp. 9.61 eV and

IE_1 ($H_3SiC{\equiv}CSiH_3$) calc. 10.40 eV, exp. 1046 eV.

Hyperconjugation models cannot often be so directly parametrized[37,40] as was the case for the two degenerate e orbitals of methylacetylene (Fig. 13). By way of example, in planar π systems, with $XR^1R^2R^3$ substituents each of the XR bonds may be resolved into a π and a σ component and π-σ orbital mixing treated in this way[40]. On the other hand, simple qualitative hyperconjugation arguments are also often useful, as can be shown by the following discussion of the first ionization potentials of alkyl- and silylethylenes[41,42].



(16)

Generally, parametrization of LCBO hyperconjugation models can incorporate only the total interaction of the XH_3 substituent. Further factoring, into inductive contributions or in the case of silylacetylene into compensating back bonding to unoccupied orbitals of π symmetry such

Hyperconjugation increasingly destabilizes a π orbital; the smaller the energy difference of the starting orbitals, the better they overlap and, what is most important, the greater is the electron density in that p atomic orbital of substituent atom X which couples the π_{CX} and σ_{XR} bonds. For example,

in (16) because of the comparable C components in the σ_{C-H} and σ_{C-C} bonds the effects of all alkyl substituents are of comparable size whereas in the sequence $\sigma_{SiH} < \sigma_{Si-C} < \sigma_{C-SiH} < \sigma_{C-SiC}$ the π ionization potentials decrease sharply. Coplanarity of the π_{CX} and σ_{XR} bonds is a requirement for hyperconjugative interaction. This conformational dependence is found both experimentally[*] and in SCF MO calculations[41,42]. These approximation calculations[41,42] however give the correct energy sequence of π ionization energies only if Si_{3d} orbitals are included in the calculation.

Finally, hyperconjugation between two π units and CH_2 bridges as a function of the angle between the π planes should be presented. The first two PE ionization energies of norbornadiene (Section 3.1: Fig. 10), which have been assigned by comparison (9) with the 7-isopropylidene derivative to the antibonding $\pi(b_2)$ and the bonding $\pi(a_1)$ linear combinations[22-24], are the starting points for this discussion. Here the dominating through space interaction leads to a natural orbital sequence according to increasing nodal number. The dihedral angle ω between the planes of the double bonds, which in norbornadiene equals 112°, widens with increasing methylene group number n in the $(CH_2)_n$ bridge. As a consequence, the π overlap and with it the π-π split each decrease, which increasingly stabilizes the antibonding $\pi_1(b_2)$ and destabilizes the bonding $\pi_2(a_1)$ (Fig. 14).

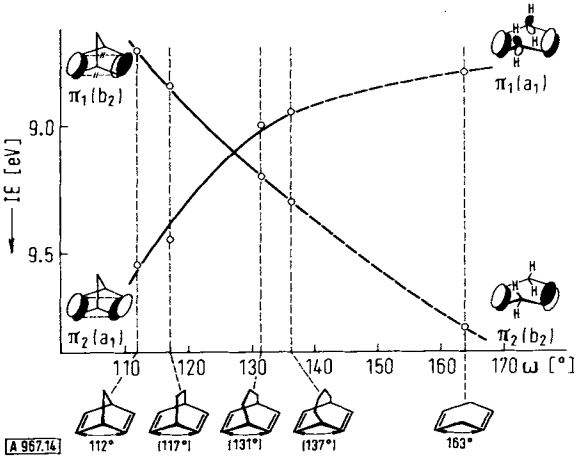


Fig. 14. Correlation diagram for through space-through bond splitting in 3,6-bridged 1,4-cyclohexadienes and 1,4-cyclohexadiene as a function of the dihedral angle ω [28].

For the $(CH_2)_3$- and $(CH_2)_4$-bridged cyclohexadienes, a π orbital sequence $\pi_1(a_1) > \pi_2(b_2)$ can be established by a comparison analogous to (9) of the spectra of bicyclo[3.2.2]nonatriene[43] and bicyclo[4.2.2]decatetraene[23] In 1,4-cyclohexadiene, dihedral angle $\omega = 163°$, the π

(17)

splitting reaches one eV[22-24]. The continuing rise of the bonding πa_1 molecular orbital and with this the reversal of the through space sequence $(\pi_1(b_2)/\pi_2(a_1) \Rightarrow \pi_1(a_1)/\pi_2(b_2)$ is traced back to increasing hyperconjugative destabilization of $\pi(a_1)$. The widening of the dihedral angle ω makes possible an increasingly stronger antibonding admixture of the σ orbital portion of π symmetry (Fig. 14).

This example should end the discussion which started with π-π splitting and proceed *via* σ-σ and π-σ interactions to π-σ-π conjugation. The simple models[44] introduced permit the approximate description of even three-dimensional molecules with π-σ mixing. These models are also supported by SCF MO calculations. He(I)/He(II) spectroscopy, which simultaneously furnishes all valence electron ionization potentials, has made important contributions to the development and verification of model concepts.

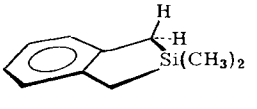
4. Molecules with Electron "Lone" Pairs

In the periodic system of the elements the ratio of the number of electrons to the number of available orbitals increases from left to right along each row. Within the nonmetals, the electron deficient element boron and the IVB elements C, Si... with half occupied (s,p) orbitals are followed by the Group V—VIII electron rich elements. These elements (V—VIII) possess, in their low coordination number compounds, "lone pair" electrons n_x on the atoms. The optimal distribution of regions of high electron density in a molecule is a structure determining factor, for example in the electron pair repulsion model of *Gillespie*[45]. Other possibilities for a favorable charge distribution in radical cations through electron pair delocalization will be discussed in the following on the basis of selected PE spectra.

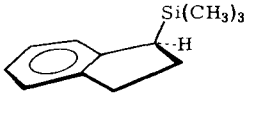
As a rule, PE spectroscopy is well suited for molecules with lone pair electrons n_X, for which in most cases there are characteristic bands in the region of low ionization energies. In an MO picture these are nonbonding electrons in a doubly occupied orbital, which ideally is localized on one center. Except where a high effective nuclear charge, as in fluorine, prevents it, these electrons are easily removed and lead to a needle like PE band (Figs. 2 and 3) which is all the sharper the greater the nonbonding character. Electron pair delocalization manifests itself therefore not only in a shift but usually also in a broadening of the PE band concerned.

We have already become aquainted with most of the MO models necessary for the interpretation of PE spectroscopic results in the preceding sections. Electron pairs n_X can usually be described in terms of p_X atomic or sp^n_X hybrid orbitals and often exhibit π symmetry character. In these

[*] An especially clear example is provided by the results of *C. G. Pitt* [J. Organometal. Chem. *23*, C 35 (1970)] for the indane derivative in which the silicon in each case occupies a β position to the benzene π system. However, where the silicon is fixed in the ring no hyperconjugation interaction of the Si—C bond is possible:



IE_1 = 8.41eV



IE_1 = 8.13eV

cases, the symmetry-determined π-π or π-σ MO models are applicable also to n_X-π, n_X-n_X, or n_X-σ interactions. It has been further pointed out that spin-orbit coupling is often easily observed for degenerate electron pairs of heavier elements. In the following, we shall discuss the PE spectra of molecules with electron pairs n_X, not element by element, but from a more general point of view, especially with regard to the use of particular MO models.

4.1. PE Spectral Correlation of the AH_2 Molecules Hydrogen Sulfide and Water

To begin with, the question to be pursued is: how can lone pair electrons be defined in MO models, and in what way do the pertinent PE spectra correspond with this? The PE spectrum of hydrogen sulfide[2a, 46] represents an example which is also educationally suitable for courses in general chemistry (Fig. 15).

gathered from the MO model of Figure 15, only one unique orbital of b_1 symmetry type exists, and therefore can not enter into bonding or antibonding combinations with other orbitals. In the MO approximation, a nonbonding "lone" or "free" electron pair can therefore be defined such that it must be describable by a single atomic orbital of a unique symmetry type.

Water is a further example of an AH_2 molecule with eight valence electrons. Among other things, it differs from H_2S because of a widening of the HAH bond angle to 105°, which in the MO correlation diagram (Fig. 15) leads to a destabilization of the $2a_1$, molecular orbital (a decrease in bonding interaction because of poorer overlap) and to stabilization of the molecular orbital $1b_1$ (an increase in bonding interaction because of better overlap)[47]. This expectation is confirmed by a comparison of the PE spectra of H_2O and H_2S (Fig. 15). The difference $IE_2 - IE_1$ decreases, and the difference $IE_3 - IE_2$ increases. The increase of the first ionization potential from 10.47 eV (n_S) to

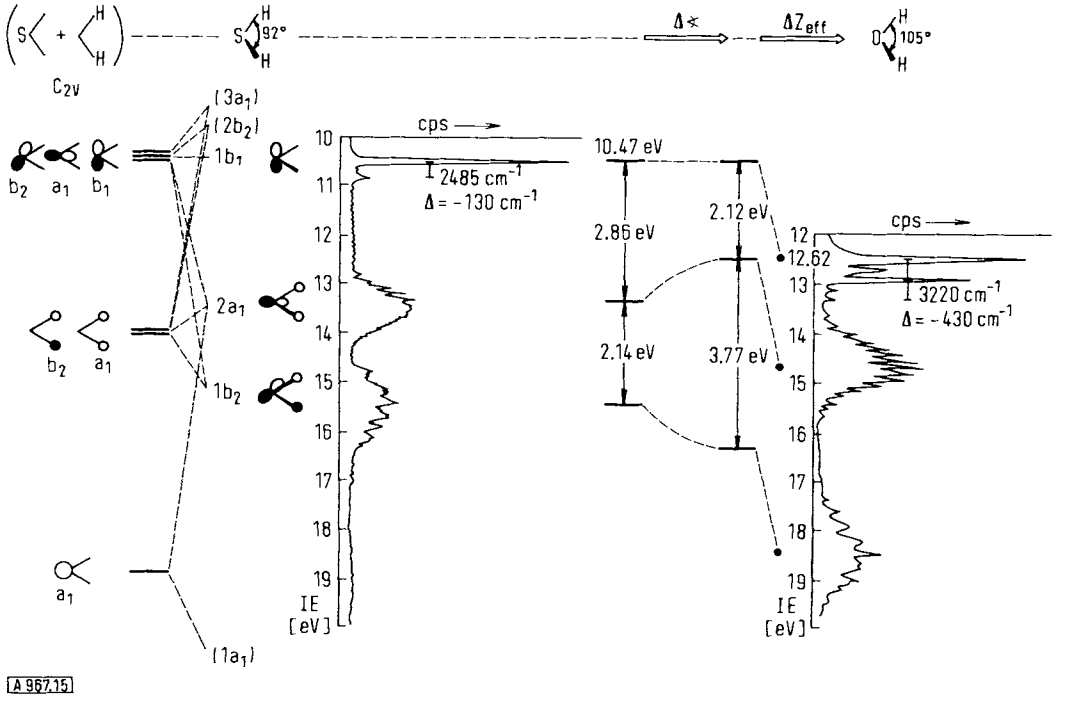


Fig. 15. PE spectra of hydrogen sulfide [2a] and water, and their interpretation in an AH_2 correlation diagram.

The six hydrogen sulfide molecular orbitals of symmetry $3\times a_1 + 2\times b_2 + b_1$ can be derived without difficulty from the symmetry-adapted combination of starting orbitals $3p_S$, $1s_H$, and $3s_S$ (Fig. 15)[19, 47]. Of the four occupied levels, only $1a_1$ with a predominant $3s_S$ contribution lies outside the He(I) measurement range. The indicated assignment can be supported by the pronounced vibrational fine structure[46]. The needle-like PE band at 10.47 eV is particularly interesting, because the vibration frequency due to the cation $H_2S^{\oplus}$ is lowered by only 130 cm^{-1} compared to the symmetric stretching vibration in the H_2S molecule. This PE spectroscopic result verifies that here a nonbonding electron was removed. As may be

12.62 eV (n_O) is caused by the higher effective nuclear charge of oxygen[48], which also polarizes the $O^{\delta-} \leftarrow H^{\delta+}$ bond and increases the charge density on oxygen ($\mu(H_2O) = 1.85$ D, $\mu(H_2S) = 1.10$ D). Within the electron pair repulsion model[45], the angle widening $H_2S \rightarrow H_2O$ can also be understood in this way. Finally both the large decrease in the bond stretching frequency of $-430\,cm^{-1}$ as well as the appearance at the same time of the deformation vibration referred to in Figure 15 are mainly to be traced back to a change in geometry in the radical cation $H_2O^{\oplus}$[46]. As may be easily seen, PE spectra provide a great deal of information about electron pairs in molecules. The aim of the following section will be to demonstrate the applica-

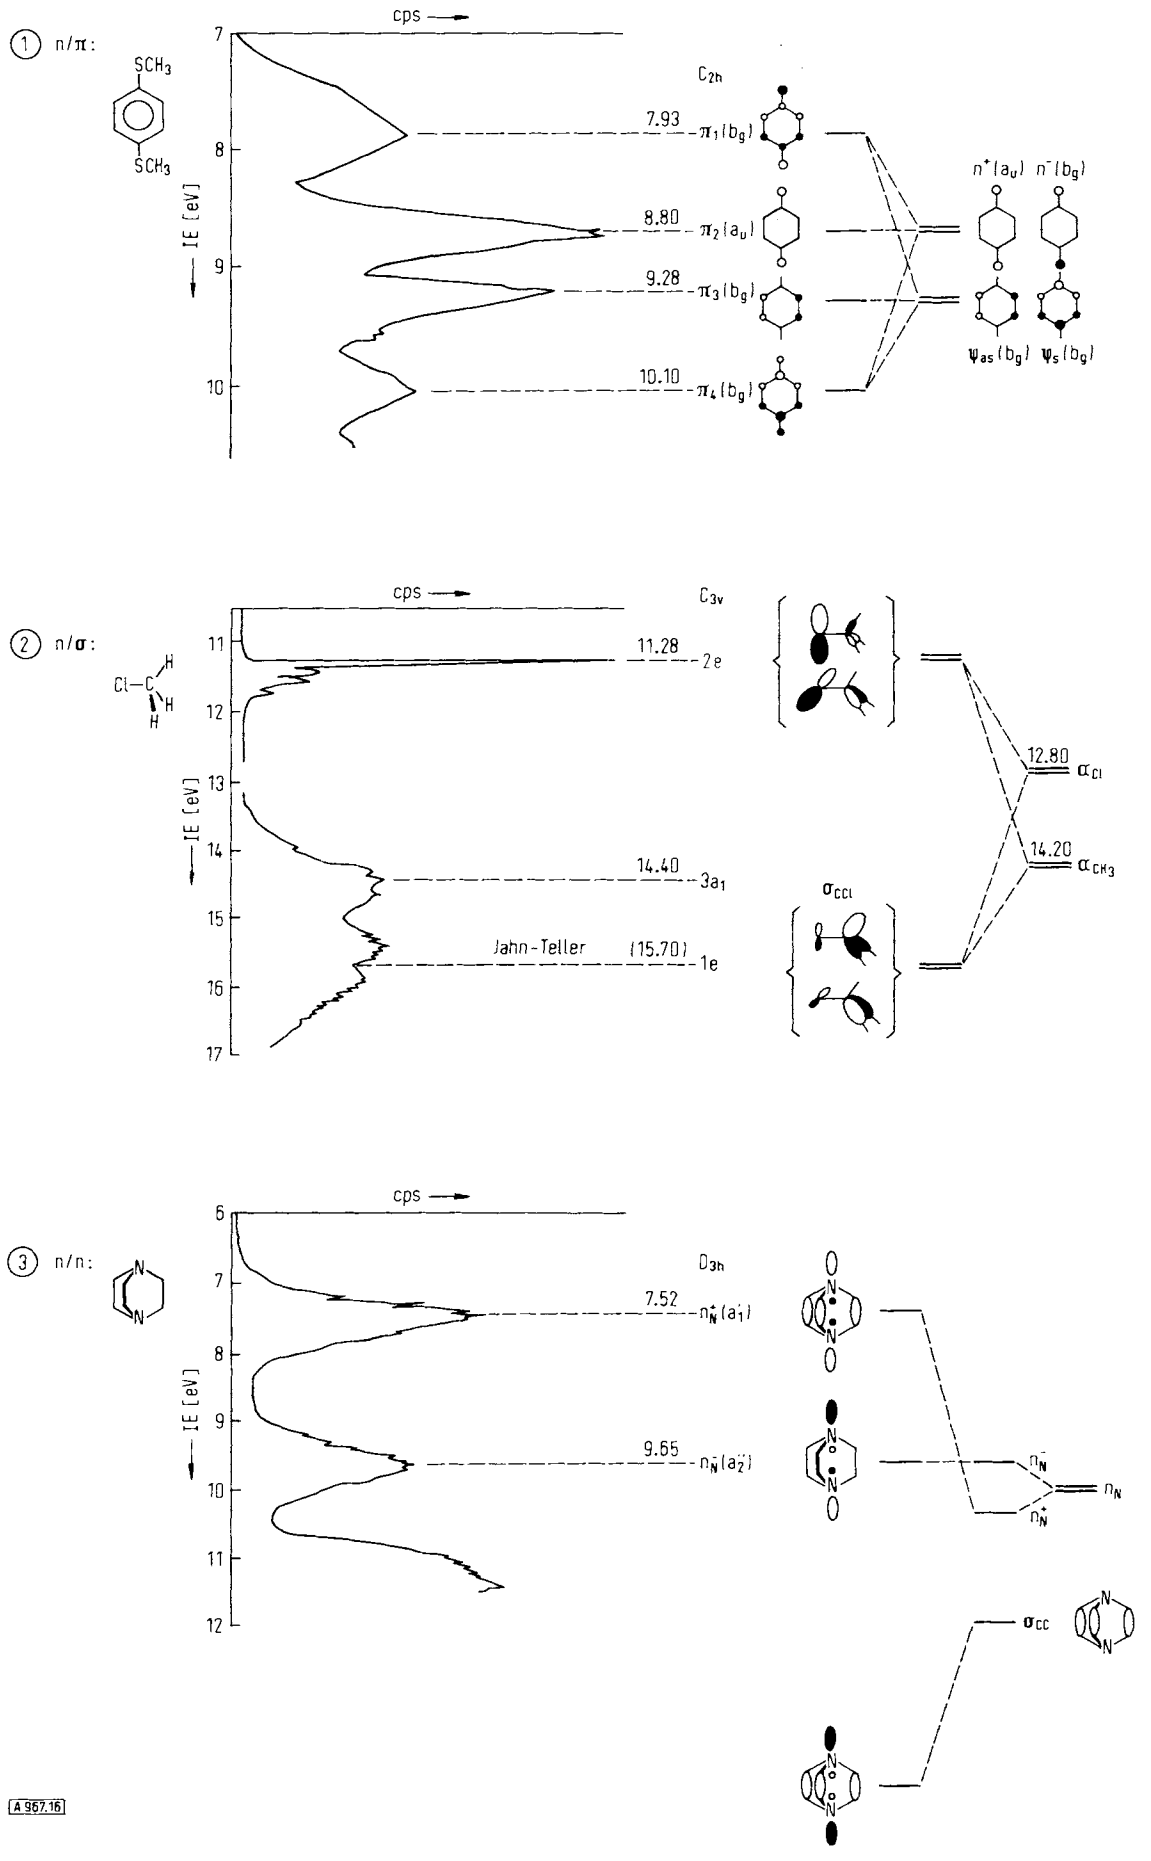

Fig. 16. PE spectra of 1,4-bis(methylthio)benzene [50] methyl chloride [20], and 1,4-diazabicyclo[2.2.2]octane and their assignment with n-π, n-σ, and n-n interaction models.

bility of the MO models introduced in Sections 2 and 3 to the assignment of PE spectra.

4.2. n-π, n-σ, and n-n Interactions

In the interpretation of PE spectra it shows that, "the term 'lone pair' frequently loses much of its meaning and electron pairs in keeping with modern social trends also prefer to live in a commune rather than pairwise isolation"[49]. In an MO picture this means that usually orbitals of the same symmetry type are present which are capable of interactions. In spite of the given general case it is helpful to distinguish between n-π, n-σ, and n-n interactions.

n-π ineractions:

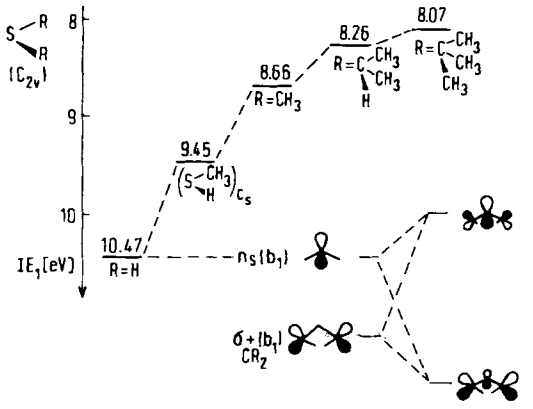
The PE spectrum ①[50] in Figure 16 shows a clearly recognizable n-π splitting. The two sulfur electron pairs can be formally subdivided into the through space combinations $n_S^+(C_{2h}:a_u)$ and $n_S^-(b_g)$, of which only the latter splits with the symmetry-correct $\psi_s(b_g)$ orbital of the 1,4-disubstituted benzene. By contrast $\psi_{as}(b_g)$, although of the same symmetry, cannot mix because of the nodal plane through the substitution centers. (According to the local D_{2h} symmetry which ignores the CH_3 groups ψ_{as} and ψ_s have *different* symmetry assignments.) The symmetry-allowed interaction between $n_S^+(a_u)$ and the nodeless third benzene π orbital (Fig. 9: π_1) is negligible because here the relatively poor n_S-π overlap and the orbital energy separation of about 3.5 eV leave the equal π splitting pattern $\pi_2-\pi_1 \approx \pi_4-\pi_3$ undisturbed.

An enumeration of all PE investigations of n-π delocalization would exceed the limitations of this article. In this connection the PE spectra of additional benzene derivatives should be pointed out with n_N[2a,2c,51–53], n_P[52,53], n_O[2a,50,51], or n_{Hal}[2a,2b,50,54] substituents. Other interesting types of compounds with n-π (n-σ and n-n) interactions are carbonyl halides $X_2C{=}O$[55–57] or thiocarbonyl halides[57,58], and the already discussed boron compounds of coordination number 3. Moreover, the differentiation of σ and π ionizations by the useful "perfluoro effect"[2b,54,55] (cf. Fig. 9) is classified under the rubric "n/π".

n-σ interactions:

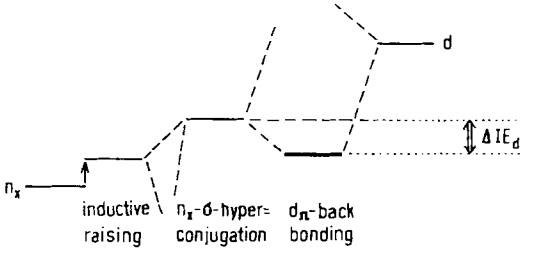
In 1,4-bis(methylthio)benzene, the ionization energy of the sulfur electron pair is lowered by about 1.7 eV relative to H_2S (Fig. 16/①: n_S^+ at 8.8 eV; Fig. 15; n_S at 10.5 eV). An equivalent decrease is found in all other alkyl sulfides[59–61], for example, and can be explained qualitatively by a hyperconjugation model as for the alkyl ethylenes (16).

In simple cases the n-σ interaction may be parametrized with the aid of PE ionization potentials. For the PE spectrum of methyl chloride[2a,62] this may be successfully carried out, analogously to the π-σ splitting in methylacetylene (Fig. 13), with the first ionization potential of hydrogen chloride $IE_1(HCl) = 12.80\,eV$[2a,4] $\equiv -\alpha_{Cl}$ and methane $IE_1(CH_4) = 14.2\,eV \equiv -\alpha_{CH_3}$ (cf. Fig. 13). Insertion into (13) affords the hyperconjugation parameter $\beta_{Cl/CH_3} = -\sqrt{(12.80-11.28)(14.2-11.28)} = -2.1\,eV$. For the PE



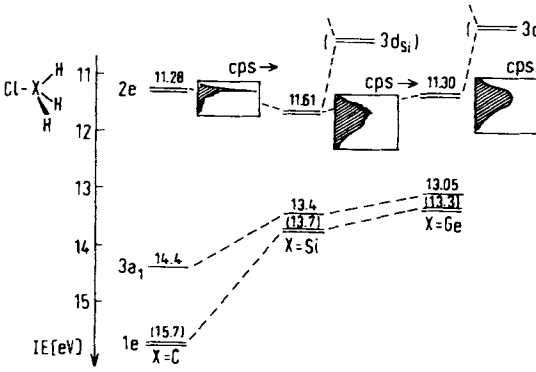
(18)

spectrum of chlorosilane[63,64] whose first band at 11.61 eV is also assigned to the n_{Cl} ionization, a similar parametrization is possible only after an inductive correction of the orbital energies $\alpha_{Cl} \equiv -12.80\,eV$ and $\alpha_{SiH_3} \equiv -12.45\,eV$ (14). A procedure such as this would not take special account of the π back bonding into unoccupied $3d_{Si}$ orbitals although, in analogy with boron ($p_B \overset{\frown}{-} \ddot{n}_X$) π systems, this should also stabilize the two n_{Cl} orbitals (cf. Fig. 7) and could on this basis qualitatively explain the increase of ≈0.3 eV in the n_{Cl} ionization potential compared to CH_3Cl.



(19)

As in the silylacetylenes (14), the overall interaction may be subdivided into individual contributions (19) only in model calculations[40]. The following PE spectroscopic results have been presented to support a significant $(p\text{-}d)_\pi$ contribution to the delocalization of the chlorine electron lone pairs in H_3SiCl. Only the orbitals σ_{XCl} ($3a_1$), σ_{XH_3} (1e) are monotonically raised with decreasing atomic p ionization potentials C (11.3 eV) > Si (8.15 eV) > Ge (7.88 eV), whereas n_{Cl} (2e) goes through a minimum at H_3SiCl.

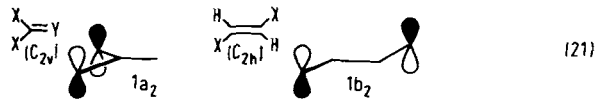


(20)

Moreover, the first PE band in the silyl and germyl derivatives is strongly broadened[63] and shows a smaller spin

orbit coupling[63] in the bromide H_3XBr, and iodide derivatives H_3X—I (cf. Section 4.3); both are evaluated as evidence of stronger electron pair delocalization than in the methyl halides[39,63]. MO models including d orbitals are also useful in the PE spectral comparison of other compounds of the elements X = C, Si, Ge. They provide a qualitative explanation of why, in all the molecules Ë $(XH_3)_n$ where Ë = O[65,66], S[65,67], Se[65], Te[65], N[68,69], As[68], the silicon derivative always exhibits the highest n_E-ionization potential (cf. (20)), and they can be parametrized, *e.g.*, for chlorosilanes H_nSiCl_{4-n}[64,70].

According to the MO definition given in Section 4.1, a delocalization of lone pair electrons n_X is always possible if other orbitals of the same symmetry type are available. For some molecules with lone pair electrons there is nevertheless only one occupied orbital of a given symmetry type which can serve in this case as an internal standard for spectral comparisons, for example[58,64,71,72].



(21)

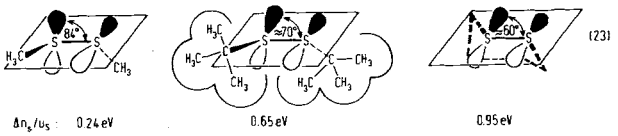
n-n interactions:

The third prototype of electron pair delocalization, with only a few exceptions predicted, is only to be observed together with n-σ interactions, (cf. Section 4.3). The first[73], predicted[74] but nevertheless surprising and therefore often quoted[2b,2c,27,105], PE spectroscopic result is the n-n splitting in 1,4-diazabicyclo[2.2.2]octane (Fig. 16/③). A detailed analysis of the vibrational fine structure exhibited supports assignment of the two first ionizations of the D_{3h} molecule to the orbital sequence $n_N^+(a_1')$, $n_N^-(a_2'')$,... This reversal of the through space splitting n_N^-/n_N^+ depends on the result that the n_N^+ orbital is raised above the n_N^- orbital through antibonding mixing with a $\sigma_{CC}(a_1')$ orbital[75].

Heilbronner and his Basel group have described numerous other n_X-n_X interactions[76-79]:

Obviously, all lone pair electron combinations are more or less mixed with σ orbitals. In each case, the antibonding σ portion determines the orbital sequence n^-/n^+ or n^+/n^- as well as their energy separation, as is especially demonstrated by a comparison of 1,3-cyclobutanedione and *p*-benzoquinone.

In nonplanar systems the n-n splitting increases with decreasing dihedral angle, i. e. with increasing overlap—in the dialkyl sulfides as a result of steric hindrance by bulky groups such as *tert*-butyl, in systems such as 1,2-dithiane[58,61] by ring fixation—and should reach as much as 2.6 eV in coplanar geometries such as five-membered rings.



(23)

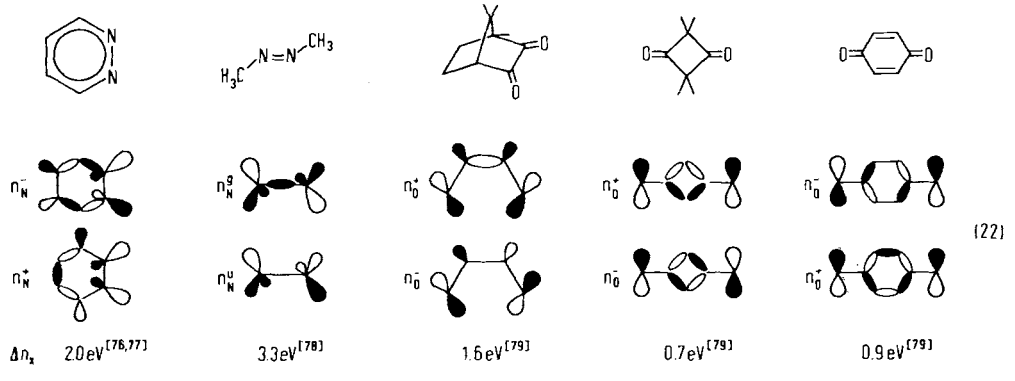
From the numerous PE investigations on molecules with several electron pairs the following random selection is representative: X_2SO[80a], X_2SO_2[80b], $E(Hal)_3$[52,81], $E(Hal)_4$[82], P_4[83], F_3NO[84], $(Hal)_3PO$[84], F_nSN[85], F_2O, Cl_2O[86], $FClO_3$[87], SF_6[81a], ClF_n, BrF_n[88], or XeF_n[89].

The previous resolution of n-π, n-σ, and n-n interactions, for each of which a characteristic PE spectrum is shown in Figure 16, can be described with the qualitative MO models introduced in Sections 3.1 to 3.3. According to the molecular skeleton and bonding partners, various antibonding—or in the case of low-lying electron pairs bonding[70] portions of equal symmetry orbitals result, and thus the broad range of electron "lone" pair ionization potentials of the individual elements can be understood.

4.3. Spin-Orbit Coupling of Electron Pairs

In PE spectra such as that of HBr (Fig. 3) the electron pair ionization energies are split by a further interaction, the coupling between orbital and electron spin angular momentum[*]. This coupling is neglected not only in simple

[*] The degeneracy of radical cation states, which are characterized by ionization of electrons from degenerate orbitals (orbital angular momentum ⩾ 1), is often removed in molecules with heavy atoms through spin-orbit coupling. The states of atoms are designated with the symbol $^{2S+1}\Gamma_J$ in which *S* gives the total electron spin (for radical cations $S = 1/2$), Γ the orbital angular momentum *L* ($S=0$, $P=1$, $D=2$...) and *J* the total value which may assume values from $L+S$, $L+S-1$,... to $L-S$. In molecules Γ is replaced with a corresponding symmetry representation in which symbols such as $^2\Pi_{3/2}$, $^2\Sigma_{1/2}$ ... for linear, or $^2A_{1/2}$, $^2E_{3/2}$, ... for nonlinear molecules appear. (Cf. textbooks such as *J. N. Murrel, S. F. A. Kettle*, and *J. M. Tedder*: Valence Theory. Wiley, London 1965.)

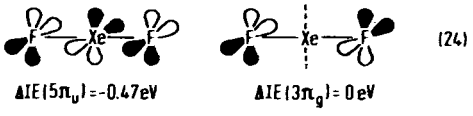


(22)

MO models, but also in most SCF calculations. On the other hand, since it is an important assignment aid in the PE spectra of molecules with heavy atoms, a few rules will be given here which make it easier to deal with spin orbit coupling effects:

a) The spin-orbit splitting increases with increasing atomic number of the atom, for example $Ar^{\oplus}$ (0.178 eV), $Kr^{\oplus}$ (0.665 eV), $Xe^{\oplus}$ (1.306 eV)[2a, 2b], or in molecules[**] for example $CH_3Br^{\oplus}$ (0.32 eV), $CH_3I^{\oplus}$ (0.62 eV)[2, 2b, 90].

b) Spin-orbit coupling can only be observed if a heavy-atom coefficient c_{ju} is included in the MO. Thus splitting is observed in the xenon difluoride $\pi_{u(1/2,3/2)}$ but not in the $\pi_{g(1/2,3/2)}$ orbital which has a node through the central xenon as shown schematically.



(24)

c) In molecules the spin-orbit coupling increases with the electron density ($c_{ju}^2 \times e$) at the heavy atom center. Thus in the PE spectrum of diiodoacetylene, I—C≡C—I, the following differences $\Delta IE(^2\pi_{3/2} - {}^2\pi_{1/2})$ are found[91]: $\Delta IE_1 = -0.44$, $\Delta IE_2 = -0.60$, and $\Delta IE_3 = -0.21$ eV.

d) Degenerate electron pairs are a requirement for strong spin-orbit coupling. Therefore, this splitting component is smaller the more the degeneracy is removed, for example, by n-π interaction. This can be illustrated in an orbital-correlation diagram[90] with increasing interaction parameter $\beta_{n/\varphi}$ ($\varphi = \pi$ or σ) as follows:

In general, spin-orbit coupling effects in molecules can be divided into first order effects, which cause the splitting of degenerate orbitals, and into second order smaller contributions.

In closing, the PE spectrum of iodine[93] will be discussed[94] (Fig. 17), which shows two different spin-orbit couplings, $\Delta IE(^2\pi_{g(3/2,1/2)}) = -0.63$ eV and $\Delta IE(^2\pi_{u(3/2,1/2)}) = -0.79$, although I_2 has the symmetry $D_{\infty h}$. The usual symmetry classification is not sufficient here to characterize the spin molecular orbitals of the iodine molecule. The symmetry group $D_{\infty h}$ can however be extended in a simple way to the douple group $D'_{\infty h}$[95] according to which the orbitals $\pi_{u(1/2)}$ and σ_u belong to the symmetry type $e_{1/2u}$ and the orbitals $\pi_{g(1/2)}$ and $3\sigma_g$ to $e_{1/2g}$. Then the symmetry-allowed mixing of σ character into $\pi_{g(1/2)}$ and $\pi_{u(1/2)}$ orbitals decreases $\Delta\pi_g$ and increases $\Delta\pi_u$ in complete agreement with the iodine PE spectrum.

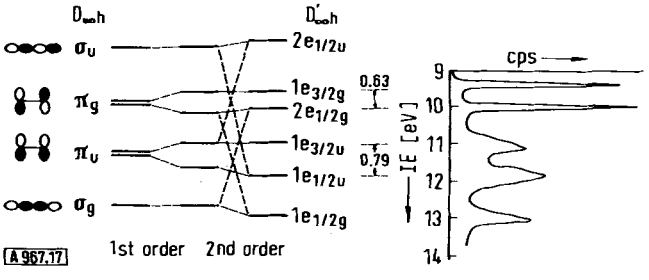


Fig. 17. PE spectrum of I_2 [93] and its interpretation with spin molecular orbitals. ($D'_{\infty h}$)

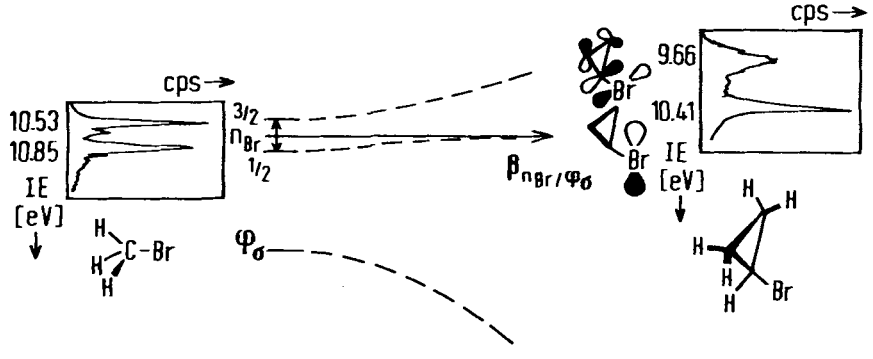

(25)

One can see from the PE spectral sections of methyl bromide and cyclopropyl bromide how the hyperconjugation interaction of a bromine electron pair with one of the degenerate cyclopropyl Walsh orbitals[2a] makes itself felt. The two n_{Br} ionization potentials are not only lowered and their difference increased[92], but the first PE band broadens[90].

This procedure demonstrated for the iodine molecule has the advantage that the spin orbit coupling is included from the beginning and need not be introduced later as a perturbation. With this useful qualitative approach, PE spectra of more complex molecules such as BI_3 can also be assigned[96].

A broad excursion through PE spectroscopy has thus led from the molecule HBr (Fig. 3) to another diatomic molecule I_2 (Fig. 17). The qualitative MO models useful for interpretation of the spectra have been developed step by step. They can be supported by SCF calculations, and therefore permit, *via* Koopmans' theorem, a simple description of the energy differences between the ground state and the radical cation states of molecules.

[**] The spin-orbit coupling in molecules through heavy atoms is always of the same order of magnitude although smaller than in the atoms themselves. Thus in the free atom the iodine 5p electrons exhibit a spin orbit coupling of 0.942 eV. In the $CH_3I^{\oplus}$ cation, in which one p_I orbital is engaged in the C—I bond, the splitting reduces to about 0.62 eV, *i.e.* 2/3 of the amount 0.942 eV. The ratio of band intensities is at the same time reduced from $^2P_{3/2} : {}^2P_{1/2} = 2:1$ in the atom to $^2\Pi_{3/2} : {}^2\Pi_{1/2} = 1:1$ in the molecule (Fig. 3).

5. Concluding Remarks

In the ten years since the construction of the early UV photoelectron spectrometers, largely by *Turner* and his coworkers[2a], the PE spectra of numerous molecules have been published. The examples selected here should illustrate for the nonspecialist the applicability of the method and the interpretation of the experimental information with MO models. In particular cases, the complete spectral assignment is not always so easy to make and so certain as the deliberately simplified MO considerations might suggest.

The flood of individual PE data may be organized under an overall point of view by qualitative MO models[19,27,31], whose utility stretches from the Hückel $(4n+2)$ rule to Woodward-Hoffmann orbital symmetry correlations. The fundamental simple concepts of symmetry, overlap, energy gap, and of orbital perturbation, which have been derived out of the comparison of chemical experience and theoretical calculations, may be successfully carried over into the discussion of photoelectron spectra and thus are reconfirmed.

The apparent common validity of Koopmans' theorem is a requirement of the close relationship between PE spectroscopy and MO theories. Known exceptions[2b,3] mostly depend on strong electrostatic interactions and electron reorganization in the radical cation, for example in easily polarizable parts of the molecule. These exceptions and also other aspects such as the relationship of PE to Rydberg states of molecules[97-99], can all serve as a starting point for theoreticians.

In contrast, the chemist will ask what help the information from a PE spectrum can give him. The following answers may be given: our knowledge of molecules is broadened, especially concerning their σ skeletons which were up to now only poorly accessible to measurement. PE ionization energies can also be correlated with numerous other physical measurement data such as half wave oxidation potentials[100], charge transfer ionization energies[50,59], pK values[77,101], or electronic transition energies[97-99,102]. Occasionally structural aspects in molecules may be elucidated[80a,103-105] and some analytical applications have been investigated[106]. Above all, however, the more general observations derived from PE spectral assignments, for example concerning substituent effects or chemically related compounds, will help the chemist in his own work.

The MO models employed in interpretation of PE spectra are useful to explain further molecular properties and in this way create overall order in a collection of otherwise solitary facts: Herein—the simple construction of the PE spectrometer will prevent its simply becoming a "black box"—lies at the same time the educational utility of PE spectroscopic arguments in the teaching of general chemistry.

The authors are thankful to numerous colleagues and friends for stimulating discussions: E. Heilbronner, E. Lindholm, D. R. Lloyd, H. Nöth, C. G. Pitt, W. C. Price, M. B. Robin, and D. W. Turner. Thanks are also due to S. Elbel for help in the literature search and to W. Fuss, D. R. Lloyd, H. Stafast and K. Wittel who previewed the manuscript. As far as use has been made of results from the group at the University of Frankfurt, the dedication and capability of the coworkers are appreciated: W. Ensslin, Dr. W. Fuss, Dr. P. Mollère, B. Solouki, H. Stafast, Dr. G. Wagner, and K. Wittel. For financial support of our investigations we would like to thank, besides the State of Hesse, especially Farbwerke Hoechst AG, the Fonds der Chemischen Industrie, and the Max-Buchner-Stiftung. B. G. Ramsey wishes to acknowledge the receipt of an Alexander v. Humboldt award and a Senior Fulbright Research Fellowship.

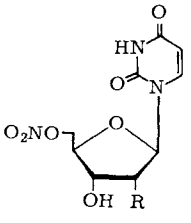
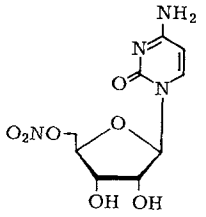
5′-Nitrates of Pyrimidine Nucleosides: Nitric Acid Analogs of Nucleotides[1][**]

By *F. W. Lichtenthaler* and *H. J. Müller*[*]

Depending upon the experimental conditions the direct reaction of unprotected pyrimidine nucleosides with nitric acid can lead to nitration at C-5 of the nucleobase accompanied by oxidation of the 5′-hydroxyl group to carboxyl[2] or to formation of nitrates from the sugar-hydroxyl groups, the latter leading to di-*O*- and tri-*O*-nitro nucleosides[3,4]. We here describe conditions that permit 5′-*O*-nitro nucleosides (nucleoside 5′-nitrates), *e.g. (1)* to *(3)*, to be obtained in preparatively useful yields directly from ribo- and deoxyribo-nucleosides[5]. As nitrate analogs of the 5′-phosphates these products warrant pharmacological interest.



(1), R = OH
(2), R = H



(3)

For example, treatment of uridine with 90% nitric acid (1.5 h, −70 °C) affords a mixture of 5′-*O*-nitrouridine *(1)*, two di-*O*-nitro compounds in the ratio 5:1, and about 40% of unchanged starting material. Extraction of this mixture with ethyl acetate gives a 44% yield of *(1)* as needles of m. p. 139 °C and $[\alpha]_D^{20} = +16°$[6], whereas from the di-*O*-nitro fraction so far only a 5% yield of pure 3′,5′-di-*O*-nitrouridine has been isolated (layer chromatography; platelets of m. p. 179—182 °C, $[\alpha]_D^{20} = +12°$).

Applying the above conditions to 2′-deoxyuridine affords the 5′-*O*-nitro derivative *(2)*, m. p. 175 °C, $[\alpha]_D^{20} = +42°$, in 20% yield with 13% of 3′,5′-di-*O*-nitro-2′-deoxyuridine, m. p. 113 °C (129 °C[3]), $[\alpha]_D^{20} = +12°$. From cytidine under the same conditions there is formed a 5:1 mixture of the 5′-*O*-nitro compound *(3)* and two dinitro derivatives, from which *(3)* can be separated in 46% yield as needles of m. p. 160—161 °C, $[\alpha]_D^{20} = +28°$.

That the products are 5′-*O*-nitro compounds follows unambiguously from the NMR spectroscopic data of *(1)*—*(3)*, in particular from the position of the 5′-CH_2 signal which is shifted paramagnetically by about 1.2 ppm from that in the starting materials.

No problem should arise in applying this process of direct 5′-*O*-nitration to preparation of further 5′-*O*-nitro derivatives of pyrimidine nucleosides.

5'-O-Nitrouridine (1)

Uridine (1.2 g, 4.9 mmol) is added with vigorous stirring to 90% nitric acid ($\rho = 1.48$; 7.5 ml) precooled to $-70\,^{\circ}C$. The solution, which soon becomes clear, is stirred for 1 h at $-70\,^{\circ}C$ and after addition of further 90% HNO_3 (7.5 ml) for a further 30 min at $-70\,^{\circ}C$[7]. The mixture is then stirred into ice-water (80 ml), covered with a layer of ethyl acetate (50 ml), and neutralized by portionwise addition of solid $NaHCO_3$. The aqueous phase[8] is extracted with ethyl acetate (6 × 50 ml), and the combined extracts are dried ($MgSO_4$) and evaporated. When the residual foam is taken up in hot ethanol, treated with charcoal, and slowly cooled, the ester *(1)* crystallizes as colorless needles of m.p. 139 °C, $[\alpha]_D^{20} = +16^{\circ}$ ($c = 1$, DMF).

[8] The organic phase contains the mononitrate *(1)* and dinitrate in the approximate proportion 1:1 (TLC in $CHCl_3/CH_3OH$ 9:1); separation by preparative layer chromatography (20 × 40 cm plates with 1.75 mm of Merck silica gel $PF_{354+366}$ and 9:1 $CHCl_3$/methanol as eluant) affords a further 100 mg (7%) of *(1)*.

How "Aromatic" are λ⁵-Phosphorins? Electrophilic Substitution Reactions

By *Werner Schäfer* and *Karl Dimroth*[*]

Dedicated to Professor Karl Winnacker on the occasion of this 70th birthday

"Aromaticity"[1] from the standpoint of preparative organic chemistry characterizes the chemical behavior of compounds like benzene where *substitution* of an H atom by another group with retention of the unsaturated system is preferred over *addition* leading to a more saturated system. On treatment of phosphonium ylides with electrophiles a two-step reaction is always observed: addition to the phosphonium salt and, if a sufficiently strong base is present, loss of a proton. If the new, substituted ylide is sufficiently stabilized by mesomerism, the proton can also be transferred to the less stabilized initial ylide, a mechanistic sequence which is called "transylidation"[2].

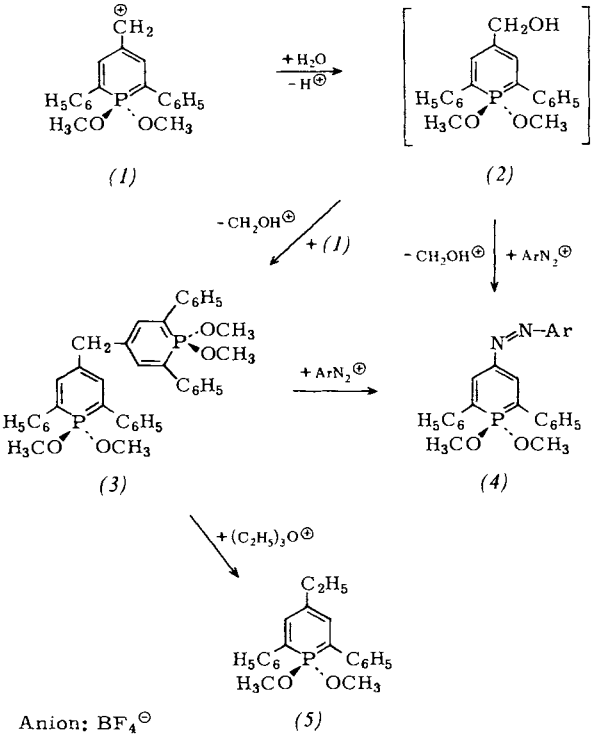
Reactions of this kind were also observed by *Märkl et al.* on treatment of cyclic 6π-delocalized phosphonium ylides such as 1,1-diphenyl- and 1,1,2-triphenyl-phosphanaphthalene[3]. With methyl iodide or diazonium salts the first products are phosphonium salts which can be converted into 4- or 2-substituted 1,1-diphenyl-λ⁵-phosphanaphthalenes by bases; on reaction with acid chlorides these products were formed directly by transylidation.

Since other concepts of aromaticity suggest that 1,1-dialkoxy-λ⁵-phosphorins[4] are considerably more "aromatic" than 1,1-dialkyl or 1,1-diaryl-λ⁵-phosphorins[1,2], these very weakly basic compounds ought to be suitable for electrophilic aromatic substitutions at C-2 or C-4. Experimental tests of this deduction have, however, been impossible since 1,1-dialkoxy-λ⁵-phosphorins with a replaceable H atom on C-2 or C-4 have hitherto been inaccessible.

In an earlier communication we reported the synthesis of λ⁵-phosphorins containing electrofugal groups other than a proton on C-4[6]. We are now able to show that these derivatives can be electrophilically substituted, smoothly and in high yield, even in acidic media, without any evidence of a phosphonium salt as intermediate.

One of these λ⁵-phosphorins is (1,1-dimethoxy-2,6-diphenyl-λ⁵-phosphorin-4-yl)carbenium tetrafluoroborate *(1)*[5]. In acetonitrile containing a little water it first produces the alcohol *(2)*, which immediately undergoes electrophilic substitution, losing formaldehyde cation, by *(1)* still present in the solution to give *(3)*[6] or by aryldiazonium tetrafluoroborates to give *(4)*.

(3) also contains a good electrofugal group. It reacts with diazonium salts, giving *(4)*, and the yields of *(4)* in the presence of water are almost quantitative by the route *(1)* → *(2)* shown. In another electrophilic substitution *(3)* can be alkylated by triethyloxonium salts to give 4-ethyl-1,1-dimethoxy-2,6-diphenyl-λ⁵-phosphorin *(5)*, which is also accessible by another route[7]. Treatment of *(3)* with triphenylcarbenium tetrafluoroborate *(6)*

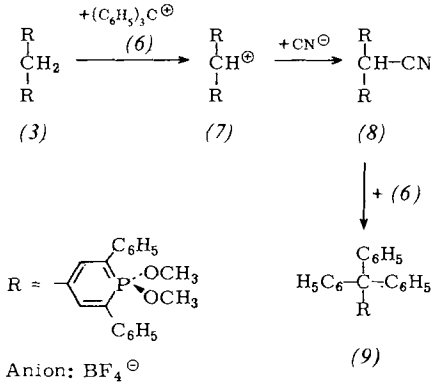


(1) (2) (3) (4) (5)

Ar	*(4)*, m.p. [°C]	*(11)*, m.p. [°C]
p-$CH_3C_6H_4$	186—188	210—211
p-$CH_3OC_6H_4$	153—156	194
2-CH_3—4-$NO_2C_6H_3$	181—183	247—250

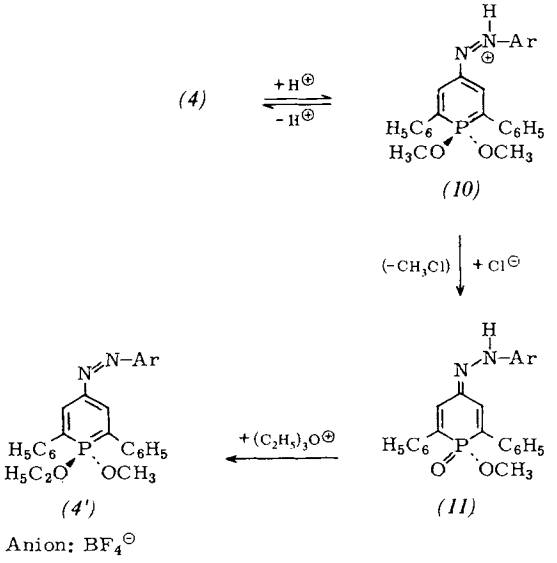
[*] Dr. W. Schäfer and Prof. Dr. K. Dimroth
Organische Chemie im Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

forms only bis(1,1-dimethoxy-2,6-diphenyl-λ^5-phosphorin-4-yl)carbenium tetrafluoroborate *(7)* by hydride transfer. However, the nitrile *(8)*, readily obtained by addition of cyanide to *(7)*, reacts smoothly with *(6)* in an electrophilic substitution yielding 1,1-dimethoxy-2,6-diphenyl-4-trityl-λ^5-phosphorin *(9)*, m. p. 144—145 °C.



Electrophilic substitution with removal of the cation of formaldehyde or benzaldehyde instead of a proton has long been known in the benzene series[8]. This reaction has been used to synthesize aldehydes starting from suitably *C*-substituted derivatives of *N*,*N*-dimethylaniline[9]. The high π-electron density at position 4 of the above λ^5-phosphorin derivatives is in full accord with theoretical calculations[10] and photoelectron spectroscopy[11]. The complete analogy of the reactions described with those of corresponding derivatives of *N*,*N*-dimethylaniline thus underlines the typical "aromatic" electron-rich character of 1,1-dialkoxy-λ^5-phosphorins[12].

The azo compounds *(4)* are protonated by acid, not on the nucleus (C-4) to give phosphonium salts, but on the β-N atom to give *(10)*. Deprotonation by ethyldiisopropylamine regenerates *(4)*.



Reaction with acids containing easily polarizable anions, *e.g.* HCl, yields, irreversibly, with loss of methyl chloride, the phosphinic acid derivatives *(11)*. These can be transformed back into azo compounds *(4')* by alkylation with triethyloxonium tetrafluoroborate in the presence of ethyldiisopropylamine[13].

Elemental analyses, mass spectra and NMR, IR, and UV spectra of all the new compounds accord with the formulas assigned.

Ligand Influences in Heterogeneous Catalysis: Modification of the Phillips Catalyst[**]

By *G. Henrici-Olivé* and *S. Olivé*[*]

Catalyst tailoring by a systematic variation of the ligands seems to be on its way to becoming a powerful tool in homogeneous catalysis on transition metal centers[1]. It appears opportune to apply the same principles to heterogeneous catalysts. We reported recently on the influence of titanium containing ligands on molybdenum oxide catalysts for the metathesis of olefins[2]. The present communication deals with the modification of the heterogeneous catalyst for the polymerization of ethylene, based on SiO_2-supported chromium oxide (Phillips catalyst), and its interpretation in terms of ligand influences.

The molecular weight of polymer in this type of catalysis depends on the relative rates of chain propagation (rate constant k_p) and chain transfer (β-hydrogen transfer; rate constant k_{tr}):

$$Cr\text{–}(P)_n + CH_2{=}CH_2 \xrightarrow{k_p} Cr\text{–}(P)_{n+1}$$

$$Cr\text{–}CH_2\text{–}CH_2\text{–}(P) \xrightarrow{k_{tr}} CrH + CH_2{=}CH\text{–}(P)$$

$(P)_n$ stands for a polyethylene chain of n monomer units.

The latter reaction is enhanced by increasing the electron affinity of the metal center[3], and can in principle be controlled by choosing the proper ligands.

[*] Dr. G. Henrici-Olivé and Dr. S. Olivé
Monsanto Research S. A.

[**] We recognize valuable experimental help from Miss *E. Arnold* and Mr. *H. Kull*.

There is good evidence that Cr^{II} is the active valence state in heterogeneous[4] and homogeneous[5] chromium catalysts. In this oxidation state the chromium center possesses poor acidity (high molecular weight polymer). In homogeneous Cr systems, a certain degree of control of the molecular weight has been achieved varying the acidity of the alkylaluminum in the active species[5]. Translating this knowledge to the heterogeneous Cr catalyst, highly acidic ligands are required if the aim is to lower the degree of polymerization. Because of the severe conditions of activation and regeneration of the supported catalysts, only metal oxides can be considered as additives: ZnO, WO_3, and MoO_3—in order of increasing activity—were found to be effective (Table 1).

The catalysts were prepared by impregnating SiO_2 (spheres of 0.2—0.5 mm diameter) with aqueous solutions of CrO_3 and/or ammonium molybdate. After removal of excess liquid, the catalysts were dried and oxidized at 500 °C in an O_2 stream. Before use they were activated with CO (500 °C, 3 h). A pyrex tube of 60 cm length and 2 cm diameter was used as reactor.

Table 1. Influence of molybdenum additive on SiO_2-supported chromium oxide catalyst. Substrate: ethylene; $T=300$ °C; $[Cr]=1\times10^{-3}$ g-atom/g catalyst.

	3	18.7	75.9	18.2	4.3	1.6	—

[a] Flow rate [mol ethylene/(min × g-atom Cr)].

Table 1 shows that the modification of the chromium catalyst has a considerable influence on the molecular weight of the product. In the absence of Mo, high polymer is formed which, for the most part, is cracked under the present conditions, to give highly branched, liquid oligomers of a molecular weight of about 250—300, with poor unsaturation. Addition of the Mo species, on the other hand, converts the Phillips catalyst into an oligomerization catalyst. The growing chains leave the catalytic center after two to three propagation steps, as butene or hexene. Only traces of octene and no higher oligomers are detected. The data show also that the molybdenum additive has a dual function, not only drastically decreasing the chain length, but also operating as a metathesis catalyst. By this latter action, oligomers with odd carbon numbers are formed, particularly C_3, the amount increasing with increasing ratio Mo/Cr.

At lower temperatures and/or lower flow rate, the modified catalysts give some polymer and cracked material besides the oligomer. The same is true at $Mo/Cr<1$. It should also be noted that MoO_3 alone, on SiO_2, is practically inactive (≤ 0.3 % conversion to butene under the conditions given in Table 1).

Magnetic measurements give some information concerning the active species. The magnetic moments, calculated from magnetic susceptibility data, are given in Table 2. Numbers in the same line refer to different catalyst preparations (oxidation-reduction cycle), and indicate the reproducibility of these data. MoO_3 alone is only partially reduced with the present treatment (30—50 % reduction to Mo^V, one unpaired electron). In the presence of chromium, the reduction appears to be much less, since the magnetic moment found for the "bimetallic" catalyst is essentially the same as that for the chromium catalyst alone.

Table 2. Magnetic moments of metal oxide catalysts. $[Cr]=[Mo]=1\times10^{-3}$ g-atom/g catalyst; $T=21$ °C; reduction: 3 h, 500 °C, CO.

Metal oxide	μ_{eff} [μ_B]	
Cr	3.92	3.97
Mo	1.03	1.27
Cr + Mo [a]	3.92	4.08

[a] Calculated for Cr.

A paramagnetic Mo species may be observed by EPR, in the bimetallic system as well as in the Mo system alone (Fig. 1). The Cr catalyst presents a weak signal, presumably due to traces of Cr^{III}; it remains unchanged in the spectrum of the bimetallic catalyst. (Cr^{II} is not expected to give a signal at room temperature.)

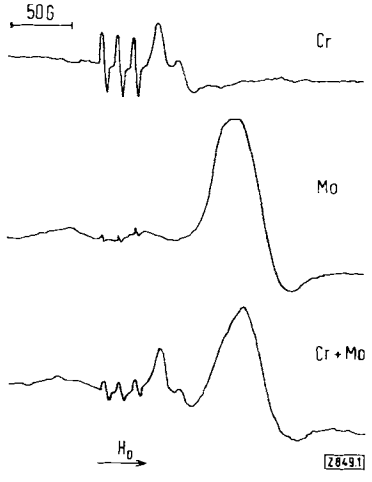

Fig. 1. EPR signals of SiO_2-supported catalysts after CO treatment. $T=20$ °C; field marker: Fremy's salt.

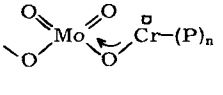
The signal of the pure Mo system clearly differs in line shape from that of the Mo peak of the bimetallic catalyst. We interpret this as evidence for an interaction between the two metals. Although only the reduced molybdenum gives an EPR signal, it is reasonable to assume a comparable interaction also for Mo^{VI}.

Our knowledge concerning the active species may be summarized as follows: It contains chromium as Cr^{II}, and molybdenum predominantly as Mo^{VI}; there is interaction between the two metals; best results are obtained when [Mo]/[Cr] is near unity. With these data, the following structure may be suggested:



where □ represents a vacancy in the coordination sphere of the chromium, available for coordination of the olefin. The withdrawal of electron density from the Cr center by the acidic molybdenum oxide is assumed to be responsible not only for the drastic reduction of the molecular weight of the product, but also for the diminution of

the overall rate (cf. Table 1). This latter influence, which is a consequence of a relative stabilization of the metal-carbon bond, is also known from homogeneous catalysis[3, 5].

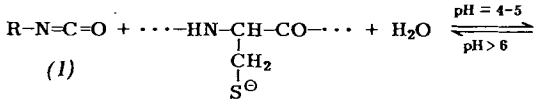
Methoxymethyl Isocyanate as a New Agent for Reversible Protection of SH Groups in Protein and Peptide Chemistry

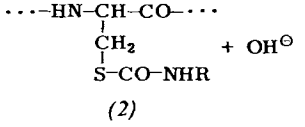
By *Harald Tschesche* and *Helmut Jering*[*]

The usual blocking reagents for use during alkylation, mercuration or oxidation of the SH group of cysteine[1] lead to irreversible formation of the derivative of the thiol group.

We have found that methoxymethyl isocyanate *(1a)* is excellently suited for rapid and selective carbamoylation of cysteine-SH at pH 4—5 in an aqueous medium and at room temperature. The reaction yielding *(2a)* occurs very fast and is complete in less than 2 min when an excess of the reagent is used. The α- and ε-amino groups do not react under the stated conditions. The *N*-methoxymethyl-*S*-carbamoyl derivative *(2a)* of cysteine is sufficiently stable at pH 6 (see Table 1). For comparison it should be noted that the half-life of the unsubstituted *S*-carbamoyl derivative *(2b)* from cyanate and cysteine is only about 10 min at 25 °C and pH 6[2].



(1)



(2)

(a), R = $H_3C-O-CH_2$; *(b)*, R = H

Methyl, ethyl, and *tert*-butyl isocyanate react only very slowly at pH 4—7 in an aqueous medium and are thus barely useful for our purpose.

Unblocking of the SH group with removal of the *N*-methoxymethyl-*S*-carbamoyl protecting group is easily achieved under mild conditions in an aqueous alkaline medium (see Table 1): at pH 9.6 its removal from cysteine is complete in 30 min and from glutathione in 60 min.

We have used methoxymethyl isocyanate *(1a)* as protecting group for reversible blocking of the SH group in cysteine, glutathione, papain and for the trypsin-kallicrein inhibitor from bovine organs after its selective reduction at Cys^{14}-Cys^{38}[3].

Table 1. Removal of the protecting group from cysteine (Cys) or glutathione (GSH) at room temperature.

pH	*t* [min]	Liberation of SH [%] Cys	GSH
9.6	30	100	80
8.6	100	100	55
7.6	100	67	20
6.0	180	2	1.5

The enzymatic activity of papain was instantaneously blocked by reaction of methoxymethyl isocyanate with the reactive thiol group of Cys^{25}. The proteolytic activity of the enzyme deactivated at pH 5.6 was restored by incubation at pH 8.8 and 20 °C within 60 min to 50%.

When the trypsin-kallicrein inhibitor from bovine organs has been selectively reduced by sodium tetrahydridoborate, the two SH groups formed from the disulfide bridge[3] react quantitatively with *(1a)* under the conditions described, and the two-fold *S*-carbamoylated inhibitor is completely inactive against trypsin. Removal of the SH-protecting groups at pH 9.5 and 20 °C in the presence of glycylglycine with subsequent oxidation of the neighboring thiol groups to the disulfide bridge by access of oxygen at the same pH regenerates the activity of the inhibitor completely within 60 min.

General experimental directions:

1 μmol of the peptide or protein is dissolved in 0.5 ml of 0.2 M sodium succinate buffer (pH 4.0, papain at pH 5.6), and for each mol of cysteine 350 μmol (for papain 20 μmol only) of methoxymethyl isocyanate *(1a)*[4], dissolved in dimethylformamide [50 μl of *(1a)* in 150 μl of DMF], is added with stirring at room temperature. Quantitative reaction occurs within 2 min with simultaneous mild evolution of CO_2. The mixture is stirred for a further 3 min for complete destruction of the reagent, and the solution is then subjected to gel filtration on Sephadex G-15 or Bio Gel P-2 in 10% acetic acid so as to separate the products and buffer salts. The *N*-methoxymethyl-*S*-carbamoyl derivative *(2a)* can be preserved in acid solution or lyophilized from acid solution. Disulfide bridges reduced under nitrogen by $NaBH_4$ can be treated with *(1a)* directly in the reaction mixture after buffering at pH 4 for removal of the acid used to destroy the excess of reducing agent.

For removal of the SH-protecting group, 1 μmol of the protected peptide or protein is dissolved in 0.5 ml of 0.1 M tris/HCl buffer (pH 9.5), 1 mg of glycylglycine is added as cyanate trap, and the solution is set aside at room temperature for 60 min. To avoid undesired reoxidation of the SH groups this removal is carried out under nitrogen.

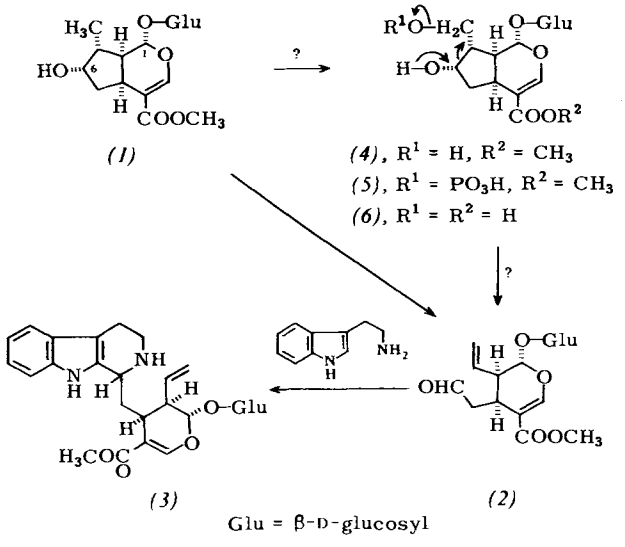
Total Synthesis of Hydroxyloganine and Hydroxyloganic Acid[**]

By *Lutz-F. Tietze*[*]

The naturally occurring monoterpene glycosides loganine *(1)* and secologanine *(2)* hold a key position in the biogenesis of *Corynanthe*[1], *Aspidosperma*[1], and *Iboga*[1], as well as *Ipecacuanha*[2] and *Cinchona*[3] alkaloids.

The conversion of loganine *(1)* into secologanine *(2)* occurring *in vivo* involves cleavage of the cyclopentane ring and formation of an aldehyde group which can react by Mannich condensation with biogenetic amines such as tryptamine to yield, from the latter, vincoside *(3)*[4].



(1)

(4), R^1 = H, R^2 = CH_3
(5), R^1 = PO_3H, R^2 = CH_3
(6), R^1 = R^2 = H

(3) *(2)*

Glu = β-D-glucosyl

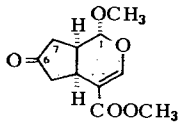
The mechanism of biological cleavage of the carbocyclic ring of *(1)* is not yet known and is difficult to understand without assumption of intermediates.

Numerous analogies are known for cleavage of a compound of hydroxyloganine type *(4)*, which can fragment in its phosphorylated form to yield *(2)* in the manner indicated[5]. Here all the centers concerned are in anticoplanar relation.

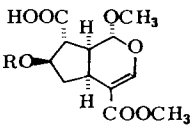
This would make the hitherto unknown hydroxyloganine *(4)* into a key compound in the biosynthetic sequence leading to the alkaloids mentioned above.

The starting material for the total synthesis of hydroxyloganine *(4)* and hydroxyloganic acid *(6)* was the ketone *(7)*, which is accessible by photoaddition of 3-cyclopentenyl 2-tetrahydropyranyl ether and methyl 2,2-diformylacetate[6]. Treatment of *(7)* with magnesium methyl carbonate in dimethylformamide at 135 °C[7] and subsequent reduction by $NaBH_4$ gave the 6-hydroxy carboxylic acid *(8)*, the carboxyl group being introduced at the sterically less hindered C-7.

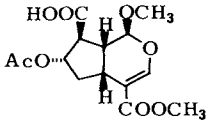
It proved impossible to resolve *(8)* into its antipodes by means of the usual bases. *(8)* was therefore acetylated, giving *(9)* [m.p. 164—165 °C, yield 69% based on *(7)*],



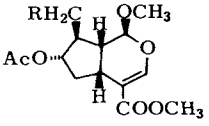
(7), (racemate)



(8), R = H(racemate)
(9), R = Ac(racemate)
(10), R = Ac



(11)

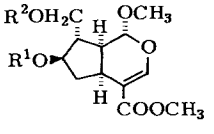


(12), R = OH
(13), R = OMs
(14), R = SC_2H_5
(15), R = H

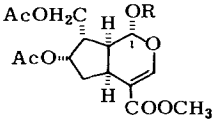
which was resolved with (−)- and (+)-α-methylbenzylamine to *(10)* (m.p. 165—166 °C, $[\alpha]_D^{25} = -68°$) and *(11)* [m.p. 164—165 °C, $[\alpha]_D^{25} = +67°$]. Reduction by diborane in tetrahydrofuran afforded the alcohols *(16)* (m.p. 128—129 °C, $[\alpha]_D^{25} = -75°$) and *(12)* (m.p. 129 to 130 °C, $[\alpha]_D^{25} = +75°$), respectively, in 92% yields.

To prove the stereochemistry assumed, *(12)* was converted successively into the mesylate *(13)*, the thioether *(14)*, and, by selective hydrogenation with Raney nickel, into the (+)-6-*O*-acetyl-1-*O*-methyl-6-epiloganin aglucone *(15)*, whose NMR, IR, and UV spectra and rotatory power agree with those of the (−)-antipode of *(15)* which was prepared from authentic loganine[8].

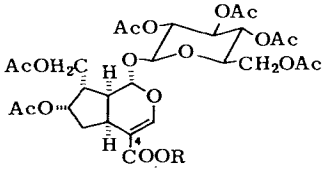
Hydrolysis of *(16)* by barium hydroxide in anhydrous methanol to the diol *(17)*, conversion thereof into the dimesylate *(18)* (m.p. 146 °C; $[\alpha]_D^{25} = -72°$), and exchange of the mesyl groups with epimerization at C-6 by means of tetraethylammonium acetate in acetone gave the diacetate *(19)* in 62% yield (m.p. 97 °C, $[\alpha]_D^{25} = -31°$).



(16), R^1 = Ac, R^2 = H
(17), R^1 = R^2 = H
(18), R^1 = R^2 = Ms



(19), R = CH_3
(20), R = H(+anomer)



(21), R = CH_3
(22), R = H

Cleavage of the acetal group of *(19)* was effected by perchloric acid in aqueous acetic acid, affording a mixture of anomeric semiacetals *(20)* in 84% yield; ^{1}H-NMR data indicate that here the isomer with pseudoaxial configuration of the OH group[9] is formed to the extent of about 90%.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the National Institute of Health, Bethesda, USA (Grant GM 9686).

Glycosidation of the anomeric semiacetals *(2)* with 2,3,4,6-tetra-*O*-acetyl-β-D-glucose and boron trifluoride-ether in dichloroethane[10] and chromatographic separation gave a 6% yield of hydroxyloganine hexaacetate *(21)* [$[\alpha]_D^{25} = -58°$; UV (CH_3OH): $\lambda_{max} = 232$ nm ($\log\varepsilon = 4.01$)]. Deacetylation and hydrolysis of the ester group on C-4 of *(21)* by barium hydroxide in aqueous methanol yielded hydroxyloganic acid *(6)*, which was converted into hydroxyloganine *(4)* [$[\alpha]_D^{20} = -61°$; UV (CH_3OH): $\lambda_{max} = 236$ nm ($\log\varepsilon = 4.02$)] by diazomethane and into hydroxyloganic acid hexaacetate *(22)* [m.p. 158 °C; $[\alpha]_D^{20} = -56°$; UV (CH_3OH): $\lambda_{max} = 234$ nm ($\log\varepsilon = 3.97$)] by acetic anhydride in pyridine.

Treatment of hydroxyloganine *(4)* with acetic anhydride in pyridine and of *(22)* with diazomethane regenerated hydroxyloganine hexaacetate *(21)*.

The identities of the new compounds were confirmed by elemental analyses, ^{1}H-NMR, IR, and UV spectra and high-resolution mass spectra.

Synthesis and feeding of hydroxyloganine specifically labeled by ^{3}H and ^{14}C is currently being carried out in collaboration with Prof. *A. R. Battersby*, Cambridge (England).

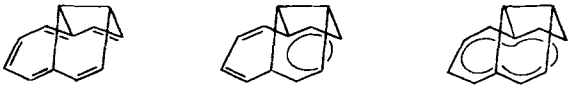
Semibullvalenes as Potential Homoaromatic Compounds

By *Emanuel Vogel*, *Udo H. Brinker*, *Klaus Nachtkamp*, *Jürgen Wassen*, and *Klaus Müllen*[*]

According to EH and MINDO/2 calculations[1], the introduction of suitable substituents into semibullvalene *(1)* may reduce the activation energy of the Cope rearrangement to negative values, so that molecules with homoaromatic properties result[2]. This supposition prompted *Paquette et al.*[3] to discuss the interesting possibility that the semibullvalene *(2)* resulting from bridging *(1)* by a 1,3-butadiene unit—and its valence isomer *(4)*—should exist either as a homoaromatic 6π- or a 10π-electron system [*(5)* and *(6)*, respectively].

(1) *(2)* *(3)*

These authors were able to synthesize a hydrocarbon to which the structure tricyclo[5.4.1.0^{4,12}]dodeca-2,5,7,9,11(1)pentaene *(4)* applied unambiguously. It was not, however, established whether or not *(4)* is in fact homoaromatic.



(4) *(5)* *(6)*

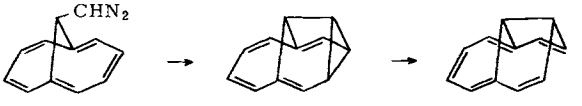
That investigation touched our studies of bridged [14]annulenes[4] in a very delicate way. Thus, if a second 1,3-butadiene unit is fused to *(1)* one arrives at compound *(3)*, a molecule which we recently encountered[5] as its valence isomer *(7)*, *i.e.* 1,6;8,13-ethanediylidene[14]annulene.

(7)

In our assessment the remarkable thermodynamic stability of *(7)* is to be ascribed primarily to the aromatic delocalization of the peripheral 14π-electron system[4, 6]. This view would doubtless require revision if it should be shown that the Paquette hydrocarbon, which is contained as a structural unit in *(7)*, has pronounced homoaromaticity, approximately comparable with that of the homotropylium ion[2] or tricarbonyl(tricyclo[4.3.1.0^{1,6}]deca-2,4-diene)-chromium[7].

We now report an independent synthesis of *(4)* and show by spectroscopic comparisons that the homoaromatic structures *(5)* and *(6)* make no important contribution to the ground state of the molecule.

The starting point of our approach to *(4)* was 1,6-methano[10]annulene-11-carbaldehyde, m. p. 103—104 °C, obtainable in 75% yield from 11-lithio-1,6-methano[10]annulene[8] and dimethylformamide in tetrahydrofuran at −70 °C. With hydrazine hydrate in methanol this aldehyde gave its hydrazone which was not isolated but was subjected directly in ethereal solution to oxidation by silver oxide; the resulting diazo compound *(8)* suffered



(8) *(9)* *(4)*

[*] Prof. Dr. E. Vogel, Dipl.-Chem. U. H. Brinker, Dipl.-Chem. K. Nachtkamp, and Dipl.-Chem. J. Wassen

Dr. K. Müllen
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule Zürich (Switzerland)

spontaneous decomposition under the reaction conditions to give a mixture of $C_{12}H_{10}$ hydrocarbons[9]. Separation of the mixture on an alumina column impregnated with $AgNO_3$ (20%) (eluant: benzene pentane 1:1) afforded the desired tricyclo[5.4.1.$0^{4,12}$]dodeca-2,5,7,9,11(1)-pentaene *(4)* which was formed by way of *(9)* and was isolated in 5—7% yield as a faintly yellow compound (actual color), extremely sensitive to air, b.p. 37—38 °C/0.02 torr, m.p. 7—8 °C (needles from methanol) [UV spectrum: λ_{max}(cyclohexane) = 245 (ε = 31 500, shoulder), 253 (32300), 338 nm (2800)]. Naphthalene (42%), benzocyclooctatetraene (6%), and 11-methylene-1,6-methano[10]annulene (2%) were obtained in addition to *(4)*.

The NMR spectrum (cf. Table 1) seemed most likely to clarify the homoaromaticity problem connected with *(4)*. If *(4)* exists as the homoaromatic species *(6)*, a diamagnetic ring current is to be expected that should manifest itself in a deshielding of the vinylic protons, in shielding of the bridge proton 11-H[**] complimentary thereto, and presumably also in equalization of the vicinal coupling constants $J_{2,3}$ and $J_{3,4}$.

For evaluation of the NMR spectrum of *(4)* it was deemed necessary to enlist the spectra of suitable model compounds for comparison. A model for a non-delocalized *(4)* seemed to us to be 1,6-divinylcycloheptatriene *(11)*[10] because strong homoconjugation such as is being discussed for *(4)* need not be considered seriously for this conformationally labile molecule. In fact the NMR spectrum of *(11)* accords to a great extent with the spectra of 1,6-alkylated cycloheptatrienes so far as comparisons are possible[11]. 1,6-Methano[10]annulene is a clear reference compound for *(4)* delocalized in the manner of formula *(6)*. For completeness bicyclo[5.4.1]dodeca-2,5,7,9,11-pentaene *(10)*[12], which occupies a position between *(4)* and *(11)*, was included in the discussion (cf. Table 1).

Table 1. ^{1}H-NMR parameters [100 MHz spectra (in CCl_4); τ values in ppm; *J* (in Hz)] of *(4)*, *(10)*, and *(11)*. The numbering of *(4)*, chosen on the basis of analogies, and not corresponding with IUPAC nomenclature, applies also to the hydrocarbons *(10)* and *(11)*.

	 *(4)*	 *(10)*	 *(11)*

[a] *syn* relative to the cycloheptatriene double-bond system.
[b] The assignment of 12-H_{syn} and 12-H_{anti} is uncertain.

The NMR spectra of *(4)*, *(10)*, and *(11)* show, as expected, analogous splitting patterns. The vinylic protons of the cycloheptatriene structural unit appear as an AA'XX' system in each case, while the protons of the terminal double bonds give rise to one or more multiplets occurring at higher field. The signals at highest field belong to the proton 11-H_{syn}[**] located above the cycloheptatriene structural moiety of *(4)* and *(10)*.

On close comparison of the spectra by means of the data in Table 1 the near relationship of *(4)* and *(10)* to one another and to compound *(11)*, our model for a non-delocalized cycloheptatriene, can be clearly recognized. In particular it can be seen that these three compounds display remarkable similarity in the NMR parameters of the protons of the cycloheptatriene structural moiety and in those of the vinylic protons 7-H and 10-H. However, *(4)* differs distinctly from 1,6-methano[10]annulene, where the double bonds are integrated in the peripheral cyclically conjugated 10π-electron system, both as regards the chemical shifts of the vinylic protons 2-H to 5-H (as well as 7-H to 10-H) and as regards the alternation of the vicinal coupling constants $J_{2,3}$ and $J_{3,4}$[13].

The consequence of these findings is that *(4)* has the π-electron structure of a 1,6-divinylcycloheptatriene and that there is no compelling reason to describe the compound by homoaromatic structures such as *(5)* and *(6)*.

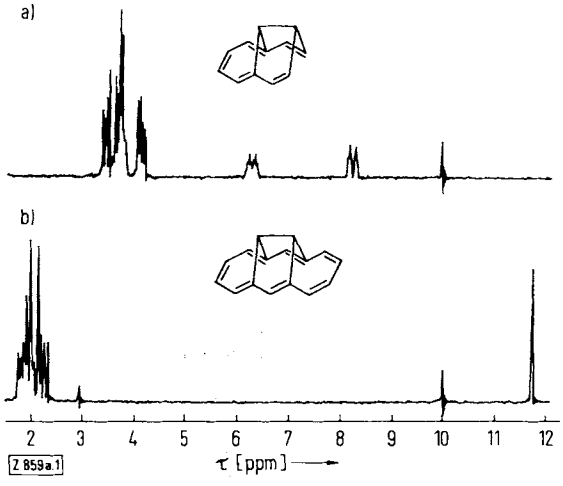

Fig. 1. ^{1}H-NMR spectra of a) tricyclo[5.4.1.$0^{4,12}$]dodeca-2,5,7,9,11(1)-pentaene *(4)* (in CCl_4) and b) 1,6:8,13-ethanediylidene[14]annulene *(7)* (in $CDCl_3$) (60 MHz; TMS as internal standard).

The assumption that the highly reactive *(4)* exists as the cyclically delocalized *(6)* appears wholly unrealistic if its NMR spectrum is compared with that of *(7)*. As is shown in Figure 1, the transition from *(4)* to *(7)* shifts the resonances of the corresponding vinylic protons by 1.2 to 1.9 ppm downfield and that of the bridge proton (11-H[**] and 15-H, respectively) by 3.6 ppm upfield. In view of such dramatic shifts it is beyond doubt that *(7)* owes its electronic and thermodynamic stability mainly to the peripheral delocalization of the 14π-electron system.

Comparison of UV spectra also fails to disclose any peculiarity in the π-electron structure of *(4)*. The UV spectra of *(4)*, *(10)*, and *(11)* are found to be very similar to one another and to correspond in type to those of 1,6-dialkylcycloheptatrienes[11]. By contrast, the spectrum of the delocalized 1,6-methano[10]annulene is related to that of benzene.

The parallelism recently reported between the ^{13}C-NMR spectra of *(4)* and 1,6-methano[10]annulene[14], which

[**] For numbering see Table 1.

was interpreted in terms of *(6)*, was falsified by an error in assignment of the ^{13}C resonance signals[15].

The homoaromaticity problem with regard to *(4)* is referred by this finding back to the still unsolved problem of the extent to which cycloheptatrienes possess homoaromatic character. The methods used here are clearly not sensitive enough to disclose homoconjugative interactions within *(4)*.

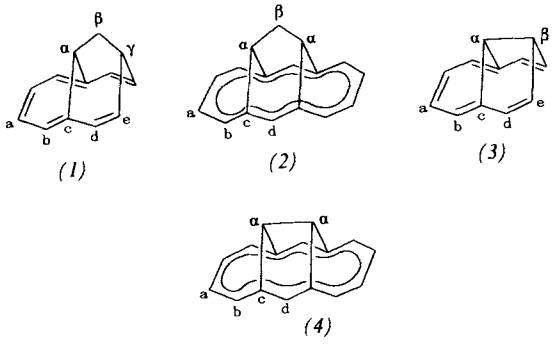
Significance of Stereochemical Factors for the Chemical Shift of the ^{13}C Resonance[**]

By *Harald Günther*, *Hans Schmickler*, *Udo H. Brinker*, *Klaus Nachtkamp*, *Jürgen Wassen*, and *Emanuel Vogel*[*]

Previous experience[1] has shown that the nuclear magnetic ^{13}C resonance frequency is sensitively influenced by stereochemical factors such as conformation, ring size, and ring strain but on the other hand is not significantly dependent on the π-electron structure of unsaturated cyclic systems. In particular, the ring current effect here plays only a minor role[2, 3]. Attempts to use ^{13}C-NMR data as criteria of aromaticity in comparative studies of olefinic and potentially aromatic systems[4–6] are not without risk, as we shall show for the cases of compounds *(1)*—*(4)*[7–9].



^1H-NMR spectra show unambiguously that *(1)* and *(3)* are olefinic[7], but that *(2)* and *(4)* are delocalized [14]annulenes[8, 9]. In contrast thereto, it follows from Table 1 that in ^{13}C-NMR spectroscopy the stereochemical relationship is dominant: according to the criterion of maximum agreement of the resonance frequencies, *(1)* must be ranked alongside *(2)*, and *(3)* alongside *(4)*, whereas the related electronic structures of the compound pairs *(1)*/*(3)* and *(2)*/*(4)* cannot be deduced from the ^{13}C data.

Table 1. δ(^{13}C) data for compounds *(1)*—*(4)* [a].

	C_c	C_a	C_b	C_d	C_e	C_α	C_β	C_γ
(1)	*119.5*	120.4	125.3	127.3	114.0	29.9 (33.8)	*24.1*	33.8 (29.9)
(2) [2]	*111.9*	*127.0*	*130.0*	*127.7*	—	*28.8*	*18.7*	—
(3)	*136.4*	*127.6*	131.3	133.5	115.1	*46.2*	*55.0*	—
(4)	*131.4*	*126.5*	*122.8*	*132.4*	—	*42.8*	—	—

[a] All values in ppm, referred to internal TMS; solvent $CCl_4/CDCl_3$ (5:1); conc. 0.1 M. Experimentally confirmed assignments are italicized, alternative possible assignments are given in parentheses. The spectra were measured on a Bruker-HX-90 instrument at 22.63 MHz with ^1H broad band decoupling by the Fourier transform technique.

[10] Low-temperature measurements gave no indication that *(3)* might be engaged in valence tautomerism.

Only after the steric contribution to the ^{13}C-NMR shift has been largely eliminated by the comparisons *(1)/(2)* and *(3)/(4)* is it possible to recognize the high field shift for the bridging C atoms C_α and C_β of the annulenes which is partially due to the ring current effect. From this it is clear that no ring current is induced in *(3)*, and the compound is not to be regarded as homoaromatic.

This finding contradicts the interpretation of the ^{13}C-NMR spectrum of *(3)* by *Wenkert et al.*[6], who considered *(3)* to be the first neutral homoaromatic compound. Further, these authors assigned the resonance of C_c incorrectly and thus fortuitously established agreement with the resonance frequency of C-1,6 in 1,6-methano[10]annulene (114.6 ppm[2]). Figure 1 shows the relevant off-resonance experiment[1], whereby the signal at 136.4 ppm can be unambiguously recognized as the C_c resonance[10].

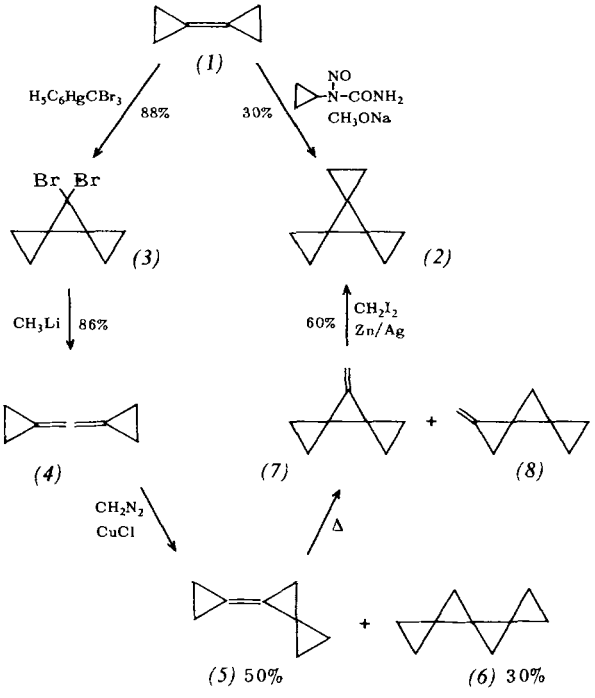
Thermal Isomerization of Cyclopropylidenespiropentane—An Unusual Route to Tricyclopropylidene ([3]-Rotane)[***]

By *Lutz Fitjer* and *Jean-Marie Conia*[*]

Starting from the observation that bicyclopropylidenes can be isomerized selectively to alkylidenespiropentanes under suitable conditions of thermolysis[2,3], we have developed a second synthesis for tricyclopropylidene ([3]-rotane) *(2)*[1], the key step being thermal isomerization of cyclopropylidenespiropentane *(5)*.

Treating bicyclopropylidene *(1)*[4] with (phenylmercuri)-tribromomethane as source of dibromocarbene[5] affords an 88% yield of 7,7-dibromodispiro[2.0.2.1]heptane *(3)* (m. p. 71 °C), which is converted by ethereal methyllithium solution into dicyclopropylidenemethane *(4)*[6] in 86% yield; the last product polymerizes with great ease.

Reaction of *(4)* with diazomethane under catalysis by CuCl[7] was then followed by gas chromatography and, if the cyclopropanation was broken off at the proper time, afforded up to 50% of cyclopropylidenespiropentane *(5)*. The trispiro[2.0.0.2.1.1]nonane *(6)* also formed could be obtained as main product by using an excess of diazomethane and is of interest as an "open chain" isomer of *(2)*. For example, we expect that experimental determination of the total strain energies of *(2)* and *(6)* will confirm the deduction, from ^1H-NMR, ^{13}C-NMR and UV spectroscopic data[1], that *(2)* does not contain a cyclic delocalized electron system.



Thermolyses of *(5)* were carried out at 210 °C and (to avoid dimerizations[8]) at 150—200 torr. The thermolysates were then investigated by gas chromatography.

After 1 h the thermolysate contained, along with 5% of unchanged *(5)*, a mixture of methylenedispiro[2.0.2.1]heptanes *(7)* and *(8)* (13:87) as sole products. After 12 h no *(5)* could be detected, but the product ratio *(7)/(8)* remained unchanged. Pure *(8)* proved to be stable under the above thermolytic conditions.

The final cyclopropanation of 7-methylenedispiro[2.0.2.1]-heptane *(7)* was achieved by use of a modified Simmons-Smith reaction[9] and led to a 60% yield of tricyclopropylidene ([3]-rotane) *(2)*, which was identified by comparison with authentic material[1].

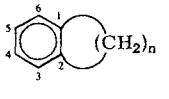
^{13}C-NMR Spectra of Benzocycloalkenes[**][***]

By *Harald Günther, Günther Jikeli, Hans Schmickler*, and *Jörn Prestien*[*]

Observations made for bridged annulenes[1, 2] indicate that the chemical shift of carbon-13 is influenced also by ring strain[3]. In order to study this aspect in greater detail, we have measured the ^{13}C-NMR spectra of the benzocycloalkenes *(1)*—*(6)* (Table 1)[4].



(1), n = 1 *(4)*, n = 4
(2), n = 2 *(5)*, n = 5
(3), n = 3 *(6)*, n = 6

Of the resonances of the aromatic carbon atoms only those of C-3,6 and C-4,5 show a systematic trend with extreme values in the case of *(4)* that conforms qualitatively with the ring strain changes in cycloalkanes and -alkenes[6]. For *(1)*—*(3)* $\delta(3,6) < \delta(4,5)$, whereas for *(4)*—*(6)* the reverse order holds. Results for ethyl-, *n*-propyl-, and *n*-butylbenzene[3a] allow the following δ-values to be calculated for the aromatic carbons in 1,2-dialkylbenzenes: δ(1,2) 143.2; δ(3,6) 128.3; δ(4,5) 125.5 ppm. These data agree well with those measured for 1,2-diethylbenzene *(7)* (Table 1) with the exception of an *ortho*-effect of 2.2 ppm. Similarly, the δ-values for *(5)* and *(6)* deviate only slightly from those predicted. Significant differences are observed, however, for *(4)* [δ(1,2)], *(2)* and *(3)* [δ(3,6)], as well as for all carbon atoms of *(1)*. With *(7)* as model the following "ring contributions" $\Delta\sigma_{ring}$ (Table 2) for the shielding of the aromatic carbons in *(1)*—*(6)* (in ppm) are obtained.

Table 2. $\Delta\sigma_{ring}$ [ppm] for the *o*-phenylene C atoms in *(1)*—*(6)*.

	C-1,2	C-3,6	C-4,5
(1)	+15.6	+13.3	−3.1
(2)	− 4.2	+ 5.9	−0.8
(3)	− 2.3	+ 4.0	−0.1
(4)	+ 4.6	− 0.8	+0.5
(5)	− 1.7	− 0.7	0
(6)	+ 0.4	− 0.7	+0.3

No linear correlation including all compounds exists between ring strain and the $\delta(^{13}C)$- or $\Delta\sigma_{ring}$-values. The $\Delta\sigma_{ring}$-values for C-3,6 and C-4,5 in *(1)*—*(3)* are, however, linearly dependent on the ring strain per CH_2-group in cyclopropene, cyclobutene, and cyclopentene[6]. For $\delta(^{13}C)$ and $^1J(^{13}C, ^1H)$ a general tend becomes apparent: in the case of C-3,6 and the α-CH_2 group increased shielding is accompanied by an increase in $^1J(^{13}C, ^1H)$. The same is true for the corresponding data[3a] in cycloalkanes up to cycloheptane. Present theory of carbon chemical shifts does not offer a simple explanation.

Table 1. ^{13}C chemical shifts [a] and one bond ^{13}C,H coupling constants [b] for benzocycloalkenes.

	δ(1,2)	δ(3,6)	δ(4,5)	δ(α-CH_2)	δ(β-CH_2)	δ(γ-CH_2)	^1J(3,H)	^1J(4,H)	^1J(α,H)
(1)	125.4	114.7	128.8	18.4	—	—	168.5	159	170
(2)	145.2	122.1	126.5	29.5	—	—	162	157.5	138
(3)	143.3	124.0	125.8	32.7	25.2	—	155.5	157	127
(4)	136.4	128.8	125.2	29.3	23.3	—	155	159	126
(5)	142.7	128.7	125.7	36.6	28.2	32.6	155	161	123
(6)	140.6	128.7	126.0	32.1	25.8 [c]	32.1 [c]	155	160	—
(7)	141.0	128.0	125.7	25.3	15.3	—	154	159	126

[a] In ppm downfield from internal TMS; conc. was 0.1—1 M in $CCl_4/CDCl_3$ (3:1); exp. error ±0.1 ppm.
[b] In Hz, maximum experimental error ±1.3 Hz; calculations for AA'BB'X spin systems showed that the error introduced by using first order treatment for the determination of the one bond coupling constants is less than 1 Hz.
[c] Assignment based on comparison with *(5)*.

CIDNP-Detection of a Photocatalyzed C—C Cleavage upon UV Irradiation of Glycolaldehyde in Aqueous Solution

By *Karl-Gerhard Seifert* and *Joachim Bargon*[*]

Glycolaldehyde *(1)* may be considered as the simplest of all sugars and as a model for the higher aldoses. Its unknown photochemical behavior is of interest in biochemistry.

We have studied the photolysis of *(1)* in aqueous solution with the Chemically Induced Dynamic Nuclear Polarization (CIDNP) method[1]. The NMR spectrum of *(1)* is rather complex because in water *(1)* is in equilibrium with two dimeric forms and with its hydrate. The monomeric aldehyde accounts for only 4% of the material in aqueous solution[2], and gives rise to the weak resonance lines at $\delta = 9.7$ (formyl proton) and $\delta = 4.5$ ppm (methylene protons)[3a].

Upon irradiation[3b] of a neutral solution of *(1)* in D_2O inside the modified probe of a Varian HA 60 NMR spectrometer these two lines turn into emission. Another emission line at $\delta = 3.5$ ppm is due to the photoproduct methanol *(2)* (Fig. 1).

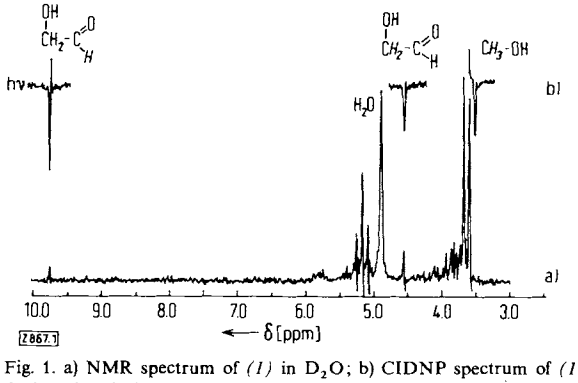

Fig. 1. a) NMR spectrum of *(1)* in D_2O; b) CIDNP spectrum of *(1)* during photolysis.

We explain these observations according to the qualitative rules of CIDNP[1,4]. Upon irradiation *(1)* cleaves from an excited triplet state into a radical pair of a formyl and a hydroxymethyl radical with triplet spin multiplicity[5].

$$\underset{(1)}{HOCH_2CHO} \xrightarrow{h\nu} \left(\overline{HOCH_2^{\bullet} \quad {}^{\bullet}CHO}\right)_T$$

This radical pair may then recombine to form *(1)* or disproportionate into CO and *(2)* in the solvent cage, which explains the negative polarization of *(1)* and *(2)*. Because of the large hyperfine coupling constant of the formyl radical ($a_H = +136$ G)[6] the aldehyde proton in *(1)* shows a much stronger polarization than the two methylene protons which experience a much smaller hyperfine coupling in the hydroxymethyl radical ($a_H = -17$ G)[7].

$$2\left(\overline{HOCH_2^{\bullet} \quad {}^{\bullet}CHO}\right) \longrightarrow \underset{(1)}{HOCH_2CHO} + \underset{(2)}{CH_3OH} + CO$$

An alternative pathway to *(2)* would be hydrogen abstraction by the hydroxymethyl radical. This possibility can be excluded, because in this case *(2)* should appear in enhanced absorption. In order to show that the starting material does not become polarized by an intermolecular photoreduction we have tried to identify the free-radical intermediates. We added some drops of CCl_4 to the D_2O solution of *(1)* and observed strongly polarized chloral hydrate (emission). The chloral is formed by random phase encounter of a formyl and a trichloromethyl radical proving the occurrence of free formyl radicals in aqueous solution during irradiation and thus the polarization of *(1)* by cleavage of the C—C bond (Norrish type I decomposition).

In presence of CCl_4 the CIDNP spectrum changes significantly: the starting material no longer shows a significant polarization in its aldehyde form, instead it exhibits emission in its *hydrated* form. Apparently, *(1)* is still photolyzed in its aldehyde form, but after recombination of the radical pair it becomes hydrated so fast that the polarization is transferred to its hydrate. We explain the accelerated rate of hydration in the presence of CCl_4 as an acid catalysis through HCl formation. This occurs after a formyl radical abstracts a chlorine atom from CCl_4, yielding formyl chloride, which decomposes into HCl and CO. This assumption is substantiated by the observation of CIDNP in the hydrate of *(1)* after adding traces of acid (HCl or HCOOH) to CCl_4-free solutions of *(1)* in D_2O. Formic acid is also a photoproduct in acid solution (Fig. 2).

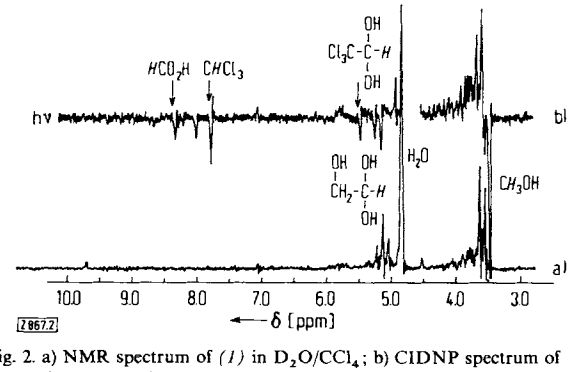

Fig. 2. a) NMR spectrum of *(1)* in D_2O/CCl_4; b) CIDNP spectrum of *(1)* during photolysis.

The CIDNP spectrum did not change after an addition of a little acetone to the D_2O solutions, indicating that even in the presence of acetone the primary photochemical step is the α cleavage of *(1)*.

The photolysis of formaldehyde in the presence of CCl_4 yields the same products as that of *(1)*. Hence, formaldehyde is photoreduced in its triplet state which results in

the same radical pair as above with the same spin multiplicity (triplet)[8].

These experiments demonstrate possible applications of the CIDNP method in investigating reaction mechanism and the kinetics of photoreactions. In particular they allow the determination of hydration rates.

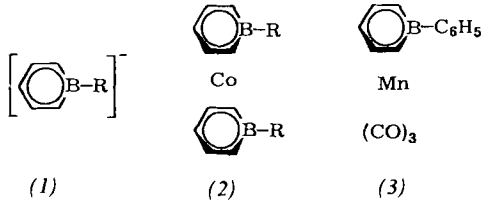
Tricarbonyl-(1-phenylborinato)manganese[1]

By *Gerhard E. Herberich* and *Hans Jürgen Becker*[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Complexes containing the borabenzene (C_5H_5B, borine) system have been previously described only with cobalt as a central metal: Thus reaction of bis(cyclopentadienyl)-cobalt with boron-halogen compounds affords sandwich complexes of cobalt in which borinate ions *(1)*[2] are bound as hexahapto ligands to the central metal atom[3]. We have now tried to prepare borinato complexes of other metals by ligand transfer[4].



(1) *(2)* *(3)*

The paramagnetic bis(borinato)cobalt complexes *(2)*[3a, 3c], which contain an excess electron and thus labilized ring-metal bonds, should be excellent starting materials for ligand transfer reactions. Indeed, bis-(1-phenylborinato)co-balt *(2)*, $R=C_6H_5$, reacts with $Mn_2(CO)_{10}$ in boiling toluene with formation of metallic cobalt, thus yielding tricarbonyl-(1-phenylborinato)manganese *(3)*:

$$Co(C_5H_5B{-}C_6H_5)_2 + Mn_2(CO)_{10} \rightarrow$$
$$2\,Mn(CO)_3(C_5H_5B{-}C_6H_5) + Co + 4CO$$

The structure of the new complex[5] follows to a large extent from the mass spectrum. The dominant mode of decomposition is seen to be successive removal of the three CO groups ($m^* = 238.7$, –, 183.3) and of the Mn atom ($m^* = 112.5$)[6]; the fragment ion $[C_5H_5B{-}C_6H_5]^+$ then decomposes further in the known manner[3a] by loss of H_2 ($m^* = 149.0$) or of C_2H_2 molecules ($m^* = 105.4$, 80.3). A surprise is the appearance of the ion $[MnC_6H_5]^+$ which is probably formed from $[MnC_5H_5B{-}C_6H_5]^+$ by rearrangement and loss of C_5H_5B [borabenzene (?)].

The IR spectrum shows three νCO bands of high and similar intensity, which is the characteristic picture of a $M(CO)_3$ group with strong perturbation of the C_{3v} symmetry by the counterligand. The wave number for these bands is, in the mean, about 19 cm^{-1} higher than for those of $Mn(CO)_3(C_5H_5)$. This indicates that the $(C_5H_5B{-}R)$ ligand (here $R=C_6H_5$) is an appreciably stronger acceptor and weaker donor than the C_5H_5 ligand, a conclusion previously derived from the mass spectrometrically determined ionization energies of borinatocobalt complexes[3c].

That an intact 1-phenylborinate ligand *(1)* is present in *(3)* follows unambiguously also from a comparison of the ^1H- and ^{11}B-NMR spectra of *(3)* with those of the $[Co(C_5H_5)(C_5H_5B{-}C_6H_5)]^+$ ion *(4)*[3a]. The proton signals of the borabenzene portion appear at higher field for the molecule *(3)* in contrast to those of the cation *(4)* and, furthermore, can be completely analyzed and assigned by a first order procedure. Cyclic conjugation of the borabenzene ring and a negative charge on the boron have been proved for the free ligand *(1)*[2]. All the proton signals of the borabenzene ring in the complex

Table 1. Data for tricarbonyl-(1-phenylborinato)manganese *(3)*.

(3) appear within a narrow range of 1.4 ppm and at relatively low field, as expected for complexes of cyclically conjugated ligands in general[7]; the ^{11}B signal is shifted slightly to higher field, as it is also for *(4)*. The borinate ligand in *(3)* thus retains its benzenoid character and, as in the known borinatocobalt complexes[3], is bonded to the Mn atom as an almost planar hexahapto ligand. An X-ray structure analysis confirms this conclusion[8].

Experimental:

A solution of $Co(C_5H_5B—C_6H_5)_2$ (300 mg, 0.83 mmol) and $Mn_2(CO)_{10}$ (650 mg, 1.66 mmol) in toluene (35 ml) is heated for 50 h under reflux (bath temp. 140 °C) and then filtered. The solvent is removed in a vacuum and the residue is chromatographed in pentane at −20 °C on a silica gel column (50 cm long, 1.2 cm wide). The highly mobile residue of $Mn_2(CO)_{10}$ is eluted, and then the main product is removed from the gel by CH_2Cl_2. After removal of the CH_2Cl_2, sublimation (high vacuum; 60—80 °C) affords analytically pure *(3)* (405 mg, 84%). The product crystallizes from organic solvents in pale yellow needles; it is stable in the solid state but in solution it is sensitive to light and to air.

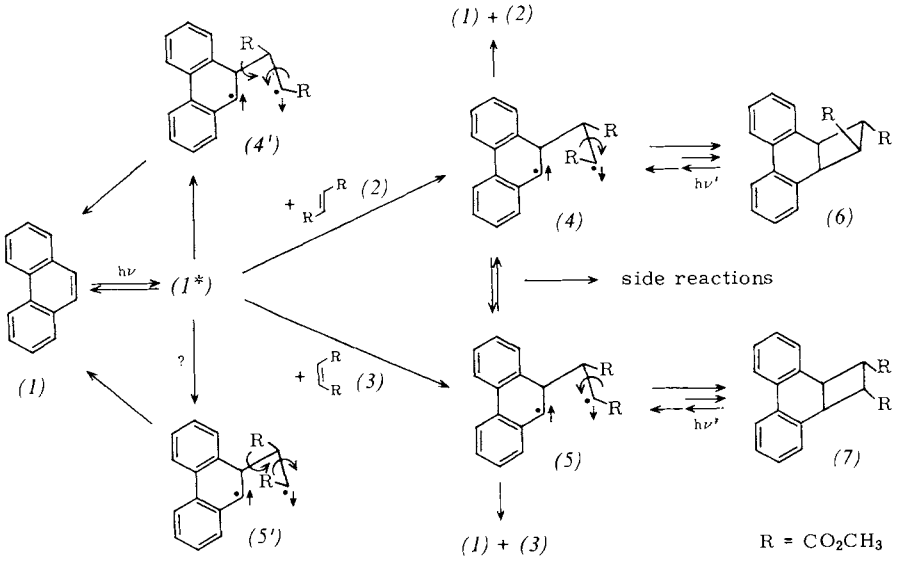
[2+2]-Photocycloadditions Involving Phenanthrene: Mechanistic Models for Two-Step Processes[**]

By *Gerd Kaupp*[*]

The continuing interest in concerted singlet and triplet photocycloadditions[1], and the experimental proof of kinetically operative intermediates among intramolecular models[2], lead to mechanistic decisions also for intermolecular examples. We now report our experimental results for a typical model system (fluorescence, selective excitation, no complicating *cis/trans* isomerization) for non-stereospecific $[2\pi+2\pi]$-photoadditions. Absence of stereospecificity indicates intermediates with internal rotation, but additional data are required to confirm the postulate of competing supra- and antara-facial additions[1]. This purpose can be achieved with photoadditions of phenanthrene *(1)*[3] to dimethyl maleate *(3)* and fumarate *(2)*, yielding *(6)* and *(7)*[4]. Meanwhile the result of these reactions has been interpreted by assumption of exciplexes[5,6] (electronically excited π-complexes with the possibility of luminescence) as well as by non-concerted triplet mechanisms[6]. However, a combination of measurements of product yield, quantum yield, and luminescence with the aid of molecular models leads to interpretation of



the near-constancy of the *(6)*:*(7)* ratio (see Table 1) on the basis of a two-step singlet mechanism[4].

The following findings are relevant to the proposed singlet mechanism:

1. The lifetime of the phenanthrene fluorescence ($\phi_{Fl}=0.13$) is relatively large at 57.5 ns[7].
2. The phenanthrene fluorescence is quenched to the extent of 92 and 48%, respectively, by *(2)* and *(3)* (4.5×10^{-2} mol/l; benzene).
3. The reaction with *(3)* is accelerated by oxygen, not decelerated.
4. The isomerization of the olefins *(2)* and *(3)*, sensitized by phenanthrene, is relatively slow in benzene and proceeds in both directions (see Table 1).

[a] Immersed high-pressure mercury lamp Hanau Q-81; Wertheimer UVW-55 filter glass [% transmission: <1 (λ=315 nm); 12.5 (334); 31 (365); <1 (410)]; N_2; 20 °C; 12 h; any anthracene present as impurity in the phenanthrene was removed by irradiation of concentrated solutions, filtration and sublimation.
[b] After cessation of reaction.
[c] By passage of oxygen.

Not only the quenching data and the preparatively important influence of oxygen, but also the extent and direction of the sensitized *cis/trans* isomerizations, show that, under the experimental conditions, there is almost complete absence of spin reversal in the electronically excited phenanthrene unless this is accelerated by external heavy-atom effects. The fact that the *(6)*:*(7)* ratio is almost the same in all cases[8] proves interconversion of the intermediates *(4)* and *(5)*, a result that is indicated also by inspection of molecular models and an apparent discrepancy: the initial quantum yields for consumption of phenanthrene in reactions with *(2)* and *(3)* are almost the same within experimental error [ϕ=0.010; 4.5×10^{-2} mol/l of *(2)* or *(3)*; benzene; N_2], although *(2)* quenches the phenanthrene fluorescence much more effectively than does *(3)* (see above). Comparison of the sensitized olefin isomerizations under standard conditions (see Table 1) shows, however, that *(2)* isomerizes faster than *(3)*.

Clearly, with little variation in the geometry of its approach to electronically excited phenanthrene, the fumaric ester *(2)* yields two isomeric intermediate products *(4)* and *(4')*, whereby the ability to fluoresce is lost[9]. The *syn*-intermediate *(4')*, which at best can afford *(6)* but cannot afford *(7)*, then decomposes to phenanthrene and *(2)* or *(3)*, because, again in agreement with molecular models, the steric hindrance and simultaneously the orbital overlap of the radical centers are decreased by partial rotation around the newly formed σ-bond. The reaction with *(3)* does not require the rather improbable assumption of *(5')*. In the *anti*-rotamers *(4)* and *(5)* the orbital overlap is more favorable for formation of a four-membered ring, leading to *(6)* or *(7)* (cf. also Ref. [2]), but the decomposition to *(1)* and *(2)* or to *(1)* and *(3)* preponderates as shown by the low quantum yields.

Table 2. 313 nm irradiation of 10^{-3} mol/l of *(6)* and *(7)* [a]; yields of phenanthrene *(1)* [b] and quantum yields (ϕ) [c].

Medium	Yield of *(1)* [%] from *(6)*	ϕ	Yield of *(1)* [%] from *(7)*	ϕ
CH_3CN/N_2	95	0.75	82	0.45
CH_3CN/O_2	96	0.8	80	0.4
1.0 mol/l *trans*-piperylene in CH_3CN/N_2	92	0.75	67	
C_2H_5Br/N_2	50	0.45	35	

[a] Band pass 4.8 nm; 20 °C.
[b] UV analysis after complete conversion.
[c] Formation of phenanthrene after up to *ca.* 30% conversion.

Further confirmation of the formula scheme is provided by irradiation of *(6)* (m.p. 114 °C)[10] and *(7)*[11] (m.p. 116 °C). Phenanthrene is formed from *(6)* (excitation of the longest wavelength band) faster than from *(7)* (see Table 2); and *(7)* can be isolated by chromatography after partial or extensive reaction of *(6)*, in agreement with the mechanism for the intermediates.

Further indications are given by the differing intensities of fluorescence [*(6)*: ϕ_{Fl}=0.015; *(7)*: ϕ_{Fl}=0.15; cyclohexane/N_2; 20 °C; $\lambda_{Fl.}^{corr.}$=311, 326, 337 sh, 355 sh, 375 sh; Stokes shift: 4 nm] and rates of photolysis [*(6)* faster than *(7)*] at −190 °C (ether/alcohol glass[12]). Since these findings show absence of appreciable thermal activation barriers in the photoreversions, in spite of the competing luminescence, it again becomes clear that stepwise mechanisms apply that involve the least possible geometrical and chemical change, and it must be concluded that the *cis*-disubstituted bond of the four-membered ring of *(6)* is cleaved first [cf. *(7)*].

Further, the photoreversions occur without temporary change in multiplicity, as shown by determinations of quantum yield and product yield under various conditions (see Table 2):

1. Oxygen has no appreciable effect on the quantum yield or yield of phenanthrene.

2. The usual triplet quencher, *trans*-piperylene, causes hardly any diminution in the rate of formation of phenanthrene from *(6)*; a decrease in the rate of formation of phenanthrene from *(7)* is to be expected owing to the lower yield of product.

3. In ethyl bromide there is no favorable heavy-atom effect on the formation of phenanthrene: lower initial rate and lower yield occur in parallel.

It is assumed that the rotamers *(4)* and *(5)* [also *(4')*] are partially trapped by materials added or formed during the reaction, yielding inhomogeneous (probably polymerizing) by-products, because phenanthrene is stable under the conditions of irradiation even for a prolonged time. The results show that very different observations, which could not be precalculated by the method of potential energy hypersurfaces[13], can however be brought together in a single scheme on an empirical-experimental basis[14]. Experiment indicates that variations in initial quantum yield under the influence of triplet quenchers or of possible heavy-atom effects should be interpreted on the basis of triplet mechanisms only if the product yields do not vary simultaneously.

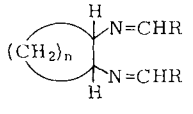
[14] Further examples and applications will be reported later.

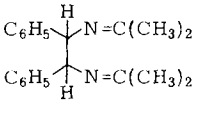
[3.3]-Sigmatropic Reactions in the *N,N'*-Dimethyleneethylenediamine System [**]

By *Fritz Vögtle* and *Ernst Goldschmitt* [*]

In 1965 *Staab* and *Vögtle*[1] described the first thermal valence isomerizations of two-fold Schiff bases of type *(1)*.



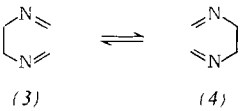
(1), n = 1,2



(2)

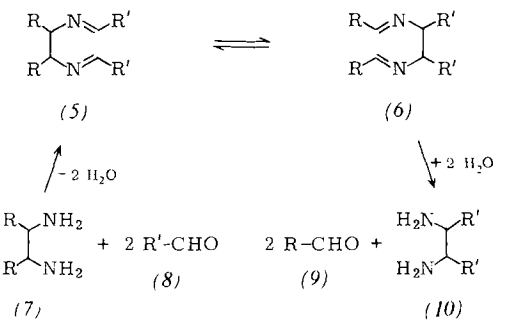
The original object of that work has not previously been achieved, namely to carry out, with compounds such as *(1)*, $n=4$, and *(2)*, [3.3]-sigmatropic rearrangements of type *(3)* ⇌ *(4)* that were not assisted by ring strain effects, in analogy to the Cope rearrangement[2,3].

It was therefore all the more surprising when, in connection with our studies of the hydrobenzamide-amarin valence



(3) *(4)*

isomerization[4], we found the valence isomerization that we had looked for was quite general for the system *(5)* ⇌ *(6)* when aromatic groups were present as substituents and that there it occurred under most unexpectedly mild conditions[5]:



(a), R = phenyl, R' = 2-pyridyl
(b), R = 2-hydroxyphenyl, R' = phenyl
(c), R = 2-hydroxyphenyl, R' = 4-methoxyphenyl
(d), R = 2-hydroxyphenyl, R' = 2-pyridyl

The rearrangement *(5a)* → *(6a)* (Table 1), which was the first that we observed, occurs so rapidly that the preparation and isolation of the Schiff base *(5a)* from *(7a)* and *(8a)* must be carried out cautiously at room temperature; even under "normal" conditions for synthesis of *(5a)*, *i.e.* in boiling benzene, a mixture of *(5a)* and *(6a)* is obtained. Further, if pure *(5a)* is heated at temperatures slightly above its melting point (181—182 °C), the separation of higher-melting crystals of the valence isomer *(6a)* can be seen (Table 1).

Table 1. Reactants, products, and hydrolysis products of the valence isomerizations *(5)* → *(6)* [a].

[*] Prof. Dr. F. Vögtle and Dipl.-Chem. E. Goldschmitt
Institut für Organische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

In the 2-hydroxyphenyl-substituted systems *(5b)*—*(5d)* the threshold of valence isomerization lies still lower: the usual method for synthesis of these Schiff bases, namely treatment of α,α'-diamino-2,2'-bibenzyldiol *(7b)* with the aldehydes *(8b)*—*(8d)* in boiling benzene, affords only the rearrangement products *(6b)*—*(6d)*, the yields thereof being 84—96% (Table 1). Acid-catalyzed hydrolysis of the crystalline products *(6b)*—*(6d)* gave in all cases pure salicylaldehyde together with the 1,2-diarylethylenediamines *(10)* that are produced by C—C bond formation and are the "parents" of the valence isomers *(6)*; of these diamines, *(10b)* could be compared with the authentic substance prepared from amarin[6]. The new, water-soluble diamine *(10d)*, which cannot be obtained by the usual methods, can be obtained on a preparative scale (yield 68%) in this way, *i. e.* by the reaction *(5d)* → *(6d)*, followed by hydrolysis (Table 1).

As the examples *(b)* to *(d)* show, the equilibrium in the reaction *(5)* ⇌ *(6)* of the 2-hydroxyphenyl-substituted compounds lies completely on the side of the valence isomers *(6)*. That the conditions necessary are unusually mild in comparison with those for [3.3]-sigmatropic migration in corresponding biallyl systems (the Cope rearrangement)[7] is shown by fact that the rearrangement products

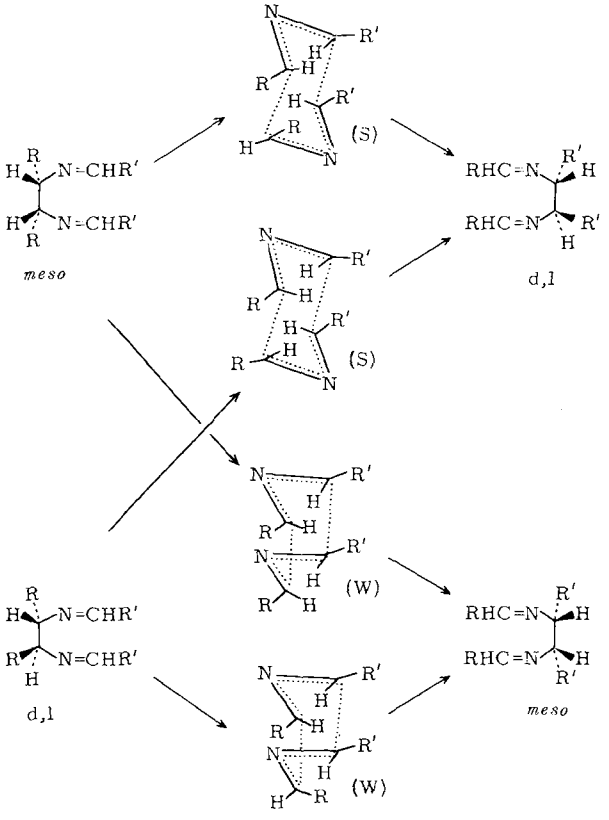

Fig. 1. Possible transition states for the valence isomerization *(5)* → *(6)* and their stereochemical consequences. S = chair-shaped and W = boat-shaped transition state.

(6b) and *(6d)* are isolated when preparation of *(5b)* and *(5d)* from, respectively, *(7b)* and benzaldehyde *(8b)* or from *(7b)* and 2-pyridinecarbaldehyde *(8d)* is attempted at room temperature; a possible explanation is that steric interactions during formation of the new C—C bond are smaller with compounds such as *(5)* than with compounds such as *(2)*, and, further, that hydrogen bonds[8] are formed that stabilize the hydroxyphenyl products *(6)*.

The isomerization observed is, however, by no means confined to cases where the substituent R is phenyl or 2-hydroxyphenyl: orienting experiments have shown that equilibrium mixtures of *(5)* and *(6)* arising by the valence isomerization are obtained also when the groups R and/or R' are varied within wide limits.

The Cope rearrangement is today formulated as a [3.3]-sigmatropic reaction of the type $[_{\sigma}2_s + _{\pi}2_s + _{\pi}2_s]$; for rearrangement of the carbon skeleton, the four-center transition state (chair form), required for reasons of orbital symmetry, has been proved by several examples[7]. However, sigmatropic [3.3]-shifts are by no means impossible in systems where the geometric relations enforce a boat-shaped transition state[9].

The starting point for our study of the stereochemical consequences in the "diaza-Cope" system is the expectation (Fig. 1) that a boat-shaped transition state will always lead to a *meso*-product *(6)*, independently of the stereochemistry of the reactant ethylenediamine *(7)*, provided that the C=N double bond has the *E* configuration[10] and that the [3.3]-shift is of the synchronous suprafacial type. We have found that the *meso*-diamines *(10b)* and *(10c)*[6] are obtained by valence isomerization of *(5b)* and *(5c)* and subsequent hydrolysis, but further studies with a large number of variously substituted compounds *(5)* and *(6)* are needed to decide whether it is justifiable to conclude therefrom that the boat form of the transition state is favored in our systems.

Reaction of Imidic Esters with Aziridines[1]

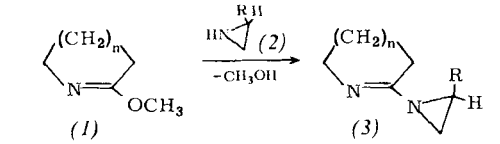
By *Dieter Bormann*[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

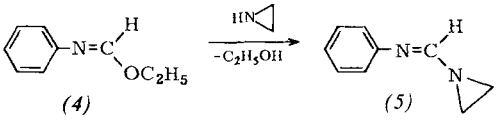
In the presence of small amounts of ammonium bromide, cyclic imidic esters such as 2-methoxy-1-pyrroline *(1a)*

[*] Dr. D. Bormann
Farbwerke Hoechst AG
623 Frankfurt (Main) 80 (Germany)

and 3,4,5,6-tetrahydro-7-methoxy-2*H*-azepine *(1b)* undergo a mild exothermic reaction with aziridines *(2)*, yielding 1-iminomethyl-substituted aziridines *(3)* (Table 1).



(1) *(3)*



(4) *(5)*

(a), n = 1; *(b)*, n = 3

The reaction takes place also with aziridine itself *(2)*, R = H, and with 2-methylaziridine *(2)*, R = CH_3, but fails under these conditions with 2,2-dimethylaziridine.

In the presence of ammonium bromide, ethyl *N*-phenylformimidate *(4)* undergoes a strongly exothermic reaction with aziridine *(2)*, R = H, even at *ca.* −10 °C, yielding compound *(5)* (Table 1).

being kept for 1 h at room temperature the solution is heated for 3 h under reflux; then the compounds *(6)* are distilled off.

The Nature of Carbocations Derived from Tricyclo[3.1.1.$0^{2,4}$]hept-6-yl and Tricyclo[3.2.0.$0^{2,7}$]hept-4-yl Systems[**]

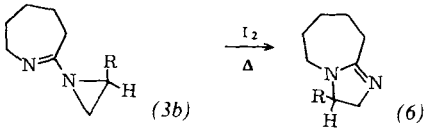
By *S. Masamune, M. Sakai, A. V. Kemp-Jones, H. Ona, A. Venot*, and *T. Nakashima*[*]

Successful generation of the structurally unique carbocation *(1)* of C_{4v} symmetry from the homotetrahedrane system *(2)*[1] has suggested that the solvolysis of *exo-anti*-tricyclo[3.1.1.$0^{2,4}$]hept-6-yl *p*-nitrobenzoate *(3a)*[2] may involve an ionic species *(4a)* of C_{2v} symmetry, a bis-homolog of *(1)*, or its equivalent. This anticipation has now been realized and we wish to demonstrate remarkable features of the carbocation.

Table 1. Compounds prepared.

Cpd.	Name	B. p. [°C/torr]	νC=N (CH_2Cl_2) [cm^{-1}]	n_D^{20}	Yield [%]
(3a), R = H	2-Aziridinyl-1-pyrroline	74/20	1634	1.4903	81
(3b), R = H	7-Aziridinyl-3,4,5,6-tetrahydro-2*H*-azepine	98/20	1658	1.4983	74
(3b), R = CH_3	3,4,5,6-Tetrahydro-7-(2-methyl-aziridinyl)-2*H*-azepine	92/20	1658	1.4900	71
(5)	*N*-(1-Aziridinylmethylene)aniline	105/5	1639	1.5795	28
(6), R = H	1,8-Diazabicyclo[5.3.0]dec-7-ene	108/10	1603	1.5122	90
(6), R = CH_3	10-Methyl-1,8-diazabicyclo-[5.3.0]dec-7-ene	105/10	1603	1.5008	89

The strongly basic aziridine derivatives *(3)* and *(5)* can be purified by distillation and, except for *(5)*, are stable for a long time; they give correct analytical figures. When heated with iodine, *(3b)*, R = H and CH_3, rearrange to 1,8-diazabicyclo[5.3.0]dec-7-enes *(6)* (Table 1). These strongly basic compounds can be used for dehydrohalogenations (for a review of the use of similar compounds see ref. [2]). Compounds *(6)*, R = H and CH_3, can be purified by distillation and give correct elemental analyses.



(3b) *(6)*

1-Iminomethyl-substituted aziridines (3):

NH_4Br (100 mg) is added to a mixture of the imidic ester *(1)* (1 mol) and aziridine (1.5 mol) at room temperature. After 8 hours' stirring without cooling, the compounds *(3)* are distilled off.

1,8-Diazabicyclo[5.3.0]dec-7-enes (6):

A solution of *(3b)*, R = H or CH_3 (0.3 mol), in acetone (100 ml) is treated with iodine (1.0 g). The solution becomes dark brown but the color fades after a few minutes. After

The 2,4-dideuterio derivative *(3b)* was prepared in a manner similar to that previously described[2, 3], but modified to provide a much improved overall yield. Thus, treatment of the dimethyl ester *(10a)* with sodium methoxide in CH_3OD and hydrolysis with D_2O (NaOD) effected incorporation of 1.8 deuterium atoms per molecule to provide *(10b)* which was converted without loss of deuterium into a dideuteriobicyclo[2.2.0]hexene derivative *(11a)* through acetylation and Kolbe electrolysis[4]. Solvolysis of the trifluoromethanesulfonate *(11b)* in acetic acid proceeded smoothly at room temperature ($\tau_{1/2}$ = approximately 45 min) to provide near-quantitative yields of bicyclo[2.1.1]hexen-5-yl acetate (1.8 D) *(12)*, which survived under the solvolytic conditions, so that the previous problem[3] arising from the facile 1,3-sigmatropic rearrangement of *(12)* is now solved. Conversion of *(12)* into *(3b)* (1.8 D) follows the earlier procedure.

The *p*-nitrobenzoate *(3b)* underwent solvolysis in 60% aqueous dioxane to afford *endo*-tricyclo[3.2.0.$0^{2,7}$]heptan-4-ol *(5a)* (*ca.* 70% yield) and the corresponding *p*-nitrobenzoate *(5b)* (*ca.* 20%). ^{1}H-NMR analysis shows that

C-4 of both products possesses 0.45 D rather than 0.9 D[5], and further the ^{13}C-NMR spectrum of *(5a)* was in accord with complete deuterium scrambling among C-2, C-4, C-5, and C-7 [δ_{TMS} ($CDCl_3$): 24.2, 78.4, 42.4, 19.4][6]. These results lead to the conclusion that the solvolysis of *(3a)* involves the intermediate cation *(4a)*, or that the equilibration of cations *(4b)* and *(4c)* of lower symmetry (C_s) is completed prior to solvent capture. Furthermore, the same cation (cations) is very likely to be responsible for the deuterium distribution observed in the acetolysis of the tosylate *(5c)*[7].

To gain further insight into the nature of the cations expressed by formulas *(4a)* or *(4b)* and *(4c)*, we have generated the long-lived ionic species from *(3c)*, *(3d)*, *(5d)* and *(5e)*[8], using superacid media. Solutions of *(3c)* and *(5d)* in a 1:5 mixture of SbF_5 and SO_2ClF at -110 °C provided identical ^{13}C-NMR and ^{1}H-NMR spectra[9]. The signal intensity and off-resonance spectra readily permitted assignment of the ^{13}C-NMR signals [δ_{TMS} = 39.38 (C-1), 8.09 (C-2), -17.15 ppm (C-7)][10]. The corresponding ^{1}H-NMR spectrum, which is consistent with the ^{13}C-NMR spectrum, showed three rather broad (partly due to the viscosity of the solution) signals at τ 5.89, 7.46, and 8.37 with the relative intensity 4:2:3 and the signal due to the proton at apical carbon-7[10] overlaps with those at C-2 (and C-5). With *(3d)* and *(5e)*, the intensity of the signal at τ 5.89 is reduced to 1/2 and 3/4, respectively, thus this signal is securely assigned to the protons at C-1, C-3, C-4, and C-6. Quenching the above superacid solutions obtained from *(3c)* and *(5d)* with methanol containing excess sodium methoxide or carbonate at -78 °C provided *(5f)* in more than 80% yield as the sole isolable product. Therefore, we formulate the cation observed at -110 °C as *(4a)*, subject to the limitation of the NMR time scale. This cation was found to be thermally labile and warming the above solutions to -80 °C brought about an irreversible rearrangement, as evidenced by the appearance of a new set of NMR signals [(TMS, external) ^{1}H-NMR: τ 7.50 (2H/d, J = 13Hz), 6.56 (1H/s), 6.13 (2H/d, J = 13Hz), 5.56 (1H/t, $J \approx$ 4Hz), 3.52 (2H/br.s), -1.09 (1H/br.s); ^{13}C-NMR: δ_{TMS} 42.3, 46.3, 86.1, 111.4, 258.3] with some ill-defined background signals due to polymeric materials. Quenching (CH_3OH—Na_2CO_3, *vide supra*) of these solutions after the warming (-80 to -40 °C) afforded 3-methoxytricyclo[2.2.1.$0^{2,6}$]heptane *(6a)*[11] in *ca.* 50% yield. The NMR signals of the corresponding bromide *(6b)* in SbF_5—SO_2ClF at -50 °C were indeed superimposable on those described above. These results permit one to assign structure *(7)* to the rearranged cation. The pathway leading to *(7)* from *(4a)* appears unexceptional.

The ^{13}C-NMR spectrum of *(4a)* is presumably comparable to that reported by *Hart* and *Kuzuya*[12], yet the high-field ^{13}C absorption (δ -17.15) due to the apical

carbon demands comment. We have previously noted that increasing strain causes an upfield ^{13}C chemical shift. Examination of spectra of several tricyclo compounds such as *(5a)*, *(3a)*, *(6a)* and tricyclo[2.2.0.0^{2,6}]hexane *(8)* shows that the highest signals appear in the range δ 15—20 ppm, *i.e. ca.* 30—40 ppm lower than that due to C-7 of *(4a)*. This definitely suggests that the s,p-hybridization of the carbon bonding orbitals is unique and further that only a minimal positive charge resides at this carbon. Although the choice between the single cation *(4a)* or an equilibrating pair of *(4b)* and *(4c)* remains to be made, other theoretical and experimental results presently accumulating tend to place a slight preference for *(4a)* rather than *(4b)* and *(4c)* as the particular species obtained in superacid media[13].

New Cryptates Containing Tricyclic Ligands: Crystal Structure of $C_{32}H_{64}N_4O_{10} \cdot 2NaI$

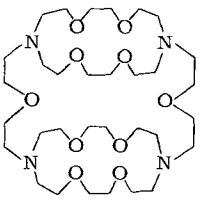
By *Michel Mellinger, Jean Fischer,* and *Raymond Weiss*[*]

In solution the macrocycle *(1)* forms inclusion complexes of the [3]-cryptate type, *e.g.* with sodium iodide it forms the 1:2 complex *(1)*·2NaI[11].

This compound crystallizes in space group $P2_1/c$ with $a = 8.726(4)$, $b = 10.114(7)$, $c = 24.422(11)$ Å, $\beta = 103.89(4)°$, $d_{exp} = 1.52 \pm 0.05$, $d_{calc} = 1.530$ g/cm^3 and $Z = 2$.

[*] Prof. R. Weiss, M. Mellinger, and Dr. J. Fischer
Institut de Chimie, Laboratoire de Cristallographie associé au C.N.R.S.
Université Louis Pasteur
F-67008 Strasbourg, B. P. 296/R8 (France)

The intensities of the X-ray reflections were measured for a spherical crystal of diameter 0.3 mm with Mo—K_α-radiation on a Picker-FACS(I) single crystal diffractometer.



(1) = $C_{32}H_{64}N_4O_{10}$

2304 independent reflections with $\sigma(I)/I < 3\sigma$ were used for the structure analysis. At present the R value amounts to 0.069.

Figure 1 shows the structure of the complex dication of *(1)*·2NaI, which has a crystallographic center of symmetry. Two sodium ions are accommodated inside the tricyclic ligand, each of them being bonded to two nitrogen and five oxygen atoms of *(1)*.

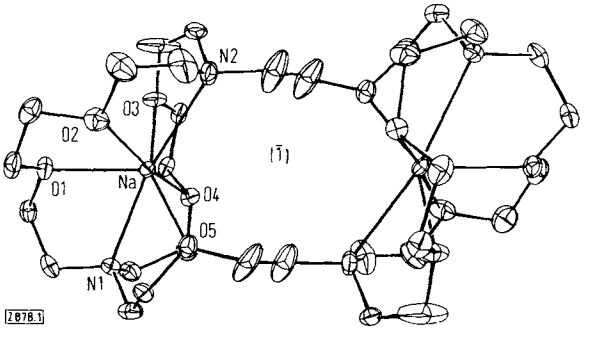


Fig. 1. Crystal structure of the complex dication of the inclusion compound *(1)*·2NaI.

The distances from Na^+ to N1 and N2 are 2.70(1) and 2.71(1) Å, respectively, and to O1, O2, O3, O4 and O5, vary between 2.39(1) and 2.48(1) Å. Similar values were found for the [2]-cryptate (222)·NaI and for the complex sodium salts with cyclic polyethers[2, 3].

The iodide ions no longer interact with the sodium ions: all the $Na^+ \cdots I^-$ separations exceed 5 Å. The distance between the two sodium ions in one ligand is 6.40 Å.

The determination of this structure confirms the finding that the tricyclic ligand *(1)* can enclose two metal cations. The two holes in this molecule have approximately the same diameter as in the bicyclic ligand (222) of the [2]-cryptate (222)·NaI, which has proved very stable[2].

The stability of the [3]-cryptate and the selectivity of the tricyclic ligand are less marked than for the [2]-cryptate and the bicyclic ligand, respectively[4]. This is probably due mainly to greater flexibility of the tricycle.

Thermolysis of Tetramethyl-1,2-dioxetane

By *Peter Lechtken* and *Günther Höhne*[*]

Dedicated to Professor Gerhard Hesse on the occasion of his 65th birthday

A 1,2-dioxetane grouping has been recognized as the active intermediate formed during the course of many bioluminescent reactions[1]. Light emission from a biological or chemical system at room temperature is, however, possible only if one of the individual steps in the reaction chain liberates sufficient energy (as reaction enthalpy) to raise a product or acceptor molecule to the electronically excited state. The sum of the activation energy (E_A) and the reaction enthalpy (ΔH_R) must be at least as great as the energy of the photon radiated. At least 75 kcal are necessary for pale blue luminescence ($\lambda \approx 420$ nm).

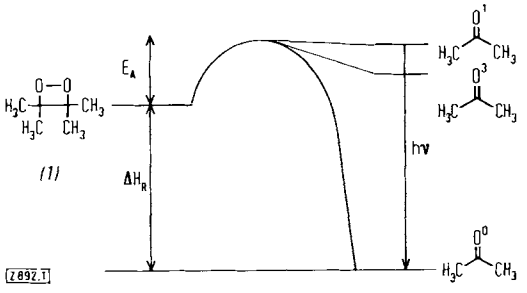

Fig. 1. Energy scheme for decomposition of tetramethyl-1,2-dioxetane *(1)* to acetone with chemiluminescence ($h\nu \approx 84$ kcal).

Tetramethyl-1,2-dioxetane *(1)*, which decomposes only slowly at room temperature, serves us as model for biogenic intermediates. Thorough investigation of the thermal fragmentation[2] in solution had shown that electronically excited acetone is formed from *(1)* in high yield, in which process the non-luminescent but energetically lower-lying triplet state[3] is favored 100-fold over the singlet state (Fig. 1). An attempted rationalization invokes a pericyclic scission[4] mechanism, but this is meaningful only if sufficient energy is available to make singlet or triplet formation equally probable. Several calculations indicate that between 60 and 100 kcal/mol should be liberated on fission of substituted dioxetanes[5].

We have now measured calorimetrically the reaction enthalpy of the thermolysis of *(1)* in the solid state and in solution. As an independent control we determined also the heat of combustion (Table 1).

Thermolysis of solid (1): A few mg of *(1)* were sealed in a cylindrical, air-tight, pressure-resistant, aluminum sample-holder (volume 90 mm³) and were then decomposed in a DSC calorimeter[6a] at a constant heating rate. Figure 2 shows the change in heat flow with temperature; the area under the curve is a measure of heat evolved. We find $Q_I = -68 \pm 3$ kcal/mol.

This value proved independent of the weight of the sample and of the rate of heating. If the rate of heating is the same, the plots of the thermograms are superposable if normalized for the weight of sample. If the rate of heating is lowered, the maximum of the decomposition is shifted,

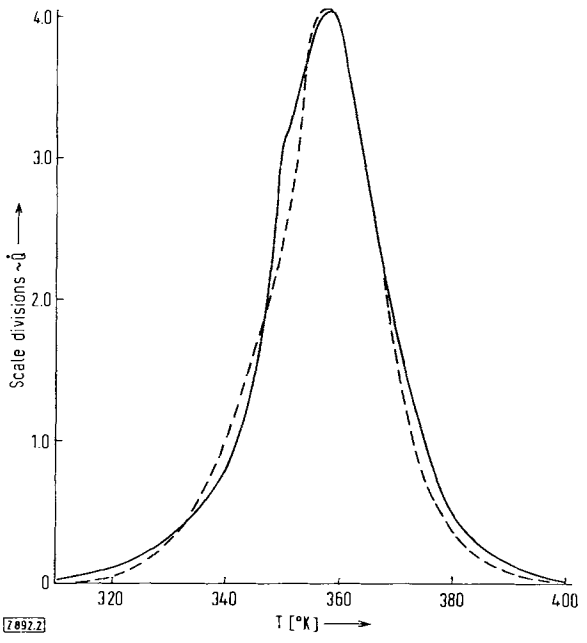

Fig. 2. Normalized thermogram of the decomposition of solid *(1)* (——) (curve I) and of *(1)* in dibutyl phthalate solution (– – –) (curve II). Rate of heating 5 deg/min.

as expected, to lower temperatures. Under these conditions *(1)* shows a melting point at *ca.* 343 K; the heat of melting can be crudely estimated as 1.5—2 kcal/mol.

Since the measurements were at constant volume, Q_I represents the internal energy ΔU, which must be recalculated into the enthalpy ΔH_I. Further a part of the heat of melting and of the heat of evaporation of acetone are included and corrections must be made appropriately[7].

Table 1. Reaction enthalpies in thermolysis of *(1)*.

Heat of reaction [kcal/mol]		No. of expts.	Change
ΔH_I	$= -71 \pm 3$	7	$(1)_{solid} \rightarrow acetone_{liq.}$
ΔH_{II}	$= -61 \pm 3$	7	$(1)_{soln.} \rightarrow acetone_{soln.}$
ΔH_{III}	$= -68 \pm 10$	2	$(1)_{solid} \rightarrow acetone_{liq.}$
ΔH_S	$= +1.8 \pm 0.3$	7	$(1)_{solid} \rightarrow (1)_{liq.}$
$\Delta H_{combstn.}$	$= -922 \pm 10$	2	combustion

Thermolysis of dissolved (1): About 3 mg of *(1)* are dissolved in *ca.* 50 mg of dibutyl phthalate and decomposed under conditions similar to those above. The value ΔH_{II} still contains the solvation energies of *(1)* and of acetone in dibutyl phthalate. For the lower exothermicity found, we have as yet no satisfactory explanation, and it is under further investigation.

Combustion in a Berthelot bomb: 60 mg samples of *(1)* were burnt in an adiabatic combustion calorimeter[6b] under 15 atm of O_2. The extremely violent reaction gave $\Delta U_{combstn.} = -920 \pm 10$ kcal/mol, which corresponds to $\Delta H_{combstn.} = -922$ kcal/mol. After taking into account the heat of combustion of acetone ($\Delta H = -426.7$ kcal/mol) we reach the value $\Delta H_{III} = -68 \pm 10$ kcal/mol.

Thus about 70 kcal/mol are liberated on cleavage of *(1)* in the solid state into two molecules of acetone, and 61 kcal/mol in solution. Adding the activation energy of decomposition in solution $E_A = 25$ kcal/mol[4], we find

$E_A + H_R = 86$ kcal/mol

at our disposal, which is just enough to produce either singlet ($E^S_{acetone} = 84$ kcal/mol) or triplet acetone ($E^T_{acetone} = 78$ kcal/mol). This accords with recent results that after taking up enough activation energy to yield an "activated complex", *(1)* needs no further addition of energy to form singlet or triplet acetone[9]. Our results now to hand indicate, however, that it may be possible to obtain considerably more luminescent singlet acetone on decomposition of *(1)* in the vapor phase than is possible in solution.

Direct Observation of the Dissociation Equilibrium of Tropylium Salts[**]

By *Horst Kessler* and *Axel Walter*[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Mechanistic studies of the S_N1 reaction have shown that dissociation to "free" carbenium ions occurs by way of an intimate ion pair and a solvent-separated ion pair, and that a steady state concentration of cations is established[1]. The definition of intermediates makes sense only if such species are separated by an energy barrier[2]. Ions (ion pairs) and nonionic molecules should be observable alongside each other by NMR spectroscopy if the time scale of the detection method[3] permits their detection and if their free energies are comparable. Hitherto, to the best of our knowledge, dissociable compounds have been observed either in nonionic or in dissociated form, but not side by side.

We have found a tropylium salt that exists in solution in dissociated and undissociated forms together, these forms being separated by relatively high energy barriers. The NMR spectrum of cycloheptatrienyl isothiocyanate *(1)*[4] in $CDCl_3$ or ether at -40 °C is the usual one for 7-substituted cycloheptatrienes [$\delta = 6.8$ (t, 3-H, 4-H), 6.4 (m, 2-H, 5-H), 5.6 (dd, 1-H, 6-H), and 4.1 (t, 7-H, $J = 5$ Hz)], but when the temperature is raised to *ca.* $+20$ °C it is reversibly broadened and all the signals coalesce, indicating migration of the NCS group around the whole seven-membered ring[5]. In acetonitrile, *(1)* dissolves only as tropylium isothiocyanate (singlet at $\delta = 9.2$), but surprisingly both forms are observed together in $CD_3CN/CDCl_3$ (1:3) at -40 °C (Fig. 1).

[*] Prof. Dr. H. Kessler and Dipl.-Chem. A. Walter
Institut für Organische Chemie der Universität
6 Frankfurt (Main), Sandhofstrasse 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

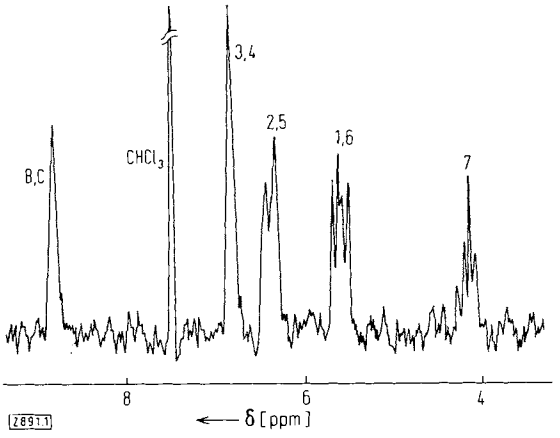

Fig. 1. ^{1}H-NMR spectrum of tropylium isothiocyanate in $CD_3CN/CDCl_3$ (1:3) at -40 °C; B, C: forms B and C of *(1)*; numerals are numbers of H atoms in A.

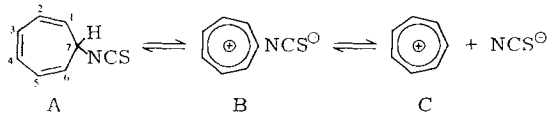

A B C

(1)

The equilibrium between the ionized form (B, C) and the nonionized form (A) was demonstrated by irradiation at the tropylium frequency at -15 °C, which led to saturation of the whole cycloheptatriene spectrum[7].

The intensity ratio of A:(B,C) can be modified by addition of tropylium tetrafluoroborate or by change in the composition of the solvent, but not by alteration of the concentration of the solute in the solvent mixture. The tropylium salt must therefore exist in this solvent mixture preponderantly as ion pairs B. With increasing amount of chloroform in the (originally pure) acetonitrile solvent, the position of the tropylium signal shifts to higher field and thus indicates increasing pairing of the ions. This also follows from the kinetics. Broadening of the tropylium signal in the solvent mixture is independent of the concentration (first-order reaction; $\Delta G^{\ddagger}_{243} = 12$ kcal/mol[8]). The barrier thus lies between the ion pair B and the cycloheptatriene A. A possible reason for its size may perhaps be seen in the aromatic tropylium system which has to be distorted on approach of the anion[10].

Tropylium halides cannot be dissolved in apolar solvents at concentrations detectable by NMR spectroscopy: in acetonitrile only the dissociated form can be detected. On the other hand, 7-cyanocycloheptatriene exists completely undissociated and there is no migration of the cyanide group. Nevertheless, equilibria between 7-substituted cycloheptatriene and their corresponding ions were observed, just as for the isothiocyanate, with the anions $N_3^{\ominus}$, $ONO^{\ominus}$, and $NCO^{\ominus}$[12]. Therefore those anions represent an intermediate position and permit a study of ion recombinations[13] that will contribute to our understanding of the S_N1 mechanism. The migration of these anions around the cycloheptatriene ring can therefore be explained by ionization. To what extent other mechanisms (*e. g.* [1,5]- or [3,3]-sigmatropic shifts) are involved remains to be investigated.

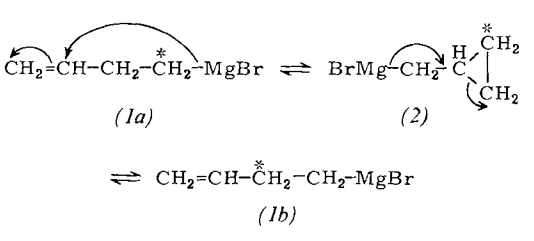
Influences of α- and β-Alkyl Groups on the Rearrangement of 3-Butenyl Grignard Reagents: A Stable Primary Cyclopropylmethyl Anion[**]

By *Adalbert Maercker, Paul Güthlein*, and *Hermann Wittmayr*[*]

Dedicated to Professor Gerhard Hesse on the occasion of his 65th birthday

By isotopic labeling experiments *Roberts et al.*[1] demonstrated that the α- and β-carbon atoms of 3-butenyl Grignard reagents gradually interchange positions: *(1a)*⇌*(1b)* (half-reaction time *ca.* 30 h at 27 °C). A cyclopropylmethyl Grignard reagent *(2)* is assumed as an intermediate but its presence in the equilibrium mixture could not be detected. If *(2)* is prepared at low temperatures by an independent route, it rearranges quantitatively to *(1)* already at −24 °C with a half-reaction time of 2 h[2]. The reason for this is the large ring strain in the cyclopropane (27 kcal/mol), which also explains why *(2)* cannot be detected in the equilibrium *(1a)*⇌*(2)*⇌*(1b)*: the energy difference between *(1)* and *(2)* was estimated to be 7 kcal/mol[2].



(1a) *(2)*

$\rightleftharpoons CH_2{=}CH{-}\overset{*}{C}H_2{-}CH_2{-}MgBr$

(1b)

The energy difference between *(2)* and *(1)* can in principle be reduced by stabilizing the three-membered ring of *(2)* or by destabilizing the 3-butenyl Grignard reagent *(1)*. The best chance of success lies in the combination of these two possibilities.

We hoped to stabilize the cyclopropane ring by introducing geminal alkyl groups (Thorpe-Ingold effect)[3-6].

A possible method of destabilizing the open-chain Grignard reagent *(1)* appeared to be the introduction of alkyl groups on the α-carbon atom, *i.e.* at the carbanionic center (cf. Ref. [7]).

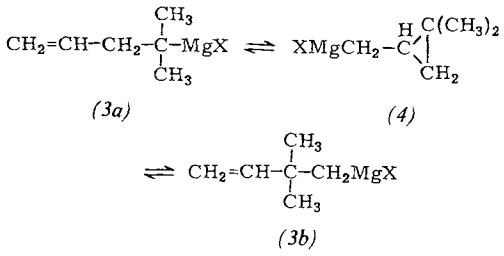
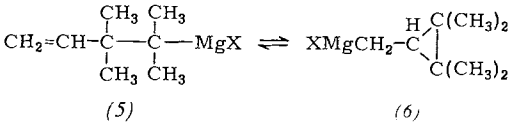
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



(3a) *(4)*

(3b)

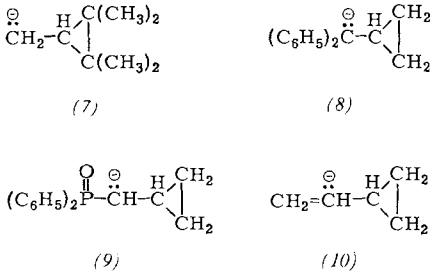
Investigation of the rearrangement *(3a)*⇌*(4)*⇌*(3b)* with X = Cl in tetrahydrofuran was only partly successful. Certainly the tertiary Grignard reagent *(3a)* rearranges quantitatively (half-reaction time *ca.* 30 h at 70 °C) and the cyclopropylmethyl compound *(4)* (*ca.* 0.07%) can be unambiguously detected but the equilibrium lies more than 99.9% on the side of the primary 3-butenyl Grignard reagent *(3b)* (determined by gas chromatography after esterification of the carboxylation products by diazomethane). Thence it follows that the two geminal methyl groups do in fact powerfully stabilize the three-membered ring, yet the Thorpe-Ingold effect alone does not suffice to shift the equilibrium in favor of the cyclopropylmethyl compound *(4)*.



(5) *(6)*

Complete success, however, followed introduction of four methyl groups. In the equilibrium mixture *(5)*⇌*(6)* (X = Cl) there is only *one* open-chain compound since the α- and the β-carbon atoms are equally substituted. This tertiary Grignard reagent *(5)* rearranges already at room temperature in tetrahydrofuran (concn. 0.04—0.4 mol/l) to give more than 99.9% of the cyclic compound *(6)* which, unlike *(4)*, cannot pass into a primary 3-butenyl Grignard reagent by ring opening.

In *(6)*, which is also accessible directly from *(6)* with Cl in place of ClMg, we have the first completely stable *primary* cyclopropylmethyl Grignard reagent [^{1}H-NMR: α-methylene doublet at $\tau = 10.9$ ($J = 7$ Hz)]. Except for the 2,2,3,3-tetramethylcyclopropylmethyl anion *(7)*, all the stable cyclopropylmethyl anions previously known were substituted at the carbanionic center, *e.g.* the benzhydryl *(8)*[8], the phosphane oxide *(9)*[9] and the vinyl anion *(10)*[10].



(7) *(8)*

(9) *(10)*

Kinetic measurements (NMR and gas chromatography) gave a half-reaction time of *ca.* 6 h for the equilibration *(5)*⇌*(6)* at 23 °C, so the rearrangement is appreciably faster than that of *(3a)*. Remarkable also is that preparation of *(5)* and *(6)* is possible only when X = Cl. Reaction

of the bromo compounds with magnesium in either diethyl ether or tetrahydrofuran gave no trace of the Grignard compound, but exclusively disproportionation products, and these—unlike the anion case—from the clearly more stable *open-chain* radical. The complete absence of cyclopropane derivatives from the products of radical reaction, even if cyclopropylmethyl bromide is used as starting material, is a further indication of the carbanionic nature of these Grignard rearrangements[11].

New Aspects of the Fries Rearrangement[1]

By *Franz Effenberger, Herbert Klenk,* and *Peter Ludwig Reiter*[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Even in the most recent literature, the Fries rearrangement of phenolic esters *(1)* not substituted in the arene nucleus (R = R' = H) is held to be an irreversible process yielding *o*- and/or *p*-hydroxyaryl ketones (acylphenols)[2]. *Rosenmund* and *Schnurr*[3] as well as *Miguel et al.*[4] have reported a reversal of the Fries rearrangement for 4-acyl-3-alkylphenols whereas *Cullinane* and *Edwards*[5] maintain that the Fries rearrangement is irreversible in this case too.

Formerly we had found that aromatic compounds can be acylated by acyl chlorides or carboxylic anhydrides under the influence of catalytic amounts of trifluoromethanesulfonic acid (TFMS)[6]. Since *C*-acylation of phenols is of great practical importance, we have investigated whether the Fries rearrangement which is usually carried out with molar amounts of $AlCl_3$ could also be achieved with TFMS-catalysis.

If solutions of phenyl benzoates *(1)* in anhydrous tetrachloroethane are heated with *ca.* 2 mol-% TFMS for 24 h at 170 °C in sealed tubes, the reaction mixture contains *o*-hydroxyaryl ketones *(2)*, phenols *(3)*, and decomposition products besides starting material (Table 1).

Reactions run on a preparative scale (*e.g.* 0.1 mol *(1a)*, 0.02 ml TFMS in 100 ml anhydrous tetrachloroethane) give

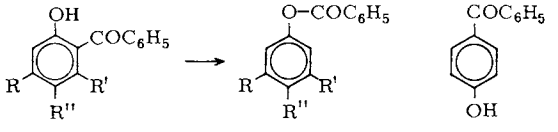
[a] Average yields from several parallel runs, determined by glc (Varian 1200).
[b] *p*-Hydroxyaryl ketones are formed in less than 2% yield, if at all.

yields identical within the error limit with those in Table 1. Phenolic esters of aliphatic carboxylic acids also undergo Fries rearrangement with TFMS.

Electron donors in position 3 of the phenolic ester favor the TFMS-catalyzed rearrangement as the results in Table 1 indicate: starting from *(1d)*, *(2d)* was obtained in 78% yield while *(1b)* remained unchanged under the reaction conditions. Surprisingly, *(1e)* did not rearrange even though the two methyl groups at C-3 and C-5 should enhance acylation of the arene nucleus. This finding can be rationalized in terms of reversibility of the Fries rearrangement.

In order to test this hypothesis, we have heated several *o*-hydroxyaryl ketones with TFMS under the conditions given above. These experiments (Table 2) clearly show the Fries rearrangement to be indeed reversible.



(2) *(1)* *(4)*

Table 2. Retro Fries rearrangement of *o*-hydroxyaryl ketones *(2)* with catalytic amounts of TFMS.

Starting material	R	R'	R''	Products [%] [a] *(2)*	*(1)*	decomp. products

(2e)	CH_3	CH_3	H	—	90	10
(2f)	H	H	CH_3	47	53	—
(4)				*(4)*, 23 *(2a)*, 9	*(1a)*, 40	28

[a] See note [a] in Table 1.

There is qualitative agreement between the isomer distribution for the Fries and the retro Fries rearrangement (Table 1 *vs.* Table 2); this is not sufficient, however, to establish a truly reversible equilibrium (which should be attained from either direction) so that further investigations are necessary.

The mechanisms proposed so far for the Fries rearrangement must now be critically reviewed since they do not take account of the reversibility of the reaction which has been established beyond doubt by the results reported here, especially since we have found the retro rearrangement also with typical Friedel-Crafts catalysts such as $FeCl_3$.

Our inference from the experimental data given is that for the acid-catalyzed Fries rearrangement product formation is subject to thermodynamic control in many cases. Since phenolic esters and hydroxyaryl ketones seem to have about the same energy they are present side by side in solution. Steric hindrance due to buttressing of two *o*-substituents as in *(2e)* shifts the isomer distribution in favor of the sterically unhindered ester (Table 2). We observe almost exclusive *o*-rearrangement which is another argument in favor of the thermodynamic control mechanism since the *o*-hydroxyaryl ketones are stabilized by intramolecular hydrogen bonding which is impossible in the *p*-isomers.

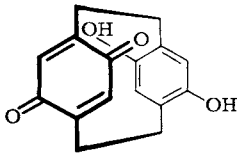
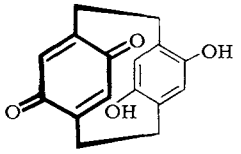
An "Intramolecular Quinhydrone"[1]

By *Walter Rebafka* and *Heinz A. Staab*[*]

In the context of our investigations of transannular interactions in [2.2]phanes[1,2] we became interested in compounds where high electron affinity in one part of the molecule and low ionization energy in the other favor intramolecular donor-acceptor interactions. Ideal conditions for this interaction should be provided by "intramolecular quinhydrones"[3] in the [2.2]paracyclophane series, for which pseudoortho- and pseudogeminal stereoisomers *(1a)* and *(1b)* can be foreseen. We report here the synthesis of *(1a)*[4].

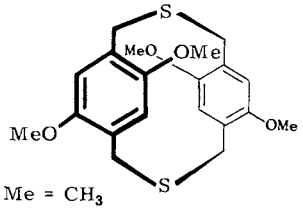


(1a)

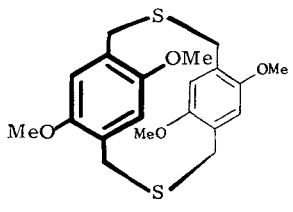


(1b)

1,4-Bis(bromomethyl)-2,5-dimethoxybenzene (0.1 M in tetrahydrofuran) and 1,4-bis(mercaptomethyl)-2,5-dimethoxybenzene (0.1 M in dimethylformamide) were cyclized by being dropped simultaneously into a suspension of anhydrous potassium carbonate (excess) in boiling tetrahydrofuran/dimethylformamide (1:1) (for apparatus see Ref. [5]), thus yielding 5,8,14,17-tetramethoxy-2,11-dithia[3.3]paracyclophane *(2a/2b)* in 20—23% yield. Chromatographic separation from chloroform on silica gel yielded the two stereoisomers of m.p. 211—213 °C and 243—246 °C[6] in the ratio *ca.* 2:1; assignment of the two compounds to the chiral *(2a)* and the achiral *(2b)* forms has not yet been unambiguously effected.

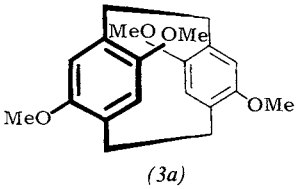


(2a)

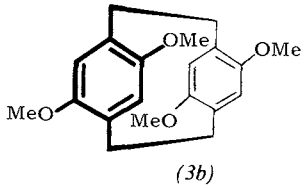


(2b)

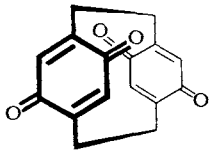
Ring contraction to give 4,7,12,15-tetramethoxy[2.2]paracyclophane *(3a)* or *(3b)* has been achieved in three ways: first, by gas-phase pyrolysis (440 °C/10^{-3} torr, 30—45% yield) of the disulfones obtained (H_2O_2, chloroform/glacial acetic acid, ≈70% yield) from *(2a)* and *(2b)* or the *(2a)/(2b)* mixture; secondly, by photolysis of the disulfones (suspension in benzene, Hg high-pressure lamp, 75 min, 50% yield); and thirdly, by direct photolytic desulfuration of *(2a)/(2b)* in triethyl phosphite in a modification of a procedure due to *Bruhin* and *Jenny*[7]. Independently of whether the starting material was *(2a)*, *(2b)* or the *(2a)/(2b)* mixture, by each of these ring contraction reactions only *one* product was obtained [m.p. 121—122 °C; ^{1}H-NMR ($CDCl_3$): τ = 3.91 (s, 4 arom. H), 6.34 (s, 12 methoxy-H), 7.6—6.6 (AA'BB', 8 methylene-H)][6]. The decision between *(3a)* and *(3b)* was established in favor of the chiral *(3a)* since partial separation of the enantiomers was effected by chromatography on (−)-2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid ["(−)-TAPA"; 10%]/silica gel from cyclohexane/methylene chloride (3:1): the maximum rotations were $[\alpha]_{365}^{28°} = +17.8°$ (1.03 g/100 ml; $CHCl_3$) and −18.0° (0.4 g/100 ml; $CHCl_3$); (−)-*(3a)* formed the more stable complex with (−)-TAPA. The subsequent products from *(3a)* very probably also have the pseudoortho conformation.



(3a)



(3b)



(4)

Demethylation of *(3a)* could only be achieved by heating with methylmagnesium iodide (15 min, 170—185 °C, under N_2)[8]. Without being purified, the resulting rather unstable tetrahydroxy[2.2]paracyclophane was oxidized by sodium periodate in tetrahydrofuran (20 °C, 40—60 min) to the bis-quinone *(4)* [yield *(3a)*→*(4)* ≈50%] which formed yellow crystals decomposing above 200 °C. ^{1}H-NMR

[*] Dipl.-Chem. W. Rebafka and Prof. Dr. H. A. Staab
Institut für Organische Chemie der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

($CDCl_3$): $\tau = 7.8$—6.5 (m, 8 methylene-H), 3.70 (d, 4 arom. H; $J \approx 0.9$ Hz); MS: M^+ 268 (base peak); the fragmentation corresponds essentially to that of simple *p*-benzoquinones (no fragmentation into halves as for true [2.2]paracyclophanes); IR (KBr): 1660 cm^{-1} s.

Catalytic hydrogenation of *(4)* (Pd/C, dioxane, calculated amount of H_2) and subsequent chromatography (silica gel, from ether/chloroform) and recrystallization from benzene/ether gave the intramolecular quinhydrone *(1a)*[6] in 70% yield. Mass spectrum: M^+ found 270.0868, calc. 270.0891; ^{1}H-NMR ([D_6]-acetone): $\tau = 7.8$—6.5 (m, 8 methylene-H), 3.95 (s, 2H), 3.80 (s, 2H), 2.22 [s, 2H (OH, concentration-dependent, exchange with D_2O and CD_3OD)]; IR (KBr): $\nu OH = 3420\,cm^{-1}$, $\nu CO = 1645\,cm^{-1}$.

In contrast to the quinhydrones, which dissociate partially in solution, the dark violet crystals of *(1a)* form wine-red solutions in polar solvents. The absorption spectrum of *(1a)* in methanol has an extremely broad absorption band ($\lambda_{max} = 515$ nm, $\varepsilon = 170$), stretching on the long-wave side far above 600 nm.

In solution, *(1a)* is oxidized to *(4)* by atmospheric oxygen. We failed in attempts to detect rapid interchange of oxidation states between the two rings, involving hydrogen transfer, which would have been shown by coalescence of the ^{1}H-NMR signals at $\tau = 3.95$ and 3.80, at temperatures up to 200 °C (in hexamethylphosphorotriamide). When treated with aqueous 0.1 N sodium hydroxide, the solution of *(1a)* in methanol changes from wine-red through green to reddish-brown, and this change is reversed by addition of the corresponding amount of 0.1 N hydrochloric acid. Presumably the dianion, which may exist as a diamagnetic donor-acceptor complex or, through complete electron transfer, as a double semiquinone radical anion, is formed through the monoanion stage.

Detection of Free Cyclobutadiene on Oxidation of a Tricarbonyl(cyclobutadiene)iron Complex

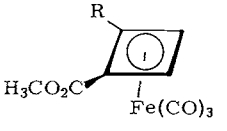
By *E. K. G. Schmidt*[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Recent work has shown that unsubstituted cyclobutadiene has a finite lifetime only under extreme conditions, *e.g.* in a noble-gas matrix at 8 °K[1]. However, this molecule has been postulated as intermediate in a series of reactions[2a], and it has been credited with an astonishing selectivity in cycloadditions even at room temperature[2b].

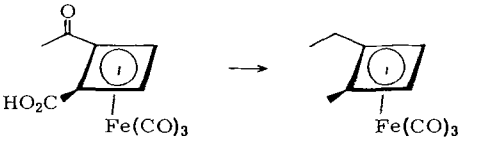
We have tested the possibilities that free cyclobutadiene is actually liberated on oxidative degradation of its tricarbonyliron complex[3] or alternatively that the molecule is still complexed during the observed additions to olefins. Earlier experiments had not led to conclusive results[4]. If the reaction of an optically active cyclobutadiene complex proceeds by way of free cyclobutadiene then racemic products are to be expected, but in other cases they should be optically active.

As a model compound we synthesized optically active tricarbonyl-(1-ethyl-2-methylcyclobutadiene)iron *(3)* as follows: Reaction of the half ester *(1a)*[5] with oxalyl chloride in pyridine led to *(1b)*, which with diazomethane afforded the diazo ketone *(1c)*. Treatment of *(1c)* with HI in acetic acid gave *(1d)* in overall yield of 72%[6].



(1a), R = CO_2H
(1b), R = COCl
(1c), R = $COCHN_2$
(1d), R = $COCH_3$

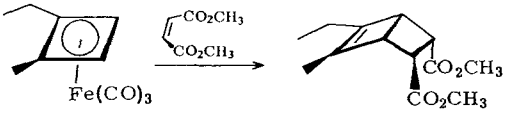
(1d) was hydrolyzed to the acid *(2)*, which was reduced by B_2H_6–BF_3 in THF to racemic *(3)* in 95% yield[7].



(2) *(3)*

Resolution of the acid by quinine afforded optically active (−)-*(2)*, $[\alpha]_{578}^{24} = -102°$ (in ethanol). Esterification with diazomethane gave (−)-*(1d)*, $[\alpha]_{578}^{24} = -280°$ (in benzene), whose optical purity (>99%) was determined by ^{1}H-NMR spectroscopy with the aid of a chiral europium complex[8]. Reduction of (−)-*(2)* gave (−)-*(3)*, $[\alpha]_{578}^{24} = -20.5°$ (in CCl_4), which should be of equal optical purity[9].

On oxidation of (−)-*(3)* in methanol at 0 °C by cerium(IV) ammonium nitrate in the presence of dimethyl maleate (37-fold excess) the diester *(4)* was obtained as sole adduct (40%)[10]. A 40% solution of the adduct in benzene, in a 10 cm cuvette, showed zero rotation (within the error of the polarimeter, ±0.003°) at 578 and at 435 nm. The presumption therefrom that *(4)* is obtained in its racemic form can be convincingly confirmed as follows: in the ^{1}H-NMR spectrum addition of the above shift reagent[8] causes splitting of the enantiotopic signals (ester-methyl, allylic methyl, and ethyl group) in the ratio 1:1 (accuracy of measurement 7%).

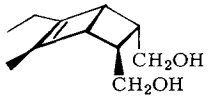


(-)-*(3)* *(4)*

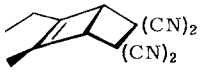
On oxidative degradation of (−)-*(3)* in the presence of the more reactive dienophile maleic anhydride (two-fold

[*] Dr. E. K. G. Schmidt
Abteilung für Chemie der Universität
463 Bochum, Postfach 2148 (Germany)

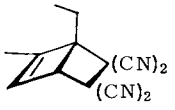
amount), again only one adduct was formed; this was reduced to the diol *(5)* by $LiAlH_4$ [40% yield referred to *(−)-(3)*[10]]. By the criteria used for *(4)*, this alcohol was also racemic. Even with the very reactive dienophile tetracyanoethylene we obtained the optically inactive adducts *(6)*, *(7)*, and *(8)* [50% based on *(−)-(3)*], of which the bicyclohexene *(6)* with two alkyl groups on the double bond is the favored product[11]. The regiospecificity observed with the less reactive dienophiles is thus lost in this Diels-Alder reaction[12].



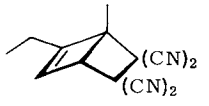
(5)



(6)



(7)



(8)

The formation of racemic adducts from the optically pure tricarbonyliron complex proves the occurrence of free cyclobutadiene. During addition of the dienophile, possible residual bonds from the cyclobutadiene to the iron or to the solvent are clearly too weak to maintain the original chiral surroundings of the complex.

[6] The new compounds were characterized by elemental analysis and ^{1}H-NMR, UV, and IR spectroscopy.

[7] Yellow liquid, b.p. 86 °C/7 torr. IR (CCl_4): 2970 w, 2039 vs, 1966 vs, 617 s, 590 s cm^{-1}. ^{1}H-NMR (C_6D_6): ring protons $\delta = 3.62$ ppm (s, 1H), 3.58 (s, 1H); methyl group 1.48 (s, 3H); ethyl group 1.82 (q, 2H), 0.87 (t, 3H, $J \approx 7.3$ Hz). Typical for tricarbonyl(cyclobutadiene) complexes is the absence of coupling between the ring protons and the diastereotopic splitting of the signals of the ethyl group [cf. *H. A. Brune, H. P. Wolff,* and *H. Hüther,* Tetrahedron *27,* 3949 (1971)]. The mass spectrum shows the molecular ion ($m/e = 234$), as well as the successive loss of three CO groups.

[8] Tris-[3-(heptafluoro-1-oxidobutylidene)-(+)camphorato]europium(III); Willow Brook Laboratories, Inc.; review: *H. L. Goering, J. N. Eikenberry,* and *G. S. Koermer,* J. Amer. Chem. Soc. *93,* 5913 (1971).

[9] *(−)-(3)* is thermally very stable; a sample was recovered unchanged after being heated in benzene for 50 h at 200 °C.

[10] Experiments with Eu shift reagents indicate the *endo*-configuration, but the validity of this assignment is of no importance for our work above.

[11] *(6)* and *(7)* were isolated in a state of purity, but *(8)* only in admixture with *(7)*.

[12] With less active dienophiles 1,2-diphenylcyclobutadiene also gave only one adduct, but with TCNE it gave two adducts: *P. Reeves, T. Devon,* and *R. Pettit,* J. Amer. Chem. Soc. *91,* 5890 (1969).

CONFERENCE REPORTS

Constitution of Nonstoichiometric Compounds and Solid Solutions

By *J. S. Anderson*[*]

Work of recent years has shown that the structure of nonstoichiometric solids cannot be explained only in terms of point defect vacancies or interstitials: the host structure is modified around a defect and a point defect is replaced by a defect complex. Alternatively, the modification may completely eliminate a sheet of lattice sites, by crystallographic shear.

Neutron diffraction has proved particularly suited to the determination of defect structure. Work on anion-excess fluorite type solid solutions has shown that these contain defect complexes of the same type as were proposed by *Willis* for U_4O_9, and that these can aggregate and extend to larger clusters. In ferrous oxide, neutron scattering from material at high temperatures, in an equilibrium gas buffer atmosphere, has shown that the ratio (cation vacancies)/(tetrahedral cations) agrees with the Koch-Cohen defect complex, with four tetrahedral cations surrounded by thirteen vacant octahedral sites. The same complex is found for all compositions, and over a wide temperature range. These complexes can again cluster to form incipient short range ordering.

In other structures (the rutile and ReO_3 structures and their derivatives), the anion/cation ratio is changed by eliminating a sheet of anion sites along crystallographic shear planes. Regularly recurrent shear planes generate families of homologous compounds; isolated shear planes eliminate large numbers of point defects—oxygen vacancies or interstitial cations—and are already present when the oxygen deficit is extremely small. In reduced rutile of composition $TiO_{1.9986}$ they are already beginning to aggregate into domains of the intermediate phases, and the residual point defect concentration in the rutile structure is less than 10^{-4}. The orientation of the shear planes in the most reduced intermediate phases is different from that in the less reduced phases, or that of isolated extended defects. There is some mechanism for pivoting around

South Parks Road, Oxford (England)

and, in the Ti—O system, this occurs between $Ti_{10}O_{19}$ and $Ti_{16}O_{31}$, which is the only range of composition in which redox reactions proceed with no hysteresis. In Cr_2O_3—TiO_2, the shear planes pivot gradually from the (121) to the (132) orientation over a wide composition range. In this rotation of shear planes, a crystal can change in composition continuously, without changing the number of shear planes present, but changing their orientation whilst maintaining a nearly constant spacing between them. A phase of this kind has a truly variable composition, whilst remaining fully ordered at every stage. The experimental evidence is that it is energetically advantageous for shear planes to retain their planarity, and bent or curved shear planes have been observed electron microscopically for only a few systems in which true inner equilibrium is attained with difficulty.

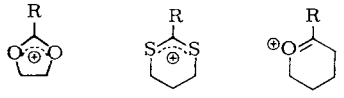
BOOK REVIEWS

Reviews

Abstracts of selected progress reports and review articles

1,3-Dioxolan-2-ylium and related heterocyclic cations are discussed by *C. U. Pittman jr., S. P. McManus,* and *J. W. Larsen.* The authors consider, *inter alia,* 1,3-dioxolan-2-ylium *(1)*, 1,3-dioxan-2-ylium, 1,3-oxathiolan-2-ylium, 1,2-



(1) *(2)* *(3)*

dithiolan-2-ylium, 1,3-dithian-2-ylium *(2)*, 1,3-oxathian-2-ylium, and related cations containing nitrogen, as well as cations of type *(3)*. A survey of recent syntheses is followed by a discussion of the mechanism of the reaction of such cations with bases or nucleophiles. Heterocyclic cations are intermediates in numerous reactions. The ions serve primarily as alkylating agents. [1,3-Dioxolan-2-ylium and Related Heterocyclic Cations. Chem. Rev. *72*, 357—438 (1972); 446 references]

[Rd 619 IE—M]

New free-radical applications in preparative organic chemistry (excluding homolytic arylation of aromatic compounds) are surveyed by *F. Minisci.* The main emphasis is placed on processes whose reactivity and selectivity are controlled primarily by the polar properties of the participating radicals and substrates. Examples: homolytic amination of aromatic compounds, selective alkylation of protonated heteroaromatic bases, Ag-catalyzed oxidative decarboxylation of acids by peroxodisulfate ions, and direct halogenation of alkanes. [Novel Applications of Free-Radical Reactions in Preparative Organic Chemistry. Synthesis *1973*, 1—24; 67 references]

[Rd 620 IE—M]

Topical aspects of electron correlation are reviewed by *P. v. Herigonte.* In nearly all quantum chemical calculations the "independent-particle" model is used for the sake of simplicity. Energies calculated with this model will differ from true energies because interactions between individual particles (correlation) are not accounted for; these differences are termed "correlation energy". In the present review three questions are discussed: 1) To what extent is correlation energy dependent on changes in the geometry of the system? 2) Are there experimental properties which depend directly on electron correlation? 3) Is it really necessary to start with the independent-particle model to get accurate wave functions? There is some evidence that in closed-shell systems correlation energy generally remains invariant during changes in geometry. All that can be said about questions 2) and 3) is that practically nothing is known about the physical meaning of the "independent particle" and hence of correlation. [Electron Correlation in the Seventies. Struct. Bonding *12*, 1—47 (1972); 103 references]

[Rd 633 IE—H]

The properties of the metal-phosphorus bond in coordination compounds are analyzed by *J. G. Verkade* in a detailed discussion of the spectroscopic characteristics of trivalent phosphorus compounds and of their metal complexes. There is also an account of two classes of compounds representing, to a certain extent, phosphorus complexes of coordination number unity: phosphoryl compounds (oxygen atom as acceptor) and adducts with boron compounds. The principal object of this review is to provide the concept of "π back-bonding" with a more quantitative basis. [Spectroscopic Studies of Metal-Phosphorus Bonding in Coordination Complexes. Coord. Chem. Rev. *9*, 1—106 (1972); 308 references]

[Rd 634 IE—H]

The production of refractory transition metal compounds is the topic of a review by *V. N. Gurin.* The significance of the refractory borides, carbides, nitrides, oxides, and silicides of the transition metals is increasing steadily in modern technology. Their production often runs into considerable difficulties, however, because the desired properties are frequently exhibited only by single crystals. The author provides a critical account of, *e.g.*, direct syntheses from the elements, electrolytic processes, metallothermal reductions of metal oxides, and gas phase

processes. [Methods for the Preparation of Refractory Compounds of Transition Metals and Prospects for Their Development. Russ. Chem. Rev. *41*, 323—340 (1972); 377 references]

[Rd 624 IE—Q]

Synthesis, absolute configuration, and optical purity of chiral allenes are considered by *R. Rossi* and *P. Diversi*. The naturally occurring, optically active, chiral allenes include those having the diyne-allene grouping and carotenoids. The asymmetric synthesis of chiral allenes and their resolution by diastereomer formation, as well as the synthesis from a chiral precursor, are illustrated with the aid of several examples. The determination of absolute configuration is also discussed. Determination of the optical purity of chiral allenes is still in its infancy. [Synthesis, Absolute Configuration, and Optical Purity of Chiral Allenes. Synthesis *1973*, 25—36; 83 references]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

A process for the production of transparent rubber-based graft polymers having good impact properties comprises two steps. In the first step, styrene and methyl methacrylate are emulsion-grafted on a rubber latex (especially polybutadiene) in the presence of a free-radical polymerization catalyst to form an intermediate product. In the second step, the grafting reaction is carried further by the addition of more catalyst and monomers in suspension, the emulsion obtained in the first step being converted into a suspension by addition of water and any suspending agent. The graft polymer is obtained in the form of free-running beads, which can be filtered off. [DOS 2155634; Dart Industries Inc., Los Angeles]

[PR 65 IE—Ö]

The preparation of polyethers in the form of fine grains from 1,2-alkylene oxides is achieved in the presence of 0.05 to 10 wt.% of a catalyst based on an alkaline earth metal compound. The catalyst is prepared by reaction, in liquid ammonia, of a) 1 mol of alkaline earth metal hexammine and/or alkaline earth metal amide with b) 0.1 to 1 mole of a 1,2-alkylene oxide and/or a polyepoxide containing 1—5 epoxy groups and c) 0.1—2 mole of a substituted hydrazine *(1)*.

$H_2N\text{-}NR^1R^2$ *(1)*

R^1, R^2 = H, alkyl (C_1 to C_7, possibly substituted with oxygen or nitrogen), cycloalkyl ($C_5 - C_8$), aralkyl ($C_7 - C_{10}$), mononuclear or dinuclear aryl, where R^1 and R^2 may form a heterocycle, possibly together with further atoms.

1,2-Alkylene oxides suitable both for the polymerization and for the preparation of the catalyst include ethylene oxide, propylene oxide, butadienemonoepoxide or butadienediepoxide, ethylene glycol diglycidyl ether, *N,N*-bis-(2,3-epoxypropyl)aniline, and dicyclopentadienediepoxide. The preferred hydrazine compounds are *N*-methylhydrazine and *N,N*-dimethylhydrazine. The properties of the polyethers obtained are good despite the presence of residual catalyst. They are effective flocculating agents and aids for textile treatment and finishing. [DOS 2054664; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

[PR 62 IE—Ö]

Modified polyacrylonitrile with basic groups, which exhibits outstanding thermal stability, is prepared by suspension-precipitation copolymerization of acrylonitrile with conventional comonomers in the presence of 0.5 to 5 wt.% (based on the total quantity of monomers) of an amine oxide *(1)* or its salts. Fibers produced from this material have a

chloropiperazinyldibenzoxazepines by nitration, reduction, and diazotization. [DOS 2153349; American Cyanamid Co., Wayne, N.J.]

[PR 95 IE—N]

Solvent Extraction Reviews. Vol. 1. Edited by *Y. Marcus*. Marcel Dekker, Inc. New York 1971. 1st ed., ix, 256 pp., numerous tables, bound $ 19.50.

The purpose of this review journal is to collect publications on solvent extraction methods which are widely scattered through numerous journals. The reviews, providing relevant information in a more readily accessible way, were to be published at intervals of several months, and then to be annually collected in book form.

The first volume of the series has been published. It contains seven contributions, ranging from fundamental studies to industrial applications: *Z. Kolařik*: Interactions of Acidic Organophosphorus Extractants in the Organic Phase (81 refs.); *C. F. Coleman* and *J. W. Roddy*: Kinetics of Metal Extraction by Organophosphorus Acids (58 refs.); *R. Blumberg*: Industrial Extraction of Phosphoric Acid (41 refs.); *P. Guillaumont* and *C. Miranda*: Solvent Extraction of Protactinium (150 refs.); *W. W. Schultz*: Extraction of Polonium (58 refs.); *J. Y. Oldshue*: Mixing Equipment in Liquid-Liquid Extraction (227 refs.); *A. H. P. Skelland*: Mass Transfer Problems in Liquid Extraction (75 refs.).

The authors make extensive use of standardized abbreviations and definitions as recommended by the editor. This standardization facilitates the reading of solvent extraction papers from various sources. The selection and level of the contributions suggest that "Solvent Extraction Reviews" will be a valuable addition to the proceedings of the International Solvent Extraction Conferences. The reviewer recommends the new series for interested workers in the fields of analytical chemistry, process engineering, radiochemistry, and coordination chemistry.

Werner Müller [NB 140 IE]

Structural Molecular Biology of Phosphates. By *J. Matheja* and *E. T. Degens*. Gustav Fischer Verlag, Stuttgart 1971. 1st ed., xii, 180 pp., 71 figs., DM 88.—.

Research results from two fields of natural science that have hitherto been treated separately are excellently correlated in the present book. The inorganic chemistry of phosphates is treated together with biochemistry, with the result that a bridge that has long been missing has now been formed.

The authors deal first with the inorganic chemistry of phosphates, with particular reference to the theory of structure and coordination, and the results are then applied to biological molecules and molecular complexes in nucleic acids and membranes and to high-energy phosphates and the proton transfer. The chemical evolution of the biological phosphates is then discussed for membranes, phospholipids, and liquid crystals, and ideas on the participation of the phosphates in the primordial phosphate metabolism and in the development of life are presented.

The themes cannot be discussed in full for reasons of space. This is partly compensated for by comprehensive literature references, which make it easy for the interested reader to deepen his knowledge. The present book should not be regarded as a textbook or reference work, but is intended to serve the scientist as a "springboard for continuing research".

For this reason, the book is strongly recommended to everyone working in the field of biochemistry. The reader is confronted with details that he has scarcely encountered before, and he will adopt coordination chemistry as a new argument in his discussions.

W. Saenger [NB 143 IE]

Computer Handling of Chemical Structure Information. By *M. F. Lynch, J. M. Harrison, W. G. Town*, and *J. E. Ash*. Macdonald, London, 1972. 1st ed., xii, 148 pp., 56 figs., bound $ 6.75.

This is an extremely lucid description of a field that has become the center of rapid developments in recent years. Modern chemical documentation, which, according to the author, has changed from a labor-intensive to a capital-intensive activity, is no longer conceivable without computers. Electronic data processing is also being increasingly used as a direct tool of chemical research. The present book fills a need.

The main emphasis is laid on the topological representations (linkage matrices, linear notations) of organic structural formulas and their input, storage, and retrieval. The description is supplemented by typical examples of procedures in practical use and a look ahead at future developments.

Considerable space is devoted to the procedures developed in the Anglo-American countries, particularly those used by the Chemical Abstracts Service. The only methods from outside the English-speaking countries to be discussed are those of the IDC (Frankfurt).

The data compiled in 1968 for a course at the University of Sheffield has been expanded and updated to the position in 1970 (but not the description of the IDC method).

The book is not a manual, since it confines itself to the fundamentals of the methods discussed. However, this material is presented extremely concisely. Literature references are similarly restricted to a few fundamental publications. The authors have been outstandingly successful in presenting the specialist with an objective orientation aid, despite the wealth of publications on this topic. However, those who are less familiar with the field may be misled by the book into an erroneous appraisal of the methods described, since the authors have not only deliberately omitted other important aspects of mechanical documentation in chemistry but also they provide practically no information on the state of development and the limitations of the methods or on their relative importance in present-day practice.

Claus Suhr [NB 146 IE]

Advances in Biochemical Engineering. Vol. 1. Edited by *T. K. Ghose* and *A. Fiechter*. Springer-Verlag, Berlin–Heidelberg–New York, 1971. 1st ed., vii, 194 pp., 70 figs., 25 tables, bound DM 48.—.

The present book is the first volume of a planned series in which numerous authors will report on aspects of modern biotechnology, with emphasis mainly on the mathematical analysis of microbiological systems and vital processes.

The first volume deals with a number of fields that have been neglected until now, such as the dynamics of fermentation liquids, separation of microorganism cells from the culture medium, kinetics of the degradation of cellulose by cellulase, production and use of microbial enzymes, regulation mechanisms in the microorganism cell and their effect on the overproduction of metabolites and enzymes, and the microbial production of biomass from hydrogen and carbon dioxide and from liquid and solid hydrocarbons.

This newly started series, which is unique in its field at present, is extremely welcome as an ambitious and up-to-date reference work for biotechnologists. The chapters in the first volume are clearly arranged, and together with the carefully compiled list of references, they provide a complete survey both of the development of the subject in question and of its present state.

It is to be hoped that this series, which also provides the interested student with a good introduction to biotechnology, will be continued in a similar manner.

Peter Rapp [NB 147 IE]

The Kinetic Isotope Method and its Application. By *M. B. Neiman* and *D. Gál*. Elsevier Publishing Company, Amsterdam–London–New York 1971. 1st ed., xii, 309 pp., numerous figures and tables, bound $ 26.50.

The central theme of this book is the kinetic isotope method developed by *Neiman* for the investigation of chemical reactions, and later successfully used by *Gál*.

The theoretical principles are described in the first three chapters, and practical examples are discussed in detail in Chapters 4–10. Very many data from original publications are used for this purpose.

As early as Chapter 1, the reader is confronted with a very complicated example of the use of the kinetic isotope method. This example does not seem particularly suitable for demonstrating the use of the method, particularly since many assumptions are made. Chapters 2 and 3 present a very formal but nevertheless very consistent account of the method. From page 36 (Chapters 4 *et seq.*), particular examples are discussed in detail: reactions in open systems (Chapter 4), thermal decomposition reactions (Chapter 5), oxidation of hydrocarbons in the gas phase (Chapter 6), free-radical reactions (Chapter 7), oxidation reactions in the liquid phase (Chapter 8), heterogeneous catalysis (Chapter 9), applications in biochemistry (Chapter 10). The book will undoubtedly be a very useful acquisition for the specialist who is interested in the practical examples provided. It seems less suitable for scientists or students approaching this field for the first time.

K. H. Lieser [NB 149 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Advances in Catalysis, Vol. 23. Edited by *D. D. Eley, H. Pines*, and *P. B. Weisz*. Academic Press, New York—London 1973. x, 352 pp., bound $ 19.00.

Contents: Metal Catalyzed Skeletal Reactions of Hydrocarbons; Specificity in Catalytic Hydrogenolysis by Metals; The Chemisorption of Benzene; The Electronic Theory of Photocatalytic Reactions on Semiconductors; Cycloamyloses as Catalysts; Pi and Sigma Transition Metal Carbon Compounds as Catalysts for the Polymerization of Vinyl Monomers and Olefins.

Radiation Chemistry of Macromolecules, Vol. 2. By *M. Dole*. Academic Press, New York, London 1973. xvii, 406 pp., bound $ 25.00.

Contents: Radiation Chemistry of Substituted Vinyl Polymers; Radiation Chemistry of Some Miscellaneous Polymers; The Effect of Radiation on Oxidation, Mechanical Properties, and Physical State; Macromolecules of Biological Interest.

Synergetics. Cooperative Phenomena in Multi-Component Systems. Edited by *H. Haken*. B. G. Teubner, Stuttgart 1973. 279 pp., stitched DM 54.—.—Proceedings of the Symposium on Synergetics, April 30 to May 6, 1972, Schloss Elmau.

International Edition in English

α-Peroxyamines

By E. G. E. Hawkins[*]

α-Peroxyamines contain the group $>N-\underset{|}{\overset{|}{C}}-O-O-$, which may also be incorporated into a ring. Numerous compounds of this type are accessible, *inter alia*, from ketones, hydrogen peroxide, or alkyl hydroperoxides and ammonia, as well as by autoxidation or photo-oxidation of amines or imines. Apart from decomposition reactions, the chemistry of these compounds is characterized by interesting cyclizations to give lactams, imides, oxaziridines, tetroxanes, *etc.*

1. Introduction

Although isolated examples of α-peroxyamines have been described in the literature, either as definite compounds or as possible intermediates in oxidation reactions, over a number of years, a systematic study of these substances (including novel cyclic 1,2,4-dioxazolidines) has been pursued only recently.

Our work in this field originated from the discovery of the new compound 3,3';5,5-bis(pentamethylene)-1,2,4-dioxazolidine *(1)* during a study of the reaction of cyclohexanone, ammonia, and hydrogen peroxide, in the presence of tungstate catalysts, reported to give cyclohexanone oxime (for references see[4]), and its decomposition to caprolactam (with bases) and 11-cyanoundecanoic acid (on pyrolysis)—which on hydrogenation provided 12-aminododecanoic acid, the monomer of Nylon 12. Extension of this work to the related peroxyamines was a natural sequel.

BP Chemicals International Ltd.
Great Burgh
Yew Tree Bottom Road
Epsom, Surrey (England)

This review is intended to describe the preparation and reactions of α-peroxyamines where the peroxy group is α to nitrogen, but does not include α-peroxyhydrazines nor α-peroxyazo compounds, and omits references to oxygenation reactions where α-peroxyamines are probable intermediates but where their isolation has not been possible.

2. *N*-Unsubstituted α-Hydroperoxyamines [$R^1R^2C(OOH)NH_2$]

2.1. Formation

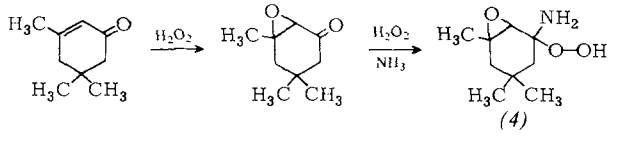
Early work with these compounds is sparse. *Schenck*[1] has stated, without detail, that they are formed by photooxidation of amines, but their isolation would have been difficult in view of the ease with which they undergo decomposition and further reaction under the experimental conditions. Small amounts of α-hydroperoxycyclohexylamine *(2)* were isolated during photo-oxidation of cyclohexylamine[2], but the major products were the amine-hydrogen peroxide adduct, and imines and amides, all of which are probably produced *via* the α-hydroperoxyamine.

The presence of *(2)* was detected, by thin-layer chromatography, in the products of ozonolysis of bis(cyclohexylidene) in the presence of ammonia[3], but was identified

only by means of the *N*-benzoyl derivative of its dehydration product, 2-pentamethyleneoxaziridine *(3)*.

(2) *(3)*

However, α-hydroperoxycyclohexylamine *(2)* may be prepared as a solid in high yield by direct reaction of cyclohexanone, hydrogen peroxide (molar ratio *ca.* 1:1), and ammonia[4]. It is unstable at room temperature, particularly when impure, and easily reverts to cyclohexanone, with loss of ammonia; storage for several weeks at −20 °C is possible. The corresponding α-hydroperoxyamines were similarly obtained, in varying yields, from other cyclic

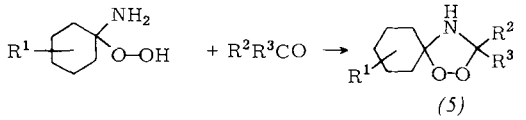


(4)

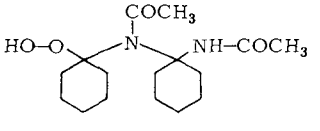
ketones (3- and 4-methylcyclohexanone, cycloheptanone, cyclododecanone, and dihydroisophorone)[5], but none was isolated from acyclic carbonyl compounds[6]. The β,γ-unsaturated ketone isophorone yielded the β,γ-epoxy-4-hydroperoxyamine *(4)* *via* the epoxide.

2.2. Reactions

The α-hydroperoxyamines reacted with carbonyl compounds to give moderate yields of 1,2,4-dioxazolidines—cyclic peroxyamines—*(5)*[4,5]. However, the products frequently also contained symmetrical cyclic peroxyamines through reaction of hydrogen peroxide and ammonia, produced by breakdown of the hydroperoxyamine, with the more reactive of the carbonyl compounds present.



(5)



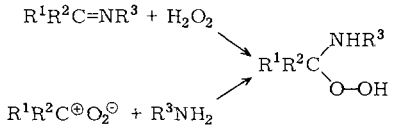
(6)

α-Hydroperoxycyclohexylamine *(2)* reacted with: (i) ferrous sulfate to yield cyclohexanone with some hexanamide and hexanoic acid; (ii) ferrous chloride to give cyclohexanone, ω-chlorohexanamide, and ω-chlorohexanoic acid; and (iii) sodium tungstate or tungstophosphoric acid to provide cyclohexanone oxime. Pyrolysis of *(2)* at 450 to 500 °C/150 torr gave products similar to those derived from 3,3;5,5-bis(pentamethylene)-1,2,4-dioxazolidine *(1)* (Section 8.1), whilst attempts at acetylation yielded a solid peroxide, thought to have the structure *(6)*, which decomposed to cyclohexanone and acetamide at higher temperatures.

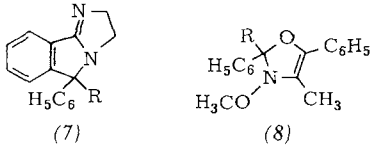
3. *N*-Monosubstituted α-Hydroperoxyamines [$R^1R^2C(OOH)NHR^3$]

3.1. Formation

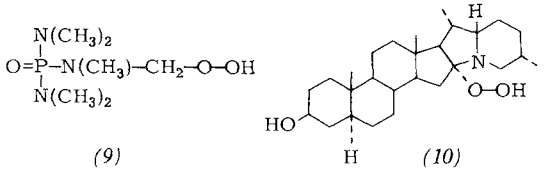
Compounds of this class have been obtained by reaction of imines with ethereal[7] or aqueous[8] hydrogen peroxide or by ozonolysis of olefins in the presence of a primary amine[3].



Hydroperoxides have been isolated from oxygenation products of certain cyclic amines, *e.g. (7)*, R = O—OH, from *(7)*, R = H[9], and *(8)*, R = O—OH from *(8)*, R = H[10], whilst photo-oxidation of hexamethylphosphoramide gave rise to the unstable *(9)*[11] which decomposed to give formaldehyde or formic acid.

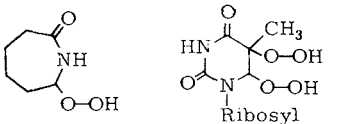


(7) *(8)*

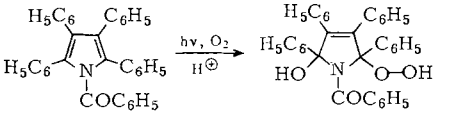


(9) *(10)*

Oxidation of 3β-hydroxysolanide-16(N)-eninium perchlorate with alkaline hydrogen peroxide provided the α-hydroperoxyamine *(10)*, which could be reconverted to the starting compound by dilute perchloric acid in methanol[12].

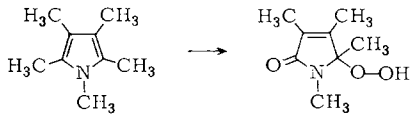


(11) *(14)*

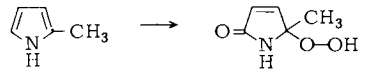


(12) *(13)*

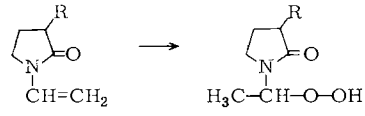
A number of α-hydroperoxyamides have been produced, either by autoxidation [*e.g. (11)* from caprolactam[13]], photooxidation [*e.g. (13)* from *(12)*[14]], irradiation [*e.g. (14)* from thymidine[15]], or reaction of hydrogen peroxide with enamines [*e.g. (16)* from *(15)*[16]; *(18)* from *(17)*[17]; *(20)* from *(19)*, R = H, CH_3[18]; and *(22)* from *(21)*, R = CH_3, $C_6H_5CH_2$[19]].



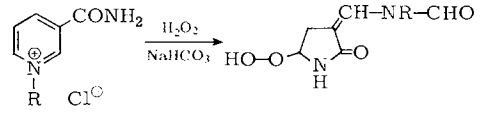
(15) (16)



(17) (18)

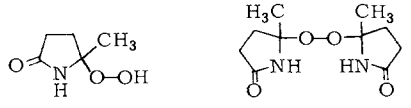


(19) (20)



(21) (22)

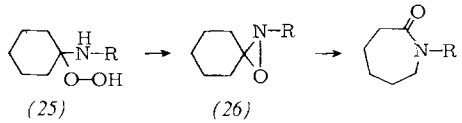
Reaction of hydrogen peroxide and ammonia with ethyl levulinate or levulinamide yielded both the hydroperoxylactam *(23)* and peroxydilactam *(24)*[6].



(23) (24)

3.2. Reactions

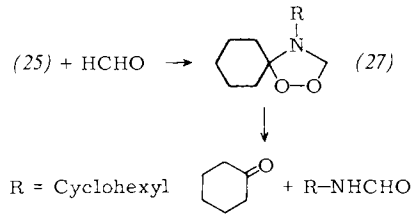
Many α-hydroperoxyamines, when heated in a solvent[7, 3] or treated with acids[8] (*e.g.* acetic acid/acetic anhydride), are converted into the corresponding oxaziridine; *N*-cyclohexyl-1-hydroperoxycyclohexylamine *(25)* is converted into *N*-cyclohexylcaprolactam (and *N*-cyclohexylidenecyclohexylamine) by lithium chloride in methanol, presumably *via* the oxaziridine *(26)*[8].



(25) (26)

R = Cyclohexyl

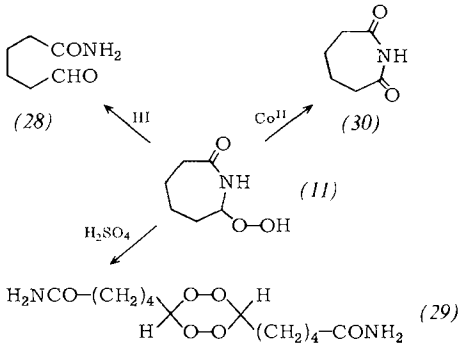
With alkali *(25)* gives the corresponding imine by loss of hydrogen peroxide, and with acidified ferrous sulfate it is partly converted into *N*-cyclohexylhexanamide and *N,N'*-dicyclohexyldodecanamide[8], products similar to those from treatment of the corresponding oxaziridine *(26)* with ferrous sulfate[20]. Reaction of *(25)* with formaldehyde gives the unstable 1,2,4-dioxazolidine *(27)*, which decomposes on storage at room temperature to form cyclohexanone and *N*-cyclohexylformamide[8].



(25) + HCHO → *(27)*

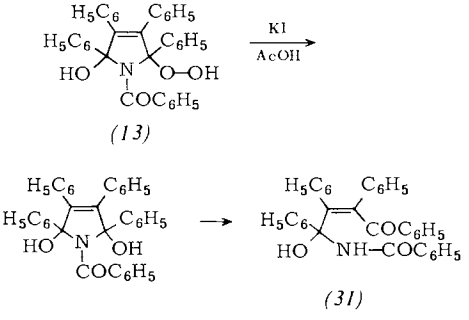
R = Cyclohexyl + R–NHCHO

The α-hydroperoxylactam *(11)* was reduced by hydriodic acid to the ω-formyl amide *(28)*[13], and converted into a 1,2,4,5-tetroxane *(29)* by 70—80% sulfuric acid[21] and into adipimide *(30)* by cobalt-catalyzed decomposition[13].



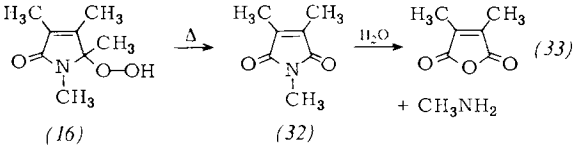
(28) *(30)* *(11)* *(29)*

Hydroperoxide *(13)* is reduced by potassium iodide/acetic acid to the corresponding diol which, in polar solvents, undergoes ring opening to yield *(31)*[14].



(13) *(31)*

Thermal decomposition of *(16)* led to the imide *(32)* by loss of methanol, and further treatment with water gave an anhydride *(33)* and methylamine[16].



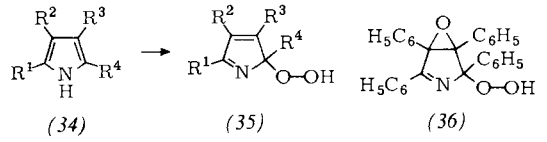
(16) *(32)* *(33)* + CH_3NH_2

4. *N*-Substituted α-Hydroperoxyimines [$R^1R^2C(OOH)N{=}R^3$]

4.1. Formation

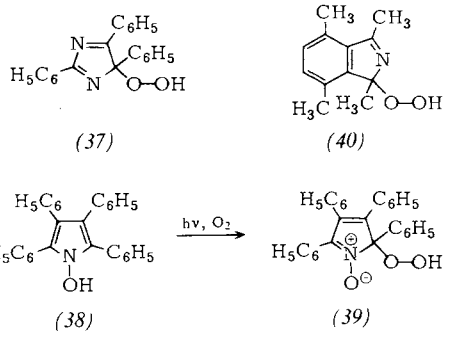
Photosensitized oxygenation of certain substituted pyrroles *(34)* [(*a*) $R^1{=}R^2{=}R^3{=}R^4{=}C_6H_5$[22]; (*b*) $R^1{=}R^4{=}$

C_6H_5, $R^2=R^3=H$; (*c*) $R^1=R^2=R^4=(CH_3)_3C$, $R^3=H$; (*d*) $R^1=R^4=(CH_3)_3C$, $R^2=R^3=H$[23]] has produced the corresponding 2-hydroperoxy-2*H*-pyrroles *(35)*; the tetraphenyl compound *(35a)*, together with the epoxyhydroperoxide *(36)* and a number of other products, was



(34) *(35)* *(36)*

also obtained by treatment of tetraphenylpyrrole *(34a)* with hydrogen peroxide[24]. Similar photo-oxidation of 2,4,5-triphenylimidazole (lophine)[25,26], or reaction of dilute hydrogen peroxide with the 2,4,5-triphenylimidazyl radical[25], gave rise to a related α-hydroperoxyimine *(37)*, and photo-oxidation of 1-hydroxytetraphenylpyrrole *(38)* provided an α-hydroperoxynitrone *(39)*[27]. Autoxi-

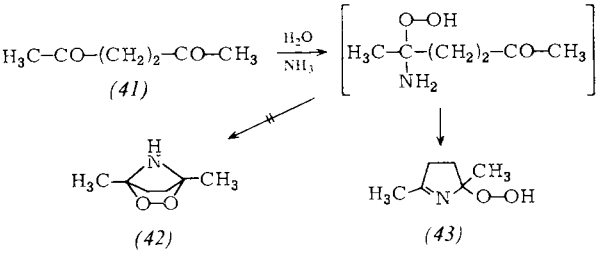


(37) *(40)*

(38) *(39)*

dation of 1,3,4,7-tetramethylisoindole in benzene/ether at room temperature led to the formation of the hydroperoxide *(40)*[28].

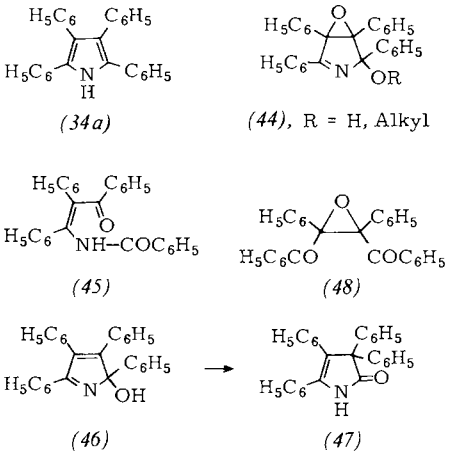
The anticipated formation of a bicyclic peroxyamine *(42)* from the reaction of 2,5-hexanedione *(41)* with hydrogen peroxide and ammonia did not occur; instead, the hydroperoxypyrroline *(43)* was obtained and intramolecular cyclization may have been prevented by steric hindrance[6].



(41) *(42)* *(43)*

4.2. Reactions

The reactions of 2-hydroperoxytetraphenyl-2*H*-pyrrole *(35a)* ($R^1=R^2=R^3=R^4=C_6H_5$) have been studied in depth[22,24,28]. Thermal decomposition of neat *(35a)* brings about formation of tetraphenylpyrrole *(34a)* and liberation of oxygen. A similar reaction occurs when heating is carried out in nonpolar solvents, but in polar solvents (*e.g.* alcohols) the major products are 5-hydroxy(or 5-alkoxy)-3,4-epoxytetraphenylpyrroline *(44)* and the amide *(45)*.



(34a) *(44)*, R = H, Alkyl

(45) *(48)*

(46) *(47)*

Strong acids convert *(35a)* into hydrogen peroxide and a salt of the corresponding hydroxy compound *(46)*, whereas strong bases afford the lactam *(47)*, which is also formed by rearrangement of *(46)* on heating. Treatment of *(35a)* with hydrogen peroxide in neutral solvents (dioxane or ethanol) yields largely the epoxide *(36)*, but in acetic acid ring-opening occurs with production of *(45)* and *(48)*.

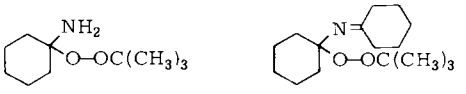
Similar products to *(48)*, on storage, and *(46)* and *(47)*, on reduction with potassium iodide/acetic acid, have been obtained from the 2-hydroperoxy-2,5-di-*tert*-butyl- and 2,4,5-tri-*tert*-butyl-2*H*-pyrroles *(35d)* and *(35c)* respectively[23].

The hydroperoxypyrroline *(43)* was converted into 2,5-dimethylpyrrole by sodium methoxide, 2,5-hexanedione by ferrous sulfate, and a mixture containing these two compounds on pyrolysis[6].

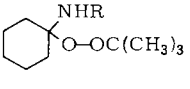
5. *N*-Unsubstituted α-Alkylperoxyamines [$R^1R^2C(OOR^3)NH_2$]

5.1. Formation

Treatment of cyclohexanone with ammonia and *tert*-butyl hydroperoxide gave an equilibrium mixture which contained 1-*tert*-butylperoxycyclohexylamine *(49)*; distillation of the product led to some decomposition, with loss of *tert*-butyl hydroperoxide. Spectroscopic examination of the higher-boiling reaction products suggested that the peroxyimine *(50)* was also formed by further reaction of *(49)* with cyclohexanone. The 1-*tert*-butylperoxycyclohexylamine *(49)* provided normal amine derivatives *(51)*



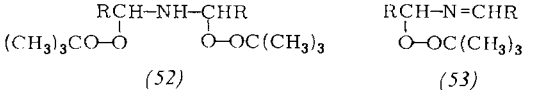
(49) *(50)*



(51), R = $CONHC_6H_5$, CH_3CO, C_6H_5CO, $CO_2C_2H_5$, Tosyl, Cl

with phenyl isocyanate, acetyl chloride, benzoyl chloride, ethyl chloroformate, *p*-toluenesulfonyl chloride, and *tert*-butyl hypochlorite[29].

Replacement of *tert*-butyl hydroperoxide by cumene hydroperoxide gave a crude product containing the peroxycyclohexylamine corresponding to *(49)*, but although this could not be distilled without decomposition its presence was proved by formation of a crystalline phenylurea derivative.

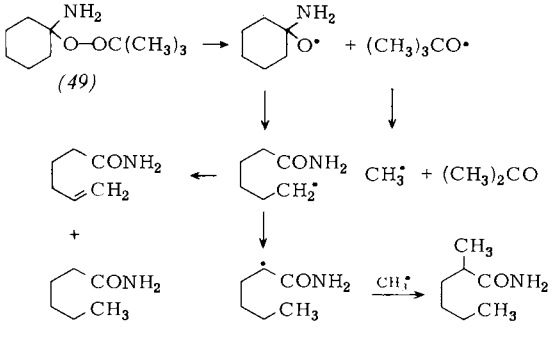


(52) *(53)*

No similar α-alkylperoxyamines could be isolated when starting with acyclic ketones (2-butanone and 3-pentanone), and acyclic aldehydes (acetaldehyde and *n*-butyraldehyde) gave products thought to be largely the diperoxyamines *(52)*, which on distillation tended to lose a molecule of *tert*-butyl hydroperoxide with formation of imines *(53)*[29].

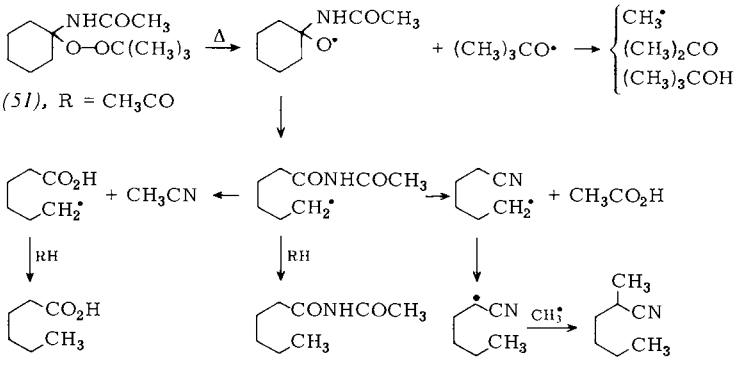
5.2. Reactions

Decomposition of *(49)* by sodium methoxide led to evolution of ammonia and formation of cyclohexanone, whereas pyrolysis at 450—550 °C gave cyclohexanone, acetone, unsaturated and saturated C_6 amides, a C_7 branched amide and traces of nitriles and acids. This thermal decomposition evidently involves both reconversion to cyclohexanone and *tert*-butyl hydroperoxide and homolytic scission of the O—O bond, followed by ring opening and methylation of 1,5-rearranged radicals:



(49)

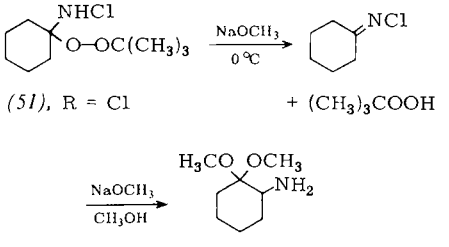
Pyrolysis of the *N*-acetyl derivative *(51)*, R = CH_3CO, led to a complex mixture of products including acetone, *tert*-butanol, cyclohexanone, acetic acid, hexanoic acid, acetamide, α-methylhexanenitrile (reported[29] incorrectly as α-methylpentanenitrile) and *N*-acetylhexanamide, as well as smaller amounts of lower molecular weight compounds. The main products are formed in free-radical reactions.



(51), R = CH_3CO

Reaction of the *N*-acetyl derivative with sodium methoxide proceeded *via* *N*-1-cyclohexenylacetamide to cyclohexanone and acetamide.

N-Chloro-*tert*-butylperoxycyclohexylamine *(51)*, R = Cl, also lost *tert*-butyl hydroperoxide on treatment with sodium methoxide to give *N*-chlorocyclohexylideneimine and thence, by a Neber reaction, 2,2-dimethoxycyclohexylamine.

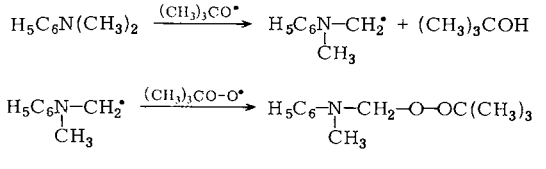


(51), R = Cl

6. *N*,*N*-Disubstituted α-Alkylperoxyamines [$R^1R^2C(OOR^3)NR^4R^5$]

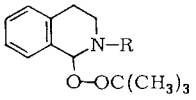
6.1. Formation

When *tert*-butyl hydroperoxide was heated with dimethylaniline in the presence of heavy metal ions *N*-*tert*-butylperoxymethyl-*N*-methylaniline was produced in high yield[30].



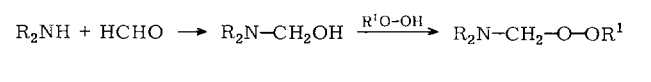
A number of 1-*tert*-butylperoxy-2-aryl-1,2,3,4-tetrahydroisoquinolines *(54)* have been similarly prepared by treat-

ment of the corresponding 2-aryltetrahydroisoquinoline with *tert*-butyl hydroperoxide and cuprous chloride in benzene[31].

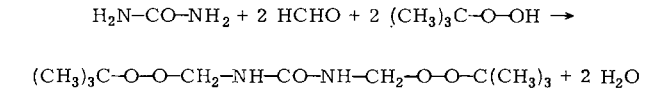


(54)

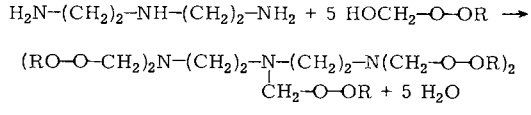
N,N-Disubstituted α-peroxyamines have also been synthesized in good yields by treatment of a secondary amine with formaldehyde and a hydroperoxide[32] or hydrogen peroxide[33].



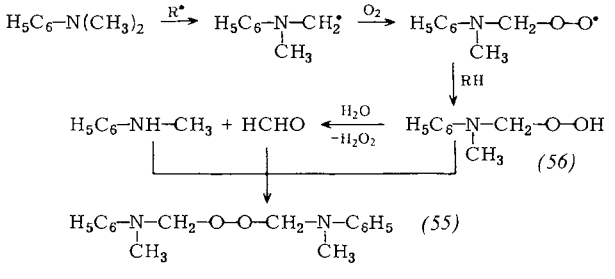
The mixture of amine and formaldehyde may be replaced by the preformed *N*-hydroxymethylamine, and the less reactive amides undergo a similar reaction in the presence of acids[32].



Similarly, α-hydroxymethyl peroxides and primary or secondary amines yield α-peroxyamines[34].

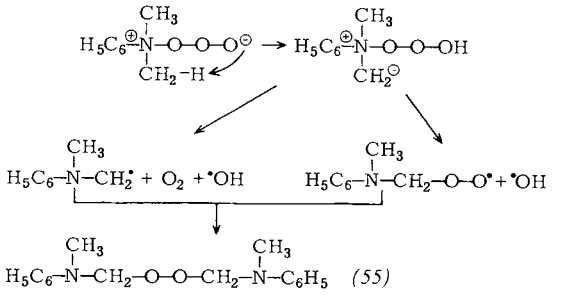


A number of symmetrical peroxyamines of type *(55)* were also produced by autoxidation of tertiary aromatic amines in the presence of an initiator[33,35], and it was suggested that the nonisolated α-hydroperoxyamines, *e.g. (56)*, were intermediates.

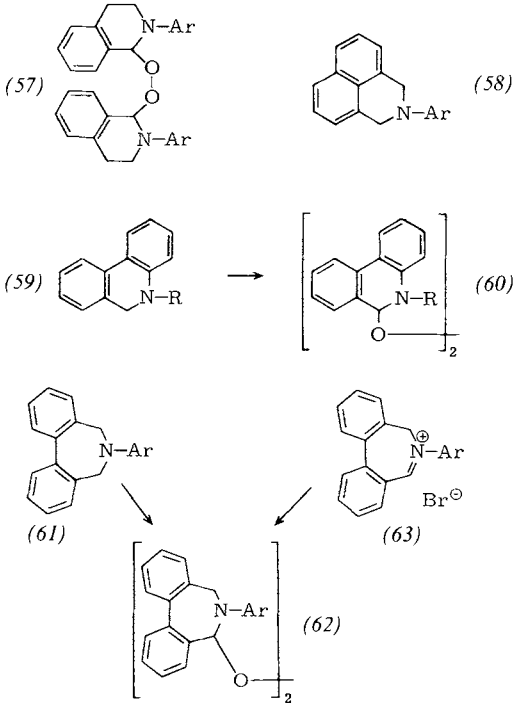


Similar symmetrical compounds have been obtained by ozonization of tertiary aromatic amines at low temperatures in nonpolar solvents, with a suggested mechanism involving initial attachment of the ozone to the nitrogen atom[36].

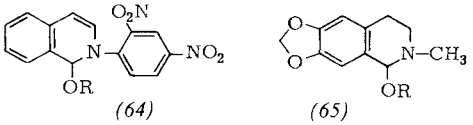
It was found that benzene solutions of *N*-aryl-substituted tetrahydroisoquinolines, on shaking with oxygen in UV light, were converted into the corresponding crystalline



bis(*N*-aryltetrahydro-1-isoquinolyl) peroxides *(57)*[37], whereas the *N*-alkyl- and 1,2-disubstituted compounds did not autoxidize[38]. Of the tricyclic amines examined, the *N*-substituted 2,3-dihydro-1*H*-benz[*d,e*]isoquinolines *(58)* did not react under similar conditions, whereas both *N*-substituted 5,6-dihydrophenanthridines *(59)*[38] and *N*-aryl-6,7-dihydro-5*H*-dibenz[*c,e*]azepines *(61)*[39] gave the symmetrical peroxides *(60)* and *(62)* respectively.

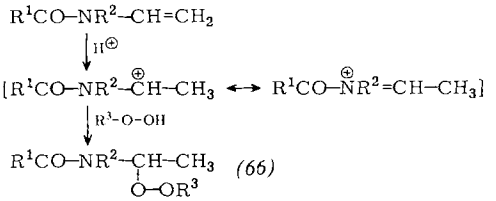


Higher yields of these symmetrical peroxyamines, *(57)* and *(62)*, were obtained by reaction of hydrogen peroxide with the corresponding dihydroisoquinolinium (or azepinium) bromide *(63)*. A similar type of reaction, with *N*-methyl-6,8-dinitroquinolinium chloride, had previously been used for obtaining crystalline derivatives from a number of primary, secondary, and tertiary hydroperoxides[40], whilst pseudo-bases [*e.g. (64)* and *(65)*, where R = H] may also be converted into peroxides [*(64)* and *(65)*, where R = OR^1] by treatment with hydroperoxides (R^1OOH)[40].

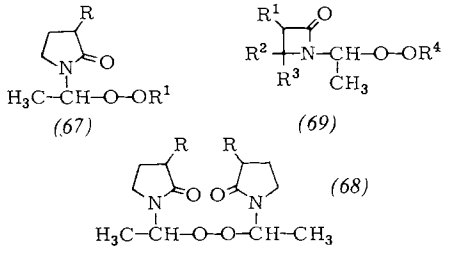


(64) (65)

A related synthesis of α-peroxy-*N*-acyl (or *N*-sulfonyl) amines, *e.g. (66)*, involves the reaction of *N*-acyl- (or *N*-sulfonyl-)*N*-vinylamines with tertiary alkyl hydroperoxides or hydrogen peroxide in the presence of acid catalysts (SO_2Cl_2 or $SOCl_2$) at low temperatures[18,41]; *N*-vinyllactams give the peroxides *(67)*, *(68)*, and *(69)*.

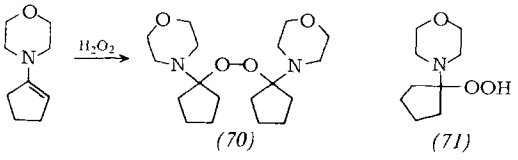


(66)



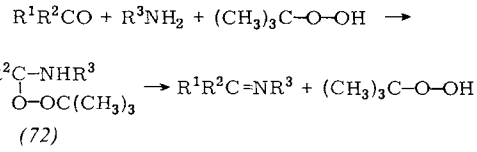
(67) *(69)* *(68)*

The enamines derived from cyclic ketones and cyclic secondary amines (morpholine or piperidine) react with ethereal hydrogen peroxide to give symmetrical α,α'-diamino peroxides[42], *e.g. (70)*, although use of more hydrogen peroxide gives rise to the intermediate α-hydroperoxyamine *(71)*[43].



(70) *(71)*

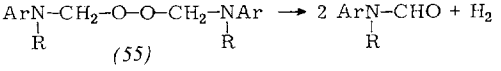
The reaction of cyclic ketones or acyclic aldehydes (but not acyclic ketones) with primary amines and *tert*-butyl hydroperoxide also yielded α-peroxyamines *(72)*; the lower-molecular-weight products were stable to distillation but the higher-boiling homologs decomposed into the corresponding imines[8].



(72)

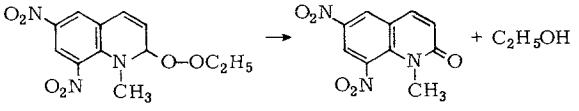
6.2. Reactions

The symmetrical peroxides of type *(55)* were easily converted back into secondary amine, formaldehyde, and hydrogen peroxide by acids[33], but, surprisingly for diprimary peroxides, are reported to be stable to alkali. They may be hydrogenated to the corresponding dialkylanilines, and on thermal decomposition in toluene yield an *N*-alkylformanilide and hydrogen (comparable with the production of formic acid and hydrogen on heating bis(hydroxymethyl) peroxide[44]).

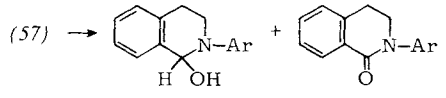


(55)

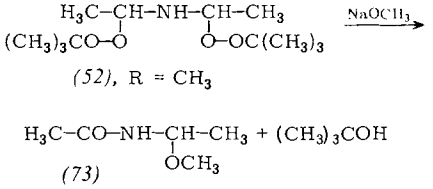
Base-catalyzed decomposition of the peroxides derived from primary or secondary hydroperoxides and *N*-methyl-6,8-dinitroquinolinium chloride (*e.g.* in pyridine) proceeds by the normal Kornblum-De La Mare mechanism[45] to give the corresponding quinolone[40]:



Peroxides *(57)* and *(60)*, when heated, disproportionated into pseudo-bases and lactams[37,38].



Pyrolysis of the α-*tert*-butylperoxyamines *(72)*, as well as their reaction with sodium methoxide, gave mainly the corresponding imine (by loss of *tert*-butyl hydroperoxide), although the thermal decomposition of *N*-ethyl-1-*tert*-butylperoxycyclohexylamine provided a product containing *N*-ethylamides indicative of homolytic fission of the peroxide bond[8].



(52), R = CH_3

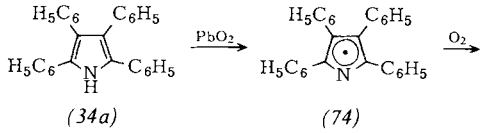
(73)

Reaction of the diperoxyamine *(52)*, R = CH_3, with sodium methoxide gave mainly the α-methoxyamide *(73)*, as well as acetamide; evidently, Kornblum-De La Mare reaction occurred at one of the peroxide systems whereas in the second simple replacement of the *tert*-butylperoxy group by methoxyl took place[29].

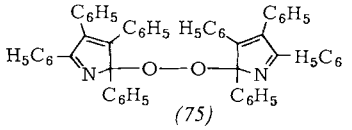
7. *N*-Substituted α-Alkylperoxyimines [$R^1R^2C(OOR^3)N{=}R^4$]

Autoxidation of the radical *(74)*, produced by reaction of 2,3,4,5-tetraphenylpyrrole *(34a)* with lead dioxide, led to the formation of the peroxide *(75)*, easily reduced to the hydroxypyrrole *(46)* by hydriodic acid[28].

The same peroxide *(75)* was obtained (in 20% yield) during electrochemical oxidation of tetraphenylpyrrole in the presence of sodium carbonate and air[46].

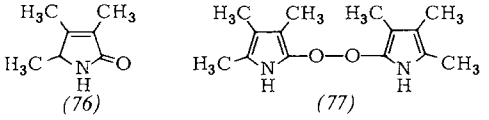


(34a) (74)

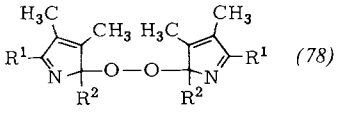


(75)

Oxidation of 2,3,4-trimethylpyrrole by hydrogen peroxide in pyridine gave mainly the lactam *(76)*, but a by-product peroxide (previously described[47]) was assigned the structure *(77)*[48]; however, it seems more likely that this peroxide was *(78)* with either $R^1=CH_3$, $R^2=H$ or $R^1=H$, $R^2=CH_3$.



(76) (77)



(78)

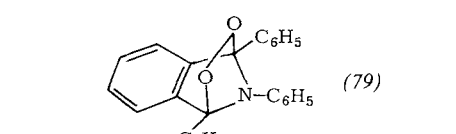
Reaction of the 2,4,5-triphenylimidazyl radical with a tertiary hydroperoxide (*tert*-butyl or cumyl) gave the corresponding 4-peroxyimidazole[25], and related chemiluminescent peroxides were obtained with phenyl replaced by other aryl groups[49].

8. 1,2,4-Dioxazolidines

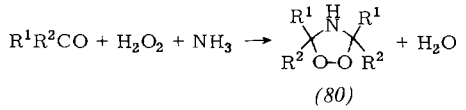
8.1. Formation

Earlier work on the production of these cyclic peroxyamines appears to have been limited to the photo-oxidation of 1,2,3-triphenylisoindole, leading to high yields of the compound *(79)*[50].

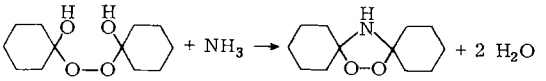
Recently it has been found that aldehydes and ketones (both acyclic and cyclic), when treated with ammonia and hydrogen peroxide, give rise to symmetrical cyclic peroxyamines (1,2,4-dioxazolidines) *(80)*[4-6]. The carbonyl compounds used included acetaldehyde, *n*-butyraldehyde, acetone, 2-butanone, cyclohexanone, cyclopentanone, cycloheptanone, 2-, 3-, and 4-methylcyclohexanone, isophorone, and dihydroisophorone, and the peroxyamines formed, sometimes solid, could all be distilled without decomposition under reduced pressure. In those cases where the intermediate α-hydroperoxyamine (Section 2.1) could be isolated, further reaction with the ketone gave the cyclic compounds *(80)*, also formed from the corresponding bis(1-hydroxyalkyl) peroxides and ammonia, *e.g.* *(1)* from *(81)*.



(79)

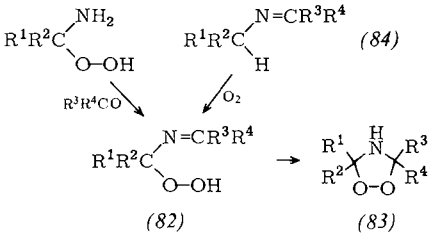


(80)



(81) (1)

Unsymmetrical 1,2,4-dioxazolidines *(83)* [see also *(5)*] could be obtained from α-hydroperoxyamines and a different carbonyl compound, although yields were often poor and the product contaminated with one or both of the symmetrical dioxazolidines. Presumably reaction proceeded *via* cyclization of the α-hydroperoxyimine, and the possibility of the formation of such intermediates by autoxidation (or photo-oxidation) of the corresponding imine *(84)* can be envisaged.



(84) (82) (83)

However, in general, attack of oxygen occurs at the methylene (or methine) group α to carbon of the C=N system[51]. Exceptions to this generalization are imines having the methylene (or methine) group α to nitrogen activated, *e.g.*, by aryl groups (cf. Section 4.1); thus, when R^1 = aryl and R^2 = alkyl or aryl, autoxidation (or photo-oxidation) at low temperatures (0 to −20 °C) led to the production of 1,2,4-dioxazolidines *(83)*, R^3, $R^4=-(CH_2)_5-$, in good yield[51]. Oxygenation of the imine *(84)*, $R^1=R^2=R^3=R^4=C_6H_5$, was extremely slow, and under forcing conditions the products obtained (benzophenone and benzanilide) were those expected from decomposition of the corresponding peroxyamine.

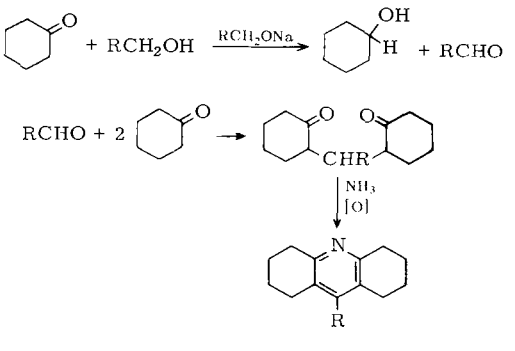
8.2. Reactions

The most detailed reaction study was carried out with 3,3;5,5-bis(pentamethylene)-1,2,4-dioxazolidine *(1)*, but the behavior of the other members of this class of compounds is very similar.

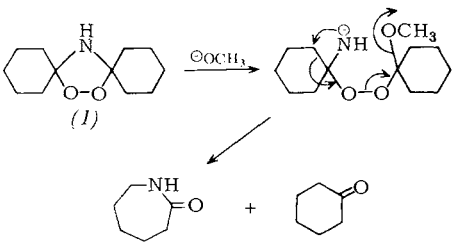
The amine group may be acetylated (by acetyl chloride) chlorinated (by *tert*-butyl hypochlorite), methylated (by methyl iodide/silver carbonate), or converted into a phenylurea (by phenyl isocyanate). Catalytic hydrogenation of *(1)* leads to cyclohexylamine or cyclohexanone, whereas treatment with aqueous acids or bases gives cyclohexanone.

With formic acid or acetic acid the cyclohexanone is accompanied by some caprolactone (through Baeyer-Villiger reaction) and ammonium formate or acetate. Treatment of *(1)* with warm ferrous sulfate afforded low yields of hexanamide and dodecanediamide, whereas ferrous chloride and cuprous chloride gave ω-chlorohexanamide and heating with copper naphthenate (catalytic amount) led to 5-hexenamide[4].

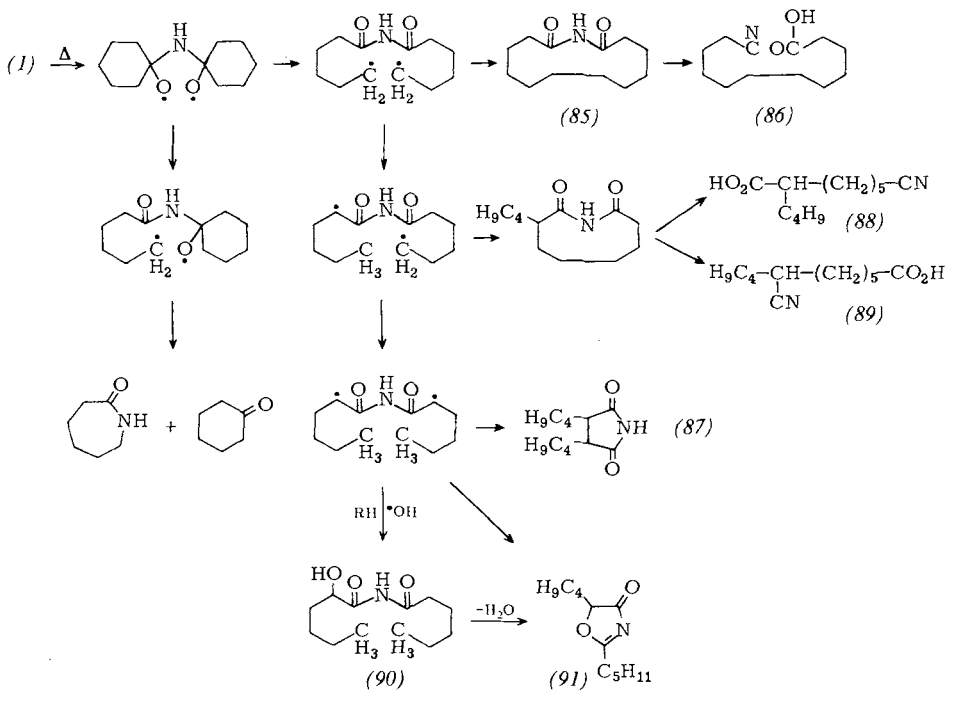
The reactions of *(1)* which were of the greatest interest were its decomposition by certain bases and its pyrolysis. When heated in methanolic solution with sodium methoxide or phenoxide, an alkali-metal hydroxide, or lithium chloride or bromide, the peroxyamine was converted in high yield into caprolactam and cyclohexanone. The use of other alkoxides, sodamide in benzene, or organic bases (*e. g.* amines) gave variable and often low yields of caprolactam, and the by-products included 2-(1-cyclohexenyl)cyclohexanone, hexanamide, 5-hexenamide, and octahydroacridines. Formation of 9-alkyl-1,2,3,4,5,6,7,8-octahydroacridines increased when higher alkoxide/alkanol systems were used, and they were then accompanied by cyclohexanol; presumably the greater activity of such alkoxides as catalysts in bringing about Oppenauer-Ponndorf oxidation-reduction reactions leads to such products.



The mechanism of formation of caprolactam and cyclohexanone probably involves nucleophilic attack of the methoxy-ion at the spiro-carbon site; removal of hydrogen from the imino group is not involved since *N*-methyl-1,2,4-dioxazolidine, under similar conditions, yields cyclohexanone and *N*-methylcaprolactam.

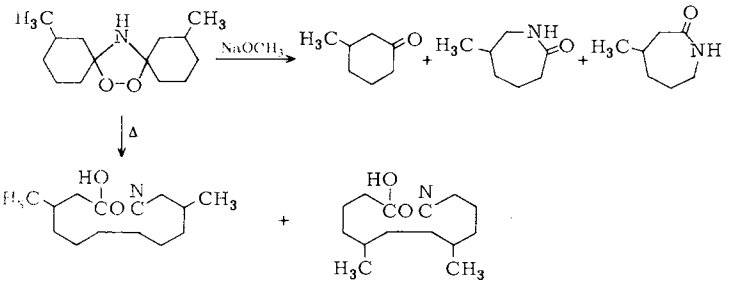


Thermal decomposition of *(1)* in the liquid phase gave a complex mixture of products, including cyclohexanone, caprolactam, and C_{12} compounds, whereas pyrolysis in the vapor phase at 350—600 °C under reduced pressure gave *ca.* 60% yields of C_{12} compounds together with caprolactam (*ca.* 20%) and cyclohexanone (< 30%). The nature of the C_{12} compounds varied with the temperature and residence time; at 350—400 °C the major product was decanedicarboximide *(85)*, and at higher temperature 11-cyanoundecanoic acid *(86)*. By-products, in minor amounts, included the monoamide of dodecanedioic acid, dodecanediamide, dibutylsuccinimide *(87)*, 2-butyl-7-cyanoheptanoic acid *(88)*, 7-cyanoundecanoic acid *(89)*, hexanamide, and a compound thought to be 1-hydroxy-*N*-hexanoylhexanamide *(90)*, which dehydrates to 5-butyl-2-pentyl-4-oxazolinone *(91)* on distillation; the formation of several of these C_{12} by-products involves 1,5-radical rearrangements.

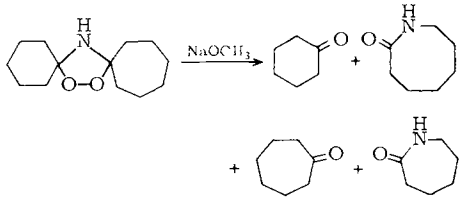


Other symmetrical cyclic peroxyamines derived from cyclic ketones behaved in a similar fashion on reaction with

sodium methoxide and on pyrolysis, although where isomeric lactams or cyano-acids were possible by rearrangement in two ways both were present in the products[5].

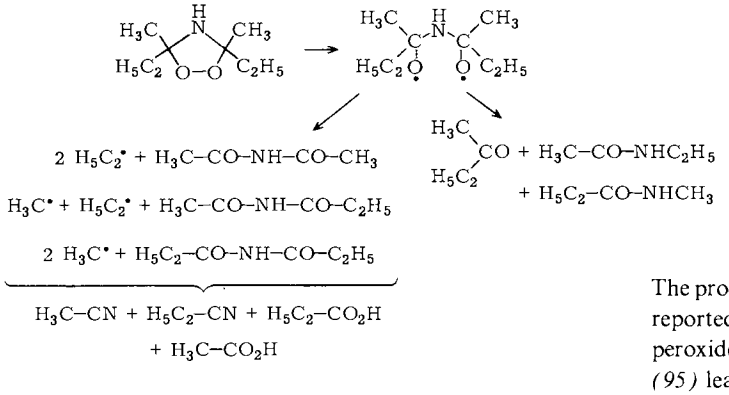


Unsymmetrical 1,2,4-dioxazolidines underwent base-catalyzed and pyrolytic decompositions to give mixtures of ketones, lactams, and cyano-acids.



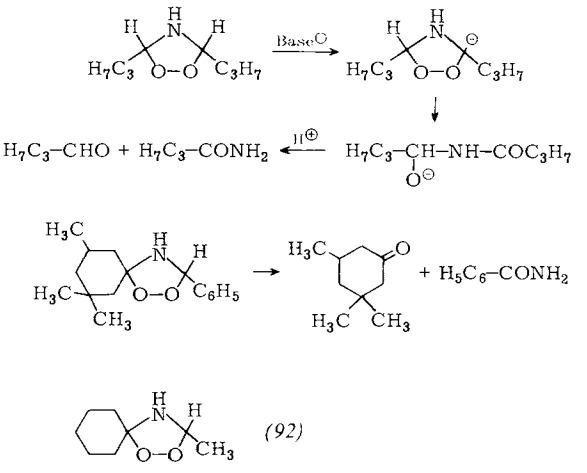
However, the unsymmetrical dioxazolidines *(83)*, R^1 and/or R^2 = aryl; R^3, R^4 = —$(CH_2)_5$—, obtained by imine oxygenation, gave a much more complex mixture of compounds on decomposition. Thus, although reaction with sodium methoxide afforded caprolactam (low yields) and benzophenones, varying amounts of benzanilides, cyclohexanone, benzonitriles, and diarylmethanols were also formed[5,11].

Pyrolysis of cyclic peroxyamines derived from acyclic ketones caused a fundamentally related decomposition to give ketones, amides, nitriles, and acids; the nitriles and acids were derived from imides, in turn produced from the diradicals by loss of alkyl radicals[6].



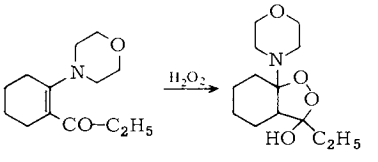
The dioxazolidines derived from aldehydes have a secondary-tertiary or disecondary peroxide system, and, in consequence, are easily decomposed by bases (*e.g.* triethylamine), by a normal Kornblum-De La Mare mechanism, to yield a carbonyl compound and amide.

Surprisingly, although 3,3-pentamethylene-5-methyl-1,2,4-dioxazolidine *(92)* similarly gives cyclohexanone and acetamide on treatment with triethylamine, it afforded a moderate amount of caprolactam on addition to a solution of lithium chloride in boiling methanol[4].

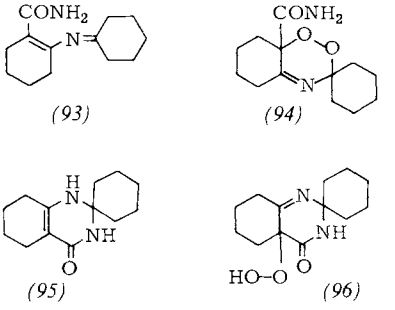


9. Miscellaneous Cyclic Peroxyamines and -imines

The addition of hydrogen peroxide to enamines to form α-peroxyamines has already been mentioned (Section 6.1)



but when the enamine also had a carbonyl group suitably positioned, intramolecular cyclization of the intermediate α-hydroperoxyamine led to a cyclic peroxide where the nitrogen was not part of the ring[12].



The product of reaction of cyclohexanone with urea, earlier reported to have the structure *(93)* and to give the cyclic peroxide *(94)* on autoxidation[13], is now thought to be *(95)* leading to a hydroperoxide *(96)*[14].

Sesquiterpenes

By Gerhard Rücker[*]

Of the 4000 or so terpenoid natural products known today, whose carbon skeleton can be divided up into isopentane units by the "isoprene rule" (C_{10}, monoterpenes; C_{15}, sesquiterpenes; C_{20}, diterpenes; C_{25}, sesterterpenes; C_{30}, triterpenes; steroids; carotenoids; polyprenes), the sesquiterpenes, numbering about 1000, represent the largest single class. According to the well founded concepts developed in recent years for the biogenesis of their highly diverse carbon skeletons, the present report is divided into nine sections dealing respectively with farnesanes, bicyclofarnesols (drimanes, iresanes), bisabolanes, cadinanes, humulanes and caryophyllanes, germacranes, "hydroazulenes", selinanes and eremophilanes, and maalianes and aristolanes. Further groups of sesquiterpenes can be derived from each of these structural types.

1. Introduction

The chemistry of the sesquiterpenes with their 15 carbon atoms—corresponding to three isopentane units—arranged in an acyclic or mono-, bi-, tri-, or tetracyclic skeleton has undergone a period of rapid development during the past two decades following the introduction of chromatographic separation techniques and physical methods of structural analysis. In 1953 about 16 sesquiterpene skeletons were known corresponding to about 30 compounds, in 1964 the respective figures were 40 and

[*] Prof. Dr. G. Rücker
Institut für Pharmazeutische Chemie der Universität
44 Münster, Hittorfstrasse 58 (Germany)

300, and in 1971 100 and 1000. Sesquiterpenes having the same carbon skeleton are classified as a single group. The farnesanes, bisabolanes, cadinanes, humulanes, germacranes, selinanes number among the larger and better known groups of sesquiterpenes (cf. Fig. 1).

The sesquiterpenes, which occur primarily in higher plants—less frequently in lower plants and in the animal kingdom (*e.g.* in insects)—are often steam volatile, and comprise not only mostly unsaturated hydrocarbons (including some alkynes) but also alcohols, ketones, aldehydes, and carboxylic acids. They may also contain three- to seven-membered ether rings and furan rings. Chlorine- and bromine-substituted sesquiterpenes, as well as about 25 nitrogen-containing compounds with 15 C atoms (sesquiterpene alkaloids) isolated predominantly from *Nymphaeaceae* also deserve mention. Compounds with only 12 or 14 carbon atoms (norsesquiterpenes) can also be derived from certain sesquiterpenes.

The sesquiterpene lactones occurring in *Compositae*, and also in other plant families, have attracted particular interest. The first compound of this class, α-santonin[1], which was isolated in crystalline form in 1830, is still the object of intensive study[2]. So far about 300 sesquiterpene lactones are known; worthy of particular mention are the germacranolides[3,4], guaianolides[3-5], pseudoguaianolides[3,6,7], selinanolides (≡ eudesmanolides)[8], and eremophilanolides[4]. Most of them are saturated or α,β-unsaturated γ-lactones. Apart from a few δ-lactones, only two β-lactones (anisatin, neoanisatin)[9] have been found. A trilactone, bilabolide[10], is also known alongside about 25 dilactones.

In addition to the isolation and structural elucidation of numerous new compounds recent advances in sesquiterpene chemistry have included a better knowledge of the stereochemistry of the molecules, their reactivity and rearrangements, and their biogenesis. In this connection the outstanding successes achieved in the synthesis of sesquiterpenes should be emphasized[*]. Several earlier structural assignments have been corrected by syntheses and application of modern physical methods[4]. Thus the "vetivanes", formerly regarded as hydroazulenes, proved to be spirocyclic agarospiranes or eremophilanes with a decalin skeleton[12]. The detection of sesquiterpenes with toxic and interesting biological properties, *e.g.* cytotoxic activity[15], also deserves mention (for reviews see refs. [13—15]). In the present brief progress report most of the studies on sesquiterpenes published in the past two decades have had to go without mention; such are included as references in the publications cited below and in reviews[3-8,11,13,15-19].

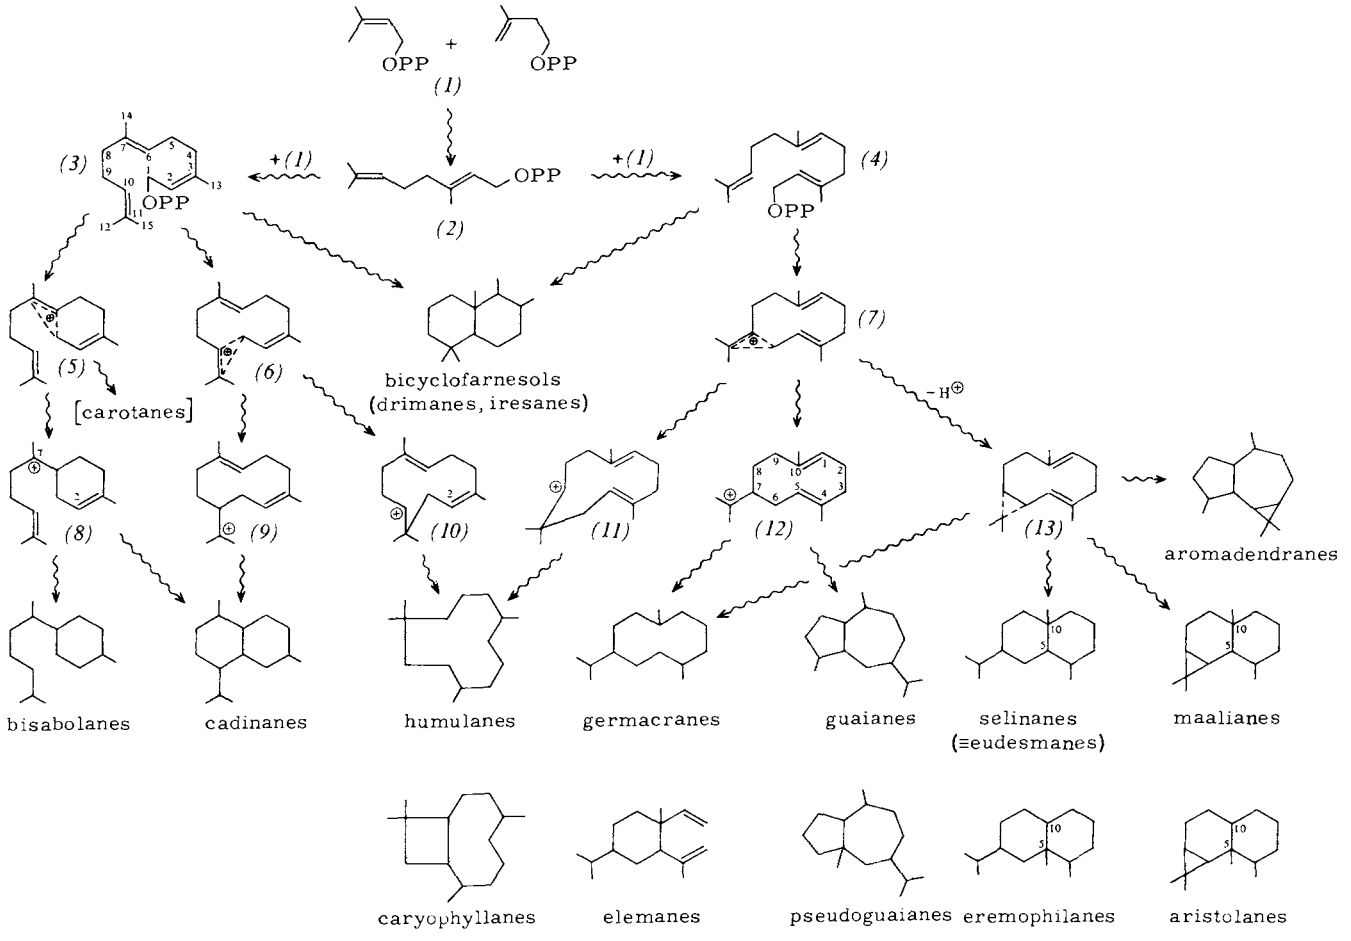

Fig. 1. Biogenesis of the sesquiterpenes. Wavy lines in this and the following figures signify biogenetic transitions. The basic skeletons are generally shown without multiple bonds.

[*] For a review see ref. [11]; for examples refs. [25, 33, 37, 38, 50, 64, 69, 82, 111, 117, 126, 130, 131, 135, 138, 145, 151, 165, 167, 173].

It was not easy to hit upon a reasonable and comprehensive scheme for a discussion of sesquiterpenes. The present report is essentially arranged in line with biogenetic considerations (Fig. 1). The nine sections deal with biogenetically related, or interconvertible, groups of sesquiterpenes. Reviews have appeared on the biogenesis of these compounds[11, 13, 17, 18, 20].

According to *Ruzicka* and *Hendrickson*, 2-*cis*-6-*trans*-farnesyl pyrophosphate *(3)* or the corresponding 2-*trans*-6-*trans* compound *(4)* is regarded as the biological precursor of almost all sesquiterpenes; it is formed from acetyl coenzyme A *via* mevalonic acid, isopentenyl pyrophosphate *(1)*, and geranyl pyrophosphate *(2)* (Fig. 1). For steric reasons, a 2-*trans*-6-*cis*-farnesyl-, a 2-*cis*-6-*cis*-farnesyl-, or a nerolidyl precursor has to be assumed for a few sesquiterpenes. Removal of the pyrophosphate group from *(3)* or *(4)* yields carbocations whose formulation as nonclassical cations *(5)* and *(6)* or *(7)* explains their cyclization to two cyclic cations each [*e.g.* *(9)* and *(10)* from *(6)*; *(11)* and *(12)* from *(7)*]. These can afford most of the sesquiterpenes by processes such as 1,2- or 1,3-hydride shifts, electronically and sterically controlled cyclizations with the two remaining double bonds ("Markownikoff" and "anti-Markownikoff cyclizations"), Wagner-Meerwein rearrangements, and 1,2-methyl shifts. Considerable significance attaches to the biogenetic formation of diastereoisomers and enantiomers. It should however be noted that many hypotheses regarding the biosynthesis of sesquiterpenes that are based on structure, stereochemistry, and reactivity still require experimental proof *in vivo*[13, 20].

The future of terpene research will still be concerned primarily with the isolation and structural elucidation of new compounds which could be important as missing biosynthetic links, as biologically active substances, or as reactants for the study of chemical problems. The sesquiterpenes throw up problems of a largely stereochemical nature. The course of their numerous rearrangements provides information about relationships between stereochemical and electronic factors and the reactivity of the compounds. The chemistry of nonclassical carbocations has also profited from work on sesquiterpenes. The photochemistry of the sesquiterpenes is still in its infancy. Syntheses of sesquiterpenes nearly always have to be carried out stereoselectively; they can contribute to the solution of problems in preparative chemistry.

Knowledge of reactivity, photochemistry, and syntheses stimulate research into sesquiterpene biogenesis, a field that will become increasingly important in the future. The aim is to elucidate the formation of the numerous carbon skeletons and to obtain information about the reasons behind the frequently complex stereospecific biosynthetic pathways that could also be of interest for the biogenesis of other natural products. In this connection, importance also attaches the site of formation and of deposition of the sesquiterpenes in plants and to their distribution throughout the plant and animal kingdoms. The biological properties of some sesquiterpenes show that they are not merely metabolic "waste products". For instance, they are of significance as plant growth substances, growth regulators, and sex attactants of fungi. Others function as the juvenile hormones essential for normal development of insects or occur as components of insect secretions. These aspects have opened up an area of sesquiterpene research that is of potential interest, *e.g.* for the solution of practical problems of influencing the growth of cultivated plants and in plant protection.

Sesquiterpenes can provide impetus to drug research too. The starting point of such work is the pharmacological effects determined so far for a relatively small number of compounds. They include cytotoxic, antibiotic, fungistatic, virostatic, anthelmintic, antiphlogistic, and sedative properties, thus covering a fairly broad spectrum. Considerable uncertainty still surrounds the extent to which the sesquiterpenes contribute to the manifold and frequently unspecific action of the essential oils in which they occur. Mention should be made here of the importance of sesquiterpene research for the chemistry of essences and of aromas and flavors.

2. Acyclic Sesquiterpenes (Farnesanes)

The first sesquiterpene whose structure was correctly determined (1913)[21] is the widely distributed 2-*trans*-6-*trans*-farnesol *(4a)*. The 2-*cis*-6-*trans* compound *(3a)* has also been found in essential oils[22]. Like other natural and synthetic compounds derivable from farnesane and bisabolane (Fig. 2), *(4a)* and *(3a)* have a juvenile hormone action on insects[13, 23]. The saturated parent hydrocarbon farnesane has also been found to occur in Nature, as have monounsaturated farnesenes. Essential oils frequently contain the fourfold unsaturated 6-*trans*-β-farnesene [(*E*)-β-farnesene] *(14)*[24, 25]. Of the four *cis-trans* isomeric α-farnesenes, which have all been synthesized, only two have so far been found in Nature[25], (*E*,*E*)-α-farnesene *(15)* and (*Z*,*E*)-α-farnesene *(16)*. The all-*trans* aldehydes β- *(17)* and α-sinensal *(18)* occur in *Citrus* species[26].

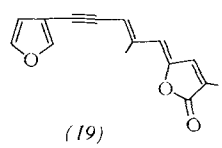
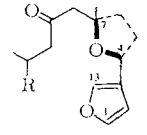
(16)



(19)



(20), R = CH_3
(21), R = CH_2OH

Only one lactone has so far been discovered in the farnesane group, *viz.* freelingyne *(19)* containing a triple bond and a furan ring[28]. The hepatotoxic substances from *Myo-*

porum species and from sweet potatoes infected with fungi [(−)-ngaione, (+)-ngaione (≡ipomeamarone) *(20)* and ipomeamaronol *(21)*], having a furan ring bridging C-1 and C-13[29] and a tetrahydrofuran ring[27] between C-4 and C-7, number among the farnesanes. Farnesanes with two furan rings are also known[30].

3. Bicyclofarnesols (Drimanes, Iresanes)

The drimanes, *e.g. (23)* and *(26)*, and iresanes, *e.g. (25)* and *(27)*, constituting the small group of the bicyclofarnesols, possess enantiomeric skeletons. Their biogenesis is assumed to involve direct *trans*-antiparallel cyclization of farnesyl pyrophosphate (Fig. 1), *(3)* possibly representing the precursor of the drimanes and *(4)* that of the iresanes[20]. Accordingly, the epoxide of *trans,trans*-farnesyl umbelliferonyl ether *(22)* cyclizes in the presence of BF_3 to give drimenol umbelliferonyl ether *(23)*[31]. Under the same conditions the epoxide of *trans,cis*-farnesyl umbelliferonyl ether *(24)* afforded a very low yield of farnesiferol A *(27)* having an iresane skeleton[31,32]. The umbelliferonyl ether of *(3)*, umbelliprenin, was isolated from *Umbelliferae* (*e.g. Ferula* species). Sterically the skeleton of the drimanes corresponds to rings A and B of most di- and triterpenes. The opposing "unusual" steric arrangement of the iresanes is found in only a few higher terpenes. Most drimanes and iresanes are unsaturated γ-lactones with the lactone ring in the 8,9 position [*e.g.* cinnamolide *(26)* and iresine *(27)*][33,34]. Farnesiferol C *(28)*[32], which has been known for some time, and the plant growth regulating abscisic acid (≡abscisin II≡dormin) *(29)*[35,36] from young cotton fruit and sycamore leaves can be derived from *(3)* or *(4)* by simple cyclization[20].

4. Bisabolanes and Related Sesquiterpenes

Precursors having the monocyclic skeleton of bisabolane—*(8)*, *(40)*, *(41)*, *(42)* (Figs. 1 and 2)—have to be considered for the biogenesis of many sesquiterpenes[20]. The bisabolane group is known to contain numerous hydrocarbons, alcohols, ketones, aldehydes, and carboxylic acids. Only β-bisabolene *(30)* will be mentioned as an example. The insect juvenile hormone (+)-juvabione *(35)* was found to deviate in the stereochemistry of its side chain[23,37]. Bisabolanes having aromatic or quinonoid six-membered rings and with tetrahydrofuran or lactone rings are also known.

Several small groups of sesquiterpenes representing isoprenologous monoterpenes can be derived from the cation *(8)* (Figs. 1 and 2) by deprotonation and cyclization. These include l-sirenin *(39)*, an isoprenologous carene (sesquicaranes), the sex attractant of the female gametes of several fungi[38]. α-Bergamotene [*(36)* or *(37)*] is an isoprenologous α-pinene, and β-bergamotene *(38)* an isoprenologous β-pinene. Synthetic studies[39] have shown that the isoprenoid side chain and the cyclohexene ring may be mutually "*trans*" or "*cis*" oriented [*(36)* or *(37)*] in natural α-bergamotene, while β-bergamotene occurs only as the "*trans*" compound *(38)* in Nature. The biogenesis of the antibiotic and cytostatic fumagillin *(34)* from *Aspergillus fumigatus*[13,14] is assumed to involve cleavage of the cyclobutane ring in *(38)*[20]. Cyclization, Wagner-Meerwein rearrangement, and deprotonation of the cation *(8)* can yield two isoprenologous camphenes, the bicyclic β-santalene *(31)*[40] and the tricyclic α-santalene *(32)*[7], which occur alongside other santalenes in Indian sandalwood oil[41]. Isoprenologous bornanes such as campherenol *(33)* are related to the bisabolane cation *(8)*[42].

The discovery of the diketone acorone *(44)* as the first sesquiterpene having a spirocyclic carbon skeleton by *Šorm et al.*[44] attracted acute interest and led to the isolation of further acoranes. Cyclization of the cation *(41)* [or *(40)*] is invoked to explain the biosynthesis of the [4.5]spirocyclic sesquiterpenes. Various stereoisomeric forms of the skeleton can apparently arise depending upon the steric course of the reaction: for instance, cation *(45)* which is regarded as a precursor of α-acorenol *(49)* and deviates sterically from acorone *(44)*. A differently substituted [4.5]spirocyclic ring system is found in the agarospiranes which are biogenetically related to the selinanes (Fig. 7).

Cation *(45)* can be transformed into the tricyclic cedranes, *e.g.* (−)-α-cedrane *(50)* by renewed ring closure[43] and is regarded as an intermediate of the acid-catalyzed conversion of *(49)* into *(50)*[43]. The small group of the cedranes[45,46] embraces hydrocarbons, *e.g. (50)*, alcohols, and carboxylic acids occurring in *Juniperus* species, cedarwood oils, and in the basic hydrolyzates of shellac, which is well known to be secreted by the insect *Lacifer lacca*[47].

Biogenetic precursors of the chamigranes such as *(52)*[48] having a spiro[5.5]undecene structure *(46)* and the cuparanes *(43)* can be formed from cation *(42)* by cyclization[20,46]. The chamigrane cation *(46)*, whose biogenesis by direct cyclization of *(3)* or *(4)* analogous to the formation of the bicyclofarnesols is also conceivable[49], is also

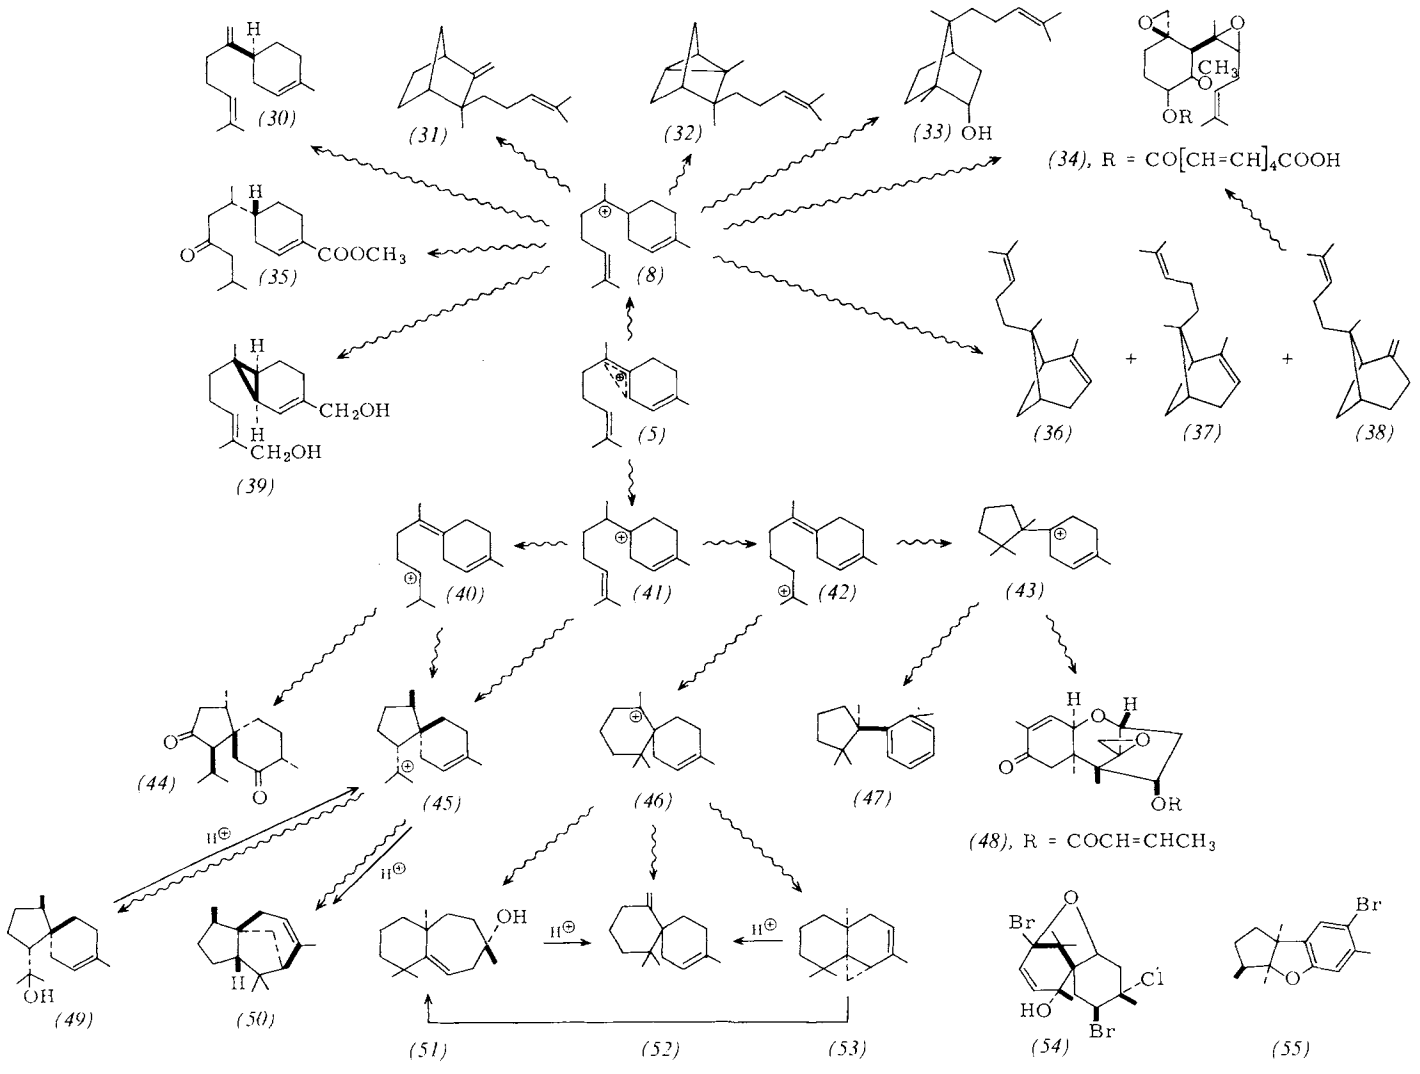

Fig. 2. Bisabolanes and related sesquiterpenes.

viewed[20] as a precursor of widdranes such as *(51)* (widdrol) and thujopsanes such as *(53)* (thujopsene)[46,50]. Acid-catalyzed transitions have been observed between these small groups of related sesquiterpenes, *e.g.* from *(51)* and *(53)* to β-chamigrene *(52)*[48] or from *(53)* to *(51)*[51]. A recent discovery was the chamigrane derivative pacifenol *(54)*, the first sesquiterpene to contain both chlorine and bromine[52]. Nearly all the cuparanes, which are mainly isolated from *Cupressaceae*, *e.g.* cuparene *(47)*, contain an aromatic ring[46]. Algae, fungi, and molluscs afforded substances such as aplysin *(55)* exhibiting a modified substitution of the parent system[53] (lauranes) which may also contain chlorine or bromine, as well as an additional ether ring, and, like *(54)*, are regarded as detoxification products of halogenated pesticides[52]. The trichothecanes, *e.g.* trichothecin *(48)*, isolated as cyclic esters (roridins, verrucarins) from microorganisms and of interest owing to their antibiotic properties[13,54], are derivable from cation *(43)*.

5. Cadinanes and Related Sesquiterpenes

Sesquiterpenes having a 1,7-dimethyl-4-isopropyldecalin skeleton (Figs. 1 and 3) are designated cadinanes, and frequently also as cadalanes, because they afford the naphthalene derivative cadalene on dehydrogenation with sulfur or selenium. The cadinanes, which all contain an α-isopropyl group, can be divided into four types according to the stereochemistry of the ring linkage (Fig. 3): the true cadinanes, *e.g. (57)* [(+)-γ-cadinene] and the bulgaranes, *e.g. (58)*[55] [(−)-ε-bulgarene], display a *trans* linkage of the two cyclohexane rings, and the muurolanes, *e.g. (59)* [(−)-α-muurolene][56], and amorphanes, *e.g. (60)* [(−)-γ-amorphene][56] a *cis* linkage.

Cyclization of the bisabolane cation *(8)* or the germacrane cation *(9)*[57] (Figs. 1 and 3) or of a 2-*cis*-6-*cis*-farnesyl precursor[20] is assumed to account for the biogenesis of these four stereochemical variants of the dimethylisopropyldecalin system. Acid treatment of bicyclogermacrene *(13)* (Fig. 1) opens the three-membered ring to give cadinanes[58]. Numerous cadinane hydrocarbons and alcohols (cadinols) have been found in higher and lower[59] plants. Either ring A or both rings of the cadinanes may be aromatic. Furans and *p*- and *o*-quinones with a cadinane skeleton have likewise been found in Nature. Biogenetic formation of the indan derivative oplopanone *(56)* may conceivably proceed *via* ring contraction of an α-cadinol[60]. Relations can also be detected between other sesquiterpenes having an indan-type carbon skeleton and

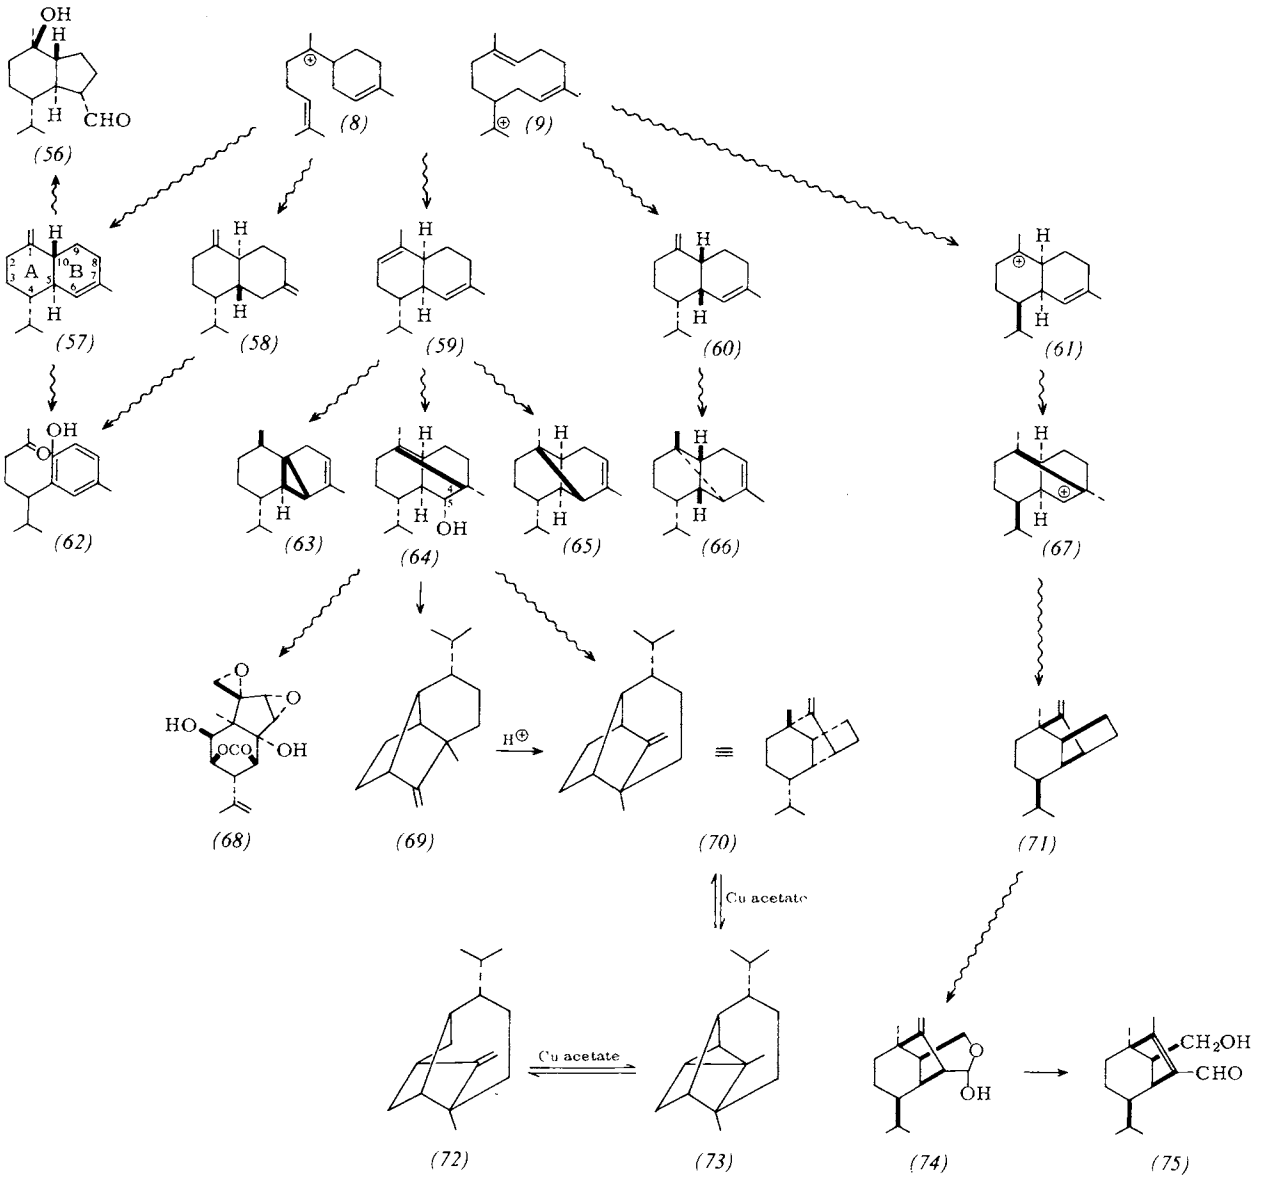

Fig. 3. Cadinanes and related sesquiterpenes.

the humulanes, germacranes, guaianes, selinanes, or eremophilanes[13,20]. Several monocyclic sesquiterpenes having carbon skeletons resembling bisabolane, *e.g.* sesquichamaenol *(62)*[61], are formed by ring cleavage from cadinanes or bulgaranes[20]. The tricyclic cubebanes, *e.g.* *(63)* (α-cubebene)[64], copabornanes *(64)*, and copaanes *(65)* can be derived biogenetically from the *cis*-fused muurolanes *(59)*, and the ylanganes *(66)*[20,62] from the amorphanes *(60)*. Model experiments also suggested that a pigment-sensitized photocyclization of germacrene D *(101)* could be operative in biogenesis of the copaanes *(65)*[63].

(+)-Sativene *(70)* can be derived from the copabornanes *(64)*; it was isolated from *Abies* species[68] and in the presence of copper acetate in acetic acid it equilibrates with cyclosativene *(73)*[68] and isosativene *(72)*[67]. The effect of acid also converts copacamphene *(69)*, which is chemically accessible[67] from *(64)*[69], into *(70)*. Derivatives of cyclocopacamphene, stereoisomeric to cyclosativene at the isopropyl group, were isolated from vetiver oil[70]. Cleavage of the 4,5 bond in *(64)* is considered a possible biogenetic route to the carbon skeleton of the poisonous picrotoxans, *e.g.* *(68)* (tutin)[71].

The grain fungus *Helminthosporium sativum* (≡*Cochliobulus sativum*) produces the helminthosporanes, unstable hemiacetals, *e.g.* *(74)* (prehelminthosporol), which display antiviral activity *in vitro*[13,65]. These compounds are partly converted into the aldehydes helminthosporol *(75)* or helminthosporal on work-up of the plant material[65]. Their biogenesis has been rationalized by invoking cyclization of the cation *(61)* to the "epicopabornane" cation *(67)*, which on deprotonation and rearrangement yields (−)-sativene *(71)*. Compound *(71)* also occurs in the same fungus and is regarded as the immediate precursor of the helminthosporanes[20,66].

6. Humulanes, Caryophyllanes, and Related Sesquiterpenes

The monocyclic humulanes, *e.g.* *(77)* (α-humulene), possess an eleven-membered ring, and the bicyclic caryophyl-

lanes, *e.g. (76)* (β-caryophyllene), a *trans* fused cyclobutane-cyclononane ring system (Figs. 1 and 4). It seemed reasonable to consider the monocyclic cation *(10)* as biological precursor for both groups of sesquiterpenes (Fig. 1)[20], particularly as *(77)* can be converted chemically by ring closure into *(76)*[74,80]. However, the assumption of a common precursor is no longer tenable since it was discovered that all three ring double bonds of α-humulene *(77)* are *trans*[72]. With the exception of caucalol *(79)*[73] which contains a *cis* double bond, the humulanes are considered to arise from the all-*trans* cation *(11)* as biogenetic precursor[20]. α-Humulene *(77)* and β-caryophyllene *(76)*[75–77], first isolated 80 years ago from clove oil, are widely distributed in Nature. In addition, epoxides and alcohols having the same basic skeleton are also known[75,78]. Both *(77)* and *(76)* readily afford tricyclic ring systems (*e.g.* tricyclohumulanes) by molecular rearrangement[74,75,77,79–81]. Starting from *(77)* and proceeding *via* the cation *(78)*[20] one obtains the antibiotically active illudins *(80)*[82,83], marasmic acid *(81)*[83], and hirsutic acid C[84].

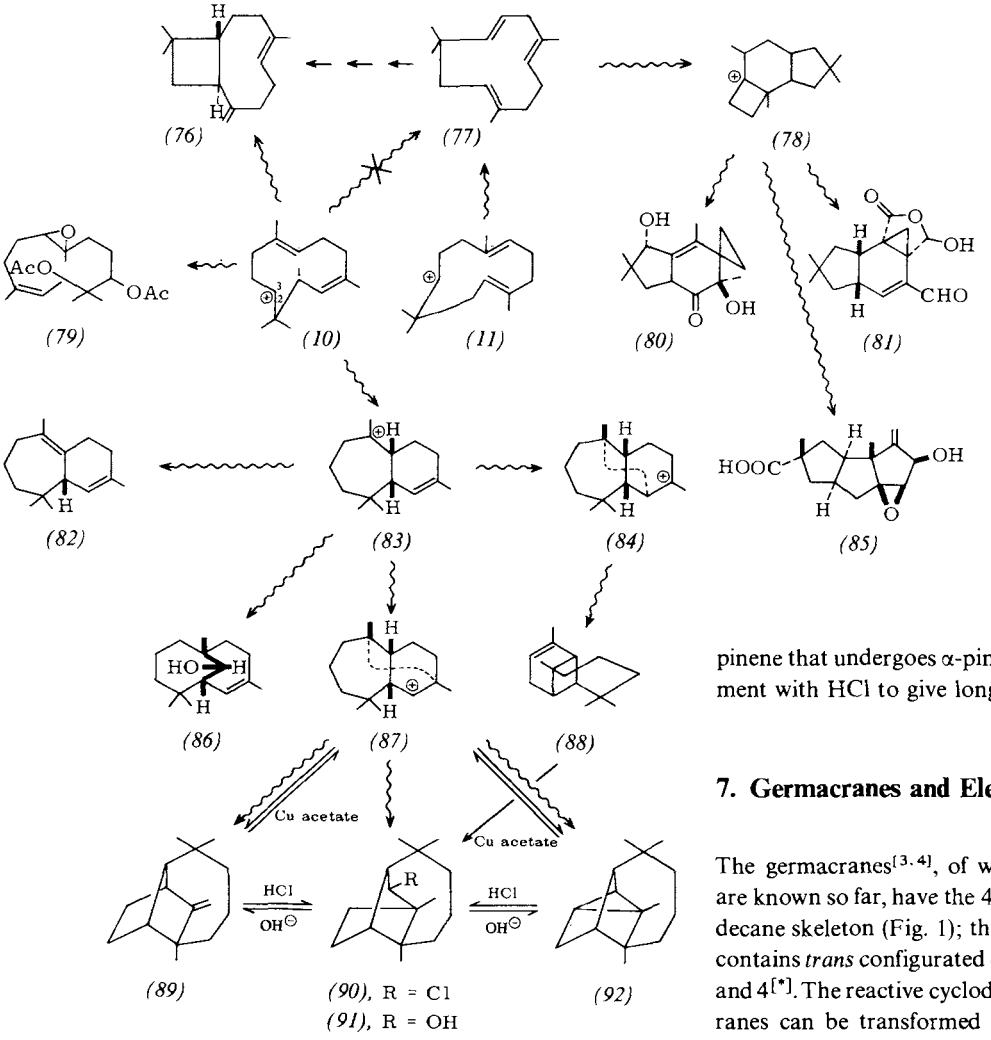

Fig. 4. Humulanes, caryophyllanes, and related sesquiterpenes.

A 1,3 hydride shift and cyclization can transform *(10)* into the cation *(83)* that is of significance as a biogenetic precursor of several small groups of sesquiterpenes[20]. The himachalanes, *e.g. (82)* (α-himachalene) and allohimachalol *(86)*[85], are representatives that have been isolated from cedar oil[86].

The biogenesis of the longifolanes is reported to proceed from *(10) via (83)* to the cation *(87)*[20], from which longifolene *(89)*, longiborneol *(91)*[85], and longicyclene *(92)* are formed. Longifolene *(89)*, which occurs in pine resins, has attracted interest on account of the Wagner-Meerwein rearrangement type reactions involving carbocations[87–89]—which are comparable with the rearrangements of sativene [*(70)*, Fig. 3][67]. In the presence of copper acetate in acetic acid, *(89)* equilibrates *via* the cation *(87)* with isolongifolene[90] and longicyclene *(92)*[67,86,88], which have likewise been isolated from pine species. It is the first naturally occurring tetracyclic sesquiterpene. Treatment with HCl transforms both *(89)* and *(92)* into (+)-longibornyl chloride *(90)*, a homolog of bornyl chloride. Solvolysis of *(90)* regenerates *(89)* and *(92)*[87].

The biogenesis of longipinene *(88)*, which similarly occurs in pine species[91], also proceeds *via* cation *(83)* involving initial cyclization to *(84)*. *(88)* is an isoprenologous α-pinene that undergoes α-pinene-bornyl chloride rearrangement with HCl to give longibornyl chloride *(90)*[87].

7. Germacranes and Elemanes

The germacranes[3,4], of which about 90 representatives are known so far, have the 4,10-dimethyl-7-isopropylcyclodecane skeleton (Fig. 1); the ten-membered ring generally contains *trans* configurated double bonds in positions 1(10) and 4[*]. The reactive cyclodecadiene system of the germacranes can be transformed into mono-, bi-, and tricyclic sesquiterpenes by thermal Cope rearrangements and acid- and light-induced cyclizations (Fig. 5). The germacranes were therefore accorded significance for the biosynthesis of other sesquiterpenes *(20)*, thus stimulating extremely

[*] The molecular skeleton was numbered by analogy with other sesquiterpenes.

intense work on this group. For the same reason relations between reactivity and stereochemistry of the cyclodecadiene system have also attracted attention. Moreover, the

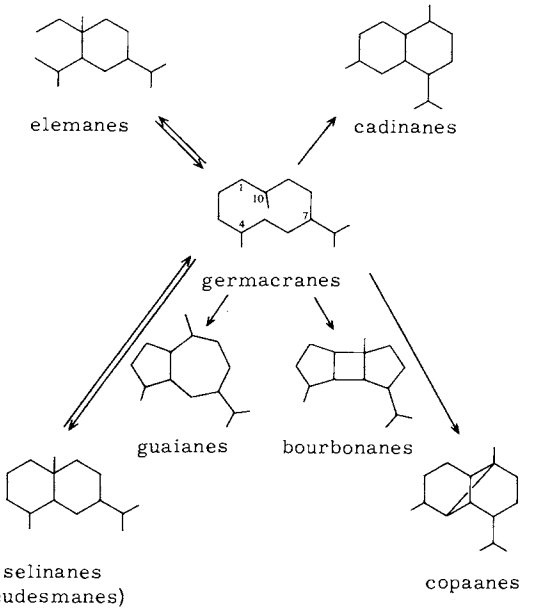

Fig. 5. Rearrangements of germacranes to other sesquiterpenes.

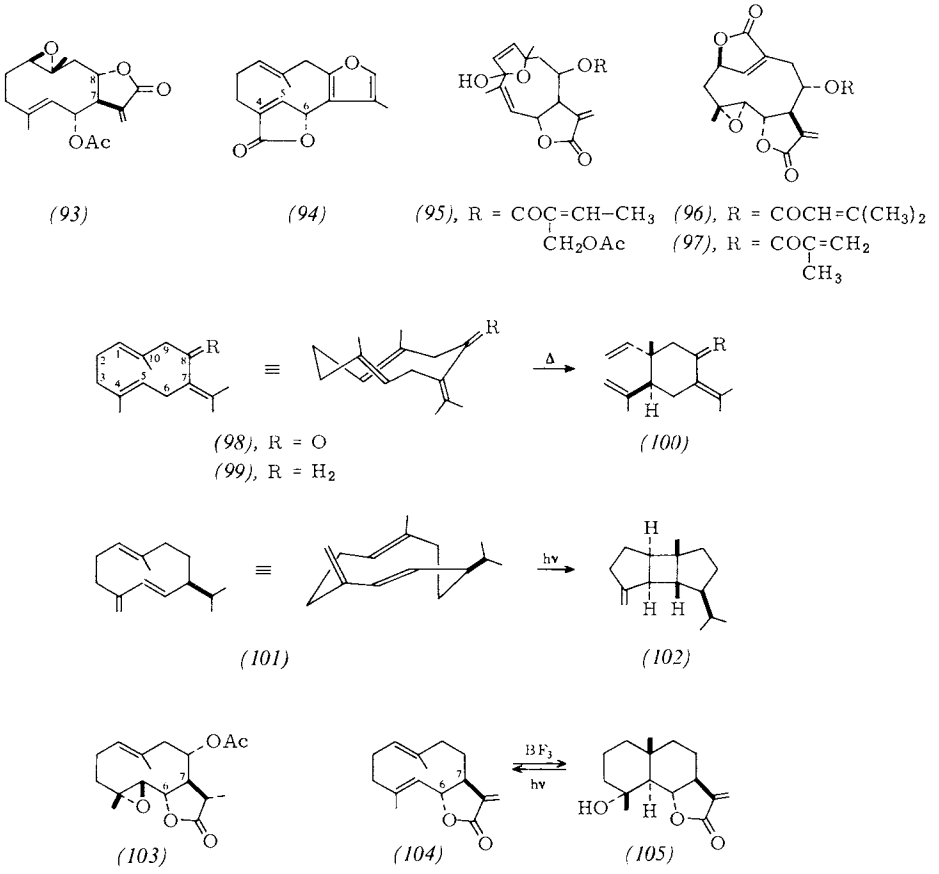
germacranes also include substances with interesting biological properties. Biogenetic formation[20] of the germacrane skeleton from *(4)* (Fig. 1) has been detected by *in vivo* experiments[92].

Most of the germacranes are lactones (germacranolides)[3,4]. Mention should be made of pyrethrosin *(93)*[93,94], the first germacrane derivative to be isolated (1957). In *(93)* the α,β-unsaturated γ-lactone ring is in the 8α,7β position; it can also be in the 6α,7β position, *e.g.* in *(104)*, and more rarely in the 4,6-position, *e.g.* in *(94)* (linderalactone), a representative of the furanogermacranolides. The cyclic hemiketal liatrin *(95)*, like the dilactones elephantin *(96)* and elephantopin *(97)*, possesses cytotoxic properties[13,14,96]. The ketone germacrone *(98)* was the first germacrane found to have no lactone ring[97,98]. Subsequently, the thermolabile germacrenes A to D were discovered to occur in Nature, *e.g.* *(99)* (germacrene B) and *(101)* (germacrene D). Mention should also be made of the bicyclogermacrene *(13)* (Fig. 1) containing a cyclopropane ring[58,99].

An important role is played by the stereochemistry of the cyclodecadiene ring in biogenetic transformations[20] and chemical conversions (Fig. 5) of germacranes into other sesquiterpenes. It could be established for numerous germacranes by X-ray analysis of halogenated derivatives[93] or silver nitrate complexes[98,101,102], by measurement of the nuclear Overhauser effect[103], and by low temperature NMR studies[103]. In the conformation with *syn*-methyl groups in positions 4 and 10 found for most compounds, *e.g.* *(98)*, *(99)*, and *(101)*, the π orbitals are positioned favorably for Cope rearrangements and electrocyclic reactions[100].

Thermal Cope rearrangements[100] of germacranes furnish elemanes[19,58,95,99,100,104], sesquiterpenes having a 1-methyl-1-vinyl-2-isopropenyl-4-isopropylcyclohexane skeleton (Figs. 1 and 5). Apart from a few exceptions[96], the elemanes isolated from essential oils, and also numerous elemane lactones (elemanolides), can be regarded as Cope



rearrangement products of germacranes[58,95,98,104]. Under certain conditions the Cope rearrangement is reversible[19,100,105]; it proceeds stereospecifically. All-*trans*-cyclodecadienes, *e.g. (99)* (germacrene B)[101] are converted into *trans*-elemanes, *e.g. (100)*[99,100], whereas 1(10)-*cis*-4-*trans*-cyclodecadienes form *cis*-elemanes[99]. This rule has been employed in determining the stereochemistry of germacranes[99].

Of the cyclization reactions of germacranes (Fig. 5) we shall first consider the formation of cadinanes in the presence of $H^{\oplus}$ ions[57,58,105,106]. UV-irradiation of germacrane D *(101)* generated *(102)*[107] having the same skeleton as the tricyclic bourbonanes[57] occurring in *Geranium* and *Mentha* species. Under the same conditions, a cyclodecadiene employed as model substance was also transformed into ketones having copaane-type skeletons (Fig. 3)[63]. The formation of guaianes from germacranes, particularly germacrane epoxides[104], has also been reported[58,98,108,109]. Isomerizations of germacranes to guaianes also extend to germacrane lactones[108]. Reports have also appeared of stereospecific[112,113] cyclizations of germacranolides to lactones having a selinane-type skeleton (Figs. 1 and 7)[4,104,11,113,114]. For instance, costunolide *(104)*[102] is converted by the action of boron trifluoride into selinanolide *(105)*[110]; *(105)* regenerated *(104)* in a photochemical process[111].

8. Sesquiterpenes Having a Hydroazulene Skeleton (Guaianes, Pseudoguaianes, and Related Sesquiterpenes)

Several groups of sesquiterpenes possess a hydrogenated azulene[173] skeleton bearing two methyl and one isopropyl groups (Figs. 1 and 6) but differ in the positions of the substituents. The largest group of these "hydroazulenes" comprises the guaianes, with about 100 members, followed by the pseudoguaianes, with about 70. Only a few represen-

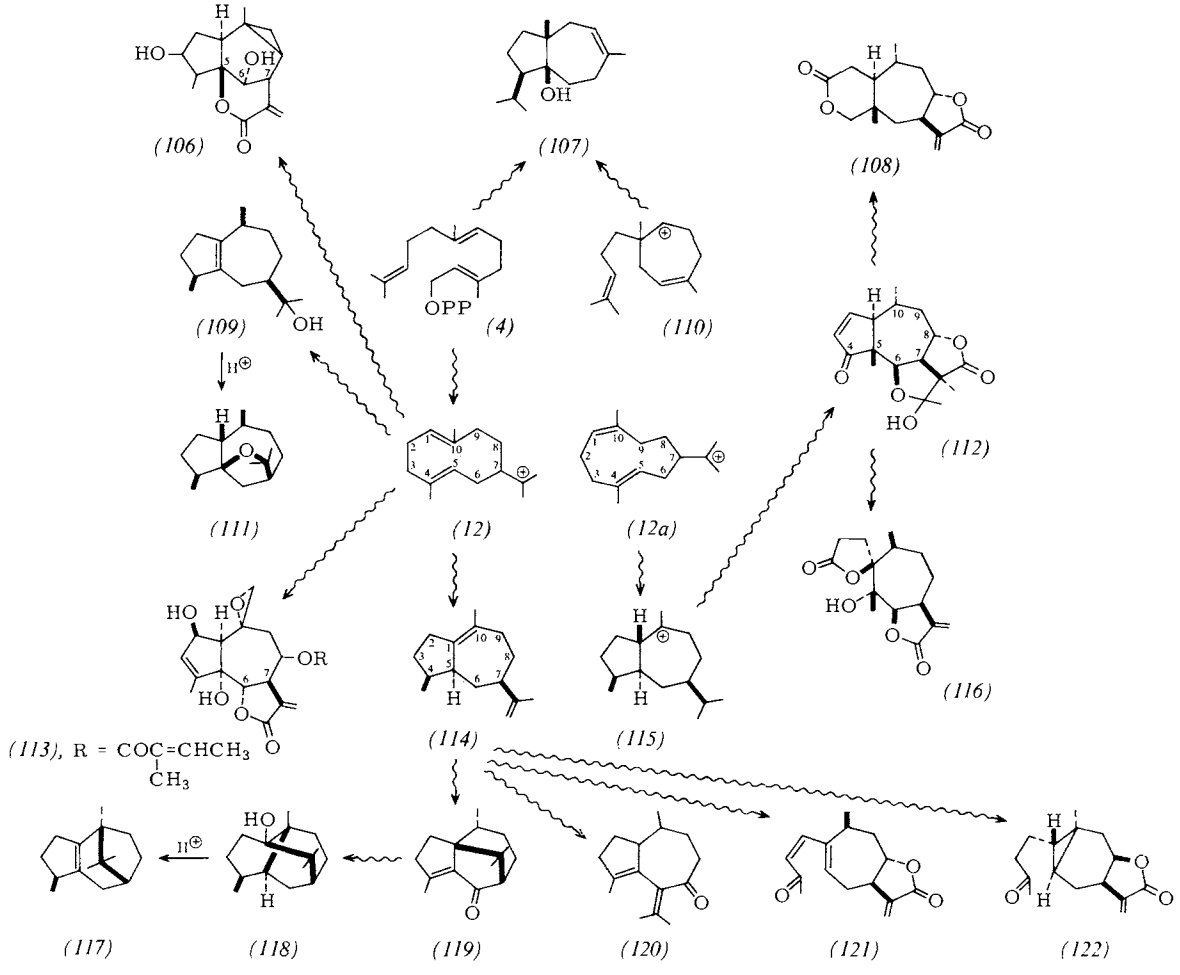


Fig. 6. Sesquiterpenes with a hydroazulene skeleton.

tatives of the carotanes, isopatchoulanes, and zieranes (Fig. 6) have so far become known.

Biogenetically[120], an "anti-Markownikoff cyclization" between C atoms 1 and 5 of cation *(12)* leads to the *cis* linked guaianes (Fig. 6). As examples of this group of sesquiterpenes we can consider α-bulnesene *(114)*[117] and guaiol *(109)*, which undergoes ready conversion into the tetrahydrofuran derivative guaioxide *(111)* by acid-catalyzed ring closure[118]. The guaiane lactones (guaianolides)[3-5] which number about 60 compounds, represent

one of the largest groups of sesquiterpene lactones[3, 5, 8, 18]. Most of them are unsaturated 6α,7β-lactones, *e.g.* euparotin *(113)*. Formation of the lactone ring in positions 7β,8α or 7β,8β is less common. Several guaianolides, *e.g. (113)*, are cytotoxic[96, 119]. Absinthin, obtained from wormwood, is a Diels-Alder adduct of two guaianolides[120]. *(106)* (zaluzanin A) comes from the small group of ivaxillaranes having a tricyclic skeleton[5, 121].

In 1962 *Herz et al.*[122] were able to show that the supposed guaianolide tenulin does not have a methyl group in position 4, but a tertiary one in position 5 *(112)*. This finding constituted the discovery of the first compound having the "pseudoguaiane" skeleton; so far only lactones are known (pseudoguaianolides). They display a pronounced structural variety and occur in *Compositae*[3, 4, 6, 7, 18, 123]. Their generally unsaturated γ-lactone ring is located at 6β,7β, at 7β,8α, or at 7β,8β. The methyl group at C-10 can be in the α or β position. Glycosides of pseudoguaianolides have also been found[124, 125]. 1,5-Cyclization of the cation *(12a)* to give *(115)* is assumed to explain the biosynthesis of the pseudoguaianolides (Fig. 6)[20] which, unlike most guaianes, exhibit *trans* linkage of the two rings. A 1,2 hydride shift and migration of the methyl group from C-4 to C-5 would account for conversion of *(115)* into the skeletons of the two pseudoguaianolides which are diastereomeric in position 10[20].

lides by cleavage of the five-membered ring[8, 15]. As examples we may consider *(121)* (xanthatin), which displays a regulating effect on plant growth[126], and *(122)* (carabrone)[126]. These "derived" sesquiterpenes also embrace dilactones, *e.g. (108)* (vermeerin)[125], and spiro-γ-lactones, *e.g. (116)* (canabrin)[127].

The guaianes are biogenetically related to the small group of isopatchoulanes, *e.g. (119)* (patchoulenone)[129, 130, 133], and the zieranes, *e.g. (120)* (zierone)[128]. Patchouli alcohol *(118)*[131, 132], a compound of unusual structure, is connected with the patchoulanes[11]; it is readily transformed into β-patchoulene *(117)* on treatment with acid. The small carotane group, *e.g. (107)* (carotol)[115, 116], represents a special case with regard to its biosynthesis (Fig. 6). Available evidence suggests either direct cyclization of *(4)*[115] or formation from *(3)* (Fig. 1) by way of *(5)* and *(110)*[20].

9. Selinanes and Eremophilanes

The bicyclic selinanes (≡eudesmanes) and eremophilanes having the basic structure of a dimethyl-7-isopropyldecalin differ only in the position of a tertiary methyl group (Figs. 1 and 7) which is bonded to C-10 in the selinanes and

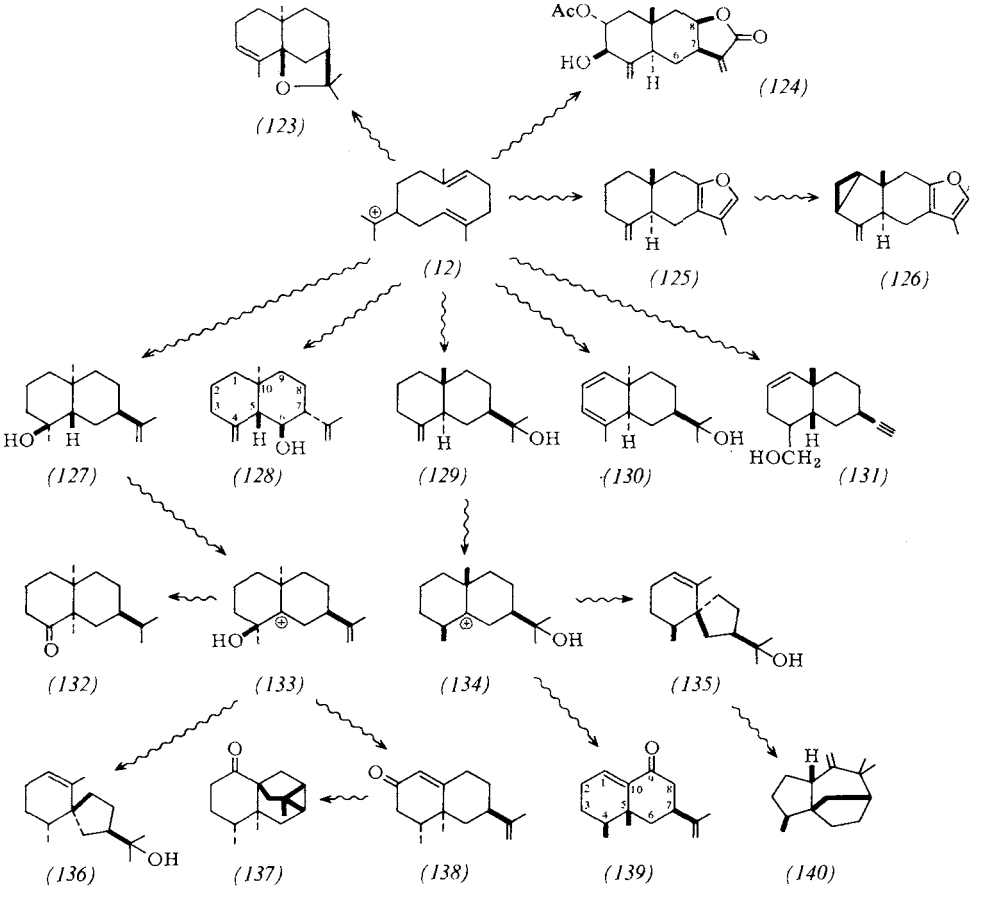

Fig. 7. Selinanes (≡eudesmanes), eremophilanes, and related sesquiterpenes.

Sesquiterpene lactones having a cycloheptane ring and which are designated as xanthinanes and carabranes (Fig. 6) can be derived from guaianolides and pseudoguaianolides to C-5 in the eremophilanes. The skeleton of the eremophilanes cannot be divided into isopentane units like that of the selinanes.

As in the case of the cadinanes (Fig. 3) the selinanes comprise four structural types[134], depending on the mode of ring fusion, whose biogenesis can proceed *via* corresponding conformers of the germacrane cation *(12)*[20,137]. Two of them are *trans*-decalins with the basic structures of (−)-selinane, *e.g. (128)*[140], and the enantiomeric (+)-selinane, *e.g. (129)*[138,139]. The "epi-eudesmanes", *e.g. (130)* [(+)-occidentalol][135], and the chamaecynanes [nor-eudesmanes bearing an ethynyl group, *e.g. (131)*][136] have a *cis*-decalin structure. The same ring linkage as in (−)-selinanes [*e.g. (128)*], but with an opposing steric arrangement of the isopropyl group, is encountered in the agarofurans, *e.g. (123)*[144], and the derivatives of intermedeol *(127)*[141–143].

Atractylone *(125)*[145] is a representative of the furanoselinanes, a group that also includes the lindenanes, *e.g. (126)* (lindenene), which feature a tricyclic skeleton[146]. Approximately 50 sesquiterpene lactones are known to have the selinane-type structure (selinanolides ≡ eudesmanolides)[4,8]. In these compounds γ-lactone ring formation can occur between C-7 and either a 6α-hydroxyl group (santonins[1,2]) or, as in *e.g. (124)* (pulchellin B)[147], an 8β-hydroxyl group.

The selinanes can be regarded as biogenetic precursors for the formation of valeranone *(132)* *via* the cation *(133)*[148]. The valeranes, which are characterized by a *cis*-decalin skeleton, have so far only been found in *Valerianaceae*[148,149]. Two diastereomeric basic structures are known for the [4.5]spirocyclic agarospiranes which are biogenetically related to the selinanes by way of cation *(134)*; the two types are found in hinesol *(135)*[12,151] and agarospirol *(136)*[12,150,152] respectively. Just as the cedranes were derived from the [4.5]spirocyclic acoranes (Fig. 2), the zizaanes (≡ tricyclovetivanes), *e.g. (140)*, can also be regarded as being related to the agarospiranes *(135)*[137], whose biogenesis has been discussed in terms of (+)-γ-curcumene as precursor[153].

The eremophilanes (Figs. 1 and 7) having the basic structure of a 4,5-dimethyl-7-isopropyldecalin have been reviewed in detail[4]. Two sterically distinct types are known: compounds of the "eremophilone type", *e.g. (139)*, have all three side chains in a β-arrangement[154], whereas eremophilanes of the "nootkatone type", *e.g. (138)*, have α-methyl groups[152,155,156]. Both types arise biogenetically from selinanes *via* cations such as *(134)* and *(133)* which undergo a 1,2-shift of the tertiary methyl group[4,7,137,142,143,155]. A spirocyclic intermediate has also been invoked[157] for this biogenetic transformation. Biogenesis of the ishwaranes *(137)* may conceivably involve ring closure by way of the isopropyl group[158].

Eremophilanes, especially lactones (eremophilanolides), have frequently been found in the plants of the *Compositae* family[8]; compounds containing a furan ring (furanoeremophilanes, furanoeremophilanolides) are also encountered.

10. Maalianes and Aristolanes, Aromadendranes

The tricyclic maalianes and aristolanes (≡ calaranes)[159] (Figs. 1 and 8) possess a decalin skeleton with a fused cyclopropane ring. The aristolanes differ from the maalianes, in the same way as the eremophilanes from the selinanes, in the position of the tertiary methyl group. The maalianes (Fig. 8) are biogenetically accessible by cyclization of the cation *(7)* *via* bicyclogermacrene *(13)*

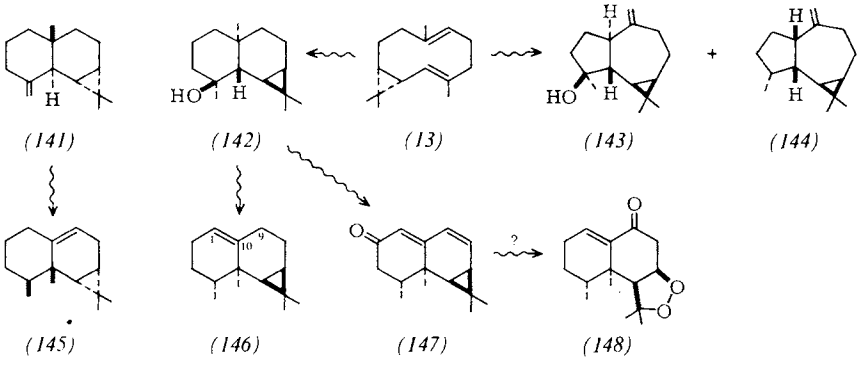

Fig. 8. Maalianes, aristolanes, and aromadendranes.

(Fig. 1)[55]. Apart from maaliol *(142)*[163], compounds are also known with an enantiomeric skeleton, *e.g. (141)* [(+)-γ-maaliene] which could be isolated from the gorgonian *Pseudopterogorgia americana*[164].

Just as the eremophilanes are formed from the selinanes, the aristolanes arise by a 1,2-methyl shift in the maalianes[20,143]. Their biogenesis is thought to proceed from the corresponding selinanes *via* ring closure to give the cyclopropane ring and a 1,2-methyl shift[137]. In addition to 1(10)-aristolene *(146)* (≡ calarene, β-gurjunene)[165] and 9-aristolene, which always occur together[143,159,160,162,166], further aristolane sesquiterpenes were subsequently isolated[160,161,167,168], including the ketone *(147)*[168] whose structure was recently discovered to apply also to the supposed selinane nardostachone[169]. The 1,2-dioxolane derivative nardosinone *(148)* from the valerian *Nardostachys chinensis*[170] is structurally and probably also biogenetically related to the aristolanes. α-Ferulene *(145)* and other enantiomeric aristolanes have likewise been found to occur naturally[164,171].

Both *trans* [*e.g.* spathulenol *(143)*] and *cis* fused compounds [*e.g.* alloaromadendrene *(144)*] are known in the tricyclic aromadendrane series[172]. Supporting evidence for the formation of these sesquiterpenes *via* bicyclo-

germacrene *(13)* is provided by the proton-catalyzed cyclization of this hydrocarbon to give the aromadendrane ledrene[58].

The Chemistry of Dichloromethylenammonium Salts[1] ("Phosgenimonium Salts")

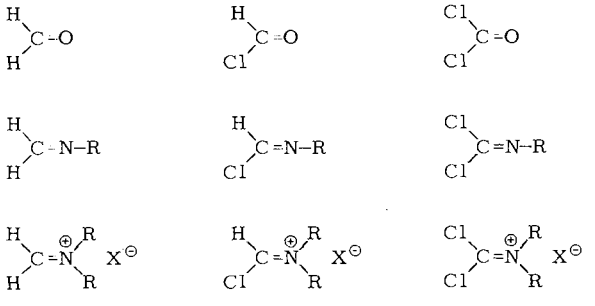
By Heinz Günter Viehe and Zdenek Janousek[*]

Dedicated to Professor Heinrich Hellmann

Dichloromethylenammonium salts, particularly dichloromethylenedimethylammonium chloride, occupy a unique place as stable but reactive building blocks for synthesis. They contain three mobile chlorine atoms activated by an amino group on the same carbon atom. These salts can be regarded as chlorinated Vilsmeier or Mannich reagents and are thus at a higher oxidation level. As in the Mannich or Vilsmeier reaction, the carbon condenses here as an electrophile with formation of C—C or C—hetero atom bonds in a variety that is still far from being exhausted.

1. Introduction

Whereas the chemistry of formaldehyde, the unstable formyl chloride, phosgene, and their imines[2] is well developed, the corresponding imonium salts, *i.e.* the dichloromethylenammonium salts *(3)*, were almost forgotten until the start of our investigations in 1969, though the first compound of this class, *N,N*-diethyl-*N*-dichloromethylenammonium chloride, was described as early as 1959[3].

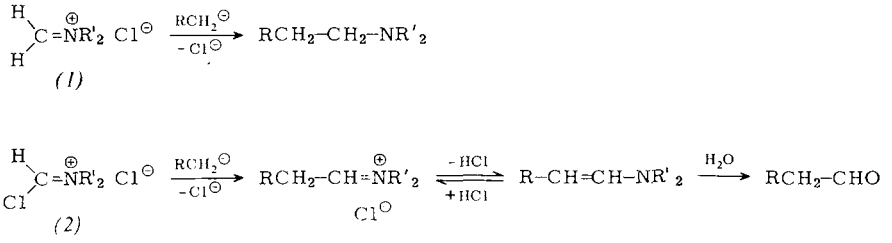


(1) *(2)* *(3)*

This neglect is the more surprising in that the high reactivity of the methylenammonium salts[4] *(1)* has been known for a long time through the Mannich reaction[5]. The chloromethylenammonium salts (Vilsmeier-Haack reagent[6a-6d] [*(2)*, $X^{\ominus}=PO_2Cl_2^{\ominus}$] and Arnold reagent[6e,6f] [*(2)*, $X^{\ominus}=Cl^{\ominus}$]) have also been in use for a long time, though the elucidation of their structures was achieved in part only a few years ago[6g,6h,7].

Mannich reagents *(1)*, as methylenammonium salts, react with nucleophiles by aminomethylation[5]. The Vilsmeier-Haack and Arnold reagents *(2)*, as chloromethylenammonium salts, give corresponding imonium compounds and particularly (by their hydrolysis) aldehydes.

Dichloromethylenammonium salts with tertiary nitrogen are relatively easily obtainable, some even commercially[14]. Dichloromethylenammonium salts with secondary and primary nitrogen can be prepared at least *in situ* from dichloromethylenamine and cyanogen chloride



(1)

Place Louis Pasteur, 1, B 1348 Louvain-La-Neuve

[cf. *(18)* and *(19)* in Section 2]. These salts are generally strongly electrophilic reagents, which may be compared with the methylenammonium and chloromethylenammonium salts (Mannich reagents and Vilsmeier-Haack and Arnold reagents).

Dichloromethylenammonium salts can substitute the two mobile chlorine atoms and can also react *via* the double bond. Monocondensation leads *e.g.* to amide chlorides *(4)* and their further reaction products such as α-chloroalkenylamines *(5)* and ketene imonium salts *(6)*[8], alkynylamines *(7)*[9a], 1,1-diamino-1-alkenes *(8)*[9b], amidines *(9c)*[9c], and acid and carboxamide derivatives. By dicondensation or tricondensation, *C*-substituted methylamines may be obtained[9d], or else C=N double bonds are formed. For example, cyanamides and the chloroformamidines *(10)* and their salts are formed in this way. Above all, cyclizations become possible, particularly those leading to amino-substituted heterocycles and their derivatives.

Practically all the reactions carried out so far with dichloromethylenammonium salts have yielded new reagents with a value of their own, which will ensure the rapid development of the hitherto neglected chemistry of the dichloromethylenammonium salts (see Table 1).

The neglect of the dichloromethylenammonium salts was due either to their incorrect formulation as trichloromethylamines[3] or to the fact that they were wrongly described as explosive in a review in 1965[10], evidently because of an error in translation from the Russian (the strongly exothermic hydrolysis to diethylcarbamoyl chloride had been described as the only reaction in the Russian article[3]).

The present article gives a review of this preparatively useful class of compounds, which we originally examined only in order to obtain amide chlorides by a combination of condensation and elimination reactions and also to obtain α-chloroalkenylamines and alkynylamines. In the course of the last three years, however, the aim of our investigations has changed in accordance with the richness of the reaction potential of the dichloromethylenammonium salts. It was useful here to know the analogous reactions of the methylenammonium salts, which were largely investigated by *Böhme*, and of the chloromethyl-

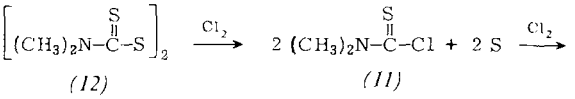
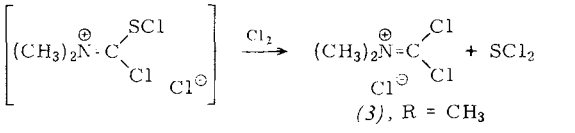
enammonium salts, whose investigation is due in particular to *Arnold* and to *Bredereck*'s school[11], the main contribution of which was the activation of the amides by salt formation. Our own earlier investigations on amide chlorides, α-chloroalkenylamines[12], and alkynylamines[9a], which, particularly with regard to the amide chlorides, was based on work by *Eilingsfeld*, *Weidinger*, and *Seefelder*[13], have helped to acquire the data now available.

2. Synthesis and Characterization of the Dichloromethylenammonium Salts[19, 21a]

The simplest and at present the best synthesis of *N*-dichloromethylene-*N*,*N*-dimethylammonium chloride *(3)*, R = CH_3, which is now commercially available[14], is the chlorination of *N*,*N*-dimethylthiocarbamoyl chloride *(11)* or of the corresponding dithiuram *(12)*[3, 10, 15–17].

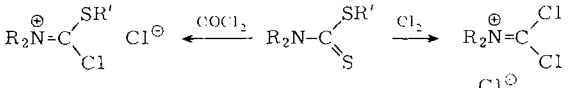


(12) *(11)*



(3), R = CH_3

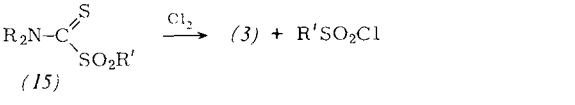
It is well known that *N*,*N*-disubstituted dithiocarbamic esters *(13)* give the salts *(14)* with phosgene, thionyl chloride, or phosphorus pentachloride[18].



(14) *(13)* *(3)*

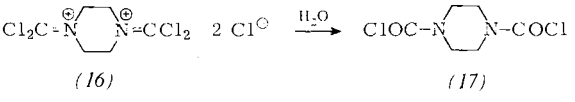
We have found that the readily obtainable dithiocarbamates *(13)* react with chlorine to give *(3)* in very good yields[19].

C-Sulfonylthioformamides *(15)* also give *(3)* on chlorination[20].



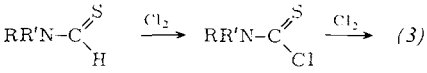
(15)

The first bis(dichloromethylenammonium) salt *(16)* is now also known[19]. Its hydrolysis yields *N*,*N'*-bis(chlorocarbonyl)piperazine *(17)*.



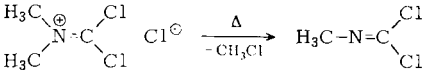
(16) *(17)*

A chemically more elegant route is the chlorination of thioformamides to dichloromethylenammonium salts; the intermediate thiocarbamoyl chlorides need not be isolated[16a]. This shows particularly clearly the relationship with the Vilsmeier and Arnold reagents, which are formed from formamides.



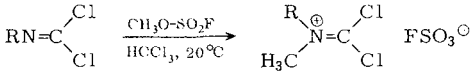
(3)

There is also a close synthetic relationship with the phosgenimines, which have been investigated in particular by *Kühle*[2], and which *Holtschmidt et al.*[15, 21b] have made available by high-temperature chlorination. The phosgenimines are formed by thermal decomposition of *(3)* above 100 °C[19, 21a].

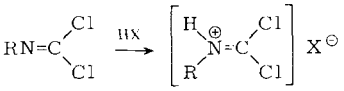


(3), R = CH_3

This reaction can be reversed if methyl fluorosulfates are used for the alkylation of phosgenimines[19]. Less active alkylating agents such as dimethyl sulfate are unsuccessful.

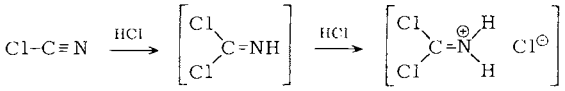


An observation of synthetic interest is that the phosgenimines also form intermediate or acid-isolable dichloromethylenammonium salts *(18)* with a hydrogen atom and an alkyl group on the nitrogen.



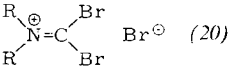
(18)

The simplest dichloromethylenammonium salt *(19)*, with only hydrogen on the nitrogen apart from the dichloromethylene group, is apparently formed as an intermediate in the reaction of cyanogen chloride with hydrogen chloride[22].



(19)

This provides above all dichloromethylenammonium salts that can be converted into primary, secondary, or tertiary amines. The trifluoromethylamines *(21)*[16b, 23] and the as yet unknown mixed chlorofluoromethylenammonium salts will also be of interest, whereas the dibromomethylenammonium salts *(20)*, unlike the apparently unstable iodine derivatives, are obtainable but are found to be much less reactive, probably on steric grounds.



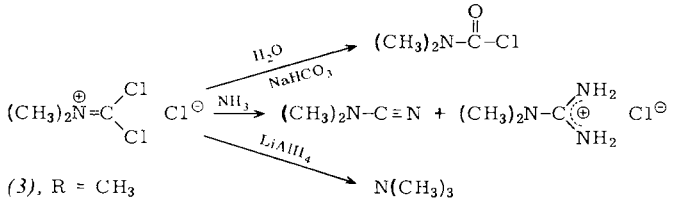
(20)

The salt nature of the dichloromethylenammonium compounds *(3)* is manifested physically in the weak solubility of the lower members of the series in apolar solvents. However, the *N,N*-diethyl derivative can already be recrystallized from dichloromethane or chloroform. Unlike the trifluoromethylamines *(21)*, which are also readily obtainable from *(3)* by reaction with HF or KF[23e], dissolve

$$(3) \xrightarrow[-3\ HCl]{3\ HF/KF} R_2N{-}CF_3 \quad (21)$$

in most solvents, and can be distilled, the dichloromethylenammonium salts show no evidence of the presence of a covalent trichloromethylamine structure. The NMR spectrum shows only one type of compound, *i.e.* that with the ammonium salt structure. In deuterionitromethane, which reacts only slowly with *(3)*, $R = CH_3$, at room temperature[24][*], a sharp singlet is observed at $\tau = 4.07$ ppm. In paraffin suspension, the stretching vibration of the methylenammonium grouping is found at 1625 cm^{-1}.

Chemical evidence of the ammonium salt structure is provided not only by thermolysis but also by hydrolysis, which, in the presence of sodium hydrogen carbonate, can be stopped at the carbamoyl chloride stage or continued to the dialkylammonium chloride, HCl, and CO_2. Reaction of *(3)*, $R = CH_3$, with ammonia leads by "triple condensation" to dimethylcyanamide as well as *N,N*-dimethylguanidinium chloride, and nucleophilic substitution of all three chlorine atoms by hydrogen can be achieved



[*] From monosubstituted nitromethane derivatives, nitriles are formed as end products. Cf. *J. Skramstad*, Acta Chim. Scand. *24*, 3424 (1970).

Dichloromethylenammonium salts and methods for their synthesis are shown in Table 2.

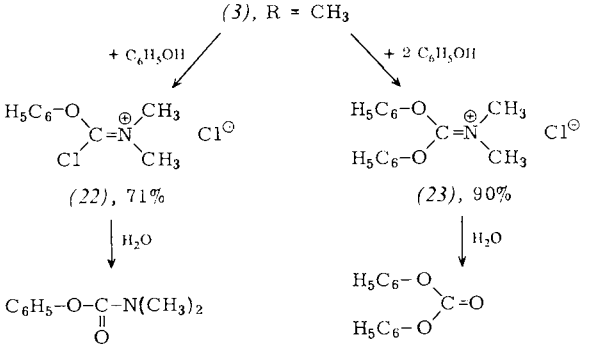
3. Reactions of Dichloromethylenammonium Salts with Hydroxy and Amino Functions

3.1. Reactions with Phenols, Alcohols, and Glycols

Phenol[26] reacts smoothly with dichloromethylenammonium salts at room temperature to form the monosubstitution product *(22)*, while heating for 30 minutes under reflux in methylene chloride with a further equivalent of phenol results in disubstitution to form the diphenoxymethylenammonium salts *(23)*, which are stable to excess phenol.

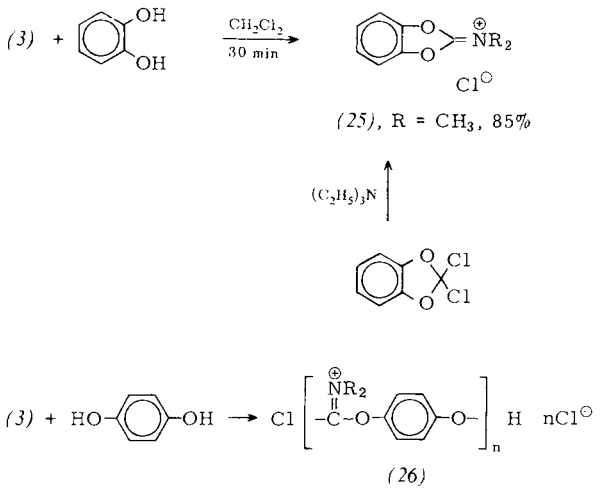


$$(23) \xrightarrow[-CH_3Cl]{140\,^{\circ}C} \begin{matrix} H_5C_6{-}O \\ H_5C_6{-}O \end{matrix}\!\!>\!C{=}N{-}CH_3 \quad (24),\ 91\%$$

They hydrolyze readily to give the diphenyl carbonates, which have been known for some time, and pyrolysis with loss of chloromethane leads in good yields to the iminocarbonates *(24)*.

Thiophenol gives the thio derivatives of *(22)* and *(23)* in yields of 97 and 99% respectively[27].

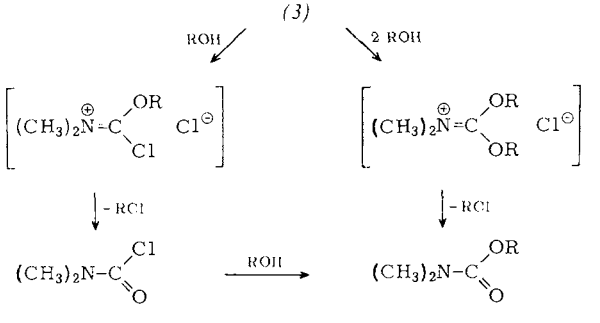
Resorcinol and hydroquinone also react smoothly with *(3)*, R = CH_3, the products being a cyclic [*(25)*] and a polymeric ammonium compound [*(26)*] respectively.



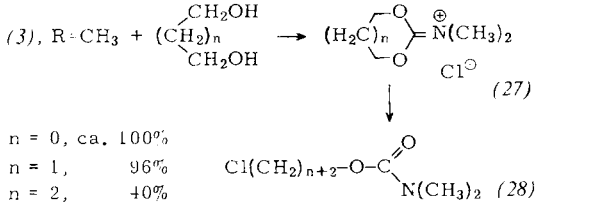
(25), R = C_2H_5, was synthesized earlier from 2,2-dichlorobenzo-1,3-dioxole and triethylamine[28].

In this reaction, *(3)* behaves differently from the methylenammonium and chloromethylenammonium salts, which mostly react with *C*-substitution instead of with *O*-substitution[6c, 29]. *(3)* thus condenses in a similar manner to phosgene.

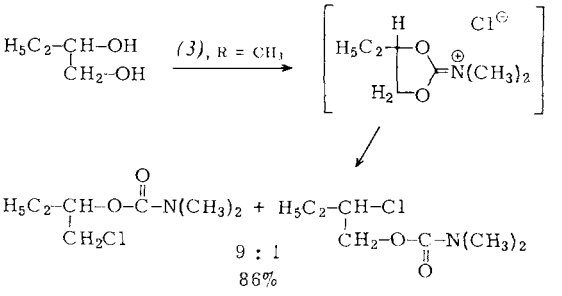
Alcohols react with *(3) via* the mono- or dialkoxymethylenammonium salts to form alkyl chlorides and carbamoyl chlorides and/or carbamates.



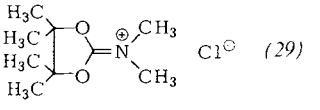
Whereas more detailed investigation of the mechanism of this reaction is still necessary, the study of the reactions of *(3)* with glycols has come to a temporary conclusion. It was found that 1,2-, 1,3-, and even 1,4-diols give ω-chloroalkyl *N,N*-dialkylcarbamates *(28)* stereospecifically and in high yields[30].



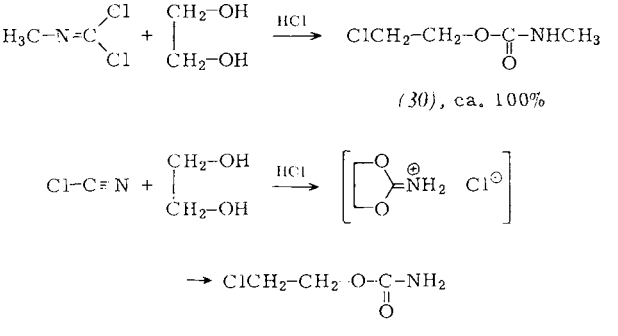
Unsymmetrical glycols give preferentially the derivatives in which the chlorine has substituted the sterically less hindered hydroxyl group[30].



As is shown by the smooth formation of *trans*-chlorocyclohexyl carbamate from *cis*-1,2-cyclohexanediol, the cyclic ammonium salts *(27)* are formed as intermediates by an S_N2 mechanism, and these undergo ring cleavage by nucleophilic substitution with the chloride ion. A similar conclusion is indicated by the observation that the reaction of *(3)* with sterically hindered diols stops at the stage of cyclic compounds of this type. Thus the ammonium salt *(29)* formed from pinacol does not undergo ring cleavage even when heated[30].

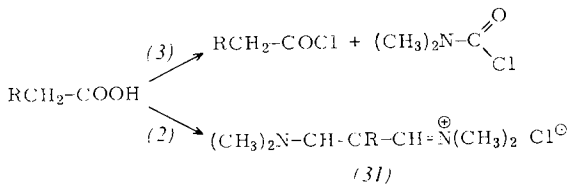


It is interesting to note that dichloromethylenamines react even at room temperature with glycols in the presence of HCl (apparently *via* the ammonium salts) to form ω-chloroalkyl carbamates *(30)* with secondary amide nitrogen[30]. The corresponding reaction of cyanogen chloride was already known[22a].



3.2. Reactions with Carboxylic Acids

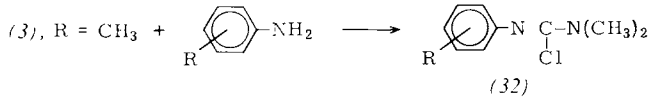
Carboxylic acids are converted into the acyl chlorides by *(3)* under very mild conditions without further condensation with methylene groups in the α position[21a]. The dichloromethylenammonium salts differ in this respect from Vilsmeier and Arnold reagents *(2)*, which are converted by condensation and decarboxylation into cyanines *(31)*[31]. This reaction probably proceeds *via* ketene intermediates[32].



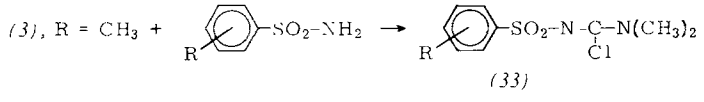
(31)

3.3. Reactions with Amines

The condensation of (3), R = CH_3, with ammonia to form dimethylcyanamide was mentioned in Section 2. Reaction with primary amines leads smoothly to the expected chloroformamidines (32) or their hydrochlorides. It is interesting to note that even such weakly basic amines as sulfonamides and 2,4-dinitroaniline react smoothly. The results are listed in Table 3.



(32)

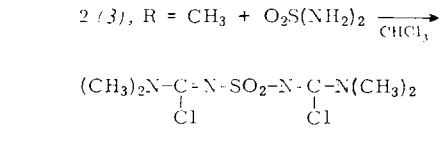


(33)

Table 3. Chloroformamidines (32) and N^2-sulfonylchloroformamidines (33) prepared from dichloromethylenedimethylammonium chloride (3), R = CH_3.

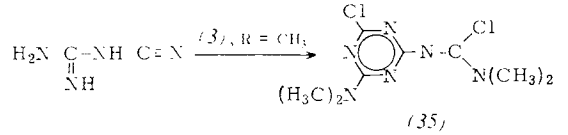
	Yield [%]	B.p. [°C/torr] M.p. [°C]	Ref.
(32), R = H	67	81/0.5	[21a]
(32), R = p-$CO_2C_2H_5$	96	65	[26]
(32), R = p-NO_2	80	102	[26]
(32), R = 2,4-$(NO_2)_2$	87	97	[26]
(33), R = H	94	65—66	[21a]
(33), R = p-CH_3	76	152—154	[17, 33]
(33), R = p-Cl	85	143	[17, 33]

Sulfamide gives the bis(chloroformamidine) (34)[33], m.p. 127—128 °C.



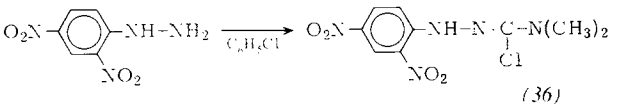
(34), 97%

1-Cyanoguanidine gives the 1,3,5-triazine derivative (35), m.p. 105—107 °C, in a yield of 81%[21a].



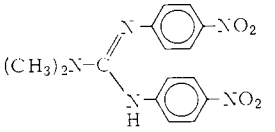
(35)

2,4-Dinitrophenylhydrazine reacts with (3), R = CH_3, to form the hydrazone (36) of *N*,*N*-dimethylcarbamoyl chloride, 87% yield, m.p. 198 °C (dec.)[21a].



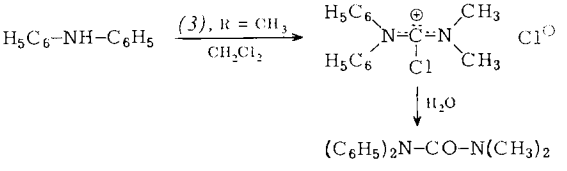
(36)

Guanidines of the type (37) have been synthesized from (3), R = CH_3, and 2 moles of *p*-nitroaniline[17].

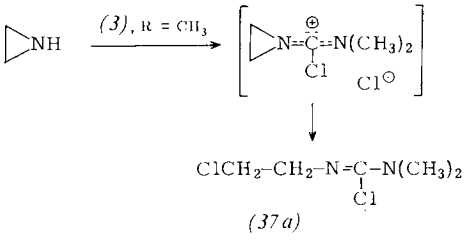


(37), 58%

Secondary amines react with (3) to form urea dichlorides. Even diphenylamine reacts smoothly at 40 °C with practically quantitative yields[21a]. Dimethyl-*N'*,*N'*-diphenylurea was obtained by hydrolysis, 83% yield, m.p. 65 °C.



Ethylenimine (aziridine) gives (37a) as a rearrangement product[27].



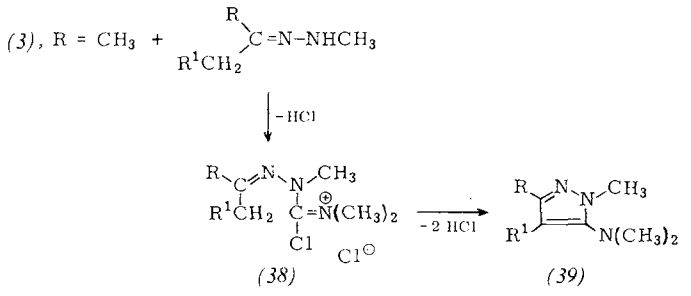
(37a)

Unlike phosgene, (3) reacts with tertiary amines simply with complex formation in most cases and without degradation. For this reason, *e.g.* triethylamine can be used as a basic catalyst in CH condensation reactions, which are discussed in Section 6.

4. Heterocyclizations with Dichloromethylenammonium Salts

4.1. Reactions with Hydrazones, Phenylhydrazines, Hydrazides, and Amidrazones

Hydrazones react with (3), R = CH_3, to form the 1,3,4-trisubstituted 5-dimethylaminopyrazoles (39). The semicarbazone dichlorides (38) can be intercepted as intermediates. When heated in chloroform solution or in the absence of solvent they cyclize[34] (Table 4).



(38) (39)

Table 4. 5-Dimethylamino-1-methylpyrazoles *(39)* prepared from hydrazones and *(1)*.

R	R^1	Yield [%]

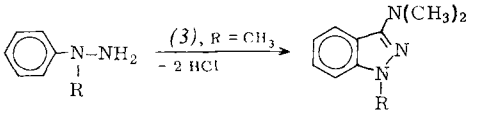
—$(CH_2)_4$—		81
—$(CH_2)_5$—		84
—$(CH_2)_6$—		84
—*o*-C_6H_4—CH_2CH_2—		76

The dialkylaminoindazoles *(40)* are formed similarly from phenylhydrazines[35]; hydrazides react with *(3)*, R = CH_3, to form 1,3,4-oxadiazoles *(41)* (Table 5). The reaction of amidrazones with *(3)*, R = CH_3, yields the 1,2,4-triazole derivatives *(42)*, of which two examples [*(42a)* and *(42b)*] are given, while heterocyclization to form five-membered rings occurs with *o*-phenylene derivatives (diamines, diols, hydroxyamines)[35,18a].



(40); R = C_6H_5, 83%

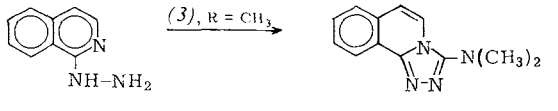
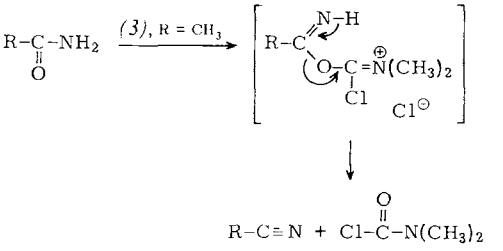
(42a), 95%



(42b), 89%

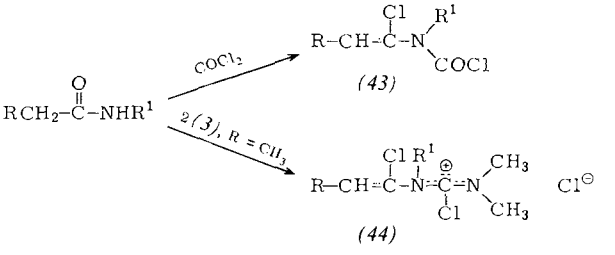
5. Reactions of Dichloromethylenammonium Salts with Primary and Secondary Acetamides

Primary amides react smoothly with *(3)*, R = CH_3, to form nitriles. Dichloromethylenammonium salts thus act merely as dehydrating agents here.



Secondary acetamides having a methylene group α to the carbonyl group react with *(3)* with *N*-acylation and also with replacement of the amide oxygen by chlorine.

Comparison of this reaction, which leads to *N*-(1-chloro-1-alkenyl)chloroformamidinium salts *(44)*[36] (Table 6), with the reaction of phosgene[37] again shows the close relationship between the two reagents.



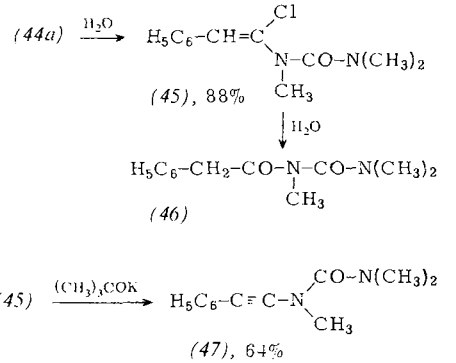
(43)

(44)

Table 6. *N*-(1-Chloro-1-alkenyl)-*N'*,*N'*-dimethylchloroformamidinium chlorides *(44)* prepared from N secondary acetamides and *(1)*.

(44)	R	R^1	Yield [%]	M.p. [°C]
(a)	C_6H_5	CH_3	97	82–85
(b)	Cl	CH_3	85	154
(c)	—$(CH_2)_4$—		86	liq.
(d)	H	CH_3	90	liq.

Hydrolysis of *(44a)* leads first to the *N*-(α-chlorostyryl)-urea *(45)* and then to the *N*-acylurea *(46)* (71% yield, b.p. 135 °C/0.2 torr)[36].

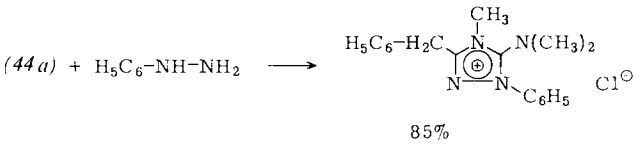


(46)

(47), 64%

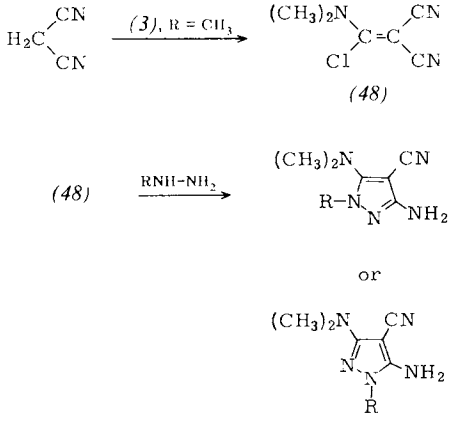
Dehydrochlorination both of *(45)* and of *(43)* leads readily to derivatives of the previously practically uninvestigated alkynylamides, *e.g. (47)*[36,38,39].

(43) and *(44)* can also be used as 1,3-di-electrophiles for heterocyclization reactions[38,59].

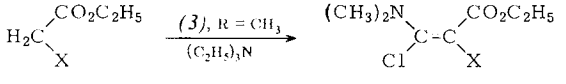


6. CC Bonds Between Activated Methylene Groups and Dichloromethylenammonium Salts

Of all the malonic acid derivatives, malodinitrile reacts most readily with *(3)*[21a]. Heating under reflux in chloroform for 30 minutes gives 2-chloro-2-(dimethylamino)ethylene-1,1-dicarbonitrile *(48)* (b.p. 180 °C/0.5 torr) in 77% yield[21a,40b]. The product promises to become a useful heterocyclization reagent, as is shown *e.g.* by the reaction with phenylhydrazine[40a].



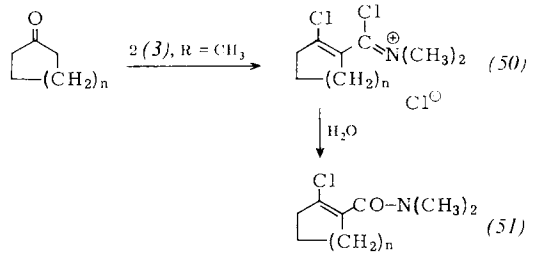
Cyanoacetic ester reacts only slowly with *(3)* without the addition of triethylamine, while malonic diester requires the base for condensation in any case. In the presence of triethylamine, both give good yields of the 2-amino-2-chloroethylene derivatives *(49)*[21a,40,42].

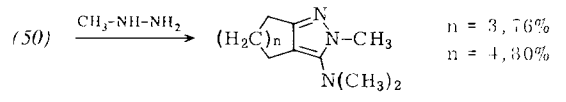


(49a), X = $CO_2C_2H_5$, 70%
(49b), X = CN, 85%

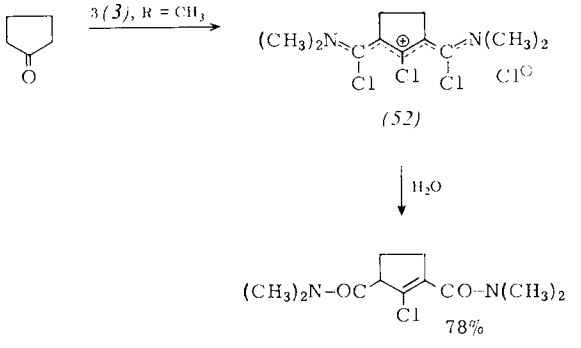
7. Condensation Reactions of Dichloromethylenammonium Salts with Ketones

Whereas phosgene usually reacts with ketones only if the latter have first been converted into the enolates[41], dichloromethylenammonium salts in many cases condense extremely readily with ketones. Thus the higher cycloalkanones give almost quantitative yields of the β-chloroacrylamide derivatives *(50)*[42], which can be readily hydrolyzed to the amides *(51)* and can be used as 1,3-di-electrophiles for numerous heterocyclizations[43] [*(50)*, $n=2$, 98%; $n=3$, 88%; $n=4$, 90%; *(51)*, $n=2$, 72%, b.p. 99 to 102 C/0.6 torr; $n=3$, 87%, b.p. 130 C/0.6 torr; $n=4$, 75%, b.p. 140 C/0.6 torr].

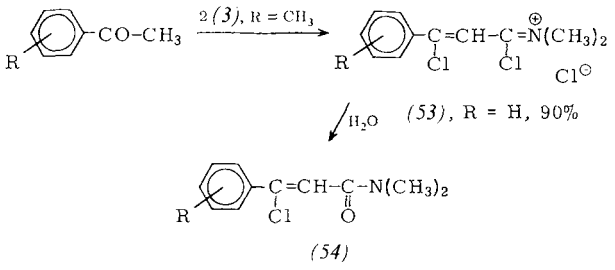




Cyclopentanone reacts with three moles of *(3)* to give a red pentamethinecyanine *(52)*, $\lambda_{max}=536$ nm; cyclobutanone (according to preliminary experiments) behaves similarly[42].

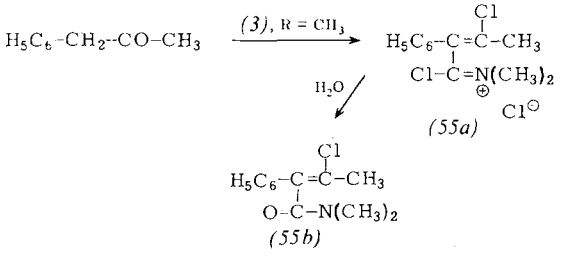


Comparison of the Vilsmeier-Haack and Arnold reagents *(2)*[44,45] with the dichloromethylenammonium salts *(3)* again shows the greater reactivity of the compounds *(2)*, which always react with dicondensation or polycondensation. Steric and electronic factors evidently have a combined deactivating effect in the dichloromethylenammonium salts. The strong dependence of the reaction on steric effects is also seen in the behavior of the dichloromethylenammonium salts toward acetophenone and propiophenone. Only acetophenone reacts smoothly to form the *N,N*-dimethylcinnamamide derivative *(53)*[21a], whereas propiophenone condenses with the Vilsmeier reagents[46] but not with dichloromethylenammonium salts. Hydrolysis of *(53)* leads to the β-chlorocinnamamide derivative *(54)*, whose dehydrochlorination readily yields the phenylpropiolamide derivative. The ring-substituted derivatives of acetophenone behave in the same way as acetophenone itself toward *(3)*[21a]. Pinacolone and even isopropyl methyl ketone are apparently too strongly hindered and do not react with *(3)*. [*(54a)*, R=H, 70%, b.p. 165 °C/0.2 torr; *(54b)*, R=*p*-Cl, m.p. 65—68 °C; *(54c)*, R=*p*-NO_2, m.p. 108—111 °C; *(54d)*, R=*m*-NO_2, m.p. 78 °C].

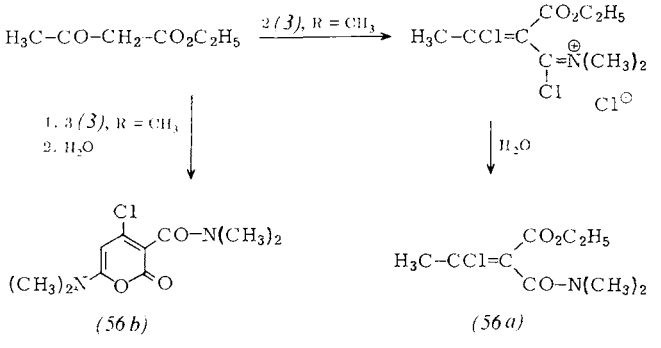


(54)

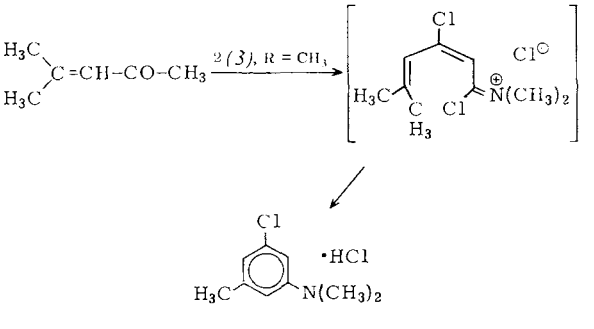
Benzyl methyl ketone reacts with *(3)*, R = CH_3, to form *(55a)*, which gives the methylacrylamide *(55b)*, b.p. 138 C/0.15 torr, in 75% yield on hydrolysis[42].



Reaction of three moles of *(3)* with acetoacetate gives not only the isolable monocondensation product *(56a)* (27% yield, b.p. 100 C/0.2 torr) but also the α-pyrone derivative *(56b)* (20% yield, m.p. 150—151 C, λ_{max} = 370 nm, ε = 33400).



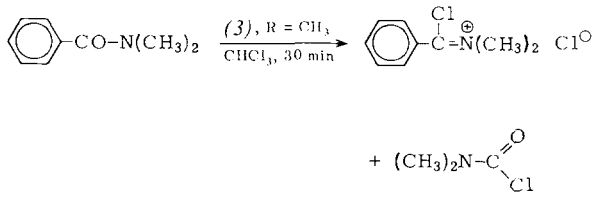
Mesityl oxide also reacts with double condensation and ring closure to form a benzene derivative [m.p. 204 C (dec.)][21a].



In view of these reactions with ketones, it is surprising that the aldehydes investigated so far do not react with dichloromethylenammonium salts with formation of a new CC bond, but undergo substitution of the aldehyde oxygen by chlorine. To explain this difference in behavior we assume that it is due to differences in the tendency to enolize and/or to steric effects.

8. Reactions of Dichloromethylenammonium Salts with Tertiary Amides

Tertiary amides have a nucleophilic oxygen atom, which is replaced by chlorine on reaction with *(3)*. Thus reaction of *N*,*N*-dimethylbenzamide with *(3)* leads readily to the amide chloride (yield 90%). Phosgene also reacts, but much more slowly[47]. The amide chloride formation merits more detailed investigation in connection with the substitution of oxygen functions by chlorine (alcohols, glycols, aldehydes, epoxides, and carboxylic acids).



So far we have studied mainly tertiary acetamides with an α-CH_2 group. Their reactions with phosgene were known to us from earlier work[12]. The amide chloride formation is followed in some cases by condensation with phosgene, though usually only in moderate yields. On the other hand, dichloromethylenammonium salts react smoothly to form the long-sought dichlorotrimethinium salts *(57)* (Table 7), which may be regarded as bis(amide chlorides) of malonyldiamides[21a, 49, 50]. Comparison with malonic acid derivatives also shows the possibility of using the compounds *(57)*, which are now readily obtainable, for the synthesis of bis(dialkylamino) heterocycles (cf. Sec-

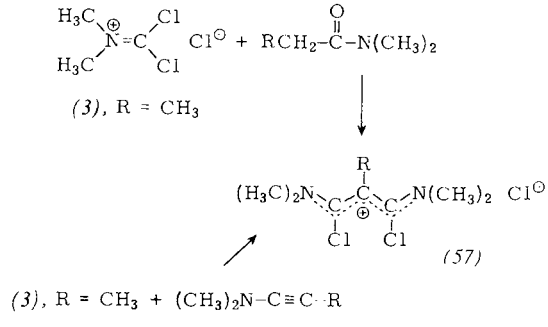


Table 7. Dichlorotrimethinium salts *(57)* prepared from N tertiary acetamides and *(1)*.

R	Yield [%]	UV (CH_2Cl_2) λ_{max} [nm]	Ref.

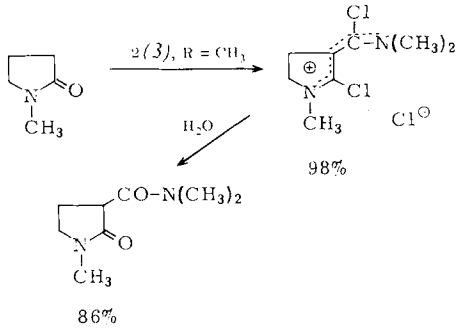
OC_6H_5	99	406	[50]

tion 9). The compounds *(57)* are also obtainable in practically quantitative yield by addition of *(3)* to alkynylamines[48].

As was to be expected, cyclic tertiary amides also couple with *(3)*[21a].



These cyanines are characterized chemically by hydrolysis, thiolysis, and aminolysis to derivatives of malonamides *(58)*, malonthioamides *(59)*, and malonamidines *(60)*[49]; these reactions are the simplest syntheses of these compounds known at present (Table 8).

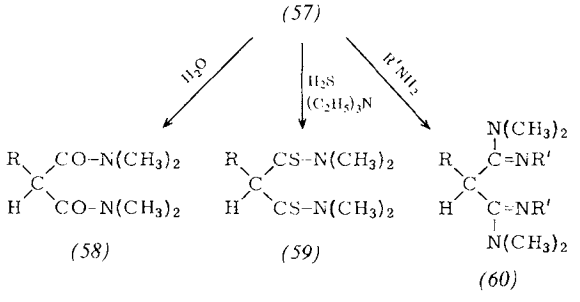


Table 8. Malonamides *(58)*, malonthioamides *(59)*, and malonamidines *(60)* prepared from *(57)*.

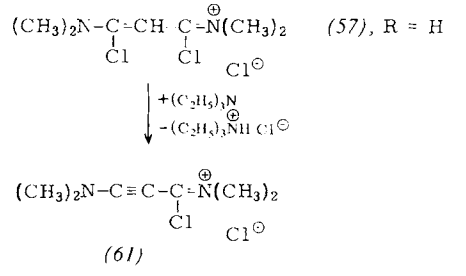
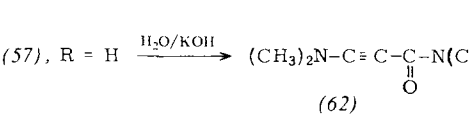
Cpd.	R	Yield [%]	M.p. [°C] b.p. [°C/torr]
(58)	C_2H_5	75	76
(58)	Cl	73	92
(58)	C_6H_5	78	149
(59)	H	70	107
(59)	C_2H_5	83	178
(59)	C_6H_5	55	193
(60)	H, R′ = CH_3	61	75/0.5



(57), R = H

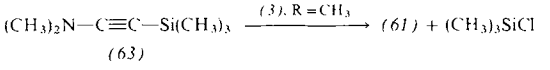


(61)

(62)

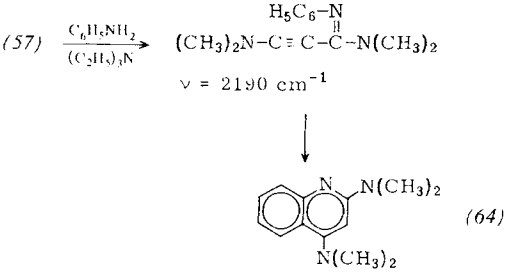
The 3-aminopropynylenammonium salt *(61)* [IR: ν = 2212, 2243 cm^{-1}] is obtainable from *(57)*, R = H, and triethylamine[21a]; reaction with aqueous alkali yields 3-dimethylaminopropiolamide *(62)*[51, 21a].

The compound *(61)* is also readily obtainable from the silylalkynylamine[52] *(63)* and *(3)*[53a], but trimethylsilyl chloride is formed as a by-product in this case.



(63)

With alkaline hydrogen sulfide, the malondithioamide *(59)* is obtained directly from *(57)*. The behavior of aniline is interesting, as it reacts readily with *(57)* to form 2,4-bis-(dimethylamino)quinoline *(64)*[53b–53d].



(64)

Secondary amines react with *(57)* to form the tetrakis(dialkylamino)allenium salts *(65)*. These are stable to hydrolysis and can be easily isolated as perchlorates or chlorides. *(65)* may be regarded as salts of tetrakis(dialkylamino)allenes *(66)*. The latter are in fact obtained from *(65)* by treatment with butyllithium or sodamide. The compounds *(66)* merit investigation as electron-rich allenes[21a, 54] (Table 9).

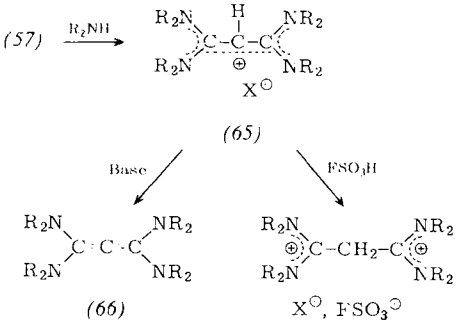


Table 9. Allenium salts *(65)* and allenes *(66)* prepared from *(1)* *via* *(57)*.

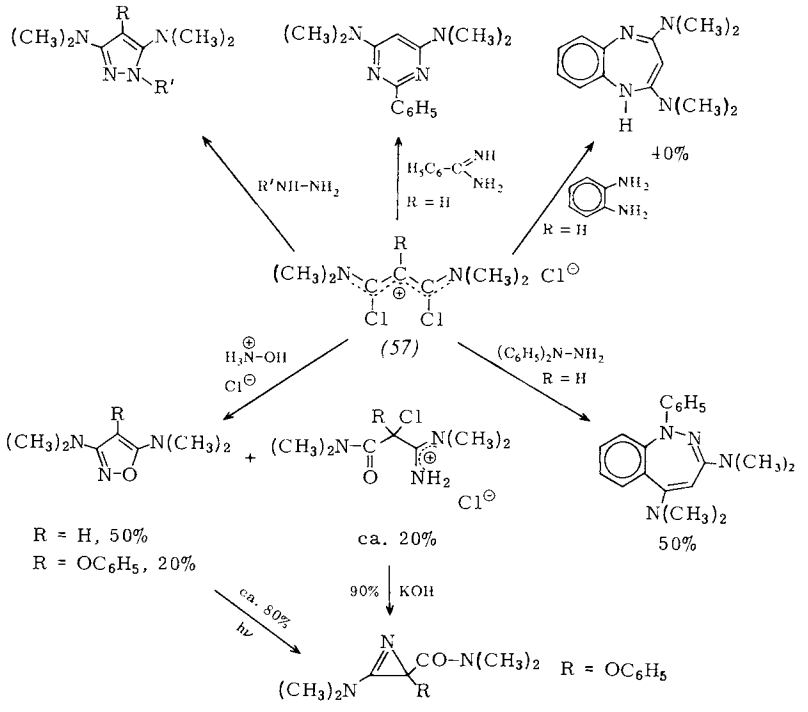
Cpd.	R	X	Yield [%]	M.p. [°C] B.p. [°C/torr]
(65a)	CH_3	ClO_4	85	174
(65b)	C_2H_5	Cl	91	liq.
(66)	C_2H_5		70	120/0.5

9. Heterocyclizations with Dichlorotrimethinium Salts *(57)*

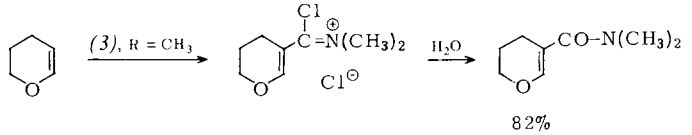
A number of heterocyclizations have been carried out with *(57)* (cf. Section 8)[58]. The compound may be

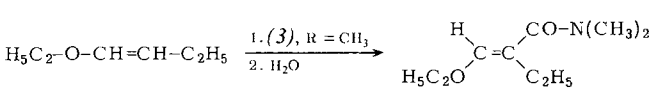


regarded as a vinylogous dichloromethylenammonium salt, like the condensation products of ketones and *(3)*, and it may therefore be expected that the cyclizations that are possible with *(3)* should also be possible with *(57)*, though rings containing two additional atoms would result. The scheme above shows the formation of five-membered and seven-membered heterocycles. We merely mention that in an attempt to synthesize an isoxazole, an azirine was also formed by free-radical side reactions[55].

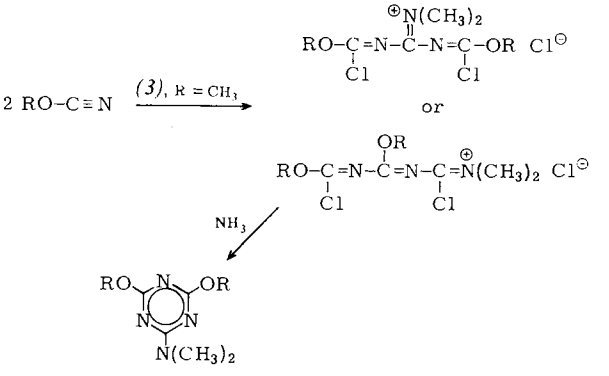
10. Addition of Dichloromethylenammonium Salts to Multiple Bonds

Electron-rich double and triple bonds undergo addition with *(3)*, and in the presence of β-hydrogen, this may be followed by elimination of HCl. *(3)* adds to vinyl ethers; subsequent hydrolysis leads to unsaturated carboxamides[21a].



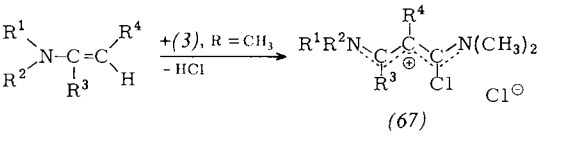


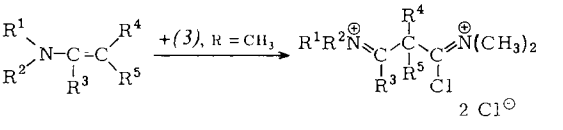
The addition of *(3)* to alkynylamines was mentioned in Section 8. Similar behavior is observed with electron-rich nitriles such as alkylcyanamides (see Section 12) and cyanates. The directiospecificity in the diaddition of cyanates has not been investigated in detail[56].



11. Reactions of Dichloromethylenammonium Salts with Alkenylamines

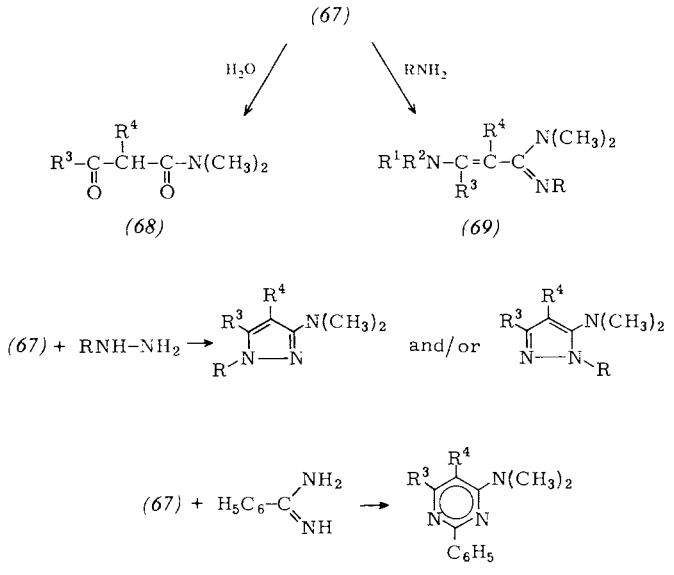
As electrophilic reagents, dichloromethylenammonium salts add readily to alkenylamines in the same way as phosgene[56].





The resulting trimethinecyanines *(67)* are useful reagents[57]. Hydrolysis yields tertiary β-keto amides *(68)*, while aminolysis leads to 3-aminoacrylamidines *(69)*.

As di-electrophiles, the compounds *(67)* condense readily with dinucleophiles, *e.g.* hydrazines and amidines.



12. Addition of Dichloromethylenammonium Salts to Cyanamides[48]

This reaction gives azacyanines *(70)* in very good yields (Table 10).

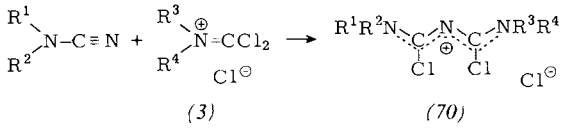


Table 10. Azacyanines *(70)* prepared with *(1)*.

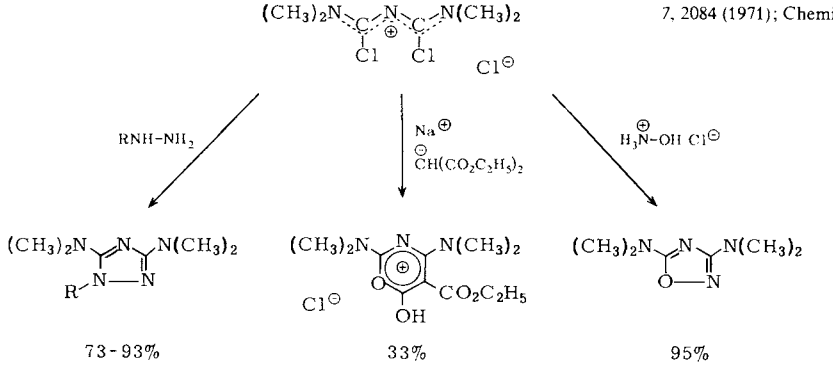
R^1	R^2	R^3	R^4	Yield [%]	λ_{max} [nm]	Ref.
CH_3	CH_3	CH_3	CH_3	93	282	[48]
CH_3	CH_3	CH_3	C_6H_5	93	285	[25]
CH_3	CH_3	CH_3	$CH_2C_6H_5$	96	286	[25]
$CH_2C_6H_5$	CH_3	CH_3	$CH_2C_6H_5$	92	289	[25]

Heterocyclizations similar to those carried out with the trimethinecyanines *(57)* are also possible with the azacyanines, *e.g. (70)*, $R^1=R^2=R^3=R^4=CH_3$[59].



We are grateful to Prof. Dr. H. Pommer and to BASF for material assistance, as well as to Prof. Dr. J. Mathieu, Roussel Uclaf/Paris. We thank Prof. Dr. J. E. Dubois and the Université de Paris for a grant.

Syntheses of Seven- and Five-Membered Rings from Allyl Cations

By H. M. R. Hoffmann[*]

The cycloaddition of allyl cations to conjugated dienes offers an efficient and general tool for the construction of seven-membered carbocycles. The silver salt route is highly suitable for generating allyl cations and can be used even in most difficult cases, *i. e.* for elusive and intractable allyl cations such as 2-methylallyl, 2-methoxyallyl, and the parent allyl cation. Cycloadditions to the 2-methoxyallyl cation come very close to the prototype of a 6π,7C reaction, since the carbonyl group introduced into the new ring can either be used for further transformations or be removed altogether. The combination of an allyl cation with π reactants, especially conjugated dienes, is a powerful and strongly convergent synthetic method since it permits one-step assembly, from a C_3 and a C_4 unit, of a cluster of up to four chiral centers in a ring which is larger than six-membered. Allyl cations combine with electron-rich 2π systems to form novel five-membered rings. The nature of the organometallic intermediates has been elucidated in many cases.

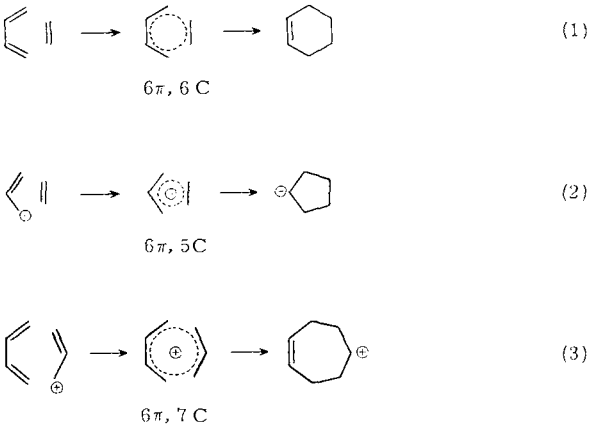
1. Introduction

Of the trilogy of cycloadditions involving 6π electrons (Scheme 1) the Diels-Alder addition [eq. (1)] discovered more than forty years ago, has remained perhaps one of the best known and most useful reactions of organic chemistry[1]. Similarly, since its general conception by *Huisgen* in the late 1950's the 1,3-dipolar addition [eq. (2)] has been firmly established and opened a standard route to a wide range of five-membered heterocycles[2]. Of course, on entropy grounds, both five- and six-membered rings are formed readily, also by various other routes, and indeed are abundant in Nature.

In contrast, seven-membered carbocycles have been much harder to come by and until recently only specialized procedures such as ring contraction and expansion sequences have been employed. While the combination of an allyl cation with a conjugated diene [eq. (3)] had been shown to be feasible, the reaction was considered a curiosity without practical interest and did not attract any general attention.

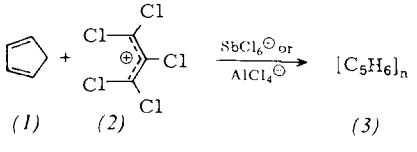
It is worth while to bear in mind that allyl systems as such have held a key position in the history of organic chemistry and, notably in the hands of *Ingold* and *Winstein*, have contributed to the evolution of concepts such as mesomerism, tautomerism, and ion pairs[3]. More recently, the enormous amount of solvolytic work has been complemented by a study of long-lived allyl cations, which were investigated in highly acidic media and also relatively weak acids such as concentrated sulfuric acid[4].

However, it is now clear that neither of the two experimental extremes employed in the past are of much use in synthetic work. Specifically, an allyl cation generated solvolytically appears to be too short-lived and to react preferentially with the solvent, whereas the highly acidic media required for observing carbocations at equilibrium preclude the coexistence of many and potentially more interesting reaction partners[5].



Scheme 1. Cycloadditions involving 6π electrons.

Interestingly, stable allyl cations can cause problems even if they can be handled in solvents which are inert to conjugated dienes. For instance, attempts to combine the long-lived pentachloroallyl cation *(2)*[6] with cyclopentadiene in dichloromethane or liquid sulfur dioxide were not successful and only cyclopentadiene polymer was observed *(3)*[7]. It cannot be entirely ruled out that a seven-membered adduct is formed initially in this reaction, but the probability of obtaining a stable neutral compound in the absence of a suitable anion seems remote.



2. The Silver Salt Route to Seven-Membered Rings[8]

In order to couple an allyl cation and a conjugated diene according to eq. (3) a number of new techniques had to be developed. For several reasons the conditions described by us early in 1968[5,8] have remained close to ideal for handling even simple and highly unstable allyl

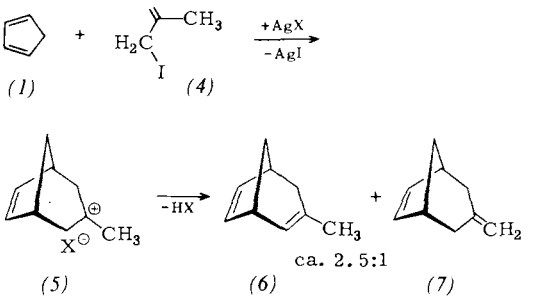
University College, London WC1H OAJ (England)

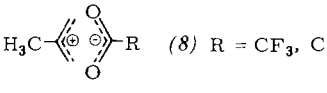
cations which are free from terminal substituents (Scheme 2).



(1) (4) (5) (6) (7)

Scheme 2. Example of the silver salt route. Reaction is carried out in isopentane or benzene at −78 to 0 °C; X = $F_3C—CO_2$ or $Cl_3C—CO_2$ [5, 8].

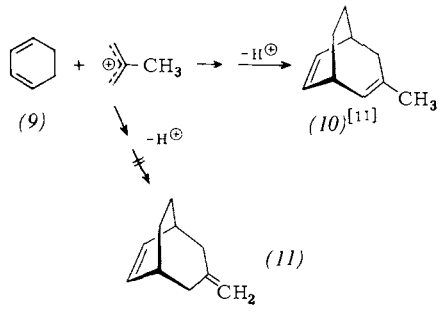
1) In choosing an allylic iodide[5] rather than a bromide or chloride, one takes advantage of the best possible leaving group that can be removed by the electrophilic catalyst. 2) Silver ion removes the iodide ion efficiently and irreversibly[9] and leaves no room for the formation of hydrogen iodide, which would attack both reactants and products. 3) Perhaps most important is the nature of the silver anion, which acts as a co-catalyst in the reaction. In general, the choice of trichloroacetate[5] and trifluoroacetate[10] represents a happy compromise in that these anions are not sufficiently nucleophilic to trap substantial amounts of the intermediate allyl cation, but might actually stabilize it as shown in (8). On the other hand, in the final stage



(8) R = CF_3, CCl_3

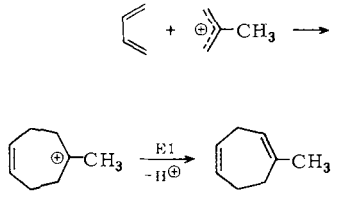
of the reaction the anion can combine with a proton to give a halogenated acetic acid which does not do any significant damage to reactants or products; alternatively the anion forms an ester with the 4-cycloheptenyl cation[*]. 4) A fairly large number of solvents ranging from liquid sulfur dioxide, benzene, diethyl ether, to benzene in CCl_4, and isopentane or even no solvent at all have been used by us. In general it seems desirable that the silver salt be present heterogeneously, since the formation of allyl ester can usually be minimized in that way. The cycloaddition in pentane or isopentane is preparatively perhaps most convenient.

Given these conditions, cyclopentadiene (1) and the 2-methylallyl cation afforded a mixture of the bicyclics (6) and (7) in a ratio of *ca.* 2.5:1. In an analogous experiment with 1,3-cyclohexadiene (9) only 3-methylbicyclo[3.2.2]nona-2,6-diene (10) was formed and none of the isomer (11)[5, 10]. This contrasting distribution of products can be ascribed to the greater flexibility of the ethano bridged 1,4-cycloheptadiene (10) *vis-à-vis* the methano analog (6). In the latter compound the newly formed double bond can be accommodated by the seven-membered ring only at the expense of additional strain and formation of the isomer (7) with an exocyclic double bond competes.



(9) (10)[11] (11)

That the final proton loss is an E1 reaction, which is subject to Saytzeff control, could be confirmed by the reaction of butadiene with the 2-methylallyl cation, which furnished the thermodynamically more stable trialkylated olefin (12) as the sole cycloadduct[10].

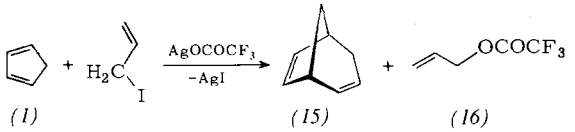


(12)

From a preparative point of view, open-chain dienes such as butadiene, isoprene, and 2,3-dimethylbutadiene present obvious problems. Since the energy level of the cisoid conformer (14) required for a concerted cycloaddition lies at least 2 kcal mol^{-1} above that of the transoid conformer (13) at any given moment the proportion of butadiene molecules available for reaction amounts to *ca.* 4% at ambient temperature, but at −78 °C to less than 0.7%[10]. Hence, a simple allyl cation which lacks the stabilization afforded by terminal substituents has only a poor chance of combining with a cisoid partner below 0 °C and it comes as no surprise that the yields are relatively low (< 10%) in this case[10].

(13) (14)

As expected cycloadditions of the parent allyl cation proved to be extremely difficult. Nonetheless, reaction has been realized, bicyclo[3.2.1]octa-2,6-diene (15) and 2-propenyl trifluoroacetate (16) being formed from simple starting materials in one stage[10].

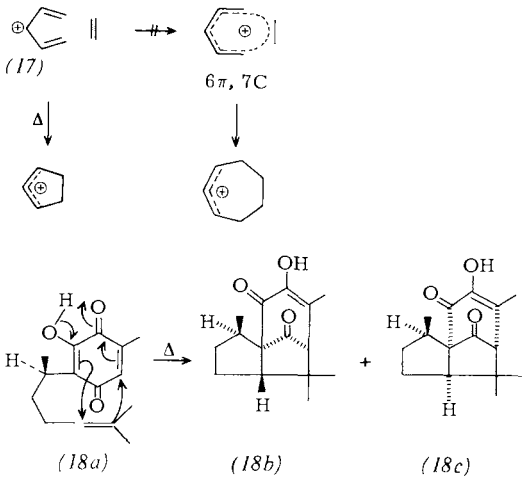


(1) (15) (16)

Parenthetically, it should be mentioned that the combination of a pentadienyl cation (17) and an olefin is frustrated

[*] Since the above was written, the use of silver salts for generating reactive 2π [10a] and 4π components [10b] in other types of cycloaddition has been reported. However, as the reactive intermediates and the products obtained were more stable than ours, the choice of silver counterion is less important and $AgBF_4$ can be employed without apparent difficulty; see also *G. F. P. Kernaghan* and *H. M. R. Hoffmann*, J. Amer. Chem. Soc. 92, 6988 (1971).

by the ease of intramolecular cyclization of the carbocation[4,12]. However, an interesting, and hitherto the only example, which is also of biogenetic interest, is the transformation of the naturally occurring perezone *(18a)* into the isomeric pipitzols *(18b)* and *(18c)* on heating in tetralin[13,14]. Note that conrotatory closure of the 4π,5C system in perezone *(18a)* is unfavorable on steric grounds, whereas no such factors mitigate against the formation of the products *(18b)* and *(18c)*, which belong to the cedrane class of sesquiterpenes.

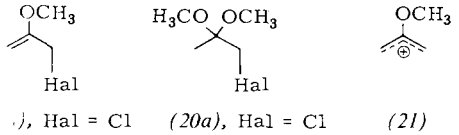


(18a) *(18b)* *(18c)*

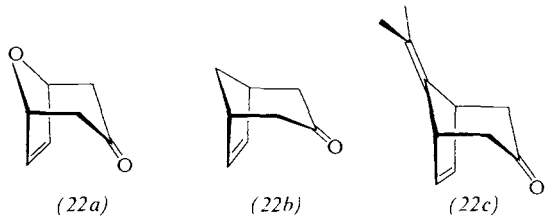
3. The 2-Methoxyallyl System

2-Alkoxyallyl halides represent a simple class of bifunctional compounds which curiously had been unknown until we uncovered two simple and efficient routes to the series of parent halides *(19a)–(19c)*. For example, 2-methoxypropene and *N*-bromosuccinimide give an array of at least five products, but under carefully controlled conditions the desired compound *(19b)* can be isolated in more than 50% yield[15].

The reactivity of the 2-methoxyallyl halides *(19)* relative to that of other allyl halides is of intrinsic interest, even though a solvolytic comparison appears to be ruled out, since the compounds *(19a)—(19c)* are also enol ethers which at least in unbuffered conditions react with all common protic solvents. Thus, on contact with neutral methanol at room temperature the ketals *(20)* were formed almost before one could scan an NMR spectrum. However, it seems clear that the methoxy grouping alters the reactivity pattern considerably. For example, *(19a)* and *(19b)* were less reactive than the corresponding 2-methylallyl halides in typical S_N2 reactions (displacement by iodide ion in acetone[5,15], by carbonylmetal anions, and by sodium alkoxides[16]).



(19a), Hal = Cl *(20a)*, Hal = Cl *(21)*
(19b), Hal = Br *(20b)*, Hal = Br
(19c), Hal = I *(20c)*, Hal = I



(22a) *(22b)* *(22c)*

In an S_N1 like reaction (silver trifluoroacetate, isopentane solvent) 2-methoxyallyl bromide *(19b)* formed 2-methoxyallyl trifluoroacetate at room temperature, whereas 2-methylallyl bromide reacted at temperatures well below 0 C[17]. Furthermore, various attempts to generate the 2-methoxyallyl cation *(21)* as a long-lived species by standard procedures have failed. Apparently, the precursor *(19b)* has proved so sensitive that only complex mixtures resulted in which nothing resembling an allyl cation could be identified[18].

It has been shown more recently that cycloadditions of the 2-methoxyallyl cation can be carried out, admittedly not before removing some formidable experimental obstacles. Thus, the starting material had to be restrained from polymerization, which in the presence of the silver salt and the silver halide formed during the reaction, tended to produce a solid, intractable black mass together with the organic material. The following precautionary measures were found essential.

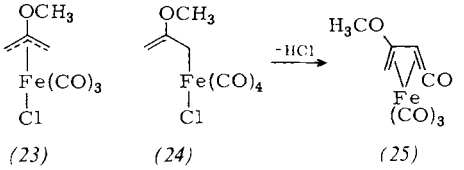
1) The silver salt should be added to the reaction mixture in small portions over an extended period (*ca.* 20 h).

2) A base or buffer compatible with the silver salt must be present to prevent accumulation of trifluoroacetic acid which in this case is harmful.

3) The reaction mixture should be kept in the dark, since silver halides are sensitive to light.

4) The most important point is that the reaction mixture must be stirred with an efficient vibromixer (100 Hz).

In this way the 2-methoxyallyl moiety could be combined with *inter alia* furan, cyclopentadiene, and 6,6-dimethylfulvene to yield the series of bicyclics *(22a)—(22c)*[19]. While bicyclo[3.2.1]oct-6-en-3-one *(22b)* had been obtained earlier in not less than six stages from norbornadiene[20], the 8-oxa analog *(22a)* had remained elusive and—being bereft of methyl substituents—would not be accessible by any of the other methods outlined below.



(23) *(24)* *(25)*

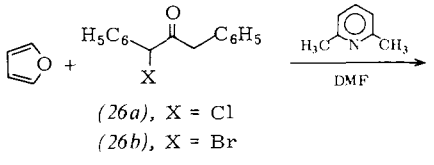
The unusual character of the 2-methoxyallyl system *(19)* is also manifest in the reactions of *(19a)* and *(19b)* with carbonylmetals. For instance, treatment of 2-methoxyallyl chloride *(19a)* with nonacarbonyldiiron does not afford the π-allyl complex *(23)* as one might have expected, but instead bright yellow volatile crystals of 3-methoxy-1,3-

butadienone(tricarbonyl)iron *(25)*. Presumably, the σ-allyl complex *(24)* is an intermediate which instead of leaking into the usually preferred π-allyl compound *(23)* is capable of forming *(25)* *via* renewed carbonylation. The organic ligand of *(25)* is a vinylketene and belongs to a class of interesting and highly reactive π systems which have not yet been studied in detail[21].

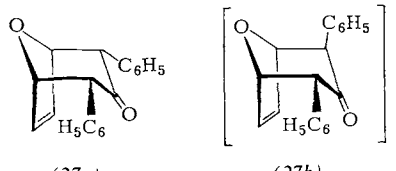
To summarize, the methoxy grouping at the central carbon appears to deactivate the allyl system toward S_N1 as well as S_N2 reactions. In this respect, the situation can be compared with the *meta* deactivation of electrophilic aromatic substitution by a methoxy group. Owing to the electron-attracting inductive effect of oxygen, the Hammett substituent constant of methoxy is positive ($\sigma_{meta} = 0.12$, more strongly electron-withdrawing than hydrogen), while σ_{para} is, of course, negative (-0.27)[22].

4. α,α′-Dihalo Ketones

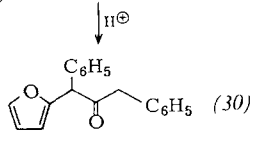
Some of the experimental difficulties in handling allyl cations can be greatly alleviated by attaching phenyl groups to the allylic termini. In an ingenious experiment published in 1962 *Fort* treated α-chlorodibenzyl ketone *(26a)* with 2,6-lutidine in the presence of furan (DMF at 25 C, 4 d) and showed that a seven-membered adduct was formed,



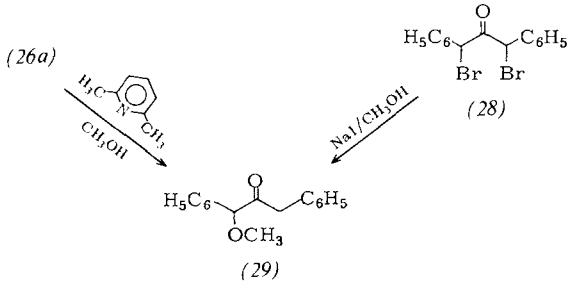
(26a), X = Cl
(26b), X = Br

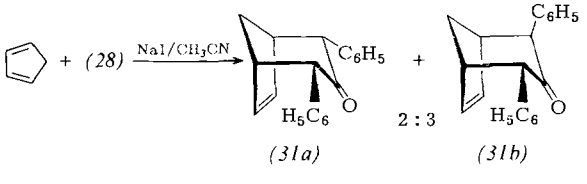


(27a) *(27b)*



(30)

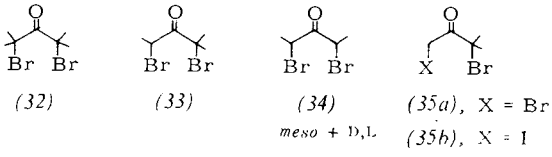




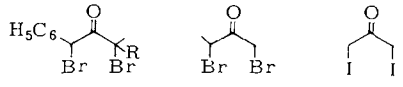
(31a) *(31b)*

the phenyl groups of which were *cis*[23a]. The same author had also reported earlier that the reaction of *(26a)* with 2,6-lutidine in methanol or the reduction of the dibromo ketone *(28)* with iodide ion in methanol yielded the α-methoxyketone *(29)*[23b]. Although it was not fully recognized at that time, there can be little doubt now that the formation of the seven-membered ring must be placed into the class of cycloadditions [eq. (3)].

Soon afterwards *Cookson* assigned the two phenyl groupings to the *cis* diequatorial positions as in [*(27a)*] and showed that this adduct could also be obtained from the dibromo ketone *(28)* and furan by treatment with (i) sodium iodide in boiling acetonitrile or acetone, (ii) mercury, or (iii) on boiling with zinc-copper couple in acetonitrile for two days; under these particular conditions varying amounts of the equatorial, axial epimer *(27b)* and the α-furyl isomer *(30)* were also isolated; *(27a)* was reported to yield *(27b)* as well as *(30)* on exposure to acid. With cyclopentadiene under fairly vigorous conditions the adducts *(31a)* and *(31b)* were found to be formed in a ratio of 2 : 3[24].



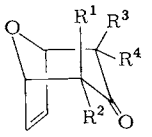
(32) *(33)* *(34)* meso + D,L *(35a)*, X = Br *(35b)*, X = I



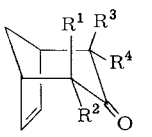
(36a), R = CH_3 *(37a)* *(37b)*
(36b), R = H

Scheme 3. α,α′-Dihalo ketones *(32)*—*(36)* can be used as precursors of allyl cations; *(37a)* and *(37b)* cannot.

As soon as the dihalo ketone is deprived of its phenyl groups, the conversion into an allyl cation is necessarily more difficult. However, by using the proper combination of dehalogenating agent and solvent it could be shown that cycloadditions proceeded more generally and under milder conditions than had previously been thought possible. In experiments going back about four years (cited in ref. [25]) we investigated the feasibility of forming allyl cations from model dihalo ketones (Scheme 3). Whereas 1,3-diiodoacetone *(37b)* and also *(37a)* showed no tendency to enter into the desired reaction, the dihalo ketones *(32)*—*(36)* were found to be suitable provided one used a reactive zinc-copper couple in combination with the right medium. After experiments with a variety of solvents, it became clear that glyme is advantageous, since it is inert to the reactants and readily forms a stable solid with the zinc halide which is liberated during the dehalogenation. In this way, the cycloaddition could be carried out at 25 C or below. By using furan and cyclopentadiene, respectively, as diene components a wide range of 8-oxabicyclo[3.2.1]oct-6-en-3-ones *(38)*—*(43)* and bicyclo[3.2.1]oct-6-en-3-ones *(46)*—*(51)* (Table 1) was obtained[26].



(38)–(45), (22a)



(46)–(53), (22b)

of the hybridization of the carbonyl carbon. If the angle is small as in cyclopropanone and cyclobutanone, the carbonyl carbon is relatively electron-attracting and the carbonyl stretching frequency is quite high, *i. e.* 1813[29a] and 1775 cm^{-1}[29b], respectively[*]. Cyclohexanones in nonpolar solvents absorb in the range 1709—1714 cm^{-1} and on continued expansion of the angle as in, say, medium rings the carbonyl stretching frequency drops further[30]. Accordingly, the observed reduction in carbonyl stretching in bicyclo[3.2.1]oct-6-en-3-ones suggests an expansion of the C—CO—C bond angle, which in this case can be brought about by deformation of the six-membered ring and flattening toward a half-boat. Now one can see that such flattening will also blur the environmental distinction of axial and equatorial methyl groups, and this seems indeed borne out by the chemical shift difference Δ. From the data in Table 1 it is evident that Δ is consistently smaller for the carbobicyclics than for the oxabicyclics, in accord with the postulated greater deformation of the cyclohexanone chair.

Table 1. Selected IR and NMR data of 8-oxybicyclo[3.2.1]oct-6-en-3-ones *(38)—(45)* and *(22a)* and the bicyclo[3.2.1]oct-6-en-3-ones *(46)—(53)* and *(22b)*.

[a] $\Delta = \delta_{axial} - \delta_{equatorial}$.
[b] The carbonyl stretching frequency reported in ref. [27c] must be too high, since the band should come at *lower* frequency than that in the corresponding oxa analog; cf. text and other bicyclics in this Table.

4.1. Configurational Assignment and Conformation of Bicyclo[3.2.1]oct-6-en-3-ones and 8-Oxabicyclo[3.2.1]oct-6-en-3-ones

Although the compounds of Table 1 represent a structurally simple class of bicyclics, they had been largely unknown and consequently, their configuration as well as conformation had to be deduced.

Axial protons and methyl protons generally resonate upfield from the signals of the corresponding equatorial protons[28]. In striking contrast, the axial proton and methyl group which are α to the carbonyl moiety of a cyclohexanone chair, were found to appear *downfield* from the equatorial proton and methyl group, respectively. A simple stereoelectronic effect, *i. e.* overlap or hyperconjugation of the axial σ bond with the π system of the carbonyl group, can be invoked to account for these observations[26].

A more detailed inspection of the spectral data of the bicyclics in Table 1 brings to light some interesting conformational subtleties, a grasp of which is useful for an understanding of the mechanistic discussion to follow (Section 9.2). Two experimental facts stand out clearly.

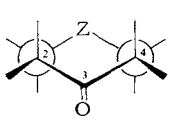
1) The IR carbonyl stretching frequency of the carbobicyclics is consistently smaller than that of the oxa analogs (cf. also Table 1, footnote [b]).

2) The chemical shift difference Δ of axial and equatorial methyl protons is consistently smaller for the carbobicyclics (cf. Table 1).

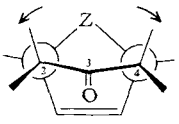
The IR stretching frequency of a carbonyl group is a function of the C—CO—C bond angle or, to rephrase,

The conformational variations of the two bicyclic systems can also be illustrated by the NMR spectrum of the parent member of each class, namely bicyclo[3.2.1]oct-6-en-3-one *(22b)* and 8-oxabicyclo[3.2.1]oct-6-en-3-one *(22a)*[19]. The axial and equatorial protons in *(22a)* appear as a well-defined AB quartet at 2.4 ppm ($J_{H_a,H_e} = 16$ Hz) and the downfield, axial protons are coupled further to the vicinal bridgehead protons ($J_{H_a,H_b} = 5$ Hz). In contrast, the α-carbonyl protons of *(22b)* coincide as an ill-resolved broad signal in the region of 2.2—2.3 ppm, *i. e.* judging by NMR they appear to have lost any distinct axial or equatorial character.

[*] *Note added in proof* (Sept. 21, 1973): According to recent studies the carbonyl frequencies of cyclopropanone and cyclobutanone appear to be even higher; cf. *W. J. M. van Tilborg*, Tetrahedron Lett. *1973*, 523.



(54)

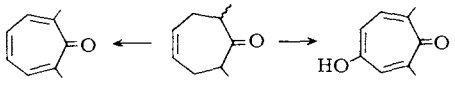


(55)

A simple mechanical model[31] seems useful for describing the differences in the two bicyclic series. On joining the 1,5-diaxial positions of a cyclohexanone chair *(54)* by an ethylene grouping the 2,4-diaxial substituents are prized apart and as a result, the chair flattens [*(55)*]. Since the methylene bridge is longer than the oxygen bridge—the carbon-carbon and carbon-oxygen bond distances are *ca.* 1.54 and 1.43 Å, respectively—deformation toward the half-boat is expected to be more pronounced in the carbocyclic series.

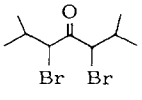
Whatever more conformational detail may come to light it is clear that the zinc-copper couple reaction enables us to introduce substituents into thermodynamically unfavorable *axial* positions. As a result bicyclo[3.2.1]oct-6-en-3-ones are now available in all their variations. α,α'-Dihalo ketones can be dehalogenated by reagents other than zinc-copper couple. Thus, dehalogenation of 1,3-dibromo-1,3-diphenylpropanone *(28)* by mercury has already been mentioned. Although metallic mercury fails to react with simple dibromo ketones such as those shown in Scheme 3, we have found that dehalogenation occurs with an excess of iodide ion in the presence of mercury or copper; the exclusion of light is desirable in this reaction (see below, Table 3 and Section 9.1.2).

In view of the great interest that must be attached to reactions of α,α'-dihalo ketones such as *(32)*—*(37)*, it is not surprising that aspects of their chemistry were investigated by other workers. Thus, the electrochemical reduction of 2,4-dibromo-2,4-dimethyl-3-pentanone *(32)* — which is particularly prone to ionization—in the presence of furan provides an alternative route to cycloadduct *(38)*[27d]. The debromination of *(32)*, *(34)*, and *(56)* with $Fe_2(CO)_9$ in the presence of conjugated dienes has also been reported: by using a bromination-debromination sequence troponoid compounds have been prepared (Scheme 4)[32].

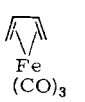


Scheme 4. Preparation of the troponoid compounds 2,7-dimethyl-2,4,6-cycloheptatrien-1-one (in two steps) and the 4-hydroxy derivative (in three steps) from 2,7-dimethyl-4-cyclohepten-1-one.

Instead of employing $Fe_2(CO)_9$ the use of diene(tricarbonyl)-iron complexes such as *(57)* has been suggested[32]; apart from ferrocene, *(57)* is perhaps the best known and most investigated organoiron complex[33].



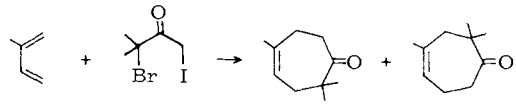
(56)



(57)

(58)

Another organoiron complex, namely trimethylenemethyl-(tricarbonyl)iron *(58)*, has been irradiated in the presence of cyclopentadiene to yield 3-methylenebicyclo[3.2.1]oct-6-en-3-one *(7)* among a complex mixture of products[34]. The direct combination of the 1,1-dimethyl-2-oxyallyl cation[*] with isoprene is of special interest. Although the dehalogenation of *(35b)* is relatively difficult, it could be accomplished on a column filled with zinc-copper couple (see below), and in the presence of isoprene gives rise to karahanaenone *(59)* and the isomer *(60)* in the ratio

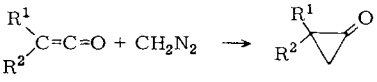


(35b) (59) (60)

2.8:1[35]. Karahanaenone is a pleasant-smelling natural product and had previously been isolated from oil of hops[36], whereas its isomer *(60)* was unknown. By using a modified debromination procedure, *i.e.* sodium iodide in the presence of mercury or copper instead of zinc-copper couple, *(59)*, *(60)* (in the ratio 1:1.2), and at least three other monocyclic monoterpenoids $C_{10}H_{16}O$ were formed in a single experimental stage (see Section 9.3)[35].

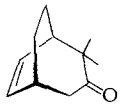
5. Cyclopropanones

The synthesis of cyclopropanone *(61a)* by treating an excess of ketene with diazomethane was discovered in 1932[37], but then seemed to sink into almost complete oblivion until *Turro* extended it to methylated cyclopropanones[29a]. Although doubt remains whether the combination of cyclopropanones and conjugated dienes actually proceeds *via* allyl cations (cf. Section 9.1.4.), there exists at least a formal relationship with the other cycloadditions described in this paper insofar as seven-membered rings may be formed. 2,2-Dimethylcyclopropanone *(61c)* which can be prepared and handled most easily, combines with furan, 2-methyl- and 3-methylfuran, furfural[27c], 2-methoxycarbonylfuran[27e], cyclopentadiene, 6,6-dimethylfulvene, and *N*-methylpyrrole.

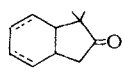


(61a), $R^1 = R^2 = H$
(61b), $R^1 = CH_3$, $R^2 = H$
(61c), $R^1 = R^2 = CH_3$

Interestingly, cycloaddition of *(61c)* to cyclohexadiene already seems difficult, *(62)* and *(63)* being tentatively identified products only. Methylcyclopropanone *(61b)*



(62)



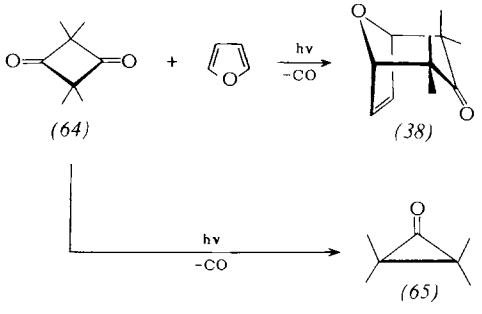
(63)

[*] Concerning the formulation of "oxyallyl", see formula *(96)* in Scheme 8 and formula *(101)*.

reacts with furan and cyclopentadiene to give the epimeric pairs *(44)* and *(45)* (ratio *ca.* 4:1) and *(52)* and *(53)* (ratio *ca.* 2:1), respectively[27c].

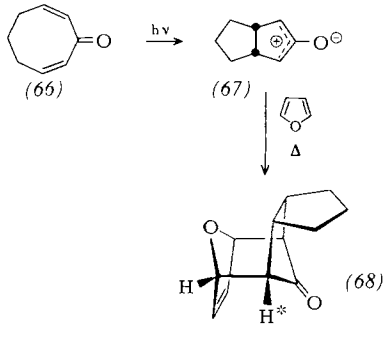
Trimethylcyclopropanone, which cycloadds to furan, can only be prepared with some difficulty by analogy with *(61a)*—*(61c)*[27e], presumably because diazoethane is less nucleophilic than diazomethane. The parent cyclopropanone *(61a)* is very prone to nucleophilic attack and polymerization and does not cycloadd to conjugated dienes at all, not even to furan[29a].

The first cycloaddition of a cyclopropanone was reported by *Cookson*[27a] who photolyzed tetramethylcyclobutanedione *(64)* in furan to obtain *(38)*; tetramethylcyclopropanone *(65)* is a known photoproduct of *(64)*, but cannot be obtained by analogy with *(61a)*—*(61c)*. Alternatively, the adduct *(38)* was formed under purely thermal conditions, *i. e.* by keeping *(65)* together with furan at room temperature[27c].



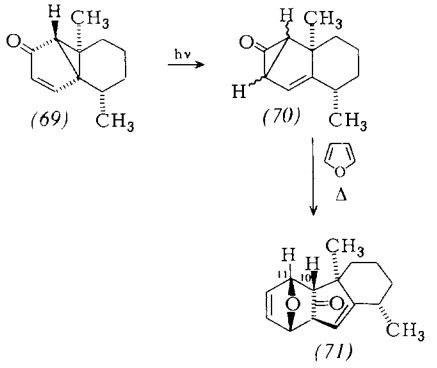
(64) *(38)* *(65)*

An interesting variation on the oxyallyl theme was provided by the irradiation of 2,7-cyclooctadienone *(66)* in furan at −78 °C, which furnished adduct *(68)*; this compound could also be prepared by irradiating *(66)* in an inert solvent at −78 °C, turning off the light source and then adding furan. The mesoionic species *(67)* has been postulated as an intermediate, although it should be borne in mind that the corresponding tricyclic cyclopropanone valence isomer is presumably more stable (cf. also *(70)* and Scheme 9). On the basis of the vicinal coupling constant $J_{H,H} = 3.5$ Hz, it has been proposed that the bridging oxygen and the carbonyl bridge of the tetracycle are *anti* to each other, as shown in *(68)*[38]. This assignment is now strongly supported by the chemical shift of the methine protons α to carbonyl (δ = 2.1 ppm), which is suggestive of an equatorial proton.



(66) *(67)* *(68)*

Irradiation of the homodienone *(69)* afforded the annelated cyclopropanone *(70)*, which was detected in an IR

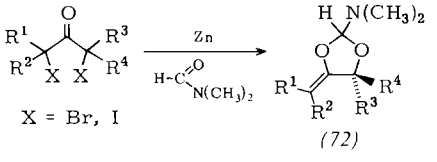


(69) *(70)* *(71)*

cell at −190 °C; cycloaddition to furan gave *(71)* and occurred subsequently as a dark reaction[39]. On the basis of the reported 10-H chemical shift (δ = 2.00 ppm) and the vicinal coupling constant ($J_{10\text{-H},11\text{-H}} = 1.5$ Hz) proton 10-H can now be assigned to the equatorial position as shown, or to restate, the tetrahydropyranone moiety in *(71)* is present in a frozen chair form [cf. also *(79)*].

6. Synthesis and Reactions of New Heterocycles

From the very beginning it seemed desirable to develop as diverse a range of allyl cation progenitors as possible. The dehalogenation of α,α′-dihalo ketones in the presence of conjugate dienes is certainly very convenient from a preparative point of view—and zinc-copper couple is a cheap reagent—but it tells us relatively little about the structure of the reactive intermediate. In this respect the dehalogenation of α,α′-dihalo ketones in dimethylformamide is an informative complementary reaction, because the organozinc intermediate is now captured in a different, yet characteristic manner (see also Section 9.3).



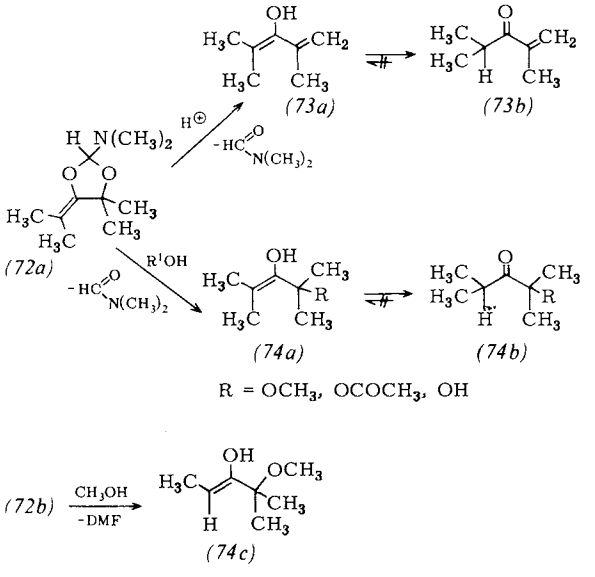
(72)

Scheme 5. Synthesis of the 4-alkylidene-2-dimethylamino-1,3-dioxolanes *(72a)*–*(72e)* from α,α′-dihalo ketones. *(72a)*, $R^1 = R^2 = R^3 = R^4 = CH_3$; *(72b)*, $R^1 = R^3 = R^4 = CH_3$, $R^2 = H$; *(72c)*, $R^1 = R^3 = CH_3$, $R^2 = R^4 = H$; *(72d)*, $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$; *(72e)*, $R^1 = R^2 = H$, $R^3 = R^4 = CH_3$.

Thus we could show quite generally that α,α′-dihalo ketones such as *(32)*—*(35)*, which on dehalogenation with zinc-copper couple cycloadd to conjugated dienes, combine with dimethylformamide and dimethylacetamide to yield 4-alkylidene-2-dimethylamino-1,3-dioxolanes *(72a)*—*(72e)* (Scheme 5). It comes as no surprise that these heterocycles are highly sensitive to heat, moisture, light, and oxygen, and that their purification and isolation at low temperature proved to be difficult. Eventually, a specifically designed reactor-extractor enabled us to continuously extract the products from the dimethylformamide mother liquor with pentane or isopentane at −40 to −50 °C[40]. By cooling the stirred pentane extract to

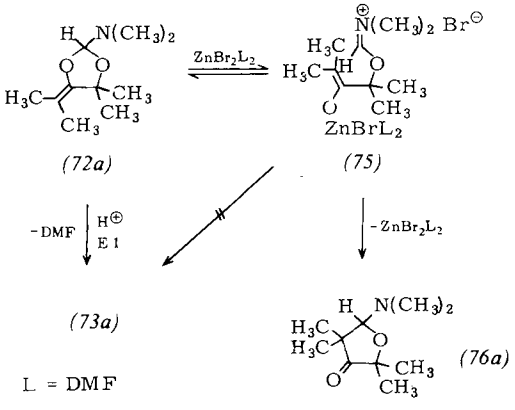
−78 °C overnight, the residual dimethylformamide could be frozen out to give the five-membered rings practically free from impurities[40b].

4-Alkylidene-2-dimethylamino-1,3-dioxolanes *(72)* can be regarded as cyclic α-aminoacetals of nonexistent (cf., however, ref. [41b]), 2-hydroxyallyl alcohols and in many reactions provide a convenient source of the oxyallyl moiety. From a mechanistic point of view the cycloadditions of *(72b)* and *(72c)* + *(72d)* to furan are of special interest, since they yield the bicyclics *(39)* and *(41)*, respectively, with high stereospecificity (cf. Section 9.2).



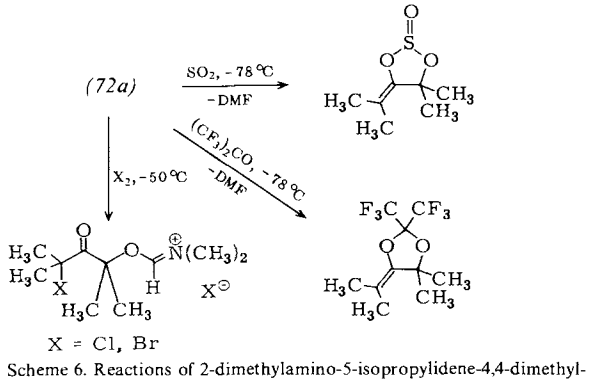
It is worthy of note that the isopropylidene-substituted heterocycle *(72a)* and furan do not give any discernible amounts of seven-membered adduct in a variety of conditions[26,40b]. Instead, *(72a)* is rather susceptible to formation of the simple aliphatic enol *(73a)*, which has been identified spectroscopically as well as chemically and which can be handled under conventional conditions at room temperature before it rearranges irreversibly into ketone *(73)*. Quite generally, by treating heterocycle *(72a)* with acidic reagents ranging from methanol to acetic acid, we succeeded in obtaining a bevy of simple aliphatic enols of the general structure *(74a)* in high concentrations (0.5 to > 1 mol/l) at room temperature[41b]. The comparative kinetic stability of these enols can be attributed to several factors including the high reactivity of the precursor and hence the mild experimental conditions of their genesis, the solvent type, and the complete alkylation of the enolic double bond. On treating heterocycle *(72b)* with methanol and *O*-deuterated methanol the simple dialkylated enol *(74c)* and its *O*-deuterio analog, respectively, could be generated and identified. However, the lifetime of these enols is considerably shorter, being *ca.* 10 min at room temperature[41c].

Electrophilic attack of the electron rich enolate oxygen in heterocycle *(72a)* is not restricted to that by protons. Aggressive dipolarophiles such as liquid sulfur dioxide and hexafluoroacetone react at −78 °C with quantitative exchange of dimethylformamide. Less electrophilic reagents like trichloroacetaldehyde and diethyl azodicarboxylate require longer reaction times and may give varying amounts of the α,β-unsaturated ketone *(73b)*[42]. On contact with perdeuteriodimethylformamide at −15 °C for 18 days, *(72a)* releases the dimethylformamide moiety and cleanly incorporates the labeled compound[41b]. Bromine and chlorine react at −50 °C or below with ring-opening to form the corresponding ammonium halides (Scheme 6)[42].

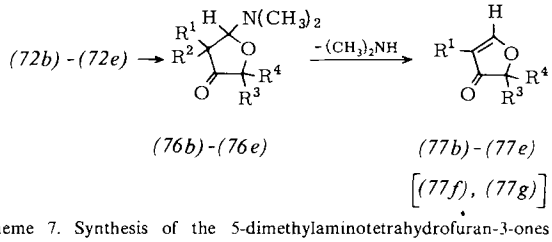


Interestingly, the E1 route to the enol *(73a)* can also be blocked when heterocycle *(72a)* is stirred in dimethylformamide in the presence of zinc bromide. In these conditions intramolecular alkylation of the highly crowded enolate moiety can be forced, the cyclic α-aminoether *(76a)* being formed after one week at room temperature (cf. Section 9.3).

The rearrangement exemplified by the formation of *(76a)* from *(72a)* is a general reaction of 4-alkylidene-2-dimethyl-



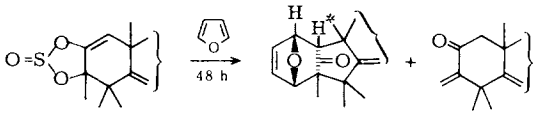
Scheme 6. Reactions of 2-dimethylamino-5-isopropylidene-4,4-dimethyl-1,3-dioxolane *(72a)* with electrophiles.



Scheme 7. Synthesis of the 5-dimethylaminotetrahydrofuran-3-ones *(76b)*—*(76e)* and the 3(2*H*)-furanone *(77b)*—*(77e)*. *(76b)*, $R^1=R^3=R^4=CH_3$, $R^2=H$; *(77b)*, $R^1=R^3=R^4=CH_3$. *(76c)*, $R^1=R^3=CH_3$, $R^2=R^4=H$; *(77c)*, $R^1=R^3=CH_3$, $R^4=H$. *(76d)*, $R^1=R^4=CH_3$, $R^2=R^3=H$; *(77d)* ≡ *(77c)*. *(76e)*, $R^1=R^2=H$, $R^3=R^4=CH_3$; *(77e)*, $R^1=H$, $R^3=R^4=CH_3$. *(77f)*, $R^1=C_6H_5$, $R^3=R^4=CH_3$, and *(77g)*, $R^1=C_6H_5$, $R^3=CH_3$, $R^4=H$, were prepared from *(36a)* and *(36b)* respectively.

amino-1,3-dioxolanes. The ease of this rearrangement yields insight into the behavior and nucleophilicity of model enolate ions. Thus, the ethylidene-substituted heterocycle *(72b)* did not cycloadd to furan, if these two compounds—instead of being kept together neat—were diluted with CCl_4 as solvent. In this case rearrangement into *(76b)* was the fastest reaction. For heterocycle *(72e)* the corresponding transformation occurred even more rapidly, being complete after standing overnight at room temperature. The 5-dimethylaminotetrahydrofuran-3-ones *(76b)*—*(76e)* so formed can be viewed as cyclic β-ketoamines, which are rendered even more labile by the α-ether grouping. Accordingly they lose dimethylamine readily and irreversibly to yield the 3(2*H*)-furanones *(77b)*—*(77d)*[43]. Occasionally, the formation of 3(2*H*)-furanones is so facile that the intermediacy of heterocycles *(72)* and *(76)* can only be inferred; thus, the debromination of the dibromoketones *(36a)* and *(36b)* affords *(77f)* and *(77g)* directly. 2,2-Dimethyl-4-phenyl-3(2*H*)furanone *(77f)* is a previously unknown isomer of bullatenone[44], which is isolated from *Myrtus bullata*, a shrub indigenous in New Zealand.

In principle, replacement of the phenyl group in *(77f)* by hydrogen leads to furanone *(77e)*, which in practice is obtained more conveniently from heterocycle *(72e)*. 2,2-Dimethyl-3(2*H*)-furanone *(77e)* is a sweet smelling oil, and it should be mentioned that 3(2*H*)-furanones are valued by perfumers because of their pleasant and varied odors and, furthermore, may serve as precursors for the synthesis of muscarins[43]. The reaction sequence described offers an unusually simple entry into this interesting, but also fairly sensitive class of compounds.



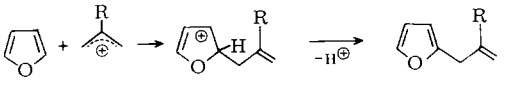
(78) *(79)* *(80)*

The compound *(78)* is formally related to the heterocycles *(72b)* and *(72c)* + *(72d)* described above in that it seems relatively reactive and combines with furan to furnish a seven-membered ring, *i. e. (79)*, and also the elimination product *(80)*[45a] (see also Scheme 6 and Section 9.1.4). On the basis of the NMR data reported ($\delta_{H^*} = 2.08$ ppm, $J_{H^*H} = 1.3$ Hz)[45b] the carbonyl group in *(79)* must be *anti* to the bridging oxygen as indicated. This assignment, like those made above, is substantiated by comparison with a wide variety of 8-oxabicyclo[3.2.1]oct-6-en-3-ones containing methylene bridges in the 2,4 positions[46].

7. The Diene Component

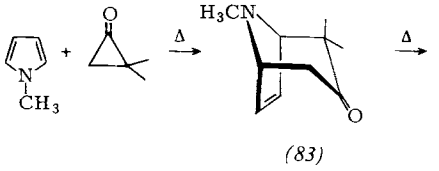
Although cyclopentadiene is somewhat more reactive, the most widely used diene component remains furan. Unlike cyclopentadiene, furan does not dimerize, and in many instances can actually be used as the solvent for the cycloaddition. Owing to the low boiling point of 31 C the excess of furan can easily be removed at the end of the reaction. Finally, the NMR spectra of the resulting 8-oxabicyclo[3.2.1]oct-6-en-3-ones are generally simple and can be interpreted readily, especially so since for any future studies a bevy of model compounds of known configuration and conformation is now available from our work[26,46].

While many allyl cations including the 2-methoxyallyl cation *(21)*[19] afford oxygen-bridged seven-membered rings with furan, it should be remembered that this is by no means valid for all allyl cations. For instance, the 2-methylallyl cation[5], the parent allyl cation[47a], the cyclopentenyl cation[47b], and others[47a] give rise to the products of electrophilic substitution, namely 2-allylfurans *(82)*. Whatever the mechanistic details of these reactions it seems clear that in the present instance an oxonium ion like *(81)* must be superior in stability to any bicyclic carbocation that may or may not be formed on the way to *(81)*[5].

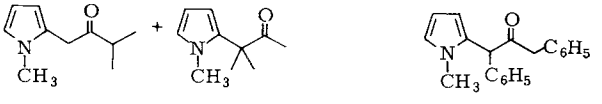


(81) *(82)*

N-Methylpyrrole and 2,2-dimethylcyclopropanone *(61c)* afford compound *(83)* which on heating rearranges into an isomeric mixture of *(84)* and *(85)*[27c,47c]. The reaction of *N*-methylpyrrole and 1,3-diphenyl-2-oxyallyl cation, generated from bis(α-bromobenzyl) ketone *(28)* and sodium iodide, has been reported to give the α-substituted derivative *(86)* directly[24b].

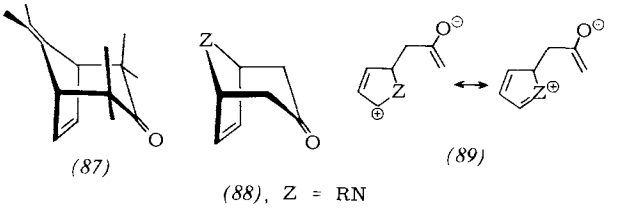


(83)



(84) *(85)* *(86)*

Cycloadditions to fulvenes can be accomplished without difficulty. For example, 6,6-dimethylfulvene has been shown to combine with 2,2-dimethylcyclopropanone *(61c)*[27c] and debromination of the ditertiary dibromo ketone *(32)* with zinc-copper couple in the presence of the same diene affords *(87)* in a clean reaction[48]; 2-methoxyallyl cation has been shown to react with fulvene as well[19].



(87) *(89)*

(88), Z = RN
(22a), Z = O
(22c), Z = $(CH_3)_2C{=}C$

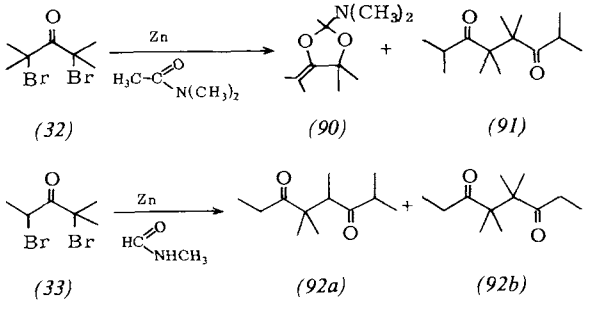
It is instructive to compare the thermal stability of the bridged 4-cycloheptenones as a function of the nature of the bridge. While dehydrotropinones such as *(88)* are relatively thermolabile, the parent 8-oxabicyclo[3.2.1]oct-6-en-3-one *(22a)* largely survives short treatment with dilute nitric acid at 60 °C and has actually been purified by sublimation under reduced pressure[19]. Nevertheless, it is clear that such compounds having an oxygen bridge do break up quite readily—especially if certain stereoelectronic requirements are fulfilled[46]—to form α-furyl derivatives. By comparison, the isopropylidene-bridged derivatives *(22c)* appear to be fairly stable, at least under nonacidic conditions. Presumably, thermal cleavage of the bicyclics *(88)*, *(22a)*, and *(22c)* proceeds *via* the zwitterion *(89)* or its protonated form. Since ammonium resonance in *(89)*, Z=RN, is more effective than oxonium resonance in *(89)*, Z=O, which in turn is probably more developed than the additional allylic resonance in *(89)*, Z=$(CH_3)_3C{=}C<$, the trend in relative stabilities is qualitatively understandable.

Cycloadditions to cyclohexadiene generally occur less readily as exemplified by the reaction with 2-methylallyl cation (*ca.* 30% yield)[5,10] and also with 2,2-dimethylcyclopropanone, where the formation of a seven-membered adduct remains to be confirmed[27c]. As expected, open-chain dienes react least readily, but given sufficiently stable allyl cations the yields are not unsatisfactory.

8. Side Reactions

8.1. Reductive Coupling

α,α'-Dihalo ketones such as *(32)*—*(35)*, which on treatment with zinc-copper couple furnish allyl cations, were found to be prone to bimolecular reductive coupling. For example, debromination of the ditertiary dihalo ketone *(32)* with zinc-copper couple affords heterocycle *(72a)* in dimethylformamide, but a solvent change to dimethylacetamide produces both *(90)* and the octanedione *(91)* (10%)[40]. If coupling is the desired reaction it can be promoted by using *N*-methylformamide as solvent which in being less nucleophilic but more acidic ($pK_a \approx 16$) than dimethylformamide and dimethylacetamide forms 1,3-dioxolanes less readily and promotes the reductive removal

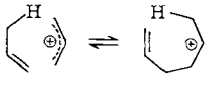


of bromine. Coupling in this manner offers a new route to 1,4-diketones from simple starting materials[40b,49].

The debromination of the mixed secondary, tertiary dibromo ketone *(33)* with zinc-copper couple in *N*-methylformamide yields all three stereoisomeric octanediones *(92a)*—*(92c)* in a ratio of 3.1 : 1.4 : 1[40b].

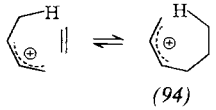
8.2. Intermolecular Hydrogen Transfer Reactions?

Since both *intra*- as well as *inter*molecular hydrogen shifts are ubiquitous in the chemistry of carbocations, the question arises whether the cycloaddition of an allyl cation might be accompanied by a bimolecular hydrogen transfer. In principle, two such reactions can be envisaged together with their converse. In reaction (4) the allyl cation takes the role of what we previously designated as the "enophile"[50], while an allyl cation containing a terminal methyl group acts as hydrogen donor in reaction (5). Were either reaction to exist it would be of intrinsic and could also be of practical interest, *e.g.* in cationic polymerization of conjugated dienes.



(4)

(93)



(5)

(94)

Using the conditions previously shown to be optimum for the cycloaddition of a simple allyl cation to conjugated dienes[10], the 2-methylallyl cation was generated from 2-methylallyl iodide and silver trifluoroacetate in isopentane at −78 °C in the presence of potential ene components such as cyclopentene, 1-pentene, 2-methoxypropene, and also more efficient hydride donors, namely 1,4-cyclohexadiene, 2,5-dihydrofuran, and cycloheptatriene. Interestingly, in no instance did we observe any defined products apart from 2-methylallyl trifluoroacetate[17]. As far as we can tell, reaction *(4)* to give cation *(93)* did not occur under any of our conditions. Presumably the energy price for carbon-hydrogen bond breaking and the stringent geometric demands of the cyclic transition state[50] are too high and not met by the gain in σ-bond energy on potential formation of the carbon-carbon bond. However, the possibility should not be discounted that reaction (4) may still come to light, perhaps as an *intra*molecular variant which optimizes orbital overlap.

9. Reaction Mechanism

9.1. Structure of the Reactive Intermediate

The ultimate objective of any mechanistic study centers on the potential energy surface of the reaction concerned. In the present instance our first task must be to elucidate the structure of the reactive three-carbon unit that com-

bines with the diene. Here we will have to draw on as wide a range of reactions as possible and scrutinize not only the cycloaddition itself, but also circumstantial evidence. Once the structure of the two π reactants and that of the products are known, it should be possible to interpolate the structure of the intervening transition state (cf. Section 9.2). An appreciation of the theoretical background will enable us to use the new reactions to their best purpose and to introduce variations in technique.

9.1.1. The Silver Salt Route

From a mechanistic viewpoint the silver salt reaction is the least ambiguous and, in point of fact, the cycloadditions realized[5,10,19] come closest to the prototype (3). Since cyclopentadiene was found not to influence the rate of formation of the silver halide, the reactive intermediate is clearly an allyl cation, which is formed in an S_N1 like reaction[7].

Now carbocations should be viewed together with their counterion and solvent rather than in isolation. According to the Winstein heterolysis scheme (Fig. 1) a covalent substrate R—X ionizes and dissociates with formation of (i) the contact ion pair, (ii) the solvent separated ion pair, and finally (iii) the free, solvated ions.

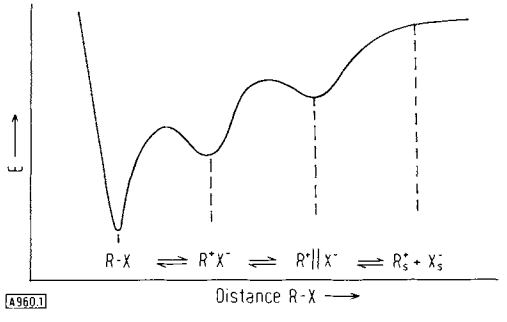


Fig. 1. Schematic energy profile for the heterolysis of an alkyl halide RX. E = potential energy. R—X = covalent substrate. R^+X^- = contact ion pair, $R^+||X^-$ = solvent-separated ion pair, $R_s^+ + X_s^-$ = free, solvated ions.

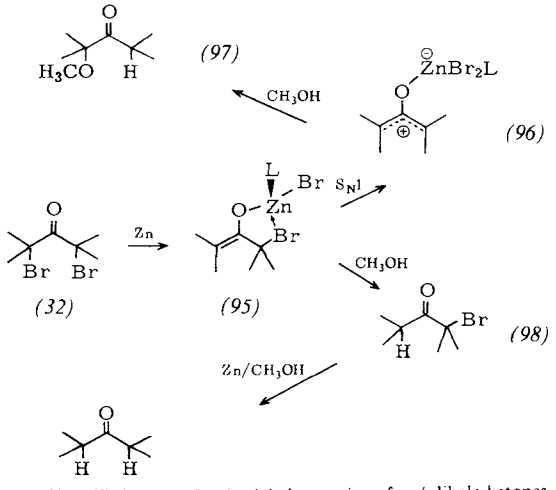
Under the prevailing heterogeneous conditions of our reactions the mechanistic situation seems less clear. If a conventional contact ion pair were involved, it would be positioned still relatively low down on the potential energy surface of heterolysis and hence might be expected to show but enfeebled reactivity and also to collapse to covalent ester. In fact, it was rather surprising to find that treatment of 2-methylallyl iodide with silver trichloroacetate in the presence of cyclopentadiene—admittedly a very reactive diene component—gave the cycloadducts *(6)* and *(7)* and less than 1% of 2-methylallyl trichloroacetate[5]. On the other hand, under homogeneous conditions—*e.g.* in ether—the yields of cycloadduct were lower, and at least the very reactive allyl cations which we used were found to form substantial amounts of covalent ester. Why the heterogeneous method is successful, is still not completely clear, but further discussion will be found elsewhere[10].

9.1.2. α,α'-Dihalo Ketones

Starting from ketones, α,α'-dibromo ketones are readily available, yet surprisingly little work[24b,51]—and none of it systematic—had been done on these compounds when we began our own investigations. From the outset it seemed desirable to obtain information which would shed light on the nature of the organometallic intermediates and would go beyond the cycloaddition to conjugated dienes.

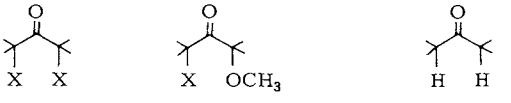


Scheme 8. Simplified scheme for the dehalogenation of α,α'-dihalo ketones with the zinc-copper couple in the presence of methanol. L = CH_3OH.

The dehalogenation of α,α'-dihalo ketones with zinc-copper couple in *methanol* has been shown to produce not only the parent ketone, but also α-methoxy ketone. This observation could appear as quite trifling, were it not for the fact that the α-methoxy ketone cannot arise by methanolysis of the starting dihalo ketone, which is inert to methanol under these conditions. It is perhaps even more interesting that the α-methoxy ketone is formed *regioselectively* in that *e.g.* the dihalo ketones *(33)* and *(35a)* + *(35b)* give rise to just one of two possible stereoisomers, which bears the methoxy moiety at the more alkylated carbon terminus (see Table 2)[52].

The dehalogenation of α,α'-dihalo ketones with zinc-copper couple in *dimethylformamide* yields 2-dimethylamino-4-

Table 2. Dehalogenation of α,α'-dihalo ketones with a zinc-copper couple in methanol at −5 to 0 °C (Schemes 3 and 8) [52].



Dihalo ketone (type A)	Products (rel. yield) α-methoxy ketone (type B)		ketone (type C)
(32)		72%	28%
(33)		76%	24%
(35a)	−35 °C:	19%	81%
	−5 °C:	14%	86%
(35b)	−35 °C:	33%	67%
	−5 °C:	5%	95%
(34)		62%	38%
(37a)	−35 °C:	0%	100%
	0 °C	0%	100%
(37b)		0%	100%
(36a)		84%	16%
(28)		100%	0%
(36b)		28%	72%

methylene-1,3-dioxolanes[40]. Interestingly, once again the dihalo ketones *(33)* and *(35a)* as well as *(35b)* react in orientationally uniform fashion in that the nucleophilic oxygen of dimethylformamide is attached exclusively to the more alkylated carbon terminus in the product, giving heterocycles *(72b)* and *(72e)*, respectively. Since the structural reorganization of the organozinc intermediate is less extensive here than in the trapping with methanol, a second stereochemical feature comes to light. By measuring the aromatic solvent induced shift (ASIS) for the complete series of heterocycles *(72a)*—*(72e)* it could be demonstrated beyond doubt that the methyl group of the exocyclic ethylidene moiety in *(72b)*, *(72c)*, and *(72d)* is present in one configuration only, which is *cis* to the vicinal oxygen[40].

What then is the role of the metal in this and related reactions of α,α'-dihalo ketones?

Clearly, it has to fulfil several functions. First, a metal such as zinc can readily donate its electrons to form the zinc enolate *(95)* as an intermediate[26,40,52]. In order to account for the stereospecific formation of heterocycles *(72b)*—*(72d)*, the intermediate *(95)* must be generated stereospecifically, at least at low temperatures, in that the methyl group of any ethylidene moiety will be *cis* to the vicinal OZnBr grouping. In the critical stage of the reaction the zinc enolate *(95)* ionizes to give the allyl cation *(96)*, here designated as "zinc oxyallyl" which will wind up as 1) α-methoxy ketone in methanol, 2) five-membered heterocycle in dimethylformamide and dimethylacetamide, 3) 1,4-dione in the presence of an excess of zinc enolate and, of course, 4) seven-membered carbocycle in the presence of conjugated diene.

As to the debromination in methanol it seems clear that the postulated zinc enolate is a finely balanced system in that it contains a) an electron-rich enolate grouping[*] which can be reduced *via* monobromoketone *(98)* into the parent ketone and b) an electrophilic zinc moiety which serves to extract bromide ion to form the desired carbocation (Scheme 8).

A priori, unsymmetrically substituted dihaloketones, such as *(33)* and *(35a)* + *(35b)* can form two zinc enolates and the question arises which isomer if any is favored thermodynamically. It has been shown in another context that thermodynamically unstable *enols* can be generated and observed the more readily, the more highly alkylated the enolic double bond[40b,41b]. Hence, if enols are to be taken as models for the corresponding zinc enolates, it seems likely that it is the more alkylated zinc enolate which is thermodynamically the more stable, and also formed preferentially.

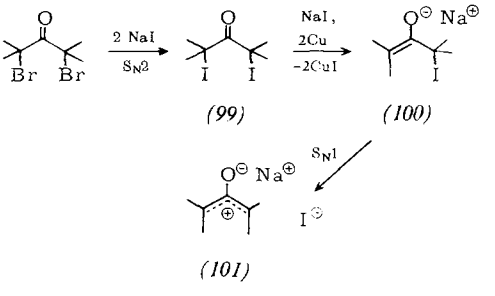
In any event, alkylation of the termini in the precursor *(95)* will also favor ionization to the allylic cation *(96)* in the next stage of the reaction. Hence the primary-tertiary dihalo ketones *(35a)* and *(35b)*, which on dehalogenation in methanol give relatively little α-methoxy ketone (Table 2), are also reluctant to form heterocycle *(72e)*, which is obtained in about 20% yield starting from *(35a)*[40b].

[*] The zinc enolate derived from 3-bromo-3-methyl-2-butanone can be acetylated with acetic anhydride at carbon; *B. K. Carpenter*, unpublished work.

Thus, it is immediately apparent that the formation of α-methoxy ketone on dehalogenation with zinc-copper couple in methanol offers an exceedingly simple and useful criterion for the feasibility of generating allyl cations and for the orientational selectivity of subsequent nucleophilic attack[52].

α,α'-Dihalo ketones which are resistant toward reaction with zinc-copper couple under ordinary conditions, can be induced to cycloadd by an important modification of technique. Adopting the very simple measure of using a long column filled with zinc-copper couple and passing the reagents down this column—if necessary several times—the dihalo ketone can be dehalogenated completely, without any remnants of possibly lachrymatory starting material in the final products. The *continuous* dehalogenation—unlike the batchwise procedure—allows repeated use of the zinc-copper couple and facilitates work up of the products[46].

The debromination of α,α'-dibromo ketones by iodide ion in the presence of mercury or copper begins with a rapid S_N2 diplacement of bromide by iodide, provided, of course, a suitable primary or secondary center is available[53]. Presumably, reductive removal of iodine by further iodide ion furnishes the enolate [*(99)*→*(100)*], the liberated iodine being trapped by mercury or copper. Subsequent ionization of *(100)* leads to allyl cation *(101)*, which, like zinc oxyallyl, combines with conjugated dienes, although the steric course of the two cycloadditions is different (cf. Table 3)[35].



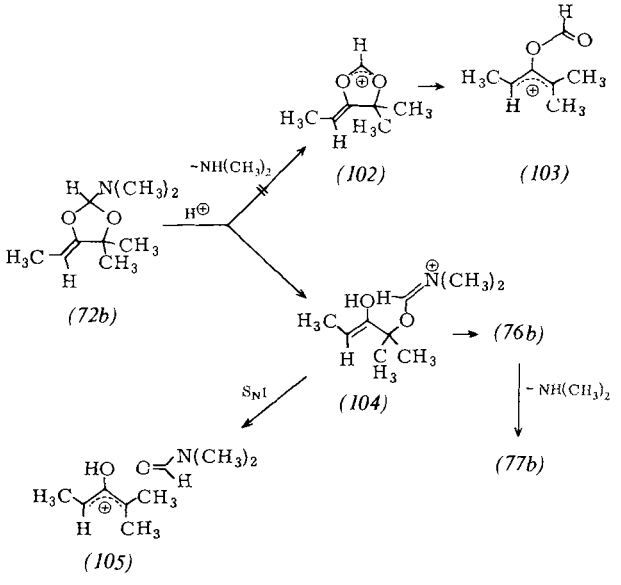
(99) *(100)* *(101)*

A few final remarks about the regioselective attack by methanol and dimethylformamide are in order. The solvolysis of allyl halides and the accompanying product spread have been studied with unusual intensity in the past[3c]. The finding that simple methylated 2-oxyallyl cations can be trapped in orientationally uniform fashion is of intrinsic interest and, to our knowledge, without precedent in solvolyses of conventional methylated allyl halides and tosylates. It should be borne in mind that: 1) all our reactions are mechanistically S_N1; 2) the zinc moiety can electrophilically assist the departure of the second bromine [*(95)*→*(96)*]; and 3) the oxygen attached to the central carbon of the allyl system contains unshared pairs of electrons which might facilitate ionization.

In effect, the intermediate which is trapped by methanol and dimethylformamide is a *delocalized* allyl cation which appears to have reached at least the solvent separated stage (cf. Fig. 1) and renounced any specific interaction with its counterion. Accordingly, it is attacked exclusively at the more electrophilic terminus, at least in the solvents methanol and dimethylformamide.

9.1.3. 4-Alkylidene-2-dimethylamino-1,3-dioxolanes

The 4-ethylidene-substituted heterocycles *(72b)* and *(72c)* + *(72d)* do not cycloadd to furan when using scrupulously dried and distilled diene. In contrast, on mixing the heterocycles with *commercial* furan, the bicyclics *(39)* and *(41)*, respectively, are formed. The cycloaddition can also be slowed down or suppressed altogether in the presence of 2,6-lutidine. It is also pertinent that formation of the enol *(73a)* from heterocycle *(72a)* is extremely sensitive to traces of acid and occurs spontaneously in commercial dimethyl sulfoxide and carbon tetrachloride, but not in spectrograde carbon tetrachloride or dry pentane[41].



During the formation of cycloadducts *(39)* and *(41)* from *(72b)* and *(72c)* + *(72d)* one observes that dimethylamine is liberated[26]. Since protonation of the amino nitrogen followed by loss of amine is a general reaction of simple 1-aminoacetals[54], one could take it as a foregone conclusion that the dioxolenium ion *(102)* is formed *en route* to allyl cation *(103)*. However, by using heterocycle *(72b)* and freeing it from dimethylformamide by the freezing-out technique it could be demonstrated more recently that *(39)* and dimethylformamide were formed in equimolar quantities, the remaining product (*ca.* 50%) being the 3(2*H*)furanone *(77b)*[40b]. Consequently, it seems more likely that the reactive species entering into the cycloaddition is the 2-hydroxyallyl cation *(105)*, which probably still interacts weakly with dimethylformamide (see below). In any event, ammonium resonance in *(104)* should be superior to oxonium resonance in *(102)*[*].

Furthermore, the 1,3-dimethyl-2-oxyallyl cation arising from heterocycles *(72c)* + *(72d)* must be different from that formed on debrominating 2,4-dibromo-3-pentanone *(34)* with zinc-copper couple; note that the two reactions give a different ratio of *cis* diequatorial epimer *(41)* to *cis* diaxial epimer *(43)* (Table 3, No. 1 and 3).

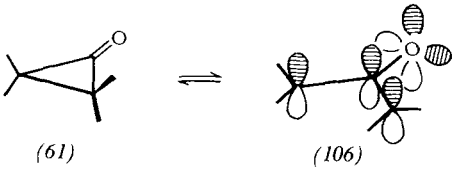
[*] Interestingly, even anhydrous hydrogen chloride in CCl_4 converts heterocycle *(72a)* quantitatively into α-chloro ketone, no dimethylamine or its hydrochloride being observed [40b].

We are now prepared to return to the isopropylidene substituted heterocycle *(72a)* which does not combine discernibly with furan under a variety of conditions, but instead affords the enol *(73a)*. It is hardly likely that a steric effect operates here, since the corresponding ditertiary dihalo ketone *(32)* can be debrominated with zinc-copper couple in the presence of furan to yield the bicyclic compound *(38)* very smoothly. Two factors appear to be responsible for these contrasting results: first, zinc oxyallyl *(96)* generated *in situ* from *(32)* should be more reactive than the corresponding 2-hydroxyallyl cation arising from heterocycle *(72a)*, and therefore combine more readily with the diene component. Secondly, dimethylformamide is more basic than bromide ion as a leaving group, and hence abstracts one of twelve peripheral methyl protons [*(72a)* → *(73a)*].

In summary, the cumulative evidence now available points to a spectrum of allyl cations including zinc oxyallyl *(96)*, sodium oxyallyl *(101)*, and hydroxyallyl cations, which, however, do not seem to occur as free, solvated cations, but rather as solvent-separated ion pairs and contact ion pairs.

9.1.4. Cyclopropanones

Clearly, the cycloadditions discussed so far proceed *via* allyl cations, which are formed under typical S_N1 conditions in the bottleneck of the overall reaction. In contrast, cycloadditions of methylated cyclopropanones appear to be different. Kinetic studies seem to implicate furan in the rate limiting stage of its reaction with several alkylcyclopropanones; hence the question arises whether the cycloaddition starts with π-oxyallyl *(106)* or the closed form *(61)*[55].

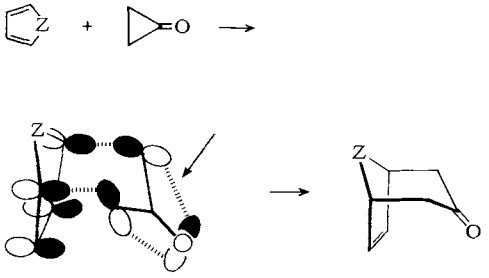


π-Oxyallyl has been proposed as an intermediate in the reaction of the heterocycle *(78)* with furan[45a]. Since the α,β-unsaturated ketone *(80)* is formed as a by-product, it is clear that at least catalytic amounts of acid must have been present in this reaction, and in the light of our work on heterocycles *(72a)*—*(72e)* it seems more likely that the reactive intermediate is actually 2-hydroxyallyl in combination with the appropriate counterion.

Theoretical conclusions and calculations as to the stability of the parent π-oxyallyl species have fluctuated. After having originally been put forward as an intermediate of the Favorskii reaction[56a], π-oxyallyl has at one time been proposed to be more stable than cyclopropanone itself[56b], but more recently been suggested to be less stable by 80 kcal/mol[56c].

The role of the carbonyl system and its electrons in the opening of (methylated) cyclopropanone(s) has never been completely clear. Because of the lone pair of electrons on oxygen, cyclopropanone can enter into reaction with the diene as a σ-component. The resulting pericycle *(107)* will be seen to contain one phase dislocation, *i. e.* it is of the

anti-Hückel[57a] or Möbius[57b] type (Scheme 9). Now, being filled with *eight* rather than six electrons, the circuit will be aromatic[57] and the reaction should be facile.



(107)

Scheme 9. Cyclopropanone as σ component in cycloadditions to conjugated dienes. The phase dislocation is indicated by an arrow.

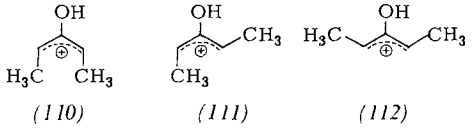
Consequently, the cycloadditions of cyclopropanones to conjugated dienes might have nothing to do with the reactions so far discussed [cf. eq. (3)] and be, strictly speaking, outside the scope of this paper.

9.2. Compact and Extended Transition States

A priori, an allyl cation can interact with a conjugated diene in the compact, boat-like transition state *(108)* or the extended chair alternative *(109)*. For an experimental distinction of the two modes at least one terminal substituent on each π-reactant is required[*].

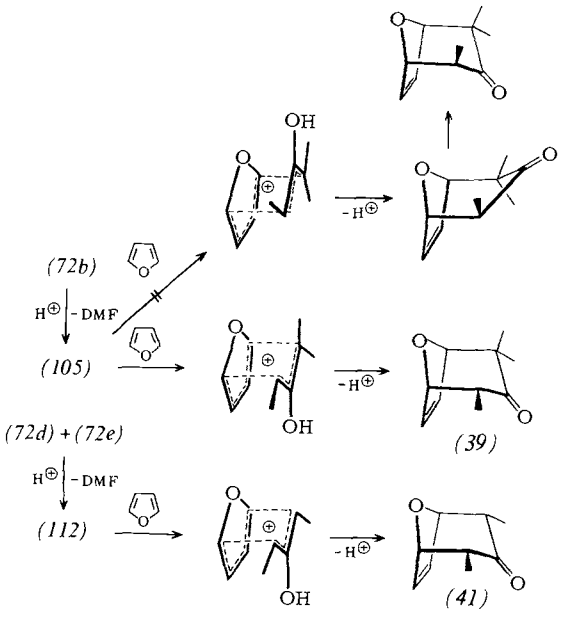
(108) *(109)*

While configurationally defined dienes are readily available, the situation is necessarily more complex with respect to the transitory allyl cation. For example, a terminally disubstituted allyl cation can exist in three configurations, namely the U form *(110)*, the sickle geometry *(111)*,



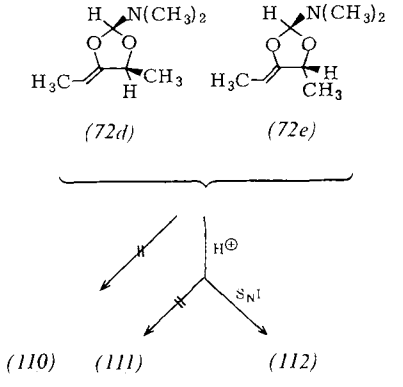
(110) *(111)* *(112)*

and the W configuration *(112)*. Ideally, one would aim to generate the allyl cation in a single and known configuration, capture it with a terminally substituted diene and finally, separate and assign any stereoisomeric adducts. By using 4-ethylidene-2-dimethylamino-1,3-dioxolanes the allyl cation geometry could be controlled. Thus, after reaction with furan, the single methyl group at C-5 of the heterocycle *(72b)* was found to have occupied the equatorial position in the adduct *(39)*. Clearly, allyl cation *(105)* is implicated as the intermediate, which combines with furan *via* the compact mode (Scheme 10).



Scheme 10. Cycloadditions *via* compact transition states.

Furthermore, the mixture of epimeric heterocycles *(72d)* + *(72e)* and furan furnished the *cis* diequatorial adduct *(41)*; thus, the intervention of the W cation *(112)*—



(72d) *(72e)*

(110) *(111)* *(112)*

rather than the sickle alternative *(111)*—is at once established; the compact course of cycloaddition is equally obvious (Scheme 10).

An extrapolation to other 2-oxyallyl cations is also feasible. For instance, debromination of 2,4-dibromo-3-pentanone *(34)*—an epimeric mixture being used—with zinc-copper couple in the presence of cyclopentadiene at 0 °C afforded the two epimers *(50)* and *(51)* in the ratio 1.67 : 1. Consequently, intervention of the W cation and leakage into the extended transition state can hardly be in doubt (cf. Table 3, No. 5)[26].

Finally, it seemed desirable to generate the 1,3-diphenyl-2-oxyallyl cation[23a,24b] and avoid any unduly harsh conditions in so doing. With furan and three different routes to the allyl cation (cf. Table 3, No. 8) intervention of

[*] In a cycloaddition involving two π-reactants any terminal substituent can be disposed *endo* or *exo* in the adduct. In order to avoid complete confusion we use the terms *endo* and *exo* to describe the configuration of *substituents*, in common with normal practice, and designate the two geometries of the π interaction as "compact" and "extended".

Table 3. Compact and extended transition states in cycloadditions of 2-oxyallyl cations [26] (see Schemes 8, 9, 10).

No.	Diene	2-Oxyallyl cation substituents	2-Oxyallyl cation precursor	Products	Transition state compact : extended
1	furan	1,3-dimethyl	heterocycle *(72d)* + *(72e)*	*(41)*	1:0
2	furan	1,3-dimethyl	halo ketone *(34)* [a]	*(41)* (94%)	≥15:1
3	furan	1,3-dimethyl	organozinc compound from *(34)*	*(41)*:*(42)*:*(43)* 81 : 9 : 10	≈8:1
4	cyclopentadiene	1,3-dimethyl	halo ketone *(34)* [a]	*(50)* (84%)	≥5:1
5	cyclopentadiene	1,3-dimethyl	organozinc compound from *(34)*	*(50)*:*(51)* 1.67 : 1	1.67:1 1.7:1 [b]
6	furan	1,1,3-trimethyl	heterocycle *(72b)*, halo ketone *(33)* [a], organozinc compound from *(33)*, cyclopropanone [27c]	*(39)*	1:0 [c]
7	cyclopentadiene	1,1,3-trimethyl	organozinc compound from *(33)*	*(47)*:*(48)* 3.8 : 1	3.8:1 2.6:1 [b]
8	furan	1,3-diphenyl	halo ketone *(26b)* [a,d], organozinc compound from *(26b)*	*(27a)*	1:0 [60]

[a] NaI induced dehalogenation in the presence of mercury or copper in acetonitrile.

[d] With 2,6-lutidine.

the W cation and the compact combination was established[60].

In discussing the results of Table 3 it must not be forgotten that a preference for one isomer by 99% represents very little in energetic terms—*i.e.* less than 3 kcal/mol—and overenthusiastic interpretation is certainly not warranted. Nonetheless, two trends seem to be discernible: 1) Cycloadditions of open-chain allyl cations to furan are more inclined to follow the compact course than those to cyclopentadiene. 2) Increasing methylation—and possibly stabilization—of the allyl cation promotes the compact transition state.

Now we recall that the six-membered ring of bicyclo[3.2.1]oct-6-en-3-ones is more prone to deformation and half-sided flattening than that of 8-oxabicyclo[3.2.1]oct-6-en-3-ones (Section 4.1). Hence, if the structure of the product is to be taken as a model for the preceding transition state, it is understandable that leakage into the extended interaction is more facile in cycloadditions to cyclopentadiene, and in fact, one may argue that the cycloadditions are subject to conformational control[58].

Yet this is probably not the complete story. Given a free choice of the two geometries *(108)* and *(109)*, the compact transition state *(108)* is unfavorable because of a weak second-order interaction, *i.e.* that of the highest occupied MO of the allyl cation and the lowest unoccupied MO of the diene[14, 59]. This interaction should become the more dominant the less stable the allyl cation (Fig. 2). In this context the formation of *cis* diaxial adduct *(43)* from the organozinc precursor (Table 3, No. 3), but not from the heterocyclic route (No. 1), is especially interesting. Since zinc oxyallyl is more electrophilic and hence less stable than the corresponding 2-hydroxyallyl species derived from the heterocyclic precursor *(72c)* + *(72d)* (Section 9.1.3), secondary orbital interaction should be more developed in the former case and be removed *via* the extended transition state, even though this has to occur at the price of placing two methyl groups into *syn*-axial

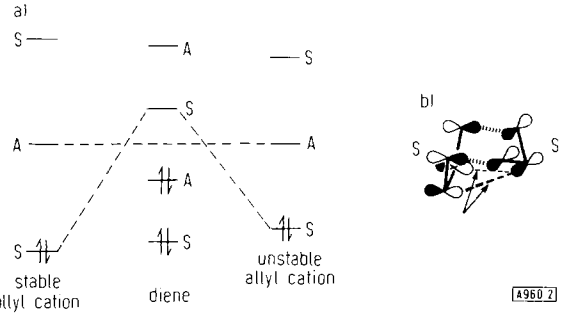

Fig. 2. Secondary orbital interaction of a diene with an allyl cation as a function of cation stability. a) The SS interaction is reduced for the more stable allyl cation, and enhanced for the less stable one. b) This compact transition state [≡ *(108)*] is less favorable than the extended one [*(109)*].

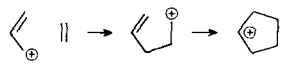
positions. On the same basis, the species derived from NaI in the presence of mercury is less electrophilic than zinc oxyallyl (cf. Table 3). Furthermore, the original work on cyclopentadiene and the 2-methylallyl cation, which showed a tendency toward an extended transition state[59], also fits nicely into the emerging pattern in that secondary orbital interaction should be especially pronounced with the highly unstable 2-methylallyl cation. In effect, one can condense our data into the rule that the more electrophilic—or the more reactive—the allyl cation, the greater the propensity toward an extended transition state.

Whatever further results may come to light, it must now be accepted as experimental fact that the steric course of the cycloaddition can be influenced and controlled by the reagents and conditions used for generating the allyl cations.

9.3. Cycloadditions of Allyl Cations to Olefins

Since allyl cations serve as π-reactants toward conjugated dienes, the question arises whether they might also combine with olefins. It has already been mentioned that intermolec-

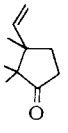
ular hydrogen transfer according to eq. (4) is as yet unobserved and presumably not very favorable on energetic as well as conformational grounds. What then is the probability of a stepwise combination of an allyl cation and an olefin to a five-membered ring (Scheme 11)?



Scheme 11. Stepwise combination of an allyl cation with an olefin.

Using the silver salt route to simple allyl cations and common olefins and dienes (cf. *e.g.* Section 8.2) we have not yet found any evidence for this reaction. In view of the general facility of forming five-membered rings, it seemed reasonable to assume that the reaction might be favored if the intermediate carbocation were sufficiently stabilized. Consequently, dimethylformamide became an obvious choice of a *hetero*olefinic component.

Although heterocycles *(72a)*—*(72e)* can formally be regarded as 1,3-dipolar adducts of oxyallyl cation to dimethylformamide, their formation can hardly be interpreted as a concerted cycloaddition. Some arguments against this reaction path have already been put forward (Section 9.1.2); the postulated stepwise formation by nucleophilic trapping of zinc oxyallyl gains further credence from the observation that heterocycle *(72a)* can be transformed into the cyclic α-amino ether *(76a)* on prolonged contact with $ZnBr_2$, *i.e.* by debrominating *(32)* with zinc-copper couple and isolating the product after one week at 25 °C rather than after 3 h at −20 °C[43]. If the ion *(75)* is the intermediate on the way from *(72a)* to *(76a)*, microscopic reversibility demands that heterocycle *(72a)* be also formed from this ion *(75)*. Overall, one can see that zinc not only serves admirably in the genesis of zinc oxyallyl from the dihalo ketone, but also in the formation of the thermodynamically more stable product *(76a)*. It should be borne in mind that under any other circumstances heterocycle *(72a)* smoothly affords the enol *(73a)* rather than *(76a)*. The deactivation of *(75)* towards the E1 route to *(73a)* recalls the reduced rate of ionization of 2-methoxyallyl halides discussed earlier. The excess of dimethylformamide can be viewed as an efficient ligand for the eventual release and disposal of $ZnBr_2$, similar to glyme which was used for the cycloadditions to conjugated dienes[26].



(113)

Given favorable electronic circumstances there seems to be no reason to exclude intermediates related to *(75)* in the reaction of 2-oxyallylic species with other olefins[61] and dienes. In fact, it has already been mentioned that the dehalogenation of the primary-tertiary dihalo ketone *(35b)* with iodide ion in the presence of mercury and isoprene yields not only the "expected" rings *(59)* and *(60)*, but also three isomeric monoterpenoids $C_{10}H_{16}O$, *i.e.*, vinylcyclopentanone *(113)* and two cyclic ethers[35]. In principle, isoprene can accommodate positive charge from the oxyallyl intermediate by forming a relatively stable dialkylated allyl cation, whereas the negative charge may be delocalized over the enolate ion. Thus the way is paved for a plethora of products. Remarkably, debromination of the di-secondary dibromo ketone *(34)* in the presence of isoprene under analogous conditions (NaI, Hg) yielded not less than twelve $C_{10}H_{16}O$ isomers[62]!

The author wishes to express his sincere thanks to his coworkers B. K. Carpenter, R. Chidgey, K. E. Clemens, G. Greenwood, A. E. Hill, D. R. Joy, G. F. P. Kernaghan, T. A. Nour, E. A. Schmidt, R. H. Smithers, and J. G. Vinter who through their experimental and intellectual skills have laid much of the basis for this article. The support granted by the Petroleum Research Fund, administered by the American Chemical Society, and that of the Science Research Council, as well as a contribution from the Dr. Carl Duisberg-Stiftung, Imperial Chemical Industries Limited, and Schering AG Berlin are also gratefully acknowledged.

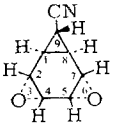
A Planar Cyclohexane Ring: X-Ray Analysis of 9-Cyano-*anti*-dioxatris-σ-homobenzene

By *Chizuko Kabuto*, *Morio Yagihara*, *Toyonobu Asao*, and *Yoshio Kitahara*[*]

Recently a general synthetic route to trishomobenzene has been established, and some interesting properties which may arise from the strained character of the molecule reported[1]. Particular interest attaches to changes in geometry of the central cyclohexane ring when annelated to three strained small rings. We have established the structure of the molecule by X-ray analysis of 9-cyano-3,6-dioxatetracyclo[6.1.0.0^{2,4}.0^{5,7}]nonane *(1)*[2]. As far as we know, this is the first structural report on the tris-σ-homobenzene system.



(1)

Compound *(1)* crystallizes in the monocyclic space group $P2_1/c$ with $a=6.501$, $b=13.215$, $c=8.795$ Å; $\beta=115.74°$; $Z=4$; $D_{exp}=1.45$ g/cm^3, $D_{calc}=1.46$ g/cm^3. A single crystal ($0.2\times0.2\times0.25$ mm) was examined with Rigaku automatically controlled four circle X-ray diffractometer; a total of 1289 reflections (within $2\theta=55°$) were measured using $Mo_{K\alpha}$ radiation. The structure was solved by a direct method and the parameters were refined by a block-diagonal least-squares method. After several refinements, all the hydrogen atoms were found from a difference Fourier synthesis. Further anisotropic least-squares refinement (C, O, N) and simultaneous isotropic least-squares refinement (H) gave an *R*-factor of 0.048.

The most important geometrical data are shown in Figure 1. As expected, the cyclohexane ring of *(1)* has a planar conformation: the maximum deviation from the plane through C^1 to C^6 is only 0.008 Å. The dihedral angle between this plane and the cyclopropane ring (75.8°) is similar to those in *anti*-bromobishomoquinone (75—77°)[3] and 2,5-dimethyl-7,7-dicyanonorcaradiene (73°)[4]. The oxirane rings inclined in the opposite direction exhibit comparable dihedral angles (75.2° for $C^3C^4O^1$ and 74.9° for $C^5C^6O^2$).

The influence of the "unsaturated character" of the three-membered ring on the bond length warrants attention: The C^1—C^6, C^2—C^3, and C^4—C^5 bonds (av. 1.480 Å) are significantly shorter than sp^3-sp^3 single bonds (1.54 Å), and close to sp^2-sp^2 single bonds (1.48 Å). This would indicate that multi-conjugated interactions occur between three-membered rings, as assumed between cyclopropane rings and double bonds[3–5].

A planar six-membered ring results in expansion of the "intracyclic" bond angles (120°), thus leading to a tilting

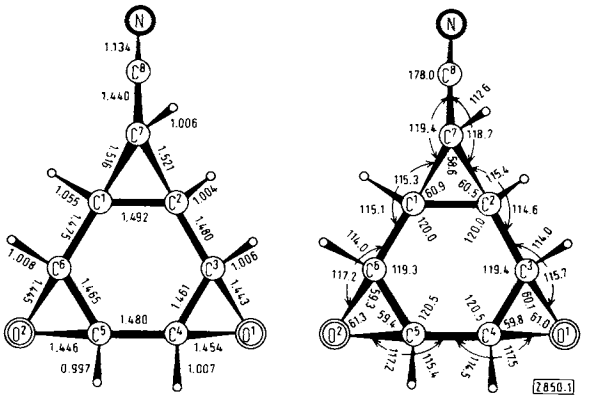


Fig. 1. Molecular structure of the trishomobenzene derivative *(1)*.—a) bond lengths [Å]; standard deviation: 0.004 for C—C, C—O, and C—N, 0.045 Å for C—H.—b) bond angles [ ]; standard deviation: 0.3 for CCC, COC, and CCN, 2.5 for CCH.

of the C—H bonds attached to this ring towards the plane of the ring (average angle 28°).

These results suggest that the central C_6H_6 skeleton assumes a structure intermediate between cyclohexane with sp^3 carbon atoms and a benzene with sp^2 carbon atoms.

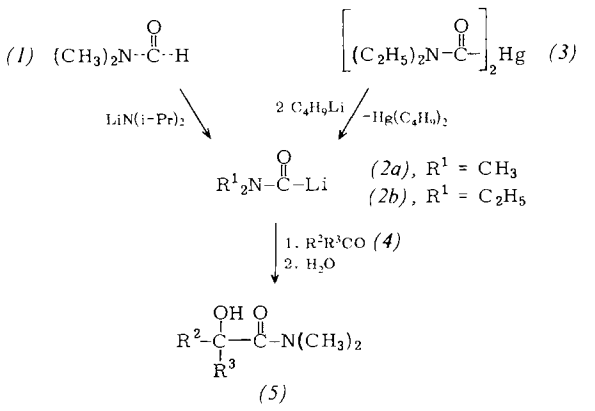
(Dimethylcarbamoyl)lithium from Dimethylformamide and Lithium Diisopropylamide; Synthesis of α-Hydroxy *N,N*-Dimethylcarboxyamides

By *Béla Bánhidai* and *Ulrich Schöllkopf*[*]

Several years ago we reported the preparation of (diethylcarbamoyl)lithium *(2b)* by cleavage of bis(diethylcarbamoyl)mercury *(3)* with butyllithium[1,2]. With carbonyl compounds, *(2b)* affords, after hydrolysis, α-hydroxy *N,N*-diethylcarboxyamides and is thus a reagent that makes it possible to introduce the carbamoyl group into carbonyl compounds[2,3]. The preparation of *(3)* is, however, rather troublesome[4] and not without danger, so we sought a simpler access to reagents of type *(2)*[5].

[*] Dr. B. Bánhidai and Prof. Dr. U. Schöllkopf
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)



We have now found that α-hydroxy *N,N*-dimethylcarboxyamides *(5)* are obtained, sometimes in good yield, by treating dimethylformamide *(1)* with lithium diisopropylamide in tetrahydrofuran/ether at −78 °C in the presence of carbonyl compounds *(4)* (Table 1). We assume the decisive intermediate to be (dimethylcarbamoyl)lithium *(2a)*[5]. We have not succeeded in metalating *(1)* smoothly and unambiguously by, *e.g.*, butyllithium[6].

Analogously, α-hydroxy *N,N*-dimethylthiocarboxamides [C=S in place of C=O in *(5)* are obtained with *N,N*-dimethylthioformamide *via* (dimethylthiocarbamoyl)lithium [C=S in place of C=O in *(2a)*] and carbonyl compounds.

α-Hydroxy N,N-dimethylcarboxyamides (5)

Dimethylformamide (40 mmol) and a carbonyl compound *(4)* (40 mmol) are dissolved in ether/tetrahydrofuran (4:1; 100 ml) (if necessary in tetrahydrofuran alone). To this solution is added at −78 °C a solution of lithium diisopropylamide that has been prepared *in situ* from diisopropylamine and butyllithium in ether (50 ml) and precooled to −65 C. The whole is stirred for 6 h at −78 °C, allowed to reach room temperature, and hydrolyzed with saturated ammonium chloride solution. The phases are then separated; the organic phase is dried over sodium sulfate and the solvent is removed in a rotary evaporator at water-pump vacuum. The crude amides *(5)* are digested with a little ether, then collected and purified (they are often very clean) either by recrystallization or by column chromatography. In particular, the α-hydroxy dimethylthiocarboxyamides are best purified by chromatography on silica gel with ether/pentane. For very expensive carbonyl compounds [see the synthesis of *(5f)*] a 5- to 10-fold excess of dimethylformamide and lithium diisopropylamide is to be used.

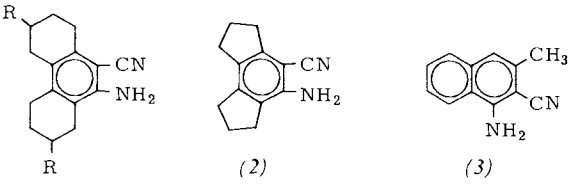
Elimination of the Nitrile Group from *o*-Amino Nitriles

By *Julian Mirek* and *Janusz Sepiol*[*]

10-Amino-1,2,3,4,5,6,7,8-octahydro-9-phenanthrenecarbonitrile *(1a)* can be prepared in almost quantitative yield by cyclization of (2-cyclohexylidenecyclohexylidene)malonodinitrile by concentrated sulfuric acid at 0 °C[1]. (2-Cyclopentylidenecyclopentylidene)malonodinitrile was recently cyclized thermally (160 °C) to 5-aminohexahydro-*as*-indacene-4-carbonitrile *(2)*[2]. Similarly, (α-methylphenethylidene)malonodinitrile is converted by concentrated sulfuric acid at room temperature into 1-amino-3-methyl-2-naphthonitrile *(3)* in high yield[3].

According to *Jäger*[1] the cyano group of *(1a)* cannot be hydrolyzed because of steric hindrance, and in *(2)*



(1a), R = H *(1b)*, R = CH_3

[*] Doz. Dr. J. Mirek and Dipl.-Chem. J. Sepiol
Department of Chemistry
Jagiellonian University
PL 30-060 Kraków (Poland)

and *(3)* it is hydrolyzed only to the amide group and then with difficulty[2,3]. We, however, have found that the *o*-amino nitriles *(1a)*, *(1b)*, *(2)*, and *(3)* are converted into the amines by heating (200 °C) for several hours with alcoholic sodium hydroxide in an autoclave. This "denitrilation" probably occurs by way of the *o*-amino carboxylic acid (or its anion), which is unstable under the reaction conditions (Table 1).

Table 1. Denitrilation of *(1a)*, *(1b)*, *(2)*, and *(3)*.

Nitrile	Reaction time [h]	Amine Yield [%]	M.p. [°C]
(1a)	8	74	65—66
(1b)	8	71	76—77
(2)	7	46	45—46
(3)	6	82	50—51 [a]

[a] M.p. 51—52 °C [4].

General experimental procedure:

The *o*-amino nitrile (5 g) and sodium hydroxide (5 g) are heated in ethanol (80 ml) in an autoclave for some hours at 200 °C. The alcoholic solution, which contains ammonia, is filtered from sodium carbonate, the filtrate is diluted with water (60 ml), and the ethanol is distilled off. The precipitate, at first oily, crystallizes on cooling. The amine that crystallizes from the solution is purified by sublimation in a vacuum and subsequent recrystallization from light petroleum.

The structures of the new amines from *(1a)*, *(1b)*, and *(2)* are proved by analytical and spectroscopic studies.

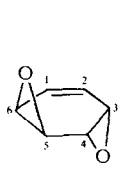
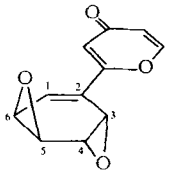
anti-Benzene Dioxide

By *Emanuel Vogel*, *Hans-Josef Altenbach*, and *Erich Schmidbauer*[*]

Benzene is theoretically capable of forming five oxides—benzene oxide[1], *syn*-benzene dioxide[2], *anti*-benzene dioxide[3,4], *syn*-benzene trioxide[5,6], and *anti*-benzene trioxide[5,7,8]—of which all except the *anti*-benzene dioxide *(1)* have been prepared within the last few years. An important stimulus for attempting the synthesis of the as yet unknown *(1)* was provided by the discovery of an antibiotic with the *anti*-benzene dioxide structure *(2)* reported very recently by *Borders et al.*[9]. Preparation of *(1)* appeared all the more desirable since our investigations of *syn*-benzene dioxide *(5)* have cast doubts upon the configuration tentatively assigned to the natural product[2].



(1)

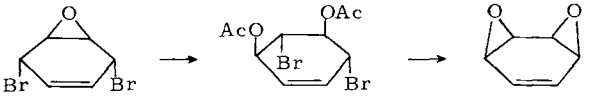


(2)

[*] Prof. Dr. E. Vogel, Dr. H.-J. Altenbach, and Dipl.-Chem. E. Schmidbauer
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

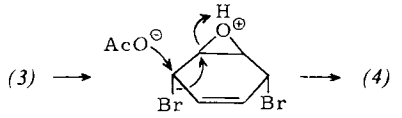
The relatively easily accessible dibromo epoxides *(3)* and *(7)* provided starting materials for the preparation of the *syn*- and *anti*-benzene dioxides, respectively.

As already reported[2b], reaction of *(3)* with acetic anhydride and sulfuric acid[10] leads to a diacetate that affords the desired *syn*-benzene dioxide *(5)* on treatment with methanolic potassium hydroxide. The structure of the diacetate was not clarified at that time, but it was apparent that it could not be the *cis*-1,2-diacetate (3*t*,6*t*-dibromo-1*r*,2*c*-diacetoxy-4-cyclohexene[11]) expected from the projected synthesis of *(5)*.



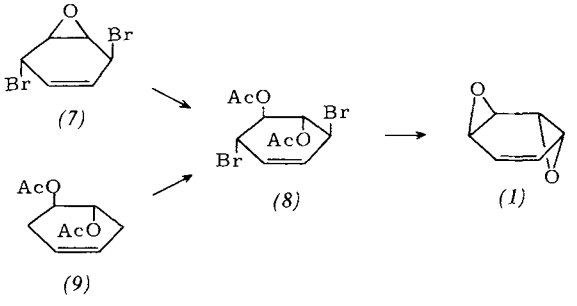
(3) *(4)* *(5)*

The intermediate diacetate has now been recognized as the *cis*-1,3-diacetate *(4)*. The structure *(4)* is indicated in particular by the chemical finding that the diacetate is converted by catalytic hydrogenation over $Pd/BaSO_4$ in ethanol into 2*t*-bromo-1*r*,3*c*-diacetoxycyclohexane[11] (m.p. 79—80 °C), from which *cis*-1,3-diacetoxycyclohexane is obtained on reductive elimination of bromine with Raney nickel in ethanol[12]. *(4)* corresponds in configuration and with great certainty also in conformation to conduritol B (5-cyclohexene-1*r*,2*t*,3*c*,4*t*-tetrol), which is known from NMR studies[13] to assume the energetically favorable half-chair conformation with four equatorial substituents. In actual fact, an NMR analysis of *(4)*[14] carried out on the basis of a half-chair conformation by double resonance and partial INDOR technique provided coupling constants that accord excellently with those for conduritol B. The formation of *(4)* becomes intelligible if one assumes that a neighboring group effect[15] comes into play on opening of the epoxide ring, as indicated in *(6)*.



(3) *(4)* *(6)*

The synthesis of *anti*-benzene dioxide *(1)* was realized starting from the dibromo epoxide *(7)*.

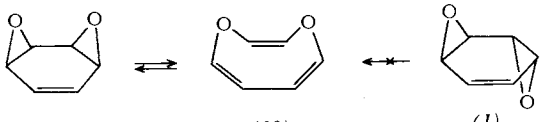


(7) *(8)* *(1)* *(9)*

When *(7)* was treated with acetic anhydride and sulfuric acid at room temperature, the main product was a *cis*-1,3-diacetate (m.p. 105 °C) formed analogously to *(4)*, but there was also obtained a small amount (1 %) of the *trans*-1,2-diacetate *(8)* [m.p. 175—176 °C; NMR ($CDCl_3$): singlet at $\tau = 4.1$ (2 olefinic H), AA'BB' system at $\tau = 4.6$ and 5.25 (4 tertiary H), and singlet at $\tau = 7.9$ (6 acetate-H)]. An alternative route to *(8)* is provided by the reaction of *trans*-1,2-diacetoxy-4-cyclohexene *(9)* with *N*-bromosuccinimide in carbon tetrachloride, which yields *(8)* in admixture with isomers from which it can be separated by fractional crystallization from ether[16].

NMR spectroscopic comparison with the conduritols, as well as catalytic hydrogenation, also proved useful for clarification of the structure and stereochemistry of *(8)*. It was shown that the NMR spectrum of the compound was wholly analogous in its splitting pattern to that of conduritol B. 5 % Methanolic potassium hydroxide causes smooth dehydrohalogenation of *(8)* with formation of a non-phenolic substance of composition $C_6H_6O_2$, m.p. 55 °C (from ether), which was identified as *anti*-benzene dioxide *(1)* by means of its spectroscopic and chemical properties.

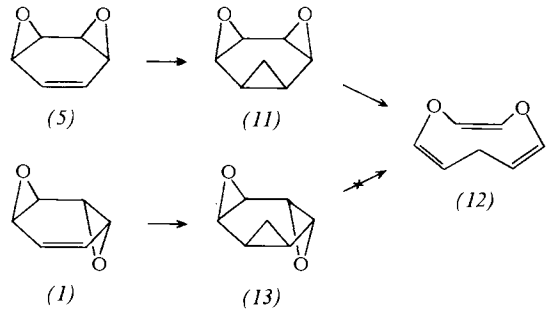
The NMR spectrum (100 MHz, CCl_4) of *(1)* is very similar to that of the *syn*-isomer in that it shows a triplet at $\tau = 3.93$ (1-H, 2-H) and multiplets at $\tau = 6.24$ (4-H, 5-H) and 6.92 (3-H, 6-H). Here too the epoxide protons were assigned on the strength of the observation that the multiplet at higher field was simplified on irradiation at the resonance frequency of the olefinic protons. The simplified multiplet and the multiplet lying downfield then formed an AA'BB' system whose analysis yielded the coupling constants of the epoxide protons ($J_{3,4} = 4.22$, $J_{4,6} = 0.75$, $J_{4,5} = 1.74$, and $J_{3,6} = 0.01$ Hz). The IR spectrum contains pronounced bands in the region 750—950 cm^{-1}, which indicate the presence of epoxide rings. There is no absorption in the UV spectrum above 220 nm. The known *anti*-1,2,3,4-diepoxycyclohexane[17] was formed, as expected, on catalytic hydrogenation of the new benzene dioxide over Pd/C in ethyl acetate.



(5) *(10)* *(1)*

On storage *(1)* suffers relatively rapid decomposition of undefined nature but it is nevertheless remarkably stable thermally: whereas *(5)* equilibrates with 1,4-dioxocin *(10)* even at 50 °C, *(1)* does not isomerize even at 150 °C (in benzene).

The synthesis of *anti*-benzene dioxide *(1)* allows the configuration assigned to the antibiotic *(2)* to be tested. Tools for this are provided not only by the thermal behavior but also by the size of the vicinal coupling $J_{4,5}$ of the epoxide protons 4-H, 5-H. If the Karplus equation is valid[18], $J_{4,5}$ should be 8.5 Hz for the *syn*-configuration and 3 Hz for the *anti*-configuration, since the epoxide protons exhibit dihedral angles of 0 and 50°, respectively. Actually, however, $J_{4,5}$ for *syn*- and *anti*-benzene dioxide are found to be 2.83 and 1.74, respectively. This diminution of the vicinal couplings with retention of the relation $J_{syn} > J_{anti}$ corresponds to observations by *Tori et al.*[19] that in the 1,2-epoxycyclohexane system $J_{vicinal}$ between an epoxide proton and the proton on the neighboring carbon



(5) *(11)* *(12)* *(1)* *(13)*

atom is appreciably smaller, for dihedral angles between 0 and *ca.* 50°, than would be expected from the Karplus equation. In the light of this finding the coupling $J_{4,5}$ of 2.8 found for *(2)* can hardly be interpreted except on the assumption that, contrary to the previous assignment, the antibiotic is a derivative of *syn*-benzene dioxide.

The two benzene dioxides *(5)* and *(1)* undergo interesting reactions. For example, if *(5)* is treated with ethereal diazomethane at 0 °C, a sterically pure pyrazoline (m.p. 67—70 °C, dec.) is formed relatively rapidly. On irradiation with a high-pressure Hg lamp this affords a dioxatrishomobenzene [m.p. 83—84 °C; NMR ($CDCl_3$): multiplets at $\tau = 6.6$ (epoxide-H), 8.65—9.0 (tertiary cyclopropane-H), 9.1—9.4 (*exo*-CH_2-cyclopropane-H), and 9.5—9.75 (*endo*-CH_2-cyclopropane-H)], which isomerizes above 150 °C by a $[\sigma 2_s + \sigma 2_s + \sigma 2_s]$ cycloreversion that affords a quantitative yield of all-*cis*-1,4-dioxa-2,5,8-cyclononatriene *(12)* [b.p. 53 °C/11 torr; $n_D^{20} = 1.4962$; NMR ($CDCl_3$): doublet at $\tau = 3.8$ (5-H, 9-H), singlet at $\tau = 4.2$ (2-H, 3-H), quartet at $\tau = 5.1$ (6-H, 8-H), and triplet at $\tau = 7.0$ (2 7-H)]. Following the rearrangement of the dioxatrishomobenzene in the temperature range 140.5—155.3 °C kinetically gave the values $E_a = 35.5 \pm 1.5$ kcal/mol and $A = 2.2 \times 10^{14}$ for the activation parameters; the relatively low activation energy for this cycloreversion provides subsequent proof that the dioxatrishomobenzene is the all-*syn*-isomer *(11)* and that the addition of diazomethane to *(5)* occurs from the side of the epoxide rings.

From *(1)* one can obtain analogously the *anti*-dioxatrishomobenzene *(13)* [b.p. 63—64 °C/0.7 torr; $n_D^{20} = 1.5013$; NMR ($CDCl_3$): multiplets at $\tau = 6.4$—6.9 (epoxide-H), 8.5—8.95 (tertiary cyclopropane-H), and 9.0—9.4 (CH_2-cyclopropane-H)], which, unlike *(11)*, remains unchanged when heated at 150 °C.

(12) is of interest because it may be possible, by hydride abstraction, to convert it into a monocyclic 10π carbenium ion containing two oxygen atoms, and attempts to generate this ion are in progress.

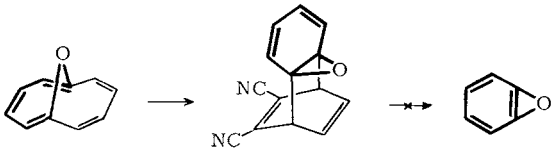
Arene Oxide-Arene Oxide Rearrangements

By *Frank-Gerrit Klärner* and *Emanuel Vogel*[*]

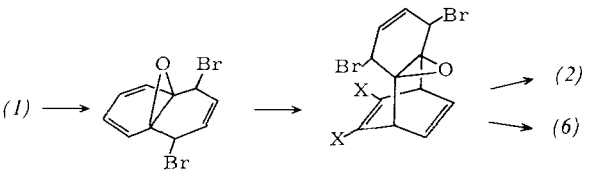
In the course of mechanistic studies of the NIH shift[1] *Bruice* and *Jerina*[2] recently subjected the isomerization of indane 3a,7a-oxide, described by us[3], to detailed kinetic analysis. These authors found that in this reaction an arene oxide-arene oxide rearrangement—a so-called oxygen walk—competes with the known dienone-phenol rearrangement. In an entirely different context, namely while trying to synthesize aryne oxide (3) (benzoxirene), we have been able to observe an arene oxide-arene oxide rearrangement directly.



(1) (2) (3)

Aryne oxide (3) should be accessible by a Diels-Alder reaction of 1,6-oxido[10]annulene (1) with dicyanoacetylene and subsequent Alder-Rickert cleavage of the expected adduct (2)[4].

Realization of the projected synthesis met with difficulties even at the first stage, since (1) did not undergo a Diels-Alder reaction either with dicyanoacetylene or with other dienophiles. An attempt was therefore made to obtain (2) circuitously, through the known dibromo adduct (4)[5] of (1). (4) added one mol of dicyanoacetylene or dimethyl acetylenedicarboxylate already at room temperature forming the adducts (5a) and (5b), respectively (m.p. ≈ 190 °C dec. for both adducts). When (5a) was then treated with sodium iodide in acetone at room temperature, the desired (2) [m.p. 122 °C (from ethyl acetate); 53% yield] was formed as expected; surprisingly, however, (2) was accompanied by an isomer [m.p. 132 °C (from ethyl acetate)] formed in 25% yield[6]. In the dehalogenation of (5b) the only product isolated (70% yield) was a substance [m.p. 91—92 °C (from ether)] corresponding to the above isomer.



(4) (5a), X = CN
[(5b), X = $COOCH_3$]

Proof of the structure of (2) rests on spectral findings. The NMR spectrum ($CDCl_3$), for which no temperature-dependence is observed, consists only of a singlet at $\tau = 3.57$ (protons of the conjugated double bonds) and an A_2X_2 system at $\tau = 3.61$ (protons of the isolated double bond) and 5.70 (bridgehead protons), corresponding to the symmetry of (2) and of its oxepin valence tautomer (7). That the product is the arene oxide valence tautomer (2) follows from the singlet at $\tau = 3.57$ which is to be regarded as a degenerate A_2B_2 system, as singlets at similar positions have been observed for arene oxide protons of (4) and tetralin 9,10-oxide[5]. Also, the UV spectrum with a maximum at 250 nm ($\varepsilon = 7270$) in dioxane can be accommodated only by the arene oxide form[3]. It is the bracket effect of the 1,6-bridge that must be held responsible for suppression of the arene oxide-oxepin equilibration of (2), as in the cases of (4) and tetralin 9,10-oxide.

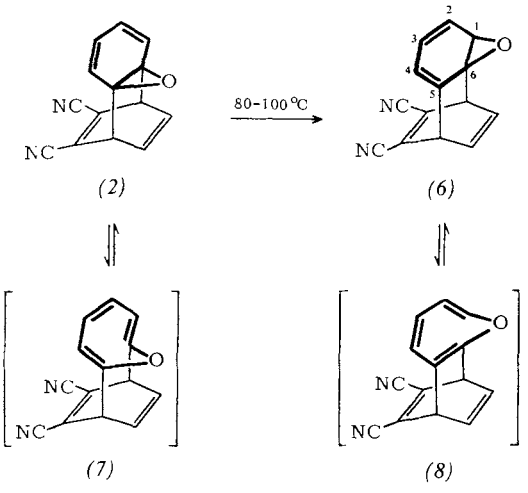
According to the IR spectrum the isomeric dehalogenation product of m.p. 132 °C is neither a phenol nor a ketone. IR bands at 805, 865, and 880 cm^{-1}, and in particular a UV maximum at 253 nm ($\varepsilon = 8080$) in dioxane, strongly suggest that the compound in question is a fixed arene oxide, as is true of (2). On the basis of this finding, the NMR spectrum (100 MHz; $CDCl_3$) of this compound can be interpreted unambiguously in terms of structure (6). The assignments, made by decoupling experiments, are as follows: multiplet at $\tau = 3.30$ (protons of the isolated double bond), multiplet at $\tau = 3.55$—3.83 (protons of the conjugated double bonds)[7], quartets at $\tau = 5.25$ and 6.15 (bridgehead protons), and quartet at $\tau = 5.70$ (epoxide-proton). The NMR spectrum of (6) remains unchanged up to 120 °C, which is the limit of stability of the compound, whence it follows that the arene oxide is not in equilibrium with any significant concentration of its oxepin valence tautomer (8). There is as yet no indication of a possible isomerization of (6) by inversion of the epoxide ring in which an intermediate formation of (8) would become manifest. Above 120 °C (6) rearranges to the expected phenol (m.p. 177 °C dec.; OH group in α-position to the annelated bicyclic system), which is obtained also by treating (2) or (6) with a Lewis acid.

At this point it must be noted, however, that the spectra do not permit unambiguous differentiation of (6) from its stereoisomer with the inverted epoxide ring. In the unlikely event that (6) should undergo an essentially irreversible inversion of the epoxide ring already under the conditions of its formation it would be necessary to revise the configuration assigned to the present arene oxide.

The reason why the arene oxide-oxepin equilibrium is not observed with (6) is clearly to be sought in the fact that the oxepin valence tautomer (8) contains a relatively strained barrelene partial structure. According to

[*] Dr. F.-G. Klärner and Prof. Dr. E. Vogel
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

Turner[8], the heat of hydrogenation of the first double bond of barrelene is 9 kcal/mol greater than for the remaining two double bonds, a value that is to be regarded as a measure of the destabilization of this molecule. Beyond doubt, therefore, the "dihydrobarrelene" *(6)* is lower in energy than *(8)* by several kcal/mol even though it contains an exocyclic double bond that must increase the strain[9]. Such an energy difference is more than enough to freeze in completely the arene oxide form *(6)*.



Contrary to expectation, thermolysis of *(2)* does not lead to liberation of the C_6H_4O unit *(3)* by Alder-Rickert cleavage. Instead of the desired cleavage process a quantitative arene oxide-arene oxide rearrangement takes place already at 80—100 °C, yielding *(6)*. Following this rearrangement kinetically (by NMR spectroscopy) in acetone gave a half-reaction time of 343 min at 80 °C; the activation parameters in the same solvent measured between 80 and 110 C are $E_a = 28.2 \pm 0.8$ kcal/mol and $A = 10^{13.0}$. The rate of the reaction does not exhibit a significant solvent dependence; the factor found for $k_{CD_3CN}/k_{C_6D_6}$ was 3, which accords with conditions in Diels-Alder reactions[10]. This last finding eliminates the possibility that a dipolar intermediate is involved. The isomerization of *(2)* to *(6)* constituting a suprafacial 1,5-sigmatropic shift is symmetry-allowed[11]. The reaction may be considered as a pendant to the Berson-Willcott rearrangement[12] of cycloheptatriene-norcaradiene systems. However, in the present case the stereochemical consequence of a concerted reaction course, namely retention of configuration of the migrating group, cannot be determined experimentally[13].

An arene oxide-arene oxide rearrangement, albeit in masked form, was already encountered by us previously in the thermolysis of 1,6-oxido[10]annulene *(1)*, which in cyclohexane at 180 C (half-reaction time *ca.* 13 h) leads almost exclusively to 1-benzoxepin[14]. We believe that a thermal arene oxide-arene oxide rearrangement would be realizable with benzene oxide itself if it became possible to suppress the catalytically-induced aromatization leading to phenol, and attempts are in progress to uncover such a rearrangement (in this case degenerate) by isotopic labeling.

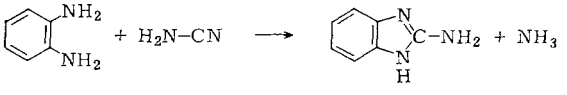
A New, Simple Synthesis of 2-Aminobenzimidazole

By *Stefan Weiss, Horst Michaud, Horst Prietzel,* and *Helmut Krommer*[*]

2-Aminobenzimidazole *(1)* is an important parent substance, *e.g.* for pesticides. Although it can be obtained by ring closure of *o*-phenylenediamine with cyanogen bromide[1], this process is unsuitable for industrial work. We have been able to prepare *(1)* in almost quantitative yield and in excellent purity by treating *o*-phenylenediamine with cyanamide, which is readily available on an industrial scale[2].



(1)

Experimental:

A 50% aqueous solution of cyanamide (23.1 g, 0.55 mol) is added dropwise during 20 min to a boiling solution of *o*-phenylenediamine (54.1 g, 0.50 mol) in concentrated hydrochloric acid (0.50 mol), and the mixture is kept at 100 C for 1 h. 50% sodium hydroxide solution (0.52 mol) is then added and the whole is heated under reflux until evolution of ammonia is almost complete. The precipitate of 2-aminobenzimidazole *(1)* is isolated, washed free from chloride, and dried in a vacuum; it forms pale brown leaflets (61.3 g, 92%), m.p. 228—229 C.

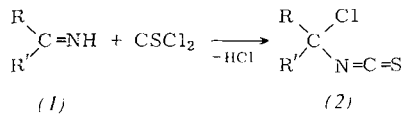
α-Chloroalkyl and α-Alkenyl Isothiocyanates

By *W. I. Gorbatenko, W. A. Bondar,* and *L. I. Samaraj*[*]

We have found[1] that ketimines *(1)* not containing a β-hydrogen atom react with thiophosgene (100—110 °C, in toluene) to afford α-chloroalkyl isothiocyanates *(2)* (cf. ref. [2]).

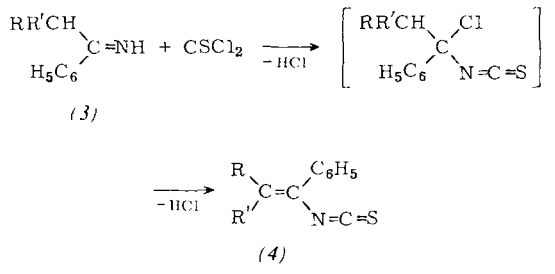


(1) *(2)*

Cpd.	R	R′	Yield [%]	B.p. [°C/torr]	n_D^{20}	d_4^{20}	νNCS (cm^{-1})
(2a)	$C(CH_3)_3$	$C(CH_3)_3$	39	115/15	1.5230	1.0648	2070
(2b)	$C(CH_3)_3$	C_6H_5	50	98/0.06	1.5778	1.1378	2040
(2c)	C_6H_5	C_6H_5	82	135/0.07	1.6380	1.2314	2020
(2d)	α-$C_{10}H_7$	α-$C_{10}H_7$	81	[a]	--	—	2010

[a] M.p. 104—105 °C.

However, α-alkenyl isothiocyanates *(4)* are obtained from the ketimines *(3)* and thiophosgene under the same conditions; α-chloroalkyl isothiocyanates are probably formed as intermediates.



(3) *(4)*

Cpd.	R	R′	Yield [%]	B.p. [°C/torr]	n_D^{20}	d_4^{20}	νNCS [cm^{-1}]
(4a)	CH_3	CH_3	73	65/0.1	1.6120	1.0820	2120
(4b)	H	n-C_3H_7	62	92/0.1	1.6000	1.0660	2100
(4c)	H	i-C_3H_7	77	85/0.1	1.6018	1.0421	2100

The compounds *(2)* and *(4)* are very reactive. As reactants we have so far used chlorine, water, alcohols, amines, sodium azide, phosphites, and dithiophosphoric esters. The IR spectra accord with the structures assigned.

Experimental:

The ketimine *(1)* or *(3)* (0.05 mol) in toluene (50 ml) is added dropwise to a stirred and ice-cooled solution of thiophosgene (0.05 mol) in dry toluene (50 ml). A precipitate separates. The mixture is boiled for 2—3 h; if the precipitate does not redissolve it is filtered off. The solvent is removed in a vacuum and the *(2)* or *(4)* is distilled.

Preparation of Carbonyl Bis(diphenylphosphide)

By *Hermann J. Becher* and *Ernst Langer*[*]

Use of diphenyl(trimethylsilyl)phosphane *(1)* as reagent for introduction of the $-P(C_6H_5)_2$ group makes it possible to obtain bis(diphenylphosphides) under mild conditions even from dicarboxylic acids such as oxalic and phthalic acid, although in these cases acyl phosphides cannot be prepared from acyl chlorides and alkali-metal diorganylphosphides[1]. Since the latter method also failed in attempts to prepare the hitherto unknown bis(organylphosphides) of carbonic acid[2], it seemed to us promising to treat *(1)* with phosgene as a continuation of our previous work[1]. Carbonyl bis(diphenylphosphide) *(2)*, which was to be expected from the reaction:

$$\underset{}{COCl_2} + \underset{(1)}{2(CH_3)_3SiP(C_6H_5)_2} \rightarrow \underset{(2)}{CO[P(C_6H_5)_2]_2} + 2(CH_3)_3SiCl$$

was indeed isolated as a yellow solid when the reactants were mixed in ether at −110 °C. Similar experiments at −60 °C or higher temperatures were unsuccessful; under these conditions we observed evolution of CO, as did also *Issleib et al.* in their experiments with alkali-metal diorganylphosphides[2]; further, we were able to prove the formation of tetraphenyldiphosphane in the solution.

When the solid product *(2)* is separated from the reaction solution at low temperature it is then fairly stable at room temperature if oxygen is excluded: in the presence of oxygen, vigorous oxidation occurs after a short delay, and the yellow color becomes paler. If heated, the compound decomposes even if air is excluded.

Elemental analyses for C, H, and P gave correct values. The IR spectrum of *(2)* was determined for a KBr disk in an evacuated low-temperature cell at −196 °C and showed, along with numerous bands of the $-P(C_6H_5)_2$ group, a band at 1602 cm^{-1} whose intensity decreased rapidly when the sample was warmed to room temperature and air was admitted to the cell; the yellow color of the sample disappeared simultaneously. This band is thus to be regarded as νCO of *(2)*, being considerably lower than for other carbonyl compounds; a similar effect was observed by *Brook et al.* for $CO[Si(C_6H_5)_2]_2$ and $CO[Ge(C_6H_5)_3]_2$[3]. These compounds resemble *(2)* also in their low stability.

Experimental:

A solution of *(1)* (7.4 g, 0.029 mol) in diethyl ether (20 ml) is added dropwise to a stirred solution of $COCl_2$ (1.42 g, 0.014 mol) in diethyl ether (35 ml) at −100 °C under nitrogen. The mixture at once becomes yellow and after

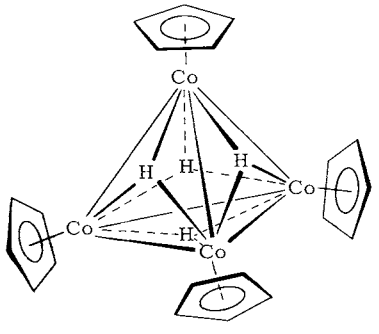
Tetrameric η-Cyclopentadienylcobalt Hydride — A New Type of Four-center Cluster with μ_3-Hydrido Bridges[**]

By *Jörn Müller* and *Horst Dorner*[*]

Relatively little is known about reactions of coordinated nitric oxide although theoretically a variety of such reactions is possible. Our earlier successful experiments with addition of carbanions to the N atom of a nitrosyl ligand[1] induced us to study the possibility of a similar hydride addition. The reduction of an NO to an NH_2 ligand has already been described for the case of reaction of cyclopentadienyldinitrosylchromium chloride with $NaBH_4$[2]. We report here the quite different course of reduction of an η-cyclopentadienylnitrosylmetal complex by a hydride reagent.

If the dimeric cyclopentadienylnitrosylcobalt[3], $[C_5H_5CoNO]_2$ *(1)*, is treated in tetrahydrofuran at 20 C under argon with $LiAlH_4$ in presence of $AlCl_3$, evolution of gas (H_2 and N_2) and change of color from dark olive to dark brown occur. After hydrolysis, a complex of composition $C_{20}H_{24}Co_4$, which forms dark violet shiny crystals, readily soluble in pentane, benzene or ether, can be isolated in 43% yield; when heated under N_2 at 300 C this neither melts nor undergoes any other change. In the solid state the compound is stable in air, but in solution it decomposes on access of air. Because of its properties and spectroscopic data we assign structure *(2)* to the complex.



(2)

The dipole moment of only 0.69 ± 0.1 D, measured in benzene—the true value is probably lower rather than higher—indicates a very symmetrical structure for the compound. The base peak in the mass spectrum is formed by the molecular ion $C_{20}H_{24}Co_4^+$ (*m/e* 500); except for the ions produced by loss of H therefrom, the intensities of other fragments are relatively low. The IR spectrum (KBr) shows the occurrence of equivalent, π-bonded, symmetrical cyclopentadienyl ligands by the following absorptions (the corresponding bands for cobaltocene are shown in parentheses for comparison): 3090 (3060), 1416 (1412), 1103 (1103), 998 (993), 817 (859) and 785 (777) cm^{-1}. Correspondingly, in the ^{1}H-NMR spectrum ([D_8]-tetrahydrofuran) there is one singlet for the five-membered ring protons at $\tau = 5.08$. The existence of bridging hydride ligands follows on the one hand from the metal-hydride vibration at only 950 cm^{-1} (expected region 1100 ± 300 cm^{-1}[4]), which characteristically appears as a broad band in the IR spectrum (a shoulder at 890 cm^{-1} and a further weaker band at 1052 cm^{-1} could also be assigned to Co—H vibrations, but proof of this through the deuteriated compound is not yet available); secondly, a signal at the unusually high τ value of 33.06 is observed in the ^{1}H-NMR spectrum. This and the high symmetry of the complex are best brought into accord with occurrence of μ_3-hydrido bridges. The diamagnetism is also in agreement with the proposed structure in which the Co atoms have noble-gas configurations and are each involved in three metal-metal bonds.

The complex *(2)* is the first organometallic four-center cluster without carbonyl ligands. The primary step in its formation is probably nucleophilic attack by hydride on the nitrosyl-nitrogen of *(1)*. The catalytic role of the aluminum chloride in the redox reaction probably consists of activation of the NO ligand by coordinative interaction with its O atom. Analogous interactions have been observed with carbonyl-metal complexes[5].

Experimental:

All operations must be carried out under argon or nitrogen. A solution of *(1)* (6.16 g, 20 mmol) and $AlCl_3$ (5.3 g) in THF (200 ml) is added dropwise to a stirred solution of $LiAlH_4$ (1.6 g, 42 mmol) and $AlCl_3$ (5.3 g) in THF (200 ml), whereupon gas is evolved (*ca.* 1.4 l). After 24 h the solvent is removed, the residue is stirred vigorously with benzene and water, and the benzene phase is washed with $NaHCO_3$ solution and dried over Na_2SO_4. Removal of the benzene affords almost pure *(2)* (2.15 g, 43%). For further purification the product is dissolved in pentane/benzene (1 : 1) and filtered from a layer (10 cm long, 3 cm wide) of Al_2O_3 (Woelm, 7% of water); it may then be recrystallized from pentane/THF (4 : 1) with severe cooling.

Concerted Fragmentation of a 1,6-Diradical on Thermolysis of 1,2-Dioxanes[1][***]

By *Waldemar Adam* and *James Sanabia*[*]

1,2-Dioxanes such as the tetramethyl derivative *(1a)*[2] should be potential precursors of the 1,6-diradical *(2a)* or the 1,4-diradical *(3a)* provided that the concerted three-

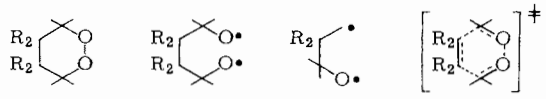
[***] This work was supported by the National Science Foundation and the Petroleum Research Fund of the American Chemical Society.

fold fragmentation of *(1a)* into acetone and ethylene by way of the activated complex *(4a)* does not predominate[3]. In order to learn about the chemical fate of such diradicals we have studied the thermolysis and photolysis of *(1)*[4].



(1) *(2)* *(3)* *(4)*

(a), R = H; *(b)*, R = D

When *(1a)* is heated in benzene solution at 200 °C, it is fragmented quantitatively into acetone and ethylene. 2,2-Dimethyloxetane, the cyclization product of the 1,4-diradical *(3a)*, could not be detected even in traces, although control experiments showed that it is stable under the conditions of thermolysis of *(1a)*.

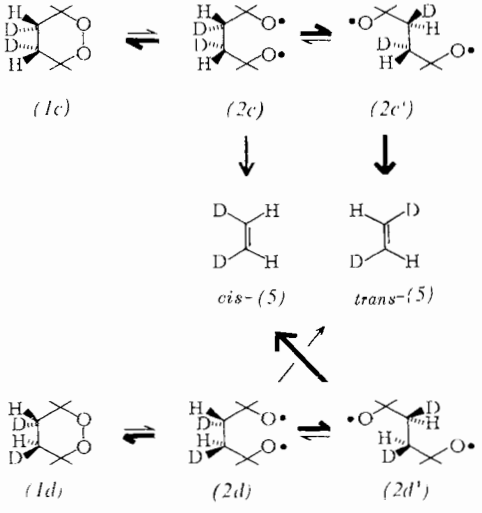
The acetone and ethylene could have been formed, at least in principle, from the 1,6-diradical *(2a)*, from the 1,4-diradical *(3a)* or by the concerted fragmentation pictured in *(4a)*. To clarify the mechanism we have measured 1. the activation parameters, 2. the secondary isotope effect and 3. the stereochemistry of the olefin formation on thermolysis of *(1)*:

1. $\Delta H^{\neq} = 32 \pm 1$ kcal/mol, $\Delta S^{\neq} = -12.6 \pm 1$ cal deg^{-1} mol^{-1}, $\Delta G^{\neq}$ (500 °K) = 38.3 ± 1 kcal/mol for *(1a)*.

2. $k_H/k_D = 1.03 \pm 0.03$, determined for *(1a)* and *(1b)*.

3. 70 ± 2% inversion of the ethylenes *(5)* on thermolysis of *(1c)* and *(1d)*, determined by IR spectroscopy from the ratio of *cis-(5)* to *trans-(5)*. Control experiments showed that *cis-(5)* and *trans-(5)* do not isomerize under the reaction conditions. [Photolysis of *(1c)* and *(1d)* in benzene at 300 nm affords 50% each of *cis-(5)* and *trans-(5)* in both cases; the two ethylenes are photostable at this wavelength.]

The thermolytic results cannot be explained by a concerted three-fold fragmentation of *(1)* by way of *(4)* because in that event the configurations of the olefins should have been quantitatively retained[3] and the secondary isotope effect should have been considerably larger[5]. The results are also not in accord with production of the 1,4-diradical *(3)* because this precursor should have led to complete isomerization of the olefin *(5)* and a considerably larger secondary isotope effect[5]. The 1,6-diradical *(2)* best meets the requirements (see Scheme 1). The stereospecificity of the fragmentation excludes stepwise fission of the 1,6-diradical *(2)* by way of the 1,4-diradical *(3)*.



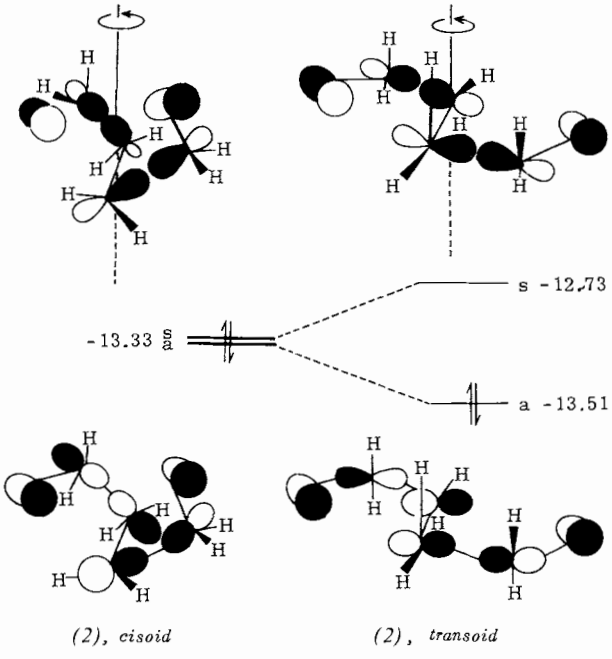
(1c) *(2c)* *(2c')*

cis-(5) *trans-(5)*

(1d) *(2d)* *(2d')*

Scheme 1

The preponderance of inverted ethylene indicates that the activation barrier for concerted double fission to ketone is greater for the cisoid diradicals *(2c)* and *(2d)* than for the transoid diradicals *(2c')* and *(2d')*. EHT calculations[6] showed that for the cisoid 1,6-diradical *(2)* the antisymmetric (a) and the symmetric (s) "diradical" MO's are degenerate, but that for the transoid *(2)* they are split by through-bond coupling[7] [see Scheme 2; there *(2)* is shown with H in place of CH_3]. Now the antisymmetric combination is *ca.* 0.8 eV more stable than the symmetric one; more important, however, is that the antisymmetric "diradical" MO in the transoid conformation is favorably situated for the fragmentation since π-bonded ethylene is formed, whereas the cisoid conformation leads to distorted ethylene. Thus this simple analysis would suggest that concerted fragmentation is more easily undergone by the transoid than by the cisoid conformer.



(2), cisoid *(2), transoid*

Scheme 2

If fragmentation of the 1,6-diradical *(2)* and not homolysis of the peroxide bond determines the rate of reaction, a small isotope effect would be expected since hybridization changes during this fragmentation. In other words, our value of $k_H/k_D = 1.03$ indicates that the energy barrier for concerted fragmentation of the cisoid and transoid 1,6-diradicals *(2)* is higher than that for reclosure to the 1,2-dioxane *(1)*; a similar situation exists for competition between rearrangement and cyclization of the trimethylene diradical[8]. The ready ring opening and recyclization would explain not only the small although not negligible isotope effect but also the negative activation entropy for thermolysis of 1,2-dioxanes *(1)*. For example, 1,2-dioxanes *(1)*, like 1,2-dioxolanes[1], are 10^3 times more stable than *tert*-butyl peroxide. This stabilization is controlled by entropy rather than by enthalpy since for *(1)* $\Delta H^{\neq}$ is *ca.* 6 kcal/mol smaller than for *tert*-butyl peroxide[9]. If reclosure of the 1,6-diradical *(2)* is easier than its fragmentation, then only special conformations of the diradical could decompose to acetone and ethylene and a negative $\Delta S^{\neq}$ value is to be expected. Our kinetic and stereochemical results

thus show that 1,6-diradicals *(2)*, formed by simple homolysis of the peroxide bond of 1,2-dioxane *(1)*, undergo the novel concerted fragmentation described here in preference to the stepwise loss of acetone by way of the 1,4-diradical *(3)*.

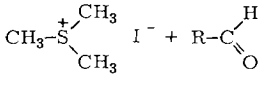
Phase-transfer-catalyzed Production of Sulfur Ylides in an Aqueous System

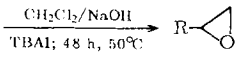
By *Andreas Merz* and *Gottfried Märkl*[*]

There is an increasing number of reports of phase-transfer-catalyzed two-phase reactions[1] in which anionic reactants are transferred from an aqueous to an organic phase by quaternary ammonium salts (benzyltriethylammonium[2] and *n*-hexadecyltrimethylammonium chloride[3] and tetra-*n*-butylammonium iodide[4]). Excellent examples are the cycloadditions[2, 3, 5] and insertion reactions[6] of halocarbenes produced with aqueous sodium hydroxide.

We recently[7] reported on Wittig olefinations by non-stabilized alkylidenetriphenylphosphoranes in the two-phase system dichloromethane/aquesous sodium hydroxide. Our assumption that phase-transfer catalysis is involved in these reactions, brought about by the phosphonium salts, is supported by similar reactions of sulfonium- and oxosulfonium salts described below, which proceed through intermediate sulfonium and oxosulfonium ylides[9]. Like tetraalkylammonium salts containing small alkyl substituents, the trimethylsulfonium ion should not be an effective phase-transfer catalyst; accordingly, trimethylsulfonium iodide *(1)* does not react with benzaldehyde in the two-phase system CH_2Cl_2/NaOH, whereas on addition of 1—5 mol-% of tetrabutylammonium iodide (TBAI) 2-phenyloxirane *(2a)* (b.p. 77 °C/11 torr; $n_D^{20} = 1.5359$[9]) can be isolated in >90% yield.



(1)



(2a), R = C_6H_5
(2b), R = C_6H_5-CH=CH

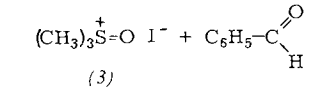
In spite of the long reaction time of 48 h at 50 °C neither hydrolysis of the sulfonium salt nor a Cannizzaro reaction of the benzaldehyde can be observed.

[*] Prof. Dr. G. Märkl and Dr. A. Merz
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

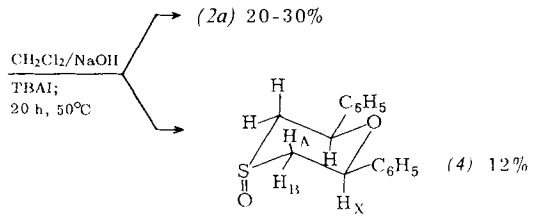
Use of cinnamaldehyde affords equally smoothly an 85% yield of 2-styryloxirane *(2b)*, b.p. 64 C/0.1 torr. ^{1}H-NMR spectrum of *(2b)* in $CDCl_3$ (ppm against internal TMS): aromatic H: 7.20—7.55 (5H); olefinic H: AB portion of an ABX spectrum, centered at 6.37 (2H) ($J_{A-X} = 2$, $J_{B-X} = 8$, $J_{A-B} = 16$ Hz); cyclopropyl-H: 3.30—3.60 m (1H), 2.85—3.15 m (1H), 2.60—2.80 m (1H).

Ketones give only small yields even after prolonged reaction. Acetophenone undergoes 36% reaction in 72 h, and benzophenone 18%, the products again being oxiranes.

The reactions of the trimethyloxosulfonium salt *(3)* are interesting. With benzaldehyde it gives only 20—30% of the oxirane *(2a)*; but this is accompanied by a 12% yield of a colorless, crystalline compound, m.p. 180 °C, which was identified as 2,6-diphenyl-1,4-oxathiane 4-oxide *(4)* by elemental analysis and spectroscopic data.



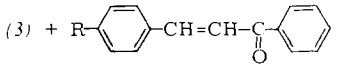
(3)

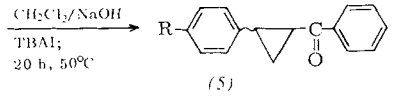


(4) 12%

IR spectrum of *(4)* (KBr disc): νS=O 1025[8], νC—O 1076 cm^{-1}. ^{1}H-NMR spectrum: 7.38 s (10H), AA'BB'X spectrum with δX = 5.60, DXD (2H) ($J_{A-X} = 2$, $J_{B-X} = 10$ Hz), AB potion 2.34—3.20 m (4H) ppm. Mass spectrum: *m/e* = 272 (M^+), 104 (C_6H_5—CH—CH_2^+). Molecular weight (osmometric) = 272 (calc. 272).

(3) reacts remarkably smoothly with α,β-unsaturated aromatic ketones:





(5)

	M.p. [°C]	Yield [%]
R = H [9]	37—43	86
R = CH_3	85—87	78
R = OCH_3	colorless oil	74

Here the same selectivity is evident as was observed by *Corey et al.*[9]: no oxirane is formed, but instead *cis/trans*-mixtures of cyclopropane derivatives.

According to the molecular ratio of the reactants, 1,5-diphenyl-1,4-pentadien-3-one affords mono- or bis-cyclopropane ketones.

2-Phenyloxirane (2a):

Benzaldehyde (10.6 g, 0.1 mol) and TBAI (0.5 g, 1.35 mol) are dissolved in dichloromethane (100 ml) and a layer of 50% aqueous sodium hydroxide is introduced underneath this solution. Trimethylsulfonium iodide (20.4 g, 0.1 mol) is then added and the whole is warmed at 50 C with

vigorous stirring for 48 h, whereupon the originally undissolved sulfonium salt disappears. The reaction mixture is next poured on ice, and the organic phase is separated, washed with water and dried. Distillation affords 11 g (92%) of *(2a)*.

Phase-transfer-catalyzed Alkylation of Alcohols by Dimethyl Sulfate in an Aqueous System

By *Andreas Merz*[*]

Alcohols cannot be converted into their methyl ethers directly by dimethyl sulfate, and only with difficulty in the form of their alkali-metal salts; exceptions are a few activated alcohols such as propargyl alcohol, benzyl alcohol, cyanohydrins, *etc.*[1,2]. *Sjöberg* and *Sjöberg*[3] describe the methylation of alcohols by dimethyl sulfate in the presence of sodium methylsulfinylmethanide as base.

Prompted by *Herriott* and *Picker*'s study[4] of the phase-transfer-catalyzed hydrolysis of *n*-bromooctane, we here report etherification of alcohols by dimethyl sulfate in a two-phase system by use of the principle of phase-transfer catalysis[5].

On addition of *ca.* 1 mol-% of tetrabutylammonium iodide (TBAI), alcohols react with dimethyl sulfate in two-phase systems involving 50% aqueous sodium hydroxide, to give almost always quantitative yields of their methyl ethers (cf. Table 1).

The organic phase can be either the alcohol itself or a mixture of the alcohol with an inert organic solvent (light petroleum, benzene, ether, dichloromethane). It is not only primary, secondary and tertiary alcohols activated by unsaturated or electron-attracting neighboring groups (examples *1—10*) that react smoothly; saturated primary alcohols do so also (examples *11—15*).

The attacking nucleophile is the alcoholate ion involved in the acid-base equilibrium[4]. Thus, because of their lower acidity secondary alcohols react considerably more sluggishly, and tertiary alcohols do not react at all. In the former case an excess of dimethyl sulfate still gives preparatively useful results (examples *16* and *17*). That steric hindrance plays no part is shown by examples *7* and *10* and also by the smooth formation of methyl neopentyl ether *(15)*.

Table 1. Phase-transfer-catalyzed formation of ethers [a] by the process:

$$ROH + (CH_3)_2SO_4 \xrightarrow{NaOH/TBAI} ROCH_3 + Na[CH_3SO_4] + H_2O$$

The two-phase system consisting of (a) a solution of the alcohol to be etherified (0.5 mol) and TBAI (1 g) in light

[*] Dr. A. Merz
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

petroleum (200 ml) (b. p. 50—70 °C) and (b) 50% aqueous NaOH (1.3 mol) is equilibrated by vigorous stirring for 15—30 min, which causes slight evolution of heat. Dimethyl sulfate (0.6 mol) is then added dropwise, with cooling, during 1 h at a rate such that the temperature does not exceed 45 °C. The whole is next stirred for 2—3 h and, after addition of concentrated aqueous NH_3 (10 ml), for a further 30 min at room temperature. The mixture is finally poured into water and the organic phase is separated, washed with water, dried over Na_2SO_4 and worked up in the usual way.

The experimental results are collected in Table 1. The yields depend to a considerable extent on good mixing; for semimicro batches with magnetic stirring a 1.5-fold excess of dimethylsulfate is therefore recommended.

Tris(dimethylamino)azacyclobutadiene[**]

By *Günther Seybold, Ulrich Jersak,* and *Rudolf Gompper*[*]

The calculated resonance energies of cyclobutadiene (−18 kcal/mol)[1] and azacyclobutadiene (azete) (−15.5 kcal/mol)[2] demonstrate both the antiaromatic character of these compounds and the stabilizing action of the N atom[3]. In view of the negative resonance energies it is not surprising that attempts to prepare monocyclic aza- and diaza-cyclobutadienes have hitherto failed[4–7]. Even pyrolysis or photolysis of trimethyl- and triphenyl-1,2,3-triazine[8,9] afforded only acetylenes and nitriles. On the contrary, however, gas-phase pyrolysis of 4-phenylbenzo- and 4-phenylnaphtho-1,2,3-triazine led to 2-phenylbenzazete and 2-phenylnaphthazete which are stable at −80 and 20 °C, respectively[10].

According to the push-pull principle[11], introducing amino groups should provide sufficient stabilization for monocyclic aza- and 1,3-diaza-cyclobutadienes to exist. To test this hypothesis we have investigated the photolysis and flash pyrolysis of tris(dimethylamino)-1,2,3-triazine[13]; we obtained this triazine from tris(dimethylamino)cyclopropenylium perchlorate and potassium azide by analogy with known procedures[12].

[**] Flash Pyrolysis of Organic Compounds, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank the Badische Anilin- & Soda-Fabrik AG, Ludwigshafen, for measuring the 220 MHz ^{1}H-NMR spectrum, and Bruker-Physik AG, Karlsruhe, for measuring the ^{13}C-NMR spectrum.

Irradiating an aqueous solution of *(1)* by a 400 W Hanovia lamp completely destroyed this molecule within a short time: only dimethylcyanamide could then be detected in the reaction solution.

Flash pyrolysis of *(1)* was carried out in an electrically heated quartz tube (25 cm long, 1.5 cm in diameter) at 527 °C and 10^{-4} torr. The quartz tube was packed with quartz wool; to avoid secondary reactions, the pyrolyzate was "frozen" at −196 °C immediately after exit from the heating zone. During the pyrolysis the trap became coated with a deep-red deposit. This was dissolved off by methylene chloride at −80 °C. Presence of the triazine *(1)* in the red methylene chloride solution was proved by thin-layer chromatography and that of dimethylcyanamide by gas chromatography. The red color slowly faded at room temperature.

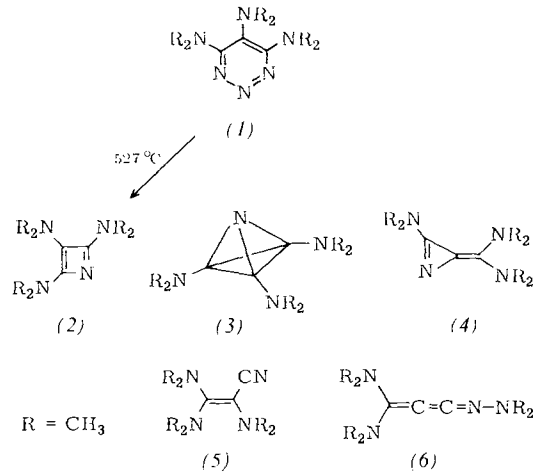
Investigation of the red solution of the pyrolyzate gave the following results:

1. *Mass spectra:* When the direct inlet rod was at a temperature of −25 °C the highest mass was due to an ion with $m/e = 182$. From −10 °C onwards the peak for *(1)* ($m/e = 210$) becomes increasingly stronger with increasing temperature, whilst $m/e = 182$ becomes increasingly weaker. At 100 °C the spectrum corresponds to that of pure triazine *(1)* in which the ion $m/e = 182$ has an intensity of only 1.3%.—The mass spectrum of a pyrolyzate solution that had been kept at room temperature for two days no longer showed the mass peak at $m/e = 182$. From 0 °C onwards new peaks were found in the region between $m/e = 210$ and 340.

We regard the ion of $m/e = 182$ in the spectrum of the fresh pyrolyzate solution as the molecular ion of the red compound, which is evidently relatively easily volatilized and is unstable at room temperature. It is also conceivable that the red product is a thermolabile valence isomer of *(1)* that loses nitrogen already at −25 °C in the mass spectrometer and gives a false mass 182; however, evolution of gas from samples of the reaction product was never observed at room temperature, although release of N_2 during the pyrolysis was recognizable from an increase in pressure from 5×10^{-6} to 10^{-4} torr.

Determination of the molecular weight by high-resolution mass spectrometry gave a value of 182.1486; thence follows a molecular formula $C_9H_{18}N_4$, to which any of the structures *(2)*—*(6)* could be assigned.

Mechanistically, compounds *(2)* and *(3)* are the most likely to be formed from *(1)*. Conversion of *(1)* into *(4)*, *(5)*, or *(6)* requires the assumption that a dimethyl-



amino group migrates in an open-chain intermediate. Compounds *(3)*, *(5)*, and (probably) *(6)* can be excluded because of the red color.

2. *IR spectra:* νC=N of *(1)* 1510 cm^{-1} (CH_2Cl_2), 1520 cm^{-1} (SO_2); νC≡N of $(CH_3)_2N$—CN: 2206 in both solvents. From the red solution new bands appear at 1630 cm^{-1} (CH_2Cl_2) or 1652 cm^{-1} (SO_2). The structures *(3)*, *(4)*, *(5)*, and *(6)* are thus excluded: aminoazirines comparable with *(4)* have a C=N band at 1760 cm^{-1}[14]; from *(5)* one would expect a C≡N band at 2190 cm^{-1} (cf. [15, 16]), and for *(6)*, as a ketene imine derivative[17], a band at 2000 cm^{-1}. Of the structures proposed the only one remaining is thus *(2)* (in 2-alkoxyazetines[18] νC=N has been observed at 1620 cm^{-1}).—The band at 1630 cm^{-1} is not to be found in the IR spectrum of a pyrolyzate solution that has been kept for 2 days at room temperature, is colorless, and no longer shows an ion of $m/e=182$ in the mass spectrum.

3. *UV spectra:* The UV spectrum of a methylene chloride solution of the pyrolyzate, measured at −40 °C, shows an intense absorption maximum at 527 nm with $\varepsilon \approx 20000$ [*(1)*: $\lambda_{max} = 352$ nm]. The disappearance of this maximum at 30 °C follows second order kinetics with a half-life of 56 min (initial absorption 1.100 OD). From theoretical considerations[19] a maximum would be expected for *(2)* at 670 nm; one would predict shorter-wave absorptions for the other structures considered.

4. *NMR spectra:* The ^{1}H-NMR spectra of the pyrolyzate in mixtures of CH_2Cl_2 and CD_2Cl_2 show signals in the range $\delta = 2.5$—3.5 ppm. Singlets at $\delta = 2.75$ and 2.9 ppm can be assigned to the triazine *(1)*, and a singlet at 2.85 ppm to dimethylcyanamide. A 60 MHz ^{1}H-NMR spectrum, measured at −60 °C, shows, besides these signals, two singlets at $\delta = 3.22$ and 2.94 ppm. An intensity ratio of 1:2 can be found from the 220 MHz spectrum. If the sample in the spectrometer is allowed to warm up to room temperature these two singlets disappear simultaneously, being no longer present after *ca.* 12 h, whilst at the same time new signals appear at $\delta = 2.31$ and 3.35 ppm; the solution then has only an extremely faint red color.

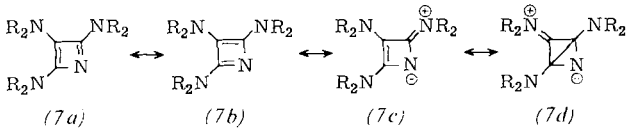
As in the ^{1}H-NMR spectrum, so in the ^{13}C-NMR spectrum two new signals arise, at 138.29 and 128.28 ppm (relative to TMS); these can be assigned to olefinic C atoms.

According to the conditions of the pyrolysis and working up, further signals of lower intensity can be observed in the ^{1}H-NMR spectra of the pyrolyzate; some of them decrease in intensity with increasing temperature.

The following properties can thus be assigned to the red compound in the pyrolyzate solution: molecular weight 182; UV: $\lambda_{max} = 527$ nm ($\varepsilon \approx 20000$); IR: νC=N = 1630 cm^{-1}; ^{1}H-NMR: singlets at $\delta = 3.22$ and 2.94 ppm (1:2).

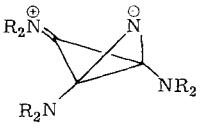
Thence we conclude that tris(dimethylamino)azacyclobutadiene *(2)* is formed on pyrolysis of *(1)*. From the ^{1}H-NMR spectrum the yield can be estimated as approximately 30%.

The relatively high thermal stability and the NMR spectra of the product indicate that *(2)* should be described as the resonance hybrid *(7a)*—*(7d)*, where especial importance attaches to the structure *(7d)*[19]. Provisionally the possibility cannot be excluded that the product has one of the angular structures derived from *(7d)*, *e.g.* *(8)*, although the IR spectrum contraindicates this (cyclopropanimine has C=N bands at 1770 cm^{-1}[20]).



(7a) *(7b)* *(7c)* *(7d)*

R = CH_3



(8)

5. *Chemical behavior:* Experiments in which *(2)* was treated with methyl iodide, tetracyanoethylene, acetylenedicarboxylic ester, phenyl isothiocyanate, tosyl isocyanate, or $Fe(CO)_5$ led to inseparable mixtures of products. The difficulties in working up were partly due to the fact that the triazine *(1)*, which is present in the pyrolyzate in excess of *(2)* (>40%), reacts with electrophiles to give deeply colored, as yet unidentified products[14]. Protonation of *(2)* also seems to take a complicated course.

The Structure of Triaminoazacyclobutadiene[**]

By *Hans-Ulrich Wagner*[*]

Cyclobutadiene *(1)* is antiaromatic; it can be stabilized by push-pull substitution[1]. Substitution as in compounds of type *(2)* has been found especially advantageous in this respect[2]. Analogously, azacyclobutadiene *(3)*, which

[*] Dr. H.-U. Wagner

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We are particularly grateful to the Leibniz-Rechenzentrum of the Bayrische Akademie der Wissenschaften.

is energetically favored in comparison with *(1)* by introduction of the ring-nitrogen that acts as acceptor, can be further stabilized by two donor groups at positions 2 and 4 [see *(4)*].

From this point of view a third donor group, as in *(5)*, has an unfavorable effect. Introducing a donor group at position 3 relative to the acceptor position, as in *(6)*, however, causes distortion of the ring to a rhombus[3] by increasing the bonding interaction and bringing positions 2 and 4 closer together.

	(1)	*(2)*	*(3)*
p_{13}	0.	−0.16	−0.40
p_{24}	0.	+0.29	+0.46

	(4)	*(5)*	*(6)*
p_{13}	−0.35	−0.34	−0.39
p_{24}	+0.25	+0.35	+0.51

The transannular interaction of atoms at opposite corners of the four-membered ring can certainly no longer be neglected since the distance between them of approximately 2 Å comes in the region of normal bond lengths. The energy change including the effect of the diagonal interaction can be estimated to a first approximation from the bond orders in the HMO scheme (see the values under the formulas)[4].

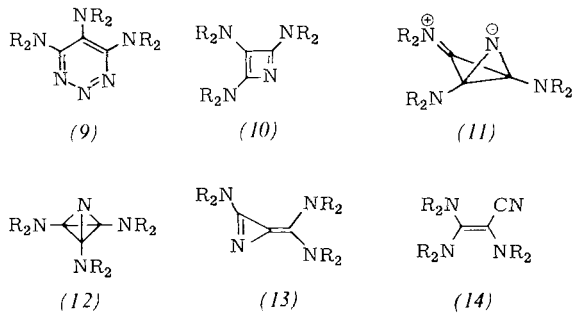
Even in the push-pull-stabilized cyclobutadiene *(2)* closer approach of centers 2 and 4 *and* further separation of centers 1 and 3 should bring an increase in energy. As shown by X-ray structure analysis[5] of *(2)* the measured angles (1—2—3 = 93, 2—3—4 = 87°) and bond lengths (2—4 = 2.00, 1—3 = 2.11 Å) indicate that the four-membered ring is in fact distorted to a rhombus[6].

Although such a distortion does not lead to an energy gain in unsubstituted cyclobutadiene *(1)*[7], considerable stabilization is to be expected for *(3)* in view of the bond orders shown. In the language of resonance theory this distortion favors the polar resonance structure *(7)*.

(7) *(8)*

In *(7)* it can be clearly seen how introducing a donor group at position 3 buttresses the transannular interaction between centers 2 and 4 by stabilizing the positive charge [resonance structure *(8)*]. This effect can also be deduced from the changes in HMO bond orders on going from *(3)* to *(6)* and from *(4)* to *(5)*.

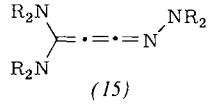
The unstable red product of molecular formula $C_9H_{18}N_4$ obtained on flash pyrolysis of 4,5,6-tris(dimethylamino)-1,2,3-triazine *(9a)*[8] can have one of the structures *(10a)* to *(15a)*. To aid clarification of the structure the electronic spectra to be expected for *(10)* to *(15)* were calculated



(9) *(10)* *(11)*

(12) *(13)* *(14)*

(a), R = CH_3
(b), R = H



(15)

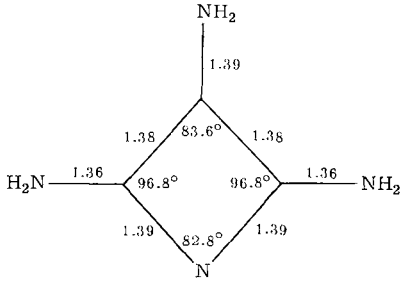
by a CNDO-CI procedure[9] (Table 1); but since it can be assumed that the methyl groups have no appreciable influence on the chromophore of the red compound, the CH_3 groups were replaced by H for the calculations[10].

Table 1. Calculated wavelengths of the longest-wave electronic transitions for various structures $C_3H_6N_4$ ($C_9H_{18}N_4$).

Structure	*(9b)*	*(10b)*	*(11b)*	*(12b)*	*(13b)*	*(14b)*	*(15b)*
λ [nm]	386	670	737	194	393	282	440

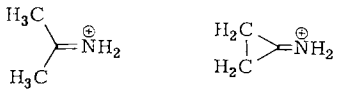
In hexane solution the longest-wave absorption maximum for the triazine *(9a)* that was used as reference molecule appears at 352 nm[11]. The calculated value is shifted to longer wavelength from the experimental value[12]. With this trend in mind it is clear from Table 1 that the red compound in question ($\lambda_{max}^{CH_2Cl_2} = 527$ nm) can have only structure *(10)* or *(11)*.

The structures *(10)* and *(11)* are topologically closely related. On minimization of the energy of *(10)* and *(11)* with respect to *all* the coordinates by the MINDO/2 procedure[13], the most favorable structure with topology close to that of *(10)* is found to be a symmetrical planar four-membered ring with strongly distorted diagonal distances as required by the considerations above (1—3 = 2.07, 2 to 4 = 1.84 Å) but approximately equal lengths for the sides:



Minimization starting from the geometry of the less stable structure *(11)* discloses a tendency towards planarity, giving a planar rhombus *(10)*. A planar structure *(10)* with localized single and double bonds is also energetically less favorable than a symmetrical delocalized structure. Bond fixation of the second order appears to play no part in *(10)*[14].

According to these results the unstable red compound should have structure *(10)*, as assigned also from the physical data[8]. However, the MINDO/2 calculation gives an astonishingly low bond index of 0.962 for the C=$\overset{\oplus}{N}H_2$



(16) (17)

bond of *(11b)*; comparing this value with the bond indices of 1.507 for *(16)* and 1.537 for *(17)* shows that the IR wave number of the C=N stretching vibration of *(11)* is not necessarily so high as for *(16)* and *(17)*.

Specific Heat and Formation of Kinks in Bimolecular Films of Long-Chain *n*-Alkyl Compounds[**]

By *Gerhard Lagaly*, *Stephan Fitz*, and *Armin Weiss*[*]

Alkyl chains may change their conformation *via* rotation about C—C bonds. Among these isomerizations, the simultaneously occurring transformation of two *trans* bonds (t) into +gauche (g) and −gauche bonds ($\bar{g}$), for example ...ttt... → ...gt$\bar{g}$... or ...ttttt... → ...gttt$\bar{g}$... *etc.*, appears to be important in crystalline, paracrystalline, or partially crystalline compounds. In these cases the two parts of chain beyond the ...gt...$\bar{g}$... conformation remain parallel to each other.

Conformations arising in this way were termed "kinks" by *Pechhold*[1]. They have been discussed as structural elements in polymers[2]; their formation and rearrangement were assigned to definite relaxation regions (cf. *e. g.* Ref.[3]).

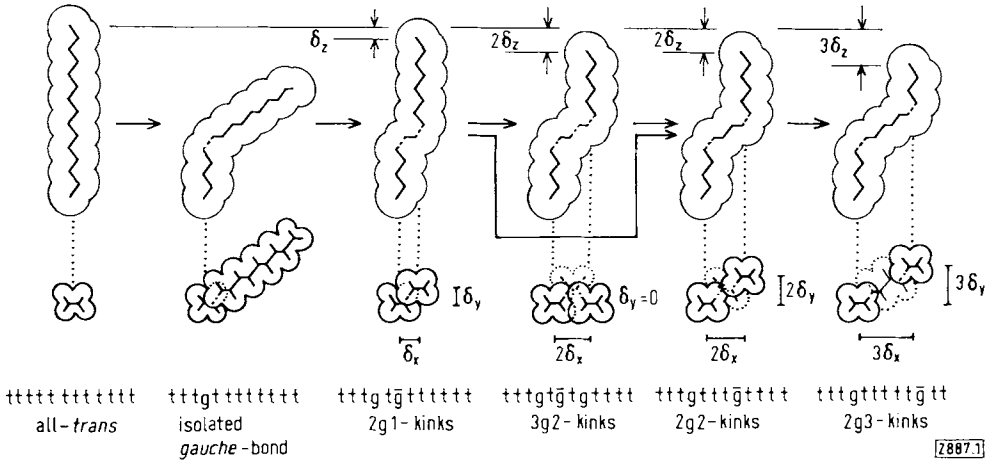

Fig. 1. Conformations of alkyl chains with isolated *gauche* bonds and kinks ($\delta_x = 1.78$, $\delta_y = 1.27$, $\delta_z = 1.27$ Å).

We succeeded in proving the existence of kinks experimentally by measurements of the shortening of the overall chain length upon kink formation[4]. As models we have used bimolecular films of *n*-alkylammonium ions and *n*-alkanols spread out between silicate layers. Kink formation was shown by a stepwise decrease of the film thickness with increasing temperature, measured by X-ray methods. Kink formation is a cooperative process in which the number of kinks per alkyl chain increases by 1 within a relatively small temperature range. For steric reasons, the kinks must be assigned to neighboring chains, so that kink blocks are formed. The cause of kink formation is the increasing thermal energy.

We have now been able to elucidate kink formation by measuring the specific heat of the same models (*e. g. n*-tetradecylammonium-beidellite/*n*-tetradecanol) in an adiabatic calorimeter. A small flask containing the sample was immersed in paraffin as bath fluid, and the specific heat was determined from the change in temperature of the paraffin (measured by an NTC resistance), while a definite amount of heat was supplied by electrical heating. The sensitivity of the calorimeter was better than 20 mcal/h. The experimental results are shown in Fig. 2: curve a)

[14] The largest eigenvalue calculated by us for the bond-bond polarizability matrix is relatively small. For the theory see: *G. Binsch*, *I. Tamir*, and *R. D. Hill*, J. Amer. Chem. Soc. *91*, 2445 (1969).

shows the decrease in basal spacings between 30 and 90 °C in three sharp steps corresponding to the cooperative introduction of kinks into the alkyl chains; curve b) shows the specific heat per mol of the tetradecanol complex of tetra-

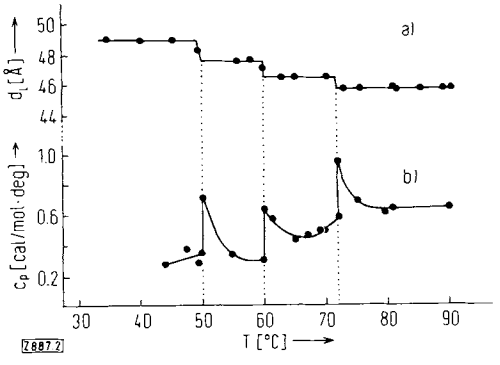

Fig. 2. Change of basal spacing d_L (a) and specific heat c_p (b) of *n*-tetradecylammonium-beidellite/*n*-tetradecanol with temperature (the c_p values are referred to 1 mol of *n*-tetradecylammonium-beidellite).

decylammonium-beidellite. c_p does not change continuously, but shows three distinctly marked transitions similar to λ-transitions occurring at the same temperatures as the steps in the basal spacing.

Table 1. Transition enthalpies and entropies in the system *n*-tetradecylammonium-beidellite/*n*-tetradecanol.

Transition temp. [°C]	ΔH [kcal/mol] [a]	ΔS [cal/deg·mol] [a]
50	0.73	2.3
60	0.72	2.3
72	0.68	2.3

[a] Per mol of beidellite.

From the c_p values the transition enthalpies can be determined by graphical integration and the transition entropies from the c_p/T-values (Table 1). Each set of values is of the same order of magnitude for each transition. Per formula unit of the layer silicate, 0.43 alkylammonium ion and *ca.* 1.58 alkanol molecules are bonded so that a total of two alkyl chains is present.

Since these chains are arranged as a bimolecular film, there are two alkyl chains per formula unit of silicate standing upon each other. Therefore, each step with a shortening of basal spacings by 1.2—1.3 Å corresponds to the formation of one 2g1 kink in one of the two chains only. The enthalpy and entropy changes shown in Table 1 thus refer to formation of one isolated kink in one of the two alkyl chains. The increase in entropy by a constant amount probably indicates that the transition between individual phases is caused by introduction of one further 2g1 kink into the alkyl chains and not (or very rarely) by rearrangement of 2g1 kinks into kinks of higher order as ...tttgt$\bar{g}$ttt... (= 2g1) → ...ttgttt$\bar{g}$tt... (= 2g2) → ...tgttttt$\bar{g}$t... (= 2g3).

A transition enthalpy of 0.7 kcal/mol is evaluated from the experimental data. This is of the same order as the values calculated for kink formation in an isolated *n*-alkyl chain (1.2 kcal/mol) and in a bundle of parallel polyethylene molecules (0.95 kcal/mol)[5]. The fact that the experimental value appears somewhat lower than the other two is probably due to looser packing of the chains in our model system.

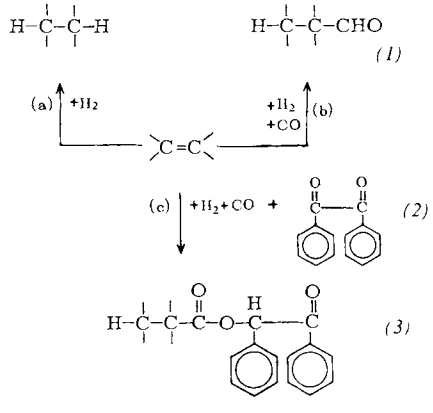
Carboxylic Esters Produced by Low-Pressure Hydroformylation of Olefins in Benzil

By *Kaspar Bott*[*]

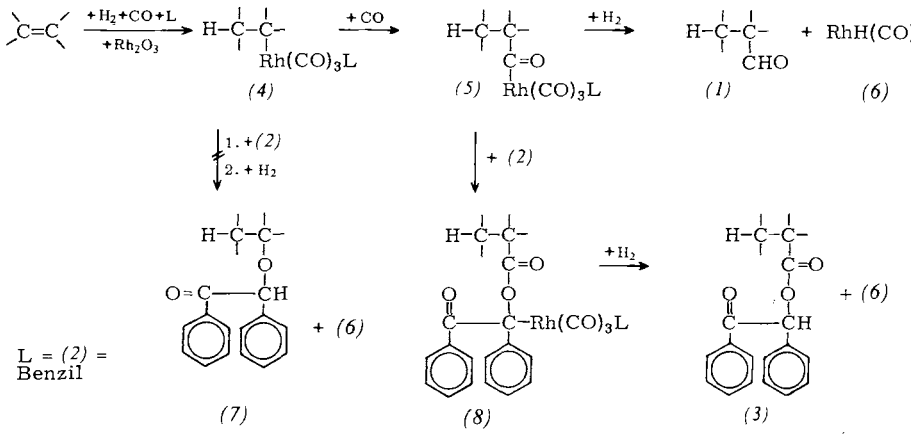
Hydrogenation (a) and hydroformylation (b) of olefins catalyzed by transition-metal carbonyl complexes differ in that in the latter reaction the addition of hydrogen is coupled with insertion of carbon monoxide. We now report a new variant (c) of hydroformylation in which hydrogen, carbon monoxide, and benzil react with the olefinic double bond in a definite order.



The α-benzoylbenzyl carboxylates *(3)* formed in this way can be regarded formally as the result of a Tishchenko-Claisen reaction between the aldehyde *(1)* (formed by hydroformylation, *i.e.* an oxo synthesis) and benzil *(2)*. This synthesis requires low pressures of synthesis gas and presence of a rhodium catalyst. The determining intermediate appears to be an acylrhodium compound *(5)* containing a benzil ligand in addition to carbon monoxide; this complex either reacts with hydrogen to give an aldehyde *(1)* or undergoes insertion of *(2)* to yield the ester precursor *(8)*. Finally the rhodium-carbon bond of *(8)* suffers fission by hydrogen.

As the first three examples in Table 1 show, benzil *(2)* can be converted into the ester *(3)* in 80—87% yield

[*] Dr. K. Bott
Forschungslaboratorien der Chemische Werke Hüls AG
437 Marl (Germany)



when the reaction is carried out with lower olefins, but the yields decrease considerably with 1-octene and cyclododecene owing to the lower molar olefin conversions.

Table 1. α-Benzoylbenzyl carboxylates *(3)* from benzil *(2)*, olefins, and synthesis gas [a].

Starting olefin	Pressure of synthesis gas [atm] ($H_2/CO = 1:1$)	*(3)*, yield [%] [b]	*(3)*, m.p. [C] or b.p. [C/torr]
1-Butene	25—35	87	150—153/0.1 [d]
Isobutene	35—45 [c]	80	56—57
Cyclohexene	25—30	80	100—101
1-Hexene	30—35	65	163—167/0.1 [d]
1-Octene	30—40	38 [e]	175—180/0.1 [d]
Cyclododecene	50	25 [f]	100—101

[a] General conditions of the synthesis are described in the example.
[b] Olefin and benzil *(2)* were used in equal amounts by weight; the yields refer to benzil.
[c] Total pressure of CO, H_2, and isobutene.
[d] Mixture of isomers shown in Table 2.
[e] Conversion of olefin = 62%.
[f] Conversion of olefin = 76%.

As required by the mechanism proposed, the proportion of benzil incorporated into the ester *(3)* increases with increasing concentration of benzil in the reaction solution and with decreasing partial pressure of carbon monoxide because the rhodium complexes *(4)*—*(6)* and *(8)* exchange the benzil ligand in a reversible reaction for carbon monoxide. If, in the example below, the synthesis gas pressure (molar ratio $CO/H_2 = 1:1$) is increased to 120—140 atmospheres, the yield of α-benzoylbenzyl cyclohexanecarboxylate is then only 16%.

The efficient catalysis of double bond migration by the rhodium-benzil system is surprising; this is shown convincingly by the equality of the isomer ratio of C_5 aldehydes obtained from both 1-butene and 2-butene (Table 2)[1]. Analogously, the hydroformylation of 1-hexene and 1-octene gives rise to formation of branched aldehydes, which must be attributed to the presence of olefins with double bonds in the "interior" of the chain. The oxo synthesis with 1-octene afforded, after 62% conversion, a residual olefin containing less than 4% of "α-isomer".

Table 2 also presents the isomer distribution of the esters *(3)*. It turns out that approximately the same proportions of unbranched aldehydes and unbranched carboxylic esters are formed from 1- and 2-butene and propene. With higher olefins the proportion of unbranched carboxylic acid in *(3)* is very little changed but that of branched aldehyde is increased.

If the phosphane-containing complex $RhH[P(C_6H_5)_3]_2CO$ is used instead of rhodium oxide as catalyst for the low-pressure hydroformylation of propene in benzil, the *n*/iso ratio rises to 69:31 for butyraldehyde and to 68:32 for the butyric ester.

Table 2. Isomer distribution of the hydroformylation products *(1)* and *(3)* from *n*-olefins.

Olefin	Aldehyde *(1)*	Rel. yield [%]	Carboxylic acid in *(3)*	Rel. yield [%]
Propene	2-Methylpropanal	50	2-Methylpropionic	49
	Butanal	50	Butyric	51
1- or 2-Butene	2-Methylbutanal	61—58	2-Methylbutyric	57—58
	Pentanal	39—42	Pentanoic	43—42
1-Hexene	2-Ethylpentanal	17	2-Ethylpentanoic	13
	2-Methylhexanal	48	2-Methylhexanoic	41
	Heptanal	35	Heptanoic	46
1-Octene	2-Propylhexanal	13	2-Propylhexanoic	9
	2-Ethylheptanal	17	2-Ethylheptanoic	12
	2-Methyloctanal	41	2-Methyloctanoic	33
	Nonanal	29	Nonanoic	46

The selectivity for conversion of the olefins into aldehydes *(1)* and esters *(3)* exceeds 90%[4]. Reaction of the alkene with benzil *(2)* and hydrogen, which would lead to the ether *(7)*, could not be detected even in absence of carbon monoxide.

Cyclohexanecarbaldehyde and α-benzoylbenzyl cyclohexanecarboxylate

Cyclohexene (250 g, 3.05 mol), benzil (250 g, 1.19 mol), and Rh_2O_3 (0.10 g) are placed in a 2-l steel autoclave previously purged with nitrogen and are heated at 120 °C with synthesis gas (20 atm cold pressure). The synthesis gas pressure is raised from 25 to 30 atm during the reaction. After 11 hours' reaction, distillation of the autoclave content affords cyclohexanecarbaldehyde (146 g) boiling at 50—56 °C/17 torr and α-benzoylbenzyl cyclohexanecarboxylate (308 g, 80% yield based on benzil), boiling at 175—177 °C/0.2 torr, m.p. 100—101 °C (from light petroleum).

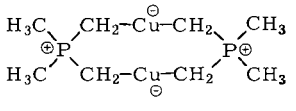
Tetrakis(dimethylphosphoniumbismethylide)-dinickel, a New Type of Cage Compound

By *Hans Heinz Karsch* and *Hubert Schmidbaur*[*]

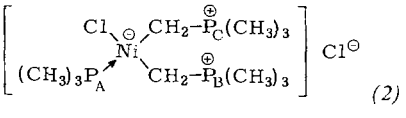
It was shown recently that metal-carbon σ-bonds of ylide complexes are appreciably more stable than those of simple alkyl derivatives. The effect of introducing of an "onium center" on otherwise unstable M—C structural units is exemplified by the unusual properties of the copper compound *(1)* and its homologs[1, 2].



(1)

We now report the synthesis of an analogous nickel compound that has a binuclear structure with no less than four Ni—C σ-bonds attached to each of the two d^8-nickel atoms.

Reaction of dichlorobis(trimethylphosphane)nickel with trimethylmethylenephosphorane[3] in *n*-pentane at room temperature affords a golden-yellow product (dec. 125 °C; yield 93%), whose composition is almost independent of the molar ratio of the reactants and which is insoluble in that solvent or in diethyl ether but soluble in methylene chloride. From the analytical data and particularly from ^{1}H- and ^{31}P-NMR findings it is concluded that it has the salt-like onium structure *(2)*, formed as shown in eq. (1a).



(2)

^{31}P-NMR (CH_2Cl_2, 85% H_3PO_4, H-decoupled, −40 °C)[4]: δP_A +19.9 ppm, d, $J(P_ANiCP_B)$ 15.2 Hz; δP_B −23.6, dd, $J(P_BCNiP_C)$ 3.4; δP_C −24.5, d, $J(P_ANiCP_C)$ 0.

[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. H. H. Karsch
Institut für Anorganische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

^{1}H-NMR (ext. TMS, other conditions as above)[4]: τCH_3P_A 8.82 ppm, d, $J(HCP_A)$ 8.1 Hz; τCH_3P_B 8.10, d, $J(HCP_B)$ 13.4; τCH_3P_C 8.02, d, $J(HCP_C)$ 13.5; τCH_2P_B 9.60, dd (broad), $J(HCP_B)$ 16.1, $J(HCP_A) \approx 13$; τCH_2P_C 9.48, dd (broad), $J(HCP_C)$ 16.2, $J(HCP_A) \approx 6$.

However, when the above-mentioned reactants are mixed, not in *n*-pentane, but in tetrahydrofuran at 0 °C, or when the product *(2)* is treated in that solvent with an excess of the ylide, a colorless precipitate of tetramethylphosphonium chloride is formed together with a yellow product *(3)* that is soluble in ether, benzene or toluene and is volatile in a vacuum (sublimes at 45 °C/0.1 torr, dec. 87 °C; yield 23%); at the same time a second molecule of trimethylphosphane is liberated [eq. (1b)].

$$2\,(CH_3)_3P + 4\,(CH_3)_3P{=}CH_2 + 2\,(2) \qquad (1a)$$

$$2\,[(CH_3)_3P]_2NiCl_2 + 8\,(CH_3)_3P{=}CH_2 \xrightarrow[\text{THF}]{\text{n-pentane}}$$

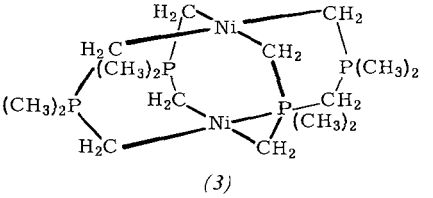
$$4\,(CH_3)_3P + 4\,[(CH_3)_4P]Cl + [(CH_3)_2P(CH_2)_2]_4Ni_2 \qquad (1b)$$

(3)

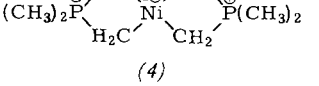
The complex *(3)* formed by two-fold metalation of the ylide is shown by cryoscopic determination of its molecular weight to be a dimer[5]. The molecular ion of the dimer appeared in the mass spectrum only at low ionization energies and high target temperature (18 eV, 85 °C), but then had the expected isotope distribution. Spectra measured at 70 eV and 30 °C, however, show only the ions of the monomer *(4)*[6].

The ^{1}H-NMR spectra of toluene solutions show only two 1:1 doublets with a 3:2 ratio of areas in the temperature range +80 to −80 °C: τCH_3P 8.77 ppm, $J(H_3CP)$ −11.9 Hz; τCH_2P 11.9, $J(H_2CP)$ −4.8. P-Decoupling leads to singlets. Double-resonance experiments prove that $J(H_2CP)$ and $J(H_3CP)$ have the same sign. In the H-decoupled ^{31}P-NMR spectrum δP, at 1.7 ppm, appears in the region for tetracoordinated onium centers[7]. The IR and Raman absorptions correspond largely to those of *(1)* and its homologs: strong bands at 665, 638 and 467 cm^{-1} can be assigned to vibrations of the skeleton of heavy atoms.

Taking our results as a whole we propose for *(3)* a structure in which two parallel square-planar $Ni(CH_2)_4$ units[8] are bonded together by four dimethylphosphonium groups.



(3)



(4)

Models indicate that such a type of bonding can be strain-free. In this structure the eight-membered ring unit of *(1)* is present twice, as in the string by which a parcel is tied up. It is conceivable that the monomer *(4)* is in equilibrium with *(3)* under the conditions of the mass

spectroscopy. We are describing other ylide complexes of nickel elsewhere[9].

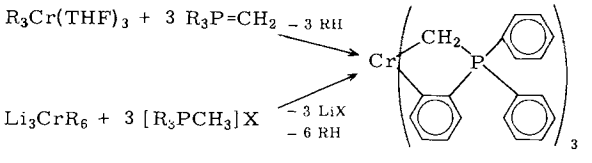
Synthesis of Tris(dimethylphosphoniumbismethylide)chromium(III)

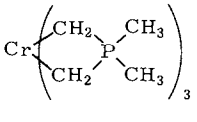
By *Erhard Kurras, Uwe Rosenthal, Herbert Mennenga*, and *Günther Oehme*[*]

Schmidbaur et al. recently described organic ylide complexes of copper, silver[1] and gold[2]. We have found[3] that reaction of methylenetriphenylphosphorane with triphenyltris(tetrahydrofuran)chromium[4] or of a methyltriphenylphosphonium halide with lithium hexaphenylchromate(III)[5] leads to the chelate complex *(1)* by *ortho*-metalation of a phenyl group of the ylide.



R = C_6H_5; X = Cl, Br, I *(1)*

However, interaction of lithium hexaphenylchromate(III) and tetramethylphosphonium chloride in tetrahydrofuran under anaerobic conditions affords analogously tris(dimethylphosphonium bismethylylide)chromium(III) *(2)*.



(2)

The latter product can also be prepared by treating $CrCl_3(THF)_3$[6] with methylenetrimethylphosphorane that has been metalated by methyl- or phenyl-lithium[7]:

$$[(CH_3)_4P]Cl + 2LiCH_3 \xrightarrow{\text{Ether}} [(CH_3)_2P(CH_2)_2]Li + 2CH_4 + LiCl$$

$$3[(CH_3)_2P(CH_2)_2]Li + CrCl_3(THF)_3 \xrightarrow{THF} (2) + 3LiCl$$

Compound *(2)* crystallizes in red needles that are extremely sensitive to oxidation and hydrolysis, melt in the region 59—68 °C, dissolve very readily in solvents that do not contain active protons (*e.g. n*-hexane, benzene, toluene or ether), and can be sublimed in a vacuum (10^{-3} torr, 30 °C). The compound is paramagnetic ($\chi_g = 16.42 \cdot 10^{-6}$ $cm^3\ g^{-1}$, 293 °K)[8]. The effective magnetic moment μ_{eff} is 3.6 μ_B, corresponding to Cr^{III} with the d^3 configuration.

The characteristic fragments, $m/e = (M-L)$ 230 (35.6%), $(M-2L)$ 141 (100) and Cr 52 (34.2) can be seen alongside the molecular ion, 319 (38.3) in the mass spectrum (70 eV; input temperature 20, ion source 270 C; LKB 9000).

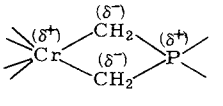
In the IR spectrum (Beckman IR 12; 0.1 M in *n*-hexane; $d = 0.1$ mm) the following bands (in cm^{-1}) are found in the regions free from solvent absorptions: 390(w), 431.5(s), 551.5(m), 660(m), 737(m), 760.5(s), 813.5(m), 933.5(vs), 970(m,sh), 1278.5(m), 1288(m), 1339(m), 1410(w), 1418(w,sh), 1425(w). The bands at 970 and 933.5 cm^{-1} are to be ascribed to the antisymmetrical and symmetrical P—C stretching vibrations; as expected, the frequencies are shifted to longer wavelengths compared with those of the free ylide ($\nu_{P=C}$: 1006 cm^{-1}[9]). In the lower frequency region the bands at 431.5 and 390 or, more probably, those at 552.5 and 431.5 cm^{-1} correspond to the antisymmetrical and symmetrical Cr—C stretching vibrations.

Compound *(2)* gives typical reactions of organometallic compounds. In ethereal solution it reacts with, for instance, carbon dioxide and benzophenone. The phosphonium salt formed by protolysis according to the equation

$$(2) + 6HCl \xrightarrow{THF} CrCl_3(THF)_3 + 3[(CH_3)_4P]Cl$$

was isolated and characterized as chloride and tetraphenylborate.

These findings indicate an octahedral arrangement of the C—Cr—C units. It is less likely that there is electron delocalization in the $>C{=}PMe_2{-}\overset{(-)}{C}<$ group as in the allyl group[10], by analogy with tris(allyl)chromium[11], together with involvement of the phosphorus. The charge distribution shown schematically in *(3)* clearly stabilizes the polar Cr—C σ-bond, and Cr—P interaction is not be excluded.



(3)

An X-ray structure analysis of *(2)* is in progress.

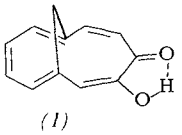
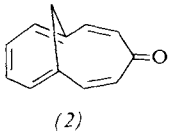
Crystal Structure of 2-Hydroxy-4,9-methano[11]annulenone

By *D. W. J. Cruickshank*, *G. Filippini*, and *O. S. Mills*[*]

Recently the synthesis of a number of 10 π-electron analogs of tropone[1] and of tropolone[2], and structure analyses of two [11]annulenones[3,4] have been reported. In this communication we present the essential structural results for 2-hydroxy-4,9-methano[11]annulenone *(1)*[2][**]. Compound *(1)* crystallizes in the triclinic system, space group $P\bar{1}$ with $a=8.448$, $b=8.184$, $c=7.803$ Å; $\alpha=110.10$, $\beta=69.09$, $\gamma=92.38$. The analysis is based upon 1639 reflections measured on a computer-controlled diffractometer, the structure was solved by direct methods and refined by least-squares techniques; the final R is 6.0%.



(1)



(2)

In preparation for the discussion of *(1)* it should be noted that definitive structural evidence now exists to show that tropone itself exists as a near-planar (slightly-boat conformation) molecule with alternating single and double bonds[5], that its derivatives[6] display similar features, and that tropolone and substituted tropolones seem also to manifest alternation of bond length[7].

We find (see Figure 1) that in *(1)* there is evidence both of an alternation of bond lengths and of delocalization within the same molecule; the eight-membered ring, which contains the α-hydroxyketone group, has two formal double bonds whose (independent) lengths are 1.353 Å, little more than the standard value for an isolated double bond[8]. The C—C bond lengths in the cycloheptatriene ring, excluding those to the methylene bridge, however show only a small variation in lengths between 1.376 and 1.399 Å.

[**] We are grateful to Prof. *E. Vogel* for supplying us with crystals of *(1)*.

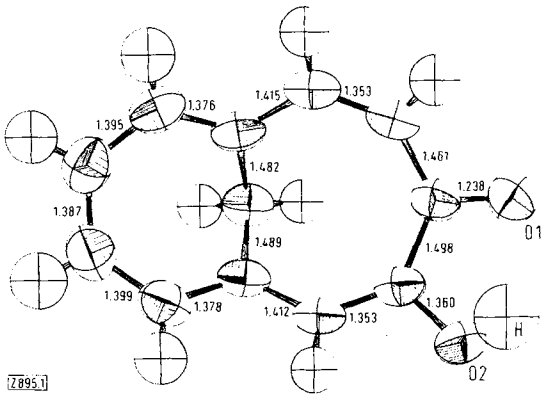

Fig. 1. Crystal structure of 2-hydroxy-4,9-methano[11]annulenone *(1)*.

We therefore suggest that considerable delocalization occurs in that ring, more than in either 4,9-methano[11]annulenone *(2)* (1.366—1.422 Å) or in 1,6-methano[10]annulene-2-carboxylic acid (1.378—1.426)[9], and more still than in cycloheptatriene (1.356—1.446 Å)[10] or its derivatives (*e.g.* 1.35—1.45 Å)[11].

The ^{1}H-NMR values reported for *(1)*[2] are in agreement with our findings. The multiplet which extends over the region $\tau=2.5$—3.2 is positioned similarly to that reported for 1,6-methano[10]annulene[12] in which a delocalized system is recognized (for bond lengths see ref. [9]), whereas in cycloheptatriene values of $\tau=3.4$—3.9 occur. Such delocalization might be expected to be associated with a pronounced ring current and consequential difference in absorption of the *syn* and the *anti* protons of the methylene group. The observed difference, 0.7 τ-units, must be the resultant of the deshielding effects of the ring current on the one proton and of the C=O group on the other. When comparison is made of the spectrum of *(1)* with that of *(2)*, however, it is important to note the change of shape between the two molecules; *(1)* is more planar than *(2)*, possibly because the hydrogen bond is *intra*-molecular, in contrast to the case of crystalline tropolone[7]. The effect of this change of shape is to increase the transannular distance between the *anti*-methylene hydrogen and the carbonyl carbon from 2.46 Å in *(2)* to 2.64 Å in *(1)*.

In the present analysis we have determined, and satisfactorily refined, the positions of all the hydrogen atoms and we confirm from these direct observations, as well as infer from the positions of the double bonds, that the hydroxyl group is located on C-2[2].

The overall structure has close to mirror symmetry perturbed only by the hydroxyl group. The C—O distances in the carbonyl and hydroxyl groups are in good agreement with usually accepted values.

Triiodogermane[**]

By *Friedrich Höfler* and *Ernst Brandstätter*[*]

Of the various trihalogermanes, only $HGeCl_3$ and $HGeBr_3$ have been previously reported; they tend to decompose according to eq. (1b)[1] or to GeX_4, GeX_2 and H_2[2]. Triiodogermane, $HGeI_3$, has been merely conjectured as an intermediate in germylation reactions of olefins with GeI_2/50% aqueous HI[3,4].

Since we succeeded in preparing pure, $GeBr_4$-free $HGeBr_3$ by dissolving $GeBr_2$[5] in anhydrous HBr, we have found also that $HGeI_3$ is formed in quantitative yield when anhydrous HI is condensed on pure GeI_2 [eq. (1a)]:

$$GeX_2 + HX \underset{b}{\overset{a}{\rightleftharpoons}} HGeX_3 \qquad (1)$$

The pale yellowish solution is stable below $-50\,^{\circ}C$ but at room temperature decomposes gradually thus:

$$HGeI_3 + HI \rightarrow GeI_4 + H_2 \qquad (2)$$

(*ca.* 50% after 7 days); dismutation to H_2GeI_2 and GeI_4 was not observable. When the solvent HI is removed, even at low temperature, only GeI_2 is left as solid residue [eq. (1b)]; and other attempts to prepare it—by $HGeCl_3$/HI, $HGeCl_3$/GeI_4 or $HGeCl_3$/$HSiI_3$ as reactants—lead also to GeI_2. However, $HGeI_3$ is formed smoothly when an excess of HI is condensed on $GeBr_2$, but in a suspension of GeI_2 in 57% aqueous HI we could not prove the formation of triiodogermane.

Thus $HGeI_3$ can exist only in liquid HI. But in such solutions we could measure the Raman spectrum, and this showed, as required for a C_{3v} molecule, three polarized and three depolarized lines (Table 1). The frequencies are in the expected regions, which can be derived from correlations and calculations for comparable vibrations for the series $HGeX_3$ (X = Cl, Br[6] or I) and $HGeX_3$/GeX_4.

Table 1. Fundamental vibrations (cm^{-1}) from the Raman spectrum of $HGeI_3$.

Type		$\tilde{\nu}$	Assignment
A_1	ν_1	2068 (0.5, p)	νGeH
	ν_2	203 (10, p)	$\nu_s GeI_3$
	ν_3	93 (5, p)	$\delta_s GeI_3$
E	ν_4	260 (1.5, dp)	$\nu_{as} GeI_3$
	ν_5	66 (6, dp)	$\delta_{as} GeI_3$
	ν_6	643 (0.6, dp)	δHGeI

[**] This work was supported by the Fonds zur Förderung der wissenschaftlichen Forschung, Vienna.

νGeH and δHGeI are slightly dependent on concentration, being 5—8 cm^{-1} higher for very dilute solutions.

In the reaction of stoichiometric amounts of HI with $GeBr_2$ or a $GeBr_4$/GeI_2 mixture there are formed, besides $HGeI_3$, the trihalides $HGeBrI_2$ and $HGeBr_2I$, which also cannot be isolated but can be recognized from their main frequencies in the Raman spectrum (220 vs,p and 239 cm^{-1} vs,p).

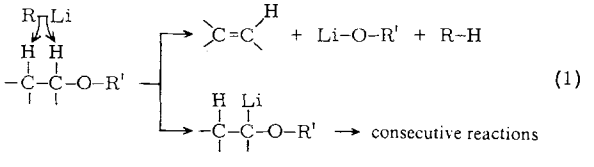
Nucleophilic Ether Fissions by 1,1-Diphenylhexyllithium[**]

By *Gert Köbrich* and *Annegrit Baumann*[*]

Because of the role of ethereal solvents in reactions of organometallic compounds, fission of ethers by organometallic and in particular organolithium compounds is very important. According to earlier investigations it is normally initiated by deprotonation at the α- or β-carbon atom of the ether[1]; very recent investigations[2] have uncovered an interesting meshing of α-,β- and,α',β-eliminations for the case of diethyl ether/alkyllithium. We propose to collect together under the general expression "protophilic ether fission" all those fissions that have proton abstraction from the ether molecule in the first reaction step as their common characteristic [eq. (1)]:

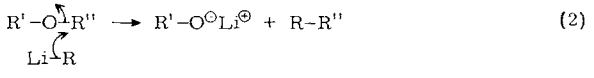
Protophilic ether fission:



(1)

We now report "nucleophilic ether fission" as a further type of reaction. This is a nucleophilic replacement by the organolithium compound [eq. (2)], in which an RO group of the ether constitutes the leaving group, thus playing the same role as do halogen atoms in the coupling of alkyl halides.

Nucleophilic ether fission:



(2)

If we let aside those reactions, formally similar but different in kind, in which complex formation at the oxygen atom by a Lewis acid is the first step, as with triphenylmethyl an-

ions in presence of triphenyl-borane or -aluminum[3a] and very probably with Grignard reagents[3b], then nucleophilic ether fission has been observed only with oxiranes[4a] and oxetanes[4b], which contain strained rings, and moreover only occasionally with tetrahydrofuran (THF) (with R_3SiLi[5a] or triphenylmethyllithium[5b]).

As organometallic reagent we used 1,1-diphenylhexyllithium (DPHLi)[6], which smoothly splits not only cyclic ethers but also alkyl phenyl, allyl and vinyl ethers (Table 1). In all these cases nucleophilic predominates over protophilic fission, as is made evident by the poor yields of 1,1-diphenylhexane (DPH—H) which is the protonation product of DPHLi. Product analyses permit the following generalizations:

1. With cyclic ethers the ease of reaction increases with decreasing ring size, corresponding to increasing ring strain. Tetrahydropyran is no longer attacked nucleophilically; and its protophilic fission by DPHLi at 70°C also occurs only to a small extent, so that this compound is more suitable as solvent for reactions involving DPHLi than is the commoner but less resistant THF.

2. Whereas the alkyl group of alkyl phenyl ethers is transferred to DPHLi [eq. (3)], it is the unsaturated group of alkyl vinyl ethers that is given up [eq. (4)]. This "transpoling" indicates an addition-elimination reaction as mechanism for the vinyl ether fissions; it is faster than the S_N2-like transfer of alkyl groups.

$$DPHLi + C_6H_5{-}O{-}Alkyl \rightarrow DPH\text{-}Alkyl + C_6H_5{-}OLi \quad (3)$$

$$DPHLi + CH_2{=}CH{-}O\text{-}Alkyl \rightarrow DPH{-}CH{=}CH_2 + Alkyl\text{-}OLi \quad (4)$$

3. Allylic rearrangement can accompany fission of substituted allyl ethers: 3-phenoxy-1-butene affords only the thermodynamically favored, rearranged product with the 2-butenyl structure. The preponderating product from the isomeric 4-phenoxy-2-butene in THF is the unrearranged product, but in hexane (in presence of 1 mol of tetramethylethylenediamine) it is mainly the unrearranged, sterically disfavored coupling product (Table 1). Product formation is thus influenced by the reaction medium.

4. Allyl ether bonds are particularly easily split; even anionized allyl alcohol is smoothly cleaved (1:1, 6h at 70 C in THP, relative yield 100%) [eq. (5)]:

$$DPHLi + CH_2{=}CH{-}CH_2{-}\overset{\ominus}{O}\overset{\oplus}{Li} \rightarrow DPH{-}CH_2{-}CH{=}CH_2 + Li_2O \quad (5)$$

5. The relative rates of nucleophilic fission of C—O bonds by DPHLi decrease in the order Allyl—O— > Vinyl—O— > Alkyl—O— ≫ Phenyl—O—.

Many of the ethers included in Table 1 were treated with benzhydryllithium instead of DPHLi, and the results were qualitatively identical and quantitatively similar. It is probable that nucleophilic ether fission is a characteristic reaction of mesomeric carbanionoids, being caused by the fact that their basicity is lower than that of other organolithium compounds and that their nucleophilicity is high, the latter being made evident by their extremely rapid coupling with alkyl halides[8].

Table 1. Conditions and products of the reaction of 1,1-diphenylhexyllithium (DPHLi) with ethers [6, 7].

Ether	Ether: DPHLi	Reaction conditions [b]	Products and relative yields [d]
a) Cyclic ethers			
Oxirane	1:1	At 0 C instantaneous in THF	DPH—CH_2—CH_2—OH (70%) + DPH—H (30%)
Oxetane	1:1	12h at room temp. in THP	DPH—CH_2—CH_2—CH_2—OH (100%)
Tetrahydrofuran (THF)	[a]	120h at room temp. and 22h at 70°C	DPH—CH_2—CH_2—CH_2—CH_2—OH (84%) + DPH—H (16%)
Tetrahydropyran (THP)	[a]	96h at room temp. and 22h at 70°C [conversion 16%]	DPH—H (16%)
b) Acyclic ethers			
$H_2C{=}CH{-}O{-}C_4H_9$-*n*	2:1	72h at room temp. and 10h at 70 C in THP	DPH—$CH{=}CH_2$ (95%) + DPH—H (5%)
$H_2C{=}CH{-}O{-}C_4H_9$-iso	2:1	72h at room temp. and 10h at 70 C in THP	DPH—$CH{=}CH_2$ (92%) + DPH—H (8%)
$C_6H_5{-}O{-}CH_3$	[a]	18h at room temp.	DPH—CH_3 (90%) + DPH—H (<10%)
$C_6H_5{-}CH{=}CH{-}O{-}CH_3$	1:1	22h at room temp. in $(C_2H_5)_2O$	DPH—CH=CH—C_6H_5 (*trans* 78%, *cis* 14%) + DPH—CH_3 (5%) + DPH—H (3%)
$C_6H_5{-}O{-}CH_2{-}CH{=}CH{-}CH_3$	1:1	15h at room temp. in THF	DPH—CH_2—CH=CH—CH_3 (94%) + DPH—$CH(CH_3)$—$CH{=}CH_2$ (6%)
	1:1	48h at room temp. in hexane [c]	DPH—CH_2—CH=CH—CH_3 (9%) + DPH—$CH(CH_3)$—$CH{=}CH_2$ (91%)
$C_6H_5{-}O{-}CH(CH_3){-}CH{=}CH_2$	1:1	3h at room temp. in THF	DPH—CH_2—CH=CH—CH_3 (100%)
	1:1	36h at room temp. in hexane [c]	DPH—CH_2—CH=CH—CH_3 (100%)

[a] The ether studied served as solvent.
[b] The DPHLi was completely consumed, unless stated otherwise.
[c] In presence of 1 equivalent of tetramethylethylenediamine.
[d] Referred to DPHLi; about 80—90% thereof was isolated.

Spiro[3.4]octa-5,7-diene[**]

By *Armin de Meijere* and *Lüder-Ulrich Meyer*[*]

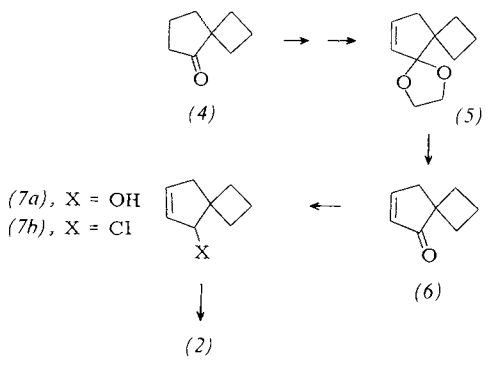
Dedicated to Professor H. Brockmann on his 70th birthday

Whereas the spiro[*n*.4]alkadienes *(1)* and *(2)* are readily accessible by cycloalkylation of the cyclopentadienyl anion by, respectively, 1,2-dibromoethane and 1,4-dibromobutane[1], the analogous reaction with 1,3-dibromopropane does not lead to *(2)*[2]. We report here the preparation and some of the chemical and spectroscopic properties of the hydrocarbon *(2)*.

(1) *(2)* *(3)*

Compound *(2)* is of interest in comparison with *(1)* and *(3)* which differ greatly in their behavior in the Diels-Alder reaction[6] and on gas-phase pyrolysis[5, 7], and also because of a possible electronic interaction between the π-orbitals of the diene component and the C—C bonding orbitals of the cyclobutane ring[8].

Our starting material was spiro[3.4]octan-5-one *(4)*[9]. On successive bromination in ethylene glycol, dehydrobromination by potassium hydroxide in methanol and hydrolysis of the acetal *(5)* this afforded the ketone *(6)*[11] (yield through 3 steps: 54%), this sequence being analogous to *Garbisch*'s general procedure[10]. Attempts to prepare the tosylhydrazone of *(6)*, and thence *(2)* by treatment with methyllithium[12], failed: 1,4-addition of tosylhydrazide to *(6)* was observed in all these attempts. However, reduction of *(6)* by aluminum hydride[13] yielded the alcohol *(7a)* (74%); subsequent treatment with thionyl chloride in tetrahydrofuran/pyridine at room temperature led to 5-chlorospiro[3.4]oct-6-ene *(7b)* (53%). Dehydrochlorination of *(7b)* by potassium *tert*-butoxide in tetraethyleneglycol dimethyl ether (tetraglyme) at room temperature in a vacuum (0.01 = torr)[14] afforded the diene *(2)* (yield 67%, determined by gas chromatography); this



compound distilled in the process, together with some *tert*-butyl alcohol, into a trap cooled in liquid nitrogen and was obtained pure by preparative gas chromatography[11].

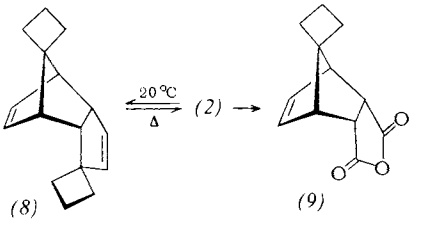
In its ^{1}H-NMR spectrum (CCl_4), *(2)* shows multiplets at $\tau = 3.61$ and $\tau = 3.91$ (each 2H, AA'BB' system of the olefinic protons) and at $\tau = 7.79$ (6H, cyclobutyl protons). The IR spectrum of *(2)* is not characteristic and does not accord with that reported by *Chiurdoglu* and *Tursch*[3]. The longest-wavelength absorption lies at 257 nm, as does that of *(1)* (see Table 1).

Table 1. UV data of the spiro[*n*.4]alkadienes *(1)*—*(3)* and of 5,5-dimethyl-1,3-cyclopentadiene [in ethanol, *(2)* in *n*-pentane].

Cpd.	λ_{max} [nm]	ε_{max}	λ_{max} [nm]	ε_{max}	Ref.
(1)	223	6300	257	2700	[15]
(2)	<200	—	257	1500 [a]	
(3)	<210	—	254	2750	[15]
(13)	<210	—	250	2900	[15]

[a] The extinction coefficient found may be too small because *(2)* dimerizes very rapidly at room temperature.

In its chemical behavior, *(2)* resembles *(3)* rather than *(1)*. Pure *(2)* dimerizes rapidly at room temperature to give *(8)*[11]. ^{1}H-NMR (CCl_4) of *(8)*: $\tau = 4.37$ (m, 2H); 4.50 (m, 1H); 4.83 (m, 1H); 6.78 (m, 1H); 7.51 (m, 3H); 8.35 (m, 12H). The half-reaction time for dimerization in dilute solution (0.86 M in CCl_4) at 50 C amounts to *ca.* 2.3 h.



On treatment with maleic anhydride in benzene (50 C, 5 h), *(2)* affords the Diels-Alder adduct *(9)*[11] (70%; m. p. 86 C; colorless crystals), ^{1}H-NMR ($CDCl_3$): $\tau = 3.81$ (t, 2H); 6.47 (dd, 2H); 6.79 (m, 2H); 8.22 (m, 6H).

Thermal rearrangement of *(2)*, which ring strain should cause to be much easier than that of *(1)* and *(3)*[16], has so far been examined only qualitatively. In a flow pyrolysis apparatus at 400 °C a 1:0.8 mixture of the isomeric bicyclo[3.3.0]octadienes *(11)* and *(12)* was formed. Thermal decomposition of the dimer *(8)* led under these conditions to a product mixture of the same composition. *(11)* and *(12)* can be separated by gas chromatography and identified by means of their ^{1}H-NMR spectra[17].

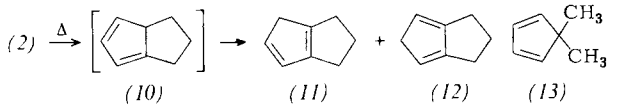
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

[**] This work was supported by grants from the Land Niedersachsen and the Fonds der Chemischen Industrie.



(10) (11) (12) (13)

It is probable that (2) yields, by a [1.5]-alkyl shift, first the compound (10), which then undergoes [1,5]-hydride shifts, yielding (11) and (12), under the conditions used.

The problem of the interaction between the cyclobutane ring and the diene portion of (2) is to be investigated by photoelectron spectroscopy (PES)[18]. Qualitative consideration of the PE spectrum of (2) and its comparison with that of (1)[19] indicate that such an interaction does occur[18].

A New Approach to the Synthesis of Oligodeoxyribonucleotides[**]

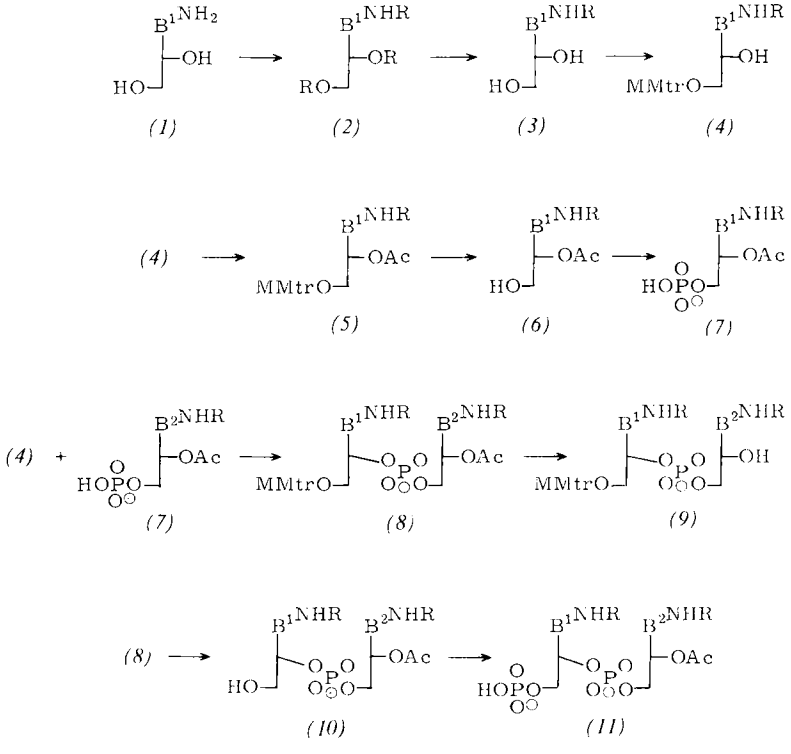
By Hubert Köster and Walter Heidmann[*]

Dedicated to Professor Friedrich Cramer on the occasion of his 50th birthday

For the synthesis of double-stranded polydeoxynucleotides with defined sequences by the standard methods[1], short chemically synthesized oligodeoxyribonucleotides are phosphorylated at the free 5'-OH group using the enzyme polynucleotide kinase and ATP and then joined with the enzyme polynucleotide ligase. The synthesis of these short oligodeoxyribonucleotides starts favorably with a 5'-blocked deoxynucleoside. For the elongation, 3'-*O*-protected deoxyribonucleoside 5'-phosphates (or 3'-*O*-protected deoxyribonucleoside diphosphates or trideoxyribonucleoside triphosphates) are necessary. To achieve unequivocal 3'-5'-internucleotidic linkage, the amino groups of the heterocyclic bases also have to be protected. Therefore a large number of intermediates [compounds of type (4), (7), and (11)] have to be prepared during synthesis of a long double-stranded polydeoxyribonucleotide.

We have developed a new approach which decreases the expense of such syntheses by using only a few key intermediates for many different reaction pathways.

We have been able to phosphorylate 3'-*O*-acetylated deoxyribonucleosides (6) almost quantitatively with phosphorus oxychloride to give the 3'-*O*-acetylated deoxyribonucleoside 5'-phosphates (7). Compounds of type (6) could easily be obtained by acetylation and subsequent detritylation of the 5'-monomethoxytritylated deoxyribonucleosides (4) which have to be prepared for the chain starts. The first extension of (4) by reaction with (7) leads to 5'-monomethoxytritylated deoxyribonucleoside monophosphates (8), which are obtainable in pure form with high yields in a short time by extraction procedures. After



Scheme 1. Synthesis of oligodeoxyribonucleotides. R = benzoyl, anisoyl, isobutyl; Ac = acetyl; MMtr = monomethoxytrityl; B = adenine, guanine, cytosine, thymine (without NH_2).

de-*O*-acetylation to give (9), this compound is ready for the next chain elongation step. Removal of the monomethoxytrityl group from compound (8), however, leads after direct phosphorylation with phosphorus oxychloride to the 3'-*O*-acetylated dideoxyribonucleoside diphosphates (11), which can be used as blocks for the chain elongation (Scheme 1).

[*] Prov.-Doz. Dr. H. Köster and Dipl.-Chem. W. Heidmann
Institut für organische Chemie und Biochemie der Universität
2 Hamburg 13, Papendamm 6 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We wish to thank Mr. A. J. Sparrow for his excellent technical assistance.

It is important to use a sterically hindered base such as 2,6-lutidine by which the reactivity of the other chlorine atoms is very much reduced. Tetrahydrofuran is used as a solvent for the phosphorylation of the 3'-*O*-acetylated deoxyribonucleosides *(6)*. The phosphorylation of *(10)* takes place in a heterogeneous medium. Of particular importance here is the choice of the liquid phase, which leads to a stable suspension. This is summarized in Figure 1, together with some yields.

Table 1. Phosphorylation of dX(Ac) and dX—dY(Ac) with $PZCl_3$ (Z = O, S).

Cpd. [2]	Z	Phosphorylation [%]	Solution or suspension medium
dT(Ac)	O	95	tetrahydrofuran
dT(Ac)	S	75	tetrahydrofuran
dbz^6A(Ac)	O	97	tetrahydrofuran
dT—dT(Ac)	O	54	tetrahydrofuran
dT—dan^4C(Ac)	O	72	diethyl ether with 20% tetrahydrofuran
dbz^6A—dT(Ac)	O	51	diethyl ether with 20% tetrahydrofuran
dan^4C—$dibu^2G$(iBu) [3]	O	57	diethyl ether with 10% petroleum ether
$dibu^2G$—$dibu^2G$(iBu) [4]	O	63	diethyl ether with 40% petroleum ether

The method described here has the following advantages:

1) Oligodeoxyribonucleotides can be synthesized starting with the relatively inexpensive deoxyribonucleosides.

2) The four 5'-protected deoxyribonucleosides are starting materials both for the synthesis of the chain starts, and for the synthesis of the 3'-*O*-acetylated deoxyribonucleoside 5'-phosphates, which are necessary for the elongation of the chain.

3) The protected dideoxyribonucleoside monophosphates—obtained during chain synthesis—can be used as starting material for the synthesis of 3'-*O*-acetylated dideoxyribonucleoside diphosphates, which are necessary for the extension of the chain.

4) Compounds of type *(4)*, *(7)*, *(8)*, and *(11)* can be obtained pure in large amounts in a short time.

Extension of this approach to the synthesis of trinucleoside triphosphates is now under investigation.

3'-O-Acetyldeoxyribonucleoside 5'-phosphates (7):

(6) (1 mmol) is evaporated three times with dry 2,6-lutidine, dissolved in tetrahydrofuran (8 ml), 2,6-lutidine (1.75 ml, 15 mmoles) is then added. The mixture is cooled in an ice bath and freshly distilled phosphorus oxychloride (0.138 ml, 1.5 mmol) is added with stirring. After 15 minutes the cooling bath is removed. After a further 15 minutes, the reaction mixture is hydrolyzed with 0.2 M aqueous triethylammonium acetate (12 ml) (pH 7) and after standing for 12 hours the reaction mixture is evaporated several times with water. The inorganic phosphate is precipitated at pH 7 with barium acetate according to known procedures. The solution is then adsorbed onto a column of DEAE-cellulose (acetate form), traces of unreacted *(6)* are removed by washing with 25 mM aqueous triethylammonium acetate containing 40% methanol. Then *(7)* is eluted with 150 mM aqueous methanolic triethylammonium acetate, evaporated, dried several times by evaporation with pyridine and then precipitated into ether.

3'-O-Acetylated dideoxyribonucleoside diphosphates (11):

(10) (1 mmol, as 2,6-lutidinium salt) is made into a fine suspension by vigorous shaking with some glass beads (diameter 2—3 mm) in the presence of the appropriate mixture (4 ml) (Fig. 1) and of 2,6-lutidine (2.91 ml, 25 mmol). The suspension is cooled to −10 C, freshly distilled phosphorus oxychloride (0.23 ml, 2.5 mmol) is added, and the mixture shaken vigorously for 15 minutes. After 1 hour it is hydrolyzed with 0.3 M aqueous triethylammonium acetate (4 ml) (pH 7) for at least 12 hours at 0 °C. Then follows chromatography on DEAE-cellulose (acetate form). Lutidine and unreacted *(10)* are washed out with 25 mM triethylammonium acetate containing 40% methanol. *(11)* is eluted using a gradient of triethylammonium acetate (linear from 25 mM to 250 mM and from 250 mM to 400 mM) containing 40% methanol. The fractions, which contain *(11)*, are collected, evaporated, dried by evaporation with pyridine, and precipitated into ether.

The Versatile (Polypyrazolyl)borates

By *Swiatoslaw Trofimenko*[*]

(Polypyrazolyl)borates of the general formula $[R_nB(pz)_{4-n}]^-$ ($n=0$, 1 or 2; R=H, F, Alkyl or Aryl; pz=1-pyrazolyl which may be C-substituted) are a new class of anion that has a well-developed tendency to form chelate compounds and can function as a bi-, tri- or even a quadridentate ligand[1, 2].

The bidentate ligands $R_2B(pz)_2^-$ and bivalent transition-metal ions form neutral chelate compounds $[R_2B(pz)_2]_2M$ that resemble those from 1,3-diketones but are always monomeric. With carbonylmetal compounds, *e.g.* $Mo(CO)_6$, they form anionic tetracarbonyl complexes that are readily converted by reaction with allyl halides into formally 16-electron complexes such as $(C_2H_5)_2B(pz)_2Mo(CO)_2$-π-$C_3H_5$ or $H_2B(pz')_2Mo(CO)_2$-π-C_3H_5. The last of these compounds contains a B—H—Mo bridge, which accounts for its chemical stability[3].

The tridentate ligands $RB(pz)_3^-$ afford not only chelates $[RB(pz)_3]_2M$ of D_{3d} symmetry that resemble metallocenes and are very stable thermally and chemically, but also compounds such as $RB(pz)_3Mo(CO)_2N{=}NAr$ that are analogous to half-sandwich compounds. Although these compounds resemble the analogous C_5H_5 complexes, most of them are considerably more stable both chemically and thermally; for example, $HB(pz)_3^-$ forms a stable monocarbonylcopper derivative $HB(pz)_3Cu(CO)$[4].

The ligand $B(pz)_4^-$ can appear doubly bidentate and afford spiro cations such as $[\pi\text{-}C_3H_5Pd(pz)_2B(pz)_2Pd\text{-}\pi\text{-}C_3H_5]^+$[5]. Various types of stereochemical instability have been studied by NMR spectroscopy with the aid of (polypyrazolyl)borates.

Although the (polypyrazolyl)borates form only σ- and not π-bonds to metals, their chelate compounds are very stable; in many cases such borates displace phosphane and cyclopentadienyl ligands. The advantages of (polypyrazolyl)borates as ligands are as follows: 1) all their salts are soluble in water as well as in organic solvents, are readily prepared, and are stable in air; 2) the ligand $HB(pz)_3^-$ can be synthesized with up to ten substituents, so that steric and electronic relations can be changed as desired whilst retaining the original C_{3v} symmetry of the ligand; 3) the C-protons are excellent symmetry probes, suitable for use in studies of dynamic processes in complexes; and finally 4) for each $R_nB(pz)_{4-n}^-$ ligand there is an isosteric and isoelectronic but neutral ligand $R_nC(pz)_{4-n}$, so that completely analogous metal complexes can be prepared that have a charge greater by +1 per ligand. This is not the case for any other ligand system.

Although these (polypyrazolyl)borates have been known for only a short time they have already proved their value as ligands and further expectations appear certainly justified.

Reactions on Coordinatively Unsaturated Chromium(II) Surface Compounds

By *Hans-Ludwig Krauss*[*]

For the catalyst of the Phillips polyethylene synthesis it has been shown that the catalytically active centers are coordinatively unsaturated metal ions in a low oxidation state (analogy to the Ziegler-Natta process!)[1]. To assume that these centers constitute a uniform species is, however, too crude a simplification. For silica gel as support, *e.g.*, two kinds of reacting OH groups could be detected; these provide two topologically different points at which Cr^{VI} surface compounds can be formed, this being the first step in the reactions. The existence of two sterically different species has also been proved for the small amounts of Cr^{V} which are obtained as a side product on preparation of the Cr^{VI} surface compounds[2]. After the reduction to Cr^{II}, which then is the coordinately unsaturated surface compound, two different types of Cr^{II} are found again; indeed, by modification of the procedure, one or the other can be made the preponderating, if not the only, species. The products differ in color (green and blue respectively), in their reaction with O_2 (with or without chemiluminescence) and in their behavior towards CO (different IR bands, different stability in vacuum). It is possible that only one of the two species takes part in the polymerization of ethylene.

If the Cr^{II} centers are saturated with strongly bonding ligands, the metal can be removed by protic solvents whilst the ligand-carrier bonds are retained. In this way new complexes can be isolated by reaction of the unsaturated center and subsequent conversion into a homogeneous phase. Especially, on removal from the carrier the bond between the ligand and chromium can be retained when one ligand is a short hydrocarbon chain formed by polymerization of ethylene[3]. Such organochromium compounds are relatively stable in cyclohexane at room temperature in absence of air and protons; they can be sublimed with loss of dipole-bonded ligands (mass spectrum!) and react with a variety of new coordination partners.

Our results provide a first insight into the topology of heterogeneous reactions on amorphous substrates. By removal from the carrier of the coordination compounds formed in this way, a new route is opened for the synthesis of metal complexes.

Reviews

Abstracts of selected progress reports and review articles

Reactions of substituted 1,3,3-trichloro-2-aza-1-propenes are treated by *K. Findeisen, K. Wagner*, and *H. Holtschmidt*. Polychloro-2-aza-1-propenes, and particularly the pentachloro derivative ("trichloromethyl isocyanide dichloride" TMI) are readily accessible by high-temperature chlorination. TMI reacts with carboxamides to give nitriles and with alcohols to give alkyl halides, alkylurethanes, and carbonic esters. Reaction with aldehydes and carboxylic anhydrides affords dichloroalkanes and acyl chlorides respectively. TMI and higher homologs are suitable for the construction of heterocycles, *e.g.* 1,3,5-triazines, pyrimidines, quinazolines, 1,2,4-triazoles, and 1,2,4-oxadiazoles. [Reaktionen der substituierten 1,3,3-Trichloro-2-aza-propene [N-(1,1-Dichloro-alkyl)-imidchloride]. Synthesis *1972*, 599—605; 14 references]

[Rd 617 IE—M]

The use of NMR spectroscopy in studies of organophosphorus compounds is surveyed by *B. I. Ionin* and *T. N. Timofeeva*. The authors systematize the chemical shifts of protons in phosphorus compounds and examine proton-proton and proton-phosphorus interactions. The values obtained serve as basis for a consideration of the nature of the P—H bond. The final section deals with the significance of NMR spectra in structural and conformational analysis of organophosphorus compounds. [Application of Proton Magnetic Resonance to the Investigation of Organophosphorus Compounds. Russ. Chem. Rev. *41*, 390—402 (1972); 167 references]

[Rd 626 IE—Q]

Progress in the chemistry of aliphatic diazo ketones is reviewed by *A. L. Fridman, G. S. Imagilova, U. S. Zahsov*, and *S. S. Novikov*. The article deals with the syntheses available and surveys the literature describing chemical properties. The physical properties and also problems of p-π conjugation and rotational isomerization as well as biological activities are considered in further sections. [Advances in the Chemistry of Aliphatic Diazoketones. Russ. Chem. Rev. *41*, 371—389 (1972); 295 references]

[Rd 627 IE—Q]

The calculation of electronic states of copper(II) complexes by semi-empirical methods is discussed by *D. W. Smith*. A review of spectra measured and assigned up to now is followed by a critical assessment of the models used for interpretation of the spectra. The author recommends the angular overlap model with corrections for electrostatic contributions for the calculation of energy levels in copper(II) compounds. Covalent and electrostatic d-level splitting parameters of the most important ligand atoms are tabulated as functions of the internuclear distance. Using these parameters one should be able to calculate the d-d spectrum of any copper(II) chromophore of known or assumed geometry. [Ligand Field Splittings in Copper(II) Compounds. Struct. Bonding *12*, 49—112 (1972); 197 references]

[Rd 632 IE—H]

Complexes of the platinum metals with molecular oxygen are the topic of a review by *V. J. Choy* and *C. J. O'Connor*. The authors restrict the subject matter to mononuclear complexes with equivalent oxygen atoms occupying two coordination sites of the metal. IR spectra and structural data (bond lengths) are discussed and the metal-oxygen bond is evaluated in terms of MO theory. This is followed by a section on the reaction kinetics of formation (and of dissociation if formation is reversible) of these compounds. Finally, stoichiometric and especially homogeneous catalytic reactions of dioxygen complexes are discussed; they are of considerable importance for our understanding of the function of metalloenzymes. [Chelating Dioxygen Compounds of the Platinum Metals. Coord. Chem. Rev. *9*, 145—170 (1972); 86 references]

[Rd 636 IE—H]

The coordination chemistry of thallium(I) is considered in detail by *A. G. Lee*. The review abounds in tables of physical and physicochemical data, partly comparing Tl(I) with the corresponding alkali compounds. The extensive list of references refers also to work from Russia and eastern Europe. [The Coordination Chemistry of Thallium(I). Coord. Chem. Rev. *8*, 289—349 (1972); 398 references]

[Rd 637 IE—H]

The spin state of pentacoordinate cobalt(II) and nickel(II) complexes depends on the ligand donor atoms and on the complex geometry. This correlation is analyzed by *L. Sacconi*. He shows in an extensive table the connection between the sum of the nucleophilic reactivity constants of the donor atoms and the spin state: a less nucleophilic set of ligands results in high-spin complexes, and a more nucleophilic one in low-spin complexes. Predictions of this type may fail if one metal-donor bond is considerably longer than the remaining four. [The Influence of Geometry and Donor-Atom Set on the Spin State of Five-Coordinate Cobalt(II) and Nickel(II) Complexes. Coord. Chem. Rev. *8*, 351—367 (1972); 117 references]

[Rd 638 IE—H]

Transition metal complexes of the N^{3-} ligand are the subject of a review by *W. P. Griffith*. A general section dealing with occurrence, stereochemistry, modes of bonding, preparation, and properties of nitrido complexes is followed by a description of the chemistry of the known complexes of this type; high-polymer and most binary nitrides are not covered. Because of its particularly interesting nitride chemistry, mercury is considered here as an "honorary member" of the transition metal group. [Transition Metal Nitrido Complexes. Coord. Chem. Rev. *8*, 369—396 (1972); 100 references]

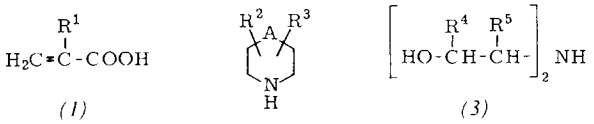
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Bubble-free polyacrylate castings, which were formerly difficult to produce, are readily obtained by the reaction of monomers having the formula *(1)* with an initiator having the formula *(2)* or *(3)* under a protective gas. The monomer is intimately mixed with the initiator in a reactor and



(1) *(2)* *(3)*

R = alkyl ($C_1 - C_{30}$); R^1 = H, alkyl ($C_1 - C_3$), R^2, R^3 = H, alkyl ($C_1 - C_5$), R^2 and R^3 are attached to different ring C atoms; A = CH_2, O, or NH; R^4, R^5 = H, alkyl ($C_1 - C_3$), R^4 and R^5 are the same or different

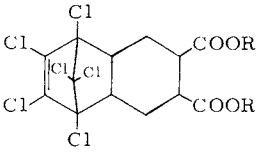
reacts to form a viscous prepolymer, which is then allowed to polymerize to completion without bubbles in stationary conditions. Examples given for initiators having the formula *(2)* are piperidine, morpholine, piperazine, and their alkyl derivatives, while initiators having the formula *(3)* include 2,2'-iminodiethanol, 1,1'-iminodiisopropanol, and similar compounds. Methyl methacrylate is used in particular as the monomer. [DOS 2145289; Texaco Development Corp., New York]

[PR 67 IE—S]

In the low-pressure polymerization of propylene in the gas phase with Ziegler catalysts, a considerable quantity of *n*-heptane-soluble material, which impairs the quality, particularly of injection-molded articles, is usually formed. This fraction can be greatly reduced and subsequent treatment for the removal of catalysts from the final product can be avoided if the catalyst components are brought together before introduction into the reactor under inert gas or under monomer at or slightly above normal pressure, and if the propylene used is so pure that the catalyst yield obtained is more than 10000 parts of polymer/part of heavy metal component and the catalyst activity is higher than 1000 parts of polymer per part of heavy metal component per hour. [DOS 2049623; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

[PR 71 IE—T]

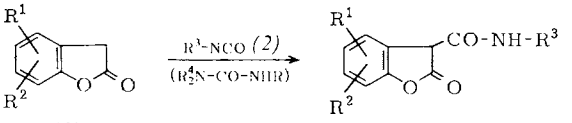
Polymers of allyl esters of hexachlorooctahydromethanonapthalenedicarboxylic acid can be obtained by free-radical polymerization of the compound *(1)*, possibly in combination with a methacrylic ester. The polymerization may be carried out in bulk, in solution, in emulsion, or in aqueous suspension at pressures above or below atmospheric and at temperatures between about 60 and 150 °C. The homo-



polymers and copolymers can be used as potting resins for electrical equipment. [DOS 1770383; Dow Chemical Company, Midland, Michigan]

[PR 82 IE—E]

2-Oxo-2,3-dihydrobenzofuran-3-carboxamides *(3)* and their pharmacologically acceptable salts can be used as anti-inflammatory agents. The compounds *(3)* can be prepared by reaction of 2-oxo-2,3-dihydrobenzofurans *(1)* with



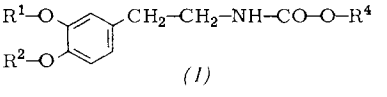
(1) *(3)*

R^1, R^2 = H, F, Cl, Br, CF_3, OCF_3, alkyl (C_1 – C_5), alkoxy (C_1 – C_5); R^3 = naphthyl, (substituted) phenyl, alkyl (C_1 – C_4), alkoxy, alkylthio, CF_3, OCF_3; R^4 = aryl

isocyanates *(2)* or trisubstituted ureas. [DOS 2150901; Pfizer Inc., New York, N.Y.]

[PR 93 IE—N]

Disubstituted *N*-phenethylcarbamic esters *(1)* can be used as antidepressants. They are also suitable for use as active ingredients for long-acting oral antiparkinsonian agents.



(1)

R^1, R^2 = H, (substituted) benzyl, $COOR^3$, $CONHR^3$, $COSR^3$; R^3 = alkyl, alkenyl, alkynyl (C_1–C_5); R^4 = alkyl, alkenyl, alkynyl, haloalkyl, cyclopropylmethyl, 2-(2-furyl)ethyl, cyclobutyl.

Progress in Bioorganic Chemistry. Vol. 1. Edited by *E. Kaiser* and *F. Kézdy*. John Wiley & Sons, Inc., New York—London 1971, 1st Edit., ix, 369 pp., numerous figures and tables, £7.—.

The less time a scientist has to consult the primary literature, the greater the importance he will attach to the secondary literature. Handbooks and progress reports give informations on advances in individual fields of science and provide a stepping stone for those wanting to break into new domains. Publishers of secondary literature are therefore assuming a steadily increasing burden of responsibility. "Progress in Bioorganic Chemistry" is the latest newcomer to the field of biochemical secondary literature. The editors understand bioorganic chemistry to be the discipline that has evolved from the interaction between biochemistry and physical organic chemistry. In their view the aim of this new science should be to promote the understanding of biological reactions on the basis of the reaction mechanisms of organic chemistry, in qualitative and quantitative terms, as well as the relationship between the reactivity and structure of the participating molecules, in other words especially catalysts. When we are also told in the Foreword that the chief representatives of this science describe themselves as enzymologists, biochemists, kineticists, and physical organic chemists, then we may conclude that this "new" science fits the old concept of enzymology or enzymatic catalysis, and this domain is hardly new. After all, this year will see the appearance of the 35th volume of "Advances in Enzymology", a series which makes claims similar to those of the new series under discussion, and which, moreover, is brought to us by the same publisher.

On the basis of the first volume it cannot be said that these new progress reports fill a gap. Together with "Advances in Enzymology", "Advances in Catalysis", "The Enzymes", and "The Proteins", they extend the existing series, and hence could in principle extend the information available in the field of enzymology. Do they in fact do so? Regrettably, the answer on the strength of this first volume must be largely no. *Kirby* and *Fersht* devote 82 pages to intramolecular catalysis. The 62-page article by *Bruice* published in "Enzymes" in 1970 deals to a considerable extent with a similar field, and many of the references cited are identical. *Hamilton*'s paper on "The Proton in Biological Redox Reactions" likewise contains material which appeared in the new edition of "Enzymes" or which will do so shortly. The main section of the book, about half, consists of an article by *Coleman* on the role of metal ions in enzymatic catalysis. This field was reported by *Vallee* and *Wacker* a year ago in even greater depth than in the present work ("The Proteins", Volume 5) and by *Mildvan* in the new edition of "Enzymes". (Why does *Coleman* on p. 314 still treat lactate, malate, and glutamate dehydrogenase as zinc enzymes?)

One puts down the first volume of "Progress in Bioorganic Chemistry" with some dissatisfaction. Such extensive overlapping with other progress reports could have been avoided, for the coverage of "Enzymes" and "Proteins" has been known for a long time. This is a poor start for a new series, and the editors will have to seek out more original subjects in order to justify its existence. If they cannot do that, then it would be better to discontinue the series.

Horst Sund [NB 127 IE]

Organophosphorus Chemistry. Vol. 3. Specialist Periodical Reports. Published by The Chemical Society, London 1972. 1st ed., x, 303 pp., bound £ 7.—.

The rapid growth of phosphorus chemistry can be seen from the third volume of "Organophosphorus Chemistry", which covers the literature between July 1970 and June 1971. The publication was again executed under the expert direction of *S. Trippett*, who had the cooperation of eight well-known British specialists as co-authors. 1254 references containing the results of 2055 authors have been taken into account. The division of material that proved successful in the earlier volumes has been retained: Phosphines and Phosphonium Salts (*D. J. H. Smith*, 29 pp.); Pentavalent Phosphorus Compounds (*S. Trippett*, 11 pp.); Halophosphines and Related Compounds (*J. A. Miller*, 13 pp.); Phosphine Oxides and Phosphine Sulfides (*J. A. Miller*, 14 pp.); Acids of Trivalent Phosphorus (*B. J. Walker*, 29 pp.); Acids of Pentavalent Phosphorus (*N. K. Hamer*, 27 pp.); Phosphates and Phosphonates of Biochemical Interest (*D. W. Hutchinson*, 28 pp.); Ylides and Related Compounds (*S. Trippett*, 37 pp.); Phosphazenes (*R. Keat*, 39 pp.); Free-Radical, Photochemical, and Deoxygenation Reactions (*R. S. Davidson*, 18 pp.); Physical Methods (*J. C. Tebby*, 45 pp.).

The value of this series of books for many preparative and also biochemical laboratories can therefore scarcely be overrated, since despite strenuous efforts, the new edition of "Kosolapoff" is constantly falling behind schedule and the series "Topics in Phosphorus Chemistry" has ceased publication.

The third volume of "Organophosphorus Chemistry", like its predecessors, makes a good impression in every respect, and can be recommended to all interested specialists.

Leopold Horner [NB 129 IE]

The Nuclear Overhauser Effect—Chemical Applications. By *J. H. Noggle* and *R. E. Schirmer*. Academic Press, New York—London 1971. 1st ed., xi, 259 pp., numerous figures and tables, bound $ 14.50.

Nearly all the textbooks on high-resolution magnetic NMR spectroscopy that have appeared in recent years and are suitable for chemists provide insufficient information on spin-lattice relaxation and the closely related nuclear Overhauser effect (NOE). Until now there has been no synopsis that both deals with the theory at a middle level and clearly shows the possibilities and limitations of the method.

This gap has now been bridged by the present monograph. A concise, clear introduction to spin-lattice relaxation by consideration of population differences and transition probabilities and an explanation of the relaxation times are followed by the derivation of the Solomon equation. Contrary to their expressed aim, the authors were evidently unable at this point to avoid referring to *Abragam*'s "Principles of Nuclear Magnetism" at the start of the calculation.

Further mainly theoretical chapters deal with the mechanisms of spin-lattice relaxation, the fundamentals of the determination of internuclear distances, and conformational analysis with the aid of the NOE. A number of sections in Chapter 5 (Experimental Methods), could,

in the review's opinion, have been omitted; examples are the sections on side-band technique, modulation, and frequency field stabilization. A clear delimitation of the term "nuclear Overhauser effect", which the authors unfortunately omit, would also have led to the exclusion of Chapter 7, which describes the application of the double resonance method to dynamic processes.

On the other hand, the reader is bound to be pleased with the extremely carefully compiled, remarkably comprehensive literature survey, which takes into account articles up to December 1970. The author does not shrink from harsh criticism in discussing the results of investigations. A comprehensive bibliography is appended.

It is to be hoped that this book will not be read exclusively by specialists. It has valuable suggestions for the preparative chemist, particularly in the field of natural products, even if he ignores the greater part of the theoretical chapters.

Wolfgang Herrig [NB 132 IE]

Analytical Photochemistry and Photochemical Analysis. Edited by *J. M. Fitzgerald*. Marcel Dekker, Inc., New York 1971. 1st ed., xiv, 360 pp., 49 figs., bound $ 23.50.

The editor, who is himself the author of Chapter 5 (Photochemical Titrations), attempts to interest both photochemists and analysts in a total of nine contributions of different lengths (11–87 pp.). The division of the subject matter has been carried out accordingly.

The first section (three chapters totalling 112 pp.) first presents general information on photochemical methods; however, the list of companies is only of limited value to the European reader. Chapter 2 then deals very concisely and clearly with lasers (theory and construction principles) and their use in Raman and emission spectroscopy among other things. The list of actinometers in Chapter 3 will be welcomed by the experimental photochemist.

The second section deals with photochemical reactions in analytical chemistry. Two chapters describe the determination of mostly inorganic substances *e.g.* by photochemical titrations, in which the reaction of a substance with photons is followed directly or by means of a photochemically produced reagent, usually with spectrophotometric determination of the end point. This section, with a length of 46 pages, is the shortest, but points to the relatively new links between photochemistry and analytical chemistry.

The third section (four chapters, 168 pp.), on analytical methods in photochemistry, is concerned not with the use of conventional analytical methods for the identification of products but with the detection of the reactive states and of short-lived intermediates. Chapter 6 deals with "radical scavenging", triplet energy transfer, matrix spectroscopy and other spectroscopic techniques. A notable omission here is the absence of any reference to CIDNP. Flash spectroscopy is also discussed, though the whole of Chapter 7 is also devoted to this subject. This overlap could have been avoided; a method as important as this deserves a self-contained treatment. The last two chapters are very special; the short chapter on analysis for coordination compounds in the solid state could have been safely omitted. On the other hand, a separate chapter on methods for the investigation of the light sensitivity of polymers would not have been out of place, in view of the practical importance of plastics.

The subject and author indexes, unlike the figures, are adequate. The book can be recommended only with reservations; it will be of advantage only to the photochemist who can make the correct selections from the 900 references.

D. Rehm [NB 142 IE]

Far-Infrared. By *K. D. Möller* and *W. G. Rothschild*. John Wiley and Sons, New York 1971. 1st ed., xix, 797 pp., numerous figures and tables, bound £ 15.25.

The aim of the book is to provide information on the research possibilities and recent developments of far-infrared (FIR) spectroscopy in the fields of physics, chemistry, and biochemistry. The chemist has learned to make correct use of many physical measuring instruments, even though he regards them only as "black boxes". For the use of FIR spectroscopy, however, he still needs information about the physical principles of the measuring instruments and of the measuring process. It is therefore gratifying to find that the present book deals first, in four chapters, with the properties of grating spectrometers, interferometers and their components, and the principles of Fourier transform spectroscopy. The principal chemical applications of FIR spectroscopy are discussed in the next four chapters; these are low-frequency stretching and deformation vibrations, FIR spectra of systems bonded by hydrogen bonds, skeletal vibrations of strained ring systems, and torsional vibrations with a periodic potential barrier. These are followed by chapters on the pure rotation spectrum of water, collision-induced spectra at long wavelengths, rotational-translational movements in condensed phases, the FIR spectra of diatomic cubic crystals, and the FIR spectra of polyatomic crystals. In six appendices, specialists present reports on defect-induced lattice absorption in the far-infrared, dielectric properties and optical phonons in paraelectric and ferroelectric perovskites, magnetic phenomena in the far-infrared, FIR-spectroscopic studies on semiconductors, superconductivity, and rapid Fourier spectroscopy. A bibliography covering the entire literature on FIR spectroscopy from 1892 to 1969, with 1512 references, completes this useful book, which provides detailed information from the many possible fields of chemistry and physics. There are few spectroscopic methods for which such a comprehensive book can be written today.

Bernhard Schrader [NB 145 IE]

Statistische Auswertungsmethoden (Statistical Evaluation Methods). By *L. Sachs*. Springer-Verlag, Berlin–Heidelberg–New York 1972. 3rd revised and expanded edition, 548 pp., 59 figs., bound DM 58.—.

The fact that new editions have been necessary at intervals of two years after the first edition in 1967 shows that the author has succeeded in producing an account of statistical evaluation methods that appeals to and satisfies a wide readership. The third edition, which is slightly larger than the second edition, again contains a description, in seven sections, of a large number of statistical approaches and procedures that have proved useful in practice, without abstract mathematical derivations and proofs. After preliminary remarks with an introduction to the elementary principles of a rational arithmetic, the first section deals with the groundwork for statistical decision-making techniques, such as the elements of probability calculations, and

the types of distribution function. After the description of applications in medicine and technology, there are two sections on simple comparison tests and other special test procedures. The large number of tests mentioned presents a hidden danger of different interpretations and judgements for the same fundamental data if the test used is left to the observer's discretion. A more detailed discussion of the conditions and reliability criteria would therefore have been advisable in places. The presentation of the methods of correlation and regression analysis, the evaluation of multi-field tables, and variance analysis in the following sections is extremely good. The material is made very understandable even to readers with little mathematical knowledge by 400 numerical examples, 59 exercises (with solutions in the appendix), and more than 210 tables. It will also be a valuable textbook and reference book in the future for readers concerned mainly with applications.

Günter Gottschalk [NB 148 IE]

Physical Chemistry—An Advanced Treatise. Vol. VIIIB. Liquid State. By *H. Eyring, D. Henderson*, and *W. Jost*. Academic Press, New York—London 1971. 1st ed., xix, pp. 413–892, numerous figures, bound $ 25.—.

The present part completes the eight volume of this compilation, which may almost be described as encyclopedic. The conception of the work cannot be too highly praised. For a comprehensive and at the same time up-to-date account of the entire field of physical chemistry, it is essential that the various chapters should be entrusted to specialists. The work as a whole must then be judged both on the quality of the individual chapters and on the degree to which the editor has succeeded in imparting unity to the work.

The present part begins with a chapter on liquid mixtures (*D. Henderson* and *P. J. Leonard*). After a brief discussion of the mixing rules known for intermolecular potentials, simple cases (one-dimensional systems, systems consisting of hard spheres and of molecules with Lennard-Jones interaction) are dealt with; the principal theories are presented in detail (quasi-lattice theory of *Guggenheim-Percus-Yevick*, perturbation theories from *van der Waals* to *Leonard-Henderson-Barker*, "n-fluid" theories), and their results are critically compared. The chapter on liquid helium (*D. ter Haar*) contains a very readable description of the theories for ^{3}He and ^{4}He. If we complain that too little space is devoted to the description of the properties of liquid helium, it is only because slightly more would have allowed a completeness that is desirable above all on didactic grounds.

The chapter on the time-dependent properties of condensed media (*B. J. Berne*) is rightly the largest chapter in the present volume. In addition to the consequences of the linear response theory (magnetic susceptibility, width of spectral lines, relaxation time), the properties of correlation functions and memory functions are discussed in detail. The section on computer experiments is too short and tells the reader nothing that he would not already know if he had worked through the book up to this point. The section on molecular orientations in gases and liquids, on the other hand, contains all the important information on experimental and theoretical methods for the study of molecular motions.

Two chapters on critical phenomena follow. *J. Stephenson* deals with the static aspects, and the chapter on dynamic critical phenomena was written by *H. E. Stanley, G. Paul*, and *S. Milošević*. *Stephenson* more than the other authors has allowed himself to be guided by didactic motives. The fundamentals of the theory are described almost without prior assumptions, and an eye-catching weight of face has been used for fundamental facts.

The present volume does what it promises. In every chapter the reader receives concise but comprehensive information on the topic discussed. The circle of readers who will be interested in this volume is naturally small. It will appeal to all physical chemists who are interested both in theoretical and in experimental methods for the study of liquids.

Arno Höpfner [NB 156 IE]

Messergebnisse und ihre Auswertung. (Experimental Results and their Evaluation). An introduction to practical work in natural science. By *G. L. Squires*. Walter de Gruyter, Berlin—New York 1971. 1st ed., 240 pp., 77 figs., bound DM 29.—.

The book is divided into three parts: "Statistical Treatment of Experimental Data", "Experimental Methods", and "Records and Calculations". A survey of the calculation and estimation of errors is given in the first part, while the second part (which is better described by its original title "Practical Physics" than by the German title) shows with the aid of selected samples the errors that can creep into an experiment and how these errors can be avoided; the third part contains hints on how experimental results should be recorded, evaluated and presented.

These topics are dealt with in an unusually original manner (*e.g.* chapter headings "Common Sense and Errors", "Logic in Experimenting", "Common Sense in Experiments"). No consideration is presented without an example (and these examples are excellently chosen) to bring out the essential point.

The book can be warmly recommended to all students of natural sciences, mainly as supplementary reading to practical exercises. However, the many Anglicisms that have crept into the German text (and these are very disturbing in places) should be eliminated in a new edition.

H.-D. Försterling [NB 169 IE]

Mathematik für Chemiker (Mathematics for Chemists). By *H. G. Zachmann*. Verlag Chemie GmbH., Weinheim/Bergstrasse 1972. 1st Edit., xvi, 593 pp., bound DM 64.—.

For the study of chemistry in the narrow sense, only a relatively modest mathematical background is expected of the student, at least in the early stages. Later in the course, as he becomes increasingly concerned with physico-chemical problems, much greater demands are very soon placed on the student's mathematical knowledge and skills. This is particularly true of students who intend to prepare a degree or doctorate thesis on a physico-chemical topic. As a result of the increasing use of physico-chemical methods in chemistry as a whole, however, other chemists must generally also have a well-grounded mathematical training designed to meet the special requirements of chemical applications.

There is no doubt that until recently, a great deal of experiment and improvisation has gone into the mathematical instruction of chemists. On the one hand, the courses designed primarily for mathematicians are often too narrow

in their scope or too demanding; on the other hand, a one-semester course on infinitesimal calculus of greatly reduced content (*e.g.* given by assistant lecturers on the university staff), possibly with the addition of a few references to other important fields of practical mathematics, is no longer adequate in view of the requirements mentioned. A similar situation is found in the German-language textbooks available until recently in this field. The earlier mathematics textbooks for chemists no longer covered the entire field of practical mathematics that should be mastered by the chemist. The compendia compiled for use in physics and chemistry are mainly of the nature of reference works, whose use calls for some existing background knowledge.

Since the chemistry student is faced with mathematical problems mainly in physical chemistry, some universities have experimented successfully with leaving the mathematical instruction of chemists to a lecturer from the field of physical chemistry. The present work is also based on courses for chemistry students at the University of Mainz. The well laid out book deals lucidly with the entire field of classical practical mathematics that is important nowadays for the treatment of chemical or physico-chemical problems. The mathematical formalism is clearly illustrated in every case by concrete examples, and the reader can check the state of his own knowledge by means of test questions and exercises incorporated into the text.

In addition to infinitesimal calculus and linear algebra, the fields of probability calculus, statistics, and group-theory, which are at least equally important to the chemist, are also dealt with. From his own experience of mathematics courses for chemists, the reviewer feels that a definite need has been filled by the publication of this book. Though the book almost attains the proportions of a reference work in some sections, it nevertheless makes an excellent impression on the whole. It should therefore always be used as an aid in the preparation of mathematics courses for chemists, and its purchase in fairly large numbers can be recommended to the libraries of institutes and training colleges. The high price is regrettable, and will undoubtedly place the book beyond the pockets of many chemistry students who would otherwise be interested.

Theodor Ackermann [NB 171 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Short Course in Biochemistry. By *A. L. Lehninger*. Worth Publishers, New York 1973. xliv, 420 pp., bound \$12.50.

Contents: Biomolecules; Catabolism and the Generation of Phosphate-Bond Energy; Biosynthesis and the Utilization of Phosphate-Bond Energy; Replication, Transcription, and Translation of Genetic Information.

Progress in Organic Chemistry, Vol. 8. Edited by *W. Carruthers* and *J. K. Sutherland*. Butterworths, London 1973. vii, 343 pp., bound £ 9.50.

Contents: Synthesis of Prostaglandins; Biogenetic-Type Synthesis of Terpenes; Advances in the Chemistry of Cannabinoids; Penicillin Chemistry; Advances in the Chemistry of Cyclic Peptides; Chemiluminescence of Organic Compounds; Recent Work on Nitration; Homogeneously Catalysed Hydrogenation.

Analytical Chemistry of Selenium and Tellurium. By *I. I. Nazarenko* and *A. N. Ermakov*. From the series "Analytical Chemistry of the Elements". Halsted Press, a division of John Wiley & Sons, Inc., New York 1973. x, 281 pp., bound £ 9.35.

Contents: Chemical and Analytical Characteristics of Selenium and Tellurium and Their Compounds; Qualitative Detection of Selenium and Tellurium; Quantitative Determination of Selenium and Tellurium; Methods for Separating Selenium and Tellurium from Foreign Elements; Determination of Selenium and Tellurium in Natural and Industrial Substances; Determination of Impurities in High-Purity Selenium and Tellurium.

Pesticide Formulations. Edited by *W. van Valkenburg*. Marcel Dekker, Inc., New York 1973. x, 481 pp., bound \$ 29.50.

Contents: Correlation of Biological Activity with Chemical Structure and Physical Properties; The Emulsifier; The Stability of Emulsions; Agricultural Formulations with Liquid Fertilizers; Formulation of Pesticidal Dusts, Wettable Powders and Granules; Plant for the Formulations of Insecticides; Reducing Pesticide Chemical Drift; Spreading and Retention of Agricultural Sprays on Foliage; Penetration and Translocation of Herbicides; Adsorption, Movement, and Distribution of Pesticides in Soils.

Mathematical Methods for Chemists. By *R. K. Mackie, T. M. Shepherd*, and *C. A. Vincent*. The English Universities Press, London 1972. v, 154 pp., bound £ 2.95 (Boards Edition); £ 1.65 (Unibook Edition).

Contents: Functions and Operations; Differential Calculus; Integral Calculus; Differential Equations; Coordinate Systems; Complex Numbers; Vector Analysis; Determinants and Matrices; Expansion of Functions; Statistical Methods; Graphical Methods; Basis Equations; Derivatives; Standard Integrals; Laplace Transforms; Solution of Polynomial Equations.

Analytical Profiles of Drug Substances, Vol. 2. Edited by *K. Florey*. Academic Press, New York, London 1973. xi, 575 pp., bound \$ 18.50.

Contents: Ampicillin; Chlorprothixene; Chloral Hydrate; Clidinium Bromide; Dexamethasone; Dioctyl Sodium Sulfosuccinate; Fluorouracil; Fluphenazine Enanthate; Fluphenazine Hydrochloride; Isocarboxazide; Isopropamide; Levallorphan Tartrate; Methyprylon; Phenelzine Sulfate; Primidone; Propiomazine Hydrochloride; Sulfamethoxazole; Sulfisoxazole; Triclobisonium Chloride; Trifluopromazine Hydrochloride; Trimethobenzamide Hydrochloride.

The Chemistry of Enamines. By *S. F. Dyke*. Cambridge University Press 1973. vii, 93 pp., stitched £ 1.40/bound £ 2.90.

Contents: Preparation and Some Properties; Reactions; Heterocyclic Enamines.

Electrophilic Substitution at a Saturated Carbon Atom. Vol. 12 of the series "Comprehensive Chemical Kinetics". Edited by *C. H. Bamford* and *C. F. H. Tipper*. Elsevier Scientific Publishing Company, Amsterdam, London, New York 1972. xiii, 256 pp., bound Dfl. 90.00/$ 31.60.

Contents: The Formation and Reactions of Carbanions; Mechanisms of Electrophilic Substitution at Saturated Carbon; The Unimolecular Mechanism, SE1.5; Mercury-for-Mercury Exchanges; Other Metal-for-Metal Exchanges; Acidolysis of Organometallic Compounds; Halogenolysis.

The Electronic Structure of Molecules: Theory and Application to Inorganic Molecules. By *G. Doggett*. Vol. 3 of the series "The International Encyclopedia of Physical Chemistry and Chemical Physics", Topic 4: Electronic Structure of Molecules. Edited by *J. W. Linnett*. Pergamon Press, Oxford, New York, Toronto, Sydney, Braunschweig 1972. xiv, 172 pp., bound £ 5.75.

Contents: Orbital Theories of Electronic Structure; The Electronic Structure of Some Molecules Containing a Central Second-Row Atom; The Electronic Structure of Transition Metal Ion Complexes; The Electronic Structure of Xenon Fluorides; Calculation of the Diagonal Matrix Element of the Molecular Electronic Hamiltonian for a Wave Function Given as an Antisymmetrized Product of One-Electron Functions (not necessarily Orthogonal); Character Tables for O_h and T_d Point Groups; Symmetry Adapted Combinations of Atomic Orbitals for an Octahedral Molecule (Point Group O_h).

Chemistry and Biology of Peptides. Edited by *J. Meienhofer*. Ann Arbor Science Publishers, Ann Arbor 1972. xxi, 762 pp., bound £ 11.00.—Proceedings of the Third American Peptide Symposium.

Säuren und Basen (Acids and Bases). By *F. Dietze, E. Hoyer, F. Lorenz, W. Seifert*, and *D. Wagler*. Verlag Chemie, Weinheim 1972. 106 pp., stitched DM 13.80.—Chemie-Programm—ein Lehrprogramm für Hochschulen.

Lehrsystem Elektronik. (Electronics Teaching System). By *G. Markesjö*. Part A: Analog Technology—Experimental and Problem Volume. Verlag Chemie, Weinheim—Carl Hanser Verlag, Munich 1973, 67 pp., stitched DM 24.80.

Contents: Oscillograph; Semiconductor Components; Simple Amplifier Stages; Differential Amplifiers; Solutions and Methods for the Preparation Problems.

An Introduction to Macromolecules. By *L. Mandelkern*. Vol. 17 of the series "Heidelberg Science Library". Springer-Verlag, Berlin, Heidelberg, New York 1972. xi, 161 pp., stitched DM 18.60/$ 5.90.

Contents: Structural Features and Preparation; Chain Structure; Rubbers and Glasses; Crystalline Polymers and Fibers; Macromolecules of Biological Importance; Macromolecules and Man.

Vom Wasser. Ein Jahrbuch für Wasserchemie und Wasserreinigungstechnik. Band 39. (On Water. A Yearbook for Water Chemistry and Water Purification Technology. Vol. 39). Edited by the Water Chemistry Group of the Gesellschaft Deutscher Chemiker. Editor responsible for text: *W. Husmann*. Verlag Chemie, Weinheim 1972. xii, 393, 133 pp., bound DM 68.—.

Schutz gegen atmosphärische Korrosion. Theorie und Technik. (Protection against Atmospheric Corrosion. Theory and Technology). By *K. Barton*. Verlag Chemie, Weinheim 1973. x, 209 pp., bound DM 65.—.

Contents: Introduction; The Atmosphere as a Corrosive Environment; Mechanism and Kinetics of Atmospheric Corrosion; Nonuniform and Structural Corrosion Phenomena; Principles of Protection against Atmospheric Corrosion; Principles of Methods for the Study of Effects of Atmospheric Corrosion; Outline of Technical and Economic Considerations in Protection against Atmospheric Corrosion.

Oxathiazinone Dioxides—A New Group of Sweetening Agents

By Karl Clauss and Harald Jensen[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

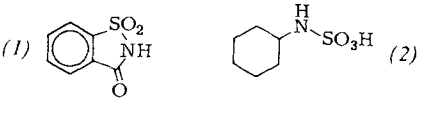
1,2,3-Oxathiazin-4(3*H*)-one 2,2-dioxides bearing lower alkyl substituents on C-5 and C-6 represent potential sweeteners. They are formed from chloro- or fluorosulfonyl isocyanate and acetylenes, ketones, β-diketones, β-oxo carboxylic esters, or benzyl vinyl ethers *via* *N*-halosulfonyl β-oxo carboxamides as common intermediates.

1. Introduction

Since time immemorial the sensation of sweetness of a fruit, a plant secretion, or honey has provided man—and probably also other animals—with a principle for the selection of suitable nourishment from the fullness of his environment. In the course of cultural development, sweet natural products were employed in the preparation of food to intentionally modify its taste. Thus began the checkered history of the development of sweeteners, starting with the domestication of the honeybee and continuing through to the migration of sugar cane from Indochina, *via* the Mediterranean, to America. Cane sugar was unknown in Central Europe until the time of the Crusades. Here the reader is reminded of the introduction of sugar beet cultivation during the Continental Blockade. Cane and beet sugar have remained the dominant sweetening agents since the foundation of the sugar industry and annual production now runs at some 75 million tonnes. This figure testifies to man's love of sweetness.

The high sugar consumption in developed countries whose populations are plagued by such civilization diseases as diabetes, hyperlipemia, obesity, cardiac infarction, caries, or gout is attracting increasing attention from physicians and nutritionalists. Thus the search for sweeteners which do not overtax the metabolism even on liberal comsumption, *i.e.* low-calorie sweeteners, has become more pressing than ever. The sugar substitutes sorbitol or fructose long used by diabetics are metabolized slowly but nevertheless completely and therefore offer no solution to the problem of low-calorie sweetening, especially since their sweetening power is no greater than that of sugar.

Anybody having to live on a diet or wishing to consume less sugar without foregoing sweetness must take recourse to a "synthetic sweetener" in the narrow sense of the term. Such agents cover a whole variety of compounds, the only real limitation being that they should be several orders of magnitude sweeter than saccharose. Many such compounds have been discovered largely by chance during the past hundred years[1]. For toxicological reasons, however, only two were permitted for general use as sweeteners until quite recently: saccharin *(1)* and cyclamate *(2)* in



the form of their neutral sodium and calcium salts. Saccharin is 100 to 500 times as sweet as saccharose, and cyclamate 30 times as sweet.

[*] Dr. K. Clauss and Dr. H. Jensen
Farbwerke Hoechst AG
623 Frankfurt (Main) 80 (Germany)

Like most synthetic sweeteners, the well-established saccharin, which was discovered in 1879, suffers from a bitter metallic aftertaste. Only cyclamate, which was introduced as a sweetener in 1950, is characterized by an almost pure sweet taste and its triumphal conquest of the sweetener market was therefore without parallel. Its success story came to a grinding halt when it was found to be partially metabolized to the carcinogen cyclohexylamine[2,3] in humans and to cause bladder cancer in rats[4]. Its use was finally banned in the USA and many other industrial countries in 1970. Almost simultaneously it was discovered that saccharin can also give rise to bladder cancer[5]. The Food and Drug Administration of the USA accordingly removed saccharin from their GRAS (Generally Recognized as Safe) list, a collection of about 1000 chemicals generally considered to have no harmful action. The toxicity of saccharin is now being studied on a world-wide basis and the results obtained may also lead to its being banned.

The intensive search for new low-calorie and toxicologically safe sweeteners can be readily appreciated against this background.

This search is still confined to the heuristic principle. There are general theories on the correlation of structure and sweetness[6-8] but they are hardly suited as a basis for a directed search for new sweeteners. Consequently, a checkered mixture of compounds whose sweet taste was discovered by accident has accumulated in recent years[9]. Their suitability as sweeteners has been studied in some cases and one of them, L-aspartyl-L-phenylalanine methyl ester[10], developed jointly by G. D. Searle Co. and Ajinomoto Co. Inc., has good prospects of official acceptance.

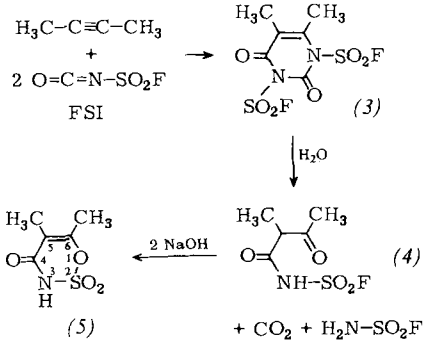
No definite regulations exist as to which stipulations of the licensing authorities must be fulfilled by a sweetener in order to be released onto the market. The situation differs from that of a pharmaceutical preparation in that a sweetener is ingested regularly for long periods and consequently requires more rigorous toxicological testing. In particular, long-term feeding experiments on several animal species and studies on possible carcinogenic, mutagenic, and teratogenic effects and on its metabolism are necessary. Moreover, a sweetener must be water-soluble and within certain limits stable to hydrolysis, *i.e.* resistant to boiling and baking, and be devoid of any aftertaste.

The human tongue is especially sensitive to fine differences in the sweet regime, such as the differences in taste between the isomeric hexoses and disaccharides, and to the presence of aftertastes. Nevertheless, it is difficult to determine how many times sweeter a sweetener is than the reference substance saccharose. Relative sweetness is measured by establishing which of a series of sugar solutions of various concentrations is just as sweet as a sweetener solution of known concentration. Since differing sensations of taste are generally being compared in such tests a certain degree of inaccuracy cannot be avoided. Moreover, the complicated[30,31] dependence of the intensity of a given taste upon concentration permits recognition of only relatively large concentration differences. However, tests on a large number of human subjects and statistical evaluation of the results do lead to reliable data[11]. The measurements show that the relative sweetness does not display a corresponding increase with rising concentration. Thus saccharin is 500 times sweeter than a 1.2% saccharose solution but only 100 times sweeter than a 8.5% saccharose solution. Apart from toxicological considerations, the organoleptic properties mainly decide the usefulness of a sweetener.

2. The FSI Method

2.1. Acetylenes

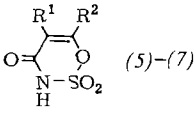
The above situation in the field of sweeteners was responsible for our interest when we encountered a sweet-tasting compound on reaction of 2-butyne with fluorosulfonyl isocyanate (FSI). The reaction[12] proceeds according to Scheme 1.



Scheme 1.

2-Butyne reacts with FSI to give bis(fluorosulfonyl)uracil *(3)*, whose structure was confirmed by X-ray analysis[13]. Hydrolysis of this compound leads to *N*-fluorosulfonyl-α-methylacetoacetamide *(4)* which undergoes surprisingly smooth ring closure to give the new heterocycle 5,6-dimethyl-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide *(5)* under the action of sodium hydroxide solution. Other alkynes such as 1-butyne or 1-hexyne undergo analogous reactions *via* uracil derivatives to the 6-alkyl derivatives *(6)* and *(7)* which also have a sweet taste (Table 1).

Table 1. Oxathiazinone dioxides from alkynes.



(5)–(7)

Cpd.	R^1	R^2	Starting material	Yield [%]	M.p. [°C]
(5)	CH_3	CH_3	2-butyne	75	108.5
(6)	H	C_2H_5	1-butyne	8	80
(7)	H	n-C_4H_9	1-hexyne	14	63

N-Fluorosulfonyl β-oxo carboxamides, *e.g. (4)*, proved to be essential intermediates for the formation of the new oxathiazinone system. A broader-based study of the sweeteners required development of a simpler preparation for these intermediates that would also permit variation of the substituents.

2.2. Ketones

Reaction of α-unsubstituted ketones with FSI was recognized as an important general method of preparing *N*-fluorosulfonyl β-oxo carboxamides[14]. Ketones of this kind generally react with halosulfonyl isocyanates with replacement of an α hydrogen atom[15]. In some cases the resulting sulfonyl fluorides *(8)* are obtained in crystalline form (Table 2)[*].

Table 2. *N*-Fluorosulfonyl β-oxo carboxamides *(8)*.

Cpd.	R^1	R^2	Starting ketone	Yield [%]	M.p. [°C]
(8a)	CH_3	CH_3	2-butanone	77	45
(8b)	$-(CH_2)_4-$		cyclohexanone	65	91
(8c)	$-o\text{-}C_6H_4-(CH_2)_2-$		α-tetralone	82	133

No isolation or purification of this precursor is necessary since ring closure also occurs with the crude products and the pronounced tendency of the oxathiazinone dioxides *(9)* to crystallize renders their purification simple. The route afforded the products listed in Table 3.

$$R^1\text{–}CH_2\text{–}CO\text{–}R^2 + O{=}C{=}N\text{–}SO_2F \xrightarrow[\text{FSI}]{}$$

(8) → *(9)*

Table 3. Oxathiazinone dioxides *(9)* obtained from ketones.

Cpd.	R^1	R^2	Starting ketone	Yield [%]	M.p. [°C]	Sweetness
(9a)	H	CH_3	acetone	13	123.5	+
(5)	CH_3	CH_3	2-butanone	45	108.5	+
(9b)	CH_3	C_2H_5	3-pentanone	60	94	+
(9c)	C_2H_5	CH_3	2-pentanone	55	102	+
(9d)	$n\text{-}C_3H_7$	CH_3	2-hexanone	50	96.5	+
(9e)	$i\text{-}C_3H_7$	CH_3	4-methyl-2-pentanone	35	114	+
(9f)	$-(CH_2)_4-$		cyclohexanone	60	123	
(9g)	C_2H_5	$n\text{-}C_3H_7$	4-heptanone	43	86	+
(9h)	H	C_6H_5	acetophenone	9	181	
(9i)	$n\text{-}C_3H_7$	$n\text{-}C_4H_9$	5-nonanone	49	47	
(9j)	CH_3	C_6H_5	propiophenone	63	123	
(9k)	C_6H_5	CH_3	phenylacetone	67	145	
(9l)	$-o\text{-}C_6H_4-(CH_2)_2-$		α-tetralone	76	216	
(9m)	$n\text{-}C_8H_{17}$	CH_3	2-undecanone	50	58	
(9n)	$n\text{-}C_4H_9$	$n\text{-}C_5H_{11}$	6-undecanone	43	35	

Homogeneous reaction products are obtained from symmetrical dialkyl ketones or from ketones bearing no α-hydrogen on one side. Ketones exhibiting sufficiently different activation of the α-hydrogens, *e.g.* methyl alkyl ketones or methyl benzyl ketones, react regiospecifically.

Ketones offering only a methyl as point of attack by FSI, *e.g.* acetone or acetophenone, react only with difficulty and yield mainly side products. A more productive route was therefore sought for preparing the 6-methyl derivative *(9a)*.

[*] *N*-Fluorosulfonyl-α,α-dimethylacetoacetamide [15] can also readily be obtained in crystalline form from methyl isopropyl ketone and FSI but the absence of a proton necessary for enolization prohibits its cyclization to oxathiazinone dioxide.

2.3. β-Diketones

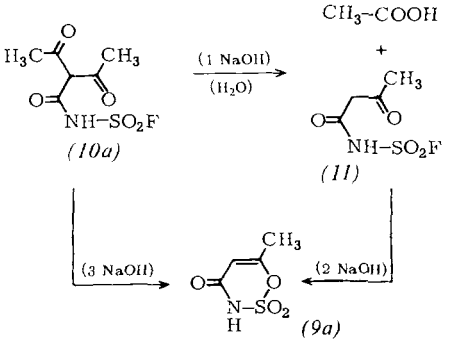
The activated methylene group of β-diketones is attacked particularly readily by FSI to give *N*-fluorosulfonyl diacylacetamides *(10)*[15].

$$R^1\text{–}CO\text{–}CH_2\text{–}CO\text{–}R^2 + O{=}C{=}N\text{–}SO_2F \xrightarrow[\text{FSI}]{}$$

(10)

These products are shown by their ^{1}H-NMR spectrum in solution to exist as the enols and to be strongly chelated ($\delta = 13.5$ and 16 ppm). The yields are very good, *e.g.* almost quantitative for acetylacetone. The *N*-fluorosulfonyldiacylacetamides *(10)* lose an acyl group on heating with ethanol or on stirring with 1 mol of aqueous alkali and thus furnish *N*-fluorosulfonyl β-oxo carboxamides [*(11)*, 75% yield] especially smoothly: the latter then cyclize to oxathiazinone dioxide with more alkali. There is no need to isolate the intermediate since addition of 3 mol of alkali effects both release of the acyl group and ring closure to give, *e.g.* 6-methyloxathiazinone dioxide *(9a)* in 80% yield.

Benzoylacetone and dibenzoylmethane react in a corresponding manner: mild deacylation readily yields the *N*-



fluorosulfonylbenzoylacetamide *(12)* whose ring closure affords 6-phenyloxathiazinone dioxide *(9h)*. A new variant

occurs if *N*-fluorosulfonyl-α-benzoylacetoacetamide *(10b)* is cyclized directly with 3 mol of sodium hydroxide solution. In this case only partial removal of the acetyl group occurs and the 5-acetyl-6-phenyl derivative *(9o)* results (Table 4).

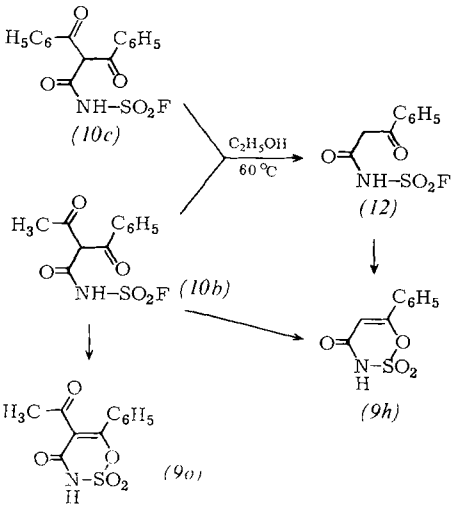


Table 4. Oxathiazinone dioxides from β-diketones.

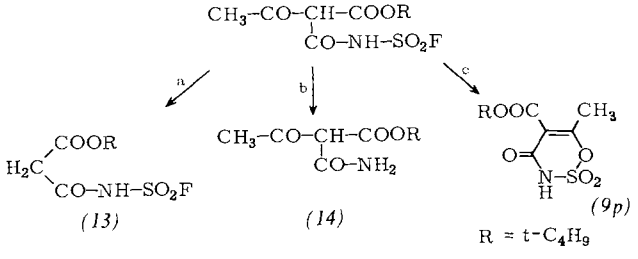
Cpd.	R^1	R^2	Starting material	M.p. [°C]
(9a)	H	CH_3	acetylacetone	123.5
(9h)	H	C_6H_5	benzoylacetone, dibenzoylmethane	181
(9o)	$CO-CH_3$	C_6H_5	benzoylacetone	164

2.4. β-Oxo Carboxylic Acid Derivatives

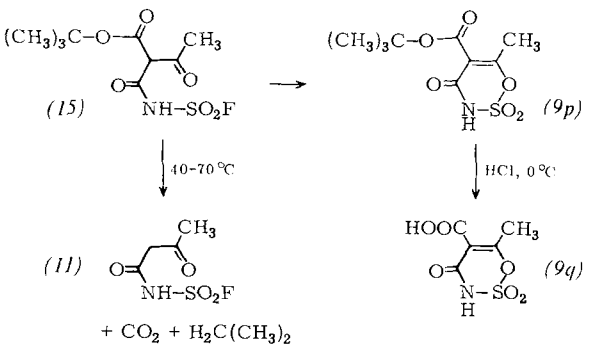
Free β-oxo carboxylic acids such as acetoacetic acid react with FSI with elimination of CO_2 to give *N*-fluorosulfonylamides *(11)*. Owing to the well-known lability of β-oxo acids this reaction has no practical importance.

The α-substitution products[15] of acetoacetic esters and FSI react in various ways on treatment with alkalis. Several parallel reactions occur and lead:

a) to malonic ester derivatives *(13)* by deacetylation;
b) to amides *(14)* by elimination of the SO_2F group;
c) to ring closure in the case of the *tert*-butyl ester.



tert-Butyl acetoacetate reacts with FSI to give a thermolabile α-substitution product *(15)*, m.p. 53 °C, 97% yield, from which a 37% yield of the oxathiazinone *(9p)* can be obtained by ring closure. Acid cleavage of the ester group with hydrogen chloride furnishes oxodihydrooxathiazine-5-carboxylic acid dioxide *(9q)*.



On standing at room temperature, or more rapidly on heating[16] to 40—70 °C, compound *(15)* eliminates CO_2 and isobutene to give *N*-fluorosulfonylacetoacetamide *(11)* in 85% yield.

Compound *(16)*, which is accessible from *N*,*N*-diethylacetoacetamide and FSI, also undergoes preferential closure of the oxathiazinone ring with alkali thus offering a preparative route to the amide *(9r)* in 54% yield (Table 5).

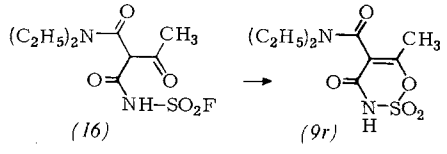


Table 5. Oxathiazinone dioxides from β-oxo acid derivatives.

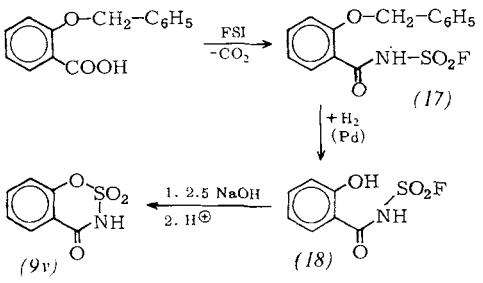
Cpd.	R^1	R^2	Starting material	Yield [%]	M.p. [°C]
(9a)	H	CH_3	acetoacetic acid	55	123.5
(9p)	$COOC(CH_3)_3$	CH_3	*tert*-butyl acetoacetate	37	66
(9q)	COOH	CH_3	*(9p)*	90	104
(9r)	$CON(C_2H_5)_2$	CH_3	*N*,*N*-diethyl-acetoacetamide	54	162

2.5. The Benzyl Ether Method[17]

In spite of the versatility of the synthetic routes discussed so far, none can provide oxathiazinone dioxides having particular combinations of substituents in positions 5 and 6. Such compounds include the benzo derivative *(9v)*, which is interesting as a homolog of saccharin, and the unsubstituted parent compound *(9s)* (Table 6). The *N*-fluorosulfonylsalicylamide *(18)*, m.p. 156.5 °C, required for synthesis of the benzoxathiazinone *(9v)* cannot be obtained directly from salicylic acid and FSI since the reactivity of the phenolic hydroxyl group proves dominant[18][*]. However, *(18)* is readily prepared in 88% yield from *O*-benzylsalicylic acid[19] by reaction with FSI to give *(17)*, m.p. 115 °C, and subsequent hydrogenation in acetic acid solution to remove the benzyl group. If hydrogenolysis is conducted in the presence of sodium hydroxide solution then the desired benz-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide *(9v)* is obtained (Table 6).

[*] Our own experiments with FSI led to *O*-(*N*-fluorosulfonylcarbamoyl)-salicylic acid having m.p. 111 °C.



If the protective group is hydrogenolyzed off in the alkaline medium then the amount of hydrogen taken up must be restricted to 1 mol since hydrogenolysis of the oxathiazinone ring will occur with more hydrogen.

The derivatives of *N*-fluorosulfonyl-β-hydroxyacrylamide *(20)* needed for preparation of 5-alkyloxathiazinone dioxides and the unsubstituted compound are produced by reaction of vinyl benzyl ethers with FSI in ether[20]. The reaction yields *N*-fluorosulfonyl-β-benzyloxyacrylamides *(19)* which suffer ring closure on catalytic hydrogenation in the presence of sodium hydroxide solution. The uptake of hydrogen must be limited to 1 mol here too (Table 6).

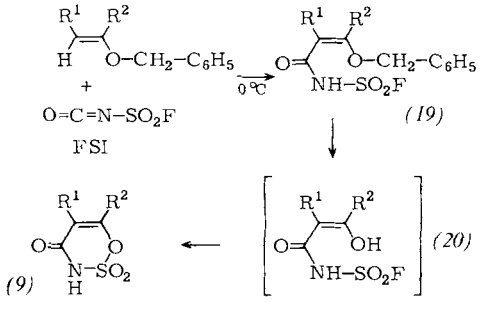


Table 6. Oxathiazinone dioxides prepared by the benzyl ether method.

Cpd.	R^1	R^2	*Starting material*	Yield [%]	M. p.	Sweetness
(9s)	H	H	benzyl vinyl ether [a]	39	107	+
(9t)	CH_3	H	benzyl propenyl ether [b]	22	81	+
(9u)	C_2H_5	H	benzyl butenyl ether [c]	25	73	+
(9v)	—(CH=CH)$_2$—		*O*-benzyl salicylic acid [19]	85	170	+

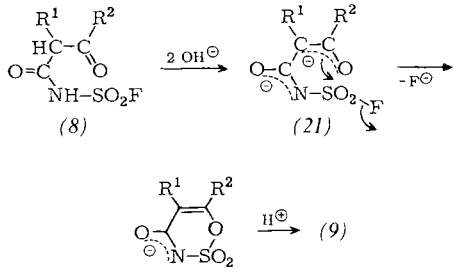
[a] Prepared by pressureless vinylation of benzyl alcohol at 130—150 C in the presence of potassium hydroxide. [b] Prepared by catalytic isomerization from allyl benzyl ether with potassium *tert*-butoxide in dimethyl sulfoxide at 25—40 C in 83% yield according to *C. C. Price* and *W. H. Snyder*, J. Amer. Chem. Soc. *83*, 1773 (1961). [c] Obtained from crotyl benzyl ether by catalytic isomerization with pentacarbonyliron and UV irradiation according to *P. W. Jolly*, *F. G. A. Stone*, and *K. Mackenzie*, J. Chem. Soc. *1965*, 6416.

2.6. *Ring Closure*

Cyclization of the intermediates prepared by the above methods is usually carried out in aqueous solution or suspension by slow addition of the necessary amount of caustic alkali, 2 mol being required for *N*-fluorosulfonyl β-oxo amides *(8)* and 3 mol for the tricarbonylmethane derivatives *(10)* accessible from β-dicarbonyl compounds if an acyl group has to be removed. As salts, the oxathiazinone dioxides are mostly readily soluble in water and are isolated from their solutions by acidification and extraction with organic solvents.

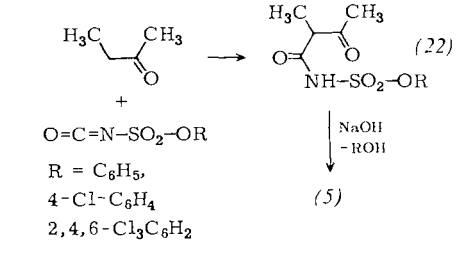
The ease of removal of the fluoride ion is surprising in view of the strength of the S—F bond. We assume that ring closure proceeds *via* nucleophilic attack by the ketonic oxygen on the fluorosulfonyl group in the dianion *(21)*.

An apparently obvious step would be to carry out the cyclization reactions with the analogous chlorosulfonyl derivatives from which the chloride ion is much more easily removed. Such attempts fail because the chlorosulfonyl group is rapidly hydrolyzed under the conditions used for the fluorides.

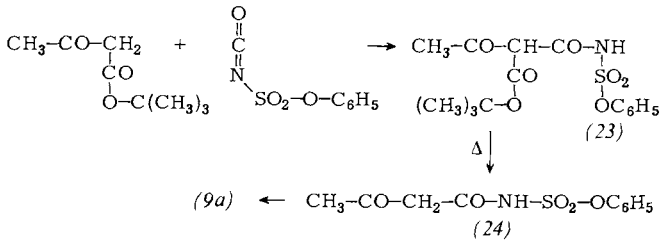


3. The Phenoxide Method[21]

A leaving group exhibiting sufficient resistance to hydrolysis and favoring cyclization is the phenoxide group. Ketones[15], β-diketones, and β-oxo carboxylic esters are attacked analogously by the aryloxysulfonyl isocyanates[22] and lead to *N*-aryloxysulfonyl β-oxo carboxamides, *e.g.* in the case of 2-butanone to the amides *(22)* and in that of *tert*-butyl acetoacetate to the tricarbonylmethane compound *(23)*, m.p. 92 C (dec.), 95% yield.



On warming, *(23)* readily loses CO_2 and isobutene to give *N*-phenoxysulfonylacetoacetamide *(24)*, m.p. 82 C, in 56% yield.

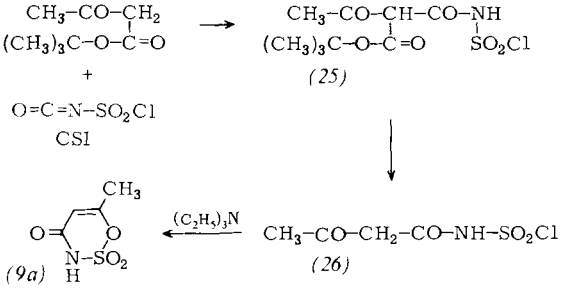


Treatment of *(22)* or *(24)* with caustic alkaline solutions removes the phenoxide ion to yield the oxathiazinone dioxides. The reaction conditions are strongly dependent upon the phenoxide group: whereas trichlorophenoxide departs easily like the fluoride ion, unsubstituted phenoxide requires considerably more stringent conditions.

4. The CSI Method[23]

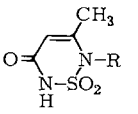
Removal of phenols or fluoride ions from the reaction products is difficult and, with regard to the use of oxathiazinone dioxides as sweeteners, gives rise to toxicological problems. It therefore appeared desirable to develop a synthesis starting from *N*-chlorosulfonyl β-oxo carboxamides. Such a route would also be attractive since all previous methods required fluorosulfonyl isocyanate which is difficultly accessible and exceptionally toxic.

Whereas ketones[15] do not react in just a single direction with chlorosulfonyl isocyanate (CSI), the more active β-dicarbonyl derivatives react very smoothly. For instance, *tert*-butyl acetoacetate in ether at 0—20 °C readily affords *tert*-butyl α-(*N*-chlorosulfonylcarbamoyl)acetoacetate *(25)*, m.p. 78 °C (dec.) in 91% yield[15]. On melting, this adduct liberates CO_2 and isobutene and furnishes *N*-chlorosulfonylacetoacetamide *(26)*, m.p. 86 °C, in 85% yield.



Unlike the fluoro- or phenoxy compound, *N*-chlorosulfonylacetoacetamide *(26)* rapidly reacts with water or alcohol at room temperature to give the sulfonic acid or its esters. In aprotic solvents such as ethyl acetate the oxathiazinone ring is readily closed with elimination of HCl on treatment with bases such as tertiary amines. This reaction is fast and gives good yields at −78 to 0 °C, possibly providing some indication of the intermediacy of the sulfonylamine (azasulfene)[24].

This cyclization is also possible with other amines. However, primary amines and ammonia also lead in part to formation of thiadiazinone dioxides *(27)*.



(27a), R = H [25], m.p. 174 C, yield 10%
(27b), R = CH_3, m.p. 162 C, yield 7%

Since the oxathiazinone dioxides are formed in a basic medium they are obtained as salts owing to the acidic nature of the —CO—NH—SO_2 group. Isolation of the acids is best performed by acidifying the aqueous salt solutions with mineral acids and extracting the oxathiazinone with ethyl acetate.

5. Properties and Reactions of Oxathiazinone Dioxides

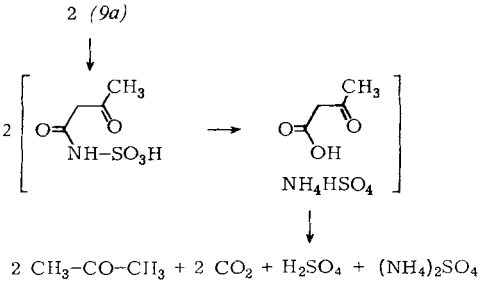
The oxathiazinone dioxides accessible by one of the above procedures are thermally and chemically stable crystalline substances that dissolve in the common organic solvents and, when only slightly substituted, also in water. As strong monobasic acids they are practically completely dissociated in water and form stable neutral salts having melting points above 200 °C with alkali metals and calcium (Table 7).

Table 7. Melting points and solubilities of some salts of 6-methyloxathiazinone dioxide *(9a)* in water.

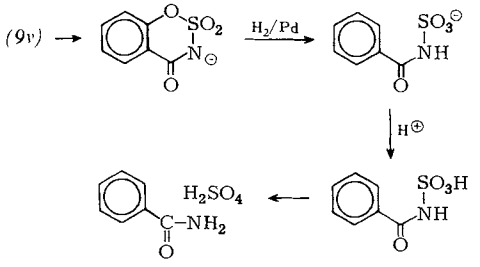
Cation		Na^+	K^+	Ca^{2+}	$[(C_2H_5)_3NH]^+$
M.p. [°C]		220	250	>310	68
Solubility [g/100 ml H_2O]	23 °C	340	25	120–130	830
	105 °C	580	135	180–190	∞

The steep temperature gradient of the solubility of the potassium salt in water makes it particularly suitable for purification of 6-methyloxathiazinone dioxide *(9a)*. 5,6-Dimethyl-*(5)* and the two ethylmethyloxathiazinone dioxides *(9b)* and *(9c)* exhibit such a high thermal stability that they can be distilled in a good vacuum or subjected to gas chromatography. The intense UV absorption at 228 nm ($\log \varepsilon \approx 4.0$) can be used to advantage for concentration determination.

The calcium salt of 6-methyloxathiazinone dioxide survives eight hours' heating at 120±2 °C of a 0.2% aqueous solution at pH 7 without measurable decomposition. The free 6-methyloxathiazinone dioxide *(9a)* decomposes when an aqueous solution is boiled to give 90% acetone alongside CO_2, ammonium sulfate, and sulfuric acid. These fragments suggest that cleavage proceeds *via* acetoacetic acid.

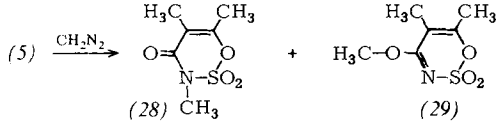


As already mentioned in Section 2.6, benzoxathiazinone dioxide *(9v)* undergoes ring cleavage in alkaline media on attack by catalytically activated (palladium) hydrogen (1 mol). The *N*-sulfonic acid can be precipitated in crystalline form and fragmented to benzamide and sulfuric acid by brief boiling in acid solution.

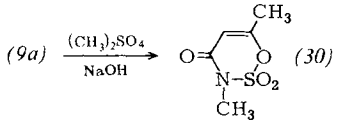


5,6-Dimethyl- and 6-methyloxathiazinone dioxide undergo a corresponding reaction with 2 mol of hydrogen. However, the *N*-sulfonic acids could not be detected in these cases: after hydrolytic release of the SO_3H group[126], ^1H-NMR spectra revealed mixtures of the amides with the free carboxylic acids.

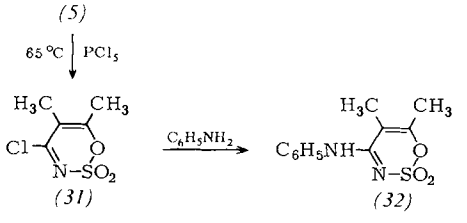
The strongly acidic proton of the oxathiazinone dioxides can be smoothly methylated by ethereal diazomethane, the product mixture containing *N*-methyl compounds with minor amounts of the *O*-methyl representative, as in the case of 5,6-dimethyloxathiazinone dioxide *(5)* [*(28)*, b.p. 66 C/0.01 torr, 68% yield; *(29)*, b.p. 110 °C/0.01 torr, m.p. 63 C, 16% yield].



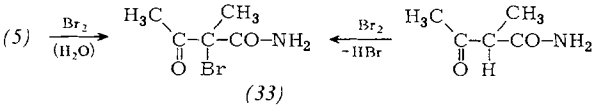
Methylation can also be accomplished by the action of dimethyl sulfate on the alkali metal salts of oxathiazinone dioxide, *e.g.* with the 6-methyl derivative *(9a)*. Reaction furnishes *(30)*, b.p. 85 °C/1 torr, m.p. 40 °C, in 40% yield.



A chlorine atom can be introduced at C-4 by phosphorus pentachloride in carbon tetrachloride solution. The resulting oxathiazine dioxide *(31)*, b.p. 98 °C/10^{-3} torr, 80% yield, is capable of further exchange reactions. For example, aniline gives the derivative *(32)*, m.p. 221 °C, in 48% yield.



In aqueous solution, bromine cleaves the oxathiazine ring of the dimethyl compound *(5)* to form α-bromo-α-methylacetoacetamide *(33)*, m.p. 68 °C, 53% yield. The same compound also results on bromination of α-methylacetoacetamide.



(33)

6. Relative Sweetness and Structure of Oxathiazinone Dioxides

Unsubstituted oxathiazinone dioxide *(9s)* and a number of slightly substituted derivatives exhibit varying degrees of sweetness. Since they also have an acidity comparable with that of mineral acids, taste comparisons are feasible only with the neutral alkali or alkaline earth metal salts. Table 8 lists those of the derivatives we have prepared which have a sweet taste, together with their relative sweetnesses. The parent compound proves to be the least sweet, and the 5-ethyl-6-methyl derivative the most sweet. Exchange of the two alkyl groups or shortening of the ethyl chain lowers the sweetness to half its original value.

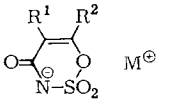


Table 8. Relative sweetness and LD_{50} of salts of oxathiazinone dioxides.

R^1	R^2	M	Relative sweetness [a]	LD_{50} [g/kg rat]
H	H	Na	10	
H	CH_3	Na	130	10.4
H	CH_3	K	130	7.4
H	CH_3	Ca	130	6.5
CH_3	H	Na	20	
CH_3	CH_3	Na	130	8.7
H	C_2H_5	Na	150	
C_2H_5	H	Na	20	
CH_3	C_2H_5	Na	130	
C_2H_5	CH_3	Na	250	9.9
H	n-C_4H_9	Na	30	
n-C_3H_7	CH_3	Na	30	
i-C_3H_7	CH_3	Na	50	
CH=CH—CH=CH		Na	*ca.* 50	
C_2H_5	n-C_3H_7	Na	70	

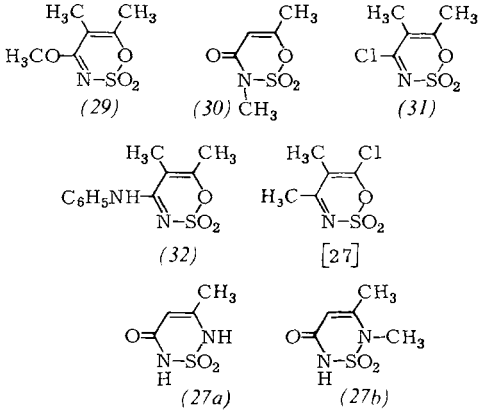
[a] Relative to cane sugar in 4% aqueous solution.

Our attention has become focused mainly on the 6-methyl derivative *(9a)* whose potassium or calcium salt is about four times sweeter than cyclamate and stands out from the others in the purity of its sweet taste. Tests with various preparations and juices show the taste of these salts to fit in particularly well for use as a sweetening agent. Their high solubility in water (see Table 7) also offers advantages in use since most synthetic sweeteners display an unsatisfactory solubility.

The salts of *(9a)* also prove sufficiently stable to hydrolysis for practical purposes. Even in highly acidic beverages

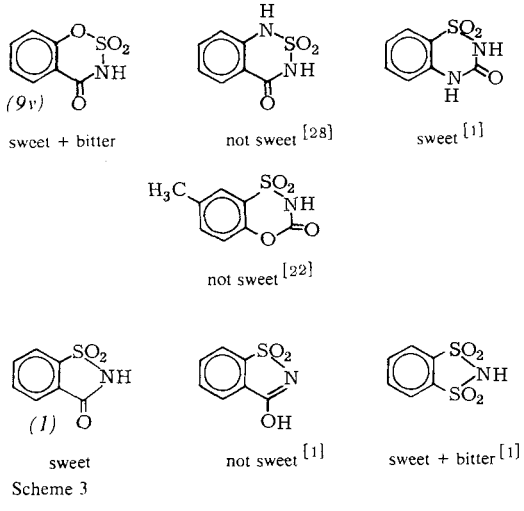
they remain unchanged for months and no deterioration in their purity of taste can be registered.

The acute toxicity was determined in various cases and is likewise given in Table 8. The substances tested can thus be regarded as practically nontoxic. Meanwhile, a 95-day feeding test on rats has been carried out with the calcium salt of the 6-methyl compound *(9a)*, with up to 5% of *(9a)* in the feed. No evidence was found that ingestion of compound *(9a)* had an influence on the increase in body weight, food consumption, blood count, serum enzyme values, urinalysis, the findings of macroscopic post mortem examinations, and organ weights. No deviations from control animals could be detected during animal growth or on histological examination of their organs. As already mentioned, these animal experiments represent only partial results and any toxicological assessment of the salts of *(9a)* with regard to their suitability as sweeteners will have to await their completion.



Scheme 2

The question of their metabolism will also have to be elucidated. If a hydrolytic route is followed, *i. e.* metabolism commences with ring cleavage to give acetoacetamide-*N*-sulfonic acid, further degradation should yield physiological substances. This is yet another reason why we prefer



Scheme 3

the salts of 6-methyloxathiazinone dioxides; they are derivatives of acetoacetic acid.

As found with other sweeteners[1, 7], any functional change of the system leads to complete loss of the sweet taste. Scheme 2 shows some derivatives completely devoid of any sweet taste.

Scheme 3 shows a number of benzo heterocyclic compounds some of which are sweet while others have no sweet taste. It accordingly still appears difficult to predict the property of sweetness for a given compound.

Application of Hansch analysis[29] to the problems of sweetening action may possibly provide a further insight into the underlying principles.

We are grateful to Dr. H. Bestian for his active interest and numerous valuable discussions.

Methylchlorophosphanes and Their Reaction Products

By Horst Staendeke and Hanss-Jerg Kleiner[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Methyldichlorophosphane and dimethylchlorophosphane can be prepared only with considerable difficulty. The ease with which they yield numerous reaction products is an indication of the pronounced reactivity of these organohalophosphanes. Possible applications of such organophosphorus compounds exist *inter alia* in the fields of plant protection, corrosion prevention, and flame retardants, as well as in the catalysis of gas phase reactions, for instance the desulfurization of gas mixtures.

1. Introduction

The large number of publications in the area of organophosphorus chemistry provides a measure for the interest commanded by this class of compounds. This applies both to the synthesis of new compounds and to the introduction of phosphorus-containing functionalities into other molecules in order to modify their chemical or physical properties.

As an example, the hydrolysis-resistant linkage of the dimethylphosphane oxide group, $(CH_3)_2P(O)$—, to organic compounds gives rise to a variety of widely differing effects, such as improved solubility, enhanced surface activity, and antistatic action.

The reduction in flammability of combustible compounds that can be achieved by incorporation of such groups has recently become of particular significance. Owing to the high phosphorus content in the small molecular group, an adequate retarding effect is provided by incorporation of relatively small amounts of the phosphorus component. So slight are the resultant changes in the skeleton of polymeric compounds that their other physical and technological properties are largely retained.

Because of their relatively poor accessibility and their special properties the present article will concentrate on the methyl compounds. (Surveys of organophosphorus compounds will be found in refs.[1, 2].)

The methylchlorophosphanes are colorless liquids that can be distilled without decomposition (CH_3PCl_2: b. p. 82 °C[3], m. p. −80 °C[17], $d_{20} = 1.30$[3], $n_D^{20} = 1.4940$[3]; $(CH_3)_2PCl$: b. p. 79 °C[3], m. p. −2 °C[17], $d_{20} = 1.07$[3], $n_D^{20} = 1.4760$[3]) and are readily soluble in inert organic solvents; their pronounced sensitivity to moisture and air [$(CH_3)_2PCl$ undergoes spontaneous combustion on admission of air] requires special apparatus for all operations.

2. Synthesis of Methyldichlorophosphane[1]

Preparations starting from methanephosphonous acid, $CH_3P(O)(H)OH$, and derivatives, from methylphosphane, from tetramethylcyclotetraphosphane, and from organometallic compounds are of little interest because the starting materials themselves are not readily available.

2.1. Synthesis from Methyltrichlorophosphonium Tetrachloroaluminate[1]

In contrast, methyldichlorophosphane is readily obtained by reduction (*e.g.* with aluminum) of the complex *(1)* formed in the Kinnear-Perren reaction

$$PCl_3 + AlCl_3 + CH_3Cl \rightarrow [CH_3PCl_3]^{\oplus}[AlCl_4]^{\ominus}$$
(1)

and subsequent addition of an equimolar quantity of alkali metal chloride.

Partial hydrolysis of the complex *(1)* or reaction with sulfur yields phosphonic dichloride, $CH_3P(O)Cl_2$, or thiophosphonic dichloride, $CH_3P(S)Cl_2$, as intermediate which may be converted into methyldichlorophosphane on treatment with reducing agents (yields *ca.* 50%) or desulfurating agents (yields up to 92%) respectively.

2.2. Synthesis by Gas Phase Reactions

2.2.1. Reaction of Phosphorus Halides with Methane[1]

The reaction of phosphorus(III) chloride and methane at around 600 °C leads to about 20% conversion into methyldichlorophosphane with residence times as low as 0.3 s. Apart from oxygen and chlorine, suitable catalysts include carbon tetrahalides[4] and phosgene[5].

Methyldichlorophosphane was produced for several years by this method in the USA.

2.2.2. Reaction of Red Phosphorus with Methyl Halides[1]

Above 200 °C red phosphorus reacts with methyl chloride to give methylchlorophosphanes. Optimum conditions for the copper-catalyzed reaction exist when the catalyst mass consists of red phosphorus and copper powder and the temperature is kept at 350—360 °C. The major product is methyldichlorophosphane; the yield (based on reacted methyl chloride) is around 25%.

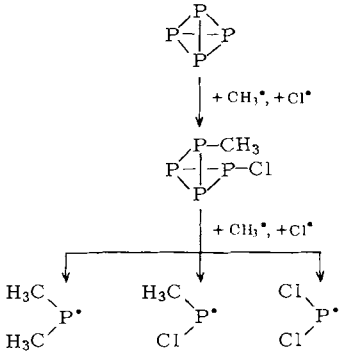
[*] Dr. H. Staendeke
Knapsack AG
5033 Knapsack (Germany)
Dr. H.-J. Kleiner
Farbwerke Hoechst AG
6230 Frankfurt (Main) 80 (Germany)

The high price of red phosphorus and the complicated preparation of the catalyst/phosphorus mixture would oppose attempts to run this reaction on an industrial scale.

If a mixture of phosphorus vapor and methyl chloride is passed over activated charcoal[6,7] at 350 °C, the main reaction products are methyldichlorophosphane and dimethylchlorophosphane. The yield amounts to 70% (again based on reacted methyl chloride).

2.2.3. Reaction Course

The gas phase alkylation reactions probably proceed *via* a radical mechanism[8] whose first step is assumed to consist in homolysis of the alkyl halide (Scheme 1). In accord with this assumption, the complete range of conceivable phosphorus compounds—$(CH_3)_3P$, $(CH_3)_2PCl$, CH_3PCl_2, and PCl_3—could be detected. Further evidence for a radical mechanism comes from the appearance of numerous by-products containing no phosphorus which could be formed by recombination reactions (Scheme 2).



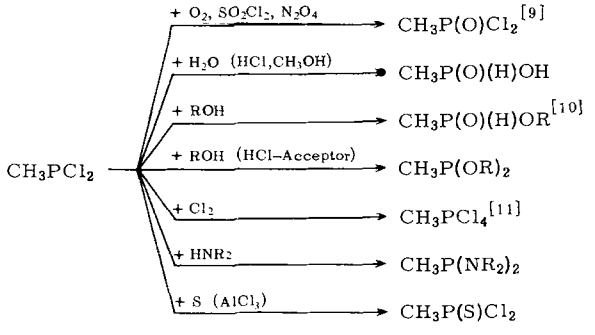
Scheme 1. Gas phase reaction of red phosphorus with methyl chloride.

$$CH_3^{\bullet} + CH_3Cl \rightarrow CH_4 + CH_2Cl^{\bullet}$$
$$2\ CH_3^{\bullet} \rightarrow C_2H_6$$
$$CH_3^{\bullet} \rightarrow CH_2{:} + H^{\bullet}$$
$$2\ CH_2{:} \rightarrow C_2H_4$$
$$2\ H^{\bullet} \rightarrow H_2$$

Scheme 2. By-products devoid of phosphorus formed in the gas phase reaction of red phosphorus with methyl chloride.

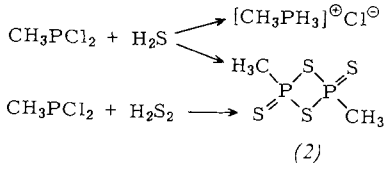
3. Reactions of Methyldichlorophosphane

Owing to the pronounced reactivity of methyldichlorophosphane, many of its products are accessible by simple reactions (Scheme 3).



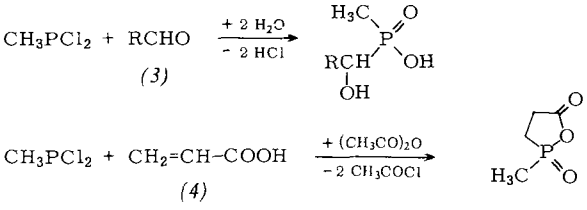
Scheme 3. Reactions of methyldichlorophosphane.

In the reaction with sulfur-hydrogen compounds, hydrogen sulfide[12] also acts as a reducing agent whereas with disulfane[13] the only reaction occurring is sulfuration to give *(2)*.

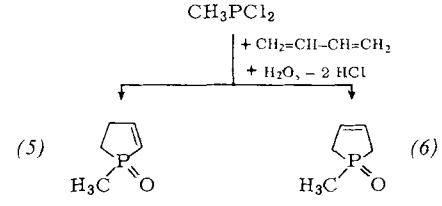


(2)

A new phosphorus-carbon bond can result from a large number of reactions[14]. Particular importance attaches to reactions with compounds of type *(3)* and *(4)* bearing C=O and C=C functions respectively.



A route to tertiary cyclic phosphane oxides such as *(5)* and *(6)* is provided by condensation reactions with dienes[15] (Diels-Alder reaction).



4. Synthesis of Dimethylchlorophosphane[1]

The preparation of compounds with the $(CH_3)_2P$ group proves considerably more difficult than that of CH_3P derivatives. Processes such as the reaction of dimethylphosphinous amides, $(CH_3)_2PNR_2$, with hydrogen chloride or of dimethylphosphane or tetramethyldiphosphane with chlorine therefore remain of no significance.

4.1. Synthesis from Dimethyldichlorophosphonium Tetrachloroaluminate[1]

If methyldichlorophosphane is available as starting compound, it can be subjected to a Kinnear-Perren type reaction:

$$CH_3PCl_2 + AlCl_3 + CH_3Cl \rightarrow [(CH_3)_2PCl_2]^{\oplus}[AlCl_4]^{\ominus}$$

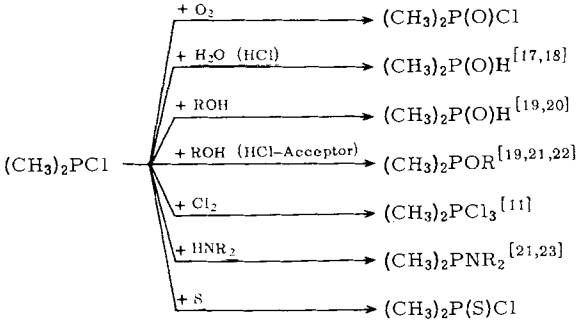
Reductive work-up of the complex yields dimethylchlorophosphane. As in the case of the monomethyl compound, this complex also furnishes the thiophosphinic chloride $(CH_3)_2P(S)Cl$, whose desulfuration (preferably with trialkylphosphanes) affords good yields of dimethylchlorophosphane.

4.2. Synthesis by Gas Phase Reactions

The low thermal stability of the dimethyl compound precludes its preparation by both the high-temperature reaction of phosphorus(III) chloride with methane and the copper-catalyzed reaction of red phosphorus with methyl chloride. However, the reaction of phosphorus vapor with methyl chloride in an active charcoal zone[6] at 350 °C yields a mixture of methylchlorophosphanes containing at least 30 % of dimethylchlorophosphane[7]. The two components can be isolated by phase separation[16] since, after conversion into the hydrogen chloride adduct, dimethylchlorophosphane is no longer miscible with methyldichlorophosphane.

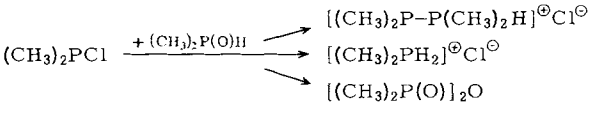
5. Reactions of Dimethylchlorophosphane

Dimethylchlorophosphane also readily undergoes a variety of reactions (Scheme 4).



Scheme 4. Reactions of dimethylchlorophosphane.

The reaction of dimethylchlorophosphane with its hydrolysis product dimethylphosphane oxide[24] appears highly complicated (Scheme 5).

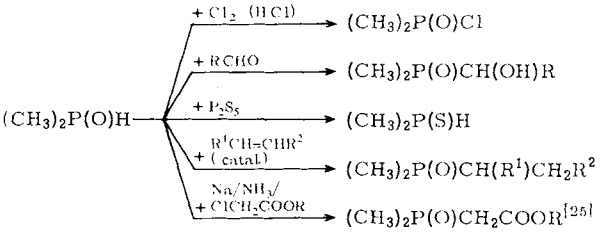


Scheme 5. Reactions of dimethylchlorophosphane with dimethylphosphane oxide.

The transition from dimethylchlorophosphane to the tertiary phosphanes and phosphane oxides can be accomplished in a variety of ways, *e. g.* by reaction with unsaturated compounds or carbonyl compounds in which a new P—C bond is formed.

5.1. Reactions of Dimethylphosphane Oxides

A number of reaction products of dimethylchlorophosphane can be advantageously prepared from dimethylphosphane oxide[21]; the latter compound is stable to air and only moderately hygroscopic (m.p. 39—41 °C; b.p. 54 °C/1 torr) (Scheme 6).

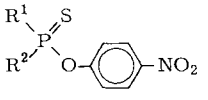


Scheme 6. Reactions of dimethylphosphane oxide.

6. Applications

6.1. Plant Protection

Numerous biologically active derivatives of phosphonic and phosphinic acids have been synthesized in connection with the development of biocidal phosphoric esters. The difficulties encountered in the preparation of the starting materials, however, make such products expensive and thus oppose their widespread use. In addition, a general observation regarding toxicity to warm-blooded animals and insecticidal activity must be taken into account, which will be illustrated here for the transition from phosphoric esters such as methylparathion *(7)* to the corresponding phosphonic *(8)* and phosphinic acid derivatives *(9)* (Table 1)[26].



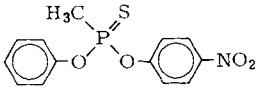
(7) – *(9)*

Table 1. Toxicity (rat) and insecticidal activity (aphid) of methylparathion *(7)* and the corresponding phosphonic *(8)* and phosphinic acid derivatives *(9)*.

Cpd.	R^1	R^2	Toxicity LD_{50} [mg/kg]	Insecticidal activity Conc. [%]	Mortality [%]
(7)	CH_3O	CH_3O	20	0.0001	100
(8)	CH_3O	CH_3	1	0.001	100
(9)	CH_3	CH_3	100	0.1	100

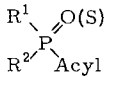
Oxidative and hydrolytic degradation of phosphonic and phosphinic esters, like that of the phosphoric acid derivatives, leads to harmless compounds, the acids.

The only insecticide we know to possess a methyl-phosphorus functionality, Colep® *(10)*[27], is remarkable because



(10)

it does not fit into the formula scheme *(11)* of the Schrader rule[26] for biologically active phosphorus compounds. In Colep an alkoxyl group is replaced by phenoxyl.



(11), R^1, R^2 = Alkyl, Alkoxy, Amino

6.2. Dyeing

On dyeing of synthetic fibers or mixed textiles in aqueous dye baths, addition of organophosphorus compounds[28], *e. g.* dimethyl methanephosphonate, improves the uniformity and depth of dyeing.

The use of carriers which "open up" the fiber and thus promote better penetration of the dye can impair the light-fastness of the dye if residues of certain carrier types remain in the fiber. However, addition of phosphane oxides[29], *e.g.* octyldimethylphosphane oxide, to the dye bath, the after-treatment bath, or the carrier preparation almost completely eliminates loss of light-fastness.

When the purification of the waste water from aqueous dye liquors proves particularly difficult an obvious solution is to carry out the process in organic solvents (in the presence of small amounts of water). Work-up of the spent dye liquor reduces to distillation of the water/solvent mixture. However, numerous commercial dyes are insufficiently soluble in organic solvents. A considerable improvement results on use of organophosphorus compounds[30], *e.g.* decyldimethylphosphane oxide:

1) the ambivalent character of the phosphane oxide (hydrophilic methyl group, lyophilic decyl group) effects ready emulsifiability of the water in the solvent;

2) the pronounced solubilization property considerably increases the dye concentration in the organic dye liquor and thereby permits uniform and deep dyeing with a much broader range of dyestuffs.

6.3. Corrosion Prevention

An important requirement for lasting protection against corrosion lies in adequate adhesion of the coating to the metal surface. Treatment of the metal with a compound with which it reacts and yet which possesses sufficient "affinity" for the protective coating should consequently have a particularly favorable effect.

The compound dimethyl-2-oxopropylphosphane oxide, $(CH_3)_2P(O)CH_2COCH_3$, represents a suitable chemisorption agent for treatment of steel, aluminum, copper, and titanium surfaces[31]. A chemisorption layer is presumably formed with the surface oxide coating, with participation of the C=O and P=O groups, whose predominantly lyophilic character ensures good binding with the protective paint.

6.4. Catalysis

The reaction

$$2H_2S + SO_2 \rightarrow 3S + 2H_2O$$

represents a possible method for removal of sulfur compounds from gaseous mixtures. If the reaction is carried out in polar aprotic solvents in the presence of phosphane oxides[32], *e.g.* trimethylphosphane oxide, the sulfur content can be lowered almost to the detection limit and crystalline sulfur obtained simultaneously in a purity exceeding 99.8%. This gas purification reaction has a broad scope: the content of hydrogen sulfide can vary between 0.0001 vol-% and more than 5 vol-%.

6.5. Formulation of Detergents

The development of new detergents must take account of the following properties: stability towards water-hardeners, powerful washing action, high dissolving power for calcium soaps, biodegradability, and resistance to hydrolysis. A group of trialkylphosphane oxides[33] in which one alkyl group contains 10—18 C atoms and the other two not more than 3 C atoms fulfills these and further stipulations:

thermal stability (important for spray drying of granular detergents)

low hygroscopicity (to avoid caking of granular detergents)

bacteriostatic activity (important for use as cold detergents).

These favorable properties suggest applications in detergents, soaps, liquid cleansers, and scouring agents[33].

6.6. Flameproofing[34, 35]

Increasing attention has recently been paid to the reduction of flammability of flammable materials for a number of applications (*e.g.* internal fittings in aircraft and automobiles, building units, textiles for hospitals). Corresponding legislation has already been introduced, particularly in the USA. These stipulations are being met by manufacturers in the development of flame resistant products. The varying combustion characteristics of plastics and textiles require development of specific flameproofing agents.

The elements chlorine, bromine, nitrogen, phosphorus, and antimony in the form of suitable compounds, which are present as additives or chemically bound to the materials concerned, have proved to be effective for this purpose. Numerous concepts exist concerning the mode of action of the flameproofing agents but we shall not go into details here. Experience has shown phosphorus to be the most effective agent. Between 1 and 6% of phosphorus must be incorporated, depending upon the chemical formulation of the material, to provide a flame-resistant product; *e.g.* cellulose becomes self-extinguishing at a 2.5—4% P content, and nonflammable at 7—8%. It was observed that the effectiveness as flameproofing agent (based on the phosphorus content) decreases along the series phosphane oxide > phosphinic acid > phosphonic acid > phosphoric acid.

An additional advantage of using phosphane oxides and derivatives of phosphinic and phosphonic acids, apart from the resistance to hydrolysis, lies in the fact that the molecular group introduced becomes firmly bound to the polymer and its chemical structure can be modified. This permits "reactive" incorporation into the matrix of polymers which has only a slight influence on the other physical and technological properties of the host material even after prolonged usage. The flameproofing treatment of cellulosic fibers will be mentioned as an example.

Ignition of cotton is preceded by depolymerization (above 180 °C) and pyrolysis to give combustible cleavage products whose concentration at 350 °C becomes so great that a flammable mixture is present. The mechanism of the pyrolytic processes is modified by the flameproofing agents in that they

1) lower the pyrolysis temperature,

2) increase the amounts of non-combustible gaseous cleav-

age products (CO_2, H_2O) because they exhibit, *inter alia*, a dehydrating action[*],

3) increase the pyrolysis residue from 10 to about 50% so that only 30—40% of flammable products are formed instead of 80%.

Dimethylphosphinic chloride[36] or methanephosphonic anhydride[37] have been proposed as flameproofing agents that are linked to the hydroxyl groups of cellulose. Greater importance attaches to the processes in which an initial impregnation of the textile with the flameproofing agent is followed by a condensation reaction with a second component with the aim of fixing the substrate to the fiber[34, 38].

The flameproofing agents THPC $[(HOCH_2)_4P^+Cl^-]$ and Pyrovatex® $[(CH_3O)_2P(O)CH_2CH_2CONHCH_2OH]$ used in this process are of particular significance. The flameproofing achieved by this process is washproof and hardly impairs the properties of the fiber (feel, tear strength, wear resistance, crease recovery).

Possibilities and Limitations of Delegated Literature Searches by Computer

By Robert Fugmann and Gottfried Ploss[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

The present-day chemist is constantly on the lookout for information which may be useful to his work. If he is able to define his interests precisely enough then he can avail himself of information scientists and of specialized literature stores. However, retaining access to such information, which only he himself can subjectively judge for relevance to his work, and which most often constitutes a powerful incentive to his creative thinking, will always require his own "browsing" literature studies or personal contacts. These are the limitations of any delegated literature search.

As a result of the steadily growing flood of publications in the natural sciences, it is no longer possible for the individual scientist himself to keep a constant watch for new publications in his field. This is due simply to lack of time; moreover, he also lacks the special knowledge required to efficiently search through large mechanized files. He must therefore pass on his literature requirements to institutions whose function it is to satisfy the information needs of others. Institutions of this kind have sprung up throughout the world for a wide range of specialist fields as a result of the recognition that it is only through their aid that optimum use can be made of the vast quantity of information that exists. Two examples of institutions that carry out delegated literature searches of this nature on a large scale in the field of chemistry are the "IDC Internationale Dokumentationsgesellschaft für Chemie mbH" in Frankfurt/Main, which undertakes retrospective and current awareness searches in its files of (at present) some 1/2 million publications, and "Chemie Information und Dokumentation Berlin", a division of the Gesellschaft Deutscher Chemiker, which searches the latest additions to the "Chemical Abstracts Condensates" magnetic types.

These large stores offer the chemist new possibilities for keeping abreast of the latest developments if he uses them properly, *i.e.* if the limitations of any delegated search are borne in mind in the formulation of the search and in the evaluation of the results. What then are the limitations of delegated searches?

When the chemist himself searches the specialist literature for publications that are relevant to his work, he allows himself to be guided largely by intuition and by his personal interests at that particular time. He may start the search with an example of a type of reaction in which he is interested, and continuously modify the objective of the search according to the nature of the publications found, their number, *etc.* The most valuable results of literature searches carried out personally are often far removed from the formulation of the problem with which the search was started. The searcher feels himself under no obligation to define his problem at any stage in his literature search.

[*] Dr. R. Fugmann and Dr. G. Ploss
Farbwerke Hoechst AG
Abteilung für Wissenschaftliche Dokumentation, F 821
623 Frankfurt am Main 80, Postfach 80020 (Germany)

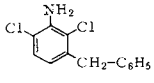
If he delegates his search, on the other hand, the continuous subjective reorientation of the search according to the publications found is no longer possible. He must now define his objective to the searcher by specifying in advance the characteristics that a publication must possess in order to be relevant to his work. In reply, therefore, he can expect to receive only publications that possess *at least the conceptual features that he himself stipulated in his phrasing of the inquiry*. This means, however, that in a delegated literature search he no longer receives suggestions from sources whose features differ from those specified, and which would have led so profitably to the continuous modification of his search objective.

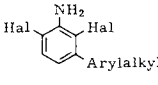
If answers that did not possess all the features required in advance, *i.e.* that were *more general* than the formulation of the problem, were permitted in a delegated literature search, it would no longer be possible to avoid large numbers of references to very general publications or patent claims. An inquiry for "dimethylbenzenes", for example, would then also include "alkylaromatic hydrocarbons" or "hydrocarbons" as answers.

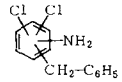
To illustrate this situation, which is unfamiliar to the chemist, Table 1 shows which general answers (right-hand column) are not to be expected to a specific inquiry of the type shown in the left-hand column.

The structures shown in the right-hand column cannot be retrieved because they do not satisfy all the requirements

Table 1. Problems of search objective definition for substances.

Inquiry	Answers that cannot be retrieved with this inquiry
	  "Alkyl derivatives of aromatic hydrocarbons"
	 






of the inquiry. If structures of these types are also desired as answers, therefore, the search must be given a more general formulation. For example, the relative positions of the substituents must not be specified, or the alkyl substituent must not be restricted to methyl. Such a generalized inquiry will also lead to retrieval of all the more specific structures.

If certain starting materials are called for in addition to the desired reaction product, this must also number among the conceptual requirements of a search. Publications in which no starting materials or different starting materials are mentioned will not then be retrieved as answers. Even if the publication mentions starting materials from which the starting material required in the search might readily have been formed as an intermediate during the reaction, the publication is not retrieved. The same is true of any intermediates that are specified in the search. Here again, no answer is obtained if the author has not indicated an intermediate or has postulated an intermediate different from that required in the search formulation.

Table 2. The problem of search objective definition for reactions.

Inquiry	Answers that cannot be retrieved with this inquiry
 (1) (2)	 (1) → (2); (1) → (2); (1) → Ring closure and reduction → (2); → (2)
 (3) (4)	In publication A:  (3) + 2 CH_2O → (5); and (3) + $CH_2{=}CH_2$ →  (6); In publication B: (5) → (4) + CH_2O + H_2O; and (6) → (4) + CH_4

If in a mechanized literature search a certain starting material and a particular reaction product are required (no matter how many reaction steps are involved) then obviously only such documents can be expected as responses in which both compounds had actually been described. This requirement is met neither in the case of the publication A nor in that of B in Table 2. However, if one searches the store with two separate inquiries, for the starting material and for the desired reaction product respectively, then the publications A and B will be retrieved with certainty. Human reasoning can then easily recognize the relation between both publications in the sense of the original inquiry.

Particular caution in phrasing the inquiry is necessary if an abstract has been used instead of the original publication in the compilation of the store. To save space, the abstractor must often incorporate the details of the original into the abstract in a generalized form; instead of "ethyl or propyl or butyl", for example, he may simply use "alkyl". It is merely for these reasons that an inquiry may have to be formulated in a suitably generalized form.

All the above examples show that in a delegated machine search, if important suggestions from sources whose peculiarity cannot be foreseen are not to be completely missed, a more general formulation of the search is always necessary than in cases where the search is being carried out by the inquirer himself. If these precautions are observed, the danger of loss of information is largely eliminated.

However, the generalization of a search may lead to the other disadvantage that the searcher is occasionally also provided with references that he regards as "ballast" from the standpoint of his present subjective interest. Perhaps he is already sufficiently familiar with these publications, or the yield and purity of the products described in them are unsatisfactory, *etc.* Since the inquirer can never exhaustively define his interests, however, he cannot expect them to be taken fully into account by another person to whom the literature search has been delegated. The only way in which all such "ballast" could be definitely avoided would be to avoid any generalization, and this would necessarily result in a serious loss of relevant information, as was shown above.

The recommendation that a search should be reasonably generalized is thus merely intended to avoid the danger of loss of unforseeably valuable information in the delegated literature search. If this danger does not arise in a given instance, or if it is consciously accepted by the inquirer, there is no obstacle to a highly specific inquiry in high-performance documentation systems.

In phrasing the inquiry, the inquirer must decide what degree of generalization is permissible for him without including too much and too irrelevant material. This will depend on whether the search is intended to be used as a check on the patent situation, as a search for novelty, or for synthetic work. On the other hand, only the information scientist knows the depth of detail with which the literature has been analyzed, and what details in an inquiry would therefore constitute unsatisfiable search conditions. Since considerable cost is involved in the deep analysis of specialist literature for machine searches and in continuously keeping this literature available for searches in a store, only the specialist literature for a limited selection of fields can always be included. Even here however, to reduce costs, pure textbook knowledge such as is often provided in publications alongside new knowledge (preparation of starting materials, degradation reactions for structural elucidation, *etc.*) cannot normally be included. In the case of patents, the description of the state of the art must usually be excluded. Information of this nature cannot therefore be expected from the store.

It must also be made clear whether a given formulation of an inquiry is intended simply as an example of a much

wider problem or whether it is intended as the problem itself. If we have to deal with only one example, more or less arbitrarily selected from a multitude of equivalent ones, then the inquiry must be generalized appropriately. However, the information scientist occasionally has to recommend greater specificity in the formulation of a search. For, on the basis of the composition and size of the store, he can often forsee that a given formulation would produce too many answers. An excessively comprehensive search result indirectly leads once more to loss of information, since it can be followed up only in part by the inquirer, who will then content himself with, say publications that appeared during the last year or in certain journals or patent classes.

The cooperation of the scientist with an institution to which he can delegate searches always calls for a certain refinement of his thinking in literature searches. His phrasing of an inquiry often forces him to realize how subjective and ill-defined many of his literature problems are, a realization that is not really surprising when one considers what a large part intuition and imagination play in research work. On the one hand, he is presented with new and promising search possibilities through the perfected search techniques of such institutions, which are run by information specialists. On the other hand, he cannot expect such institutions to solve all his information problems. Many stimuli for his work arise simply from his immersion in the specialist literature, and apart from contact with other workers, this is the only way for him to keep abreast of fundamental innovations in science in general and in his field in particular. Even in an age of very large stores that can be searched with a high degree of efficiency, therefore, there will still be a place for the continuous publication of specialist literature and the scientist's own literature studies.

Chemical Applications of Raman Spectroscopy[**]

By Bernhard Schrader[*]

Raman spectroscopy is—like infrared spectroscopy—a method for the study of the vibrations of molecules and crystals. The two methods are complementary: if a vibration results in a change of the polarizability of a molecule, it is Raman active; if a change in the molecular dipole moment results, it is infrared active. Vibrations of nonpolar groups and totally symmetrical vibrations of molecules are often only Raman active. IR and Raman spectra together give information about the symmetries and structures of molecules and crystals and about the properties of chemical bonds and intermolecular interactions. Until about 10 years ago Raman spectra could only be recorded on relatively large amounts of essentially colorless substances. After the advent of laser light sources the situation changed completely. The amount of sample substance required is now in the region of milli- and micrograms. Gases, liquids and solid samples, especially air-sensitive and reactive substances, single crystals, crystal needles and filaments as well as aqueous solutions can be readily investigated. The identification of molecules and the elucidation of molecular structures, biochemical analysis, and control of environmental pollution are important applications of Raman spectroscopy. Raman spectroscopy now constitutes an additional powerful tool in instrumental analysis.

1. Introduction

Raman spectroscopy, which until recently had been used relatively infrequently, now attracts the interest of many chemists and physicists. Modern Raman spectrometers fitted with laser light sources have greatly facilitated the measurement of Raman spectra. The number of instruments in use and the number of relevant papers being published have increased considerably. Raman spectroscopy has found many new applications; many chemists presently using IR, UV, NMR, and mass spectroscopy are now considering whether they should resort to Raman spectroscopy and if purchase of a Raman spectrometer would justify itself. This paper is intended to help answer this question. The fundamentals of Raman spectroscopy, its applicability to chemical problems, and also its limitations will be considered.

46 Dortmund, Bunsen-Kirchhoff-Strasse (Germany)

[**] See also: *B. Schrader* and *W. Meier*: Raman/IR Atlas. Verlag Chemie, Weinheim 1974. Here the reader will find a systematic collection of Raman and IR (FIR) spectra of *ca.* 1000 typical compounds (combinations of the most important molecular skeletons and substituents) including polymers and complex molecules of biological interest. This atlas will serve as a basis for automatic evaluation of spectra.

Comprehensive accounts of the fundamentals and applications can be found in the classic works of *Kohlrausch*[1], *Herzberg*[2,3], *Brandmüller* and *Moser*[4], *Wilson*, *Decius*, and *Cross*[5], *Colthup*, *Daly*, and *Wiberley*[6], and other authors[7-12]. The special problems of Raman spectroscopy with laser light sources are discussed in several monographs[13-17]. A number of reviews deal with other problems: sample preparation and measurement technique[18], chemical applications[19-21], properties of the instruments[22,23], theory[24], and applications to problems in physics[25-27]. Access to individual works is facilitated by bibliographies with "multidimensional indexes" or "SDI" documentation services[27a,27b].

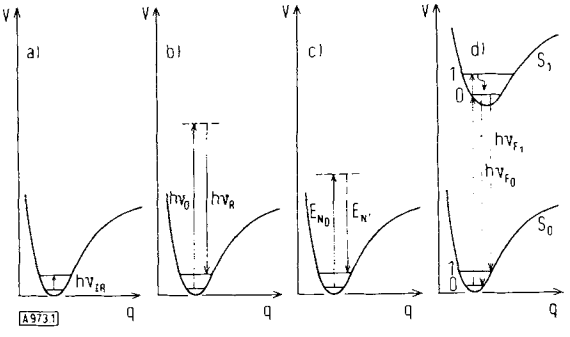

Fig. 1. Term diagrams of different methods for the observation of vibrational states: a) by IR spectroscopy ($h\nu_s = h\nu_{IR}$), b) by Raman spectroscopy ($h\nu_s = h\nu_0 - h\nu_R$), c) by neutron spectroscopy ($h\nu_s = E_{N_0} - E_{N'}$), d) by fluorescence spectroscopy ($h\nu_s = h\nu_{F_0} - h\nu_{F_1}$). S_0 = ground state, S_1 = excited state of the valence electrons. For details see text.

2. Fundamentals

2.1. The Methods of Vibrational Spectroscopy

Molecules consist of atoms, which are joined by elastic bonds. Such systems can perform vibrations. An n-atomic non-linear molecule may perform $3n$-6 independent normal vibrations whose frequencies ν are of the order of $10^{12} \ldots 10^{14}$ Hz, or given as wave numbers, $\tilde{\nu} = \nu/c$, about $10 \ldots 4000\,\mathrm{cm}^{-1}$. There are several ways in which these molecular vibrations can be observed. Figure 1 shows the potential energy V of a diatomic molecule as a function of the interatomic distance q together with the energy levels of a vibrational ground and excited state. Molecular vibrations can be excited directly by light quanta if their energy $h\nu$ is equal to the energy difference between the ground level and the excited vibrational level (Fig. 1a). Suitable light quanta belong to the infrared region of the electromagnetic spectrum ($\tilde{\nu} = 10 \ldots 4000\,\mathrm{cm}^{-1}$, $\lambda = 1000 \ldots 2.5\,\mu$). The energy $h\nu_{IR}$ corresponding to the absorption bands in the IR spectrum is equal to the energy $h\nu_s$ of the vibrational states of the molecule $h\nu_s = h\nu_{IR}$. On the other hand, molecular vibrations can be observed indirectly: by the Raman effect. When molecules are illuminated by a strong incident beam of monochromatic light some light quanta are scattered inelastically by the molecules. A part of the energy of the quanta $h\nu_0$ is transferred to the molecules, in the course of which vibrations are excited (Fig. 1b). The energy $h\nu_R$ of the inelastically scattered light quanta can be analyzed by means of a spectrometer. From the resulting Raman spectrum the vibrational energy of the molecules is given by $h\nu_s = h\nu_0 - h\nu_R$. Other possible methods for the study of vibrations in molecules are: analysis of the inelastic scattering of monoenergetic neutrons of energy E_{N_0} (Fig. 1c)[28] and of the fluorescence spectrum (Fig. 1d)[29,30]. However, these methods are by no means as generally applicable as infrared and Raman spectroscopy.

2.2. Historical Survey

The Raman effect is named after *Chandrasekhara Venkata Raman*[35], the Indian physicist who first observed the effect in the spring of 1928, following its prediction by *Smekal*[31], *Kramers* and *Heisenberg*[32], *Schrödinger*[33], and *Dirac*[34] in the years 1923 through 1927[35]. Shortly after its discovery a number of French and Russian authors also reported their work on this phenomenon[35a,35b]. Raman spectroscopy was born and immediately aroused the interest of many physicists and chemists. Infrared spectroscopy, which also provides information about vibrations of molecules, had been known since the beginning of the century[36], but measurement of the spectra was extremely difficult. Raman spectra, on the other hand, were more easily accessible. In nearly every spectrographic laboratory there was the necessary equipment for Raman spectroscopy: a mercury arc lamp and a prism spectrograph. However, the Raman effect is very weak, so Raman spectroscopy was not without its limitations. Exposure times of the order of a few hours to several days had to be used and, generally, only colorless liquids in amounts of a few milliliters could be investigated. Furthermore, the fluorescence of impurities can mask the Raman spectrum completely. Despite these difficulties, however, about 2000 papers dealing with Raman spectroscopy were published in the first decade after the discovery of the Raman effect[1]. They provided the basis for a great deal of our present-day knowledge of vibrational spectroscopy. After the second world war more efficient infrared spectrometers were developed, which were simple in operation and which provided spectra from milligram samples in any state. As a consequence, interest in Raman spectroscopy declined and until about 5 years ago Raman spectroscopy was not a widely used technique.

The steady development of laser light sources since 1960[37,38] has initiated a renaissance of Raman spectroscopy. Present-day Raman light sources have a spectral radiance that can be as much as 10 powers of ten higher than that of the mercury arc lamps used in the earlier days of Raman spectroscopy. Since the intensity of the scattered Raman radiation of a sample is proportional to the radiance of the light source, satisfactory Raman spectra can now be obtained with only one milligram to 1 microgram of substance in the liquid, solid or gaseous state. But in spite of the use of laser sources the Raman radiation remains weak: the radiant flux of a Raman band, excited by laser radiation is in the order of only 10^{-10} watt (cf. Section 2.4). Today one can also record Raman spectra of colored or fluorescent substances, if an exciting line is used which is far from the region of absorption of the substance. Today Raman spectroscopy is as readily

applicable as infrared spectroscopy for the study of molecular vibrations; currently, more than 1000 papers on Raman spectroscopy are being published each year.

2.3. Theory of Raman Spectroscopy

Raman spectra are produced by the interaction of light quanta with molecules. Light quanta have the properties of particles and of waves. Therefore the interaction can be explained in terms of classical physics both on the basis of the collision of a light particle with a molecule as well as the modulation of a light wave by the vibrations of a molecule.

During an *inelastic impact* of a light quantum with a molecule the vibrational energy can be transferred from the light quantum to the molecule or can be given from the molecule to the light quantum (Fig. 2a). The number of molecules in the first excited vibrational state N_s relative to the number in the vibrational ground state N_0 is given by the Boltzmann law (Figs. 2b and 2c):

$$N_s = N_0 \cdot e^{-\frac{h\nu_s}{kT}}. \qquad (1)$$

At 300 °K and a vibrational frequency of 1000 cm^{-1} only about 1 % of the molecules are in the first excited state. Therefore an inelastic impact of a light quantum with

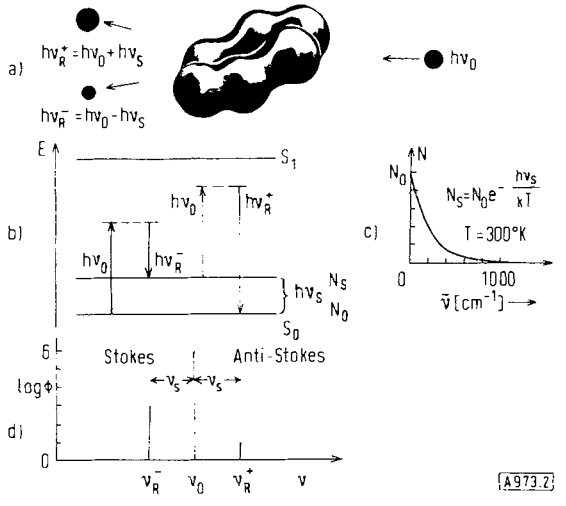

Fig. 2. Raman effect as inelastic impact of a light quantum with a molecule. a) impact process, b) energy level diagram, c) relative occupation of vibration level at $\tilde{\nu}$ cm^{-1} and 300 K, d) Stokes and anti-Stokes Raman spectra.

a molecule, in the course of which vibrational energy is given to the molecule, is approximately 100 times more probable than an inelastic impact in which the vibrational energy is transferred from the molecule to the light quantum. Normally, therefore, the more intense Raman spectrum on the long wavelength side of the exciting line (Fig. 2d), the so-called Stokes Raman spectrum[*], is observed. From the relative intensity of the Stokes and the anti-Stokes Raman lines one can calculate the vibrational temperature of the molecules [cf. eq. (10)].

[*] Stokes rule states that a fluorescence band is on the long wavelength side (at lower energies) of the absorption band of the substance. Application of this concept to Raman spectra is illogical [1], but common.

An elastic impact occurs with much greater probability than an inelastic impact. The former produces Rayleigh scattering at the frequency of the exciting radiation.

The absolute intensity of the vibrational bands in a Raman spectrum can be explained in terms of the *interaction* of a molecule with an electromagnetic *wave*. When a molecule is exposed to an electric field (Fig. 3), there will be a small shift of the center of the positive charges relative to the center of the negative charges. An induced dipole moment $\boldsymbol{\mu}'$ is created which is proportional to the electric field strength E and the "elasticity" of the charges in the molecule, *i.e.* the polarizability $\boldsymbol{\alpha}$:

$$\boldsymbol{\mu}' = \boldsymbol{\alpha}\mathbf{E} \qquad (2)$$

The polarizability of a molecule is generally greatest in the direction of the largest dimension of a molecule. The directional dependence of the polarizability is described by the components α_{ij} (i, j = x, y, z), which constitute the so called polarizability tensor.

$$\begin{aligned} \mu_x' &= \alpha_{xx}E_x + \alpha_{xy}E_y + \alpha_{xz}E_z \\ \mu_y' &= \alpha_{yx}E_x + \alpha_{yy}E_y + \alpha_{yz}E_z \\ \mu_z' &= \alpha_{zx}E_x + \alpha_{zy}E_y + \alpha_{zz}E_z \end{aligned} \qquad (3)$$

For non-chiral molecules this tensor is symmetrical, that is $\alpha_{ij} = \alpha_{ji}$, and therefore it has only 6 different components.

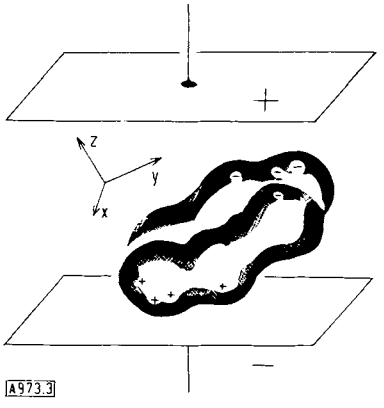

Fig. 3. Induced dipole moment of a molecule in an electric field.

If an alternating electric field is incident upon the molecule, the magnitude of the induced dipole moment will change with its frequency ν_0. Like a Hertz dipole the molecule will then emit radiation of the same frequency ν_0. This radiation is called the Rayleigh radiation.

If, at the same time, there is also mechanical vibration of the molecule, bonds will be compressed, stretched or

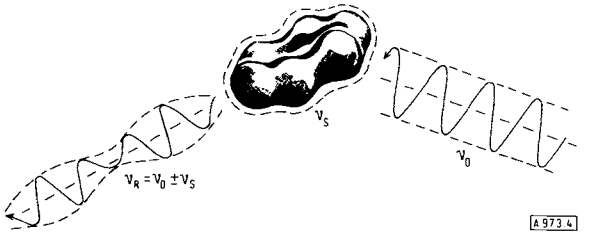

Fig. 4. Modulation of the scattered radiation of a vibrating molecule.

bent, during the course of which the coulombic attraction of the valence electrons by the nuclei will change with the frequency of the vibration. This means that the electron polarizability of the molecule will change with the frequency of the vibration. As a consequence the amplitude of the emitted wave will also change in phase with the mechanical vibration: The molecule emits—like an AM radio antenna—an amplitude-modulated electromagnetic wave (Fig. 4).

The classical description for this mechanism is as follows: The electric field strength of the exciting radiation changes with the frequency ν_0:

$$\mathbf{E} = \mathbf{E}_0 \cos 2\pi \nu_0 t \tag{4}$$

The polarizability tensor $\boldsymbol{\alpha} = (\alpha_{ij})$; i, j = x, y, z of the molecule, which is vibrating with a frequency ν_k, has two components: the unchanging polarizability, $\boldsymbol{\alpha}_0$, and a component that changes with the frequency ν_k:

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}_0 + \left(\frac{\partial \boldsymbol{\alpha}}{\partial Q_k}\right)_0 \mathbf{A}_k \cos 2\pi \nu_k t \tag{5}$$

$Q_k = \mathbf{A}_k \cos 2\pi \nu_k t$ is called the normal coordinate, $\mathbf{A}_k$ describes the amplitude of the individual atoms during the normal vibration k. From eqs. (4) and (5) the induced dipole moment $\boldsymbol{\mu}' = \boldsymbol{\alpha}\mathbf{E}$ will be:

$$\boldsymbol{\mu}' = \boldsymbol{\alpha}_0 \mathbf{E}_0 \cos 2\pi \nu_0 t + \left(\frac{\partial \boldsymbol{\alpha}}{\partial Q_k}\right)_0 \mathbf{A}_k \mathbf{E}_0 \cos(2\pi \nu_0 t) \cos(2\pi \nu_k t) \tag{6}$$

This may be transformed into the following formula which describes the induced dipole moment of a molecule that performs a mechanical vibration of frequency ν_k and at the same time is exposed to an electromagnetic field of frequency ν_0:

$$\boldsymbol{\mu}' = \boldsymbol{\alpha}_0 \mathbf{E}_0 \cos(2\pi \nu_0 t) + \frac{1}{2}\left(\frac{\partial \boldsymbol{\alpha}}{\partial Q_k}\right)_0 \mathbf{A}_k \mathbf{E}_0 [\cos 2\pi(\nu_0 - \nu_k)t + \cos 2\pi(\nu_0 + \nu_k)t)] \tag{7}$$

The first term in eq. (7) describes the Rayleigh radiation with the frequency ν_0, the second the Stokes $(\nu_0 - \nu_k)$ and anti-Stokes Raman radiation $(\nu_0 + \nu_k)$.

The intensity of the Raman lines is proportional to the square of the change of the induced dipole moment and thus also to the square of the change of the polarizability, $(\partial\boldsymbol{\alpha}/\partial Q_k)_0^2$, during vibration of the atoms about their equilibrium position.

The prediction of eq. (7), that anti-Stokes and Stokes Raman lines should have the same intensity does not take into account the different population of the vibrational ground and excited states and is therefore not in accord with observation. Quantum mechanical treatment gives the right answer. On this basis *Placzek* was able to derive equations which accurately reproduce the observed intensities[39,40]. However, these expressions are valid only in the case where excitation of the Raman effect is effected in a spectral region far away from absorption bands of the molecule, *i.e.* when there is no "resonance Raman effect". The Raman scattering coefficient, for an oriented molecule or a unit cell of a crystal, is, for the Stokes Raman radiation:

$$S^-_{k,rr'} = \frac{2\pi^2 h}{c} \cdot \frac{(\tilde{\nu}_0 - \tilde{\nu}_k)^4}{\tilde{\nu}_k [1 - \exp(-hc\tilde{\nu}_k / kT)]} \cdot g_k \left(\frac{\partial \alpha_{rr'}}{\partial Q_k}\right)_0^2 \tag{8}$$

and for the anti-Stokes radiation:

$$S^+_{k,rr} = \frac{2\pi^2 h}{c} \cdot \frac{(\tilde{\nu}_0 + \tilde{\nu}_k)^4}{\tilde{\nu}_k [\exp(hc\tilde{\nu}_k / kT) - 1]} \cdot g_k \left(\frac{\partial \alpha_{rr'}}{\partial Q_k}\right)_0^2 \tag{9}$$

It is assumed here that the electric vector of the exciting radiation is parallel to one axis r of a molecularly- or crystallographically-fixed Cartesian coordinate of the molecule or crystal, and the electric vector of the observed Raman radiation is parallel to r'; $\tilde{\nu}_0$ and $\tilde{\nu}_k$ are the frequencies of the exciting radiation and the vibration (in wave number units, cm^{-1}), T is the absolute temperature of the sample, g_k is the degree of degeneracy and $(\partial\alpha_{rr'}/\partial Q_k)_0$ is the change in the component $\alpha_{rr'}$ of the polarizability tensor by the normal vibration k. The order of magnitude of the Raman scattering coefficients is 10^{-28} cm^2·molecule^{-1}·sr^{-1}. The intensity ratio of anti-Stokes to Stokes Raman bands is, according to eqs. (8) and (9):

$$\frac{S^+_k}{S^-_k} = \frac{(\tilde{\nu}_0 + \tilde{\nu}_k)^4}{(\tilde{\nu}_0 - \tilde{\nu}_k)^4} \cdot e^{h\nu/kT}. \tag{10}$$

Calculation of the scattering coefficient for molecules in gases or liquids requires use of the mean value $\bar{\alpha}'$ and of the anisotropy γ' of the change of polarizability by a normal vibration k:

$$\bar{\alpha}' = \tfrac{1}{3}(\alpha'_{xx} + \alpha'_{yy} + \alpha'_{zz}) \tag{11}$$

$$\gamma'^2 = \tfrac{1}{2}[(\alpha'_{xx} - \alpha'_{yy})^2 + (\alpha'_{yy} - \alpha'_{zz})^2 + (\alpha'_{zz} - \alpha'_{xx})^2 + 6(\alpha'^2_{xy} + \alpha'^2_{xy} + \alpha'^2_{xz})] \tag{12}$$

Here $\alpha_{rr'} = (\delta\alpha_{rr'}/\delta Q)_0$; in all the terms a subscript k has been left out.

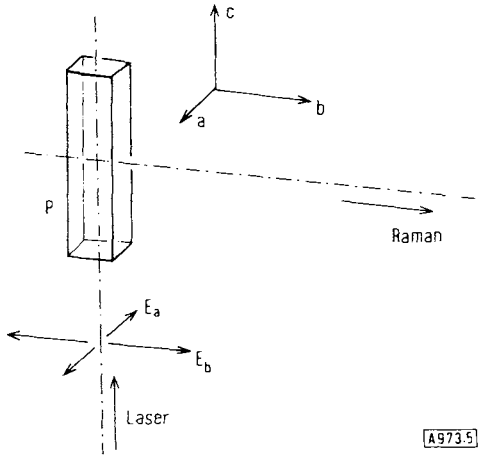

Fig. 5. Measurement of the degree of depolarization of the Raman radiation on excitation with a laser light-source.

If, according to Figure 5, the substance is illuminated by polarized exciting light in the direction of the c axis and if one observes without an analyzer the Raman radiation emitted in the b direction, two scattering coefficients must be taken into consideration: $S_{\parallel}$ for the electric vector of the exciting radiation parallel to the direction of the observation b and $S_{\perp}$ for the electric vector of the exciting radiation perpendicular to the direction of observation, *i.e.* parallel to the a axis:

$$S_{k\parallel}^{-} = \frac{2\pi^2 h}{c} \frac{(\tilde{\nu}_0 - \tilde{\nu}_k)^4}{\tilde{\nu}_k[1-\exp(-hc\tilde{\nu}_k/kT)]} g_k \frac{6}{45}\gamma_k'^2 , \quad (13)$$

$$S_{k\perp}^{-} = \frac{2\pi^2 h}{c} \frac{(\tilde{\nu}_0 - \tilde{\nu}_k)^4}{\tilde{\nu}_k[1-\exp(-hc\tilde{\nu}_k/kT)]} g_k \left(\bar{\alpha}_k'^2 + \frac{7}{45}\gamma_k'\right)^2 . \quad (14)$$

The ratio of the two scattering coefficients is called the degree of depolarization $\rho_{k,n}$:

$$\rho_{k,n} = \frac{S_{k\parallel}}{S_{k\perp}} = \frac{6\gamma'^2}{45\bar{\alpha}'^2 + 7\gamma'^2} . \quad (15)$$

Normal vibrations which are symmetric with respect to all symmetry elements of a molecule—totally symmetric vibrations—may modulate all components of the polarizability tensor and therefore also $\bar{\alpha}'$ and γ'. Hence[*],

$$0 \leqq \rho_{k,n} \leqq 6/7 \quad (16)$$

For totally symmetric vibrations of molecules with cubic symmetry $\gamma' = 0$, and therefore

$$\rho_{k,n} = 0 \quad (17)$$

In the case of vibrations which are antisymmetric with respect to any symmetry element, however, $\bar{\alpha}' = 0$ and

$$\rho_{k,n} = 6/7 \quad (18)$$

In the Raman spectra of liquids or gases the totally symmetric normal vibrations can be determined by measuring the degree of depolarization.

To illustrate the activity of normal vibrations in the Raman and infrared spectrum let us consider the CO_2 molecule. The CO_2 molecule is capable of performing two stretching vibrations of the CO bonds: the symmetric (ν_s) and antisymmetric (ν_a) stretching vibrations:

Figure 6 shows schematically the change of the electron system as a consequence of these vibrations. For the symmetric stretching vibration ν_s of the CO_2 molecule both CO bonds are stretched or compressed at the same time (Fig. 6a). The coulombic attraction of the valence electrons by the atomic nuclei will change its magnitude with the frequency of the vibrations. Consequently the polarizability α of the CO_2 molecule will also change. The symmetric stretching vibration will thus be Raman active.

The dipole moment of the whole molecule remains equal to 0 because both dipole moments of the CO bonds are, at any one time, antiparallel and equal. A normal vibration

[*] If the Raman radiation is observed through an analyzer, equations (13)—(18) are changed; for example, in (16) and (18) 3/4 should replace 6/7 [4, 40].

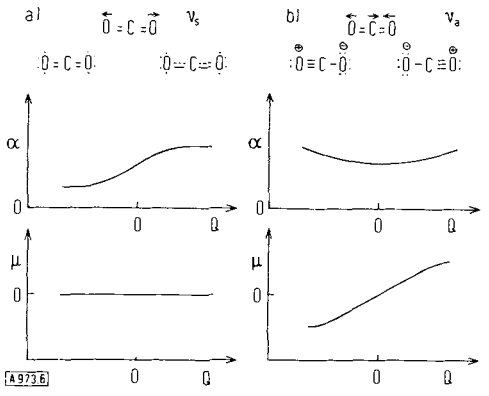

Fig. 6. Change of the polarizability α and the dipole moment μ of a) the symmetric, and b) the antisymmetric stretching vibration of the CO_2 molecule.

can be excited by radiation from the infrared region only if it changes the molecular dipole moment. Consequently the symmetric stretching vibration is infrared inactive.

For the antisymmetric stretching vibration of the CO_2 molecule everything is just the other way round: The polarizabilities of both states of the molecule shown in Figure 6b are of equal magnitude. For the position of the equilibrium with $Q=0$ also $(\partial\alpha/\partial Q_k)_0 = 0$. This vibration is not Raman active. The dipole moments of the two CO bonds are no longer equal in magnitude and the molecule as a whole has a dipole moment that changes its direction in rhythm with the vibration. The antisymmetric stretching vibration of the CO_2 molecule is therefore infrared active.

The CO_2 molecule provides us with a simple example for illustrating an important selection rule, *the rule of mutual exclusion:* If a molecule has a center of symmetry, then all vibrations symmetric with respect to this center of symmetry are forbidden in the infrared spectrum, and all vibrations which are antisymmetric with respect to the center of symmetry are forbidden in the Raman spectrum. Here, the term "forbidden" means that the mechanical vibrations are not observable as bands in the IR or Raman spectrum respectively.

The possible vibrations of the molecules may be divided into symmetry species, according to their symmetry or antisymmetry with respect to the symmetry elements of the molecule. The infrared or Raman activity of these species is given by so called "character tables"[1-6] which have been obtained by the rules of group theory. By counting the number of vibrations which are shown only in one of both spectra and those which show up in both spectra, one can often ascertain the symmetry properties of a molecule. This is facilitated by measurement of the degree of depolarization of the Raman lines, from which the total symmetric vibration can be recognized immediately.

2.4. Raman Spectrometers with Laser Light Sources

The laser principle (*l*ight *a*mplification by stimulated *e*mission of *r*adiation) allows the construction of light sources, the spectral radiance of which is not—as is the case in "classical" light sources like the sun and the mercury arc

lamp—limited by the temperature according to Planck's radiation law. By a "pumping" process more atoms, ions or molecules of the active substance are brought into an excited state of the electron system than there are in a state of lower energy which may be reached by emission of light quanta $h\nu$. Due to this inversion of the population of the states in the active substance it has the properties of an amplifier for light of frequency ν by stimulated emission. If the active substance is enclosed between highly reflecting mirrors coherent light beams of high spectral radiance may be produced. There are some noble gas lasers (He-Ne, Ar^+, Kr^+ lasers) which may be used as light sources for Raman spectroscopy. These give continuous waves and produce monochromatic and completely polarized light in all regions of the visible spectrum. Their spectral radiance (radiant flux per solid angle, area and spectral band width) is higher by as much as 10 powers of 10 compared to the mercury arc lamp.

The radiant flux of Raman radiation scattered by a sample is proportional to the spectral radiance of the light source. It is possible therefore not only to reduce the amount of sample required for recording a Raman spectrum by three powers of 10 from the gram to the milligram region but also to record spectra with a higher signal-to-noise ratio, at a higher recording speed and using a lower concentration of the substance, than was possible with the earlier mercury arc spectrometers.

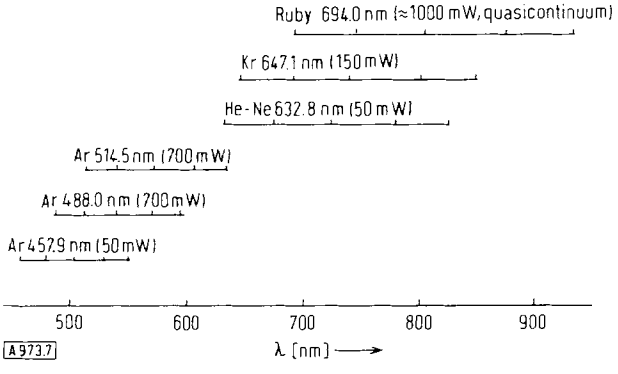

Fig. 7. Range of the Raman spectrum by excitation with different laser light-sources. The scale under the name of the laser light-source is marked 0 –3700 cm^{-1} (divisions 0, 1000, 2000, 3000, 3700 cm^{-1}).

Figure 7 shows the wavelengths of some lasers used for Raman spectroscopy and the region of the Stokes Raman spectrum excited by them. The intensity of the Raman lines is approximately proportional to the fourth power of the frequency of the exciting line ["ν^4-law". eq. (12), (13)]; therefore, it is advisable to use exciting light of a high frequency (*i.e.* short wavelength), for example the strong lines of the argon laser in the blue and green region of the spectrum (488 and 515 nm). For colored substances, which show absorption bands in this region, it is in most cases not possible to record a Raman spectrum. The exciting radiation is absorbed by the substance, and as a result the substance is heated, vaporized or decomposed. Often one can then use another exciting line from a spectral region, for instance the red, in which there is no absorption by the substance. At the same time possible interference of the Raman spectrum by the fluorescence spectra of impurities may be reduced when exciting light of longer wavelength is used. However, the use of laser light sources in the red region of the spectrum is not generally advisable, not only because of the ν^4-law but also because the radiation detectors for this spectral region are of lower sensitivity compared to those for the blue-green region of the spectrum. It is preferable therefore to have one laser (argon laser) for the blue and another laser (krypton laser) for the red region of the spectrum.

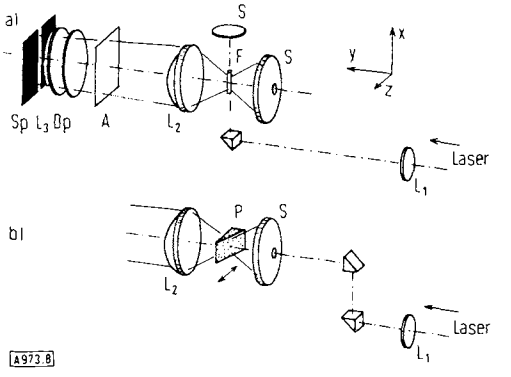

Fig. 8. Sample arrangements in a Raman spectrometer with laser light-source: a) for transparent samples, b) for crystal powders.

The most satisfactory arrangement for illumination of the sample in a Raman spectrometer furnished with a laser light source is to place the sample at the focus of the laser beam[41] (Fig. 8a). This yields a high radiation intensity in a small sample. Depending on the focal length of the focusing lens L_1[42], the diameter of the beam near the focus is in the order of 10 ... 100 μm. The narrow cylinder-like part of the sample illuminated by the laser is imaged into the entrance slit Sp of a monochromator by means of a high-power magnifying lens L_2. In front of the monochromator there is usually an analyzer A, for measurement of the degree of depolarization of the Raman lines, and a "polarization scrambler" Dp which reduces falsification of this measurement by the polarizing effect of the gratings in the monochromator. The amount of sample to be used in such an arrangement is determined by the volume of a tube which is large enough to enclose the laser beam in the region of the focus and which has a length H of about 2 ... 5 mm, so as to fully illuminate the whole length of the entrance slit of the monochromator. The mirrors S increase the radiant flux, from the exciter, and the Raman radiation.

For the optical setup shown in Figure 8a, without mirrors S, the radiant flux of a Raman line (watt) "seen" by the lens L_2 is approximately given by:

$$\Phi_k = \Phi_0 \cdot S_k \cdot N \cdot H \cdot L \cdot 4\pi \sin^2(\alpha/2) \qquad (19)$$

Φ_0 is the radiant flux of the exciting radiation within the sample (watt), S_k is the Raman scattering coefficient according to equations (8), (9), (12) and (13), N is the number of molecules (or unit cells respectively) per cm^3, H is the length of sample used, L is a factor, which takes into account the influence of the refractive index and the internal field effect of the sample[4, 43] and α is the half

angle of the light beam, seen by lens L_2. For a Raman scattering coefficient of about $10^{-28} \ldots 10^{-30}$ cm^2·molecule^{-1}·sr^{-1}, according to eq. (19)—taking into account the transmittance of the monochromator and the spectral slit width—and a laser of radiant flux about 1 watt, only about 10^{-9} to 10^{-11} watts is available when a Raman line is recorded by the spectrometer. The limit of detection of a photomultiplier is in the order of 10^{-16} watts[15].

If one could dispense with sample cells an amount of sample in the order of some thousandths of a cubic millimeter would be sufficient for Raman spectroscopy. However, for convenience of handling, a few milligrams of sample are normally used. Melting-point capillaries are often adequate as cells for Raman spectroscopy. Spectra of all transparent substances may be recorded with the arrangement shown in Figure 8a: liquids, solutions, gases. This arrangement is also suitable for recording the Raman spectra of crystal needles, filaments, and single crystals. By irradiation of the sample with the laser beam in different directions and by using different directions of polarization of laser beam and Raman radiation up to six different Raman spectra may be recorded. From such measurements the symmetry species of the vibrations and also the arrangement of the molecules in a crystal may be deduced (cf. Section 3.6).

Because of multiple reflections and normal and double refractions by the crystallites neither the intensity nor the polarization of the Raman lines in the spectra of crystal powders show any dependence on direction. Moreover, since the exciting radiation undergoes multiple reflections and refractions within the sample, a high amount of this "unshifted" radiation is mixed with the Raman radiation, which is about 5 to 10 powers of 10 weaker. The unshifted radiation produces stray light within the spectrometer, which may mask the Raman spectrum completely (see below).

By suitable preparation and alignment of the sample this stray light may be diminished. Crystal powders may be so arranged that either the "transmitted" or the "reflected" radiation will be analyzed[44]. The angle between the exciting radiation and the Raman radiation to be analyzed is then 0 or 180° respectively. The theory of the balance of Raman radiation from crystal powders[45], which is similar to the Kubelka-Munk theory[46,47], shows that the 0° arrangement is superior to the 180° arrangement, since it gives only 1/10 to 1/1000 of the intensity of the unshifted radiation. Both arrangements give Raman radiation of about the same intensity. The optimal thickness[48] of the sample for maximum Raman intensity can readily be found by shifting the sample sideways in a wedge-shaped cell P (see Fig. 8b). The intensity of the Raman spectrum of crystal powders is greater when the size of the crystallites is larger or when the powder is pressed into a disk[49,50]. If however the sample absorbs in the region of the exciting line it is, according to theory[45], more suitable to use the 180° arrangement. Decomposition of an absorbing sample by the laser beam can be avoided by rotation of the sample[51].

Even when the optimum arrangement of sample has been achieved the Raman light to be analyzed is mixed with unshifted light that is more intense by three to eight powers of ten. A good monochromator reduces the false light by about 5 powers of 10. Therefore one has to use double or even triple monochromators, only one of which effects the spectral dispersion; the others are—rather expensive—filters. They may be replaced by small band interference filters or resonance absorption filters. For example, we have built a simple Raman spectrometer in which a single monochromator is coupled with an interference filter in a triple reflection arrangement[52]. The exciting line is reduced selectively by the interference filter by 5 powers of 10. Iodine vapor may be used as absorption filter for the line of the argon laser near 514.5 nm[53,54]. Technical details of monochromators, radiation detectors, amplifiers and recording equipment have been described elsewhere[14,15,23].

3. Applications

3.1. Experimental Possibilities of Raman Spectroscopy

Until recently the application of vibrational spectroscopy was largely determined by the experimental conditions of infrared spectroscopy; Raman spectroscopy renders some kinds of measurements easier and offers new possibilities[55]:

1. The whole frequency region (10 ... 4000 cm^{-1}) of molecular and lattice vibrations is covered with *one* instrument.

2. The amount of sample needed is in the milli- to microgram region. Raman spectra of gas-chromatographic samples in the order of 1 nl and of crystals of less than 1 μg have been recorded[56,56a,57].

3. Water shows only a very weak Raman spectrum and is therefore suitable as solvent. Infrared spectroscopy of solutions in water is very difficult because of the very strong continuous absorption bands and the solubility of most window materials.

4. The intensity of the Raman lines of a substance is proportional to the concentration. It can be measured acurately over a range of about 4 powers of ten.

5. Simple glass vessels, *e.g.* melting-point capillaries, are suitable as sample cells. Sensitive, reactive or precious substances may be analyzed in their sealed containers (*e.g.* ampules) without decomposition and without loss.

6. The Raman spectra of samples at high temperatures (molten salts[13,59-61], flames[62,63]) and near the absolute zero[64,65] can been recorded.

7. The matrix-isolation technique[66,68] allows the investigation of unstable molecules such as the noble gas compounds[69,70], of monomeric dihalides of elements of the 4th main group[71,72], of products from plasma reactions[73], and of conformational isomers[74], as well as the determination of the isotopic structure of vibration bands[75].

8. The use of pulsed lasers as light sources makes it possible to measure Raman spectra within a few milliseconds, *i.e.* very fast reactions can be investigated[58].

9. Intermolecular interactions may be studied by application of high pressures[76-78] or by using adsorbed substances[79-83].

10. The determination of contaminants in air and of the temperature of the atmosphere would seem possible over distances of some km with a laser-radar[84–89].

11. Contrary to all expectations, the recording of Raman spectra of highly absorbing substances such as silicon[90], Fe_2O_3, and CrO_3[91] as well as black substances like graphite and coal[92–94] is possible.

Two examples will suffice to demonstrate the applicability of Raman spectroscopy to the non-destructive analysis of precious substances and to production control respectively. In both cases Raman spectra have been recorded on samples in their original ampules as supplied by the manufacturer. Figure 9 shows the Raman spectrum of

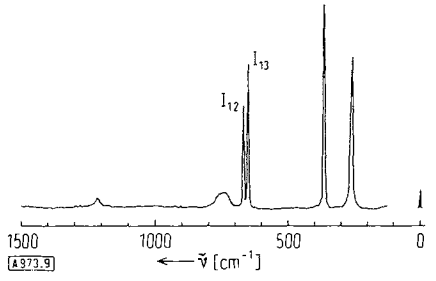

Fig. 9. Raman spectrum of chloroform 57.6% labeled with ^{13}C; in original ampoule. Evaluation of the band pair near 670 cm^{-1} yields $I_{13}/(I_{12}+I_{13})=58.7\%$ ^{13}C.

^{13}C-labeled chloroform (1 ml ampule), which according to the manufacturer is 57.6% enriched with ^{13}C. The symmetric C—Cl stretching vibration near 670 cm^{-1} is split into two components, which are to be assigned to the molecules with ^{12}C- and ^{13}C-atoms respectively. An evaluation of the relative intensity of these bands (as measured by peak height) gives a ^{13}C content of 58.7%. Figure 10a shows the Raman spectrum of crystallized luminal, and Figure 10b that of a 20% solution of luminal in

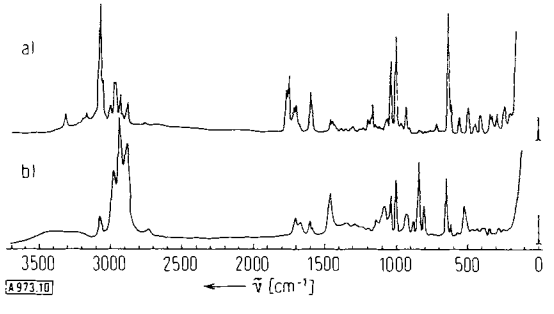

Fig. 10. Raman spectra of a) crystalline luminal, b) a 20% solution of luminal in propyleneglycol, ethanol and water in original ampule (Merck).

a mixture of propylene glycol, ethanol, and water (original ampule). The solvents give rise to bands in the spectrum at 2800—3000 cm^{-1} (C—H stretching vibration), at 1460 cm^{-1} (C—H bending vibration), and at 800—850 cm^{-1} (C—C stretching vibration); the vibrations of the CO and OH groups give only weak bands at 1080 and 3400 cm^{-1}. This non-destructive method of analysis permits simultaneous combination of the qualitative and quantitative analysis by Raman spectroscopy with the determination of fluorescing compounds (by measurement of the "background") and of colloidal particles (by the measurement of Tyndall scattering).

By coupling Raman spectrometers with computers the applications of Raman spectroscopy can be improved and extended, *e.g.* as regards the measurement of integral intensities, compensation of the properties of the spectrometers[95–97], resolution of overlapping bands[98], measurement of extremely weak spectra by multi-scan averaging[99–101], multiple component analysis[102], and the determination of characteristic bands for the elucidation of structure[103].

3.2. Potentialities of the Combination of Raman with Infrared Spectroscopy

A complete understanding of the vibrational spectra of a compound can give considerable information about bond strengths, molecular shapes, *etc.* The molecular vibration frequencies obtained from Raman spectra are to a great extent the same as those obtainable from infrared spectra. However, depending on symmetry, some frequencies in the Raman spectrum are absent in the infrared spectrum and *vice versa* (see Table 1).

Table 1. General overview of vibrational spectroscopy.

Characteristic features of the vibration spectrum	Properties of molecules or Bravais unit cells
Number of normal vibrations z	Number of atoms n, $z=3n-6$, for linear molecules $z=3n-5$
Frequencies	Masses of atoms, geometry, force constants (elastic properties of bonds)
Intensities in the infrared spectrum	Change in properties of the electron system with changing position of atoms change of dipole moment
Raman spectrum	change of polarizability
	IR and Raman activities are dependent on the symmetry of the vibrations and the molecules or Bravais cells

From Table 1 it is at once apparent that Raman spectroscopy and infrared spectroscopy are complementary methods which, when used in combination, provide considerable information about the molecules of the substance under examination:

The frequencies as well as the intensities of the vibrations are determined by the most important parameters of the molecular structure; therefore, both spectra may be used as "fingerprints" for the identification of molecules.

Structural units of molecules may also be identified by their characteristic frequencies and intensities. Generally the vibrations of polar groups and antisymmetric vibrations of atomic groups are stronger in the infrared spectrum because the dipole moment is strongly modulated, whereas vibrations of nonpolar groups and molecular skeletons and total symmetric vibrations are often stronger in the Raman

spectrum, since they strongly modulate the polarizability of the molecule.

From a comparison of infrared and Raman spectra the symmetry of molecules and the structure of isomers may be determined.

On the one hand, calculation of the frequencies and intensities of both spectra provides data about bond orders as well as about the polarities and polarizabilities of bonds, while, on the other, from a comparison of measured and calculated spectra the structures of unknown compounds may be determined. Finally, infrared and Raman spectra also provide data about intermolecular interactions and about the symmetry and structure of complexes, macromolecules or crystals. Particularly valuable here are measurements with polarized radiation.

Examples of such applications are discussed in the following paragraphs.

3.3. Characteristic Bands in the Raman Spectrum

For most vibrations of a molecule several bonds or angles are deformed simultaneously. However, a vibration may be localized in one group of the molecule when the vibrational frequency of this group, taken as isolated oscillator, is different from the frequencies of neighboring groups. In this case the frequencies and intensities of the vibration in the infrared and Raman spectrum are characteristic for this group, *i.e.* the vibration is independent of the rest of the molecule and may therefore be useful for detection of the group.

Characteristic frequencies in infrared spectra were first established by *Coblentz* in 1905[36]. Numerous publications contain tables of characteristic infrared bands. In some cases the intensity of these bands in the Raman spectrum is also discussed, both for organic compounds[6, 104, 105] as well as for inorganic compounds[106–108]. Some publications deal especially with Raman spectroscopic data[1, 7, 8, 109, 110]. Table 2 shows some characteristic bands, which may be used for investigations using the Raman spectrum alone or a combination of Raman and infrared spectra.

The infrared and Raman spectra of cystine (Fig. 11) show clearly the complementary nature of the two spectra. The infrared spectrum shows, in the region of 3000 cm^{-1}, the broad band of the NH_3^+ stretching vibrations of the zwitterionic form. In the Raman spectrum, on the other hand, only the CH (2915 cm^{-1}) and CH_2 stretching vibrations (ν_s: 2915, ν_a 2970 cm^{-1}) are to be seen in this region. In the infrared spectrum the NH_3^+ bending vibration and the antisymmetric stretching vibration ν_a (CO_2^-) appear at about 1600 cm^{-1}. Both are weak in the Raman spectrum, whereas the symmetric stretching vibration ν_s (CO_2^-) at 1410 cm^{-1} is strong both in the infrared and in the Raman spectrum. The strongest Raman band, 497 cm^{-1}, is very weak in the infrared spectrum; it may be assigned to the stretching vibration of the non-polar S—S bond, ν(SS). The position and intensity of this band, together with the ν(CS) near 680 cm^{-1}, can be used for determining the conformation of the disulfide bridges in proteins[111].

bidden), but may be easily recognized by its large intensity in the Raman spectrum. Table 3 shows the frequencies of isolated C=C double bonds with different substituents and bond angles. The strong dependence of the frequency of the C=C stretching vibration (1525—1875 cm^{-1}) on the substituents in cyclopropene derivatives is remarkable. This is not due to a change in the C=C force constants, but to a vibrational coupling with the neighboring bonds. When two oscillators of different frequencies are coupled the higher frequency will be shifted to higher values, the lower frequency to lower values, the shifts being greater the closer the frequencies of the isolated oscillators. Hence, the ν(C=C) of cyclopropenes is shifted to smaller frequencies when CH and especially when CD neighboring groups are present, and to higher frequencies when C—CH_3 groups are present.

The infrared spectrum of a compound, which was prepared by *Scharf* and *Seidler*, and which was known to have the molecular formula $C_6H_6OCl_2$ but was of unknown structure, (Fig. 12) showed only one band characteristic

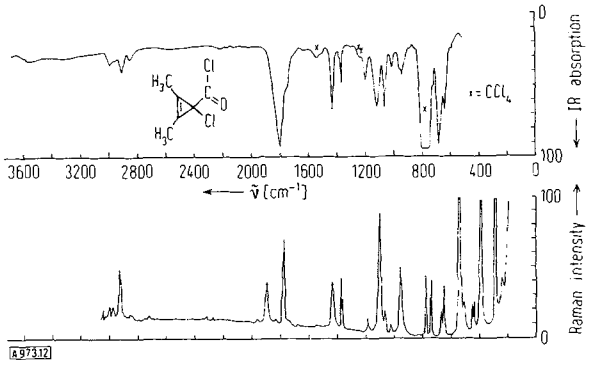

Fig. 12. IR and Raman spectra of 1-chloro-2,3-dimethyl-2-cyclopropene-1-carbonyl chloride ($C_6H_6OCl_2$). Infrared spectrum of the solution in CCl_4, Raman spectrum of the liquid substance.

of an acid chloride group at 1795 cm^{-1} in the region of the double bond frequencies. The Raman spectrum, however, showed, in addition to this band, another band at about 1898 cm^{-1}, which suggested the presence of a substituted cyclopropene ring. The structure tentatively

assigned to the compound is shown in Figure 12; this assignment was later proved correct[112]. The change of dipole moment by the C=C stretching vibration of this compound is obviously nearly 0. For other cyclopropane derivatives this vibration may be observed not only in the Raman, but also in the infrared spectrum (Fig. 13: 1,2,3-triphenylcyclopropene, ν(C=C): 1825 cm^{-1})[113]. Since the C=O- and the C=C-groups of 1-chloro-2,3-dimethyl-2-cyclopropene-1-carbonyl chloride (Fig. 12) are not conjugated, the vibrations of these groups behave as those of independent oscillators.

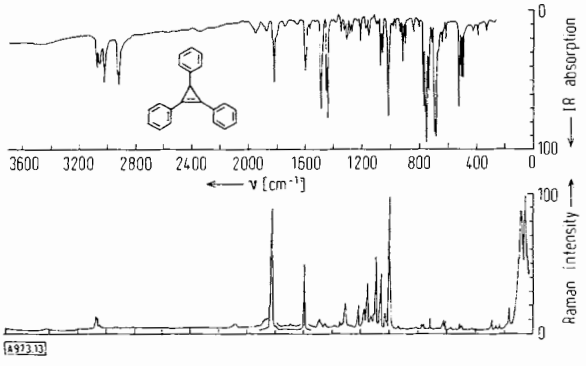

Fig. 13. Infrared and Raman spectra of crystalline 1,2,3-triphenylcyclopropene.

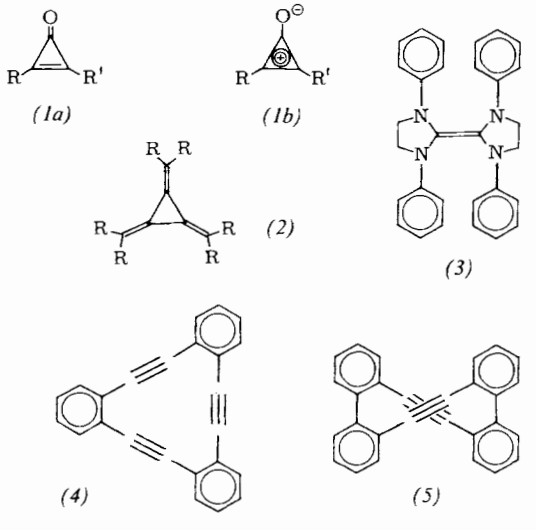
This is not so in the case of the cyclopropenones *(1)*. Here an investigation of the infrared and Raman spectra[114] and a calculation of the vibrational frequencies[115] showed that a band occurring at about 1610 cm^{-1} must be assigned to an in-phase vibration of both double bonds in the cyclopropenone system and a band near 1840 cm^{-1} to an out-of-phase vibration. Both vibrations are very strong in the infrared spectrum; in the Raman spectrum, however, the in-phase vibration is much stronger than the out-of-phase vibration. Analysis of the spectra would suggest participation of the zwitterionic structure *(1b)*, which would also explain the surprising stability of compound *(1)*.

The symmetric stretching vibration of the three-membered aromatic ring in triphenylcyclopropenylium bromide gives rise to a band near 1840 cm^{-1} in the Raman spectrum



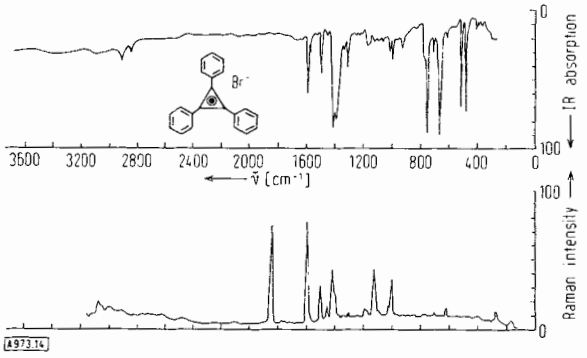


Fig. 14. Infrared and Raman spectra of crystalline triphenylcyclopropenylium bromide.

(Fig. 14). The infrared spectrum shows no trace of a band near this frequency. This is proof for the cyclopropenylium ion having a planar structure with a threefold symmetry axis, in which case the total symmetric vibrations are forbidden in the infrared spectrum, *i.e.* for the D_3 point group of the molecule[115,122]. The unsymmetric (degenerate) stretching vibration of the ring system shows a strong band near 1410 cm^{-1} both in the infrared and in the Raman spectrum. According to frequency calculations the force constants of the bonds in the cyclopropenylium ion are larger than those of the bonds in benzene[115,122]. The structure of the hexamethyl[3]radialene *(2)*, R = CH_3, has been established by observation of a strong Raman band of the ν_s(C=C) near 1880 cm^{-1} and absence of infrared bands of the same frequency[116]. Identification of the central double bond in compound *(3)* was also possible by observation of the ν(C=C) band (near 1640 cm^{-1}) in the Raman spectrum[117].

The stretching vibration of the N=N double bond in azo compounds is forbidden in the infrared spectrum if it is situated at the center of a centrosymmetric compound such as *trans*-azobenzene. However, *Lüttke* has been able to show by the frequency shifts introduced by ^{15}N-labeling that unsymmetric aromatic azo compounds exhibit a weak ν(N=N) in the infrared spectrum in the region 1410 ... 1440 cm^{-1}[118].

N=N stretching vibrations normally lead to medium or strong bands in the Raman spectrum[26,119]. This vibration appears at about 1520 cm^{-1} in the Raman spectra of mixed aromatic-aliphatic azo compounds (Fig. 15a); in the case of aliphatic azo compounds it is to be found near 1570 cm^{-1} (Fig. 15b)[120,121].

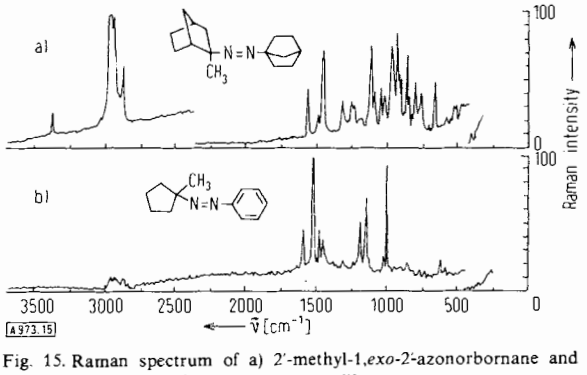

Fig. 15. Raman spectrum of a) 2'-methyl-1,*exo*-2'-azonorbornane and b) (1-methylcyclopentylazo)benzene, crystalline.

The stretching vibration of the C≡C grouping gives rise, if at all, to very weak bands in the infrared spectrum. Since the change in polarizability of this electron-rich group during vibration is large, it shows very strong bands in the Raman spectrum. Consequently, this group can be located very easily, even in large molecules like the steroids[124,125]. The Raman spectra of haloacetylenes have been studied by *Klaboe et al.*[126]. *Staab et al.* have investigated the properties of molecules containing several narrowly adjacent C≡C bonds. The Raman spectra showed that the C≡C bonds of the cyclododecatriyne *(4)* and -diyne *(5)* show a normal vibration frequency of 2220 cm^{-1}[127-130], and thus that there is no detectable mutual perturbation of these bonds.

The polar —C≡N-group can usually be recognized by a strong characteristic band in the infrared spectrum at 2100...2300 cm^{-1}[123]. If there is an electronegative substituent on the neighboring C-atom, then the change of dipole moment of the molecule by the C≡N vibration is so small that a band may not be seen in the infrared but only in the Raman spectrum[131,110]. Figure 16 shows as an example the infrared and Raman spectra of (1-cyanoethyl) acetate.

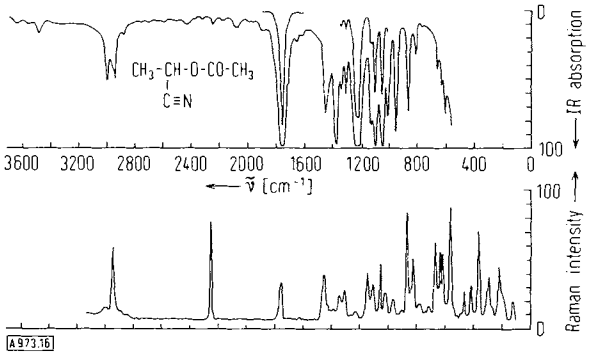

Fig. 16. Infrared and Raman spectra of (1-cyanoethyl)acetate.

The intensities of the vibration bands of X—H bonds in the Raman spectrum are often contrary to those in the infrared spectrum. The stretching vibrations of the OH groups lead to strong bands only in the infrared spectrum, whereas bands due to the vibrations of NH bonds are generally of medium intensity in both spectra. The stretching vibration of an acetylenic ≡C—H bond gives rise to a strong band in the infrared spectrum near 3300 cm^{-1}; in the Raman spectrum this band is very weak. An olefinic =C—H bond shows the stretching vibration near 3000—3100 cm^{-1} which is relatively stronger in the Raman than in the infrared spectrum. Aliphatic C—H groups show bands of medium intensity near 2800—3000 cm^{-1} in both spectra. The CH_2 and CH_3 bending vibrations also show bands of medium intensity in both spectra, near 1450 cm^{-1}. The symmetric bending vibration of the CH_3 group on carbon skeletons usually shows a band in the infrared spectrum near 1380 cm^{-1}. For saturated molecular skeletons this band is hardly detectable in the Raman spectrum; however, if the methyl group is attached to an olefinic or aromatic system a band of weak or medium intensity appears in the Raman spectrum at 1380 cm^{-1}[132]. From the intensity ratio v of this band

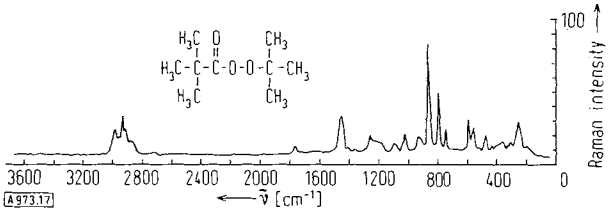

Fig. 17. Raman spectrum of liquid peroxypivalinic acid *tert*-butyl ester, 1 µl.

to that of the degenerate CH_3-bending vibration near 1440 cm^{-1} one can determine the number z of the CH_3-groups at a C=C-bond[133]: $z=1$, $v=0.26...0.56$; $z=2$, $v=0.50...0.80$; $z=3$, $v=0.82...1$ for open-chain compounds.

Some of the characteristic vibrations listed in Table 2 can usually only be found by means of the Raman spectrum; for example, the stretching vibrations of the O—O, S—S, and Se—Se groups. The O—O grouping in peroxides, peracids, and peresters gives rise to a strong Raman band in the range 700—900 cm^{-1}. Figure 17 shows this band near 868 cm^{-1} in the Raman spectrum of the *tert*-butyl ester of peroxypivalinic acid[120].

3.4. Structure Elucidation by Characteristic Band Groups

If there are n identical atomic groups in a molecule, then there are n vibrations of different frequency. All groups participate in these vibrations, but the vibrations of a particular groups are relatively independent of those of the rest of the molecule. If there are only two identical groups, one observes an "in-phase" and an "out-of-phase" vibration. The difference in the frequencies of these two vibrations is all the greater the stronger the dynamical coupling of the two groups. This coupling depends on the distance between the groups as well as on the spatial arrangement of the coupling bonds or atoms respectively. The frequencies therefore reflect the structure of configurational and conformational isomers. In the infrared and Raman spectra of isoprene (Fig. 18) the in-phase vibration ν_s of the two C=C bonds shows strong Raman bands near 1640 cm^{-1}, whereas the out-of-phase vibration ν_a gives an infrared band near 1600 cm^{-1}. All conjugated dienes in the *s-trans* conformation show $\nu_s > \nu_a$, whereas

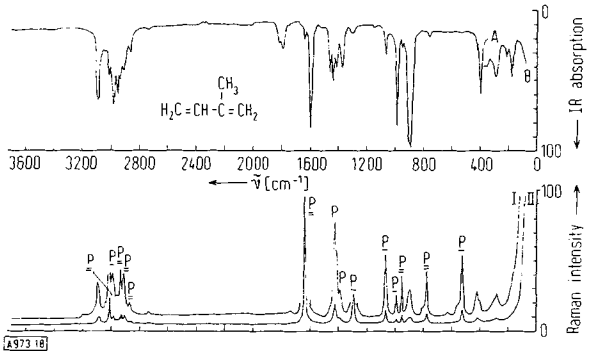

Fig. 18. Infrared and Raman spectra of liquid isoprene. IR spectrum: thickness A 20 µm, B 1000 µm; Raman spectrum: 0.3 ml, I amplification 1×, II amplification 0.2×. P: degree of depolarization $\rho=0.4...0.6$; P: 0.2...0.4; P: <0.2.

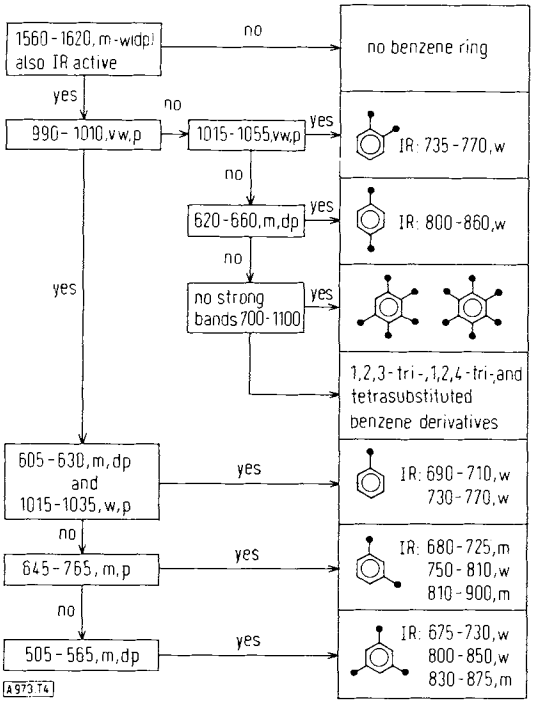
s-cis dienes show the in-phase vibration at a lower frequency than the out-of-phase-vibration, $\nu_s < \nu_a$. The position and the frequency difference of the vibrations provide information about the relative position of the two double bonds[134]. Since the vibrations which chiefly involve the single bonds between the double bonds show strong bands in the Raman spectrum, and since their frequency in the region 900 ... 1300 cm^{-1} is very sensitive to the conformation of the molecule, these can also be used for gaining information about the structure of the molecule. Characteristic groups of bands in Raman spectra have been used for elucidating the structures of several terpenes[135-138].

Until recently the band-rich Raman spectra of steroids have been accessible only with difficulty[139,140]: "The measurement of each Raman spectrum had been a miniature research problem of its own". The new techniques in Raman spectroscopy now allow the measurement of complete Raman spectra of steroids. By a systematic empirical evaluation of the frequencies and intensities, predictions about the number and the position of multiple bonds and about the *cis* and *trans* coupling of rings A and B have been made[124,125,141,142]. A scheme, similar to that shown in Table 4, has been drawn up which will facilitate such an evaluation of the relative intensities and frequencies of groups of bands in the spectra by a sequence of yes/no decisions.

The group of bands near 1450 cm^{-1} (δCH_2 and $\delta_a CH_3$) in the steroid spectra serves as a reference group: If this is the strongest band in the spectrum then presence of a saturated structure is indicated; steroids with an aromatic ring show stronger bands at lower frequencies only; if there are only bands at higher frequencies that are stronger than the reference band, isolated or conjugated double bonds at the five-membered ring D or homoannular dienes are likely. The presence of conjugated double bonds in or at the six-membered rings leads to stronger bands above and below 1450 cm^{-1}. The number and positions of these bands afford information about the nature and position of these structural elements[125]. Considerations of this kind may be generally applied also to other classes of compounds; in principle they can be used for an automatic evaluation of the spectra. The interpretation of infrared spectra by a similar scheme has been described recently[123].

It is well known that an analysis of the infrared and Raman spectra of benzene derivatives provides information about the nature of the substitution pattern and the interactions of the substituents[1,143,144]. Substituents are fingerprinted by their characteristic vibrations and by so-called "X-sensitive vibrations", the frequencies of which are strongly dependent on the mass of the substituents at the benzene system[145-152]. Here also, just one band alone is of little value—one must, as in the case of the steroid spectra, consider the existence, position and relative intensity of a group of bands. This evaluation is simplified considerably if the questions to be answered are arranged as a sequence of decisions. Table 4 shows such a scheme by which the pattern of substitution of benzene derivatives may be determined[153]. The pattern of the substituents of pyrazines also can be found from the Raman spectrum[56a].

Table 4. Scheme for the determination of the substitution pattern of benzene derivatives with the aid of characteristic bands in the Raman spectrum; intensities: m medium, s strong, vs very strong; degree of polarization: p polarized, dp depolarized. IR denotes characteristic band in the infrared spectrum [153].



A similar procedure has been used by *Willis et al.* for the identification of barbiturates by Raman spectroscopy[154].

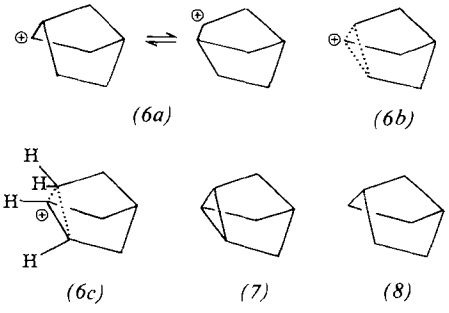
For mono-, di- and polyhalogen substituted alicycles the position and environment of the substituents may be determined by the positions and intensities of bands in the infrared and Raman spectra[155-158]. In the case of cyclic and open chain halogen substituted hydrocarbons the spectra of the possible conformational isomers can be observed and, from the temperature dependence, the free enthalpy difference may be calculated[159-165].

For some time now there has been some uncertainty about the structure of carbenium ions. By using a "super acid" as solvent *Olah et al.* were able to produce and stabilize carbenium ions, and, as a result, NMR and Raman spectra could be used in combination for the determination of structure[166,167]. They found that the *tert*-butyl cation shows practically the same vibration frequencies as trimethylboron[168,169], which is known to be planar and belongs to the point group C_{3h}. They conclude, therefore, that also the *tert*-butyl cation must be planar. A strong and polarized band appears near 347 cm^{-1} in the Raman spectrum, although—like an out-of-plane bending vibration of the skeleton—it should be Raman inactive. This finding is explained by the authors as being due to an unsymmetric arrangement of the CH_3 groups or to an association with a "gegenion" by which the symmetry is reduced from C_{3h} to C_{3v}.

The structure of the norbornyl cation *(6)* has been controversial for some time. The ^{1}H-NMR spectrum of *(6)* in "magic acid" (FSO_3H—SbF_5—SO_2) shows three signals with an intensity ratio 1:6:4, so it was impossible to make a decision between classical ions *(6a)*, which undergo

very fast Wagner-Meerwein rearrangements, and a nonclassical structure *(6b)* with delocalized σ-electrons.

Unperturbed NMR spectra of molecular species can be observed only when the life-time is larger than the duration of the spectral transition, which is in the order of $10^{-2}...10^{-4}$ seconds. In short-lived molecules, the nuclei, whose surroundings change during a reaction, only give signals of average position. In vibrational spectroscopy the duration of the spectral transition is in the order of $10^{-11}...10^{-13}$ seconds. This time is shorter than the half-life of any chemical reaction. Contrary to NMR spectra, Raman and infrared spectra should show the bands of all the components even of very fast reactions—provided that the concentration of the components is high enough.



(6a) *(6b)*

(6c) *(7)* *(8)*

Olah et al. showed that in the region of skeletal vibrations the Raman spectrum of *(6)* is very similar to that of nortricyclane *(7)*, but considerably different from that of norbornane *(8)*. These findings, as well as recent investigations of the ^{1}H- and ^{13}C-NMR spectra at low temperatures, suggest that the norbornyl cation has a nonclassical edge-protonated structure *(6c)*[170]. Further, in a similar way they recognized that 2-alkyl- and 1,2-dialkylnorbornyl cations have nonclassical structures analogous to *(6c)*, but that there are, at the same time, fast Wagner-Meerwein reactions[171,172]. It may be anticipated that Raman spectroscopy will yield important contributions to our knowledge of the structure of short-lived molecules[173].

3.5. Evaluation of Spectra with Computers and Calculation of Vibrational Spectra

In band-rich spectra of compounds of known structure, characteristic band groups may be found with the help of a computer[142]. Computers may be used for the automatic evaluation of frequencies and intensities for the elucidation of structures[123,125,153,154]. Computer programs have been developed, which use "machine intelligence" to reproduce and improve the evaluating procedures normally used by spectroscopists[174]. *Jurs et al.*[175-177] have described a procedure for the analysis of unknown substances by a weighting vector, which was developed *via* a training process in the computer. These programs are especially successful if the results of different spectroscopic procedures are combined and if, in addition, the physical laws relating to the spectra are taken into consideration. It is anticipated that Raman spectra will contribute significantly to this procedure.

The identification of unknown compounds by comparison of their spectra with the spectra of known compounds taken from spectral libraries can now be carried out rapidly by using computers[178-181]. This procedure is only meaningful, however, when the spectral libraries are large enough. Several collections of Raman spectra are already available, others are being prepared[182-186].

In view of the fact that frequencies and intensities in the Raman and infrared spectra contain more information about the properties of molecules in the electronic ground state than most other spectra, one of the most attractive chemical applications of computers is the interpretation of these spectra by calculation. Information about chemical bonds and their interactions can be obtained by comparison of simulated and observed spectra; suggested structures of unknown compounds may be confirmed or rejected. Observed vibrations may be explained, and non-observable vibrations may be calculated. Finally, from the complete set of vibrations, the thermodynamic properties of the substances may be calculated. Nowadays, the computation of vibrational frequencies is possible even for polyatomic molecules, polymers and crystals. The procedure may be briefly outlined: The potential energy of the molecule is described as a function of the change of the "inner coordinates" (bond length, bond angles, torsions) R_i in "harmonic approximation":

$$V = \tfrac{1}{2} \sum_i \sum_j f_{ij} R_i R_j \tag{20}$$

where

$$f_{ij} = \left(\frac{\partial^2 V}{\partial R_i \partial R_j} \right)_0 \tag{21}$$

are force constants, which constitude the matrix

$$\mathbf{F} = [f_{ij}] \tag{22}$$

The kinetic energy of the molecule is dependent on the velocity of change of the inner coordinates $\mathring{R}_i$:

$$T = \tfrac{1}{2} \sum_i \sum_j G_{ij}^{-1} \mathring{R}_i \mathring{R}_j \tag{23}$$

as well as the quantities G_{ij}^{-1}, which are given by the masses and the geometry of the molecule. By application of the Lagrange law of motion one obtains the secular equation[5]:

$$|\mathbf{FG} - \mathbf{E}\lambda| = 0 \tag{24}$$

whose eigenvalues λ_k yield the frequencies $\tilde{\nu}_k$:

$$\lambda_k = 4\pi^2 \tilde{\nu}_k^2 c^2 \tag{25}$$

and whose eigenvectors describe the forms of the vibrations. The frequency of a two-atomic molecule is, as is well known:

$$\tilde{\nu} = \frac{1}{2\pi c} \sqrt{f \left(\frac{1}{m_1} + \frac{1}{m_2} \right)} \tag{26}$$

where m_1 and m_2 are the atomic masses and f is the force constant.

The force constants f_{ij} describe the elastic properties and interactions of the valence electron system.

For i=j a force constant f_{ii} describes the force which is necessary for the stretching of a bond or bending of an angle. The stretching force constants are approximately proportional to the order of the bond; they are of the order 1 ... 20 mdyn/Å. The evaluation of correct interaction force constants f_{ij} with i≠j presents a difficult problem. They describe the change of elastic properties of one internal coordinate R_i when another, R_j, is stressed. A negative interaction force constant for changes in bond lengths means an increase in the bond order of R_i if R_j is stretched. Although these "off-diagonal" force constants, f_{ij}, have a value of about one tenth of the diagonal force constants f_{ii} of the matrix of the force constants [eq. (22)], their influence may not be neglected. For calculation of the vibrations of an n-atomic molecule with $z=3n-6$ normal vibrations, a maximum of $z\,(z+1)/2$ force constants is required, for example, 45 for $n=5$, 20880 for $n=50$.

Fortunately, many of the interaction force constants may be neglected because they have of very small values. For symmetric molecules several are zero by symmetry considerations and for molecules with several identical groups many of the force constants f_{ij} have the same value. Nevertheless, the number of force constants is generally larger than the number of normal vibrations. Consequently, several sets of force constants may be calculated which will reproduce *exactly* all the frequencies of a vibrational spectrum but which are *meaningless* physically. Physically "correct" sets of force constants have been established by a simultaneous evaluation of the spectra of homogolous and isotopic molecules[106,107,187–189]. The correct sets of force constants may be also sectionalized[2,3] by adjustment of the most probable distribution of the vibrational energy and by evaluation of the constants of the Coriolis-coupling and the centrifugal distortion, which may be calculated from gas spectra[190–192]. Finally, it is possible to calculate the force constants as well as the quantities which determine the intensities in the spectra $[(\partial\alpha/\partial Q)_0^2$ and $(\partial\mu/\partial Q)_0^2]$, by quantum chemical calculations: all quantities are an expression for the response of the electron system to the changed positions of the atomic nuclei[193–196].

Some years ago, in the field of inorganic chemistry complete sets of force constants for many small and symmetric molecules were derived from which the properties of the chemical bonds could be explained[106,107,197]. Calculations of the vibrations of organic and metallorganic compounds have provided a wealth of data on bonds and molecular structure[198–208].

Questions about the structure of organic compounds, for example the interactions of the bonds in conjugated compounds, may be answered by model calculations[114,115,209]. Sets of transferable force constants for organic chemical compounds have been developed by investigation of many, partly isotopically labeled molecules[187,190,210–213]. On this basis, by adjustment with observed spectra, the force constants of hexamethylbenzene, hexamethyl(Dewar benzene) *(9)*, and hexamethylprismane *(10)* have been computed and information obtained on the nature of the CC bonds[214,214a].

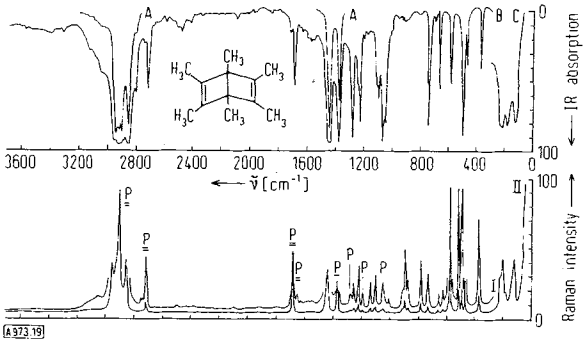


Fig. 19. IR and Raman spectra of liquid hexamethyl(Dewar benzene); IR spectrum: layer thickness A 20, B 60, C 1000 μ; Raman spectrum: I amplification 5×, II amplification 1×; degrees of polarization as in Fig. 18.

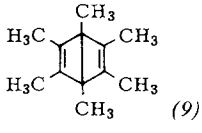
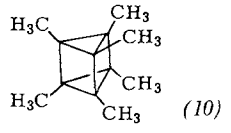
Figure 19 shows the infrared and Raman spectra of *(9)*. The calculated forms of the vibrations show that only a few vibrations are characteristic for distinct groups. The



(9)



(10)

CH_3 torsional vibrations in the region 100—250 cm^{-1} as well as the CH_3 rocking vibrations in the region 900—1100 cm^{-1} are strongly "mixed" with skeleton vibrations. Figure 20 shows some skeleton vibrations of hexamethyl-

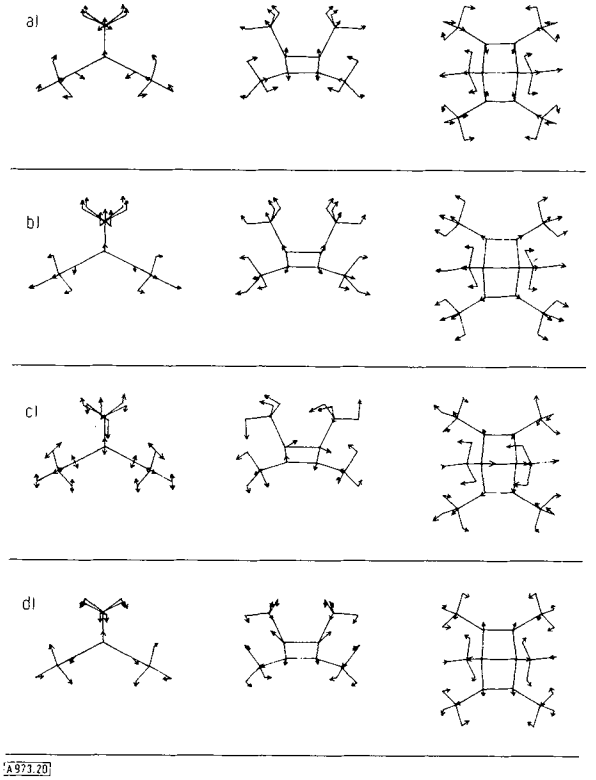


Fig. 20. Calculated amplitudes for some skeleton vibrations of the hexamethyl(Dewar benzene): 3 different views of the molecule. a) IR: 490; Raman 492, calc. 491 cm^{-1}; species A_1. b) IR: 576, Raman: 577, calc. 583 cm^{-1}; species A_1. c) IR: 659, Raman 658, calc. 657 cm^{-1}; species B_1. d) IR: 1276, Raman 1281, calc. 1274 cm^{-1}; species A_1.

(Dewar benzene), which have been drawn by a data plotter coupled with a computer. A bending vibration about the central single bond is found near 491 cm^{-1}; this band is strong in the infrared spectrum. The breathing vibration, which is the in-phase stretching vibration, appears at 583 cm^{-1} as the strongest Raman band. Also for the vibrations near 1274 cm^{-1} all CC bonds are stressed, but, in this case, in an out-of-phase mode. This band is strong in the infrared spectrum, whereas in the Raman spectrum it is very weak. A skeleton deformation vibration near 657 cm^{-1} shows very clearly a coupling of the movement of all atoms.

The in-phase and out-of-phase stretching vibrations of the C=C double bonds are found, according to calculation, to occur near 1685 or 1678 cm^{-1} respectively. Bands have been observed near 1684 (Raman) and near 1681 (infrared) cm^{-1}. Figure 21 shows the stretching force constants of the CC bonds of this molecule together with the bond lengths and bond orders which have been calculated from the force constants according to a rule given by *Siebert*[215].

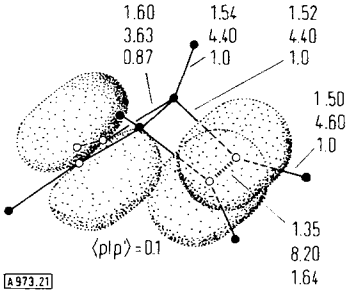

Fig. 21. Bond lengths [Å], calculated force constants [mdyn/Å], and bond orders for the CC bonds of hexamethyl(Dewar benzene).

The low bond order, 0.87, of the central single bond is not surprising, when the bond length of 1.60 Å is taken into consideration[216,217]. Moreover, the double bonds have a bond order of only 1.64; since they are of the same order as that of the double bonds in butadiene it may be concluded that mesomerism takes place. In butadiene the central bond is strengthend as a result of mesomerism (bond order 1.1), whereas in (Dewar)benzene none of the bonds in the neighborhood of the double bonds have a bond order significantly different from unity. The lower bond order of the double bond may be explained by overlap of the π-orbitals through space-homoconjugation[214a,218]. Homoconjugation in hexamethyl(Dewar benzene) is also illustrated by a splitting of the π-electron bands by 0.41 eV in the photoelectron spectrum[214a].

For hexamethylprismane *(10)*, calculation shows that the energy of the molecule, which is about 90 kcal/mol higher than that of hexamethylbenzene, is not reflected by the force constants. The bond order of the CC bonds in prismane don't deviate significantly from unity[214]. In the investigations just cited the definite assignment of calculated and observed vibrations and the adjustment of the force constants were facilitated by calculation of approximate intensities in the infrared and Raman spectra according to several different models. A coupling of the calculation of the vibrational frequencies and modes with the calculation of the dipole moments of the distorted molecule by means of the CNDO-method would seem to be promising for the evaluation of infrared intensities[214,220]. A combination of such calculations with quantum chemical calculations proves to be advantageous for many problems[219–231] and allows refinements of the results of both methods of calculation.

3.6. Raman Spectroscopy of Molecular Crystals; Intermolecular Interactions

At first sight there are only small differences between the vibrational spectra of crystalline substances and those of melts, solutions or vapors. Therefore, for many applications—for example the interpretation of the spectra by means of characteristic bands—it is of no consequence on which state of aggregation the spectra have been recorded. However, a more detailed analysis of the band positions and intensities, especially for bands at low frequencies and in the spectra of single crystals using polarized radiation, provides a wealth of information about the molecules, their interactions and their arrangement in the crystal.

In the crystal the molecule is situated on lattice sites, which are determined by the equilibrium between attractive and repulsive forces. The incorporation of a free molecule into a crystal lattice has important consequences:

1. Free rotation of molecular groups is hindered: usually the molecules are incorporated into the lattice only in one distinct conformation. The symmetry of the site is often lower than that of the isolated molecules, so vibrations, which—for the free molecule—belong to "forbidden" species, may become active and degenerate vibration levels may split. Finally, the static forces in the lattice may change the molecular force field and therefore may produce a shift of band frequencies (Figs. 22a and

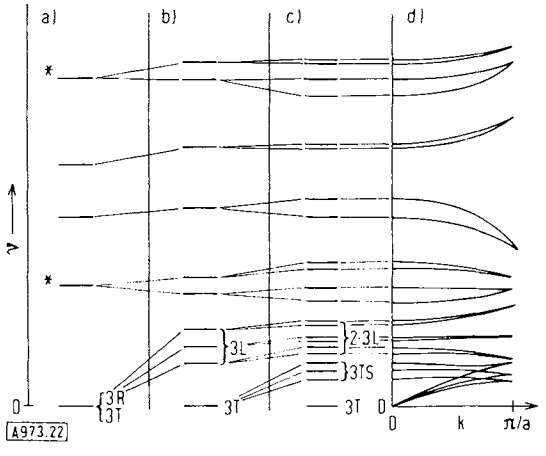

Fig. 22. Variation of the frequencies by the incorporation of a tetraatomic molecule with two degenerate vibrational states (*) in a crystal lattice; a) spectrum of the free molecule, R = rotations, T = translations; b) static influence of the crystal lattice. The degenerate states split, the free rotations change into librations L; c) dynamic coupling of the vibrations of molecules within a primitive unit cell with $z = 2$ molecules. Each vibrational level of a molecule splits into z components and $3z-3$ translational vibrations TS and $3z$ librations L appear; d) dependence of the vibrational frequencies on the wave vector k of the coupled vibrations of all unit cells in the lattice. The three "acoustic branches" arise from the three free translations with $\tilde{\nu} = 0$ and $k = 0$ of the unit cell; all vibrations of the unit cells with $\tilde{\nu} = 0$ and $k = 0$ are "optical branches".

22b). In spite of these influences the spectra may be interpreted to a first approximation by the "oriented-gas-model". From the intensities of the bands in the spectra of a single crystal, the angle between the molecular and the crystal axes may be calculated and the vibrations may be assigned to the vibrational species of the molecule[231-234].

2. In addition to the static lattice forces dynamic interactions of the vibrating molecules are also shown by the spectra. The primitive unit cell (which may be a fraction of the crystallographic unit cell) is the dynamical unit of the lattice, the symmetry properties of which determine the selection rules. The vibrational terms of the molecules split into as many components as there are molecules in the primitive cell. For these vibrations all molecules in the cell are moving similarly, but with different relative phase. The three free rotations and the three translations of each molecule are "frozen" in the lattice; instead of these, one observes for z molecules in the unit cell $3z$ librations (torsional vibrations) and $3z-3$ translational vibrations (Fig. 22c). These vibrations are called "external vibrations" or lattice vibrations.

3. Finally, the vibrations of neighboring primitive cells also couple. A lattice consisting of N primitive cells contains in fact N times as many different vibrational states as one primitive cell. They differ in the phase difference ($\varphi = 0 \ldots \pi$) of the same vibrations in different primitive cells. For the characterization of these vibrations one uses the "wave vector" $k = \varphi/a$, where a is the lattice constant. The frequencies of the "inner" vibrations, librations, and translational vibrations of the primitive cell constitute, when plotted as a function of k, the so-called optical branches. The (for $k = 0$) free translations of the primitive cell constitute the so-called acoustic branches (Fig. 22d). This name indicates that this branch describes those elastic vibrations which form the basis of the Debye theory of specific heat.

The sum of all vibrational states is reflected by the "inelastic neutron spectra" and by thermodynamic properties of the crystal. The wave lengths of the radiation, by which the Raman spectra are excited and the infrared are observed, are 1000 to 10000 times as large as the lengths of the axes of the primitive cell. Therefore one observes in the spectra only those vibrational states of the crystals for which neighboring primitive cells are vibrating almost in-phase, that is with $k \sim 0$. Hence, for the interpretation of the vibrational spectra it is sufficient to analyze all vibrations of *one* primitive cell.

(11)   *(12)*

 *(13)*

(14)   *(15)*

The theory of the vibrational spectra of crystals is based on the work of several authors[235-245]; some new monographs and reviews on this subject have been published recently[246-248a, 265c]. In the Raman spectra of molecular crystals the strongest expression of the crystal forces are the lattice vibrations—the librations and translational vibrations, usually occurring in the region 10—200 cm^{-1} (Fig. 23). The number, frequency, and width of the observed bands depend on the shape of the molecules, the symmetry of the lattice sites, and the interactions of the molecules in the lattice.

Figure 23 shows typical spectra of lattice vibrations taken from an investigation of the lattice vibrations of numerous molecular crystals[249]. For molecules having centers of symmetry there are only librations active in the Raman spectra. In the case of naphthalene there are two centrosymmetric molecules in the primitive cell, so one finds 6 librations, in-phase and out-of-phase vibrations of both molecules about the axes of inertia (Fig. 23a). The intensity

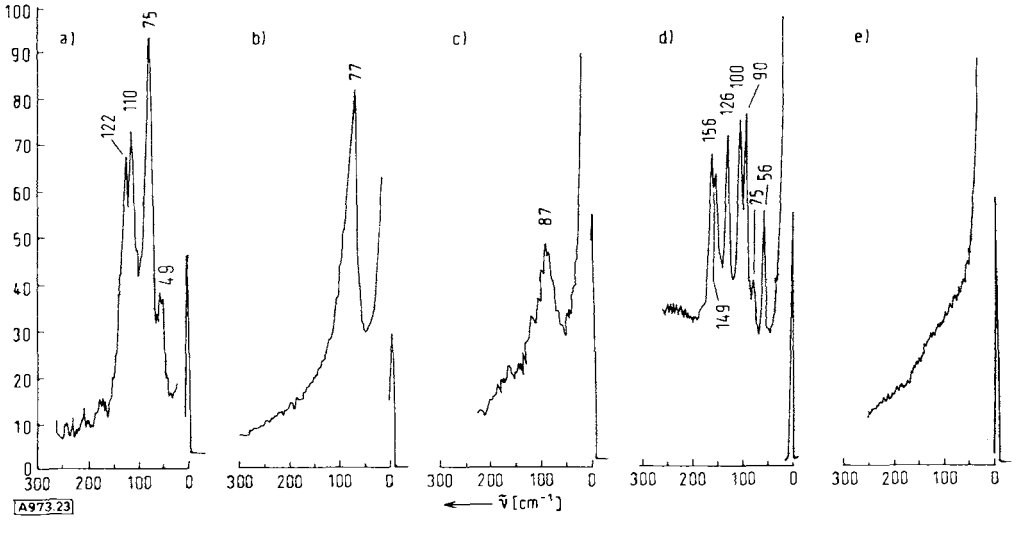

Fig. 23. Range of the librations and translational vibrations in the Raman spectra of some crystal powders: a) naphthalene *(11)*, b) *p*-aminoanisole *(12)*, c) guanidinium iodide *(13)*, d) melamine, *(14)*, e) urotropine *(15)*. The spectra were recorded using the exciting line 4358 Å of a Hg low-pressure arc [249].

of the librations in the Raman spectrum is larger, the larger the differences of the main polarizabilities of the molecules[235, 236, 241]. As a consequence the Raman spectra of hexamethylenetetramine, a molecule with cubic symmetry, shows no librations. In guanidinium iodide *(13)* (Fig. 23c) and melamine *(14)* (Fig. 23d) the polarizability in the direction of the threefold axis is significantly smaller than that in the molecular plane. Similarly, in *p*-aminoanisole *(12)* (Fig. 23b) one of the polarizabilities, in the direction of the substituents, is significantly larger than the polarizabilities perpendicular to this axis. In the case of these three compounds, therefore, one should expect only two librations of the molecule to modulate the polarizability of the crystal and thus to give rise to bands in the Raman spectrum. Their frequencies may coincide if the moments of inertia and significant intermolecular force constants for both vibrations are equal. It can be seen from Figure 23d that melamine shows at least seven bands. Here, significant force constants for the different librations about axes in the molecular plane are different, and, in addition, translational vibrations are also active[249, 250].

Predictions as to the number and the properties of the vibrations of the primitive cell may be made with the aid of factor group analysis[246–248a]. The magnitudes of the intermolecular and intramolecular force constants may be determined by calculation of the vibrations. If possible, the spectra of the single crystals are used as a basis.

As Figure 24 shows, in the case of the imidazole single crystal different Raman spectra are obtained for each of the six different components ($\alpha_{ij} = \alpha_{ji}$, i, j = x, y, z) of the polarizability tensor of the crystal[251, 252]. Imidazole crystallizes monoclinically (C_{2h}^5) with four molecules in the primitive cell, where the two pairs are parts of chains which line up the molecules in the z-direction by hydrogen bonds.

As a consequence of the intermolecular N ... H—N hydrogen bonds the frequency of the NH-stretching vibration is reduced from about 3200 to 2800 cm^{-1}; due to Fermi resonance with overtones and combinations of skeleton vibrations near 1200 ... 1500 cm^{-1}[252, 253] there is a band of peaks[254] instead of just one peak. As expected, this band shows up strongest in the spectrum of the tensor component α_{zz} of the crystal. Since the molecular planes are tilted only slightly from the yz plane of the crystal, the planar skeleton vibrations and the CH stretching vibrations show up strongest in the spectra of the components α_{zz}, α_{yy} and α_{yz}. In the calculation of the vibrations of crystalline imidazole[252], and of other molecular crystals[255–258], it has been shown that the intermolecular force constants also influence the frequencies of the inner vibrations. In the calculation of external force constants one gets values that are too small if one assumes that the molecules are rigid.

External force constants for the elastic forces between non-bonded atoms may be also calculated by using the second derivatives ($\partial^2 V/\partial r^2$) of potential functions which have been established by other methods. One may use atom-atom potential functions of the *Lennard-Jones* or *Buckingham* type[259], such as for example, those according to *Warshel* and *Lifson*[260] or *Kitaigorodski*[261]. *Shimanouchi* has shown that the force constants depend mainly on the repulsive term in the potential functions[255, 262].

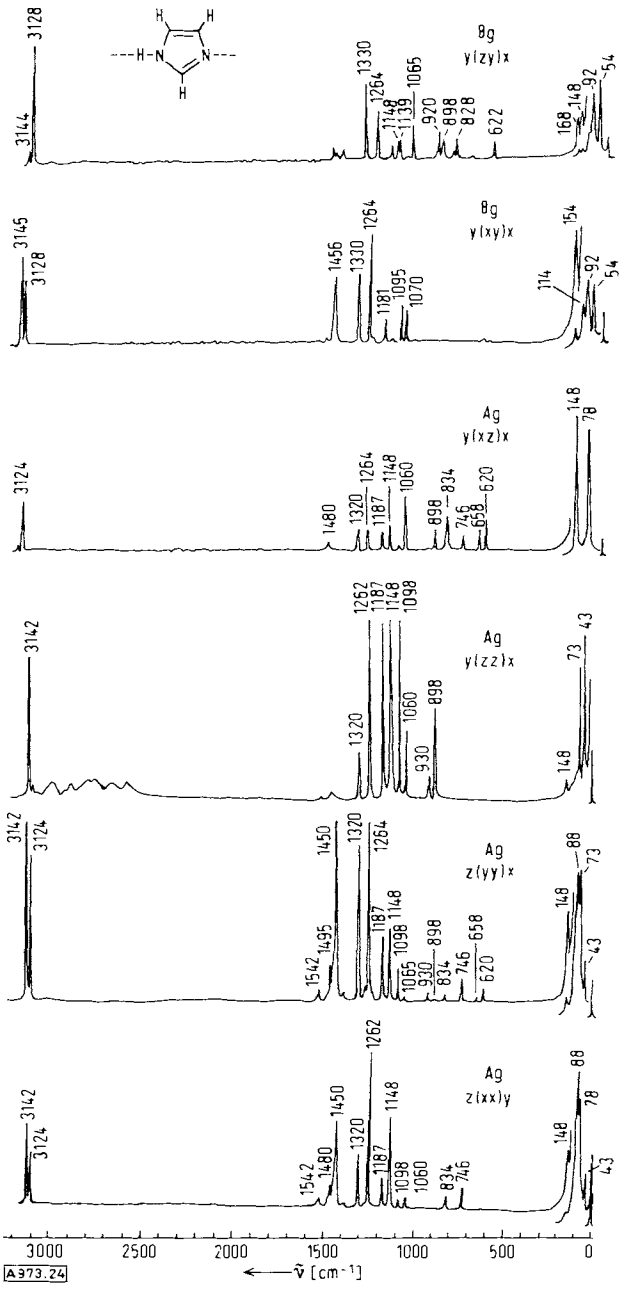

Fig. 24. Raman spectrum of an imidazole single crystal; y(zy)x means: illumination parallel to the crystal axis y, electric vector of the exciting radiation parallel to z, electric vector of the Raman radiation parallel to y, and direction of observation x. The librations and the translational vibrations are in the range 20 —200 cm^{-1}. The vibrations of the N—H bonds appear in the spectrum Ag, y(zz)x in the region about 2700 cm^{-1} together with some Fermi resonance bands (cf. also Table 5).

In Figure 25 the force constants for intermolecular H ... H, C ... H, O ... H and S ... H-bonds are given which have been found by calculation of the vibrations of crystalline benzene, naphthalene[255], thiourea[257, 263], and benzoic acid[264, 265]. From Figure 25, it can be seen that the stretching force constants of inner vibrations are in the region of 2 ... 20 mdyn/Å. Most of the intermolecular force constants are of the order of 0.001 ... 0.1 mdyn/Å. Stretching force constants in the region 0.1 ... 1 mdyn/Å are either related to forces between non-bonded atoms in the same molecule or indicate hydrogen bonds. We have been able

talline thiourea[256, 257, 263]. The frequencies of all lattice vibrations, including those with $k \neq 0$ (Fig. 22), have been calculated for a number of different small molecules in the crystalline state[265a]. Recently a method for calculation of the vibration of glass-like molecular networks has been developed and applied to As_2Se_3 and As_2S_3[265b]. The interpretation and calculation of the vibrational spectra of inorganic solids has been discussed by *Becher*[265c].

The intensities of the vibrations, especially those of the lattice vibrations in crystals, make it possible to draw conclusions about the interactions of neighboring molecules in the lattice. During translational vibrations the molecular polarizability ellipsoid is shifted parallel; so, as was previously assumed, there may be no change in the polarizability of the crystal for these vibrations. Actually, translational vibrations often lead to very strong bands such as, for example, the bands near 43 and 73 cm^{-1} in the spectrum of imidazole (Fig. 24, Table 5). The intensity of the librations in the Raman spectrum may be calculated from the molecular polarizabilities using a model developed by *Kastler* and *Rousset*[235,236]. Here also, the measurements of absolute intensities[266] show that the observed intensities are very much greater than the calculated intensities. For thiourea the intensity of the libration at 119 cm^{-1} (species A_g) has been calculated to be 0.40, whereas the observed value was 2.26 ($\cdot 10^{-28}$ cm^2/molecule)[266]. These discrepancies may not be explained by a coupling with other vibrations or by a dipole or quadrupole interaction[267,268], for these effects would be too small. They show rather the intermolecular perturbation of the electronic system of neighboring molecules in the crystal. Crystal orbitals are formed from molecular orbitals by intermolecular bonding and antibonding interactions. As a result of the modulation of the intermolecular distances in lattice vibrations the intermolecular overlap-integrals are also modulated and, consequently, also the energy levels of the crystal orbitals, the polarizabilities, and the dipole moments. This perturbation can therefore also be observed from the intensities of the bands in the far-infrared spectra and can be determined by quantum mechanical calculations[269].

Table 5. Calculation of the lattice vibrations of imidazole. Assignment of the librations L and translational vibrations T of the species Ag to the observed bands. Calculated frequencies and potential energy distributions for the force constants (see also Fig. 24).

Vibration	Frequency $\tilde{\nu}$ [cm^{-1}] obs.	calc.	Distribution of the potential energy of the vibrations
L_z	148	134	63% H...H
T_x	88	108	50% N...H—N
L_x	78	76	44% H...H + 22% C...H
T_y	73	69	38% H...H + 26% C...H + 16% N...H—C
T_z	43	25	45% N...H—C + 42% C...H

The Raman spectrum also provides information about the mechanism of the change of crystal modifications, *e.g.* about the Λ-point of hexamethylbenzene[214,270] or about the transformation into the ferroelectric state in thiourea[256,257,263]. In many investigations information about the properties and structures of crystalline complexes have been derived. Examples are: complexes with xenon difluoride[271], complexes and inclusion compounds of urea and thiourea[48,234,272], and charge-transfer complexes[273–276].

Investigations on the temperature dependence of the line widths and on the change of frequencies and intensities during phase transitions yield information about intermolecular interactions, and about the structures of liquids[277–280], for example, in the crystalline, glass-like, and liquid states of glycerine[281–282] and other compounds containing hydrogen bonds[283]. From the temperature dependence of the line widths and line shapes of the librations the times of reorientation and characteristics of the anharmonicity of the lattice potentials may be calculated[283a].

3.7. Raman Spectroscopy of Synthetic Polymers

Macromolecular compounds often contain both crystalline and amorphous structural elements. Raman spectroscopy makes it possible—as was described in Section 3.6—to obtain data on the properties of crystalline structures. In addition to this the spectra reveal characteristic properties of the molecules and of parts of the molecules. Consequently, there are numerous applications in the field of macromolecular compounds: from the frequency of the total symmetric bending vibration of chain molecules (accordion vibration, δ_s(CC) in Table 1) in the region 10 ... 200 cm^{-1} conclusions can be drawn about the length of the chains or the length of the straight parts of folded macromolecules[1,284]. Decisions about the structures of the crystalline region[285,286] have been made possible and data has been obtained on crystallinity[287–290], tacticity[291–293], interactions at the interfaces in glass-fiber reinforced polymers[294], the structure of polarizing foils[295] and cross-linked polyesters[296], the kinetics of to show that there are S ... H—N hydrogen bonds in crys-

polymerization[297] and vulcanization[298] and finally, the conformation of dissolved polymethacrylic acids[299]—these examples serve to illustrate the scope of applications in the field of macromolecular compounds. Here also, model calculations lead to the most definite results, so the large expense incurred is often worth while[300-302]. Unfortunately, the applicability of Raman spectroscopy to the field of macromolecular compounds is limited by fluorescent impurities. Often they cannot be removed and therefore may render the recording of a Raman spectrum of a polymeric substance impossible. This is also true in the case of the biopolymers discussed in the next paragraph.

3.8. Raman Spectroscopy and Problems in Biochemistry

Raman spectroscopy is a suitable method for use in investigating biochemical problems, largely because the study of molecules in their normal environment—aqueous solutions of low concentration—is possible. This is not so in the case of infrared spectra because of the strong absorption bands of water. Moreover, in the case of Raman spectroscopy the amount of sample required may be as little as 1 mg or less[303]. Although the investigations are often beset with difficulties because of the low intensity of the Raman bands and possible interference by fluorescence spectra, a number of most interesting applications to biomolecules have been made in recent times. In many cases the fact that the intensity of the Raman lines is enhanced when the exciting line is shifted into the neighborhood of the absorption bands of the compounds (resonance Raman effect) has been used. Utilizing this effect, *Rimai, Gill et al.* have been able to record the Raman spectra of samples of carrots and tomatoes. These spectra are almost identical with those of carrot juice and tomato juice and of solutions of β-carotin and lycopène in *n*-hexane[304]. The Raman spectra of some stereoisomeric vitamin A derivatives were also recorded and bands in the region 1100—1400 cm^{-1} have been shown to be characteristic for the different isomers[305].

The same workers also showed that by a systematic shift of the exciting line, excitation profiles for the Raman spectra of carotinoids could be derived which permitted recognition of electronic states (triplet states) that were otherwise accessible only with difficulty[306, 307].

Intact bovine retinas gave a Raman spectrum that is similar to the spectrum of retinylidenehexylamine in acid solution[308]. The spectra of 11-*cis* retinal, of other stereoisomers, and of Schiffs bases of the visual pigments, which have been models for the study of the visual process[309, 310], have been recorded. Resonance Raman spectra of metalloporphyrins[311] and haemoglobins[312] have also been recorded and information on the structure of the chromophore has been obtained. Some publications describe the investigation of the nature of the bonds of the iron atom in iron proteins, *e.g.* enzymes of the respiratory chain[313-315].

The Raman spectra of carbohydrates are more characteristic of the skeleton than are the infrared spectra; some recent investigations deal *inter alia* with the monosaccharides, with the disaccharides maltose and cellobiose[316], and with the conformation of the side-chains in celluloses of cell walls[317]. Perturbations of the structure of micelles in liquid dipalmitoyllecithine layers by cholesterin[318, 319] have been studied by observing the changes of bands in the region 1100 cm^{-1}. Raman spectroscopy should be a suitable method for the analysis of membranes *in situ*[320]. The application of Raman spectroscopy to the analysis of terpenes and steroids has already been discussed[124, 125, 135-138, 141, 142].

In the Raman spectra of proteins, as *Lord et al.* have shown for the spectra of ribonuclease, α-chymotrypsin, and lysozyme[321-323] the different amino acids can be recognized by the vibrations of their side chains. These are dependent on the conformation of the peptide bonds. The ν(SS) and ν(CS) near 500 and 700 cm^{-1} of different proteins occur at different positions and with different intensities. This allows conclusions to be drawn about the number and conformation of the SS bonds. Finally, the structure of the chain may be deduced from the frequency of the Raman bands of the amide groups. In the series α-helix, coil, β-arrangement (pleated sheet), for example, the frequency of the amide III band (in-phase vibration of the CO and CN bonds) is decreased from 1266 through 1248—1232 cm^{-1} in the spectra of glucagon[324]; in the region of the amide I band (namely the CO stretching vibration) near 1630—1700 cm^{-1}, on the other hand, the frequency is raised from 1660 through 1665—1674 cm^{-1}. The spectra of human serum-albumin have been analyzed[325] and deductions have been made about the structure of natural and denaturated insulin and various denaturation processes in lysozyme[326-329].

Several chain vibrations at low frequencies reveal the conformations of the peptide chains[330]. Further investigations describe the interactions between proteins and ligands[331] as well as the consequences of tissue calcification[332].

Harada and *Lord* have investigated the Raman spectra of the complex of 1-methylthymine with 9-methyladenine and of some crystalline bases of the nucleic acids. By way of frequency calculations they have been able to locate the hydrogen bond vibrations as weak Raman bands in the region 70 ... 125 cm^{-1}; also strong librations and translational vibrations occur below 100 cm^{-1}[333]. *Tsuboi et al.*[334] used the bands due to the different bases in the Raman spectra of formylmethionine transfer-RNA from *E. Coli* for a quantitative analysis[334]. *Peticolas et al.* examined the various implications of chain conformation upon the spectra of DNA and RNA[335, 336]: the total symmetric ring stretching vibrations of the bases show lower intensity when the rings are stacked side by side. Bands near 800 cm^{-1}, attributed to the symmetric stretching vibration ν_s(O—P—O) of the polyester backbone, are especially sharp and intense for the double helix structure of the nucleic acids. Finally, in the region of the C=O and the C=C double bond vibrations, bands are to be found which are sensitively dependent on the arrangement of the bases. With the aid of these bands the structures of and denaturating processes in natural nucleic acids—soluble and transfer-RNA from yeast and calf thymus-DNA—could be elucidated[335-338].

3.9. Conclusion

In this paper only a small part of the old and new chemical applications of Raman spectroscopy have been considered. In our selection of material we have naturally referred to results from our own field of work, and work in other fields, for example, inorganic chemistry, may have been somewhat neglected.

Applications to problems of solid state physics have scarcely been touched upon, while the large field of "non-linear" effects (for example the hyper-Raman-effect[339]) have not even been mentioned. The inelastic scattering of electromagnetic radiation by inner electrons or by nuclei, both of which have also been called "Raman effects" (X-ray-Raman-effect[340, 341], nuclear Raman effect[342]) still don't offer any interesting applications in chemistry. There will possibly be some analytical applications of the resonance Raman effect, which, at the moment, is of interest mainly for theoretical investigations[24, 343].

Techniques which use the Raman effect for the investigation of "extremely fast" reactions (in the range $10^{-7} \ldots 10^{-12}$ sec) will help to solve a number of chemical problems[344, 345]. The combined use of data from Raman and photoelectron spectroscopy has only just begun[214a, 346]. The application of circular polarized exciting radiation for the measurement of an effect similar to circular dichroism, the "Raman circular intensity difference" has been investigated theoretically[347, 348] and may, in the future, contribute significantly to the elucidation of the structures of chiral molecules[349]. Data complementary to those of UV or infrared rotational dispersion[350] are anticipated; here, there is also a Faraday effect variant[351].

Whether a Raman-radar technique for the determination of air contaminants fulfils expectations[84–89] remains open: nevertheless, the experiments in this field yield important data on scatter cross sections[352] and molecular constants and are providing new methods for the measurement of temperatures and concentrations in gases[353, 354]. The determination of contaminants in water by means of Raman spectroscopy would seem not to be unrealistic[355]. Several developments may be expected regarding apparatus: improvement of the sample arrangement and light power of the instruments, construction of inexpensive routine instruments, and perfection of tunable laser light-sources.

The apparently universal application of Raman spectroscopy in the temperature range from 1 to 2000 °K for amounts of substance in the nanogram region, for highly diluted solutions, for air sensitive, explosive and colored substances tends to conceal the limitations and difficulties of the method. Sometimes Raman spectra can be recorded only after great effort has been put into the preparation and purification of the sample. Many samples referred to as being "analytically pure" show strong fluorescence due to products of decomposition or traces of stop cock grease which may mask the Raman spectrum completely. Procedures have been developed for the preparation of samples especially for Raman spectroscopy[18]. In the case of polymers the purification is sometimes very difficult, if not impossible. Compounds which absorb over the whole visible region often give no Raman spectrum at all. Photochemical reactions during the excitation of Raman spectra sometimes lead to fluorescent impurities being transformed into non-fluorescent compounds; in a few cases the reverse process is observed. Substances which contain mechanical impurities like dust may decompose by the heat created by absorption of the laser beam. Liquids of low boiling point sometimes boil in the region of the focus of the laser beam, while biological samples may denaturate. The successful application of Raman spectroscopy is only possible if the limits of the method are taken into account and if it is recognized beforehand that preparation of the sample is often more difficult than the actual recording of the spectrum. Careful preparation of the samples is therefore just as important as the procurement of reliable spectrometers and light sources.

Today Raman spectroscopy can be applied to the study of most problems where this technique is known, in principle, to be suited. There are some investigations in which Raman or infrared spectra can yield equally informative data. Since Raman spectroscopy is more sensitive toward interferences (for example by absorbing of fluorescing impurities) and since infrared spectroscopy and infrared spectrometers are more commonplace, the solution of such problems will generally be accomplished by infrared spectroscopy. It has been estimated that about only 5 to 10% of the problems encountered in a normal infrared spectroscopy laboratory in industry are best solved by Raman spectroscopy. Only in the case of problems where a complete knowledge of vibrational spectra is necessary does one have to combine the use of Raman and infrared spectroscopy; for example, in the determination of the symmetry of molecules, in the calculation of spectra or force constants, and in the determination of thermodynamic properties. On the other hand, it has been shown that Raman spectroscopy is more suitable than infrared spectroscopy for a number of analytical problems.

It is to be expected that Raman spectrometers will find a future in large laboratories of the chemical industry, in many research institutes, and in most chemical departments of universities. Raman spectroscopy should prove to be an important instrument in the orchestra of modern physical methods in chemistry.

Valuable contributions to this paper by Fräulein Dr. E. Steigner, Frau Dr. L. Colombo, Frau R. Schüth as well as Dr. P. Bleckmann, Dr. D. Bougeard, Dr. K. Gottlieb, Dr. W. Meier and Dr. G. Wollbold are gratefully acknowledged. We wish to thank Professor Dr. H. Kaiser, Professor Dr. D. A. Long, Privatdozent Dr. J. Buddrus, Dr. H. Monien and Professor Dr. J. Behringer for valuable advice in preparing the manuscript. Thanks are also due to the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung, Nordrhein-Westfalen and the Fonds der chemischen Industrie for financial support of our investigations.

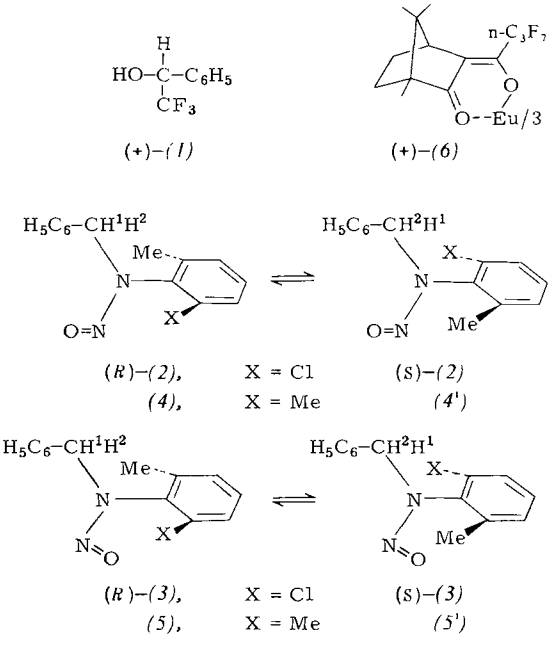
Determination of Rate of Internal Rotation by ^{1}H-NMR Spectroscopy in the Presence of Optically Active Auxiliary Compounds[**]

By *Albrecht Mannschreck*, *Violet Jonas*, and *Bernd Kolb*[*]

Different NMR spectra can be observed for enantiomers which undergo a sufficiently strong interaction with an optically active auxiliary compound[2, 3]. For example, addition of 2,2,2-trifluoro-1-phenylethanol (+)-*(1)* causes most of the ^{1}H-NMR signals of racemic nitrosoamine *(2)*[4] to split at 10 °C[1]. *(R)*-*(2)* and *(S)*-*(2)* interconvert through a half rotation about the *N*-aryl bond[5], so that a kinetically induced coalescence of the signals of matching protons in each diastereomeric association complex is possible[1]. We are now for the first time reporting this type



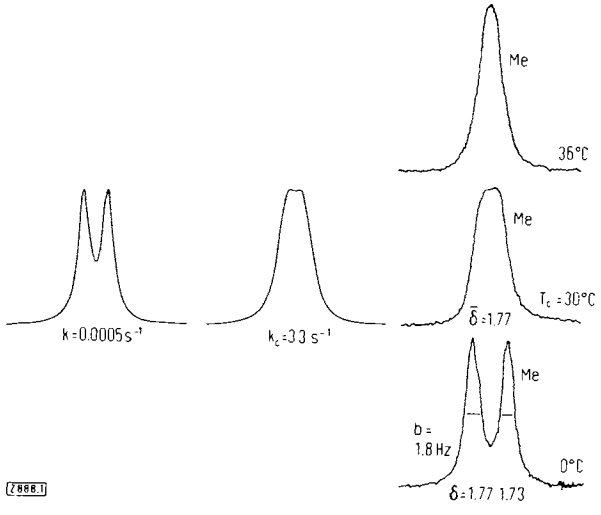


Fig. 1. ^{1}H-NMR signals (100 MHz) of the methyl groups of (*E*)-(2,6-dimethylphenyl)-benzylnitrosoamine *(4)* in CCl_4 in the presence of (*S*)-2,2,2-trifluoro-2-phenylethanol, (+)-*(1)*, as auxiliary compound; see Table 1. *b*: Width at half height of both methyl signals. For the spectrum at 30 °C (right), two simulations [9] with different *k*-values for half-rotation about the *N*-aryl bond are shown: $k = 3.3\,s^{-1}$ (middle, fitting) and $k = 0.0005\,s^{-1}$ (left, non-fitting). For both simulations $\Delta\delta = 0.024$ and $b = 1.4$ Hz [9] were used.

Table 1. ^{1}H-NMR data for nitrosoamines *(2)* and *(4)* in the presence of the optically active auxiliary compounds (+)-(1) and (+)-*(6)*.

	Auxiliary cpd. solvent [a]	*T* [°C]	δ(CH_2) [b] δ(CH_2).	δ(Me) [b] Δδ(Me)	T_c [°C]	$\Delta G_c^{\neq}$ [kcal/mol]

[**] Application of NMR Spectroscopy of Chiral Associates, Part 2. This work was supported by the Fonds der Chemischen Industrie.—Part 1: [1].

of coalescence and a new method, based upon this phenomenon, of determining the rates of intramolecular processes in molecules capable of association.

Compound *(2)* seemed to us to be especially suitable for the first experiments with this objective because here

the *N*-aryl rotation takes place at a favorable rate for NMR line-broadening measurements[5]. However, we also introduced the *achiral (4)* into the investigation. In unassociated *(4)* it is *not* possible to follow the rotation by NMR spectroscopy, because the shifts of the methylene protons H^1 and H^2 must be identical, this also being true for both methyl groups. However, *(4)* should form an "*enantiomeric* association complex" with an optically active auxiliary compound, with the result that H^1 and H^2, as well as both methyl groups, become diastereotopic to each other, thus potentially leading to different δ-values in each case[6].

In fact, after the addition of (+)-*(1)*[8], *(4)*[4,7] displays two methyl signals at 0 °C (Table 1), which coalesce upon raising the temperature (Fig. 1, right). We could simulate[9] the line shape at $T_c = 30$ °C assuming that a fast *N*-aryl rotation corresponding to *(4)* ⇌ *(4')* takes place with a rate constant $k_c = 3.3\,s^{-1}$ ($\Delta G_c^{\neq} = 17.0$ kcal/mol) (Fig. 1, middle). Use of an arbitrary but very small *k*-value led to an incorrect curve (Fig. 1, left). Thus, the observed coalescence of the methyl signals is not a consequence of the likewise detected decrease of their chemical shift difference Δδ with increasing temperature; rather, a coalescence which is brought about *kinetically* is involved. This conclusion is substantiated by the use of (+)-*(6)*[8] as the auxiliary compound; here Δδ corresponding to the two methyl resonances of *(4)* is of such a size that their broadening, coalescence, and sharpening upon raising the temperature is already clearly recognizable without simulation (Fig. 2). The resultant $\Delta G_c^{\neq}$ value of 16.7 kcal/mol at 39 °C is similar to that obtained upon addition of (+)-*(1)*. Analogous results (Table 1) were obtained for chiral *(2)*[4], which in contrast to *(4)* forms diastereomeric association complexes[11].

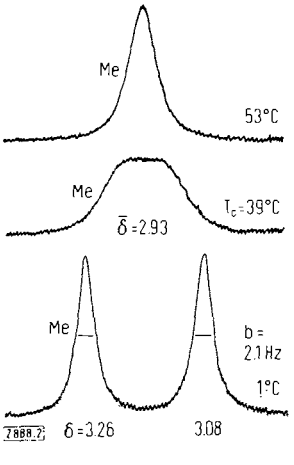

Fig. 2. ^{1}H-NMR signals (60 MHz) of the methyl groups of (*E*)-(2,6-dimethylphenyl)-benzylnitrosoamine *(4)* in CCl_4 in the presence of tris[3-(heptafluoropropylhydroxymethylene)-D-camphorato]europium(III), (+)-*(6)*, as auxiliary compound; see Table 1. *b*: width at half height of both methyl signals.

Beginning with the not quite certain assumption of 1:1 association complex formation between *(4)* and the auxiliary compound (+)-H, one obtains for this case the following kinetic scheme:

$$\begin{array}{ccc} (4) + (+)\text{-H} & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & (4)\cdots\cdots(+)\text{-H} \\ k_f \uparrow\downarrow k_f & & k_a \uparrow\downarrow k_a \\ (4') + (+)\text{-H} & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & (4')\cdots\cdots(+)\text{-H} \end{array}$$

The association complex formation (k_1) and its dissociation (k_{-1}) are generally considered to be fast in comparison to rotation in the association complex (k_a) or in the free nitrosoamine (k_f). The question whether k_a or k_f correspond to the measured *k*-value must at present remain open. However, the kinetic results for *(2)* in CCl_4 and in $CCl_4/CFCl_3$ at 26 and 32 °C[10], respectively (Table 1) are similar to the barrier of 16.5 kcal/mol obtained in the absence of an auxiliary compound in C_4Cl_6 at 70 °C using the coalescence of the signals of H^1 and H^2[5]. The exact experimental comparison of all activation parameters under consistent conditions, as well as the measurement of $\Delta G^{\neq}$ at different concentrations of (+)-*(6)* will help to clarify the problem further.

[4] Because of the partial N—N double bond, in addition to the (*E*) isomer *(2)*, the (*Z*) isomer *(3)* coexists in solution, for which diastereomeric association complexes were also detected [1]. That the barrier to *N*-aryl rotation in *(3)* is greater than 20 kcal/mol [5], is confirmed by investigation of the association complex up to 100 °C. The hitherto unknown barrier to *N*-aryl rotation was found to be $\Delta G_c^{\neq} = 24$ kcal/mol at *ca.* 160 °C for *(5)* in C_4Cl_6 in the presence of (+)-*(6)*.

[8] (+)-*(1)*: $[\alpha]_D^{23} = +31.40$ (neat); (+)-*(6)*: $[\alpha]_D^{23} = +151$ ($c = 1.27$, CCl_4). The spectra obtained using (+)-*(6)* as the auxiliary compound showed an additional peak at δ = 5.3 at 1 °C in the case of *(4)* and at δ = 6.0 at 1 °C in the case of *(2)* which seems to be due to H_2O; integration indicates approximately 4 moles H_2O per mole (+)-*(6)*.

[9] For the simulation of line shape, a computer program [*V. Jonas*, Thesis, University of California, Riverside 1970, p. 226] was used, which is based upon the line shape equation of *M. T. Rogers* and *J. C. Woodbrey* [J. Phys. Chem. 66, 540 (1962)]. The width at half height in the absence of fast exchange (1.4 Hz at 30 °C) was measured using a solution which contained racemic (±)-*(1)* instead of (+)-*(1)*; see [1].

[10] For *(2)* in $CCl_4/CFCl_3$ in the presence of (+)-*(6)*, simulations were carried out for spectra which had been obtained at seven temperatures between 21 and 35 °C, yielding $\Delta G^{\neq} = 16.5$ kcal/mol at both 32 and 70 °C ($\Delta H^{\neq} = 16.5$ kcal/mol, $\Delta S^{\neq} = 0$ e. u., 32 °C). In the case of *(4)* in CCl_4 in the presence of (+)-*(6)*, kinetic data were obtained at 10 temperatures between 26 and 53 °C, yielding $\Delta G_c^{\neq} = 16.7$ kcal/mol at 39 °C ($\Delta H^{\neq} = 15.4$ kcal/mol, $\Delta S^{\neq} = -4$ e. u., 39 °C).

A Variation of the Sulfide Contraction Procedure for Synthesis of Corrinoid Systems[**]

By *Erwin Götschi, Walter Hunkeler, Hans-Jakob Wild, Peter Schneider, Walter Fuhrer, John Gleason*, and *Albert Eschenmoser*[*]

The "sulfide contraction procedure" developed during the synthesis of vitamin B_{12} has proved an efficient general method for construction of corrinoid chromophore sys-

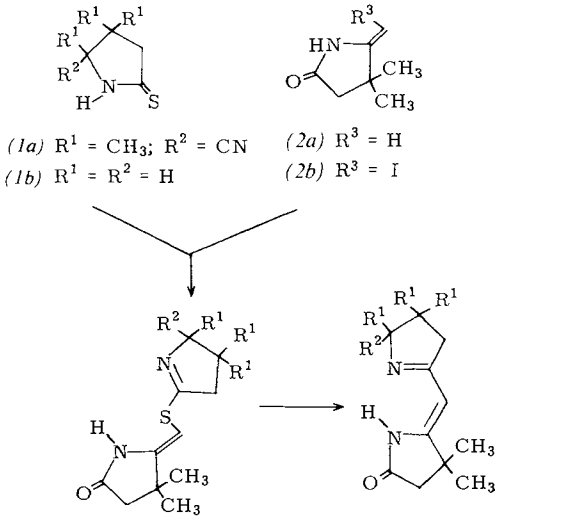
tems[1-4][*]. However, in the condensation of thiolactam derivatives with cyclic enamide systems, cases have also been met in which the original procedure of oxidative coupling by benzoyl peroxide[8] is either unsatisfactory or fails completely. Difficulties of this kind could be overcome by using iodinated enamides, and this alternative method is illustrated by examples below[9].



(1a) $R^1 = CH_3$; $R^2 = CN$ *(2a)* $R^3 = H$
(1b) $R^1 = R^2 = H$ *(2b)* $R^3 = I$

(3a) $R^1 = CH_3$; $R^2 = CN$ *(4a)* $R^1 = CH_3$; $R^2 = CN$
(3b) $R^1 = R^2 = H$ *(4b)* $R^1 = R^2 = H$

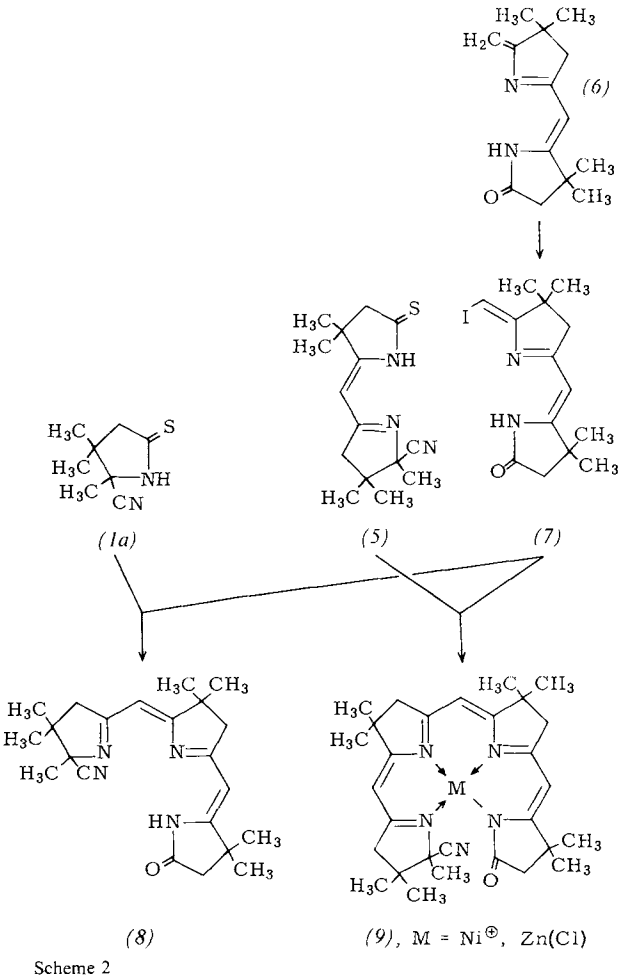
(1a) + *(2a)* $\xrightarrow{A(90\%)}$ *(3a)* $\xrightarrow{C(90\%)}$ *(4a)*
(1b) + *(2a)* $\xrightarrow{A(0\%)}$ *(3b)*
(1a) + *(2b)* $\xrightarrow{B(88\%)}$ *(3a)*
(1b) + *(2b)* $\xrightarrow{B(60\%)}$ *(3b)* $\xrightarrow{C(92\%)}$ *(4b)*

Scheme 1. Method A: 1.0 mol of *(1a)* or *(1b)* + 1.5 mol of *(2a)* + 1.1 mol of dibenzoyl peroxide in benzene; *ca.* 20 C; 24 h [2, 11]. Method B: 1.0 mol of *(1a)* or *(1b)* + 1.0 mol of *(2b)* + 2.0 mol of K *tert*-butoxide in $(CH_3)_3COH$/benzene; *ca.* 20 C; 3 or 15 h, respectively [12]. C: Excess of $(C_2H_5O)_3P$ in xylene; 130 C; 20 h [2, 11, 12].

Whereas oxidative coupling of 4,4-dimethyl-5-methylene-2-pyrrolidone *(2a)*[10] with 5-cyano-4,4,5-trimethyl-2-thiopyrrolidone *(1a)* with dibenzoyl peroxide (method A, Scheme 1) gives the thioether *(3a)* in excellent yield, this method fails on attempted coupling of *(2a)* with the unsubstituted 2-thiopyrrolidone *(1b)*. The cause of this failure is undoubtedly the (experimentally demonstrated) extreme lability of the unsubstituted bisimidoyl disulfide[2] that is derived from thiopyrrolidone *(1b)*, which would have to act as mediator for the coupling reaction; the substituted analog from *(1a)*, namely *(12)*, is much more stable[2].

The alternative procedure B (see Scheme 1) is successful in both these cases. Here, 5-(iodomethylene)-4,4-dimethyl-2-pyrrolidone *(2b)* [prepared from the enamide *(2a)* by iodination][13] is treated with the thiopyrrolidone reactant *(1)* in the presence of a strong base, bringing about the (formal) displacement of the vinylically bound iodine by the thiolactam-sulfur. The bromo derivative undergoes this replacement reaction only to a very limited extent. The contraction to the "semicorrinoid" system *(4b)* occurs in excellent yield when *(3b)* is heated in presence of triethyl phosphite, as in the case *(3a)* → *(4a)* described previously[2]. The new compound *(4b)* is an intermediate in the synthesis of a 1-hydroxycorrin derivative[14].

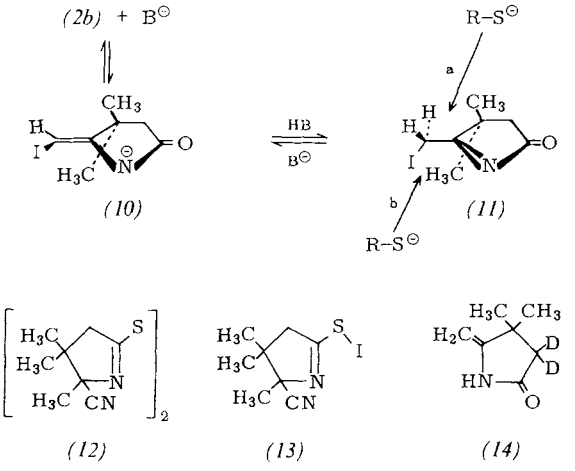
[*] A completely different method for the construction of corrinoid chromophoric systems has been described recently by *G. Traverso et al.* [5] and by *R. V. Stevens et al.* [6]. For *A. W. Johnson*'s route to corrin complexes see [7].



Scheme 2

The wide applicability and superiority of the new procedure is further illustrated by the examples shown in Scheme 2. The base-induced coupling of the bicyclic iodoenamide *(7)*[15] with the thiopyrrolidone derivative *(1a)* by method B occurs in 70% yield[12]; the contraction of the product to the tricyclic system *(8)* has been described previously[2]. Finally the procedure provides a simple synthesis of more complicated *seco*-corrinoid systems such as the tetracyclic complexes *(9)*. Coupling the bicyclic reactants *(5)* and *(7)* in acetonitrile at room temperature in the presence of 1,5-diazabicyclo[5.4.0]undec-5-ene proceeds in 64% yield[16]; in this case, the subsequent contraction to *(9)* with triphenylphosphane is clearly assisted by complexation, for it occurs remarkably readily in the presence of nickel or zinc perchlorate (50 C; 2 h; spectroscopic yields 76 and 83%; isolated 63 and 65%, respectively[12]). The complex *(9)* is of interest with regard to the synthesis of metal-free corphin derivatives[17].

The reaction mechanism for this base-induced coupling of thiolactam derivatives with iodinated enamide systems is as complex as its preparative realization is simple. The course of the reaction envisaged originally as a working hypothesis was initial base-induced tautomeric equilibration *(2b)* ⇌ *(10)* ⇌ *(11)* (see Scheme 3) of the iodoenamide, followed by rapid trapping of the unstable isomer *(11)* in an S_N2 reaction by the thiolactam-sulfur at the iodomethyl-carbon atom (path a[1-4]). However, in the case of the change *(1a)* + *(2b)* → *(3a)* this route contributes only very little, if at all, to product formation. Following the course of the reaction by NMR spectroscopy disclosed that in the initial phase of the reaction small amounts (*ca.* 10 mol-%) of the bisimidoyl disulfide *(12)* and of



Scheme 3

the iodine-free enamide *(2a)* are rapidly formed; the concentration of the latter remains stationary, but *(12)* disappears again towards the end of the reaction. Experiments with equimolar amounts of the components *(1a)*, *(2b)*, and dideuterioenamide *(14)* led to incorporation of up to 50% of the deuterated enamide in the product *(3a)*[18]. In the absence of the reactant *(1a)* the iodoenamide *(2b)* is effectively stable under the reaction conditions, but it is almost completely deuterated at the vinyl position under similar conditions in the presence of *O*-deuterio-*tert*-butyl alcohol. Treating the iodoenamide *(2b)* with two equivalents of the thiolactam *(1a)* in benzene containing one equivalent of 1,4-diazabicyclo[2.2.2]octane at room temperature for 8 h gives none of the coupling product *(3a)* but, instead, a 79% yield of the disulfide *(12)* along with the enamide *(2a)*.

These observations support the view that the iodoenamide tautomer *(11)* undergoes mainly a *reductive* displacement of iodine (path b) and that formation of the coupling product *(3a)* occurs chiefly by reaction of the deprotonated enamide *(2a)* with the oxidation products *(13)* and/or *(12)* of the thiolactam. However, this mechanism of thiolactam-iodoenamide coupling must be very sensitive to reaction conditions and structural features; this is shown by the finding that reaction of the bicyclic iodoenamide *(7)* with the thiopyrrolidone derivative *(1a)* in the presence of one equivalent of the enamide *(2a)* and 3 equivalents of potassium *tert*-butoxide affords only the tricyclic coupling product *(8)* (62%) and *none* of the bicyclic product *(3a)*. Since it is known from a control experiment that under such conditions the monocyclic enamide *(2a)* is much more reactive than the bicyclic iodine-free enamide *(6)* towards the disulfide *(12)*[2], it must be concluded that the disulfide *(12)* does *not* act as coupling mediator in the reaction *(1a)* + *(7)* → *(8)* (Scheme 2), although it appears to do so in process *(1a)* + *(2b)* → *(3a)* (Scheme 1). It remains undecided whether, among other possibilities, the former reaction proceeds by the alternative path a (Scheme 3) or whether initial displacement *via* path b is followed by direct coupling of species *(13)*.

c	H	H	CH_3	H	Zn(Cl) [4b]
d	$COOCH_3$	H	H	CN	Cd(Cl) [4c]

Our experience with this photochemical ring-closure indicates that it has considerable preparative scope; in the series of methyl-substituted corrin systems the reaction has so far been successful in the cases *a–d* summarized in Scheme 1[1,2,4]. The recent variation[5] in the synthesis of corrinoid chromophore systems has now made it possible to examine the question[6] whether this ring closure also occurs if the secocorrinoid reactant contains a carbonyl double bond instead of the exocyclic methylene double bond on ring A [cf. *(1)*]. The synthesis of *rac.*-1-hydroxy-3,3,8,8,13,13-hexamethylcorrin-chlorozinc complex *(6)* outlined in Scheme 2 provides the answer to this question.

Under comparable conditions of irradiation, cycloisomerization of the 1-oxo-A/D-secocorrin complex *(5)* is distinctly

Scheme 2. Spectroscopic data for *(3)*, *(4)*, *(5)*, and *(6)*. Data are arranged in the order: λ_{max} (ε in brackets; selected bands from the IR spectra; signals of the proton resonance spectrum (δ values referred to δ(TMS) = 0 ppm); selected signals from the mass spectrum. The compounds formulated were isolated in crystalline form, homogeneous on thin-layer chromatography, and gave correct analytical data. Detailed directions are available in [7].

slower than that of the 1-methylene analogs *(1a)* (M = ZnCl) and *(1c)*. Here, as in comparable cases, rigorous exclusion of air is a prerequisite for the success of this cycloisomerization (yield up to 89%); oxygen inhibits the photocyclization of secocorrinoid zinc complexes very effectively[2] and also affects the product (presumably by oxidation)[10].

Assignment of constitution to the irradiation product *(6)* is based on the characteristic spectral changes (UV/VIS, IR, ^{1}H-NMR, and MS) in going from the educt to the product, and on the significant correspondence of spectroscopic data for the product with those of known corrin complexes of analogous structure, especially *(2c)*. When compared with that of the educt the electronic spectrum of *(6)* shows the expected hypsochromic shifts, and corresponds to the spectrum of the chlorozinc-corrin complex *(2c)* with respect to both position and structure of the absorption bands[11]. The IR spectrum shows an absorption in the $\tilde{\nu}$(OH) region[12] and lacks the carbonyl band of the educt; the absorption pattern in the structure-sensitive chromophore stretching region between 1650 and 1480 cm^{-1} agrees with that in the spectrum of complex *(2c)*[11]. A tripletoid one-proton signal at 3.65 ppm in the ^{1}H-NMR spectrum of *(6)* reveals the presence of the tertiary CH group created by the ring closure; the spectrum also shows an OH singlet at 3.98 ppm identified by deuterium exchange. Finally the structural change *(5)* → *(6)* is also reflected in the expected manner in the mass spectra of the two compounds (cf. Scheme 2).

The configuration of the linkage between rings A and D in *(6)* is assumed to be *anti* in analogy with the known steric outcome of the reactions *(1)* → *(2)*; the close correspondence of the UV/VIS and IR spectroscopic data of *(6)* and *(2c)* supports this assignment. However, further studies are needed to decide whether the light-induced ring closure *(5)*—*(6)* is a simple oxa analog of the reaction type *(1)*—*(2)*, not only from a constitutional, but also from a mechanistic point of view.

Metal-Free Derivatives of the Corphin Ligand System[**]

By *Peter M. Müller, Saleem Farooq, Bruno Hardegger, William S. Salmond*, and *Albert Eschenmoser*[*]

Metal-free derivatives of the corrin ligand system can be obtained from corrin complexes containing metal ions such as those of zinc, cadmium, or magnesium that are easily displaced by acidolysis[1]. However, there is still no method of removing transition-metal ions such as those of nickel, cobalt, palladium or platinum from their robust complexes with the corrin ligand without destruction of the latter. The same is true for the corresponding derivatives of the corphin ligand system[3], where the first member was obtained as a palladium complex[2]. We report here a process by which metal-free derivatives of this corrinoid-porphinoid structural type now become accessible[4].

The complexes *(1a)* and *(1b)* can be readily prepared by the iodoenamide-thiolactam coupling procedure (cf. Scheme 1)[5]. The cyanide protecting group can be removed in high yield from the nickel complex *(1a)* by treatment with potassium *tert*-butoxide to give the precorphinoid complex *(2a)*. Under carefully controlled conditions the nickel in *(2a)* can be replaced by zinc through treatment with potassium cyanide and, immediately thereafter, complexing with zinc perchlorate; the unstable zinc complex *(2b)* is not isolated in pure form but can be cyclized directly to the chlorozinc-corphin complex *(3a)* by alkylation with triethyloxonium tetrafluoroborate in the presence of ethyldiisopropylamine. A more direct sequence, that of decyanidation → cyclization starting from the cyanide-protected zinc complex *(1b)* is also feasible, but this formally shorter route proved preparatively delicate and less reliable[4].

The precorphinoid palladium complex *(2c)* has been described previously in connection with the original synthesis of the palladium-corphin complex *(3c)*[2]. The transcomplexation-cyclization step *(2)* → *(3)* proved just as successful with this palladium complex *(2c)* as with the corresponding nickel derivative; thus the chlorozinc complex *(3a)* can now be obtained in two ways. The two routes differ, however, in that the old one is limited to the synthesis of corphin derivatives of centrosymmetric structure, *e.g.* *(3)*[6], whereas the route involving iodoenamide-thiolactam coupling can in principle also serve for the synthesis of corphin ligands with asymmetrical structure.

The chlorozinc-corphin complex *(3a)* is recovered almost unchanged under the mild conditions that suffice to decomplex the corresponding corrin complexes (trifluoroacetic acid in acetonitrile). However, acidolytic decomplexation can be smoothly effected with concentrated hydrochloric acid at room temperature. The corphinium ion *(4)* can be isolated as chloride, bromide, or perchlorate in crystalline form. The structure assigned to it is best illustrated by the proton resonance spectrum, in which four proton types are evident as singlets in the intensity ratio 2:5:6:24. On forward titration with tetramethylammonium hydroxide in methylcellosolve-water (4:1 w/w) the corphinium ion *(4)* shows an apparent pK_{MCS} value

Scheme 1. Properties of compounds of types *(1)*, *(2)*, *(3)*, *(4)*, and *(5)*. Spectroscopic data in the following order: λ_{max} (ε in brackets); selected bands from the IR spectra; signals from the proton resonance spectrum (δ values referred to δ(TMS) = 0 ppm); selected signals from the mass spectra. Except for *(2b)* and *(5)*, all the compounds formulated were obtained in homogeneous crystalline form and gave correct analytical values. Detailed description of the experiments can be found in [4].

of *ca.* 7.3, approximately comparable with that of a carboxylic acid[8]. Treatment of *(4a)* with nickel acetate in boiling acetonitrile gives the nickel complex *(3b)*, isolated as its crystalline perchlorate; with cobalt(II) chloride[9] in the presence of sodium acetate in methanol at 50 °C, the dicyanocobalt(III)-corphin complex *(3d)* can easily be obtained following work up with cyanide in contact with air[10].

The complexes *(3a)* and *(3c)*, as well as the metal-free corphinium ion *(4)*, exist in trifluoroacetic acid as derivatives of the more highly symmetrical (*trans-cis*)$_4$-1,5,9,13-tetraaza[16]annulene system *(5)*; in trifluoroacetic acid their proton resonance spectra are reduced to three singlets[11] and the corresponding electronic spectra show unambiguously the presence of a non-corrinoid chromophore in this solvent [cf. data for *(5)* in Scheme 1]. The signals of the vinyl and methylene protons of the *doubly* positively charged tetraazaannulene system *(5)* are at distinctly *higher* field than the corresponding groups of signals from the *singly* positively charged corphinium ion *(4)*[12]; the interpretation of this shift as an effect of a paramagnetic ring current[13] in the pericyclically conjugated $4n$-π-system *(5)* constitutes specific support for the structural assignment.

New experimental findings[14] concerning the biosynthesis of vitamin B_{12} have caused us to lose confidence in a hypothesis we have cherished for a number of years, namely, that the corphin ligand system might play a role in the biosynthesis of naturally occurring corrinoids[2]. Fortunately, however, the compounds of type *(5)* merit interest as the porphinoid representatives of the heteroanalogs of carbocyclic annulenes[15].

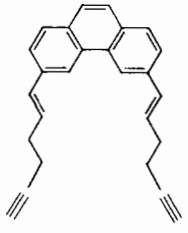
Z 898.1

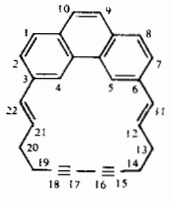
Fig. 1. Comparison of the ^{1}H-NMR spectra of *(4)* and *(2)*.

(2), in which the annulene conjugation competes with only *one* benzenoid phenanthrene unit.

For the synthesis of *(2)*, 3,6-dimethylphenanthrene was prepared from 4,4'-dimethyl-*trans*-stilbene (Hg high-pressure lamp, 0.01 M solution in 5:1 cyclohexane/benzene; iodine; 61% yield) or from 2-(4'-methylphenethyl)magnesium bromide and 4-methylcyclohexanone *via* 4-methyl-1-(4'-methylphenethyl)cyclohexanol[4] and 1,2,3,4,4a,9,10,10a-octahydro-3,6-dimethylphenanthrene (overall yield 25%). Successive conversion into 3,6-bis(bromomethyl)phenanthrene[4] (NBS/CCl_4, 57% yield) and 3,6-bis(triphenylphosphoniomethyl)phenanthrene dibromide[4] (triphenylphosphane/acetonitrile, 80% yield), and a double Wittig reaction with 4-pentynal[5] afforded 3,6-bis(1-hexen-5-ynyl)phenanthrene *(3)* (45% yield)[4], which was cyclized in 50% yield to the 18-membered ring system *(4)*[4] by copper(II) acetate in dimethylformamide. Isomerization with potassium *tert*-butoxide in *tert*-butyl alcohol/benzene finally yielded *(2)*[4] as red crystals (from cyclohexane; dec. above 200 °C; 48% yield).



(3)



(4)

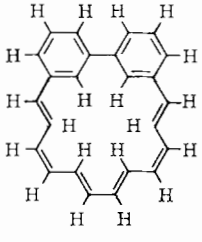
The ^{1}H-NMR spectrum of *(2)* contains the following absorptions (220 MHz, CS_2)[6]: $\tau = 1.87$ and 2.15 (AB system, $J_{AB} = 8$ Hz, 1-H, 8-H and 2-H, 7-H), 1.94 (s, 9-H, 10-H), 2.57 (d, $J = 16$ Hz, 11-H, 22-H), 2.87—3.09 (m, 6 external H), 3.21 (br. s, 4-H, 5-H), 4.50 (~dd, $J_1 = 16$ Hz, $J_2 \approx 10$ Hz, 12-H, 21-H), 4.78 (m, 15-H, 18-H).

This spectrum is remarkable for the following reasons: The signals cannot be divided between "aromatic" and "olefinic" protons; instead, the signals of all the inner protons are shifted to higher field strength and those of the external protons are shifted to lower field strength. This observation, which indicates a diamagnetic ring current in the macrocyclic system, is particularly clearly shown when a comparison is made with the corresponding ^{1}H-NMR absorptions of the precursor *(4)* that is not cyclically conjugated (see Fig. 1)[7].

The opposite shifts of the signals of the neighboring proton pairs 11-H, 22-H and 12-H, 21-H in, respectively, the α- and the β-positions to the phenanthrene unit are striking; even more so is the large shift of the signals of 4-H, 5-H to higher field strength beyond those of all the external protons, including those of the "olefinic" part of the molecule, whereas in phenanthrenes, including the macrocyclic *(1)*[2], it is precisely these protons that normally absorb at lowest field strength.

Because of the importance of this finding the assignment of the two 2H singlets at $\tau = 1.94$ and 3.21 to 9-H, 10-H and 4-H, 5-H, respectively, was checked by synthesis of a molecule *(2)* deuteriated at the 9,10-positions: 4,4'-dimethyltolane was catalytically ($Pd/BaSO_4$ + pyridine, ethyl acetate) deuteriated to α,β-dideuteriostilbene; photochemical cyclodehydrogenation afforded 9,10-dideuterio-3,6-dimethylphenanthrene, which was converted by the reaction series given above into a species *(2)* selectively deuteriated at positions 9 and 10. With this compound the signal at $\tau = 1.94$ did not occur; the signal at $\tau = 3.21$ can therefore be assigned unequivocally to 4-H, 5-H.

Dibenzo[*ab*,*de*]cyclooctadecene *(5)* differs from *(2)* in that the *m*-linkage of the benzene rings prevents complete cyclic conjugation around the macrocyclic system. The synthesis of *(5)* from 3,3'-dimethylbiphenyl *via* 3,3'-bis(1-hexen-5-ynyl)biphenyl was effected analogously to that of *(2)*. *(5)*[4] formed dark red crystals (m. p. 160 °C, dec.) that are extremely sensitive to air. Its ^{1}H-NMR spectrum (CS_2, 100 MHz) is in accordance with an aromatic and an olefinic part in the molecule. In particular, with *(5)* the absorption of the two inner aromatic protons, which correspond to 4-H, 5-H in *(2)*, occurs at the lowest field strength ($\tau = 1.56$). Since the geometrical relations within the 18-membered rings of *(2)* and *(5)* are similar, it must thence be concluded



(5)

[1] Conjugation in Macrocyclic Bonding Systems, Part 21.—Part 20: *H. A. Staab, F. Graf, K. Doerner* and *A. Nissen*, Chem. Ber. *104*, 1159 (1971).

[2] *H. A. Staab, H. Bräunling*, and *K. Schneider*, Chem. Ber. *101*, 879 (1968).

[3] For ease of discussion of their ^{1}H-NMR spectra the C atoms of the phenanthrene portions of *(2)* and *(4)* are numbered as is usual in phenanthrenes.

[4] Correct elemental analyses and molecular weights were obtained for these compounds; the spectroscopic data accord with the structures assumed.

[5] *F. Bohlmann* and *R. Miethe*, Chem. Ber. *100*, 3861 (1967).

[6] We thank Dr. *W. Brügel*, BASF Ludwigshafen, for recording this spectrum.

[7] In this comparison it must, nevertheless, be remembered that in *(4)*, 12-H,21-H and, to a smaller extent, also 4-H, 5-H are under the deshielding influence of the anisotropy of the diacetylene group, although this shifts these signals by no more than 0.5 ppm to lower field strength, as shown by the comparison with the spectrum of *(3)*.

that the strong shielding of 4-H, 5-H in *(2)* cannot be the result of local anisotropic effects of the double bonds. If the induction of a diamagnetic ring current is taken as the criterion of aromaticity, it follows that the macrocyclic system in *(2)*, unlike those in *(1)* and *(5)*, exhibits annulenoid aromaticity. Comparison with the very much stronger shielding of the inner protons in the monocyclic [18]annulene shows, however, that the annulene character of *(2)* is substantially weakened by fusion with the phenanthrene system and that there is here a borderline case between benzenoid and non-benzenoid aromaticity.

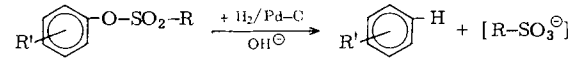
Hydrogenative Removal of Phenolic Hydroxyl Groups

By *Karl Clauss* and *Harald Jensen*[*]

Dedicated to Professor Werner Schultheis on his 70th birthday

The hetero ring of 1,2,3-benzoxathiazin-4(3*H*)-one 2,2-dioxide opens between oxygen and carbon on catalytic hydrogenation with palladium-charcoal in the presence of an equivalent amount of base[1]. Application of this finding to aryl sulfonates *(1)* showed that phenolic hydroxyl groups in general, in the form of their sulfonic esters, can be removed by catalytic hydrogenation at 20—40 °C and atmospheric pressure.



(1)

Bases such as sodium hydroxide solution, alkali-metal alkoxides or tertiary amines accelerate the reaction appreciably, equivalent amounts of the base favoring smooth reaction. Suitable solvents are water and, in particular, methanol. It is advisable to choose a temperature between 20 and 40 °C so as to prevent over-hydrogenation. Palladium on charcoal is a suitable catalyst; platinum and nickel catalysts do not have comparable activity. Contrary to the case of the known fission of aryl sulfonates by an excess of Raney nickel[2–5], catalytic amounts of palladium suffice in our reaction (1.0—1.5 mg of Pd per mmol of ester).

Examples of this hydrogenolysis are collected in Tables 1—3.

Chloro substituents are removed by the hydrogenation, so that a correspondingly larger amount of base must be added to bind the liberated hydrogen chloride. Groups such as formyl, susceptible to hydrogenation, are hydrogenated, so that the otherwise difficultly accessible 3-methoxybenzyl alcohol can be obtained from vanillin in this way.

Table 1. Hydrogenative cleavage of phenyl esters C_6H_5—O—SO_2R to benzene (palladium-charcoal as catalyst).

R	Solvent	Base	Yield [%]
H_2N	H_2O	NaOH	50
H_2N	CH_3OH	CH_3ONa	65
CH_3	CH_3OH	CH_3ONa	75
CH_3	CH_3OH	Et_3N	82
CH_3O—CONH	CH_3OH	CH_3ONa	90
C_6H_5—CONH [a]	H_2O	NaOH	70

[a] The chloride of this acid was synthesized from benzoic acid and chlorosulfonyl isocyanate according to [6].

Table 2. Hydrogenative cleavage of aryl methanesulfonates (palladium-charcoal in methanol, triethylamine as base).

Aryl	Product	Yield [%]
1-Naphthyl	Naphthalene	72
2-Naphthyl	Naphthalene	91
3-Methoxyphenyl	Anisole	65
4-Methoxyphenyl	Anisole	72
3-Chlorophenyl	Benzene	90
4-Chlorophenyl	Benzene	85
4-Formyl-2-methoxyphenyl	3-Methoxybenzyl alcohol	70

Table 3. Hydrogenative cleavage of aryl *N*-(methoxycarbonyl)amidosulfates [a] to benzene (palladium-charcoal in methanol, sodium methoxide as base).

Aryl	H_2 [mol]	Base [mol]	Yield [%]
Phenyl	1	1	90
4-Chlorophenyl	2	2	82
2,4,6-Trichlorophenyl	4	4	55

[a] Prepared by addition of methanol to aryloxysulfonyl isocyanates [7].

Experimental:

The phenol is esterified with methanesulfonyl chloride in the presence of the equivalent amount of pyridine at 20 to 60 °C. For the hydrogenation, this aryl sulfonate (60 mmol) in methanol (100 ml) is stirred with triethylamine (60 mmol) and 1.5 g of catalyst (containing 5 % palladium on charcoal) under hydrogen at 25—40 °C until the calculated amount of hydrogen has been consumed. The catalyst is filtered off and the cleavage product is isolated (benzene was not isolated but was determined by gas chromatography).

Simple Synthesis of Carbonyl Chloride Fluoride and Carbonyl Bromide Fluoride

By *Günter Siegemund*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

The methods reported previously for preparation of carbonyl chloride fluoride and carbonyl bromide fluoride

[*] Dr. K. Clauss and Dr. H. Jensen
Farbwerke Hoechst AG,
vormals Meister Lucius & Brüning
623 Frankfurt/Main (Germany)

[*] Dr. G. Siegemund
Farbwerke Hoechst AG
623 Frankfurt 80, Postfach 800320 (Germany)

require use of halogen fluorides or hydrogen fluoride or, in the latter case, application of pressure. In addition, these syntheses[1-3] lead to mixtures of carbonyl halide fluorides of various compositions.

We have found that the catalyzed reaction of carbon tetrachloride with sulfur trioxide[4], leading to phosgene, can be applied also to chlorofluoro- and bromofluoromethane, thus providing a convenient route to COFCl and COFBr requiring only the use of conventional glass apparatus.

Reaction of SO_3 with trichlorofluoromethane in the presence of mercury salts or sulfuric acid, even at room temperature, affords only carbonyl chloride fluoride and sulfuryl chloride or polysulfuric chlorides.

$$CFCl_3 + SO_3 \xrightarrow[\text{or } H_2SO_4]{Hg^{I}/Hg^{II}} COFCl + ClSO_2(SO_3)_nCl$$

The COFCl contains as only impurity the $CFCl_3$ that is carried over with it, and the two are readily separated by distillation.

Tribromofluoromethane[5] and SO_2 afford carbonyl bromide fluoride, sulfur dioxide and bromine in a homogeneous reaction in the absence of catalysts.

$$CFBr_3 + SO_3 \rightarrow COFBr + SO_2 + Br_2$$

Here too COF_2 cannot be detected on gas chromatography. Of the by-products, bromine can be removed by addition to trichloroethylene, and sulfur dioxide by a wasteful distillation although it is rarely a disturbing ingredient.

Carbonyl difluoride can also be prepared by this method, namely by treating CF_2Br_2 with SO_3.

Carbonyl chloride fluoride:

65% oleum (600 g) is placed in a 1-l three-necked flask fitted with a thermometer, dropping funnel whose tube dips into the liquid, and two Dimroth condensers one above the other (+10 °C, −30 °C), and to it $CFCl_3$ (275 g, 2 mol) is added at 28—34 °C during 5 h. The gas evolved is passed through a condenser and a H_2SO_4 wash bottle into a cold trap (−78 °C), where a mixture (138 g; CO_2 3%, $CFCl_3$ 23%, COFCl 74% ≙ 60% yield) condenses. SO_3 (470 g, 5.87 mol) containing 1 g each of Hg_2SO_4 and $HgSO_4$ was treated in a similar apparatus with $CFCl_3$ (227 g, 1.66 mol) during 3 h, the temperature rising to 61 °C. The product condensed in the cold trap (142 g) was fractionated by distillation at a low temperature [yield 114 g ≙ 83% of COFCL, b. p. −45° to −40 °C ([1]: −42 °C]).

Carbonyl bromide fluoride:

SO_3 (200 g, 2.5 mol) was placed in a 500-ml three-necked flask fitted with a thermometer, dropping funnel, magnetic stirrer and two condensers one above the other (+10 °C, 0 °C) and was treated with $CFBr_3$ (135 g, 0.5 mol) during 2 h at 37—43 °C. To remove the bromine, the product was passed, before condensation, through a wash bottle containing $CHCl{=}CCl_2$ irradiated by UV light. The trap content (80 g) afforded a mixture (60 g), b. p. −17.5 to −10 °C, of CO_2 3%, SO_2 29.5% and COFBr 67.5% ≈ 64% yield.

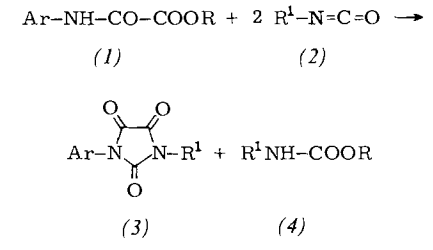
Reactions of *N*-Aryloxamidic Esters with Isocyanates[1]

By *Kurt Kraft* and *Johannes Reese*[*]

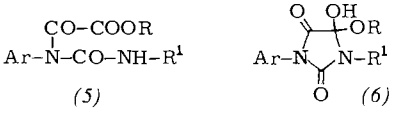
Dedicated to Professor Werner Schultheis on his 70th birthday

We have obtained the 1,3-disubstituted 2,4,5-imidazolidinetriones *(3)* by base-catalyzed reaction of *N*-aryloxamidic esters *(1)* (R = CH_3, C_2H_5 or C_4H_9) with isocyanates *(2)*. Triethylamine, tributylamine and 1,4-diazabicyclo-[2.2.2]octane are particularly good catalysts. The alcohol



(1) *(2)* *(3)* *(4)*

ROH liberated reacts with the isocyanate to give the urethane *(4)*. The expected urea derivatives *(5)* could not be detected even after reaction under the mildest conditions, and this indicates formation of semiacetals *(6)* as unstable intermediates.



(5) *(6)*

Table 1. 1,3-Disubstituted 2,4,5-imidazolidinetriones *(3)*.

Ar	R^1	M.p. [°C]	Yield [%]
C_6H_5	n-C_8H_{17}	67	65
4-C_6H_5—N=N—C_6H_4	n-C_8H_{17}	152	68
C_6H_5	c-C_6H_{11}	149	67
4-NO_2—C_6H_4	C_6H_5	209	72
4-CH_3O—C_6H_4	C_6H_5	136	78
3-Cl—C_6H_4	C_6H_5	183	84
3-CF_3—C_6H_4	C_6H_5	193	69
4-C_6H_5—N=N—C_6H_4	C_6H_5	200	98
2-Pyridyl	C_6H_5	163	91
4-$(CH_3)_2N$—C_6H_4	3-Cl—C_6H_4	124	95
4-Cl—C_6H_4	3-Cl—C_6H_4	224	89
4-CH_3CO—C_6H_4	3-Cl—C_6H_4	212	67
9,10-Dioxo-9,10-dihydro-2-anthryl	3-Cl—C_6H_4	269	96
4-CH_3SO_2-3-Cl—C_6H_3	4-Cl—C_6H_4	251	96
1-Naphthyl	4-Cl—C_6H_4	248	81
3-CF_3—C_6H_4	3,4-Cl_2—C_6H_3	231	89

[*] K. Kraft and Dr. J. Reese
Reichhold-Albert-Chemie AG, Forschungsabteilung Kunstharze
6202 Wiesbaden-Biebrich, Postfach 9101 (Germany)

The substituents on *(3)* can be varied over a wide range (Table 1). Reactive isocyanates afford *(3)* in an exothermic reaction even at 10—20 °C. *N*-Alkyl- and *N*-cycloalkyloxamidic esters do not afford compounds *(3)* under the conditions described.

If the reactants and solvents are chosen suitably the compounds *(3)* and *(4)* can be separated without difficulty. The possible choice of reactants is increased because compounds *(3)* with aromatic R^1 can be formed either from ArNH—CO—COOR and R^1NCO or from R^1NH—CO—COOR and ArNCO. When R^1 is aliphatic or cycloaliphatic, separation is easy because of large differences in the solubility of *(3)* and *(4)*.

Table 2. Bis(3-aryl-2,4,5-trioxo-1-imidazolidinyl)arenes *(7a)* and *(7b)*.

Ar	—R^2— [a]	R^3	M.p. [°C]	Yield [%]

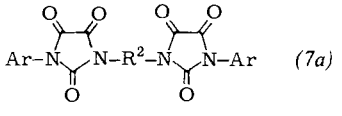
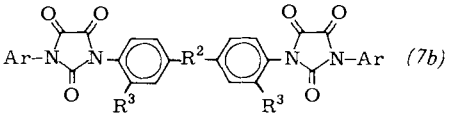
2-Cl—C_6H_4	—CH_2—	H	256	65
3,4-Cl_2—C_6H_3	—O—	H	295—297	92

[a] Dashes (—) in this column denote valence bonds; the compounds are biphenyl derivatives.



(7a)



(7b)

The hitherto unknown compounds *(7)* with two 2,4,5-imidazolidinetrione rings can be synthesized by the same method (Table 2)[1]. This class of compound is characterized by high melting points and low solubility. Their preparation is particularly easy in dimethylformamide, dimethylacetamide or 1-methylpyrrolidone. Poly-2,4,5-imidazolidinetriones can be obtained by treating diisocyanates with *N,N'*-arylenedioxamidic esters[2] and are characterized by high thermal stability, elasticity and surface hardness.

1,3-Diphenyl-2,4,5-imidazolidinetrione:

Ethyl *N*-phenyloxamidate (193 g, 1 mol) and phenyl isocyanate (238 g, 2 mol) in anhydrous benzene (1000 ml) are stirred together at 25 °C and treated with triethylamine (3 ml) with good cooling. The temperature rises to about 50 °C. After boiling for 1 h under reflux the mixture is diluted with light petroleum (700 ml) and cooled to 15 °C. The crystalline product is filtered off, washed with ligroin and dried at 100 °C in a vacuum: yield 231 g (87 %); m.p. 204 °C ([3]: 204 °C). Only ethyl phenylcarbamidate (m.p. 52 °C) and further amounts of the trioxo compound can be isolated from the mother liquors. Both compounds were identified by mixed melting points and IR spectra.

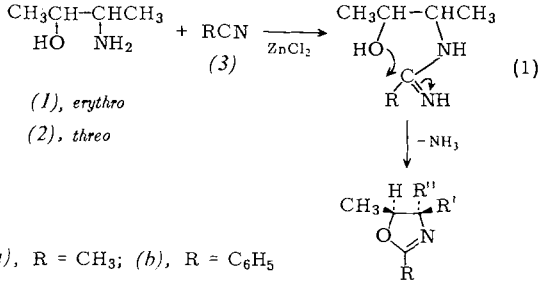
Stereochemistry of the 2-Oxazoline Synthesis from β-Amino Alcohols and Nitriles

By *Ronald A. Wohl*[*]

Witte and *Seeliger* recently reported a convenient synthesis of 2-oxazolines from β-amino alcohols and nitriles in the presence of a Lewis acid catalyst such as zinc acetate or zinc chloride[1,2]. In connection with other work on 2-oxazolines[3] we were interested in establishing the stereochemistry of this reaction.

erythro-3-Amino-2-butanol *(1)* on reaction with acetonitrile or benzonitrile in the presence of $ZnCl_2$ gave the *cis*-2-oxazolines, *(4a)* and *(4b)*, exclusively. *threo*-3-Amino-2-butanol *(2)* similarly afforded the corresponding *trans*-2-oxazolines, *(5a)* and *(5b)*, exclusively. The purity of the products was established by IR and NMR spectra and GC analysis and based upon comparison with authentic samples[3]. In agreement with the observed retention of configuration, the mechanism of the above reaction therefore may be formulated as shown in eq. (1).



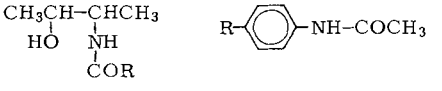
(1)

(1), erythro
(2), threo

(a), R = CH_3; *(b)*, R = C_6H_5

(4), R' = CH_3, R'' = H
(5), R' = H, R'' = CH_3

We attempted to substitute amides for the nitriles: *threo*-3-amino-2-butanol *(2)* on reaction with acetamide or benzamide in the presence of 0.04 eq. of $ZnCl_2$ gave the corresponding *trans*-2-oxazolines, *(5a)* and *(5b)*, in good yield. The reaction here proceeds presumably *via* the intermediate amide *(6)*. *erythro*-3-Amino-2-butanol, on the other hand, under the above conditions did not give any of the *cis*-oxazolines *(4)*, but the reaction stopped at the amide stage *(6)*.



(6a), R = CH_3 *(7a)*, R = H
(6b), R = C_6H_5 *(7b)*, R = CH_3

[*] Dr. R. A. Wohl
School of Chemistry
Rutgers University
New Brunswick, N. J. 08903 (USA)

This discrepancy in the behavior of the *erythro* and *threo* amino alcohols, *(1)* and *(2)*, reflects the increased steric strain of ring closure to give the *cis*-2-oxazolines *(4)* which possess two vicinal eclipsed methyl groups. The widely different ease of cyclization of *N*-(2-hydroxyalkyl) amides to 2-oxazolines has been noted repeatedly[2].

Because $ZnCl_2$ seemed to catalyze the *N*-acylation of the starting amino alcohols *(1)* and *(2)* with acetamide to give *(6a)* we investigated the reactions of aniline and *p*-toluidine with acetamide to yield the corresponding amides *(7a)* and *(7b)* and ammonia. $ZnCl_2$ showed a pronounced catalytic effect in this reaction, *i.e.* acetamide is a much superior acetylating reagent in the presence of $ZnCl_2$. BF_3 has been reported to have a similar effect[4].

Stereospecific Attack of Nucleophilic Reagents on Nitrooxirane Sugars

By *Satoru Kumazawa*, *Tohru Sakakibara*, *Rokuro Sudoh*, and *Toshio Nakagawa*[*]

Newman and *Angier*[1] succeeded in synthesizing nitrooxiranes (α-nitro epoxides) which enter into reaction with nucleophilic compounds. Shortly thereafter we[2] and also *Baer* and *Rank*[3] prepared some "nitrooxirane sugars". We have now found that reaction of the new sugar derivatives with nucleophiles is not only smooth but also highly stereospecific, involving denitration and fission of the epoxide ring, so that these derivatives should be useful intermediates.

Hydrogenation of methyl *(1a)* and phenyl 2,3-anhydro-4,6-*O*-benzylidene-3-*C*-nitro-β-D-allopyranoside *(1b)*[4] by $LiAlH_4$ (in THF, 2 h at room temperature) leads almost quantitatively to the 2-deoxyglucosides *(2a)* and *(2b)*, respectively[5], which were isolated and characterized as the 3-*O*-acetates *(3a)* [m.p. 141—142 °C (from ethanol); $[\alpha]_D = -69.3°$ ($CHCl_3$, $c = 1.00$); ^{1}H-NMR ($CDCl_3$): $\tau = 8.00$ (3H/s, equat. *O*-Ac[6]), $J_{2^a,3} = 11$ Hz, $J_{3,4} = 9$ Hz] and *(3b)* [m.p. 136—137 °C (from ethanol); $[\alpha]_D = -65.6°$ ($CHCl_3$, $c = 1.00$); ^{1}H-NMR ($CDCl_3$): $\tau = 7.96$ (3H/s, equat. *O*-Ac[6]), $J_{2^a,3} = 11$ Hz, $J_{3,4} = 9$ Hz]. After catalytic hydrogenation of *(1b)* over Pd/C or Raney Ni in ethyl acetate only the 3-deoxy-3-nitroglucoside *(14)*[4] was isolated (over 85% yield).

On treating *(1a)* with lithium bromide (monohydrate, excess in THF at room temperature) we obtained, in 75% yield, methyl 4,6-*O*-benzylidene-2-bromo-2-deoxy-β-D-*ribo*-3-hexulopyranoside *(4)* [m.p. 210—212 °C (dec.; from ethanol); $[\alpha]_D = -131°$ ($CHCl_3$, $c = 1.00$); ^{1}H-NMR (D_6-DMSO): $\tau = 5.15$ (d, 1-H), $J_{1,2} = 9$ Hz; IR (KBr): $\nu_{C=O} = 1728\ cm^{-1}$ (equat. α-bromo ketone[7])]. With lithium azide, *(1a)* gave the unstable 2-azide analog *(5)*, which, after hydrogenation with Pd/C in dioxane/acetic anhydride, was isolated and characterized as the 2-acetamide *(6)* [m.p. = 204—205 °C (dec.; from acetone/ethanol); $[\alpha]_D = -49.8°$ (DMSO, $c = 1.00$); ^{1}H-NMR (D_6-DMSO): $\tau = 5.28$ (d, 1-H), $J_{1,2} = 8.5$ Hz] in 83% yield based on *(1a)*.

An interesting result was that the phenyl analog *(1b)* with lithium bromide gave, not the corresponding 2-bromoglycoside, but only (77% yield) the 2-bromo compound *(11)* [m.p. = 174—175 °C (dec.; from ethanol); $[\alpha]_D = +213°$ ($CHCl_3$, $c = 1.00$); ^{1}H-NMR (D_6-DMSO): $\tau = 1.85$ (s, 1-H)] with β-elimination of phenol. The again unstable 2-azido compound *(12)* was obtained in over 76% yield by use of sodium azide; this could be characterized by hydrogenation to the 2-acetamide *(10)* [m.p. 242 °C (dec.; from ethanol); $[\alpha]_D = -55.5°$ (DMSO, $c = 1.00$); ^{1}H-NMR (D_6-DMSO); $\tau = 5.79$ (dd, 1^a-H) and 6.48 (dd, 1^e-H), $J_{1^a,1^e} = 10.5$ Hz, $J_{1^a,2} = 8$ Hz, $J_{1^e,2} = 2$ Hz].

On treating *(1a)* with concentrated methanolic ammonia we obtained the pentacyclic compound *(9)* in 78% yield

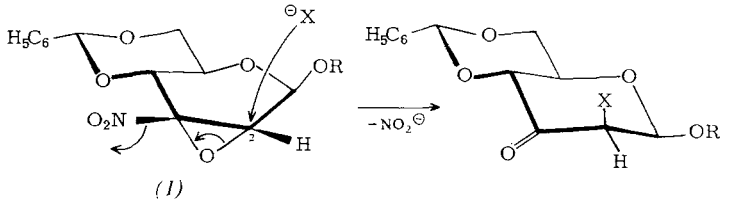
Prof. Dr. T. Nakagawa
Department of Chemistry, Yokohama City University,
Mutsuura-cho, Kanazawa-ku, Yokohama 236 (Japan)

[**] New address: Research Laboratory, Nippon Kayaku Co. Ltd., Tokyo 115 (Japan).

[m. p. = 248—250 °C (dec.; from methanol); $[\alpha]_D = -129°$ (DMSO, $c = 1.00$); ^{1}H-NMR (D_6-DMSO); $\tau = 4.13$ and 4.18 (s, 1-H + 1'-H and s, 2 α-benzyl-H, or *vice versa*); MS: 520 (M^+)]. The amino ketone *(8)* is probably first formed, being later aromatized by dimerization and air oxidation to yield *(9)*.

The first step in this nucleophilic denitration and ring opening of *(1a)* and *(1b)* can be interpreted as S_N2'-like attack by the nucleophiles H^-, D^-, Br^-, N_3^- and $:NH_3$ on C-2.

In the reaction with $LiAlH_4$ the ulose first formed is hydrogenated to the compound *(2)* having an equatorial hydroxyl group[8], this reaction course being proved by reduction of *(1b)* with $LiAlD_4$ and subsequent acetylation by acetic anhydride in pyridine to afford the homogeneous [2^a,3-D_2]-2-deoxyglucoside *(13)* in more than 75% yield; the [2^e,3-D_2]-epimer could not be detected by NMR spectroscopy.



(1)

(a), R = CH_3; *(b)*, R = C_6H_5

From the two following experiments it can be concluded that in the conversion of *(1a)* into *(4)* the attack of the bromide ion is not S_N1-like but S_N2'-like and that because of the Δ2-effect[9] the unstable 2^a-bromo ulose is at once isomerized irreversibly to the 2^e-bromo isomer *(4)*: 1. Treating *(1a)* with anhydrous lithium bromide in D_2O-THF afforded the 2^e-bromo-2^a-deuterio compound *(7)* as almost sole product. 2. *Only* the starting material *(4)* could be recovered from a solution of *(4)* in D_2O-THF containing lithium bromide and nitrite. It is probable that *(1a)* is converted into *(5)* analogously.

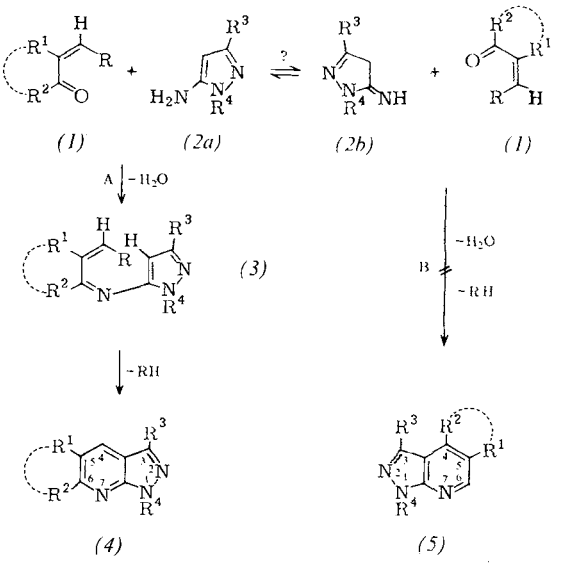
A New Variant for the Synthesis of 1*H*-Pyrazolo[3,4-*b*]pyridines[**]

By *Jochen Häufel* and *Eberhard Breitmaier*[*]

A generally applicable method for the synthesis of 1*H*-pyrazolo[3,4-*b*]pyridines *(4)* involves the cyclocondensation of 1,3-dicarbonyl compounds with 5-aminopyrazoles *(2)* in glacial acetic acid[1]. We have found that the 1,3-dicarbonyl compounds may be replaced by 2-(hydroxymethylene)cycloalkanones, 2-alkyl-3-alkoxy- or 2-alkyl-3-amino-acroleins *(1)*, R = OH, OR', or NH_2. Such condensations make it possible to prepare numerous 1*H*-pyrazolo[3,4-*b*]pyridines *(4)* that were not previously accessible (Table 1).



(1) *(2a)* *(2b)* *(1)*

(3)

(4) *(5)*

R = OH, OR', NH_2

Ring closure to *(4)* can occur in two ways (A and B), according to whether the 5-aminopyrazole reacts as the enamine *(2a)* or the imine *(2b)*. The decision between the two routes A and B can be made only with compounds *(1)* where $R^2 \neq H$.

Table 1. Examples of new 1*H*-pyrazolo[3,4-*b*]pyridines *(4)* [a].

R^1	R^2	R^3	R^4	Variant	Yield [%]	M. p. [°C] B. p. [°C/torr]

[a] Mass spectra, ^{13}C-NMR, ^{1}H-NMR and UV spectra of all the compounds accord with the structures assigned.

With 3-alkoxy-2-alkyl- or 2-alkyl-3-amino-acroleins *(1)*, R^1 = alkyl, R^2 = H, both routes lead to the same products. However, 2-(hydroxymethylene)cycloalkanones *(1)*, R = OH, $R^1-R^2 = -(CH_2)_n-$, would yield the 5,6-cycloalkeno compound *(4)* by route A or the 4,5-cycloalkeno isomer *(5)* by route B. In fact, the reaction proceeds by route A as can be shown both chemically and spectroscopically. In the absence of glacial acetic acid the 2-(hydroxymethylene)cycloalkanones *(1)*, $R^1-R^2 = -(CH_2)_n-$, react to give isolable Schiff bases *(3)*, whose structure can be proved by their mass, IR and ^{1}H- and ^{13}C-NMR

spectra. If these products *(3)* are heated in glacial acetic acid, they afford 5,6-cycloalkeno-1*H*-pyrazolo[3,4-*b*]pyridines *(4)* whose structures follow especially from their ^{13}C chemical shifts and the $^{13}C—^{1}H$ coupling constants of the carbon atoms of the pyridine ring: the unsubstituted carbon atom C-4 of the 5,6-cycloalkeno-1*H*-pyrazolo[3,4-*b*]pyridines obtained appears as a doublet at $\delta \approx -128$ ppm with a coupling constant $J_{CH} \approx 155-160$ Hz. These values accord with the δ and J_{CH} data found for C-4 of pyridines[2], in contrast to $\delta \approx -145$ to -150 ppm and $J_{CH} \approx 150$ to 175 Hz found for C-2 of pyridines.

1H-Pyrazolo[3,4-b]pyridines (4)

Compounds *(1)* (0.02 mol) and *(2)* (0.02 mol) are heated together under reflux in glacial acetic acid for 24 h. If the product *(4)* does not crystallize on cooling, isolation is achieved by variant A, B or C below.

Variant A: The reaction mixture is treated cautiously with water. The precipitate is collected and recrystallized from ethanol/water. *Variant B:* The reaction mixture is treated with sodium hydroxide solution until alkaline. The oil that separates is extracted with ether. After removal of the ether in a rotary evaporator the residue is recrystallized from ethanol/water. *Variant C:* The acetic acid is distilled off and the oil is distilled at *ca.* 0.1–0.9 torr.

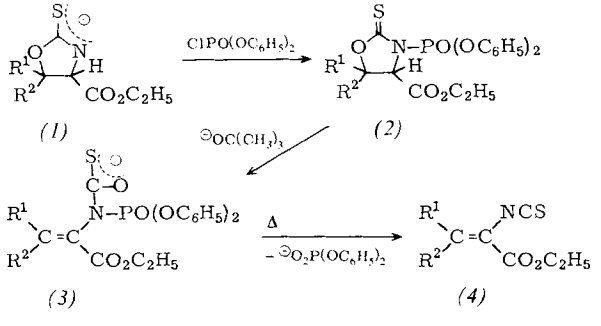
3-Substituted 2-Isothiocyanatoacrylic Esters[**]

By *Dieter Hoppe*[*]

Dedicated to Professor Hans Brockmann on the occasion of his 70th birthday

2-Isothiocyanatoacrylic esters *(4)*, hitherto unknown, can be conveniently prepared in a single-flask synthesis if oxazolidine-2-thione anions *(1)* (prepared by basic condensation of ethyl isothiocyanatoacetate with carbonyl compounds[1]) are phosphorylated by diphenyl phosphorochloridate at 20—30 °C in tetrahydrofuran and the resulting ethyl 3-(diphenoxyphosphoryl)-2-thioxooxazolidine-4-carboxylates *(2)* are then ring-opened by potassium *tert*-butoxide to *N*-phosphoryl-*N*-vinylthiocarbamates *(3)*[2],



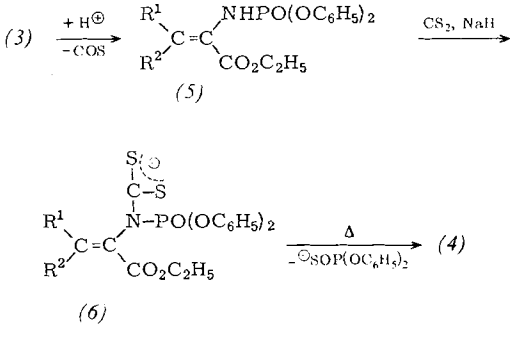
which fragment to *(4)* and diphenyl phosphate (variant A) (Table 1).

Table 1. Ethyl 2-isothiocyanatoacrylates *(4)* synthesized.

(4) R^1	R^2	Variant	Yield [a] [%]	M. p. [°C]
(a) CH_3	CH_3	A [b]	67	34—35
(b) —$(CH_2)_5$—		A [b]	65	—
(c) —$(CH_2)_4$—		A [b]	63	32—33
(d) $(CH_3)_2CH$	H	B [b]	60	—
(e) C_6H_5	H	B [c]	51	30—31
(f) C_6H_5—CH=CH	H	B [c]	54 [d]	75—83
(g) C_6H_5	CH_3	B [c]	56 [e]	—

[a] Based on ethyl isothiocyanatoacetate.
[b] Extraction by *n*-pentane, see text.
[c] Extraction by cyclohexane, see text.
[d] Mixture of isomers.
[e] *E*/*Z* ratio 1.5:1.

3-Aryl-substituted and 3-monosubstituted acrylic esters *(4)* sensitive to alkoxides cannot be prepared in this way, or at most in unsatisfactory yields. This complication can be avoided by variant B, according to which *(3)* is first converted into a 2-(diphenoxyphosphorylamino)acrylic ester *(5)* by glacial acetic acid at -60 °C, which is then allowed to react with carbon disulfide and sodium hydride, affording an *N*-phosphoryldithiocarbamate *(6)* which decomposes at 20—40 °C to *(4)* and *O,O'*-diphenyl thiophosphate[3] (Table 1).



Starting from the diastereoisomeric anions *(1)* only one isomer of the (3-monosubstituted) esters *(4d)* and *(4e)* is obtained, which on the basis of their NMR spectra presumably have the *Z*-configuration. For comparison, *(4a)* was also prepared, in 80% yield, by sulfuration of ethyl 2-isocyano-3,3-dimethylacrylate[4] [—NC in place of —NCS in *(4a)*] by 2-methyl-2-propanethiol and azobisisobutyronitrile[5].

The structures of the compounds *(4)* are proved by their IR, NMR, and UV spectra and by their CH analyses. The IR absorptions of the isothiocyanato groups (2020—2050 cm^{-1}) and the ester carbonyl groups (1720 cm^{-1}) are shifted towards long wavelengths in comparison with those of saturated 2-isothiocyanatoalkanoic esters.

The intermediates *(2c)* [m.p. 89 °C; IR: 1735 (C=O), 1580 (OC_6H_5), and 1320 cm^{-1} (P→O)] and *(5e)* [m.p. 112 °C; IR: 3150 (NH), 1715 (C=O), 1625 (C=C), and 1585 cm^{-1} (OC_6H_5)] were isolated and characterized.

In 2-isothiocyanatoacrylates *(4)* the NCS group undergoing ready attack by nucleophiles is attached to a C=C double bond which is capable of ring closure. Hence the esters *(4)* can serve as starting materials for synthesis of thiazole derivatives.

2-Isothiocyanatoacrylic esters

To a solution of *(1)* (40 mmol; prepared by use of sodium hydride[11]) are added dry tetrahydrofuran (30 ml) at 20 °C and, instead of glacial acetic acid[11], diphenyl phosphorochloridate (10.8 g, 40 mmol), the mixture then being stirred for a further 30 min at 20—30 °C. Next potassium *tert*-butoxide (5.6 g, 50 mmol) in tetrahydrofuran (50 ml) is added dropwise at −60 °C and after 15 min a sample is warmed to 20 °C and examined by IR spectroscopy. If intense absorption at 2050 cm^{-1} is observed, the mixture is warmed to 20 °C and worked up *(variant A)*. In other cases *(variant B)* the mixture is neutralized by glacial acetic acid (3.0 g) at −60 °C and freed from solvent in a vacuum (bath temp. max. 40 °C). A solution of the residue in benzene (200 ml) is clarified by neutral silica gel (8 g), and the solvent is removed in a vacuum. The residual *(5)* is dissolved in tetrahydrofuran (50—100 ml) and carbon disulfide (10 ml) and added dropwise to a stirred suspension of finely powdered sodium hydride (1.1 g, 44 mmol) in tetrahydrofuran (20 ml) at 20—40 °C, and the whole is left to react for a further 3 h at 30—40 °C under N_2. For working up, the solvent is removed in a vacuum (bath temp. max. 40 °C), the residue is stirred with light petroleum (b.p. 40—60 °C)/ether (2:1) (150 ml) and set aside for 1 h at 0 °C. The solution is decanted or sucked free from undissolved material (caution: contains NaH). The filtrate is evaporated in a vacuum and the residue is extracted with 100 ml of *n*-pentane or cyclohexane (see Table 1). After at least 8 h standing at 0—5 °C the solution is separated from undissolved material and on evaporation of the solvent affords a 50—70% yield of *ca.* 95% pure *(4)*. For complete purification of *(4)* this product is chromatographed over neutral silica gel in a column cooled with ice-water and eluted with peroxide-free ether/*n*-pentane (1:2) (R_F = 0.5—0.6). Readily volatile esters *(4)* (mol. wt. <200) withstand distillation at 0.1 torr (bath temp. <70 °C).

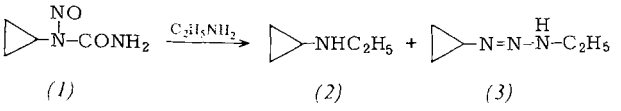
Azo Coupling by Cyclopropanediazonium Ions

By *Wolfgang Kirmse, William J. Baron*, and *Ulrich Seipp*[*]

Azo coupling of aromatic diazonium salts plays an important part in the synthesis of intermediates and of dyes[1], whereas aliphatic diazonium salts almost always react with elimination of nitrogen[2]. We report here the ability of cyclopropanediazonium ions to undergo azo coupling.

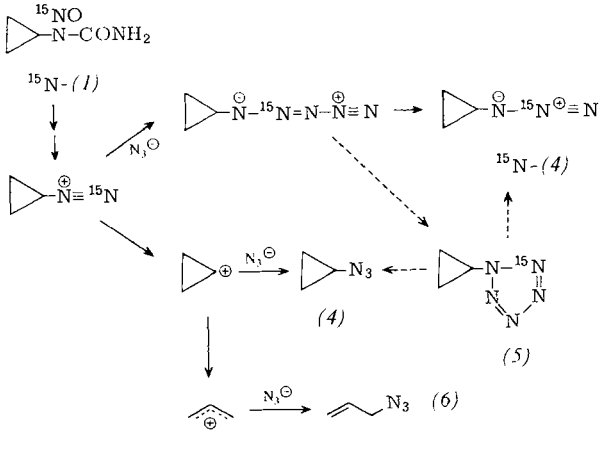
Alkaline fission of nitrosoacylamines leads to diazonium ions and/or diazo compounds in a sequence of several steps[3]. By treatment of *N*-cyclopropyl-*N*-nitrosourea *(1)*[4] with ethylamine/methanol (molar ratio 2:1) at −8 °C we obtained cyclopropyl methyl ether (12%), *N*-ethylcyclopropylamine *(2)* (8%), and 1-cyclopropyl-3-ethyltriazene *(3)* (30%). The triazene *(3)* [IR: 3435 (NH), 3085, 3010, 1020 (cyclopropane), 1503 cm^{-1} (N=N); NMR: δ = 6.9 (s, br. 1H), 3.37 (q, 2H), 3.1 (m, 1H), 1.15 (t, 3H), 0.73 (m, 4H)] agreed in all its properties with a sample prepared by a known triazene synthesis[5] from cyclopropyl azide[4] and ethylmagnesium bromide.



(1) *(2)* *(3)*

A triazene was also obtained from *(1)* and dimethylamine, but in poorer yield (*ca.* 5%) and lower purity. However, isobutanediazonium ions and methanediazonium ions gave no triazene under corresponding conditions but only substitution products.

Treatment of *(1)* with lithium azide in methanol afforded cyclopropyl azide *(4)* as the main product[4]. Use of ^{15}N-labeled *(1)* (96% of ^{15}N) led to a sample of *(4)* that according to its mass spectrum contained 68% of ^{15}N. This accords with the intensity ratio of the azide bands of labeled (2054 cm^{-1} in CCl_4) and unlabeled *(4)* (2107 cm^{-1}). The frequency difference indicates labeling at N-2 of the azide group: for terminally labeled *p*-toluenesulfonyl azide $\Delta\nu_{N_3}$ has been found to be −19 cm^{-1} and for the non-terminally labeled azide −41 cm^{-1}[6]. Cyclopropanediazonium ions thus react with azide ions for the most part by a pentazene mechanism. Whether unlabeled *(4)* is formed by way of a pentazole *(5)*[7] or by "direct" substitution must remain open for the time being; experiments at 0 and 25 °C showed no difference in the ^{15}N content of *(4)*, and below 0 °C the reaction was very slow. Simultaneous formation of small amounts of allyl azide *(6)* (*ca.* 6%) shows that decomposition of cyclopropanediazonium ions competes with azo coupling even in the presence of azide.



Under the above reaction conditions ^{15}N-labeled *N*-butyl-*N*-nitrosourea gave 1-butyl azide not containing ^{15}N. The observed differences in reactivity suggest that cyclopropanediazonium ions occupy a position between the purely aliphatic and the aromatic diazonium ions.

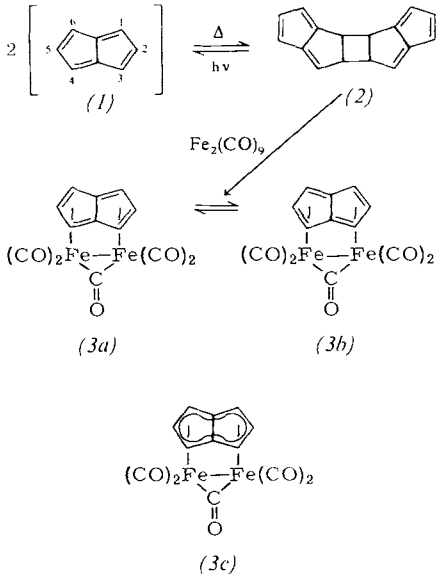
Synthesis of Carbonyliron Complexes of Pentalene and Its Derivatives

By *Wolf Weidemüller* and *Klaus Hafner*[*]

Pentalene *(1)* and its methyl derivatives are characterized—like cyclobutadiene[1]—by a highly pronounced tendency to dimerization[2, 3]. The only alkyl derivative hitherto isolated, 1,3,5-tri-*tert*-butylpentalene, is, for steric reasons, not capable of dimerization[4]. On photolysis in a matrix at −196 °C several dimeric pentalenes could be converted to the corresponding, UV-spectroscopically detectable monomers.



We have now observed that fission of pentalene dimers is also achieved by transition metals. Treating *(2)*[5] with $Fe_2(CO)_9$ at 50 °C (in methylcyclohexane under carbon monoxide in a sealed vessel) yielded the pentalene-pentacarbonyldiiron complex *(3)* as yellow-brownish crystals, stable at room temperature under nitrogen[6] [yield 9%, m. p. 140 °C dec., 100 MHz ^{1}H-NMR spectrum (in C_6D_6): A_2B system at $\tau = 4.54$ (t, $J = 2.5$ Hz, H-2, H-5) and $\tau = 6.77$ (d, $J = 2.5$, H-1, H-3, H-4, H-6); IR spectrum (KBr pellet): 2030, 1985, 1945 cm^{-1} (terminal CO), 1750 cm^{-1} (bridging CO)]. Similarly the corresponding complex of 1,3-dimethylpentalene could be synthesized in 21% yield from its dimer[3] as green crystals, melting at 136 °C [100 MHz ^{1}H-NMR spectrum (in C_6D_6): A_2B system at $\tau = 5.61$ (t, $J = 2.5$ Hz, H-5) and $\tau = 6.93$ (d, $J = 2.5$ Hz, H-4, H-6); $\tau = 6.00$ (s, H-2) and $\tau = 8.87$ (s, $2CH_3$); IR spectrum (KBr pellet): 2020, 1980, 1940 cm^{-1} (terminal CO), 1750 cm^{-1} (bridging CO)]. Like the IR spectra the mass spectra of these complexes too resemble those of the 1-dimethylamino and 1-phenyl derivatives[8] of *(3)* obtained from the corresponding 1,2-dihydropentalenes[7] and $Fe(CO)_5$. Besides molecular ion peaks ($M^+ = 354$ and 382) fragment peaks due to successive cleavage of five carbonyl groups and two iron atoms also appear.

The NMR spectra of these complexes do not allow distinction of either structures *(3a)*⇌*(3b)* with rapidly oscillating π-electron system or *(3c)* with a delocalized pentalene ligand. *F. G. A. Stone et al.*[9] recently reported the comparable bis(trimethylgermyldicarbonylruthenium) complex obtained by dehydrogenative transannular cyclization of cyclooctatetraene. Its bonding structure proposed on the basis of an X-ray analysis is not incompatible with a structure of type *(3c)*.

Synthesis of 4-Mercapto-2-azetidinones having α-Isopropylideneacetate Groups on Nitrogen

By *Rudolf Lattrell*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

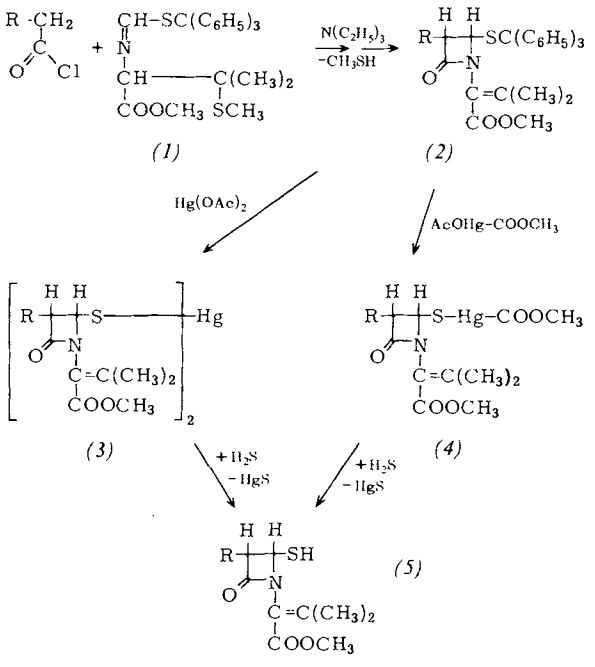
4-Mercapto-2-azetidinones (4-mercapto-β-lactams) having α-isopropylideneacetate groups attached to the nitrogen have not hitherto been described although they have long been discussed in connection with degradation reactions of penicillins and biosynthesis of penicillins and cephalosporins[1]. We have now found a general method for the synthesis of 4-mercapto-2-azetidinones[2], and in particular for compounds of type *(5)* named in the title.

Starting materials were the *cis*- or *trans*-4-tritylthio-2-azetidinones *(2)* that have been obtained from the cysteine derivative *(1)* and substituted acetyl chlorides. Methanethiol can be split from the primary products of the β-lactam syntheses under mild conditions[2, 3].

[*] Dr. R. Lattrell
Farbwerke Hoechst AG
6230 Frankfurt/Main 80 (Germany)

The (tritylthio)azetidinones *(2)* react with mercury(II) acetate or (methoxycarbonyl)mercury acetate in methanol at room temperature to give good yields of the (mercurithio)-azetidinones of type *(3)* or *(4)*, respectively. These relatively apolar compounds can be purified without decomposition by chromatography on silica gel.

The products *(3)* and *(4)* react instantaneously with hydrogen sulfide in an inert solvent, even in the cold, with deposition of mercury sulfide and quantitative formation of the relatively stable 4-mercapto-2-azetidinones *(5)*.



The structures of the compounds *(5)* (Table 1) was proved by IR [3.9 μm (SH), 5.6 μm (lactam-CO)] and NMR spectra (the SH-proton appears as a doublet with $J = 8$ Hz in the region $\delta = 2$ ppm) and, for the crystalline compounds, also by elemental analysis.

Table 1. Mercaptoazetidinones *(5)* prepared from *(2)* by way of *(3)* or *(4)*.

	R	*(5)* Configuration	*(5)* Yield [%]	*(5)* M.p. [°C]	*(3)* or *(4)* M.p. [°C]	*(3)* or *(4)* Yield [%]
a	N_3	*cis*	100	Oil	*(3)* amorphous	70
b	N_3	*trans*	100	Oil	*(3)* amorphous	68
c	phthal-imido	*cis*	80	160—162	*(3)* 228 (dec.)	80
d	phthal-imido	*trans*	98	155—156	*(4)* 180 (dec.)	96
e	phenyl-acetamido	*cis*	100	105—107	*(4)* amorphous	83

Methyl cis-2-[2-(methoxycarbonyl)mercurithio-4-oxo-3-(phenylacetamido)-1-azetidinyl)-3-methylcrotonate (4e)

cis-(2e)[3] (2.95 g, 5 mmol) and (methoxycarbonyl)mercury acetate[4] (3.2 g, 10 mmol) are stirred together in methanol (50 ml) and methylene chloride (10 ml) for 2 h at room temperature. After working up with water and methylene chloride, the oily residue from the organic phase is chromatographed over silica gel (Woelm, 0.02—0.5 mm, deactivated with 10% of water; column 2.5 × 110 cm) with ethyl acetate/cyclohexane (2:1). *(4e)*, $R_F = 0.19$, is eluted as an amorphous foam (yield 2.5 g, 83%).

Methyl cis-2-[2-mercapto-4-oxo-3-(phenylacetamido)-1-azetidinyl]-3-methylcrotonate (5e)

A slow stream of hydrogen sulfide is passed for 4 h through a solution of *(4e)* (0.6 g, 1 mmol) in methylene chloride (10 ml) at 0 °C. After filtration from the precipitated mercury sulfide the solvent is removed in a vacuum. The resinous residue (0.36 g, quantitative yield) is pure *(5e)*. Dissolution in benzene and cooling to 10 °C affords colorless crystals of m.p. 105—107 °C.

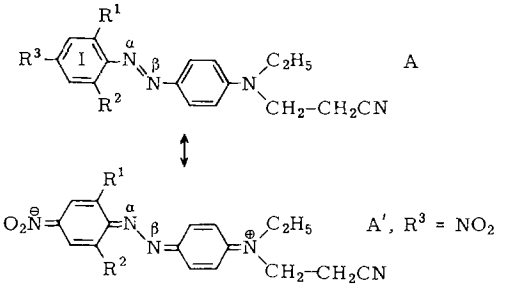
Steric Hindrance in Strongly Polar 2,6-Disubstituted Azobenzenes

By *Ernst Hoyer*, *Rudolf Schickfluss*, and *Willi Steckelberg*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Azobenzenes of type A are of industrial interest as dispersion dyes for polyester fibers since by substitution at positions 2, 4 and 6 of ring I colors can be obtained ranging from yellow to violet. To clarify the relations between structure and color, the substituents R^1, R^2 and R^3 were varied systematically and the absorption spectra of the dyes *(1)—(33)* obtained were measured in the region of the long-wave π-π* bands that determine the shade and depth of color of the compounds.



It is known that *trans*-azobenzene is planar[1] and that substituents at position 2 to the azo bridge exert steric hindrance that can lead to twisting of the substituted benzene ring in relation to the —N=N— bond[2—5]. However, those investigations relate mainly to slightly polar azobenzenes symmetrically substituted by methyl groups and halogen atoms and do not permit unequivocal relation of steric hindrance to the position of the π-π* bands.

We have found that in strongly polar compounds of type A, $R^3 = NO_2$, these bands are particularly strongly influenced by steric hindrance if R^1 and R^2 are halogen or tetrahedral substituents. The bands are shifted to shorter wavelength by an unusually large amount and their intensity decreases [Table 1, *(1)–(9)*].

[*] Dr. E. Hoyer, Dr. R. Schickfluss, and Dr. W. Steckelberg
Farbwerke Hoechst AG
623 Frankfurt/Main 80 (Germany)

However, even if only one of the substituents R^1 and R^2 is a "planar" group ($-NO_2$, carbonyl function), then a pronounced steric effect on the azobenzene group appears to be prevented because these substituents relinquish their coplanarity with the phenyl nucleus I in order to avoid hindrance by the azo bridge [*(1)*, *(10)–(14)*].

This explanation is supported by the observation that with such substituents the bathochromic influence at position 4 to the azo group is greater than at position 2 [*(18)*, *(27)–(29)*, *(1)*] while in the case of spherical or tetrahedral substituents it is almost equal at positions 2 and 4 [*(18)–(26)*].

Steric effects are not brought about by substitution with nitrile groups. The hypsochromic shift in 2,6-substituted azobenzenes is considerably reduced when there is no nitro group at position 4 (R^3) [compare *(18)*, *(21)*, *(33)* with *(1)*, *(4)*, *(5)*].

Table 1. Absorption (λ_{max}) and extinction maxima (ε) of the π-π^* bands of azobenzenes of formula A (in methanol). The compounds which were purified by column chromatography and recrystallization were homogeneous on thin-layer chromatography and afforded correct elemental analyses.

Cpd.	R^1	R^2	R^3	λ_{max} [nm]	ε
(1) [a]	H	H	NO_2	453	44000
(2)	CH_3	H	NO_2	454	42000

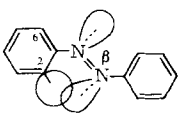
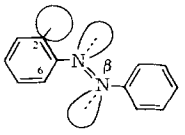
(24)	H	H	CF_3	416	41000
(25)	$SO_2C_2H_5$	H	H	429	45000
(26)	H	H	$SO_2C_2H_5$	430	40000
(27)	COC_6H_5	H	H	419	36000
(28)	H	H	COC_6H_5	432	43000
(29)	NO_2	H	H	425	36000
(30)	CN	H	H	434	42000
(31)	H	H	CN	433	45000
(32)	NO_2	NO_2	H	450	27000
(33)	Cl	Cl	H	396	22000

[a] *Bridgeman* and *Peters* [8] obtained the same results from measurements in ethanol.

As shown in Table 1, steric hindrance is strikingly evident in the position of λ_{max} when (i) R^1 and R^2 are bulky substituents and (ii) a strongly polar azobenzene system capable of mesomerism is involved. A qualitative explanation has been given previously[6] for similar relations in the stilbene steries.



B



C

A planar *trans*-azobenzene with one substituent on C-2 can assume conformation B or C, that of C being sterically more favorable than that of B. Thus stronger steric hindrance is to be expected only when C-2 and C-6 of one benzene ring are both substituted so that one substituent necessarily overlaps the sp^2 electrons of the β-nitrogen atom. In strongly polar azobenzenes of type A, $R^3 = NO_2$, quinonoid structures such as A′ contribute more to the mesomerism than in less polar azobenzenes and this leads to shortening of the distance between the substituent and the β-nitrogen atom.

Since A′ is more strongly involved in the excited state than in the ground state[6, 7] the steric hindrance is greater in the excited than in the ground state and a short-wave shift of the π-π^* bands is always produced.

Hydrogenation of a Substituted Glutarodinitrile

By *I. Leupold* and *H.-J. Arpe*[*]

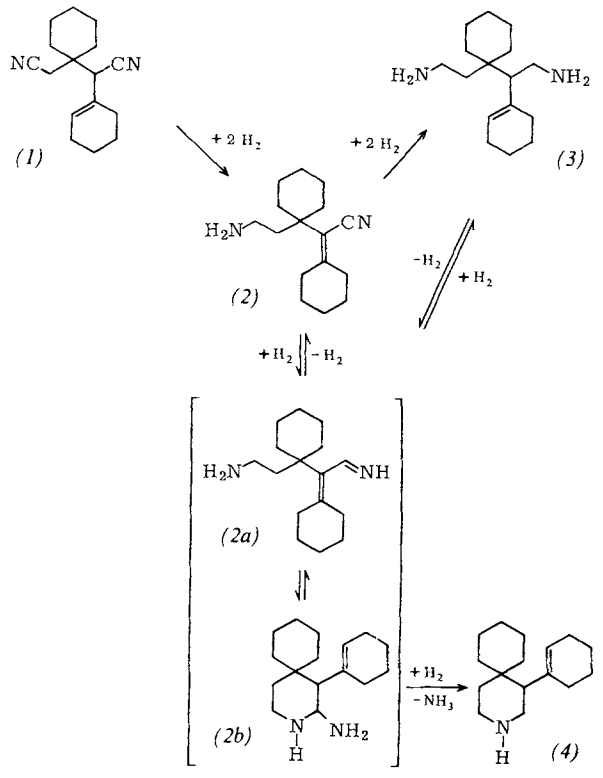
Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Suitably substituted diamines with at least four C atoms between the amino groups are desirable starting materials for preparation of transparent polyamides by condensation with dicarboxylic acids. Economic access to them is provided by dinitriles since these can be hydrogenated to diamines by use of cobalt catalysts and a large excess of NH_3. By-products are obtained owing to loss of ammonia, *e. g.* pyrrolidines and piperidines from the parent succinodinitriles and glutarodinitriles, respectively[1, 2].

Thus on catalytic hydrogenation of 2-(1-cyclohexenyl)-3,3-pentamethyleneglutarodinitrile *(1)*, the diamine *(3)* and the piperidine derivative *(4)* are both obtained, but in addition the partially hydrogenated amino nitrile *(2)* can also be isolated. Any one of the products *(2)*, *(3)* and *(4)* containing an irreducible double bond can be made to preponderate by choice of reaction conditions (see Experimental).

The primary nitrile group is more easily hydrogenated than the secondary one, so that, with simultaneous migration of the double bond into conjugation, 2-cyclohexylidene-3,3-pentamethylene-5-aminovaleronitrile *(2)*, m. p. 148 °C, can be obtained under mild conditions of hydrogenation. Since cyclization to 1-(1-cyclohexenyl)-3-azaspiro[5.5]undecane *(4)*, m. p. 50 °C, is hindered by the bulky cyclohexane rings, 2-(1-cyclohexenyl)-3,3-pentamethylene-1,5-pentanediamine *(3)*, m. p. 59 °C, is formed preferentially below 150 °C, the double bond migrating back to its original position. At higher temperatures *(4)* is the main product. This reaction opens an easy route to a 3-azaspiro[5.5]undecane.

[*] Dr. I. Leupold and Dr. H.-J. Arpe
Farbwerke Hoechst AG
623 Frankfurt/Main 80 (Germany)



The formation of *(4)* probably occurs by intramolecular amine-imine addition and hydrogenative deamination by way of the unisolated intermediates *(2a)* and *(2b)*. This is indicated also by smooth reaction to give the piperidine *(4)* when the individual compounds *(2)* and *(3)* are hydrogenated at about 200 °C.

Experimental

(1)[3] (60 g) is shaken in a 1-l V4A autoclave with a hydrogenation catalyst (5 g), containing 39 wt.-% of cobalt as well as SiO_2, at a hydrogen pressure of 200 atm for 24 h, with the tabulated results.

T [°C]	Solvent [g]	Yields [mol-%] (2)	(3)	(4)
100	150 Dioxane, 75 NH_3	61	35	2
130	100 NH_3	10	75	6
200	150 Dioxane	< 1	< 1	97

Separation of the products was by chromatography with ethanol/conc. NH_3 (4:1) on silica gel. The products are eluted in the order *(2)*, *(4)*, *(3)*. The structures assigned accord with C, H, N and ^{1}H-NMR, IR and MS data.

Removal of Allyl groups by Formic Acid Catalyzed by (Triphenylphosphane)palladium

By *H. Hey* and *H.-J. Arpe*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

In the presence of (triphenylphosphane)palladium catalysts, allyl phenyl ether and allyl carboxylates react with carboxylic acids by exchange of the allyl group for the acidic H of the acid[1, 2].

$$C_6H_5O\text{—Allyl} + R'COOH \xrightarrow{Cat.} C_6H_5OH + R'COO\text{—Allyl}$$

$$RCOO\text{—Allyl} + R'COOH \xrightarrow{Cat.} RCOOH + R'COO\text{—Allyl}$$

However, in an attempt to obtain allyl formate in this way from allyl acetate and formic acid, the starting materials decomposed to acetic acid, CO_2 and propene.

$$CH_3COO\text{—Allyl} + HCOOH \xrightarrow{Cat.} CH_3COOH + CO_2 + H\text{-Allyl}$$

This reaction can be applied also to other allylic and substituted allylic compounds (Table 1).

Table 1. Examples of the removal of allyl groups by formic acid. Typical experiment: A solution of palladium acetate (112 mg, 0.5 mmol) and triphenylphosphane (1.572 g, 6.0 mmol) in allyl acetate (75 g, 0.75 mol) was treated under argon with formic acid (11.5 g, 0.25 mol) and warmed to 90 °C. Rapid evolution of gas began at 70 °C and was complete within 1 h. The solution contained, besides catalyst and unchanged allyl acetate, 0.24 mol of acetic acid, and the gas contained 48 vol.-% of CO_2, 50 vol.-% of propene and 1 vol.-% of H_2 (from decomposition of formic acid).

Starting materials Allyl cpd.	[mol]	HCOOH [mol]	Liquid products	[mol]	Gaseous products [a] olefin [vol.-%]	CO_2	H_2
allyl propionate	0.4	0.05	propionic acid	0.05	propene 49	51	
allyl phenyl ether	0.36	0.05	phenol	0.04	propene 47	52	
methallyl acetate	0.41	0.05	acetic acid	0.05	isobutene 48	52	
2-butenyl acetate	0.4	0.05	acetic acid	0.05	1-butene 34, *trans*-2-butene 7, *cis*-2-butene 2.5	56	
cinnamyl acetate	0.2	0.2	acetic acid 1-phenylpropene 3-phenylpropene	0.1 0.08 0.02		74	26 [b]
triallylamine	0.49	0.05	diallylamine, allylamine and other products		propene 17	50	32 [b]

[a] Measured in a sample of the gas.
[b] Formed by decomposition of formic acid.

[*] Dr. H. Hey and Dr. H.-J. Arpe
Farbwerke Hoechst AG
623 Frankfurt/Main 80 (Germany)

Catalysts that can be used with triphenylphosphane, in place of palladium acetate, are bis(pentanedionato)palladium, palladium chloride, bis(benzonitrile)palladium chloride and tetrakis(triphenylphosphane)palladium; also a combination of tributylphosphane and palladium acetate. The molar ratio Pd:P should be at least 1:4 to prevent separation of palladium.

The reaction of allyl acetate and formic acid occurs differently from the formally similar reduction of, *e.g.*, butyraldehyde[3] and alkenes[4] by formic acid in the presence of transition-metal catalysts. Monodeuteriopropene is obtained on treatment of allyl acetate with DCOOD and CH_3COOH (1:1) but not with HCOOH and CH_3COOD (1:1). We also observed a kinetic isotope effect: At 80 °C in the second experiment deallylation occurred twice as fast as in the first experiment. Thus fission of the C—H bond of formic acid is slow, as well as in the oxidative degradation of formic acid on a Pd^{II}/Cu^{II} catalyst[5].

On incomplete reaction of allyl acetate with formic acid the solution contained about 2% of allyl formate which decomposed rapidly into CO_2 and propene even at 60 °C in presence of (triphenylphosphane)palladium acetate. Cleavage of a substituted allyl formate, 2,7-octadienyl formate, in presence of palladium acetate and dimethylformamide has been described recently[6].

Simplified Synthesis of Pentafluoro-1-iodoethane and Heptafluoro-2-iodopropane

By *Hans Millauer*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Perfluorinated alkyl iodides such as pentafluoro-1-iodoethane *(1)* and heptafluoro-2-iodopropane *(2)* are of preparative interest in the laboratory and in industry as, *e.g.*, telogens for preparation of perfluorinated telomers Hitherto they have been prepared mainly by treatment of iodine pentafluoride/iodine mixtures ('IF') with tetrafluoroethylene *(3)* or hexafluoropropene *(4)* by one of various techniques[1]. *(1)* is also formed on reaction of tetrafluoro-1,2-diiodoethane *(5)* or a $CF_2{=}CF_2/I_2$ mixture with hydrogen fluoride and mercury oxide[2] or lead dioxide[3].

We have now found that the iodides *(1)* and *(2)* can be advantageously synthesized by treating the corresponding perfluoroalkene *(3)* or *(4)* and iodine with a readily obtainable, non-metallic oxidizing agent in an excess of hydrogen fluoride. Also, *(5)* may be used in place of *(3)* and iodine. Suitable oxidizing agents are oxo acids of quinque- or hepta-valent halogens (*e.g.* $HClO_3$, HIO_3, H_5IO_6), nitric acid, chlorine and sulfuryl chloride. These reagents have the advantage over oxides of higher-valent metals that they form only volatile reduction products. The reactions with Cl_2 or SO_2Cl_2 occur under anhydrous conditions and are catalyzed by antimony(v) halides. The stoichiometry generally depends on the available number of oxidation equivalents, *e.g.*:

$$7\ CF_2I{-}CF_2I + 7\ HF + H_5IO_6 \xrightarrow[150\ °C]{\text{excess HF}} 7\ CF_3{-}CF_2I + 4\ I_2 + 6\ H_2O$$

Experimental

$CF_2I{-}CF_2I$ *(5)* (177 g, 0.50 mol), periodic acid (17.1 g, 0.075 mol) and hydrogen fluoride (200 g, 10 mol) are heated at 150 °C for 5h in a 1-l autoclave (Hastelloy C) fitted with a push-pull stirrer and electric heating. After cooling to 120 °C the volatile products are allowed to escape slowly, being led first through a wash bottle containing 800 ml of water, then through a second containing 200 ml of 20% KOH (all vessels and connections of PVC) and finally through a drying tower containing granulated $CaCl_2$ into a trap cooled to −78 °C. The condensate (109 g) consists of $CF_3{-}CF_2I$ *(1)* (*ca.* 98 vol.-%) and $CF_2{=}CF_2$ *(3)* (2 vol.-%; gas chromatography).

	Starting materials [mol]		T [°C]	Reaction time [h]	Main product Yield (%) calc. on F cpd.
0.5 *(5)*	0.10 $NaIO_3$		150	5	74 *(1)*
0.5 *(5)*	0.17 HNO_3		155—165	5	84 *(1)*
0.5 *(5)*	0.25 Cl_2		100—130	3	72 *(1)*
0.5 *(5)*	0.27 SO_2Cl_2		160—170	3	77 *(1)*
0.5 *(5)*	0.27 SO_2Cl_2	0.05 $SbCl_5$	160—170	3	94 *(1)*
1.0 *(3)*	0.50 Cl_2	2.35 I_2	160	5	64 *(1)*
0.5 *(4)*	0.17 HNO_3	0.32 I_2	150—160	3	75 *(2)*
0.5 *(4)*	0.28 Cl_2	0.32 I_2 + 0.10 $SbCl_5$	100—140	5	86 *(2)*

The tabulated results were obtained analogously.

^{1}H-NMR Spectrum of [^{15}N]Pyridine in the Nematic Phase

By *Christian Schumann* and *Roger Price*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

The only method for determining the geometrical structure of molecules in the liquid phase is NMR spectroscopy in liquid-crystalline solvents. It has hitherto been restricted to small molecules[1] with up to ten magnetically active nuclei[2], usually protons. Comparison of the results with those from electron-diffraction, microwave spectroscopy or X-ray analysis has shown that direct dipole-dipole coupling constants between protons generally give correct structural data, whereas for couplings in which other nuclei are involved larger systematic deviations may occur. This has been ascribed to the anisotropy of the indirect coupling constants and to the influence of molecular vibrations on the direct coupling constants.

Since, with the availability of modern techniques, nuclei other than protons are assuming ever increasing importance, we have selected [^{15}N]pyridine for an examination as to whether ^{15}N—^{1}H coupling constants also afford incorrect structural parameters. For this purpose the ^{1}H-NMR spectrum was measured at two concentrations in a 1:1 mixture of $CH_3OC_6H_4CH{=}NC_6H_4OCOPr$ and $C_5H_{11}COOC_6H_4COOC_6H_4OC_2H_5$[3]: HFX-90 and WH-90 apparatus from Bruker was used; Fourier transform technique without stabilization was applied. This technique, together with the larger number and smaller width of the lines, allows a considerably better precision in the measurement of the coupling constants than in earlier determinations on [^{14}N]pyridine[4]. Thus nuclear distances could be calculated with good accuracy in spite of the small values of the ^{15}N—^{1}H coupling constants.

Six anisotropic ^{1}H—^{1}H and three anisotropic ^{1}H—^{15}N coupling constants are obtained (Table 1), so that the positions of the protons and the nitrogen nuclei can be determined independently. The modified[4] program UEANMRITR[5] was used for analysis of the spectra. As indirect coupling constants we used the values reported by *Roberts et al.*[6]. 83 lines of spectrum I were assigned with a standard deviation of 0.42 Hz, and 55 lines of spectrum II (standard deviation 0.20 Hz). Figure 1 shows a comparison of the measured and calculated spectrum I; for the plot the line width was taken to be 6 Hz.

Two orientation parameters and three coordinates were calculated from the six ^{1}H—^{1}H coupling constants by a weighted least-squares procedure[7]. Labeling of nuclei and coordinates is shown in Figure 2; the results are collected in Table 2. The structural parameters agree with the microwave geometry[8] within experimental error.

Three values for the coordinate y_6 can be calculated from the three ^{1}H—^{15}N coupling constants. The values obtained

from D_{26} and D_{36} agree with each other and with the microwave values (Table 2). If D_{16} is calculated from this nitrogen position one obtains 40.28 Hz for (I) and 45.23 Hz for (II), *i.e.* a discrepancy of 0.50 and 0.58 Hz, respectively, which, however, can be removed by a vibrational correction[9]. The difference between the harmonic vibrational corrections for the CCH and the CCCCH fragments in benzene[9] (=0.0076 Å) is used for this purpose, with the assumption that the vibrational behavior of the NCH and NCCCH fragments in pyridine is similar. With $\partial D_{16}/\partial r_{16} = 58$ (I) and 62 Hz/Å (II), this affords the corrections 0.44 and 0.47 Hz for the coupling constants D_{16}. These two coupling constants now agree within experimental error with the experimental values.

It can thus be seen that NMR spectra of oriented molecules provide precise geometrical data from coupling constants between nuclei that are separated by three or more bonds, but that vibrational corrections must be applied when the nuclei are closer together, in particular for the directly bonded CH fragment[9]. For $^{19}F—^{19}F$ coupling constants only, a further source of error, namely anisotropy of the indirect coupling constants, seems to be important[10].

Simple Synthesis of 4-Monosubstituted Arsa- and Phospha-benzenes

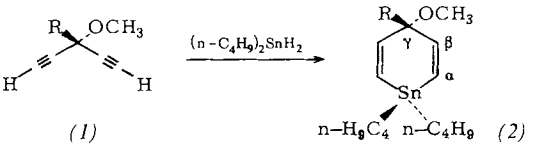
By *Gottfried Märkl* and *Fritz Kneidl*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Apart from the unsubstituted arsa- and phosphabenzenes[1], only the 2,3,6-tri- and higher aryl-substituted arsabenzenes, prepared by ring expansion of five-membered arsoles, and the 2,4,6-tri- and higher aryl- or alkyl-substituted phosphabenzenes, which are accessible by several routes, have previously been reported[2].

We here report the first preparation of 4-mono-substituted arsa- and phosphabenzenes *(4)* and *(5)* respectively from 4-substituted 4-methoxy-1,4-dihydrostannins *(2)*. These compounds are of particular interest in connection with studies on electrophilic aromatic substitution of arsa- and phosphabenzenes.

Starting materials are the 3-substituted 1,4-pentadiyn-3-ols[3] that are readily accessible from carboxylic esters and Na acetylide; etherification[4] with phase-transfer catalysis affords the 3-methoxy derivatives *(1)* in good yield [*(1a)*, b.p. 84 °C/0.01 torr, yield 78%; *(1b)*, b.p. 86 °C/0.01 torr, yield 87%; *(1c)*, m.p. 36 °C, yield 92%].



(1) *(2)*

a, R = C_6H_5; *b*, R = c-C_6H_{11}; *c*, R = t-C_4H_9

The pentadiynes *(1)* react smoothly with di-*n*-butyltin dihydride in boiling methylcyclohexane containing azoisobutyrodinitrile, cycloaddition affording the 1,4-dihydrostannins *(2)* (see Table 1). The ^{13}C-NMR spectra show conclusively that the six-membered and not the possible, frequently observed[5] five-membered cyclic adducts are formed[6].

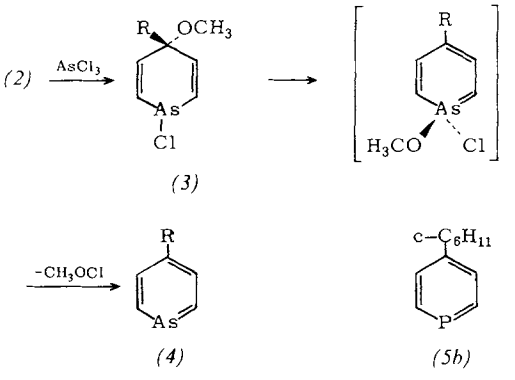
Table 1. Compounds of type *(2)* prepared.

(2a), yield 68%, b.p. 154–158 °C/0.02 torr; *^1H-NMR spectrum* ($CDCl_3$): *n*-C_4H_9: τ = 8.3–9.5 (m), 18 H; OCH_3: 6.65 (s), 3 H; C_6H_5: 2.4–3.0 (m), 5 H; H_α,H_β: 3.6 (s), 3 H, ^{117,119}Sn satellites, $^2J_{Sn-H_\alpha}$ (d) = 57 Hz, $^3J_{Sn-H\beta}$ (d) = 86 Hz, 1 H

(2b), yield 58%, b.p. 160–165 °C/0.02 torr; mol. wt. (osmom.) 415, calc. 412

(2c), yield 61%, b.p. 154–158 °C/0.02 torr; *mass spectrum* (70 eV): M^+ 386, rel. int. 1%; $[M-C_4H_9]^+$ 329, 43%; $[M-2C_4H_9-OCH_3]^+$ 241, base peak; *^{13}C-FT-NMR-spectrum* at 25.2 Hz (Varian XL-100-15, computer 620 i) ($CDCl_3$): $2C_\alpha$, δ = 130.2 (based on i. TMS), $2C_\beta$, 151.2; C_γ, 83.4 ppm; *^1H-NMR-spectrum* ($CDCl_3$): *t*-C_4H_9, *n*-C_4H_9: τ = 8.3–5 (m), 27 H; OCH_3: 6.8 (s), 3 H; H_α, H_β: 3.6 (s), 3 H; ^{117,119}Sn satellites: band complex centered at 4.8 and 2.8, 1 H

The elegant synthesis of boron, phosphorus and arsenic heterocycles by treatment of the tin heterocycles[7–9] with the appropriate halide takes a surprising course with *(2)*: 4-substituted arsabenzenes *(4)* are formed directly from *(2)* and $AsCl_3$ in boiling tetrahydrofuran.



The 1,4-dihydroarsenins *(3)* that occur as intermediates can be detected by NMR spectroscopy on careful working, but they decompose spontaneously, perhaps by way of the 1-chloro-1-methoxyarsabenzenes[10]. The methyl hypochlorite expected as leaving group has an oxidizing action on *(4)*[10]; if this oxidant is trapped with triphenylphosphane[11] (reaction of *(2)* with $AsCl_3$ in the presence of stoichiometric amounts of phosphane), the yield of *(4)* is significantly increased. The arsabenzenes *(4)* are isolated by chromatography on silica gel with *n*-heptane/benzene, forming colorless, distillable, air-sensitive oils; 4-phenylarsenin *(4a)* crystallizes spontaneously (see Table 2).

The arsabenzenes *(4)* exhibit chemical reactivities characteristic of this system: reaction with nucleophiles, *e.g.* phenyllithium, giving dihydroarsenins, and with dienophiles,

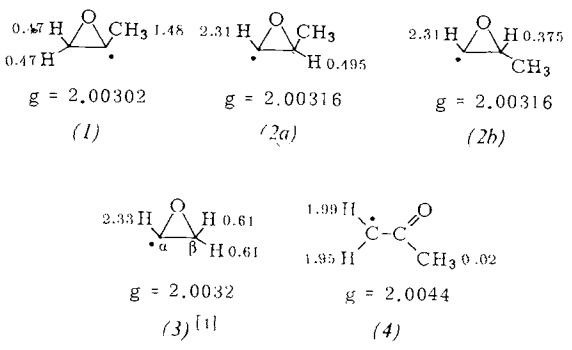
Proof of the Pyramidal Configuration of the Oxiranyl Radical: Two Isomers of the 3-Methyl-2-oxiranyl Radical

By *Günter Behrens* and *Dietrich Schulte-Frohlinde*[*]

If di-*tert*-butyl peroxide in methyloxirane is photolyzed (Philips type SP 1000) between −60 and −30 °C the ESR spectra of three radicals—*(1)*, *(2a)*, and *(2b)*—can be observed (data for hyperfine structure splitting in mTesla).



The unusual coupling constants of the known oxiranyl radical *(3)* have been explained by the assumption of a pyramidal geometry at the C_α atom[11]. Experimental proof of this pyramidal structure has hitherto been lacking because for radical *(3)* only a single form with two magnetically equivalent β-hydrogen atoms is observed.

Our discovery of two isomers *(2a)* and *(2b)* of the 3-methyl-2-oxiranyl radical provides conclusive proof for the occurrence of a pyramidal configuration.

Assuming a pyramidal structure, the observed equivalence of the β-hydrogen atoms of *(1)* and *(3)* can be explained by sufficiently rapid inversion (as for the cyclopropyl radical[12]).

From symmetry reasons the inverted forms of *(1)* and *(3)* have equal energy, whereas *(2a)* and *(2b)* differ energetically. The spectra (Fig. 1) show that *(2b)* occurs somewhat more frequently than *(2a)*.

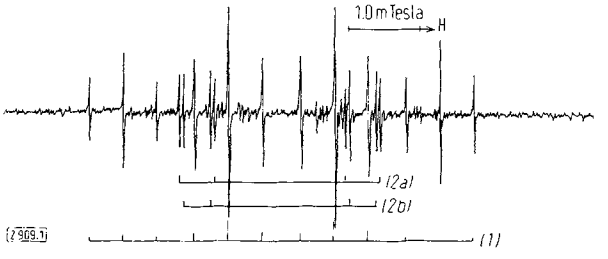


Fig. 1. ESR spectra of the 2-methyl-2-oxiranyl radical *(1)* and the isomeric 3-methyl-2-oxiranyl radicals *(2a)* and *(2b)* obtained on photolysis of 3% of di-*tert*-butyl peroxide in methyloxirane at −40 °C.

A further argument for the pyramidal configuration at C_α of the oxiranyl radical *(3)* is based on the magnitude of the H_α splitting, whose absolute value is shown by our measurements (cf. Table 1) to be greater than that of the methyl radical (−2.304 mT at −177 °C in liquid methane[12]) and must therefore be positive since the H_α coupling of any substituted methyl radical is more positive than that of the methyl radical itself. The large positive splitting proves the strong sp hybridization of the unpaired electron. According to *Fessenden*'s semiempirical relationship[13] from the α-coupling there results an angle of ≈41°

Table 1. Splitting constants of the oxiranyl radical *(3)*.

Solvent	*T* [°C]	a_{H_α} (1) [mTesla]	a_{H_β} (2) [mTesla]	*g*
Water [1]	+20	+2.33	0.61	2.0032
Acetone	−60	+2.43	0.53	2.00320
Ethyl acetate	−70	+2.44	0.52	
Di-*tert*-butyl peroxide	−30	+2.45	0.49

433 Mülheim (Ruhr), Stiftstrasse 34–36 (Germany)

between the C—H_α bond and the C—O—C plane, in very good agreement with INDO calculations[1].

The small values of the H_β splittings for *(1)*, *(2)*, and *(3)* can be ascribed to superposition of two coupling mechanisms. Besides the contribution from hyperconjugation, which is positive, there arises, owing to the sp hybridization, an interaction from the π-σ polarization, whose contribution is negative and increases with the s character. This reduces the H_β coupling. Our interpretation is supported by the observed change of the hyperfine structure of the radical *(3)* with the experimental conditions (see Table 1), since an increase of the H_α coupling is connected with a decrease of the H_β splittings.

It is interesting that the acetonyl radical *(4)*[4] occurs during photolysis of di-*tert*-butyl peroxide in methyloxirane above -10 C. This indicates that the oxirane ring of the radical *(1)* opens at these temperatures. Analogous ring opening of *(3)* with formation of the formylmethyl radical cannot be observed under comparable conditions[5].

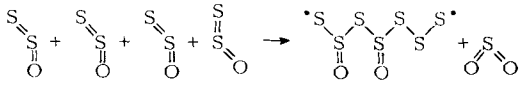
Photoelectron Spectra and Molecular Properties: SSO and OSO[1]

By *Hans Bock, Bahman Solouki, Pavel Rosmus*, and *Ralf Steudel*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 70th birthday

Sulfur burns in oxygen at low pressure to form mixtures of sulfur dioxide and disulfur monoxide[2]. These two triatomic, iso(valence)electronic molecules differ considerably in chemical behavior: thus, in contrast to OSO, SSO polymerizes when its frozen condensate is thawed, or even in the gas phase at partial pressures > 1 torr, by a radical mechanism[3] with partial redox-disproportionation, yielding polysulfur oxides[2]:



The structure of SSO, determined by microwave spectroscopy in gas discharge mixtures ($S+SO_2 \overset{\downarrow}{\rightarrow}$)[2]

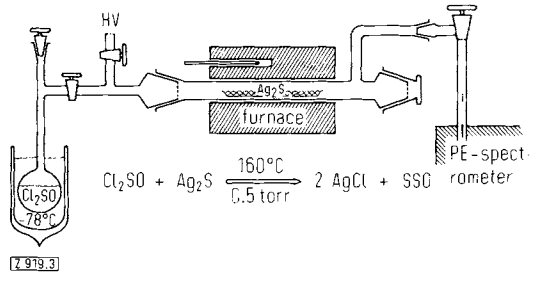
shows a smaller bond angle, and a longer S—O bond than OSO; the S—S bond is relatively short[4]. What are the electronic changes brought about by the replacement O→S?

The photoelectron (PE) spectrum of the stable OSO was published some time ago[5]. For recording that of the unstable SSO it was first necessary to find a method of preparation which, unlike the gas discharge ($S+SO_2 \overset{\downarrow}{\rightarrow}$), would guarantee a steady molecular beam containing more than 75% of SSO for several hours. This was achieved by synthesis from thionyl chloride and silver sulfide[3] directly in front of the spectrometer inlet.



The PE spectra of SSO and OSO (Fig. 1) do not overlap completely in any region, so that the first six bands from SSO can be identified unambiguously.

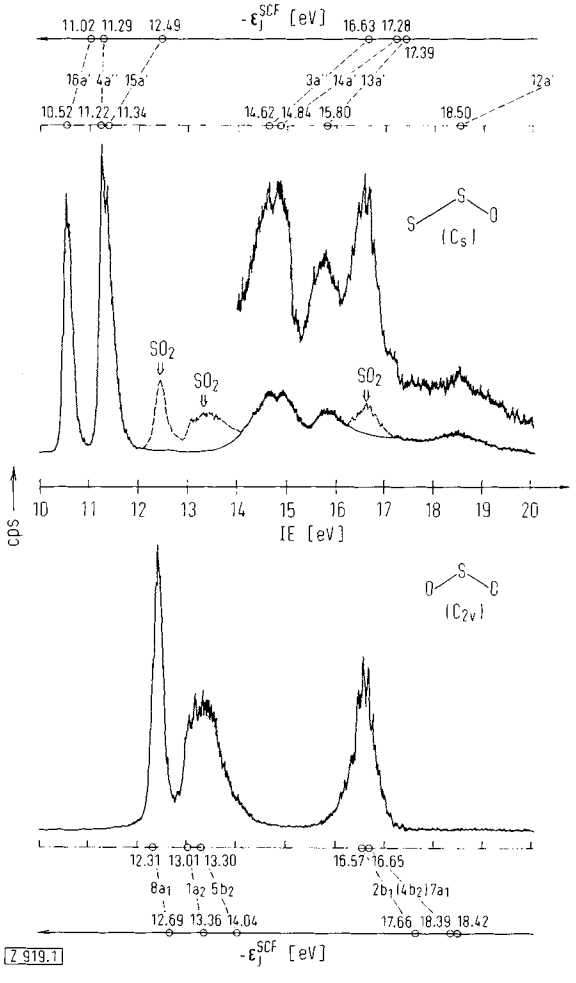


Fig. 1. PE spectra of SSO and OSO (- - - impurity SO_2) with assignment according to *ab initio* orbital energies $-\varepsilon_j^{SCF}$.

For the assignment of the SSO ionization energies IE_n an *ab initio* SCF calculation was carried out with inclusion

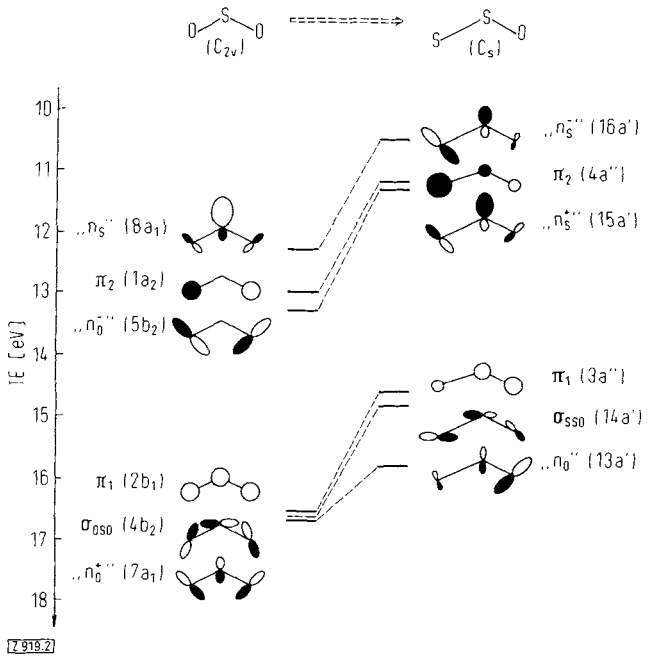

Fig. 2. Orbital correlation OSO→SSO.

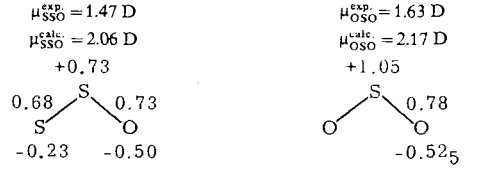
of d orbitals (gaussian basis S: 12*s*/9*p*/1*d*; O: 9*s*/5*p*/1*d*), which affords a total energy close to the attainable quality, the Hartree-Fock limit. The calculated orbital energies $-\varepsilon_j^{SCF}$ are listed in Figure 1 together with those for OSO[7]. The assignment, made on the assumption that Koopmans' theorem $-\varepsilon_j^{SCF} = IE_n$[8] is valid, can be partly supported by the vibrational fine structures visible in the spectra[5,6].

The differences in the PE spectra of SSO and OSO are illustrated by the orbital diagram in Figure 2: The replacement O→S raises all the orbitals because of the lower effective nuclear charge of sulfur. At the same time the symmetry C_{2v} is lowered to C_s and thus additional mixing becomes possible for the orbitals which are now of the same symmetry type.

This leads for instance to the result that the oxygen electron pair orbitals $1a_2$ and $5b_2$ non-bonding in OSO obtain in SSO preponderant sulfur contributions (→4*a*" and 15*a*'). It is also easily recognized that the almost energetically degenerate orbitals π_1, σ_{OSO} and n_0^+ in OSO—in the PE spectrum (Figure 1) all of them are assigned to the band at 16.6 eV[5]—on replacement O→S will split due to then different contributions from sulfur; correspondingly the PE spectrum of SSO shows three separate bands (Fig. 1).

In the ground state SSO and OSO have dipole moments μ of comparable size[1,7], the small difference between them being satisfactorily reproduced by the calculations. Nevertheless, the calculated charge distributions and bond (overlap) populations[6,7] differ characteristically:



Obviously, for SSO there results an unsymmetrical charge distribution with unequally charged sulfur atoms. The SO bond population, being reduced relative to OSO, reflects the longer SO bond length in SSO. Comparison of the SO and SS bond populations leads to the conclusion that the S—S double bond is weaker than the S—O double bond.

Like OSO, SSO is thermodynamically stable with respect to elemental sulfur and oxygen[2,6]. Its tendency to polymerize is derived, according to the SCF calculation[6] that can be correlated with the PE spectrum, from the polarizable sulfur-sulfur double bond.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The reaction of nitriles with acyl chlorides in the presence of hydrogen chloride is treated by *S. Yanagida* and *S. Komori.* This reaction represents a new route to six-membered heterocycles and novel reactive open-chain compounds. The initial step is seen in attack by the acyl chloride on the N atom of the intermediate imidoyl chlorides or α-chloro enamines formed from nitrile and HCl. The intramolecular reactions lead, *e.g.*, to quinazoline, isoquinoline, 2-pyridone, 1,3-benzothiazine derivatives. The intermolecular reaction of nitriles with acyl chlorides, *e.g.* malonyl chloride, permits synthesis of 1,3-oxazines, 2-pyridones, 3,4-dihydropyrimidines, and reaction with phosgene to synthesis of pyrimidines, 1,3-dichloroisoquinolines, α,β-unsaturated isocyanates and 1,3,5-triazines. Reactions at the N atom of the α-C atom of nitriles are also possible. [The Re-

action of Nitriles with Acyl Chlorides in the Presence of Hydrogen Chloride. Synthesis *1973*, 189—202; 39 references]

[Rd 652 IE—M]

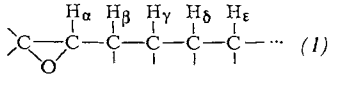
The problem of competitive coordination in complexes is reviewed by *A. D. Garnovskii, O. A. Osipov*, and *S. B. Bulgarevich*. The object of study is the position of the coordinative bond in systems possessing several potential electron donor centers. The authors conclude from numerous examples that the problem is soluble in nonconjugated systems in terms of the concept of hard and soft acids and bases. Complications arise in conjugated systems. [The Principle of Hard and Soft Acids and Bases and the Problem of Competitive Coordination in Complex Compounds. Russ. Chem. Rev. *41*, 341—359 (1972); 441 references]

[Rd 625 IE—Q]

The structures of the rare-earth silicates is reviewed by *J. Felsche*. Owing to their relatively large cations, these silicates contain isolated SiO_4 tetrahedra, Si_2O_7, and Si_3O_{10} groups. The cations show six- to ten-fold oxygen coordination. The types of structures found in this group and their stability ranges, which depend on the cation size, are described. In keeping with the topic, the review is rich in figures and tables of structure data. [The Crystal Chemistry of the Rare-Earth Silicates. Struct. Bonding *13*, 99—197 (1973); 90 references]

[Rd 655 IE—H]

Base-catalyzed rearrangements of epoxides are reviewed by *V. N. Yandovskii* and *B. A. Ershov*. Depending on the structure of the epoxide *(1)* it is possible to abstract an



(1)

α-, β-, or more distant proton with strong bases. The authors describe the subsequent reactions of the resulting carbanions. Since epoxides play an important role in the biogenesis of natural products such reactions could be of interest as models. [Base-catalyzed Rearrangements of Epoxides. Russ. Chem. Rev. *41*, 403—410 (1972); 135 references]

[Rd 656 IE—Q]

Biological and biochemical phenomena of pheromonal action are discussed for the specific example of lepidopteral sex attractants by *P. Karlson* and *D. Schneider*. Many insect pheromones are chemically related to bombykol from *Bombyx mori*. They are long-chain alcohols, aldehydes, and esters, presumably formed from long-chain fatty acids, or terpenoids. The pheromones are transported by diffusion and convection and on reaching the antennae they travel by diffusion to the receptor cell membrane where they interact with an acceptor molecule by way of weak binding forces. The pheromone stimulation releases an electrical potential (electroantennogram) whose characteristic reveals the specificity of the receptors. The question of the evolution of the highly specialized pheromone systems and their further development are discussed, as well as their species specificity. [Sexualhormone der Schmetterlinge als Modelle chemischer Kommunikation. Naturwissenschaften *60*, 113—121 (1973); 133 references]

[Rd 649 IE—M]

Ebullioscopy with salt solutions as "solvents" is described by *B. Magyar*. Solutions of salts in molecular solvents do not show a linear connection between colligative properties and concentration. Therefore such measurements are generally useless for the investigation of the ionic structure of salts, since extrapolation to zero concentration is impossible. This drawback is avoided by "salt ebullioscopy": the vapor pressures above two salt solutions, both in equilibrium with solid salt, one containing some foreign salt, are compared *via* the temperature difference between the solutions that develops in the common solvent vapor atmosphere. One obtains a linear relation of measured temperature difference *vs.* molality of foreign salt; thus, *e.g.*, the number of solute particles per formula weight of foreign salt can be determined. The method is particularly valuable for the investigation of the ionic structure of complex salts, an application which is illustrated with examples. [Salzebullioskopie. III. Theorie und Anwendung zur Bestimmung des Kondensationsgrades polynuklearer Metallkomplexe. Struct. Bonding *14*, 111—140 (1973); 22 references]

[Rd 653 IE—H]

Chalcogeno compounds of transition metals with d^0 electron configuration are reviewed by *E. Diemann* and *A. Müller*. Compounds of this type are so far known with central ions of Groups V, VI, and VII. The authors consider preparative chemistry, formation and decomposition in solutions, thermal decomposition, analytical use, industrial significance, and structural and spectroscopic properties. [Schwefel- und Selenverbindungen von Übergangsmetallen mit d^0-Konfiguration. Coord. Chem. Rev. *10*, 79—122 (1973); 222 references]

[Rd 654 IE—H]

The chemical effects of laser beams are described by *Yu. P. Yampol'skii*. A brief review is given of the various types of lasers and of the properties of laser beams. Lasers can be utilized for the generation and study of short-lived excited states. A number of examples illustrate the high specificity of laser-induced reactions. [Chemical Effects of Laser Radiation. Russ. Chem. Rev. *41*, 529—549 (1972); 140 references]

[Rd 664 IE—Q]

The use of reversed gas chromatography in the study of polymers is described by *V. G. Berezkin* and *A. M. Genkin*. Classical gas chromatography is unsuitable for polymer analysis because the high-molecular compounds are not volatile. This problem can be circumvented by utilizing destructive gas chromatography, which exploits the relationships between the gas chromatogram of the pyrolysis products and the original polymer structure. An alternative method uses reversed gas chromatography, in which the polymer under investigation is employed as carrier for the stationary phase on which volatile standard substances are separated. The behavior of the standard substances provides information about the composition, structure, and other properties of the polymer system. [Use of Reversed Gas Chromatography in the Investigation of Polymeric Compounds. Russ. Chem. Rev. *41*, 542—553 (1972); 67 references]

[Rd 665 IE—Q]

Reactions of the radicals $RO^{\cdot}$, $RS^{\cdot}$, and $RO_2^{\cdot}$ with phosphites and phosphanes have been studied by *D. G. Pobedimskii, N. A. Mukmeneva*, and *P. A. Kirpichnikov*. The article first provides a quantitative description of the kinetics of these reactions, and then applies this knowledge to mechanistic investigations on the free-radical oxidation of polymers. Phosphites inhibit these reactions by radical exchange. [Reaction of $RO^{\cdot}$, $RS^{\cdot}$, and $RO_2^{\cdot}$ Radicals with Phosphites and Phosphines. Russ. Chem. Rev. *41*, 555—564 (1972); 49 references] [Rd 666 IE—Q]

The association of hydrocarbon hydroperoxides is reviewed by *O. P. Yablonskii, V. A. Belyaev*, and *A. N. Vinogradov*. The hydroperoxides can associate with themselves, with alcohols, aromatic compounds, dienes, and olefins by way of inter- and intramolecular hydrogen bonds. The mechanism and thermodynamics of these reactions are described. [Association of Hydrocarbon Hydroperoxides. Russ. Chem. Rev. *41*, 565—573 (1972); 53 references] [Rd 667 IE—Q]

Cleavage of C—N bonds in heterocycles is described by *E. I. Levkoeva* and *L. N. Yakhontov*. Electrophilic reagents such as acids, acid anhydrides, esters, and acyl halides can cleave the C—N bond. von Braun degradation of amines and reactions under inverse Ritter conditions are considered in detail. parent compounds of biologically important substances such as riboflavin (vitamin B_2) and flavine adenine dinucleotide (FAD). The review considers, *inter alia*, tautomerisms, oxidations, reductions, and nucleophilic and electrophilic substitutions. [Reactivities of Alloxazines and Isoalloxazines. Russ. Chem. Rev. *41*, 574—591 (1972); 245 references] [Rd 670 IE—Q]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

To prepare flame-resistant and hydrolysis-resistant polyurethanes containing chemically bound phosphorus, reaction products of a chloroalkyl phosphorochloridate containing on average 0.5—2.5 chlorine atoms bonded directly to a phosphorus atom in the molecule and a primary or secondary amine, possibly containing other functional groups (*e.g.* aminoalkanol or iminodialkanol, ethylenediamine, piperazine) are used as flameproofing phosphorus compounds that can be incorporated. The reaction is carried out at 0—100 °C in the presence of excess propylene oxide as a hydrogen chloride acceptor, practically one molecule of amine being used per chlorine atom in the chloroalkyl phosphorochloridate. The chloroalkyl phosphorochloridate is prepared by reaction of phosphorus oxide chloride with ethylene or propylene oxide (molar ratio 1 : 0.5—2.5) at 0—100 °C in the presence of a catalyst such as pyridine or phosphorus trichloride. The resulting phosphorus compounds are generally amber-colored, hydrolysis-resistant liquids that react with organic polyisocyanates and possibly phosphorus-free polyols (*e.g.* polypropylene oxide) to form polyurethanes having good mechanical properties and excellent flame resistance. [DOS 1745191; Naphthachimie, Paris] [PR 63 IE—Ö]

Fruits can be made to fall and can thus be harvested more economically if the fruit-bearing trees or bushes are treated with an agent containing a thiourea derivative *(1)* shortly before the fruits ripen. Some mechanical assis-

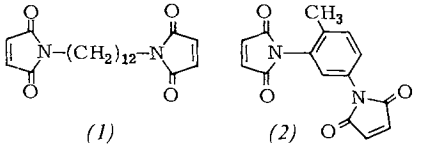
$R^1 = H, CH_3$; $R^2 = H, CH_3, C_2H_5$; X = halogen, $-O-SO_2$-alkyl, $-O-SO_2$-aryl

methods, *e.g.* by reaction of the piperidine grouping with furylmethyl derivatives or with formaldehyde and furan derivatives. [DOS 2109155; C. H. Boehringer Sohn, Ingelheim]

[PR 112 IE—N]

Poly-1,12-bis(maleimido)dodecane and poly-2,4-bis(maleimido)toluene are obtained by thermal polyaddition of the monomers *(1)* and *(2)* above their melting points. Poly-1,12-bis(maleimido)dodecane is formed as an intensely



(1) *(2)*

brown-yellow, dense substance, and poly-2,4-bis(maleimido)toluene as an intensely yellow, dense substance. Both polymers are crosslinked, are insoluble in organic media, and do not melt without decomposing. They have good mechanical properties even above 200 °C, and can be used for the production of heat-resistant molded articles such as fiber-reinforced coil formers. [DOS 2165979 + DOS 2165982; Technochemie GmbH, Heidelberg]

[PR 123 IE—S]

Plastics having the ability to retain electrostatic charges are obtained if compounds containing polar groups are incorporated into the polymers by known methods. Silicone oligomers and polymers, aromatic oligomers and polymers, and polymers and copolymers of acrylic and methacrylic acids and their esters may be used as the polymers, and alcohols, metal hydroxides, chlorine-carbon compounds, carbonyl compounds, and organic acids and their metal salts as the compound containing polar groups. If a charge is applied to the surface of the polymer, its electric conductivity decreases in the xerographic sense. [DOS 2217645, Xerox Corp., Rochester]

[PR 131 IE—E]

Polymeric hydrogels with high water contents, *e.g.* 55 to 85%, are obtained by copolymerization of a hydroxyalkyl acrylate or methacrylate and a vinyl comonomer that has a greater affinity for water than a homopolymer of the hydroxyalkyl acrylate or methacrylate in the presence of a crosslinking monomer, *e.g.* an ethylene dimethacrylate or diacrylate. Contact lenses can be made from the copolymers. Their good tolerance by the human eye is assumed to be at least partly due to the similarity of the water contents of the lenses and of the cornea. [DOS 2205391; John T. de Carle, London]

[PR 117 IE—E]

BOOK REVIEWS

Transition Metal Hydrides. Vol. I. The Hydrogen Series. By *E. L. Muetterties, B. A. Frenz, J. A. Ibers, J. P. Jesson, R. A. Schunn,* and *C. A. Tolman.* Marcel Dekker Inc., New York 1971. 1st ed., xv, 342 pp., numerous figures, bound $ 14.50.

The first volume of the new series "The Hydrogen Series" deals with the topical subject of transition metal hydrides. Since good reviews on binary transition metal hydrides have already been published, only a short chapter (22 pages) is devoted to this sector. Also for the sake of completeness, the volume is introduced by a brief outline of the physical properties of hydrogen and its isotopes. Many literature references are given for both chapters.

The actual theme of the book, the hydrido complexes of the transition metals, is introduced in the third chapter. This begins with the problem of the localization of hydrogen in structural analyses, which is followed by a well illustrated survey of all the crystal structure investigations that have now been published. The subsequent part of the book, which is the largest section, deals with the stereochemistry of the hydrido complexes in solution. A critical survey of the measuring methods that can be used for the determination of structures (with special reference to NMR and IR) is followed by a description of the structures found for the complexes. NMR data in particular are presented and discussed here. The chapter ends with a discussion on non-rigid systems. The fifth chapter deals with the preparation of the hydrido complexes, arranged according to synthesis methods, and with their reactions. Since the index of the book is very inadequate with regard to this very chapter, the search for a given compound can be very time-consuming. Improvement of the index or the inclusion of a table arranged according to substances at the end of the chapter would be desirable. The last chapter deals with homogeneous catalysis, particularly with the change in the properties of the ligands as a result of complexing, and with the reactions of the M—H bond. Special emphasis is placed here on reaction mechanisms.

The book covers the literature up to and including 1970. Chapters 3, 4, and 5 can make some claim to being substan-

tially complete. On the whole this volume is a good start to the new series. It can be strongly recommended to all those who wish to gain a detailed understanding of the hydrido complexes of the transition metals.

Mathias Höfler [NB 155 IE]

Chemical Analysis of Additives in Plastics. By *T. R. Crompton*. Pergamon Press, Oxford—New York 1971. 1st ed., xi, 162 pp., numerous figures, bound £ 7.—.

Few plastics are used at present without additives such as plasticizers or stabilizers. The identification and determination of such substances is frequently necessary for a wide variety of reasons, but is very difficult and expensive in some cases. The very extensive literature in this field is widely scattered and often applicable only to very special cases, so that there is a clear need for a good survey that would be of use to the practical worker.

The present book deals with the analysis of additives, not according to their chemical structure or fields of use, but mainly from the standpoint of methods. The qualitative analysis of known additives (phenolic and amine antioxidants, plasticizers, UV absorbers, peroxides, and various monomers) by spectroscopic methods and by thin layer and column chromatography is discussed in the first two chapters. The chromatographic methods, partly in combination with spectroscopy, for the identification and quantitative determination of unknown additives are then considered; the final chapter contains examples of the applications of gas chromatography, and the determination of monomers and volatile impurities is also discussed.

In comparison with the existing literature, the total of 330 references is rather small, but they cover the principal topics, though sometimes in a very arbitrary selection. The experimental data in the book are too concise in most cases, so that they cannot be followed directly in practice. One major disadvantage is that practical procedures and descriptive passages follow one another with little rhyme or reason, so that it is often very difficult to obtain a general picture. Little help is offered in this respect by the very brief list of contents and the index, which includes only about 170 keywords.

Apart from these limitations, the book will undoubtedly be a useful aid to the experienced plastics analyst, and should have a place in every reference library in this field. In a second edition, we would like to see a better arrangement and the inclusion of a greater number of more critically selected practical procedures.

Dietrich Braun [NB 157 IE]

Oxidation-Reduction Potentials of Inorganic Substances in Aqueous Solution. IUPAC—Selected Constants. By *G. Charlot, A. Collumeau*, and *M. J. C. Marchon*. Butterworths, London 1971. 1st ed., 73 pp., bound £ 3.50.

With the support of employees from the Laboratoire de Chimie Analytique, Paris, and from the Centre National de la Recherche Scientifique, *G. Charlot et al.* in the Electrochemical Commission of the Analytical Chemistry Division of the IUPAC have compiled a collection of data that should be useful to any inorganic chemist. The data refer mainly to complexes with oxide, hydroxide, halide, azide, cyanide, and thiocyanate as ligands. Complex redox pairs with organic ligands are unfortunately not tabulated. It is left to the reader to calculate these for himself from the data given and from constants tabulated elsewhere for complex equilibria.

Standard potentials (based on the activity $a=1$) and formal potentials (based on the concentration $c=1$) are listed separately; this takes into account the requirements of thermodynamically correct terminology. Though the majority of the potentials given are for 25 °C, the corresponding temperature is given in every case. An important advantage for comparison purposes is that the method used for the determination of the literature value is also indicated.

This tabulation covers the literature from 1900 up to December 31, 1967. The arrangement in alphabetic order of the elements is based on practical requirements, though it makes comparisons within individual chemical groups more difficult. About a dozen half-cell reactions contain errors of stoichiometry, and should be corrected with respect to the balance of particles and charges. Moreover, the symbols Es (instead of En) for einsteinium and Md (instead of Mv) for mendelevium should have been used.

To sum up, it may be said that this tabulation of about 100 redox potentials in a small volume should be a useful addition to the existing collections of data.

Norbert Kirsch [NB 159 IE]

The Identification of Organic Compounds. By *S. Veibel*, G. E. C. Gad Publisher, Copenhagen 1971. 7th ed., xvi, 471 pp., numerous figures, bound Dk 115.—.

Six years after its last edition, this well-established book is now available in its 5th English edition. The book contains the chemical methods for the detection and determination of organic compounds. The first section deals with the testing of purity, and includes chromatographic methods as one of its new features. The second section contains the methods for the detection and determination of the elements, while general methods for the examination of organic substances are given in the third section. The last and by far the largest chapter contains the methods for the detection and determination of functional groups.

In comparison with the last edition, methods that have proved less useful have been eliminated and new methods have been introduced. The latter include in particular the methods of titration in non-aqueous media. The book ends with a table of a wide range of reagents in the required concentrations and a large author and subject index.

It is undoubtedly difficult to bring a book that first appeared in 1927 up to date by constant additions and revisions. Nevertheless, this book is certainly useful and can be recommended, as long as one is interested only in chemical methods. However, the claim that can be inferred from the title cannot be upheld when one considers that spectroscopic methods, which are dominant today, are practically ignored.

Hermann Stetter [NB 162 IE]

Organosilicon Derivatives of Phosphorus and Sulfur. Monographs in Inorganic Chemistry. By *S. N. Borisov, M. G. Voronkov*, and *E. Ya. Lukevits*. Plenum Press, New York—London 1971. 1st ed., xiv, 343 pp., numerous tables and formulas, bound $ 28.—.

An element whose first organo derivatives were prepared to disprove *Mendeleev*'s system, whose second encounter with organic chemistry was motivated by the idea of using organosilicon compounds for the study of optical activity (which did not work either, at least not in this way), and which only at the third attempt found a

significant position in organoelement chemistry thanks to the technical breakthrough of organosilicon chemistry, may surprise the reader not familiar with the growth rate of its literature by now having an entire book published on only two special groups of compounds, *i.e.* organo derivatives of silicon and phosphorus and of silicon and sulfur.

This is a very concisely arranged and instructively written book by authors who have themselves made substantial contributions in this field and in whose country this branch of chemistry receives particular attention. The first 140 pages are devoted to the chapter on organosilicon derivatives of phosphorus, and a further 176 pages to the chapter on organosilicon derivatives of sulfur, both chapters being divided into sections according to characteristic bonds, *e.g.* Si—O—P, —O—S—P, —N—P, —C—P, —C—O—P, and Si—S—H, —S—C, —S—Si, —O—S, —N—S, —NCS, —C—S, —C—S—C. These sections begin with preparative methods; a few examples are used for the discussion of the behavior of the classes of substances in question, and the physical data for the various compounds are given, mostly in tabulated form.

As a result, the picture of the organoelement compounds from this part of the periodic system has been rounded off, analogies and relationships have come out, and differences have become less pronounced. The book will be rewarding both to the fundamental scientist and to those active in this field; it has much to offer to the advanced student also.

Walter Simmler [NB 161 IE]

Reaction Mechanisms in Sulfuric Acid and other Strong Acid Solutions. By *M. Liler*. Academic Press, London—New York 1971. 1st ed., xiii, 350 pp., numerous figures and tables, bound £ 6.—.

The investigation of organic compounds in very strong acids has been carried on intensively during the past few years and has led to a whole series of unique findings. A comprehensive monograph on the reaction behavior of mainly organic substances in sulfuric acid, which is probably the most versatile and the most interesting of the strong acids from the historical point of view, is therefore very welcome.

After a brief historical introduction, the first section deals with the physical (density, viscosity, conductivity, *etc.*), thermodynamic (phase transitions, heat capacity, *etc.*), and spectroscopic (Raman, IR, UV, NMR) properties of sulfuric acid/water mixtures. The section ends with a brief discussion of dideutero and ^{35}S-sulfuric acid (25 pp.). The second section is devoted to the acidity functions. The acidity functions for simple protonations, protonations of olefins, and complex ionizations are considered. The individual acidity functions (H_0, H_0', H_A, H_I, H_+, H_R, *etc.*) and their physical significance are then briefly discussed (33 pp.). The third section deals with the protonation of very weak bases, the experimental methods for the determination of basicity in sulfuric acid being discussed in the first part and individual classes of compounds with nitrogen, phosphorus, oxygen, *etc.* as the basic center, as well as basic hydrocarbons, in the second part (86 pp.). Complex ionizations of organic and inorganic substances (determination and discussion of their *i* factors) are the subject of the fourth section. The fifth and final section takes up about half of the book (139 pp.) and has the same title as the book itself. After a general discussion of the main reaction types in strongly acidic solutions, individual classes such as hydrolysis, hydration, isomerizations and rearrangements, decarbonylation and decarboxylation, electrophilic aromatic substitution, and special cases of carbonium ion reactions are discussed.

On the whole the book gives a good and comprehensive survey of reactions in sulfuric acid, the emphasis generally being placed on quantitative aspects. Preparative problems are left somewhat in the background. In the discussion of cyclizations in strong sulfuric acid, for example, a comparison with hydrogen fluoride or polyphosphoric acid would have been valuable to the organic chemist. In the discussion of the reactions of azides, one finds no reference to the extensive work of *Bamberger* on the decomposition of aryl azides in strong acids.

Hans-Jürgen Hansen [NB 165 IE]

The Radiation Chemistry of Water. By *I. G. Draganić* and *Z. D. Draganić*. Academic Press, London—New York 1971. 1st ed., xi, 242 pp., numerous figures and tables, bound $ 14.—.

Great advances, resulting in numerous publications, have been achieved in the field of the radiation chemistry of water during the past ten years, mainly through the discovery of the hydrated electron and the development of the pulse radiolysis technique.

Much of the recent knowledge is surveyed in the present monograph, which is strictly confined to the radiation chemistry of liquid water. The authors link up with an account by *A. O. Allen*, which has been one of the standard works on radiation chemistry for ten years.

The book is divided into eight chapters. It begins with a survey of the last 70 years in the radiation chemistry of water. The physical processes involved in the absorption of radiation in water are discussed in detail. Chapters 3 and 4 are devoted to the properties and chemical reactions of the primary radicals produced by radiation, *i.e.* the hydrated electrons, hydrogen atoms, and hydroxyl radicals. These two central chapters are unfortunately very incomplete, and clarity is lost through the repetition of historical considerations.

The radiation-chemical yield (G value) of primary radicals and molecular products (H_2 and H_2O_2) as a function of pH, pressure, temperature, LET, and dose rate has a chapter to itself. This is followed by a discussion of a number of new diffusion-kinetic models with a comparison of data obtained theoretically and experimentally. The book ends with a survey of experimental methods (radiation sources, pulse radiolysis technique, sample preparation, *etc.*) and dosimetry in water and with aqueous solutions.

The long compilation of original literature, which is complete up to 1967 but covered only in part up to 1969, must be specially mentioned, as well as the chapters on the radiation-chemical yield and on the diffusion-kinetic models. Another commendable feature is the summary that precedes each chapter, from which the main ideas can be repeatedly picked out, and which pleasantly break up the description, which is otherwise rigorous and often goes into great detail. The book will undoubtedly be useful to the specialist and to the interested scientist.

Klaus Eiben [NB 168 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

College Chemistry. By *G. B. King, W. E. Caldwell,* and *M. B. Williams.* 6th Edit. Van Nostrand Reinhold Company, New York—Cincinnati—Toronto—London—Melbourne 1972. ix, 696 pp., bound £ 5.65.

Analytical Chemistry of Fluorine. By *N. S. Nikolaev, S. N. Suvorova, E. I. Gurovich, I. Peka,* and *E. K. Korchemnaya.* From the series "Analytical Chemistry of the Elements". Halsted Press, a Division of John Wiley & Sons, New York 1973. xiv, 222 pp., bound £ 9.35.

Contents: Physicochemical and Analytical Description of Fluorine and Fluorine Compounds; Chemical and Physical Methods for the Determination of Fluorine; Separation of Fluorine; Determination of Fluorine in Natural and Industrial Products; Determination of Fluorine in Actinide Compounds; Determination of Fluorine in Water, Air and Biological Objects; Determination of Elementary Fluorine in Gases; Determination of Fluorine, Hydrogen Fluoride, and Impurities in Hydrofluoric Acid and in Liquid Hydrogen Fluoride.

Modern Inorganic Chemistry. By *J. H. Lagowski.* Marcel Dekker, New York 1973. xiii, 806 pp., bound $ 13.75.

Contents: Atoms and Their Characteristics; Ionic Compounds; Covalent Compounds; Theories of Bonding; Hydrogen; Solvent Properties of Covalent Hydrides; Alkali Metals; Alkaline-Earth Metals; Group III Representative Elements; Group IV Elements; Group V Elements; Group VI Elements; The Halogens; The Rare Gases; The Transition Elements; Transition-Metal Complexes: Theoretical Aspects; Organic Derivatives of the Transition Metals.

Grundriss der Biochemie. Für Studierende der Medizin, Zahnmedizin und Naturwissenschaften. By *E. Buddecke.* 3rd Edit. Walter de Gruyter, Berlin—New York 1973. xxxii, 515 pp., stitched DM 29.50.

Ultrarotspektroskopische Untersuchungen an Polymeren. (Infrared Spectroscopic Investigations on Polymers). By *J. Dechant.* Akademie-Verlag, Berlin 1972. xi, 516 pp., bound DM 93.—.

Contents: General Principles of Infrared Spectroscopy; Theory of Infrared Spectroscopy; Experimental Methods of Infrared Spectroscopic Investigations on Polymers; Special Problems of Infrared Spectroscopic Investigations of Polymers: Results of Infrared Spectroscopic Investigations on Special Polymers.

Water and Water Pollution Handbook, Vol. 4. Edited by *L. L. Ciaccio.* Marcel Dekker, New York 1973. xi, 1945 pp., bound $ 29.50.

Contents: Determination of Minor Metallic Elements in the Water Environment; Determination of Radioactive Nuclides in Water; Monitoring of Water Systems; Automated and Instrumental Methods in Water Analysis; Gas Chromatographic Analysis of Water and Waste Waters; Mass Spectrometry in Water Analysis; Infrared Spectroscopy in Water Analysis; Luminescence Techniques in Water Analysis; Electrochemical Techniques in Water Analysis.

Grundlagen der Mathematik. Eine Einführung in die mathematischen Methoden. (Principles of Mathematics. An Introduction to Mathematical Methods.) By *F. H. Young.* Verlag Chemie, Weinheim—John Wiley & Sons, New York 1973. xii, 405 pp., bound DM 44.—.

Contents: Historical Development; Numbers and Number Systems; Set Theory and Logic; Divisibility; Analytical Geometry; Functions; Differential and Integral Calculus; Vectors and Matrices; Computers.

Lebensmittel—Fortschritte in der Verfahrenstechnik der Lebensmittelverarbeitung (Foods—Advances in the Technology of Food Processing). Dechema-Monograph No. 1327—1350 (Vol. 70). Edited by Deutsche Gesellschaft für Chemisches Apparatewesen. Verlag Chemie, Weinheim 1972. 429 pp., bound DM 110.—. 24 lectures, delivered to the 4. European Symposium "Lebensmittel—Fortschritte in der Verfahrenstechnik der Lebensmittelverarbeitung mit besonderer Berücksichtigung der Proteine, Enzyme und Aromen", October 25—28, 1971, in Frankfurt.

Carbenes, Vo. 1. Edited by *M. Jones, Jr,* and *R. A. Moss.* John Wiley & Sons, New York, London, Sydney, Toronto 1973. 356 pp., bound £ 12.50.

Contents: Carbenes from Diazo Compounds; The Application of Relative Reactivity Studies to the Carbene Olefin Addition Reaction; Generation of Carbenes by Photochemical Cycloelimination Reactions.

Mass Spectrometry, Vol. 2. By *D. H. Williams.* The Chemical Society, London 1973. xi, 356 pp., bound £ 8.00.—A volume in the series "Specialist Periodical Reports".

Organic Phosphorus Compounds, Vol. 1. Edited by *G. M. Kosolapoff* und *L. Maier.* Wiley-Interscience, New York, London, Sydney, Toronto 1972. xiii, 545 pp., bound £ 13.25.

Contents: Primary, Secondary, and Tertiary Phosphines; Organophosphorous-Metal Compounds; Biphosphines, Triphosphines; Tetraphosphines, Cyclopolyphosphines, and Corresponding Oxides, Sulfides, and Selenides; Phosphine Complexes with Metals.

Magnetochemie. Grundlagen und Anwendungen. (Magnetochemistry. Principles and Applications). By *A. Weiss* and *H. Witte.* Verlag Chemie, Weinheim 1973. ix, 281 pp., bound DM 59.—.

Contents: Physical Principles of Magnetochemistry; Measuring Methods; Diamagnetism; Paramagnetism; Cooperative Phenomena; Examples of Application of Magnetochemistry to Chemical Problems.

Current Problems in Electrophotography. Edited by *W. F. Berg* and *K. Hauffe.* Walter de Gruyter, Berlin—New York 1972. xv, 387 pp., stitched DM 140.—.—Lectures delivered to the 3rd European Colloquium, Zürich, August 1971.

Chemical Thermodynamics, Vol. 1. By *M. L. McGlashan.* The Chemical Society, London 1973. xii, 362 pp., bound £ 8.00.—A volume in the series "Specialist Periodical Reports".

Developments in Inorganic Nitrogen Chemistry, Vol. 2. Edited by *C. B. Colburn*. Elsevier Scientific Publishing Company, Amsterdam—London—New York 1973. x, 228 pp., bound Dfl. 100.00/$ 31.25.

Contents: Reactions of Nitrogen(II) Oxide; The Chemistry of Dinitrogen Pentoxide; Nitrogen Compounds of Chlorine, Bromide and Iodine.

The Isoquinoline Alkaloids. Chemistry and Pharmacology. By *M. Shamma*. Volume 25 of the series "Organic Chemistry". Academic Press, New York—London—Verlag Chemie, Weinheim 1972. xviii, 594 pp., bound DM 122.—.

Gmelins Handbuch der anorganischen Chemie. 8th Edit., part B 4 Niob, System No. 49. Verlag Chemie, Weinheim 1973. xxiv, 473 pp., bound DM 641.—.

Contents: Oxoniobate der Alkalimetalle; Niobverbindungen mit weiteren Kationen und Anionen; Kohlenstoffverbindungen des Niob.

Industrielle Destillation. By *R. Billet*. Verlag Chemie, Weinheim 1973. xi, 502 pp., bound DM 108.—.

Contents: Die Verfahren der thermischen Flüssigkeitszerlegung; Thermodynamische Grundlagen der Gemische; Kontinuierlich arbeitender Rektifizierapparat; Diskontinuierlich arbeitender Rektifizierapparat; Semi-kontinuierlich arbeitender Rektifizierapparat; Verfahrenstechnische Bewertung, Kostenoptimierung und Auswahl von Kolonneneinbauten; Optimierung der Trennungen; Unterlagen zur Dimensionierung von Trennkolonnen; Partielle Destillation; Partielle Kondensation; Destillation in Laboratoriums- und Technikumskolonnen; Molekulardestillation; Zubehör von Trennanlagen; Einsatz von Computern.

Laboratory Experiments in College Chemistry. By *G. B. King, W. E. Caldwell*, and *M. B. Williams*. 3rd Edit. Van Nostrand Reinhold Company, New York—Cincinnati—Toronto—London—Melbourne 1972. vi, 280 pp., stitched £ 2.60.

Spectroscopy and Kinetics. Edited by *J. S. Mattson, H. B. Mark, Jr.*, and *H. C. MacDonald, Jr.* Vol. 3 of the series "Computers in Chemistry and Instrumentation". Marcel Dekker, New York 1973. xi, 330 pp., bound $ 19.75.

Organic Functional Group Preparations, Vol. 3. By *S. R. Sandler* and *W. Karo*. Vol. 12-III of the series of monographs "Organic Chemistry" Academic Press, New York—London 1972. xi, 496 pp., bound $ 24.50.

Contents: Acetals and Ketals; Anhydrides; Monoalkyl Sulfates; Sulfenic Acids and Sulfenic Acid Derivatives; Isonitriles; Amidines; Imidines; Imidates; Nitrones; Hydroxylamines and Substituted Hydroxylamines; Oximes; Hydroxamic Acids; Thiohydroxamic Acids.

Zerkleinern. Dechema Monograph No. 1292—1326 (Vol. 69). Edited by Deutsche Gesellschaft für Chemisches Apparatewesen. Verlag Chemie, Weinheim 1972. Two parts having a total of 948 pp., bound DM 192.50.—35 Lectures and discussions held at the 3rd European Symposium on "Size Reduction" October 5—8, 1971 at Cannes.

Electronic Transitions and the High Pressure Chemistry and Physics of Solids. By *H. G. Drickamer* and *C. W. Frank*. From the series "Studies in Chemical Physics". Edited by *A. D. Buckingham*. Chapman and Hall, London 1973. x, 220 pp., bound £ 5.00.

Contents: Introduction; Theories of Electronic Energy Levels in Molecules and Solids; Thermal Versus Optical Transitions; Phenomenological Description of Continuous Electronic Transitions; Methods for Studying Electronic Structure at Very High Pressure; Shifts of Energy Levels with Pressure; Electronic Transitions in Metals and Insulator-Metal Transitions; Spin Changes in Iron Complexes; The Reduction of Ferric Iron; Changes of Oxidation State and Spin State; Reactions in Aromatic Molecules and Complexes.

Die Struktur der Proteine. By *H. Fasold*. Vol. 12 of the series "Chemische Taschenbücher". Edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie, Weinheim 1972. x, 298 pp., stitched DM 32.—.

Contents: Aminosäuren und Peptide; Verfahren zur Reinigung und Charakterisierung der Proteine; Aufklärung der Primärstruktur; Raumstruktur der Peptidketten (Sekundär- und Tertiärstruktur); Quartärstruktur von Proteinen; Evolution eines Proteinmoleküls und Determination seiner Tertiär- und Quartärstruktur; Denaturierung von Proteinen; Enzyme; Beispiele einiger Proteinfamilien.

The "Nickel Effect"

By Karl Fischer, Klaus Jonas, Peter Misbach, Reinhold Stabba, and Günther Wilke[*]

In Memory of Karl Ziegler

Whereas the reaction of ethylene and triethylaluminum under pressure at 100 °C yields trialkylaluminum compounds having long alkyl chains, the presence of small amounts of nickel salts induces the formation of butene. The discovery of this "nickel effect" represents the starting point for the development of the Ziegler catalysts. Comparatively little was formerly known about the nature and the mode of action of the catalytically active nickel species. A basis for the elucidation of the effect was provided by studies on the reduction of nickel compounds by organoaluminum compounds, on the occurrence and existence of nickel hydrides, and on interactions between nickel(0) and Lewis acids as well as organic compounds of main group metals. The most significant result of these studies is the recognition that multicenter bonding systems involving trialkylaluminum compounds and nickel atoms are involved. These react further with complex bonded ethylene in what is probably a concerted manner.

1. Introduction

The appearance of this review practically coincides with the twentieth anniversary of the discovery of the "Nickel Effect" by *Ziegler* and *Holzkamp*[1]. This discovery, the systematic investigation of which led to the Ziegler catalysts[1b, 2], started an avalanche which caused a revolution in certain areas of chemistry, and led to the development of new large-scale technical processes as well as heralding an almost unimaginable flood of patents and publications. Years later the "nickel effect" initiated a further development which can be described as the chemistry of "naked nickel"[3]. This in turn led to the pure π-allyl transition metal systems[4] of which bis(π-allyl)nickel[5] has become the prototype.

In the following article the opportunity is taken to report on some new results from the Mülheim Institute concerning the chemistry of nickel complexes. Initially, however, it seems relevant to describe the original observations which led, twenty years ago, to the "nickel effect", and then to answer the question: What do we know about it today?

Ziegler and *Gellert*[6, 1c] observed that triethylaluminum reacts at 100 °C with ethylene under pressure to give trialkylaluminum compounds whose alkyl chains may have molecular weights of *ca.* 3000 in extreme cases. In other words, higher trialkylaluminum compounds can be prepared in an organometallic synthesis involving the repeated addition of the Al—C bond to the C=C bond of the ethylene molecule. Hydrolysis of these higher alkyls produces wax-like *n*-paraffins whose molecular weights were found to depend upon the ratio of triethylaluminum to ethylene.

An extended series of experiments always led to more or less the same result until unexpectedly one experiment, although carried out as usual, produced almost exclusively

[*] Dr. K. Fischer, Dr. K. Jonas, Dr. P. Misbach, Dr. R. Stabba, and Prof. Dr. G. Wilke
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

butene—the dimer of ethylene. A systematic search for the component responsible for this effect, although initially fruitless, finally revealed that traces of nickel salts, in particular bis(2,4-pentanedionato)nickel [$Ni(acac)_2$], present as cocatalysts in the triethylaluminum caused chain cleavage after each insertion step[1]. In the original experiment a V2A autoclave had been cleaned with sulfuric acid and as a result traces of nickel salts had been left behind[1b].

Subsequently we learnt how to generate a highly active, stable cocatalyst and the following recipe was developed on a purely empirical basis[7]:

$Ni(acac)_2$ is dissolved in xylene, phenyl acetylene (1:30) added, and the mixture treated as carefully as possible with $(C_2H_5)_2AlOC_2H_5$. The actual catalyst—triethylaluminum—is then added to the resulting orange-red solution. Using this system it is possible to convert ethylene into butene in over 90% yield.

At that time hardly anything was known about π-complexes and it was therefore assumed that the orange-red solution contained colloidal nickel stabilized by phenylacetylene[1,7]. The basis of the principle which we developed later for the synthesis of transition metal complexes by reduction of transition metal compounds by alkylmetal compounds in the presence of molecules capable of functioning as ligands[8] is already latent in the above procedure. It is also a curious coincidence that the cocatalyst in this procedure is itself able to catalyze the cyclooligomerization of butadiene to cyclooctadiene and cyclododecatriene[9]. Such is the early history.

Although the "nickel effect" has had such important consequences, the mechanism of the reaction has received relatively little attention, and even in the face of an extensive organic chemistry of nickel, conclusive mechanistic evidence is still lacking today. The following discussion, however, should contribute substantially towards an explanation.

2. Reduction of Bis(pentanedionato)nickel by Trialkylaluminum[10]

2.1. Reduction by Trimethylaluminum

When a solution of bis(pentanedionato)nickel [$Ni(acac)_2$] *(1)* in toluene is treated with $Al(CH_3)_3$ *(2)* elemental nickel is rapidly deposited, even at temperatures below −100 °C, and methane and ethane are liberated. The overall reaction is described approximately by:

$$\underset{(1)}{Ni(acac)_2} + 2\ \underset{(2)}{Al(CH_3)_3} \rightarrow Ni + [0.25\ C_2H_6 + 0.5\ (CH_3)_2Alacac] + [1.5\ CH_4 + 1.5\ H_3C{-}\underset{\displaystyle -CH_2}{\overset{\displaystyle |}{Alacac}}]$$

Experiments in D_8-toluene show that the CH_3 radicals, presumably produced by the decomposition of an intermediate $Ni(CH_3)_2$ species, preferentially abstract H atoms from the $Al(CH_3)_3$ since practically no CH_3D is formed. The $Al{-}CH_2$ group could not be detected as $Al{-}CH_2{-}Al$, in contrast to the results obtained, for example, by *Sinn et al.*[11] with the $(C_5H_5)_2TiCl_2$ and $Al(CH_3)_3$ systems. The use of $Al(CD_3)_3$ in toluene produces a mixture of CD_3H and CD_4 in the ratio 1.5:1, apparently as the result of an isotope effect, *i.e.* the H atoms of the toluene are somewhat more easily abstracted than the D atoms of $Al(CD_3)_3$. Experiments carried out in the continuous flow cell of an ESR spectrometer demonstrate that free radicals are not formed in measurable concentrations.

It has been possible to isolate a stable derivative of dimethylnickel by working in the presence of α,α′-bipyridyl; the complex bpy·$Ni(CH_3)_2$ *(3)*, recrystallizable from boiling benzene, is obtained[12]. This complex is particularly suitable for studying the decomposition of $Ni(CH_3)_2$ since the bipyridyl can be removed, for example, by treatment with Lewis acids at room temperature.

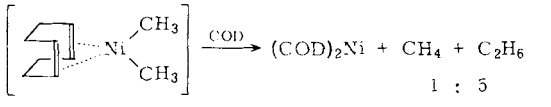
$$\underset{(3)}{bpy\ Ni(CH_3)_2} \xrightarrow{2\ Al(CH_3)_3} \underset{(4)}{bpy \cdot 2\ Al(CH_3)_3} + Ni + CH_4 + C_2H_6 \quad (5:1)$$

$$\underset{(3)}{bpy\ Ni(CH_3)_2} \xrightarrow{2\ BF_3} bpy \cdot 2\ BF_3 + Ni + CH_4 + C_2H_6 \quad (1:7)$$

The composition of the gas is markedly dependent upon the Lewis acid, and only the extreme cases are shown above. However, from a series of experiments using $Al(CH_3)_3$, $Al(CH_3)_2Cl$, $AlCH_3Cl_2$, $AlCl_3$, and BF_3 it is possible to follow the change in the $CH_4:C_2H_6$ ratio from 5:1 to 1:7.

These experiments also demonstrate that the H atom is abstracted preferentially from the organoaluminum component. If the Lewis acid contains no H atoms then mainly dimerization occurs. The same behavior is also observed on addition of the chelating ligand 1,5-cyclooctadiene (COD).

$$\underset{(3)}{bpy \cdot Ni(CH_3)_2} + \underset{(2)}{2\ Al(CH_3)_3} + COD \rightarrow \underset{(4)}{bpy \cdot 2\ Al(CH_3)_3} +$$

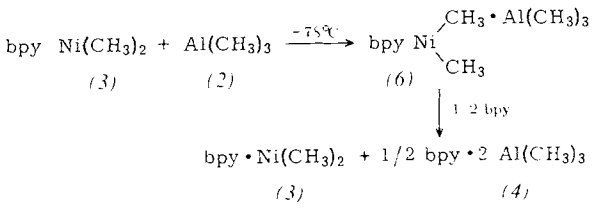


$$\rightarrow (COD)_2Ni + CH_4 + C_2H_6 \quad (1:5)$$

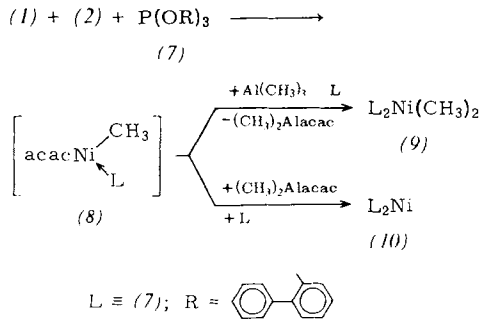
(5)

Apparently the CH_3 groups in complex *(5)* (which has not been isolated) are held in a *cis*-arrangement so that homolysis of the Ni—C bond leads preferentially to coupling. This could be interpreted as indicating that the CH_3 radicals which abstract H atoms result from a linear $Ni(CH_3)_2$ species. It has been possible to isolate a crystalline intermediate *(6)* in the decomposition of *(3)* by *(2)* by working at low temperature.

At higher temperature *(6)* decomposes in the normal manner and may be reconverted into *(3)* by use of excess bipyridyl.



It is relevant to mention the somewhat different behavior observed in the related reaction of *(1)* with *(2)* in the presence of tris(2-biphenylyl) phosphite *(7)* (L) as a function of the concentration of *(2)*[12, 13a].

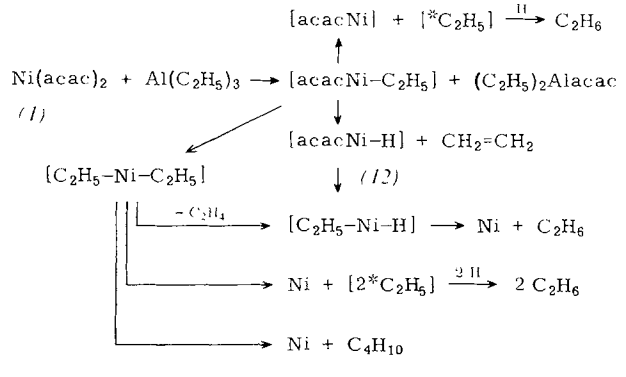


The intermediate *(8)* reacts with excess *(2)* to give the stable complex *(9)*, while an initial ratio of *(1)*:*(2)* of 1:1 leads exclusively to *(10)*. The interaction of *(8)* with the pentanedionate group in $(CH_3)_2Al(acac)$ is clearly important here. When L = tricyclohexylphosphane, *(8)* could be isolated in crystalline form[13b] and its structure determined by X-ray crystallography[13c].

Thus the reduction of the nickel in *(1)* by $Al(CH_3)_3$ is considered to proceed, in general, by homolysis of the Ni—C bond of an intermediate dimethylnickel species. Under certain conditions the CH_3 groups preferentially couple giving ethane.

2.2. Reduction by Triethyl- or Triisobutylaluminum

A somewhat different behavior is observed in the reduction of $Ni(acac)_2$ by alkylaluminum compounds whose alkyl groups have a H atom in a β position to the Al atom:



homolysis giving alkyl radicals, which abstract H atoms, and the dimerization of alkyl groups, are accompanied by a β H elimination to give a Ni—H species and an olefin. Under suitable conditions gas yields of 85—100% can be obtained.

The extent to which the reaction follows a particular direction is dependent upon a number of external factors (purity of $Ni(acac)_2$, hydride content of the $Al(C_2H_5)_3$, solvent, temperature, presence of ligands). The following behavior is typical:

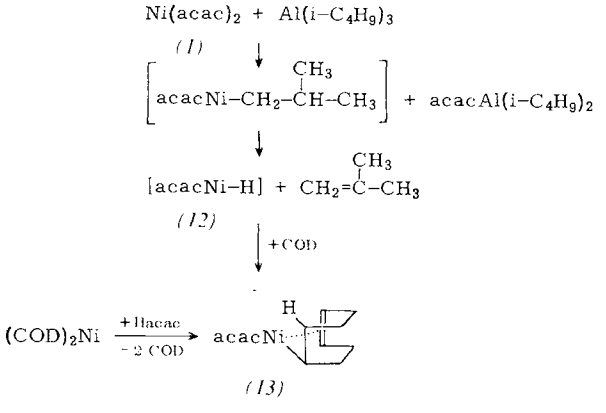
$Ni(acac)_2$ (3 mmol) in toluene (10 ml) at −78 °C, treated with hydride-free $Al(C_2H_5)_3$ (6 mmol), on warming to 20 °C generates ethane (2.5 mmol), ethylene (0.4 mmol), butane (1.5 mmol), and butene (0.1 mmol). Thus the ethyl groups corresponding to the 6 mmol which are used for the reduction of the $Ni(acac)_2$ appear almost quantitatively in this gas mixture.

The main reactions are again H abstraction (ethane) and dimerization (butane), the β elimination (ethylene) appearing to play a less important role.

The reaction of *(1)* with $Al(i\text{-}C_4H_9)_3$ occurs almost exclusively as a β-H elimination without coupling and without radical H abstraction: isobutane and isobutene are produced in an almost exact 1:1 ratio in over 90% yield.

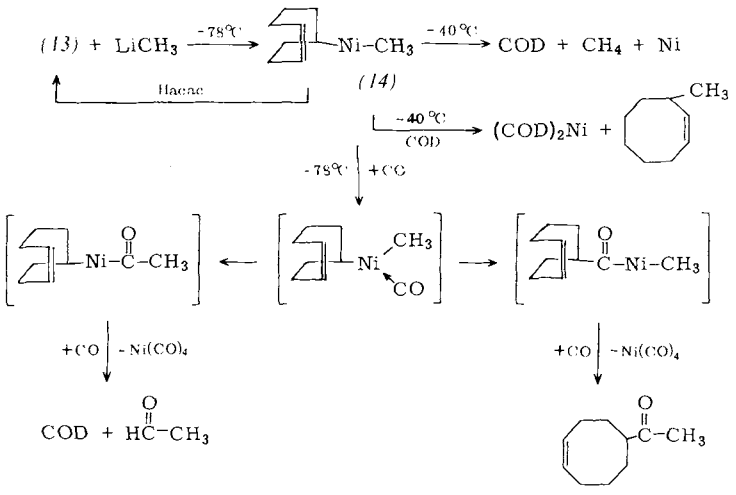
2.3. Trapping of the Intermediate Pentanedionatonickel Hydride

In the reaction scheme shown in Section 2.2, pentanedionatonickel hydride *(12)* is formulated only as a possible intermediate. That it is involved may be indicated by working in the presence of cyclooctadiene:

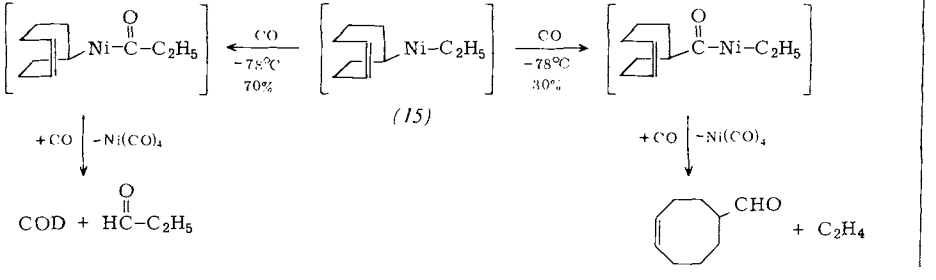


On addition of the Ni—H bond to a C=C bond of 1,5-cyclooctadiene, 4-cyclooctenyl(pentanedionato)nickel *(13)* is produced and can be isolated in crystalline form. We have previously synthesized *(13)* from $(COD)_2Ni$ and 2,4-pentanedione[8] and its structure has been established by an X-ray structural analysis[14]. It is obvious that *(13)* cannot be formed in reactions involving $Al(CH_3)_3$.

(13) can itself be regarded as an intermediate since further reduction in the presence of COD leads to bis(cyclooctadiene)nickel. In this reaction alkyl(4-cyclooctenyl)nickel complexes are involved and the methyl derivative *(14)* has been isolated as a red crystalline solid:



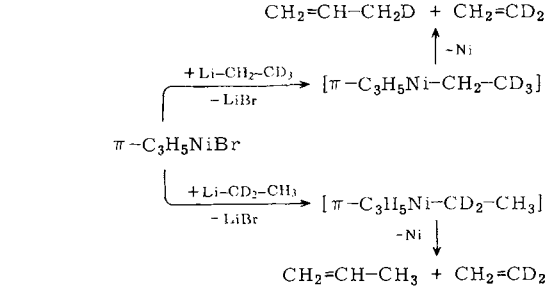
Decomposition of *(14)* occurs by β-H elimination to give COD and CH_4. Decomposition in the presence of COD, however, occurs almost exclusively by coupling [*viz.* bipy·$Ni(CH_3)_2$] and is accompanied by isomerization, since 3-methylcyclooctene and not 5-methylcyclooctene is produced. β-H elimination on the one hand and coupling on the other are even observed in the products resulting from carbonylation. The ethyl compounds *(15)*, corresponding to *(14)*, cannot be isolated but their formation may be indirectly established by investigating the products of carbonylation.



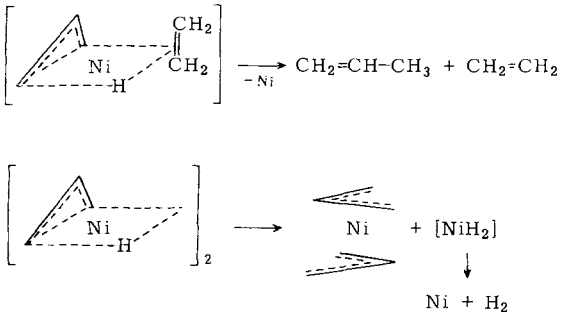
The acyl derivatives obtained from *(15)* react exclusively by β-H elimination.

2.4. A Model for β-H Elimination[15]

We have observed a particularly convincing example of the β-H elimination in the reaction of π-allylnickel bromide with ethyllithium deuterated in either the α- or β positions. At −70 °C the ethyl group is transferred to the nickel to give π-allyl(ethyl)nickel which immediately undergoes a β-H elimination to give ethylene and the unstable π-allylnickel hydride; this, in turn, reacts further by transfer of the hydride atom to the allyl group to generate propene and elemental nickel. The gaseous reaction products (yield >95%) consist of either 3-deuteriopropene and 1,1-dideuterioethylene or of propene and 1,1-dideuterioethylene, depending upon the position of deuteration in the ethyllithium used.



The course of the reaction is apparently influenced by the ethylene generated, since the observed decomposition of the intermediate π-allylnickel hydride complex to propene and nickel only occurs under the conditions described above. In contrast, the reaction of π-allylnickel bromide with NaH·$B(CH_3)_3$[24] is accompanied by disproportionation of the π-allylnickel hydride into essentially pure *trans*-bis(π-allyl)nickel[16] and the unstable NiH_2, which decomposes into nickel and hydrogen. From these results one can conclude that the coupling reaction which leads to propene is the result of the complexation of the ethylene; in the absence of ethylene the dimeric π-allylnickel hydride presumably disproportionates.

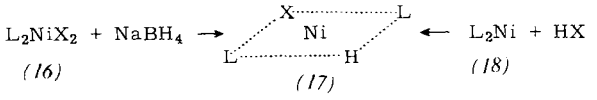


The results described in Sections 2.1 to 2.4 are not only relevant to the nickel-effect but also of general interest, since the same processes are observed in the synthesis of transition metal complexes, in the preparation of catalysts for olefin oligomerization, and also in the catalytic reactions themselves[17] (see, *inter alia* ref. [40]).

3. Stable Nickel Hydrides

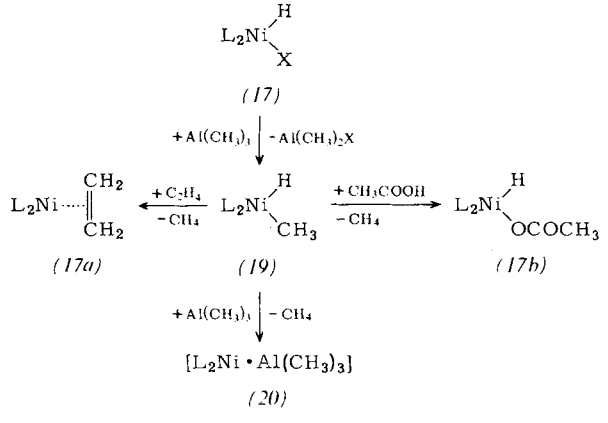
Interest in a possible NiH_2 species in conjunction with the catalytic hydrogenation using nickel catalysts stems from the year 1923[18]. However, more recent results[19] have not supported the early work. A series of carbonylnickel hydrides have been known since 1953 in which several nickel atoms are bridged by CO molecules; however, these complexes are of no relevance here.

The first evidence for the existence of phosphanenickel halide hydrides was obtained in 1959—1960[20] when a high field signal was observed in the ^{1}H-NMR spectrum of a reaction mixture consisting of $(R_3P)_2NiCl_2$ *(16)* and $NaBH_4$ dissolved in THF. A definite compound, however, could not be isolated and ten years elapsed before a complex of the type $(R_3P)_2NiHX$ *(17)* was prepared—practically simultaneously by *Green*[21] and ourselves[22] although by completely different routes: *Green* and *Saito* treated *(16)* with $NaBH_4$ while we prepared *(17)* by the oxidative addition of HX to an L_2Ni-system *(18)*.



L = P(Alkyl)$_3$, P(Cycloalkyl)$_3$
X = Cl, Br, I, $OCOCH_3$, OC_6H_5, 1-Pyrrolyl

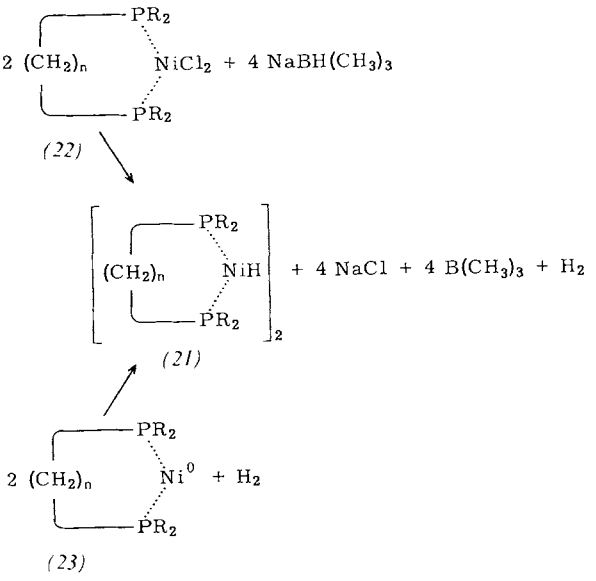
Complexes of type *(17)* are most probably planar with the phosphane ligands in a *trans*-arrangement[*] [L = $P(C_6H_{11})_3$, X = Cl; τ = 34.6 (t, H_{Ni-H}; J_{PH} = 73.5 Hz)]. At least 20 further examples of this type of compound are now known. *(17)* can be viewed as a model for the catalysts described in the preceding sections[17]. Its reactions to give *(17a)*, *(17b)*, and *(20)* are characteristic.



The product *(19)* of the reaction between *(17)* and $Al(CH_3)_3$ is stable at room temperature and releases methane on protonolysis with acetic acid to give *(17b)*[22]. Treatment with ethylene effects a coupling reaction to give methane and an ethylene complex *(17a)*. Compound *(19)* also reacts with $Al(CH_3)_3$, releasing methane, to give the rather indefinite product *(20)*. (Compounds of this type are treated in Section 4.)

Nickel hydrides *(21)* having a remarkable structure[23] are formed when nickel chloride bonded to an oligomethylenebis(phosphane) *(22)* is treated with a toluene solution of $NaBH(CH_3)_3$[24].

The resulting complexes *(21)* are diamagnetic and of unusual stability (*(21a)* does not decompose below 150 °C). The structure of *(21b)* has been determined by X-ray



(a), n = 2; *(b)*, n = 3; *(c)*, n = 4; R = c-C_6H_{11}

crystallography (Fig. 1). It also proved possible to locate the bridging H atoms[25] (Fig. 2).

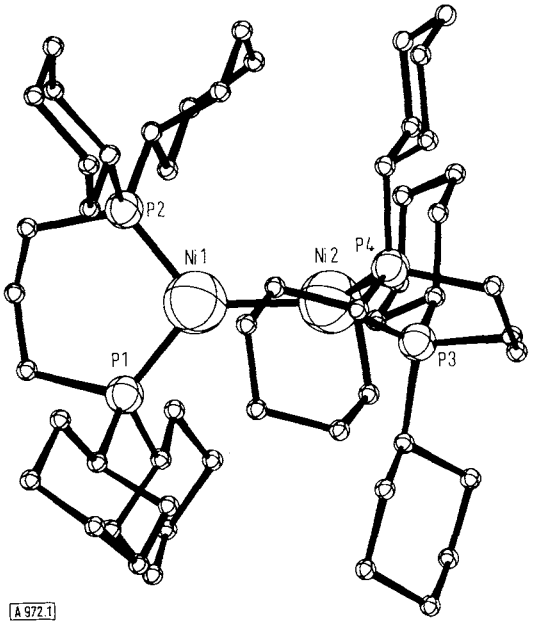


Fig. 1. Crystal structure of di-μ-hydridobis[trimethylenebis(dicyclohexylphosphane)nickel] *(Ni—Ni) (21b)*.

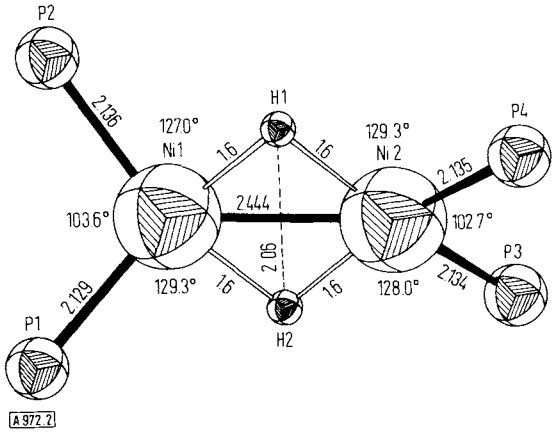

Fig. 2. Arrangement of bridging H atoms in *(21b)*.

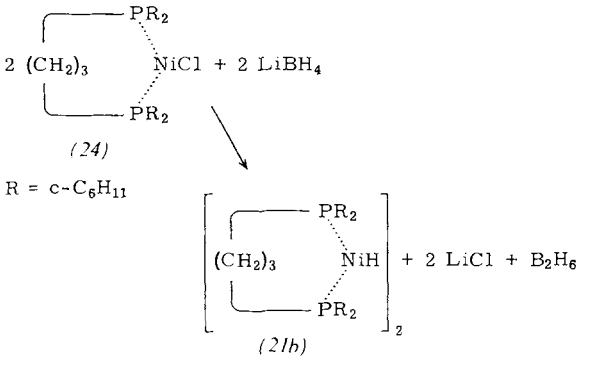
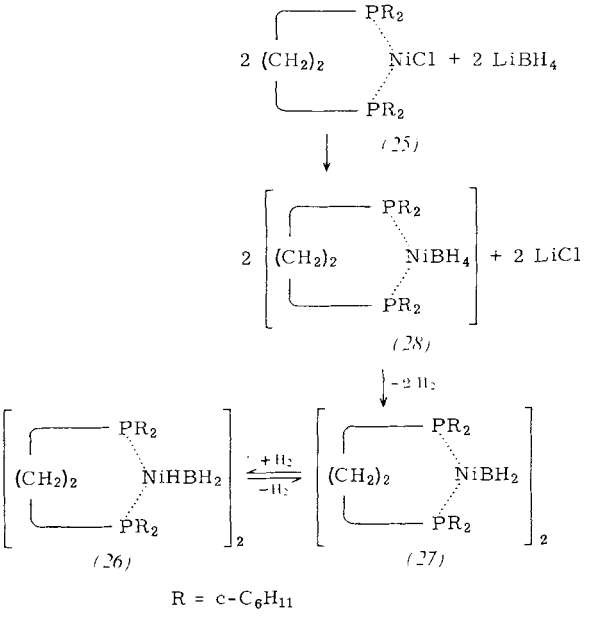
[*] An X-ray structural determination of $[i\text{-}(C_3H_7)_3P]_2NiHCl$ confirms this arrangement. Personal communication from *U. A. Gregory* and *B. T. Kilbourn*, quoted by *B. A. Freny* and *I. A. Ibers* in: Transition Metal Hydrides. Dekker, New York 1971, p. 45.

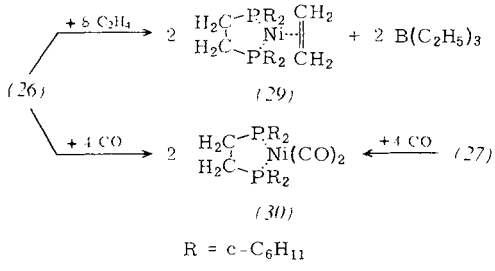
The ^{1}H-NMR spectrum is in full accord with this structure (H_{NiHNi}, $\tau = 21.4$, quintet, $J_{PH} = 23.5$ Hz). Owing to the Ni—Ni bond the nickel(I) hydride *(21b)* is diamagnetic. *(21a)* is also obtained when the bis(phosphane)nickel(0) system *(23a)* is treated with molecular hydrogen. Thus an impressive model is available for the cleavage of the H_2 molecule occurring during catalytic hydrogenations at nickel surfaces. *(21b)* also results from the nickel(I) complex *(24)* and $LiBH_4$.



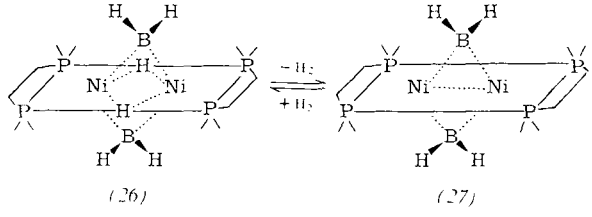
However, if the bridge between the phosphorus atoms consists of only two CH_2 groups *(25)*, then a complex *(26)* can be isolated after reaction with $LiBH_4$.



In the first step *(25)* is postulated to give an unstable $NiBH_4$ system *(28)*[*] from which H_2 is released to give the nickel boron compound *(27)*; this in turn absorbs hydrogen and is converted into *(26)*. The isolated complex *(26)* releases hydrogen to give *(27)* which can also be isolated. This step is reversible, although limited by the gradual decomposition which occurs. *(26)* absorbs ethylene smoothly to give *(29)* and $B(C_2H_5)_3$, while both *(26)* and *(27)* react with CO to give *(30)*, although in neither case could a product containing the BH_3 or BH_2 group be isolated.

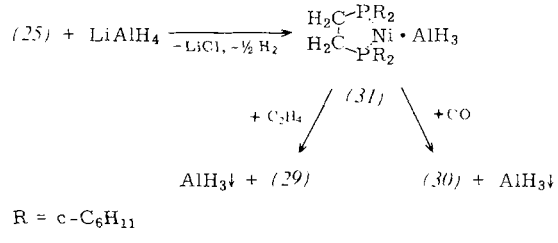


Both *(26)* and *(27)* are diamagnetic and are suggested, by analogy with *(21b)*, to be dimeric.



The IR-spectrum of *(26)* contains bands attributable to both terminal and bridging H atoms.

The corresponding AlH_3 derivative *(31)* is presumed also to belong to the same class of compounds and may be prepared in an analogous manner by treating *(25)* with $LiAlH_4$.



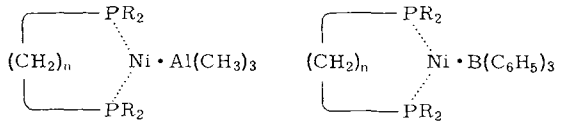
Although AlH_3 is not normally monomeric it is complexed in this form to the bis(phosphane)nickel system of *(31)* from which it may be eliminated by treatment with ethylene or CO, simultaneously polymerizing. The reaction of *(31)* with ethylene differs from that of *(26)*; although *(29)* is formed, no $Al(C_2H_5)_3$, corresponding to the formation of $B(C_2H_5)_3$, is produced.

4. Interaction of Nickel(0) with Organometallic Compounds and Lewis Acids

It has repeatedly been observed that solutions of nickel(0) with or without donor ligands, are stabilized by aluminum alkyls. However, in most cases it has not proved possible to isolate any well defined products. The stabilization could be the result of Lewis acid—Lewis base interaction in which the nickel(0) is regarded as a Lewis base. However, the generation of multicenter bonds between the nickel(0) and the metal alkyl seems to be of more significance.

[*] *M. L. H. Green, H. Munakata,* and *T. Saito* have described a stable $L_2Ni(H_2BH_2)$ system; J. Chem. Soc. *A 1971*, 469.

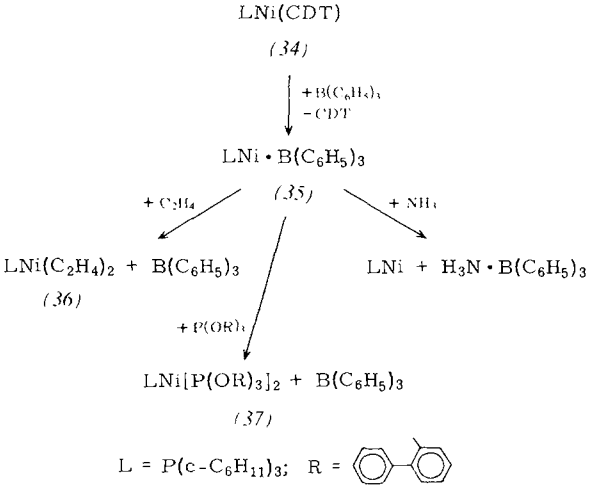
The incompletely characterized compound *(20)* mentioned in Section 3 can be viewed as an example of this type of interaction. Other isolable complexes include a 1:1 adduct *(32)* of the bis(phosphane)nickel(0) complex *(23)* and $Al(CH_3)_3$, as well as the complexes *(33a)* and *(33b)*.



(32) *(33)*

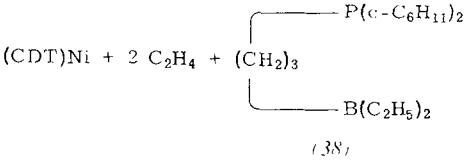
(a), n = 2; *(b)*, n = 3; R = c-C_6H_{11}

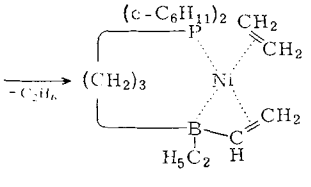
It is not essential for adduct formation that the nickel atom be bonded to a bis(phosphane) system, and particularly interesting is the displacement of the 1,5,9-cyclododecatriene (CDT) from the 1:1 complex *(34)* (formed by reaction of cyclododecatrienenickel with P(c-C_6H_{11})$_3$) by reaction with $B(C_6H_5)_3$. The resulting product *(35)* is a complex of tricyclohexylphosphanenickel and triphenylborane.



(35) can be cleaved both by those ligands which bond preferentially to nickel(0) as well as by Lewis bases *e.g.* ethylene, tri-(2-biphenylyl)phosphite and ammonia.

Complexes *(20)*, *(21)*, *(27)*, *(31)*, *(32)*, and *(33)* are either of low stability or are readily cleaved by ligands such as phosphanes or olefins. In the hope that stable





(39)

complexes could be prepared if the Lewis acid were part of a chelating ligand bonded to the nickel, borylphosphanes of type *(38)* were synthesized[27] and allowed to react with (CDT)Ni and ethylene: displacement of the CDT from the nickel by the borylphosphane *(38)* and ethylene occurred.

An X-ray structural analysis[28] of the crystalline complex *(39)* (Fig. 3) as well as its NMR spectrum show that upon complexation an alteration in *(38)* has occurred: an ethyl group has been exchanged for a vinyl group which is complexed to the nickel. The B—Ni distance of ≈ 2.5 Å does not allow a final decision to be made as to whether a bonding situation exists between the boron and nickel.

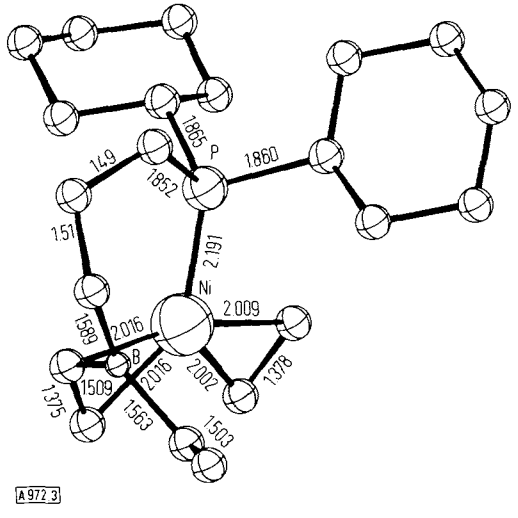


Fig. 3. Crystal structure of ethylene[ethyl(vinyl)borylpropyldicyclohexylphosphane]nickel(0) *(39)*.

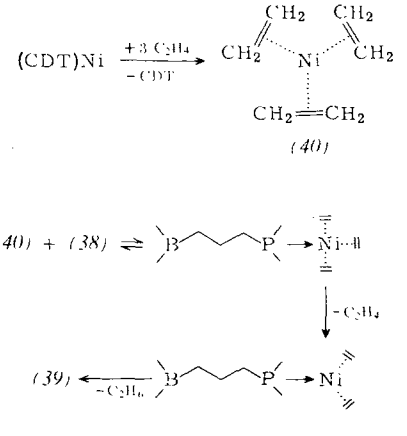
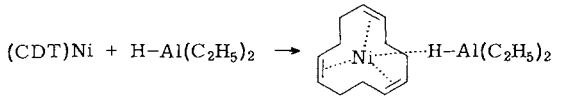
The intermediates involved in the formation of this complex and in particular the process leading to the vinyl group remain unknown. Almost certainly the first step is the displacement of the CDT by ethylene, since (CDT)Ni does not react with *(38)* in the absence of ethylene. Tris(ethylene)nickel(0) *(40)*, first discovered in this experiment[29], is formed and reacts further in a synchronous process



in which an H atom of a complexed ethylene molecule is transferred to the *B*-ethyl group, liberating ethane and generating the *B*-vinyl system.

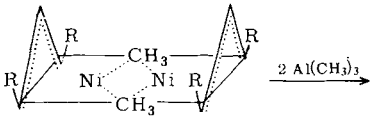
At the beginning of this section we mentioned the stabilizing effect of aluminum alkyls upon solutions containing nickel(0) as well as the fact that well defined products cannot, in general, be isolated. In this context it is of interest that a crystalline compound *(41)*[27] can be prepared by reacting (CDT)Ni and dialkylaluminum hydride (1:1) at −78 °C. Protonolysis of the decomposition product [*(41)* decomposes above −60 °C] gives a mixture of cyclododecadiene, cyclododecene, and cyclododecane, in addition to cyclododecatriene (CDT), showing that addition of the Al—H bonds to the C=C bonds has occurred. The ^{1}H-NMR spectrum of *(41)* indicates that the hydridic hydrogen atom of the diethylaluminum hydride is bonded to the fourth coordination position of the nickel (Al—*H*—Ni, τ = 15.2, s; free $(C_2H_5)_2AlH$, τ = 7.36).



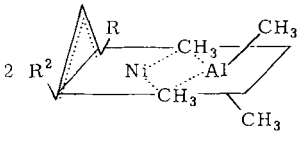
(41)

With ether *(41)* forms a 1:1 adduct, in contrast to free $(C_2H_5)_2AlH$ which is highly associated. This example illustrates that multicenter bonds of this type need to be considered in any discussion on the interaction of organoaluminum compounds with nickel complexes.

Multicenter bonds between like species have been conclusively demonstrated in the nickel(I) hydride *(21b)* as well as in the dimer of π-allyl(methyl)nickel *(42)*[30]. This last compound even shows a molecular peak in the mass spectrum corresponding to a dimer, *i.e.* the Ni—CH_3—Ni group is relatively stable. Apparently the Ni—CH_3—Al bond is of even greater stability since on reaction of *(42)* or *(43)* with $Al(CH_3)_3$ *(2)* monomerization occurs to give the 1:1 adduct *(44)* or *(45)*.



(42), R = H
(43), R = CH_3



(44), R = H
(45), R = CH_3

The ^{1}H-NMR spectrum of *(44)* at low temperature consists of three signals (2:1:1) for the CH_3 protons. The signal having an intensity of 2 is assigned to the protons of the bridging CH_3 groups and the remaining two to the terminal CH_3 groups. In the case of the more stable complex *(45)* it is possible to show from the ^{1}H-NMR spectrum that the bridging and terminal CH_3 groups are rapidly exchanging positions at higher temperatures[30b].

The formation of such multicenter bonds is not limited to the nickel(0)-aluminum hydride or -alkylaluminum systems and recent investigations[31, 26] have shown that the alkyl and aryl groups of organolithium compounds can also bond to nickel(0). Phenyllithium reacts with (CDT)Ni to give a 1:1 adduct in which the phenyl group is presumed to occupy the fourth coordination position at the nickel, thereby forming a Ni—C—Li bridge. The existence of such a bridge in $[(LiC_6H_5)_3Ni]_2N_2 \cdot 2O(C_2H_5)_2$ (which contains π-bonded dinitrogen[32]) has been established by an X-ray structural analysis[33].

Ethyllithium and ethylene react with bis(cyclooctadiene)nickel at −30 °C with complete displacement of the olefin molecules: at low temperatures a complex *(46)* may be isolated in which the ethyl groups apparently interact with the nickel[26].

$$(COD)_2Ni + C_2H_4 + 2LiC_2H_5 \xrightarrow[-2COD]{+O(C_2H_5)_2} (LiC_2H_5)_2Ni \cdot C_2H_4 \cdot O(C_2H_5)_2$$

(46)

If the reaction is carried out at 20 °C without an excess of ethylene, then *(47)* is formed almost quantitatively[26].

$$(COD)_2Ni + 3LiC_2H_5 \rightarrow (LiH)_3Ni \cdot C_2H_4 + 2COD + 2C_2H_4$$

(47)

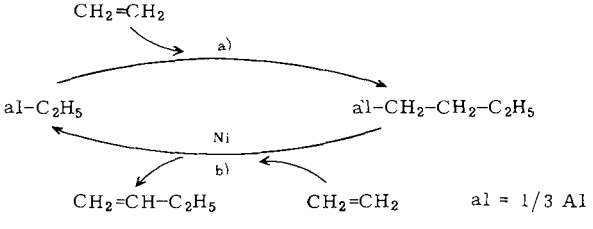
Complex *(47)* has a certain similarity with the well known complex $K_4[Ni(C{\equiv}CH)_4]$[34], although in the former case the four coordination positions around the nickel(0) are occupied by three hydride ions and an ethylene molecule.

Of special interest is the coordination of ethyllithium to nickel(0): under the influence of the nickel, cleavage into lithium hydride and ethylene occurs at room temperature (in the absence of nickel a temperature of at least 100 °C is necessary). In this case the nickel facilitates, particularly effectively, stoichiometric β-H elimination in an alkyl compound of a main-group metal.

5. Mechanism of the "Nickel Effect"

5.1. Former Concepts

The "nickel effect" was discovered in 1955 during a study of the insertion of ethylene into $Al(C_2H_5)_3$ (see Section 1). The catalytic cycle in which ethylene is dimerized can be divided into an insertion step (a) and a displacement step (b) as illustrated schematically below:



Only step b) is influenced by the nickel and can be carried out, independently of the insertion reaction, with any trialkylaluminum.

$$Al(CH_2{-}CH_2{-}R)_3 + 3\,CH_2{=}CH_2 \xrightarrow{Ni} Al(C_2H_5)_3 + 3\,CH_2{=}CH{-}R$$

The mechanism of the nickel-catalyzed displacement reaction has been considered by four groups of authors.

Ziegler et al. expressed themselves as quoted below:[7] "The activity of the (colloidal) nickel is still not understood. It could be that it catalyzes a genuine displacement (in a bimolecular collision) of the type

$$R'al + olefin^{II} \rightarrow R^{II}al + olefin^{I}\ [*]$$

in which the dialkylaluminum hydride does not function as an intermediate".

Eisch and *Foxton*[35] later suggested the following mechanism without actually having investigated the reaction experimentally[**]:

$$(C_4H_9)_3Al + NiZ_2 \rightleftharpoons C_4H_9NiZ + (C_4H_9)_2AlZ$$

$$C_4H_9NiZ \rightleftharpoons HNiZ + C_4H_8$$

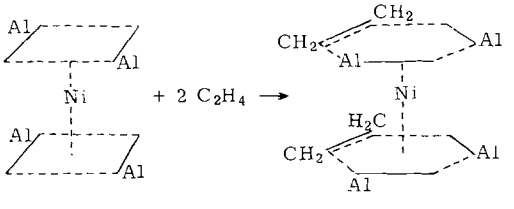
$$C_2H_4 + HNiZ \rightleftharpoons CH_2{=}CH_2 \rightleftharpoons H_2C{-}CH_2$$

(Ni, H, Z; ZNi, H)

$$H_2C{-}CH_2 + (C_4H_9)_3Al \rightleftharpoons H_2C{-}CH_2 + C_4H_9NiZ$$

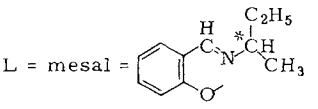
(ZNi, H; $(C_4H_9)_2Al$, H)

Lucas[36] has discussed a π-complex of the following type:



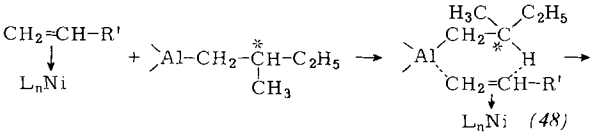
Experimental evidence for the existence of such complexes was not presented.

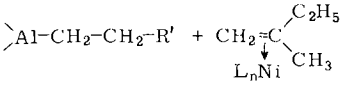
The most extensive study has been made by *Pino et al.*[37]. They were able to show that the use of nickel(II) compounds containing optically active groups induces optical activity during the displacement reaction. It was concluded that at least one optically active group remains bonded to the catalytically active nickel. This conclusion is supported by the observation that the original nickel compound could be regenerated by protonolysis after the reaction with alkylaluminum[***]. In addition, the participation of HNiZ intermediates could be largely eliminated. The displacement reaction can be summarized as shown below[****]:

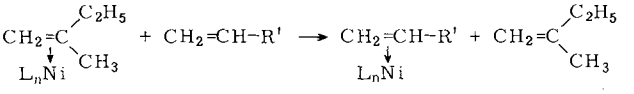


$$Ni(mesal)_2 + xAlR_3 \rightarrow L_nNi$$

$$L_nNi + CH_2{=}CH{-}R' \rightarrow CH_2{=}CH{-}R'$$
$$\downarrow$$
$$L_nNi$$







The complex *(48)* formed from L_nNi, the olefin, and the alkylaluminum is regarded as being of central importance.

5.2. Recent Experimental Results[27]

Before considering the various mechanistic suggestions we shall present some recent experimental results which enable the further discussion to be placed on a more certain basis.

The extremely sensitive tris(ethylene)nickel *(40)*[29], obtained by treating (CDT)Ni with ethylene at 0 °C, is stabilized significantly by $Al(C_2H_5)_3$ without any reaction being observed; however, when perdeuterioethylene is used a deuterated triethylaluminum results. If $Al(C_4H_9)_3$ is reacted instead of $Al(C_2H_5)_3$ in a ratio of 1:1 then the following conversion occurs instantaneously and almost quantitatively:

$$Ni(C_2H_4)_3 + Al(C_4H_9)_3 \rightarrow 3\,C_4H_8 + Al(C_2H_5)_3 + Ni$$
(40)

This is the first example in which a well defined nickel(0) complex takes part in a stoichiometric displacement reaction with a trialkylaluminum. The ethylene molecule causing the displacement is that originally bonded to nickel(0) which, however, does not prove that the reacting ethylene is in a complexed state. The reaction is catalytic if carried out in the presence of excess ethylene and $Al(C_4H_9)_3$. Various other nickel(0) complexes catalyze the reaction of ethylene with trialkylaluminum compounds in a manner similar to *(40)* and high catalytic activity is observed

[*] al = 1/3 Al.

[**] The original scheme is applied here, in simplified form, to the $Al(C_4H_9)_3{-}C_2H_4$ system.

[***] Protonolysis in the presence of atmospheric oxygen produces nickel(II) which reacts immediately with the liberated phenol *e.g.* H mesal, to give the original nickel(II) compound.

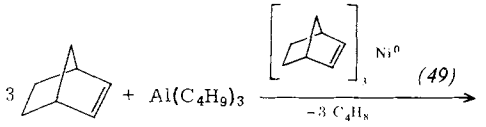
[****] Original formulation.

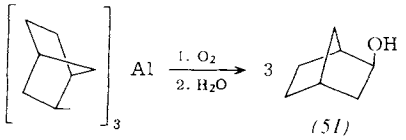
for those complexes in which the nickel atom is associated either solely with olefinic ligands or at the most with a single phosphane-like ligand. If more than one coordination position is blocked by a phosphane then the activity of the catalyst sinks sharply.

Unexpectedly, the nickel(0) also loses its activity if, for example, tris(ethylene)nickel(0) *(40)* is treated with diethylaluminum hydride. The origin of this behavior is still unknown.

The following observations are also of relevance to the discussion of the "nickel effect":

Bicycloheptene and $Al(C_4H_9)_3$ do not react to any significant extent at 20°C; however, upon addition of a catalytic amount of tris(bicycloheptene)nickel(0) *(49)*[38] butene is released and the organoaluminum compound *(50)* is formed. The main product of the air oxidation of *(50)* and subsequent hydrolysis is *exo*-norbornanol *(51)*[41].





(50) *(51)*

The X-ray structural analysis of *(49)*[39] shows that the nickel atom is attached *exo* to the double bond of the bicycloheptene molecule (Fig. 4).

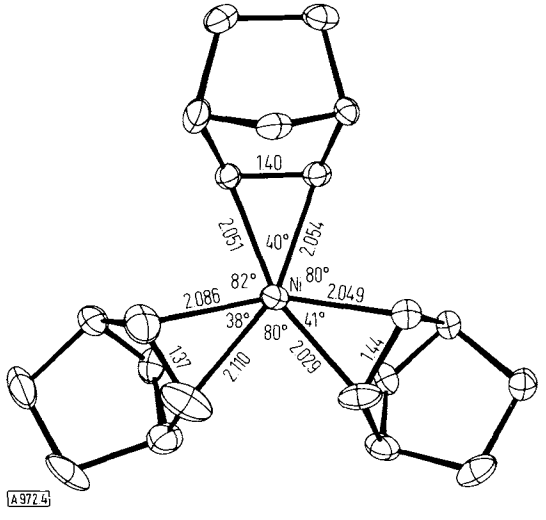


Fig. 4. Crystal structure of tris(bicycloheptene)nickel(0) *(49)*.

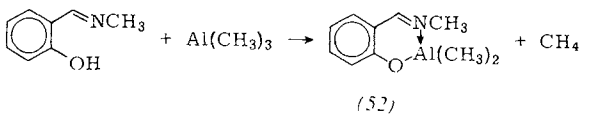
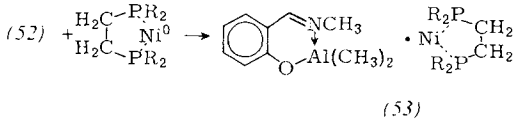
Finally, it has been possible to synthesize a model compound *(53)* relevant to the mechanism proposed by *Pino*.

Compound *(53)* is crystalline and stable up to 100°C. Its structure is not known with complete certainty but it can be assumed that the C=N bond is complexed to the nickel atom.



(52)



(53)

R = c-C_6H_{11}

5.3. Discussion of the Mechanism

Although colloidal nickel cannot be completely ruled out as the active species, the reactions of $Al(C_4H_9)_3$ with both tris(ethylene)nickel(0) *(40)* and tris(bicycloheptene)-nickel(0) *(49)* demonstrate that complexes of nickel(0) actively promote the "nickel effect". Diethylaluminum hydride can be discounted as an intermediate since it even functions as a catalyst poison.

The investigations of *Pino et al.* have effectively eliminated the possible intermediacy of an HNiZ species (Z = appropriate ligand). In addition, all experiments show that nickel compounds, particularly at higher temperatures, are quantitatively reduced by trialkylaluminum compounds to nickel(0), *i.e.* the original anions bonded to the nickel are transferred to the aluminum.

This result is in conflict with *Pino*'s assumption that the L_nNi system (L = mesal) is responsible for the induced optical activity. The model compound *(53)* shows that nickel(0) is able to form complexes with compound *(52)*, and the slight induction of optical activity observed can be attributed to complexes of this type.

Although the π-complexes formulated by *Lucas* are not based upon experimental evidence, they nevertheless come closest to the mechanism suggested below since they imply an interaction between the nickel, the olefin, and the trialkylaluminum.

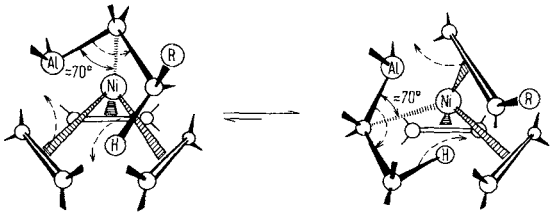
The ability of nickel(0) to complex with olefins has been established for a whole series of examples, and in the context of this article tris(ethylene)nickel(0) *(40)* and tris-(bicycloheptene)nickel(0) *(49)* are particularly relevant examples. The interaction of nickel atoms with alkyls and hydrides of main group metals to form multicenter bonds has also been established in a number of cases [*e.g. (41)*, *(44)*, *(45)*, *(46)*, $[(LiC_6H_5)_3Ni]_2N_2 \cdot [O(C_2H_5)_2]_2$].

The stereochemical course of the reaction between bicycloheptene and $Al(C_4H_9)_3$ in the presence of tris(bicycloheptene)nickel(0) *(49)* shows that tributylaluminum attacks the double bond from the same side as that to which the nickel atom is complexed, and, since no reaction is observed in the absence of nickel, it can be assumed that complexation is a necessary step.

Based upon these results and deductions we propose the following mechanism for the nickel-catalyzed displacement reaction, *i.e.* for the "nickel effect":

The nickel(II) compound introduced as the catalytic component is reduced by the trialkylaluminum, generating nickel(0) which then reacts with the olefins present in

the reaction mixture to form an olefin complex, *e. g.* tris(ethylene)nickel(0) *(40)*. A multicenter bond is formed between the nickel(0) complex and the trialkylaluminum in which the α-C atom of the trialkylaluminum bridges the nickel and aluminum atoms. It can be seen from models that in an arrangement of this sort the C atoms of the complexed olefinic double bond, as well as a β-H atom of the alkyl group, closely approach the Al atom, thereby permitting an electrocyclic reorganization process (Fig. 5).



A 972.5

Fig. 5. Reaction of tris(ethylene)nickel(0) *(40)* with tributylaluminum. $R = C_2H_5$.

The equilibrium shown in Figure 5 is known from experience to lie to the right—this is supported, for example, by the almost quantitative reaction of $Ni(C_2H_4)_3$ *(40)* with $Al(C_4H_9)_3$ which we have already discussed. The driving force for the reaction can be viewed as the energetically favored formation of butene from ethylene. The difference in the heat of hydrogenation is 3 kcal/mol, and it is possible that the energy of association of $Al(C_2H_5)_3$ is slightly higher than that of $Al(C_4H_9)_3$, which would also favor the reaction.

According to the present state of our knowledge the "nickel effect" is seen to result from complexation of ethylene to nickel(0) with simultaneous formation of multicenter bonds between the nickel(0) and the trialkylaluminum.

Asymmetric Syntheses with the Aid of Homogeneous Transition-Metal Catalysts

By Borislav Bogdanović
Based upon the work of Borislav Bogdanović, Biserka Henc, Arnold Lösler, Burkhard Meister, Horst Pauling, and Günther Wilke[*]

In Memory of Karl Ziegler

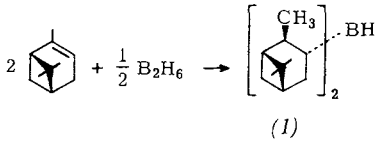
The progress made in the field of homogeneous catalysis during the last five to six years has led, *inter alia*, to the development of highly selective catalysts for asymmetric syntheses. Homogeneous asymmetric hydrogenation, using well defined transition metal catalysts, may be achieved with optical yields of 85 to 90% or more. Catalytic reactions, in which the chiral centers are generated by C—C bond formation, can result in optical yields of 70 to 80%. The hydrogenation catalysts consist primarily of rhodium(I) complexes containing "Horner phosphanes", phosphanes with chiral C atoms, or optically active amides. Catalysts which induce optical activity through the formation of C—C bonds have been developed from π-allylnickel halides, Lewis acids, and phosphanes containing chiral C atoms. The results obtained signify a breakthrough in an area of catalysis previously restricted to syntheses involving enzymes.

1. Introduction

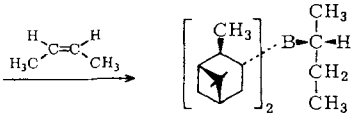
In 1848 *Pasteur*[1] succeeded in effecting the first separation of the two enantiomeric forms of the chiral compound, sodium ammonium tartrate. However, the preparation at will of optically active compounds of high optical purity[****] still remains a challenging problem waiting for a satisfactory solution.

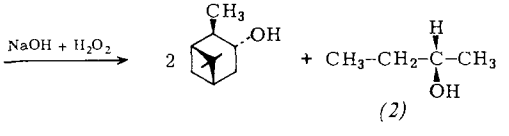
When achiral reactants are used in normal chemical synthesis the products are obtained only in the racemic form. Although racemic mixtures may sometimes be conveniently separated (*e.g.* the technical synthesis of lysine[4]), most separation methods[3] are relatively difficult, requiring large quantities of optically active reagents in relation to the yield of the optically active product obtained.

It is significantly more elegant to set out to prepare optically active compounds more directly with the aid of optically active reagents[5]. A particularly impressive asymmetric hydroboration has been reported by *H. C. Brown et al.*[6]: diisopinocampheylborane *(1)*, obtained by addition of diborane to α-pinene, reacts with 1,2-disubstituted olefins such as *cis*-2-butene to give a new chiral center. Oxidation



(1)





(2)

of the B—C bond, followed by hydrolysis, leads to the secondary alcohol *(2)* in an optical yield of *ca.* 90%. However, it should be noted that at least two moles of the optically active reagent—in this case α-pinene—are required to produce each mole of optically active alcohol *(2)*.

Only those systems involving enzymes[7] are able to convert optically inactive starting materials into optically active compounds of practically 100% optical purity without the help of large quantities of optically active reagents.

Understandably, much effort has been expended in attempts to develop asymmetric catalysts modeled on enzyme systems in the hope that with such systems it would be possible to synthesize optically active substances at will and independently of nature. Until recently such

[****] *The optical purity* (*O. P.*) is defined as the specific rotation [α] of a substance divided by the specific rotation [*A*] of the pure enantiomer. It is expressed as a percentage:

$$O.P.\,[\%] = \frac{[\alpha]}{[A]} \times 100$$

The value obtained for the optical purity is equivalent to that found for the *enantiomer purity*, which is a measure of the excess of one enantiomer over the other:

$$\text{enantiomer purity}\,[\%] = \frac{F_+ - F_-}{F_+ + F_-} \times 100$$

F_+ and F_- represent the mole fractions of the dextro- and levorotating enantiomers, respectively [2].

The optical yield [%] obtained in an asymmetric synthesis is defined as the optical purity of a reaction product multiplied by 100 and divided by the optical purity of the optically active reactant or catalyst used in the synthesis.

attempts were relatively unsuccessful, but in 1956 *Akabori, Sakurai, Izumi,* and *Fujii*[8-10] succeeded in effecting the asymmetric hydrogenation of various oxime and oxazolone derivatives: optical yields of up to 35%[*] were obtained using a heterogeneous catalyst consisting of metallic palladium drawn out on silk. (Progress in the field of heterogeneous asymmetric hydrogenation is described in reference[11].) The first experiments in which the polymerization of optically inactive monomers were asymmetrically induced using optically active organometallic or Ziegler catalysts were described early in the last decade by *G. Natta et al.*[13]. However, in all these cases the optical yields remained low (6—7%).

Since 1968 cases of catalytically induced asymmetric hydrogenation in the homogeneous phase have been reported; catalysts for these reactions include rhodium complexes containing ligands such as "Horner phosphanes"[**], phosphanes with chiral C-atoms, or optically active amides.

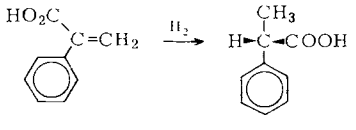
In the catalytic asymmetric hydrogenation reactions the chiral centers are generated during the formation of C—H bonds. However, since 1966 organonickel catalysts containing phosphane ligands incorporating chiral C atoms have been developed here in the Mülheim Institute, and these catalyze asymmetric syntheses in which the chiral center is formed through the linkage of C atoms.

In the following article, a brief review of the developments made in the area of asymmetric hydrogenation is followed by an account of the present status of catalytic asymmetric synthesis involving C—C bond formation.

2. Catalytic Asymmetric Hydrogenation in the Homogeneous Phase

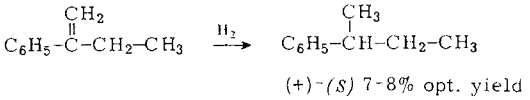
The basis for the development of homogeneous asymmetric hydrogenation catalysts was laid, on the one hand, by the discovery of the versatile rhodium hydrogenation catalysts of the type $Rh(PR_3)_3X$ (X = halogen) by *Wilkinson et al.*[14], and, on the other, by the synthesis of the first optically active phosphanes to contain chiral phosphorus atoms by *Horner et al.*[15]. (The preparation of Horner phosphanes is also described in references[16-18].)

In 1968 two groups of workers, *Knowles* and *Sabacky*[19a], and *Horner, Siegel,* and *Büthe*[20], almost simultaneously reported the first asymmetric homogeneous hydrogenations of optically inactive compounds. The Monsanto group[19a] (see also references[19b, 19c]) prepared the catalyst from the rhodium complexes RhL_3Cl_3 (L = optically active phosphane) by treatment with hydrogen (20 atm) in benzene-ethanol solution in the presence of triethylamine. Using (−)-(*R*)-methyl(phenyl)propylphosphane it was possible to convert atropic acid into (+)-(*S*)-hydratropic acid in an optical yield of 15%.



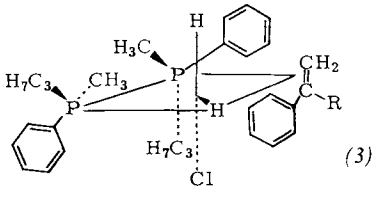
(+)-(*S*) 15% opt. yield

Horner et al.[20b], using a catalyst prepared *in situ* from $[Rh(1,5\text{-hexadiene})Cl]_2$ and (+)-(*S*)-methyl(phenyl)propylphosphane in benzene, effected several hydrogenations including the conversion of α-ethylstyrene to (+)-(*S*)-2-phenylbutane at normal pressure. Optical yields of 7—8% were obtained.



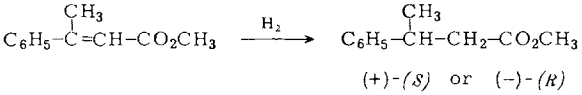
(+)-(*S*) 7-8% opt. yield

The authors attempted to correlate the configuration of the optically active product with that of the optically active phosphane involved using *(3)* (R = *e.g.* C_2H_5, OCH_3) as a model of the catalyst[20b].



(3)

In 1969 *Abley* and *McQuillin*[21] reported the first asymmetric hydrogenation reaction to proceed with an optical yield of over 50%. Methyl β-methylcinnamate was hydrogenated to methyl 3-phenylbutyrate using a catalyst system prepared by reducing $RhCl_3(py)_3$ (py = pyridine) with $NaBH_4$ in *solvents* such as (+)- or (−)-(*N*-1-phenylethyl)-formamide, or other optically active amides.



(+)-(*S*) or (−)-(*R*)
54% opt. yield

Later in this work[22] the catalyst was prepared in ethyl digol[***] to which only 5% (+)-*N*-(1-phenylethyl)formamide had been added (instead of in the pure optically active *N*-(1-phenylethyl)formamide), and the same asymmetric induction (50—60%) was observed. It was therefore concluded that the optically active amide became coordinated to the rhodium atom—most probably *via* the oxygen atom—during the asymmetric hydrogenation reaction.

Morrison et al.[23] were the first to successfully effect asymmetric hydrogenation using a rhodium catalyst and a phosphane containing an optically active moiety[24], namely neomenthyldiphenylphosphane. The catalyst, probably a Rh^IL_3Cl complex, was prepared *in situ* from rhodium(I)-olefin complexes and neomenthyldiphenylphosphane (L); it was used to hydrogenate, *e.g.*, (*E*)-β-methylcinnamic acid *(4)* to (*S*)-3-phenylbutyric acid *(5)*, and (*E*)-α-methylcinnamic acid *(6)* to (*R*)-2-benzylpropionic acid *(7)*, in optical yields of 61 and 52% respectively (solvent: benzene/ethanol).

Dang and *Kagan*[25] synthesized the chiral bis(phosphane) *(8)* (L) from the diethyl ester of (+)-tartaric acid, and

[*] According to the authors these results are difficult to reproduce [12].

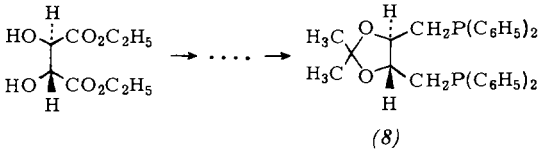
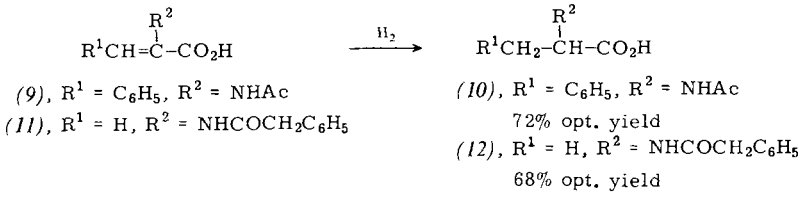
used this as the chiral agent in rhodium(I)-complex-catalyzed asymmetric hydrogenation.



(8)

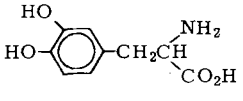
The catalyst, probably a Rh(L)ClS complex (S = solvent) generated by reaction between *(8)* and $[Rh(cyclooctene)_2Cl]_2$, assisted in effecting the reduction of α-acetylaminocinnamic acid *(9)* to (*R*)-*N*-acetylphenylalanine *(10)* and of α-phenylacetylaminoacrylic acid *(11)* to (*R*)-*N*-phenylacetylalanine *(12)*. At 20 °C and under a hydrogen pressure of one atmosphere these reactions proceeded with optical yields of 72 % and 68 % respectively (solvent: benzene/ethanol).



(9), $R^1 = C_6H_5$, $R^2 = NHAc$
(11), $R^1 = H$, $R^2 = NHCOCH_2C_6H_5$

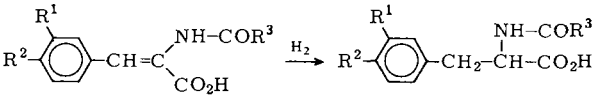
(10), $R^1 = C_6H_5$, $R^2 = NHAc$
72% opt. yield
(12), $R^1 = H$, $R^2 = NHCOCH_2C_6H_5$
68% opt. yield

The high optical yields observed using this catalyst are attributed to the conformational rigidity of the chelating bis(phosphane), and also to the part played by the acidic functional group in the substrate. In a later publication[26] by the same authors it was reported that this catalyst system effected the hydrogenation of β-substituted α-acetylaminoacrylic acid derivatives and that, *in general*, optical yields of 70—80 % were obtained. This route permits the convenient synthesis of a series of biologically important optically active amino acids including Dopa *(13)*, thereby convincingly demonstrating the potential technical and commercial importance of catalytic asymmetric hydrogenation reactions.



(13)

The highest optical yield yet to be achieved during catalytic asymmetric synthesis has recently been reported by *Knowles, Sabacky*, and *B. D. Vineyard*[27]. The catalysts $[RhL_2Cl]$ were prepared from rhodium(I)-olefin complexes and optically active cyclohexyl-(*o*-methoxyphenyl)methylphosphane *(18)*; hydrogenation of the α-acylaminocinnamic acids *(14)* and *(15)*, and their derivatives *(16)* and *(17)*, to the corresponding precursors of phenylalanine, *(19)* and *(20)*, and Dopa, *(21)* and *(22)*, respectively, was accomplished with product purity of 85 %—90 %. As the Horner phosphane *(18)* was probably not more than 95 % optically pure, the authors believe that this catalyst system is almost completely stereoselective in its operation.



(14), $R^1 = R^2 = H$, $R^3 = CH_3$

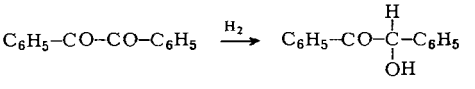
(18)

Ohgo, Takeuchi, and *Yoshimura*[28] have shown that high optical yields may be obtained using catalyst systems based on transition metals other than rhodium. Thus, benzil may be homogeneously hydrogenated to benzoin in an optical yield of 61.5 % using an asymmetric catalyst, bis(2,3-butanedionedioximato)cobalt(II) modified by the addition of quinine.



3. Catalytic Asymmetric Syntheses with Catalysts Comprising π-Allylnickel Halides, Phosphanes, Lewis Acids

3.1. Catalytic Asymmetric Synthesis of 3-Vinyl-1-cyclooctene and 3-Methyl-1-pentene

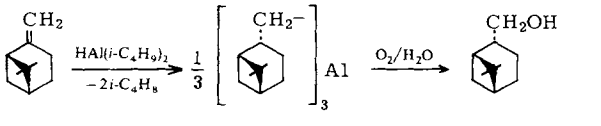
The discovery of the synthesis of 1,5,9-cyclododecatriene from butadiene at the Mülheim Institute in 1956[29] was the starting point for systematic investigations of the catalytic properties of transition metal compounds, particularly those of nickel.

Highly active catalyst systems for the dimerization, oligomerization, codimerization, and isomerization of olefins

are produced when π-allylnickel halides are activated by the addition of Lewis acids such as aluminum halides or alkylaluminum halides. An important observation, which stimulated research in this area, was made in 1963; the addition of phosphanes to the basic catalyst for the dimerization of propylene in the molar ratio 1:1 allows the course of the reaction to be controlled to produce, for instance, either 2-methylpentenes or 2,3-dimethylbutenes as the major products[30–34].

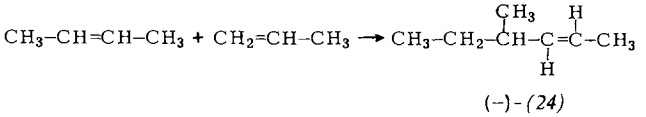
It was later found that the phosphanes were not only responsible for changes in the relative rates of formation of the respective propylene dimers, but also strongly influenced the activity of the catalyst with respect to olefin isomerization[34]. Further, in the oligomerization of ethylene the degree of oligomerization was controlled by the phosphane added, and the catalytic changes undergone by 1,5-dienes (*i.e.* the formation of five-membered ring products as opposed to the 1,3- or 1,4-diene isomerization products) were also phosphane dependent. Recent research has shown that such phosphane effects are essentially steric in nature[35].

The discovery that the course of these nickel-catalyzed reactions is extremely sensitive to the smallest change in phosphane structure soon led to the consideration that such catalysts, modified by the addition of optically active phosphanes, might possibly be employed in asymmetric synthesis. As the preparation of Horner phosphanes is generally complicated, phosphanes containing optically active organic groups which could be synthesized easily from natural products were prepared and applied for the first time in catalytic asymmetric synthesis[24]. An early success was achieved in 1967[36] when butene and propylene were found to codimerize in the presence of a catalyst consisting of π-allylnickel chloride, (−)-tris(*trans*-myrtanyl)phosphane *(23)* (prepared from β-pinene), and aluminum bromide.



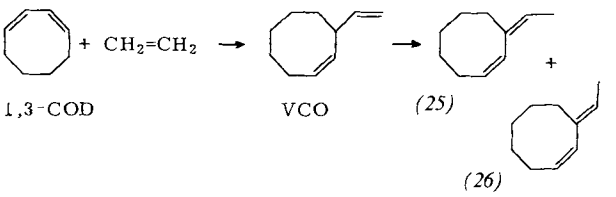
(23)

In this way it was possible to prepare small quantities of (−)-*trans*-4-methyl-2-hexene *(24)* in an optical yield of *ca.* 3%.



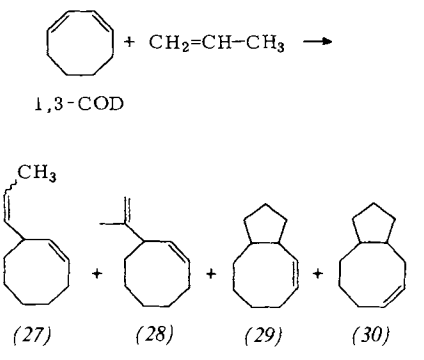
(−)-(24)

Decisive progress followed the discovery that this catalyst system facilitated smooth codimerization between cyclic 1,3-diolefins such as 1,3-cyclooctadiene (1,3-COD) and monoolefins such as ethylene or propylene[37]. Representative of the 3-substituted cycloalkenes produced is 3-vinyl-1-cyclooctene (VCO), which is formed together with the isomerization products (*Z*)- and (*E*)-3-ethylidene-1-cyclooctene [*(25)* and *(26)*] when ethylene and 1,3-COD are codimerized.



1,3-COD VCO *(25)* *(26)*

In addition, depending on the nature of the phosphane used, varying quantities of ethylene oligomers and higher molecular weight products are formed. The codimerization of propylene and 1,3-COD yields a mixture consisting principally of the four products 3-(1-propenyl)- and 3-isopropenyl-1-cyclooctene [*(27)* and *(28)*], and bicyclo[6.3.0]undec-2-ene and -3-ene [*(29)* and *(30)*].



1,3-COD

(27) *(28)* *(29)* *(30)*

These codimerizations may also be controlled, by varying the phosphane employed, to yield either *(27)* or *(28)* as the main product. In these catalytic reactions chiral C atoms are produced *via* C—C bond formation, and are consequently particularly suitable for the study of asymmetric catalysis. In fact, the catalysis using optically active phosphanes does lead to the generation of the products *(25)* and *(27)*—*(30)* in optically active form; the codimerization of 1,3-COD and ethylene at 0 °C using (−)-tris(*trans*-myrtanyl)phosphane *(23)* yields VCO with a specific rotation, $[\alpha]_D^{22}$, of −19°, corresponding to an optical purity of 11—12%[38]. (Optically pure (−)-VCO (see below) has a specific rotation, $[\alpha]_D^{22.8}$, of −162.3°.)

A series of new optically active phosphanes have been prepared (Table 1) and, by varying the phosphane, the reaction temperature, and the nickel:phosphane ratio in the catalyst, it was possible to increase the optical yield of VCO from 11—12% to *ca.* 70%[39]. During the course of these experiments it was also observed that the ethylene trimer, 3-methyl-1-pentene *(31)*, produced as a side product in the codimerization of 1,3-COD with ethylene, also appeared in an optically active form. It was therefore possible to follow the dependence of the degree of asymmetric induction on the catalyst and the reaction conditions

(31)

Table 1. Dependence of the optical yield of the reaction of 1,3-COD with ethylene, to give 3-vinyl-1-cyclooctene (VCO) and 3-methyl-1-pentene *(31)*, on the nature of the phosphane employed. Catalyst: π-$C_3H_5NiCl + (C_2H_5)_3Al_2Cl_3 + PR_3$ (molar ratio: 1:2.5:1.2) in C_6H_5Cl; reaction temperature: 0°C (Standard conditions).

employed by means of two, parallel, catalytic processes. Table 1 shows the dependence of the optical yield of VCO and *(31)* on the nature of the phosphane used.

The highest optical yields under these standard conditions were obtained, in the case of VCO, using (−)-isopropyldimenthylphosphane (27%) and, in the case of *(31)*, using (−)-dimenthyl(methyl)phosphane (46%). It thus appears that the menthyl group is more efficient in the optical induction than the other optically active groups studied—*cis*- and *trans*-myrtanyl, bornyl, and 2-methylbutyl. The Horner phosphane (−)-methyl(phenyl)propylphosphane gave rise to unexpectedly poor optical yields (*ca.* 5%). The values obtained for the optical purities of VCO and *(31)* show that the catalysts are to a certain extent substrate specific, since the recognizably smooth fall in the optical purity of VCO as Table 1 is descended is not reflected by a similar trend in the optical purity of *(31)*.

As the temperature is lowered the optical purity achieved generally increases. The high activity of the catalysts allows reactions to be carried out at and below −75°C (see also Section 3.2); in this way full advantage can be taken of the small differences in activation enthalpy involved when the diastereomeric catalyst-substrate intermediates react further to form the products. From the values in Table 2 a difference of 1.1 kcal/mol in the activation energy required to form the two antipodes of VCO may be calculated; this value should, however, be regarded only as an estimate of the order of magnitude of the parameter.

In the case of *(31)* the optical yield is maximized at −40°C (56%) but may be increased to 64% by reducing the reaction time from 6 h to 30 min. This result may be interpreted as showing that the initially produced enantiomer ratio is subsequently changed through temperature-dependent isomerization or oligomerization processes.

The highest optical yield of VCO yet to be observed (70%) was achieved at 0°C by employing an excess of (−)-isopropyldimenthylphosphane in the catalyst (Ni:P = 1:3.8; see Fig. 1). Thus, the excess of the phosphane has a decisive effect which may be due either to the coordination of a second molecule of the inducing phosphane to the nickel atom, or to the supression of a dissociation process. However, an increase in the P:Ni ratio causes a marked reduction in the reaction rate, and consequently even fewer moles of VCO per mole of catalyst may be obtained before the catalyst becomes inactive.

Table 2. Temperature dependence of the optical yields of (−)-(*S*)-VCO and (+)-(*S*)-*(31)*. (Reaction and catalyst as for Table 1.) Reaction time: 6 h.

[b] Solvent CH_2Cl_2.

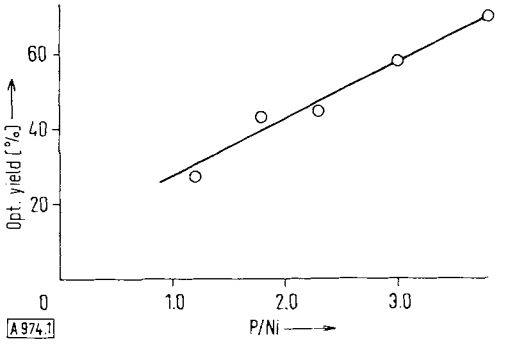

Fig. 1. Dependence of optical yield of VCO on phosphane:nickel ratio on use of (−)-isopropyldimenthylphosphane at 0°C (reaction as in Table 1).

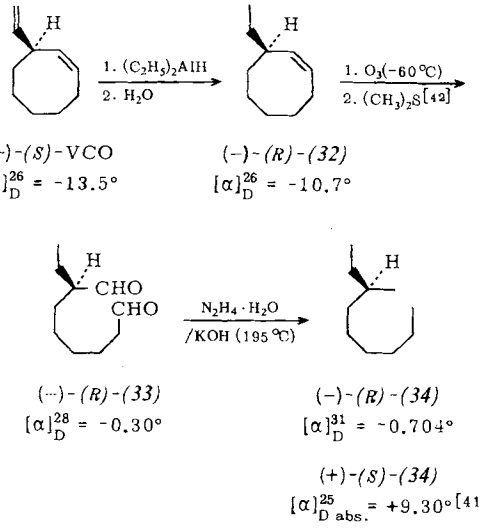
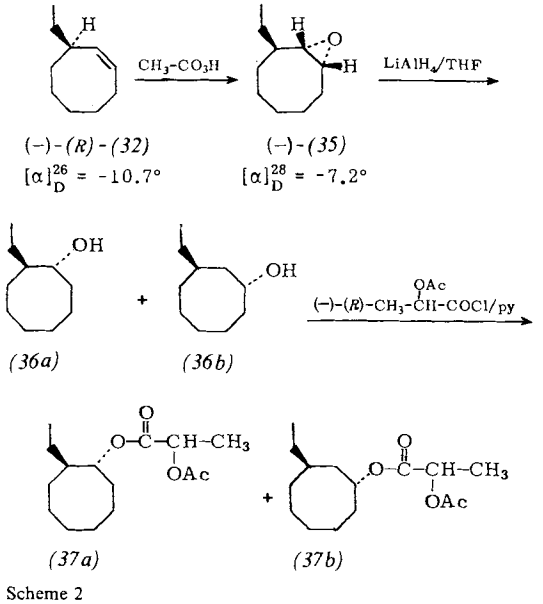
The absolute configuration and the specific rotation of optically pure (−)-VCO were determined in three independent ways[38]:

1. A sample of the catalytically prepared (−)-VCO ($[\alpha]_D^{26} = -13.5°$) was transformed into (−)-3-methylnonane *(34)* (see Scheme 1); this was then correlated with the known[41] (+)-(*S*)-3-methylnonane. In this way (−)-VCO was shown to have the *S*-configuration, and the original sample of (−)-VCO proved to be 7.6% optically pure.



Scheme 1

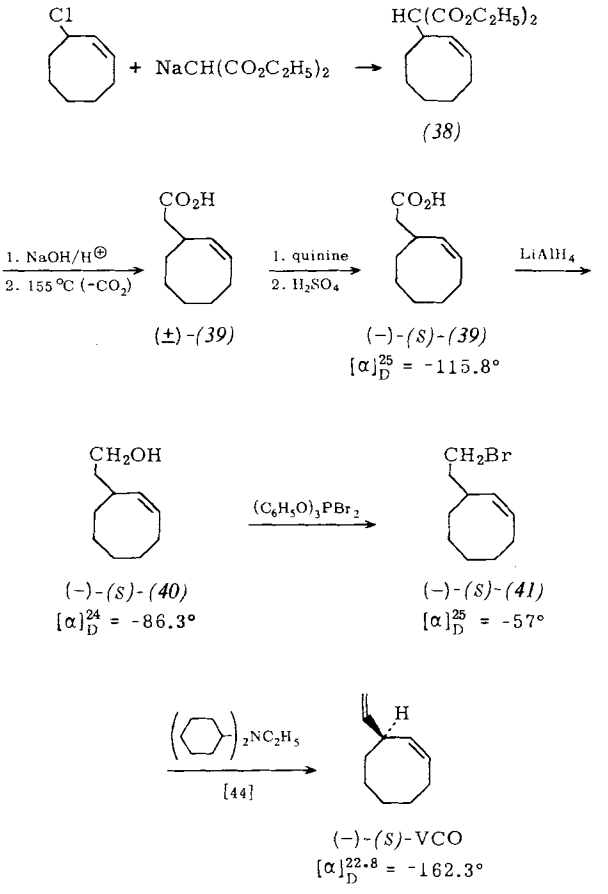
2. Epoxidation of (−)-(*R*)-3-ethyl-1-cyclooctene *(32)* with peracetic acid yielded only *trans*-3-ethyl-1,2-epoxycyclooctane *(35)*, which upon reduction with $LiAlH_4$ produced the mixture of alcohols *(36a)* and *(36b)* in the ratio 1:2.2 (see Scheme 2). This mixture of alcohols was treated with the (−)-*R* form of the acid chloride of acetylated lactic acid in pyridine, which produced a mixture of isomers *(37a)* and *(37b)*[43] giving rise to four peaks in the gas chromatogram [*R,R*- and *R,S*-forms of *(37a)* and *(37b)*]. Inspection of the ratio of *(R,R)-(37b)* to *(R,S)-(37b)*



Scheme 2

revealed that the original sample of (−)-VCO was 7.0% optically pure.

3. Optically pure (−)-(*S*)-VCO was obtained in a seven-stage synthesis *via* an intermediate racemate separation of the quinine salts of (2-cyclooctenyl)acetic acid *(39)* by fractional crystallization (Scheme 3).



Scheme 3

The synthesis shown in Scheme 3 yielded (−)-(*S*)-vinylcyclooctene with a specific rotation $[\alpha]_D^{22.8}$ of −162.3° (*c* = 4.8, C_6H_6), which corresponds to an optical purity of 8.3% for the samples of (−)-VCO $\{[\alpha]_D^{26} = -13.5°\}$ used in the above two methods. This result agrees relatively well with those of the other two methods.

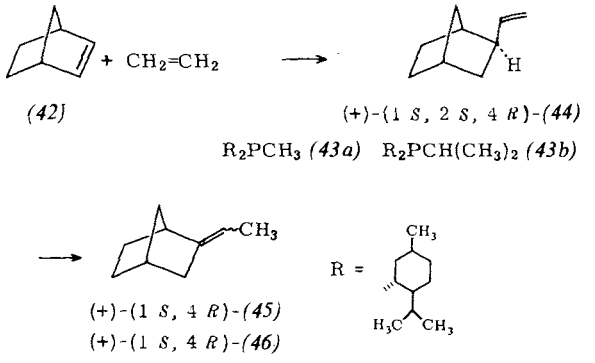
The codimerization of 1,3-COD and ethylene to give optically active 3-vinyl-1-cyclooctene is the first example of a catalytic asymmetric synthesis in which the chiral center is produced in high optical purity *via* C—C bond formation.

3.2. Catalytic Asymmetric Codimerizations of Norbornene, Norbornadiene, or (±)-2-Bornene with Ethylene[45]

The catalytic codimerizations of norbornene, norbornadiene, and (±)-2-bornene with ethylene have proved to be practically ideal examples in the study of asymmetric synthesis using the π-allylnickel halide catalysts. Since these olefins incorporate double bonds activated by ring strain, it is possible to effect the syntheses at very low temperatures.

Using a catalyst system made up of π-allylnickel chloride, triethyldialuminum trichloride, and the optically active

phosphane (−)-dimenthyl(methyl)phosphane *(43a)* or (−)-isopropyldimenthylphosphane *(43b)*, it was found that norbornene *(42)* and ethylene codimerized in chlorobenzene to give optically active *exo*-(+)-2-vinylnorbornane *(44)* as the only primary reaction product; *i.e.* the ethylene added only from the sterically less hindered side of the norbornene C=C double bond.



According to the reaction conditions and the phosphane used variable quantities of the isomerization products of *(44)*, (*Z*)- and (*E*)-2-ethylidenenorbornane *(45)* and *(46)*, are produced. In this process the chiral center at C-2 is lost but those at C-1 and C-4 remain, thereby retaining the total chirality of the molecule.

The codimerization of norbornene with ethylene under the control of (−)-isopropyldimenthylphosphane was investigated at temperatures ranging from +10 to −97 °C. Even at −83 °C the time required for all the norbornene to react was acceptable, and it was found in addition that low temperatures selectively favored the isolation of *(44)*. The most surprising result of these experiments is undoubtedly the nearly linear increase in the optical yield of (+)-*(44)* as the temperature is lowered. This relationship was practically independent of the isomerization to *(45)* and *(46)* (see Fig. 2). At −97 °C an optical yield of 80.6% was obtained, this being the highest optical yield yet observed in a catalytically asymmetric synthesis involving C—C bond formation.

minum trichloride, and a chiral phosphane yielded (+)-(1*R*, 4*S*, 5*S*)-5-vinylnorbornene *(47)* irrespective of whether the phosphane involved was *(43a)* or *(43b)*; *i.e.* in this case too the ethylene approaches the norborna-

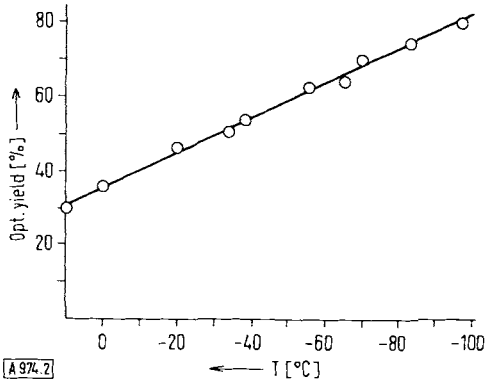


Fig. 2. Variation of the optical yield of (+)-*(44)* with temperature in the codimerization of norbornene with ethylene. Catalyst prepared from π-allylnickel chloride, $(C_2H_5)_3Al_2Cl_3$, and (−)-isopropyldimenthylphosphane *(43b)*; solvent: chlorobenzene.

diene from the *exo* side. When *(43a)* was used the optical yield of *(47)* was found to lie in the range 38—45% (see Table 3) and to be only slightly dependent on the conversion and the temperature. On the other hand, when *(43b)* was used the optical yield increased as the temperature was lowered; at −65 °C with quantitative norbornadiene conversion, *(47)* was obtained with an optical purity of 77.5%.

The reactions used in establishing the optical purity and absolute configurations of the compounds *(44)*—*(46)* and *(47)* are summarized in Scheme 4.

During the codimerization of racemic 2-bornene *(50)* with ethylene using either a (−)-*(43a)*- or a (−)-*(43b)*-modified catalyst incomplete conversion is accompanied by the preferential reaction of the (+)-2-bornene with the ethylene, leaving the substrate to become richer in (−)-2-bornene.

Table 3. Dependence of the optical yield of (+)-5-vinylnorbornene *(47)* on temperature and conversion (catalyst as in Table 1). C_9 = *(47)* + *(48)* + *(49)*; C_{11} = codimers from C_9 and ethylene.

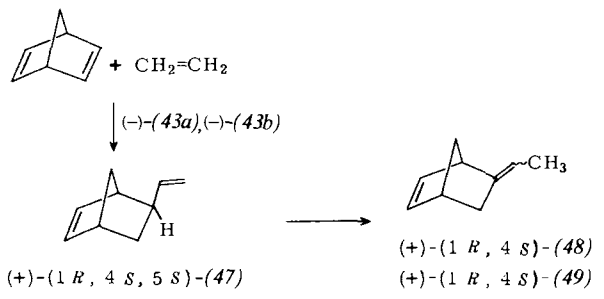
[a] Based on reacted norbornadiene; the remainder comprises higher oligomers.

From the temperature dependence of the optical yield a value of 1.5 kcal/mol was calculated for the difference in the activation energies ($\Delta\Delta E^{\neq}$) leading to the formation of (+)- and (−)-*(44)*.

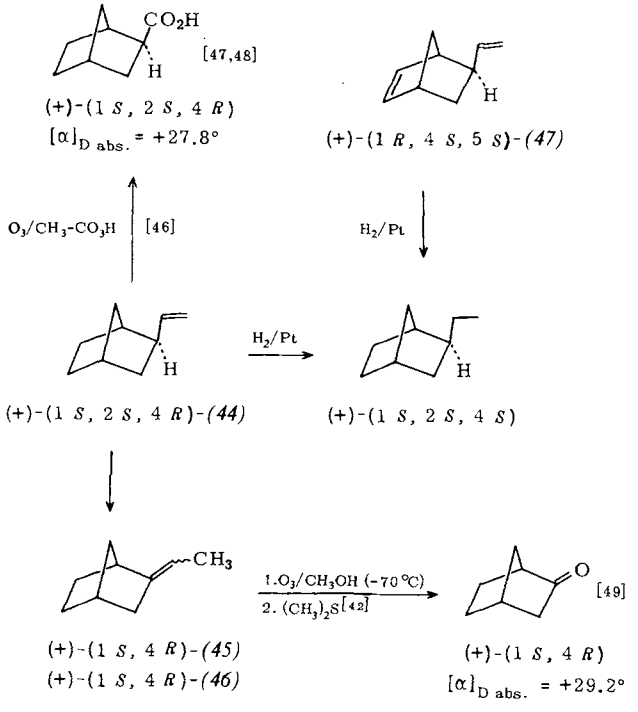
Codimerization of norbornadiene with ethylene using a catalyst made up of π-allylnickel chloride, triethyldialu-

In other words we are here concerned with an "enantioelective catalytic codimerization" reaction. It is interesting to note that in this codimerization the methyl group on C-1 of the bornene directs the reaction such that C—C bond formation takes place entirely at the 3-position of *(50)*. The reaction product was not, however, the expected

3-vinylbornane; instead its isomerization products (*Z*)- and (*E*)-3-ethylidenebornane *(51)* and *(52)* were formed. The

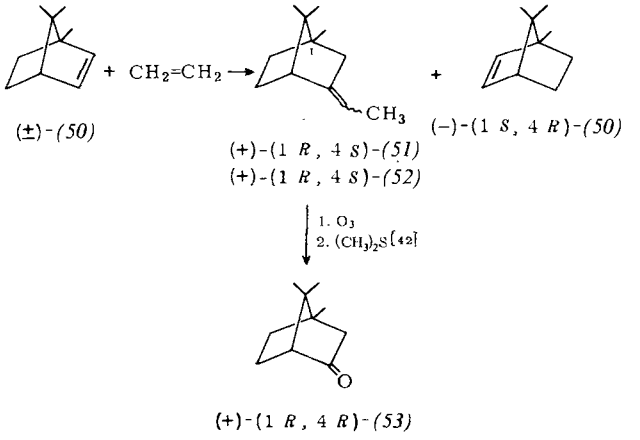


catalytically formed products *(51)* and *(52)*, showing positive rotations, possess the same configuration as (+)-2-bornene, namely the (1*R*,4*S*)-configuration.



Scheme 4. Reaction of *(44)* to *(45)*, *(46)* was catalyzed by π-$C_3H_5NiCl \cdot AlX_3 \cdot P(CH_3)_3$ [33].

The maximum optical yield of *(51)* and *(52)* to be achieved (*ca.* 20%) resulted from an experiment in which 40% of *(50)* was converted using a (−)-*(43b)*-modified catalyst at 0 °C. Ozonolysis of (+)-*(51)*, *(52)* leads to (+)-epicamphor *(53)*, and so the codimerization of (±)-*(50)* with ethylene under the influence of the optically active catalyst *(43)* (or, conversely, the codimerization of optically active 2-bornene with ethylene using an optically inactive catalyst made up of π-C_3H_5NiCl, $(C_2H_5)_3Al_2Cl_3$ and an optically inactive phosphane) opens up a new route for the preparation of optically active epicamphor.



3.3. An Attempt to Interpret Asymmetric Catalysis in Terms of a Model of the Optically Active Catalyst

The catalysts described above are generally prepared from π-allylnickel halides, Lewis acids, and phosphanes; the phosphanes are coordinatively bound to the nickel atoms, and the Lewis acid molecules interact with the halogen atoms in the π-allylnickel halide. A three-dimensional X-ray crystallographic structure of a compound of this type, *(54)*, is already available[50,51] (see Fig. 3).

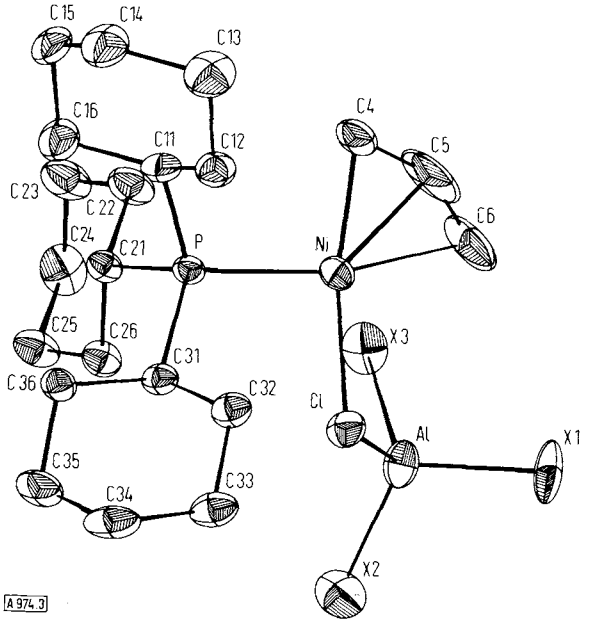


Fig. 3. Molecular structure of the complex *(54)* comprising π-allylnickel chloride, tricyclohexylphosphane, and methylaluminum dichloride.

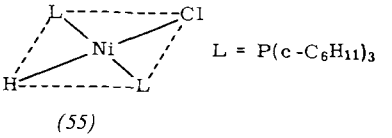
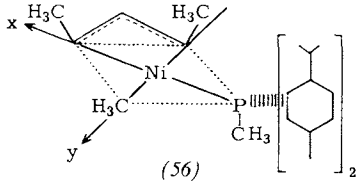
In a model experiment[34] it was shown that the π-allyl groups were lost during the first stages of the transformations undergone during olefin catalysis.

As active catalyst species a nickel hydride system is formed which could not, however, be isolated as such during the catalytic reactions, but for which known models, such as the square planar[52] L_2NiHCl complex *(55)*, exist.



(55)

In the following an attempt will be made using a model of the optically active catalyst to correlate the absolute configurations of the modifying phosphane *(43a)* and the optically active product, vinylnorbornane (VNB). The attempted correlation is based partly upon the molecular structure and the absolute configuration[53] of the complex *(56)* formed from methyl(π-1-methyl-2-butenyl)nickel and



(56)

(−)-dimenthyl(methyl)phosphane *(43a)* as determined by X-ray crystallography[54] (see Fig. 4).

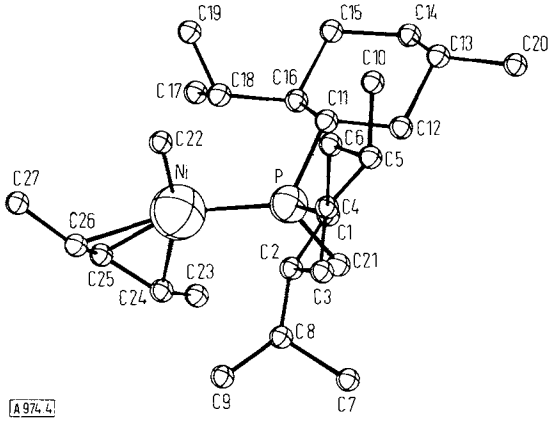


Fig. 4. Molecular structure of the complex *(56)* formed from methyl(π-1-methyl-2-butenyl)nickel and (−)-dimenthyl(methyl)phosphane *(43a)*.

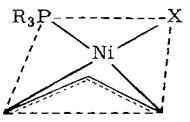
The coordination about the nickel in this compound approaches square planar, the four coordination sites being occupied by the atoms C-22, C-26, C-24, and P. The two menthyl groups are oriented in a propeller-like fashion about the phosphorus atom, and their longitudinal axes are approximately perpendicular to each other.

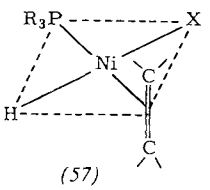
Inspection of Stuart molecular models along the direction of the x-axis reveals that the isopropyl group (C-17, C-18, C-19) of one menthyl group is situated close to the nickel atom above the *x-y* plane; the space below this plane is, however, relatively free. This observation applies, of course, to the stationary situation prevailing during a crystallographic study, and it must be remembered that in solution individual groups of atoms may move relative to others within the molecule. The static situation does, nevertheless, afford useful information as to the most favored arrangements.

The complex *(54)* has also been shown by X-ray crystallography to possess a square planar structure (see Fig. 3). This complex differs from the catalytically active *(57)* only in that in the latter two coordination sites are occupied by an olefin molecule and a hydrogen atom instead of by a π-allyl group. By analogy with the L_2NiHCl complex *(55)*, in which the phosphane ligands are *trans* to each other, the olefin in *(57)* is formulated as occupying the coordination site *trans* to the phosphane.

In the particular case of norbornene-ethylene codimerization it may also be assumed that during the catalysis the norbornene becomes bound to the nickel atom from the *exo*-side, such that no steric interaction ensues between



(54), R = c-C_6H_{11}
X = $ClAl(CH_3)Cl_2$



(57)

the methylene bridge on the olefin and the bulky complex anion X. The structural arrangement *(a)* in Figure 5 would thus seem to be the most probable representation at the start of the catalytic cycles A and B.

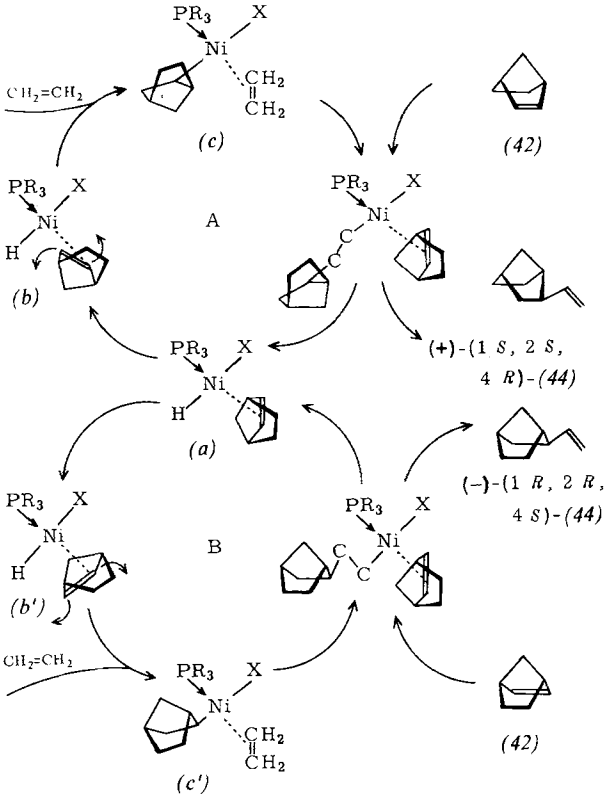


Fig. 5. Synthetic cycles leading to (+)- and (−)-vinylnorbornane *(44)*.

As the olefinic double bond lies perpendicular to the *x-y* plane of the catalyst, insertion into the Ni—H bond (during which step optical induction is already taking place) must occur either *via* a clockwise (cycle B) or an anticlockwise (cycle A) rotation of the complexed norbornene molecule. At the same time an ethylene molecule, which may act as an "accelerating ligand" in this process, can approach the *x-y* plane of the complex from above or from below. After the norbornene has inserted into the Ni—H bond the ethylene may occupy the vacated nickel coordination site.

When the above dynamic processes are simulated with a Stuart molecular model, in which the orientation of the phosphane ligand is the same as that depicted for

complex *(56)* in Figure 4, it can be seen that, whereas clockwise rotation of the norbornene molecule (cycle B) leads to an unfavorable steric interaction with a menthyl group, anticlockwise rotation (cycle A) is essentially sterically unhindered. Such a rotation leads to a norbornylnickel bond which, after ethylene insertion, yields (+)-(1*S*,2*S*,4*R*)-2-vinylnorbornane. This is the product which in fact predominates.

According to this concept, insertion of the norbornene into the Ni—H bond is accompanied by a change from a relatively unhindered steric state (where the double bond is coordinated perpendicular to the *x*-*y* plane, *trans* to the phosphane) to a state in which distinct steric interaction occurs with the phosphane causing optical induction.

4. Further Catalytic Asymmetric Syntheses and General Prospects

A review concerning the present state of research in the field of catalytic asymmetric synthesis using homogeneous transition metal catalysts would be incomplete without mention of the following additional developments. Optically active cyclopropane derivatives have been obtained with maximum optical yields of *ca.* 8%[55,56] by reacting olefins with diazo compounds in the presence of optically active copper complexes. *Yamamoto, Kumada, et al.*[57–59] have described the asymmetric hydrosilylation of olefins using Ni-, Pd-, and Pt-catalysts modified with optically active phosphanes; the highest optical yield (17.6%) was attained using the nickel complex. Recently *Pino et al.*[60,61] have effected the asymmetric hydroformylation of various aromatic and aliphatic olefins. The catalyst was the complex formed from RhCl(CO) and *(8)*[25], and optical yields ranged up to 27%.

The results so far obtained encourage us to predict that it may be possible, through the development of more refined optically active ligands, to produce catalysts which will enable homogeneous catalytic asymmetric synthesis to be as efficient as enzyme-catalyzed synthesis. At present the choice of the optically active ligand is empirical, but the accumulation of more experimental data may enable precise correlations to be made between the structure and configuration of the catalyst and the optically active reaction product. With the help of such knowledge it should be possible in the future to prepare "tailor-made" asymmetric catalysts.

The accomplishment of these goals would provide us with a means producing unlimited amounts of optically active compounds independently of natural sources, the importance of which can hardly be overstressed.

The Allylcobalt System

By Helmut Bönnemann
Based upon the work of Helmut Bönnemann, Charles Grard, Werner Kopp, Wichard Pump, Kenjiro Tanaka, and Günther Wilke[*]

In Memory of Karl Ziegler

The following report describes the preparation and reactions of organocobalt compounds, especially the thermally unstable tris(π-allyl)cobalt and cyclooctenylcobalt compounds. The stoichiometric and catalytic transformations of these highly reactive organocobalt systems give an insight into the rôle of cobalt in homogeneous catalysis involving alkenes and alkynes.

1. Preparation of Tris(π-allyl)cobalt Systems

Tris(π-allyl)cobalt was first prepared ten years ago by *G. Wilke* and *K. Tanaka*[1] in the course of a comparative study of transition metal allyl compounds[1–3]. This thermally very unstable compound was obtained in yields of 45—50% by allyl exchange between tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) and allylmagnesium chloride [eq. (1)]. The reaction between cobalt(II) chloride and allylmagnesium chloride gives (in addition to a black decomposition product) tris(π-allyl)cobalt, in up to 50% yield, as a result of a disproportionation reaction [eq. (2)][3]. Although tris(π-allyl)cobalt can be prepared by both methods, the product was not obtained sufficiently pure for structural studies. Only recently has a careful reinvestigation allowed the preparation of this compound in pure form. For this reason the synthesis of tris(π-allyl)cobalt is described here in detail. This is followed by a discussion of the structural problem.

$$Co(acac)_3 + 3\,C_3H_5MgCl \xrightarrow[45\text{–}50\%]{} \underset{(1)}{(C_3H_5)_3Co} + 3(acac)MgCl \qquad (1)$$

$$2\,CoCl_2 + 4\,C_3H_5MgCl \xrightarrow[<50\%]{} \underset{(1)}{(C_3H_5)_3Co} + [C_3H_5Co^{I}] + 4\,MgCl_2 \qquad (2)$$

acac = 2,4-pentanedionate

Bis(allyl)cobalt, which is the primary product of the reaction of cobalt(II) chloride with allyl Grignard, is not stable under normal reaction conditions (decomposing even at $-60\,^{\circ}C$) and spontaneously disproportionates into tris(allyl)cobalt *(1)* and an allylcobalt(I) species, which, in the absence of stabilizing ligands, immediately decomposes. A recently discovered artifice[5] enables half of the reactant which is lost in the disproportionation reaction to be converted into further tris(allyl)cobalt: free allyl halide and additional allylmagnesium chloride are added to the reaction mixture and, as a result, the formation of the black side-product is suppressed. The allylcobalt(I) species (resulting from the disproportionation) reacts with the allyl halide to give an intermediate bis(allyl)cobalt halide which reacts further with the allylmagnesium chloride to give the tris(allyl) compound. This combination of disproportionation and allyl halide cleavage [eq. (3)] enables a very pure product to be prepared in high yield and is also particularly useful for the synthesis of homologs containing substituted allyl groups (Table 1) which, in some cases, cannot be prepared by the route shown in eq. (1).

$$2\,CoCl_2 + 5\,C_3H_5MgCl + C_3H_5X \xrightarrow[75\%]{} \underset{(1)}{2(C_3H_5)_3Co} \quad (3)$$

$$X = \text{halide} \qquad + 4\,MgCl_2 + MgXCl$$

The success of these syntheses depends to a large extent upon the exact adherance to a number of reaction and isolation conditions[5][*]. Well resolved ^{1}H-NMR spectra cannot be obtained if the product is contaminated with traces of magnesium or halogen containing compounds. Vanishingly small amounts of decomposition products have a similar effect. The low-temperature apparatus (developed for the preparation of highly unstable metal complexes[6]) shown in Figure 1 has been found particularly useful for the preparation of tris(allyl)cobalt.

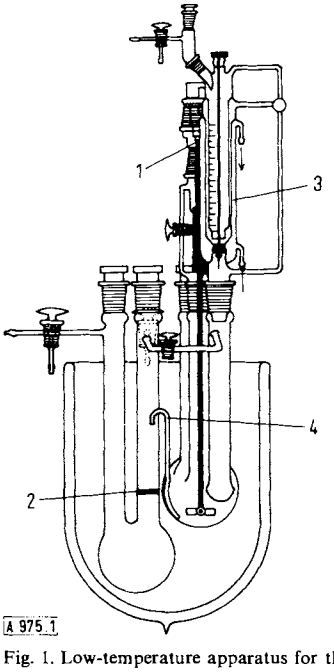

Fig. 1. Low-temperature apparatus for the syntheses of highly sensitive transition metal compounds. 1 = KPG stirrer with magnetic coupling, 2 = sintered disk (D 3), 3 = dropping funnel with cooling jacket, 4 = syphon.

[*] The cobalt salt is reacted with the Grignard reagent at -55 to $-60\,^{\circ}C$ in diethyl ether, taking care that the stationary concentration of the free Grignard reagent in solution is as low as possible. The insoluble side-products are removed by filtration at -55 to $-60\,^{\circ}C$ and the ether is evaporated. The soluble organocobalt compounds are extracted, preferably with liquid butane, to give a 0.05 M solution from which the tris(allyl)cobalt *(1)* is precipitated (as orange-red, irregular prisms) by cooling to between $-100\,^{\circ}C$ and $-130\,^{\circ}C$. For NMR purposes, the product is recrystallized several times; even in a highly pure form it must be stored at temperatures below $-70\,^{\circ}C$.

Solutions of tris(allyl)cobalt decompose at temperatures above $-50\,^{\circ}C$; if crystals are allowed to warm under argon, spontaneous deflagration occurs at $-20\,^{\circ}C$ (cf. Section 3, case 1). The compound burns with a fierce flame on exposure to air. As can be seen from Table 1, the methyl substituted derivatives are of greater stability, while the replacement of an allyl group by a cyclopentadienyl group lends unusual stability to the product. The methyl substituted compounds do not burn spontaneously in air, while the cyclopentadienyl derivative is only slowly attacked by atmospheric oxygen. The compounds shown in Table 1 are sufficiently volatile at low temperatures for their mass spectra to be studied; in each case the molecular ion corresponds to a monomer.

Table 1. Preparation and properties of some organocobalt compounds.

2. Spectral Properties and Structure of Tris(π-allyl)-cobalt

Because of its high sensitivity, it was some time before it proved possible to characterize tris(allyl)cobalt *(1)* on the basis of its physical data. *W. Pump* reinvestigated the problem in 1970[5] using a newly developed low-temperature technique. The following results were obtained with very pure samples.

2.1. Mass Spectrum

It proved possible to obtain interpretable spectra by using a direct injection system cooled to $-30\,^{\circ}C$. In addition to the molecular ion, elimination of C_3H_5 radicals is observed. This type of fragmentation is typical for allyl transition metal compounds.

Characteristic is the successive elimination of two H_2 molecules from the molecule ion. In addition propene is eliminated from both the molecular ion and the bis(allyl)cobalt ion ($m/e = 141$); this can be attributed to H-abstraction from an allyl group.

The spectrum also contains peaks due to ions and hydrocarbon fragments apparently formed by the coupling of the allyl groups ($124 = C_9H_{16}$, $82 = C_6H_{10}$, $67 = 82 - CH_3$);

Table 2. Characteristic masses in the spectrum of $(C_3H_5)_3Co$ *(1)*.

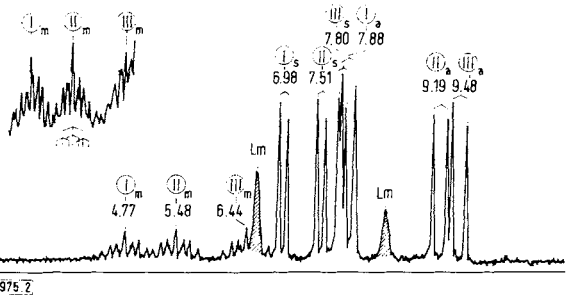
m/e	Ion	*m/e*	Ion
182	Molecule peak	101	$141-C_3H_4$
180	$M-H_2$	99	$141-C_3H_6$
178	$M-2H_2$	59	Co
141	$M-C_3H_5$	41	C_3H_5
140	$M-C_3H_6$ [a]		
138	$180-C_3H_6$ and/or $140-H_2$		

[a] A metastable ion (M = 107.7) was found for this transition.

these are the products of partial decomposition of the complex.

2.2. ^{1}H-NMR Spectrum

The ^{1}H-NMR spectrum of tris(π-allyl)cobalt shown in Figure 2 consists of three independent AM_2X_2 systems (Ⓘ Ⓘ, and Ⓘ) with intensities 1 : 1 : 1. The splitting of the *meso* protons[*] into nonets can be observed in a low-temperature CAT (computer accumulation technique) spectrum. Using decoupling procedures it proved possible to assign all the *meso*, *syn*, and *anti* signals for Ⓘ, Ⓘ, and Ⓘ.

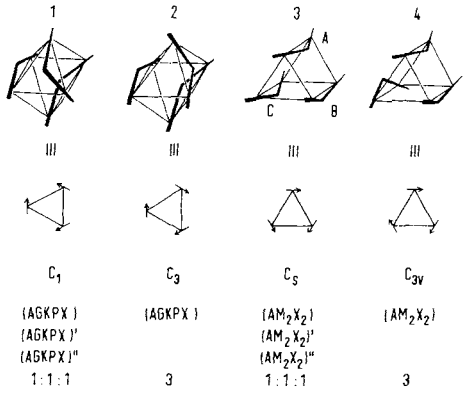


A 975.2

Fig. 2. The 60 MHz spectrum of tris(π-allyl)cobalt *(1)* at −75 °C m = *meso*, s = *syn*, a = *anti*. Ⓘ ≙ A, Ⓘ, Ⓘ ≙ B, C (see formula 3 in Fig. 3).

It is possible to arrange the three allyl groups around the central atom in four different ways: two trigonal prismatic and two octahedral (Fig. 3). Of these possibilities only the prismatic structure 3 is in agreement with the observed spectrum since only this form can generate three independent AM_2X_2 spin systems[**].

Accordingly, the allyl groups in tris(π-allyl)cobalt *(1)* adopt two different arrangements: two almost parallel basal groups (B and C) and an axial group A. This characteristic structural feature appears to be reflected in the chemical



A 975.3

Fig. 3. Possible arrangements of the allyl groups in tris(π-allyl)cobalt *(1)*.

properties of tris(π-allyl)cobalt since the basal and axial allyl groups are of differing reactivity.

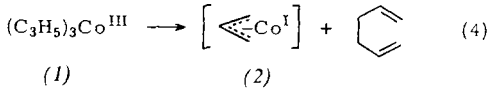
The ^{1}H-NMR spectrum of tris(1-methylcrotyl)cobalt can be interpreted as evidence that the substituted compounds also have a prismatic structure similar to tris(π-allyl)cobalt *(1)*. The interpretation of the ^{1}H-NMR spectra of the unsymmetrically substituted tris(allyl)cobalt compounds, *e.g.* tris(π-crotyl)cobalt, is greatly complicated by the presence of stereoisomers. This problem has been discussed elsewhere for the case of bis(π-crotyl)nickel[2a].

3. Reactions of Tris(π-allyl)cobalt

The allyl groups in *(1)* are of differing reactivity and three types of reaction can be distinguished.

1. Reactions involving the loss of all three allyl groups: The allyl groups in tris(π-allyl)cobalt are cleaved at −40 °C in an atmosphere of hydrogen to give propane. When recrystallized tris(π-allyl)cobalt is cautiously warmed to between −40 and −30 °C, 80% of the allyl groups are to be found in the organic decomposition product as C_1 to C_9 hydrocarbons. These compounds are the product of C—C coupling ($\Sigma \approx 1.7$ allyl groups), H-transfer ($\Sigma \approx 0.8$ allyl groups) and C—C bond cleavage ($\Sigma \approx 0.1$ allyl groups). Thus approximately two allyl groups react by coupling—a reaction commonly observed in allyl-transition metal compounds—while the hydrogen transfer and C—C cleavage reaction seem to be characteristic for cobalt. The facile hydrogen migration reaction is also observed in the catalytic reactions (see Section 6).

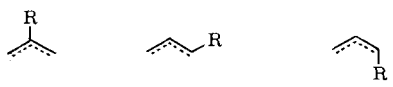
2. Reductive elimination of the basal allyl groups B and C from *(1)* with liberation of a coordinatively unsaturated allylcobalt(I) species *(2)*. It is possible to trap *(2)* by complexation with neutral ligands or by oxidative addition reactions (cf. Sections 3.1 and 3.2).



(1) *(2)* (4)

Reactions of this type are characterized by a change in the formal oxidation number of the cobalt from (III) to (I).

[*] The nomenclature for the position of a substituent in the π-allyl group is as follows:



meso *syn* *anti*

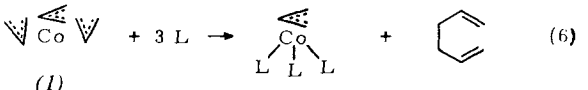
[**] On the basis of ^{1}H-NMR data, a similar prismatic structure has been assigned by *J. K. Becconsall* and *S. O'Brien* [7] to the thermally stable tris(π-allyl)rhodium. An X-ray structural analysis of the rhodium compound carried out by *C. Krüger* in our Institute showed at least that the arrangement of the allyl groups A, B and C correspond to formula 3 in Fig. 3, although a refinement was not possible because of decomposition of the sample in the X-ray beam.

3. Nucleophilic attack and replacement of the axial allyl group in *(1)* by an anion X (see Section 3.2), *e.g.* eq. 5:

$$\underset{(1)}{(C_3H_5)_3Co} + HX \longrightarrow (C_3H_5)_2CoX + C_3H_6 \qquad (5)$$

3.1. The Action of Neutral Ligands

Ligand molecules having free electron pairs cause coupling of the basal allyl groups in tris(π-allyl)cobalt systems such as *(1)* to give 1,5-hexadiene, which is displaced from the metal. This process can be followed by ^{1}H-NMR spectroscopy: when a solution of tris(π-allyl)cobalt is treated with diolefins the signals assigned to the basal allyl groups ⓘⓘ and ⓘⓘⓘ (see Fig. 2) disappear slowly above −35 °C, while the spin system Ⓘ assigned to the axial allyl group remains unchanged. The allylcobalt(I) species *(2)* can be trapped in the form of the stable complex *(3)*[8,9] by using CO or PF_3 as the ligand.

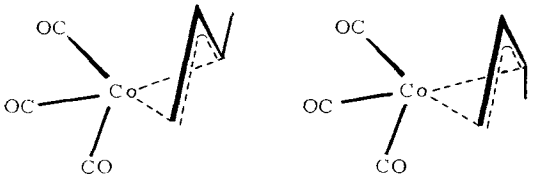


(6)

(1)

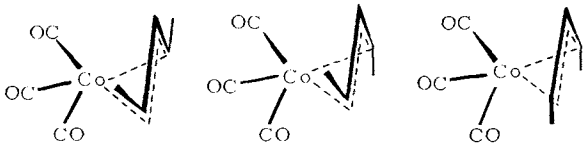
(3a), L = CO
(3b), L = PF_3

Analogous tricarbonyl complexes can be prepared at low temperatures from tris(π-crotyl)cobalt or the 1,3-dimethylallyl derivative; it has been possible, by means of ^{1}H-NMR spectroscopy, to determine quantitatively the *syn-anti* ratio in what was originally the axial allyl group. In the case of the π-crotylcobalt derivatives *(4)* and *(5)* the "axial" allyl group exists to 80% in the thermodynamically preferred *syn* form.



syn, *(4)* *anti*, *(5)*

The "axial" allyl group in tricarbonyl(1-methylcrotyl)cobalt could adopt the *syn/anti* conformations *(6)*, *(7)* and *(8)*; at −20 °C[*] only *(6)* and *(7)* are present in the ratio 4:1[**].



syn/syn *syn/anti* *anti/anti*

(6) *(7)* *(8)*

[*] A *syn/anti* transition at this temperature was ruled out.

[**] The tricarbonyl complexes *(4)*—*(7)* have been prepared earlier by other methods; the *syn/anti* ratio varies according to the method of preparation[10–12].

In this context it is of interest that the presence of different substituents on the terminal atoms of the allyl group creates a chiral tris(π-allyl)cobalt system (Fig. 4).

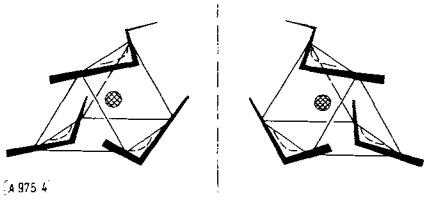


Fig. 4. The chirality of tris(π-allyl)cobalt.

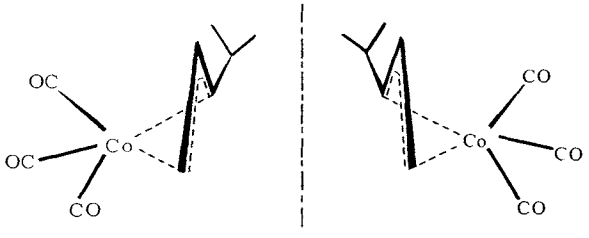
We have prepared an analogous chiral π-crotylcobalt system *(9)* from $NaCo(CO)_4$ and 1-chloro-4-methyl-2-pentene, using published procedures[8]:



(9a) *(9b)*

It can be seen from the ^{1}H-NMR spectrum of the complex (Fig. 5) that *(9)* exists only as the *syn* isomer. The diastereotopic splitting of the signals ⑥ and ⑦ assigned to the methyl protons in the prochiral π-4-methyl-2-pentenyl group bonded to cobalt clearly establishes the chirality of compound *(9)*.

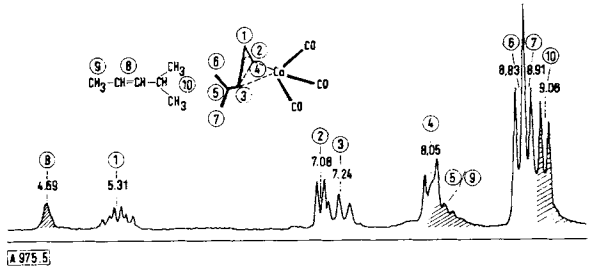


Fig. 5. The ^{1}H-NMR spectrum of tricarbonyl(π-4-methyl-2-pentenyl)cobalt (measured at −80 °C without solvent and using a Varian XL-100).

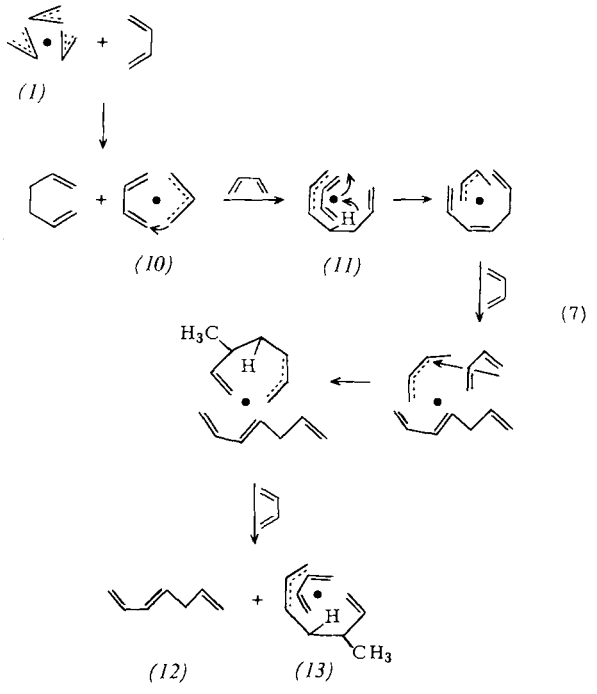
3.1.1. The Stoichiometric Reaction of Tris(π-allyl)cobalt with Butadiene[13,14]

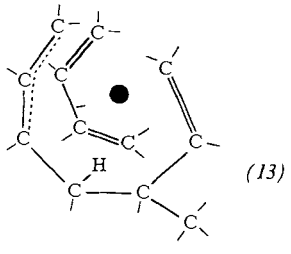
The difference in reactivity between the basal and axial allyl groups in tris(π-allyl)cobalt can be followed in a stepwise manner by allowing the complex to react with stoichiometric amounts of butadiene. The initial reaction at −40 °C is the reductive elimination of the basal groups to give the intermediate complex *(10)* (the point represents the cobalt atom) which can be observed in the ^{1}H-NMR spectrum[5]. At −15 °C insertion of a second molecule of butadiene into the Co—C bond of the allyl group occurs to give a butadiene(heptadienyl)cobalt intermediate *(11)* which can be identified mass spectroscopically (*m/e* = 208). This is followed by elimination of a β-hydrogen atom and its transfer to a further butadiene molecule. Release of a stoichiometric amount of heptatriene *(12)* leads to

the formation of the stable complex *(13)* which was first prepared by *Natta, Pino et al.*[15] by another route.



(7)

It can thus be seen that *(13)* is the key intermediate in the dimerization of butadiene initiated by tris(π-allyl)cobalt (cf. Section 6.1), a fact which had been suggested as early as 1966[2b]. The steric arrangement of the organic groups around the cobalt is based upon an X-ray structural analysis[16].



(13)

Two butadiene molecules are coupled together to form a chain (branched in the 5-position) which is bonded to the cobalt atom by means of a π-allyl group and a vinyl double bond. A third butadiene molecule is coordinated to the cobalt in a single-*cis* conformation.

3.1.2. Bimetallic Complexes

The allylcobalt(I) species *(2)* can also be stabilized, by means of organometallic ligands, in the form of a bimetallic complex[5]. With bis(allyl)magnesium a yellow-ocher compound *(14)* is produced, which is stable at room temperature.

$$\underset{(1)}{(C_3H_5)_3Co} + \underset{}{(C_3H_5)_2Mg} \xrightarrow[-40\,^\circ C]{} \underset{(14)}{C_3H_5CoMg(C_3H_5)_2} + 1,5\text{-hexadiene} \qquad (8)$$

The reaction with allyllithium under the same conditions produces a 1:2-adduct *(15)*.

$$\underset{(1)}{(C_3H_5)_3Co} + 2C_3H_5Li \longrightarrow \underset{(15)}{C_3H_5Co(LiC_3H_5)_2} + 1,5\text{-hexadiene} \qquad (9)$$

Both *(14)* and *(15)* are generated in completely insoluble forms. The allylcobalt moiety in *(14)* can be cleaved with iodine and trapped as allylcobalt diiodide (cf. Section 3.2).

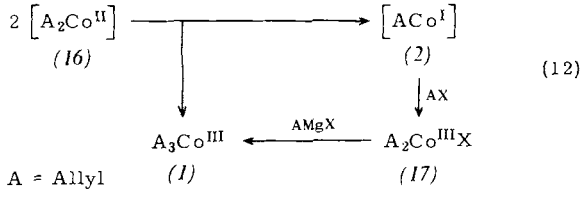
$$(14) + 2I_2 \longrightarrow C_3H_5CoI_2 + MgI_2 + 1,5\text{-hexadiene} \qquad (10)$$

3.2. Allylcobalt Halides

Allylnickel halides can be prepared by a cleavage reaction involving nickel(0) complexes and allyl halides [eq. (11)][2c] (COD = 1,5-cyclooctadiene).

$$(COD)_2Ni + CH_2{=}CH{-}CH_2X \longrightarrow \tfrac{1}{2}\left[\text{allyl-Ni-X}\right]_2 + 2\ COD \qquad (11)$$

The new variation of the synthesis of tris(allyl)cobalt shown in eq. (3) already contains an indication that cleavage of the allyl halide (similar to that shown in eq. (11)) can occur with the allylcobalt(I) intermediate *(2)*.

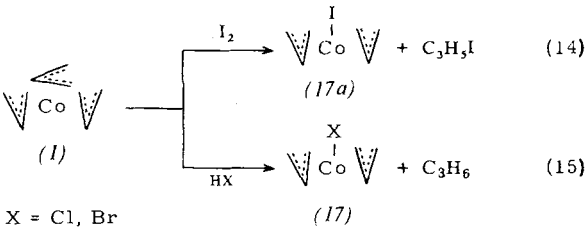


(12)

The Co^I intermediate *(2)*, formed by disproportionation of the unstable complex *(16)*, cleaves the allyl halide AX [eq. (12)] and releases an intermediate bis(allyl)cobalt halide *(17)*. This oxidative addition reaction[5] can be used to convert tris(π-allyl)cobalt *(1)* quantitatively into bis(allyl)cobalt iodide *(17a)* [eq. (13)].

$$\underset{(1)}{A_3Co} \xrightarrow[-50\,^\circ C]{COD} \underset{(2)}{[ACo^I]} \xrightarrow{AI} A_2CoI \qquad (13)$$

On the other hand it is possible to exchange the axial allyl group of *(1)* for halogen by means of a nucleophilic

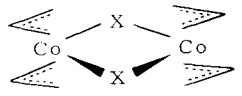


(14)

(15)

substitution reaction with elemental iodine or hydrogen halide at −55 °C, eqs. (14) and (15) [cf. eq. (5)].

The bis(allyl)cobalt halides *(17)* are produced in the reactions (13), (14) and (15) as beautiful red crystals. They are thermally sensitive, extremely insoluble, and probably exist as dimers [eq. (17)] in which the bridging halogen atoms function as double axial groups



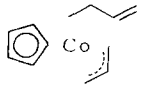
(18)

X = Cl, Br, I

Exchange of the halogen in *(17)* allows the introduction of other groups into the bis(allyl)cobalt system. For example, one can prepare bis(allyl)cyclopentadienylcobalt *(19)* from bis(allyl)cobalt iodide *(17a)*[5].

$$(C_3H_5)_2CoI + C_5H_5Li \longrightarrow \underset{(19)}{C_5H_5Co(C_3H_5)_2} \qquad (16)$$
$$\underset{(17a)}{}$$

The ^{1}H-NMR spectrum of *(19)* indicates that one of the allyl groups has adopted a σ-form, thereby avoiding the introduction of more than 18 electrons into the outer electronic shell of cobalt.



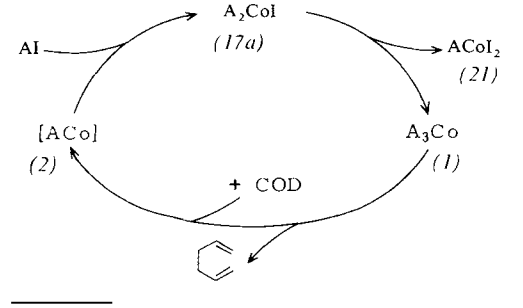
(19)

In this case also the addition of olefins causes the displacement of the allyl groups from cobalt and cyclopentadienyl-(diene)cobalt complexes *(20)* result[*].

$$(Cp)Co(C_3H_5)_2 + \text{diene} \longrightarrow \underset{(20)}{(Cp)Co(\text{diene})} + \text{1,5-hexadiene} \qquad (17)$$

Cp = π-cyclopentadienyl
diene = for example, butadiene, 1,5-cyclooctadiene, *cis*-1,2-divinylcyclobutane

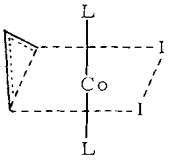
At temperatures above −45 °C, bis(allyl)cobalt iodide *(17a)* undergoes a ligand exchange reaction in which, in addition to tris(allyl)cobalt, a stable allylcobalt diiodide *(21)* is formed. Under similar conditions a mixture of *(1)* and allyl iodide in the presence of 1,5-cyclooctadiene undergoes a series of cleavage and ligand exchange reactions to give *(21)* in quantitative yield[5].



(18)

[*] This class of compounds has already been prepared by other methods [17—20].

Allylcobalt diiodide *(21)* forms green crystals which melt at +10 °C without decomposition. In the presence of additional ligands, *e.g.* phosphanes or pyridine, 2:1 adducts are quantitatively formed; presumably these have an octahedral structure, *e.g. (22)* (L = PR_3, pyridine).



(22)

4. Preparation of the 1,5-Cyclooctadiene(cyclooctenyl)cobalt System

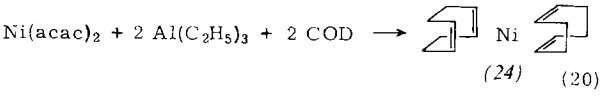
4.1. Reduction with Organoaluminum Compounds

In 1960 *Wilke et al.*[21a] discovered a general synthetic method for the preparation of low-valent transition metal complexes:

$$M'X_n + nM-R \xrightarrow[-nMX]{} \underset{(23)}{M'R_n} \xrightarrow{mL} L_mM' + nR \qquad (19)$$

M' = transition metal, M = main group metal, R = alkyl, L = ligand

From the reaction of bis(pentanedionato)nickel and triethylaluminum with COD as ligand one obtains Ni(COD)$_2$ *(24)*, *i.e.* the alkyl intermediate *(23)* decomposes with resulting reduction of the metal to the zero-valent state[21b].



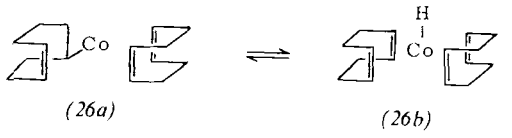
(20)

In 1966 *Grard*[22,23] extended this reaction to cobalt. The reaction of tris(pentanedionato)cobalt(III) with alkyl aluminum in the presence of COD occurred smoothly to give a diamagnetic cobalt(I) complex having the composition *(25)*. In other words, in the case of cobalt the reduction of the alkyl intermediate *(23)* does not proceed beyond the monovalent stage.

$$Co(acac)_3 + 3AlR_3 + 2COD \rightarrow \underset{(25)}{(COD)_2Co{-}R} + 3AlR_2(acac) + 2[R^\bullet] \qquad (21)$$

R = C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *n*-C_8H_{17}

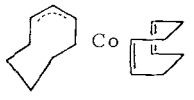
It is possible to generate the parent compound *(26)* in this series by using dialkylaluminum hydride as reducing agent. Complex *(26)* forms black, lustrous crystals which ignite spontaneously in air. Although the 1,5-cyclooctadiene(σ-cyclooctenyl)cobalt complex *(26a)* is in equilibrium with the bis(1,5-cyclooctadiene)cobalt hydride *(26b)* [cf. eqs. (28) and (30)] in solution, it is possible that one of these two forms is present in the crystalline compound. An X-ray structural analysis would clarify this point.



(22)

(26a) (26b)

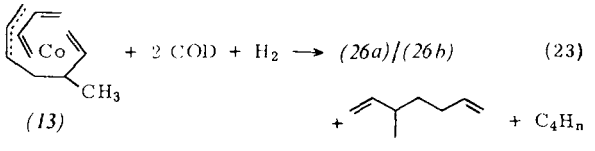
Use of an excess of dialkylaluminum hydride leads to the by-product 1,5-cyclooctadiene(π-cyclooctenyl)cobalt which results from an unrelated reaction (cf. Section 5):



(26c)

4.2. Displacement by Hydrogenation[26]

A second synthetic route to *(26a)* and *(26b)* involves the cobalt(I) species butadiene(methylheptadienyl)cobalt *(13)*. The open-chain enyl group is cleaved by hydrogen and, in the presence of COD, *(26a)* and *(26b)* are formed quantitatively.



(23)

(13)

4.3. Reduction with Sodium[24]

In 1968 *Otsuka* and *Rossi*, inspired by the initial reports[23] of *Grard*'s work, began studying the system *(26)*. On reducing $CoCl_2$ in pyridine/THF with sodium in the presence of COD they obtained 1,5-cyclooctadiene(π-cyclooctenyl)-cobalt *(26c)* in the form of dark brown leaflets.

$$CoCl_2 + 2COD + 2Na \xrightarrow[25\%]{} \underset{(26c)}{\pi\text{-}C_8H_{13}CoC_8H_{12}} \quad (24)$$

Deuteration experiments have shown that the hydrogen atom, needed to produce *(26c)*, does not originate from the pyridine.

4.4. Electrochemical Reduction[25]

Lehmkuhl et al. have developed an electrochemical synthesis for 1,5-cyclooctadiene(π-cyclooctenyl)cobalt *(26c)* [eq. (25)]. In this case methanol or ethanol functions as the proton donor.

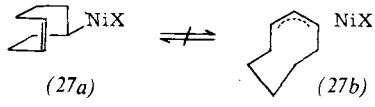
$$Co(acac)_2 + 2COD + H^{\oplus} \xrightarrow{+e^{\ominus}(cath.)} \underset{(26c)}{\pi\text{-}C_8H_{13}CoC_8H_{12}} \quad (25)$$

5. Structural Consideration and Reactions of 1,5-Cyclooctadiene(cyclooctenyl)cobalt Systems

Differing physical properties indicate that the product from the organoaluminum synthesis and the hydrogenation reaction is not identical with that produced by alkali metal or electrochemical reduction (cf. Section 4.1 to 4.4). *Otsuka* and *Rossi*[24] have shown that *(26c)*[*] is not in equilibrium with the other isomers while our experiments[26] show that *(26a)* and *(26b)* are in equilibrium with each other in solution but not with *(26c)*.

$$(26a) \rightleftharpoons (26b) \not\rightleftharpoons (26c) \quad (26)$$

These findings are consistent with those for the analogous cyclooctenylnickel compounds[28–33]: the σ-enyl and π-allyl forms *(27a)* and *(27b)* are stable and are not interconvertible.



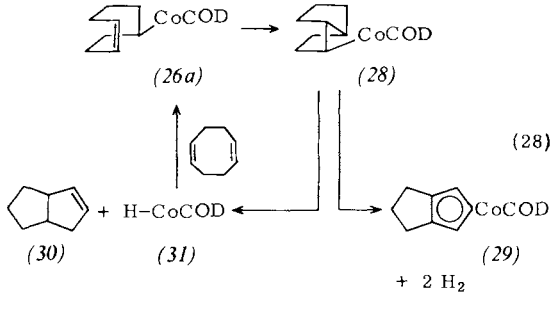
(27)

(27a) (27b)

X = acac[28,29], Br[30,31], CH_3[32,33]

As expected *(26a)* and *(26b)* are more reactive than 1,5-cyclooctadiene(π-cyclooctenyl)cobalt *(26c)*; the former are spontaneously inflammable and decompose at 40 °C, while the latter is only slowly attacked by atmospheric oxygen and melts at 65 °C.

Solutions of *(26a)* and *(26b)* are slowly converted at +40 °C into the cyclopentadienylcobalt derivative *(29)*. Apparently, under these conditions the σ-cyclooctenyl group undergoes transannular ring contraction to give the perhydropentalenyl group *(28)* from which hydrogen is eliminated to give stable *(29)*. β-H elimination to give *(30)* is observed to a lesser extent. The presence of free 1,5-cyclooctadiene results in addition to *(31)* with regeneration of *(26a)*. This process, by which COD is catalytically isomerized to *(30)*, continues until the active catalytic species *(31)* is completely converted into the catalytically inactive complex *(29)*.



(28)

(26a) (28) (30) (31) (29)

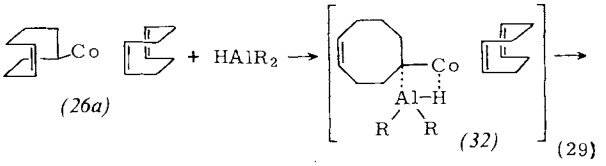
+ $2H_2$

Reaction with diisobutylaluminum hydride causes quantitative cleavage of the σ-enyl group and its elimination as cyclooctene. Presumably the reaction occurs as shown in eq. (29) with the initial displacement of the coordinated double bond of the σ-cyclooctenyl group from the cobalt and generation of a bridged cobalt-aluminum species *(32)*[**]. The intermediate *(32)* can react further by transfer-

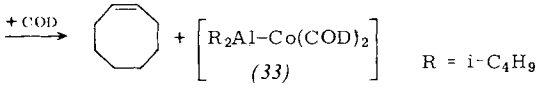
[*] The arrangement of the organic groups around the Co atom in *(26c)* has been established by X-ray structural analysis [27].

[**] For a comparison with the corresponding results obtained in the aluminum-nickel system, see the accompanying article: *K. Fischer, K. Jonas, P. Misbach, R. Stabba,* and *G. Wilke,* Angew. Chem. *85*, 1002 (1973); Angew. Chem. internat. Edit. *12*, 943 (1973).

ring the bridging hydrogen atoms to the enyl group, a step which should be accompanied by formation of the bimetallic complex *(33)*.

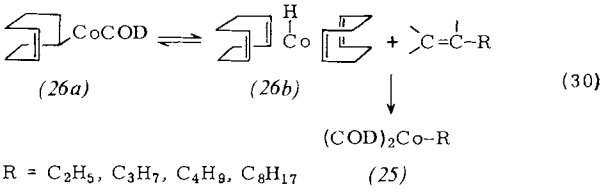


(29)



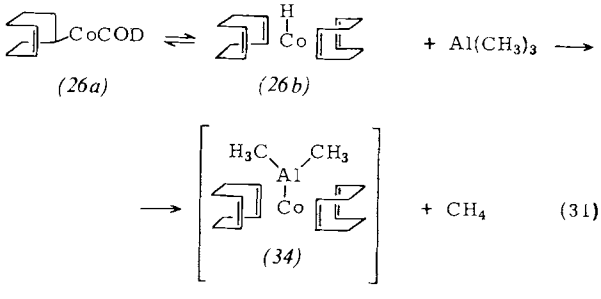
Interestingly, excess 1,5-COD is isomerized to 1,3-COD. This observation is of relevance to the discovery that the use of excess dialkylaluminum hydride in the synthesis of *(26)* is accompanied by the formation of the π-allyl form *(26c)*, which may be derived from 1,3-COD.

The σ-cyclooctenyl compound *(26a)* reacts with monoolefins through the hydride form *(26b)* (with which it is in equilibrium): addition occurs to give an alkyl bis(cyclooctadiene)cobalt *(25)*.



(30)

The hydrogen atom of the hydride form *(26b)* reacts quantitatively with trimethylaluminum with liberation of methane: a red brown diamagnetic complex is deposited from the solution at 0 °C which, although it has not been further characterized, presumably has structure *(34)*. Formally *(34)* can be compared with $NaCo(CO)_4$.

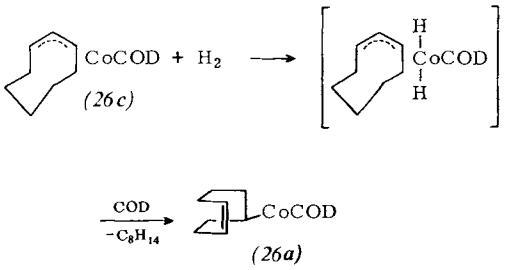


(31)

We have already mentioned that the π-form *(26c)* is less reactive than the σ-enyl isomer *(26a)* and does not react with either monoolefins or trimethylaluminum[*]. Displacement of the π-cyclooctenyl group as cyclooctene can, however, be effected by hydrogenation and in this way it is possible to convert the π-allyl form into the σ-derivative *(26a)* [eq. (32)].

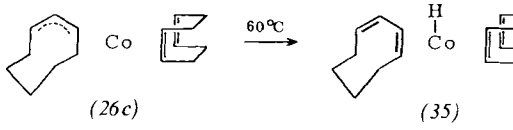
The rearrangement shown in eq. (33) indicates, however, that at higher temperatures the π-cyclooctenyl compound *(26c)* can react through an additional hydride form *(35)*.

[*] The ^{1}H-NMR spectrum of a 1:1 mixture of $Al(CH_3)_3$ and *(26c)* is identical with a superimposition of the spectra of the pure components.

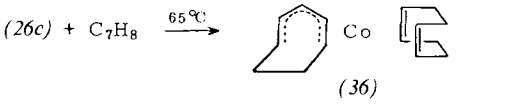


(32)

It is in this sense that *(26c)* reacts with excess cycloheptatriene: a π-cycloheptadienylcobalt complex *(36)*[34] is produced, presumably by addition of *(35)* to the seven-membered ring.

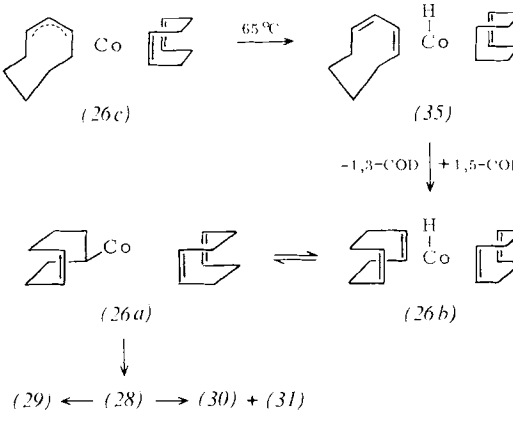


(33)



(34)

The formation of *(29)* and *(30)* from the reaction of *(26c)* with COD at temperatures above +60 °C has been reported on several occasions[25,35] and can also be regarded as proceeding *via* the hydride form *(35)* [eq. (35)]. Under the reaction conditions the compounds *(26c)*, *(35)*, *(26b)* and *(26a)* are not isolable.

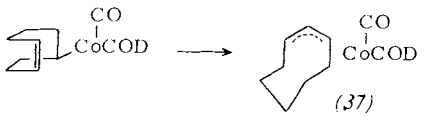


(35)

In the first step the 1,3-cyclooctadiene is displaced by the better chelating ligand 1,5-COD to give the hydride *(26b)*, which reacts further in the σ-enyl form *(26a)* according to eq. (28).

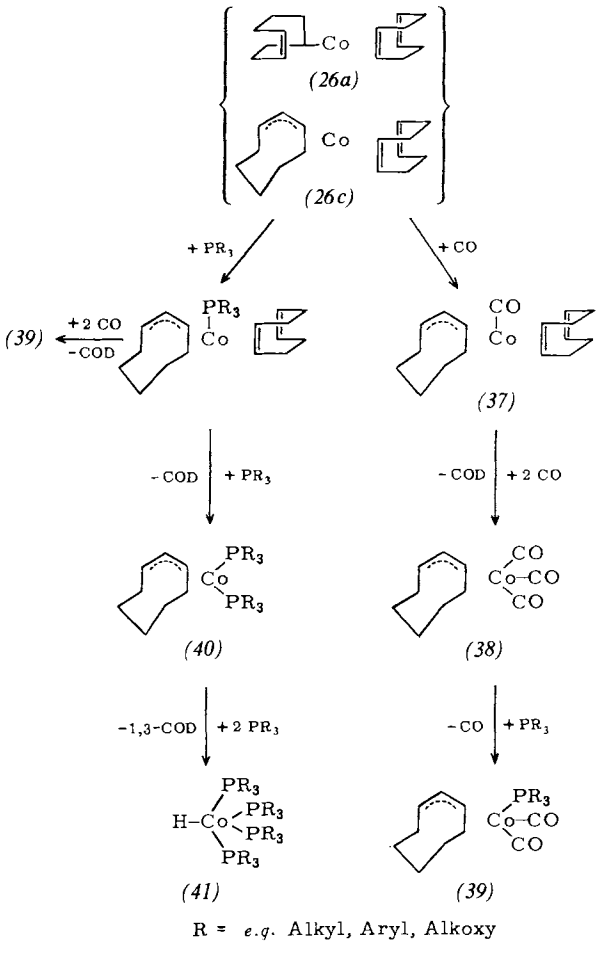
5.1. Reaction with Neutral Ligands

In the cyclooctenyl compounds *(26)* the coordination number of the cobalt atom does not exceed 4. Hence the compounds absorb carbon monoxide at low temperature[22,26,36]; interestingly, the same π-cyclooctenyl derivative *(37)* is formed both from *(26a)* and from *(26c)*. This would indicate, therefore, that the complexation of



(36)

an additional ligand causes isomerization of the σ-enyl group into a π-allyl form.



R = *e.g.* Alkyl, Aryl, Alkoxy

Additional CO displaces the 1,5-cyclooctadiene from *(37)* and produces the tricarbonylcobalt complex *(38)*[22,33,36]. *(38)* is related to the π-allyl(tricarbonyl)cobalt complex *(3a)*. PF_3 reacts with *(26)* to give the corresponding tris(ligand) complex[37]. One of the carbonyl groups bonded to the cobalt can be selectively substituted by reaction with phosphanes of type PR_3 to give the compounds *(39)*[22,26]. If *(26)* is reacted directly with phosphanes then, in general, the bis(ligand) adduct *(40)* is produced[33,38]. Although the π-allyl group in π-allyl(tricarbonyl)cobalt *(3)* cannot be displaced by reaction with CO[3], excess of phosphane reacts with *(26)* to produce compounds of the type *(41)*. A detailed study[38] of the effect of ligands has shown that equilibration occurs: the position of equilibrium depending upon the π-acceptor and σ-donor properties of the complex partner.

6. Processes Catalyzed by π-Allylcobalt Complexes

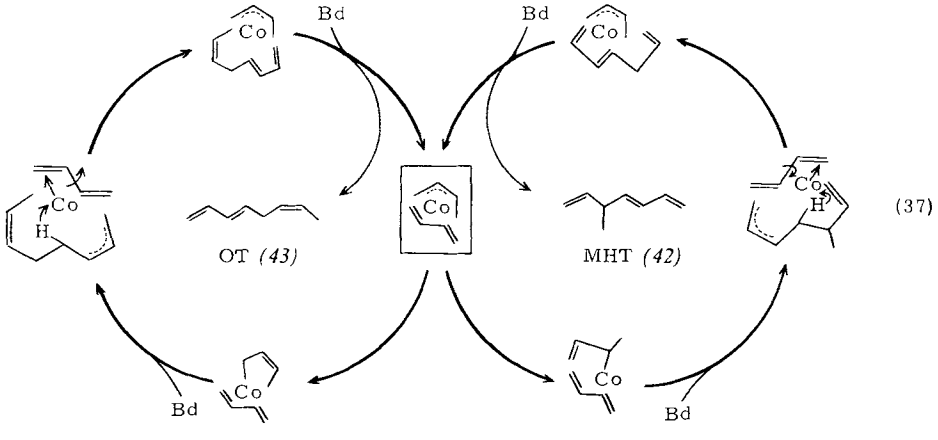
6.1. The Oligomerization of Butadiene

The ability of tris(π-allyl)cobalt to catalytically convert butadiene into open chain dimers was discovered by *Tanaka* in 1963[2]. At 20 °C 5-methyl-1,3,6-heptatriene *(42)* (MHT) and 1,3,6-octatriene *(43)* (OT) are formed with high selectivity in the ratio 9:1.

(42) *(43)*

It was shown by *Kopp*[13,14] that the butadiene displaced all three π-allyl groups [eq. (7)] and hence, using the definition suggested by *Wilke* for nickel, we are dealing here with a "naked cobalt(I)".

As can be seen from eq. (7), the stoichiometric conversion of tris(π-allyl)cobalt into the catalytically active 5-methyl-heptadienylcobalt(I) complex *(13)* is the result of a sequence of C=C insertion and β-H addition-elimination steps. Eq. (37) (Bd = butadiene) illustrates that the same processes are involved in the catalytic dimerization of butadiene on "naked cobalt".

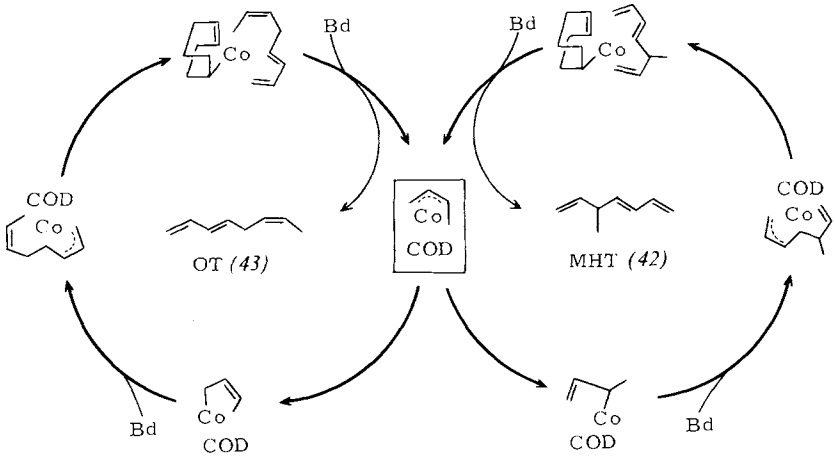


(37)

The *anti* substituted π-crotylcobalt intermediate shown in eq. (37) can be regarded as a crossing-point for the 'OT' and 'MHT' cycles: whether linear dimers *(43)* or branched dimers *(42)* are produced depends upon whether the butadiene attacks C-1 or C-2 of the crotyl group. The cyclooctenylcobalt complex *(26)* is also able to catalytically convert butadiene into the open chain dimers *(42)*

and *(43)* and can be regarded as a "modified" organocobalt-catalyst[14]. However, in this case the chelating ligand COD remains bonded to the cobalt throughout the whole of the catalytic reaction. In addition, the COD acts as the "hydrogen depot" [eq. (38)] (Bd = butadiene).

The linear dimers *(42)* and *(43)* are also 1,3-dienes and are able to react with further butadiene to give higher oligomers in a manner analogous to that shown in eq. (37) and/or (38). The formation of oligomers, using the "naked cobalt" catalysts *(1)* and *(13)* increases greatly



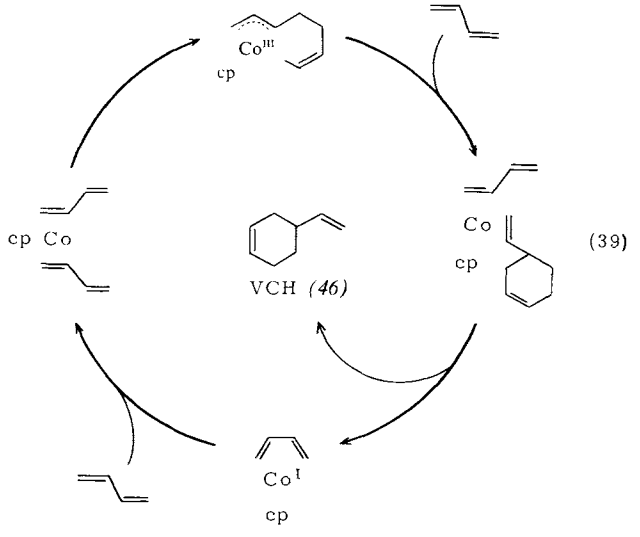
(38)

Cobalt(I) catalysts containing the π-cyclopentadienyl group as the "cycloolefin" ligand act in a completely different manner from *(1)*, *(13)* or *(26)*. The catalysis takes place on the π-cyclopentadienylcobalt moiety [*(44)* and *(45)*], without hydrogen insertion, to give cyclic dimers.

(44)  Co^I Co^I *(45)*

The derivative *(29)*, formed by transannular contraction, also belongs to the π-cyclopentadienylcobalt catalysts[20] and catalytically converts butadiene to 4-vinylcyclohexene (VCH) *(46)*[26].

The reaction is believed to occur in a manner analogous to that involving nickel[39] and an intermediate π-allyl(σ-allyl)C_8-chain bonded to cobalt may be postulated. The transition from $cpCo^{III}$ to $cpCo^I$ shown in eq. (39) corresponds to the stoichiometric conversion of *(19)* into the diene complex *(20)* [cf. eq. (17)] (cp = π-cyclopentadienyl).



(39)

when the butadiene conversion exceeds 40%. However, this effect can be suppressed by using the COD modified system *(26)* (see Table 3).

Table 3. The oligomerization of butadiene with various cobalt catalysts (60 °C and 70% conversion).

Product distribution	Catalyst *(1)/(13)*	*(26)*	*(29)*
Dimer	38% [a]	89% [a]	92% [b]
Trimer	34%	2%	—
Higher oligomers	28%	9%	8%

[a] 5-methyl-1,3,6-heptatriene *(42)* + 1,3,6-octatriene *(43)*.
[b] 4-vinylcyclohexene *(46)*.

The composition of the trimeric fraction is shown in Table 4.

Compound	Amount [%]
	35%
	25
 [a]	35
	≈ 4
5-methylundecatetraene	< 1

[a] Quoted compound plus isomers.

6.2. Co-oligomerization of Butadiene with Alkenes and Alkynes

The results obtained from the oligomerization of butadiene indicate that the electivity[*] of the reaction can be

[*] The "electivity" is the ability of a catalyst to activate certain components in a mixture and cause them to react preferentially.

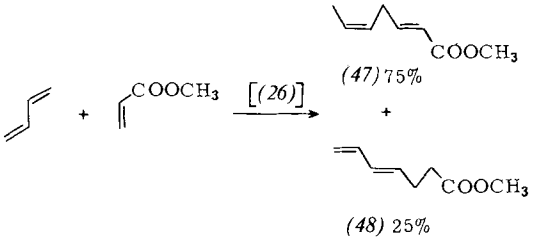
increased by modifying the "naked cobalt" catalyst (see Table 3). The difference in the electivity of *(1)*, *(13)*, *(26)* and *(29)* can be clearly seen from the results of the co-oligomerization of butadiene with alkenes. Although the simultaneous reaction of butadiene and ethylene with *(1)* or *(13)* does produce 1,*trans*-3-hexadiene and, moreover, in 97% purity, the yield of co-dimer (based on converted butadiene) is only 10%—the main product is MHT *(42)*. On the other hand, an almost quantitative codimerization to hexadiene is obtained in the presence of COD as ligand[13]. The main product using *(29)* is cyclohexene (see Table 5).

Table 5. The codimerization of butadiene and ethylene at 60 °C.

Product distribution	Catalyst *(1)/(13)*	*(26)*	*(29)*
Codimer	10% 1,3-hexadiene	98% hexadiene [a]	80% cyclohexene
Butadiene oligomers	90% [b]	2%	20% [c]

[a] 1,4-Hexadiene and 1,3-hexadiene in a 3:2 ratio.
[b] Dimer *(42)* + *(43)* and higher oligomers in a 2:3 ratio.
[c] VCH *(46)* and higher oligomers in a 9:1 ratio.

Acrylic ester can be used successfully in place of ethylene in the cobalt catalyzed co-oligomerization and similar "electivity" is observed. With *(26)* as the catalyst, the methyl esters of heptadienoic acid *(47)* and *(48)* are obtained in 96% yield[40]. The *trans*-2,*cis*-5-ester *(47)* corresponding here to the substituted *cis*-1,4-hexadiene and *(48)* to the *trans*-1,3-hexadiene. The "naked cobalt" catalysts *(1)* and *(13)* are of lower electivity, only about a 60% yield of the C_7-esters *(47)* and *(48)* is obtained—the remainder being higher oligomers.

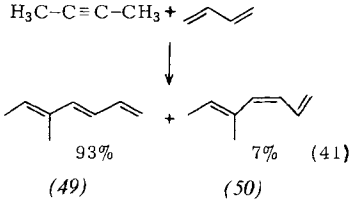


(40)

As expected, the co-dimerization using *(29)* leads, in this case, also to the cyclic products, namely methyl 4-cycloheptenoate *(46)* (60%) and VCH.

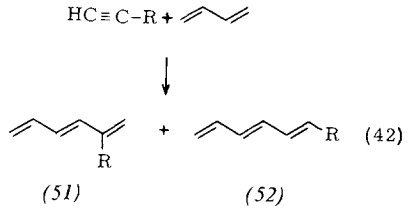
Butadiene and alkynes can be converted smoothly by *(1)*, *(13)* or *(26)* (30 min, 50 °C) into substituted hexatrienes[13,14].

The reaction of butadiene with 2-butyne yields the codimers *(49)* and *(50)* in accordance with eq. *(41)*.



(41)

In general, 1-alkynes are converted (under the same conditions) into the conjugated trienes *(51)* and *(52)* (R = *e.g.* CH_3, C_4H_9) [eq. (42)].



(42)

A side-product (*ca.* 20%) of this catalytic reaction is the cyclohexadiene derivative *(53)* a part of which is dehydrogenated to the aromatic system *(54)*.

By using the "cyclization" catalyst *(29)* it is possible to produce the six-membered ring systems *(53)* and *(54)* in pure form at 80 °C—100 °C.

The author's thanks are due to Dr. J. Brandt, Dr. D. Henneberg, Prof. E. G. Hoffmann, Dr. G. Schomburg, Dr. K. Seevogel and their co-workers for the measurement and interpretation of the analyses and spectra. The assistance of H. W. Hofstadt, U. Nienhaus, R. Pump and U. Schaffeld with the technical and preparative work is also gratefully acknowledged.

Cyclooligomerization with Transition Metal Catalysts[**]

By Paul Heimbach[*]

In memory of Karl Ziegler

This report is concerned not only with the syntheses of new ring systems and the preparation of derivatives of known rings but also with new types of catalysts based upon, *e.g.*, nickel, iron, molybdenum, manganese, and palladium. The broad applicability of the methylene insertion reaction as a method for identifying mono- and di-methyl-substituted eight-, ten-, and twelve-membered rings is also demonstrated. A further section is concerned with the possible mechanism of C—C bond formation in transition metal complexes; several earlier suggestions have been revised in the light of new experimental data. In addition, experimental results are discussed which indicate that the reactivity and selectivity of the complexes formed by the nickel-ligand catalyst and olefins or alkynes depend upon the structure of the ligands.

1. Introduction

At the outset of this progress report we shall briefly consider earlier catalytic ring syntheses [eq. (1)–(7)] which have been reviewed elsewhere[1–7].

As can be seen, the low-valent nickel catalysts have received particular attention [eq. (3)—(6)][***]. In several cases they have been modified to nickel-ligand catalysts by the addition of an equivalent of phosphane or phosphite (L). Reduction of the nickel in, for example, bis(pentanedionato)nickel(II) ($Ni(acac)_2$), has been carried out with organoaluminum compounds[3,17] and electrochemically[18,19]. In addition, nickel(II) alkoxides can be converted into low-valent nickel catalysts by heating them in liquid butadiene at temperatures above 80 °C whereupon, *inter alia*, an O—C coupling reaction occurs[20]. The thermal degradation of nickel(II) alkoxides was originally observed by *Meerwein*[21]. Stable nickel(0) complexes *e.g.* $Ni(CH_2{=}CH{-}CN)_2$, can also

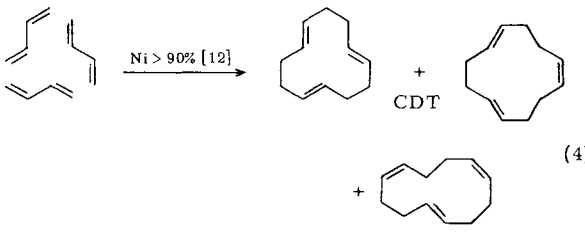
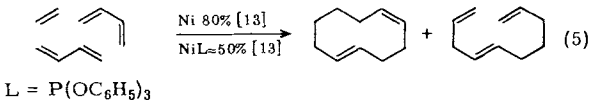
[**] Based upon the work and ideas of *W. Brenner, H. Buchholz, W. Fleck, H. J. Hey, R.-V. Meyer, M. Molin, K.-J. Ploner, W. Scheidt, R. Schimpf, K.-H. Scholz, H. Selbeck, K. Tani, F. Thömel, E. Troxler, W. Wiese*, and *W. Zaar*, whose results have not as yet been published in detail.

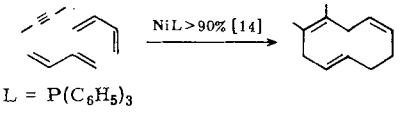
[***] "Ni" is used to denote the nickel catalyst employed *e. g.* $Ni(COD)_2$.



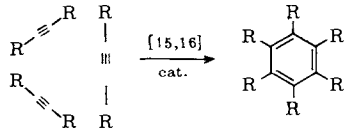
(4)



(5)



(6)

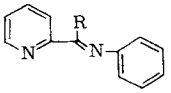


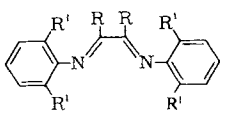
(7)

be converted into highly reactive nickel catalysts by displacement of the strongly bonded ligands with butadiene at elevated temperatures[22,23]. Similarly, the CO groups in $Ni(CO)_4$[4] or $L_2Ni(CO)_2$[10] can be more or less completely displaced. All of these various reactions produce the same catalytically active species in varying yields.

In was demonstrated for the first time in the synthesis of 1,5,9-cyclododecatriene (CDT) that, in addition to nickel, other metals *e.g.*, chromium, titanium[24], or manganese[25], could be used to prepare catalysts for the cyclotrimerization of butadiene. Likewise, the synthesis of 1,5-cyclooctadiene (COD) from butadiene is not confined to nickel-ligand catalysts[11]; the diene is also formed, although only as by-product, using bis(cyclooctatetraene)iron[26] and π-allyldicarbonyldinitrosyl iron[27]. This last catalyst yields mainly four- and six-membered rings at temperatures below 150 °C. The yield of eight-membered ring can be increased to 60% by introducing 2,2'-bipyridyl (bipy) as an additional ligand[28,29]. Other iron catalysts capable of generating cyclooctadiene have been described by two further research groups[30,31]. However, the rates of these reactions are extremely low even in the presence of the phosphanes and phosphites[31] which have proved particularly valuable as additional ligands in nickel catalysis.

Several groups have reported, essentially independently of each other, that Schiff bases having the structure shown are particularly effective additional ligands for the cyclodimerization of 1,3-dienes using iron catalysts[32-34]. In some cases the rates of reaction are greater than those involving



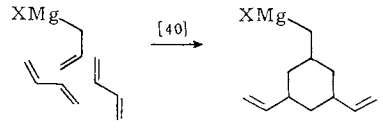


nickel-ligand catalysts of comparable selectivity. It is of interest that the cyclooctadiene formation occurs in a manner differing from that using a nickel-ligand catalyst[35]. Butadiene can also be converted into cyclooctadiene using a rhodium catalyst[36] as well as a cobalt catalyst associated with suitable ligands[37-39].

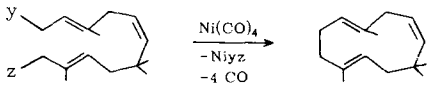
2. Recent Preparative Results in Catalytic Cyclooligomerization

2.1. New Types of Catalytic Ring Syntheses

Occasionally the term catalytic is erroneously applied to reactions in which a metal atom or -cluster or a catalyst-complex residue[*] is introduced essentially as an auxiliary group into an olefin or alkyne but is not available for further reaction. In these reactions, which can really only be regarded as being metal-induced, the metal or metal



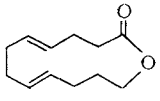
(8)



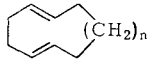
(9)

[41]

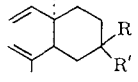
complex is employed in stoichiometric amounts. Nevertheless, such reactions have been included here where they lead to a ring system. Examples are shown in eq. (8) and (9) as well as in the syntheses of the cyclic compounds *(1)*—*(3)*.



(1) [42]



(2), n = 4, 6, 10
[43]



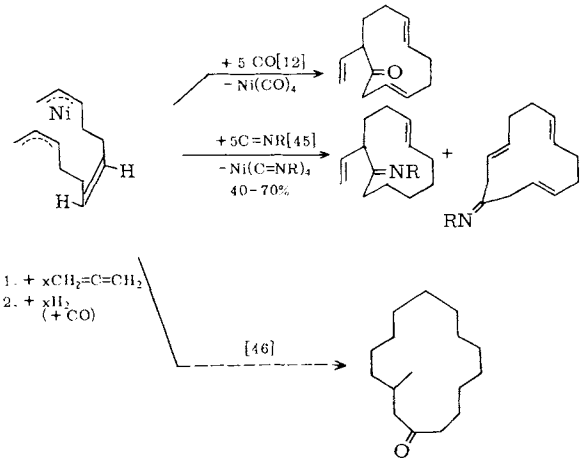
(3) [44]

Starting from a C_{12}-chain bonded to nickel (prepared from three butadiene molecules) it is possible to synthesize eleven-[12,45], thirteen-[45], and, by reaction with allene, fifteen-membered rings[46] [eq. (10)]. One or more of these reactions could probably be rendered catalytic by varying the reaction conditions or the ligand.

In the following, we consider some examples of catalytic syntheses of new ring systems. The classification is based upon *ring size*. Whereas complete conversion of butadiene [using the tri(2-biphenylyl)phosphitenickel catalyst] leads to 95% of *cis,cis*-1,5-cyclooctadiene and 4-vinylcyclohexene (2%)[**], up to 85% conversion produces the following product composition: 4-vinylcyclohexene (2%), *cis*-1,2-divinylcyclobutane (36%), and *cis,cis*-1,5-cyclooctadiene (36%)[11].

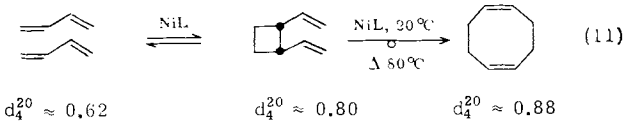
[*] The designation catalyst-complex residue is used to describe the metal and those ligands which do not play a direct role in the reaction.

[**] Unless otherwise indicated, the percentage yields are based upon the amount of olefin converted and not upon the amount initially present.



(10)

This "catalytic Cope rearrangement" is of pseudo zero order with respect to the four-membered ring and depends only upon the concentration of the catalyst and the nature of the phosphorus-containing ligand. The extensively stu-

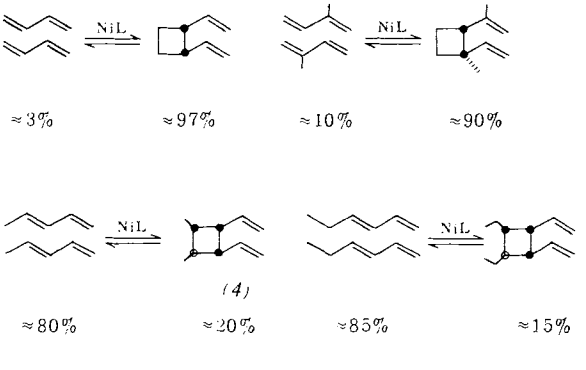


(11)

$d_4^{20} \approx 0.62$ $d_4^{20} \approx 0.80$ $d_4^{20} \approx 0.88$

died thermal Cope rearrangement of *cis*-1,2-divinylcyclobutane is first order[48,49]. A temperature-dependent equilibrium is established between butadiene and the four-membered ring in the presence of the nickel-ligand catalyst[47].

The position of the thermodynamic equilibrium—neglecting a slight catalyst-influence—depends upon the position and nature of the substituents on the 1,3-diene (values at 30 °C)[47,50,51].



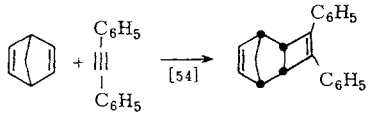
In the case of *trans*-piperylene (1,3-pentadiene)[47], as expected, the equilibrium constant at 30 °C ($K = 2.3 \times 10^{-2}$ l/mol) is found to be independent of the nature of the phosphorus-containing ligand bonded to the nickel. However, the maximum yield of *(4)* using the tricyclohexylphosphane-nickel catalyst is obtained when only 20% conversion has occurred owing to the temperature-dependent thermodynamic equilibrium. The yield decreases with further conversion because a second four-membered ring and two eight-membered rings are formed in a slow reaction.

A similar dependence of the conversion (and hence of the yield based upon the initial amount of monomer) upon the temperature—arising from a reversible monomer-polymer equilibrium—has been observed by *Calderon*[52] during the metathesis of cyclopentene with molybdenum catalysts [eq. (12)].

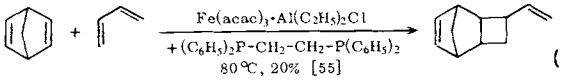
(12)

The synthesis of divinylcyclobutane has been effected using palladium(II) salts containing anions such as ClO_4^- and BF_4^- which cannot complex with the metal[53].

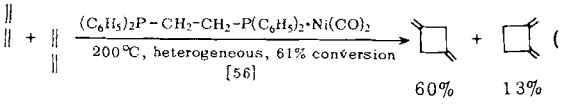
The four-membered ring syntheses shown in eq. (13)—(16) have so far only been carried out with activated olefins or alkynes (MA = maleic anhydride).



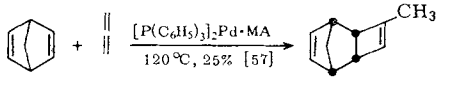
(13)



(14)

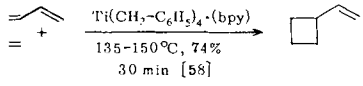


(15)

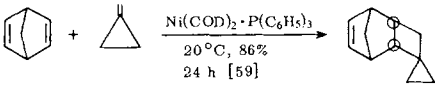


(16)

Few examples are known of the codimerization of two olefins to give a four-membered ring in a highly selective manner [*viz.* eq. (17) and (18)]. In eq. (17) butadiene, ethylene, and the catalyst (bipy = 2,2'-bipyridyl) were allowed to react in the ratio 140:180:1. A discussion of the mechanism of these catalytic, formally $(2\pi + 2\pi)$ cycloadditions is reserved for Section 3.1.



(17)

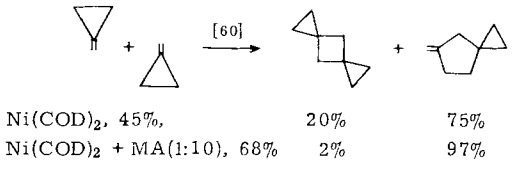


(18)

A few novel catalytic syntheses of *five-membered rings* are shown in eq. (19)—(22).

Whereas the reaction of butadiene with dialkyl-, arylalkyl-, and diaryl-substituted alkynes using a triphenylphosphanenickel catalyst gives 4,5-disubstituted *cis,cis,trans*-1,4,7-cyclododecatriene in high yield, alkyl- and aryl-substituted acetylenecarboxylic esters react with butadiene to give 5-vinyl-1,3-cyclohexadiene species *(six-membered rings)*[64,65] [eq. (23): the reaction of, *e.g.*, 2-butyne with butadiene using the same catalyst is shown in eq. (6)].

All the catalytic co-trimerization reactions leading to cyclodecatriene or 5-vinyl-1,3-cyclohexadiene species are nor-



$Ni(COD)_2$, 45%, 20% 75%
$Ni(COD)_2$ + MA(1:10), 68% 2% 97%

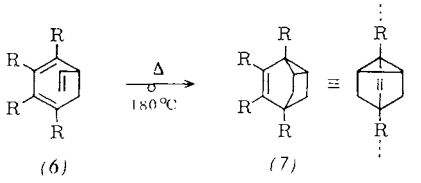
(24)

mally carried out under standard conditions: 20 °C, Ni : triphenylphosphane = 1 : 1 ; 1,3-diene : alkyne = 5 : 1 ; catalyst : 1,3-diene = 1 : 150.

In some cases, in order to maximize the yield of the desired product, it is necessary to vary both the reaction conditions and the method of addition. Thus, under the standard conditions, phenylacetylene and butadiene react to give *(5)* in only 25% yield; this can, however, be raised to 80% by adding the phenylacetylene dropwise into a butadiene-saturated solution of the catalyst in benzene at 40 °C.

Whereas the synthesis of 1,2,3,4-tetramethyl-5-vinyl-1,3-cyclohexadiene from 2-butyne and butadiene using a nickel catalyst free from phosphorus-containing ligands only gives low, often non-reproducible yields[20], *(6)* can be prepared in relatively good yield using a homogeneous $TiCl_4$—$Al(C_2H_5)_2Cl$ catalyst[66][*]. On heating to 180 °C these catalytically prepared, substituted 5-vinyl-1,3-cyclohexadiene species undergo an intramolecular Diels-Alder reaction to give tricyclooctene systems[64,65][**]. (Two other examples have also been reported[67,68].) *(7)*, R = CH_3 has a plane of symmetry. The vinylcyclohexadiene *(5)*, prepared from phenylacetylene and butadiene, has been shown in a ^{1}H-NMR investigation to be in equilibrium at 180 °C with only 30% of the corresponding trimer[64].

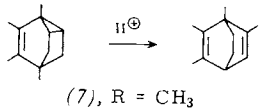


(6) *(7)*

(25)

The intramolecular Diels-Alder reaction occurs at room temperature in the presence of a heterogeneous $TiCl_4$—$AlC_2H_5Cl_2$ catalyst[66].

The acid-catalyzed rearrangement of the tetramethylcyclooctene *(7)*, R = CH_3[69], leads to a bicyclooctadiene system[70].



(7), R = CH_3

(26)

As well as 1,3-dienes it is also possible to react 1,3,5-trienes or a mixture of a 1,3,5-triene and a 1,3-diene with a nickel-ligand catalyst. The main products are no longer four- or eight-membered rings, but derivatives of 3,4-divinylcyclohexene. The products resulting from the reactions of *trans*- and *cis*-1,3,5-hexatriene or all-*trans*-2,4,6-octatriene with a tri(2-biphenylyl)phosphitenickel catalyst are summarized in eq. (27)—(29) (the conversions are shown beneath the arrows).

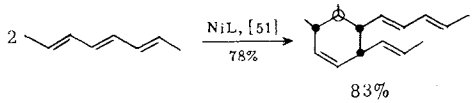
84%

(28)



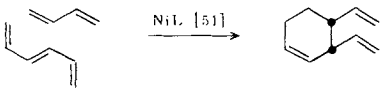
83%

(29)

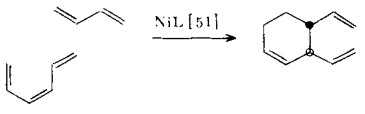
[*] In addition, the 1 : 1 codimer 1,2-dimethyl-1,4-cyclohexadiene is formed. The term "codimer" is discussed in Section 2.2.

[**] In reference [65] it is mistakenly reported that *(5f)* (instead of *(1f)*) reacts with diethyl acetylenedicarboxylate.

The codimerization of butadiene with *trans*- or *cis*-1,3,5-hexatriene occurs in over 90% yield, based on triene consumed [eq. (30) and (31)].



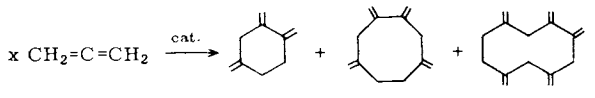
(30)



(31)

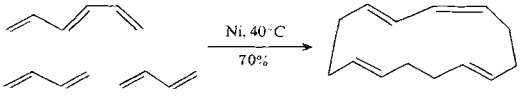
Substituted conjugated trienes react, under suitable conditions, with substituted 1,3-dienes to give derivatives of 3,4-divinylcyclohexene[51,71,72].

The catalytic cyclooligomerization of allene has been investigated by several research groups[73–75]; depending upon the reaction conditions and the catalyst, six-, *eight*-, and *ten-membered* rings can be obtained [eq. (32)].



(32)

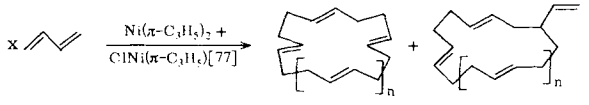
A *fourteen-membered ring* can be formed from two molecules of butadiene and one molecule of 1,3,5-hexatriene with a phosphane- or phosphite-free nickel catalyst. The yields of this simple synthesis are 70% based upon the reacted hexatriene and 40% based on reacted butadiene[72,76].



(33)

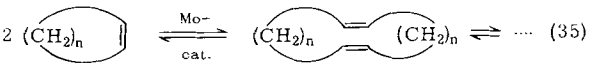
Reaction of a 30:70 mixture of *cis*- and *trans*-1,3,5-hexatriene produces a mixture of fourteen-membered rings containing 55% of the isomer shown in eq. (33).

Sixteen-membered rings can, according to *Miyake*[77], be prepared in 5—7% yield from butadiene using a mixed catalyst prepared from bis(π-allyl)nickel and allylnickel chloride [eq. (34)].



(34)

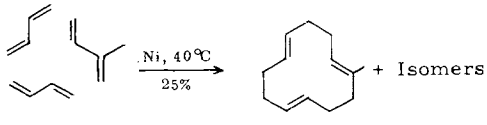
In addition to *twenty*-, *twenty-four*-, and *twenty-eight*-membered rings *etc.*, vinyl-substituted rings containing two carbon atoms less are also formed. The *sixteen*-membered ring has been prepared in up to 6% yield by *Leuchte* and *Lehmkuhl*[78] using a nickel catalyst and suitable solvent combinations. The advantage of this synthesis is that cyclododecatriene is the only side product. *Medium* and *large* rings can be prepared in up to 15% yield in a metathetic reaction using molybdenum catalysts [eq. (35)][79].



(35)

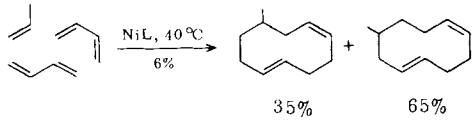
2.2. Catalytic Preparation of Methyl- and Alkyl-Substituted Eight-, Ten-, and Twelve-Membered Rings

The catalytic preparations of the above ring systems are possible using cross-oligomerization, co-oligomerization, or a combination of both. By cross-oligomerization we mean the oligomerization of unsaturated compounds of the same type but with different substituents or configuration, *e.g.*, the cyclodimerization of butadiene and isoprene (1:1) to give 1-methyl-1,5-cyclooctadiene, or the cyclodimerization of *trans*- and *cis*-piperylene (1:1) to give *cis*-3,4-dimethyl-1,5-cyclooctadiene. By co-oligomerization we mean an oligomerization of different classes of unsaturated compounds *e.g.* the cyclotrimerization of butadiene with ethylene (2:1) to give *cis,trans*-1,5-cyclodecadiene or of 2-butyne with butadiene (2:1) to give 1,2,3,4-tetramethyl-5-vinyl-1,3-cyclohexadiene. Eq. (37)–(39) summarize the yields and selectivities of some of the reactions in which a triphenylphosphitenickel catalyst has been used.



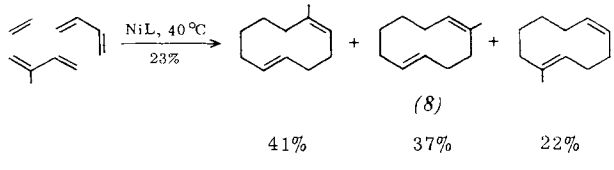
(36)

The cross-cyclotrimerization of butadiene and isoprene[81,82] is shown in eq. (36) while eq. (37) gives an example of a co-cyclotrimerization in which open-chain



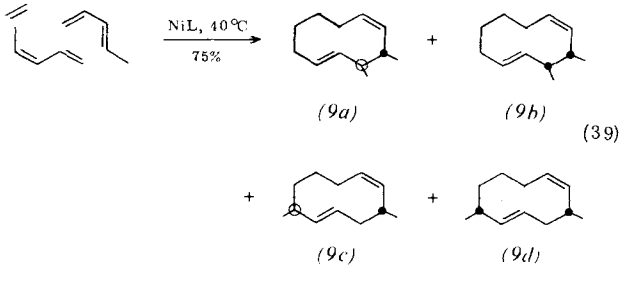
(37)

co-trimers are also formed[80]. The cross-co-cyclotrimerization of butadiene, isoprene, and ethylene is shown in eq. (38)[80,81]. The only cross-co-trimer formed using a nickel catalyst having no phosphorus-containing ligands is *(8)*.



(38)

Co- and cross-co-cyclotrimerization are observed in the reaction of a mixture of *cis*- and *trans*-piperylene with



(39)

ethylene[80]: *(9a)* and *(9d)* are formed from two molecules of *cis*- or *trans*-piperylene and a molecule of ethylene [eq (39)].

We synthesized nearly all of the possible mono- and dimethyl derivatives of the four-, six-, eight-, ten-, and twelve-membered rings for the following reasons:

1) to investigate the preparative extension of the building-block principle to nickel-catalyzed ring syntheses

2) to obtain further information on the course of reaction. The methyl group, in particular, is regarded as a perturbing group in the 1,3-diene, monoolefin, or the intermediate complexes.

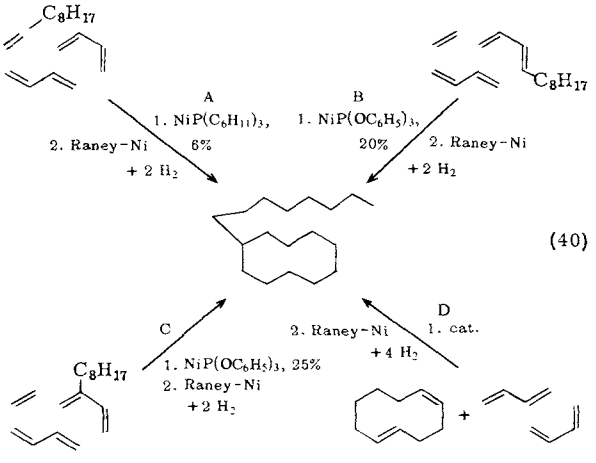
Two reactions were particularly important in determining the exact structures and configurations of the mono- and dimethyl-substituted rings:

1) the thermal[48,49] and catalytic[47,50] Cope rearrangement of 1,5-dienes, and

2) the methylene insertion reaction (Section 2.3).

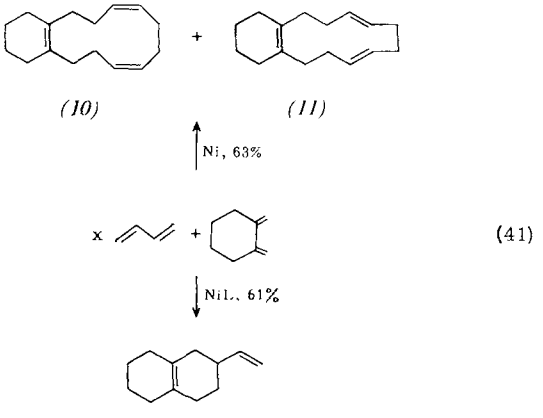
Effective and reproducible gas-chromatographic separation of the isomers is a necessary condition.

Alkyl groups larger than methyl can also be introduced into the olefin. The scope of catalytic ring syntheses utilizing the building-block principle will be illustrated for the synthesis of octylcyclodecane[13,20] as an example [eq. (40)]. The catalyst for reaction path D was $Ni(COD)_2$. The yield is 15% based upon reacted butadiene.



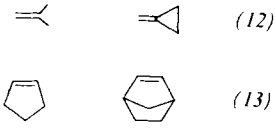
(40)

Further examples are shown in eq. (41)[82]. Compound *(10)* is the only example of a catalytically formed derivative of all-*cis*-1,5,9-cyclododecatriene.



(41)

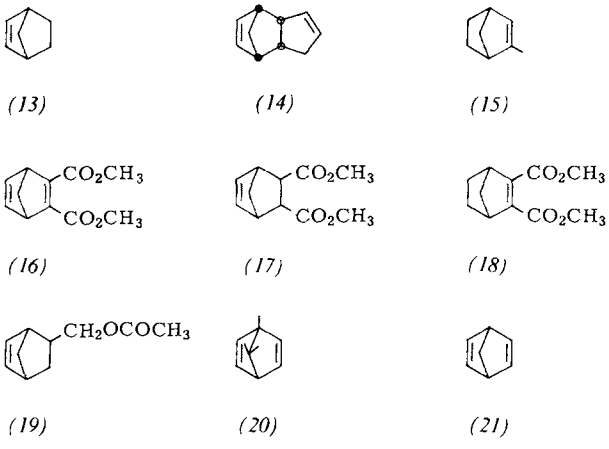
Compounds such as isobutene and cyclopentene hardly react at all in the presence of the nickel-ligand catalyst, whereas systems such as *(12)* and *(13)* are particularly reactive[83]. This obviously results in part from strain in the olefin[84].



(12)

(13)

The bicyclo[2.2.1]hept-2-ene derivatives *(13)*—*(21)* have been treated with butadiene in the presence of nickel ligand catalysts, compounds *(17)* and *(19)* were used as mixtures of *exo*- and *endo*-isomers. Derivatives of *cis,trans*-1,5-cyclodecadiene are formed. The reaction with norbornene is shown in eq. (42).

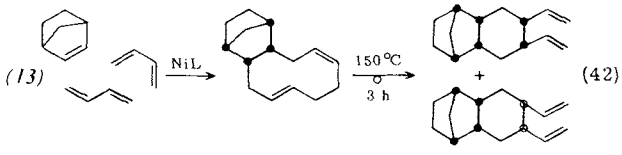


(13) *(14)* *(15)*

(16) *(17)* *(18)*

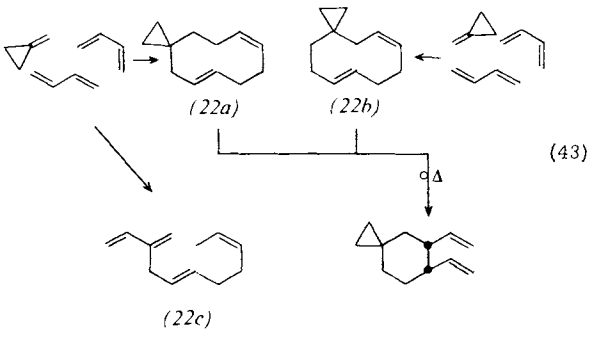
(19) *(20)* *(21)*

Only the strained double bond of dicyclopentadiene *(14)* took part in the catalytic reaction. The bicycloheptene derivatives having tri- or tetra-substituted double bonds [*e.g. (15)* or *(18)*] or subject to steric hindrance [*e.g. (20)*] cannot be co-oligomerized with butadiene. Each double bond in norbornadiene *(21)* can react individually as a monoene and both 2:1 and 4:1 adducts may be isolated.



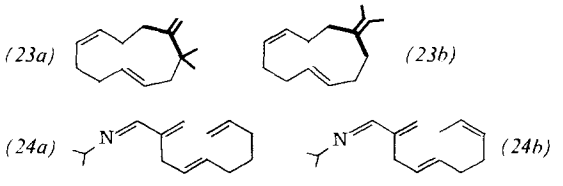
(42)

Whereas the bicyclo[2.2.1]heptene derivatives give exclusively cyclic products, the following examples show that the product distribution can be influenced to a large extent by an appropriate choice of the phosphorus-containing ligand present in the nickel catalyst. For example, the catalytic co-oligomerization of butadiene with methylenecyclopropane (for preparation see[85]) in the presence of tri(2-biphenylyl)phosphite leads predominantly to the spirododecadiene derivatives *(22a)* and *(22b)* while the use of tricyclohexylphosphane leads to 90% of the open-chain adduct *(22c)* [eq. (43)].



(43)

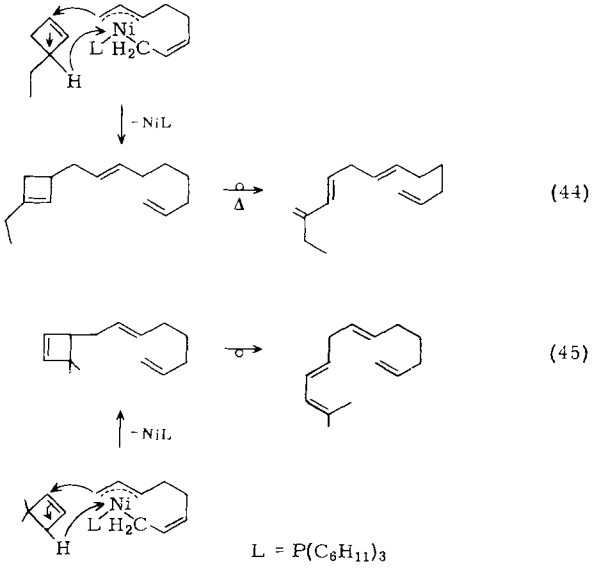
1,1-Dimethylmethylenecyclopropane[86] reacts to give, in addition to spirododecadiene compounds, the eleven-membered rings *(23a)* and *(23b)*. Similar cyclic and open-chain products to those obtained from methylenecyclopropane are also obtained by reacting *N*-isopropyl-2-methylenaziridine[87] with butadiene *e.g.* to give *(24a)* and *(24b)*[83].



The co-oligomerization of butadiene with 3-ethylcyclobutene and with 3,3-dimethylcyclobutene yields, in addition to the expected substituted cyclodecadiene derivatives, cyclobutene systems. These undergo a facile thermal rearrangement to open-chain tetraenes. The structure of the cyclobutene derivatives suggests that a different mechanism is involved [eq. (44) and (45)].

Two extreme situations can be distinguished in the cross-cyclooligomerization and the co-cyclooligomerization:

1) The molecules A and B react, independently of each other, at different rates with the catalyst in parallel reactions. In this case the difference in reactivity of A and B can be influenced by varying the concentration.



(44)

(45)

2) The molecules A and B react in different steps of a consecutive reaction. It is thus possible, for example, that B is only able to react with the catalyst after this has been modified by reaction with A. Nevertheless, a reversal of the reaction sequence can, in a few cases, be effected by the introduction of substituents into A and/or B (see *e.g.* eq. (6) and (23); further examples will be discussed in ref. [88]).

2.3. The Methylene Insertion Reaction

The usefulness of the methylene insertion reaction in the identification of catalytically formed mono- and di-methyl derivatives will be illustrated for 1- and 3-methyl-1,5-cyclooctadiene. Approximately 2% of diazomethane (the low concentration enables double or multiple reaction to be avoided) is dissolved in 1- and/or 3-methyl-1,5-cyclooctadiene. Irradiation with a mercury-vapor lamp causes the formation of singlet methylene which inserts in an essentially statistical manner into the C—H bonds (for this reason this methylene has been described by one American as "the most democratic reagent in organic chemistry"). At the same time reaction with the double bonds leads to cyclopropane derivatives; these can also be prepared by heating 1- or 3-methylcyclooctadiene with diazomethane in the presence of copper powder[89] and hence be identified in a mixture of methylene insertion products. A particular advantage of the method is that the structure and configuration of the original olefin are maintained[*][81].

This reaction of diazomethane was originally discovered by *Meerwein*[90] and exploited specifically for the identification of the next higher homologs by *von Doering*[91], *Dvoretzky*[92], and in particular *Schomburg*[93].

By reacting the methylene with 1- and 3-methyl-1,5-cyclooctadiene, it proved possible to prepare a mixture containing small amounts of all the dimethyl- and ethyl-derivatives of *cis,cis*-1,5-cyclooctadiene and to then determine their retention indices in capillary columns. Further identi-

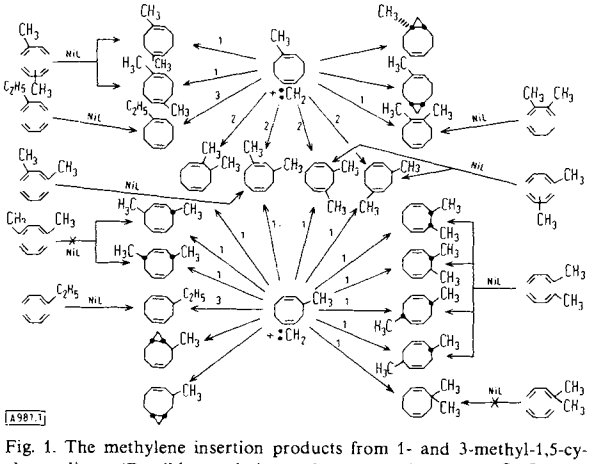


Fig. 1. The methylene insertion products from 1- and 3-methyl-1,5-cyclooctadiene. (Possible catalytic syntheses are also shown [81].) The number on the arrows show the statistical weight with which the isomers can be expected to be generated.

[*] Difficulties in the application of the methylene insertion reaction have so far only been experienced with *cis*- and *trans*-hexatriene. Isomerization of the triene could be avoided by using a filter which absorbs the radiation up to a wavelength of 300 nm [72].

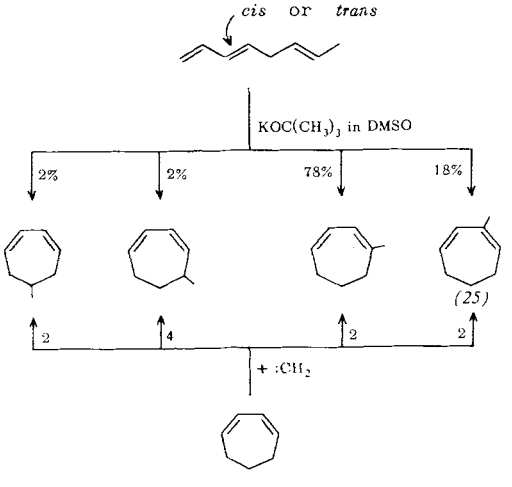
fication followed by chemical means and by comparison with the catalytically formed products (Fig. 1).

A brief explanation is appropriate. For example, only four isomers are common to both the methylene insertion reactions into 1- as well as into 3-methyl-1,5-cyclooctadiene; of these, 1,4- and 1,7-dimethylcyclooctadiene can be prepared catalytically by the cross-dimerization of isoprene and piperylene, and 1,3-dimethylcyclooctadiene by the cross-dimerization of butadiene with 2-methyl-1,3-pentadiene. Hence the fourth isomer can only be 1,8-dimethylcyclooctadiene. In addition, it can be deduced that, for example, catalytically synthesized, eight-membered dimers of isoprene can only be produced by methylene insertion reaction from 1-methylcyclooctadiene and those of piperylene only from 3-methylcyclooctadiene, in complete agreement with the experimental results.

An initially unanswered problem was that of the assignment of the two methyl groups in the 3,4-, 3,7-, and 3,8-positions of 1,5-cyclooctadiene. Their *cis*- or *trans*-arrangement were established indirectly by, *inter alia*, use of the Cope rearrangement of the corresponding four-membered rings[47] and by a ^{1}H-NMR study of the $PdCl_2$ complexes formed by the eight-membered rings[94]. Structural information was also frequently obtained from the retention behavior of the isomers[95].

In a similar manner we determined the structure and configuration of the mono- and di-methyl derivatives of *cis*, *trans*-1,5-cyclodecadiene, *cis*-1,2-divinylcyclohexane, *trans*-1,4,9-*n*-decatriene[80,81], of *trans,trans,trans*-, *trans,trans, cis*-, and *trans,cis,cis*-1,5,9-cyclodecatriene[81,82] as well as the trimethyl derivatives of *cis*- and *trans*-3,4-divinylcyclohexene formed by reaction of all-*trans*-2,4,6-octatriene with methyl-substituted 1,3-dienes[51,71]. All the 1,2-, 1,3-, 1,4-, 1,5-, 1,6-, and 1,7-dimethyl derivatives of cyclododecane could be assigned in pairs[81,82].

Isomerization of the octatrienes, which can be readily prepared from butadiene using an amine-modified nickel[96,97] or palladium[98,99] catalyst, leads preferentially to two of the four methyl-1,3-cycloheptadiene isomers. *Zuech et al.*[100] and *Kloosterziel et al.*[101] employed amides as the catalyst. However, better results were obtained using potassium *tert*-butoxide in DMSO[102] at 60 °C[103] [eq. (46)].



(46)

Good yields of 1-methylcycloheptene can be obtained by partial hydrogenation[20].

All four isomers of methylcycloheptadiene could be identified quickly and without isolation by using a combination of methylene insertion reactions (statistical weight of the resulting isomers and retention behavior) and a study of the maleic anhydride (MA) adduct of *(25)*. As can be seen from this last example, *seven-membered rings* can be easily prepared using a combination of catalysis and ring-closure isomerization.

3. Mechanism of C—C Bond Formation in Transition Metal Complexes

The following section is devoted to a discussion, in simple, understandable terms, of the similarities shared by the various reactions.

Two review articles[104,105] by *Nyholm* deal, from the standpoint of an inorganic chemist, with the main factors determining the structure and reactivity of a complex. Reviews dealing with individual aspects are also available[6,106-117].

In the following, special attention has been given to the problems associated with symmetry control.

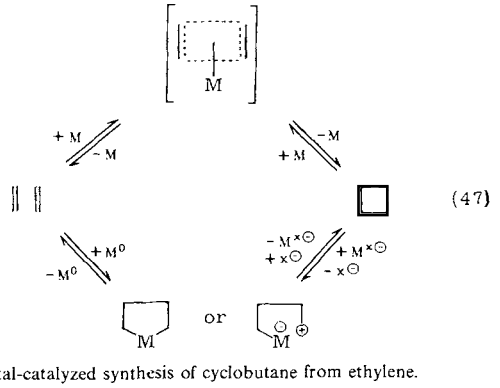
3.1. Symmetry Control in Metal-Catalyzed C—C Bond Formation

The synthesis of four-membered rings (a simple reaction to carry out catalytically) has during the last few years become the topic of a scientific controversy. According to the Woodward-Hoffmann rules[118], [2π-2π]-cycloadditions as a suprafacial process are thermally forbidden but photochemically allowed. According to a hypothesis developed by *Mango* and *Schachtschneider*[119,120] ("forbidden-to-allowed catalysis") these processes become allowed in a metal complex because d orbitals of appropriate symmetry are able to accept and donate electrons. The authors neglect to take into account the following variables which influence the MO scheme and hence the correlation possibilities:

1) the geometry of the transition state,

2) the number of electrons,

3) other ligands on the metal.



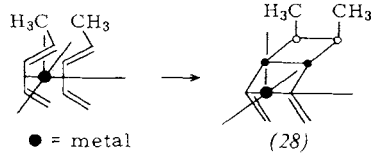
(47)

Fig. 2. Metal-catalyzed synthesis of cyclobutane from ethylene.

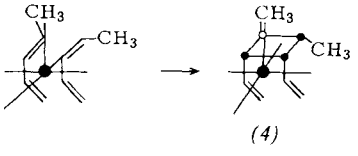
For these reasons the MO scheme must be calculated[121-123] or, where possible, backed by experimental evidence[124,125] (for difficulties see refs. [125–127]).

The approach developed by *Mango* and *Schachtschneider* has been used, in some cases with fundamental alterations, by other authors[128-130]. In Figure 2 we show an alternative mechanism for this reaction which is supported by the experimental results.

The extension of the hypothesis developed by *Mango*[131] for the metal-catalyzed formation of *cis*-1,2-divinylcyclobutane from butadiene to piperylene produces the situation shown in eq. (48) (concerted reaction). However, in contrast, *(28)* is formed by the reaction of one molecule each of *cis*- and *trans*-piperylene and *(4)* is formed from two molecules of *trans*-piperylene. We believe that the reaction pro-



(48)



ceeds in a stepwise manner in which each step, *i.e.*, the cyclization to a metalaring[132] is a concerted process.

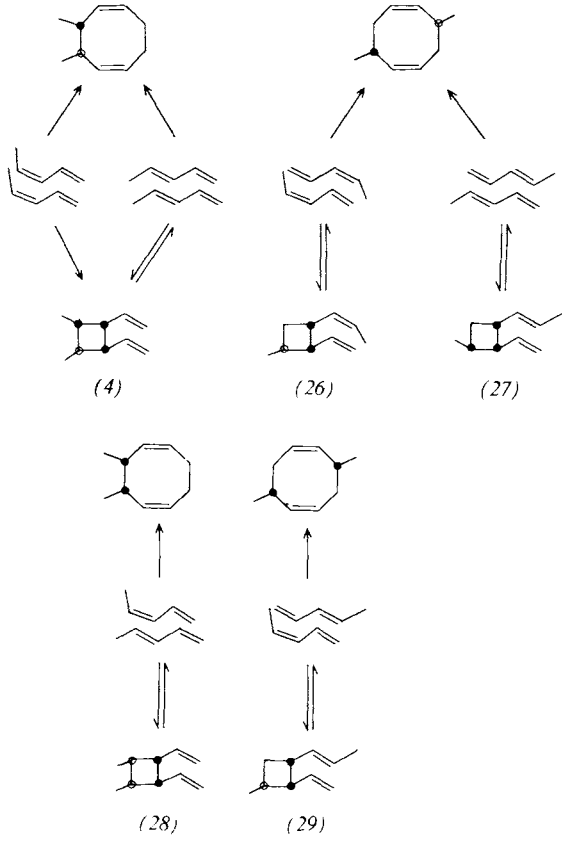


Fig. 3. Formation of four- and eight-membered rings from *cis*- and *trans*-piperylene using a nickel-ligand catalyst[47].

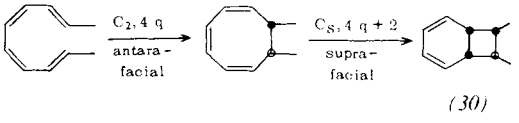
Figure 3 illustrates the stereochemical relationships in the formation of four- and eight-membered rings from two molecules of *cis*- or *trans*- as well as from one molecule each of *cis*- and *trans*-piperylene.

The assignment was initially complicated by an isomerization of *cis*-piperylene to *trans*-piperylene which could occur *via*, for example, the four-membered ring *(4)*[*]. The stereochemical course of reaction can, however, be established with certainty by cleaving the four-membered rings into *cis*- or *trans*-piperylene on a tri(2-biphenylyl)phosphite-nickel catalyst at 50 torr. The 1,3-diene produced (in addition to the eight-membered ring) is immediately removed from the reaction mixture and hence does not isomerize (a reaction which could proceed through the intermediacy of *(4)*).

At a first glance it seems contradictory to propose that the catalytic four-membered ring synthesis proceeds in a stepwise manner and that each step is a concerted symmetry-controlled process. The synthesis of a four-membered ring from *trans,cis,cis,trans*-2,4,6,8-decatetraene described by *Huisgen et al.*[133] can be introduced to illustrate this point [eq. (49)].



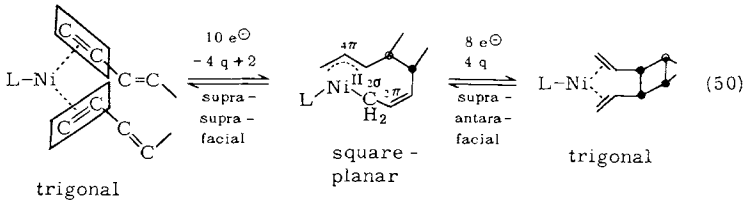
(49)

In analogy to this we suggest that the first step in the formation of *(4)* occurs in a supra-supra-facial manner ($10\,e^- = 4$ electrons from each 1,3-diene + 2 electrons from the metal = (4q + 2) process) and the second in a supra-antara-facial manner ($8\,e^- = 4$ electrons from the π-allyl group + 2 electrons from the Ni—C bond + 2π-electrons from the double bond). The same result would be obtained if an antara-antara-facial step were followed by an antara-supra-facial step. However, in this case the methyl groups in the C_8-chain would occupy axial instead of equatorial positions.

According to this approach the C—C bond formation occurs outside the complex sphere; the necessary redox-process occurring within the complex sphere (concerning "formal redox-processes" see refs. [3, 5]).

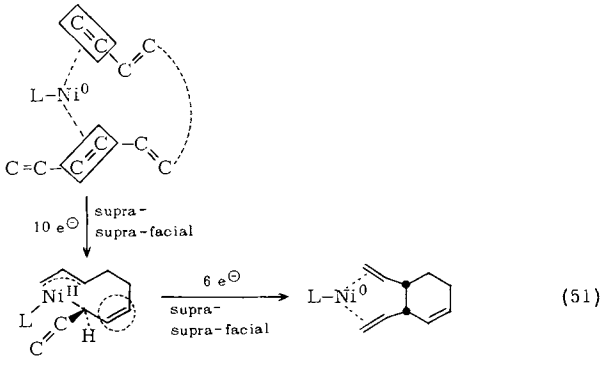
As far as the stereochemistry of *(30)* and *(4)* is concerned, it is of no consequence whether the four-membered ring is formed in a thermal or a catalytic reaction. The two reactions differ in that in the first step of the catalytic C—C bond formation, the metal contributes two electrons to the π-system. In the case of the thermal formation of the four-membered ring, symmetry control is the result of direct conjugation (the two "*trans*-piperylene" moieties are joined by a C—C σ-bond) while in the catalytic reaction, symmetry control is the result of coupling of the piperylene molecules through the metal. Stepwise reaction mechanisms are also proposed for both the rearrangement of the highly strained molecule cubane[134] (see below) as well as for the cyclodimerization of piperylene for which only a small thermodynamic driving force exists.

[*] Isomerization of *cis*- to *trans*-piperylene which occurs during the formation and cleavage of the C_8-chain (which is perhaps faster) is neglected here.



(50)

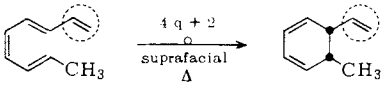
Non-involvement of the circled *cis*-double bond in complex *(31)* [eq. (51)] in the oxidative C—C bond formation[*] (2 electrons less, (4q+2) process) leads to a supra-supra-facial reaction. In agreement with experimental results and the reactions course as suggested by models, *cis*-3,4-divinylcyclohexene is formed from butadiene and *trans*-1,3,5-hexatriene and *trans*-3,4-divinylcyclohexene from butadiene and *cis*-1,3,5-hexatriene (*e.g.* $6e^- = 4$ electrons from the π-allyl group + 2 electrons from the Ni—C bond = (4q+2) process).



(51)

(31)

The additional vinyl group accelerates the reductive C—C bond formation without being directly involved as a π-system in the rearrangement. This should be compared with the thermal ring-closure reaction shown in eq. (52).

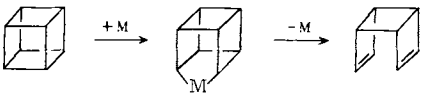


(52)

Symmetry-allowed rearrangement in a ligand system must correspond to symmetry-allowed processes at the metal (see for example ref. [134]).

Finally, we should mention that the correlation found for the initial C—C bond formation during the cyclodimerization of piperylene also applies to dimethyl-substituted *cis,trans*-1,5-cyclodecadiene[80,81] and *cis*-3,4-divinylcyclohexene[51,71].

A stepwise reaction mechanism has also been postulated by other authors. For example, *Cassar*, *Eaton*, and *Halpern*[135] could show that the highly strained molecule cubane reacts in the presence of a rhodium complex to give *syn*-tricyclooctadiene *via* a metalacyclopentane system [eq. (53)].



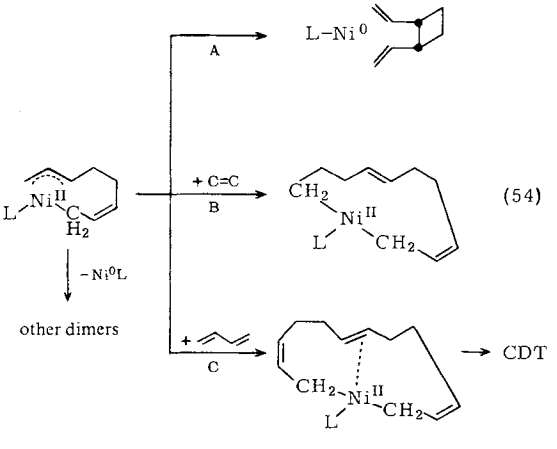
(53)

Recently, it has been possible to show that a metalacyclopentane compound is formed as an intermediate (X-ray results and chemical conversion to a cyclobutane derivative) in the formation of a four-membered ring system from the iridium-catalyzed cyclodimerization of bicycloheptadiene[136]. The proposition that the ring-closure reaction occurs in a stepwise manner does not allow any conclusions to be drawn concerning the implementation of the symmetry rules to metal-catalyzed reactions.

3.2. Further General Considerations

In the preceding section, we have assumed that the stepwise formation of *cis*-1,2-divinylcyclobutane occurs in a redox process involving the central metal atom and the ligands: the first step involves oxidation of the zerovalent metal (reductive C—C bond formation) and the second step reduction of the metal (oxidative C—C bond formation).

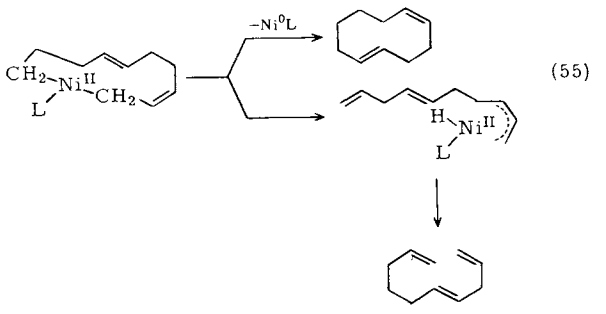
A spontaneous redox process between the metal and the ligands accompanied by an alteration in the arrangement of the ligands has been investigated for cobalt complexes by *Collman et al.*[137] using IR techniques (see also ref. [165]).



(54)

A number of nickel-catalyzed processes are, however, known which lead to C—C or C—H bond formation and which do not involve a change in the oxidation state of the metal, *e.g.* nucleophilic ligand exchange on Ni(II) and electrophilic ligand exchange on Ni(0). These reactions are in competition with each other and which process actually occurs will depend upon the complete ligand field. Particularly interesting are those cases in which only one parameter is altered. Thus, *Tolman*[138] has correlated the electronic effect of phosphanes and phosphites in $LNi(CO)_3$

[*] The terminology reductive or oxidative C—C bond formation as well as nucleophilic or electrophilic ligand exchange used by the author, refer to that bond in the hydrocarbon which is involved in the reaction (see Section 3.2).



(55)

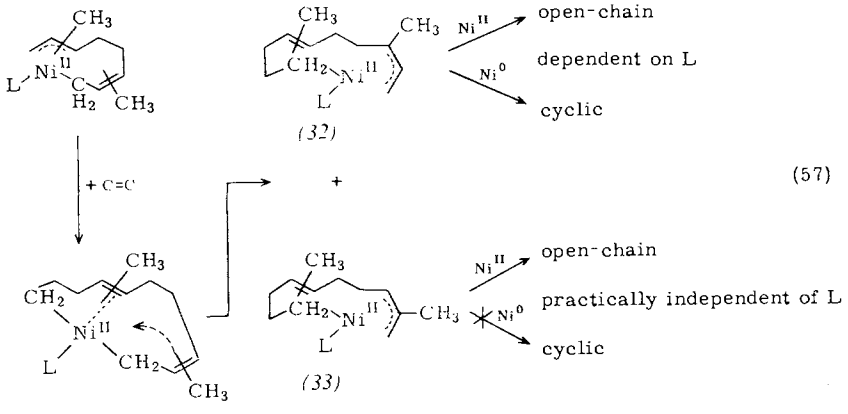
complexes with the $\nu_{CO}(A_1)$ frequency. We shall discuss this electronic effect associated with the ligand using as examples the nickel-catalyzed co-oligomerization of butadiene and ethylene, and also part of the process leading to the co-oligomerization of isoprene with ethylene. The first step here is the formation, from the 1,3-diene, of a C_8-chain bonded to nickel (the ethylene reacts only after oxidation of the metal has occurred) (Fig. 4).

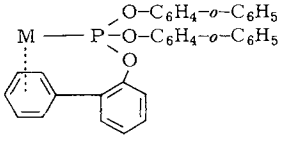
The electronic situation created by the ligands determines whether the simultaneous presence of, for example, ethylene and butadiene cause the next step to be attack of the disubstituted double-bond (reaction A), or the attack of ethylene with nucleophilic ligand exchange (reaction B), or attack by butadiene (reaction C) [eq. (54)]. It can be seen from eq. (55) that the C_{10}-chain which is produced (similar to eq. (54) (reaction B)) either undergoes oxidative C—C bond formation to give *cis,trans*-1,5-cyclodecadiene or nucleophilic exchange followed by oxidative C—H bond formation to give 1,4,9-decatriene.

In the case of tri(2-biphenylyl)phosphite steric effects can also be of importance and hinder both the entry of further ligand molecules and disproportionation of the complex in the sense shown in eq. (56)[139]. In addition a chelate effect (and associated electronic effect) is possible with this ligand.

(56)

The formation of open-chain and/or cyclic dimethyl-C_{10}-compounds during the co-dimerization of isoprene with ethylene is dependent upon the nature of the phosphane or phosphite and/or the position of the methyl-group in the π-allyl system [eq. (57)]. The position of the methyl group in *(33)* favors the Ni(II) configuration to such an extent that open-chain products are formed almost exclusively. On the other hand, in *(32)* the formation of open-chain or cyclic products is a function of the electronic character of the ligand L.





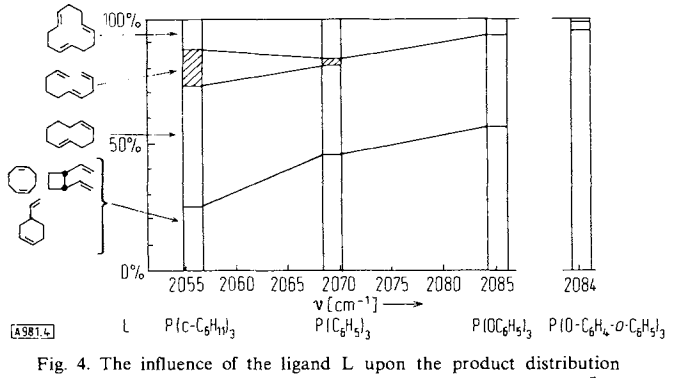


Fig. 4. The influence of the ligand L upon the product distribution in the LNi-catalyzed co-trimerization of butadiene and ethylene [see eq. (54) and (55)]. The $\nu_{CO}(A_1)$ frequency of the $LNi(CO)_3$ complexes has been chosen as a measure of the electronic effect of the ligand (the more C_{10}-compounds produced the greater is the proportion of open-chain C_{10}-compounds [13]). Reaction conditions: 40 °C. Molar ratio butadiene: ethylene = 1 : 1.

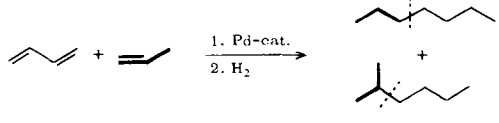
The formation of the *iso*- and *n*-heptane skeleton during the co-dimerization of butadiene with propylene using a phosphane- or phosphite-containing allylpalladium-chloride-AlX_3 catalyst[140], is also dependent upon the nature of the ligands [eq. (58)].



(58)

The effect of the ligand in complex *(32)* can be attributed to a preferred formation of a Ni(0) complex (oxidative C—C bond formation to give cyclic compounds) or a Ni(II) complex (nucleophilic ligand exchange = β-H-elimination in *(32)* followed by oxidative C—H bond formation to give open-chain compounds).

The formation of the iso- or *n*-heptane skeleton can be attributed to a ligand-dependent nucleophilic or electrophilic attack on the complex by the propylene. The HOMO

and LUMO coefficients for propylene, according to a CNDO calculation, have the following values (the square of the coefficients is a measure of the electronic density[*]).

	C-1	C-2	1 2
LUMO	0.68	−0.72	CH=CH—CH_3
HOMO	0.71	0.63	

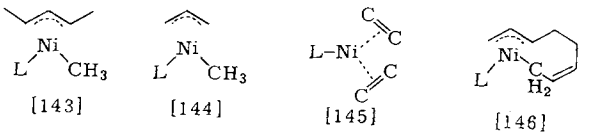
These values make it understandable that C-1 prefers to attack the metal in a nucleophilic and C-2 in an electrophilic manner. This type of argument is based upon the principles of the frontier-orbital theory developed by *Fukui*[141] in which electron-acceptor or -donor interaction occurs preferentially at that position which has the highest value for the square of the coefficient in the HOMO (highest occupied molecular orbital) or the LUMO (lowest unoccupied molecular orbital) (for a review see ref. [142]).

It would probably be worthwhile to attempt to use the frontier-orbital theory to predict the reactivity (initially qualitatively) of olefins in metal-catalyzed processes. Drastic assumptions are necessary and we are at present testing the relevance of the qualitative predictions obtained[20].

4. Prospects

An attempt has been made in this progress report to indicate some common aspects of metal-catalyzed reactions. In particular, we have tried to show that the metal complexes not only act as suitable matrices by causing the reaction to occur in one particular spatial arrangement but can also be profitably regarded as auxiliary substituents which are introduced into the π-system, thereby reinforcing or reversing its electrophilic or nucleophilic character. The metal complex is of particular value, as an auxiliary substituent since changes in the electronic configuration can cause a reversal in behavior during the individual bond-formation steps. The introduction of additional ligands on the metal provides another variable.

Many investigations are necessary in order to obtain an understanding of a catalytic process. For example, a series of reactant-, product-, and intermediate complexes have been isolated and their behavior studied[143–147].

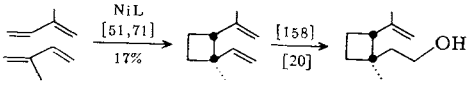


[143] [144] [145] [146]

Kinetic and competition experiments have also been used to investigate, for example, whether an isolated intermediate complex is relevant to the main- or side-path of the reaction or whether a reaction is kinetically or thermodynamically controlled.

An important point has, however, been completely neglected. There is an almost complete absence of thermodynamic data for alkylmetals and allylmetals to mention just two classes of compounds (see for example refs. [106, 148]).

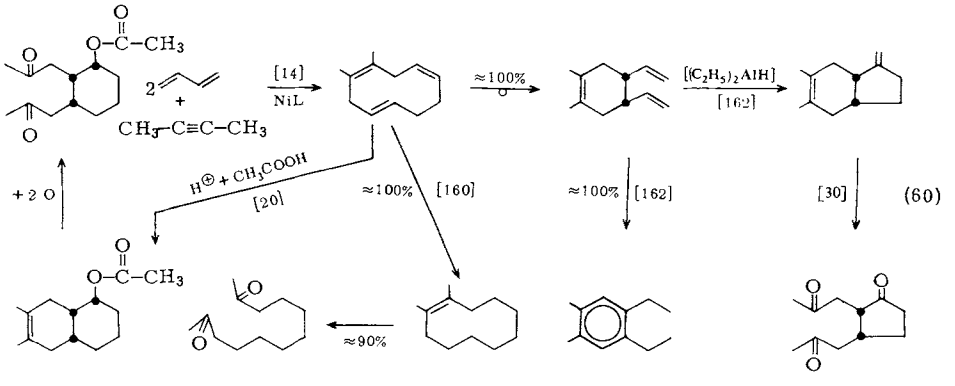
In the past the main interest in metal-catalyzed reactions has centered on petrochemical processes such as the production of aldehydes and alcohols[149,150], acetaldehyde[151], C_{12}-dicarboxylic acids or lactams[152], olefins[153,154], and α-olefins[155–157]. However, we expect that in the future there will be an increase of interest in the preparation of fine chemicals in general—particularly by the perfumery and pharmaceutical industries. Catalysis may also be expected to be used in the partial syntheses of natural products (*e.g.* terpenes from isoprene). An example is the two-step synthesis of the sex attractant of the boll weevil [eq. (59)][158,20]. The first step is metal-catalyzed and the second (addition of >B—H followed by oxidation) is metal-induced.



(59)

A large variety of products will also become available from organic syntheses using catalytically formed compounds as starting materials. This possibility has been thoroughly investigated, for example, in the case of the 4,5-disubstituted-*cis,cis,trans*-cyclodecatriene system [eq. (60)][76,154–162].

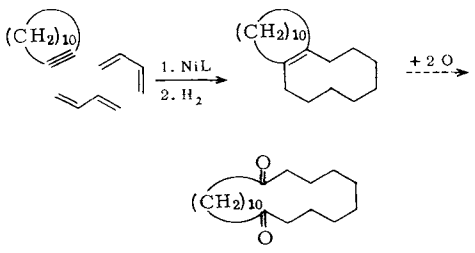
A wide variety of mono- and dialkynes have been reacted in addition to 2-butyne. A ring-expansion sequence has been developed using cyclic alkynes, *e.g.* the expansion



(60)

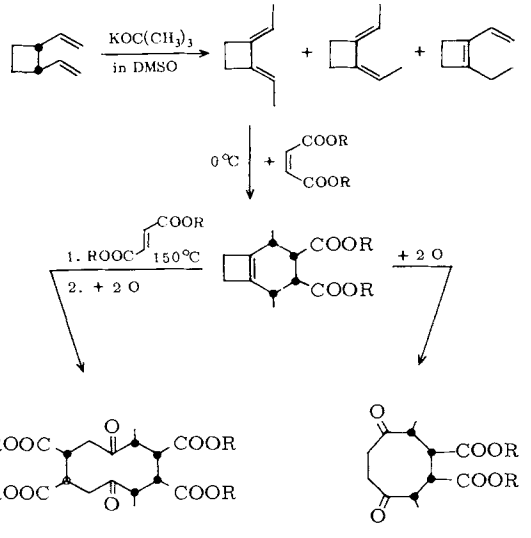
by eight C-atoms shown in eq. (61), by a combination of catalytic and stoichiometric reactions[163].

[*] The calculations were kindly carried out by Dr. *F. Mark*.



(61)

A number of interesting syntheses have likewise been carried out starting from *cis*-1,2-divinylcyclobutane. A few examples are shown in eq. (62)[164].



(62)

I wish to express my thanks, also on behalf of my co-workers, to the Director of the Max-Planck-Institut für Kohlenforschung Prof. Dr. G. Wilke for his support of our work and for many useful suggestions. In particular I gratefully acknowledge continuing financial and academic support even after my acceptance of a position at the Gesamthochschule Essen. I also wish to acknowledge the friendly assistance of Dr. D. Henneberg, Prof. Dr. E. G. Hoffmann, Dr. J. Leittich, Dr. G. Schomburg and their co-workers in the measurement and interpretation of the mass-, IR-, and ^{1}H-NMR-spectra and gaschromatographic analyses. Thanks are also due to Prof. Dr. H. Bock (Frankfurt) and Priv.-Doz. Dr. H. Lehmkuhl for valuable suggestions.

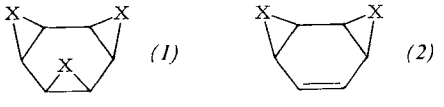
cis-Triazatris-σ-homobenzene (*cis*-"Benzene Triimine")[**]

By *Reinhard Schwesinger* and *Horst Prinzbach*[*].

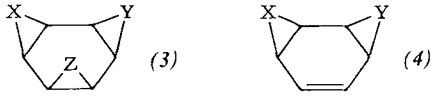
Directed nucleophilic substitutions of *cis*-trioxatris-σ-homobenzene (*cis*-"benzene trioxide")[1a] have given access to a series of potential precursors for the synthesis of aza-, thia- and phospha-analogous compounds *(1)* and the related bishetero-bishomobenzene systems *(2)*[1b].



(1) *(2)*

X = —O—, —NR—, —S—, —PR—, —CR^1R^2—

New possibilities also open up for construction of carbocyclic[2] and mixed *cis*-tris- and *cis*-bis-σ-homobenzene derivatives *(3)*[3] and *(4)*[4]. Here we describe the preparation



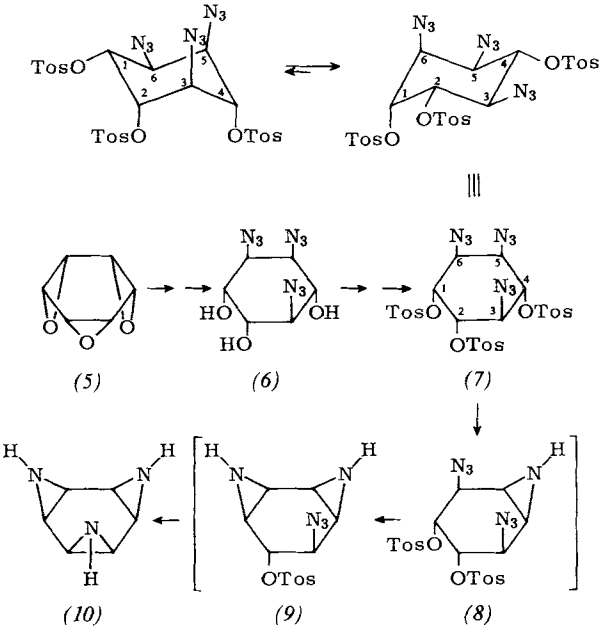
(3) *(4)*

X,Y,Z = —O—, —NR—, —S—, —PR—, —CR^1R^2—

of *cis*-triazatris-σ-homobenzene (*cis*-"benzene triimine"; 3,6,9-triazatetracyclo[6.1.0.$0^{2,4}$.$0^{5,7}$]nonane) *(10)* as the first example of such syntheses starting from *cis*-"benzene trioxide" *(5)*[5].

Reaction of *(5)* with six equivalents of NaN_3 in $MgCl_2$-buffered methanol (65 °C; 48 h) affords crystalline 3,5,6-triazido-1,2,4-cyclohexanetriol *(6)* in 98% yield; tosylation thereof with 4.5 equivalents of *p*-toluenesulfonyl chloride (pyridine, 20 °C, 14 days) gives the triester *(7)* in almost quantitative yield. The *chiro*-inositol configuration is proposed for *(6)* and *(7)* because of the behavior of *(5)* with univalent nucleophiles[1b] and is proved unambiguously by ^{1}H- and ^{13}C-NMR analysis of *(7)*. Here it is noteworthy that once more[1b] all the cyclohexane-protons and -carbon atoms can be assigned on the basis of heteronuclear double resonance experiments (Table 1)[6].

Three-fold reduction and elimination to give *(10)* can be achieved in one operation by known procedures[7] (4.5 mol of $LiAlH_4$, tetrahydrofuran, 20 °C, 10 min). We have not found any indication of formation of isomeric by-products. The specificity of the reaction makes it probable, for steric reasons and as required by our working hypothesis, that the equatorial azide group on C-5 of *(7)* is reduced first and that after inversion the monoaziridine *(8)* is the primary product, although it has not yet been isolated.



(5) *(6)* *(7)* *(10)* *(9)* *(8)*

The geometry and symmetry of *(8)* allow the sole route leading to *(10)* by way of *(9)*[8].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The triimine *(10)* separates from CH_2Cl_2 as colorless crystals [45% yield calculated on *(5)*: not optimized]; it is very readily soluble in water or methanol, less readily in ethanol and sparingly in methylene chloride, chloroform, acetonitrile, acetone or tetrahydrofuran. *(10)* is thermally stable up to *ca.* 150 °C; when heated rapidly to *ca.* 200 °C it explodes.

For the singly *(11)* and doubly *(12)* protonated compounds in aqueous perchloric acid we obtained the pK_a values 6.42 and 2.71 (20 °C), respectively. A pK_a value of *ca.* −1.0 can then be calculated for the trication *(13)* by extrapolation, but the true value is probably lower owing to steric compression of the three inner hydrogen atoms. The $N \cdots H_{inner}$ distance (*ca.* 2.35 Å) and the good agreement of the measured pK_a values for *(11)* and *(12)* with those estimated by means of model compounds make it improbable that the conjugated acid *(11)* profits significantly from a delocalization of the inner proton in the sense of *(11a)*[11].

Comparison with aziridine discloses no unusual features in the UV, ^{1}H- or ^{13}C-NMR or IR data of *(10)* (Table 1), due to the special relative arrangement of the three aziridine rings in the latter; and in this respect trioxa-*(5)* and triaza-σ-trishomobenzene *(10)* behave similarly. This similarity is emphasized by the mass spectra of *(5)* and *(10)* which show much correspondence in their fragmentation pattern and relative intensities (Table 1)[14].

[5] Attempts to obtain derivatives of *(10)* by a method analogous to the synthesis of *cis*-monoazatris-σ-homobenzene from azepines and diazomethane [3] have so far failed (*H. Prinzbach, G. Kaupp, R. Fuchs, M. Joyeux, P. Kitzing*, and *J. Markert*, Chem. Ber., in the press).

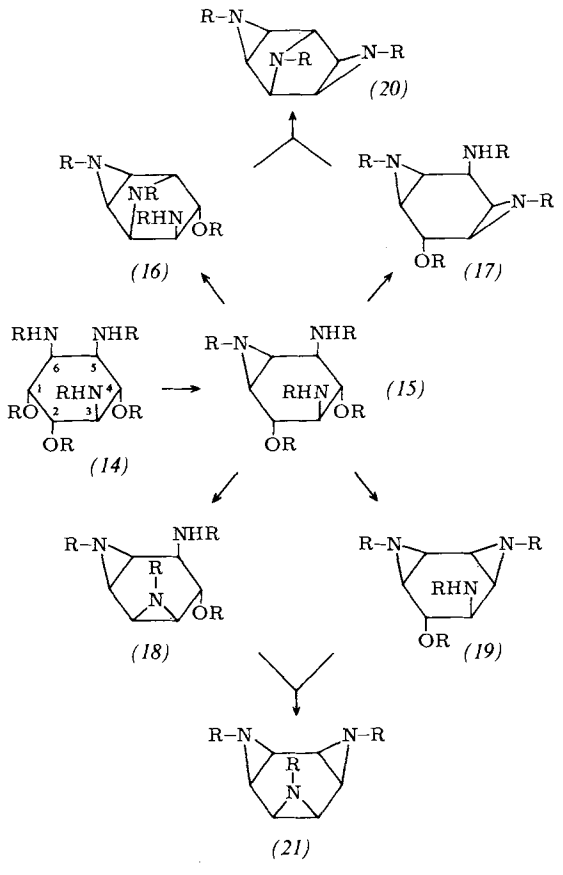
[8] In syntheses involving triamine intermediates of type *(14)* [numbered as *(7)*] corresponding to *(7)*, the first cyclization should preferably involve participation of the *trans*-diaxial substituents on C-1/C-6, yielding *(15)*. However, unlike the situation with *(8)*, the geometric relations



in *(15)* permit four competing partial eliminations, leading to *(16)*—*(19)* and finally to a mixture of *(20)* and *(21)* in proportions that can hardly be estimated in advance. We are in the process of testing this hypothesis experimentally for the case of 3,5,6-tribromo-1,2,4-cyclohexanetriol [9]. That the preparatively accessible, symmetrical 2,4,6-triamino-1,3,5-cyclohexanetriol [1b] [used as tris(hydrogen sulfate)] with the all-equatorial configuration shows little tendency for the formation of aziridines is hardly surprising in view of the extremely unfavorable position of the equilibrium with the all-axial conformer [10].

[11] Piperazine is a good model for the N···N separation in *(10)* (estimated as 2.88 Å). The inductive influence of the nitrogen atom in the β-position on the acidity of the piperazinium monocation can be estimated as 0.9 pK_a unit by comparing the pK_{a1} value (9.83) with the pK_a value (10.73) of the dimethylammonium ion [12]. Starting from $pK_a = 8.0$ [13] for aziridine one thus obtains for *(11)* a pK_a value of $8.0 - 2 \cdot 0.90 = 6.20$. From $pK_{a2} = 5.56$ for the piperazinium dication [12], a value of $pK_a = 6.20 - 4.27 = 1.93$ follows for *(12)*.

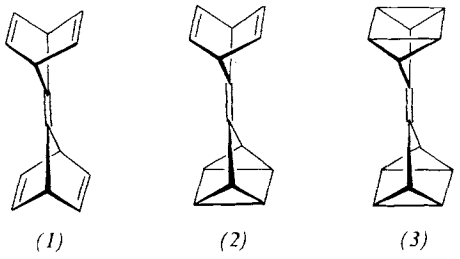
[14] The structural parameters as determined by X-ray analysis of tris-oxa- *(5)* and trisaza-σ-trishomobenzene *(10)* are essentially comparable (*W. Littke* and *U. Drück*, in preparation).

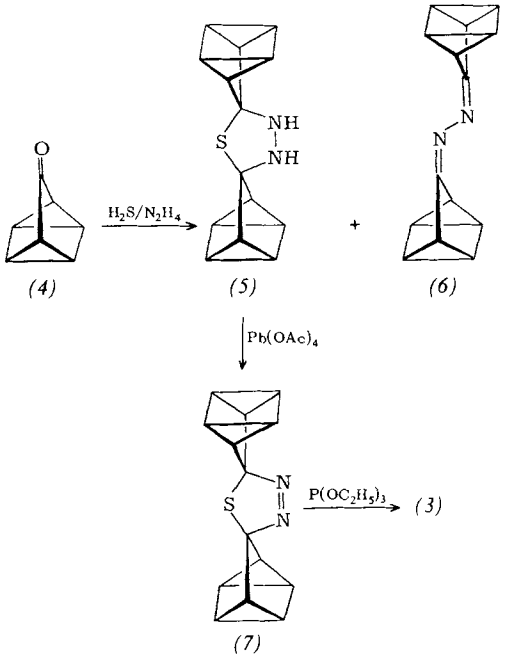
Binorbornadienylidene, Biquadricyclanylidene[1][**]

By *Hubert Sauter, Heinz-Günther Hörster*, and *Horst Prinzbach*[*]

Binorbornadienylidene *(1)*, norbornadienylidenequadricyclane *(2)*, and biquadricyclanylidene *(3)* warrant inter-



est, *inter alia*, as potential intermediates for the synthesis of cyclic cross-conjugated π systems[2,3] and of new polycycles[4].



Starting from quadricyclanone *(4)*[5] we have synthesized *(3)* by the thiadiazolidine method[6,7]. The reaction of H_2S-saturated DMSO solutions of *(4)* with aqueous hydrazine at 0°C leads to about 80% yields of mixtures of *(5)* and *(6)* in a ratio of 6:4. Without separation of the components *(5)* is dehydrogenated to the thiadiazoline *(7)* by lead tetraacetate (CH_2Cl_2; 0°C). After subsequent treatment with triethyl phosphite (80°C), preparative layer chromatography (silica gel, pentane) affords about 20% of *(3)* [based on *(4)*] as colorless readily sublimable prisms.

In the presence of catalytic amounts of palladium(II) chloride norbornadiene complex[8], *(3)* isomerizes in solution

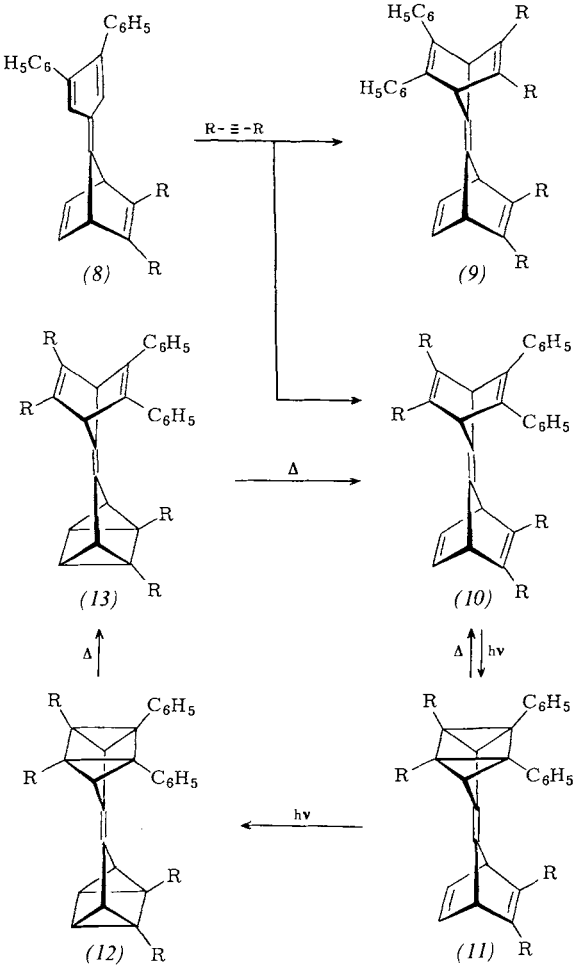
(CH_2Cl_2) to crystalline binorbornadienylidene *(1)*; ^{1}H-NMR measurements show the conversion to proceed *via (2)*.

(9a), *(9b)*, *(10a)*, *(10b)*, stable derivatives of *(1)*, were obtained by reaction of *(8a)*[3] with dimethyl acetylenedicarboxylate [20°C; *(9a)*:*(10a)* ≈ 1:3 78%] and of *(8b)*[9] with hexafluoro-2-butyne [bomb tube, 20°C; *(9b)*:*(10b)* ≈ 1:1; 90%][10] (isomers separated by preparative layer chromatography).

Direct excitation of *(10a)* with light of wavelength $\lambda > 370$ nm effects selective [2π+2π]cycloaddition in the fourfold substituted norbornadiene partial structure to give *(11a)* (100 mg in 650 ml of CH_2Cl_2; 0 °C; 20 min; Hanovia 450 W Hg high pressure lamp; filter: Pyrex and a 1.4% solution of phenanthrene in CH_2Cl_2). In the case of *(10b)*, irradiation with light of wavelength $\lambda > 280$ nm (150 mg in 300 ml of ether, 0 °C; 2 h; Hanau Q 81 Hg high pressure lamp; pyrex filter) preferentially generates *(11b)* in addition to a little *(12b)*.

Expectedly, *(11a)* is thermally reisomerized readily (60 °C)[11], and *(11b)* less readily (130 °C)[12], to *(10a)* and *(10b)* respectively.



(a), R = CO_2CH_3; *(b)*, R = CF_3

The conversion *(11a)*→*(12a)*, necessarily with light of shorter wavelength ($\lambda > 280$ nm; Hanau Q 81 lamp, Pyrex filter) takes a nonuniform course. *(12a)* can be isolated in 50—60% yield alongside several minor products, some of which are colored. The same result is obtained when *(12a)* is prepared by direct photolysis of *(10a)* (Pyrex filter). Owing to short-wavelength absorption by *(11b)*—direct irradiation (CH_3CN, Vycor filter) leads mainly to polymeric products—*(12b)* is prepared by acetone-sensitized excitation from *(11b)* or directly from *(10b)*.

The ease with which *(12a)* (60 °C) and *(12b)* (130 °C) undergo 2σ→2π cleavage to *(13a)* and *(13b)*, respectively, again differs. At 140 °C *(13a)* affords *(10a)* in about 10% yield.

The structures of all new compounds are confirmed by elemental analysis, by their spectral data (Table 1), and by their mutual interconversions. Assignment of the isomeric pairs *(9a)/(10a)* and *(9b)/(10b)*, and hence the *anti* position of the four R groups in the subsequent products, it is not unequivocal.

Chemistry of *cis*-Trioxatris-σ-homobenzene. Substitutions by Univalent Nucleophiles[**]

By *Reinhard Schwesinger, Hans Fritz*, and *Horst Prinzbach*[*]

Previous studies of the chemistry of *cis*-trioxatris-σ-homobenzene ("*cis*-benzene trioxide") *(1)* concerned, mainly the $3\sigma \rightarrow 3\pi$ fission to trioxacyclononatriene[1] and the properties as "crown ether"[1a]; preparative applications by substitutions with nucleophiles (Nu) could also be foreseen[1a]. In this connection our interest became directed to the cyclitols *(6)* and/or *(7)* to be expected as a result of three-fold epoxide ring cleavage[2]. We report here typical reactions of *(1)* with univalent N-, S-, O- and C-nucleophiles[3].

[*] Prof. Dr. H. Prinzbach and Dipl.-Chem. R. Schwesinger
Lehrstuhl für Organische Chemie der Universität
78 Freiburg, Albertstrasse 21 (Germany)
Dr. H. Fritz
Ciba-Geigy AG, Basel (Switzerland)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Reaction of *(1)* with an excess of anhydrous methylamine (autoclave, 2h at 20 °C, 1h at 50 °C and 120 °C) affords the 3,5,6-tris(methylamino)-1,2,4-cyclohexanetriol *(6a)*, isolated as the trihydrochloride *(6b)* in 60% yield and liberated by means of an anion exchanger. Proof of the substitution pattern [to be compared with those in *(7a)*] and in particular the e,e,e,e,a,a-conformations of *(6a)* and *(6b)* follow from the numbers and coupling patterns of the ^{1}H-NMR signals obtained for the six ring protons and the methyl protons and also from the ^{13}C-NMR data.

	(a)	(b)	(c)	(d)	(e)	(f)
Nu	$NHCH_3$	$\overset{\oplus}{N}H_2CH_3Cl^{\ominus}$	N_3	$SCH_2C_6H_5$	OH	Br

The behavior of *(1)* with sodium azide is analogous; the triazide *(6c)* is obtained in almost quantitative yield and can be converted into *cis*-triazatris-σ-homobenzene ("*cis*-benzene triimine")[2].

As our first S-nucleophile we used benzyl thiol[4]. With a *ca.* 1.5-fold excess of the thiol (methanol/sodium methoxide, 12 h, 60 °C) we could isolate only 3,5,6-tris(benzylthio)-1,2,4-cyclohexanetriol *(6d)*, which also was proved to have the e,e,e,e,a,a-conformation by the H,H coupling constants. The ^{13}C signals could be assigned to the six cyclohexane carbons atoms by selective heteronuclear decoupling experiments; the resulting order of the chemical shifts of the ^{13}C(OH) nuclei corresponded to those of *chiro*-inositol[5].

Our first hydrolysis experiments with *(1)* were carried out with 2% aqueous perchloric acid. After *ca.* 24 hours' storage at 20 °C and subsequent heating at 70 °C (1 h), NMR control indicated an epoxide-free product, from which crystallization afforded pure inositol in more than 90% yield; on comparison with data in the literature (m. p. IR)[6], this product proved to be *chiro*-inositol *(6e)*.

The fact that the symmetrical substitution pattern *(7)* was not found in any of these substitutions indicates that the

second substitution of *(2)* does not lead to *(5)* but provides substituents Nu at position 4 or 2, giving *(3)* or *(4)*, respectively. However, at least partial reaction by way of *(5)* cannot be excluded, for it must be remembered that acid hydrolysis of, *e.g.*, the epoxide *(5e)* from conduritol B affords mainly *chiro*-inositol *(6e)* by way of the e,e,e,e-conformation and only a little *scyllo*-inositol *(7e)* by way of the a,a,a,a-conformation[7].

To date we have examined two nucleophilic substitutions of *(2)*. The diazide and the dibromide[8] resulting from the 1,2-attack have structures *(4c)* and *(4f)* respectively.

Structure *(4c)* was differentiated from *(3c)* by proton double resonance experiments at 270 MHz which showed that each H—C(OH) proton is flanked by one oxirane and one H—C(N_3) proton. It remains, however, to be clarified to what extent this 1,2-attack on *(2)*, which is undoubtedly surprising on steric grounds, is favored also by other nucleophiles. Since the third substitution step *(4)*→*(6)* is distinctly slower than the steps *(1)*→*(2)* and *(2)*→*(4)*, isolation of the two-fold substituted product *(4)* presents no problem, and there appear to be attractive prospects for synthesis of mixed three-fold substituted 1,2,4-cyclohexanetriols. Correct elemental analyses are available for all the compounds prepared, and ^{1}H- and ^{13}C-NMR spectra for *(4c)*, *(6a)*, *(6b)*, and *(6d)*.

[8] Obtained together with 3,5,6-tribromo-1,2,4-cyclohexanetriol by the action of HBr/KBr/H_2O on *(1)*. The monosubstitution product *(2)* (Nu=CF_3CO_2) was also found after reaction of *(1)* with CF_3CO_2H. This product was originally but erroneously considered to be 1,4-dioxocin-6-ol [1a] (*L. Knothe* and *H. Prinzbach*, unpublished work).

Chemistry of *cis*-Trioxatris-σ-homobenzene. Substitutions by Bivalent Nucleophiles[**]

By *Reinhard Schwesinger*, *Hans Fritz*, and *Horst Prinzbach*[*]

According to previous experience, three-fold substitutions of *cis*-trioxatris-σ-homobenzene ("*cis*-benzene trioxide") *(1)* by univalent N-, S- and O-nucleophiles lead preferentially, if not exclusively, to unsymmetrical 3,5,6-substituted 1,2,4-cyclohexanetriols[1]. By using bi- or poly-functional nucleophiles it should be possible to attain other substitution patterns through intramolecular two-fold substitution.

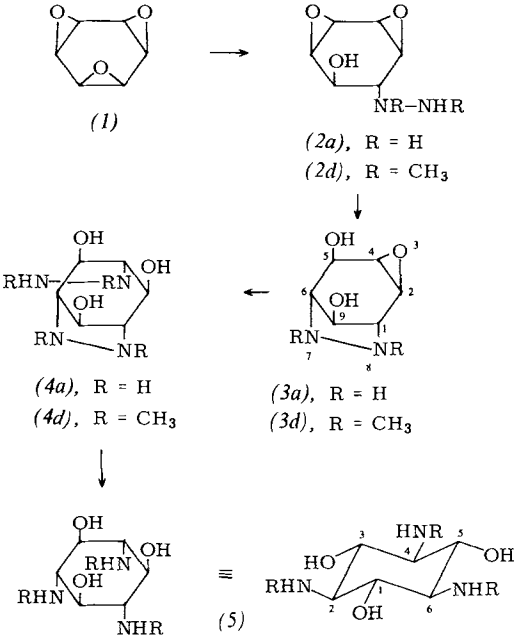
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The symmetrical 2,4,6-triamino-substituted cyclitols *(5)*, originally desired for synthesis of *cis*-triazatris-σ-homobenzene[2], can indeed be obtained by treatment of the trioxide *(1)* with hydrazines. For example, reaction of *(1)* with an excess of anhydrous hydrazine and subsequent hydrogenation over Raney nickel, without isolation of the probable intermediates *(2a)*—*(4a)*, afford 2,4,6-triamino-1,3,5-cyclohexanetriol *(5a)* in 85% yield[3]. The all-equatorial arrangement of the six substituents (*scyllo*-inositol structure) follows from the 270 MHz ^{1}H-NMR spectrum, which shows two triplet signals of equal intensity with $J \approx 10$ Hz for the six ring protons. Correspondingly the ^{13}C-NMR spectrum consists of only two signals. The shifts of the H—C(NMR) signals on three-fold protonation to give *(5b)* or acetylation to give *(5c)* are of the usual magnitude. As judged by the selectivity of the reaction *(1a)*→*(5a)*, the reaction, here intramolecular, that follows the stage *(2a)*, clearly occurs preferentially at the 1,3-positions with formation of *(3a)*; *(3a)*, however, can have only the a,a,a,a-conformation that is required for formation of *(4a)* and *(5a)*[3].

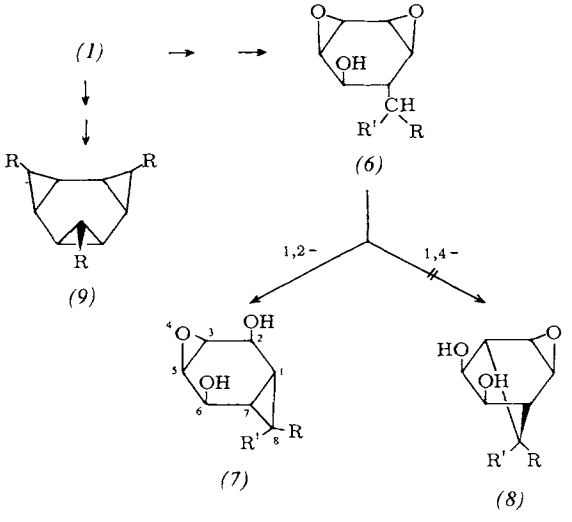
Compounds *(3a)* and thus *(4a)* are experimentally proved to be precursors of *(5a)* by the results of the reaction with *N*,*N'*-dimethylhydrazine. A crystalline 1:1 adduct is obtained (although so far only in the moderate yields of 20—30%) for which ^{1}H-NMR spectra indicate structure *(3d)* with good certainty. We are studying compounds of types *(3)* and *(4)* with a view to using them for preparation of streptamine or similar products[4].



(5)	(a)	(b)	(c)	(d)
R	H	$H_2^{\oplus}$	$COCH_3$	CH_3

Analogously to "*cis*-benzene triamine"[2], carbocyclic *cis*-tris-σ-homobenzene compounds *(9)* should be accessible from *(1)* by three-fold "reversal" of the epoxide ring by means of C-nucleophiles. Because of the known ready σ→π cleavage of *(9)* we sought derivatives containing π-acceptor groups, whose stabilizing effect on the σ-structures has been repeatedly demonstrated[5]. *(1)* (1.2 mol) reacts quantitatively with methyl cyanoacetate (catalytic

amounts of sodium methoxide, 24 h, 20 °C). However, according to its ^{1}H- and ^{13}C-NMR spectra the product, of composition $C_{10}H_{11}NO_5$, is not *(6a)* but methyl 8-cyano-2,6-dihydroxy-4-oxatricyclo[5.1.0.0^{3,5}]octane-8-carboxylate *(7a)*. This arises by intramolecular substitution at the 1,2-positions of the carbanion formed from *(6a)*. The ^{1}H- and ^{13}C-NMR data cannot be brought into accord with the alternative *(8a)* resulting from 1,4-substitution of *(6a)* and also characterized by a symmetry plane; *inter alia*, the occurrence of a cyclopropane ring is proved by the signals of protons 1-H, 7-H ($\tau = 7.95$) and their large ^{13}C—H coupling (> 150 Hz). The stereochemistry at C-8 is uncertain, although *endo*-arrangement of the cyano group is probable. The neighboring group effect in *(6a)*, which is unfavorable for formation of *(9)* and has often been observed in inositol and sugar chemistry[6], also determines the result of reaction with maleodinitrile in methanol: This affords the analogous imidic ester *(7b)* in *ca.* 70% yield, and *(7b)* is converted into the cyano ester *(7a)* when heated in very dilute acetic acid.



(a), R = CO_2CH_3, R' = CN
(b), R = $C(OCH_3)$=NH, R' = CN

We are currently investigating to what extent univalent [*e. g.* CN^-, $C(CO_2R)_3^-$] and α,γ-bivalent carbanions [*e. g.* from $CO(CH_2CO_2R)_2$, $P(CH_2CO_2R)_3$] can be applied for synthesis of, respectively, unbridged[7] and bridged[8] derivatives of *(9)*[9].

Correct elemental analyses are available for all the new compounds except *(5b)*, also ^{1}H-NMR spectra for *(3d)*, *(5b)* and *(7b)*, and both ^{1}H- and ^{13}C-NMR spectra for *(5a)*, *(5c)* and *(7a)*.

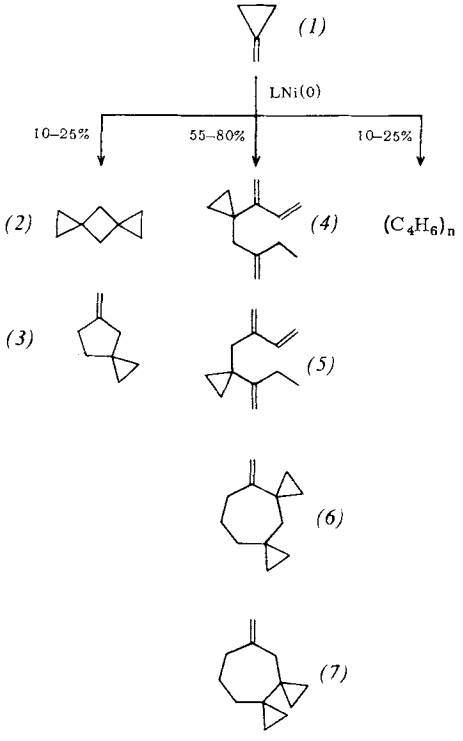
Trimerization of Methylenecyclopropane on Triorganophosphane-Modified Nickel(0) Catalysts

By *Paul Binger* and *John McMeeking*[*]

In Memory of Karl Ziegler

Methylenecyclopropane *(1)* can be converted into the cyclodimers *(2)* and *(3)* on nickel(0) catalysts[1] and particularly well on such catalysts if modified by fumaric or maleic esters[2]. We have now found that, on triorganophosphane-modified nickel(0) compounds, *(1)* affords trimer mixtures in up to 80% total yield. The mixture consists mainly of the trienes *(4)* and *(5)*, together with the dispiromonoenes *(6)* and *(7)* containing a seven-membered ring. These products are always accompanied by 10—25% of dimers and undistillable higher oligomers (see Table 1).



The trimers *(4)*—*(6)* are very probably formed *via* the same intermediates as the dimers *(2)* and *(3)*[1], with subsequent addition of a Ni—C linkage to the C=C bond of *(1)*.

[*] Dr. P. Binger and Dr. J. McMeeking
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

The catalysts are prepared from $Ni(COD)_2$[3] and phosphane in the molar ratio 1:1. *Ca.* 1 mol of *(1)* can be converted by 1 mmol of the Ni catalyst. Apparently the C—C bond formation occurs on a LNi(0) species, since an excess of the phosphane does not influence the course of reaction. Accordingly, *(1)* is oligomerized only slowly, incompletely, and less specifically on $L_2Ni(0)$ compounds (L_2 = tetraphenyl- or tetracyclohexyl-ethylenebisphosphane) even at 50—60 °C. Triaryl phosphite-Ni(0) complexes are catalytically inactive towards *(1)* under comparable conditions; they probably form stable ligand-nickel(0)-olefin complexes in a stoichiometric reaction[4].

Table 1. Oligomerization [a] of methylenecyclopropane *(1)* on phosphane-modified nickel(0) catalysts prepared from equimolar amounts of $Ni(COD)_2$ and a phosphane PR_3.

PR_3	Dimers (C_8H_{12}) [b] yield [%]	*(2)* : *(3)* : rest [d]	Trimers ($C_{12}H_{18}$) [b] yield [%]	*(4)*	*(5)* : *(6)* : *(7)* : rest [d]	Higher oligomers [c] yield [%]

[a] At 25—60 °C with >90% conversion of *(1)*.
[b] The isomer proportions were determined by gas chromatography.
[c] Undistillable in a high vacuum.
[d] Numerous hydrocarbons each <1%.
[e] As well as *(4)* an unidentified compound appeared with almost the same retention time [6].
[f] Contain 15% of a compound with the same retention time as dispiro[2.0.2.2]octane [5].

The influence of the phosphane substituents on the course of the reaction and the composition of the products is shown in Table 1. The structures of the new $C_{12}H_{18}$ compounds were determined by means of their IR, MS, and particularly their ^{1}H-NMR spectra.

Trimerization of methylenecyclopropane (1)

(1) (40 g, 0.74 mol) was added dropwise to a yellow catalyst solution, prepared from $Ni(COD)_2$ (0.57 g, 2.1 mmol) and *tert*-butyldiisopropylphosphane (0.5 g, 2.7 mmol) in benzene (20 ml) over 2 h at room temperature. The red solution rapidly warmed to 50 °C (max.; occasional water-bath cooling). Reaction was complete after 6 h at 30—50 °C. Subsequent distillation gave, besides a residue (3.3 g), a colorless distillate (51.8 g) of b.p. 0—52 °C/0.5 torr, shown by gas chromatography to have the composition: *(1)* 1.6%, benzene 36.7%, *(2)* 0.4%, *(3)* 5.4%, 1,4-COD 1.4%, 1,5-COD 0.9%, *(4)* and unidentified compound[6] 4.2% and 5.8%, *(5)* 4.3%, *(6)* 30.1%, *(7)* 4.9%, rest 4.3%, 11 peaks <1%. Fractional distillation through a 1.5-m spinning-band column afforded *(6)* (10.3 g: 74.8% pure by gas chromatography) of b.p. 88—92 °C/12 torr, which contained 13.6% of *(7)* as impurity; the rest was shown by gas chromatography to contain *(4)* 1.2%, unidentified compound[6] 2.2%, *(5)* 3.5%, inidentified compound 2.4%, and a residue 1.9%, *ca.* 8 peaks <1%.

Preparation of 4,6-Dioxa-1-azabicyclo[3.3.0]-octanes from Iminodiethanols and Nitriles

By *Klaus Burzin* and *Roland Feinauer*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

Alkyl-substituted bicyclic amide acetals of type *(3)* (R^1 or R^3 = H) have only recently become available, namely by cycloaddition of epoxides to Δ^2-1,3-oxazolines[1-3].

The amide acetals *(3)* studied so far (R^1 or R^3 = H) have proved very reactive compounds by whose reactions with carboxylic acids, phenols, amines, aldehydes and alkylating agents numerous new classes of compounds have become accessible[3].

Within the framework of studies of the preparation of Δ^2-1,3-oxazolines from amino alcohols and nitriles[4] we have now found a simpler route for synthesis of alkyl-substituted 4,6-dioxa-1-azabicyclo[3.3.0]octanes *(3)*, namely by treatment of iminodiethanols *(1)* with aliphatic nitriles *(2)* in the presence of catalytic amounts of the sodium alcoholate derived from the iminodiethanol reactant. In this way the trisubstituted derivatives *(3i)*—*(3l)* also become available in a single-stage process that avoids the need for preparation (often experimentally difficult) of Δ^2-1,3-oxazolines from the cheap components *(1)* and *(2)*.

The structures of the compounds *(3)* are proved by IR, ^{1}H-NMR and ^{13}C-NMR spectra as well as by elemental analyses. For *(3a)*, *(3b)*, *(3e)* and *(3f)* it was shown that their physical properties accord with those of material prepared by other routes[1].

From the NMR spectra it is clear that the compounds *(3e)*—*(3l)* are diastereoisomeric mixtures; their separation has not yet been attempted.

π-Bonded Nitrogen in a Crystalline Nickel-Lithium Complex

By *Klaus Jonas*[*]

In Memory of Karl Ziegler

A few years ago we reported on the first dinitrogen-nickel(0) complex $[(C_6H_{11})_3P]_2NiN_2Ni[P(C_6H_{11})_3]_2$[1] in which two nickel atoms are bonded end-on to the two nitrogen atoms[2]. This kind of bonding (M–N≡N or M–N≡N–M) has been foun in all dinitrogen transition metal complexes so far discovered and subjected to X-ray analysis. Such bonding is also in accord with theoretical considerations and calculations[3] which predict complexes having π-bonded (edge-on) N_2 to be less stable than those with end-on bonded nitrogen.

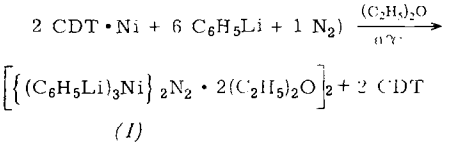
In 1970 *Armor* and *Taube* first reported π-bonded dinitrogen in a ruthenium complex[4]: they postulated the occurrence of

as transition state in the intramolecular $^{14}N—^{15}N$ exchange

$[(H_3N)_5Ru\cdot{}^{14}N^{15}N]^{2+} \rightleftharpoons [(H_3N)_5Ru\cdot{}^{15}N^{14}N]^{2+}$.

Evidence constituting a direct proof of π-bonded dinitrogen, albeit at very low temperature (10 K), has recently been obtained by *Ozin* and *Vander Voet*[5] from IR studies in a cobalt matrix. The present communication describes a crystalline nickel-lithium complex having molecular nitrogen unequivocally π-bonded to the transition metal which is stable at room temperature.

Studies on the action of nickel(0) complexes on organometallic compounds of Group IB to IIIB elements[6] have revealed, *inter alia*, that reaction of all-*trans*-1,5,9-cyclododecatrienenickel(0)[7] with phenyllithium in the presence of molecular nitrogen leads to a complex *(1)* which is stable at room temperature:



(1)

Volumetric determinations show that 1 N_2/2 Ni is consumed during formation of complex *(1)*. Its stoichiometric composition follows from the Ni content and from the reaction of *(1)* with ethanol, during which Ni is precipitated quantitatively as the metal. The filtrate is shown by GC to contain a quantity of diethyl ether corresponding to formula *(1)* and an alkalinity determination reveals $3\,C_6H_5Li$/Ni.

The nitrogen *(1)* can be partly or completely displaced by 1,5-cyclooctadiene or $(C_6H_5)_2P(CH_2)_2P(C_6H_5)_2$/$B(C_6H_5)_3$ [$LiB(C_6H_5)_4$ only being formed in 30% yield]. The reaction of *(1)* with ethylene is particularly characteristic since the nitrogen is then liberated quantitatively.

Apart from the characteristic frequencies of the phenyl groups and ether, the IR spectrum of complex *(1)* contains no other bands that can be assigned to vibrations of the N_2 system. Possibly the NN vibration, if it is at all IR active, may be shifted to such long wavelengths (<1550 cm^{-1}) that it is obscured by other bands.

X-ray analysis[8] shows *(1)* to be dimeric ($n=2$) and the complex to contain Ni—Ni bonds to which the two π-bonded N_2 molecules are oriented at right angles. The N—N bond is extremely long (1.35 Å). This may be

[*] Dr. K. Jonas
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

due to a cooperative effect since N_2—Ni_2 π-bonding seems to be accompanied by an interaction between the lithium atoms and the end-on positions of the nitrogen. A cooperative effect of this kind, *i.e.* a joint action of several metal atoms (Fe and Mo) on N_2, is also suspected in enzymatic nitrogen fixation.

The ability of ethylene to smoothly displace the clearly strongly activated (N—N: 1.35 Å) nitrogen is truly remarkable. This reaction presumably also involves liberation of phenyllithium as well as N_2 to form a novel bimetal-olefin complex *(2)*, which can be prepared independently from phenyllithium, CDT·Ni, and ethylene.

$$2\ C_6H_5Li + CDT \cdot Ni + C_2H_4 \xrightarrow{(C_2H_5)_2O}$$

$$(C_6H_5Li)_2NiC_2H_4 \cdot (C_2H_5)_2O + CDT$$

(2)

The ^{1}H-NMR spectrum of *(2)* in [D_8]tetrahydrofuran shows a singlet at $\tau = 9.87$ for the ethylene protons. The extremely pronounced shielding of the protons attached to the complexed double bond compared to that in phosphane-olefin- and pure olefin-nickel(0) complexes, suggests an enhanced electron density on ethylene in *(2)*. This probably also applies to the dinitrogen complex *(1)* and is manifested in the extreme elongation of the N—N bond.

The systems CH_3Li/CDT·Ni and C_6H_5Li/C_6H_5Na/CDT·Ni also bind molecular nitrogen in the ratio $Ni:N_2 = 2:1$. Studies are in progress to establish whether the nitrogen in the above systems can be induced to react stoichiometrically or even catalytically.

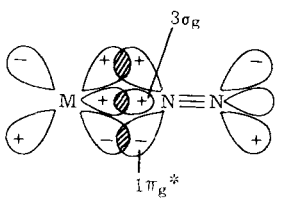
Molecular Structure of a π-Dinitrogen-Nickel-Lithium Complex

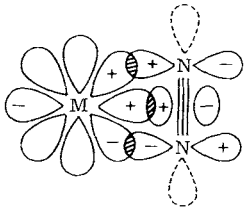
By *Carl Krüger* and *Yi-Hung Tsay*[*]

In Memory of Karl Ziegler

Structural analyses of dinitrogen complexes of numerous transition metals[1] have so far always indicated a linear M—N≡N arrangement *(1)*. We recently reported the structure of such a system having nickel as central atom[2]. The fixation of the N_2 ligand in compounds of this type is accomplished by a σ bond between the $3\sigma_g$ orbital of the nitrogen and hybrid orbitals of the metal and by back bonding from the metal to the vacant $1\pi_g^*$ orbital of the nitrogen (see *(1)*)[3].



(1)



(2)

A bonding involvement of the nitrogen lone pair should permit formation of olefin-like π complexes[4] such as are assumed in the reaction sequence of natural nitrogen fixation. X-ray structure analysis of the novel complex $[(C_6H_5Li)_6Ni_2N_2\{(C_2H_5)_2O\}_2]_2$[5] shows that the N_2 ligand does indeed possess an arrangement like that in *(2)*.

The complex forms dark red crystals from diethyl ether (unit cell: $a = 14.591(3)$, $b = 25.503(3)$, $c = 14.126(4)$ Å; $\beta = 113.32(2)°$; $P2_1/a$; $Z = 2$). The heavy atom skeleton was determined by direct methods from 4915 measured uncorrected structure amplitudes ($I_0 > 2\sigma(I_0)$; $\lambda = 1.5418$)[6], and the arrangement of the rest of the molecule could be deduced from repeated Fourier syntheses. Anisotropic refinement has so far led to an *R* value of 9.3. The geometry of the centrosymmetric dimeric molecule is shown in Figure 1; Figure 2 depicts the internal skeleton of the strongly polar complex (Ni, N, and Li atoms).

A considerably elongated Ni—Ni linkage (2.687 Å)[7] is bridged by a nitrogen molecule almost at right angles with respect to the N—N bond. The two independent Ni atoms display a strongly distorted trigonal pyramidal geometry. The trigonal planes contain two phenyl carbon atoms and the N_2 molecule and the apices are occupied by a Ni atom and a Li atom.

The two nitrogen molecules are linked *via* two Li atoms to form a centrosymmetric six-membered ring $(—Li6—N1—N2—)_2$ (see Fig. 2), and the two halves of the molecules are additionally linked *via* a bridge Li2—A—Li5. Whereas the N2 atom is bonded end-on to a Li atom (Li1), the N1 atom is bonded to three Li atoms (Li3, Li5, Li6) to form a tetrahedron. This grouping can be derived from the skeleton of $[LiCH_3]_4$[8] and analogous compounds[9] by replacing one Li atom by nitrogen and assuming the formation of a two-electron four-center bond between N1 and Li3—Li5—Li6. The Li—Li distances found correspond to those in $[LiCH_3]_4$. A further coordination site of this system is occupied by a phenyl ring (Fig. 1, B), leading approximately to a trigonal-bipyramid with Li3—Li5—Li6 as base. Li3 and Li4 additionally bridge the Ni—Ni bond, whereas Li2 and Li4 are only bonded to one Ni atom each. The compound contains two σ-bonded phenyl groups per nickel atom (C, D, E, F; Ni—C: 1.96 Å, C—Ni—C: 102 and 104°), C and D undergoing additional bonding *via* Li4 (I). The phenyl rings A and B are not bonded to nickel but only to lithium.

[*] Dr. C. Krüger and Dr. Y.-H. Tsay
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Lembkestrasse 5(Germany)

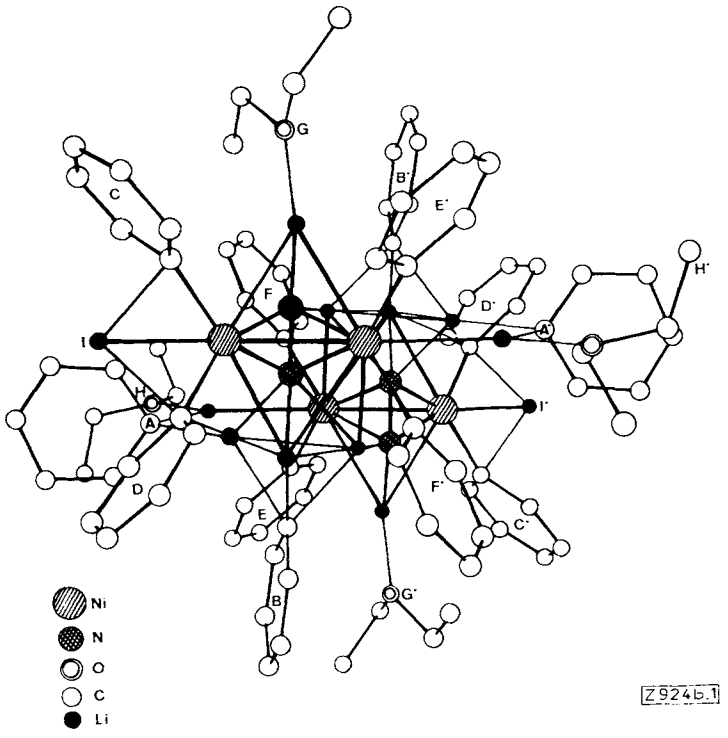


Fig. 1. Molecular structure of the complex $[(C_6H_5Li)_6Ni_2N_2\{(C_2H_5)_2O\}_2]_2$.

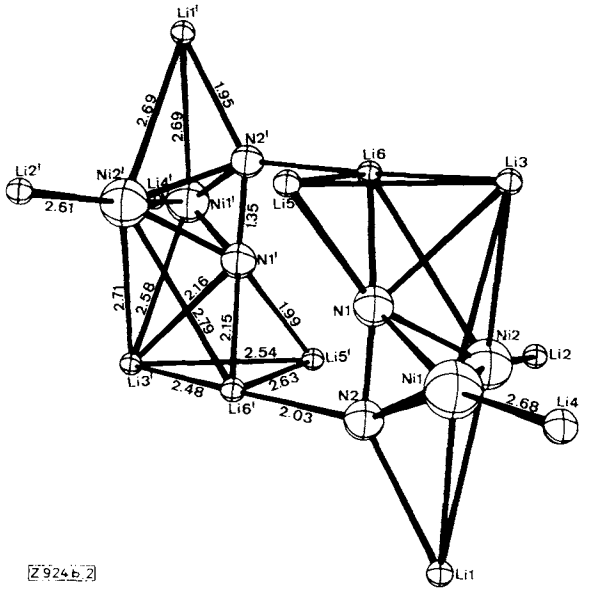

Fig. 2. Internal skeleton of the complex $[(C_6H_5Li)_6Ni_2N_2\{(C_2H_5)_2O\}_2]_2$.

Vacant coordination sites on Li1 and Li2 are occupied by ether molecules (G, H); an analogous, but only partial ($\approx 30\%$), occupation of the coordination site on Li4 (not shown in Fig. 1) hinders further refinement.

On complex formation the N—N bond undergoes extreme elongation to 1.35 Å (1.097 Å in free N_2 and similar values in end-on N_2 complexes[1, 2]). This elongation and also the very fact that π bonding to nickel is possible at all (Ni1—N1: 1.92 Å; Ni1—N2: 1.91 Å; Ni2—N1: 1.93 Å; Ni2—N2: 1.94 Å) are attributable primarily to the electron acceptor properties of the lithium (Li1 and Li3, Li5, Li6 respectively) which enhance the back bonding from the nickel to the nitrogen.

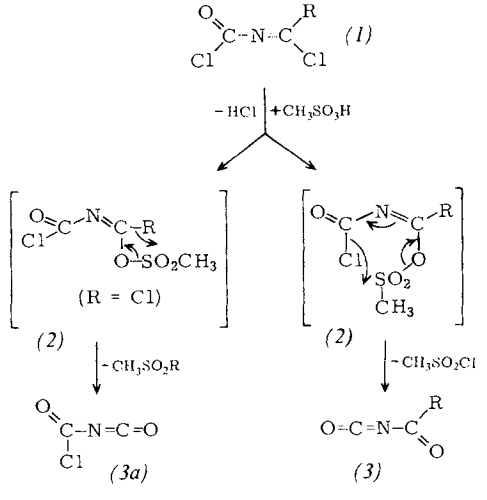
Acyl Isocyanates from *N*-(Chlorocarbonyl)imidoyl Chlorides

By *Hermann Hagemann*[*]

Acyl isocyanates *(3)* are extremely reactive compounds which, unlike the sulfonyl isocyanates of comparable reactivity, cannot be prepared by phosgenation of the corresponding amides. By the following considerations and experiments it has been found that they can be obtained by partial hydrolysis of the readily accessible imidoyl chlorides *(1)*[1–3].



Isocyanide dichlorides can, in general, be converted into isocyanates by, *e.g.*, methanesulfonic acid with replacement of both chlorine atoms by an oxygen atom[4]. However, *N*-chlorocarbonyl isocyanate *(3a)* would be obtained from chlorocarbonyl isocyanide dichloride even if only one chlorine atom of the isocyanide dichloride group were replaced whilst the second chlorine atom to be exchanged was that of the chlorocarbonyl group. 1,4- in place of

[*] Dr. H. Hagemann

509 Leverkusen (Germany)

1,2-elimination of methanesulfonyl chloride from the hypothetical intermediate *(2)* would have to occur. That such a reaction can occur has been shown by conversion of the *N*-(chlorocarbonyl)imidoyl chlorides *(1b)*—*(1d)* (R ≠ Cl)[1-3] into the acyl isocyanates *(3b)*—*(3d)* (Table 1)[5].

Table 1. Acyl isocyanates *(3)* obtained from *N*-(chlorocarbonyl)imidoyl chlorides *(1)*.

	R	B.p. [°C/torr]	Yield [%]	Ref.
a	Cl	64/760	88	[4c, 6]
b	phenylthio	120/14	92	[7]
c	*p-tert*-butylphenoxy	140/13	75	
d	phenyl	90/12	90	[8]

N-Chlorocarbonyl isocyanate (3a)

Methanesulfonic acid (924 g, 9.53 mol) is added dropwise to a solution of *(1a)*[3,9] (1530 g, 9.53 mol) in toluene (600 ml) at *ca.* 30 °C. When evolution of hydrogen chloride ceases the mixture is heated to a bath temperature of 125 °C and the chlorocarbonylcarbamidoyl chloride (ClCONHCOCl) that crystallizes in the condenser is continuously returned to the flask by means of hot toluene (*ca.* 230 ml). Pure *(3a)* is then distilled off through a column. As soon as the boiling point rises, the column is shut off and evolution of hydrogen chloride resumed through a reflux condenser. 887 g of *(3a)* are obtained.

N-(Phenylthio)carbonyl isocyanate (3b)

Methanesulfonic acid (54.8 g, 0.57 mol) is added dropwise over *ca.* 1 h to *(1b)* (133.5 g, 0.57 mol) at 50 °C. Vigorous evolution of HCl sets in and is complete after 2 h at 100 °C. 94 g of *(3b)* are obtained by distillative separation from methanesulfonyl chloride.

Bis(amido)sulfur Tetrafluorides[**]

By *Rainer Höfer* and *Oskar Glemser*[*]

Addition of sulfur tetrafluoride to the SN triple bond of the difluoronitridosulfur amides $N{\equiv}SF_2{-}NSF_2$ *(1)* and $N{\equiv}SF_2{-}NSOF_2$ *(4)* affords the disubstituted derivatives of sulfur hexafluoride $F_2SN{-}SF_4{-}NSF_2$ *(2)* and $F_2SN{-}SF_4{-}NSOF_2$ *(5)*, which exist in the reaction mixture as *cis-trans*-isomers.

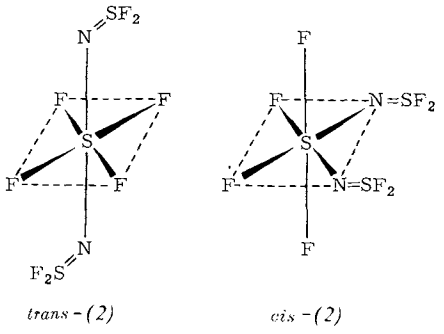

Fig. 1. Structure of the *cis-trans*-isomers of bis(*N*-difluorosulfuramido)sulfur tetrafluoride *(2)*.

In this way bis(*N*-difluorosulfuramido)sulfur tetrafluoride *(2)* is obtained by treating SF_4 with *N*-(difluoronitridosulfur)sulfur imide difluoride[1] *(1)* as follows:

$$N{\equiv}SF_2{-}NSF_2 + SF_4 \xrightarrow[CsF]{80\,^\circ C} F_5S{-}N{=}SF_4{-}N{=}SF_5$$

(1) *(2)*

or with bis(*N*-trimethylsilylimido)sulfur difluoride[2] *(3)* as follows:

$$(CH_3)_3Si{-}N{=}SF_2{=}N{-}Si(CH_3)_3 + 2\,SF_4$$

(3)

$$\xrightarrow[CsF]{100\,^\circ C} \textit{(2)} + 2\,(CH_3)_3SiF$$

(2) is a water-clear liquid that polymerizes within a few days to a viscous, dark brown product but can be kept for a longer time in quartz vessels cooled in Dry Ice. Both the compound itself and the polymer are extremely sensitive to hydrolysis; reaction with water leads to explosive decomposition. The composition of *(2)* is proved by complete elemental analysis, and the structure by NMR and IR spectra.

IR (cm^{-1}): 1260 vs (νS=N); 835 vs, 805 vs, 736 vs, 684 s, (ν_sSF, ν_{as}SF); 655 m, 584 s, 578 s, 480 m, 470 sh, 438 w, 392 m. ^{19}F-NMR (ext. $CFCl_3$): Evaluation of the spectrum is made difficult by the existence of a mixture of geometrical isomers (*cis*:*trans* = 25:75). *trans-(2)* gives a spectrum of the 1st order: $\delta SF_4 = -111.06$ (quintet), $\delta NSF_2 = -55.73$ ppm (quintet); $^4J_{FF} = 14.7$, *cis-(2)* gives a spectrum of higher order of the type $A_2BBX_2X'_2$, whose analysis is not yet complete[3], provisional data being: $\delta SF_e(BB')$ and $\delta SF_a(A) = -100$ to -105, δNSF_2 (XX') $= -54.0$ ppm; J_{AB}, $J_{AB'}$, $J_{BB'} \approx 150$, J_{AX}, $J_{AX'}$, J_{BX}, $J_{B'X'} = 12$ to 14, $J_{B'X}$, $J_{BX'} \approx 1$ Hz.

Mass spectrum: *m/e* (rel. intensities) = 276 M^+ (0), 257 $(M-F)^+$ (13), 238 $(M-F_2)^+$ (1), 219 $(M-F_3)^+$ (1), 200 $(M-F_4)^+$ (0.5), 168 $(NSF_2)_2^+$ (1), 154 $SF_2NSF_2^+$ (15), 135 $SFNSF_2^+$ (3), 108 SF_4^+ (3), 89 SF_3^+ (100), 84 NSF_2^+ (90), 70 SF_2^+ (100), 65 NSF^+ (38), 51 SF^+ (40), 46 NS^+ (100). Mol.-wt.: calc. 276.1, found 274, 276 (Regnault).

The bis(amido)sulfur tetrafluoride *(5)*, which is differently substituted on N and N', is formed on reaction of SF_4

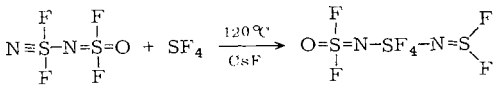
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

with *N*-(difluoronitridosulfur)sulfur imide oxide difluoride[4] *(4)*, analogously to the first of the above syntheses of *(2)*, thus:



(4) *(5)*

(5) is a colorless liquid, which is appreciably more stable than *(2)* since it can be kept without decomposition for days in glass vessels. Its composition, also, is proved by elemental analyses and its structure by IR and NMR spectra.

IR (cm^{-1}): 1420 vs ($\nu_{as}NSO$); 1296 s ($\nu S{=}N$); 1240 vs ($\nu_s NSO$); 860 vs br, 820 sh, 765 vs, 732 s, 685 s (ν_s, $\nu_{as}SF$); 580 s, 570 s, 490 vw, 468 vw, 457 w, 393 vw) (deformation vibrations). ^{19}F-NMR (ext. $CFCl_3$): for *trans-(5)* the spectrum of the 1st order corresponds to the type $A_4K_2X_2$. The NSF_2 group is readily identified in the general spectrum; the signal of the $NS(O)F_2$ group, however, overlaps the signals of the *cis*-isomer: $\delta NS(O)F_2(K) = -45.6$, $\delta NSF_2(X) = -53.5$, $\delta SF_4(A) = -112.0$ ppm; $J_{AK} = 14.3$, $J_{AX} = 10.5$, $J_{KX} < 0.5$ Hz. Provisional data for *cis-(5)* ($A_2BCK_2X_2$) are: $\delta SF_a(A) = -102$ to -105, $\delta SF_e(B)$ and $\delta SF_e(C) = -100$ to -102, $\delta NSF_2(X) = -50.0$ to -51.5, $\delta NS(O)F_2(K) = -45.5$ ppm; J_{AB}, J_{AC}, $J_{BC} \approx 150$, J_{AK}, J_{AX}, J_{CX}, $J_{BK} = 9$—12, J_{BX}, $J_{CK} \approx 1$ Hz.

Mass spectrum: *m/e* (rel. intensities) = 292 M^+ (0), 273 $(M-F)^+$ (12), 254 $(M-F_2)^+$ (3), 235 $(M-F_3)^+$ (1), 216 $(M-F_4)^+$ (1), 184 $NSF_2NSOF_2^+$ (1), 170 $SF_2NSOF_2^+$ (13), 165 $NSFNSOF_2^+$ (0.5), 151 $SFNSOF_2^+$ (3), 135 SF_2NSF^+ (3), 100 $NSOF_2^+$ (70), 89 SF_3^+ (100), 84 NSF_2^+ (65), 81 $NSOF^+$ (43), 70 SF_2^+ (100), 67 SOF^+ (58), 65 NSF^+ (35), 51 SF^+ (43), 48 SO^+ (100), 46 NS^+ (90); mol.-wt.: calc. 292.2, found 289 (cryoscopic in benzene).

Experimental:

(2) from *(1)* and SF_4: SF_4 (8.0 g, 0.08 mol) is condensed with *(1)* (8.4 g, 0.05 mol) and CsF (0.5 g) in an autoclave at -180 °C. After thawing, the mixture is heated at 80 °C and stirred for 5 h. After cooling, the excess of SF_4 is removed at 50 torr and the product is isolated at 0.01 torr in a trap cooled with methanol and Dry Ice. Yield 70%, b. p. 40 °C/20 torr.

(2) from *(3)* and SF_4: SF_4 (10.8 g, 0.1 mol) is condensed with *(3)* (6.0 g, 0.025 mol) and CsF (0.5 g) in an autoclave. After thawing, the mixture is heated at 100 °C and stirred for 12 h. Isolation is as above. Yield 56%.

(5) from *(4)* and SF_4: SF_4 (15 g, two-fold excess) is condensed with *(4)* (13.0 g, 0.07 mol) and CsF (0.5 g) at -180 °C. After thawing, the autoclave is heated to 120 °C and the contents are stirred for 12 h at that temperature. Then, after cooling, the autoclave is opened at 50 torr. Unchanged SF_4 is collected at the temperature of liquid air, and *(5)* and unchanged *(4)* are recovered in a trap cooled with methanol and Dry Ice. The separation is effected by gas chromatography. Yield 30%; b. p. 45 °C/13 torr.

Dichotomy of C≡C Bonds and Formation of η-Cyclopentadienylchromium Complexes

By *Horst Benn*, *Günther Wilke*, and *Dieter Henneberg*[*]

In Memory of Karl Ziegler

In 1959 it was reported[1] that bis(hexamethylbenzene)-chromium(I) and -chromium(0) *(1)* is formed during a cyclotrimerization of 2-butyne on a catalyst prepared from CrO_2Cl_2 and $Al(C_2H_5)_3$ which converts butadiene into 1,5,9-cyclododecatriene. The chemical behavior, elemental analysis, and—with certain reservations—the mass spectrum indicated the presence of a bis(arene)-chromium complex. The highest mass observed in the mass spectrum was not that of the molecular ion $m/e = 376$ but $m/e = 349$ ($M^+ - CCH_3$). This appeared to be explainable with the assumption that a C—CH_3 group is cleaved from one of the two hexamethylbenzene ligands during the ionization of *(1)* with formation of pentamethylcyclopentadienyl, *i.e.* of a ligand presumably strongly favored by the chromium atom.

This uncertainty surrounding the structure determination prompted us to reinvestigate the system, for, in the meantime, it has become possible by means of a method described by *Fischer et al.*[2] to synthesize bis(hexamethylbenzene)chromium(0) and to characterize it mass spectrometically on the basis of the molecular ion $m/e = 376$. The findings of our recent investigations have led not only to a reassessment of our previous suggestions regarding structure but also to the discovery of a new kind of phenomenon pertaining to such a system. If crystalline $CrCl_3$ instead of CrO_2Cl_2 is allowed to react with $Al(C_2H_5)_3$ and 2-butyne in benzene or toluene a crystalline, paramagnetic ($\mu_{eff} = 2.99$ μ_B[3]) complex *(2a)* containing aluminum and chromium is obtained in yields >70% (referred to almost quantitative reaction of $CrCl_3$) which, on reaction with $LiAlH_4$ or after hydrolysis with dithionite affords crystalline, paramagnetic ($\mu_{eff} = 1.76$ μ_B) hexamethylbenzene(pentamethylcyclopentenedienyl)chromium(I) *(3)* in yields of 60—70%. *(3)* has been unequivocally characterized on the basis of elemental analysis, paramagnetism, and its mass spectrum (*inter alia* $m/e = 349$) and has been shown to be identical with the compound *(1)* bbtained from CrO_2Cl_2.

The hexamethylbenzene in complexes *(2a)* and *(3)* is formed by cyclotrimerization of 2-butyne; but how the five-membered ring is formed was at first unclear, *i.e.* at least the origin of a C—CH_3 group remained to be clarified. A possible explanation was that the reduction of $CrCl_3$ with $Al(C_2H_5)_3$ gives rise to formation of intermediary Cr—C_2H_5 groups, which, by twofold abstraction of an α-H atom[4] are converted into Cr—C—CH_3 systems that finally react with two 2-butyne molecules to give pentamethylcyclopentadienyl.

Such a route, however, could be clearly ruled out by corresponding experiments with $Al(CH_3)_3$ and $Al(C_3H_7)_3$, in

[*] Prof. Dr. G. Wilke and H. Benn
Dr. D. Henneberg [**]
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm Platz 1 (Germany)

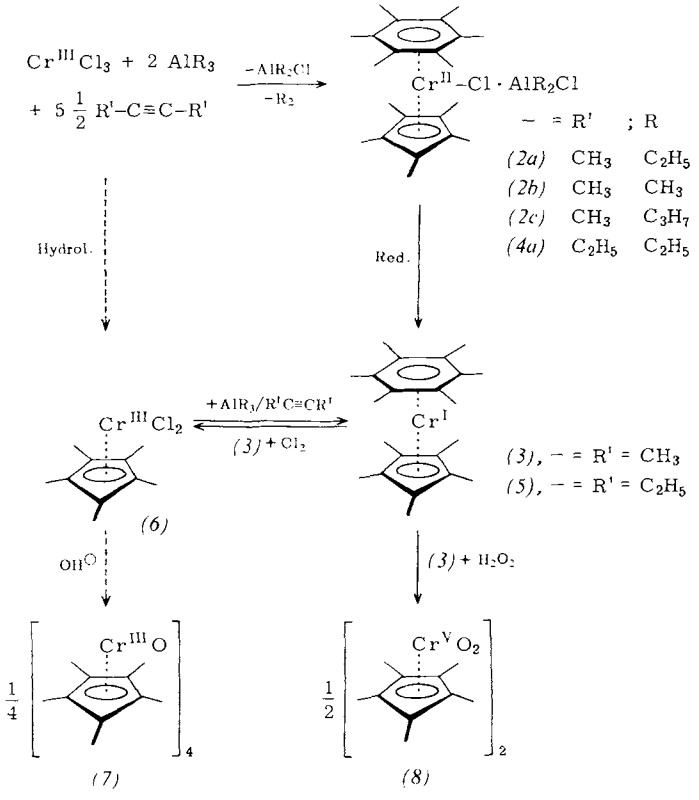
[**] Responsible for the mass spectra.

which *(3)* is likewise formed in high yields as end product, for, in these cases CH- and C—C_2H_5 groups instead of a C—CH_3 group would be incorporated into the five-membered ring. The intermediates *(2b)* and *(2c)* differ from *(2a)* only in that they contain $Al(CH_3)_2Cl$ and $Al(C_3H_7)_2Cl$ instead of $Al(C_2H_5)_2Cl$.

On the basis of these findings the formation of the five-membered ring can be explained only on the assumption that a butyne molecule is halved at the C≡C bond[5], each of the two halves then reacting with a further two molecules of butyne with ring closure. Further, conclusive evidence for this route was provided by the analogous reaction of 3-hexyne, which also undergoes cleavage at the C≡C bond with formation of the chromium(II) complex *(4a)*, which can be reduced to hexaethylbenzene(pentaethylcyclopentadienyl)chromium(I) *(5)*. *(5)* was characterized by elemental analysis, its mass spectrum ($m/e = 503$), and its paramagnetism ($\mu_{eff} = 1.73\ \mu_B$).

To our knowledge this is the first case of a high-yield scission of a C≡C bond. We refer to this phenomenon as dichotomy[6].

With the old method in which CrO_2Cl_2 is employed, *(3)* is obtained in yields of, at most, 5—10%, whereas with crystalline $CrCl_3$ the yields are >70%. We presume that the ordered surface of the $CrCl_3$, or of the initial reduction product with $Al(C_2H_5)_3$, plays a decisive role here and that the dichotomy possibly follows formation of a complex of one butyne molecule with two chromium atoms situated a certain distance apart from each other on the surface. Evidence for this is provided by the fact that deep blue, crystalline pentamethylcyclopentadienylchromium chloride *(6)* can be isolated as a minor product on working up the reaction mixture; that is, formation of the five-membered ring takes place first and only after further reduction is the six-membered ring formed and complexed. Thus, in this sense, *(6)* reacts with $Al(C_2H_5)_3$ and 2-butyne to give *(2a)* and *(3)*. The paramagnetic complex *(6)*[7] is soluble both in hydrocarbons and in water and can be salted out of the aqueous phase by NaCl. *(6)* can also be formed from *(3)* and chlorine.



A further by-product which we have obtained on working up the reaction mixture (cf. reaction scheme) is, according to the mass spectrum, a tetrameric pentamethylcyclopentadienylchromium oxide *(7)* ($[C_{10}H_{15}OCr]_4$, $m/e = 182$), whose structure is possibly similar to that of a previously reported cyclopentadienylchromium oxide[8]. In this connection it is also of interest to note that treatment of *(3)* with H_2O_2 leads to cleavage of hexamethylbenzene and conversion into a dimeric pentamethylcyclopentadienylchromium dioxide *(8)* ($[C_{10}H_{15}O_2Cr]_2$, $m/e = 438$).

Stabilization of Monomeric Dichlorogermylene

By *Peter Jutzi, Hans Joachim Hoffmann, David John Brauer*, and *Carl Krüger*[*]

In Group IVB, the stability of divalent compounds increases from carbon to lead owing to known criteria. Thus in contrast to dichlorocarbene, dichlorogermylene is stable under normal conditions; however, except for a dioxane adduct[1], it exists as a polymer of unknown structure. We now report the stabilization of monomeric dichlorogermylene by complex formation with aromatic nitrogen bases.

Whereas organotrichlorogermanes undergo a reaction analogous to transsilylation[2] with 1,3-benzothiazol-2-yltrimethylsilane *(1)*, forming di- and tribenzothiazol-2-ylgermanes[3], we observed uniform and quantitative addition to the C=N bond on reaction of trichlorogermane with *(1)*, affording 2,3-dihydro-2-trimethylsilyl-2-trichlorogermylbenzothiazole *(2)*: ^{1}H-NMR (in $CDCl_3$, TMS internal): δ_{N-H} 14.43 ppm, variable (1); $\delta_{aromatic\,H}$ 7.67—8.94 ppm, M (4); $\delta_{Si(CH_3)_3}$ 0.85 ppm (9). IR (in Nujol): $\nu_{N-H} = 3200$, $\delta_{Si(CH_3)_3} = 1255$, $\nu_{GeCl_3} = 320$, 270 cm^{-1}. M. W.: calc. 387.27, exp. (in C_6H_6) 350.

(2) decomposes exothermally at 91 °C[3a] with liberation of trimethylchlorosilane; from the residue we obtained the dichlorogermylene-benzothiazole adduct *(3)* in 75%

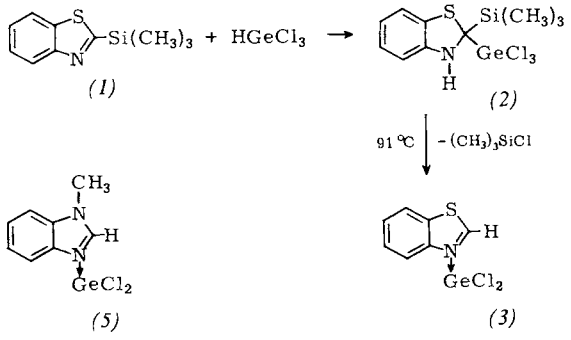
yield after recrystallization from benzene as colorless crystals of m.p. 131 °C.

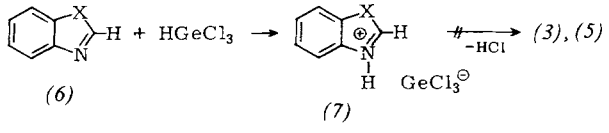


(3) proves surprisingly resistant to hydrolysis and to be thermally stable, dissolving readily in anhydrous ethanol, ethylene bromide, and chloroform, and moderately in benzene. Molecular-weight determinations (in $(CH_2)_2Br_2$) confirm the monomeric structure *(3)*; the monomeric molecular ion with the expected isotopic distribution also occurs as the uppermost peak in the mass spectrum.

The ^{1}H-NMR spectrum (in $CDCl_3$, TMS internal) of *(3)* exhibits signals typical of the benzothiazole skeleton: a multiplet at 7.67—8.68 ppm (4) and a singlet for C^2—H at 10.17 ppm (1). The IR spectrum (in Nujol, 4000—250 cm^{-1}) is almost superimposable upon that of free benzothiazole, the additional bands at 350 and 295 cm^{-1} being assigned to Ge—Cl stretching vibrations.

In the reaction of trichlorogermane with *N*-methylbenzimidazol-2-yl-trimethylsilane *(4)* we have not isolated the initial addition product[4] since in this case the loss of trimethylchlorosilane occurs already at room temperature, with immediate formation of dichlorogermylene-*N*-methylbenzimidazole adduct *(5)*: m.p. 172 °C (dec.); ^{1}H-NMR (in $CDCl_3$, TMS internal): $\delta_{\text{aromatic H}}$ 7.43—8.10 ppm (4); δ_{C^2-H} 9.05 ppm (1), δ_{NCH_3} 4.09 ppm (3); M.W. 276 (mass spectrum).

Synthesis of $GeCl_2$ adducts *via* the non-silylated heterocycles *(6)* is impossible since no addition to the C=N bond takes place but instead protonation to give the thermally stable immonium salts *(7)*.



X = S, NCH_3

The structure of *(3)* (cell data: $a = 15.276(6)$, $b = 8.108(3)$, $c = 8.260(3)$ Å; $\beta = 109.52(3)°$; space group $P2_1/c$; $Z = 4$; $d_{calc.} = 1.92$ g cm^{-3}) was determined by three-dimensional X-ray structure analysis.

From the 4227 reflections recorded by a computer-controlled diffractometer (Mo-Kα, $\lambda = 0.71069$ Å), 2112 structure amplitudes corrected for absorption effects ($\mu = 40.5$ cm^{-1}) were derived, 193 measurements being regarded as unobserved ($I > 2\sigma(I)$). The molecular structure was established by the heavy atom method; least-squares refinement of the atomic parameters (isotropic for H, anisotropic for all other atoms) led to an *R* value of 0.037.

The bond angles at the threefold coordinated germanium are about 90°, the distance Ge—Cl and the angle Cl—Ge—Cl resemble those in Cl_2Ge^{II}·dioxane[5] and $Cl_2Ge^{IV}[\pi\text{-}C_5H_5Fe(CO)_2]_2$[6]; however, these values differ consider-

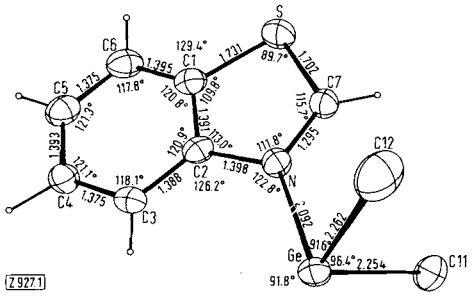


Fig. 1. Perspective representation of 3-dichlorogermylene-1,3-benzothiazole *(3)*. Standard deviations for bond lengths (Å): 0.001 Ge—Cl, 0.002 Ge—N, 0.003 S—C, 0.005 C—N, C—C; for angles (°): 0.1 Cl—Ge—Cl, N—Ge—Cl, all other angles 0.2.

ably from those in $Ge^{IV}Cl_4$ (2.08(2) Å, 109.5°)[7]. The Ge—Cl distances and Cl—Ge—Cl angles in polychlorinated Ge compounds thus reflect not only the oxidation state of the germanium, but also the electronegativity of the coordinated atoms. This finding is in accord with both electron-pair repulsion theory[8] and hybridization theory[9].

The measured Ge^{II}—N distance is 0.13 Å greater than the sum of the covalent radii[10], but 0.10 Å smaller than the Ge^{IV}—N distance in $Cl_4Ge\cdot N(CH_3)_3$[11]. The Ge atom in *(3)* lies 0.168 Å above the plane of the planar (±0.016 Å) benzothiazole skeleton, which bisects the angle Cl—Ge—Cl. The bond length S—C7 is 0.061(4) Å shorter than the corresponding bond length in 2-methylaminobenzothiazole[12]. This finding suggests π-electron delocalization in the five-membered ring, probably with participation of sulfur d orbitals. Adduct formation at the nitrogen does not significantly modify the benzothiazole skeleton. Two short intermolecular distances, between germanium and sulfur (3.618(1) Å) and germanium and chlorine (3.499(1) Å), could be indicative of weak bonding interactions[13].

Chemical Reactions of Morpholine in a Plasma Discharge

By *Klaus Gorzny* and *Günther Maahs*[*]

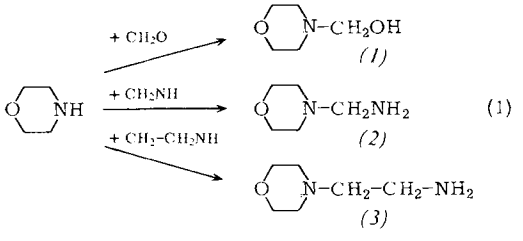
Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

If morpholine is passed through the plasma of a high-frequency glow discharge (27 MHz), reaction proceeds at high conversion rates to yield two main products: dimorpholinomethane and morpholinoacetonitrile. This unexpected reaction course can be explained on the basis of the mass-spectrometric fragmentation pattern of morpholine—a strategy already employed in the interpretation of other plasma reactions[1, 2].

The mass spectrum of morpholine contains the following main peaks[3]:

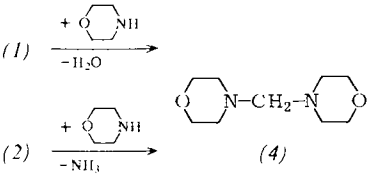
m/e	29	28	57	30	87	56	27	42	43
%	100	74	73	41	36	24	20	15	4

Hence it may be seen that the degradation preferentially generates CH_2O and CH_2NH, and to a lesser extent, $CH_2—CH_2—NH$ fragments. In view of these cleavage products, reaction mechanism *(1)* would appear reasonable.

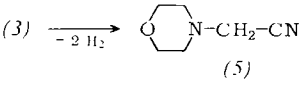


(1)

The intermediates *(1)* to *(3)* are probably in a highly excited state. *(1)* and *(2)* can then undergo further reaction with unreacted morpholine.



In contrast, *(3)* is dehydrogenated to morpholinoacetonitrile *(5)*, since this stabilization appears to be more favorable than the analogous 1,2-dimorpholinoethane formation.



By variation of the reaction parameters pressure and power consumption the reaction course can be controlled at will to produce *(4)* or *(5)* as main product. Thus 95.4% conversion takes place at 0.5—1 torr and 150—200 W to give 138 g/kWh of *(4)* and 14 g/kWh of *(5)*, whereas at 2 torr and 150—300 W conversion is about 80% to give 15 g/kWh of *(4)* and 125.5 g/kWh of *(5)*. A small amount (up to 8 g/kWh) of β-morpholinopropionitrile could be detected as minor product.

The experiments were carried out in quartz glass apparatus with capacitative coupling to a high-frequency generator[2, 4]. The reaction mixture was collected in low-temperature traps and analyzed by gas chromatography. The output was vacuum fractionated to isolate and identify the main products. *(4)*: b.p. 115—120 °C/3 torr, $n_D^{20} = 1.4802$; *(5)*: m.p. 59—60 °C (from methanol). The structures of *(4)* and *(5)* were established by IR, NMR, and mass spectrometry.

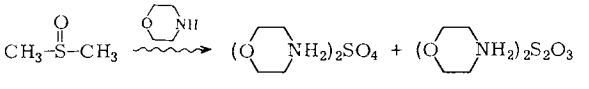
Chemical Reactions of Dimethyl Sulfoxide in a Plasma Discharge

By *Klaus Gorzny* and *Günther Maahs*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

Dehydrodimerizations, cyclizations, and eliminations are the preferred reactions under the conditions of a low-pressure high-frequency glow discharge[1]. Only a few examples are known of reactions in which a reactive species generated in the plasma is scavenged by another molecule to give a main product[1, 2].

Morpholine is a particularly suitable scavenger for plasma-generated reactive intermediates[2]. For instance, if morpholine is passed with dimethyl sulfoxide through the plasma of a glow discharge, a mixture of morpholinium sulfate and thiosulfate is formed in yields of up to 163 g/kWh, alongside gaseous products which were not further investigated. The same products are also obtained when the morpholine is added behind the plasma zone, thus confirming the scavenger action of morpholine.



Dimethyl sulfoxide decomposes, both in the presence of light[3] and in the mass spectrometer[4], to give methyl and methylsulfinyl radicals. An analogous fragmentation may also be expected in a plasma[1, 2]. However, no products arising form these intermediate fragments, *e.g.* 4-Methylsulfinylmorpholine, could be detected in the reaction mixture. It may therefore be concluded that the SO—CH_3 fragment is unstable under plasma conditions and decomposes further to SO and CH_3 fragments, the SO fragment undergoing stabilization to sulfate and thiosulfate ion.

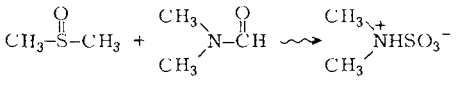
The reaction of dimethyl sulfoxide and aniline proceeds analogously but in poorer yield (up to 54.5 g/kWh).

Optimum results (for apparatus see ref.[2]) were obtained at pressures of 0.4—1 torr and power consumptions between 50 and 150 W. The products were characterized by elemental analysis and on the basis of their IR, NMR,

[*] Dr. K. Gorzny and Dr. G. Maahs
Forschungslaboratorien der Chemische Werke Hüls AG
437 Marl, Postfach 1180 (Germany)

and mass spectra. The composition of the mixtures varied between wide limits: the proportion of sulfate was 10—50% and that of thiosulfate 50—90%; in addition, small amounts of sulfite were also detectable in all cases.

The reaction of dimethyl sulfoxide with formamide takes a completely different course. In the plasma, the reactants yield dimethylamidosulfuric acid (0.4—4.0 torr, power consumption 100—150 W; yield *ca.* 5 g/kWh; m.p. (dec. 161 to 163 °C) alongside unidentified gaseous products. This product is not formed when one of the two reactants is added behind the plasma zone, and must therefore arise from the combination of reactive species of both components.



To our knowledge this is the first example of a plasma synthesis in which a product is formed from fragments of two different organic molecules.

Tetrakis(η-cyclopentadienyl)tetranickel Trihydride—An Unusual Tetranuclear Cluster

By *Jörn Müller*, *Horst Dorner*, *Gottfried Huttner*, and *Hans Lorenz*[*]

Reduction of dimeric cyclopentadienylnitrosylcobalt with $LiAlH_4/AlCl_3$ produces diamagnetic tetrameric cyclopentadienylcobalt hydride[1], $[C_5H_5CoH]_4$ *(1)*, a tetranuclear cluster with μ_3-hydrido bridges. In order to test whether this kind of reaction is suitable as a general synthetic route for the preparation of cyclopentadienylmetal clusters we subjected dimeric cyclopentadienylnitrosyliron[2], $[C_5H_5FeNO]_2$ *(2)*, as well as cyclopentadienylnitrosylnickel[3], C_5H_5NiNO *(3)*, to the action of the above reducing agent in tetrahydrofuran (THF) at 20 °C. Complex *(2)* afforded exclusively ferrocene. Chromatography of the product mixture obtained from the reaction of *(3)* afforded nickelocene and a compound having the composition $C_{20}H_{23}Ni_4$ *(4)*.

The blackish violet crystals of *(4)* dissolve readily in benzene and THF, less readily in pentane, and do not melt below 320 °C when heated under nitrogen. Its solutions are air-sensitive.

In the mass spectrum of *(4)* the molecular ion appears at *m/e* 495 (based on ^{58}Ni) and exhibits an isotopic distribution characteristic of four Ni atoms. Apart from species arising from loss of up to three H atoms, the 50-eV spectrum contains the ions $C_{15}H_{15}Ni_4^+$, $C_{10}H_{10}Ni_2^+$, $C_{10}H_{10}Ni^+$, $C_5H_5Ni^+$, and Ni^+ as characteristic fragments. Prolonged residence of the sample in the ion source results in gradual decomposition with liberation of H_2 and in partial degradation of the Ni_4 unit; 12-eV spectra reveal that the complexes $C_{20}H_{22}Ni_4$, $C_{20}H_{21}Ni_4$, and $C_{20}H_{20}Ni_4$ are also formed as thermolysis products in addition to nickelocene.

The IR spectrum (KBr pellet) of *(4)* indicates the presence of π-bonded symmetrical cyclopentadienyl ligands; the following bands appear (the corresponding absorptions of nickelocene are given in paratheses for comparison): 3098 (3095), 1420 (1425), 1332 (1332), ≈1270 (1261), 1108 (1111), 1050 (1046), 999 (1000), 800 (798), 770 (768), 342 (357) cm^{-1}. The paramagnetic compound also gives a ^1H-NMR spectrum with a very broad signal at $\tau = 157$ (in THF) which can also be assigned to cyclopentadienyl protons. Accordingly, compound *(4)* is to be regarded as tetrakis(η-cyclopentadienyl)tetranickel trihydride $[C_5H_5Ni]_4H_3$. In contrast to *(1)*, no ν_{NiH} absorption can be recognized in the IR spectrum, which, however, cannot be construed as contraindicating the presence of metal hydride groups[4].

The structure of *(4)* was proved by X-ray analysis[5]. Crystal data: space group C2/c; $a = 2832 \pm 2$, $b = 923 \pm 1$, $c = 1503 \pm 1$ pm; $\beta = 102.77 \pm 0.08°$; $V = 3831 \pm 10 \times 10^6$ pm^3; $d_{calc.} = 1.726 \pm 0.005$, $d_{exp.} = 1.78 \pm 0.05$ g cm^{-1}; $Z = 8$; $R_1 = 0.064$ for 1227 independent nonzero structure factors.

The molecule consists of a slightly distorted Ni tetrahedron having a π-bonded cyclopentadienyl ring at each corner (average distances: Ni—Ni 246, Ni-ring center 177.7, Ni—C 210, and C—C_{ring} 138 pm). The hydride hydrogen atoms could not be directly located in the electron density diagram of a difference Fourier synthesis; however, their positions could be deduced from the deviations of the molecule from strictly tetrahedral symmetry. The rings (C21 ... C25), (C31 ... C35), and (C41 ... C45) form angles with the basal face Ni2—Ni3—Ni4 that are significantly smaller than the corresponding angles formed by all the rings with the other tetrahedral faces, *i.e.* an average of 63.4° compared with 73.0°. The prevailing steric conditions can be interpreted by assuming that the three H atoms act as

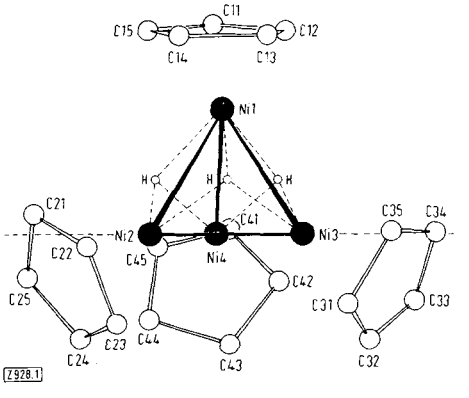

Fig. 1. Schematic representation of the molecule $[C_5H_5Ni]_4H_3$ *(4)*; projection perpendicular to the Ni2—Ni3—Ni4 plane.

μ_3 bridges across three tetrahedral faces. This is in accord with the elongation of the Ni—Ni distances by *ca.* 10 pm compared to Ni—Ni single bonds[6].

[**] Reactions of Nitrosyl Complexes, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 2: [1].

The dipole moment of 2.0±0.1 D measured in benzene is also in accord with the deviation of the structure of *(4)* from an ideal tetrahedron.

In contrast to *(1)*, compound *(4)* exceeds the noble gas rule. Tetrahedral $[C_5H_5Ni]_4$ would be isoelectronic with *(1)* and therefore diamagnetic. The three hydride hydrogen atoms in $[C_5H_5Ni]_4H_3$ supply three additional electrons. It is, however, remarkable that no spin pairing takes place in the complex; instead, magnetic measurements both by the Gouy method (77°K: $\chi_g = 44.35 \times 10^{-6}$ cm^3 g^{-1}, $\mu_{eff} = 3.72 \pm 0.08\ \mu_B$; 295°K: $\chi_g = 13.84 \times 10^{-6}$ cm^3 g^{-1}, $\mu_{eff} = 4.10 \pm 0.08\ \mu_B$; χ_g independent of field) and by the ^{1}H-NMR shift method ($\mu_{eff} = 4.10 \pm 0.1\ \mu_B$) indicate the presence of three unpaired electrons. No explanation of the observed paramagnetism and its temperature independence has yet been forthcoming; accidental orbit degeneracy may be present.

(1) and *(4)* are the first organometallic tetranuclear clusters containing only hydrogen and cyclopentadienyl as ligands. All other known cyclopentadienyl-metal clusters having four and more directly linked metal atoms are stabilized by carbonyl or hetero ligands in addition to C_5H_5 ligands. Attempts to prepare the hydride-free complex $[C_5H_5Ni]_4$ which appears at least momentarily under thermolytic conditions in the mass spectrometer, have so far been unsuccessful. For instance, mild oxidation of *(4)* with a substoichiometric quantity of iodine in pyridine yielded merely nickelocene and NiI_2 (as pyridine adduct) as well as pyridinium iodide. This finding suggests that the stability of the nickel cluster is largely due to the hydride bridges.

Procedure:

All operations must be carried out under nitrogen.

A solution of *(3)* (2 ml, 20 mmol) and $AlCl_3$ (2.7 g) in THF (80 ml) is slowly added dropwise to one of $LiAlH_4$ (0.76 g, 20 mmol) and $AlCl_3$ (2.7 g) in THF (110 ml), the color changing from dark red to blackish green. After 2 hours' stirring, the reaction mixture is hydrolyzed with water (200 ml) with ice-cooling and extracted with ether. The ether phase is washed with $NaHCO_3$ solution, dried over Na_2SO_4, and the ether is drawn off. The black residue is dissolved in benzene and Al_2O_3 (Woelm, 10% H_2O) is added until the solution has been completely absorbed, the benzene then being drawn off. The dark green solid mixture is placed in the head of a chromatography column (2 cm diam., 80 cm length) packed with Al_2O_3 (Woelm, 6% H_2O) in pentane. Nickelocene and unreacted *(3)* are first eluted with pentane, and then *(4)* as a dark green zone with benzene. Removal of the benzene and recrystallization from ether/pentane (1:3) at low temperature affords 150 mg of *(6)* in analytically pure form.

5-Substituted Ethyl 2-Thiazoline-4-carboxylates

By *Ulrich Schöllkopf* and *Dieter Hoppe*[*]

Ethyl 2-thiazoline-4-carboxylates[1,2] of type *(4)*, unsubstituted at position 2, are of interest for synthesis of penicillin derivatives[2]. We have found that they are obtained in good yield and relatively pure if a solution of an ethyl 2-isocyanoacrylate *(1)*[3] and *ca.* 10 mol-% of a weak base (such as triethylamine or pyridine) in chloroform is saturated with hydrogen sulfide at 20—40 °C and the mixture is then distilled.

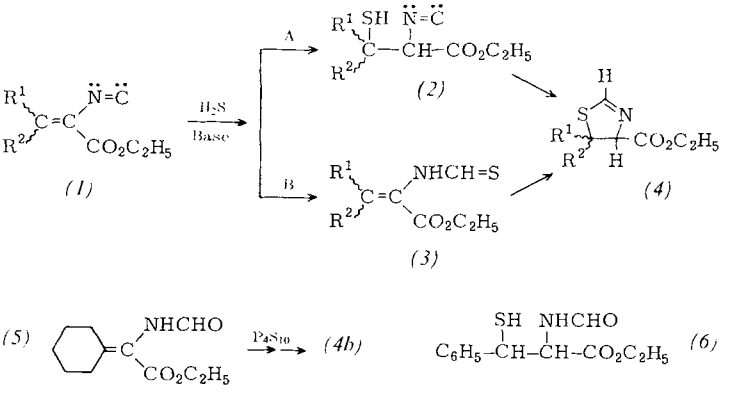

Table 1. Ethyl 2-thiazoline-4-carboxylates *(4)* synthesized from ethyl 2-isocyanoacrylates *(1)*.

[a] Isomer ratio determined by NMR spectroscopy.
[b] Crude product.
[c] 72% of the thioformamide *(3f)*, m. p. 154 °C, was isolated (see text).
[d] The ratio can be increased to *ca.* 9:1 on subsequent equilibration by 10 mol-% of sodium ethoxide in ethanol (1 h, 20 °C).

The reaction probably proceeds mainly by route A, *i.e.* by base-catalyzed addition of hydrogen sulfide to the activated double bond of *(1)*, yielding β-mercapto isocyanides *(2)* which cyclize to *(4)*. In an experiment with *(1d)* the intermediate *(2d)* was detected by IR spectroscopy

[*] Prof. Dr. U. Schöllkopf and Dr. D. Hoppe
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

(band at 2150 cm^{-1}). Apparently, the extent to which reaction proceeds by route B depends on the nature of R^1 and R^2; by this route, the hydrogen sulfide adds first to the isocyanide group, yielding the thioformamide *(3)* which then undergoes ring closure to *(4)*. Formation of the non-cyclizing ethyl 3,3-diphenyl-2-(thioformylamino)acrylate *(3f)* from *(1f)* and hydrogen sulfide shows that formation of thioformamides cannot be disregarded.

The 2-thiazoline-4-carboxylic esters *(4)* are formed also, although in less pure state, on reaction of ethyl 3-substituted 2-(formylamino)acrylates[4] with tetraphosphorus decasulfide; *e.g.* we obtained 50% of *(4b)* when we heated ethyl 2-cyclohexylidene-2-(formylamino)acetate *(5)* in benzene with P_4S_{10} for 5 h; optimization of the procedure and exploration of its scope are in progress because this may be a more convenient method of preparing large amounts of *(4)* since the conversion of the 2-(formylamino)acrylic ester[4] into *(1)*[3] becomes unnecessary.

In preliminary experiments the thiazolinecarboxylic esters *(4)* were readily hydrolyzed to β-substituted *N*-formylcysteine esters[5]. For example, we obtained *N*-formyl-β-phenylcysteine ethyl ester *(6)* when *(4d)* was chromatographed on neutral silica gel in moist ether. This identifies a simple synthesis of *S*-unprotected β-substituted cysteines. *(6)* was obtained as a mixture of diastereoisomers; one isomer was obtained pure by recrystallization from ether [m. p. 91 °C; ^{1}H-NMR ($CDCl_3$): τ = 1.90 and 3.45 (s and br. d, resp.; NH—CHO); 7.80 (d, SH, $J_{3\text{-H/SH}} = 6$ Hz); 4.85 (q, 2-H, $J_{2\text{-H/NH}} = 10$ Hz, $J_{2\text{-H/3-H}} = 6$ Hz); 5.50 (t, 3-H); 2.70 (C_6H_5); 4.85 and 8.80 (q and t, resp., OC_2H_5). IR (KBr): ν = 3230 (NH), 2550 (SH), 1720 (C=O), 1650 (CH=O) cm^{-1}].

Ethyl 5,5-dimethyl-2-thiazoline-4-carboxylate (4a)

Hydrogen sulfide is passed into a solution of *(1a)*[3] (6.8 g, 44.5 mmol) and triethylamine (0.5 g, 5.0 mmol) in chloroform (10 ml) with stirring at 20—40 °C until the isocyanide band at 2120 cm^{-1} is no longer detectable. The solvent is removed in a rotatory evaporator at water-pump vacuum and the residue distilled. This affords *(4a)* (6.6 g, 80%); IR (film): ν = 1560 (C=N), 1725 and 1740 (C=O) cm^{-1}. (Similar IR bands are also observed for other compounds *(4)* but without splitting of the carbonyl frequency.)

Ethyl cyclohexanespiro-5'-(2'-thiazoline-4'-carboxylate) (4b)

(5)[4] (6.3 g, 30 mmol) is heated in benzene (30 ml) with finely powdered P_4S_{10} (1.45 g, 3.0 mmol) for 5 h under reflux. The solution is then decanted and the solvent is removed in a rotatory evaporator in a vacuum. Distillation finally affords *ca.* 90%-pure *(4b)* (yield 3.8 g, 55%), giving the same NMR spectrum as an authentic sample (see above).

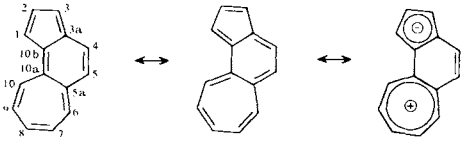
Stable Phenazulene Derivatives by [12+2]Additions to 8,9-Dicyanosesquifulvalene[1][**]

By *Horst Prinzbach* and *Heinz-Walter Schneider*[*]

The $C_{14}H_{10}$ hydrocarbon phenazulene *(1)*[2] (cyclohept-[*e*]indene) is a 14π-perimeter molecule, which because of the transannular bonds between C-3a and C-10b and between C-5a and C-10a can be regarded as a higher homolog of azulene[3]. In accord with the π-electron density distribution indicated by the limiting structures, a significant resonance stabilization and a considerable polarity has been postulated for this conformationally rigid [14]annulene[4].

After earlier attempts at synthesis had proved fruitless[5], we have obtained derivatives of *(1)* *via* [12+2]addition to 8,9-dicyanosesquifulvalene *(2)*[6]. The compound *(2)*



(1)

is resistant to electron-deficient dienophiles but reacts quantitatively with the enol ethers *(3a)* and *(3b)* [510 mg (2.5 mmol); 5 mmol of *(3)*, R = C_2H_5] in bromobenzene (200 ml) at 150 °C (3 h); the adducts *(4a)* and *(4b)* rapidly

lose alcohol and, by migration of hydrogen, afford mixtures of the isomeric dihydrophenazulenes *(5a)*—*(7a)* and *(5b)*—*(7b)*, respectively[8]. With weak bases such as pyridine these products give anions smoothly, but because of very rapid addition of conventional hydride-eliminating reagents, these anions are not suitable precursors of *(9a)* and *(9b)*.

Hydride elimination can be achieved by means of trityl tetrafluoroborate (CH_2Cl_2; 20°C), smoothly from *(5a)* and *(5b)*, but very much more slowly from *(6a)* and *(6b)* or *(7a)* and *(7b)*, yielding the phenazulenium salts *(8a)* and *(8b)*. These salts are very acidic, so that *(8b)* is deprotonated to a considerable extent under the conditions of its preparation [21% based on *(5b)*—*(7b)*], and the isolated *(8a)* is deprotonated to *(9a)* by the action of weak bases (pyridine) [93% based on *(8a)*]. Without isolation of intermediates *(5a)*—*(7a)* are oxidized to *(9a)*, and *(5b)*—*(7b)* to *(9b)*, by chloranil or dichlorodicyanobenzoquinone (CH_2Cl_2; 20°C), though the latter reagent rapidly reacts further with *(9a)* and *(9b)*[9].

Table 1. Physical data for compounds *(8a)*, *(9a)*, and *(9b)*.

Cpd. [a] M.p. [°C] M^+ [m/e]	UV λ_{max} [nm] (ε)	NMR (τ)
(8a)	268 (18700), 298 (17900), 327 (19500), 342 (20100), 378 (16000), 406 (23300), 500 (sh, 3080), 580 (sh, 2340), [b]	−0.3–0.3 (m, 6-H, 10-H), 0.6–1.2 (m, 7-H–9-H), 5.06 (s, 21-H), 6.1–6.65 (m, α, α′-CH_2), 7.65–8.0 (m, β,β′-CH_2) [c]
(9a) 272–273 282	252 (27800), 292 (sh, 25400), 305 (26900), 339 (sh, 8350), 386 (sh, 20000), 410 (26200), 567 (6750), 680 (sh, 2900) [d]	0.55–0.8 (m, 10-H), 1.0–1.2 (m, 6-H), 1.9–2.2 (m, 7-H–9-H), 2.12 (s, 1-H), 6.3–6.5 (m, α-CH_2), 6.7–6.9 (m, α′-CH_2), 7.9–8.15 (m, β,β′-CH_2) [e]
(9b) 241–242 304	241 (36100), 286 (29100), 382 (26400), 404 (29400), 576 (7600), 700 (sh, 4800) [d]	0.5–0.7 (m, 10-H), 1.2–1.35 (m, 6-H), 1.8–2.15 (m, 7-H–9-H), 1.94 (s, 1-H), 2.2–2.5 (m, 5-H, C_6H_5) [e]

[a] Correct elemental analyses were obtained for the compounds isolated. The numbering of *(9b)* is retained for *(8a)* and *(9a)*.
[b] In H_2SO_4/CH_3COOH.
[c] In CF_3COOH.
[d] In CH_2Cl_2.
[e] In $CDCl_3$.

In accord with the low basicity of *(2)* and the high acidity of the salts *(8)*, the deep blueish-violet, extremely sparingly soluble phenazulenes *(9a)* and *(9b)* are only very weakly basic, although they can be reprotonated to *(8a)* and *(8b)* by conc. H_2SO_4 in glacial acetic acid (UV concentration measurement). The UV, IR, ^{1}H-NMR[10], and MS data, as well as some subsequent reactions[9], accord with the structures *(8)* and *(9)*. For *(9a)* the assignment of 6-H, 10-H, and for *(9b)* assignment of 1-H, 5-H, was made according to the calculated π-electron density at their respective carbon atoms (see [4]). The lower of the α,α′-CH_2 signals from *(9a)* was assigned to that CH_2 group which was attached to the C atom with the lower π-density.

Irrespective of such uncertainties and of the influence of substituents, the chemical shifts of the perimeter protons of *(9a)* and *(9b)*—particularly in comparison with the shifts of the perimeter protons of *(2)*, *(5a)*—*(7a)*, *(5b)* to *(7b)*, and *(8a)*—as well as the shifts of the α,α′-CH_2 protons of *(9a)* [τ = 6.3–6.5; 6.7–6.9; to be compared with 6.6–7.4 for *(6a)*, *(7a)*] may well indicate[11] the existence of a diamagnetic ring current in *(9a)*, *(9b)* and a polarity that is increased by the CN groups[12]. A strongly polar ground state is also indicated by the strongly negative solvatochromism in the electron spectrum of *(9a)* [λ_{max} (CH_3CN): 660 sh, 550, 400, 302, 250 nm; (CCl_4): 772 sh, 718, 597, 420, 310, 276 nm].

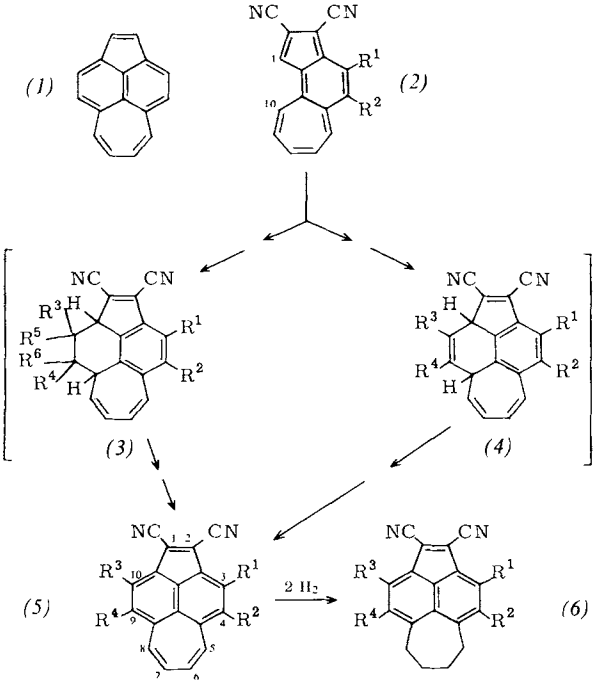
A New Route to the Acepleiadylene System[1][**]

By *Horst Prinzbach, Lothar Knothe*, and *Heinz-Walter Schneider*[*]

In the synthesis developed by *Boekelheide et al.*[2] for the 14π-perimeter system[3] acepleiadylene *(1)* (cyclohept[*fg*]-acenaphthylene) a five-membered and a seven-membered ring were attached to a given naphthalene skeleton. The reverse route, namely attachment of the six-membered rings to the sesquifulvalene skeleton, has been realized by us for some derivatives. This new type of synthesis is useful for the preparation of specifically substituted derivatives and can be varied within certain limits; it succeeds because the strongly polar 2,3-dicyanophenazulenes *(2)*[11] undergo cycloaddition at positions C-1 and C-10 with both electron-rich and electron-deficient ethylene and acetylene derivatives[4].



Typical of the reactivity of the phenazulenes *(2)* towards enamines is the reaction of *(2a)* with 1-(1-cyclohexenyl)piperidine. When their solutions are mixed (1 : 2 mol, CH_2Cl_2, 20 °C) there is immediate fading of the color towards yellow and on storage—even with exclusion of oxygen—a gradual deepening of the color to reddish-violet. On chromatography on silica gel (CH_2Cl_2) a 42% yield of 1,2-dicyano-3,4:9,10-dicyclohexenoacepleiadylene *(5a)*[5], which crystallizes in reddish-violet needles, can be isolated from the single band that migrates. *(5a)* can also be obtained from *(2a)* and 1-ethoxycyclohexene, but this enol ether usually adds only at higher temperatures (bromobenzene, 150 °C) and these conditions suffice for the phenazulene to undergo subsequent thermal reactions (dimerization?). *(5a)* can also be obtained, without isolation of *(2a)* but in poorer yield (*ca.* 20%), directly from 8,9-dicyanosesquifulvalene and 1-(1-cyclohexenyl)piperidine (1 : 2 mol, CH_2Cl_2, 20 °C). By this convenient procedure we have also prepared the symmetrically substituted acepleiadylenes *(5b)*—*(5d)* in *ca.* 20% yields from the sesquifulvalene with 1-(1-cyclopentenyl)piperidine and with α- and β-styrylpiperidine[7]. As for the precursors of *(2a)*[1], we must leave open the question of possible intermediates such as *(3a)* and the mechanism of the dehydrogenation.

The dicyanophenazulenes also react differently from 8,9-dicyanosesquifulvalenes with electron-deficient reagents such as dimethyl acetylenedicarboxylate (ADM), maleic anhydride (MAA), dichlorodicyanobenzoquinone, chloranil *etc.*; these reactions, however, usually occur sufficiently fast only at 120 °C when competing reaction of *(2)* reduces the yield substantially. From *(2a)* and ADM (120 °C) a 30% yield can be obtained of the product *(5e)*, crystallizing in reddish-violet needles, without any indication of *(4e)* or of disproportionation products. The MAA adduct, obtainable only at 150 °C and in lower yield, was isolated after esterification and was characterized in the same way as *(5e)*.

The course of the reaction with dichlorodicyanobenzoquinone (1 : 2 mol, CH_2Cl_2, 20 °C) is surprising. According to elemental analysis and the mass spectrum, the blueish-violet product (55%), formed even at 20 °C, has the composition $C_{24}H_{12}N_4$ (mol. wt. 356) and spectral data indicate unambiguously the structure *(5f)*. Formulation of *(3f)* as an intermediate is supported by the result with chloranil (bromobenzene, 150 °C); in spite of the distinctly higher temperature there is no fragmentation, but instead, twofold elimination of HCl to yield the acepleiadylene *(5g)* (30%)[6]. The attractive interpretation of the transition *(3f)* → *(5f)* as a retro-Diels-Alder decomposition is excluded: in the presence of methanol there is formed, besides *(5f)*, not dimethyl 2,3-dichlorosuccinate, but dimethyl 2,3-dichloromaleate in 46% yield[8]. The structures of the acepleiadylenes *(5a)*—*(5g)* are proved by spectroscopic data. Also, *(5a)* and *(5d)* were converted selectively into acenaphthylene derivatives *(6a)* and *(6d)* respectively by hydrogenation (CH_2Cl_2, $Pd/CaCO_3$). In agreement with

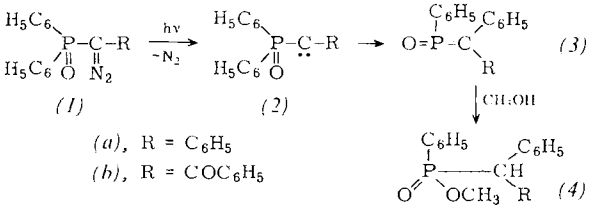
[9] The π-electron densities and π-bond orders calculated for 1,2-dicyanoacepleiadylene deviate only slightly from the values obtained for *(1)* (*R. Zahradník*, personal communication; *R. Zahradník, H. Prinzbach, et al.*, unpublished work).

Detection of Alkylideneoxophosphoranes by Cycloaddition of Carbonyl Compounds[**][1]

By *Manfred Regitz, Hans Scherer, Walter Illger*, and *Helmut Eckes*[*]

Irradiation of (diphenylphosphoryl)diazomethanes *(1)* in methanol affords phosphinic esters *(4)* in amounts that vary with the nature of the group R; their formation is readily explained as occurring by way of the carbene *(2)* and the alkylidenephosphorane intermediates *(3)*[2].

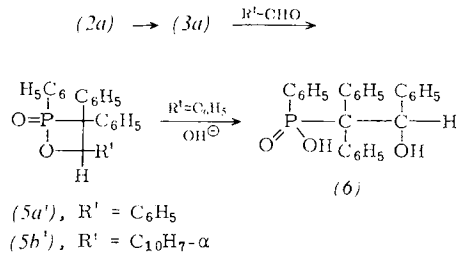


(1) *(2)* *(3)*

(a), R = C_6H_5
(b), R = COC_6H_5

(4)

To trap the hitherto unknown heterocumulenes *(3)*, they were prepared in the presence of carbonyl compounds. On irradiation of *(1a)* in benzene containing benzaldehyde or 1-naphthaldehyde the solvent was first cyclopropanated by the carbene *(2a)*, yielding 7-(*exo*-diphenylphosphoryl)-7-*endo*-phenylnorcaradiene [15% yield; m.p. 179 to 180°C; NMR ($CDCl_3$): δCH-cyclopropane = 3.46, d, $^3J_{H,P}$(*cis*) = 14 Hz[1,3]]. However, at least 18% of *(2a)* was rearranged by a *P/C*-phenyl shift, yielding *(3a)* which undergoes [2+2]-cycloaddition with the aldehydes, thus forming the 1,2-oxaphosphetanes *(5a')* and *(5b')* [m.p. 246 and 249°C, respectively; NMR ($CDCl_3$): δCH-ring

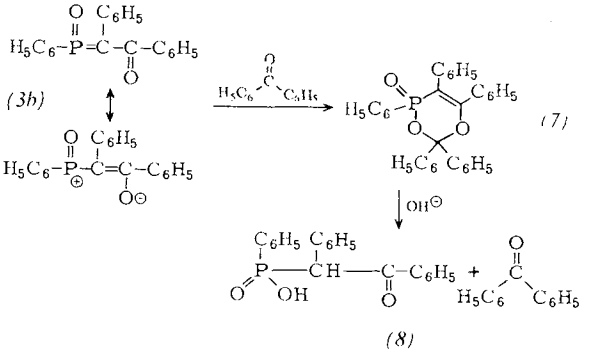


(5a'), R' = C_6H_5
(5b'), R' = $C_{10}H_7$-α

(6)

= 4.8 and 5.0 d, $^3J_{H,P}$ = 23 and 26 Hz, respectively]. A fragment $M^+ - C_6H_5PO_2$ appearing in the mass spectrum of *(5a')* and *(5b')* is not consistent with the alternative orientation of the aldehyde in the cycloaddition. Furthermore, alkaline ring fission of *(5a)* to the β-hydroxy phosphinic acid *(6)* [m.p. 140°C; NMR ($CDCl_3$): δCH-β = 5.42 d, $^3J_{H,P}$ = 8 Hz] accords with the structure assigned to the cycloadducts.

The α-benzoylbenzylideneoxophosphorane *(3b)* is obtained by analogous photochemical reaction in a melt of *p*-dichlorobenzene (60°C), this product being expected because of the 1,4-dipolar reactivity due to the differing electronegativities of phosphorus and oxygen. In agreement therewith, the product [yield 15%; m.p. 182—183°C (from ethyl acetate/ether); no CO absorption in the IR spectrum] trapped by benzophenone has the 1,5,2-dioxaphosphorin structure *(7)*.



(3b) *(7)*

(8)

Thermal fragmentation (215°C, $5 \cdot 10^{-3}$ torr) of *(7)* to diphenylacetylene, benzophenone and the hypothetical fragment $C_6H_5PO_2$[4] also supports formula *(7)*, as does hydrolysis by 20% potassium hydroxide in ethanol/water at room temperature to the phosphinic acid *(8)* [yield 83%; m.p. 148°C; IR (KBr): 2225, 2560 (OH, br), 1675 cm^{-1} (CO); NMR ($CDCl_3$): δCH-α = 5.50 d, $^2J_{H,P}$ = 20 Hz] and benzophenone. On use of acetophenone as trapping agent for *(3b)* there is formed, analogously to *(7)*, a 30% yield of an oily mixture of diastereoisomers that could not hitherto be separated. In its NMR spectrum ($CDCl_3$) the methyl signals occur at 2.47 and 2.04 ppm (the latter is split, $^4J_{H,P}$ = 2 Hz, rel. areas 2:1).

Correct analytical data were obtained for all the products.

2-Oxo-2,3,3,4-tetraphenyl-1,2λ⁵-oxaphosphetan (5a') and 4-(α-naphthyl)-2-oxo-2,3,3-triphenyl-1,2λ⁵-oxaphosphetan (5b'):

30 mmol (9.54 g) of *(1a)* and 100 mmol of benzaldehyde or 1-naphthaldehyde in benzene (750 ml) were irradiated (Duran-50 filter, Philips HPK 125 W) until at least 50% of the theoretical amount of nitrogen was liberated. Evaporation, dissolution of the residue in methanol (50 ml) and crystallization at −20°C gave *(5a')* or *(5b')*. The filtrate was evaporated and the residue chromatographed in benzene (1000 ml) on Woelm silica gel (300 g, 0.05 to

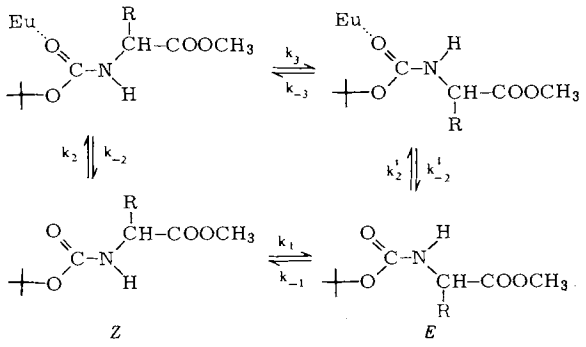
Dynamic NMR Measurements of Boc-amino Esters with Application of Lanthanoid Shift Reagents[1][**]

By *Horst Kessler* and *Michael Molter*[*]

Highly resolved NMR spectra are extremely well suited for demonstration of intramolecular mobility. The method fails, however, when the NMR spectra of the isomers do not differ sufficiently (accidental equivalence) and when the equilibrium lies greatly to one side. We have found that the use of lanthanoid shift reagents such as Eu(fod)$_3$ [tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octane-dionato)europium(III)] can lead to success in such cases.

The ^{1}H-NMR spectra of Boc-glycine methyl ester *(1)* and Boc-L-alanine methyl ester *(2)* in $CDCl_3$ at 90 MHz are independent of temperature and it is not possible to recognize any hindrance to rotation around the urethane N—C bond from these spectra. Nevertheless all the signals are doubled in the spectrum of *(1)* or *(2)* in $C_2D_2Cl_4$ at 0 °C after addition of Eu(fod)$_3$[2], showing the presence of the two rotamers side by side. The complexation occurs preferentially with the *E*-isomer that is present in smaller amounts. Its signals are more strongly shifted and become more intense as the concentration of Eu(fod)$_3$ is increased. Only if the molar ratio of Eu(fod)$_3$ to substrate approaches unity do the signals of the *Z*-isomer, now present in smaller amount, follow the same pattern.



(1), R = H; *(2)*, R = CH_3; *(3)*, R = CH_2-C_6H_5

Assignment of the rotamers is effected by comparing the lanthanoid-induced shifts Δ[4]. It can be assumed that complexation occurs at the urethane-carbonyl group. The signals of the *tert*-butyl group are thus relatively strongly shifted in both rotamers. Although the C_α-protons are further away from the europium ion in the *E*- than in the *Z*-conformation, the signal of the former is at first more shifted because of its greater complex formation. However, with increasing Eu(fod)$_3$ concentration [*e.g.*, for *(1)* > 38 mol-%] the strength of this signal is, as expected, overhauled by that of the *Z*-C_αH signal because of the increased complexation of the *Z*-form that now clearly occurs. If the shifts of the C_αH-protons are referred to those of the *tert*-butyl groups, the values shown in Table 1 are obtained, whence the assignments follow unambiguously. Extrapolation of the Eu(fod)$_3$ concentration to zero shows that the Boc-α-amino acids studied exist in $CDCl_3$ or $C_2D_2Cl_4$ preferentially in the *Z*-conformation, but the *E*-conformations are clearly better complexed so that their contribution increases with increasing Eu(fod)$_3$ concentration.

If the solution of *(1)* containing Eu(fod)$_3$ is warmed one observes coalescence of four groups of signals, corresponding to occurrence of rotation around the urethane bond. The chemical shifts $\Delta\nu$ (without exchange) in the low-temperature region are only slightly temperature-dependent, so they can be extrapolated without much difficulty. The free activation enthalpies of rotation around the urethane bond can be determined from the line broadenings in the usual way and are found to lie in the expected range (see Table 1)[1,5].

To interpret the barriers we can start with the fact that the equilibrium of complexation (k_2) is established rapidly on the NMR time scale. The process observed is thus, to a first approximation, the rotation (k_1) around the urethane bond in the uncomplexed molecule. However, the barrier observed can become somewhat greater as the $Eu(fod)_3$ concentration is increased, because the double-bond character of the C—N bond increases on complex formation.

Use of lanthanoid shift reagents thus broadens the field of application of dynamic NMR spectroscopy[6] in that small amounts of energetically unfavorable isomers can be recognized and the kinetics of the interconversion can be followed. A particular advantage is the ability to change considerably the isomeric ratios, but a prerequisite for this is that the energetically unfavorable isomer shall be better complexed than the isomer that is favored without addition of the shift reagent.

[6] It has been shown very recently for the case of dimethylformamide (see ref. [3]) that the isomeric ratio and the splitting $\Delta\nu$ (without exchange) can be changed by addition of lanthanoid shift reagents [7]. The examples described above are, to the best of our knowledge, the first determinations of previously unknown barriers to rotation.

Synthesis of Valinomycin by the Phosphite Method[**]

By *Manfred Rothe* and *Wolfgang Kreiss*[*]

Dedicated to Professor Hans Brockmann on the occasion of his 70th Birthday

Valinomycin is a macrocyclic depsipeptide[1] built up of alternating amino and hydroxy acids, and having the structure cyclo(Val-D-Hyv-D-Val-Lac)$_3$[2]. Its antibiotic activity and ability to transport potassium ions through lipid membranes justify the development of efficient synthetic methods.

All previous methods of its preparation proceed through a linear dodecapeptide which is obtained by fragment condensation (classical and solid phase methods) and subsequent cyclization by the acid chloride method[3]. We have used the phosphite method for the ring closure[4] which was used previously by us for the synthesis of gramicidin S[5] and fungisporin[6].

As a further substantial simplification, the symmetrical structure permits direct synthesis from a tetradepsipeptide unit by cyclotrimerization. Moreover, the known[7] oligomeric cycloocta- and cyclohexadeca-peptide as well as the unknown first member of the polymer-homologous series, namely cyclo(Val-D-Hyv-D-Val-Lac) were obtained. All four cyclic compounds can be separated by gel chromatography (Sephadex LH 20/methanol) and characterized by mass and IR spectroscopy ($n=1-3$; cf. Table 2); the known compounds can also be characterized by comparison of m.p. and $[\alpha]_D$ data with values given in the literature.

Table 1. Cyclization of the tetradepsipeptide H(Val-D-Hyv-D-Val-Lac)OH.

Tetradepsipeptide c [mol/l]	Cyclodepsipeptide, yield [%] Tetra-	Octa-	Dodeca- (Valinomycin)
0.05	5	14	2
0.01	7	1	0.1

Cyclization experiments were carried out under various conditions with the sequences H(Val-D-Hyv-D-Val-Lac)$_n$OH having $n=1,2$ and 3. The products formed from the sequence with $n=1$ contained, besides the cyclotetradepsipeptide, the next two ring homologs with $n=2$ and 3 (including valinomycin). The linear octaptide gave the cycloocta- and cyclohexadecadepsipeptide, whereas on cyclization of the dodecapeptide ($n=3$) no cyclic product other than valinomycin was obtained. Yields and proportions of the cyclic oligomers depend greatly on the concentration of the linear peptide used and accord with the dilution principle (Table 1).

The highest yields of cyclodepsipeptide varied with the chain length of the linear depsipeptide used (Table 2), presumably for steric reasons.

Table 2. Dependence of the cyclization tendency on chain length.

n	H(Val-D-Hyv-D-Val-Lac)$_n$OH c [mol/l]	cyclo(Val-D-Hyv-D-Val-Lac)$_n$ Yield [%]
1	0.01	9
2	0.001	74
3	0.01	33

The results already obtained prove the suitability of the phosphite method for ring closure of depsipeptide sequences. Noteworthy are the rapid and simple procedure (batch method) and the easy working up. The reaction conditions (relatively high temperature, diethyl phosphite as solvent) indicate its use particularly for sparingly soluble sequences and for those where cyclization is sterically hindered.

General procedure:

The linear depsipeptide is dissolved together with 2 equiv. of *o*-phenylene chlorophosphite in diethyl phosphite and heated under nitrogen at a bath temperature of 100 °C. For cyclization a solution of 3 equiv. of triethylamine dissolved in 10 ml of diethyl phosphite is added dropwise to the reaction mixture with vigorous stirring. The reaction mixture is stirred for 30 min at the above temperature, then cooled and evaporated under oil-pump vacuum. The oily residue is dissolved in methylene dichloride, extracted with 10% $NaHCO_3$ solution, and then with water. After evaporation, the residue is chromatographed on Sephadex LH 20 (eluant: methanol); the oligomeric cyclodepsipeptides are obtained from the fractionated eluates.

Direct Synthesis and Separation of Asymmetric Phosphane-Manganese Complexes[1]

By *Henri Brunner* and *Wolfgang Rambold*[*]

The following optically active compounds have so far found application in the preparation of diastereoisomeric organometallic compounds of the transition elements: the mentholate ion $OC_{10}H_{19}^-$[2,3]; the isocyanide $C{\equiv}NCH(CH_3)(C_6H_5)$[3]; the amine $H_2NCH(CH_3)(C_6H_5)$[4]; and the chelate Schiff bases of 2-pyridinaldehyde and of the 2-pyrrolaldehyde anion with α-phenylethylamine[3]. Since phosphanes are excellent ligands in transition metal complexes of lower oxidation states, optically active phosphanes should be universally applicable for the direct introduction of diastereoisomerism.

The reaction of the secondary amine (*S*)-(−)-$(CH_3)HNCH(CH_3)(C_6H_5)$[5] [obtainable from (*S*)-(−)-$H_2NCH(CH_3)(C_6H_5)$] with diphenylchlorophosphane does not involve the center of asymmetry; the conveniently accessible potential ligand *(1)* is therefore optically pure.

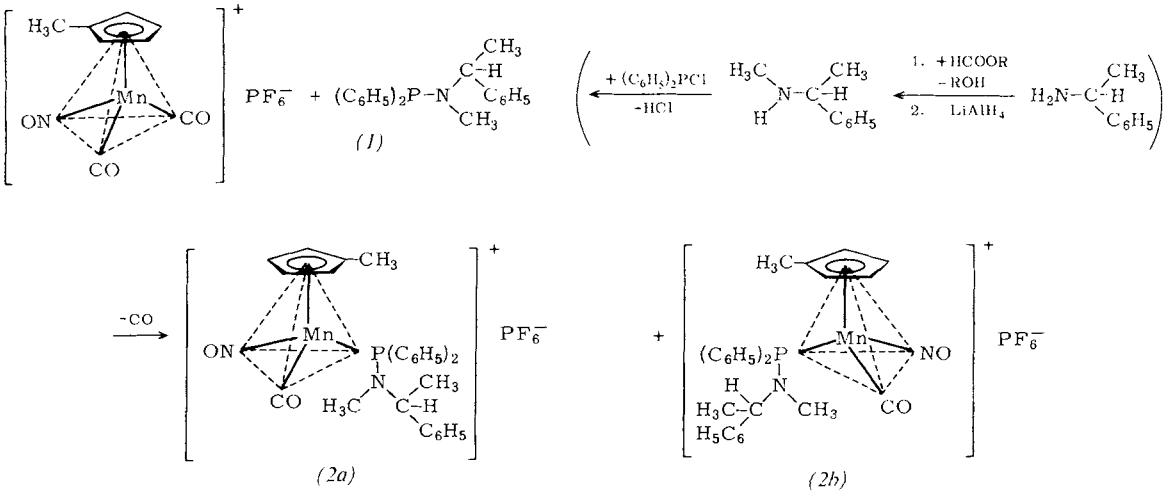
Reaction of $[C_5H_5Mn(CO)_2NO]^+PF_6^-$ with $P(C_6H_5)_3$ affords the monosubstitution product $[C_5H_5Mn(CO)(NO)P(C_6H_5)_3]^+PF_6^-$[6]. Correspondingly, *(1)* displaces one of the enantiotopic CO groups in $[CH_3C_5H_4Mn(CO)_2NO]^+PF_6^-$ (KBr: ν_{CO} 2150 and 2100 cm^{-1}; ν_{NO} 1860 cm^{-1}). There results a diastereoisomeric pair *(2a)/(2b)* which can be resolved owing to solubility differences. The optical purity of the fractions obtained in the individual separation steps can be established by NMR spectroscopy since the two diastereoisomers differ in their ^{1}H-NMR spectra.

(2a) and *(2b)* display identical IR spectra (KBr): ν_{CO} 2060 cm^{-1}; ν_{NO} 1795 cm^{-1}. Their specific rotations and ^{1}H-NMR parameters are listed in Table 1.

Like the enantiomers (+)- and (−)-$[C_5H_5Mn(CO)(NO)P(C_6H_5)_3]^+PF_6^-$, the optically active diastereoisomers *(2a)* and *(2b)* are configurationally stable[7]. The rotations of their solutions remain constant for a long period in the absence of light and oxygen.

Preparation of
(S)-(+)-(C_6H_5)PN$(CH_3)CH(CH_3)(C_6H_5)$ (1)

(*S*)-(−)-α-Phenylethylamine is at first formylated with $HCOOC_2H_5$ and then reduced with $LiAlH_4$ to give (*S*)-(−)-$(CH_3)NHCH(CH_3)(C_6H_5)$[5]: $[\alpha]_D^{25} = -82°$ (neat, $d^{25} = 0.92\,g\,cm^{-3}$). A solution of freshly distilled diphenylchlorophosphane (18.4 g, 0.08 mol) in ether (50 ml) is added dropwise to this amine (30 g, 0.22 mol) in diethyl ether (200 ml) at 0—5 °C over 2 h with exclusion of air and moisture. The reaction mixture is refluxed for 4 h, the solvent drawn off (after filtration to remove the amine hydrochloride), and the residue extracted with three 30-ml portions of pentane. After concentration of the pentane extract to 20 ml, residual hydrochloride is removed first at −20 °C and the solvent and excess amine are then removed in a high vacuum. Yield of *(1)* 93%; mass spectrum: molecular ion *m/e* 319, rel. int. 72% (based on *m/e* 262, rel. int. 100%).



Preparation of the diastereoisomeric complex salts (2a) and (2b)

$[CH_3C_5H_4Mn(CO)_2(NO)]^+PF_6^-$ (1.57 g, 4.3 mmol) in acetone (50 ml) is united with *(1)* (1.38 g, 4.3 mmol) in acetone (20 ml) at room temperature with exclusion of air (vigorous liberation of CO). After 4 h the solution is filtered and the solvent drawn off. The residue is chromatographed in CH_2Cl_2 (5 ml) over Sephadex LH 20/CH_2Cl_2. Removal of the CH_2Cl_2 leaves an oily residue which can be converted into powder form by prolonged stirring in pentane. Only

part of the yellow salt dissolves in a 30-ml portion of methanol. The more sparingly soluble fraction is dissolved in acetone and cooled to −20 °C with addition of ether (until crystallization starts). This separating operation is repeated with the resulting recrystallized product to give the less soluble (+)-rotatory diastereoisomer *(2a)* in optically pure (^{1}H-NMR) form; yield *ca.* 10%; dec. 145 °C. The methanolic solution obtained in the first fractionation is evaporated down to a volume of 3 ml and allowed to crystallize at −20 °C. After repetition of this separating step the residual solution contains the more readily soluble (−)-rotatory diastereoisomer *(2b)*, contaminated, according to the ^{1}H-NMR spectrum, with about 15% of *(2a)*; yield *ca.* 15%, dec. 130 °C.

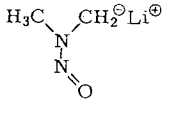
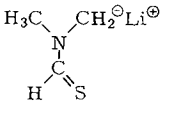
Nucleophilic Thioacylation with Solutions of Dimethylthiocarbamoyllithium[**]

By *Dieter Enders* and *Dieter Seebach*[*]

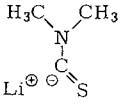
Methods for nucleophilic acylation[1] have recently found increasing application in organic synthesis[2]. In connection with our studies on nucleophilic aminoalkylation with metalated nitrosamines[3] such as *(1)* we have sought other "activating" groups and checked the possibility of preparing the lithium derivative *(2)* from dimethylthioformamide[4]. Much to our surprise a yellow solution of dimethylthiocarbamoyllithium *(3)*[5] is formed in almost quantitative yield (according to deuterolysis) on adding thioformamide to the THF solution of lithium diisopropylamide at −100 °C. Addition of benzophenone leads to the adduct *(4a)* in 85% yield (see experimental section and Table 1).



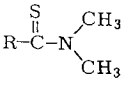
(1)



(2)



(3)



(4)

If the reaction mixture is allowed to warm to −78 °C within 15 min after the metalation and then stirred for a further 15 min period at this temperature, only 20% of *(4a)* is obtained. As shown in Table 1 other aliphatic and aromatic aldehydes and ketones can be converted into α-hydroxythioamides in good yields. Reaction with methyl iodide leads to *(4h)*, and with methyl benzoate to *(4g)* (Table 1).

Experimental:

N,N-Dimethyl-2-hydroxy-2,2-diphenylthioacetamide (4a)

To a stirred solution of lithium diisopropylamide (10 mmol) in THF/hexane (5:1) is added a solution of *N,N*-dimethylthioformamide (0.88 g, 10 mmol) in THF (2 ml) over 1 min at −100 °C. After 3 min the resultant yellow solution is treated with a solution of benzophenone (1.82 g, 10 mmol) in THF (7 ml). The bath temperature is allowed to rise to −70 °C over a period of 1 h and the reaction mixture then neutralized with glacial acetic acid (0.6 ml). Work-up

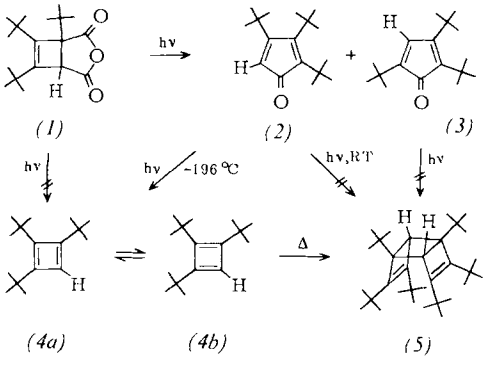
Tri-*tert*-butylcyclobutadiene[1][**]

By *Günther Maier* and *Arnaldo Alzérreca*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th Birthday

The predicted antiaromaticity of cyclobutadiene requires great reactivity, particularly towards dimerization. By introduction of sterically demanding groups it should be possible to prolong the lifetime of this molecule without disturbing the electronic character of the ring system. That this concept is correct is shown by the fact that the considerable reactivity of unsubstituted[2] and of mono-*tert*-butylcyclobutadiene[2] decreases in 1,2-di-*tert*-butyl-[3,4] and still further in 1,3-di-*tert*-butyl-cyclobutadiene[4]. Tri-*tert*-butylcyclobutadiene *(4)* might thus be able to exist as the monomer at room temperature—a suggestion that has now been proven by experiment.

Irradiation of the anhydride *(1)*[4] at room temperature leads to the cyclopentadienones *(2)* and *(3)*. As a result of an observation that the carbonyl bands of the dienones become less intense on prolonged irradiation of *(1)* in a matrix at −196°C, we have investigated their photochemical behavior further and have found that *(3)* is photostable at all temperature regions but *(2)* only at room temperature. Irradiation of *(2)* at −196°C induces elimination of carbon monoxide. The CO can be detected by IR spectroscopy, but the structure of the resulting hydrocarbon follows from the result of preparative irradiation of *(2)* in a matrix of Rigisolve[***] at −196°C: if the solution obtained on thawing is kept for a day at room temperature, the dimer *(5)* {m.p. 126—127°C; MS: $m/e = 440$ (M^+); correct elemental analyses[5]} of tri-*tert*-butylcyclobutadiene *(4)* can be isolated in 82% yield.



On irradiation for 3 h at −196°C in a glass of perdeuteriated methylcyclohexane (sealed quartz NMR tube), *(2)* is converted almost completely into a new species that is relatively stable even after warmup to room temperature and is characterized by three signals in the 100 MHz ^{1}H-NMR spectrum [$\tau = 4.65$ (1 H), 8.86 (9 H) and 8.95

[***] Rigisolve (Merck): 2,2-dimethylbutane/*n*-pentane (8:3).

(18 H)]. If this product is kept for a day at room temperature, only the spectrum of the dimer *(5)* [$\tau = 7.55$ (2 H), 8.58 (18 H), 8.79 (18 H) and 8.86 (18 H)] is recorded. It must be concluded, therefore that the intermediate is tri-*tert*-butylcyclobutadiene *(4)*.

Thus, for the first time, a cyclobutadiene has been produced that is stable at room temperature but is substituted only by alkyl groups and must therefore contain an essentially genuine π-electron system[6].

Tri-*tert*-butylcyclobutadiene *(4)*[10] is extremely sensitive to oxygen: on admission of air autoxidation is faster than dimerization.

The chemical shift of the isolated proton ($\tau = 4.65$) lies appreciably higher than that of the ring protons in 1,2,3,5-tetra-*tert*-butylbenzene (3.07[11]). It is remarkable[12, 13] that the external protons of [16]annulene (4.67[14]) and 1,7-methanol[12]annulene (4.2—4.6[15]) have almost the same chemical shift as the isolated proton in *(4)*. Consequently the NMR spectrum of *(4)* can be considered as an indication for a paramagnetic ring current (antiaromatic character) comparably strong as in the higher planar [4*n*]annulenes.

The fact that both the *tert*-butyl groups next to the hydrogen atom appear as one signal in the NMR spectrum of *(4)* can have one of two causes: either *(4)* has a square structure and a triplet ground state, or it exists as a singlet molecule with alternating bond lengths and the NMR spectrum is the result of a rapid valence isomerization *(4a)*$\rightleftharpoons$*(4b)*. We favor the second alternative, not least because of the electron spectrum of *(4)*, which has no well-developed band above 300 nm, in agreement with the predicition for a singlet cyclobutadiene that departs from D_{4h} symmetry[16].

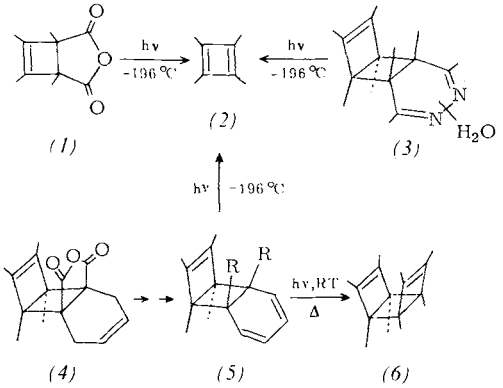
Tetramethylcyclobutadiene, an Excellent Donor Molecule[1][**]

By *Günther Maier, Wolfram Mayer, Claus Haacke*, and *Rainer Askani*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th Birthday

Tetramethylcyclobutadiene *(2)* can be prepared photochemically by removal of the anhydride grouping from *(1)*[2] or of tetramethylpyridazine from *(3)*[3]. UV-spectroscopic detection of the cyclobutadiene *(2)* frozen in a matrix at -196 °C after low-temperature photofragmentation of *(1)* is difficult because of the tetramethylcyclopentadienone that is also present[4]. On the other hand it appears reasonable to assign to the cyclobutadiene *(2)* the maximum observed on matrix-irradiation of *(3)*. Yet it remains uncertain how far charge-transfer interaction between *(2)* and tetramethylpyridazine might falsify the picture.

To obtain answers to these problems, we have sought further photoprecursors of *(2)* and have applied to the compounds *(5a)*—*(5d)* the principle used with *(3)*, namely to force formation of the cyclobutadienes by removing a component stabilized by delocalization.



(1) *(2)* *(3)*

(4) *(5)* *(6)*

(5a), R-R = -CO-O-CO- *(5c)*, R = CO_2CH_3

(5b), R-R = $-CH_2-O-CH_2-$ *(5d)*, R = CH_2OH

The anhydride *(4)* is available for preparation of *(5a)*—*(5d)*; it is readily accessible by treatment of 1,4-cyclohexadiene-1,2-dicarboxylic anhydride with 3,4-diiodo-1,2,3,4-tetramethylcyclobutene in the presence of mercury. Addition of bromine and double elimination of HBr with 1,8-diazabicyclo[5.4.0]undec-7-ene affords the anhydride *(5a)* (m.p. 112—114 °C). The action of CH_2N_2 on *(5a)* in CH_3OH leads to the diester *(5c)* (m.p. 110 °C), reduction by $LiAlH_4$ yields the alcohol *(5d)* (m.p. 165 °C); and the ether *(5b)* (m.p. 124—125 °C) is formed on reaction of *(5d)* with 1 mol of *p*-toluenesulfonyl chloride.

The structures of *(5a)*—*(5d)* are proved by their spectral data. The mass spectra show that the cyclobutadiene ring is easily split off. *(5c)* and *(5d)* contain, contrary to expectation[5], an intact bicyclo[4.2.0]octadiene ring ske-

leton although there is no additional five-membered ring to act as anchor[6].

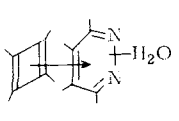
Irradiation (Hg low-pressure lamp, Vycor) of the photoprecursors *(5)* at room temperature leads to smooth cleavage in the desired manner. Products are the *syn*-tricycle *(6)* and the corresponding benzene derivative. Photofragmentation (Hg high-pressure lamp, Solidex) in acetone proved particularly suitable. Sensitized and direct irradiation of *(5a)* to *(5d)* give the same products. By way of contrast, the heterocycle yields exclusively octamethylcyclooctatetraene in place of *(6)* on sensitization by benzophenone[7].

(5a) to *(5d)* are readily split to tetramethylcyclobutadiene *(2)* and the aromatic component even on matrix irradiation (Hg low-pressure lamp, Vycor) at −196 °C. After thawing, again only the tricycle *(6)* and the appropriate benzene derivative can be detected, along with very small amounts of octamethylcyclooctatetraene.

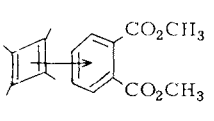
Accordingly, the same UV maximum should appear on low temperature fission of *(5a)*—*(5d)* and of *(3)*. The experimental result is, however, completely different: on irradiation of the anhydride *(5a)* the matrix becomes red (ether, pentane, tetrahydrofuran; $\lambda_{max} = 495$ nm), with the diester *(5c)* yellow (tetrahydro-2-methylfuran; $\lambda_{max} = 385$ nm), but with *(5b)* (Rigisolve) and *(5d)* (tetrahydro-2-methylfuran) the matrix remains colorless.

This means that a different UV spectrum is obtained by starting from each of six precursors although it is certain that in each case the same species, namely tetramethylcyclobutadiene, is present in the matrix. Our explanation for these contradictory results is as follows: if the photofission produces an acceptor molecule alongside the extremely good electron donor *(2)*, then a charge-transfer complex can be formed in the matrix. The necessary geometrical arrangement is already prescribed by the starting materials *(3)* and *(5)*. This possibility does not exist with the anhydride *(1)*.

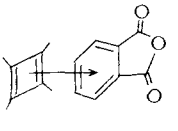
Hence: The maximum at 423 nm (tetrahydro-2-methylfuran) observed on cleavage of *(1)* arises from tetramethylcyclopentadienone; the band at 375 nm (ether, isopentane, ethanol) in the case of *(3)* has its origin in formation of the charge-transfer complex *(7)*; this interaction is better developed in the complex *(8)* and still more so in *(9)*; the absorption band is shifted to 385 and 495 nm, respectively, owing to the better acceptor properties of dimethyl phthalate and phthalic anhydride. Only on fragmentation of *(5b)* and *(5d)* "free" tetramethylcyclobutadiene *(2)* is formed—phthalan and 1,2-phenylenedimethanol do not act as acceptors. Thus, like tri-*tert*-butylcyclobutadiene[8], uncomplexed *(2)* shows no absorption band above 300 nm.



(7)



(8)



(9)

This result is in agreement with the prediction[9] for a rectangular singlet cyclobutadiene, which should have no allowed transition above a band at 198 nm, whereas a maximum at 380 nm is calculated for square triplet cyclobutadiene. Unsubstituted[10,11] and mono-*tert*-butyl-cyclobutadiene[10] are characterized by an absorption band at 305 nm. Further experiments are necessary to decide whether UV spectra may in fact be used in drawing such conclusions and whether a multiplicity exchange occurs depending on the number of substituents.

It is important in this connection that *(5a)*, *(5c)*, and *(5d)* can be split also thermally to yield tetramethylcyclobutadiene *(2)*, again with formation of *(6)*. The anhydride *(5a)* fragments even at room temperature, although then very slowly[12]; this offers the possibility of using pyrolysis to obtain information about the properties of tetramethylcyclobutadiene also at high temperatures.

ESCA Studies on N_2-, N_2H_2-, N_2H_4- and NH_3-Complexes of Manganese[**]

By *Herbert Binder* and *Dieter Sellmann*[*]

In the recently described series of manganese complexes $[C_5H_5Mn(CO)_2]_xL$ with $L = N_2$, N_2H_2, N_2H_4, NH_3, and $x = 1$ or 2 (for N_2H_2), we have, for the first time, species in which all possible reduction states of the N_2 molecule during nitrogen assimilation are bound to one and the same metal[1]. Their investigation by X-ray photoelectron (ESCA) spectroscopy ought to give an indication as to whether the formal oxidation numbers of the nitrogen in this series can be also confirmed physically, as well as providing further information about the electronic structure of the individual complexes.

Contrary to expectation the N1s binding energies of the N atoms bound directly to the metal do not reveal a regular progression on going to more negative oxidation numbers; this is even less so in the case of the Mn- and

C1s-binding energies (Table 1). Hence no strict physical significance can be attached to the formal character of the oxidation number. The results do indicate, however, that the Mn—N bonds in all complexes have about the same polarity. The N1s energy differences (Mn—N) can be ascribed to two causes: on the one hand, due to different bond orders and electronenegativities, the atoms or groups of atoms attached to these N atoms influence the effective charge—here, the different number of H atoms should be especially mentioned; on the other hand, the Mn—N bond in the various complexes has undoubtedly different σ-π character.

other hand, the N1s binding energy of the NH_3 ligand is higher by about 0.1 eV; that is, complexation effects a reversal of the N1s binding energy ratio since the N_2 molecule is rendered considerably more negative than the NH_3 molecule. This is in agreement with the generally accepted assumption that N_2 functions as a σ-π ligand, NH_3, however, as a pure σ ligand.

$$\overset{\ominus}{Mn}-\overset{\oplus}{N}\equiv N \longleftrightarrow Mn=\overset{\oplus}{N}=\overset{\ominus}{N} \qquad \overset{\ominus}{Mn}-\overset{\oplus}{N}H_3$$

(1a) *(1b)* *(2)*

Table 1. Binding energies [eV] relative to C1s (286.6 eV) of the C_5H_5 ligands and charges on the nitrogen atoms [a].

Compound	Oxidation number of the N-Atom (N—Mn)	N1s	$Mn2p_{3/2}$	Mn3s	C1s (CO)	q_p
$C_5H_5Mn(CO)_3$	—	—	642.1	86.7	288.6	—
$C_5H_5Mn(CO)_2N_2$	0	403.0; 401.8	641.8	85.9	288.9	+0.36; +0.16
$[C_5H_5Mn(CO)_2]_2N_2H_2$	−1	403.6	642.2	86.8	288.2	+0.47
$C_5H_5Mn(CO)_2N_2H_4$	−2	402.7; 401.7	641.8	85.9	288.1	+0.31; +0.14
$C_5H_5Mn(CO)_2NH_3$	−3	403.1	641.7	85.8	290.0	+0.39

[a] The charges were determined from the correlation diagram given in Ref. [3].

The doublet structure of the N1s spectrum (Fig. 1a) of the N_2 complex is a direct indication of terminal bonding of the N_2 molecule to the Mn atom; since, according to chemical findings, the second N atom exhibits Lewis basicity and must therefore be negatively polarized it is very likely represented by the lower binding energy peak at 401.8 eV. ESCA studies on different N_2 complexes[2] also reveal "end-on" bonding and greater negative charge on the terminal N atom. According to *Nordberg et al.*[3] the N1s binding energy varies almost linearly with the charge (calculated on the basis of Pauling electronegativities), 5 eV corresponding to one atomic unit of charge. Accordingly, the difference of 1.2 eV between the two N1s lines in the N_2 complex corresponds to a charge separation of 0.24 atomic charge units. The N1s spectrum of the N_2H_4 complex (Fig. 1b) shows only one broad band, which originates from an unresolved doublet (distance between components, according to a computer analysis *ca.* 1.0 eV).

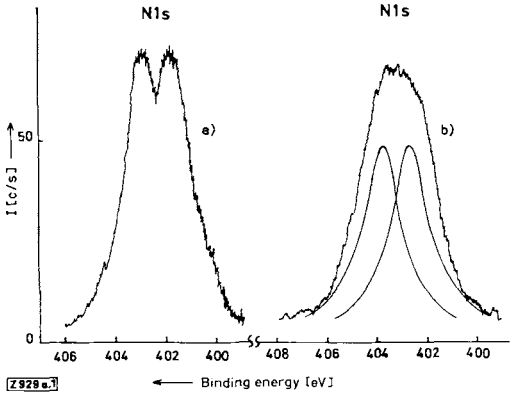

Fig. 1. ESCA spectrum of the 1s electrons of the nitrogen in a) $C_5H_5Mn(CO)_2N_2$, b) $C_5H_5Mn(CO)_2N_2H_4$.

Of special interest are the electronic changes which such different molecules as N_2 and NH_3 experience during complexation with a metal. In the gaseous phase N_2 has a binding energy about 4.3 eV higher than that of NH_3[4]. After addition to the $C_5H_5Mn(CO)_2$-fragment, on the

This also explains why a larger formal charge separation is observed for the N atom in $C_5H_5Mn(CO)_2N_2$ than in $C_5H_5Mn(CO)_2N_2H_4$. In contrast to the terminal N atom of the N_2H_4 complex, that in the N_2 complex can accept a negative charge, thus leading to increased polarity of the N—N bond. As in the case of the N_2 complex, ligand-metal σ-π interactions can be assumed to take place also in the N_2H_2 complex.

$$\overset{\ominus}{Mn}-\overset{\oplus}{N}H=\overset{\oplus}{N}H-\overset{\ominus}{Mn} \longleftrightarrow Mn=\overset{\oplus}{N}H-NH-\overset{\ominus}{Mn} \longleftrightarrow \overset{\ominus}{Mn}-NH-\overset{\oplus}{N}H=Mn$$

(3a) *(3b)* *(3c)*

Vibrational and ^{1}H-NMR spectroscopic findings would indicate the contributing form *(3a)* to be the most important form; this would also explain the relatively high N1s binding energy of 403.6 eV.

The binding energies of the $Mn2p_{3/2}$ levels are almost the same in all the complexes (Table 1), thus indicating that the charges on the manganese are roughly equal and that "long range" effects by the next but one neighboring atoms can be ruled out. Remarkably, however, the $Mn2p_{3/2}$ energy in $C_5H_5Mn(CO)_3$ decreases by 0.3 eV on substitution of a CO by the N_2 ligand. It can be concluded, therefore, that the total electron density of the Mn atom is greater in $C_5H_5Mn(CO)_2N_2$ than in $C_5H_5Mn(CO)_3$.

Experimental:

The X-ray photoelectronic spectra were recorded with a AEI-ES-100 spectrometer [photoionization with Al-$K\alpha_{1,2}$ (1486.6 eV)]. In order to avoid charge effects the compounds were sublimed at 20 °C as a thin film onto a cooled sample holder.

cis-Diiminebis(pentacarbonyltungsten)[1]

By *Dieter Sellmann, Alfred Brandl*, and *Ralf Endell*[*]

Diimine, H—N=N—H, in complexed form is being discussed as an intermediate in N_2-assimilation[2]. The only transition metal complexes of diimine known to date are those with manganese and with chromium[1,3]. In an attempt to prepare the corresponding complex with tungsten by an analogous route we have found that the hydrazine complexes of chromium and tungsten employed as starting materials exhibit surprisingly different reactivities. Even more striking is the influence of the central metal atom in the comparable N_2H_4- and N_2H_2-bridged complexes of molybdenum: They are obviously so labile that until now only their intermediate existence has been observed. The different reactivities of Cr, Mo, and W complexes may reflect why molybdenum functions as an active center in nitrogenases. The analogous reaction for the synthesis[1] of $N_2H_2[Cr(CO)_5]_2$ *(1)*

$$\underset{(2)}{N_2H_4[W(CO)_5]_2} + H_2O_2 \xrightarrow[Na_2SO_4/-20\,^\circ C]{THF/HCl/Cu^{2+}} \underset{(3)}{N_2H_2[W(CO)_5]_2} + 2H_2O \quad (1)$$

led to a red coloring of the previously yellow reaction solution; thus indicating the formation of *(3)*. However, the desired tungsten complex could not be isolated. Only on using a tenfold excess of H_2O_2 could a very small quantity of *(3)* (<1%) be extracted from the insoluble reaction products.

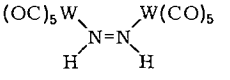
The oxidative formation of binuclear diimine from mononuclear hydrazine complexes, *e.g.* in the case of $N_2H_2[C_5H_5Mn(CO)_2]_2$ *(4)*, involves the occurrence of several reactive intermediates, which accounts for the very low yield of end product[3]. It is surprising, therefore, to find that a much better method for the preparation of *(3)* lies in the oxidation of the mononuclear hydrazine complex *(5)*:

$$\underset{(5)}{(OC)_5W{-}N_2H_4} + H_2O_2 \xrightarrow[Na_2SO_4/0\,^\circ C]{THF/Cu^{2+}} (3) + (2) + \text{decomposition products} \quad (2)$$

The compound *(3)* (black crystals after recrystallization from dark red-violet solutions in THF) decomposes in a sealed tube at 142—145 °C to give, *inter alia*, $W(CO)_6$. Even more surprising than the synthesis according to eq. (2), however, is the finding that *(3)* is obtained in the *cis*-form. Steric considerations, as well as the synthesis of *(4)*, would lead one to expect the *trans*-form. The *cis* structure of *(3)* is deduced from the IR spectrum (KBr), which shows five medium strong bands in the range 4000 to 600 cm^{-1}, very clearly separated from the typical absorptions of the $W(CO)_5$ groups. The five bands are characteristic for the *cis*-N_2H_2 ligand: 3450, 3250 (ν_{as} and ν_sNH), 1385 (νN=N), 1355 and 1085 cm^{-1} (δ_{as} and δ_sH—N—N—H). The shift of 30 cm^{-1} of the ν(N=N) vibration to lower frequencies compared to *(1)* points to a certain coupling with the νM—N vibration.

The ^{1}H-NMR spectrum ([D_6]-acetone, 26 °C) shows only a single peak at 16.38 ppm (referred to TMS), whose large shift is typical for protons of complexed diimine. The acidity derived therefrom is shown also in the H-D exchange with CD_3OD, which proceeds much more rapidly than in *(2)* or $(CO)_5WNH_3$.

IR, ^{1}H-NMR, and mass spectra, and the results of an elemental analysis lead us to propose the following structure, *i.e. cis*-diiminebis(pentacarbonyltungsten) for *(3)*.



UV-irradiation of a THF solution at −78 °C converts *(3)* into a dark blue compound, the color of which remains unchanged during evaporation of the solvent. The blue product is extremely thermolabile and is reconverted at −40 °C, both in the solid state as well as in solution, into the starting product *(3)*. Further investigations should clarify whether this blue substance is *trans*-*(3)* or perhaps the nitrene complex $(CO)_5WNH$ *(7)*.

Procedure:

All operations are carried out under nitrogen in anhydrous solvents.

0.75 g (2.1 mmol) of *(5)* is dissolved in THF (3 ml) in a Schlenk tube, cooled to −78 °C and stirred under addition of 4 g of Na_2SO_4, 0.05 ml of 0.1 N $CuSO_4$—H_2O solution, and 0.1 ml of H_2O_2 (70%) in 0.5 ml of THF. The highly viscous pulp is allowed to warm to 0 °C. After about 10 seconds the reaction starts and the yellow suspension changes color to red; after a further 10 seconds evolution of gas begins. After a total period of 5 minutes and evolution of *ca.* 140 ml of gas the reaction comes to a standstill. The solvent is evaporated at −20 °C; the black-brown residue is dried for 8 hours between −20° and +10 C in a high vacuum and then extracted four times with 10 ml of THF. The combined extracts are filtered at −20 °C and cooled down to −78 °C for 2 hours. Approximately 100 mg of crude *(3)*, contaminated with *(2)*, is precipitated. Twofold recrystallization from 5 ml of THF at −78 C affords pure *(3)*. Yield about 80 mg.

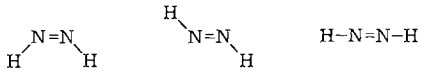
Structure of Diimine: IR Spectra of N_2H_2-, N_2D_2-, and $^{15}N_2H_2[Cr(CO)_5]_2$[1]

By *Dieter Sellmann, Alfred Brandl*, and *Ralf Endell*[*]

Such contradictory spectroscopic reports have seldom been made for a molecule as for diimine, HN=NH *(1)*. The

[*] Dr. D. Sellmann, Dipl.-Chem. A. Brandl, and Dipl.-Chem. R. Endell
Anorganisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

published studies on *(1)* are all characterized by the following features: 1) the samples contained large proportions of contaminants, *e. g.* up to 80% of NH_3; 2) the IR spectra were so poorly reproducible that agreement could not be reached even about the strong bands; 3) the theoretically required number of absorptions has never been found in the IR or UV spectra of *(1)*. Thus it is hardly surprising that the *cis* structure *(1a)*[2], the *trans* structure *(1b)*[3], and even mixtures of both[4] have all been deduced from the existing spectroscopic data. Other structures, such as *(1c)*, were ruled out only for chemical reasons; in no case has an unambiguous assignment of all the vibrational frequencies of *(1)* been possible.

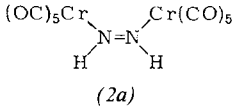


(1a) *(1b)* *(1c)*

However, unequivocal statements concerning the vibrational frequencies and the structure of *(1)* become possible with the IR spectra of the μ-diimine complexes $N_2H_2[Cr(CO)_5]_2$ *(2)*, $N_2D_2[Cr(CO)_5]_2$ *(3)*, and $^{15}N_2H_2[Cr(CO)_5]_2$ *(4)*. Complex *(3)* is obtained from *(2)* by H/D exchange with CH_3OD, while *(4)* is prepared by the same method as *(2)*[5] but with ^{15}N-labeled N_2H_4. H/D exchange with *(2)* and *(3)* proceeds so rapidly that protons are repeatedly reintroduced into pure *(3)*.

The characteristic absorptions of the $Cr(CO)_5$ groups, whose assignment is established by comparison with other compounds, appear in *(2)*, *(3)*, and *(4)* at the same frequencies. Their number, position, and intensity in the solid and in THF solution (νCO: 2055 w, 1950 vs, 1923 s cm^{-1}) indicate an almost undistorted C_{4v} symmetry of the $Cr(CO)_5$ groups and justify the assumption of local symmetry for the N_2H_2 ligands too. $Cr(CO)_5$ groups show no (typical) absorptions between 4000 and 2100, and 1800 and 700 cm^{-1} respectively; for this reason alone the bands appearing in these regions can be attributed to the diimine ligands. This assignment is supported by the spectra of the isotopically labeled compounds.

Since the selection rules require that 5, 3, and 2 normal modes of *(1a)*, *(1b)*, and *(1c)*, respectively, be IR active, the number of bands observed indicate that *(1)* has the *cis* form *(1c)* in the complex *(2)*. Particularly characteristic of *(1a)* is the occurrence of an N=N stretching vibration which is IR inactive in *(1b)* and *(1c)*. This constitutes the first spectroscopic proof for diimine in the *cis* form, corresponding to the proposed structure *(2a)* for the complex *(2)*.



(2a)

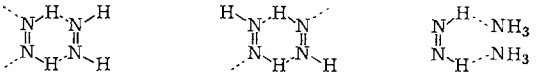
The frequencies observed[7] for the diimine ligands in *(2)*, *(3)*, and *(4)* are listed in Table 1.

Thus, contrary to previous observations[2-4], the NH stretching vibrations have values to be expected for NH compounds, and particularly for those in which the N atom participates in multiple bonds. Surprisingly, the isotopic shifts agree fairly accurately with the values calculated for free diimine; nevertheless, the N=N and Cr—N stretching vibrations are probably coupled, since the (N=N) vibration in $N_2H_2[W(CO)_5]_2$ *(5)*, an analog of *(2)*, is observed at 1385 cm^{-1}. The other N_2H_2 vibrations, however, display a remarkable lack of sensitivity to changes of the central metal and display practically the same frequency in *(2)* as in *(5)*; they thus represent almost pure diimine vibrations.

Table 1. IR frequencies (KBr; cm^{-1}) of the diimine ligands in the complexes *(2)*, *(3)*, and *(4)*.

N_2H_2	N_2D_2	$^{15}N_2H_2$	Assignment
3480	2445	3435	ν_{as}(NX)
3250	2380	3250	ν_s(NX)
1415	1415	1370	ν(N=N)
1352	998	1350	δ_{as}(XNNX)
1105	820	1105	δ_s(XNNX)

A close relationship between the vibrational frequencies of complexed and free diimine is clearly apparent. A series of observations[6] suggests that diimine most probably forms strong hydrogen bonds with Lewis bases in the solid state. Such a Lewis base may be diimine itself *(1d)* or *(1e)* or, for example, NH_3 *(1f)*.



(1d) *(1e)* *(1f)*

Solid state IR spectra, even of pure diimine[6b], can therefore only be expected to display frequencies that are shifted relative to those of free diimine. Association as in *(1d)*—*(1f)* is ruled out for the diimine in *(2)* which can thus be regarded to a first approximation as free *(1)* embedded in a matrix of $Cr(CO)_5$ molecules.

Diphosphane-Transition Metal Complexes: $P_2H_4[Cr(CO)_5]_2$ and $P_2H_4[C_5H_5Mn(CO)_2]_2$[1]

By *Dieter Sellmann*[*]

Spontaneous combustion in air, thermolability, extreme sensitivity to light, and toxicity make disphosphane, P_2H_4, a substance that can be handled only when special safety precautions are enforced. However, for studying the reactivity of complexed molecules such properties—apart from toxicity—are often highly desirable. They favor reactions under conditions which are mild enough to prevent breakage of the metal-ligand bond.

[*] Dr. D. Sellmann
Anorganisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

It has now become possible, for the first time, to complex P_2H_4 with a transition metal. Compared to the instability of the free molecule, the diphosphane complexes are surprisingly stable.

Reaction of P_2H_4[2] according to eq. (1),

$$2(OC)_5CR\cdot THF\,[3] + P_2H_4 \xrightarrow[-78\ C]{THF} P_2H_4[Cr(CO)_5]_2 + 2\,THF \qquad (1)$$

(1) (2)

removal of the solvent at $-30\,°C/10^{-3}$ torr, and threefold recrystallization of the residue from tetrahydrofuran (THF) at -78 C affords the THF adduct of the P_2H_4-bridged complex *(2)* as colorless crystalline needles, which on drying (20 $C/10^{-3}$ torr) decompose to a yellow powder, the analytically pure diphosphanebis(pentacarbonylchromium) *(2)*.

(2) is soluble in THF and in acetone, but insoluble in non-polar solvents; in the solid state it is converted into brown or green decomposition products, only after several hours exposure to light or air respectively. *Inter alia*, $(OC)_5CrPH_3$ *(3)*[4] could be detected in the brown products. *(2)* melts at 165—168 C with decomposition to a black liquid, which, on further heating, solidifies with evolution of gas and formation of $Cr(CO)_6$. An attempt to prepare the mononuclear manganese complex $C_5H_5Mn(CO)_2P_2H_4$ *(4)* according to eq. (2) and using an excess of P_2H_4 proved unsuccessful. Contrary to expectation a dinuclear complex is formed.

$$C_5H_5Mn(CO)_2\cdot THF\,[3] + 3\,P_2H_4 \xrightarrow[-78\ C]{THF} P_2H_4[C_5H_5Mn(CO)_2]_2 \quad (2)$$

(5) (6)

+ by-products

After dropwise addition of *(5)* (30 mmol in 400 ml THF) to a solution of P_2H_4 (90 mmol) in THF (30 ml) all volatile fractions were removed by evaporation at -30 C and the resulting residue dried for 24 h at 20 $C/10^{-3}$ torr. Fivefold recrystallization of the black-brown residue from toluene at -78 C afforded analytically pure diphosphanebis(cyclopentadienyldicarbonylmanganese) *(6)* as pale brown crystalline needles. According to IR and ^{1}H-NMR spectra the mother liquors contained, in addition to *(5)*, at least one further compound containing $C_5H_5Mn(CO)_2$- and P_xH_y groups which, however, has not yet been identified.

(6) is soluble in benzene, toluene, THF, and acetone but insoluble in petroleum ether. Like *(2)* the compound is surprisingly stable towards light and air but not in solution, whereupon it is rapidly converted into black-brown products. *(6)* melts with decomposition at 152—155 °C.

The binuclear character of *(2)*, like that of *(6)* was established by the mass spectra, in which the molecular ions appear at $m/e = 452$ and 418 respectively.

The ^{1}H-NMR spectrum of *(2)* (in [D_6]-acetone, 30 C) shows a doublet for the P_2H_4 protons at $\delta = 5.07$ ppm, $J_{PH} = 351$ Hz. The IR spectrum (KBr) contains, alongside the νCO frequencies of the $Cr(CO)_5$ groups (2070, 1950, and 1910 cm^{-1}), characteristic absorptions for the P_2H_4 ligands at 2380w, 2345m (νPH), 1075m and 750s cm^{-1} (δPH_2). In the ^{1}H-NMR spectrum of *(6)* (in C_6D_6, 25 C), two signals appear at $\delta = 4.16$ and 4.42 (intensity ratio 5:2) due to the C_5H_5- and P_2H_4-protons respectively. The P_2H_4 signal is split by P—H coupling into a doublet ($J_{PH} = 334$ Hz), the C_5H_5 signal into a pseudo-triplet ($J_{P-C_5H_5} = 1.5$ Hz). The IR spectrum (KBr) contains, in addition to the $C_5H_5Mn(CO)_2$ bands, absorptions at 2355vw, 2335m, 1075m and 755s cm^{-1}, which can be ascribed to the P_2H_4 ligand.

Elemental analysis and mass, IR, and ^{1}H-NMR spectra confirm the bridging function of diphosphane in the complexes *(2)* and *(6)*. The surprising stability of the two complexes in the solid state might be due to matrix-like embedding of the reactive diphosphane into the bulky carbonylmetal groups and back-bonding effects.

Triethyloxonium and Nitrosyl Tetrafluoroborate: Reagents for Preparative and Mechanistic Organic Chemistry

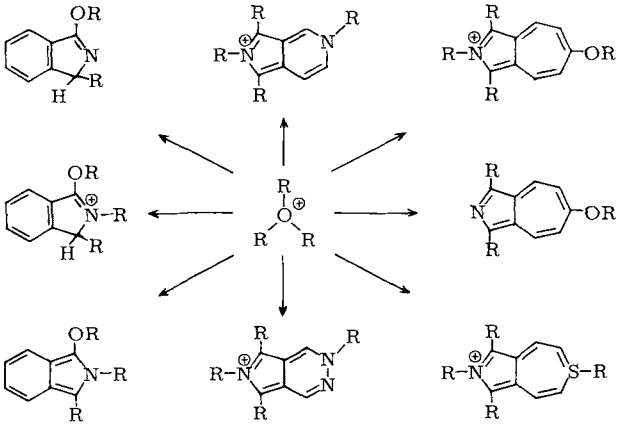
By *Richard Kreher*[*]

Trialkyloxonium tetrafluoroborates *(1)*, introduced into preparative chemistry by *Meerwein*[1], are characterized by their electrophilic reactivity and have acquired experimental importance, in particular for selective alkylation of ambifunctional compounds. In these conversions the reagents usually display a preference for oxygen-containing functional groups[2].

$[R_3O^+]\,BF_4^-$ *(1)* $[N{\equiv}O^+]\,BF_4^-$ *(2)*

Nitrosyl tetrafluoroborate *(2)* often exhibits similar properties as an electrophilic reagent[3]; however, towards ambivalent compounds the nitrosyl cation displays a complementary behavior. A remarkable affinity for nitrogen-containing functional groups is observed as a consequence of nitrosation reactions in general[4].

In our experience[5] the tertiary oxonium salt *(1)*, $R = C_2H_5$, has proved an important alkylating agent in the synthesis of *c*-fused pyrrole and pyrrolenine derivatives with $(4n+2)\pi$- and $4n\pi$-electrons. For this purpose 3-alkyl- and 3-aryl-isoindolin-1-ones, also 3-alkyl- and 3-aryl-1-alkoxy-isoindolenines, were alkylated; and for the same reason alkylation reactions were carried out with 5-aza- and 5,6-diaza-isoindoles and with pyrrolo[3,4-*d*]tropones and pyrrolo[3,4-*d*]thiepins. The spectroscopic and chemical properties of the conjugated heterocyclic π-systems synthesized in this way were determined by the presence of benzenoid, quinonoid, or fulvenoid structural units.



Scheme 1. Synthesis of conjugated heterocyclic $(4n+2)\pi$- and $4n\pi$-systems.

In order to substantiate the selectivity rules we investigated the alkylation of isoelectronic heterocycles containing cyclic hydroxylamide, hydrazide, acid amide and amidine structures. As model compounds we used the six-membered 2,3-1*H*-benzoxazin-1-ones, 2,4-1*H*-benzoxazin-1-ones, 2,4-1*H*-benzodiazin-1-ones, and 1,2,3-4*H*-benzotriazin-4-ones; and as further examples the ambifunctional behavior of the five-membered isoxazolinones, pyrazolinones and imidazolinones was investigated.

The tertiary oxonium salts *(1)* also play an important role in the formation of nitrenoid intermediates from *N*-alkoxy-*N*-arylcarboxamides. Acyclic hydroxylamine derivatives can be converted by *O*-alkylation and solvolysis into aromatic azo compounds; the course of the reaction may involve *N*-alkoxy-*N*-arylamide ions which are important precursors on the way to reactive nitrenes. Formation of azo compounds depends on electronic and steric factors. The intermolecular course was established by competitive reactions. This reaction sequence is applicable not only to acyclic but also to cyclic hydroxylamine derivatives.

From a mechanistic viewpoint the electrophiles *(1)* and *(2)* are also relevant to the study of cationic intermediates with a central nitrogen atom[6]. In particular the systematic application of nitrosyl tetrafluoroborate *(2)* has been studied on a more general basis for generation of *N*-diazonium ions *(3)* and nitrenium ions *(4)*.

(3) *(4)*

For this purpose mainly the nitrosation of 2-tetrazenes and hydrazine derivatives containing a protecting group was investigated. Nitrosation of organic azides[7] opens a route to the reactive diazonium ions *(3)*, $R' = NO$, to be considered as possible precursors of the electrophilic nitrenium ions. The reactions specific to the cationic intermediates *(3)* and *(4)*—namely intermolecular alkylation and amination of benzenoid compounds, and intramolecular isomerization leading to immonium salts—to a large extent can be explained mechanistically[8].

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Reactions of hydrazones are summarized by *Yu. P. Kitaev* and *B. I. Buzykin*. Compounds containing the structural unit $\geq C{=}N{-}N \leq$ display a variety of reactions of preparative interest. They react with electrophiles and nucleophiles and undergo additions and cycloadditions with multiple bonds. These reactions provide a good route to heterocyclic systems. [The Reactions of Hydrazones. Russ. Chem. Rev. *41*, 495—515 (1972); 412 references]

[Rd 662 IE—Q]

Production and reactions of diazomalonic esters *(1)* are considered by *B. W. Peace* and *D. S. Wulfman*. Their synthesis is carried out by diazo transfer from tosyl azide to malonic esters in the presence of a base, generally an amine. *(1)* provides an entry to a series of geminally substituted cyclopropanes, *endo*-substituted bicyclo[*n*.1.0] systems, and selectively cyclopropanated polyolefins, a photolytic step leading to intermediate formation of carbenes $C(COOR)_2$. Addition of *(1)* to olefins in the presence of Cu and Cu salt catalysts is characterized by appearance

$$N_2C(COOR)_2 \qquad (1)$$

of cyclopropane, accompanied by allyl insertion products.—The review covers the reactions of *(1)* with ethers, alkyl sulfides, amines, sulfoxides, allyl sulfides, and halides. [Preparation and Reactions of Diazomalonic Esters, Synthesis *1973*, 137—145; 36 references]

[Rd 651 IE—M]

The stereochemistry of free-radical additions to norbornene and norbornadiene systems has been studied by *V. A. Azovskaya* and *E. N. Prilezhaeva*. The authors discuss the influence of the degree of substitution of the bicyclic compound on the direction of free-radical attack, taking account of steric and electronic effects. The resulting norbornene radicals often undergo radical rearrangements. [Stereochemistry of Free-Radical Additions in the Bicyclo[2.2.1]heptene and Bicyclo[2.2.1]heptadiene Row. Russ. Chem. Rev. *41*, 516—528 (1972); 109 references]

BOOK REVIEWS

The Chemistry of Thallium. By *A. G. Lee*. Elsevier Publ. Comp., Amsterdam—London—New York 1971. 1st ed., xi, 336 pp., 41 figs., 61 tables, bound, *ca.* DM 70.—.

It is usually difficult to obtain a complete survey of the chemistry of elements for which no volume of Gmelin has appeared for more than 20 years. The present monograph on thallium contains 1644 references covering the literature from the publication of the last volume of Gmelin on this element (1940) up to the beginning of 1970, and in addition to a survey of earlier knowledge on thallium it describes in particular the lines of development of the last decade.

The book is divided into six chapters on the inorganic chemistry of thallium, two detailed chapters on organothallium compounds, a theoretical chapter on redox reactions of thallium, and a chapter on alloys, borides, carbides, nitrides, and hydrides. Despite the abundance of subject matter, the text is fluid and readable, and in addition to the information on the compounds, which is often presented in the form of tables, it offers a good balance between thermodynamic and structural approaches. The only area in which there is still some lack of clarity is in the author's discussion of bond theory, which reflects the considerable gaps that still exist in our knowledge on this aspect of thallium chemistry. One omission is a detailed discussion of the nuclear resonance of thallium, on which, apart from a few references scattered through the rest of the text, there are only three consecutive pages, which deal almost exclusively with Tl—H coupling constants. On the other hand, the material on the Tl(I)—Tl(III) transition has been very carefully assembled.

In addition to its description of the present position of thallium chemistry, the monograph also points out many gaps that still exist in our knowledge, and should thus stimulate future thallium research. It should find a place in any inorganic chemistry library, and should also be of great value of organometallic chemists.

Martin Dräger [NB 166 IE]

Heterogene Katalyse (Heterogeneous Catalysis). By *E. G. Schlosser*. Verlag Chemie GmbH, Weinheim/Bergstr. 1972. 1st ed. ix, 171 pp., 55 figs., 10 tables, bound DM 24.—.

According the author's foreword, this modern book is intended as a primer covering the basic principles of the extensive field of heterogeneous catalysis.

The book is divided into five chapters, which can be read more or less independently of one another. The introduction deals with the structure of the catalyst and the principles of reaction kinetics, and the second chapter describes the interactions between the reactant and the catalyst. The third chapter (Reaction Mechanisms and Kinetics) deals with the formal kinetics of decomposition and combination reactions, absolute values of the reaction rate, fundamental mechanistic conceptions, and geometric and electronic factors. Reactions and technical processes are given as examples in the next chapter. A link with technical

aspects is provided by the final chapter, Transformation in the Reactor. This chapter describes the technical execution of reactions particularly with respect to transport phenomena and selectivity. The chapter ends with a discussion of the optimum catalyst.

The book is clearly written and readable throughout. In view of the abundance of facts and the clear presentation, it is to be hoped that it will be of use not only to students but also to chemists in research and industry.

Kurt Thomke [NB 173 IE]

Ausgewählte Methoden der Wasseruntersuchung. (Selected Methods of Water Investigation). Vol. 1. Published by the Institut für Wasserwirtschaft, Berlin. VEB Gustav Fischer Verlag, Jena 1971. 1st ed., xv, 250 pp., 6 figures, 6 tables, loose leaf volume DM 29.—.

This collection of water investigation methods written by a group of authors under the editorship of *Christa Legler* is based mainly on experience in the laboratories of water authorities, health establishments, and polytechnics in the member countries of the Council for Mutual Cooperative Association. The first part, which comprises about 40 system numbers, is to be supplemented by two others at intervals of about one year each.

The classification of the subject matter follows well-known patterns, and is based on the nature of the substances present in the water, *e.g.*, dissolved gases, cations, anions, organic substances, *etc.* The authors' approval of well-known works in the literature can also be seen in the treatment of the objects of investigation. A brief introduction is followed by sections on special sampling, preservation of the sample, qualitative and quantitative determination, range of application of the method, possible sources of interference and their elimination, equipment and chemicals required, investigation procedure, calculation, and expression and rounding-off of the results.

Corresponding to the importance of sampling, a general, very detailed section is first devoted to this topic. Special emphasis is placed, *inter alia*, on the detailed indication of preservatives where sampling and examination are separated by a period in which changes in the substances contained in the water could occur.

It remains to be seen whether all the data in this section will survive the results of more recent and still current investigations. Doubts are certainly in order when one reads about "very mild preservation" by storage of the water sample in the dark at 1 to 3°C with no reference to the extremely effective method of deep freezing.

The principal methods discussed in this first part include those for the determination of iron, manganese, and mercury ions, cyanide phosphate, and silicate ions, the biochemical and chemical oxygen demands, and phenols and surfactants; for these methods the literature has been covered in part up to 1970, but the last five years appear to have been overlooked in places.

The presentation is generally clear and easy to grasp; in places, however, both in the wording of the text and in the reproduction of physical quantities and equations, one misses the exactness that is to be expected and that is in fact found on other pages. However, this critical observation can in no way detract from the value of the part that has appeared so far, but should encourage the team of authors to pay due attention to the "externals" in future parts.

B. Braukmann [NB 158 IE]

Selective Ion Sensitive Electrodes. By *G. J. Moody* and *J. D. Thomas*. Merrow Publ. Co. Ltd., Watford 1971. 1st ed., vii, 140 pp., numerous figures, bound £ 2.25.

The booklet under review very strongly stresses the practical use of ion-selective electrodes. Thus there is a distinct emphasis on the assessment of parameters of the various types of electrodes, which are divided into glass electrodes and homogeneous and heterogeneous solid and liquid membrane electrodes. The discussion deals particularly with the selectivity of the electrodes (with the methods for its determination), speed of response, e.m.f. stability, reproducibility, life, detection limits, and general construction. Valuable hints on the calibration of the electrodes and their effective practical use are also given. A particularly useful feature is the remarkably objective assessment of a series of commercial ion-selective electrodes, which is documented by numerous tables and illustrations and has been partly supplemented by the authors' measurements.

The theoretical treatment of the membrane phenomena and their practical consequences are somewhat oversimplified in places, or are even totally absent; minor shortcomings (cf. *e.g.* Fig. 29) occasionally call for some additional thought on the reader's part.

Nevertheless, the book can be recommended strongly and without reservations to all those who have to use ion-selective sensors in analytical practice.

Wilhelm Simon [NB 160 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Activation and Decay Tables of Radioisotopes. By *E. Bujdosó, I. Fehér*, and *G. Kardos*. Elsevier, Amsterdam 1973. 575 pp., bound Dfl. 100.00/$ 35.00.

Advances in Inorganic Chemistry and Radiochemistry, Vol. 15. Edited by *H. J. Emeléus* and *A. G. Sharpe*. Academic Press, New York—London 1972. vii, 451 pp., bound $ 24.00.

Contents: Secondary Bonding to Nonmetallic Elements; Mössbauer Spectra of Inorganic Compounds: Bonding and Structure; Metal Alkoxides and Dialkylamides: Fluoroalicyclic Derivatives of Metals and Metalloids; The Sulfur Nitrides.

Principles of Reaction Kinetics. by *P. G. Ashmore*. 2nd Edit., in the series "Monographs for Teachers". The Chemical Society, London 1973. 78 pp., stitched 80 p.

Contents: Introductory Survey; Rates and Rate Laws for Elementary Reactions; Rate Laws for Some Complex Reactions: Chain Reactions; Résumé of Aims and Principles.

Foreign Compound Metabolism in Mammals, Vol. 2. By *D. E. Hathway et al.* The Chemical Society, London 1973. xv, 513 pp., bound £ 11.00.—A volume in the series "Specialist Periodical Reports".

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
PR = Patent abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSORPTION of light by organic molecules in electric fields—some new applications (CR) 84 [G.E. *85*, 47 (1973)]

Accelerator, A delayed-action ~ (PR) 86

Acepleiadylene, New route to the ~ system (SC) 1009 [G.E. *85*, 1113 (1973)]

Acetylene, Formation of 1,2,4-triazolin-5-ones from tert-butylnitro-~ and phenylhydrazines (SC) 406 [G.E. *85*, 447 (1973)]

Acoustics, Molecular ~ (Book Review) 89

Acrylates, Ethyl 3-acyl-2-thioxo-1,3-oxazolidine-4-carboxylates and their conversion into ethyl α-(N-acylamino)-~ (SC) 656 [G.E. *85*, 659 (1973)]

Acrylic esters, 2-Alkylthio-2-oxazoline-4-carboxylic esters and their conversion into α-(N-alkylthiocarbonylamino)-~ (SC) 658 [G.E. *85*, 660 (1973)]
3-Substituted 2-isothiocyanato-~ (SC) 923 [G.E. *85*, 909 (1973)]

Acrylonitrile copolymer films, fibers, and filaments having stable luster (PR) 936

Acylation, Stereoselective ~ of racemic secondary alcohols with phenyltrifluoromethylketene as an experimental test of the stereochemical analogy model (FP) 25 [G.E. *85*, 16 (1973)]
Syntheses of heterocycles by intramolecular ~ of nitrile-hydrogen halide adducts (FP) 119 [G.E. *85*, 155 (1973)]

Acyl chlorides, Reaction with nitriles in the presence of hydrogen chloride (LA) 934

Acyl migration, 1,3-Dipolar addition of cyclic diazo ketones to alkynes and cyclopropene. Synthesis of heterocycles by [1,5]-~ (SC) 240 [G.E. *85*, 259 (1973)]

Acylneuraminic acids, Chemistry and biology (FP) 127 [G.E. *85*, 128 (1973)]

Acyl phosphates, Five-membered cyclic ~, a new class of extremely reactive phosphorylating agents (SC) 66 [G.E. *85*, 39 (1973)]

Addition polymerization, Thermodynamics of ~ processes (FP) 487 [G.E. *85*, 533 (1973)]

Additives, Chemical analysis of ~ in plastics (Book Review) 939

Alcohols, Stereoselective acylation of racemic secondary ~ with phenyltrifluoromethylketene as an experimental test of the stereochemical analogy model (FP) 25 [G.E. *85*, 16 (1973)]
Phase-transfer-catalyzed alkylation of ~ by dimethyl sulfate in an aqueous system (SC) 846 [G.E. *85*, 868 (1973)]

Aldehydes, New method for addition of ~ to activated double bonds (SC) 81 [G.E. *85*, 89 (1973)]
Conversion of ketones or ~ into the next higher nitrile (SC) 407 [G.E. *85*, 402 (1973)]

Alkaloids, Photochemical synthesis of isoquinoline ~ (LA) 343
Application of phenolic oxidation to total synthesis of isoquinoline- and related ~ (LA) 512

Alkenes, Stereospecific oxidation of ~ by iodine tris(trifluoroacetate) (SC) 163 [G.E. *85*, 175 (1973)]

Alkylation, ~ and redox behavior of a squaric amidine (SC) 149 [G.E. *85*, 143 (1973)]
Phase-transfer-catalyzed ~ of alcohols by dimethyl sulfate in an aqueous system (SC) 846 [G.E. *85*, 868 (1973)]
New methods for ~ of carbonyl compounds (CR) 586 [G.E. *85*, 630 (1973)]

Alkyl compounds, Specific heat and formation of kinks in bimolecular films of long-chain n-~ (SC) 850 [G.E. *85*, 915 (1973)]

Alkynes, 1,3-Dipolar addition of cyclic diazo ketones to ~ and cyclopropene. Synthesis of heterocycles by [1,5]-acyl migration (SC) 240 [G.E. *85*, 259 (1973)]
Dichotomy of C≡C bonds and formation of η-cyclopentadienylchromium (SC) 1001 [G.E. *85*, 1052 (1973)]

Allene derivatives, Semiempirical use of chirality functions for description of optical activity of ~ in the transparent region (FP) 20 [G.E. *85*, 10 (1973)]

Allenedicarboxylic acid, Crystal structure (SC) 158 [G.E. *85*, 150 (1973)]

Allenes, Mechanism of allenic dimerization (SC) 504 [G.E. *85*, 511 (1973)]
Cycloadditions of electron-deficient ~ (SC) 567 [G.E. *85*, 582 (1973)]
Synthesis, absolute configuration, and optical purity of chiral ~ (LA) 780

Alloxazines, Reactivity of ~ and isoalloxazines (LA) 936

Allyl cations, Syntheses of seven- and five-membered rings from ~ (FP) 819 [G.E. *85*, 877 (1973)]

Allyl compounds, The allylcobalt system (FP) 964 [G.E. *85*, 1024 (1973)]

Allyl groups, Removal by formic acid catalyzed by (triphenylphosphane)palladium (SC) 928 [G.E. *85*, 986 (1973)]

Amavadine, Determination of the structure of the vanadium compound ~ from fly agaric (SC) 508 [G.E. *85*, 542 (1973)]

Amidines, Use of ~ (LA) 447

Amines, Nitrile/amine conproportionation to two imines (SC) 238 [G.E. *85*, 230 (1973)]

Amino acid, N-Sulfenyl-~ N-carboxyanhydrides (SC) 74 [G.E. *85*, 86 (1973)]

Amino acid esters, High resolution NMR measurements of boc-~ with application of lanthanoid shift reagents (SC) 1011 [G.E. *85*, 1059 (1973)]

Amino alcohols, 5,6-Dihydro-4H-1,3-oxazines and γ-~ from α-metalated isocyanides and epoxides (SC) 323 [G.E. *85*, 355 (1973)]
Stereochemistry of the 2-oxazoline synthesis from β-~ and nitriles (SC) 920 [G.E. *85*, 956 (1973)]

Aminoazimines, Structure (SC) 236 [G.E. *85*, 229 (1973)]

2-Aminobenzimidazole, New simple synthesis (SC) 841 [G.E. *85*, 866 (1973)]

α-Amino-ε-caprolactam, Racemization of optically active ~ by microbiological means (PR) 344

Ammonioamidates, New surface-active ~ (PR) 513

Ammonium salts, Chemistry of dichloromethylen-~ ("phosgenimonium salts") (FP) 806 [G.E. *85*, 837 (1973)]

Analysis, Chemical ~ of synthetic fibers (FP) 602 [G.E. *85*, 691 (1973)]

Anhydrides, N-Sulfenylamino acid N-carboxy-~ (SC) 74 [G.E. *85*, 86 (1973)]

Anhydroaureomycin, Total synthesis (SC) 497 [G.E. *85*, 508 (1973)]

Anisole, Formation of a Dewar-~ by bicyclopropenyl rearrangement (SC) 152 [G.E. *85*, 147 (1973)]

Annulenes, Synthesis of 9,10:15,16-bis(tetramethylene)cyclooctadeca-7,9,15,17-tetraene-2,4,11,13-tetrayne-1,6-dione, a tetraalkylated tetradehydro[18]-annulenedione (SC) 68 [G.E. *85*, 41 (1973)]
Does a "ring current effect" exist for ^{13}C-nuclear magnetic resonance? A study of bridged ~ (SC) 243 [G.E. *85*, 261 (1973)]
A [17]annulenyl anion (SC) 325 [G.E. *85*, 350 (1973)]
A [16]annulenediyl dication (SC) 327 [G.E. *85*, 352 (1973)]
An aza[13]annulene (SC) 328 [G.E. *85*, 353 (1973)]
Synthesis of a methylene-bridged didehydroaza[21]annulene, a diatropic heteroannulene (SC) 410 [G.E. *85*, 404 (1973)]
Synthesis of a methylene-bridged didehydroaza[19]annulene, a paratropic heteroannulene.—The alternation of electromagnetic properties between hetero[4n + 1]-~ and hetero[4n − 1]-~ (SC) 411 [G.E. *85*, 406 (1973)]
An aromatic-olefin equilibrium: 1,6-methano[10]annulene-tricyclo[4.4.$10^{1,6}$]undeca-2,4,7,9-tetraene valence tautomerism (SC) 570 [G.E. *85*, 585 (1973)]
Semibullvalenes as potential homoaromatic compounds (SC) 758 [G.E. *85*, 760 (1973)]
Significance of stereochemical factors for the chemical shift of the ^{13}C resonance (SC) 760 [G.E. *85*, 762 (1973)]
Crystal structure of 2-hydroxy-4,9-methano[11]annulenone (SC) 855 [G.E. *85*, 870 (1973)]
Cyclooctadeca[cdefg]phenanthrene ("[18]annuleno[cdefg]phenanthrene") (SC) 916 [G.E. *85*, 957 (1973)]

Anodic oxidation, Kinetic investigations of anodic oxide layers on niobium and tantalum (CR) 341 [G.E. *85*, 311 (1973)]

Antibodies, Insolubilized antigens and ~ (LA) 343

Antiferromagnets, NMR in ferromagnets and ~ (LA) 436

Antigens, Insolubilized ~ and antibodies (LA) 343

Antistatic agents for treatment of high polymers (LA) 437

Antithrombogenic plastic components (LA) 437

Arene oxides, Arene oxide-arene oxide rearrangement (SC) 840 [G.E. *85*, 864 (1973)]
Significance of ~ and the NIH shift in metabolism, toxicity, and carcogenicity of aromatic compounds (LA) 512

Aromaticity, Direct proof of the non-~ of phospholes and arsoles (SC) 145 [G.E. *85*, 140 (1973)]
How "aromatic" are λ^5-phosphorins? Electrophilic substitution reactions (SC) 753 [G.E. *85*, 815 (1973)]

Arsabenzenes, Simple synthesis of 4-monosubstituted ~ and phosphabenzenes (SC) 931 [G.E. *85*, 990 (1973)]

Arsoles, Direct proof of non-aromaticity of phospholes and ~ (SC) 145 [G.E. *85*, 140 (1973)]

Arterial tissue, Biogenic macromolecules of ~ and cartilage (CR) 83 [G.E. *85*, 94 (1973)]

Asymmetric induction by a chiral bisphosphane-rhodium complex in the hydroformylation of aliphatic olefins (SC) 669 [G.E. *85*, 663 (1973)]

Asymmetric syntheses with the aid of homogeneous transition-metal catalysts (FP) 954 [G.E. *85*, 1013 (1973)]

Aureomycin, Total synthesis of anhydro-~ (SC) 497 [G.E. *85*, 508 (1973)]

2-Azaallyllithium, 1,3-Anionic cycloadditions of ~ compounds to nitriles (SC) 569 [G.E. *85*, 584 (1973)]

Azaannulenes, An aza[13]annulene (SC) 328 [G.E. *85*, 353 (1973)]
Synthesis of a methylene-bridged didehydroaza[21]annulene, a diatropic heteroannulene (SC) 410 [G.E. *85*, 404 (1973)]
Synthesis of a methylene-bridged didehydroaza[19]annulene, a paratropic heteroannulene.—The alternation of electromagnetic properties between hetero-[4n + 1]annulenes and hetero[4n − 1]annulenes (SC) 411 [G.E. *85*, 406 (1973)]

Azacyclobutadiene, Tris(dimethylamino)-~ (SC) 847 [G.E. *85*, 918 (1973)]
Structure of triamino-~ (SC) 848 [G.E. *85*, 920 (1973)]

2-Azapentalene, A stable ~ (SC) 418 [G.E. *85*, 450 (1973)]

1,2λ^5-Azaphosphoridines, Synthesis (SC) 502 [G.E. *85*, 542 (1973)]

2-Aza-1-propenes, Reactions of substituted 1,3,3-trichloro-~ (LA) 862

Azaquinones, Chemistry and biochemistry (FP) 139 [G.E. *85*, 163 (1973)]

2-Azetidinones, Synthesis of 4-mercapto-2-~ having α-isopropylideneacetate groups on nitrogen (SC) 925 [G.E. *85* 983 (1973)]

1-Azetines, 1,3-Dipolar cycloreversion of ~ (SC) 155 [G.E. *85*, 149 (1973)]

Azide reaction, A novel covalent ~ in phosphorus chemistry (SC) 425 [G.E. *85*, 454 (1973)]

Azides, Thermolysis of cyclopropyl-~ (SC) 161 [G.E. *85*, 173 (1973)]
Reaction of olefins with lead(IV) acetate ~ (LA) 85

Azimines, Structure of amino-~ (SC) 236 [G.E. *85*, 229 (1973)]

Azines, Simple synthesis of hexafluoroacetone ~ (SC) 502 [G.E. *85*, 541 (1973)]

Aziridine, Reactions of carbonylmetal hydrides with ~ and propylene sulfide (2-methylthiirane) (SC) 77 [G.E. *85*, 87 (1973)]
Reaction of imidic esters with ~-s (SC) 768 [G.E. *85*, 817 (1973)]

Azobenzenes, Steric hindrance in strongly polar 2,6-disubstituted ~ (SC) 926 [G.E. *85*, 984 (1973)]

Azo compounds, Spectroscopic properties of organic ~ (FP) 224 [G.E. *85*, 248 (1973)]
First divinylazo compound and its radical anion (SC) 655 [G.E. *85*, 657 (1973)]

Azo coupling by cyclopropanediazonium ions (SC) 924 [G.E. *85*, 994 (1973)]

BACTERIA, Extrachromosomal DNA in ~ (FP) 517 [G.E. *85*, 569 (1973)]

Bee venom, Chemical structure and biological action of components (CR) 83 [G.E. *85*, 47 (1973)]

Benzene dioxide, anti-~ (SC) 838 [G.E. *85*, 862 (1973)]

Benzene triimine, cis-Triazatris-σ-homobenzene (cis-"~") (SC) 989 [G.E. *85*, 1007 (1973)]

Benzene trioxide, Chemistry of cis-trioxatris-σ-homobenzene. Substitutions by univalent nucleophiles (SC) 993 [G.E. *85*, 1110 (1973)]
Chemistry of cis-trioxatris-σ-homobenzene. Substitutions by bivalent nucleophiles (SC) 994 [G.E. *85*, 1111 (1973)]

Benzil, Carboxylic esters produced by low-pressure hydroformylation of olefins in ~ (SC) 851 [G.E. *85*, 911 (1973)]

Benzimidazole, New simple synthesis of 2-amino-~ (SC) 841 [G.E. *85*, 866 (1973)]

Benzocycloalkenes, ^{13}C-NMR spectra (SC) 762 [G.E. *85*, 826 (1973)]

Benzofuran-3-carboxamides, 2-Oxo-2,3-dihydro-~ (LA) 863

Benzoic esters, Substituted p-carbamoyloxy-~ (PR) 936

Benzothiazine, benzoxazine, and indolinone derivatives (PR) 780

Benzoxazine, benzothiazine, and indolinone derivatives (PR) 780

3,1-Benzoxazin-4-ones, 8-Quinolinecarboxylic acid from ~ and enamines (SC) 495 [G.E. *85*, 505 (1973)]

Benzvalene, Cycloadditions of ~ (SC) 660 [G.E. *85*, 666 (1973)]

Bicyclic systems, Bredt compounds and the Bredt rule (FP) 464 [G.E. *85*, 494 (1973)]

Bicyclobutane, Direct cyclobutene-~ valence isomerization (SC) 162 [G.E. *85*, 174 (1973)]

Bicyclo[6.1.0]nona-2,6-diene, Cope rearrangement of cis-~ and its 9-hetero analogs (SC) 507 [G.E. *85*, 514 (1973)]

Bicyclo[4.2.1]nona-2,4,7-triene, Methylene-~ (SC) 81 [G.E. *85*, 45 (1973)]

Bicyclopropenyl rearrangement, New mechanistic concept for the ~ (SC) 150 [G.E. *85*, 145 (1973)]
Formation of a Dewar-anisole by ~ (SC) 152 [G.E. *85*, 147 (1973)]

Bicyclopropylidene, [2 + 2]- and [2 + 4]-cycloadditions of ~ (SC) 159 [G.E. *85*, 151 (1973)]
Eliminations from three-membered rings: cyclopropylcyclopropene and ~ from 1-chlorobicyclopropyl (SC) 332 [G.E. *85*, 347 (1973)]

8,8'-Biheptafulvenyl, Synthesis (SC) 76 [G.E. *85*, 93 (1973)]

3,3'-Bi(1H-isoindole), X-ray structure analysis of 1,1,1',1'-tetrakis(trifluoromethyl)-~ (SC) 157 [G.E. *85*, 170 (1973)]

Binorbornadiene, Binorbornadienylidene, biquadricyclanylidene (SC) 991 [G.E. *85*, 1106 (1973)]

Binorbornadienylidene, Biquadricyclanylidene (SC) 991 [G.E. *85*, 1106 (1973)]

Biochemical engineering, Advances in ~ (Book Review) 781

Biochemistry, Molekulare Prozesse des Lebens (Book Review) 347

Bioorganic chemistry, Progress in ~ (Book Review) 864

Biphenylene, ^{13}C shifts in ~ and analogous compounds (SC) 241 [G.E. *85*, 260 (1973)]

"Biuret trichlorides", from N-dichloromethylene-N,N-dimethylammonium chloride and dimethylcyanamide (SC) 74 [G.E. *85*, 90 (1973)]

Bond, Physical mechanism of the chemical ~ (FP) 546 [G.E. *85*, 551 (1973)]

Bonding, Zintl phases: Transitions between metallic and ionic ~ (FP) 694 [G.E. *85*, 742 (1973)]
Photoelectron spectra of nonmetal compounds and their interpretation by MO models (FP) 734 [G.E. *85*, 773 (1973)]

Boracyclopentasilane, a new type of heterocyclic silane (SC) 315 [G.E. *85*, 304 (1973)]

Borane, μ-Phosphinodi-~ (SC) 413 [G.E. *85*, 410 (1973)]

Borates, The versatile (polypyrazolyl)-~ (CR) 861 [G.E. *85*, 873 (1973)]
Reduction of functional groups by sulfurated hydrido-~ (LA) 512

Boric acid gels, Column-chromatographic separation of neutral sugars on a dihydroxyboryl-substituted polymer (SC) 417 [G.E. *85*, 412 (1973)]

Boron compounds, Tetraphenylborate ion as NMR-shift reagent for sulfonium compounds (SC) 400 [G.E. *85*, 404 (1973)]
Tricarbonyl-(1-phenylborinato)manganese (SC) 764 [G.E. *85*, 817 (1973)]

Boron tris(trifluoroacetate) for removal of protecting groups in peptide chemistry (SC) 147 [G.E. *85*, 142 (1973)]

Bredt compounds, and the Bredt rule (FP) 464 [G.E. *85*, 494 (1973)]

Bredt rule, Bredt compounds and the ~ (FP) 464 [G.E. *85*, 494 (1973)]

Bridgehead carbenium ions, Stabilized ~: 1-trishomobarrelyl and 1-trishomobullvalyl cations (SC) 399 [G.E. *85*, 400 (1973)]

1,3-Butadiene, ^{13}C^{13}C Coupling constants of ~ (SC) 339 [G.E. *85*, 357 (1973)]
New catalyst for simultaneous production of ~ and methacrolein (PR) 344

CAGE compounds, Tetrakis(dimethylphosphoniumbismethylide)dinickel, a new type of cage compound (SC) 853 [G.E. *85*, 910 (1973)]

Calorimetry, Mechanistic analysis of solution reactions by non-isothermal ~ (FP) 381 [G.E. *85*, 381 (1973)]

Caprolactam, Model calculations for hydrolytic polymerization of ~ (CR) 434 [G.E. *85*, 463 (1973)]

Carbamate, Low-temperature X-ray structure analysis of ammonium ~ (SC) 322 [G.E. *85*, 308 (1973)]
Synthesis of chloroalkyl ~-s from diols and phosgeneimmonium salts (SC) 404 [G.E. *85*, 445 (1973)]

Carbamic esters, Disubstituted N-phenethyl-~ (LA) 863

p-Carbamoyloxybenzoic esters, Substituted ~ (PR) 936

Carbazole, Light-induced and free-radical initiator-induced cationic polymerization of N-vinyl-~ in the presence of CBr_4 (CR) 433 [G.E. *85*, 461 (1973)]

Carbenes, Reactions of hexachlorodisilane with methylene and dichlorocarbene (SC) 500 [G.E. *85*, 507 (1973)]

Carbenium ions, Stabilized bridgehead ~: 1-trishomobarrelyl and 1-trishomobullvalyl cations (SC) 399 [G.E. *85*, 399 (1973)]

Carbocations, ~ and electrophilic reactions (FP) 173 [G.E. *85*, 183 (1973)]
Nature of ~ derived from tricyclo[3.1.1.$0^{2,4}$]hept-6-yl- and tricyclo[3.2.0.$0^{2,7}$]hept-4-yl systems (SC) 769 [G.E. *85*, 829 (1973)]

Carbohydrates, Chemistry and biology of acylneuraminic acids (FP) 127 [G.E. *85*, 128 (1973)]
Chemistry and significance of the carbohydrate moieties of human serum glycoproteins (FP) 721 [G.E. *85*, 803 (1973)]
Stereospecific attack of nucleophilic reagents on nitrooxirane sugars (SC) 921 [G.E. *85*, 992 (1973)]
Stereochemistry of ~ (Book Review) 89

Carbonic acid derivatives, Reactive monomeric ~ (FP) 630 [G.E. *85*, 633 (1973)]

Carbon monoxide, Acetylnickel halides by insertion of ~ into Ni—Cσ bonds (SC) 402 [G.E. *85*, 403 (1973)]

Carbon-nitrogen compounds, Gmelins Handbuch der anorganischen Chemie (Book Review) 87

Carbonyl bromide fluoride, Simple synthesis (SC) 918 [G.E. *85*, 982 (1973)]

Carbonyl chloride fluoride, Simple synthesis (SC) 918 [G.E. *85*, 982 (1973)]

Carbonyl compounds, New methods for alkylation of ~ (CR) 586 [G.E. *85*, 630 (1973)]
Detection of alkylideneoxophosphoranes by cycloaddition of ~ (SC) 1010 [G.E. *85*, 1115 (1973)]

Carbonylmetalate anions, Onium salts containing ~ (SC) 235 [G.E. *85*, 228 (1973)]

Carbonylmethylene, Phosphorus ylide complexes of group VI as sources of ~ (SC) 667 [G.E. *85*, 668 (1973)]

Carbosilanes having a new silicon-carbon skeleton ("silascaphanes") (SC) 654 [G.E. *85*, 587 (1973)]

Carboxyamides, (Dimethylcarbamoyl)lithium from dimethylformamide and lithium diisopropylamide; synthesis of α-hydroxy N,N-dimethyl-~ (SC) 836 [G.E. *85*, 861 (1973)]

Carboxylic esters produced by low-pressure hydroformylation of olefins in benzil (SC) 851 [G.E. *85*, 911 (1973)]

"Carboxypeptidase A: a mechanistic analysis" (LA) 512

Carbyne complexes, trans-Halogeno[alkyl-(aryl)carbyne]tetracarbonyl complexes of chromium, molybdenum, and tungsten—a new class of compounds having a transition metal-carbon triple bond (SC) 564 [G.E. *85*, 618 (1973)]

Carotenoids (Book Review) 345

Carpyrinic acid, Syntheses (LA) 513

Cartilage, Biogenic macromolecules of arterial tissue and ~ (CR) 83 [G.E. *85*, 94 (1973)]

Catalysis, Ligand influences in heterogeneous ~: modification of the Philips catalyst (SC) 754 [G.E. *85*, 827 (1973)]
Use of polymerization kinetics for investigation of homogeneous catalytic processes (CR) 429 [G.E. *85*, 457 (1973)]
Use of X-ray analysis in studies on amorphous ~ (LA) 342
Recent developments in ~ of hydroformylation (LA) 436
Catalyst studies (LA) 436
Heterogene Katalyse (Book Review) 1024

Catalysts, Asymmetric syntheses with the aid of homogeneous transition-metal ~ (FP) 954 [G.E. *85*, 1013 (1973)]
Cyclooligomerization with transition metal ~ (FP) 975 [G.E. *85*, 1035 (1973)]
Influence of ligands on ~ for the heterogeneous metathesis of olefins (SC) 153 [G.E. *85*, 148 (1973)]
Trimerization of methylenecyclopropane on triorganophosphane-modified nickel(0) ~ (SC) 995 [G.E. *85*, 1053 (1973)]

Cations, Carbo-~ and electrophilic reactions (FP) 173 [G.E. *85*, 183 (1973)]

Cellulose, Initial stage of oxidative degradation of native ~ by molecular oxygen (CR) 434 [G.E. *85*, 462 (1973)]

Cephalosporin, Synthesis of deacetoxy-~ S-oxides by oxidative trapping of sulfenic acids from penicillin S-oxides (SC) 67 [G.E. *85*, 40 (1973)]

Chalcogeno compounds of transition metals (LA) 935

Chemical bond, Physical mechanism (FP) 546 [G.E. *85*, 551 (1973)]

Chemiluminescence, Chemiluminescent paracyclophanes (SC) 425 [G.E. *85*, 451 (1973)]

Chemiluminescent paracyclophanes (SC) 425 [G.E. *85*, 451 (1973)]

Chemisorption complexes (LA) 343

Chirality, Proof of ~ of rapidly interconverting enantiomers (SC) 583 [G.E. *85*, 590 (1973)]

Chirality functions, Semiempirical use for description of optical activity of allene derivatives in the transparent region (FP) 20 [G.E. *85*, 10 (1973)]
Semiempirical use for description of optical activity of methane derivatives in the transparent region (FP) 30 [G.E. *85*, 21 (1973)]

Chloro-2-aza-1-propenes, Reactions of substituted 1,3,3-tri-~ (LA) 862

Chromatograms, Direct quantitative photometry on thin layer ~ (FP) 298 [G.E. *85*, 334 (1973)]

Chromatography, Column-chromatographic separation of neutral sugars on a dihydroxyboryl-substituted polymer (SC) 417 [G.E. *85*, 412 (1973)]

Chromium complexes, 1,4-Diazabicyclo[2.2.2]octane(phenylmethoxy)methylenepentacarbonylchromium(0), a novel nitrogen ylide-transition metal complex (SC) 563 [G.E. *85*, 617 (1973)]
trans-Halogeno[alkyl(aryl)carbyne]tetracarbonyl complexes of chromium, molybdenum, and tungsten—a new class of compounds having a transition metal-carbon triple bond (SC) 564 [G.E. *85*, 618 (1973)]
ESCA investigations of bis(arene)-~ (SC) 659 [G.E. *85*, 665 (1973)]
Synthesis of tris(dimethylphosphonium-bismethylide)chromium(III) (SC) 854 [G.E. *85*, 913 (1973)]

Chromium compounds, Dichotomy of C≡C bonds and formation of η-cyclopentadienylchromium (SC) 1001 [G.E. *85*, 1052 (1973)]
Diphosphane-transition metal complexes: $P_2H_4[Cr(CO)_5]_2$ and $P_2H_4[C_5H_5Mn(CO)_2]_2$ (SC) 1020 [G.E. *85*, 1123 (1973)]
Structure of diimine: IR spectra of N_2H_2-, N_2D_2-, and $^{15}N_2H_2[Cr(CO)_5]_2$ (SC) 1019 [G.E. *85*, 1122 (1973)]
Reactions on coordinatively unsaturated chromium(II) surface compounds (CR) 861 [G.E. *85*, 921 (1973)]

Chromophores, Iron-sulfur proteins: structural chemistry of their ~ and related systems (FP) 390 [G.E. *85*, 390 (1973)]

CIDNP spectroscopy, CIDNP-Detection of a photocatalyzed C—C cleavage upon UV irradiation of glycoaldehyde in aqueous solution (SC) 763 [G.E. *85*, 768 (1973)]

Claisen rearrangement, CIDNP evidence for divergent behavior of singlet and triplet radical pair encounters in the photo-~ (SC) 662 [G.E. *85*, 669 (1973)]

Coal, Use of spectroscopic methods in the structural analysis of ~ and petroleum (LA) 511

Coating materials, Composition that can be cured with ionizing radiation (LA) 1024

Cobalt complexes, Spin state of pentacoordinate cobalt(II) and nickel(II) complexes (LA) 862

Cobalt compounds, The allylcobalt system (FP) 964 [G.E. *85*, 1024 (1973)]
Tetrameric η-cyclopentadienylcobalt hydride—a new type of four-center cluster with μ_3-hydrido bridges (SC) 843 [G.E. *85*, 867 (1973)]

Coenzyme A, Stereochemistry of the coenzyme-B_{12}-dependent methylmalonyl-~-mutase reaction. Investigation with ethylmalonyl-~ (SC) 671 [G.E. *85*, 721 (1973)]

Colors, Quartz crystals and their ~ (FP) 283 [G.E. *85*, 281 (1973)]

Complexes, Molecular and cation ~ of macrotricyclic and macrotetracyclic ligands (SC) 579 [G.E. *85*, 622 (1973)]
Preparative and mechanistic aspects of the reactions of cyclopentadienylmetal ~: The route to the triple-decker sandwich (CR) 247 [G.E. *85*, 265 (1973)]
Problem of competitive coordination in ~ (LA) 935
Chemisorption ~ (LA) 343

Computer handling of chemical structure information (Book Review) 781

Configuration, Proof of pyramidal ~ of the oxiranyl radical: two isomers of the 3-methyl-2-oxiranyl radical (SC) 932 [G.E. *85*, 993 (1973)]
Determination of ~ of polybutadienes and poly-α-methylstyrenes by ^{13}C-NMR spectroscopy (CR) 427 [G.E. *85*, 455 (1973)]

Conformation, Photoelectron spectra and ~ of hydrazine derivatives (SC) 408 [G.E. *85*, 410 (1973)]
Determination of ~ of cyclic polypeptides in solution (LA) 436

Cope rearrangement, ~ of cis-bicyclo[6.2.0]nona-2,6-diene and its 9-hetero analogs (SC) 507 [G.E. *85*, 514 (1973)]
Rapid reversible ~ between the sym-oxabicyclo[5.1.0]octa-2,5-dienes (SC) 580 [G.E. *85*, 624 (1973)]

Copper complexes, Calculation of electronic states of copper(II) complexes (LA) 862

Copper compounds, New unusually stable type of organo-copper and -silver compounds (SC) 415 [G.E. *85*, 448 (1973)]
Tetravalent copper: $Cs_2[CuF_6]$ (SC) 582 [G.E. *85*, 590 (1973)]

Corphin, Metal-free derivatives of the ~ ligand system (SC) 914 [G.E. *85*, 954 (1973)]

Corrinoids, Variation of the sulfide contraction procedure for synthesis of ~ (SC) 910 [G.E. *85*, 950 (1973)]

Corrins, Formation of a 1-hydroxycorrin complex by photochemical A/D-secocorrin → corrin cycloisomerization (SC) 912 [G.E. *85*, 952 (1973)]

Corrosion protection, Handbuch des kathodischen Korrosionsschutzes (Book Review) 515

Coupling constants, $^{13}C^{13}C$ ~ of 1,3-butadiene (SC) 339 [G.E. *85*, 357 (1973)]

Spin-spin ~ between geminal and vicinal protons (LA) 343

Cryptates, New ~ containing tricyclic ligands: crystal structure of $C_{32}H_{64}N_4O_{10}$·2NaI (SC) 771 [G.E. *85*, 828 (1973)]

Crystals, Quartz ~ and their colors (FP) 283 [G.E. *85*, 281 (1973)]
Synthetic precious stones (FP) 291 [G.E. *85*, 326 (1973)]
Structural information from the habit of ~ (FP) 528 [G.E. *85*, 595 (1973)]
Chemistry and applications of liquid ~ (FP) 617 [G.E. *85*, 706 (1973)]

Crystal structure, Structural information from the habit of crystals (FP) 528 [G.E. *85*, 595 (1973)]
~ of allene-dicarboxylic acid (SC) 158 [G.E. *85*, 150 (1973)]
~ of 1,3-di-tert-butyl-2-trans-4-dichloro-2,4-dioxo-1,3,2λ^5,4λ^4-diazadiphosphetidine; stereochemistry of oxidation at phosphorus(III) by dimethyl sulfoxide (SC) 311 [G.E. *85*, 343 (1973)]
Molecular structure and ~ of $NH_4[S_4N_5O]$—A new sulfur-nitrogen cage (SC) 316 [G.E. *85*, 307 (1973)]
Low-temperature X-ray structure analysis of ammonium carbamate (SC) 322 [G.E. *85*, 308 (1973)]
Polymeric octamolybdate ions in the ~ of $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$ (SC) 409 [G.E. *85*, 409 (1973)]
Anion structure of tributylammonium decatungstate $[HN(C_4H_9)_3]_4W_{10}O_{32}$ (SC) 420 [G.E. *85*, 417 (1973)]
~ and molecular structure of cyclooctasulfur oxide, S_8O (SC) 423 [G.E. *85*, 452 (1973)]
Structural investigations of tellurium subhalides: modified tellurium structures (SC) 499 [G.E. *85*, 504 (1973)]
New cryptates containing tricyclic ligands: ~ of $C_{32}H_{64}N_4O_{10}$·2NaI (SC) 771 [G.E. *85*, 828 (1973)]
~ of 2-hydroxy-4,9-methano[11]annulenone (SC) 855 [G.E. *85*, 870 (1973)]

Cubane structure, $Te_3Cl_7^-$: a novel ionic degradation product of the cubane-type compound $(TeCl_4)_4$ (SC) 666 [G.E. *85*, 662 (1973)]

Cycl[4.3.2]azine-4,5-dicarboxylate, Diethyl ~ (SC) 501 [G.E. *85*, 543 (1973)]

Cycloadditions, Polar ~ (FP) 212 [G.E. *85*, 235 (1973)]
Syntheses of seven- and five-membered rings from allyl cations (FP) 819 [G.E. *85*, 877 (1973)]
[2+2]- and [2+4]-~ of bicyclopropylidene (SC) 159 [G.E. *85*, 151 (1973)]
~ of electron-deficient allenes (SC) 567 [G.E. *85*, 582 (1973)]
1,3-Anionic ~ of trans,trans-1,3-diphenyl-2-azaallyllithium to heterocumulenes (SC) 568 [G.E. *85*, 583 (1973)]
1,3-Anionic ~ of 2-azaallyllithium compounds to nitriles (SC) 569 [G.E. *85*, 584 (1973)]
Metal-catalyzed [4+2]-~ of a vinylcyclopropane group to a C—C bond of a cyclopropane ring: synthesis and degenerate valence isomerization of a bishomobenzene-$Fe(CO)_3$ derivative (SC) 574 [G.E. *85*, 628 (1973)]
~ of benzvalene (SC) 660 [G.E. *85*, 666 (1973)]
[2+2]-Photo-~ involving phenanthrene: mechanistic models for two-step processes (SC) 765 [G.E. *85*, 766 (1973)]
Detection of alkylideneoxophosphoranes by ~ of carbonyl compounds (SC) 1010 [G.E. *85*, 1115 (1973)]

Cyclobutadiene, Detection of free ~ on oxidation of a tricarbonyl(~)iron complex (SC) 777 [G.E. *85*, 828 (1973)]
Tris(dimethylamino)aza-~ (SC) 847 [G.E. *85*, 918 (1973)]
Structure of triaminoaza-~ (SC) 848 [G.E. *85*, 920 (1973)]
Tri-tert-butyl-~ (SC) 1015 [G.E. *85*, 1056 (1973)]
Tetramethylcyclobutadiene, an excellent donor molecule (SC) 1016 [G.E. *85*, 1057 (1973)]

Cyclobutene, Direct ~-bicyclobutane valence isomerization (SC) 162 [G.E. *85*, 174 (1973)]

Cyclohexadienones, Transient ~ by novel reversal reactions from cage photodimers derived from N-chloroacetyltyramines (SC) 72 [G.E. *85*, 85 (1973)]

1,4-Cyclohexadiyl, Diradicals as intermediates in chemical reactions: 2,3-dimethylene-~ (SC) 503 [G.E. *85*, 510 (1973)]
The diradical 2,3-dimethylene-~ as intermediate in thermal gas phase rearrangements (SC) 505 [G.E. *85*, 512 (1973)]

Cyclohexane, A planar ~ ring: X-ray analysis of 9-cyano-anti-dioxatris-σ-homobenzene (SC) 836 [G.E. *85*, 860 (1973)]

Cyclooctadeca[cdefg]phenanthrene, ("[18]Annuleno[cdefg]phenanthrene") (SC) 916 [G.E. *85*, 957 (1973)]

1,5-Cyclooctadiyne (SC) 671 [G.E. *85*, 723 (1973)]

Cyclooctasulfur oxide, Crystal and molecular structure of ~, S_8O (SC) 423 [G.E. *85*, 452 (1973)]

Cycloolefins, Ring-opening polymerization of ~ in the presence of metathesis catalysts (CR) 430 [G.E. *85*, 458 (1973)]

Cyclooligomerization with transition metal catalysts (FP) 975 [G.E. *85*, 1035 (1973)]

Cyclopentadiene, Dichotomy of C≡C bonds and formation of η-cyclopentadienylchromium (SC) 1001 [G.E. *85*, 1052 (1973)]
Tetrakis(η-cyclopentadienyl)tetranickel trihydride—an unusual tetranuclear cluster (SC) 1005 [G.E. *85*, 1117 (1973)]

Cyclopentasilane, the first unsubstituted cyclic silicon hydride (SC) 316 [G.E. *85*, 304 (1973)]

Cyclophanes, Transannular π-π interaction in ~ (SC) 402 [G.E. *85*, 408 (1973)]
Chemiluminescent para-~ (SC) 425 [G.E. *85*, 451 (1973)]
An "intramolecular quinhydrone" (SC) 776 [G.E. *85*, 831 (1973)]

Cyclopropane, [2+2]- and [2+4]-cycloadditions of bicyclopropylidene (SC) 159 [G.E. *85*, 151 (1973)]
Synthesis and solvolysis of (1-bromo-1-cyclopropylmethylene)-~: A particularly stable vinyl cation (SC) 318 [G.E. *85*, 309 (1973)]
Metal-catalyzed [4+2]-cycloadditions of a vinyl-~ group to a C—C bond of a ~ ring: synthesis and degenerate valence isomerization of a bishomobenzene-$Fe(CO)_3$ derivative (SC) 574 [G.E. *85*, 628 (1973)]

Cyclopropanediazonium ions, Azo coupling by ~ (SC) 924 [G.E. *85*, 994 (1973)]

Cyclopropanimine, Methyleneaziridine-~ valence isomerization (SC) 414 [G.E. *85*, 411 (1973)]

Cyclopropene, New mechanistic concept for the bicyclopropenyl rearrangement (SC) 150 [G.E. *85*, 145 (1973)]
Formation of a Dewar-anisole by bicyclopropenyl rearrangement (SC) 152 [G.E. *85*, 147 (1973)]
1,3-Dipolar addition of cyclic diazo ketones to alkynes and ~. Synthesis of heterocycles by [1,5]-acyl migration (SC) 240 [G.E. *85*, 259 (1973)]

Cyclopropyl azides, Thermolysis (SC) 161 [G.E. *85*, 173 (1973)]

Cyclopropylcyclopropene, Eliminations from three-membered rings: ~ and bicyclopropylidene from 1-chlorobicyclopropyl (SC) 332 [G.E. *85*, 347 (1973)]

Cyclopropylidenespiropentane, Thermal isomerization of ~-an unusual route to tricyclopropylidene ([3]-rotane) (SC) 761 [G.E. *85*, 832 (1973)]

Cyclopropylmethyl anion, Influences of α- and β-alkyl groups on the rearrangement of 3-butenyl Grignard reagents: a stable primary ~ (SC) 774 [G.E. *85*, 823 (1973)]

Cycloreversion, 1,3-Dipolar ~ of 1-azetines (SC) 155 [G.E. *85*, 149 (1973)]

Cytochalasans: a new class of biologically active microbial metabolites (FP) 370 [G.E. *85*, 369 (1973)]

Cytostatics, The cytochalasans: a new class of biologically active microbial metabolites (FP) 370 [G.E. *85*, 369 (1973)]

DEOXYRIBONUCLEIC acid, Repair processes (FP) 264 [G.E. *85*, 289 (1973)]

Deoxyribonucleotides, New approach to the synthesis of oligo-~ (SC) 859 [G.E. *85*, 917 (1973)]

Deuterated compounds, Use in the study of tyrosine-dopa metabolism in phenylketonuria (CR) 165 [G.E. *85*, 176 (1973)]

Deuteriopropanol, Preparative-scale synthesis of (1R)- and (1S)-mono-~ by enzymatic exchange reactions (SC) 146 [G.E. *85*, 141 (1973)]

Dewar-anisole, Formation by bicyclopropenyl rearrangement (SC) 152 [G.E. *85*, 147 (1973)]

Diazo chemistry, Two new synthetic methods from ~ (LA) 85

Diazo ketones, 1,3-Dipolar addition of cyclic ~ to alkynes and cyclopropene. Synthesis of heterocycles by [1,5]-acyl migration SC) 240 [G.E. *85*, 259 (1973)]
Progress in the chemistry of aliphatic ~ (LA) 862

Diazomalonic esters, Production and reactions (LA) 1023

Diazonium compounds, Supports containing diazonium groups for biologically active compounds (CR) 428 [G.E. *85*, 456 (1973)]

Diazonium ions, Azo coupling by cyclopropane-~ (SC) 924 [G.E. *85*, 994 (1973)]

Dibenzo[c,h][1,5]naphthyridine, New type of dimerization of nitrile ylides (SC) 156 [G.E. *85*, 169 (1973)]
X-ray structure analysis of 6,12-dihydro-6,6,12,12-tetrakis(trifluoromethyl)-~ (SC) 157 [G.E. *85*, 171 (1973)]

Dibenzoxazepines, Chlorohydroxypiperazinyl-~ (PR) 780

Dicarbonyl compounds, Conversion of vicinal diols into ~ by manganese dioxide (SC) 401 [G.E. *85*, 401 (1973)]

Dichlorogermylene, Stabilization of monomeric ~ (SC) 1002 [G.E. *85*, 1116 (1973)]

Dichloromethylenammonium salts, Chemistry of ~ ("phosgenimonium salts") (FP) 806 [G.E. *85*, 837 (1973)]

N-Dichloromethylene-N,N-dimethylammonium chloride, "Biuret trichlorides" from ~ and dimethylcyanamide (SC) 74 [G.E. *85*, 90 (1973)]

Dictionary, The condensed chemical ~ (Book Review) 348

Differential thermal analysis, Mechanistic analysis of solution reactions by non-isothermal calorimetry (FP) 381 [G.E. *85*, 381 (1973)]

(±)-Dihydropalustraminic acid, Synthesis (SC) 160 [G.E. *85*, 172 (1973)]

1,5-Dihydropentalenes, Simple synthesis (SC) 335 [G.E. *85*, 361 (1973)]

Diimine, cis-~-bis(pentacarbonyltungsten) (SC) 1019 [G.E. *85*, 1121 (1973)]
Structure of ~: IR spectra of N_2H_2-, N_2D_2-, and $^{15}N_2H_2[Cr(CO)_5]_2$ (SC) 1019 [G.E. *85*, 1122 (1973)]

1,2-Dimethoxyethylene, Polymerization and copolymerization (CR) 433 [G.E. *85*, 463 (1973)]

Dimethylcyanamide, "Biuret trichlorides" fromN-dichloromethylene-N,N-dimethylammonium chloride and ~ (SC) 74 [G.E. *85*, 90 (1973)]

2,3-Dimethylene-1,4-cyclohexadiyl, Diradicals as intermediates in chemical reactions; ~ (SC) 503 [G.E. *85*, 510 (1973)]
The diradical ~ as intermediate in thermal gas phase rearrangements (SC) 505 [G.E. *85*, 512 (1973)]

N,N'-Dimethyleneethylenediamine, [3.3]-Sigmatropic reactions in the ~ system (SC) 767 [G.E. *85*, 824 (1973)]

Dimethylformamide, (Dimethylcarbamoyl)-lithium from ~ and lithium diisopropylamide; synthesis of α-hydroxy N,N-dimethylcarboxyamides (SC) 836 [G.E. *85*, 861 (1973)]

3,5-Dimethylpyridine, Novel production (PR) 343

Dimethyl sulfate, Phase-transfer-catalyzed alkylation of alcohols by ~ in an aqueous system (SC) 846 [G.E. *85*, 868 (1973)]

Dimethyl sulfoxide, Crystal structure of 1,3-di-tert-butyl-2-trans-4-dichloro-2,4-dioxo-1,3,2λ⁵,4λ⁵-diazadiphosphetidine; stereochemistry of oxidation at phosphorus(III) by ~ (SC) 311 [G.E. *85*, 343 (1973)]
Chemical reactions in a plasma (SC) 1004 [G.E. *85*, 1055 (1973)]

Dinitridodioxosulfate(VI), $SN_2O_2^{4-}$: a new derivative of the sulfate ion (SC) 339 [G.E. *85*, 355 (1973)]

Diols, Conversion of vicinal ~ into dicarbonyl compounds by manganese dioxide (SC) 401 [G.E. *85*, 401 (1973)]
Synthesis of chloroalkyl carbamates from ~ and phosgeneimmonium salts (SC) 404 [G.E. *85*, 445 (1973)]

4,6-Dioxa-1-azabicyclo[3.3.0]octanes, Preparation from iminodiethanols and nitriles (SC) 996 [G.E. *85*, 1055 (1973)]

1,2-Dioxanes, Concerted fragmentation of a 1,6-diradical on thermolysis of ~ (SC) 843 [G.E. *85*, 914 (1973)]

Dioxatris-σ-homobenzene, A planar cyclohexane ring: X-ray analysis of 9-cyano-anti-~ (SC) 836 [G.E. *85*, 860 (1973)]

1,2-Dioxetane, Thermolysis of tetramethyl-~ (SC) 772 [G.E. *85*, 822 (1973)]

1,3-Dipolar cycloreversion of 1-azetines (SC) 155 [G.E. *85*, 149 (1973)]

Diradicals, ~ as intermediates in chemical reactions; 2,3-dimethylene-1,4-cyclohexadiyl (SC) 503 [G.E. *85*, 510 (1973)]
Mechanism of allenic dimerization (SC) 504 [G.E. *85*, 511 (1973)]
The diradical 2,3-dimethylene-1,4-cyclohexadiyl as intermediate in thermal gas phase rearrangements (SC) 505 [G.E. *85*, 512 (1973)]
Thermal rearrangement of 2-methylenetricyclo[4.1.0.0^{1,3}]heptane (SC) 505 [G.E. *85*, 512 (1973)]
Concerted fragmentation of a 1,6-diradical on thermolysis of 1,2-dioxanes (SC) 843 [G.E. *85*, 914 (1973)]

Diseases, Hereditary ~—causes, cures, and problems (FP) 1 [G.E. *85*, 28 (1973)]

Displacement reactions of phosphorus(V) compounds and their pentacoordinate intermediates (FP) 91 [G.E. *85*, 99 (1973)]

Dissociation equilibrium, Direct observation of the ~ of tropylium salts (SC) 773 [G.E. *85*, 821 (1973)]

Disulfur monoxide, Photoelectron spectra and molecular properties: SSO and OSO (SC) 933 [G.E. *85*, 987 (1973)]

Documentation, Possibilities and limitations of delegated literature searches by computer (FP) 882 [G.E. *85*, 978 (1973)]
Computer handling of chemical structure information (Book Review) 781

Double bonds, New method for addition of aldehydes to activated ~ (SC) 81 [G.E. *85*, 89 (1973)]
Ionization potentials of deformed π-bonds (SC) 312 [G.E. *85*, 302 (1973)]

EBULLIOSCOPY with salt solutions as "solvents" (LA) 935

Elasticity moduli, The quasi-static ~ of semicrystalline copolymers of ethylene (CR) 431 [G.E. *85*, 459 (1973)]

Electric fields, Absorption of light by organic molecules in ~—some new applications (CR) 84 [G.E. *85*, 47 (1973)]

Electrochemistry, One-step synthesis of pyrroles by anodic dimerization of enamino ketones or esters (SC) 245 [G.E. *85*, 264 (1973)]

Electrode processes, Role of solvated electrons in ~ (LA) 342

Electrodes, Selective ion sensitive ~ (Book Review) 1025

Electron configuration, The loose connection between ~ and the chemical behavior of the heavy elements (transuranics) (FP) 12 [G.E. *85*, 1 (1973)]

Electron correlation, Topical aspects (LA) 779

Electron donor-acceptor systems, Spectroscopic studies on ~ (LA) 512

Electronic states, Calculation of ~ of copper(II) complexes (LA) 862

Electrophilic reactions, Carbocations and ~ (FP) 173 [G.E. *85*, 183 (1973)]

Electrostatic charges, Plastics having the ability to retain ~ (PR) 938

Emodin, Alkaline condensation to isohypericin: a simple synthesis of the meso-naphthodianthrone (phenanthro[1,10,9,8-opqra]perylene) system (SC) 79 [G.E. *85*, 88 (1973)]

Enamines, 8-Quinolinecarboxylic acid from 3,1-benzoxazin-4-ones and ~ (SC) 495 [G.E. *85*, 505 (1973)]

Enamino ketones, one step synthesis of pyrroles by anodic dimerization of ~ or esters (SC) 245 [G.E. *85*, 264 (1973)]

Enantiomers, Proof of the chirality of rapidly interconverting ~ (SC) 583 [G.E. *85*, 590 (1973)]

Encyclopedia, Real-Lexikon der Medizin (Book Review) 514

Enediamines, Vilsmeier fomylation (SC) 323 [G.E. *85*, 346 (1973)]

Energy transfer, Direct chemical evidence for ~ between identical molecules (SC) 314 [G.E. *85*, 300 (1973)]

Enols, A simple dialkylated enol (SC) 239 [G.E. *85*, 227 (1973)]

Environment, Toxicological problems relating to changes in the ~ (FP) 274 [G.E. *85*, 317 (1973)]

Enzyme complex, Molecular structure and biosynthesis of the fatty acid synthetase-multi-~ of yeast (CR) 341 [G.E. *85*, 365 (1973)]

Enzymes, Prebiotic evolution of enzyme-like systems (CR) 247 [G.E. *85*, 231 (1973)]
Quaternary structure and activity (CR) 430 [G.E. *85*, 458 (1973)]
~ insolubilized on inorganic supports (LA) 342

Ether fissions, Nucleophilic ~ by 1,1-diphenylhexyllithium (SC) 856 [G.E. *85*, 916 (1973)]

Episomes, Episome (Book Review) 88

Epoxides, 5,6-Dihydro-4H-1,3-oxazines and γ-amino alcohols from α-metalated isocyanides and ~ (SC) 323 [G.E. *85*, 355 (1973)]
Base-catalyzed rearrangements (LA) 935

Epoxysuccinate, The cis isomer of disodium ~ (PR) 514

ESCA studies on N_2-, N_2H_2-, N_2H_4- and NH_3-complexes of manganese (SC) 1017 [G.E. *85*, 1120 (1973)]

Esters, One-step synthesis of pyrroles by anodic dimerization of enamino ketones or ~ (SC) 245 [G.E. *85*, 264 (1973)]
Preparation of ~ of 2,3-dihydroxy-1-propanesulfonic acid with alkenecarboxylic acids (PR) 937

Ether, Mechanism of cleavage of diethyl ~ by alkyllithium compounds: differing mechanisms of decomposition of α- and β-deuterated diethyl ~ (SC) 75 [G.E. *85*, 90 (1973)]
Aryl alkynyl ~-s (PR) 937

Ethylenediamine, [3.3]-Sigmatropic reactions in the N,N'-dimethylene-~ system (SC) 767 [G.E. *85*, 824 (1973)]

Evolution, The origin of life (FP) 349 [G.E. *85*, 422 (1973)]
Prebiotic ~ of enzyme-like systems (CR) 247 [G.E. *85*, 231 (1973)]

Excitation mechanism of photoreceptor cells (CR) 164 [G.E. *85*, 153 (1973)]

Experimental data, Messergebnisse und ihre Auswertung (Book Review) 866

FAST reactions (Book Review) 90

Fats, Progress in the chemistry of ~ and other lipids (Book Review) 346

Fatty acid synthetase, Molecular structure and biosynthesis of the ~-multienzyme complex of yeast (CR) 341 [G.E. *85*, 365 (1973)]

Ferritin, Structure and function (FP) 57 [G.E. *85*, 53 (1973)]

Ferromagnets, NMR in ~ and anti-~ (LA) 436

Fiber optics, Light guide systems for the ultraviolet region of the spectrum (FP) 439 [G.E. *85*, 468 (1973)]

Fibers, Chemical analysis of synthetic ~ (FP) 602 [G.E. *85*, 691 (1973)]

Field emission, Polymerization induced by field ionization and ~ in various liquid monomers (CR) 427 [G.E. *85*, 455 (1973)]

Field ionization, Polymerization induced by ~ and field emission in various liquid monomers (CR) 427 [G.E. *85*, 455 (1973)]

Films, Specific heat and formation of kinks in bimolecular ~ of long-chain n-alkyl compounds (SC) 850 [G.E. *85*, 915 (1973)]

Flagella, The bacterial ~ and the flagellar protein flagellin (FP) 683 [G.E. *85*, 731 (1973)]

Flagellin, The bacterial flagella and the flagellar protein ~ (FP) 683 [G.E. *85*, 731 (1973)]

Fluorides, Simple synthesis of carbonyl chloride fluoride and carbonyl bromide fluoride (SC) 918 [G.E. *85*, 982 (1973)]
Bis(amido)sulfur tetra-~ (SC) 1000 [G.E. *85*, 1105 (1973)]

Fluorine compounds, Simple synthesis of hexafluoroacetone azine (SC) 502 [G.E. *85*, 541 (1973)]
Simplified synthesis of pentafluoro-1-iodoethane and heptafluoro-2-iodopropane (SC) 929 [G.E. *85*, 988 (1973)]

Fluoroolefins, Reactive compounds from ~ (CR) 1023 [G.E. *85*, 1062 (1973)]

Fly agaric, Determination of the structure of the vanadium compound, amavadine, from ~ (SC) 508 [G.E. *85*, 542 (1973)]

Formic acid, Removal of allyl groups by ~ catalyzed by (tripenylphosphane)palladium (SC) 928 [G.E. *85*, 986 (1973)]

Formylation, Vilsmeier ~ of enediamines (SC) 323 [G.E. *85*, 346 (1973)]

Fragmentation, Concerted ~ of a 1,6-diradical on thermolysis of 1,2-dioxanes (SC) 843 [G.E. *85*, 914 (1973)]

Fries rearrangement, New aspects (SC) 775 [G.E. *85*, 819 (1973)]

Fulvenes, π-Ionization potentials of alkyl-~, or the limitations of Koopmans' theorem (SC) 422 [G.E. *85*, 414 (1973)]

Functional groups, Reductions by sulfurated hydridoborates (LA) 512

GAS chromatography, Use of reversed ~ in the study of polymers (LA) 935

Germanes, Triiodogermane (SC) 856 [G.E. *85*, 870 (1973)]

Germanium compounds, Stabilization of monomeric dichlorogermylene (SC) 1002 [G.E. *85*, 1116 (1973)]

Germyl compounds, Silyl-, germyl-, and stannyl-substituted ketenes (CR) 675 [G.E. *85*, 673 (1973)]

Glutarodinitrile, Hydrogenation of a substituted ~ (SC) 927 [G.E. *85*, 985 (1973)]

Glycoaldehyde, CIDNP-Detection of a photocatalyzed C—C cleavage upon UV irradiation of ~ in aqueous solution (SC) 763 [G.E. *85*, 768 (1973)]

Glycoproteins, Chemistry and significance of the carbohydrate moieties of human serum ~ (FP) 721 [G.E. *85*, 803 (1973)]

Gold compounds, Phosphorus ylides as structural units in organo-~ (SC) 416 [G.E. *85*, 449 (1973)]

Grafted chains, Determination of the lengths of ~ and incompatibility of graft polymers (CR) 432 [G.E. *85*, 460 (1973)]

Grafting, Kinetic and morphological studies on the free-radical ~ of styrene on polybutadienes (CR) 428 [G.E. *85*, 456 (1973)]

Grignard reagents, Influences of α- and β-alkyl groups on the rearrangement of 3-butenyl ~: a stable primary cyclopropylmethyl anion (SC) 774 [G.E. *85*, 823 (1973)]

Glycines, Preparation of N-disubstituted (PR) 514

HABIT, Structural information from the ~ of crystals (FP) 528 [G.E. *85*, 595 (1973)]

Hemostasis, Surface effects in ~ and thrombosis (LA) 84

Hereditary diseases—causes, cures, and problems (FP) 1 [G.E. *85*, 28 (1973)]

Heterocumulenes, 1,3-Anionic cycloadditions of trans,trans-1,3-diphenyl-2-azaallyllithium to ~ (SC) 568 [G.E. *85*, 583 (1973)]

Heterocycles, Syntheses by intramolecular acylation of nitrile-hydrogen halide adducts (FP) 119 [G.E. *85*, 155 (1973)]
1,3-Dipolar addition of cyclic diazo ketones to alkynes and cyclopropene. Synthesis of ~ by [1,5]-acyl migration (SC) 240 [G.E. *85*, 259 (1973)]
~ from compounds containing two nucleophilic centers and phosgenimmonium salts (SC) 405 [G.E. *85*, 446 (1973)]
Cleavage of C—N bonds in ~ (LA) 936

Heterocyclic cations, 1,3-Dioxolan-2-ylium and related ~ (LA) 779

Hexafluoroacetone azine, Simple synthesis (SC) 502 [G.E. *85*, 541 (1973)]
Synthesis of 1,2λ⁵-azaphosphoridines (SC) 502 [G.E. *85*, 542 (1973)]

Hexachlorodisilane, Reactions with methylene and dichlorocarbene (SC) 500 [G.E. *85*, 507 (1973)]

Homoaromatic compounds, Semibullvalenes as potential ~ (SC) 758 [G.E. *85*, 760 (1973)]

Homobenzene, Metal-catalyzed [4+2]-cycloadditions of a vinylcyclopropane group to a C—C bond of a cyclopropane ring: synthesis and degenerate valence isomerization of a bis-~-Fe(CO)$_3$ derivative (SC) 574 [G.E. *85*, 628 (1973)]
cis-Triazatris-σ-~ (cis-"benzene triimine") (SC) 989 [G.E. *85*, 1107 (1973)]
Chemistry of cis-trioxatris-σ-homobenzene. Substitutions by univalent nucleophiles (SC) 993 [G.E. *85*, 1110 (1973)]
Chemistry of cis-trioxatris-σ-~. Substitutions by bivalent nucleophiles (SC) 994 [G.E. *85*, 1111 (1973)]

Homoconjugation, Thermolysis of the tetracyclo[4.4.0.0^{2,5}.0^{7,10}]deca-3,8-diene system π-~ or σ-hyperconjugation (SC) 572 [G.E. *85*, 615 (1973)]

Hormones, Chemistry and biosynthesis of the hypothalamic releasing and inhibiting neuro-~ (FP) 255 [G.E. *85*, 271 (1973)]

Hybridization, sp^2-~ on the sulfur-substituted nitrogen in diethyl 2,2-(heptasulfane-1,7-diyl)-1,1-hydrazinedicarboxylate (SC) 148 [G.E. *85*, 143 (1973)]

Hydrazidinyl radicals: 1,2,4,5-tetraazapentenyls, verdazyls, and tetrazolinyls (FP) 455 [G.E. *85*, 485 (1973)]

Hydrazine, Formation of 1,2,4-triazolin-5-ones from tert-butylnitroacetylene and phenyl-~-s (SC) 406 [G.E. *85*, 447 (1973)]
Photoelectron spectra and conformation of ~ derivatives (SC) 408 [G.E. *85*, 410 (1973)]

1,1-Hydrazinedicarboxylate, sp^2-Hybridization on the sulfur-substituted nitrogen diethyl 2,2-(heptasulfane-1,7-diyl)-~ (SC) 148 [G.E. *85*, 143 (1973)]

Hydrazones, Reactions (LA) 1023

Hydrides, Reactions of carbonylmetal ~ with aziridine and propylene sulfide (2-methylthiirane) (SC) 77 [G.E. *85*, 87 (1973)]
Transition metal ~ (Book Review) 938

Hydrido bridges, Tetrameric η-cyclopentadienylcobalt hydride—a new type of four-center cluster with μ$_3$-~ (SC) 843 [G.E. *85*, 867 (1973)]

Hydrocarbon hydroperoxides, Association (LA) 936

Hydroformylation, Asymmetric induction by a chiral bisphosphane-rhodium complex in ~ of aliphatic olefins (SC) 669 [G.E. *85*, 663 (1973)]
Carboxylic esters produced by low-pressure ~ of olefins in benzil (SC) 851 [G.E. *85*, 911 (1973)]
Recent developments in catalysis of ~ (LA) 436

Hydrogels, Polymeric ~ with high water contents (PR) 938

Hydrogenation, Hydrogenative removal of phenolic hydroxyl groups (SC) 918 [G.E. *85*, 981 (1973)]
~ of a substituted glutarodinitrile (SC) 927 [G.E. *85*, 985 (1973)]
~-s and isomerizations over zinc oxide (LA) 512

Hydrogen transfer reaction for preparation of unsaturated compounds (LA) 437

Hydroperoxides, Association of hydrocarbon ~ (LA) 936

Hydroxy groups, Hydrogenative removal of phenolic ~ (SC) 918 [G.E. *85*, 981 (1973)]

Hydroxyloganine, Total synthesis of ~ and hydroxyloganic acid (SC) 757 [G.E. *85*, 763 (1973)]

Hyperconjugation, Semiquantitative proof (SC) 307 [G.E. *85*, 299 (1973)]
Thermolysis of the tetracyclo[4.4.0.0^{2,5}.0^{7,10}]deca-3,8-diene system. π-homoconjugation or σ-~ (SC) 572 [G.E. *85*, 615 (1973)]

Hypothalamus, Chemistry and biosynthesis of the hypothalamic releasing and inhibiting neurohormones (FP) 255 [G.E. *85*, 271 (1973)]

Hysteresis, Molecular ~ and its significance (FP) 356 [G.E. *85*, 430 (1973)]

IDENTIFICATION of organic compounds (Book Review) 939

Imidazolidinediones, Amino-~ and imino-~ (PR) 513

Imidic esters, Reaction with aziridines (SC) 768 [G.E. *85*, 817 (1973)]

Imidophosphates as new nucleotide derivatives (SC) 70 [G.E. *85*, 43 (1973)]

Imidoyl chlorides, Acyl isocyanates from N-(chlorocarbonyl)-~ (SC) 999 [G.E. *85*, 1058 (1973)]

Imines, Nitrile/amine conproportionation to two ~ (SC) 238 [G.E. *85*, 230 (1973)]

Iminodiethanols, Preparation of 4,6-dioxa-1-azabicyclo[3.3.0]octanes from ~ and nitriles (SC) 996 [G.E. *85*, 1055 (1973)]

Incompatibility, Determination of the lengths of grafted chains and ~ of graft polymers (CR) 432 [G.E. *85*, 460 (1973)]
Inhomogeneous polymer networks through ~ (CR) 433 [G.E. *85*, 461 (1973)]

Indolinone, Benzoxazine, benzothiazine, and ~ derivatives (PR) 780

Infrared spectroscopy, Far-Infrared (Book Review) 865

Insect pheromones, Recent results in insect pheromone chemistry (FP) 644 [G.E. *85*, 647 (1973)]

Insertion, Acetylnickel halides by ~ of CO into Ni—C δ bonds (SC) 402 [G.E. *85*, 403 (1973)]

Insertion reagent, Tetrasulfur tetranitride—a new ~ (SC) 424 [G.E. *85*, 453 (1973)]

Iodine compounds, Tetraiodosilanebis[tricarbonyliron(0)] (SC) 760 [G.E. *85*, 720 (1973)]
Simplified synthesis of pentafluoro-1-iodoethane and heptafluoro-2-iodopropane (SC) 929 [G.E. *85*, 988 (1973)]

Iodine tris(trifluoroacetate), Stereospecific oxidation of alkenes by ~ (SC) 163 [G.E. *85*, 175 (1973)]

Ionic bonding, Zintl phases: Transitions between metallic bonding and ~ (FP) 694 [G.E. *85*, 742 (1973)]

Ionic solvation in nonaqueous and mixed solvents (LA) 436

Ionization potentials, of deformed π-bonds (SC) 312 [G.E. *85*, 302 (1973)]
π-~ of alkylfulvenes, or the limitations of Koopmans' theorem (SC) 422 [G.E. *85*, 414 (1973)]

Ion-selective electrodes, Selective ion sensitive electrodes (Book Review) 1025

Iron complexes, Metal-catalyzed [4+2]-cycloadditions of a vinylcyclopropane group to a C—C bond of a cyclopropane ring: synthesis and degenerate valence isomerization of a bishomobenzene-$Fe(CO)_3$ derivative (SC) 574 [G.E. *85*, 628 (1973)]
Detection of free cyclobutadiene on oxidation of a tricarbonyl(cyclobutadiene)iron complex (SC) 777 [G.E. *85*, 828 (1973)]
Syntheses of carbonyl-~ of pentalene and its derivatives (SC) 925 [G.E. *85*, 958 (1973)]

Iron compounds, Structure and function of ferritin (FP) 57 [G.E. *85*, 53 (1973)]
The first oxoferrate(III) having a discrete anion: $K_6[Fe_2O_6]$ (SC) 673 [G.E. *85*, 589 (1973)]
Tetraiodosilanebis[tricarbonyliron(0)] (SC) 760 [G.E. *85*, 720 (1973)]

Iron-sulfur proteins: structural chemistry of their chromophores and related systems (FP) 390 [G.E. *85*, 390 (1973)]

IR spectroscopy, of nucleic acids (LA) 342
The recording of weak IR signals (LA) 343

Isoalloxazines, Reactivity of alloxazines and ~ (LA) 936

Isocyanates, Methoxymethyl isocyanate as a new agent for reversible protection of SH groups in protein and peptide chemistry (SC) 756 [G.E. *85*, 765 (1973)]
Reactions with N-aryloxamidic esters (SC) 919 [G.E. *85*, 982 (1973)]
Acyl ~ from N-(chlorocarbonyl)imidoyl chlorides (SC) 999 [G.E. *85*, 1058 (1973)]

Isocyanides 5,6-Dihydro-4H-1,3-oxazines and γ-aminoalcohols from α-metalated ~ and epoxides (SC) 323 [G.E. *85*, 355 (1973)]

Isohypericin, Alkaline condensation of emodin to ~: a simple synthesis of the meso-naphthodianthrone (phenanthro[1,10,9,8-opqra]perylene) system (SC) 79 [G.E. *85*, 88 (1973)]

Isoindole, X-ray structure analysis of 1,1,1',1'-tetrakis(trifluoromethyl)-3,3'-bi-(1H-~) (SC) 157 [G.E. *85*, 170 (1973)]

Isoindolenines, 5-Amino-1,2,4-thiadiazoles from 1-amino-3-iminoiso-~ (SC) 237 [G.E. *85*, 226 (1973)]

Isomerizations and hydrogenations over zinc oxide (LA) 512

Isopropylideneacetate, Synthesis of 4-mercapto-2-azetidinones having α-~ groups on nitrogen (SC) 925 [G.E. *85*, 983 (1973)]

Isoquinoline alkaloids, Photochemical synthesis (LA) 343

Isothiocyanates, α-Chloroalkyl and α-alkenyl ~ (SC) 842 [G.E. *85*, 866 (1973)]

2-Isothiocyanatoacrylic esters, 3-Substituted ~ (SC) 923 [G.E. *85*, 909 (1973)]

Isotope distribution, Occurrence and ~ of xenon in terrestrial and extraterrestrial material (LA) 85

Isotopes, The kinetic isotope method and its application (Book Review) 782

KETENE, Stereoselective acylation of racemic secondary alcohols with phenyltrifluoromethyl-~ as an experimental test of the stereochemical analogy model (FP) 25 [G.E. *85*, 16 (1973)]
^{13}C-NMR spectrum of ~ (SC) 668 [G.E. *85*, 671 (1973)]
Silyl-, germyl-, and stannyl-substituted ~-s (CR) 675 [G.E. *85*, 673 (1973)]

Ketene thioacetals, "Michael-type" addition to conjugated ~ (SC) 69 [G.E. *85*, 42 (1973)]

Ketones, One-step synthesis of pyrroles by anodic dimerization of enamino ~ or esters (SC) 245 [G.E. *85*, 264 (1973)]
Conversion of ~ or aldehydes into the next higher nitrile (SC) 407 [G.E. *85*, 402 (1973)]

Kinetics, Very low-pressure pyrolysis (VLPP); a versatile kinetic tool (FP) 534 [G.E. *85*, 602 (1973)]

Kinks, Specific heat and formation of ~ in bimolecular films of long-chain n-alkyl compounds (SC) 850 [G.E. *85*, 915 (1973)]

Koopmans' theorem, π-Ionization potentials of alkylfulvenes, or the limitations of ~ (SC) 422 [G.E. *85*, 414 (1973)]

LACTIC acid (Book Review) 347

β-Lactones, Preparation, structure, and mechanical properties of block copolyesters from ~ (CR) 432 [G.E. *85*, 460 (1973)]

Lanthanoid shift reagents, Dynamic NMR measurements of boc-amino esters with application of ~ (SC) 1011 [G.E. *85*, 1059 (1973)]

Laser beams, Chemical effects (LA) 935

Lead(IV) acetate azides, Reaction with olefins (LA) 85

Leucine, Asymmetric stereoselective polymerization of the N-carboxy anhydrides of D,L-~ (CR) 428 [G.E. *85*, 456 (1973)]

Life, Origin (FP) 349 [G.E. *85*, 422 (1973)]

Ligand influences in heterogeneous catalysis: modification of the Philips catalyst (SC) 754 [G.E. *85*, 827 (1973)]

Light guide systems for the ultraviolet region of the spectrum (FP) 439 [G.E. *85*, 468 (1973)]

Liquid crystals, Chemistry and applications (FP) 617 [G.E. *85*, 706 (1973)]

Liquid state, Physical chemistry—an advance treatise (Book Review) 866

Literature searches, Possibilities and limitations of delegated ~ by computer (FP) 882 [G.E. *85*, 978 (1973)]

Lithium compounds, Mechanism of cleavage of diethyl ether by alkyl-~: differing mechanisms of decomposition of α- and β-deuterated diethyl ether (SC) 75 [G.E. *85*, 90 (1973)]
Lithium derivatives of silanol and related compounds (SC) 317 [G.E. *85*, 344 (1973)]
Transmetalation and double metal exchange: a convenient route to organolithium compounds of the benzyl and allyl type (SC) 508 [G.E. *85*, 544 (1973)]
1,3-Anionic cycloadditions of trans,trans-1,3-diphenyl-2-azaallyllithium to heterocumulenes (SC) 568 [G.E. *85*, 583 (1973)]
1,3-Anionic cycloadditions of 2-azaallyllithium compounds to nitriles (SC) 569 [G.E. *85*, 584 (1973)]
Nucleophilic ether fissions by 1,1-diphenylhexyllithium (SC) 856 [G.E. *85*, 916 (1973)]
π-Bonded nitrogen in a crystalline nickel-lithium complex (SC) 997 [G.E. *85*, 1050 (1973)]
Molecular structure of a π-dinitrogen-nickel-lithium complex (SC) 998 [G.E. *85*, 1051 (1973)]
Nucleophilic thioacylation with solutions of dimethylthiocarbamoyllithium (SC) 1014 [G.E. *85*, 1104 (1973)]

Lithium diisopropylamide, (Dimethylcarbamoyl)lithium from dimethylformamide and ~: synthesis of α-hydroxy N,N-dimethylcarboxyamides (SC) 836 [G.E. *85*, 861 (1973)]

Loganine, Total synthesis of hydroxy-~ and hydroxyloganic acid (SC) 757 [G.E. *85*, 763 (1973)]

Luminescence, Thermolysis of tetramethyl-1,2-dioxetane (SC) 772 [G.E. *85*, 822 (1973)]

MACROMOLECULAR colloquium (CR) 427 [G.E. *85*, 455 (1973)]

Macromolecules, Biogenic ~ of arterial tissue and cartilage (CR) 83 [G.E. *85*, 94 (1973)]

Malignant cells, Interactions between normal cells and ~ (LA) 342
Manganese compounds, Tricarbonyl-(1-phenylborinato)manganese (SC) 764 [G.E. *85*, 817 (1973)]
Direct synthesis of diastereoisomeric phosphane-manganese complexes (SC) 1013 [G.E. *85*, 1118 (1973)]
ESCA studies on N_2^-, $N_2H_2^-$, $N_2H_4^-$, and NH_3-complexes of manganese (SC) 1017 [G.E. *85*, 1120 (1973)]
Diphosphane-transition metal complexes: $P_2H_4[(CrCO)_5]_2$ and $P_2H_4[C_5H_5Mn(CO)_2]_2$ (SC) 1020 [G.E. *85*, 1123 (1973)]

Manganese dioxide, Conversion of vicinal diols into dicarbonyl compounds by ~ (SC) 401 [G.E. *85*, 401 (1973)]

Mass spectroscopy, Elektronenanlagerungs-Massenspektrographie organischer Substanzen (Book Review) 514

Mathematics, Mathematik für Chemiker (Book Review) 866

Medicine, Real-Lexikon der Medizin (Book Review) 514

Mercury, Structural chemistry (CR) 435 [G.E. *85*, 418 (1973)]

Mercury compounds, Structural chemistry of mercury (CR) 435 [G.E. *85*, 418 (1973)]

Mesomolecules, Polyaza-polyoxa macropolycyclic systems (SC) 578 [G.E. *85*, 621 (1973)]

Metal exchange, Transmetalation and double ~: a convenient route to organolithium compounds of the benzyl and allyl type (SC) 508 [G.E. *85*, 544 (1973)]

Metallic bonding, Zintl phases: Transitions between ~ and ionic bonding (FP) 694 [G.E. *85*, 742 (1973)]

Metathesis, Influence of ligands on catalysts for the heterogeneous ~ of olefins (SC) 153 [G.E. *85*, 148 (1973)]

Methacrolein, New catalyst for the simultaneous production of 1,3-butadiene and ~ (PR) 344

Methane derivatives, Semiempirical use of chirality functions for description of optical activity of ~ in the transparent region (FP) 30 [G.E. *85*, 21 (1973)]

4,9-Methano[11]annulenone, Crystal structure of 2-hydroxy-~ (SC) 855 [G.E. *85*, 870 (1973)]

Methylchlorophosphanes and their reaction products (FP) 877 [G.E. *85*, 973 (1973)]

Methyleneaziridine-cyclopropanimine valence isomerization (SC) 414 [G.E. *85*, 411 (1973)]

Methylenebicyclo[4.2.1]nona-2,4,7-triene (SC) 81 [G.E. *85*, 45 (1973)]
Methylenecyclopropane, Trimerization on triorganophosphane-modified nickel(0) catalyst (SC) 995 [G.E. *85*, 1053 (1973)]
Methyleneimmonium salts, Studies on ~ (CR) 586 [G.E. *85*, 592 (1973)]
2-Methylenetricyclo[4.1.0.0^{1,3}]heptane, Thermal rearrangement (SC) 505 [G.E. *85*, 512 (1973)]
Methylmalonyl-CoA-mutase reaction, Stereochemistry of the coenzyme-B_{12}-dependent ~. Investigation with ethylmalonyl-CoA (SC) 671 [G.E. *85*, 721 (1973)]
Microwaves, Use of high-frequency microwave energy in graft copolymerization (PR) 937
Miscibility, Partial ~ of polymer solutions (CR) 431 [G.E. *85*, 460 (1973)]
Molding compositions, Thermosetting ~ (PR) 86
Molybdenum complexes, trans-Halogeno[alkyl(aryl)carbyne]tetracarbonyl complexes of chromium, molybdenum, and tungsten—a new class of compounds having a transition metal-carbon triple bond (SC) 564 [G.E. *85*, 618 (1973)]
Polynuclear π-cyclopentadienyl-sulfur-molybdenum complexes from propylene sulfide and π-cyclopentadienylcarbonyl-molybdenum hydrides (SC) 582 [G.E. *85*, 625 (1973)]
Molybdenum compounds, A macroisopolyanion of molybdenum: $Mo_{36}O_{112}^{8-}$ (SC) 330 [G.E. *85*, 305 (1973)]
Polymeric octamolybdate ions in the crystal structure of $(NH_4)_6Mo_8O_{27}.4H_2O$ (SC) 409 [G.E. *85*, 409 (1973)]
Morpholine, Chemical reactions in a plasma (SC) 1004 [G.E. *85*, 1054 (1973)]

NAPHTHODIANTHRONE, Alkaline condensation of emodin to isohypericin: simple synthesis of the meso-~ (phenanthro[1,10,9,8-opqra]perylene) system (SC) 79 [G.E. *85*, 88 (1973)]
Neuraminic acids, Chemistry and biology (FP) 126 [G.E. *85*, 128 (1973)]
Neurohormones, Chemistry and biosynthesis of the hypothalamic releasing and inhibiting ~ (FP) 255 [G.E. *85*, 271 (1973)]
Neutron diffraction, Determination of the radius of gyration of polymethylmethacrylate in the vitreous state by ~ (CR) 431 [G.E. *85*, 459 (1973)]
Nickel-carbon bond, Acetylnickel halides by insertion of CO into Ni—C σ bonds (SC) 402 [G.E. *85*, 403 (1973)]
Nickel complexes, Tris(ethylene)nickel(0) (SC) 565 [G.E. *85*, 620 (1973)]
Spin state of pentacoordinate cobalt(II) and nickel(II) complexes (LA) 862
Nickel compounds, The "Nickel Effect" (FP) 943 [G.E. *85*, 1002 (1973)]
Tetrakis(dimethylphosphoniumbismethylide)dinickel, a new type of cage compound (SC) 853 [G.E. *85*, 910 (1973)]
Trimerization of methylenecyclopropane on triorganophosphane-modified nickel(0) catalyst (SC) 995 [G.E. *85*, 1053 (1973)]
π-Bonded nitrogen in a crystalline nickel-lithium complex (SC) 997 [G.E. *85*, 1050 (1973)]
Molecular structure of a π-dinitrogen-nickel-lithium complex (SC) 998 [G.E. *85*, 1051 (1973)]
Tetrakis(η-cyclopentadienyl)tetranickel trihydride – An unusual tetranuclear cluster (SC) 1005 [G.E. *85*, 1117 (1973)]
Niobates, Gmelins Handbuch der anorganischen Chemie (Book Review) 515
Niobium, Kinetic investigations of anodic oxide layers on ~ and tantalum (CR) 341 [G.E. *85*, 311 (1973)]
Gmelins Handbuch der anorganischen Chemie (Book Review) 87
Nitrido complexes, Transition metal complexes of the N^{3-} ligand (LA) 862
Nitriles, Syntheses of heterocycles by intramolecular acylation of nitrile-hydrogen halide adducts (FP) 119 [G.E. *85*, 155 (1973)]
Nitrile/amine conproportionation to two imines (SC) 238 [G.E. *85*, 230 (1973)]
Conversion of a ketone or an aldehyde into the next higher nitrile (SC) 407 [G.E. *85*, 402 (1973)]
1,3-Anionic cycloadditions of 2-azaallyllithium compounds to ~ (SC) 569 [G.E. *85*, 584 (1973)]
Elimination of the nitrile group from o-amino ~ (SC) 837 [G.E. *85*, 861 (1973)]
Stereochemistry of the 2-oxazoline synthesis form β-amino alcohols and ~ (SC) 920 [G.E. *85*, 956 (1973)]
Hydrogenation of a substituted glutarodinitrile (SC) 927 [G.E. *85*, 985 (1973)]
Preparation of 4,6-dioxa-1-azabicyclo-[3.3.0]octanes from iminodiethanols and ~ (SC) 996 [G.E. *85*, 1055 (1973)]
Reaction with acyl chlorides in presence of hydrogen chloride (LA) 934
Nitrile ylides, New type of dimerization (SC) 156 [G.E. *85*, 169 (1973)]
Nitrogen complex, 1,4-Diazabicyclo[2.2.2]-octane(phenylmethoxy)methylenepentacarbonylchromium(0), a novel nitrogen ylide-transition metal complex (SC) 563 [G.E. *85*, 617 (1973)]
Nitrogen compounds, $(CH_3)_2SnS_2N_2$: A compound containing a five-membered tin-sulfur-nitrogen ring (SC) 674 [G.E. *85*, 722 (1973)]
π-Bonded nitrogen in a crystalline nickel-lithium complex (SC) 997 [G.E. *85*, 1050 (1973)]
Molecular structure of a π-dinitrogen-nickel-lithium complex (SC) 998 [G.E. *85*, 1051 (1973)]
Bis(amido)sulfur tetrafluorides (SC) 1000 [G.E. *85*, 1105 (1973)]
ESCA studies on N_2-, N_2H_2-, N_2H_4-, and NH_3-complexes of manganese (SC) 1017 [G.E. *85*, 1120 (1973)]
Gmelins Handbuch der anorganischen Chemie (Book Review) 87
Nitrosamine, Isolation and identification of v-tetrazine derivatives on decomposition of ~ anions (SC) 495 [G.E. *85*, 504 (1973)]
NMR-shift reagent, Tetraphenylborate ion as ~ for sulfonium compounds (SC) 400 [G.E. *85*, 404 (1973)]
Dynamic NMR measurements of boc-amino esters with application of lanthanoid shift reagents (SC) 1011 [G.E. *85*, 1059 (1973)]
NMR spectroscopy, ^{13}C shifts in biphenylene and analogous compounds (SC) 241 [G.E. *85*, 260 (1973)]
Does a "ring current effect" exist for ^{13}C-nuclear magnetic resonance? A study of bridged annulenes (SC) 243 [G.E. *85*, 261 (1973)]
$^{13}C^{13}C$ Coupling constants of 1,3-butadiene (SC) 339 [G.E. *85*, 357 (1973)]
Proof of the chirality of rapidly interconverting enantiomers (SC) 583 [G.E. *85*, 590 (1973)]
^{13}C-NMR spectrum of ketene (SC) 668 [G.E. *85*, 671 (1973)]
Significance of stereochemical factors for the chemical shift of the ^{13}C resonance (SC) 760 [G.E. *85*, 762 (1973)]
^{13}C-NMR spectra of benzocycloalkenes (SC) 762 [G.E. *85*, 826 (1973)]
Determination of rate of internal rotation by ^1H- ~ in the presence of optically active auxiliary compounds (SC) 909 [G.E. *85*, 994 (1973)]
^1H-NMR spectrum of [^{15}N]pyridine in the nematic phase (SC) 930 [G.E. *85*, 989 (1973)]
High resolution NMR measurements of boc-amino esters with application of lanthanoid shift reagents (SC) 1011 [G.E. *85*, 1059 (1973)]
Analysis of the tacticity of polymers by ^{19}F-NMR spectroscopy (CR) 434 [G.E. *85*, 463 (1973)]
Determination of the configuration of polybutadienes and poly-α-methylstyrenes by ^{13}C-NMR spectroscopy (CR) 427 [G.E. *85*, 455 (1973)]
Spin-spin coupling constants between geminal and vicinal protons (LA) 343
~ in ferromagnets and antiferromagnets (LA) 436
~ of molecules oriented in electric fields (LA) 512
Use of ~ in studies of organophosphorus compounds (LA) 862
Pulse and Fourier transform NMR (Book Review) 89
Nonstoichiometric compounds, Constitution of ~ and solid solutions (CR) 778 [G.E. *85*, 833 (1973)]
Norbornene, Stereochemistry of free-radical additions to ~ and norbornadiene (LA) 1023
Nuclear medicine and radiochemistry (FP) 712 [G.E. *85*, 793 (1973)]
Nuclear Overhauser effect, The ~ (Book Review) 864
Nucleic acids, Extrachromosomal DNA in bacteria (FP) 517 [G.E. *85*, 569 (1973)]
IR spectroscopy (LA) 342
Nucleosides, Structure and function of ~ and nucleotides (FP) 591 [G.E. *85*, 680 (1973)]
Nucleotide derivatives, Imidophosphates as new ~ (SC) 70 [G.E. *85*, 43 (1973)]
Nucleotides, Structure and function of nucleosides and ~ (FP) 591 [G.E. *85*, 680 (1973)]
Polyvinyl alcohol substituted by nucleotides as carrier for liquid phase oligo-~ synthesis (SC) 246 [G.E. *85*, 263 (1973)]
5'-Nitrates of pyrimidine nucleosides: Nitric acid analogs of ~ (SC) 752 [G.E. *85*, 765 (1973)]
New approach to the synthesis of oligodeoxyribo-~ (SC) 859 [G.E. *85*, 917 (1973)]
Physicochemical characteristics of oligo-~ and poly-~ (Book Review) 90
Nylon 4, Shaped objects of ~ (PR) 87

OLEFINS, Influence of ligands on catalysts for the heterogeneous metathesis of ~ (SC) 153 [G.E. *85*, 148 (1973)]
Asymmetric induction by a chiral bisphosphane-rhodium complex in the hydroformylation of aliphatic ~ (SC) 669 [G.E. *85*, 663 (1973)]
Carboxylic esters produced by low-pressure hydroformylation of ~ in benzil (SC) 851 [G.E. *85*, 911 (1973)]
Reactive compounds from fluoro- ~ (CR) 1023 [G.E. *85*, 1062 (1973)]
Reaction of ~ with lead(IV) acetate azides (LA) 85
Hydrogen transfer reaction for the preparation of unsaturated compounds (LA) 437

Oligodeoxyribonucleotides, New approach to the synthesis of ~ (SC) 859 [G.E. *85*, 917 (1973)]

Oligonucleotide, Polyvinyl alcohol substituted by nucleotides as carrier for liquid phase ~ synthesis (SC) 246 [G.E. *85*, 263 (1973)]

Onium salts containing carbonylmetalate anions (SC) 235 [G.E. *85*, 228 (1973)]

Optical activity, Semiempirical use of chirality functions for description of ~ of allene derivatives in the transparent region (FP) 20 [G.E. *85*, 10 (1973)]
Semiempirical use of chirality functions for description of ~ of methane derivatives in the transparent region (FP) 30 [G.E. *85*, 21 (1973)]

Orbital models, Photoelectron spectra of nonmetal compounds and their interpretation by MO models (FP) 734 [G.E. *85*, 773 (1973)]

Organophosphorus chemistry (Book Review) 864

Organosilicon compounds of phosphorus and sulfur (Book Review) 939

Oxabicyclo[5.1.0]octa-2,5-dienes, Rapid reversible Cope rearrangement between the sym-~ (SC) 580 [G.E. *85*, 624 (1973)]

Oxamidic esters, Reactions of N-aryl-~ with isocyanates (SC) 919 [G.E. *85*, 982 (1973)]

Oxathiazinone dioxides – a new group of sweetening agents (FP) 869 [G.E. *85*, 965 (1973)]

Oxathiazinones, New N-trichloromethylthio-~ (PR) 513

1,3-Oxazine, 5,6-Dihydro-4H-~-s and γ-amino alcohols from α-metalated isocyanides and epoxides (SC) 323 [G.E. *85*, 355 (1973)]
Derivatives of ~ and 1,3-thiazine (LA) *85*

1,3-Oxazolidine-4-carboxylates, Ethyl 3-acyl-2-thioxo-~ and their conversion into ethyl α-(N-acylamino)acrylates (SC) 656 [G.E. *85*, 659 (1973)]

2-Oxazoline, Stereochemistry of the ~ synthesis from β-amino alcohols and nitriles (SC) 920 [G.E. *85*, 956 (1973)]

2-Oxazoline-4-carboxylic esters, 2-Alkylthio-~ and their conversion into α-(N-alkylthiocarbonylamino)acrylic esters (SC) 658 [G.E. *85*, 660 (1973)]

Oxidation, Stereospecific ~ of alkenes by iodine tris(trifluoroacetate) (SC) 163 [G.E. *85*, 175 (1973)]
Application of phenolic ~ to the total synthesis of isoquinoline- and related alkaloids (LA) 512

Oxidation-reduction potentials of inorganic substances in aqueous solution (Book Review) 939

Oxidative degradation, Initial stage of ~ of native cellulose by molecular oxygen (CR) 434 [G.E. *85*, 462 (1973)]

Oxide layers, Kinetic investigations of anodic ~ on niobium and tantalum (CR) 341 [G.E. *85*, 311 (1973)]

Oxirane, Stereospecific attack of nucleophilic reagents on nitro-~ sugars (SC) 921 [G.E. *85*, 992 (1973)]

Oxiranyl radical, Proof of the pyramidal configuration two isomers of the 3-methyl-2-~ (SC) 932 [G.E. *85*, 993 (1973)]

Oxonium ions in organic chemistry (Book Review) 438

Oxygen, Initial stage of oxidative degradation of native cellulose by molecular ~ (CR) 434 [G.E. *85*, 462 (1973)]

Oxygen compounds, Complexes of the platinum metals with molecular oxygen (LA) 862

PALLADIUM compounds, Removal of allyl groups by formic acid catalyzed by (triphenylphosphane)palladium (SC) 928 [G.E. *85*, 986 (1973)]

Palustraminic acid, Synthesis of (±)-dihydro-~ (SC) 160 [G.E. *85*, 172 (1973)]

Paracyclophanes, Chemiluminescent ~ (SC) 425 [G.E. *85*, 451 (1973)]

Penicillin, Synthesis of deacetoxycephalosporin S-oxides by oxidative trapping of sulfenic acids from ~ S-oxides (SC) 67 [G.E. *85*, 40 (1973)]

Pentalene, Simple synthesis of 1,5-dihydro-~-s (SC) 335 [G.E. *85*, 361 (1973)]
Concerning ~, 2-methyl-~ and 1,3-dimethyl-~ (SC) 337 [G.E. *85*, 362 (1973)]
Syntheses of ironcarbonyl complexes of ~ and its derivatives (SC) 925 [G.E. *85*, 958 (1973)]

Peptide chemistry, Methoxymethyl isocyanate as a new agent for reversible protection of SH groups in protein and ~ (SC) 756 [G.E. *85*, 765 (1973)]

Peptides, Boron tris(trifluoroacetate) for removal of protecting groups in peptide chemistry (SC) 147 [G.E. *85*, 142 (1973)]
Sequencing (LA) 84

Peptide synthesis, Solid phase synthesis of peptides with carboxyl-terminal amides—thyrotropin-releasing factor (TRF) (SC) 664 [G.E. *85*, 672 (1973)]

α-Peroxyamines (FP) 783 [G.E. *85*, 850 (1973)]

Petroleum, Use of spectroscopic methods in structural analysis of coal and ~ (LA) 511

Phase-transfer catalysis, Phase-transfer-catalyzed production of sulfur ylides in an aqueous system (SC) 845 [G.E. *85*, 867 (1973)]
Phase-transfer-catalyzed alkylation of alcohols by dimethyl sulfate in an aqueous system (SC) 846 [G.E. *85*, 868 (1973)]

Phenanthrene, [2+2]-Photocycloadditions involving ~: mechanistic models for two-step processes (SC) 765 [G.E. *85*, 766 (1973)]
Cyclooctadeca[cdefg]-~ ("[18]Annulene-[cdefg]-~") (SC) 916 [G.E. *85*, 957 (1973)]

Phenazulene, Stable ~ derivatives by [12+2]-additions to 8,9-dicyanosesquifulvalene (SC) 1007 [G.E. *85*, 1112 (1973)]

Phenolic oxidation, Application to total synthesis of isoquinoline- and related alkaloids (LA) 512

Phenolic resins, Preparation of flexible ~ (PR) 937

Phenols, Hydrogenative removal of phenolic hydroxyl groups (SC) 918 [G.E. *85*, 981 (1973)]
Agents for the extermination of rodents (PR) 344

Phenylketonuria, Use of deuterated compounds in the study of tyrosine-dopa metabolism in ~ (CR) 165 [G.E. *85*, 176 (1973)]

Pheromones, Recent results in insect pheromone chemistry (FP) 644 [G.E. *85*, 647 (1973)]
Biological and biochemical phenomena of pheromonal action (LA) 935

Philips catalyst, Ligand influences in heterogeneous catalysis: modification of the ~ (SC) 754 [G.E. *85*, 827 (1973)]

Phosgenimonium salts, Chemistry of dichloromethylenammonium salts ("~") (FP) 806 [G.E. *85*, 837 (1973)]
Synthesis of chloroalkyl carbamates from diols and ~ (SC) 404 [G.E. *85*, 445 (1973)]
Heterocycles from compounds containing two nucleophilic centers and ~ (SC) 405 [G.E. *85*, 446 (1973)]

Phosphabenzenes, Simple synthesis of 4-monosubstituted arsabenzenes and ~ (SC) 931 [G.E. *85*, 990 (1973)]

Phosphanes, Methylchloro-~ and their reaction products (FP) 877 [G.E. *85*, 973 (1973)]
Removal of allyl groups by formic acid catalyzed by (triphenylphosphane)palladium (SC) 928 [G.E. *85*, 986 (1973)]
Trimerization of methylenecyclopropane on triorganophosphane-modified nickel(0) catalysts (SC) 995 [G.E. *85*, 1053 (1973)]
Direct synthesis of diastereoisomeric phosphane-manganese complexes (SC) 1013 [G.E. *85*, 1118 (1973)]
Diphosphane-transition metal complexes: $P_2H_4[Cr(CO)_5]_2$ and $P_2H_4[C_5H_5Mn(CO)_2]_2$ (SC) 1020 [G.E. *85*, 1123 (1973)]
Reactions of the radicals $RO^{\cdot}$, $RS^{\cdot}$, and $RO_2^{\cdot}$ with phosphites and ~ (LA) 936

Phosphates, Imido-~ as new nucleotide derivatives (SC) 70 [G.E. *85*, 43 (1973)]
Structural molecular biology of ~ (Book Review) 781

Phosphazene, [Bis(trimethylsilyl)amino][(trimethylsilyl)imino]phosphane, a ~ with tervalent phosphorus (SC) 585 [G.E. *85*, 586 (1973)]

μ-Phosphinodiborane (SC) 413 [G.E. *85*, 410 (1973)]

Phosphite method, Synthesis of valinomycin by the ~ (SC) 1012 [G.E. *85*, 1103 (1973)]

Phosphites, Reactions of the radicals $RO^{\cdot}$, $RS^{\cdot}$, and $RO_2^{\cdot}$ with ~ and phosphanes (LA) 936

Phospholes, Direct proof of the non-aromaticity of ~ and arsoles (SC) 145 [G.E. *85*, 140 (1973)]

Phosphonamides, High-molecular-weight, fully aromatic copolyamide-~ (PR) 513

Phosphonodithiolic acids, Esters (PR) 344

Phosphoranes, Wittig reaction of alkylidenetriphenyl-~ with sodium α-hydroxy sulfonates (SC) 237 [G.E. *85*, 230 (1973)]
Abnormal ring opening of silacyclobutane by trialkylalkylidene-~ (SC) 320 [G.E. *85*, 344 (1973)]
Detection of alkylideneoxo-~ by cycloaddition of carbonyl compounds (SC) 1010 [G.E. *85*, 1115 (1973)]

Phosphorins, How "aromatic" are λ^5-~? Electrophilic substitution reactions (SC) 753 [G.E. *85*, 815 (1973)]

Phosphorus chemistry, Organophosphorus chemistry (Book Review) 864

Phosphorus compounds, Displacement reactions of phosphorus(V) compounds and their pentacoordinate intermediates (FP) 91 [G.E. *85*, 99 (1973)]
Crystal structure of 1,3-di-tert-butyl-2-trans-4-dichloro-2,4-dioxo-1,3,2λ^5,4λ^5-diazadiphosphetidine: stereochemistry of oxidation at phosphorus(III) by dimethyl sulfoxide (SC) 311 [G.E. *85*, 343 (1973)]
Alkyl- and aryl-hydridobis(o-phenylenedioxo)phosphate(1−), a stable spiroanion containing hexacoordinated phosphorus (SC) 419 [G.E. *85*, 444 (1973)]
A novel covalent azide reaction in phosphorus chemistry (SC) 425 [G.E. *85*, 454 (1973)]

Asymmetric induction by a chiral bisphosphane-rhodium complex in the hydroformylation of aliphatic olefins (SC) 669 [G.E. *85*, 663 (1973)]
Preparation of carbonyl bis(diphenylphosphide) (SC) 842 [G.E. *85*, 910 (1973)]
Tetrakis(dimethylphosphiniumbismethylide)dinickel, a new type of cage compound (SC) 853 [G.E. *85*, 910 (1973)]
Synthesis of tris(dimethylphosphoniumbismethylide)chromium(III) (SC) 854 [G.E. *85*, 913 (1973)]
Reactivity of cyclic organic ~ (LA) 342
Properties of the metal-phosphorus bond (LA) 779
Use of NMR spectroscopy in studies of organo- ~ (LA) 862
Organosilicon derivatives of phosphorus and sulfur (Book Review) 936

Phosphorus trisulfur pentanitride, A bicyclic ~ (SC) 415 [G.E. *85*, 413 (1973)]

Phosphorus ylide complexes of group VI as sources of carbonylmethylene (SC) 667 [G.E. *85*, 668 (1973)]

Phosphorus ylides as structural units in organogold compounds (SC) 416 [G.E. *85*, 449 (1973)]

Phosphorylating agents, Five-membered cyclic acyl phosphates, a new class of extremely reactive ~ (SC) 66 [G.E. *85*, 39 (1973)]

Photochemistry, Transient cyclohexadienones by novel reversal reactions from cage photodimers derived from N-chloro-acetyltyramines (SC) 72 [G.E. *85*, 85 (1973)]
CIDNP-Detection of a photocatalyzed C—C cleavage upon UV irradiation of glycoaldehyde in aqueous solution (SC) 763 [G.E. *85*, 768 (1973)]
Formation of a 1-hydroxycorrin complex by photochemical A/D-secocorrin → corrin cycloisomerization (SC) 912 [G.E. *85*, 952 (1973)]
Photochemical synthesis of isoquinoline alkaloids (LA) 343
~ in macromolecular systems (LA) 511
Analytical ~ and photochemical analysis (Book Review) 865

Photo-Claisen rearrangement, CIDNP evidence for divergent behavior of singlet and triplet radical pair encounters in the ~ (SC) 662 [G.E. *85*, 669 (1973)]

Photocycloadditions, [2+2]-~ involving phenanthrene: mechanistic models for two-step processes (SC) 765 [G.E. *85*, 766 (1973)]

Photoelectron spectroscopy, Photoelectron spectra of nonmetal compounds and their interpretation by MO models (FP) 734 [G.E. *85*, 773 (1973)]
Semiquantitative proof of hyperconjugation (SC) 307 [G.E. *85*, 299 (1973)]
Photoionization cross sections: Differing relative band intensities in He-I and He-II photoelectron spectra (SC) 308 [G.E. *85*, 358 (1973)]
Spiroconjugation (SC) 310 [G.E. *85*, 360 (1973)]
Photoelectron spectra and conformation of hydrazine derivatives (SC) 408 [G.E. *85*, 410 (1973)]
Photoelectron spectra and molecular properties: SSO and OSO (SC) 933 [G.E. *85*, 987 (1973)]

Photoionization cross sections: Differing relative band intensities in He-I and He-II photoelectron spectra (SC) 308 [G.E. *85*, 358 (1973)]

Photometry, Direct quantitative ~ on thin layer chromatograms (FP) 298 [G.E. *85*, 334 (1973)]

Photoreceptor cells, Mechanism of excitation (CR) 164 [G.E. *85*, 153 (1973)]

Photosynthesis, Primary processes (CR) 510 [G.E. *85*, 515 (1973)]

Physical chemistry—an advance treatise (Book Review) 866

Piperidines, 1-Furylmethyl-4-methoxycarbonyl-4-phenyl- ~ (PR) 938

Plasma chemistry, Chemical reactions of morpholine in a plasma (SC) 1004 [G.E. *85*, 1054 (1973)]
Chemical reactions of dimethyl sulfoxide in a plasma (SC) 1004 [G.E. *85*, 1055 (1973)]

Plastics, Chemical analysis of additives in ~ (Book Review) 939

Platinum complexes, Complexes of the platinum metals with molecular oxygen (LA) 862

Poisoning, Toxicological problems relating to changes in the environment (FP) 274 [G.E. *85*, 317 (1973)]

Polar cycloadditions (FP) 212 [G.E. *85*, 235 (1973)]

Polyacrylate castings, Bubble-free ~ (LA) 863

Polyamides, Properties of N-chloro-~ (CR) 430 [G.E. *85*, 459 (1973)]
High-molecular-weight, fully aromatic copolyamide-phosphonamides (PR) 513

Poly-1,12-bis(maleimido)dodecane and poly-2,4-bis(maleimido)toluene (PR) 938

Poly-2,4-bis(maleimido)toluene and poly-1,12-bis(maleimido)dodecane (PR) 938

Polybutadienes, Determination of the configuration of ~ and poly-α-methylstyrenes by ^{13}C-NMR spectroscopy (CR) 427 [G.E. *85*, 455 (1973)]
Kinetic and morphological studies on the free-radical grafting of styrene on ~ (CR) 428 [G.E. *85*, 456 (1973)]

Polyesters, Preparation, structure, and mechanical properties of block copolyesters from β-lactones (CR) 432 (G.E. *85*, 460 (1973)]

Polyethers, Mesomolecules. Polyazapolyoxa macropolycyclic systems (SC) 578 [G.E. *85*, 621 (1973)]
Molecular and cation complexes of macrotricyclic and macrotetracyclic ligands (SC) 579 [G.E. *85*, 622 (1973)]
Preparation in the form of fine grains (PR) 780

Polyethylenes, International molecules (CR) 430 [G.E. *85*, 458 (1973)]
Quasi-static elasticity moduli of semicrystalline copolymers of ethylene (CR) 431 [G.E. *85*, 459 (1973)]

Polylactones, Production of dyed objects from ~ (PR) 86

Polymerization, Thermodynamics of addition ~ processes (FP) 487 [G.E. *85*, 533 (1973)]
~ induced by field ionization and field emission in various liquid monomers (CR) 427 [G.E. *85*, 455 (1973)]
Asymmetric stereoselective ~ of the N-carboxy anhydrides of D,L-leucine (CR) 428 [G.E. *85*, 456 (1973)]
Ring-opening ~ of cycloolefins in presence of metathesis catalysts (CR) 430 [G.E. *85*, 458 (1973)]
~ reactions of 4-vinylpyridinium salts in aqueous solutions (CR) 432 [G.E. *85*, 461 (1973)]
~ and co-~ of 1,2-dimethoxyethylene (CR) 433 [G.E. *85*, 463 (1973)]
Light-induced and free-radical initiator-induced cationic ~ of N-vinylcarbazole in presence of CBr_4 (CR) 433 [G.E. *85*, 461 (1973)]
Model calculations for hydrolytic ~ of caprolactam (CR) 434 [G.E. *85*, 463 (1973)]
Growth of crystals of polyoxymethylene during equilibrium ~ of trioxane (CR) 435 [G.E. *85*, 462 (1973)]

Polymerization kinetics, Use for investigation of homogeneous catalytic processes (CR) 429 [G.E. *85*, 457 (1973)]

Polymer networks, Inhomogeneous ~ through incompatibility (CR) 433 [G.E. *85*, 461 (1973)]

Polymers, Chemical analysis of synthetic fibers (FP) 602 [G.E. *85*, 691 (1973)]
Method for the investigation of stress-induced rearrangement processes in ~: crystal transition II to I of poly-1-butene by mechanical stresses (CR) 429 [G.E. *85*, 457 (1973)]
Polymeric reagents (CR) 429 [G.E. *85*, 457 (1973)]
Determination of lengths of grafted chains and incompatibility of graft ~ (CR) 432 [G.E. *85*, 460 (1973)]
Analysis of the tacticity of ~ by ^{19}F-NMR spectroscopy (CR) 434 [G.E. *85*, 463 (1973)]
Antistatic agents for the treatment of high ~ (LA) 437
Resin compositions or objects made from them that are decomposed and degraded by the action of light (LA) 437
Antithrombogenic plastic components (LA) 437
~ of allyl esters of hexachlorooctahydromethanonaphthalenedicarboxylic acid (LA) 863
Use of reversed gas chromatography in the study of ~ (LA) 935
Polymer masses containing fibrous electrically conducting material (PR) 343
Process for production of transparent rubber-based graft ~ (PR) 780
Plastics having the ability to retain electrostatic charges (PR) 938
Polymer science and materials (Book Review) 347
Properties of ~. Correlations with chemical structure (Book Review) 348

Polymer solutions, Partial miscibility (CR) 431 [G.E. *85*, 460 (1973)]

Polymethylmethacrylate, Determination of radius of gyration of ~ in the vitreous state by neutron diffraction (CR) 431 [G.E. *85*, 459 (1973)]

Poly-α-methylstyrenes, Determination of the configuration of polybutadienes and ~ by ^{13}C-NMR spectroscopy (CR) 427 [G.E. *85*, 455 (1973)]

Polynucleotides, Physicochemical characteristics of oligonucleotides and ~ (Book Review) 90

Polyolefins, Fire-resistant, loaded melt compositions based on atactic ~ (PR) 937

Polyoxymethylene, Growth of crystals of ~ during equilibrium polymerization of trioxane (CR) 435 [G.E. *85*, 462 (1973)]

Polypeptides, Determination of conformation of cyclic ~ in solution (LA) 436

(Polypyrazolyl)borates, The versatile ~ (CR) 861 [G.E. *85*, 873 (1973)]

Polysaccharides, Plant structure ~: structure and biosynthesis (CR) 428 [G.E. *85*, 456 (1973)]

Polyurethanes, Preparation of flame-resistant and hydrolysis-resistant ~ (PR) 936

Polyvinyl alcohol substituted by nucleotides as carrier for liquid phase oligonucleotide synthesis (SC) 246 [G.E. *85*, 263 (1973)]

Precious stones, Synthetic ~ (FP) 291 [G.E. *85*, 326 (1973)]

Propanol, Preparative-scale synthesis of (1R)- and (1S)-monodeuterio-~ by enzymatic exhange reactions (SC) 146 [G.E. *85*, 141 (1973)]

Propylene polymerization, Low-pressure ~ (LA) 863

Protecting groups, Boron tris(trifluoroacetate) for removal of ~ in peptide chemistry (SC) 147 [G.E. *85*, 142 (1973)]
Methoxymethyl isocyanate as a new agent for reversible protection of SH groups in protein and peptide chemistry (SC) 756 [G.E. *85*, 765 (1973)]

Proteinase inhibitors, Structure and function of natural ~ (CR) 510 [G.E. *85*, 545 (1973)]

Proteins, Structure and function of ferritin (FP) 57 [G.E. *85*, 53 (1973)]
Iron-sulfur ~: structural chemistry of their chromophores and related systems (FP) 390 [G.E. *85*, 390 (1973)]
The bacterial flagella and the flagellar protein flagellin (FP) 683 [G.E. *85*, 731 (1973)]
Chemistry and significance of the carbohydrate moieties of human serum glyco-~ (FP) 721 [G.E. *85*, 803 (1973)]
Toxic ~ capable of inhibiting protein synthesis (LA) 512

1H-Pyrazolo[3,4-b]pyridines, New variant for synthesis (SC) 922 [G.E. *85*, 959 (1973)]

Pyrazolylborates, The versatile (polypyrazolyl)borates (CR) 861 [G.E. *85*, 873 (1973)]

Pyridine, ^{1}H-NMR spectrum of [^{15}N]- ~ in the nematic phase (SC) 930 [G.E. *85*, 989 (1973)]
Syntheses of carpyrinic acid (LA) 513
Novel production of 3,5-dimethyl- ~ (PR) 343

Pyridinium salts, Polymerization reactions of 4-vinyl-~ in aqueous solutions (CR) 432 [G.E. *85*, 461 (1973)]

Pyrimidine nucleosides, 5'-Nitrates of ~: Nitric acid analogs of nucleotides (SC) 752 [G.E. *85*, 765 (1973)]

Pyrolysis, Very low-pressure ~ (VLPP); a versatile kinetic tool (FP) 534 [G.E. *85*, 602 (1973)]

Pyrroles, One-step synthesis by anodic dimerization of enamino ketones or esters (SC) 245 [G.E. *85*, 264 (1973)]

Pyrrolidine-1-carboxanilides (PR) 1024

QUARTZ crystals and their colors (FP) 283 [G.E. *85*, 281 (1973)]

Quinhydrone, An "intramolecular ~" (SC) 776 [G.E. *85*, 831 (1973)]

Quino acids, Stable α-addition products of four-component condensation (SC) 79 [G.E. *85*, 92 (1973)]

8-Quinolinecarboxylic acid from 3,1-benzoxazin-4-ones and enamines (SC) 495 [G.E. *85*, 505 (1973)]

Quinolinobenzazepines, Partly hydrogenated ~ (PR) 937

Quinones, Chemistry and biochemistry of aza-~ (FP) 139 [G.E. *85*, 163 (1973)]

Quinonoid vat polymers (PR) 86

Quinuclidinium perchlorates, 4-Substituted ~ as models for the determination of polar substituent effects (SC) 319 [G.E. *85*, 310 (1973)]

RACEMIZATION of optically active α-amino-ε-caprolactam by microbiological means (PR) 344

Radiation chemistry of water (Book Review) 940

Radical anions, The first divinylazo compound and its radical anion (SC) 655 [G.E. *85*, 657 (1973)]

Radical ions, Polysulfide ~ (SC) 420 [G.E. *85*, 416 (1973)]

Radical pair combinations, CIDNP evidence for divergent behavior of singlet and triplet radical pair encounters in the photo-Claisen rearrangement (SC) 662 [G.E. *85*, 669 (1973)]

Radicals, Hydrazidinyl ~: 1,2,4,5-tetraazapentenyls, verdazyls, and tetrazolinyls (FP) 455 [G.E. *85*, 485 (1973)]
Proof of the pyramidal configuration of the oxiranyl radical: two isomers of the 3-methyl-2-oxiranyl radical (SC) 932 [G.E. *85*, 993 (1973)]
New free-radical applications in preparative organic chemistry (LA) 779
Reactions of the ~ $RO_2^{\cdot}$, $RS_2^{\cdot}$, and $RO_2^{\cdot}$ with phosphites and phosphanes (LA) 936
Stereochemistry of free-radical additions to norbornene and norbornadiene (LA) 1023

Radiochemistry, Nuclear medicine and ~ (FP) 712 [G.E. *85*, 793 (1973)]

Radius of gyration, Determination for polymethylmethacrylate in the vitreous state by neutron diffraction (CR) 431 [G.E. *85*, 459 (1973)]

Raman spectroscopy Chemical applications (FP) 884 [G.E. *85*, 925 (1973)]

Rare-earth silicates, Structures (LA) 935

~ of 1,1,1',1'-tetrakis(trifluoromethyl)-3,3'-bi(1H-isoindole) (SC) 157 [G.E. *85*, 170 (1973)]
~ of 6,12-dihydro-6,6,12,12-tetrakis(trifluoromethyl)dibenzo[c,d]-[1,5]naphthyridine (SC) 157 [G.E. *85*, 171 (1973)]
Structure of aminoazimines (SC) 236 [G.E. *85*, 229 (1973)]
A planar cyclohexane ring: ~ of 9-cyano-anti-dioxatris-σ-homobenzene (SC) 836 [G.E. *85*, 860 (1973)]

YLIDE complexes, Phosphorus ~ of group VI as sources of carbonylmethylene (SC) 667 [G.E. *85*, 668 (1973)]

ZINC oxide, Hydrogenations and isomerizations over ~ (LA) 512

Zintl phases: Transitions between metallic and ionic bonding (FP) 694 [G.E. *85*, 742 (1973)]
