Hereditary Diseases—Causes, Cures, and Problems

By Roscoe O. Brady[*]

The nature of the biochemical abnormalities in over a hundred inherited diseases of humans is now convincingly established. This impressive achievement has provided numerous practical benefits, amongst which are: 1. accurate methods for the diagnosis of patients with these diseases; 2. identification of symptom-free heterozygous carriers of the defective genes; and 3. procedures for the antenatal detection of a large number of these disorders in fetuses. It is anticipated that equally impressive advances will be made in the future regarding the therapy for patients with these diseases who escape prenatal detection, or in cases when an affected fetus is identified but is carried to term in compliance with the decision of the parents. The current concepts regarding the therapy of heritable metabolic diseases are outlined and potential innovations for future corrective procedures are indicated in this report.

1. Introduction

At the onset of the twentieth century, *Sir Archibald Garrod* began his classic studies on alcaptonuria, a human disease characterized by the gradual darkening of urine when allowed to stand at an alkaline pH, gray to bluish black pigmentation of the patient's tissues, and arthritis which begins at an unusually early age. *Garrod* analyzed the urine of these individuals and clearly demonstrated that they excreted large quantities of homogentisic acid which was present in only trace amounts in normal human urine[1]. He discovered that this disorder occurred in various relatives of the patient. He also showed the same familial penetrance of other human diseases which included: a) albinism which is characterized by a failure of pigment formation; b) pentosuria, in which there is an increased quantity of pentose in the urine; and c) cystinuria, in which patients have an abnormally high level of urinary cystine.

From these observations, *Garrod* derived the remarkable conclusion that these individuals suffered from an inherited deficiency of an enzyme required to catalyze a specific metabolic step in each of these diseases[2]. He correctly predicted the lack of homogentisic acid oxidase in alcaptonuria (Fig. 1). Some 50 years later, the correctness of *Garrod*'s hypothesis was shown by *La Du et al.*[3].

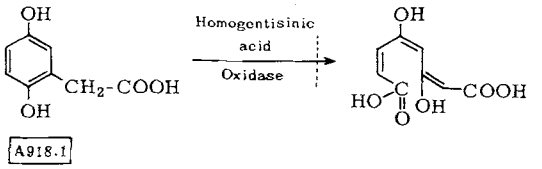

Fig. 1. Homogentisic acid is normally transformed into maleylacetoacetic acid (3,5-dihydroxy-2,4,6-octatrienedioic acid) by the action of homogentisic acid oxidase. The enzyme is lacking in alcaptonuria and no degradation takes place.

Inborn errors of metabolism are directly involved in more than 100 human diseases. These disorders include ab-

National Institutes of Health,
Bethesda, Maryland 20014 (USA)

normalities of amino acid metabolism such as phenylketonuria, histidinemia, and hyperprolinemia; derangements of purine metabolism as in orotic aciduria, xanthinuria, and the Lesch-Nyhan syndrome; abnormalities of carbohydrate metabolism such as fructosuria, galactosemia and glycogen storage diseases; derangements of porphyrin metabolism; abnormalities of protein synthesis as in sickle cell disease, agammaglobulinemia and abetalipoproteinemia; and heritable disorders of lipid metabolism such as Gaucher's disease and Tay-Sachs disease.

It is not feasible to discuss or even list all of the known human disorders of metabolism in the present contribution. Excellent standard texts are available in which these disorders and their clinical manifestations are catalogued[4,5]. It is my intention to indicate in this communication how some of the extremely perplexing problems involved in the discovery of the nature of the abnormal enzymology in such diseases have been resolved and to describe some of the practical benefits which resulted from these investigations. It will also be my task to provide a summary of various forms of therapy which seem to be useful at the present time and to suggest avenues of approach which may be helpful in the foreseeable future. I shall deal with lipid storage diseases to a major extent because a number of important, universally applicable concepts were established during investigations of the pathogenesis and management of these disorders.

2. Sphingolipidoses

2.1. General Description

The are now ten distinct disorders of lipid metabolism for which the etiology is convincingly established. The principal clinical manifestations of these diseases are summarized in Table 1. The hallmark of each of these disorders is the accumulation of particular lipids which have a portion of their molecular structure in common. This shared moiety is called ceramide (*N*-acyl sphingosine).

$$CH_3{-}(CH_2)_{12}{-}CH{=}CH{-}CH(OH){-}CH(NHCOR){-}CH_2OH$$

These sphingolipids are primarily localized in membranous elements of the cells throughout the body. One or more molecules of carbohydrate or a phosphorylamine residue is attached to the primary hydroxy group of the sphingosine (Table 2).

Except for Fabry's disease, all of the sphingolipid storage diseases are inherited as autosomal recessive genetic mutations. This means that both parents must be carriers of the defect (heterozygotes) in order to produce an affected child. Carriers are usually entirely free of the signs and symptoms of the disorders. When both parents are carriers, one of four children will have the disease on a statistical basis. Such a child is called a homozygote. Two of their children will be heterozygotes like the parents, and one child will not be involved at all.

Table 1. Salient clinical features of the sphingolipidoses.

Gaucher's disease	Mental retardation (infantile form only); enlarged liver and spleen; hip and long bone erosion; lipid-laden cells in bone marrow which also stain for carbohydrate; increased serum acid phosphatase; mild anemia; and decreased blood platelets.
Niemann-Pick disease	Generally similar to Gaucher's disease; 30% with cherry-red spot in macula; foam cells in bone marrow which stain for lipid and phosphorus; severe emaciation.
Globoid leukodystrophy (Krabbe's disease)	Mental retardation; almost total absence of myelin; severe scar formation in the brain; multinucleated "globoid bodies" in white matter.
Metachromatic leukodystrophy	Mental retardation; psychological disturbances; decreased nerve conduction time; yellow-brown droplets in nerve fibers when stained with cresyl violet (metachromasia).
Ceramide lactoside lipidosis	Slowly progressing brain damage; large liver and spleen; anemia; decreased number of white blood cells and platelets.
Fabry's disease	Reddish-purple raised rash on abdomen and scrotum; kidney damage; corneal opacities; peripheral nerve pain and electrocardiographic abnormalities.
Tay-Sachs disease	Mental retardation; blindness; cherry-red spot in the retina; enlarged skull; nerve cells distended with "membranous cytoplasmic bodies."
Generalized gangliosidosis	Mental retardation; cherry-red spot in macula (50% of patients); large liver and spleen; foam cells in bone marrow; rarefaction of bones and skeletal deformities.
Fucosidosis	Progressive mental degeneration; weakness and spasticity of muscles; emaciation; thickening of the skin and enlargement of the heart.

The genetic transmission of Fabry's disease is on the X chromosome, and the disorder is therefore carried by the female. Half of the sons born to a female carrier of Fabry's disease will have the full-blown syndrome of Fabry's disease. Fifty percent of her daughters will be carriers, and the other daughters will not be involved. Unlike other sphingolipidoses, the female Fabry heterozygotes may have some of the clinical manifestations of the disease although they usually are much milder than those found in an afflicted male.

The underlying metabolic defect in all of the sphingolipid storage diseases is an attenuation or complete absence of a specific hydrolytic enzyme required for the catabolism of a lipid which occurs in the body as a consequence of the normal turnover of cells and tissues. A second important fact is that the *degree* of enzyme deficiency is similar in all of the organs and cells of the patient. Thirdly, cells obtained from patients with lipid storage disease and grown in tissue culture show the same proportional enzyme deficiency as that which occurs in the organs of the patient from whom the cells were derived. The acquisition of this information now permits the accurate diagnosis of individuals afflicted with any of these lipid storage diseases[6], identification of heterozygous carriers of these disorders[7], and the prenatal detection of fetuses afflicted with any of these diseases[8].

Knowledge of the specific enzymatic defects in the hereditary diseases is mandatory for the development of rational

Table 2. Accumulating sphingolipids and missing enzymes in sphingolipidoses. Cer = ceramide; Glc = glucose; PChol = phosphorylcholine; Gal = galactose; NAcNA = *N*-acetylneuraminic acid; NAcGal = *N*-acetylgalactosamine; Fuc = fucose; NAcGlc = *N*-acetylglucosamine. The position of normal degradation is indicated.

	Disease	Major sphingolipid accumulated		Enzyme defect
1	Gaucher		ceramide glucoside (glucocerebroside)	β-glucosidase
2	Niemann-Pick		sphingomyelin	sphingomyelinase
3	Krabbe		ceramide galactoside (galactocerebroside)	β-galactosidase
4	Methachromatic leukodystophy		ceramide galactose-3-sulfate (sulfatide)	sulfatidase
5	Ceramide lactoside lipidosis		ceramide lactoside	β-galactosidase
6	Fabry		ceramide trihexoside	α-galactosidase
7	Tay-Sachs		ganglioside G_{M2}	hexosaminidase A
8	Tay-Sachs variant		globoside (plus ganglioside G_{M2})	total hexosaminidase
9	Generalized gangliosidosis		ganglioside G_{M1}	β-galactosidase
10	Fucosidosis		H-isoantigen	α-fucosidase

therapeutic measures for the amelioration of these disorders. Wherever feasible, due consideration will be given to potentially useful corrective procedures for the treatment of patients who are not identified prenatally or where the parents have elected to continue the pregnancy despite the identification of an affected fetus.

2.2. Gaucher's Disease

Gaucher's disease is the first sphingolipodystrophy in which the nature of the metabolic derangement was conclusively demonstrated. A number of important concepts were established in the course of studies on Gaucher's disease which have been applied to all other lipid storage diseases. A brief description of historical developments will be presented since the discovery of the etiology of many other inherited disorders followed these precepts.

The lipid which accumulates in the tissues of patients with Gaucher's disease is glucocerebroside (Table 2, row 1). The hexose portion of glucocerebroside is to be contrasted with that in galactocerebroside, the predominant glycolipid of the myelin sheath of nerves (Table 2, row 3). This difference gave rise to several hypotheses regarding the etiology of Gaucher's disease which included:

1) an abnormality of carbohydrate (galactose) metabolism;

2) an overproduction of glucocerebroside in tissues; and

3) a deficiency of a catabolic enzyme required for the degradation of glucocerebroside.

The first two hypotheses were shown to be untenable in studies by *Thannhauser*[9] and by *Trans* and *Brady*[10], respectively. The nature of the metabolic defect in Gaucher's disease was established by the following series of experiments. Glucocerebroside was synthesized with ^{14}C in the D-glucose portion of the molecule[11]. With this labeled material as substrate, an enzyme was demonstrated in all of the tissues of the body which catalyzes the hydrolysis of glucocerebroside.

$$\text{Glucocerebroside} + H_2O \xrightarrow{\text{glucocerebrosidase}} \text{glucose} + \text{ceramide}$$

This enzyme was found in high activity in the spleen and was partially purified from this tissue. Optimal incubation conditions, kinetics, and products of the reaction were determined. The activity of the glucocerebrosidase was then measured in samples of human spleen tissue obtained at operation from a control series of patients and from patients with Gaucher's disease. The mean level of glucocerebrosidase activity in the specimens from patients with the "adult" form Gaucher's disease was 15% of that found in the controls[12–15]. Specimens of spleen tissue obtained from patients with the more rapidly progressing "infantile" form have extremely little if any glucocerebrosidase activity.

The glucocerebroside which accumulates in the spleen, liver, and bone marrow is derived from lipids in the membranes of senescent red and white blood cells. The principal neutral glycolipid of leukocytes is ceramide lactoside (Table 2, row 5). A second important source of glucocerebroside in peripheral tissues is globoside (Table 2, row 8), the principal glycolipid of red blood cells. These substances are degraded enzymatically in a stepwise fashion to cer-

amide-glucoside (glucocerebroside) which accumulates in patients with Gaucher's disease because of the deficiency of the requisite β-glucosidase. Glucocerebroside also accumulates in the nerve cells of patients with the infantile form of Gaucher's disease and probably arises from the turnover of gangliosides (Table 2, rows 7 and 9).

The diagnosis of Gaucher's disease can be established by measuring glucocerebrosidase activity with ^{14}C-labeled glucocerebroside in samples of tissues obtained by biopsy or in leukocytes obtained from small quantities of venous blood[16]. Leukocyte preparations and cultured skin fibroblasts are also useful for the detection of Gaucher heterozygotes[7]. The fluorogenic artificial substrate 4-methylumbelliferyl β-D-glucoside (Fig. 2) has recently been used for the detection of homozygotes and heterozygotes[17,18].

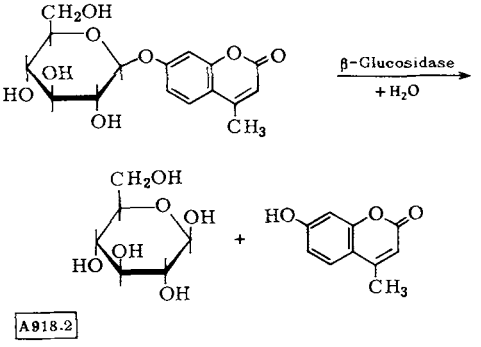

Fig. 2. 4-Methylumbelliferyl β-D-glucopyranoside, an artificial substrate for measuring β-glucosidase activity. The resulting 4-methylumbelliferone fluoresces.

Diagnostic enzyme assays are of maximum utility when applied to the monitoring of pregnancies at risk for heritable metabolic diseases. At the present time the procedure of choice is the determination of activity in extracts of cultured fetal cells obtained by amniocentesis (Fig. 3). This technique may be used for the identification of fetuses which are heterozygous[7] and homozygous[19] for Gaucher's disease. It is anticipated that eventually artificial substrates will become useful for prenatal diagnosis of Gaucher's disease.

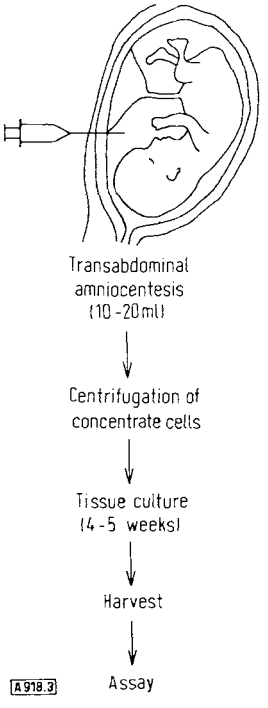

Fig. 3. Prenatal detection of genetic abnormalities.

2.3. Niemann-Pick Disease

Klenk was the first to identify sphingomyelin as the accumulating lipid in patients with Niemann-Pick disease[20]. Once again, the deficiency of a catabolic enzyme was shown by metabolic studies performed with sphingomyelin labeled in the choline portion of the molecule[21]. The mean level of sphingomyelinase activity in liver preparations from Niemann-Pick patients was 7% of that of control series[22]. Erythrocyte stroma is again a likely source of the accumulating sphingomyelin, since, next to lecithin and phosphatidyl ethanolamine, it is the predominant phospholipid of the red cell membrane. Sphingomyelin is also a major lipid constituent of all subcellular elements and the plasma membrane of cells; therefore, it seems likely that sphingomyelin could arise as a consequence of turnover of cellular elements in most if not all tissues.

The diagnosis of Niemann-Pick disease may be confirmed by determining sphingomyelinase activity in tissue biopsies, sonicated leukocytes[16], or extracts of cultured skin fibroblasts[23]. An artificial chromogenic substrate, 2-*N*-acylamido-4-nitrophenylphosphorylcholine, for measuring sphingomyelinase activity has recently been proposed[24] (Fig. 4). It must be determined whether this compound will provide an accurate indication of sphingomyelinase activity in various cells and tissues. Satisfactory assay procedures have recently been developed for the detection of heterozygous carriers of Niemann-Pick disease[6,7]. The prenatal diagnosis of fetuses afflicted with Niemann-Pick disease is now a proven procedure[25]

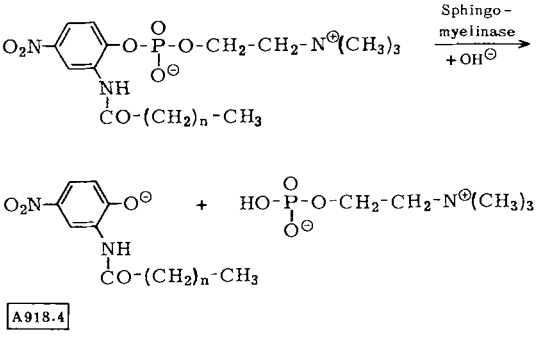

Fig. 4. 2-*N*-Acylamido-4-nitrophenylphosphorylcholine, an artificial substrate for measuring sphingomyelinase activity. The resulting 2-*N*-acylamido-4-nitrophenoxide ion is yellowish orange.

2.4. Globoid Leukodystrophy: Krabbe's Disease

The metabolic defect in patients with this disorder is a deficiency of a β-galactosidase which catalyzes the hydrolysis of galactocerebroside (Table 2, row 3)[26]. The accu-

mulating galactocerebroside is presumed to arise from the turnover and restructuring of myelin during the development of the nervous system. Patients with this disorder may be diagnosed by determining galactocerebrosidase activity in circulating leukocytes and cultured skin fibroblasts[27]. Heterozygotes are best demonstrated through similar assays with serum samples. The prenatal detection of a fetus afflicted with Krabbe's disease has recently been reported[28].

2.5. Metachromatic Leukodystrophy (MLD)

Sulfatide (Table 2, row 4) accumulates in various tissues of patients with this disease. The biochemical defect in MLD is a deficiency of the enzyme which catalyzes the hydrolysis of sulfatide[29, 30]. The enzyme is generally designated as arylsulfatase A because its catalytic activity is frequently determined using arylsulfate esters as substrate (Fig. 5). Patients and heterozygous carriers may be detected by determining arylsulfatase A activity in circulating leukocytes[31–33] and extracts of cultured skin fibroblasts[34]. It is anticipated that this assay procedure will be useful for the prenatal detection of fetuses with MLD.

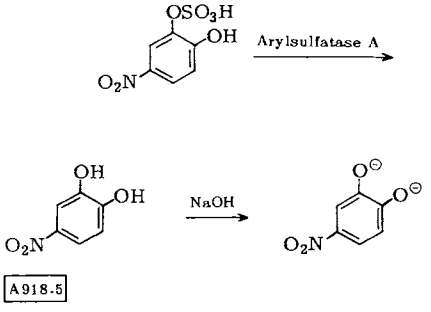

Fig. 5. 2-Hydroxy-5-nitrophenyl sulfate, an artificial substrate for measuring arylsulfatase activity. The sulfate and 4-nitropyrocatechol are yellow, the anion (pH = 11—12) is red.

2.6. Ceramide Lactoside Lipidoses

A patient has recently been described in which ceramide lactoside (Table 2, row 5) is the principal accumulating lipid. The metabolic defect is a deficiency of the β-galactosi dase which catalyzes the hydrolytic cleavage of the molecule of galactose from ceramide lactoside[35]. For the accurate identification of homozygotes and heterozygotes[36] the use of galactose-labeled ceramide lactoside[37] is mandatory at the present time.

2.7. Fabry's Disease

This condition is a lipid storage disease in which ceramide trihexoside (Table 2, row 6) accumulates in various tissues of these patients, especially in the kidney. The enzymatic defect is a deficiency of ceramide trihexoside-α-galactosidase[38]. Highly purified enzyme has been obtained from small intestinal tissue[39]. The principal source of accumulating ceramide trihexoside is globoside (Table 2, row 8) from senescent erythrocytes.

Enzymatic assay with biopsy specimens of small intestinal mucosa is a satisfactory procedure for diagnosing patients and heterozygotes[38]. A more convenient procedure has recently been developed in which artificial chromogenic or fluorogenic α-galactopyranosides are used as substrates[40]. Refined methods have been developed for measuring glycolipids in urine sediment and this procedure is a useful adjunct both for identifying patients with Fabry's disease as well as other sphingolipidoses[41]. The prenatal detection of Fabry's disease is now an established procedure[42].

2.8. Tay-Sachs Disease

This disease occurs in approximately one in 6000 births in infants of Ashkenazic Jewish parentage. The disorder has been reported in many other groups, but the frequency in non-Jews is on the order of one-hundredth of that in the Jewish race. Histological examination of the brain reveals swollen neuronal cells in various stages of degeneration, and many of them contain concentrically-layered electron-dense "membranous cytoplasmic bodies" (MCB's) (Fig. 6). The MCB's are comprised of protein, cholesterol, phospholipid, and Tay-Sachs ganglioside (G_{M2}) (Table 2, row 7), the pathognomonic substance which accumulates in the brain of patients with this disorder. Another sphingolipid,

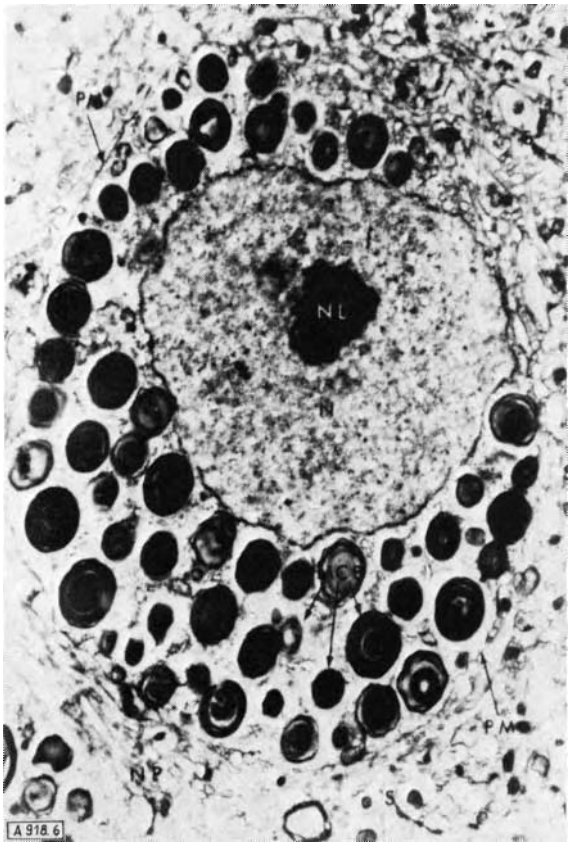

Fig. 6. Membranous cytoplasmic bodies (MCB) in a nerve cell from a patient with Tay-Sachs disease [43]. N = nucleus; NP = nucleolus; PL = plasma membrane.

asialo-Tay-Sachs ganglioside[*] (ceramide-glucose-galactose-*N*-acetylgalactosamine) is also increased in the brain in these infants, but to only one-fifth of the extent of G_{M2}. The accumulating lipids are primarily confined to the central nervous system with the notable exception that the neurons of the intestine are frequently involved.

The discovery of the specific enzymatic defect in Tay-Sachs disease was hindered by the difficulties encountered in preparing appropriately labeled G_{M2} for metabolic studies. This molecule has yet to be synthesized by organic chemists. In time, G_{M2} labeled with ^3H in the *N*-acetylneuraminic acid moiety was prepared by a combination of biosynthesis *in vivo* and selective enzymatic degradation of the mixed radioactive gangliosides obtained in this fashion[44]. G_{M2} labeled with ^{14}C in the *N*-acetylgalactosaminyl moiety was also prepared through enzymatic synthesis *in vitro*[45]. Using these specifically labeled substances, it was shown that the catabolism of G_{M2} can be initiated either by the cleavage of the molecule of *N*-acetylneuraminic acid[46] or the molecule of *N*-acetylgalactosamine[47]. G_{M2}-neuraminidase activity is normal in tissues obtained from patients with Tay-Sachs disease[48] whereas there is a drastic attenuation of G_{M2}-hexosaminidase[48-50]. These findings support the concept that the hexosaminidase isozyme A which was shown by artificial substrates to be lacking in patients with Tay-Sachs disease[51] is involved in the catabolism of G_{M2}. The complete elucidation of the pathogenesis of Tay-Sachs disease is complicated by the fact that these two pathways exist for the degradation of G_{M2} in normal human tissues and that only one of them, the hexosaminidase route, is disturbed in patients with Tay-Sachs disease[49, 50, 52].

In the tissues of patients with a second or "O variant" form of Tay-Sachs disease there is a decrease of total hexosaminidase activity[53]. This disorder is confined mainly to patients of non-Jewish extraction. In addition to the accumulation of G_{M2} in the brains of these patients, globoside accumulates in peripheral organs (Table 2, row 8).

There is also a third category of patients with Tay-Sachs disease called the "AB-variant" in which hexosaminidase isozymes A and B are both *present* when assayed with artificial substrates; however, the catabolism of G_{M2} is impaired in these patients[53]. Nevertheless, with the exception of the "AB-variant," the diagnosis of Tay-Sachs homozygotes and heterozygotes is readily accomplished through hexosaminidase assays using serum samples[54]. The prenatal detection of fetuses afflicted with Tay-Sachs disease has been reported[55, 56].

2.9. Generalized (G_{M1}) Gangliosidosis

The principal substance which accumulates in the nervous system of patients with this disorder is ganglioside G_{M1} (Table 2, row 9). This condition is therefore frequently referred to as G_{M1}-gangliosidosis. Along with some accumulation of G_{M1}, a keratan sulfate-like mucopolysaccharide is increased in the peripheral tissues of patients with this disorder. The disease is caused by a deficiency of G_{M1}-ganglioside-β-galactosidase which catalyzes the hydrolysis of the terminal molecule of galactose from monosialyltetrahexosyl ganglioside[57]. Patients with this disorder have a decrease of total tissue β-galactosidase activity as measured with artificial substrates.

Due to this very drastic lowering of galactosidase, it might be anticipated that other substances having a terminal molecule of galactose such as galactocerebroside (Table 2, row 3) or ceramide lactoside (Table 2, row 5) might accumulate along with G_{M1}. This has not been observed; in fact, the activity of the enzymes which catalyze the hydrolysis of galactocerebroside and ceramide lactoside are actually increased 4- to 5-fold in the tissue of these patients[58]. Nonetheless, artificial galactopyranoside substrates are very useful for the diagnosis of homozygotes, for identifying heterozygotes[59], and for the prenatal detection of G_{M1}-gangliosidosis[60]. The accumulating G_{M1} may arise from the turnover of plasma membrane components of various cells since gangliosides are highly concentrated in these structures[61, 62].

2.10. Fucosidosis

A discussion of lipid storage diseases should include some recent observations on a small group of patients with a disorder called fucosidosis[63]. The enzymatic defect is a complete deficiency of α-L-fucosidase in the tissues of these patients[64]. The natural substrate(s) of this enzyme is not well established; however, it is well known that intestinal tissue, red blood cells, and certain other tissues contain fucoglycolipids with H, Le^a, and Le^b isoantigenic activity[65]. In accordance with the anticipated pathophysiology of this disorder, a very large increase in pentahexosylfucoglycolipid has been observed in liver tissue obtained from a patient with fucosidosis[66]. It is presumed that the specific metabolic defect in this disease will soon be conclusively demonstrated and that it will be a deficiency of a fucosidase involved in the catabolism of fucolipids (Table 2, row 10).

3. Treatment

3.1. Gaucher's Disease

A number of potential forms of therapy have been envisaged for the correction of inherited metabolic diseases[67, 68], but so far only a modest amount of direct experimentation has been carried out. Patients with Gaucher's disease often require supportive therapy such as vitamins, supplemental iron or liver extract for the anemia, and splenectomy because of the development of hemorrhagic tendencies. Aside from these palliative measures, the principal concept for the therapy of Gaucher's disease is the hope of devising a procedure for restoring enzyme activity in the tissues of these patients (Table 3). Since spleen has high glucocerebrosidase activity, transplantation of this organ has long been considered as a therapeutic procedure for these patients[67]. Techniques have been developed for this

[*] *N* or *O*-Acylated neuraminic acids are also called sialic acids.

operation and it has recently been performed on a patient with Gaucher's disease[69]. The total plasma lipid hexose level decreased for a short period of time post-operatively in this patient; however, there was only a slight diminution in circulating glucocerebroside. The patient expired three months after the operation. It must be concluded from this important study that spleen transplantation is still a very hazardous undertaking and the efficacy of the procedure for the treatment of patients with Gaucher's disease is very much in doubt.

Table 3. Therapeutic possibilities.

1. Enzyme replacement
   1.1. Organ transplantation
2. Parenteral administration of purified enzymes
   2.1. Animal sources
   2.2. Human preparations
   2.3. Encapsulated enzyme in biodegradable microspherules
3. Percolation of blood over stably bound enzyme
4. Administration of DNA
   4.1. Transducing viruses
5. Anti-enzyme antibodies
6. Hybridization and replacement of patient's cells
7. Administration of metabolic cooperativity material

The therapeutic approach which is receiving the most serious consideration at the present time is the possibility of replacing the missing enzyme by parenteral administration of purified glucocerebrosidase. The enzyme has been partially purified from human spleen[11], and a more highly enriched preparation has been obtained from beef spleen tissue[70]. Glucocerebrosidase has recently been obtained in a high degree of purity from human placental tissue[71]. We prefer to use enzyme isolated from human sources because of the expectation that such preparations will be the least likely to cause an untoward immunological reaction when injected into patients. Considerable experimental evidence indicates that exogenously administered enzymes will be taken up by the cells of the reticuloendothelial system[72], a highly desirable situation for attempting to treat patients with Gaucher's disease. One wonders if the concentration of exogenous enzyme would be increased in these cells if the enzyme were encapsulated in a biodegradable "liposome"[73]. The rationale of parenteral enzyme therapy receives some support from investigations in which α-glucosidase was administered to mice and to patients with glycogen storage disease. Liver glycogen fell in the experimental animals[74] and in two patients with glycogenosis[75, 76].

However, a negative report of an essentially similar therapeutic attempt has appeared[77]. All of the preceding studies were performed with very crude glucosidase preparations obtained from the fungus *Aspergillus niger* and there was a wide variation in the frequency and quantity of enzyme injected. It is therefore virtually impossible to draw relevant conclusions regarding the effectiveness of this therapeutic approach from these published reports.

Enzyme replacement procedures may eventually become useful for reducing the level of the accumulated lipid in peripheral organs and tissues, but it seems doubtful whether a sufficient quantity of parenterally administered enzyme would cross the blood-brain barrier to be an effective form of treatment for patients with central nervous system difficulties. Alternative procedures have been contemplated for increasing the level of enzymatic activity in the brain and all of the current concepts seem potentially quite dangerous. One technique which may be examined for its clinical usefulness is the temperary opening of the blood-brain barrier by the intracarotid injection of a hypertonic solution of urea or other solute[78]. Much refinement and additional experimentation must be carried out prior to clinical attempts with this procedure since in its present form it often causes a variable degree of paralysis in experimental animals.

Another potential form of therapy which may still be remote, but has recently been brought a little bit closer to the experimental stage is the long-sought procedure for transducing human cells with a virus carrying the genetic message for a missing enzyme—genetic engineering[79].

Two major obstacles must be overcome before this approach can be considered appropriate for human trial. The first of these is the enormous number of infectious virus particles which must be administered in order to obtain a stably transduced cell. At the present time, this ratio ranges from 1000 to 10000 virus particles per cell. The viremia and viral encephalitis which must necessarily accompany such a therapeutic attempt are clearly unsupportable. It may be hoped that procedures will be discovered which will drastically reduce the presently required high multiplicity of infectious particles; for example, development of a technique similar to the use of heat-inactivated Sendai virus which has been so helpful for preparing hybridized cells.

Secondly, the viruses presently available for cell transduction are primarily of the λ-phage group which normally infect and extract DNA from *E. coli*. As far as known, this microorganism does not contain any of the sphingolipid hydrolases, and therefore another source of the replacement cistron must be sought. One conceivable source may be *H. ciferii*, a yeast which is rich in sphingolipids. It is not known whether an appropriate virus can be obtained for transduction experiments with such cells.

An additional concept regarding potential forms of therapy of lipid storage diseases should be borne in mind. It has been shown in a number of instances that anti-enzyme antibodies cause an enhancement of enzymatic activity under certain conditions[80–83]. This is potentially an important finding since the first two of these reports deal with the activation of mutant enzymes obtained from *E. coli* which are catalytically inactive in the absence of the appropriate antibody. When antibody was added to the assay mixtures, the level of enzymatic activity approached that of the wild type nonmutated enzyme. The potential importance of this observation is underscored by the fact that there are proteins in the tissues of patients with several genetic diseases which cross-react with antibodies directed towards the normal human enzymes[84, 85]. It is therefore conceivable that mutated human enzymes with low catalytic efficiency might be activated through administration of an appropriate antibody. This novel concept also requires extensive additional experimentation

before attempting to exploit this phenomenon for the treatment of human diseases, since the possibility of induced amyloidosis[86] must be rigidly excluded.

3.2. Niemann-Pick Disease

Again one must consider the possibility of exogenous administration of the requisite enzyme. Sufficient quantities of purified human sphingomyelinase have not been available for therapeutic trials. Perhaps in time it will be possible to consider liver transplantation for the amelioration of this disease. Alternatively, it may be worthwhile exploring the possibility of administering sphingomyelinase prepared from other than human sources, such as beef liver or even a suitably purified enzyme from bacteria[87]. However, an additional precaution must always be kept in mind when considering enzyme replacement therapy for Niemann-Pick disease, namely the ubiquitousness of sphingomyelin. It is conceivable that the parenteral administration of sphingomyelinase might cause hemolysis of erythrocytes and general cellular disintegration with serious sequelae. In order to preclude such untoward effects, sphingomyelinase may well be an ideal enzyme for administration in biodegradable microspherules.

3.3. Krabbe's Disease

Enzyme replacement therapy is high on the list of possible restorative procedures although again the possibly limited access of a parenterally administered enzyme to the nervous system may preclude its effectiveness. The investigation of therapeutically distinct approaches in this disease has one particular advantage which is the well documented observation that certain strains of dogs are affected with a form of globoid cell leukodystrophy which resembles the disorder in humans in many respects[88]. An unusual opportunity is thereby afforded for examining potential remedial procedures with this animal model. The principal limitation at present is the lack of sufficient quantities of highly purified galactocerebrosidase for these investigations. Hopefully this restriction will soon be surmounted.

3.4. Metachromatic Leukodystrophy (MLD)

There have been two noteworthy attempts of enzyme replacement therapy for MLD. The first was carried out by *Austin* in 1967, when he infused a relatively crude preparation of human urinary arylsulfatase intrathecally into a patient with MLD[89]. The patient had a severe pyrogenic reaction and there was no evidence of clinical improvement. In another study, a partially purified preparation of beef brain arylsulfatase A was administered intravenously and intrathecally[90]. The patient became febrile and again no clinical improvement was observed. Enzymatic activity was detected in the liver following intravenous infusion, but no enzyme was found in the brain.

These studies are very discouraging from the standpoint of enzyme replacement therapy. However, a glimmer of encouragement may be derived from the recent report that the quantity of sulfatide in cultured fibroblasts derived from a patient with MLD decreased when crude urinary arylsulfatase A was added to the culture medium[91]. These studies re-emphasize the need for devising new concepts and approaches to try to overcome the enzymatic deficiency in the nervous system.

3.5. Fabry's Disease

The administration of moderate quantities of diphenylhydantoin often relieves the pain of the peripheral neuralgia which rather commonly occurs in teenage patients with Fabry's diesease[92]. We have obtained homogeneous preparations of ceramide trihexosidase from human urine and placenta[93]. Replacement trials with these enzyme preparations will be undertaken soon.

Another approach which has been suggested for the treatment of patients with Fabry's disease is the possibility of kidney transplantation[94]. An informative study along these lines was carried out by *Phillippart*[95] who found a temporary decrease in the level of plasma ceramide trihexoside postoperatively. However, there was a gradual return of ceramide trihexoside towards the preoperative level in the plasma after the kidney transplants in spite of apparently satisfactory function of the grafted kidneys.

Another procedure which has been investigated for the amelioration of Fabry's disease is the infusion of fresh normal human plasma into these patients. It has been claimed that the circulating ceramide trihexoside level decreased as a result of this procedure and that plasma ceramide trihexosidase activity in the patients increased to a surprisingly high value[96]. This report has caused much concern and more than a little controversy since most laboratories[97, 98], including the author's, have been unable to demonstrate the hydrolysis of galactose-labeled ceramide trihexoside catalyzed by plasma preparations. Therefore, I feel it is necessary to withhold judgment at this time regarding the effectiveness of plasma infusion for the treatment of Fabry's disease.

The possible use of polymer-bound enzymes deserves consideration at this point. We have very recently covalently coupled ceramide trihexosidase to a polyacrylamide matrix[99]. The rationale for this approach is the desire to pass whole blood (or plasma) over a column of the stabilized enzyme in the hope that the elevated level of circulating ceramide trihexoside in patients with Fabry's disease[100] will be decreased by this procedure. It is anticipated that such a lowering of plasma ceramide trihexoside will induce the egress of the accumulated glycolipid from the tissues of these patients. The major obstacle of this form of therapy is the complicated procedure involved in providing an absolutely sterile exteriorized arterio-venous shunt. The difficulties are comparable to those of hemodialysis, a procedure often required for treating patients with Fabry's disease. However, an additional constraint on this procedure for the treatment of Fabry patients is the fact that the maximal catalytic activity of the enzyme occurs at pH 5.0; many predictable problems will be encountered if the pH of the blood or plasma is lowered to this value.

3.6. Tay-Sachs Disease

A considerable amount of investigative effort is currently directed towards enzyme replacement therapy for patients with the "B-variant" form of Tay-Sachs disease. The missing enzyme, hexosaminidase A, has been purified to homogeneity from human placenta and urine[101]. An investigation has been carried out on the distribution of the enzyme after intravenous infusion in a patient with Tay-Sachs disease. Enzymatic activity disappears very rapidly from the blood stream with the kinetic course indicated by the following equation[102]:

$$\text{Hexosaminidase activity} = e^{e^{(-.0083t + 1.84)}}$$

Some hexosaminidase A activity appears in the liver after infusion; however, only a very small amount of enzyme entered the brain. Obviously, much additional investigation must be carried out along these lines.

Since there is considerable hexosaminidase A and B activity in serum, as measured with artificial substrates, a number of therapeutic trials may be expected utilizing fresh human plasma as a source of hexosaminidase. There are several major drawbacks to this approach among which are the large quantities of plasma which would have to be infused; however, this limitation might be circumvented to a degree by enzyme concentration procedures.

A second, more important drawback, is the complete lack of evidence that circulating plasma hexosaminidase catalyzes the hydrolysis of G_{M2}, the accumulating lipid. Thirdly, there is the ever-present doubt whether a sufficient quantity of enzyme can enter the brain from the blood. Other than altering the permeability of the blood-brain barrier[78] which is at best a potentially hazardous procedure, or genetic engineering[79] which is currently viewed with extreme skepticism, the most logical approach appears to be to try to devise a procedure to chemically modify hexosaminidase so that it will pass through the blood-brain barrier while retaining activity towards the natural substrate. I suggest that an attempt be made to chemically modify the enzyme by the covalent attachment of medium chain length aliphatic amino alcohols to the protein. I predict that this procedure will be a principal avenue of investigation for the treatment of Tay-Sachs disease in the near future.

3.7. G_{M1}-Gangliosidosis

Concepts relevant to the treatment of patients with this disorder generally follow those described for Tay-Sachs disease and the other lipid storage diseases. The β-galactosidase involved has been obtained in a purified form from mammalian liver tissue[103]. One important advantage of this enzyme preparation is its high activity toward G_{M1}, the natural lipid substrate. However, the precautions discussed in the section on Niemann-Pick disease regarding enzyme infusion may well apply when considering replacement trials for G_{M1}-gangliosidosis since gangliosides are important components on the surfaces of many cells.

3.8. Additional Measures

A potential corrective procedure which is receiving considerable attention at the present time is the possibility of hybridizing some of the patient's cells with other human cells which contain the cistron for the defective enzyme. A very interesting experiment along these lines was reported by *Nadler et al.* who hybridized human cells from patients with galactosemia[104]. These individuals are deficient in the enzyme galactose-1-phosphate uridyl transferase:

Galactose-1-phosphate + uridinediphosphate glucose $\xrightarrow{\text{transferase}}$ uridinediphosphate galactose + glucose-1-phosphate

The hybrid cells contained catalytically active enzyme. These data suggest that the enzymatic defects in the parent cell lines were due to different point mutations in the genetic code and that interallelic complementation (correction) had occurred in the hybrid cells. These experiments open the possibility of reimplanting cells in patients after hybridization has been carried out in tissue culture.

Two very important precautions must be constantly kept in mind when contemplating the therapy of human disease by this procedure. The first is the danger of producing an antigenically incompatible cell which would be rapidly rejected by the recipient. Perhaps this potential difficulty can be circumvented by proper selection and cloning of hybridized cells whose complement of antigens is compatible with the recipient. Secondly, and perhaps potentially even more hazardous, is the fact that spontaneous malignant transformation is not an infrequent phenomenon in cultured cells. It is especially likely to occur if repeated passages of the cells are carried out. Tests to exclude this untoward reaction are very difficult since they would have to be performed in experimental animals. The reliability of data obtained in this fashion for extrapolation to humans would certainly be questionable.

Some very recent reports contain data which permit my closing this dissertation on a cautious note of optimism. In 1966, *Suback-Sharpe, Bürk*, and *Pitts* reported that baby hamster kidney cells which were deficient in inosinic acid pyrophosphorylase (Fig. 7) showed evidence of correction

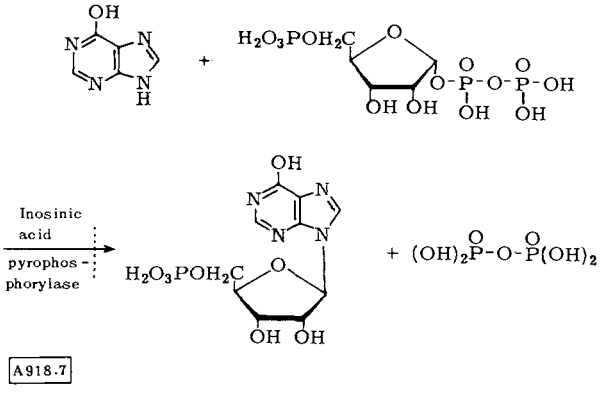

Fig. 7. Hypoxanthine and α-5-phospho-6-ribosyl 1-pyrophosphate are normally transformed into inosinic acid and pyrophosphate by the action of inosinic acid pyrophosphorylase.

of the metabolic defect if they were grown in the presence of normal cells or cells deficient in a different enzyme[105]. This observation has been amply confirmed and the restoration phenomenon is called "metabolic cooperativity". It appears that a "factor" passes between the cells and the agent responsible for such correction in patients with mucopolysaccharidoses appears to be a protein[106]. Similar corrective factors have been found in blood plasma and urine. The latter observations prompted *Di Ferrante et al.* to undertake therapeutic trials of plasma infusion in patients with mucopolysaccharide accumulation[107]. The investigators were encouraged by their results and the experiments were extended to an examination of the effect of transfusing leukocytes in a patient with a similar disorder[108]. The patient was said to have benefited by this procedure and the results were considered to be superior to those obtained with plasma infusion.

These reports have prompted a spate of clinical investigations along this line and both positive[109] and negative[110] clinical responses have been obtained. It is my feeling that this technique clearly warrants extensive investigation at this time. It is certain that leukocyte transfusion will be tried in other metabolic diseases, for example in the sphingolipidoses. The reasonableness of this approach is indicated by the fact that leukocytes contain glucocerebrosidase[16], galactocerebrosidase[111], and sphingomyelinase[16] activity. Caution and restraint are required on the part of the investigator lest he carry this concept too far. For example, implantation of bone marrow cells has been suggested as a possible approach for providing a stable, constant source of cells for patients with immunological deficiencies. It was concluded in a recent survey that this form of therapy is a very hazardous procedure at this time[112].

4. Conclusions

I have attempted to provide a précis of current concepts for the therapy of inherited diseases and to indicate points of departure for future explorations. Circumspection, imagination, and caution are required in order to mount effective therapeutic regimes for the treatment of these disorders. A number of potential approaches are described and evaluated in this review. Some of these possibilities are worthy of exploration at this time; others must await further innovation and improvement. High on the list of potentially effective procedures are replacement trials with purified enzymes and the administration of metabolic cooperativity factors. These approaches appear likely to be beneficial for a limited number of conditions. Other, more generally useful, forms of therapy must be developed for the amelioration of the majority of heritable human diseases.

The Loose Connection between Electron Configuration and the Chemical Behavior of the Heavy Elements (Transuranics)[**]

By Christian Klixbüll Jørgensen[*]

There is no straightforward relation betwee n the ground electron configuration of the neutral atom and the chemistry of a given element. n particular, the choice of oxidation state depends on the comparison between consecutive onization energies of the gaseous ions and the hydration energy or Madelung energy w] ich by preference stabilizes increased oxidation numbers. Special ligands, such as oxide, may introduce unexpectedly high oxidation numbers. The baricenters of electron configurations are discussed with vanadium and thorium as specific examples. The chemistry of the elements with $Z=101$, 102, 103, 104, 105, and 112 (of which some thousand atoms have been reported) and the (yet unknown) elements with $Z=108$, 109, 114, 126, 164, and 184 is discussed.

Originally, *Mendeleev* arranged the elements in periods of the same length, each period containing seven elements, and after the discovery of the noble gases, eight elements. This proved to be unsatisfactory for various reasons; not only do three "triad elements" sometimes replace one noble gas, but also the oxidation numbers of copper(II) and gold(III) are higher than the number of the column in the Periodic Table, thus giving an impression of transitional "tetrads". *Rydberg* was the first, in 1906, to suggest increasingly long periods of 2, 2, 8, 8, 18, 18, 32, 32, 50, ... elements, these numbers being twice the squares of integers[1]. This conjecture turned out to be right with exception of the two "elements" nebulium and coronium, which ought to form the second period; and the spectral lines of nebulium and coronium corresponded exactly with those of highly ionized oxygen and iron, respectively. If *Rydberg* was right, fourteen rare earths follow lanthanum, all being predominantly trivalent, whereas hafnium is quadrivalent and tantalum mainly quinquivalent. This proved to be in complete agreement with subsequent discoveries. Actually, all the lanthanoids had already been separated by painstaking fractional crystallization[2]; the one exception being $Z=61$, which has only radioactive isotopes, and which is now isolated from fission products under the name promethium. Hence, *Rydberg* rationalized the phenomenon most incompatible with the "short period" version of the Periodic Table, *viz.* the existence of fifteen consecutive elements having almost the same chemical properties and, surprisingly, exhibiting a far more pronounced similarity than in the triads such as iron, cobalt, and nickel.

The quantum numbers introduced in *Bohr*'s model of the hydrogen atom in 1913 and elaborated by *Sommerfeld* were only intended for atoms containing one electron. However, the regularities found by *Rydberg* in the line spectra of atoms of the alkali metals and of unipositive ions of the alkaline earths strongly suggested that the noble gas atoms form a kind of neutral background (Atomrumpf) to which one external electron (Leuchtelektron) is added. The whole idea of *electron configuration* was not fully clarified by 1923, as can be seen from the commemorative volume of "Naturwissenschaften" published ten years after the Bohr postulates.

We discuss here the quantum numbers n and l introduced according to the quantum mechanics theory of *Schrödinger* and *Heisenberg*[3]; still, it is instructive to make comparisons with the experimental evidence obtained from atomic spectra[4]. According to the "Aufbau principle" the electron configuration consists of the filling of the lowest shells $n\,l$ each capable of containing at most $(4l+2)$ electrons. The trivial symbols s, p, d, f, g, h, ... for $l=0, 1, 2, 3, 4, 5, \ldots$ derive from the former designations of the so-called sharp, principal, diffuse, and fundamental series in the alkali metal line spectra. The main argument for the existence of inner shells stems from X-ray (Röntgen) spectra and, more recently, from photoelectron spectra[5, 6]. Frequently, the positive l-values correspond to two rather different ionization energies, one each for electrons having the quantum numbers $j=(l+1/2)$ and $j=(l-1/2)$. The corresponding relativistic effect ("spin-orbit coupling") is rather weak for external electrons.

The consecutive filling of shells with $(4l+2)$ electrons is in perfect agreement with the observations of *Rydberg*, but, in detail, several irregularities appear. In chemical textbooks, the ground state of the neutral atom is perhaps overemphasized. Firstly, an electron configuration with 2 to $4l$ electrons in a partly filled shell provides several energy levels, which are characterized by different quantum numbers, particularly the total spin S. The main origin of energy differences between such levels is slightly different interelectronic repulsion[3] and it can be shown[7, 8] that a general expression exists for the *spin-pairing energy*,

$$D[\langle S(S+1)\rangle - S(S+1)] \qquad (1)$$

where $\langle S(S+1)\rangle$ is the average value for the partly filled shell l^q. This illustrates one of Hund's rules[4], according to which if more than one value of S is possible ($2 \leqslant q \leqslant 2l$) the highest S corresponds to the lowest energy. Hence, the average energy of an electron configuration (*i.e.* its *bari-*

[**] This paper is based on an invited lecture given at the Hauptversammlung der Gesellschaft Deutscher Chemiker in Karlsruhe on September 17, 1971 [cf. Angew. Chem. *83*, 911 (1971); Angew. Chem. internat. Edit. *10*, 837 (1971)].

center) with partly filled shells is higher than the ground state. Thus, the ground state of the gaseous nickel atom derives from the configuration $[Ar]3d^84s^2$, but the baricenter of this configuration is higher than the baricenter of $[Ar]3d^94s^1$. Secondly, many transition group atoms have energy levels belonging to different configurations, but all lie within 10 percent of their first ionization energy[9]; such energy differences are trivial, when compared with those in the chemical effects to be discussed below.

To a first approximation, the neutral atoms fill their shells in the following order,

$$1s \ll 2s < 2p \ll 3s < 3p \ll 4s < 3d < 4p \ll 5s < 4d < 5p \ll 6s < 4f < 5d < 6p \ll 7s < 5f \ldots \quad (2)$$

where the double inequality signs indicate the noble gas configurations containing 2, 10, 18, 36, 54, 86, ... electrons. Many of the exceptions to (2) are connected with the spin-pairing energy (cf. (1))—*e.g.* when the ground state of the neutral chromium atom belongs to $[Ar]3d^54s^1$ and not to $[Ar]3d^44s^2$. If baricenters are considered, the latter configuration is slightly lower. However, a much more important question is whether 3d or 4s electrons are more stable in the iron group. It might be argued that the presence of two 4s electrons in most of the neutral atoms would indicate that 3d electrons are not preferred, any more than they are in the calcium atom. On the other hand, the 4s electrons are the first to be removed by ionization, and, as a matter of fact[9], all the gaseous ions M^{2+}, M^{3+}, and M^{4+} fill their shells in the order,

$$1s \ll 2s < 2p \ll 3s < 3p \ll 3d < 4s < 4p \ll 4d < 5s < 5p \ll 4f < 5d < 6s < 6p \ll 5f < 6d < 7s \ldots. \quad (3)$$

there being only four exceptions, namely La^{2+}, Gd^{2+}, Ac^{2+}, and Th^{2+}. This apparent discrepancy can be explained by other interelectronic repulsion effects. As example we may consider vanadium, which is the first typical transition element having several oxidation states of comparable stability. Using the energy of the argon core V^{5+} as zero-point of reference, the energies in kK (1 kilokayser $=1000\ cm^{-1}=0.124$ eV $=2.85$ kcal/mole) of the less ionized states are:

		ground state	baricenter
V^0	$[Ar]3d^34s^2$	−1312	−1306
	$[Ar]3d^44s^1$	−1310	−1292
	$[Ar]3d^5$	−1292	−1265
V^{1+}	$[Ar]3d^4$	−1258	−1241
	$[Ar]3d^34s^1$	−1255	−1247
V^{2+}	$[Ar]3d^3$	−1140	−1126
	$[Ar]3d^24s^1$	−1096	−1087
V^{3+}	$[Ar]3d^2$	− 903	− 895
	$[Ar]3d^14s^1$	− 807	− 797
V^{4+}	$[Ar]3d^1$	− 526	− 526
	$[Ar]4s^1$	− 378	− 378

(4)

It should be noted that the calculated values reported in the literature for the consecutive ionization energies have changed considerably with time[9] and, in particular, that the ionization energy of V^{3+} is now known[10] to be 377 kK.

It is possible to construct a model for the tabulated data (4) using a phenomenological baricenter polynomial[11] and to write the average energy of the configuration $(nl)^a(n'l')^b$ containing (a + b) external electrons relative to the closed-shell system:

$$-aI_\varepsilon(nl)-bI_\varepsilon(n'l')+\frac{a(a-1)}{2}A(nl,nl)+abA(nl,n'l')+\frac{b(b-1)}{2}A(n'l',n'l') \quad (5)$$

where $I_\varepsilon(nl)$ is the ionization energy observed for a system containing only one electron in the *nl*-shell outside the closed shells, and where the various *A*-parameters relate to interelectronic repulsion. Assuming $A(3d,3d)=140$ kK, $A(3d,4s)=90$ kK and $A(4s,4s)=70$ kK, and using the observed values $I_\varepsilon(3d)=526$ kK and $I_\varepsilon(4s)=378$ kK, (5) gives the following calculated values (in kK):

V^0	$[Ar]3d^5$	−2630+1400	= −1230
	$[Ar]3d^44s^1$	−2482+1200	= −1282
	$[Ar]3d^34s^2$	−2334+1030	= −1304
V^{1+}	$[Ar]3d^4$	−2104+ 840	= −1264
	$[Ar]3d^34s^1$	−1956+ 690	= −1266
	$[Ar]3d^24s^2$	−1808+ 570	= −1238
V^{2+}	$[Ar]3d^3$	−1578+ 420	= −1158
	$[Ar]3d^24s^1$	−1430+ 320	= −1110
	$[Ar]3d4s^2$	−1282+ 250	= −1032
V^{3+}	$[Ar]3d^2$	−1052+ 140	= − 912
	$[Ar]3d^14s^1$	− 904+ 90	= − 814
	$[Ar]4s^2$	− 756+ 70	= − 686

(6)

This model does not take into account the variation of the radial functions of 3d and 4s on going from V^0 to V^{4+}. Parameters of interelectronic repulsion such as *D* of eq. (1) and *A* of eq. (5) are expected to be proportional to the reciprocal average radius $\langle r^{-1}\rangle$ of the partly filled shell and hence to decrease when the electronic density expands. However, at the same time, I_ε decreases and there seems to be a compensation in neutral l^q systems: $(q-1)A$ and I_ε remain comparable, and the electron affinity of the neutral atom is almost zero. The value calculated for V^{1-} $[Ar]3d^6$ according to eq. (6) is −1056 kK, which suggests spontaneous removal of an electron; this would even be true for $[Ar]3d^44s^2$, with a calculated value of −1230 kK. The values in eq. (6) illustrate the important fact[11] that one-electron energies are not additive in the configuration baricenters. This lack of additivity does not need to be explained by correlation effects, though we must remember that our description of interelectronic repulsion involves phenomenological parameters[8, 12] which are decreased by a kind of inner dielectric effect by a factor of about $(z+2)/(z+3)$ relative to the Hartree-Fock values calculated for a monatomic ion with charge *z*.

Chemistry is very different from atomic spectroscopy in that high oxidation numbers (the highest known being ruthenium(VIII), osmium(VIII), and xenon(VIII)) are frequently stable, whereas the q'th ionization energy of $M^{(q-1)+}$ to M^{q+} tends to be approximately proportional to q (and is $I_\varepsilon-(k-q)A$ when the core is M^{k+}), as long as the same *nl*-shell loses the electrons. The choice of ligands[13] has a great influence on the preferred oxidation state. Thus, vanadium forms the two aqua ions $[V(H_2O)_6]^{3+}$ and $[V(H_2O)_6]^{2+}$ (though the latter is thermodynamically unstable toward hydrogen evolution in aqueous solution) whereas oxo ligands are well-known from the vanadate(V) ion VO_4^{3-} and the vanadyl ion $[VO(H_2O)_4]^{2+}$ (with V^{IV}); finally, carbon monoxide stabilizes the $3d^5$ system vanadium(0) in $V(CO)_6$ and the $3d^6$ system vanadium (−I) in $[V(CO)_6]^-$. There is no apparent connection between these facts and the relationship (4). It is clear that one reason why fluorides and oxides of high oxidation states are known

is that elemental F_2 and O_2 are difficult to form; *Kruck*[14], on the other hand, has shown that phosphorus trifluoride is an excellent ligand for formation of low oxidation states such as $[Ru(PF_3)_4]^{2-}$ and $[Ir(PF_3)_4]^-$ analogous to those in $[Cr(CO)_5]^{2-}$ and $[Fe(CO)_4]^{2-}$

When calculations of the Madelung electrostatic energy of crystals became feasible[15] it was clear that the very high ionization energies of atomic spectroscopy are to a large extent compensated by the electrostatic attraction of the surrounding anions. Actually, the atomic ionization energies even seem to be overcompensated in the sense that many closed-shell cations such as alkali metals M^I, alkaline-earth metals M^{II}, Al^{III}, Sc^{III}, Zn^{II}, Y^{III}, Zr^{IV}, and Th^{IV} represent the only oxidation states of the element considered in non-metallic compounds. It is possible to introduce the concept of *differential ionization energy*[11,16] and to calculate the most stable fractional atomic charges by minimizing the sum of the total interatomic Coulomb (Madelung) energy and a quantity (for each atom) of which the differential quotient is I(z). The function I(z) adapted to eq. (4) for vanadium with the charge z (that is $(5-z)$ electrons in the 3d shell) is (in kK) $-18+75\,z+10\,z^2$.

For many compounds, the minimal energy is obtained for full ionicity with z equal to the oxidation number, whereas in other circumstances, fractional charges between 1 and 2 are predicted for the metallic element. Thus, the central atom in the tetrahedral molecule vanadium(IV) chloride has a fractional charge close to 2. This treatment can be refined by taking into account effects of covalent bonding[11,16] and what is essentially the repulsion between closed-shell cores of adjacent atoms first introduced in the Madelung description by *Born* and *Haber*.

Fajans was the first to emphasize that alkali metal halides (with the exception of lithium salts) dissolve in water with only weak endothermic or exothermic effects. This allows the important conclusion that the sum of the hydration energy of the cation and the anion is almost equal to the Madelung energy of the crystal. The entropy contributions making the difference between enthalpy and free energy are negligible in this connection, and it is possible, for the species which loses one electron, to define the *chemical ionization energy* I_{chem} as the sum of 36 kK (or 4.5 eV) and the product of 8.07 kK and the *standard oxidation potential* U_0. Thus, I_{chem} for $[V(H_2O)_6]^{2+}$ with $U_0=-0.25$ V equals 34 kK. It is possible to discuss the *hydration energy difference*[17] as the difference between the ionization of gaseous $M^{(z-1)+}$ and I_{chem} of the aqua ion, whose oxidation number changes from $(z-1)$ to z. This *hydration energy difference* can be written to a good approximation as:

$$I_z - I_{chem} = \kappa(2z-1) \qquad (7)$$

where the parameter κ is close to 45 kK for beryllium(II) and aluminum(III), 43 kK in the 3d series, 35 kK in the 4f series, and about 31 kK in the 5f series. Expressions of type (7) would also be obtained for the hydration, if it could be represented as the introduction of an ion with radius r_{ion} into a perfect dielectric medium. In this case $\kappa = 57$ kK/r_{ion} if r_{ion} is measured in Å and differential effects of changing ionic radius during the ionization are neglected. *Latimer*[18] pointed out that such an interpretation works well for anions, but that cations seem to have r_{ion} values some 0.8 Å larger than the conventional ionic radii. In any case, κ decreases with increasing radii in the case of the heavier elements. Hence, I_{chem} for $[Ti(H_2O)_6]^{3+}$ (36 kK) is smaller than for cerium(III) aqua ions (51 kK), though I_4 for Ti^{3+} is 349 kK and for Ce^{3+} only 296 kK. The sub-shell energy difference in octahedral complexes of 3d elements is sufficiently large (8 to 20 kK) for "ligand field stabilization" effects to be detected in the apparent irregular variation of the U_0 values for hexaaqua ions[19,20].

It might be argued that hydroxo and oxo complexes are formed by deprotonation of known or hypothetical aqua ions, and that the theory of hydration energy difference can readily be extended to such systems. However, in view of the known I_{chem} values of 41 kK for RuO_4^{2-} and 44 kK for RuO_4^- in aqueous solution, it is not easy to obtain a reliable connection with the very large I_7 and I_8 for gaseous ruthenium ions, and it is doubtful whether it could have been possible to predict the existence of the perxenate anion XeO_6^{4-} in this way.

There is not the slightest doubt, however, that no simple relation exists between the electron configuration of the ground state of the neutral atom and the chemistry of the element under consideration. Thus, iron and ruthenium differ much more from each other chemically than do nickel, palladium, and platinum, though the configurations are analogous ($[Ar]3d^64s^2$ and $[Kr]4d^65s^2$) in the former case but differ ($[Ar]3d^84s^2$, $[Kr]4d^{10}$, and $[Xe]4f^{14}5d^96s^1$) in the latter. The most spectacular discrepancy between the spectroscopic and chemical versions of the Periodic Table is that helium is an alkaline earth element from the point of view of atomic spectroscopy, since its ground configuration does not terminate with np^6 like the other noble gases. Hence, it is not too surprising that the almost invariant trivalency of the lanthanum series has little to do with the ground states of the neutral atoms.

Hund[4] believed that these atoms have three valence electrons $[Xe]4f^q5d^16s^2$. However, this is only true[21] for lanthanum, cerium, gadolinium, and lutetium (which can most conveniently be considered as the first member of the 5d series), whereas the atoms of the remaining eleven lanthanoids have ground states belonging to $[Xe]4f^{q+1}6s^2$ and are really barides (baroids) from this point of view. The reason for the almost constant trivalency in the 4f series differs from that for the trivalency of aluminum, where the Madelung potential[15] or other chemical stabilizations cannot compensate the very large I_4 of 968 kK necessary for removing a 2p electron from the neon core, whereas an added electron would enter the loosely bound 3s orbital. It was first pointed out by *Connick*[22] in a comparative study of standard oxidation potentials that the *electron affinity* of a partly filled 4f shell is much smaller than the ionization energy because of interelectronic repulsion effects such as $A(4f,4f)$ in eq. (5). This explains why a definite number of 4f electrons may be much more stable, in analogy to eq. (6), and why for sufficiently low ionic charges, it is necessary to have one or two 5d and 6s electrons present. Thus, the cerium atom ground state $[Xe]4f^15d^16s^2$ ionizes to gaseous $Ce^{2+}[Xe]4f^2$, though a low concentration of Ce^{II} in CaF_2 has the ground configura-

tion[23] $[Xe]4f^15d^1$ and excited levels of configuration $[Xe]4f^2$. Incidentally, these solid solutions containing Ce^{II} or Gd^{II} are among the rare case of *two* partly filled shells in chemistry, other examples being gaseous molecules such as TiO, whose ground state[24] is closely related to the configuration $[Ar]3d^14s^1$. At the other end of the 4f series, the closed systems $[Xe]4f^{14}$ form the ground state (well below the first excited level) of gaseous Yb^{2+}, Lu^{3+}, Hf^{4+},

and the corresponding ytterbium(II), lutetium(III), hafnium(IV), tantalum(V), ... compounds. Other $[Xe]4f^{14}$ systems are unstable, but in analogy to (6), because of a high $A(4f,4f)$, the neutral erbium atom has the configuration $[Xe]4f^{12}6s^2$, that of free Er^{2+}, like Er^{II} in the fluorite lattice have the configuration $[Xe]4f^{12}$, and free Tm^+ has the configuration $[Xe]4f^{13}6s$.

Addition of a 4f electron to M^{III} to give M^{II}, or removal of a 4f electron to give M^{IV} requires an energy which varies in a characteristic way with the number of 4f electrons. This variation can be obtained by an extension of eq. (1) to include further, smaller effects of interelectronic repulsion and first-order relativistic effects. It was first used[25] to explain the variation of the electron transfer spectra[26] of bromides in nearly anhydrous ethanol and of dialkyldithiocarbamate complexes. Later studies included the variation of $4f^q \rightarrow 4f^{q-1}5d^1$ transitions in M^{II}[27] and M^{III} systems[28] in fluorite lattices, the variation of standard oxidation potentials[29], and electron transfer spectra of hexachloro, hexabromo[30], and hexa-iodo complexes[31] of trivalent lanthanoids. All of these applications refer to the change of one 4f electron, but direct evidence for a slight chemical variation of the considerable amount of spin-pairing energy (1) having a minimum for $q=7$ and $S=7/2$ (with $D=6.5$ kK) was obtained[32, 33] from the "tetrad effect" which was first discovered by *Fidelis* and *Siekierski* by careful studies of equilibrium constants. Only recently has it been possible to determine the ionization energies of 4f electrons in compounds of rare-earth metals[34, 35] and in the subsequent compounds[36] of Hf, Ta, W, Re, ... by photoelectron spectrometry, whereby solid samples were bombarded with 1486.6 eV photons from an aluminum anticathode. Though it is well established from the *nephelauxetic effect*[11, 37] (the interelectronic repulsion changes only 5 percent in the transition from free Pr^{3+} to praseodymium(III) compounds and, in generally, only 1 to 2 percent between different compounds of the same M^{III} systems having from two to twelve 4f electrons) that the covalent bonding of the 4f shell produces only a very weak (radial) expansion and delocalization (which can be treated by the *angular overlap model*[38, 39]), it is remarkable that the ionization energy of the 4f shell is comparable or slightly larger (between 11 and 18 eV) than that of the ligand orbitals. This finding is not surprising when it is remembered that the electron affinity of the 4f shells is far smaller because of interelectronic repulsion; nevertheless, it casts some doubts whether the diagonal elements in a Hückel-Wolfsberg-Helmholz type model can be identified with orbital ionization energies[8].

Now that the internal mechanism of the lanthanoids is better understood it is recognized that the trivalency is to some extent an accidental result of the numerical parameters of hydration energy (7), whereas an almost invariant oxidation number is a more general consequence of a large difference between the electron affinity and ionization energy (such as is true also for beryllium or aluminum).

In the specific case of a partly filled shell the magnitude of A in eq. (5) is considerably greater than that of 2κ in eq. (7).

The chemistry of protactinium and of uranium is, in certain respects, different from that of tantalum and tungsten, but at least these elements most frequently have the oxidation states Pa^V and U^{VI} corresponding to the closed-shell configuration of 86 electrons in radium(II) and actinium(III). Around 1925, very little doubt was expressed about the 5f group beginning somewhere among the unknown elements following uranium. Exactly as for the three valence electrons of lanthanoid atoms, it was felt (without direct spectroscopic evidence) that the very line-rich arc spectrum of uranium belonged to an atom with the ground configuration $[Em]6d^47s^2$ (symbolized Em, "emanation"; radon is, for the writer, merely the name of an isotope like deuterium). However, the geochemist *Goldschmidt* suggested that thorium starts a new series of mainly quadrivalent rare earth elements. This proposal was mainly based on the existence of the oxides MO_2 (now known for M = Th, Pa, U, Np, Pu, Am, Cm, Bk, and Cf), which crystallize in the particularly stable fluorite lattice with a high Madelung energy. Much more interesting for us is the fact that *Ephraïm*[40] found the narrow absorption bands of several uranium(IV) compounds which are, in close analogy to praseodymium(III) compounds[11], indicative of the configuration $[Em]5f^2$. Unfortunately at that time, it could not be argued convincingly that only partly filled f shells produce narrow absorption bands in samples in the condensed state (crystalline, vitreous, or liquid). Certain 3d group central atoms, such as the chromophore $Cr^{III}O_6$ of ruby or the isoelectronic MnF_6^{2-} ion, have excited levels producing narrow absorption (and frequently line luminescence) bands belonging to the same sub-shell as the ground state. Hence, the excitation energy is mainly due to interelectronic repulsion being more pronounced in the excited state (as in the f groups), while the electronic density remains practically unchanged in three-dimensional space. It is interesting to note that the first application of *Bethe*'s electrostatic ligand field approach (nonspherical part of the Madelung potential) to visible spectra was carried out by *Finkelstein* and *Van Vleck*[41], who found the narrow, spin-forbidden ($S=3/2 \rightarrow S=1/2$) intra-sub-shell transitions in ruby and complained that the spin-allowed transitions between the lower and the upper sub-shell were hidden by broad coincident absorption bands. *Tanabe* and *Sugano*[42] later pointed out that it is simply these transitions that produce the broad bands, since the equilibrium internuclear distances are larger in the excited states containing an anti-bonding 3d electron. Hence, in this case, the Franck-Condon principle, which describes the superposition of vibrational coexcitation on the electronic transition, comes into operation[8].

As described in the Gmelin volume, "Uranium", it was originally thought that the fission products obtained by neutron bombardment were transuranium elements. However, when neptunium was identified by *McMillan* and *Abelson* in 1940, its chemical properties appeared so similar

to those of uranium that it was felt that the beginning of a 5f series, designated *uranides* had been discovered. *Seaborg* collaborated in the discovery of the subsequent eight elements and became more and more convinced that the transuranium elements, like the rare earths, tend toward trivalency; he therefore suggested the designation "*actinides*" (now called actinoids according to IUPAC rules) for the 5f elements. During the second world war, *Spedding* developed the technique of ion-exchange for the separation of elements of the lanthanum series. This technique proved to be a much more convenient and rapid method of separation than fractional recrystallization for the separation of such elements. Assuming that the new elements Am, Cm, Bk, Cf, Es, and Fm also exist in solution as M^{III} aqua ions, the same method of separation was resorted to and it became possible to separate and identify them. It must be remembered that at the time of their discovery, such elements were available in quantities ranging from only 10^{16} atoms (a few micrograms) down to 10^6 atoms.

As the chemistry of the transuranium elements was further developed[43,44] it was soon realized that the true situation was not quite so simple. Uranium, neptunium, and plutonium all assume the oxidation states M^{III}, M^{IV}, M^{V}, and M^{VI}. This turned out to be true also for americium, although in this case no hexafluoride could be prepared, but only the americyl ion AmO_2^{2+}. These linear dioxo complexes must be particularly stable; the electron transfer band does not occur at very low wave numbers (not much below that in the blue region of UO_2^{2+} which usually is luminescent and had contributed to the somewhat accidental discovery of radioactivity in 1896). Curium, berkelium, and californium are most stable as M^{III}, but can also occur as M^{IV} in the form of oxides and fluorides. The position of the electron transfer band of orange $BkCl_6^{2-}$ has been determined[29]. Only the M^{III} state is definitely known in the case of einsteinium and fermium; however, it cannot be argued any longer that only positive deviations from M^{III} occur at the beginning of the 5f series. It was shown by tracer experiments[45] that mendelevium(III) can be reduced to a species similar to europium(II)[*]; the standard oxidation potential, however, is $U_0 = -0.1$ V. This is a most striking difference from the Am^{II} system, which must be far more strongly reducing. This trend at the end of the 5f series could be predicted immediately the electron transfer bands of californium(III) and einsteinium(III) bromo complexes in ethanol had been detected[46]. Nobelium(II) aqua ions ($Z = 102$) are exceedingly difficult to oxidize in aqueous solution. On the other hand, dark green neptunium(VII) and dark blue plutonium(VII) oxo complexes (of type MO_5^{3-} or perhaps in the form of mixed hydroxo-oxo complexes with additional water of constitution) represent species with unexpectedly high oxidation states[47] in the beginning of the 5f series; in the meantime the crystal structures of systems containing such anions[48] and of Li_5MO_6, which is isotypic[49] with the previously known orthoperrhenate(VII) Li_5ReO_6, have been determined.

Recent progress in the chemistry of the transuranium elements clearly shows that the 5f series has the same relation to the 4f series as has the 4d (palladium) group to the 3d (iron) group[17]. At the beginning of the series one finds species such as MoO_4^{2-} and TcO_4^-, which are far less oxidizing than CrO_4^{2-} and MnO_4^-, and the volatile compounds RuF_6, RuO_4, and RhF_6, for which there are no analogies in iron and cobalt chemistry. On the other hand, at the end of the group, we have silver(I), which is much more difficult to oxidize than copper(I). Such a difference between a group with rather low and constant oxidation number (as in the 3d and 4f group, where $n = l+1$, and the radial function has no nodes) and a group in which the oxidation number varies from high at the beginning to low at the end (as in the 4d, 5d, and 5f groups, where n is larger than $(l+1)$) can be described[50] by the parameter $(E-A)$. This parameter was first introduced[25,26] to indicate the more or less steeply increasing oxidizing character of the central atom in a given transition series, when the oxidation state is kept constant. It is the difference between the more negative one-electron energy E, when the central field is changed by increasing the atomic number Z by one unit, and the increased interelectronic repulsion A due to the presence of an additional electron in the partly filled shell. In other words: in strongly screened systems, $(E-A)$ is small and has a value close to 2.9 kK for trivalent lanthanoid complexes having various ligands; a value of 8 kK is obtained when derived[19] from the standard oxidation potential of M^{II} hexaaqua ions of the 3d elements and 8.5 kK when derived from M^{III} aqua ions of the 5f elements[29]. When $(E-A)$ is small, as in the 3d and 4f groups, the tendency toward invariant oxidation number is pronounced, whereas a large value of $(E-A)$ produces high oxidation numbers at the beginning and low oxidation numbers at the end of a given transition series. This is the reason why the writer does not recommend the word "actinide" and would rather speak of a 5f group or a group of transthorium elements.

There is no intrinsic contradiction[51,52] between the presence of 5f electrons and the high and varying oxidation states for Z between 91 and 98. The spectroscopic properties of M^{III} systems and higher oxidation states in compounds are unconditionally in favor of the presence of 5f electrons besides the closed-shell emanation core. The manifest chemical differences between the chemistry of protactinium and praseodymium, and between uranium and neodymium, are of the same kind as the "chemical" difference between beryllium and helium seen from the point of view of a spectroscopist. There is a difference between the neutral thorium atom and the cerium atom, insofar as the ground state of the former atom[53] corresponds to the configuration $[Em]6d^27s^2$, whereby the element constitutes a higher homolog of zirconium. Th^{2+} is a particularly interesting system[54,55] in that the ground state corresponding to $[Em]6d^2$ is followed within 0.81 kK by the first level of the $[Em]5f^16d^1$ configuration. Actually, the baricenters (in kK relative to the ground state) are:

$[Em]6d^2$	6.6	$[Em]6d^17s^1$	7.2
$[Em]5f^16d^1$	9.5	$[Em]5f^17s^1$	5.4
$[Em]5f^2$	24.4	$[Em]7s^2$	11.9

(8)

There are reasons[56] for assuming the ionization energy of Th^{2+} to be 150 kK. When this estimated value is combined

[*] *Note added in proof:* Meanwhile mendelevium(I) has also been detected [73].

with the known I_s values of 228 kK for 5f, 219 kK for 6d, and 208 kK for 7s in Th^{3+}, the parameters of interelectronic repulsion of eq. (5) are as follows:

$$\begin{array}{ll} A(5f, 5f) = 102 & A(5f, 7s) = 63 \\ A(5f, 6d) = 78 & A(6d, 7s) = 56 \\ A(6d,6d) = 67 & A(7s, 7s) = 50 \end{array} \quad (9)$$

The increase in average radius in the series $5f < 6d < 7s$ is seen to have the same effect in the tabulated list (9) as the series $3d < 4s$ in eq. (6). It can now be understood why 5f electrons in the case of thorium are stabilized only at high ionic charges. The situation is more clear-cut in the case of uranium, where the ground state of the neutral atom derives from $[Em]5f^36d^17s^2$, and where the three 5f electrons remain in uranium(III) compounds. The general opinion today is that the ground state of neutral Pa, U, Np, and Cm belong to $[Em]5f^q6d^17s^2$ and of Pu, Am, Bk, and subsequent elements to $[Em]5f^{q+1}7s^2$. However, as we have seen, this has little bearing on chemical behavior, and there is no doubt that the narrow absorption bands of M^{III} compounds are due to transitions within the configuration $[Em]5f^q$, whereas broad, intense bands due to $5f \rightarrow 6d$ transitions are known to occur in many compounds of Pa^{IV}, U^{III}, U^{IV}, Np^{III}, Np^{IV}, Pu^{III}, Pu^{IV}, Am^{III}, Bk^{III}, *etc.*[11, 29, 46, 51, 57].

Herrmann and *Seyb*[58] and *Keller*[44] discuss the possibilities of preparing heavier elements. In practice, this has until recently been carried out by bombarding gram quantities of plutonium or curium with oxygen or neon ions in electrostatic accelerators. The leading research groups in Berkeley (California) and Dubna (Russia) have obtained thousands, or only hundreds, of atoms of the elements 103, 104, and 105. The study of these elements necessitates the use of subtle techniques previously unresorted to in chemistry, even on an ultramicro-scale. Despite their short half-life, in some cases only a few seconds, their behavior has been studied by carrying out volatility experiments with anhydrous chlorides of other elements. There is no doubt that 102^{II}, 103^{III}, 104^{IV}, and 105^{V} have the closed-shell configuration $[Em]5f^{14}$ in analogy with $[Xe]4f^{14}$ of hafnium(IV) compounds *etc.* It is highly probable that elements 106, 107, and 108 can also occur in their highest oxidation states VI, VII, and VIII; the higher ionic radius of element 108 would suggest octahedral coordination as being plausible in the MO_6^{4-} system or in mixed hydroxo-oxo complexes—as is already known[13] in the osmate(VI) system $[OsO_2(OH)_4]^{2-}$. It is more difficult to ascertain whether element 109 could achieve the as yet unknown oxidation state IX.

A few years ago, the hope of making trans-105 elements seemed very remote because of the rapidly decreasing yields (extrapolating to less than an atom per experiment) and half-lives. The main difficulty is the pronounced deficit of neutrons obtainable by normal nuclear reactions; even high-flux neutron sources and subterraneous nuclear explosions do not seem to lead to formation of elements beyond fermium. However, it has been known since 1948, when *Maria Goeppert-Mayer* and *Hans Jensen*[59] published their nucleonic shell model, that certain numbers N of neutrons or Z of protons form particularly stable nuclei; well-known examples are oxygen 16, calcium 40, zirconium 90, and lead 208, which have both N and Z belonging to the class of nucleonic, closed shells 8, 20, 40, 50, 82, and 126. All isotopes of the elements immediately following lead, namely Po, At, Em, and Fr, have particularly short half-lives, while several isotopes between Th and Cm have longer half-lives. The next possible closed proton shell would be at $Z = 114$ and theoreticians believe that several isotopes of 112, 133, and 114 may have half-lives (the main decomposition mode being spontaneous fission) around $10^{5\pm4}$ years, the upper limit bringing them into the range of geochemical possibilities.

The tungsten bricks employed to stop the 24 GeV protons generated at CERN (near Geneva) have been recently studied[60] and an added trace of inactive mercury was found to trap a highly unusual isotope which undergoes spontaneous fission and emits high-energy α-particles. Some skepticism was expressed as to whether this isotope really is eka-mercury ($Z = 112$) and it has recently been shown[61] that two-thirds of the activity is due to californium 252. It is not yet known whether this is an unexpected impurity or an ingrowing daughter. Be that as it may, the origin of the remaining activity cannot be explained this way; unusual properties have to be accounted for; the fission does not seem to be binary but may be ternary or of a higher order. One has to be somewhat cautious; several isotopes of elements between thorium and curium have metastable isomers with much larger ellipticity than the ground state and correspondingly shorter half-lives relative to spontaneous fission[62]. Fortunately, the suspected eka-mercury has a half-life of longer than six months, possibly of several centuries. Quite recently, in the laboratory at Orsay (near Paris), thorium has been bombarded with 500 MeV Kr^{24+} ions and unknown α-activities of 13 to 15 MeV have been detected[63].

It is generally agreed[64, 65] that eka-lead ($Z = 114$) is a more volatile metal than lead and that the 114^{II} aqua ion must be stable in aqueous solution, though "soft" sulfur-containing ligands and iodide also ought to be strongly coordinated and could favor the formation of higher oxidation numbers, such as those of the $6d^8$ system 114^{VI}. According to *Rydberg*, element 118 should be a noble gas, but it has already been pointed out by *Grosse*[66] that this element possibly exists as a semimetal, which, like mercury, is converted into a monatomic gas on evaporation. Recent developments in the chemistry of xenon[67, 68] show that there is little doubt that 118^{IV} should be fairly stable. Unfortunately, this element cannot be observed because of its nuclear properties.

In the region of the Periodic Table considered here, the relativistic effect that s orbitals (and with smaller probability $p_{1/2}$ orbitals) have a finite density at the nucleus producing an electrodynamic stabilization becomes chemically important. This effect may already contribute to the well-known preference for the oxidation states Tl^{I}, Pb^{II}, and Bi^{III} and manifests itself most clearly in the spectroscopic finding that the ionization energies of gaseous Ra and Ra^+ are just slightly larger than those of Ba and Ba^+. Correspondingly, the two 8s electrons of the atom

with $Z=120$ are more strongly bound than the outermost s electrons of radium.

Though the number 126 may correspond to a well-established closed shell of neutrons, it is less probable that it is a closed shell of protons. Many Dirac-Fock calculations have been performed on neutral atoms having Z between 121 and 130, and the relative occupation numbers estimated for the 8s, 8p, 7d, 6f, and 5g shells deviate from one another substantially[69]. However, for the chemist, the important point is that the average radius of the 5g shell is very small and the difference between ionization energy and electron affinity correspondingly very large. As we have seen above, this situation favors a fixed oxidation state in compounds of such elements, and it has been suggested[50] that the most likely candidate is 126^{IV} with the electron configuration $[118]5g^4$. This would make its chemistry rather similar to that of thorium(IV), and macroscopic amounts should therefore be strongly colored because of the many low-lying excited levels of the configuration $[118]5g^36f^1$.

If the nucleus was a point, the Dirac treatment for Z above 137, *i.e.* for the reciprocal fine-structure constant, would be divergent. However, when the finite radius and the approximately invariant density of the nucleus are taken into account[70], finite ionization energies somewhat larger than the non-relativistic Hartree-Fock values are found. The next candidate for a closed proton shell would have $Z=164$. Extrapolation of the series (2) would give the ground configuration $[118]5g^{18}6f^{14}7d^{10}8s^28p^2$ for dwi-lead (which is called "zwei-blei" in New Mexico) in agreement with Dirac-Fock calculations[71, 72]. However, a major difference from lead is the relativistic stabilization of the 8s and $8p_{1/2}$ electrons, whose ionization energy ought to exceed that of several other orbitals. It is suggested that the 164^{II} aqua ion contains the partly filled shell $7d^8$ besides the other electrons of the free atom. This would make the chemistry closely analogous to that of palladium(II), the hydration energy differences being determined by the consecutive ionization energies of the 7d shell[72]. The atoms condense to a fairly noble metal, similar to the palladium atoms in the closed-shell configuration $[Kr]4d^{10}$.

An extrapolation according to *Rydberg* suggests the next noble gas as being at $Z=168$. It is definitely known that such a situation does not occur before $Z=172$, since the following orbitals 9s and $9p_{1/2}$ are stabilized for relativistic reasons. A closed proton shell may occur at $Z=184$. This element contains a partly filled 6g shell. If one can extrapolate[8] from the lower transition series with $n=l+2$, one would expect varying oxidation states from 184^{IV} with the configuration $[172]6g^8$ (perhaps stabilized if the relativistic separation between the eight $6g_{7/2}$ and the ten $6g_{9/2}$ electrons is large) to 184^{XII} with the closed-shell [172] configuration, which could perhaps form a volatile hexoxide or fluoro-cations such as $(184)F_8^{4+}$. If this hypothesis were correct, element 184 would be a super-ruthenium with its oxidation state changing by many units like that between Ru^{-II} with $[Kr]4d^{10}$ and Ru^{VIII} with $[Kr]4d^0$ However, *Fricke* and *Waber* have suggested a smaller average radius of the 6g shell favoring a constant oxidation number. This is a question to some extent determined by eq. (7), though strong effects of polarization and Van der Waals attraction (cf. the high sublimation temperature of WCl_6) and high formation constants of complexes with "soft" ligands (according to *Pearson*) could necessitate modification of this simple description.

Fricke, *Greiner*, and *Waber*[71] have questioned whether the Dirac treatment becomes divergent when the one-electron eigenvalues E (which are slightly below mc^2 in light atoms by an amount corresponding to the ionization energy found by X-ray or photoelectron spectra) approach $-mc^2$ for the 1s orbital at $Z\approx174$ and for the $2p_{1/2}$ orbital at $Z\approx190$. The point is that for the "Dirac sea", an overall equally dense continuum of one-electron functions, all E values lie below $-mc^2$. The Dirac interpretation of a positron as a hole in this continuum which is capable of annihilating an electron and forming the conventional vacuum. This question is related to the problem whether in Nature a higher limit exists for electric field strength, a dielectric screening being introduced by the formation of positron-electron pairs. The writer is not an expert regarding this subject but would like to suggest that the risk of divergence would occur only for the much higher Z^* values for which the *total energy* (which, after all, is the quantity minimized in Hartree-type models) approaches $-Z^*mc^2$. For lighter atoms, the total energy including the rest-mass of the electrons is approximately

$$(2\cdot137^2Z - Z^{2.4}) \text{ rydberg units} \qquad (10)$$

But this is a non-relativistic result, valid only for Z below 100. The electron cloud is entirely different from the atomic nucleus, the two 1s electrons contributing a significant amount, almost $-2Z^2$ rydberg units, of the total binding energy.

Some concern has been expressed among nuclear theoreticians as to whether the very heavy nuclei conserve their spherical or moderately ellipsoidal shape[62]. It is conceivable that nuclei may develop cavities and become positively charged bubbles. In such a case, the usual nucleon shell model[59] would no longer be applicable. Nevertheless, it would still be possible that quite definite combinations of Z and N would have particularly long half-lives.

From the practical point of view of how to attempt to make an element with Z above 120, the major problem is the neutron deficit of the starting materials; it is quite possible that the only solution is a supernova explosion or cutting a slice of a neutron star. It is instructive, however, for conventional inorganic chemistry that only a very loose and very sophisticated relation exists between the ground electron configuration and the chemical properties of a given element. If we are ever going to hunt one of the trans-105 atoms, we shall never be in the fortunate situation enjoyed by those who sought promethium, where it was known since the time of *Moseley* that the chemical properties would lie very accurately between those of neodymium and samarium. Actually, the higher ionic charges are, considering eq. (7), of greater interest than are the neutral atoms, and the whole question of selection of oxidation state[11] is far better understood today than it was just a few years ago.

Discussion between physicists, who like beautiful but oversimplified treatments, and chemists, who swim in complexity, is nevertheless occasionally fruitful.

Semiempirical Use of Chirality Functions[1a, 1b] for the Description of the Optical Activity of Allene Derivatives in the Transparent Region

By Ernst Ruch, Wolfgang Runge, and Günter Kresze[*]

A comparison of calculated and experimental data shows that the optical rotatory power of phenylallenecarboxylic acids is quantitatively described by the polynomial expression developed in (1). The T_d component of this expression, the only relevant one for the case of methane derivatives turns out to be negligibly small in the case of allene derivatives. Therefore, and because allene derivatives belong to category a[16] the sequence of the λ-parameter values of the ligands may be used to determine the configuration and the sign of rotation.

1. Theoretical

The rotation of the polarization plane of polarized light upon passing through a non-racemic mixture of chiral molecules in an achiral solvent is a special example of a chirality observation. Chirality observation as generally defined is the measurement of numerical values of objects (or mixtures thereof) with experimental devices, leading to the value zero if the object is achiral (or the mixture racemic) and to identical numbers with opposite signs if the objects or mixtures are enantiomeric.

Chirality observations provide structural insight, and chirality functions, serving as mathematical expressions, represent this structure in a lucid form if we study the chirality of molecular classes defined as follows. A molecular class contains molecules with a common achiral skeleton and varying achiral ligands at given skeleton sites. We supplement this definition by an additional restricting condition, namely that the manner in which a ligand is attached does not depend upon the nature of the neighboring ligands, and molecules with exclusively identical ligands have the symmetry of the skeleton. This requirement implies a certain selection of permitted ligand types. The ligands must be of such a kind and fixed in such a manner that symmetry operations of the skeleton belonging to the subsymmetry of a fixed site are also symmetry operations of the corresponding ligand. Insofar as deviations from this condition have little influence on the result of the measurement, they may be treated as a perturbation. An essentially algebraic theory applicable to any type of chirality observation and any class of molecules of the type mentioned was presented in ref.[1a] and has been outlined recently without mathematical details in a review[1b]. The results present three different aspects for the chemist:

1. For the forementioned classes of molecules, the theory yields a structural concept for the chirality phenomenon corresponding in nature and significance to the concept of symmetry in spectroscopy.

2. Thus it also provides structural clues for a quantum-mechanical or classical treatment of particular chirality observations of such molecules.

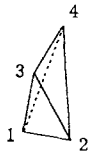
3. In the form of special expressions[1,2] characterized by mathematical simplicity, semiempirical methods for the calculation of chirality observations can be proposed. Only formally defined elements of the expression, such as ligand-specific parameters *etc.*, are determined experimentally and may be interpreted physically *a posteriori* if desired. The quantitative description of a chirality observation by a chirality function naturally guarantees the theoretical determination of the configuration of a molecule.

It is the last-mentioned aspect 3, in particular, which we treat here by testing the quantitative description of the optical rotation of allene derivatives. However, statements of the general theory concerning our particular problem will be sketched first so that the reader may obtain a better understanding of the relationship between our experimental arrangements and the theoretical questions.

The algebraic analysis allows us to establish exactly which additional properties a chirality function must also have in order to be different from zero, in principle, when applied to any possible non-racemic mixture of isomers. A chirality function of this type has been called "qualitatively complete". This requirement arises from reservations concerning the quality of specific expressions for chirality functions. This problem may differ from one molecular class to another, but disappears in any case if the expression has the property mentioned above[1a]. It should be pointed out that nearly all the existing theories of optical activity fail to satisfy this requirement. It is found that the "qualitatively complete chirality function" for a class is made up additively of components with different structures. In the case of a molecular class with ligand sites at

[*] Prof. Dr. E. Ruch
Institut für Quantenchemie der Freien Universität
1 Berlin 45, Holbeinstrasse 48 (Germany)
Prof. Dr. G. Kresze and Dr. W. Runge
Organisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

the corners of a tetrahedron of symmetry D_{2d}, corresponding to allene derivatives, there are two such components.



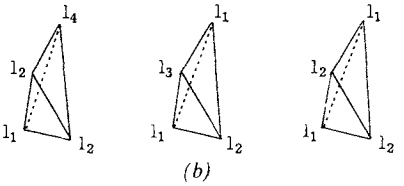
(a)

We write the qualitatively complete chirality function $\varphi(l_1, l_2, l_3, l_4)$ depending on some parameters for each ligand on skeleton sites 1, 2, 3, and 4 (compare *(a)*) in the form:

$$\varphi(l_1, l_2, l_3, l_4) = \varphi_1(l_1, l_2, l_3, l_4) + \varphi_2(l_1, l_2, l_3, l_4) \quad (1)$$

The structures of the two components φ_1 and φ_2 can be found from the general theory[1a]. We confine ourselves to stating here the consequences which can be verified on the particular qualitatively complete chirality function (3).

The function $\varphi_2(l_1, l_2, l_3, l_4)$ vanishes if two of the ligands are identical, a fact which seems surprising in the case of chiral molecules of type *(b)*.



(b)

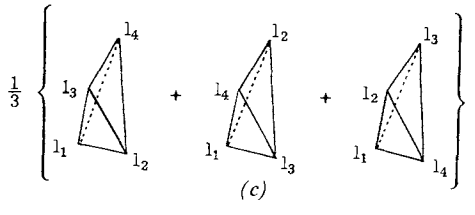
The function $\varphi_1(l_1, l_2, l_3, l_4)$ satisfies the zero identity:

$$\varphi_1(l_1, l_2, l_3, l_4) + \varphi_1(l_1, l_3, l_4, l_2) + \varphi_1(l_1, l_4, l_2, l_3) \equiv 0 \quad (2)$$

Therefore it does not contribute to the expression

$$\tfrac{1}{3}\{\varphi(l_1, l_2, l_3, l_4) + \varphi(l_1, l_3, l_4, l_2) + \varphi(l_1, l_4, l_2, l_3)\}$$

which describes the chirality observation of a non-racemic isomer mixture of the type shown in *(c)*, if we assume linear superposition of contributions from the single compounds in this mixture.



(c)

Two special types of chirality functions have been developed[1,2] which can be used for semiempirical purposes. One type of function consists of polynomials of lowest degree in ligand-specific parameters for each component. The expression needed here is a sum of polynomials denoted by $\chi(l_1, l_2, l_3, l_4)$ and it has the form:

$$\begin{aligned}\chi(l_1, l_2, l_3, l_4) = {} & \varepsilon_1[\lambda(l_1) - \lambda(l_2)][\lambda(l_3) - \lambda(l_4)] \\ & + \varepsilon_2[\mu(l_1) - \mu(l_2)][\mu(l_2) - \mu(l_3)][\mu(l_3) - \mu(l_1)] \\ & \times [\mu(l_1) - \mu(l_4)][\mu(l_2) - \mu(l_4)][\mu(l_3) - \mu(l_4)]\end{aligned} \quad (3)$$

The λ- and the μ-polynomial evidently have the above-mentioned properties of φ_1 and φ_2. The parameters λ and μ can be determined either on the basis of a quantum-mechanical treatment from which they also receive their physical interpretation, or from optical activity measurements. The coefficients ε_1 and ε_2 are sign factors $+1$ or -1, which are the same for all molecules of the class, and can also be found quantum-mechanically or experimentally. Molecules of type *(b)* or isomer mixtures of type *(c)* represent experimental arrangements where an optical activity measurement depends only upon one kind of parameter in our expression (3). This can be seen from equations (4) and (5):

$$\chi(l_1, l_2, l_2, l_4) = \varepsilon_1[\lambda(l_1) - \lambda(l_2)][\lambda(l_2) - \lambda(l_4)] \quad (4)$$

$$\begin{aligned}\tfrac{1}{3}\{\chi(l_1, l_2, l_3, l_4) + \chi(l_1, l_3, l_4, l_2) + \chi(l_1, l_4, l_2, l_3)\} \\ = \varepsilon_2[\mu(l_1) - \mu(l_2)][\mu(l_2) - \mu(l_3)][\mu(l_3) - \mu(l_1)] \\ \times [\mu(l_1) - \mu(l_4)][\mu(l_2) - \mu(l_4)][\mu(l_3) - \mu(l_4)]\end{aligned} \quad (5)$$

The transformation properties of the two component functions allow a further physical interpretation.

In the case of a skeleton having regular tetrahedral symmetry, the mixture of type *(c)* represents a chiral molecule in three different positions. Therefore the chirality function for derivatives having a skeleton of symmetry T_d must remain unchanged if applied to the mixture of type *(c)*. Thus it follows from (5) that the λ-polynomial vanishes in this case and the μ-polynomial then represents the qualitatively complete chirality function for this class. On the other hand, with increasing deviation from T_d-symmetry, the λ-component becomes increasingly more important. It describes ultimately the relevant part of the phenomenon.

In the case of methane derivatives we certainly have one limiting case of a skeleton with the symmetry of a regular tetrahedron. Allene derivatives on the other hand may possibly represent the opposite situation, because the allenic double bonds form the chromophore skeleton undergoing strong interactions with light and these very definitely differ from the T_d-symmetry. The conjecture that the μ-polynomial may be very small, negligible perhaps relative to the λ-component, follows also from the quantum-mechanical theory[3].

This conjecture can be checked experimentally.

First, the optical rotation of an isomer mixture of type *(c)*, *i.e.* the arithmetic mean of the rotations of the individual components of the mixture, should be zero or at least small in relation to the rotations of the individual compounds if our assumption is correct.

Secondly, chiral allene derivatives having one or two pairs of like ligands exhibit pronounced optical activity. This means that the λ-component makes substantial contributions. Therefore we calculate the λ-parameters of ligands from the optical data of corresponding compounds. The question whether the μ-component may be neglected,

i.e. whether the "shortened approximation" yields quantitatively adequate information, can be answered if the optical rotation of allene derivatives having four different ligands can be calculated with sufficient accuracy from the derived λ-parameters alone.

Our λ-polynomial is formally identical with a formula given by *Brewster*[4] which is derived from an analogy with the interaction of spirals with plane-polarized light. The Brewster formula, however, contains physically prejudiced parameters. Its use necessitates that the polarizabilities of the ligands be known. Its scope is limited by the greatly simplified model.

If our formula in the qualitatively complete equation (3) or in the shortened form (4), *i.e.* neglecting the μ-polynomial, is quantitatively confirmed for a number of allene derivatives appreciably greater than the number of parameters to be determined, *i.e.* if the quantitative validity of the polynomial expression may be looked upon as a rule, we know how to interpret deviations from this rule. Discrepancies then provide valuable chemical information, *e.g.* concerning association, dimerization, specific interaction between particular ligands in neighboring positions, *etc.* Since our expression refers to all classes of molecules with ligands at the corners of a tetrahedron having symmetry D_{2d}, a comparison of ligand parameters for classes with different skeletons, such as the derivatives of spiranes, of biphenyl, of biazulene, *etc.* should prove interesting regarding the special role played by the particular skeleton. Deviations from D_{2d}-symmetry due to twisting of two parts of the skeleton into the symmetry D_2, as *e.g.* in the case of the biphenyl derivatives, should then be recognizable in the form of additive contributions to the optical activity. These contributions can be investigated by suitable experimental means. The principle is similar to that discussed here for the separate measurement of the λ- and μ-components.

The number of different pairs of enantiomers $Z_p(\rho)$ fundamentally possible for ρ different kinds of ligands shows the heuristic value of the expression (3). The determination of parameters λ(l) and μ(l) is necessary only up to a common additive constant, since both polynomials depend only on differences in the values of the parameters. Therefore we choose the values of the parameters for hydrogen to be zero, *i.e.* $\lambda(H)=\mu(H)=0$. The numbers $Z_p(\rho)$ of different enantiomeric pairs of chiral molecules which can be built up with altogether ρ kinds of ligands follow from general formulas derived in ref.[5].

$$Z_p(\rho)=\tfrac{1}{8}\rho(\rho-1)\{(\rho-2)(\rho+1)+4\}$$

Table 1.

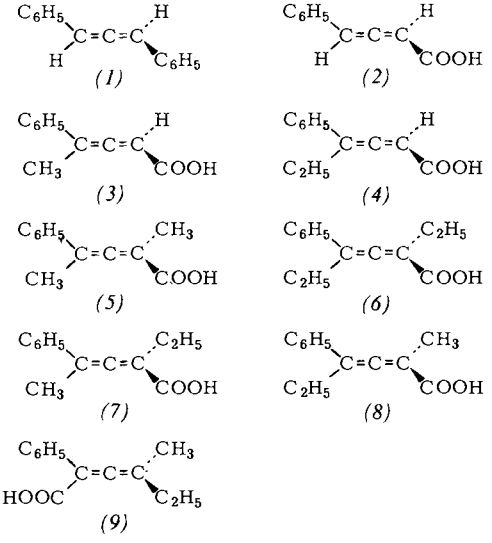
ρ	1	2	3	4	5	6	10
$Z_p(\rho)$	0	1	6	21	55	130	1035

Table 1 shows a number of examples illustrating the formula and gives some idea of the heuristic value of a semiempirical procedure using the λ-polynomial.

2. Experimental Test

The experimental test requires a number of optically pure derivatives not related to one another as enantiomers. This number should be greater than the number of kinds of ligands that occur. Many optically active allenes are described in the literature. In most cases the compounds have not been completely resolved into their antipodes or their optical purity is unknown. Therefore it was necessary to synthesize new compounds and resolve them into enantiomers for the above purpose.

It was found to be experimentally advantageous and theoretically permissible to restrict the test initially to the ligands H, CH_3, C_2H_5, C_6H_5, and COOH and investigate the compounds *(1)–(9)*, or their enantiomers.



The molecular rotations of the optically pure allene derivatives *(1)*[6] and *(2)* to *(4)*[7] were known. We synthesized the other compounds and resolved *(5)–(8)* into the antipodes[8]. Resolution was not achieved in the case of *(9)*, despite repeated attempts.

For this reason it has not yet been possible to perform a direct measurement of the μ-component by observing the optical rotation of the mixture composed of the compounds *(7)*, *(8)*, and *(9)*. Therefore we have used measurements on chiral derivatives with pairs of like ligands knowing that the μ-component vanishes in this case. Compounds of this type, *(1)*, *(2)*, *(5)*, and *(6)* allow us to determine ε_1- and the λ-values of all the ligands occurring pounds are calculated with these values on the assumption that the μ-component makes no noticeable contribution. Because this description works we have an indirect proof of the smallness of the μ-component.

For the test, conditions for measuring the molecular rotations must be as similar as possible. To rule out the influence of dissociation, association, and possible solvation, especially for carboxylic acids, the measurements were carried out in solutions of approximately equal concentration in ethanol. Rotation values for the compound *(1)* in ethanol and compound *(2)* in methanol were available

from the literature. The rotation for *(2)* was converted into the value for ethanol with the aid of the Lorentz factor $(n^2+2)/3$. Though this correction is problematic, it is small and therefore not critical. Tables 2–6 give rotation values for solutions in ethanol which are marked with an asterisk (*) if they were not measured in this solvent but calculated from the values found in methanol with the aid of the correction mentioned. The rotations are for the sodium D line ($\lambda = 589$ nm).

It was established by chemical degradation for the compounds *(2)*, *(3)*, and *(4)*[7] and shown by kinetic resolution of the racemate for the previously[10] partly resolved compounds *(5)* and *(8)* to be probable that the components with positive rotation have the (*S*) configurations as indicated in the formulas. The dextrorotatory compound *(1)* also has this configuration[9]. Therefore it may be assumed that the configurations indicated give a positive rotation for the similar derivatives *(6)* and *(7)*. We have confirmed this by comparison with circular dichroism spectra[8].

3. Results and Discussion

The second column in Table 2 shows the experimentally determined values of the molecular rotation $[\Phi]_D^{25}$. These give $\varepsilon_1 = 1$ and with $\lambda(H) = 0$ the values of the parameters $\lambda(C_6H_5)$, $\lambda(COOH)$, $\lambda(CH_3)$, and $\lambda(C_2H_5)$. The molecular rotations as described by the λ-polynomial are listed in the third column. It should be noted that discrepancies between corresponding numbers in the second and third column are only due to the parameter values having been rounded off.

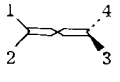
Table 2. Measured and calculated [eq. (4)] optical rotation of allene derivatives having the (*S*) configuration.

Cpd.	$[\Phi]_D^{25}$	χ
(1)	+1958	+1960
(2)	+ 686*	+ 682
(5)	+ 280	+ 282
(6)	+ 88.8	+ 89

$\lambda(H) = 0$
$\lambda(C_6H_5) = +44.3$
$\lambda(COOH) = +15.4$
$\lambda(CH_3) = +7.7$
$\lambda(C_2H_5) = +12.6$

Table 3 similarly shows experimental and theoretical rotation values now calculated from known parameter values according to Table 2 for the compounds *(3)*, *(4)*, *(7)*, and *(8)*. The deviation for *(4)* is little more than that corresponding to the experimental error. Therefore at least for the allenecarboxylic acids we may say that for practical purposes the μ-component vanishes and that the shortened expression

$$\chi(l_1, l_2, l_3, l_4) = [\lambda(l_1) - \lambda(l_2)][\lambda(l_3) - \lambda(l_4)] \qquad (4a)$$



is sufficient for the calculation of rotation angles.

Table 3. Measured and calculated [eq. (4a)] optical rotation of allene derivatives having the (*S*) configuration.

Cpd.	$[\Phi]_D^{25}$	χ
(3)	+565*	+564
(4)	+537*	+488
(7)	+103	+102
(8)	+253	+244

The algebraic theory mentioned in Section 1, the starting point for our analysis, yields the polynomial as an approximation for the optimum chirality function depending on two parameters λ and μ. The approximation is based on the assumption that for "similar" ligands the general expression in ligand-specific parameters can be terminated with the first non-vanishing term in a series expansion in these parameters. Without this approximation the qualitatively complete function could be written as a linear combination of the two components of formula (3), the coefficients being totally symmetrical functions in the corresponding parameters. Thus the approximation is justified by the assumption that with a suitable choice of these parameters, *i.e.* with a suitable concept of similarity, the totally symmetrical factors become practically constant and can be expressed by correspondingly changed λ- and μ-values, the coefficients simplifying themselves to the factors $\varepsilon_1 = \pm 1$ and $\varepsilon_2 = \pm 1$.

From a semiempirical point of view there is no reason to prefer the molar rotation; it may well be possible to obtain good results with the specific rotation. Naturally the parameters must then be redetermined. A test exactly similar to that described above for the specific rotation is illustrated in Tables 4 and 5.

Table 4. Measured and calculated specific rotation of allene derivatives having the (*S*) configuration.

Cpd.	$[\alpha]_D^{25}$	χ
(1)	+1020	+1018
(2)	+ 428*	+ 421
(5)	+ 149	+ 148
(6)	+ 41	+ 41

$\lambda'(H) = 0$
$\lambda'(C_6H_5) = +31.9$
$\lambda'(COOH) = +13.2$
$\lambda'(CH_3) = +7.2$
$\lambda'(C_2H_5) = +11.2$

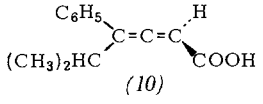
Table 5. Measured and calculated specific rotation of allene derivatives having the (*S*) configuration.

Cpd.	$[\alpha]_D^{25}$	χ
(3)	+ 324*	+ 326
(4)	+ 286*	+ 273
(7)	+ 51	+ 49
(8)	+ 125	+ 124

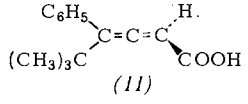
The data available are insufficient to permit a decision between the degree of approximation for molar and speci-

fic rotation. The agreement in both cases is surprisingly good. We regard this as sufficient reason on the one hand for further experiments and on the other for a quantum-mechanical treatment with the aim of correlating the parameter values with physical quantities and of getting a more precise concept of the degree of accuracy.

The experimental (molecular) rotations of compounds *(10)* and *(11)*[7], corrected for ethanol as the solvent, are used to determine further parameters (Table 6).



(10)



(11)

Table 6. Measured optical rotation of allene derivatives having the (*S*) configuration.

Cpd.	$[\Phi]_D^{25}$
(10)	+422*
(11)	+390*

$\lambda((CH_3)_2CH) = +16.9$
$\lambda((CH_3)_3C) = +18.9$

Table 7 shows a comparison of the measured molecular rotations in various solvents for the partly resolved allene derivatives *(12)–(16)* and those which are calculated by using the λ-polynomial for the component present in excess and related to ethanol as the solvent. The components present in excess have the configurations shown in the extended formulas.

Table 7. Measured and calculated optical rotation of mixtures of enantiomers and of the pure predominant component.

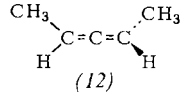
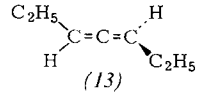
(16)	[15]	not given	− 45.4	− 76

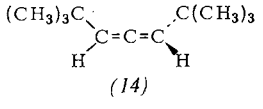
[a] $[\Phi]_{578}^{25}$ was measured.



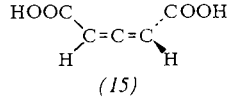
(12)



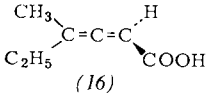
(13)



(14)



(15)



(16)

Since resolution of the racemate is often incomplete and the degree of resolution generally difficult to assess, the semiempirical aspect of our theory becomes particularly important due to the present test on the allenes. If the ligand parameters are known, one may calculate the degree of resolution from the measured rotation without experimental knowledge of the optical activity of the pure compounds, and determine the configuration of the component present in excess. Table 7 accordingly gives an idea of the optical purity of the compounds listed.

Only for molecular classes belonging to category "a" as defined below can a subclassification distinguishing heterochiral molecules be given which is free from arbitrary definitions and exclusively based on chiral properties. Consequently a nomenclature using the concepts "right" and "left" can be used to denote chirality properties of molecules even if they are neither identical nor enantiomeric.

With regard to classes of category "a" this classification has been to correspond to the sign of the chirality polynomial of lowest degree. The sign, on the other hand, is determined by the sequences of the λ-values for the ligands according to the distribution at the skeleton sites with a given numbering.

Generally a class with two skeleton sites belongs to category "a" or for $n>2$ if and only if the skeleton has mirror planes each containing $n-2$ sites.

In the case of allene derivatives the skeleton has four sites and two mirror planes each containing two sites, which shows that the above conditions for category "a" are fulfilled. We may conclude from our experiments that the polynomial predicts the correct sign of optical rotation insofar as the experimentally established λ-values are used and the rotation angle is not extremely small. Therefore we may relate the signs of rotation angles to a classification according to (R_λ)- and (S_λ)-configurations referring to the λ-values instead of those used by *Cahn, Ingold,* and *Prelog*[17] and propose two theorems which should apply if the rotation angle is not very small.

1. 1,3-Disubstituted allenes with substituents whose λ-values are greater than zero lead to positive rotation angles if (S_λ)-configurated, and to negative angles if (R_λ)-configurated.

2. Optically active allene derivatives having two pairs of like ligands, *i.e.* derivatives having the symmetry C_2, lead to positive rotation angles if (S_λ)-configurated, and to negative angles if (R_λ)-configurated.

The Stereoselective Acylation of Racemic Secondary Alcohols with Phenyltrifluoromethylketene as an Experimental Test of the Stereochemical Analogy Model

By Ernst Anders, Ernst Ruch, and Ivar Ugi [*]

Validity of the stereochemical analogy model[1,2] for stereoselective reactions is tested on acylations of racemic chiral secondary alcohols with phenyltrifluoromethylketene. The product ratios for the diastereomeric esters formed can be calculated using a formula derived from the general model for the special case, the results agreeing with the experimental data within the accuracy of the measuring method (integration of the ^{19}F-NMR signals).

1. Theoretical

Stereoselective reactions are chemical reactions that lead exclusively or preferentially to one of several possible or conceivable stereoisomeric products. From the standpoint of their theoretical treatment stereoselective reactions can be divided into two categories.

One category is characterized by the fact that obvious physical or geometrical features indicate the direction of the selection. The simplest example of this is strong steric hindrance for some reaction products. Less obvious, but still capable of being discussed in conventional terms, are cases in which a decision is provided by the answer to the question whether a geometric rearrangement with continuous change of the electron system proceeds *via* transition complexes with bonding or antibonding states. The application of symmetry criteria to the bonding orbital system or qualitative aspects of a quantum-mechanical calculation are sufficient in such cases. Contributions to this topic have been made by various authors, examples being quantum-mechanical investigations by *Fukui*[3], *van der Lugt* and *Oosterhoff*[4], *Van der Hart, Mulder,* and *Oosterhoff*[5], and *Dewar*[6], as well as rules that can be justified by such analyses, such as the Woodward-Hoffmann rules[7].

The second category cannot be treated by these methods. It comprises reactions characterized by the absence of qualitative differences in bonding of competing situations. It includes *e.g.* asymmetrically induced syntheses, reactions in which the inducing part, the chiral reference system, of a reacting molecule does not participate directly in the reaction. *Cram*[8] and *Prelog*[9] have proposed empirical rules for direction of the stereoselectivity of certain types of asymmetrically induced reactions.

In the absence of qualitative differences in the bonding behavior for stereoisomeric products or transition complexes, predictions concerning the stereoselectivity of reactions of the second category can be based on the analogy of eigenstates. This analogy can be stated mathematically and has consequences that can be tested experimentally. States of stereoisomers may be considered analogous if they correspond to electron distributions and motion of the atomic nuclei, but belong to molecules which differ by ligand permutations on a common molecular skeleton. Thus analogous states represent geometrically different but energetically similar situations. Since most states, with the possible exception of those with very high energies, can be classified in this manner, the free enthalpy of formation of a stereoisomeric species is substantially determined by a molecular skeleton, its bonds with ligands, and the nature of the ligands. Contributions due to the mutual interaction of the ligands are relatively small. The free enthalpies of various stereoisomeric species are thus functions of the properties of the ligands, and may be permuted, or may remain unchanged on constitution-preserving permutations of the ligands, depending on whether the ligand permutation corresponds to a change of configurations or merely conformational interconversions within the same species. These functions may be regarded as a basis for a representation of the group of constitution-preserving permutations. The situation just outlined is stated *per definitionem*

[*] Prof. Dr. E. Ruch and Dipl.-Chem. E. Anders

in the "stereochemical analogy model"[1]; in any particular case its validity depends on how well the states can be classified according to the analogy discussed.

The model allows conclusions regarding the stereoselectivity of the thermodynamic equilibrium of stereoisomeric products, and applies also to kinetically controlled reactions if stereoisomeric transition complexes in thermodynamic equilibrium can be conclusively assigned to the products. In both cases we have "corresponding reactions". In corresponding reactions the logarithms of the concentration ratios of the reaction products and their free enthalpies, or the free enthalpies of the corresponding transition complexes, are a basis for the representation of the group of constitution-preserving permutations. The model is useful in connection with classes of reactions that differ in the set of ligands attached to a molecular skeleton which is characteristic of the class. Depending on the geometry of the skeleton, we obtain a certain transformation behavior with regard to constitution-preserving permutations for the logarithms of concentration ratios of stereoisomeric reaction products or for the logarithms of products of such ratios. One can verify that it is reasonable according to our conditions to approximate these logarithms by mathematically simple functions of ligand-specific parameters with an appropriate transformation behavior. An empirical determination of these parameters then allows the calculation of the stereoselectivity with the aid of such expressions.

The "stereochemical analogy model" was proposed in 1966[1], and was discussed in greater detail later[2]. It refers to corresponding reactions, but also allows the treatment of complex kinetic systems that can be resolved into steps of corresponding reactions (cf.[2], p. 103).

In this paper we shall be particularly concerned with a class of asymmetrically induced syntheses, by which two diastereomeric products are formed in different quantities because of the inducing effect of a center of chirality (cf. reaction scheme I). In reactions of this type, three ligands of the inducing center (L_i, L_j, L_k) do not participate in the reaction, whereas a new center of asymmetry is formed at the fourth ligand. Accordingly, the ratio of the products depends on the nature of the three non-participating ligands L_i, L_j, L_k and their relative positions on the inducing center. The reaction products in this class of reactions are thus characterized by the configurational characteristics of the induced center, and the logarithm of their ratio $\ln c_R/c_S$ is a function of the nature of the ligands L_i, L_j, L_k and of their distribution, and this function has certain transformation properties with regard to permutations of the ligands. The function is invariant towards even permutations, assuming free rotation about the σ bond to the fourth ligand, and its sign is changed by odd permutations, since the free energy values of the transition complexes leading to the (*R*) and to the (*S*) configuration, respectively, are interchanged. We approximate this function with a polynomial of ligand-specific parameters $\lambda(L_i)$ that satisfies the transformation condition mentioned and is of the lowest order in these parameters. We obtain a chirality product, a polynomial that vanishes only if the inducing center carries two similar ligands (ligands having the same parameter value) and accordingly the stereoselectivity of the reaction vanishes.

We assign numbers to the skeletal sites on the inducing center as shown in (*A*), obtaining the formula (1).

(*A*)

$$\ln \frac{c_R}{c_S} = \rho(\lambda_1(L_i)-\lambda_2(L_j))(\lambda_2(L_j)-\lambda_3(L_k))(\lambda_3(L_k)-\lambda_1(L_i)) \quad (1)$$

The subscript of λ refers here to the position numbers. ρ is a reaction parameter that is assumed to be constant for reactions of the same class and similar reaction conditions. On the other hand

$$\ln \frac{c_R}{c_S} = -(G_R^* - G_S^*)/RT \quad (2)$$

where G_R^* and G_S^* are the free enthalpies of the transition complexes.

In eq. (1), reference can be made to the configuration on the inducing center with the aid of a nomenclature factor δ if the fourth ligand on the inducing center, *i.e.* the ligand participating in the reaction, retains in all reactions its relative, sequential priority according to the Cahn-Ingold-Prelog convention[22]. This condition is satisfied in our experiments (Section 2). Eq. (1) can thus be written in the form (1 a):

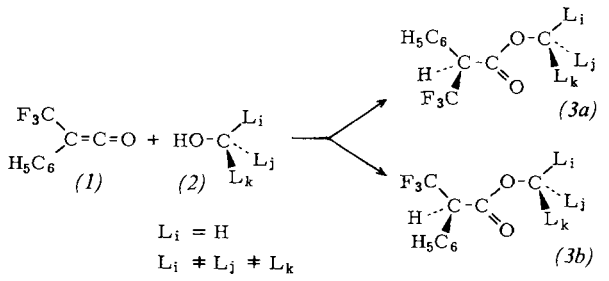
$$\delta \ln \frac{c_{RR}}{c_{SR}} = \rho(\lambda_1(L_i)-\lambda_2(L_j))(\lambda_2(L_j)-\lambda_3(L_k))(\lambda_3(L_k)-\lambda_1(L_i)) \quad (1\,a)$$

where $\delta = +1$ for the (*R*) configuration of the inducing center and $\delta = -1$ for the (*S*) configuration. In the stereochemical analogy model, eq. (1) or (1 a) is a special form for a particular case. It may be interpreted as the first term of a Taylor series and also as the first term of an orthogonal polynomial expansion for a function with the required symmetry behavior[10, 11]. Other expressions, such as that based on the second approximation method[12], are possible, but are not discussed in this article.

Experimental data given by *Prelog et al.* for syntheses of the type described[13, 14] were used by *Prelog* only to confirm a qualitative rule. Though the quantitative evaluation of these data does not lead to conflict with our theory[2], we felt it necessary to test the validity of the stereochemical analogy model in the special form (1 a) by a reliable and sufficiently accurate set of measurements based upon a type of reaction that can be expected to yield quantitatively reliable data under suitably chosen conditions.

2. Experimental

The asymmetric acylation of chiral secondary alcohols *(2)* with phenyltrifluoromethylketene *(1)* (Scheme I) was chosen as the model reaction.



Scheme I.

In this reaction, the tricoordinate carbon atom of the ketene group is converted into a tetracoordinate center of chirality which has the (*S*) configuration in the ester *(3a)* and the (*R*) configuration in *(3b)*. The reasons for choosing this reaction type were the following:

Investigations by *Pracejus*[15,16] demonstrate that the stereoselective addition of 1-phenylethylamine to phenylmethylketene in suitable solvents is exclusively kinetically controlled over a wide temperature range. The description of the experiments[16] contains clear evidence that the competing reactions leading to the two diastereomeric products are a pair of corresponding reactions. Accordingly, the asymmetric acylation of secondary alcohols of the type *(2)* with similar ketenes should also have these properties. There are two types of experimental evidence indicating that reactions such as that in Schema I proceed by a pair of corresponding reactions. In the case of corresponding reactions, the concentration ratio of the products *(a)* and *(3b)* does not depend on the concentrations of the starting compounds *(1)* and *(2)*, and the logarithm of the concentration ratio (log *Q*) is a linear function of the inverse absolute temperature. Therefore, the temperature dependence of the addition of 1-phenylethanol to *(1)* was investigated between -61 and $+25$ °C as a model reaction for Scheme I. It was found that in toluene the reaction does not exhibit the required temperature dependence, whereas the linear relation was observed in methylene chloride (see Fig. 1). In both solvents the concentration ratio of the end products is independent of the initial concentrations of the reactants. It may therefore be inferred that the stereochemical analogy model, and hence also eq. (1), is valid for kinetically controlled reactions corresponding to Scheme I in methylene chloride.

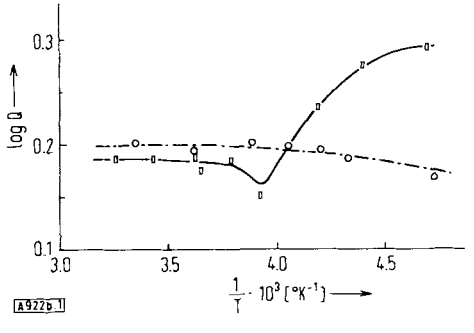


Fig. 1. Temperature dependence of the product ratio in the reaction of phenyltrifluoromethylketene with 1-phenylethanol: —— in toluene; in methylene chloride.

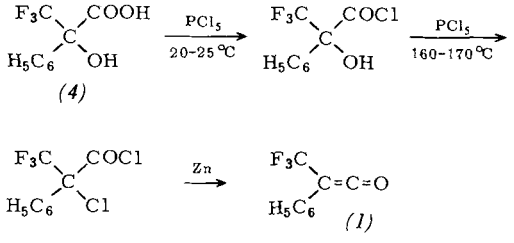
To test eq. (1), the number of reactions of type I investigated must be greater than the number of different ligands of the inducing chirality center. Adding the same number to all the parameter values does not affect the value of the polynomial, and multiplication by a common factor can be compensated by the reaction parameters. Thence two λ values can be chosen arbitrarily. With the λ value for hydrogen = zero ($\lambda(H) = 0$) and that for the methyl group = one ($\lambda(Me) = 1$), we have (together with ρ) one parameter less to determine than the number of ligand types occurring in the secondary alcohols *(2)* in the reactions investigated. The number of possible constitutionally different alcohols that can be derived from a set of ligands $\{L_1, L_2, \ldots, L_N\}$ is $\binom{N}{3}$. With increasing N, the number of data that can be calculated increases steeper than the number of measurements required for the determination of the parameters.

We have investigated twelve reactions, whose calculation requires six parameters.

Phenyltrifluoromethylketene *(1)* was prepared as indicated in Scheme II from α-trifluoromethylmandelic acid *(4)*. The latter has been described by *Mosher et al.*[17].



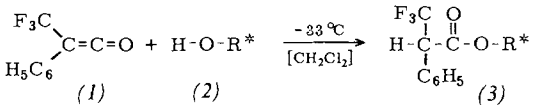
Scheme II.

The alcohols *(2)* with the ligands L_i, L_j, L_k = H, CH_3 (Me), C_2H_5 (Et), $CH(CH_3)_2$ (iPr), $C(CH_3)_3$ (tBu), C_6H_5 (Ph), 2,4,6-$(CH_3)_3C_6H_2$ (Mes) were prepared by known methods[18] and were reacted with the ketene *(1)* under standard conditions (0.09 M *(1)*, 1.1 M *(2)*; -33 ± 2 °C; in CH_2Cl_2) in accordance with Scheme I. The product ratio of *(3a)* to *(3b)* was determined by ^{19}F-NMR; this ratio can be measured sufficiently accurately with trifluoroacetic acid as an *external*[*] standard[19]. Since the signals of the two diastereotopic[20] trifluoromethyl groups are not affected appreciably by the ^{1}H signals of the other parts of the molecule of *(3)* or by small quantities of impurities, the analysis can be carried out on crude ester mixtures *(3)*.

In two cases the configuration of the carboxylic acid moiety of the preferentially formed ester *(3)* was determined on a sample which was obtained by acylation of optically pure alcohol *(2)* [(*S*)-(−)-1-phenylethanol and (*S*)-(+)-1-*tert*-butylethanol]. Each of the resulting ester mixtures was then hydrolyzed with acid and the optical rotations of the resulting α-trifluoromethylphenylacetic acid were measured. The results show that (*R*,*S*) diastereomers are preferentially formed in both cases. The NMR-spectroscopic

[*] As an *internal* standard, trifluoroacetic acid can increase the difference in the chemical shifts of diastereotopic trifluoromethyl groups [19], but it may also affect the ratio of the quantities of diastereomeric esters.

Table 1. Results of checking the validity of a special formula (1a) arising from the stereochemical analogy model for the special case (Scheme I).



(1) (2) (3)

R*	^{19}F-NMR	% (R, S)–(3) c_{exp}	% (R, S)–(3) c_{calc}	R*	^{19}F-NMR	% (R, S)–(3) c_{exp}	% (R, S)–(3) c_{calc}
Mes -C-Me H *(a)*		68	67.3	Mes -C-iPr H *(g)*		56	67.3
Mes -C-Et H *(b)*		66	67.3	tBu -C-iPr H *(h)*		54	54.0
Ph -C-iPr H *(c)*		64	62.0	tBu -C-Et H *(i)*		53	54.0
Ph -C-Me H *(d)*		61	62.0	iPr -C-Et H *(j)*		52	50.0
Ph -C-Et H *(e)*		61	62.0	iPr -C-Me H *(k)*		50	50.0
tBu -C-Me H *(f)*		55	54.0	Et -C-Me H *(l)*		50	50.0

studies show that the doublet signal of the trifluoromethyl group of the preferentially formed product appears at a lower field than the corresponding doublet of the other component. A similar result was obtained by *Mosher et al.*[21] in a different context. On attempting to synthesize the optically pure (*S*,*R*) ester from optically pure starting compounds (acyl chloride of (*S*)-(+)-α-trifluoromethylphenylacetic acid and (*R*)-(+)-phenyl-*tert*-butylmethanol), as a result of partial diastereoisomerization we obtained an ester mixture, which was reduced with $Li[AlH_4]$ for configurational assignment.

The preferentially formed diastereoisomer in this reaction, as in the reactions in accordance with Scheme I, has the (*R*,*S*) configuration, and its ^{19}F doublet appears at a lower field than that of the other component. Racemic alcohols *(2)* can therefore be reacted according to Scheme I, and the stereoselectivity of the reaction determined by ^{19}F-NMR analysis.

The results of our investigations are summarized in Table 1. c_{exp} is the experimentally determined percentage of the (*R*,*S*) component in the ester mixture. The values of the parameters that were used to calculate the percentage of the (*R*,*S*) components (c_{calc}) were:

$\lambda(H) = 0.00$, $\lambda(Me) = 1.00$ } *per definitionem*
$\lambda(Et) = 1.00$
$\lambda(iPr) = 1.00$
$\lambda(tBu) = 1.25$
$\lambda(Ph) = 1.60$
$\lambda(Mes) = 1.79$
$\rho = 0.512$

Except in the case of reaction (g), these calculated values are found to agree with the experimental percentages to within the accuracy of the integration of the ^{19}F-NMR signals (approx. ± 3 to ± 5%).

The deviation in reaction (g) (mesitylisopropylmethanol) is presumably due to racemization of the ester, which is also observed in the corresponding reaction product of *Mosher et al.* The assumption of a side reaction or of a further reaction that leads to a decrease in the stereoselectivity is also supported by the direction of the deviation from the theoretical value. The calculation using the λ values confirmed by experiments (j) and (k) (λ(iPr) = λ(Me) = λ(Et)) gives too high a stereoselectivity for *(3g)*.

We are grateful to the Deutsche Forschungsgemeinschaft for financial support, and to Dr. D. Marquarding (Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG, Leverkusen) for advice in the ^{19}F-NMR spectroscopic investigations that were carried out by courtesy of Farbenfabriken Bayer AG.

Semiempirical Use of Chirality Functions[1,3] for the Description of the Optical Activity of Methane Derivatives in the Transparent Region

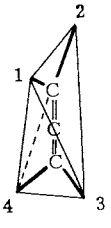
By Wolf Jürgen Richter, Bernd Richter, and Ernst Ruch[*]

The optical activity can provide detailed information about the configuration and conformation of methane derivatives if the chirality function is resolved, according to the theory of chirality functions[3] and the quantum mechanical theory of the optical activity of methane derivatives[4], into its components which are compared with experimental data. A first step in this direction is undertaken in the present article and it will be shown that the second approximation method for determining the conformationally independent contribution to the optical activity yields quantitatively good results. Description of the overall optical rotation by this component is expectedly poor where interactions between ligands, *e.g.* hydrogen bonding, tend to favor specific conformations. A quantitative understanding of such additional effects appears promising in conjunction with analyses of the kind described.

1. Theoretical

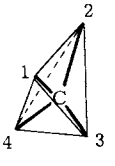
The semiempirical use of chirality functions based on the polynomial method[1,3] has been tested experimentally in the special case of the optical activity of allene derivatives. From the good results achieved[2], we draw the justification for attempting the same test in the case of the more complicated class of methane derivatives. Though the polynomials and the expressions based on a so-called second method[1,3] each correspond to the same mathematical approximation principle for different classes of molecules, the various classes show characteristic differences in the heuristic value of such a procedure, the mathematical effort, the amount of experimental information required, and the accuracy of the approximation. It is therefore appropriate to begin with a comparative outline of the problems arising in an analysis of the optical activity of allene and of methane derivatives from the theoretical point of view and from the standpoint of experimental verification.

The concept "class of molecules", on which the general theory of chirality functions[3] is based, involves an idealization necessary for a proper formulation of class-specific influences upon a pseudoscalar observation like the optical activity for all molecules of a given class. In the case of methane derivatives this idealized situation is the following: The central tetracoordinate carbon with its bond directions is regarded as a molecular skeleton of symmetry T_d. The C_{3v}-symmetry axes coinciding with a bond direction define the symmetry of the corresponding ligands. Therefore the ligand symmetry must be C_{3nv} where $n \geq 1$ or $C_{\infty v}$ if the ligands are rigidly fixed, or $C_{nv}, n \geq 1$, or $C_{\infty v}$ if they exhibit free rotation. Inasmuch as methane derivatives fulfill this condition we call them T_d-derivatives. Allene derivatives with the skeletal symmetry D_{2d} and with ligands having the subsymmetry C_s of D_{2d} referring to the ligand sites may be called D_{2d}-derivatives. Whereas a quantitatively complete chirality function of D_{2d}-derivatives contains two components which may be designated as D_{2d} and T_d-components, T_d-derivatives contain only the T_d-component. This statement applies also to all quantitatively complete approximative descriptions for optical rotation, *e.g.* to expressions corresponding to the first and to the second method mentioned above.



$$\chi(l_1,l_2,l_3,l_4) = \varepsilon_1[\lambda(l_1)-\lambda(l_2)][\lambda(l_3)-\lambda(l_4)] + \varepsilon_2[\mu(l_1)-\mu(l_2)][\mu(l_1)-\mu(l_3)][\mu(l_1)-\mu(l_4)] \times [\mu(l_2)-\mu(l_3)][\mu(l_2)-\mu(l_4)][\mu(l_3)-\mu(l_4)] \quad (1a)$$

$$\tilde{\chi}(l_1,l_2,l_3,l_4) = \varphi_1(l_1,l_3)+\varphi_1(l_2,l_4)-\varphi_1(l_1,l_4)-\varphi_1(l_2,l_3) + \varphi_2(l_1,l_2,l_3)-\varphi_2(l_2,l_3,l_4) + \varphi_2(l_3,l_4,l_1)-\varphi_2(l_4,l_1,l_2) \quad (1b)$$



$$\chi(l_1,l_2,l_3,l_4) = \varepsilon[\mu(l_1)-\mu(l_2)][\mu(l_1)-\mu(l_3)][\mu(l_1)-\mu(l_4)] \times [\mu(l_2)-\mu(l_3)][\mu(l_2)-\mu(l_4)][\mu(l_3)-\mu(l_4)] \quad (2a)$$

$$\tilde{\chi}(l_1,l_2,l_3,l_4) = \varphi(l_1,l_2,l_3)-\varphi(l_2,l_3,l_4)+\varphi(l_3,l_4,l_1)-\varphi(l_4,l_1,l_2)$$

where (2b)

$$\varphi(l_1,l_2,l_3) = \varphi(l_2,l_3,l_1) = \varphi(l_3,l_1,l_2) = -\varphi(l_1,l_3,l_2) = -\varphi(l_3,l_2,l_1) = -\varphi(l_2,l_1,l_3)$$

In formula (2a), $\mu(l_i)$ is a real ligand-specific parameter for the ligand l in the bond direction of the tetrahedral skeleton denoted by *i*. The value of the factor ε is either $+1$ or -1 for the entire class of T_d-derivatives, which as $\mu(l)$ must be determined empirically. $\varphi(l_i,l_j,l_k)$ in formula (2b), a function of the three ligands l_i, l_j and l_k in positions 1, 2, and 3, changes its sign on odd permutations of the ligands and is the empirical determinative element of the second method.

The experimental data for allene derivatives in[2] could be explained by neglecting the T_d-component. That means that well-defined contributions to the optical rotation which are in principle non-vanishing and can be separated by experimental means and measured, are negligibly small in the case of allene derivatives. The problem of the relevance of various components does not arise in the case of T_d-derivatives but it becomes significant for methane derivatives not subject to the T_d-condition. Apart from the difficulty of finding derivatives which satisfy the T_d-condition, at least approximately, there is the problem of establishing whether the T_d-component can be described precisely enough by one or both of the two approximative Ansätze. In the case of allene derivatives the λ-polynomial turned out to be perfectly satisfactory[2]. In the case of methane derivatives we shall approach this question first by referring to the results of a quantum-mechanical theory for this class.

A quantum-mechanical treatment of the optical activity of methane derivatives has been explicitly carried out up to the second order of perturbation defined as the interaction between ligands[4]. Apart from the assumption of fixed atomic nuclei, the model used contains no further serious simplifications. In this theory the T_d-component appears as a part of the second order correction, whereas contributions to the optical activity due to deviations from the T_d-condition are already described by corrections of the zeroth or first order. They vanish therefore for T_d-derivatives. The quantum-mechanical form of the T_d-component coincides exactly with Ansatz (2b). The polynomial on the other hand, generally a simplifying specialization of the expression based on the second method, can be obtained from the quantum-mechanical expression only with drastic simplifications. The parameters are correlated here with "representative lengths" corresponding very roughly to the distances between the central carbon and the positive charge centers of the ligands. A reasonably acceptable description by means of the polynomial, therefore, can be expected only for derivatives of a special selection, which cannot be specified *a priori*.

However, despite the superiority of Ansatz (2b), Ansatz (2a) is still of interest. Like the D_{2d}-derivatives of allene, the methane derivatives corresponding to the T_d-condition belong to the very few classes where it is possible in principle to give a classification of configurations according to "left" and "right" and referring exclusively to chirality and not to some further arbitrary definitions[5]. The principle for this differentiation is provided by the sign of the polynomial. If we assign different values of the parameter to different types of ligands, the polynomial (2a) becomes zero if and only if the molecule described is achiral. As far as the polynomial can be used to describe the optical rotation, at least to predict the sign, the sign of the optical rotation simultaneously gives a classification of configurations and this classification refers to the sequence of the parameter values for ligands according to their fixation on numbered sites of the skeleton. This seems to work for the allene derivatives investigated in ref.[2] and it would be worth stating if it should also apply in the case of methane derivatives, even if the polynomial does not give the amount of the optical rotation in a satisfactory manner.

2. Test Method

In order to determine the optical rotation of different $\binom{N}{4}$ pairs of enantiomers which can be built up with N different types of ligands, we need experimental data for the determination of $N-1$ parameters and of ε if we are concerned with the polynomial. If concerned with the second method, we need at least $\binom{N-1}{3}$ experimental optical rotation values. The above discussion suggests the following steps for an experimental test.

1. Since formula (2b) may be considered as the result of a second order perturbation quantum-mechanical treatment as far as T_d-derivatives are concerned, we test this expression for those derivatives or use it as a criterion of whether the T_d-condition is satisfied sufficiently well.

2. Appreciable deviations of the optical rotation from the theoretical values according to expression (2b) are attributed to a deviation in the geometry from the T_d-condition. We may explain such deviations as additional contributions that have to be accounted for by expressions of the first or zeroth order of perturbation according to the general formulas for methane derivatives published in ref.[4].

3. Derivatives for which expression (2b) can be confirmed are tested against the simpler expression (2a) in the hope of obtaining at least a correct description of the sign of the optical rotation for derivatives belonging to a certain subclass.

Only points 1 and 3 were examined on the basis of the experiments discussed here, since a detailed analysis according to point 2 seems sensible only after having a more detailed knowledge of the degree of approximation in the description of the rotatory power of T_d-derivatives.

For the experimental test we use a functional equation which follows from expression (2b) and does not depend on the special type of functions $\varphi(l_i,l_j,l_k)$ chosen.

$$\tilde{\chi}(l_1,l_2,l_3,l_4) = \tilde{\chi}(l,l_2,l_3,l_4) + \tilde{\chi}(l_1,l,l_3,l_4) + \tilde{\chi}(l_1,l_2,l,l_4) + \tilde{\chi}(l_1,l_2,l_3,l) \quad (3)$$

The chirality function on the left-hand side of equation (3) does not depend on the choice of the ligand l. The equation can be verified by decomposing each of the chirality functions on the right-hand side of (3) into the three-ligand functions according to (2b). Due to the sign reversal of $\varphi(l_i,l_j,l_k)$ on odd permutations of the ligands, one finally obtains the left-hand side of (3). Formula (3) leads to a very simple

experimental test for expression (2b), since it predicts a linear dependence of the measured optical rotations for various T_d-derivatives, which is specific for our expression and is not a triviality that can be verified by symmetry arguments. This statement becomes evident through the fact that the mixture

$\frac{1}{5}$  (4)

is not racemic if all the ligands are different and equation (3) leads to the zero identity (5)

$$\tilde{\chi}(l_2,l_1,l_3,l_4) + \tilde{\chi}(l,l_2,l_3,l_4) + \tilde{\chi}(l_1,l,l_3,l_4) + \tilde{\chi}(l_1,l_2,l,l_4) + \tilde{\chi}(l_1,l_2,l_3,l) \equiv 0 \quad (5)$$

for the optical rotation of such a mixture.

Of course this is a theoretical approximation for the measured angle of rotation of the mixture, but it should be a very good one as far as the T_d-condition for all the five constituting chemical compounds is fulfilled.

Experimentally accessible methane derivatives, separable into antipodes, measurable under analogous conditions, and allowing the formation of several mixtures of type (4) normally do not match the selection principle for T_d-derivatives. Therefore we have to use compounds for which the T_d-condition is not perfectly fulfilled but where it seems sensible to assume that the T_d-component contributes the main part to the optical rotatory power. We have to test this assumption by the relation (5), knowing that there are additional contributions falsifying the value zero for the mixture and knowing that even the T_d-component sums up to zero in so far as it is correctly described by formula (2b) or (2a). For this purpose we proceed as follows:

We measure the molar optical rotations $\varphi(l_i,l_j,l_k,l_s)$ of five non-enantiomeric derivatives belonging to an ensemble of type (4) and establish the experimental value $\bar{\Phi}$ of the corresponding mixture according to equation (6).

$$\bar{\Phi} = \tfrac{1}{5}\{\Phi(l_2,l_1,l_3,l_4) + \Phi(l_5,l_2,l_3,l_4) + \Phi(l_1,l_5,l_3,l_4) + \Phi(l_1,l_2,l_5,l_4) + \Phi(l_1,l_2,l_3,l_5)\} \quad (6)$$

We compare the absolute value $|\bar{\Phi}|$ with the absolute average value for a mixture of type (4) expected if there is no preferred relation like (5). If $|\bar{\Phi}|$ is found to be smaller than this average value for any mixture, except those where the T_d-condition is seriously violated for obvious chemical reasons, we may take this as an indication that a T_d-component described by (2b) is relevant and the non-vanishing value $|\bar{\Phi}|$ is mainly due to contributions from slight geometrical deviations from the T_d-condition.

The absolute value of the molar optical rotation of mixtures like (4) lies between 0 and $\bar{M}$ where $\bar{M}$ is the arithmetic mean of positive rotation angles measured on each component of the mixture or the corresponding enantiomers. The statistical mean rotation angle for the mixture (4) containing no enantiomeric compounds is then $\frac{3}{8}\bar{M}$. Therefore our criterion reads:

$$|\bar{\Phi}| < \tfrac{3}{8}\bar{M} \quad (7)$$

With increasing experimental information on mixtures of the type mentioned we arrive at a test of our assumption. Measured optical rotation angles of the pure compounds which fulfill the criterion (7) are then approximated by least-square error deviations with numbers that satisfy the zero identity (5). These numbers are taken as empirical values for an optimum function $\tilde{\chi}$ for the experimental T_d-component. With the aid of equation (3) it should be ultimately possible to make reliable predictions about the T_d-component of rotation angles that have been measured and to correlate deviations lying outside the expected degree of approximation with the T_d-deviation of the geometry in the compounds under consideration.

If relation (7) is fulfilled by a sufficient amount of experimental material, we may go further to test Ansatz (2a). With respect to expression (2a) the identity (5) can be formulated in the form of a zero identity of a determinant. If we make use of the equivalent formulation for $\chi(l_1,l_2,l_3,l_4)$ by the Vandermonde determinant (2a') we obtain (5) in the form of (5').

$$\chi(l_1,l_2,l_3,l_4) = \varepsilon \begin{vmatrix} 1 & 1 & 1 & 1 \\ \mu(l_1) & \mu(l_2) & \mu(l_3) & \mu(l_4) \\ [\mu(l_1)]^2 & [\mu(l_2)]^2 & [\mu(l_3)]^2 & [\mu(l_4)]^2 \\ [\mu(l_1)]^3 & [\mu(l_2)]^3 & [\mu(l_3)]^3 & [\mu(l_4)]^3 \end{vmatrix} \quad (2a')$$

$$\begin{vmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ \mu(l_1) & \mu(l_2) & \mu(l_3) & \mu(l_4) & \mu(l_5) \\ [\mu(l_1)]^2 & [\mu(l_2)]^2 & [\mu(l_3)]^2 & [\mu(l_4)]^2 & [\mu(l_5)]^2 \\ [\mu(l_1)]^3 & [\mu(l_2)]^3 & [\mu(l_3)]^3 & [\mu(l_4)]^3 & [\mu(l_5)]^3 \end{vmatrix} \equiv 0 \quad (5')$$

Numerical values satisfying condition (5) and approximating the optical rotation angles for derivatives of a mixture (4) are also values of the polynomial (2a) if certain additional relations are satisfied, as shown by *Weimann*[6].

The Newton approximation method offers a way of calculating the $\mu(l_i)$. For this purpose one uses the equations (5'')

$$\begin{vmatrix} 1 & 1 & 1 & 1 & 1 \\ [\mu(l_1)]^\nu & [\mu(l_2)]^\nu & [\mu(l_3)]^\nu & [\mu(l_4)]^\nu & [\mu(l_5)]^\nu \\ \mu(l_1) & \mu(l_2) & \mu(l_3) & \mu(l_4) & \mu(l_5) \\ [\mu(l_1)]^2 & [\mu(l_2)]^2 & [\mu(l_3)]^2 & [\mu(l_4)]^2 & [\mu(l_5)]^2 \\ [\mu(l_1)]^3 & [\mu(l_2)]^3 & [\mu(l_3)]^3 & [\mu(l_4)]^3 & [\mu(l_5)]^3 \end{vmatrix} \equiv 0 \text{ with } \nu = 0,1,2, \text{ and } 3 \quad (5'')$$

and the invariance of the polynomial χ and of the determinant (5'') toward the substitution $\mu'(l_i) = \mu(l_i) + k$ with a constant k independent of i. With $\mu'(l_1) = 0$ and the substitutions $\tilde{\chi}(l_1,l_3,l_4,l_5) = a_2$, $\tilde{\chi}(l_1,l_2,l_4,l_5) = a_3$, $\tilde{\chi}(l_2,l_1,l_3,l_5) = a_4$, $\tilde{\chi}(l_1,l_2,l_3,l_4) = a_5$ for the values of the function χ, we calculate numerical values x, y, and z from the following rapidly converging iteration equations:

$$\begin{pmatrix} x_{n+1} \\ y_{n+1} \\ z_{n+1} \end{pmatrix} = \begin{pmatrix} x_n \\ y_n \\ z_n \end{pmatrix} - \frac{1}{(x_n-y_n)(y_n-z_n)(z_n-x_n)} \begin{pmatrix} \frac{1}{a_3} y_n z_n (z_n-y_n) & \frac{1}{2a_3}(y_n^2-z_n^2) & \frac{1}{3a_3}(z_n-y_n) \\ \frac{1}{a_4} x_n z_n (x_n-z_n) & \frac{1}{2a_4}(z_n^2-x_n^2) & \frac{1}{3a_4}(x_n-z_n) \\ \frac{1}{a_5} x_n y_n (y_n-x_n) & \frac{1}{2a_5}(x_n^2-y_n^2) & \frac{1}{3a_5}(y_n-x_n) \end{pmatrix} \times \begin{pmatrix} a_3 x_n + a_4 y_n + a_5 z_n - a_2 \\ a_3 x_n^2 + a_4 y_n^2 + a_5 z_n^2 - a_2 \\ a_3 x_n^3 + a_n y_n^3 + a_5 z_n^3 - a_2 \end{pmatrix}$$

$$x = \lim_{n\to\infty} x_n,\quad y = \lim_{n\to\infty} y_n,\quad z = \lim_{n\to\infty} z_n$$

One finds the values of the parameters then from the equations:

$$\mu'(l_1) = 0$$
$$\mu'(l_2) = \left\{ \frac{a_2}{\varepsilon xyz(x-y)(x-z)(y-z)} \right\}^{\frac{1}{6}}$$
$$\mu'(l_3) = \mu'(l_2)\cdot x$$
$$\mu'(l_4) = \mu'(l_2)\cdot y$$
$$\mu'(l_5) = \mu'(l_2)\cdot z$$

Parameter values for a given ligand calculated this way from differing mixtures are naturally not the same; however, if they are not too different, it is worthwhile to seek an approximation for all the data that can be described by the expression (2b) by using the polynomial (2a) in optimum parameters. The determination of optimum values for the parameters from a large number of measurements is facilitated by the prior determination of parameter values for individual mixtures (4) by the iteration method sketched out above.

For the polynomial we must also be certain that the data are sufficient to fix the factor ε, *i.e.* only one of the two values $\varepsilon = \pm 1$ can give an acceptable approximation to the experimental data. The sign of the optical rotation for such derivatives is then determined by the sequence of the parameter values of ligands with reference to fixed numbered skeletal sites, irrespective of whether the values of the polynomial give a good approximation of the experimental data as regards absolute values.

3. Experimental

As starting materials we chose five compounds that exist as or can be derived from natural products (Table 1). Their absolute configurations have been established and their optical purity has been checked in various ways. The other 49 derivatives in Tables 2—4 were obtained by reactions in which the configuration of the products can be deduced with certainty because the central carbon is not attacked.

The reduction of the carboxyl group in the reference compounds yields alcohols of mixture *(9)* which are likewise known in optically pure form.

Esterification under mild conditions yields the ethyl esters (mixture *(13)*), which are listed together with the acids in Table 4.

The mixtures *(1)*—*(8)*, given together with mixture *(9)* in Table 2, are obtained by reactions of the amino group, leaving the four other ligands unchanged.

Table 1.

	(*R*)-Isovaline
	(*R*)-2-Aminobutyric acid
	(*R*)-Alanine
	(*R*)-2-Aminobutane (resolution of racemates, stereospecific degradation of (*R*)-2-methylbutyric acid)
	(*R*)-2-Methylbutyric acid (from fermentation amyl alcohol)

The CH_2OH groups of the compounds of mixtures *(3)* and *(8)* can be etherified with the bulky $Si(CH_3)_3$ group to obtain the derivatives in Table 3 (mixtures *(10)* and *(11)*).

The optical rotations were measured under identical conditions with plane-polarized light of the sodium D line.

The references[8-22] in Tables 2 and 4 relate only to the preparation of the compounds in question. For the preparation of all other derivatives see ref.[7].

The experimental data in Tables 2 to 4 are arranged according to mixtures of Type (4), those containing a common derivative being listed in one table. In each case the experimental values of the molar rotation $[\Phi]$ for the derivatives of the various mixtures (Na D line at 25 °C; in approx. 5% ethanolic solution, mixture *(12)* in aqueous solution) are given in the first row. The second row gives values of a function according to expression (2b) that we found as described below. Relation (7) can be assessed from the columns for $\bar{\Phi}$ and $\frac{3}{8}\tilde{M}$.

Relation (7), which is a necessary but not a sufficient condition in the individual case, gains in importance when found in agreement with known chemical facts about the T_d-condition. Therefore, derivatives whose rotation angles undoubtedly contain additional contributions due to deviations from the T_d-situation are also included in Tables 2—4. Since these additional contributions, as was mentioned, are of first or zeroth order of the perturbation treatment, they will increase rapidly with the geometrical deviation and will ultimately exceed

Table 2.

the T_d-contribution. Large rotation angles must therefore be discussed with this reservation.

For the reasons mentioned, theoretical data on each mixture in the second row, which approximate the experimental values in the sense of the least-square error deviation with condition (5), may be regarded as possible values of a function according to expression (2b), it being noted that the validity of the relation (7) justifies this view. A combination of the aspects mentioned above leads us to an estimation of the theoretical figures if on the one hand we propose a maximum permissible value for $|\bar{\Phi}|$, *e.g.* $|\bar{\Phi}| \leq 2$, and if on the other hand we ignore those mixtures for whose derivatives marked deviations from the T_d-situation must be assumed on chemical grounds. For the cases that remain, the figures in the second row should in fact give an idea of the T_d-component.

It can be concluded from IR spectroscopic studies that the pairs of ligands NH_2/CH_2OH, $NHCHO/CH_2OH$, and $NH_2/COOH$ give rise to the formation of intramolecular or intermolecular hydrogen bonds. Some compounds of the mixture *(13)* are known to undergo considerable dimerization even at room temperature to form diketopiperazines. Bulky ligands such as $N{=}CHC_6H_5$ and $CH_2OSi(CH_3)_3$ restrict the free rotation of neighboring ligands and can thus considerably upset the T_d-situation in the time average. Compounds containing the ligand $N{=}CHC_6H_5$ are pale yellow, so that the Na D line lies at the limit of the transparent region. The dispersion ratio $\Phi_{365}/\Phi_{Na\text{-}D}$ is 3.5—6.4 here, as against 2.2—3.0 for the other compounds.

If we adopt chemical arguments of this type and the relation $|\bar{\Phi}| \leq 2$ as selection principles, we are left with the derivatives of the mixtures *(1)—(5)* as experimental material, and we shall take the data in every second row as approximate values for the T_d-components.

The attempt to approximate the function values found for expression (2b) with the polynomial (2a) shows that although the iteration method discussed earlier gives

μ-parameters by means of which the function values can be accurately described for a given mixture in several cases, common parameter values lead to a reasonable approximation only for the mixtures *(1)—(5)*. It is also found that the factor $\varepsilon = -1$ is the only possible solution for the mixtures *(1)—(5)*. With the polynomial (2a), the parameter values from the last column of Table 6 and the factor $\varepsilon = -1$, we obtain the figures in the third row of Table 5. For the sake of comparison, rows 1 and 2 again give the experimental data and the values according to expression (2b).

The parameter values found for each of the mixtures *(1)—(4)* by the iteration method and the optimum common values for all the compounds from *(1)—(5)* are shown in Table 6. From this table we obtain the following sequence:

$$\mu(H) < \mu(C_2H_5) < \mu(CH_3) < \mu(CH_2OH) < \mu(N(CH_3)_2)$$
$$< \mu(NH_3^+Cl^-) < \mu(NH(CH_3)_2^+Cl^-) \lesssim \mu(NH_2CH_3^+Cl^-) < \mu(NHCH_3)$$

As in the case of allene derivatives[2], a nomenclature based on the sequence of values of the parameter μ can be proposed for methane derivatives. If we designate as the (R_μ) or (S_μ) configuration of a methane derivative an arrangement of ligands that correspond to the definition of *R* and *S*, but unlike the latter is based on the μ-sequence, then at least for the available data on derivatives having ligands from Table 6 we can say:

Derivatives having the (R_μ) configuration are levorotatory, whereas derivatives having the (S_μ) configuration are dextrorotatory.

This should also be true for compounds that are not listed here, provided that only ligands from Table 6 are present and the magnitudes of the experimentally found optical rotations are not extremely small.

4. Summary

The discussion of the available data in relation to the pure structural statements of the theory, *i. e.* without calculation of the optical activity by means of detailed quantum-mechanical formulas and with deliberate limitation of the discussion to the semiempirical aspect of the chirality functions, confirms the second approximation method. On chemical grounds the practical test rules out the use of derivatives having an ideal T_d-situation. The experimental material requires an analysis of the T_d-component and simultaneously of how well it is approximated by expression (2b). Therefore the quantitative reliability of function values should be improved by a further increase in the amount of experimental data.

Even with the existing material, however, the distribution of the values found for $\bar{\Phi}$ in the range $0 \leq |\bar{\Phi}| \leq \bar{M}$ shows beyond any doubt that the separation of the optical rotation into a contribution from a T_d-component formulated by (2b) and others corresponds to well defined

geometrical properties of the methane derivatives. A more detailed analysis has to be based upon this fact.

The polynomial (2a) appears to describe the T_d-contribution in an acceptable approximation, at least for those derivatives having ligands from Table 6, and to predict the correct sign for derivatives whose optical rotations are not too small. It should be profitable on the one hand to continue the test in the form described and on the other to use the results of a quantum-mechanical theory of the phenomenon, which have been completely disregarded here, to correlate the T_d-component and contributions due to deviations from the T_d-situation with physical or geometrical details. It should ultimately be possible to obtain information from the optical activity about preferred conformations in methane derivatives or about changes in the geometric arrangement as a result of association, solvent effects, *etc.* We regard the test carried out here as a first successful step on the way to this goal.

We thank B. Weimann (MPI für Kohlenforschung, Mülheim) for the calculation of optimum values of the parameters and for the program required for this purpose. We thank the Deutsche Forschungsgemeinschaft for financial support of B. R.

The Perturbation Treatment of Chemical Reactivity[**]

By Robert F. Hudson[*]

The perturbation method of treating chemical reactions is discussed in a simple manner, by invoking the general hypothesis that the *initial perturbation determines the course of a reaction*. This approach is used to develop a general theory, as an alternative to the transition state theory. Such apparently diverse concepts as the symmetry rules for cyclic processes, and hard and soft acids and bases can be derived by this treatment, which is applied to radical reactions and aliphatic and aromatic substitution.

1. Introduction

The quantitative treatment of reactivity remains one of the most difficult and yet intriguing problems of chemistry, of particular importance in the field of reaction mechanisms. Chemical reactivity is usually discussed in terms of the transition state theory[1], but this method has severe limitations[2] in that neither the activation energy nor the activation entropy can be calculated to within reasonable limits of accuracy, except for the simplest of reactions (*e.g.* $H+H_2$).

The chemist requires an approach which can be applied to large molecules, and he is particularly concerned with the influence of regular structural changes on reactivity and product composition. In recent years the principle of conservation of orbital symmetry, which delineates in a simple way those reactions which can occur and those which cannot, has been particularly successful in dealing with concerted reactions[3]. It is becoming apparent that these rules are part of a wider scheme of treating chemical reactions[4], and of estimating potential energy surfaces in an approximate way. The perturbation theory is central to

Canterbury, Kent (England)

[**] Based on a course of lectures given at the University of Rochester, New York (Sptember-December 1970) and the universitet i Bergen (August-September 1971).

most of these developing methods, and in this article an attempt is made to develop this method in a simple manner which should be intelligible to any experimental chemist. The basic equations will then be applied to a wide range of chemical processes.

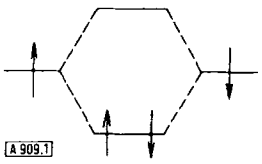

Fig. 1. Interaction of two singly occupied degenerate orbitals.

2. The Perturbation Method

In contrast to the transition state theory, the perturbation method[5] does not normally attempt to calculate the activation energy of a reaction. Rather, the energy change in the initial stages of the reaction as the orbitals of the reactants mutually interact (*i.e.* perturb each other) is calculated, and in effect the initial slope of the potential energy curve is estimated.

The basic idea of the perturbation method is that on the approach of two interacting systems, the combined wave function of the perturbed system is given by appropriate combinations of the wave functions of the two unperturbed molecules. By considering the interaction of each pair of orbitals separately, the total perturbation energy can be found.

The orbitals may interact in various ways depending on their symmetry and relative energies. In the perturbation method, this is represented by a Hamiltonian operator H' which is a modification of that of the initial system H^0, thus

$$H = H^\circ + H'$$

The Schrödinger equation may be solved by the usual variational treatment leading to a set of simultaneous equations

$$\begin{vmatrix} \alpha_1 - E & \beta \\ \beta & \alpha_2 - E \end{vmatrix} = 0 \qquad (1)$$

for the energy E due to the interaction of orbitals ψ_1 and ψ_2 of energy α_1 and α_2 respectively; β is the resonance integral for the specific interaction:

$$\beta = \langle \Psi_1 | H | \Psi_2 \rangle \qquad (2)$$

Two general situations are of importance corresponding to the interaction of degenerate and non-degenerate orbitals.

2.1. Degenerate Orbitals

When $\alpha_1 = \alpha_2$, *e.g.* for the interaction of two identical atoms or radicals, solution of the Schrödinger equation (with neglect of overlap) gives

$$E_+ = \alpha + \beta; \quad E_- = \alpha - \beta \qquad (3)$$

The combination of two orbitals thus gives rise to splitting to give bonding and anti-bonding orbitals (Fig. 1). For two electrons the bond energy is 2β.

For the combination of two organic radicals R and S at atoms r and s respectively:

$$\beta = \langle \Psi_j | H | \Psi_k \rangle = \langle C_{rj}\varphi_j | H | C_{sk}\varphi_k \rangle = C_{rj}C_{sk} \langle \varphi_j | H | \varphi_k \rangle = C_{rj}C_{sk}\beta_{rs}$$

where C_{rj} and C_{sk} are the coefficients for the electron in orbital j at atom r, and in orbital k at atom s respectively. Hence

$$\Delta E = 2C_{rj}C_{sk}\beta_{rs} \qquad (4)$$

This is known as a *first order perturbation.*

As an example[6], consider the dissociation of allylic and benzylic compounds, for which the non-bonding orbital coefficients are given by the Longuet-Higgins rule[7]. The dissociation energy, ΔE, is given by the combination of the appropriate radical and atom X. This is produced mainly by the perturbation[8] of the non-bonding orbital of the radical by the atomic orbital of X.

$$CH_2{=}CH{-}CH_2{-}X \xrightarrow[-1/\sqrt{2}]{1/\sqrt{2}} CH_2{=}CH{-}\dot{C}H_2 + X^\cdot$$

The dissociation energy is given by σ bond and π bond energy changes, *i.e.*

$$\Delta E_A = E_{C-X} + \Delta E_\pi = E_{C-X} + 2\beta(1 - (1/\sqrt{2}))$$

Likewise for the dissociation

$$C_6H_5{-}CH_2{-}X \xrightarrow{(2/\sqrt{7}))} C_6H_5{-}\dot{C}H_2 + X^\cdot$$

we have:

$$\Delta E_B = E_{C-X} + \Delta E_\pi = E_{C-X} + 2\beta(1 - (2/\sqrt{7}))$$

Hence

$$\Delta E_B - \Delta E_A = -2\beta((2/\sqrt{7}) - (1/\sqrt{2})) \approx -0.10\,\beta$$

If $\beta \approx 1$ eV, $\Delta E_B - \Delta E_A \approx 3$ kcal/mol, a value which is close to the difference in bond energies of benzyl and allyl compounds.

By taking the coefficients C_{rj} calculated by a simple Hückel method, *Fukui*[9] has applied this equation to the dissociation energies of various kinds of aliphatic molecules (Fig. 2).

First order perturbations are additive, so for interaction at several points in the molecule,

$$\Delta E = 2\sum C_{rj}C_{sk}\beta_{rs} \qquad (5)$$

This equation is of importance when concerted reactions are considered.

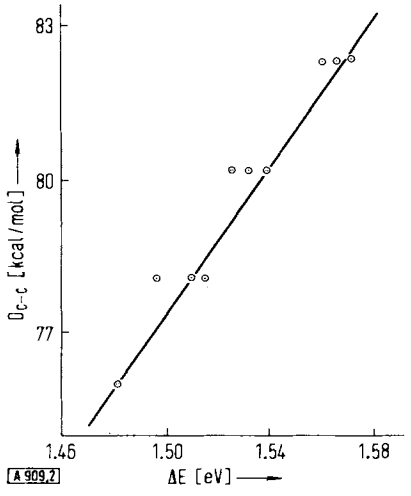

Fig. 2. Comparison of calculated perturbation energies ΔE [eq. (4)] and experimental bond energies D_{C-C} for the hydrocarbons: *n*-hexane (1-methylpentane), 2-methylpentane, 2,3-dimethylbutane, and 2,2'-dimethylbutane.

If the orbitals are doubly filled, then according to equation (3),

$$\Delta E = 2\beta - 2\beta = 0$$

This cannot be exact since the interaction of two closed shells, *e.g.* two helium atoms, leads to a net increase in energy, *i.e.* a repulsion. This can be introduced indirectly by retaining the overlap integral S in the solution of equation (1) which gives

$$E_+ = \frac{\alpha + \beta}{1 + S} \quad \text{and} \quad \frac{\alpha - \beta}{1 - S} = E_- \tag{6}$$

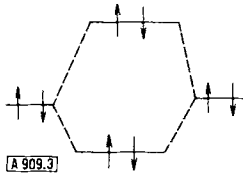

Fig. 3. Interaction of two doubly occupied degenerate orbitals.

For two electrons in each orbital, the change in energy ΔE, on interaction of the two doubly filled atomic orbitals is given by

$$\Delta E = \frac{4\alpha S^2 - 4\beta S}{1 - S^2} \tag{7}$$

If the Mulliken approximation[10] is made, *i.e.* $\beta = KS$, eq. (7) becomes

$$\Delta E = -(K - \alpha)S^2 \tag{8}$$

This relates the repulsion energy of closed shells to the overlap integral, which is amenable to calculation[11].

2.2. Non-Degenerate Orbitals

Usually $\alpha_1 \neq \alpha_2$, *i.e.* the interacting orbitals are non-degenerate. This corresponds to the interaction of an electron donor (a 2-electron orbital) of energy α_1, with an unoccupied level of an electron acceptor, α_2.

Solution of eq. (1) then gives

$$E = \frac{\alpha_1 + \alpha_2}{2} \pm \sqrt{(\alpha_1 - \alpha_2)^2 + 4\beta^2} \tag{9}$$

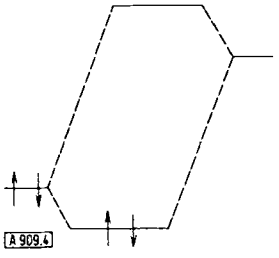

Fig. 4. Interactions of a doubly occupied orbital of energy α_1 with an unoccupied orbital of energy α_2.

If $\alpha_1 \gg \alpha_2$,

$$E = 2\alpha_1 + 2\beta^2/\alpha_1 - \alpha_2$$

Thus

$$\Delta E = 2\beta^2/(\alpha_1 - \alpha_2)$$

By analogy with eq. (4) it follows for interaction between atoms r and s of two molecules R and S that

$$\Delta E = \frac{2(C_{rj}C_{sk}\beta_{rs})^2}{\alpha_j - \alpha_k} \tag{10}$$

This method can be illustrated by calculation of π bond energy changes for the combination of two double bonds to give butadiene. The first order perturbation energy is *ca.* zero (S neglected), but the second order term gives an energy of 0.5 β (cf. resonance energy of 0.48 β by the Hückel method).

In general the situation is more complex, and the interaction of several filled orbitals, j, of the donor *e.g.* a conjugated nucleophile or aromatic hydrocarbon, with acceptor orbitals k must be considered. These perturbations are additive and the total energy then becomes[5]

$$\Delta E = 2\sum_{j}^{occ}\sum_{k}^{unocc}\frac{C_{rj}^2 C_{sk}^2 \beta_{rs}^2}{\alpha_j - \alpha_k} \tag{11}$$

In some reactions, several atoms of each molecule interact mutually in the transition state, and hence the appropriate wave functions, Ψ_j and Ψ_k must be used [cf. eq. (5)]. In the general case where filled orbitals j of molecule R interact with vacant orbitals k of molecule S, and filled orbitals k of molecule S interact with vacant orbitals j of molecule R, we have[5]:

$$\Delta E = 2\sum_{j}^{occ}\sum_{k}^{unocc}\frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_j - \alpha_k} + 2\sum_{k}^{occ}\sum_{j}^{unocc}\frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_k - \alpha_j} \tag{12}$$

This equation applies particularly to cycloadditions and similar concerted processes (see Section 8). In the special case where a particular orbital k localized on atom s of molecule S interacts with orbitals j of R (*e.g.* as in some simple π-complexes), eq. (12) simplifies to

$$\Delta E = 2\sum_{j}^{occ} \frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_j - \alpha_k} \qquad (13)$$

When polar molecules are involved, allowance must be made for the Coulombic attraction and interelectronic repulsion. A polyelectronic perturbation treatment[12] which introduces nuclear-nuclear and electron-electron interaction explicitly, within the framework of a central field approximation, into the Hamiltonian operator leads to the following approximate equation for the perturbation energy,

$$\Delta E \simeq q_r q_s \Gamma_{rs}\, 1.2 + 2\sum_{j}^{occ}\sum_{k}^{unocc} \frac{C_{rj}^2 C_{sk}^2 \beta_{rs}^2}{\alpha_j - \alpha_k} \qquad (14)$$

where q_1 and q_2 are the formal charges on r and s.

The one electron Hamiltonian operator, H is replaced by $H = H' - (e^2/R_{rs})$ and the electron-electron interaction is given by

$$\int \varphi_i(1)\,\varphi_k(2)\,H\varphi_j(1)\,\varphi_i(2)d\tau_1 d\tau_2$$

The core-core interaction is given by the energy $Z_R Z_S e^2/R_{rs}$.

Eq. (14), which reduces to eq. (11) for the interaction of neutral species, is of particular use in the interpretation of nucleophilic substitutions (see Section 3).

3. Reaction Paths

The energies calculated by the procedures given in Section 2 refer to small interactions only, as under these conditions the wave function of the combined system can be adequately represented by a combination of the ground state functions. A chemical reaction proceeding through a transition state, however, involves considerable displacement of the nuclei, and we must therefore ask the question, "under what conditions does the initial perturbation represent the chemical reactivity"?

Let us consider, for example, the interaction of an electron donor with a C—Cl bond, the orbitals of which are given by

$$\psi_+ = C_1\varphi_C + C_2\varphi_{Cl} \quad \text{and} \quad \psi_- = C_2\varphi_C - C_1\varphi_{Cl}$$

where $C_2 > C_1$. This means that the electron density around the chlorine atom is greater than around carbon, as required by the polarization C→Cl. The mechanism of substitution is explained classically by the attraction of the nucleophile to the carbon atom by Coulombic forces.

Moreover, the coefficient on carbon of the antibonding orbital, ψ_- is greater than that of chlorine ($C_2 > C_1$). Consequently the second term of eq. (14) also directs the nucleophile to the carbon atom, along the line of the C—Cl nuclei, as shown by a consideration of the symmetry of the antibonding orbital (Fig. 5).

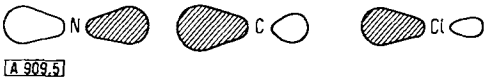

Fig. 5. Interaction of a nucleophile with the antibonding orbital ψ_- of a C—Cl bond in the initial stage of the substitution reaction.

Since the interaction energy is given by eq. (10) *i.e.*

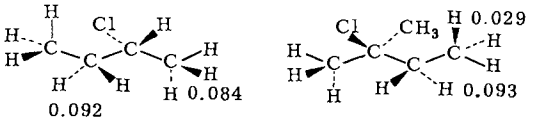
$$\Delta E \sim C_C^2/(\alpha_N - \alpha_E)$$

(where N refers to nucleophile, E to electrophile) the relative reactivities of a series of alkyl halides may be related[13] to C_c, since changes in $1/(\alpha_N - \alpha_E)$ are relatively small (Table 1)[*].

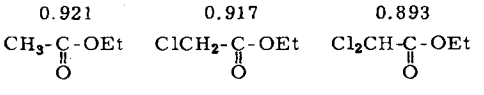
Table 1. Reactivity coefficients for a series of alkyl halides; calculated by the EH method [13].

RCl	α_E [eV]	C_C^2	$C_{\beta-H}^2$
CH_3Cl	1.870	1.091	—
C_2H_5Cl	1.624	0.929	0.0793
$(CH_3)_2CHCl$	1.487	0.914	0.0862
$(CH_3)_3CCl$	1.237	0.847	0.0911

The relative rate of β-elimination is similarly given by the coefficients on the β-hydrogen atom of the lowest unoccupied molecular orbital (LUMO) of the alkyl halide[13] (Table 1). Moreover the Saytzeff rule[14] for the direction of elimination in an alkyl halide is explained by the magnitude of these orbital coefficients as shown by the following examples—the *gauche* form (as required for an *anti*-elimination[**]) being assumed.



In the case of highly polar molecules, however, the reactivity does not usually follow the magnitude of these orbital coefficients[13] *e.g.* the rates of hydrolysis of the following esters change in the reverse order of the coefficients C_c:



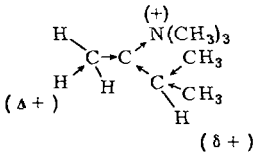
CH_3-C(=O)-OEt $\quad$ $ClCH_2$-C(=O)-OEt $\quad$ Cl_2CH-C(=O)-OEt

The changes are however small, and in this case the increasing charge on the carbonyl carbon atom determines the reactivity order, *i.e.* the first term of eq. (14) is dominant.

[*] Because of the low energy of the nucleophile orbital compared with α_E.

[**] Calculations show that the value of $C_{\beta-H}$ is a maximum for this configuration, thus predicting *anti*-elimination [15].

Similarly the Hoffmann rule for elimination in onium salts leads to a reverse order of rate of elimination to that given by the Saytzeff rule[14]. Here Coulombic forces may control the reaction[*], as given by the large inductive effects first considered by *Ingold*[16]:



Now, in the case of substitution of an alkyl halide considered above, the interaction given by eq. (10) leads to a combined system (Fig. 4) involving some charge transfer from ψ_N to ψ_-. Accordingly, the anti-bonding orbital ψ_- becomes partially occupied, *i.e.* the C—Cl bond becomes more antibonding, with a consequent weakening and slight displacement of the nuclei along the reaction coordinate. This parallelism between charge transfer and bond exchange has recently been discussed by *Fukui*[17] on the basis of the simple Hückel treatment

For the i-th MO

$$(\alpha_r - E_i)(C_r^i)^2 + \Sigma C_r^i C_s^i \beta_{rs} = 0$$

where the summation extends over neighbouring atoms, *i.e.*

$$\sum_s (C_r^i)(C_s^i) = \frac{\alpha_r - E_i}{(-\beta_{rs})} (C_r^i)^2 \qquad (15)$$

The energies of occupied orbitals are usually lower than α_r, and those of unoccupied orbitals are higher. Thus the summation term is positive for occupied MOs and negative for unoccupied MOs. Hence the position of largest coefficient density in the HOMO and in the LUMO[**] is liable to weaken bonds with neighboring atoms in the charge transfer process.

Further extension of the C—Cl bonds, as required to reach the transition state, leads to regular changes in orbital energies and coefficients. As the overlap decreases,

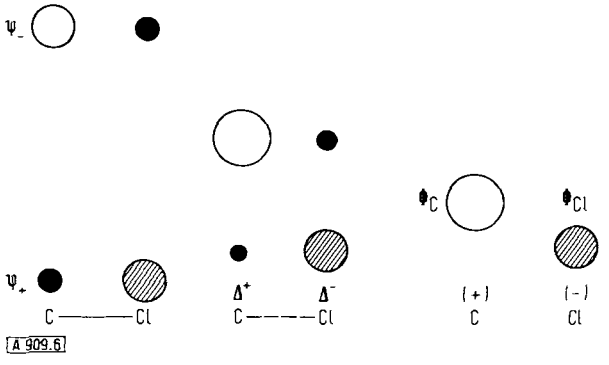


Fig. 6. Loosening of a C—Cl bond with charge transfer in nucleophilic substitution.

[*] The Brønsted β value is much greater for the elimination of onium salts than for neutral substrates [16b].

[**] HOMO = highest occupied molecular orbital; LUMO = lowest unoccupied molecular orbital.

the energy of ψ_- decreases which reduces the gap between α_N and α_E until the nuclei are separated (Fig. 6). At the same time, C_{Cl} of ψ_+ and C_C of ψ_- increase to the final value of unity for the separated atoms.

This behavior, similarly to that previously described in an empirical treatment of nucleophilic reactivity[18], is formulated by *Fukui* in the following rules:

1. The position of the largest density in the HOMO or LUMO is also that position most likely to weaken the bonds with neighboring atoms for electron releasing or electron attracting interaction respectively.

2. The energy difference between the orbitals of donor and acceptor decreases as reaction proceeds.

3. The coefficients in these orbitals increase (to the ultimate value of unity) as the reaction proceeds.

These changes are more pronounced for σ bonds than for π-bonds, in view of the greater influence of the overlap integral in saturated systems, and lead to re-hybridization as in the formation of an S_N2 transition state. The reaction progress involves the conversion of the initial orbitals into 3 molecular orbitals characterizing the transition state as shown by the correlation diagram in Figure 7.

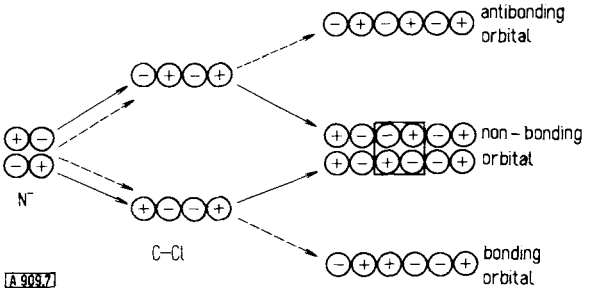

Fig. 7. Correlation diagram for the interaction of an electron donor with a C—Cl bond.

It is seen that the interaction of the nucleophile orbital with the antibonding orbital of the electrophile transforms into the non-bonding orbital (expressed originally[19] as a resonance hydrid of N^-RX and $NR\ X^-$). The initial perturbation thus directs the formation of the transition state.

It is now necessary to discuss the general experimental method which provides information on the extent of interaction between the reactants leading to the transition state. The interaction of two *similar* nucleophiles of orbital energies α and α′ with an acceptor orbital, ψ*, of energy α_s and coefficient C_s at the reaction site (Fig. 8) leads to a difference in second order perturbation energy $\Delta\Delta E$:

$$\Delta\Delta E = \frac{2C_s^2\beta^2}{\alpha - \alpha_s} - \frac{2C_s^2\beta^2}{\alpha' - \alpha_s} \approx 2C_s^2 \frac{(\alpha' - \alpha)}{(\alpha - \alpha_s)^2}\beta^2$$

Similarly for the interaction with an atomic orbital, φ_s, of energy α_s^0, leading to the formation of a covalent bond,

$$\Delta\Delta H \approx \frac{2\beta^2(\alpha' - \alpha)}{(\alpha - \alpha_s^0)^2}$$

so that

$$\Delta\Delta E \approx C_s^2\left(\frac{\alpha-\alpha_s^0}{\alpha-\alpha_s}\right)^2 \Delta\Delta H$$

i.e.

$$\Delta\Delta E \approx \chi\cdot\Delta\Delta H \qquad (16)$$

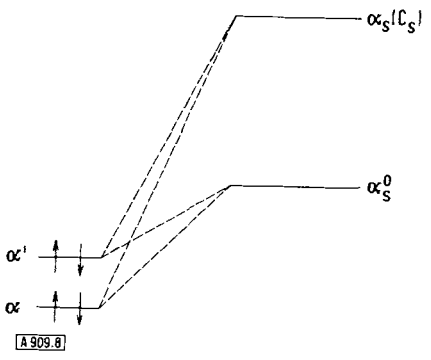

Fig. 8. Interaction of two similar nucleophiles with acceptor orbitals.

Accordingly, when $\alpha_s \ll \alpha_s^0$, $\chi \to 0$, and as $\alpha_s \to \alpha_s^0$ and $C_s \to 1$, $\chi \to 1$.

These are the boundary conditions for a generalized *linear free energy relationship*, usually derived[*] parametrically[20] or from potential energy profiles[21]. Thus for reaction at a hydrogen atom (neglecting differences in entropy), the Brønsted relation is derived,

$$\log k/k' = \chi(pK_a - pK_a') \qquad (17)$$

The value of χ for a particular reaction changes considerably with the nature of the substrate. Thus in the base catalyzed enolization of ketones[22], χ changes from *ca.* 0.9 to 0.4 as the basicity of the displaced anion decreases. Bond formation in the transition state is therefore more advanced with the less basic nucleophile, a rule first deduced by *Swain*[23].

In β-elimination, the magnitude of χ changes[16b, 24] from 0.17 to 0.88 representing a change from the E_1 to the E_1CB type of transition state[25].

Eq. (17) is now applied to reactions at a wide range of electrophilic centers[26] and although anomalies are found[26], χ usually provides a measure of the interaction in the transition state. In aromatic chemistry, the rate of electrophilic substitution of a range of polycyclic alternant hydrocarbons is related logarithmically to the basicity[27] as represented by the protonation equilibria in HF. Similarly, the relative reactivity of two similar aromatic compounds, *e.g.* toluene and benzene, towards different electrophiles gives a measure of the extent of interaction in the transition state as assumed in the rule of *Brown* and *Nelson*[28]. Since the selectivities[**] given in this way vary from *ca.* 1.5 to 10^4, a wide range of transition state structures, as found for S_N2 and E_2 reactions must occur. The transition state may thus differ considerably in structure from a Wheland intermediate[29].

We reach the general conclusion therefore that the magnitude of the coefficient of a linear free energy relationship (LFER) (sometimes referred to as reagent selectivity) is a measure of the perturbation between the reactants in the transition state.

The generalized LFER is a quantitative statement of the non-crossing rule[30] (not to be confused with the identically named rule in correlation diagrams). Moreover, the perturbation energy is a measure of $\partial E/\partial r$, *i.e.* the initial slope of the potential energy curve. As seen from the schematic representation in Figure 9 activation energy differences are given by differences in these slopes $(s_1 - s_2)$, provided that the energy profiles for two similar reactions have similar shapes[*]. Thus, when the non-crossing rule holds,

$$\Delta\Delta E \sim \Delta s \sim \Delta\Delta H \qquad (18)$$

a relationship which can be derived analytically[31].

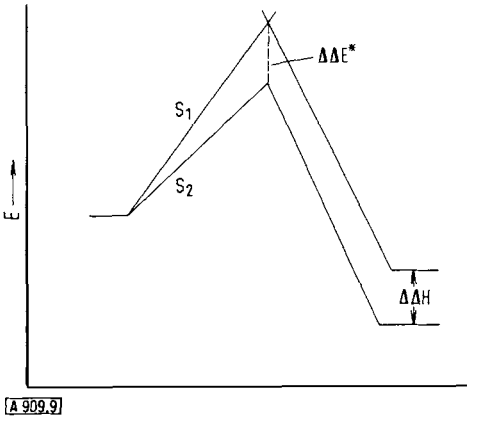

Fig. 9. Schematic representation of the energy profiles of two similar reactions.

It follows therefore that the perturbation energy usually determines the reaction path, and provides a measure of reactivity if the non-crossing rule holds.

4. Radical Abstraction Reactions

Radical reactions may be treated in the same way as nucleophilic substitutions, but here the interaction with occupied orbitals also must be considered. According to Figure 10, perturbations of various kinds have to be considered, but to a first approximation[32] [(cf. eq. (12)],

$$\Delta E = \sum_k^{occ} \frac{C_{rj}^2 C_{sk}^2 \beta_{rs}^2}{\alpha_j - \alpha_k} - \sum_k^{unocc} \frac{C_{rj}^2 C_{sk}^2 \beta_{rs}^2}{\alpha_j - \alpha_k} \qquad (19)$$

[*] χ is used in the place of β to avoid confusion of the Brønsted coefficients (β) with the resonance integral β.

[**] Defined as reactivity relative to that of benzene.

[*] This assumption is made in all derivations of linear free energy relationships.

The perturbation energy, ΔE, (eq. 10) is a stabilization whereas the P.E. of the reacting system increases (Fig. 9). This increase is due to the repulsion term (eq. 7) which for simplicity is taken to be constant. It is readily introduced [75] into eq. 10. According to the present treatment, differences in S are due mainly to changes in ΔE.

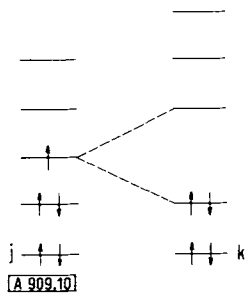

Fig. 10. Interaction of a singly occupied orbital ψ_j with the HOMO- and LUMO orbitals ψ_k.

In general, the interaction of the singly occupied j level with the highest occupied and lowest unoccupied k orbitals will determine the perturbation energy.

Let us consider the interaction of a radical R˙ with a saturated hydrocarbon R'CH_2—H (Fig. 11). The C—H bond is originally formed by the combination of C and H atomic orbitals as shown in Figure 11. Owing to the overlap term [eq. (6)], the energy of σ^* is usually very high (see Table 1) and consequently R˙ interacts more strongly with σ than with σ^*. In other words, radicals behave as weak electrophiles[*], as shown for example by the ρ values[33] in reactions of substituted toluenes ($\rho = -1.46$ for $CCl_3^{\cdot}$; -1.36 for $Br^{\cdot}$ and -1.08 for $(CH_3)_2N^{\cdot}$).

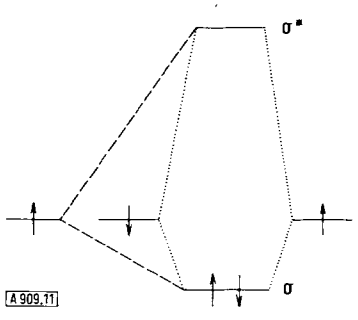

Fig. 11. Interaction of a radical with the C—H bond of a saturated hydrocarbon.

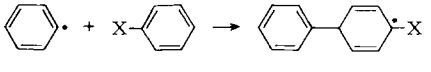
The reactivity of a series of radicals with various alkanes, as given by eq. (19), is shown in Figure 12, and the agreement is seen to be very satisfactory.

A wide range of radical abstraction reactions can be treated in this way including the extraction of halogen atoms from alkyl halides by alkyl radicals, sodium atoms and hydrogen atoms. The calculated perturbation energies are compared with experimental activation energies (ΔE^*) for two series of alkyl halides in Table 2.

[*] This is not necessarily the case for other types of radical reaction. Addition to aromatic systems is assisted by both electron donating and electron attracting substituents, *e.g.*



This is because π^* orbitals are usually lower in energy than σ^* orbitals, and hence the interactions of the lone electron with π and π^* levels are comparable.

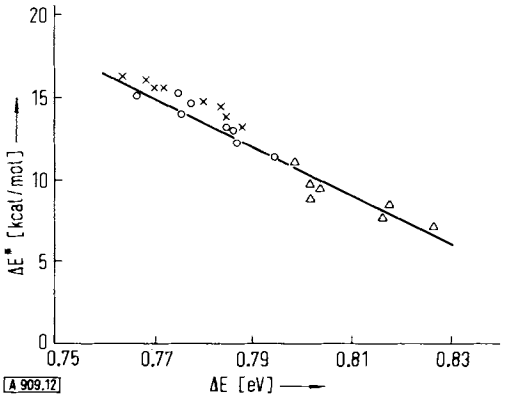


Fig. 12. Comparison of the activation energy, ΔE^*, for the radical abstraction from saturated hydrocarbons and the perturbation energy, ΔE, [eq. (19)].

Table. 2. Comparison of perturbation energy and activation energy for some radical abstraction reactions [32].

$RCl + Na \rightarrow R^{\cdot} + NaCl$		
	ΔE [eV]	ΔE^* [kcal/mol]
CH_3Cl	1.379	9.7
C_2H_5Cl	1.404	9.5
i-C_3H_7Cl	1.494	8.9
tert-C_4H_9Cl	1.496	8.0

$CH_nCl_{4-n} + H \rightarrow CH_nCl_{3-n}^{\cdot} + HCl$		
	ΔE [eV]	ΔE^* [kcal/mol]
CH_3Cl	1.379	7—9
CH_2Cl_2	1.756	6
$CHCl_3$	3.20	4.3
CCl_4	3.83	3.5

The relative rate of hydrogen abstraction from various positions in complex alkanes can be predicted[32] and average values of the relative reactivity of primary, secondary and tertiary H atoms are given in Table 3.

Table 3. Values of perturbation energies, ΔE, and reaction rates for hydrogen atom abstraction from alkanes.

H atom	ΔE [eV]	$10^{-3}k$[l/mol s] at 180 °C
CH_4	0.993	—
prim. C—H	1.004	0.3
sec. C—H	1.014	2.7
tert. C—H	1.033	15

5. Stabilized Radicals

Radicals can be stabilized in two main ways:

1. By conjugation as in the benzyl and allyl radicals (see Section 2.1). Here the energy of the lone electron in a non-bonding orbital is similar to that of a methyl radical[*]. Since the perturbation energy [eq. (19)] depends on the orbital coefficient, C_{rj}, of the terminal atom of the radical, the methyl radical ($C_{rj} = 1$) is more reactive than the benzyl radical ($C_{rj} = 2/\sqrt{7}$). The same conclusion is reached

[*] This shows the limitation of the simple HMO tretment. Electron repulsion differences lead to a lower ionization potential for the benzyl radical [34].

by calculating the resonance energy of the benzyl radical and then relating reactivity to thermodynamic stability. Thus a benzyl radical is formed more readily than a methyl radical (p. 37) and conversely it is less reactive. This is not always the case however. For example $\cdot CH_2—CN$ is a stable radical but it is formed less readily from $CH_3—CN$ than $C_2H_5^{\cdot}$ is from C_2H_6. This must be due to increased C—H bond energy in the ground state of CH_3CN. Hence the perturbation energy is less as required by [eq. (19)].

2. Certain radicals are stabilized by 3-electron bonds[35]. In MO terms, an orbital containing 2 electrons interacts with a singly occupied orbital according to eq. 6 to give orbital splitting, *e.g.* for the degenerate case

$$\Delta E = \frac{2\alpha + 2\beta}{1+S} + \frac{\alpha - \beta}{1-S} - 3\alpha = \frac{(\beta - \alpha S)(1-3S)}{1-S^2}$$

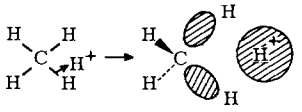
Since, in practice, $\beta > \alpha S$ the radicals are stabilized if $S_{12} < 0.33$. A consideration of overlap integrals[11] suggests that for $p_\pi - p_\pi$ interaction, S_{12} is usually less than 0.25. Consequently radicals such as $R_2N—O^{\cdot}$ (cf. NO), $RO_2^{\cdot}$, $R\dot{C}HOR$, $R\dot{C}HCl$ are stabilzed in this way, and their reactivity is less than that of a simple radical[*].

Thus in contrast to the greater reactivity of HO_2^- compared to that of HO^-, $HO_2^{\cdot}$ radicals are less reactive[37] than $RO^{\cdot}$ radicals in the abstraction of hydrogen from toluene (*e.g.* $\Delta \log k \approx 4.0$ for $HO_2^{\cdot}$ and $(CH_3)_3CO^{\cdot}$ radicals) and in the oxidation of certain organometallic reagents[38].

The stability of radicals of this kind explains the recently proposed radical pair mechanisms[39] for the Stevens, Meisenheimer, Wittig[40] and related rearrangements. It is possible that some aromatic rearrangements *e.g.* benzidine[41] and Fischer-Hepp may proceed through intimate radical pairs.

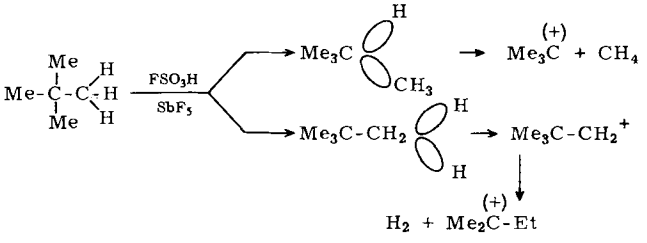
6. Electrophilic Aliphatic Substitution

To take the treatment one stage further, σ-bonds should interact strongly with electrophilic centers, but until recently few such reactions have been investigated. The basic reason is that most electrophiles, *e.g.* H^+, NO_2^+, Cl^+, CH_3CO^+, R^+, are very strongly solvated or complexed in solution, which effectively increases the energies of the corresponding "unoccupied" orbitals. Certain organometallic compounds are reactive electrophiles and mercuration[42] in particular has been studied mechanistically. In contrast to S_N2 processes, most reactions proceed with retention of configuration[42][**]. The transition state thus resembles "electron-deficient" compounds *e.g.* the boron hydrides and certain metal alkyls, in having 3 center 2-electron bonds[43]. The detection of stable CH_5^+ ions in the gas phase[44] shows that in the absence of solvent, the interaction between σ-bonding electrons and a 1s hydrogen orbital is strong. By analogy with radical reactions (Fig. 11) the energies of the σ-orbital and 1s H orbital are probably similar and lead to a strong perturbation:

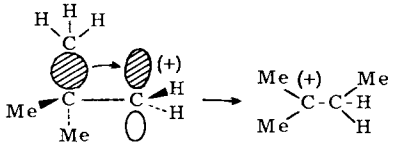


The carbon atom preserves its tetrahedral symmetry, rather than adopting a bipyramidal configuration[45].

Electrophilic protolysis and alkylation proceed by similar interactions[46] *e.g.*



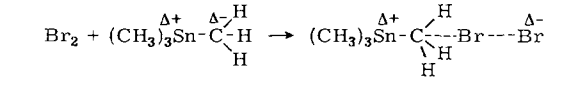
The final Wagner-Meerwein rearrangement proceeds by an intramolecular perturbation of the same kind, *viz.*



This type of interaction in the ground state, which is a second order perturbation, is equivalent to hyperconjugation[*] involving small overlap of the mixing orbitals.

[*] It is to be noted that electrostatic factors influencing the state of hybridization may oppose and reduce the importance of this orbital splitting. Thus, whereas the $CH_3^{\cdot}$ radical is planar, the radical $\cdot CH_2F$ like $NH_2O^{\cdot}$ retains the pyramidal structure [36].

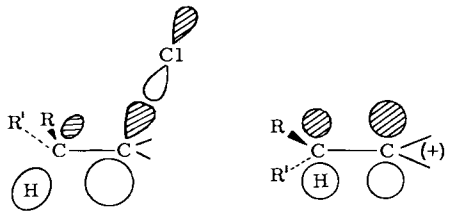
[**] Some organometallic compounds react with inversion of configuration (*F. R. Jensen* and *D. D. Davies*, J. Amer. Chem. Soc. *93*, 4048 (1971); *F. R. Jensen*, *V. Madan*, and *D. H. Buchanan*, *ibid.*, 5283) which may be due to the polarity of the bond. The carbon atom then acts as a carbanion in a typical interaction with an electrophile, *viz.*



[*] The use of this word is perhaps unfortunate in view of the controversy which surrounds this concept. We take it to mean orbital mixing leading to an energy decrease; σ-σ* interactions are particularly weak and must involve other orbitals near the continuum.

This interaction ($\sigma - \sigma^*$) also determines the stereochemistry of all 1,2-rearrangements, *e.g.* Beckmann, Schmidt, Lossen on nitrogen, Baeyer-Villiger oxidation, hydroperoxide rearrangements, and E_2 eliminations. Rearrangements to a carbanionic site (*e.g.* Stevens, Meisenheimer) are symmetry forbidden.

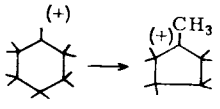
The perturbation approach can explain many apparent anomalies and structural effects, difficult to explain in classical terms; *e.g.* the anomalous gas phase acidity order for alcohols (*J. I. Brauman* and *L. K. Blair*, J. Amer. Chem. Soc. *90*, 6561 (1968)) may be attributed to $n \rightarrow \sigma^*$ and other stabilizing interactions. These are much weaker for amines (large ionization potentials) and the same basicity order is found as for aqueous solution. Weak perturbations involve many acceptor orbitals, *e.g.* the influence of sulfur on stabilizing carbanions and in assisting E_2 reactions (*e.g.* $MeS \cdot CH_2CH_2Cl$) may involve $n \rightarrow \sigma^*$, $p_\pi—d_\pi$, $2p_\pi—4p_\pi$ interactions since the σ^*, d_π, $4p_\pi$ levels may have similar energies (so-called polarization orbitals). The summation of eq. 11 then gives a measure of polarization energy.



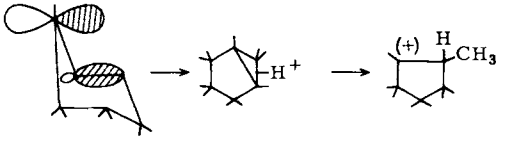
"hyperconjugation" stabilized carbonium ion

The large decrease in ionization potential of the radicals $CH_3^{\cdot} > CH_3CH_2^{\cdot} > (CH_3)_2CH^{\cdot} > (CH_3)_3C^{\cdot}$ is due to the same cause, but this is effectively a strong first order perturbation (approximately).

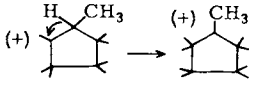
Rearrangements of this kind may proceed by several stages involving second order perturbation, *e.g.*



This involves the mutual perturbation of a C—C σ-bond and a p-orbital of a classical carbonium ion in the first stage, *viz.*



Similar interaction of the tertiary C—H bond[*] and carbonium ion leads to the most stable product[47].



According to *Olah*, non-classical carbonium ions—*e.g.* the norbornyl ion[48] (Fig. 13)—should be regarded as

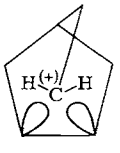


Fig. 13. Norbonyl cation.

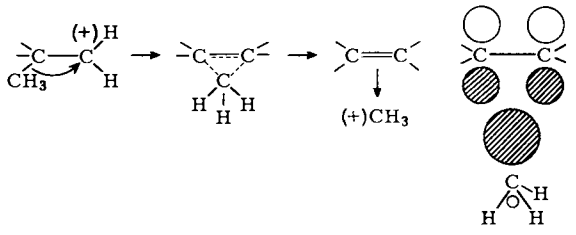
derivatives of CH_5^+, and other electrophilic displacements on carbon—*e.g.* nitration by nitryl salts—proceed through similar intermediates, *e.g.*

$$R{-}H \xrightarrow[CH_2Cl_2/\text{sulfolane}]{NO_2^+PF_6^-} R{-}NO_2 + H^+$$

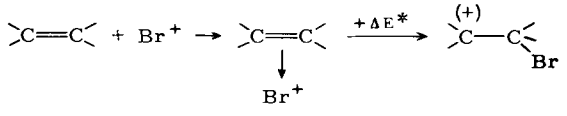
[*] The reactivity of $R_3C{-}C$, $R_2CH{-}C$, $RCH_2{-}C$ follows the ease of homolysis of these bonds.

7. π-Complexes and Aromatic Substitution

The perturbation described above may lead to a symmetrical intermediate usually termed a non-classical carbonium ion[*]. This structure may be regarded as a π complex[50], formed from a π orbital and a vacant sp^3 orbital of a migrating alkyl or aryl group.



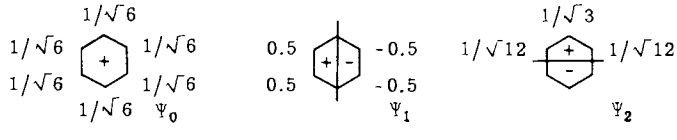
The mechanism of electrophilic addition to olefins has recently been explained in a similar way[51]. Thus most electrophiles, *e.g.* Br^+, I^+, give stable π-complexes, which react further with anions.



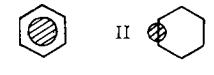
Protons however form a more stable σ-complex, owing to the small overlap with 2 carbon atoms, and the high C—H bond energy.

π-Complexes are of particular interest in the reactions of aromatic compounds although their exact role is still a matter of controversy[52]. The interaction energy can be calculated from eq. (13) since perturbation methods are particularly suitable for calculating weak interactions[53]. In detailed treatments, dispersion and polarization forces must also be taken into consideration.

Let us consider the interaction of benzene with the S and σ* orbitals of acceptors. The occupied orbitals of benzene have the following symmetry:



Two kinds of simple π complex have been detected, the centrosymmetric structure (I)[54], the asymmetric structure (II)[55].



The relative stabilities can be calculated from eq. (13)

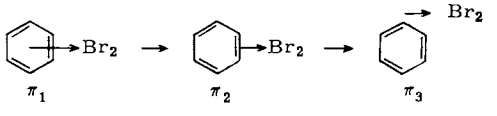
$$E_I = 2(6/\sqrt{6})^2\beta_I^2/(11.5 - \alpha_s)$$
$$E_{II} = 2(2\cdot 0.5)^2\beta_{II}^2/(9.25 - \alpha_s) + 2(2/\sqrt{6})^2\beta_I^2/(11.5 - \alpha_s)$$

[*] The structures and energetics of these intermediates are still the subject of much controversy [49].

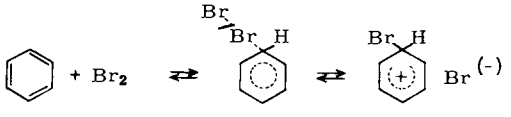
Relative values of β_I and β_{II} can be obtained from the corresponding overlap integrals[56] using the Mulliken approximation[10] (see Section 2.1.). It is readily apparent that structure I is promoted by low values of α_s, *i.e.* low electron affinities (*e.g.* Cl_2, I_2, Br_2, $E_A \approx 0$) and structure II by large values of α_s (*e.g.* Ag^+, I.P. 7.6 eV). Thus we reach the general conclusion that *the symmetry of the π complex formed by a donor with acceptor orbitals of a given symmetry, depends on the magnitude of the perturbation.*

This method has been used by *Herndon et al.*[57] to predict the orientation of π-complexes by an extended Hückel type of procedure. The predicted orientations are not always in agreement with X-ray structures[58], but the energy differences are small in most cases.

We may now apply these considerations to aromatic substitution[29], *e.g.* bromination. If the progress of the reaction is regarded as a gradual extension of the Br—Br bond, the energies of the σ and σ* orbitals (cf. Br_2) tend to approach each other as described previously (Fig. 6). Consequently the perturbation increases as $\alpha_j - \alpha_k$ decreases, and according to the argument presented above, produces a change in structure of the π-complex from π_1 to π_2.



Finally, more energy is required to localize the halogen atom on carbon as in π_3, and hence this structure is at an energy maximum, *i.e.* at the transition state[*]. Further increase in perturbation leads to rehybridization with decrease in energy on formation of the σ complex[59]. Structure π_3 is equivalent to the partially formed σ complex usually taken as the transition state for the rate determining stage of electrophilic substitution[60]:



Accordingly the formation of the transition state involves the perturbation of the π system at a particular carbon atom as originally proposed by *Fukui et al.*[61] and *Brown*[62] to form a "pseudo π-orbital". For this interaction, eq. (11) becomes

$$\Delta E = 2C_{sk}^2\beta_{rs}^2 \sum_j^{occ} \frac{C_{rj}^2}{\alpha_j - \alpha_k}$$

If $\alpha_j - \alpha_k$ is large, *i.e.* if the σ* orbital of the electrophile lies near to the continuum (*e.g.* E_A of $Br_2 \approx 0$) then $1/(\alpha_j - \alpha_k) \approx 1/\alpha_j$ and hence

$$\Delta E = 2C_{sk}^2\beta_{rs}^2 \sum_j^{occ} \frac{C_{rj}^2}{\alpha_j} \qquad (20)$$

[*] Cf. the mechanism of alkyl group migration, *e.g.* the Jacobsen rearrangement.

The term

$$\sum_j^{occ} \frac{C_{rj}^2}{\alpha_j}$$

called *superdelocalizability* by *Fukui*[61] gives a satisfactory measure of the relative reactivity of the various positions in polycyclic hydrocarbons (Fig. 14). Since the highest occupied orbital (HOMO) interacts most strongly with σ*, this is usually the most important orbital in directing the substitution. Accordingly the isomer distribution in the substitution of a particular aromatic hydrocarbon is determined by the magnitude of these coefficients in the so-called "*frontier*" *orbitals*[61].

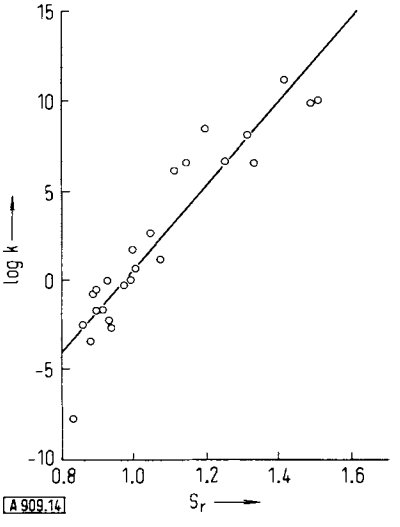


Fig. 14. Relationship between superdelocalizability and rate of nitration of polycyclic aromatic hydrocarbons.

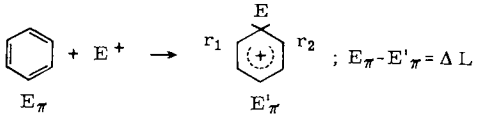
Various reactivity indexes have been developed to represent the rate of aromatic substitution, and it is interesting to note that these have similar degrees of success. The localization energy, ΔL, *i.e.* the energy required to localize the π electrons at the reaction center for formation of the σ-complex is widely used[63].



This may be found by calculating the π-electron energies of ground state and σ-complex, or by the approximate method developed by *Dewar*[64], who pointed out that the Wheland complex is an odd alternant hydrocarbon characterized by a non-bonding orbital, the coefficients of which can be obtained simply by the Longuet-Higgins method[7]. Combination of this non-bonding orbital of the π system of the Wheland complex with a degenerate carbon $2p_\pi$ orbital to give the π system of the original hydrocarbon involves an energy change, ΔE_π, given by

$$\Delta E_\pi = 2(C_{r_1}^0 + C_{r_2}^0)\beta_{C=C} \qquad (21)$$

Since $-\Delta E \sim \log k$ it follows that $\log k \sim (C_{r_1}^0 + C_{r_2}^0)$[*]. Linear relationships of this kind have been observed for a wide range of aromatic substitutions[64]. The slopes of these linear relationships vary considerably with the nature of the reaction leading to values of β (*ca.* 3–13 kcal/mol) *i.e.* considerably less than the value of β for a carbon $p_\pi - p_\pi$ bond. The discrepancy is explained by assuming incomplete bond formation and hence partial bond delocalization in the π system in the transition state[111].

The linearity of the $\log k - \Delta E_\pi$ relationships (Fig. 15) depends on the general linear free energy relationship (cf. eq. (18)) and hence localization energies can only give a measure

$$\Delta\Delta E^* \sim \Delta\Delta H \sim L \qquad (22)$$

of reactivity providing that the non-crossing rule holds. As explained in Section 3 pertubation energy changes are also directly related to $\Delta\Delta E$ providing this rule holds, and this appears to be the basic reason[31] why an index such as superdelocalizability and localization energy are equally satisfactory measures of chemical reactivity particularly of alternant hydrocarbons. (cf. Figs. 14 and 15).

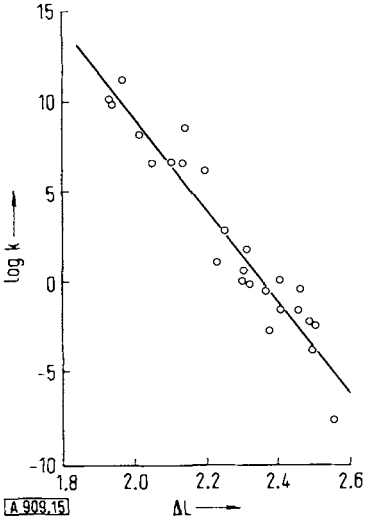


Fig. 15. Relationship between localization energy (L) and rate of nitration of polycyclic aromatic hydrocarbons.

8. Symmetry Controlled Reactions

A great deal has been written in recent years concerning the dominant role played by orbital symmetry in chemical reactions[65]. We shall here simply show how the perturbation method, applied in the same way as in the preceding examples, leads to the Woodward-Hoffmann symmetry rules, which are usually derived from correlation diagrams[66]. In the latter method the symmetries of the orbitals of reactants and products must be known, and also the order of orbital energies.

[*] Changes in σ bond energies and in ΔS^* are assumed to be the same for reactions of similar molecules.

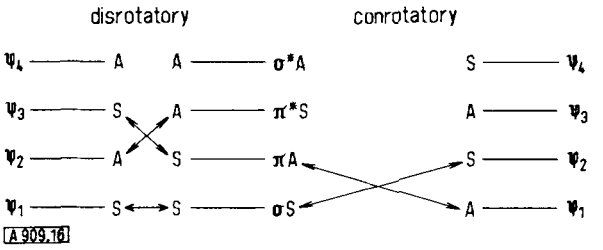

Fig. 16. Correlation diagram for the transformation of cyclobutene into butadiene.

In the perturbation method, the symmetry and coefficients of the orbitals *of reactants only*[*] must be known. As pointed out by *Salem*[4], it is intriguing to note that once again the initial perturbation decides the reaction path.

Let us consider the well known case of the ring opening of cyclobutene, the order of the orbitals is self-evident, *i.e.* σ, π, π*, σ*. In the group theoretical method[66] we enquire into the symmetry of these orbitals as the terminal bonds are rotated in conrotatory or disrotatory modes. These are then correlated with the ψ orbitals of butadiene rotated in the same sense. This gives rise to the correlation diagram in Figure 16.

To illustrate the perturbation method[67], consider the cyclization of butadiene by conrotatory and disrotatory modes.

These rotations produce partial σ bonds, with resonance integral γ. First order perturbation leads to the following interaction energies:

$$\text{conrotatory } \Delta E_c = 2c_{12}\,c_{42}\gamma - 2c_{11}c_{41}\gamma$$
$$\text{disrotatory } \Delta E_d = 2c_{11}\,c_{41}\gamma - 2c_{12}\,c_{42}\gamma$$

Both procedures lead to one incipient bond and one incipient antibond. Now, from the nodal properties of the orbitals, it is apparent that $c_{12} > c_{11}$ and $c_{42} > c_{41}$, hence the conrotatory process leads to greater stabilization[**].

When one electron is promoted from ψ_2 to ψ_3, then interaction of carbon atoms 1 and 4 for orbitals ψ_2 and ψ_3 are equal and opposite, hence

$$\Delta E_d = 2c_{11}\,c_{41}\gamma \quad \text{and} \quad \Delta E_c = -2c_{11}c_{41}\gamma$$

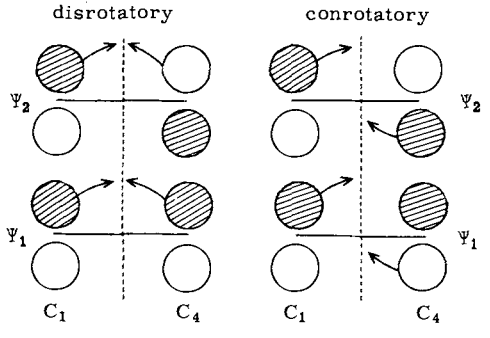

Fig. 17. Disrotatory and conrotatory ring closure of butadiene.

[*] Or the products only.

[**] The energy difference for conrotatory and disrotatory processes is estimated to be 0.89β (*ca.* 30 k·cal/mol). This is of the same order of magnitude as the activation energy differences calculated theoretically [70a].

and the disrotatory mode is favored, as shown by the correlation diagram. The wave functions of polyenes can be represented in closed form[68].

$$C_{rj} = \frac{1}{\sqrt{n+1}} \sin \frac{jr\pi}{n+1} \quad j = 1, 2, 3 \text{ for } \psi_1, \psi_2, \psi_3$$

and hence the above treatment can be generalized[67]. In the case of hexatriene, interaction of the three orbitals at the terminal carbon atoms shows the disrotatory mode to be favored thermally.

$$-\Delta E_c \equiv \Delta E_d = 2c_{13}c_{63}\gamma - 2c_{12}c_{62}\gamma + 2c_{11}c_{61}\gamma$$

Considering now the opening of the cyclobutene ring, the initial perturbation leads to a stabilization when second order perturbation between σ and π^*, and π and σ^* is possible[*]. This is so, as already shown for the analogous ring closure for a conrotatory process (cf. Fig. 18).

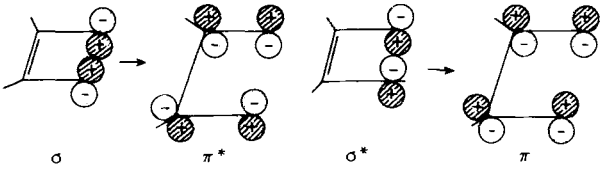

Fig. 18. Orbital interaction of σ with π^* and of π with σ^* in the conrotatory ring opening of cyclobutene.

It is seen therefore that the initial perturbations for ring closing and ring opening processes lead to the same symmetry rules as considerations based on the symmetry of reactants and products. The perturbation approach has the advantage that relative reactivities can, in principle, be calculated from a knowledge of orbital coefficients.

9. Cycloadditions[**]

The calculation of relative reactivities for cyclization reactions, where both stereochemistry and reactivity have been investigated, will now be considered. It is now widely held that $2\pi+2\pi$ and $4\pi+4\pi$ systems cannot cyclize by a synchronous mechanism, whereas $2\pi+4\pi$ reactions, *e.g.* Diels-Alder addition and similar reactions are symmetry allowed[69]. These rules may be extended to σ-systems[70], *e.g.* the hydrogenation of olefins and various addition reactions of diatomic molecules. In particular the addition of hydrogen to halogens is symmetry forbidden. This follows directly from eq. (12) since the initial perturbation involves the interaction of filled bonding and unfilled antibonding orbitals of the two reactants, as shown by the orbital diagram in Figure 19.

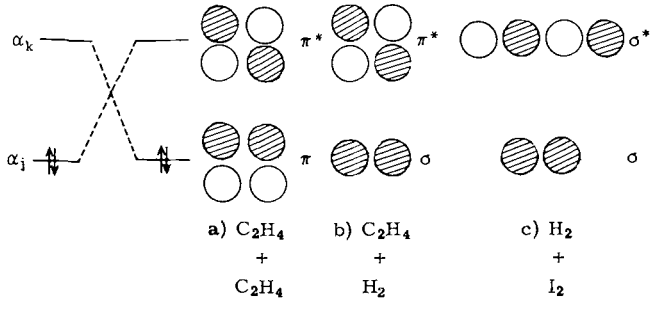

Fig. 19. Orbital interaction between $\pi+\pi$, $\pi+\sigma$, and $\sigma+\sigma$ systems.

The symmetry restrictions can in fact be removed if the reactant (*e.g.* H_2) is initially coordinated to a metal (*e.g.* Pt, Pd) which thus acts as a hydrogenation catalyst. A diimide can similarly add hydrogen in a concerted fashion, as the symmetry is now correct[70] (cf. Fig. 20).

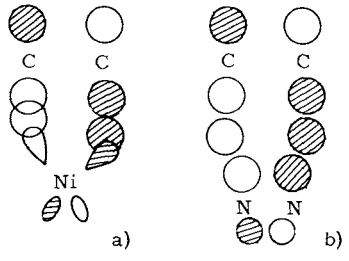

Fig. 20. Catalyzed and concerted hydrogenation of a metal and diimide.

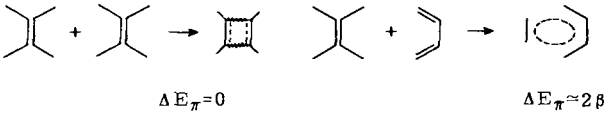
According to eq. (12), the perturbation energy of a system represented by (a)→(c) in Figure 19 is given by

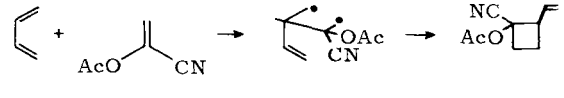
$$\Delta E = \frac{2(C_{rj}C_{sk} - C'_{rj}C'_{sk})^2\gamma^2}{\alpha_j - \alpha_k} + \frac{2(C_{rj}C_{sk} - C'_{rj}C'_{sk})^2\gamma^2}{\alpha_j - \alpha_k} = 0 \qquad (22)$$

since $C_{rj} = C_{sk} = C'_{rj} = C'_{sk}$

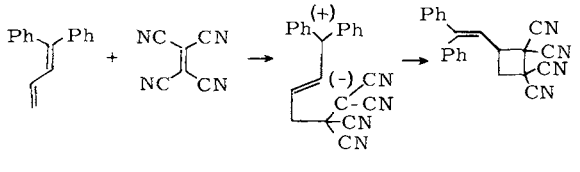
This is equivalent to the explanation originally proposed by *Dewar*[6] that synchonous interaction of two 2π systems leads to the incipient formation of a system resembling cyclobutadiene, *i.e.* $\Delta E_\pi = 0$, whereas $4\pi+2\pi$ systems give a transition state resembling benzene, with positive resonance energy, and hence are energetically favorable.



Thermal reactions of 4π systems should involve radicals[71], *e.g.*



or possibly zwitterions[72], *e.g.*



[*] Sigmatropic rearrangements can be treated in a similar manner.
[**] See also recent articles by W. Herndon, Chem. Rev. *72*, 157 (1972); *N. D. Epiotis*, J. Amer. Chem. Soc. *94*, 1924 (1972).

as inferred from solvent effects. The photochemical cyclization however may be concerted since promotion to π^* leads to positive stabilization (Fig. 21).

Fig. 21. Photochemical cyclization of two 2π systems.

The reactions of dienes with activated olefins (dienophiles) are, on the other hand, symmetry allowed, as shown by the following perturbation treatment[73] for the interaction of two π-systems

$$\Delta E = 2\sum_{j}^{occ}\sum_{k}^{unocc}\frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_j-\alpha_k} + 2\sum_{j}^{unocc}\sum_{k}^{occ}\frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_k-\alpha_j} \qquad (23)$$

$$i.e.\ \Delta E = 2\left(\sum_{j}^{occ}\sum_{k}^{unocc} - \sum_{j}^{unocc}\sum_{k}^{occ}\frac{(\Sigma C_{rj}C_{sk}\beta_{rs})^2}{\alpha_j-\alpha_k}\right)$$

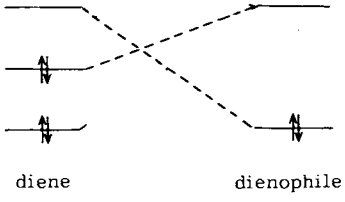


Fig. 22. Reaction of dienes with activated olefins.

From the relative positions of the orbitals, it follows that interactions of occupied orbitals of the diene with unoccupied levels of the dienophile are more important than the interactions of occupied dienophile levels with unoccupied diene orbitals[*]. The coefficients of polyene orbitals change in a regular way[**]. Thus for a chain of n atoms,

$$(C_1 \equiv C_n)_{\psi_{n+1}} > (C_1 \equiv C_n)_{\psi_n}$$

Considering the reaction of butadiene with ethylene

$$\Delta E = \frac{2(C_1' C_1^0 + C_4' C_2^0)^2 \beta_{rs}^2}{\alpha_1' - \alpha_2} \qquad (\alpha_1')\frac{(+)\,(-)}{C_1'\ \ C_4'}, \quad \frac{(+)\,(-)}{C_1^0\ \ C_2^0}(\alpha_2)$$

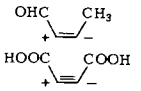
dienophile

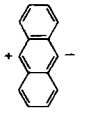
$$+ \frac{2(C_1 C_1^0 + C_4 C_2^0)^2 \beta_{rs}^2}{\alpha_1 - \alpha_2} \qquad (\alpha_1)\frac{(+)\,(+)}{C_1\ \ C_4}$$

$$i.e.\ \Delta E \approx \frac{2(C_1' C_1^0 + C_4' C_2^0)^2 \beta_{rs}^2}{\alpha_1' - \alpha_2} \qquad \text{diene} \qquad (24)$$

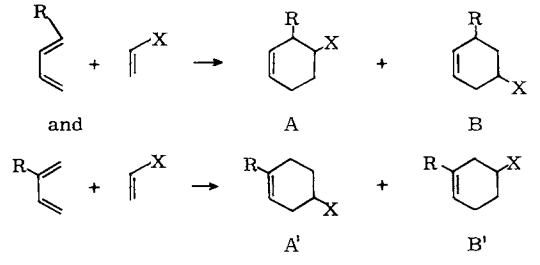
The perturbation is thus determined mainly by the interaction of the highest occupied orbital of the diene with the lowest unoccupied orbital of the dienophile as postulated in the original paper by *Hoffman* and *Woodward*[69] and by *Fukui*[74]. The symmetry of the frontier orbitals of diene and dienophile are, in general, correct for concerted bond formation[74] (Table 4).

Table 4. Perturbation-determining frontier orbital in the reaction of dienes with dienophiles.

Frontier orbital of diene (HOMO)	Frontier orbital of dienophile (LUMO)
					




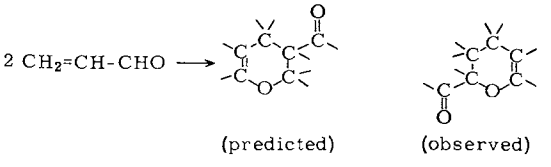
The perturbation equation has been used to predict the isomer ratios formed in the following reactions:



R = C_6H_5, CH_3; X = CN, CO_2CH_3, CHO, C_6H_5

In all cases formation of isomer A (or A') is predicted; the result is in agreement with experimental findings, *e.g.* when $R = C_6H_5$, $X = CO_2CH_3$: $A \approx 90\%$; $A' \approx 80\%$.

In some cases, however, the incorrect isomer is predicted[75] *e.g.* in the selective dimerization of acrolein



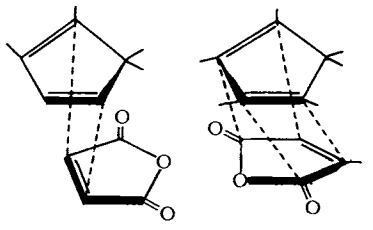
Here, the Coulomb term[*] in eq. 14 makes an important contribution and determines the isomer composition[76];

[*] 1,3 Dipolar additions can be treated in this way.
[**] This can readily be written in analytical form.

[*] According to *O. Eisenstein, J. M. Lefour,* and *Nguyen Trong Anh* (Chem. Commun. *1971*, 969), the regiospecificity is determined by interaction of the atoms with highest HOMO and LUMO coefficients (*e.g.* ).

there is some doubt, however, as to whether this and similar reactions are concerted or two stage processes[76a].

In addition, the stereochemistry of the product can be ascertained from the perturbation treatment. Thus cyclic reagents can give rise to *exo* or *endo* products, such as *e.g.* the reaction between cyclopentadiene and maleic anhydride (Fig. 23).



exo-Addition *endo*-Addition

Fig. 23. Cycloaddition of cyclopentadiene with maleic anhydride.

The preferential formation of the *endo* product is attributed to secondary interactions involving C2 and C3 atoms of the diene with the activating function of the dienophile (*e.g.* the carbonyl groups of maleic anhydride)[77].

Inclusion of these interactions leads to the perturbation energies[78] in Table 5.

Table 5. Perturbation energies of cycloadditions.

Diene	Dienophile	ΔE (kcal/mol) *endo*	*exo*
CPD	+ CPD	11.8	9.5
CPD	+ MA	18.9	14.2
CPDO	+ CPDO	41.7	29.2
CPDO	+ MA	20.6	13.2
CPD	+ CPDO	28.0	—
CPDO	+ CPD	21.8	—

CPD = cyclopentadiene, CPDO = cyclopentadienone, MA = maleic anhydride.

10. The Influence of Polarity

So far we have concentrated mainly on the reactions of non-polar π systems and molecules of weak polarity, *e.g.* radicals, where orbital interactions normally determine the course of the reaction. For polar molecules, the energy of Coulomb interaction (eq. (14)) may become important and Coulomb and orbital terms may be in opposition[12].

If a nucleophile is represented by a doubly filled atomic orbital ($C_{rs}=1.0$) eq. (14) becomes

$$\Delta E = q_r q_s \Gamma_{rs} + 2C_{sk}^2\beta_{rs}^2/(\alpha_j - \alpha_k) \qquad (14a)$$

For certain restricted series of reagents these two terms change in the same direction with a change in structure of the nucleophile. For example, consider the substitution of an electron attracting substituent A in an alkoxide ion

$$CH_3\text{-}O^{(-)} \qquad {}^{(\delta-)}A\text{-}CH_2\text{-}O^{(\Delta-)}$$

This has the effect of (i) reducing the formal negative charge on the nucleophile and (ii) reducing the energy of the "nucleophilic" orbital, (j), leading to decreased orbital interaction. Under these conditions the two nucleophiles show the same relative reactivity order to all electrophilic centers as required by the Brønsted relation (Section 3).

This is however not always the case, and the nucleophilic order may change with the nature of the electrophile[79]. This may be understood by comparing alkylation and acylation. The first term of eq. (14) is small for alkyl halides, and hence the reactivity order[80] follows the perturbation given by the second term, *e.g.* $I^- > Br^- > Cl^- > F^-$ (Fig. 24), *i.e.* it is *orbital controlled.*

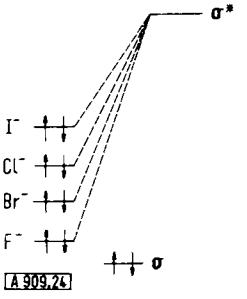


Fig. 24. Orbital interaction in alkyl halides.

On the other hand in acylation, the first term in eq. (14) is large in view of the high positive charge on the carbonyl carbon atom, and, although the orbital term is also increased, since a π* level is lower than a σ* level, the first term is dominant and leads to a reverse nucleophilic order[*], *i.e.* to *charge control*[12]. By also including the solvation energy term in the Hamiltonian operator, *Klopman*[81] was able to show (Table 6) that the nucleophilic order changes in a regular way with the change in the relative magnitude of α_j and α_k. (For simple nucleophiles α_j gives the effective electronegativity of the nucleophile, which is related to the Coulomb term.)

Table 6. Change in nucleophilic reactivity with the orbital energy of the electrophile.

	I^-	Br^-	Cl^-	F^-	HS^-	CN^-	OH^-
R_{HX}(Å)	1.60	1.41	1.27	0.92	1.34	1.06	0.96
$-2\beta_X$(eV)	3.16	3.60	4.10	4.48	4.0	3.8	4.50
$-\alpha_j$	8.31	9.22	9.94	12.18	8.59	8.78	10.45
$\Delta E(\alpha_k = -7\,eV)$	2.52	1.75	1.54	1.06	2.64	2.30	1.49
$\Delta E(\alpha_k = -5\,eV)$	1.07	0.98	0.97	0.82	1.25	1.17	1.01
$\Delta E(\alpha_k = +1\,eV)$	0.451	0.479	0.516	0.535	0.551	0.557	0.58

It should be noted that the relative magnitude of the two terms usually changes with the extent of interaction between the reactants, *i.e.* with the magnitude of the perturbation or the position of the transition state along the reaction path[18]. This is given quantitatively[**] by the

[*] This provides a theoretical basis for the concept of "hard" and "soft" acids and bases [82].

[**] Except in anomalous cases.

Brønsted coefficient, χ, which therefore changes in a regular way with the nucleophilic order. A striking example is β-elimination[16a,24] where the transition state structure may be E_1-like ($\chi \rightarrow 0$) or E_1CB-like ($\chi \rightarrow 1$), viz:

$$B: + CH_3\overset{(+)}{-}CH_2 + \overset{(-)}{X} \rightarrow B\cdots H\cdots CH_2{=}CH_2\cdots X \rightarrow \overset{(+)}{B}H + \overset{(-)}{C}H_2{-}CH_2X$$

E_1 $\qquad$ E_2 $\qquad$ E_1CB

increase of χ ⟶

increase of k_H/k_D ⟶ ⟵ increase of k_H/k_D

The relative reactivity of thioalkoxide to ethoxide ions decreases regularly[16b] with increase in χ, since the Coulomb term becomes more important in the transition state (Table 7).

Table 7. Change in nucleophilic reactivity with transition state structure for β-elimination.

	k_{RS^-}/k_{RO^-}	β
tert.-C_4H_9Cl	8.3	0.17
tert.-$C_4H_9S(CH_3)_2^+$	0.31	0.46
Cyclohexyl tosylate	7.0	0.27
Cyclohexyl chloride	0.73	0.39
DDT	7.1×10^{-5}	0.88

Other examples have been found, and it appears to be a general rule that a *change of transition state leading to an increase in both charge and orbital terms usually produces a change from orbital to charge control*[*]. We shall invoke this principle when dealing with "ambident reagents".

11. The α-Effect.

Some nucleophiles, *e.g.* HO_2^-, ClO^-, RS^-, NH_2OH, N_2H_4, and some oximes and hydroxamic acids are more reactive than predicted[83] by the appropriate Brønsted relation (see Section 3). This appears to be due to the lone pair of electrons adjacent to the nucleophilic atom[84]. If this has the correct orientation with respect to the lone pair of electrons which enter into covalent bond formation with an electrophile, the orbitals will split[85] according to eq. (6). Such splitting can be seen directly in the photoionization spectra[86], and is responsible for changes in ionization potential, polarizability, redox potential, and modified UV spectra[87].

Accordingly the (occupied) π* orbital interacts more strongly with an "electrophilic" orbital (σ*) than do the unperturbed electrons of a simple nucleophile[88] (Fig. 25); thus leading to an increased reactivity. This is however modified by the Coulombic term of eq. (14). In general the adjacent atom with lone pairs will be more electronegative than carbon or hydrogen and hence will exert a positive inductive effect. This tends to reduce the reactivity of the so-called "α-nucleophile", and in particular the interaction with a proton is so large as to outweigh the orbital splitting effects. This means that the reactivity change (*e.g.* HO_2^- and HO^-) is in the opposite direction to the pK_a change (H_2O_2 is a stronger acid than H_2O by *ca.* 4 pK_a units). Typical rate data for HO_2^- and HO^- are given in Table 8.

Table 8. Relative reactivity of hydroperoxide and hydroxide ions in aqueous solution.

	C_6H_5CN	$CH_3OOC{-}C_6H_4{-}NO_2$	$(RO)_2POF$	$C_6H_5CH_2Br$
$k_{HO_2^-}/k_{HO^-}$	10^5	10^3	2×10^2	≈50

In some cases, however, the conformation of the nucleophile is such as to minimize electron repulsion[84] and when the two orbitals in question are orthogonal, the splitting is zero[*]. Some examples are shown in Fig. 26 in the form of idealized Newman projections.

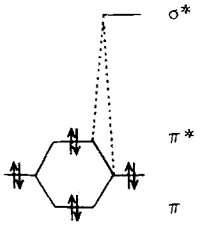

Fig. 25. Orbital interaction in the α-effect.

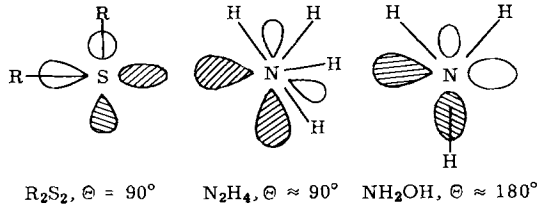


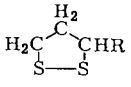
R_2S_2, Θ = 90° $\qquad$ N_2H_4, Θ ≈ 90° $\qquad$ NH_2OH, Θ ≈ 180°

Fig. 26. Conformations of nucleophiles with minimal electron repulsion.

[*] This is due to the large Coulombic term in polar bonds.

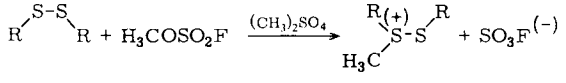
[*] As evidenced for instance by their normal refractivities, and PE spectra.

However, hydrazines and hydroxylamines do show enhanced reactivity[89] (*e.g.* in certain acylations and phosphorylations), and this has been ascribed to intramolecular base catalysis. These nucleophiles show "normal" reactivity[*] (*i.e.* follow the Brønsted rule) in alkylation[90] and general base catalysis in certain reactions[91]. Conformational factors may increase the overlap of the lone pairs, *e.g.* in trimethylene disulfide

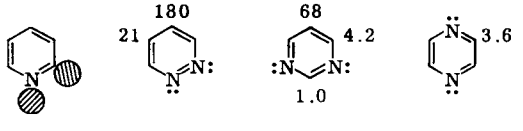


the dihedral angle is *ca.* 24°, and the sulfur atom is much more reactive, as in oxidation, to give the sulfone, than tetramethylene disulfide or non-cyclic disulfide[92].

We have shown[92a] that log $k \sim \cos^2\theta$, as required by eq. 8, for the alkylation of cyclic disulphides.



The influence of lone-pair interactions is also shown by the acidity of the hydrogen atoms of nitrogen heterocycles. Thus base catalyzed deuterium exchange[93] of pyridine shows that exchange at the 4 position is preferred, although Hückel charge densities suggest that the 2-position is the more acidic[94]. Extended Hückel calculations[95] suggest that the 2-carbanion is de-stabilized by lone-pair lone-pair repulsion.



Similarly the rate of base catalyzed deuterium exchange of diazenes can be explained readily by invoking lone pair repulsion between the electrons on nitrogen and the incipient carbanion[96].

Pyridazine and *iso*thiazole show α-effects in acylation and alkylation; pyrazine, pyrimidine and thiazole do not in reactions with 2,4-dinitrophenyl acetate[96a].

12. Positional Reactivity

The perturbation method is particularly useful in the prediction of the relative reactivity of two or more nucleophilic centers in a given nucleophile towards a range of electrophilic reagents. This is because the coefficients on atoms of the various orbitals of alternant hydrocarbons and their heteroatomic analogs usually change in a regular way. The influence of the heteroatom can be introduced as a perturbation as in the method of *Coulson* and *Longuet-Higgins*[97], which modifies the form of the wavefunction.

This may be illustrated graphically (Fig. 27) by reference to the allylic and enolate ions.

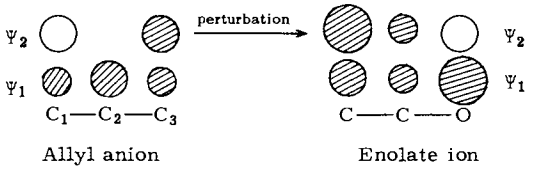


Fig. 27. Perturbation theoretical relationship between allyl anion and enolate ion.

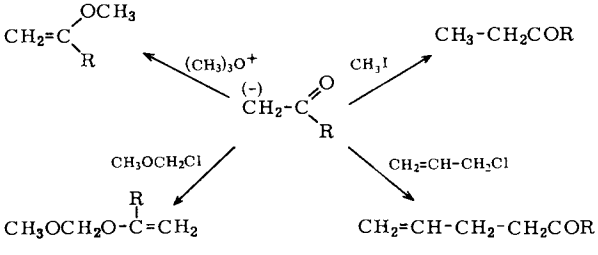
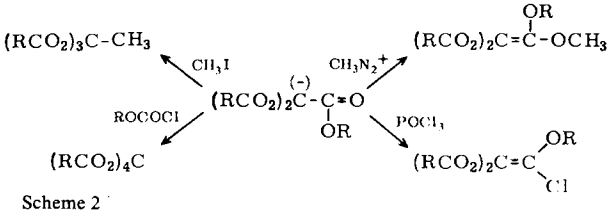
The charges on the 1,3 carbon atoms of allylic anions are −0.5 e as the coefficients in the HOMO are equal. Substitution of oxygen for carbon atom 3 results in a concentration of electrons on oxygen in ψ_1, and a *reversal of the magnitude of the coefficients* on atoms 1 and 3 in orbital ψ_2. Thus $q_o > q_c$, but $C_c^f > C_o^f$ (C^f = frontier-orbital coefficient). Consequently when the Coulomb term is large, as in the reactions with cations—in particular protons and incipient carbonium ions (see Schemes 1 and 2)—the reaction becomes *charge controlled* with reaction on oxygen[*].

As the charge decreases the reaction becomes *orbital controlled*, and as shown by the reactions in Schemes 1 and 2, alkylation (and acylation) occurs on carbon.



Scheme 1.



Scheme 2

These are examples of the concept of *ambident reactivity* introduced in important papers by *Kornblum et al.*[98], who have shown that (for homogeneous reactions)[**] the

[*] See however *J. E. Dixon* and *T. C. Bruice*, J. Amer. Chem. Soc. *92*, 2052 (1972).

[*] NMR measurements show a concentration of charge on the oxygen atom of enolate ions (*G. J. Heiszwolf* and *H. Kloosterziel*, Rec. Trav. Chim. Pays Bas, *86*, 807, 1345 (1967). Extensive quantitative measurements have been reported by *A. L. Kurts*, *A. Marcias*, *I. P. Beletskaya*, and *O. A. Reutov* (Tetrahedron, *27*, 4759, 4769 (1971) and by *G. J. Heiszwolf* and *H. Kloosterziel*, Rec. Trav. Chim. Pays Bas *89*, 1153, 1217 (1970) on enolate ions and anions of imines.

[**] Heterogeneity introduces complications and specific explanations are required.

product composition changes in a regular way with structure, *e.g.*

$$Me\text{-}NO_2 \xleftarrow{MeI} O{=}N{=}O \xrightarrow{{}^tBuCl} {}^tBu\text{-}O\text{-}N{=}O$$

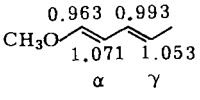
$$CH_3OC_6H_4CH_2\text{-}O\text{-}N{=}O \xleftarrow{CH_3OC_6H_4CH_2Cl} NO_2^- \xrightarrow{NO_2C_6H_4CH_2Cl} NO_2C_6H_4CH_2\text{-}NO_2$$

Again the S_N1 tendency leads to greater alkylation on oxygen. Rate determining protonation is almost invariably charge controlled in view of the large Coulombic term and relatively small orbital term, since the proton is strongly covalently bonded as H_3O^+ in solution. The perturbation thus involves a high energy σ^* orbital of the $H\text{—}\overset{+}{O}<$ bond. The pK_a however cannot be evaluated satisfactorily in this way, as the proton forms a complete covalent bond with the base. The perturbation then essentially involves an unoccupied 1s orbital, thus explaining the inadequacy of charge density in predicting the pK_a of certain aromatics[*].

The protonation of enolate ions and nitroalkane anions occurs initially on oxygen (kinetic control), and subsequently on carbon (thermodynamic control)[99].

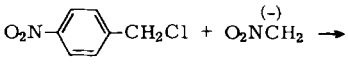
$$CH_2{=}\overset{+}{N}\text{-}\overset{O}{O}^{(-)} + H^+ \rightleftharpoons CH_2{=}\overset{+}{N}\text{-}\overset{\ddot{O}}{O}H \longrightarrow CH_3\text{-}NO_2$$

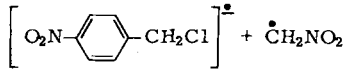
Likewise conjugated enol ethers undergo proton-deuterium exchange at the position of maximum charge density[100], *e.g.*

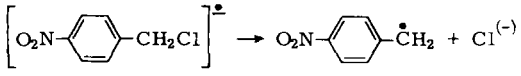


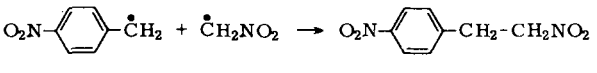
For a series of such ethers, $\log k_\alpha/k_\gamma \sim (q_\alpha - q_\gamma)$ and no correlation with localization energy is found.

On the other hand, interacting radicals are almost degenerate and subject to *orbital control*. This may explain the exclusive formation of C alkylated product in the reaction of nitroalkanes with *p*-nitrobenzyl bromide, which proceeds *via* a mechanism of the type[102]:









[*] Well known exceptions are encountered in protonation of heterocyclic bases [101].

The exact mechanism is not established, but radicals are certainly involved (probably in a chain reaction[102b], and the above explanation holds for other mechanisms, *e.g.*

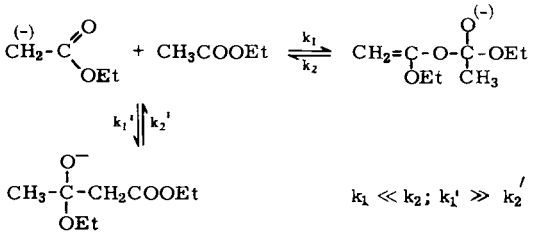
since the Coulomb term is negligible and the interacting orbitals are nearly degenerate.

These principles may be applied to the reactions of other conjugated nucleophiles (Table 9).

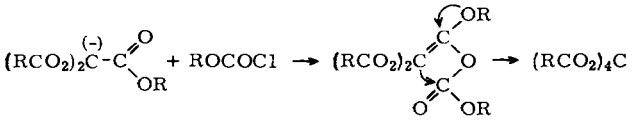
Table 9. Ambident activity of nucleophiles.

	CH_3OCH_2Cl	CH_3Cl	CH_3COCl	$(RO)_2POCl$
Orbital term	small	small	large	large
Charge term	large	small	large	large
$NCS^\ominus$	C—N	C—S	C—N	P—N
$R\overset{\ominus}{C}H\text{—}COR$	C—O	C—C	C—O	P—O
$R_2P(O)S^\ominus$	—	C—S	C—O	P—O

In general, a small charge with small orbital term leads to orbital control (*e.g.* alkylation), whereas a large charge with large orbital term leads to charge control (*e.g.* acylation and phosphorylation). The products however vary with the nature of the substrate and medium, and the interpretation is complicated by rearrangements and formation of products under thermodynamic control. Interesting examples of the relative importance of charge control and orbital control are found in the reaction of enolate ions with the phosphonium center[103], and the benzoylation of chelated 1,3 diketones[104] The Claisen condensation normally leads to *C*-acylated product, but this may be due to the influence of pre-equilibria, *e.g.*



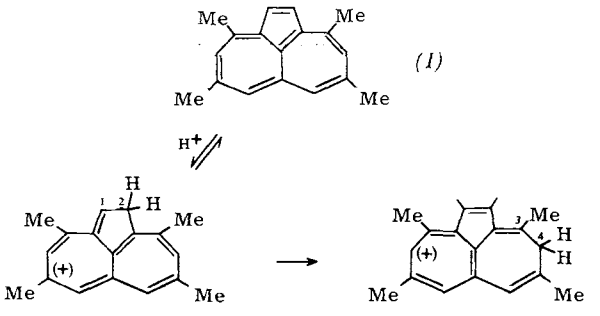
Similarly the formation of the fourfold acylated product in Scheme 2 could be formed by a rearrangement.



13. Aromatic Compounds

13.1. Charge Controlled Reactions

As the electron density on each carbon atom of an alternant hydrocarbon is unity, the Coulomb term of eq. (14) vanishes, and hence these reactions cannot be charge controlled. This is not the case for non-alternant hydrocarbons, and recently *Hasselbach*[105] has shown the first example of charge control in the protonation of *(1)* (Table 10). The kinetic product subsequently rearranges to give the thermodynamically stable product.



(1)

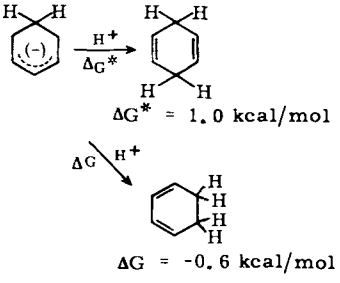
Such a behavior was predicted by *Brown*[62] who pointed out that the non-crossing rule is probably violated for non-alternants if the orders of q and ΔL (localization energy) differ.

Table 10. Parameters of charge controlled protonation.

$q_{1,2} = 1.125$	$q^f_{6,7} = 0.330$	$\Delta L_{6,7} = 1.875$
$q_{6,7} = 1.092$	$q^f_{4,9} = 0.276$	$\Delta L_{4,9} = 1.995$
$q_{4,9} = 1.088$	$q^f_{1,2} = 0.122$	$\Delta L_{1,2} = 2.014$

Streitwieser found similar results for aceheptylene[106].

The mechanism of the Birch reduction[107] of benzene involving the formation of a cyclopentadienyl anion has aroused much interest since the thermodynamically less stable 1,4-dihydrobenzene is formed.

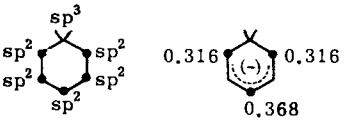


$\Delta G^* = 1.0$ kcal/mol

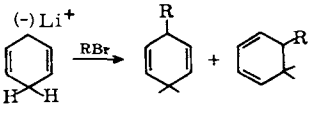
$\Delta G = -0.6$ kcal/mol

Simple Hückel calculations predict equal charge densities at positions 2 and 4[*], but when allowance is made for differences in electronegativities of these carbon atoms, SCF calculations give a higher charge density in the 4-position[107].

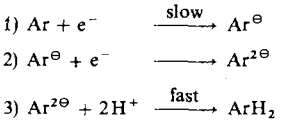
[*] In this case the charge densities and frontier electron densities are identical.



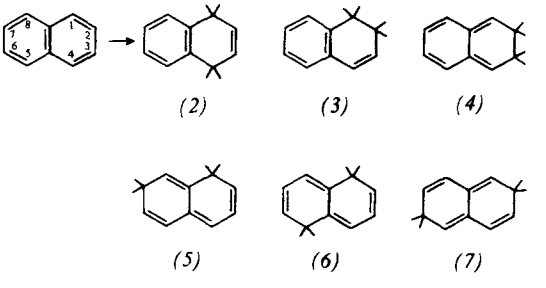
Similarly, alkylation gives a 3:1 mixture of 1,4 and 1,2 isomers[109]:



The products of polarographic reduction of polycyclic aromatics can be explained in a similar manner. The work of *Wawzonek* and *Latinen*[108] has established an irreversible mechanism for this reduction:



Here the addition of electrons to the lowest unoccupied level of the hydrocarbon is rate determining and hence the rate of reduction is related directly to the energy of this orbital. In the case of naphthalene there are six possible products of reduction. Compound *(3)* obviously has the highest resonance energy but this is not formed. The product is therefore determined by kinetic competition and since this involves the addition of protons to a dianion, the pertinent reaction is presumably charge controlled.



(2) *(3)* *(4)*

(5) *(6)* *(7)*

The charge density is given by the coefficients of the highest occupied orbital (HOMO) of the dianion[*], *i.e.*

$$\psi_6 = 0.4253(\varphi_1 + \varphi_4 - \varphi_5 - \varphi_8) - 0.2628(\varphi_2 + \varphi_3 - \varphi_6 - \varphi_7)$$

Thus

$$q_1 = q_4 = q_5 = q_8 = 0.181$$
$$q_2 = q_3 = q_6 = q_7 = 0.069$$

Hence only compounds *(2)* and *(6)* should be formed. Now the resonance energy of *(2)* is greater than that of *(6)* so that compound *(2)* is the normal product of reduction (Birch reduction also). It should be noted that

[*] Since the parent hydrocarbon is alternant and hence $q_r = 1.0$.

charge coefficients and frontier coefficients predict the same isomers in this case, since the charge distribution is given by the frontier orbital coefficients.

13.2. Charge and Orbital Control

In general however the reactions of aromatic species will be charge or orbital controlled in view of the extensive interaction with the π-system.

The wave functions are modified in a regular way by a heteroatom (or carbon atom of different hybridization, as in toluene) according to the rule of alternating coefficients[*]. Thus we shall be concerned with the *o/p* ratios in electrophilic substitution, which have not been explained unambiguously[**], and show that the perturbation treatment leads to a general electronic explanation. The charge densities (C_{rj}^2) on *o*- and *p*- carbon atoms of toluene (also for aniline, anisole *etc.*) can be represented diagrammatically (Fig. 28). Again the alternation leads to the conclusion that

$q_o > q_p$ but $q_p^f \gg q_o^f$

Thus strong perturbation (as measured by a large Brønsted coefficient, or a large reaction selectivity), should lead to exclusive *p*-substitution (as in Friedel Crafts acylation), weaker perturbation should lead to greater *o*-substitution.

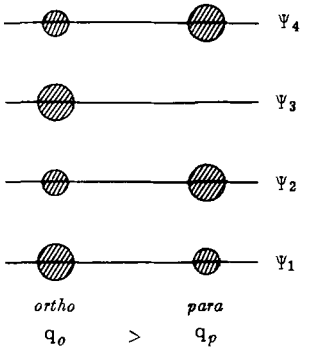


Fig. 28. Charge densities on the *o*- and *p*-carbon atoms in toluene.

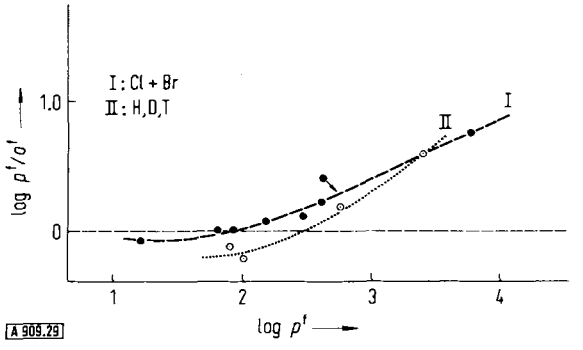

Fig. 29. Relationship between the *ortho-para* isomer ratio and selectivity (log p^f) for electrophilic substitution of toluene.

[*] For the benefit of prowling theoreticians, we acknowledge that this rule is not theoretically derived.

[**] *Norman et al.* [110] attributed high *o*-ratios to the charge distribution in the Wheland intermediate; *Kovacic* [111] has invoked specific *o*-group attractions.

The available experimental data[112] for toluene (in homogeneous solution) are in general agreement with these predictions. Thus in Fig. 29 two separate lines are obtained for (i) the deuteration and tritiation of toluene under various conditions, and (ii) for the reactions of Cl_2 and Br_2 in various media. It should be pointed out that the perturbation (eq. (14)) involves the resonance integral β for the incipient bond. This is the reason for the separate lines in Fig. 29. It is highly probable that the β values for C—Br and C—Cl bonds are similar[*].

In the cases of acylation, alkylation, and nitration a similar behavior is observed, *e.g.* o^f/p^f for nitration is *ca.* 1 when p^f is *ca.* 70. The influence of steric hindrance however appreciably reduces reaction at the *o*-position (as can be seen for example by considering the Friedel Crafts reaction of alkyl halides). *Olah*[29] has recently commented on the regular decrease in p^f/o^f with p^f for the reaction of substituted benzyl halides with toluene.

It is emphasized that the above treatment is an oversimplification of the process, and in particular all the orbitals $\psi_1 \rightarrow \psi_4$ should be considered. This leads to interesting results in the case of pyridine oxide, where calculations of the total perturbation energy (eq. (14)) with gradually changing values of $(\alpha_j - \alpha_k)$ show a change in reactivity from $C_2 \rightarrow C_4 \rightarrow C_3$. It is interesting to note that electrophilic substitution has been observed in these three positions with change in electrophile[113], the energy of the acceptor orbital of which probably increases in the following order[**]

$$Hg^{2+} < NO_2^+ < SO_3$$

Nucleophilic addition to π systems will now be considered. For example, Michael addition to α, β unsaturated ketones may be attributed to the large coefficient on the terminal carbon atom in the lowest unoccupied orbital (LUMO) ($C_3^2 = 0.435$; $C_1^2 = 0.303$ using $k=1$ and $h=1$)[***]. The charge densities are in the opposite direction however ($q_3^+ = 0.286$ $q_1^+ = 0.392$) and hence reactions involving

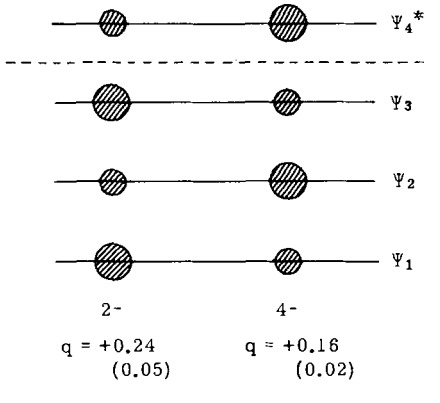

Fig. 30. Charge densities in positions 2 and 4 of pyridine.

[*] β also changes with selectivity, but in a regular way.

[**] Hg^{II} is a subgroup B metal, hence Coulombic forces are small; NO_2^+ has a relatively low lying π* orbital. SO_3 has high energy 3d orbitals.

[***] In the usual procedure $\beta_{C-X} = k\beta_{C=C}$; $\alpha_X = \alpha_C + h\beta$.

strong Coulombic interaction *e.g.* reduction with AlH_4^- or BH_4^- proceed at the carbonyl group.

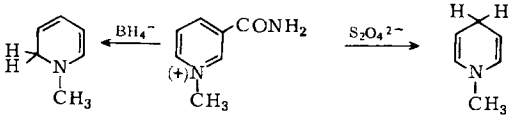
Similarly in the reduction of pyridine and pyridinium salts[114] the lowest unoccupied orbital is used in the initial stages of bond formation.

Figure 30 shows that the coefficients on C2 and C4 alternate, such that for the LUMO, $C_4^0 > C_2^0$, but $q_2^+ > q_4^+$. This means that reagents which interact strongly, react in position 4, whereas reagents which experience a large Coulombic interaction tend to react in position 2. Charge densities at the various atoms calculated by HMO and SCF methods are in the same order (Table 11)[115].

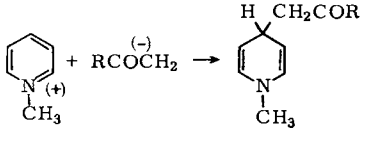
Table 11. π-Electron densities for pyridine.

	HMO	SCF [113]	VESCF [114]
q_1	1.180	1.100	1.107
q_2	0.943	0.950	0.952
q_3	0.992	1.010	1.004
q_4	0.950	0.980	0.981

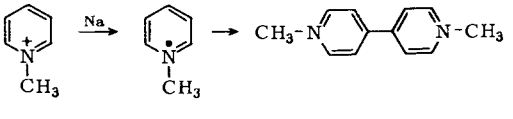
Experimentally[116] it is found that $S_2O_4^{2-}$, which forms a strong complex, reduces the 4-position, whereas BH_4^-, which cannot interact covalently, reduces the 2-position.



Similarly enolate ions which also form strong complexes and hence interact strongly with the HOMO, add at the 4-position[117].



The same considerations determine the almost exclusive formation of 4,4'-dipyridyl derivatives (*e.g.* "paraquat") by reduction *via* free radicals[118] (or radical anions).



Here there is no doubt that the maximum pertubation leads to coupling in the 4,4' positions. Similarly quinoline forms the 4,4' isomer and isoquinoline should form the 2,2' isomer. In both cases, however, total charge densities predict the same result.

Structure and Function of Ferritin[**]

By Robert R. Crichton[*]

Ferritin is the major iron storage protein of mammals and consists of up to 4500 atoms of ferric iron surrounded by a shell of protein subunits. The protein component, apoferritin, consists of 24 identical polypeptide chains each of molecular weight 18500. The function of ferritin is to store iron in a soluble form from which it can be readily mobilized. Recent results concerning the structure of the protein are reported, and progress in the elucidation of the mechanisms whereby iron is introduced into apoferritin and released from ferritin is reviewed.

1. Introduction

"*Schmiedeberg*, the well known German pharmacologist, described in 1894 a protein substance which he called ferr*a*tin ... and contained 6% of iron and a variable quantity of phosphorus. Our efforts to isolate the iron rich component in a pure state from horse liver were not fruitful. It was not until we had chosen the spleen of the horse that we were able to prepare the pure substance. We have given to this new protein the name of ferr*i*tin, in memory of the ferr*a*tin of *Schmiedeberg*. On analysis ferritin contains 20% of Fe, 9.9% of N, and 0.9% of P. In the opinion of the author, ferritin must be a substance which serves as a depot for iron in the organism".

The isolation and crystallization of horse spleen ferritin thus described by *Laufberger*[1] in 1937 was the catalyst that led to recognition of the widespread distribution of this protein and to the establishment of its fundamental role in the storage of iron within the tissues and in the regulation of iron absorption from the intestine. In the present article the results of recent investigations on a number of selected aspects of the structure and function of ferritin will be considered.

2. Structure of Horse Spleen Ferritin

Although ferritins from a wide range of tissues and organisms have been studied, the most extensively characterized protein is still that from horse spleen. The present review will deal exclusively with horse spleen ferritin, and so in the text mention of ferritin implies this protein. The term apoferritin will be used to describe the iron-free protein, whether prepared from native ferritin by centrifugal techniques, or by chemical removal of the iron from ferritin. The demonstration that ferritins of differing structure occur within different tissues of the same species, that certain tumors contain atypical ferritins, and that the administration of iron either *in vivo* or *in vitro* causes stimulation of ferritin synthesis has been reviewed elsewhere[2].

2.1. Isolation and Gross Anatomy of Ferritin

Ferritin can be readily isolated from horse spleen by virtue of its stability at high temperature, ease of precipitation by 35% $(NH_4)_2SO_4$, and ready crystallization from 5% $CdSO_4$ solution. The isolation of the protein from other tissues and species presents a number of problems[3]. Ferritin consists of a shell of protein subunits surrounding a micelle of ferric hydroxide oxide phosphate. The iron can be removed by reduction with any suitable reducing agent, preferably in the presence of a suitable chelating agent to assist in removal of the Fe^{2+}. The original procedure described by *Granick*[4] involved $Na_2S_2O_3$ with α,α'-bipyridyl at pH 4.5. This suffers from the disadvantage that any molecular oxygen present causes the production of colloidal sulfur, which binds strongly to the protein and seriously interferes with subsequent investigations[5]. Accordingly we routinely remove the iron by treatment of ferritin with thioglycolic acid[6]. No precautions to exclude oxygen are necessary, and the thioglycolate functions both as reductant and chelator. Ascorbic acid at concentrations of 0.5–1.5 mol/l and pH values between 3 and 5 will also effectively remove iron from ferritin[6].

Apoferritin can be prepared from native ferritin solutions by centrifugation in an isopycnic density gradient[7], since native ferritin varies in its iron content from zero up to an estimated maximum of 4300 atoms/molecule[7] (Fig. 1). Whereas ferritin is inhomogeneous on account of its variable iron content, apoferritin is homogeneous, colorless, and can also be crystallized from 5% $CdSO_4$ solution[4]. It has the same electrophoretic mobility as ferritin

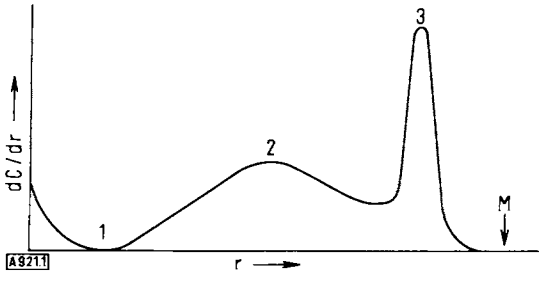

Fig. 1. Concentration gradient observed on sedimentation of native ferritin. The change in the concentration dC/dr is plotted against the distance from the center of rotation, r. Full ferritin (1) is at the bottom of the cell whilst iron-free apoferritin (3) is closest to the meniscus (M). Between these is partially filled ferritin of varying iron content (2).

and is equally well precipitated by horse ferritin antiserum[8]. These data, together with electron microscopic studies[9], make it clear that the iron in ferritin is encapsulated within a protein shell.

2.2. Structure of the Micelle

Ferritin has a red-brown color on account of the large amount of ferric iron in the molecule (typically in unfractionated ferritin around 20% on a dry weight basis). The precise chemical nature of the iron core is not certain, but it seems that it contains all of the phosphorus of ferritin, and a possible composition $8\,Fe(OH)\cdot FeO(PO_3H_2)$ has been proposed[10,11]. The cores can be separated from the protein by precipitation with 1 N NaOH[12], and contain only 23% of the total phosphorus. The supernatant contains the protein and the remainder of the phosphorus, but it is not known whether this is bound to the protein or is present as free orthophosphate. Cores prepared in this way have the same X-ray diffraction pattern as intact ferritin[13]. Thus it has been concluded that the phosphate is not an essential structural component of the core, nor does it seem to contribute significantly to the diffraction pattern. Confirmation of this view is found in the observation that ferritins reconstituted from apoferritin by three different procedures in the absence of phosphate gave diffraction patterns similar to native ferritin. The cores released by alkali also retain much of their original shape as seen by electron microscopy[13]

A low angle X-ray scattering study[7] showed that at a resolution of 20 Å the core approximates to a single uniform density object of average diameter 75 Å. The core has sufficient density to be seen in the electron microscope without staining, and it was originally proposed that the iron was distributed in four electron-dense regions[9]. A more recent study using an electron microscope with an instrumental resolution better than 4 Å[14] indicates that no particular number of electron-dense groups is common. Both by direct viewing and by electron diffraction it was shown that, at least in the vacuum of the electron microscope, the iron oxide is present in the form of small crystallites, of varying number in different molecules, more or less randomly distributed within the protein shell.

Powder patterns typical of ferritin core preparations can be obtained from stationary single wet crystals of ferritin[13]. Both sharp spots, due to the protein crystal lattice, and very weak diffuse rings caused by the iron cores, can be seen simultaneously. The latter give no indication of preferred orientation with respect to the crystal lattice of the protein. This, together with the electron microscope study referred to above, supports the conclusion originally derived from the examination of X-ray diffraction photographs of single crystals of ferritin and apoferritin[15] that the atomic arrangement of the cores is not specifically related to the structure of the protein. This implies that either the protein does not have specific binding sites for the core, or else that if it does, the core material is bound to these sites randomly.

The X-ray diffraction pattern of the ferritin cores are typical of poorly crystalline material, with broad lines relatively weak in comparison to the background. The pattern is not identical with that of any known mineral but has some similarity to δ-ferric hydroxide oxide, and can be indexed on a hexagonal cell. A structure for the ferric hydroxide oxide of the ferritin core has been proposed by *Harrison et al.*[13] and also by *Towe* and *Bradley*[16]. The two structures have closely related unit cells.

The Mössbauer spectrum of ferritin at liquid N_2 temperatures and above consists of a quadrupole split line with an isomer shift with respect to stainless steel of 0.47–0.50 mm/s[17,18]. A six-line magnetic hyperfine spectrum is observed at low temperatures (5 °K) indicative of magnetic ordering. As the temperature is raised, the hyperfine spectrum is gradually replaced by the paramagnetic, quadrupole-split doublet spectrum. This superparamagnetism is thought to be characteristic of very fine magnetic particles[19].

The effective magnetic moment of ferritin was found to be 3.81–3.85 BM[10,20,21] and it was suggested that the reduced moment was due to transfer of two electrons from oxygen atoms to ferric atoms caused by the cation-anion-cation superexchange[20]. However, when a thorough field dependence study of the magnetization was carried out, a moment of 5.08 BM/iron was found[17]. The low value of the apparent moment shows that the ferritin particles are antiferromagnetic when behaving as superparamagnets.

2.3. Dissociation; Subunit and Oligomer Molecular Weight

The earliest determination of the molecular weight of apoferritin gave a value of 465 000[22]. It is clearly unlikely that such a molecule consists of a single polypeptide chain, and evidence for a subunit structure was obtained from X-ray diffraction studies and from chemical studies which are discussed below. The apoferritin molecule has a sedimentation coefficient of 17.6 S[22] and can be dissociated into subunits which sediment at 2–3 S by a number of techniques. Incubation of apoferritin at pH 12.6 results in dissociation into a 2.1 S component, but only to the extent of 50%[23]. However, treatment with 67% acetic acid at 0 °C leads to complete dissociation and the molecule remains dissociated on dialysis into 0.01 M glycine-HCl buffer, pH 3.0, and sediments at 2.7 S[24].

Dissociation of apoferritin and ferritin can be achieved by treatment with sodium dodecyl sulfate[23,25,26] and by the use of guanidine hydrochloride at concentrations of 5–6 M[27,28], although it has been recently reported that this latter process is strongly pH-dependent[29]. Urea, even at concentrations of 8 mol/l does not cause the protein to dissociate[23], although this process seems also to be pH-dependent[29]. We found that maleylation of the lysine residues of apoferritin[6] or their conversion to homoarginine residues[30] does not cause the protein to dissociate into subunits. It was previously reported that succinylation of the lysine residues caused dissociation[31]. Of the nine lysine residues per subunit only seven can be modified with maleic anhydride or with *O*-methylisourea, and eight of the nine arginine residues per subunit can be modified with cyclohexanedione. Only one out of the five

tyrosine residues per subunit can be nitrated with tetranitromethane[30].

Apoferritin can be dissociated into subunits by extremes of pH. We have analyzed this process by sedimentation velocity techniques and by gel filtration. The oligomer is stable beween pH 2.8 and 10.6. However, between pH 2.8–1.6 and 10.6–13.0 the oligomer gradually dissociates into subunits. The mid-points of the dissociation, at which equal amounts of 17 S and 2–3 S component can be detected in the ultracentrifuge, are respectively pH 2.16 and 11.62. When apoferritin is completely dissociated into subunits at pH 1.6 and then dialyzed against buffers of pH 1.8–5.0 a reassociation to oligomer is observed in the range pH 3.1–4.3, with the mid-point at pH 3.76[30]. Analysis of the dissociation and reassociation by gel filtration reveals not only monomeric subunits but also dimers and tetramers as intermediates: these intermediates were not observed by the sedimentation velocity techniques[30a]. UV difference spectroscopy of the dissociation process at low pH has established that the five tyrosines of the apoferritin subunit, which are buried in the interior of the molecule in the oligomer, become exposed to the solvent in the fully dissociated subunit. During the reassociation, they return to their original "buried" state[30].

The pH-dependence of protein denaturants such as guanidine hydrochloride and urea may reflect the importance of salt linkages in the quaternary structure. It is known that hydrophobic interactions play a major role in stabilizing the quaternary structure of oligomeric proteins and the effects of such reagents as guanidine hydrochloride and sodium dodecyl sulfate on the dissociation of apoferritin are consistent with such a role. Apoferritin has a relatively high content of hydrophobic amino acids, especially leucine (Table 1).

Table 1. Amino acid composition of apoferritin.

Amino acid residues	No of residues/ 18500 daltons	No of residues/ 23000 daltons
Cysteic acid	2.9	3.6
Aspartic acid	17.3	21.6
Threonine	5.5	6.9
Serine	9.0	11.3
Glutamic acid	23.9	29.9
Proline	2.8	3.5
Glycine	9.9	12.4
Alanine	14.0	17.5
Valine	7.0	8.8
Methionine	2.8	3.5
Isoleucine	3.5	4.3
Leucine	25.0	31.0
Tyrosine	5.0	6.2
Phenylalanine	7.3	9.0
Histidine	5.8	7.2
Lysine	8.7	10.8
Arginine	9.5	11.8
Tryptophan	2.1	2.6

The molecular weight of the apoferritin subunit was originally determined by sedimentation equilibrium studies with sodium dodecyl sulfate-dissociated protein[23]. A value of 25000–27000 was found on calculating the amount of detergent bound by equilibrium dialysis. We have redetermined the subunit molecular weight of apoferritin by polyacrylamide-gel electrophoresis in sodium dodecyl sulfate[25], gel filtration on calibrated columns of Sepharose 6B in 6 M guanidinium chloride, and sedimentation equilibrium studies on the acetic acid-dissociated protein, after dialysis into glycine buffer to remove bound acetic acid, and on the guanidine-dissociated protein[27]. In all cases we find a value of 18500. When the earlier data is recalculated assuming 1.4 g of detergent bound/g protein[32] a molecular weight of 18000–19000 is obtained[27]. Conformation of the value of 18500 for the subunit molecular weight has been reported from an American laboratory[28].

The apoferritin molecule has a tendency to aggregation which could easily lead to estimates of the molecular weight which are too high. However the use of UV optics in the analytical ultracentrifuge enables molecular-weight determination to be made by sedimentation equilibrium at concentrations of less than 1 mg/ml where there is no evidence of aggregation or other non-ideal behavior. Using a value of 0.731 for the partial specific volume ($\bar{v}$) a molecular weight of 443000 is obtained for the oligomer[33]. Results from a previous sedimentation diffusion study[22] and from X-ray diffraction[15] used a value of 0.747 for $\bar{v}$. With the new $\bar{v}$ these earlier estimates would reduce to 446000 and 443000 respectively. A value of 431000 was found by light scattering[34], and a recently published sedimentation equilibrium study using $\bar{v}$ of 0.732 gave 440000–465000[28]. We can conclude that the apoferritin molecule has a molecular weight of around 445000 and most probably consists of 24 subunits each of molecular weight 18500.

2.4. Primary Structure of Apoferritin

There are few things more boring than a progress report on determination of the primary structure of a protein without the actual sequence itself. The author is fully aware of this, but since it is germane to the arguments to be presented in Section 2.6, we will briefly discuss the present state of sequence studies which are proceeding currently in our laboratory in Berlin. It was established in the early sixties that the apoferritin molecule consisted of subunits and it was concluded on the basis of chemical[23,35,36] and subsequently of crystallographic evidence that the number of subunits was most probably 20. This evidence has recently been reviewed[27,37]. However, it is clear that on the basis of the present physicochemical evidence, the subunit molecular weight of apoferritin is 18500, not 23000–24000. A comparison of the two sets of data for the amino acid analysis of the protein (Table 1) reveals that there ought to be three methionine residues per subunit instead of four and hence following cleavage with CNBr we ought to find three new N-terminal groups. In fact after CNBr digestion we find equimolar amounts of three new end groups, namely, glutamic acid (or glutamine), isoleucine, and glycine[38]. Chromatography of the CNBr digests leads to the isolation of four peptides[39–42] which have amino acid compositions[38,42] whose sum closely corresponds to the amino acid composition of the apoferritin subunit. The molecular weights of these peptides can be readily estimated by chromatography on the same

Sepharose 6B column in 6 M guanidinium chloride as was used for determination of the subunit molecular weight of the protein, and it can be shown that the sum of their molecular weights is in good agreement with the subunit molecular weight[43].

Fingerprinting of tryptic digests of apoferritin reveals 25 peptides[5,35], rather more than would be predicted from the amino acid analysis (Table 1). However, in the course of our sequence studies we have already found several peptides which are the products of partial tryptic digestion, and in one case of non-tryptic digestion[44], which accounts for our finding more tryptic peptides than expected. The N-terminal pentapeptide and C-terminal octapeptide sequences of apoferritin have been determined[45,46]. Determination of the sequence of the tryptic peptides and the CNBr peptides is proceeding steadily.

It has been suggested that apoferritin is inhomogeneous since a heterogeneous pattern of bands has been observed on isoelectric focusing of ferritin and apoferritin in polyacrylamide gels and in sucrose density gradients[47,48]. There is, however, good reason to doubt whether the appearance of multiple bands is necessarily an indication of heterogeneity[49], and it seems that in the case of horse spleen ferritin the apparent microheterogeneity may be an artifact[50,51]. It has also been reported[28] that in dissociating solvents two lower molecular weight components are present which together account for some 10% of the total protein. We have found no evidence for such low molecular weight components under dissociating conditions[27].

2.5. Secondary and Tertiary Structure of Ferritin and Apoferritin

Analysis of ferritin by optical rotatory dispersion (ORD) and circular dichroism (CD) reveals that the content of α-helix is about 50%[52,53]. The spectra obtained are independent of the iron content of the ferritin. Chemical reduction of ferritin to give apoferritin produces a pronounced increase in secondary structure[52,53] as can be seen from the spectra presented in Figure 2. This is in marked contrast to the observations from X-ray crystallographic investigations. Not only does chemically prepared apoferritin crystallize in a form isomorphous with one form of ferritin[15], it has also been found that at low resolution no differences can be detected in the intensities of reflections due to the protein for ferritins of varying iron content and for apoferritin[54] which would indicate that the protein conformation is essentially unchanged. It has been recently reported that native apoferritin prepared by density gradient centrifugation has the same dichroic spectrum as ferritin[29].

Apoferritin is digested more rapidly and to a greater extent by trypsin, chymotrypsin, and subtilisin than is ferritin[5,55,56]. Pepsin and cathepsin D however digest both proteins equally well at pH 3.0, a fact that can be explained by the relatively non-specific nature of these two enzymes. With pepsin at pH 2.5, apoferritin is digested much more effectively than ferritin, and it was suggested

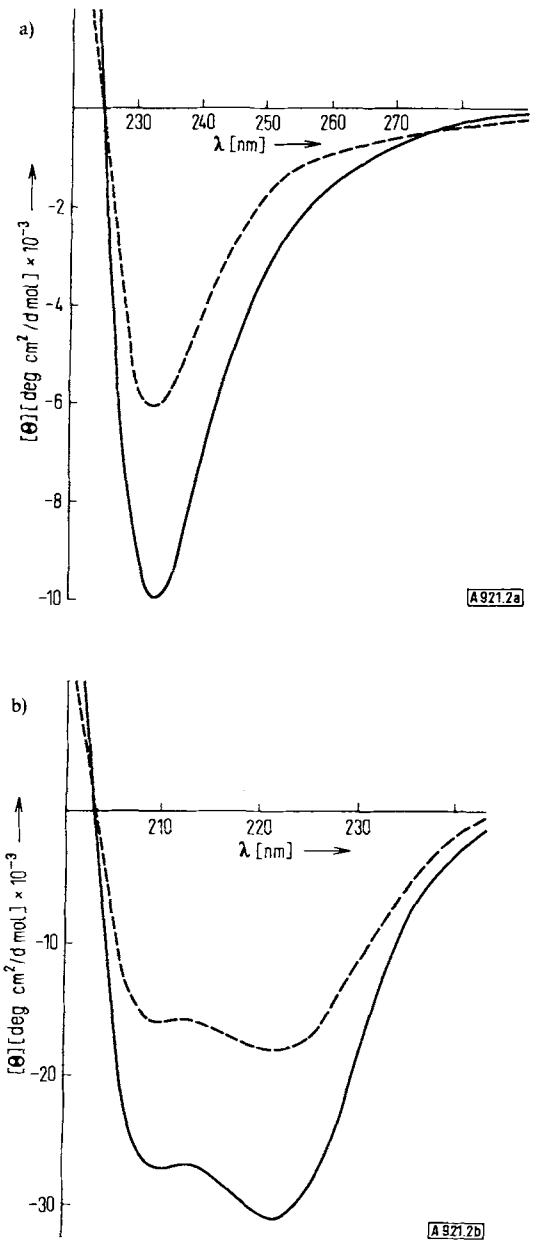

Fig. 2. ORD (a) and CD (b) spectra of ferritin (----) and apoferritin, prepared by reduction with thioglycolate (—). The depths of the trough at 233 nm in (a) and at 222 and 208 nm in (b) are a measure of the content of secondary structure present [52].

that this might reflect a partial unfolding of the apoferritin structure at low pH. An analysis of the effect of pH on the conformation of both proteins using ORD and CD revealed marked changes in the spectra of both proteins in the pH range of 3.1–2.2 which are consistent with a loss of about 10% of their ordered structure[52]. In the case of apoferritin (Fig. 3) marked changes in the near-UV dichroic spectrum were seen which suggest that the environment of the tyrosine and tryptophan residues of the protein changes considerably. The effect of protein denaturants on the secondary structure has been investigated[29] and it was shown that in 7 M guanidinium chloride, pH 7.5, complete disruption of helical segments occurred in ferritin and the protein was broken down into subunits. In contrast, under these conditions little change was seen in the dichroic spectrum of apoferritin. However,

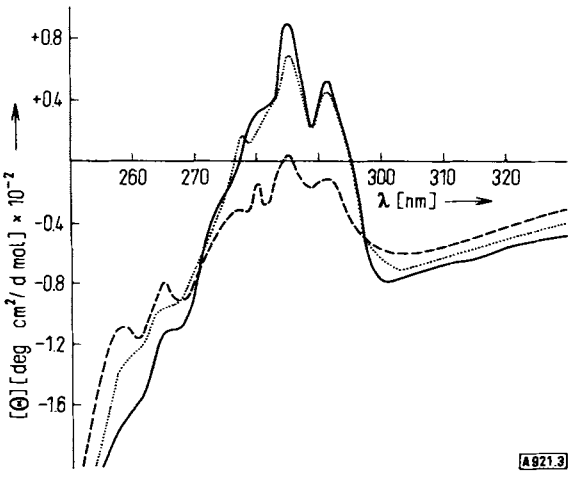

Fig. 3. CD spectra of apoferritin in citrate buffers: (——) at pH 3.11; (-----) at pH 2.80; (— —) at pH 2.50 [52].

at pH 4.5 apoferritin was also dissociated into subunits and unfolded in 7 M guanidinium chloride. Analogous effects were found with 10 M urea, where the native three-dimensional structure of ferritin and apoferritin was unaffected at pH 5.0–8.0 but was disrupted at lower pH values. The optical rotatory properties of ferritin at 233 nm in several organic solvents were similar to the rotations in aqueous solutions[53]. Thus it seems that the disruption of hydrophobic interactions does not induce additional α-helix formation.

2.6. Quaternary Structure of Apoferritin

Early X-ray powder photographs[57] indicated that ferritin and apoferritin were cubic and isomorphous. It was subsequently found by *Hodgkin*[58] and by *Cowan*[59] that single crystals of ferritin are orthorhombic, not cubic, wet unit cell dimensions being $a=130$ Å, $b=130$ Å, $c=184$ Å. The space group $P2_12_12_1$ was derived but it was subsequently concluded that this was not the true space group. A reinvestigation of apoferritin and two crystalline forms of ferritin, A and B[15], showed that all three crystals had identical lattice repeats: wet crystals of apoferritin and ferritin B were face-centered cubic with $a=184$ Å, while ferritin A was pseudocubic, and was truly face centered on only one face. The lattice of ferritin A could be described in terms of an orthorhombic cell with identical dimensions to those found previously. None of the space groups was determined unequivocally from the X-ray data, but it was concluded that the space group of apoferritin was probably F 432, the unit cell containing four molecules. In this case each molecule would have point group symmetry 432 and hence be composed of 24 n subunits, where n is an integer. A possible molecular structure was suggested consisting of 24 subunits situated at the vertices of a snub cube (Fig. 4).

In further investigations of this same cubic form[60] the X-ray photographs were found to contain a mixture of both sharp reflections extending to spacings of 1.0–1.4 Å, and diffuse streaks, characteristic of a structure having "ordered disorder". The existence of this non-uniform diffuse background was interpreted as indicating that although the unit cells repeat with geometric regularity, the internal arrangement was not the same for every unit cell. This situation could readily be produced by nearly

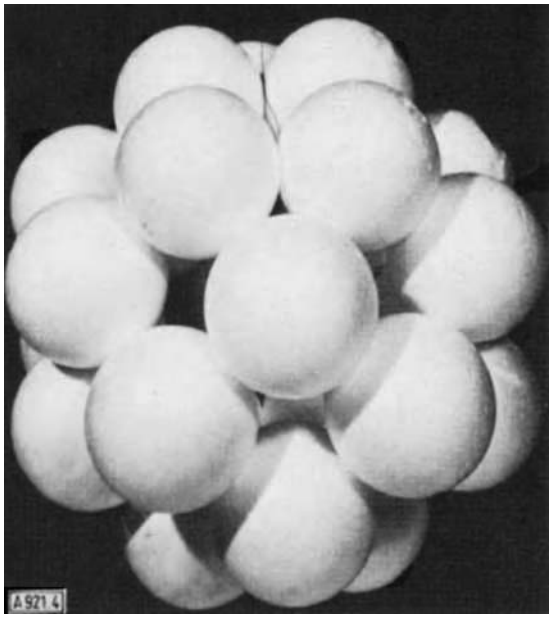

Fig. 4. Photograph of a possible spatial arrangement for a 24-subunit model. The subunits are situated at the vertices of a snub cube ({100} with {111} and {110}). The model shows a rhombohedral-dodecahedral face at the top and a cubic face standing on an apex at the front.

spherical molecules occupying equivalent lattice positions, but not all having the same orientations at corresponding positions of neighboring unit cells. Specifically it was proposed that the apparent 432 symmetry and the diffuse background could be accounted for by molecules with point group symmetry lower than 432 lying on the lattice points, but having several orientations such that the crystal symmetry was produced statistically.

The possibility that apoferritin molecules have 532 symmetry, or pseudo-532 symmetry was suggested by the rather strong intensities near the directions of the non-crystallographic five-fold axes and apparently convincing X-ray diffraction evidence for this pseudo-icosohedral symmetry together with the chemical and physico-chemical data discussed earlier led to the proposal that apoferritin consisted of twenty subunits situated at the vertices of a pentagonal dodecahedron with a small central hole in each pentagonal face. It was noted that certain features of the diffuse parts of the X-ray diffraction pattern were also consistent with this model.

It is clear from the data on the subunit and oligomer molecular weight presented above that a 20 subunit model is no longer likely for apoferritin. Indeed, as has been recently pointed out, the chemical and physico-chemical evidence for the existence of eicosameric structures in general is rather weak[37]. The problem of an eicosameric structure is that the subunits cannot all occupy equivalent positions in the structure, so that there must either be at least two different kinds of subunit, or else the same subunit

must be able to exist in two distinct conformations within the one quaternary structure[37,61]. As we have seen above, no evidence for the existence of more than one type of subunit has been forthcoming to date.

A 24-subunit structure would now seem to be most likely for apoferritin, although the exact arrangement of the subunits must await a more detailed X-ray analysis. *Harrison*'s original suggestion of a structure with 24 subunits distributed at the vertices of a snub cube[15] (Fig. 4) possesses some of the features which would be expected from a structure having icosohedral symmetry. Thus, for example, it gives strong intensities near the non-crystallographic five-fold axis of molecules with 532 symmetry.

3. Function of Ferritin

The principal function of ferritin is to serve as an intracellular iron storage depot particularly in spleen, liver, and bone marrow, in which excess iron can be deposited and from which iron can be mobilized when required. Tissue ferritin is in dynamic equilibrium with plasma iron: the iron in plasma is transported bound to transferrin, a β_1-globulin which has two binding sites, each capable of carrying one atom of ferric iron[62]. It has been demonstrated that transferrin binds to specific receptor sites on the cell membranes of maturing reticulocytes[63,64], and there is considerable evidence that ferritin iron in reticulocytes is utilized for hemoglobin synthesis[65,66]. Ferritin is also found in the mucosal cells of the small intestine and the possibility that it plays a role in the regulation of iron absorption from the intestine has been current for some time. It seems likely that it acts as an iron "curtain", trapping excess iron within the mucosal cell, and so ensuring that it is not absorbed but is lost when the mucosal cell is shed at the end of its life span.

3.1. *In Vitro* Studies on Ferritin Formation

Preliminary investigations showed that incubation of apoferritin in HCO_3^- buffer at pH 7 and 4–6 °C gave a product on air oxidation which could be crystallized with $CdSO_4$ and had an N:Fe ratio of 2.4:1[67]. The importance of this contribution was that it enabled a simple redox model for ferritin formation to be formulated:

$$\text{apoferritin} + Fe^{2+} + O_2 \rightarrow \text{ferritin}$$

It was subsequently reported that oxidation of ferrous ammonium sulfate in the presence of apoferritin either with O_2 in hydrogen carbonate buffer pH 6.8–8.0, with potassium iodate in sodium thiosulfate at pH 5.4–7.4, or with O_2 in imidazole buffer pH 6.7–7.0 gave a product which had the usual red-brown color of ferritin, had a sedimentation coefficient considerably larger than apoferritin, could be seen to have a dense core in the electron microscope, and had an X-ray diffraction pattern similar to native ferritin. In the absence of apoferritin, oxidation led respectively to the formation of α-ferric hydroxide oxide, γ-ferric hydroxide oxide, and a third unidentified product[13]. It was also noted that apoferritin appeared to affect the rate of oxidation of Fe^{2+}

An elaboration of this model was proposed by *Niederer*[68] who postulated that small molecules and ions could penetrate to the interior of the apoferritin molecule through holes in the protein shell. On the inner surface he suggested that apoferritin has active sites which could catalyze the oxidation of Fe^{2+}. The nascent ferric ions would readily form an intramolecular precipitate, which would eventually be too big to escape (Fig. 5).

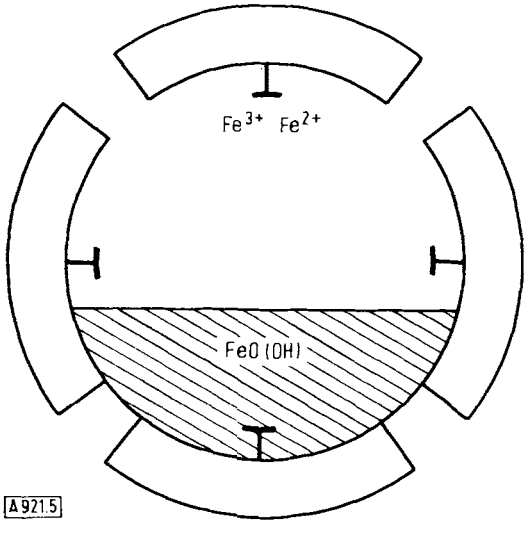

Fig. 5. Model for the formation of ferritin. Ferrous iron is oxidized to the ferric form by a suitable electron acceptor in a reaction catalyzed by active sites on the apoferritin subunits. The ferric hydroxide oxide forms a micelle which eventually becomes too large to escape from the protein shell.

As supporting evidence for this hypothesis it was shown that apoferritin stimulated the oxidation of Fe^{2+}. Treatment of apoferritin with formaldehyde and β-propiolactone, which react with amino groups and histidine residues, and with bromoacetate, a weak histidine alkylating agent, inhibited the iron uptake. Iodoacetamide and tetrazolediazonium chloride were reported to have no effect and Zn^{2+}, which is known to inhibit the *in vivo* formation of ferritin[69], inhibited the reaction strongly.

This process has been intensively studied both in our laboratory in Berlin and by *Harrison* and her colleagues in Sheffield. It has been reported[70] using potassium iodate as oxidant together with thiosulfate in imidazole buffer, pH 7.4, that the kinetics of iron uptake by apoferritin are complex. Apoferritin has a catalytic effect, as does bovine serum albumin, although the product formed is not the same as with apoferritin. We have found that at lower pH values using O_2 as oxidant, normal Michaelis-Menten kinetics are observed and the catalytic effect of other proteins such as lysozyme and bovine serum albumin is practically nil[71]. Carboxymethylation of two cysteine

residues and one histidine residue in each subunit leads to complete loss of catalytic activity[71].

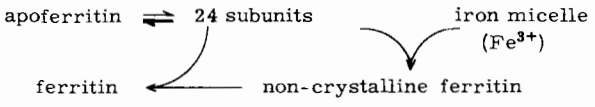

Fig. 6. Formation of ferritin from iron cores and apoferritin subunits. An equilibrium is postulated between apoferritin and its subunits. Ferric iron chelates hydrolyze and polymerize to give iron micelles, which cause a shift in this equilibrium by associating with subunits to form non-crystalline ferritin. This intermediate, lacking the complete protein shell, is rapidly converted to crystallizable ferritin.

Saltman et al.[72] have proposed an alternative model for formation of ferritin, which assumes the assembly of apoferritin subunits around a preformed iron micelle (Fig. 6). It is argued[73] that the chemistry of ferric chelates such as ferric fructose, ferric citrate, and ferric hydroxide nitrate in aqueous solutions is dominated by a tendency to hydrolyze and polymerize, giving soluble micelles which have approximately the same size as the core of full ferritin (70 Å). In the case of ferric hydroxide nitrate[74], the polymer, which has the approximate composition $Fe_4O_3(OH)_4(NO_3)_2$, has magnetic and Mössbauer properties which are very closely similar to those of ferritin. The results of an experiment in which an excess of apoferritin was incubated for various time intervals with the non-crystallizable fraction of ferritin, and the product crystallized from cadmium sulfate solution, showed that in 45 min it was possible to recover 100% of the iron originally present in non-crystalline ferritin as crystalline ferritin. This, together with electron microscopic evidence, is presented as support for the view that non-crystalline ferritin consists of ferritin molecules that lack the full complement of protein subunits, and implies that the presence of the iron micelle causes apoferritin to dissociate into subunits, which can then assemble around the micelle to give ferritin[72]. A recent preliminary report indicates that when an acidic solution of apoferritin subunits is added to natural polymeric iron cores isolated from ferritin, or to various synthetic polymers of ferric nitrate, ferric citrate, ferric fructose, and ferric-ATP, and rapidly neutralized, a product is formed which resembles ferritin in its elemental composition, electrophoretic and sedimentation behavior, and its appearance in the electron microscope[75].

A number of objections to the chelate model have been presented[76]. In the first place the observation that non-crystalline ferritin is deficient in protein subunits is at variance with observations of *Farrant*[9] who found ferritin and non-crystalline ferritin to be identical in electron micrographs. Non-crystalline ferritin has the same Fe:N ratio as the crystalline ferritin from which it was prepared[72] which leads one to conclude that if it contains incomplete protein shells, it must also contain free subunits. Indeed, the model assumes that apoferritin molecules are in equilibrium with the subunits.

There is at present no evidence for the dissociation of apoferritin into subunits under physiological conditions. According to the hypothesis presented in Figure 6, only two intermediates in the formation of ferritin should exist: iron-free apoferritin, and ferritin with the full complement of iron. However in experiments on the biosynthesis of ferritin induced by administration of iron, it was found using [^{14}C]leucine that radioactivity appeared first in iron-poor ferritin, and only after a relatively long period in iron-rich ferritin[77,78]. From this, one would conclude that the newly synthesized apoferritin was gradually filled with iron. *Niederer*[68] has pointed out that if one assumes that iron stabilizes ferritin so that subunit dissociation is very slow from iron rich ferritin by comparison with iron-poor ferritin or apoferritin, then newly-synthesized apoferritin would be incorporated into iron-poor ferritin present in the pre-existing liver ferritin pool rather than into iron-rich ferritin. He briefly reviews results which show that there is a gradual uptake of iron by apoferritin when the product is analyzed by isopycnic centrifugation in an urografin gradient[68]. This leads him to reject the chelate model but he neglects to note that the conditions of iron uptake used by him (see above) are such that the micellar aggregates found by *Pape et al.*[72] would not be formed. It can therefore be concluded that although there have been many criticisms of the chelate model, none of these is completely unequivocal, and the model cannot be excluded on the basis of the present evidence.

3.2. Mobilization of Iron from Ferritin

As was pointed out earlier[4], reduction of the ferric iron of ferritin to the ferrous form can liberate iron from the protein. *Bielig* and *Bayer*[79] showed that it was possible to mobilize iron from ferritin by the use of biological reducing agents such as ascorbate, glutathione, and NADH. However, the rates of mobilization, even with high concentrations of these reducing agents, are very low. In the search for a physiological redox system *Mazur et al.*[80] suggested that xanthine oxidase was responsible for ferritin iron reduction and mobilization in the liver. Such a role for xanthine oxidase had been proposed earlier by *Tanaka*[81], who found that the magnetic susceptibility of a ferritin solution slowly increased on treatment with xanthine oxidase and methylene blue and with reduced diaphorase. The observation that a patient with hemochromatosis, an inherited condition in which there is excessive iron storage, excreted xanthine in the urine, and had a markedly reduced level of liver xanthine oxidase led *Ayzvasian*[82] to propose the linked reduction of ferritin iron with the oxidation of xanthine and hypoxanthine, as outlined in Figure 7. The site for reduction of ferritin iron

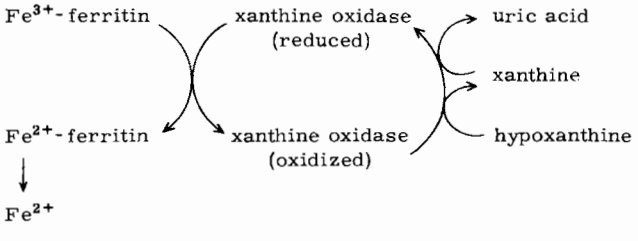

Fig. 7. The possible role of xanthine oxidase in the mobilization of iron from ferritin.

was thought to be the non-heme iron of xanthine oxidase[80]. However, several compounds such as allopurinol (4-hydroxypyrazolo[3,4-*d*]pyrimidine) which severely inhibit xanthine oxidase have little or no effect on iron metabolism[83].

The mobilization of iron from ferritin at rates of physiological significance can be accomplished by using specific low molecular weight chelating agents in the absence of reducing agents[84]. However, the most satisfactory chelating agent used in this study, nitrilotriacetate, is certainly not likely to have any physiological role. Whether a suitable cellular metabolite could function as effectively in non-reductive mobilization of ferritin iron remains to be established.

The possibility that physiologically available reducing or chelating agents might mobilize ferritin iron has recently been tested by us. We find that with the exception of ascorbate at concentrations greater than 200 mM and pH values lower than 5 and cysteine at concentrations greater than 100 mM none of the agents which we have examined either alone or in combination with other reductants or chelators is able to release iron from ferritin at rates which would be significant in the mammalian cell. The same is true for xanthine oxidase, which, in our hands, does not mobilize ferritin iron at all *in vitro*[6].

A specific enzyme activity has recently been found in mammalian liver homogenates, and partially purified by CM-Sephadex chromatography and ultracentrifugation which reductively mobilizes ferritin iron. The enzyme requires NADH and FMN for reduction of ferritin-bound Fe^{3+} to free Fe^{2+} presumably by transfer of electrons from NADH to ferritin. The reaction is reported to be inhibited by O_2, but not by allopurinol, which suggests that the enzyme is not liver xanthine oxidase. The enzyme is very heat-labile and has a pH optimum of 7.2–7.4. Hypoxanthine, succinate, ethanol, and glucose are not effective as electron donors. Preliminary ultracentrifugal studies suggest that the enzyme, for which the name ferriductase is proposed, is located mainly in the soluble fraction of the cell[85].

3.3. Iron Transfer between Ferritin and Transferrin

Transfer of iron from ferritin to transferrin across a semipermeable membrane was demonstrated by *Bielig* and *Bayer* to require ascorbic acid[79]. In the same year it was demonstrated[86] that ferritin containing small amounts of ferrous iron and free SH groups in liver slices could transfer iron to transferrin. It was subsequently found that ATP was specifically required for transfer of iron from transferrin to ferritin by liver slices and homogenates[87]. In a more detailed study using a model system in which the transfer of ^{59}Fe from transferrin to ferritin across a semipermeable membrane was measured, it was established that iron transfer required the presence of both reducing agents and chelating agents[88]. ATP was shown to act as a chelating agent, and not as a source of energy. The process of iron transfer from transferrin to ferritin was thus formulated as involving reduction, chelation, and oxidation as outlined in Figure 8. No specific compound was required

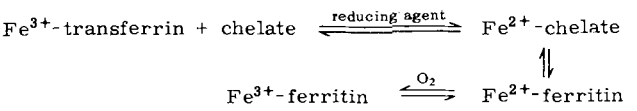

Fig. 8. Model for iron transfer from transferrin to ferritin. Transferrin-bound ferric iron is reduced and chelated, and the ferrous chelate then transfers its iron to ferritin. The ferrous iron is oxidized to the ferric form by molecular O_2.

as chelator, and a number of biologically available chelating agents such as sugars, ATP, ADP, and AMP were found to be effective.

Of the reducing agents that were examined, ascorbate was by far the best. The iron content of the ferritin and transferrin used regulated the amount of transfer that was observed. Transferrin that was 50% saturated or less did not transfer iron. Ferritin took up most iron when it was about 50% saturated with iron. Preliminary experiments have shown that when apotransferrin is dialyzed against ferritin in the presence of reducing and chelating agents, the reverse transfer continues until the transferrin is 40% saturated with iron[89]. Thus both the forward and reverse reactions can be explained by the mechanism outlined in Figure 8.

4. Outlook

From the results which have been briefly reviewed here it can be seen that the study of the structure and function of ferritin is rapidly reaching a phase of intense interest and enormous activity. The establishment of the primary structure of the horse spleen protein together with the identification of those parts of the primary structure which are involved in catalysis of the oxidation of ferrous iron should give great incentive to a reinvestigation of the three-dimensional structure of the protein.

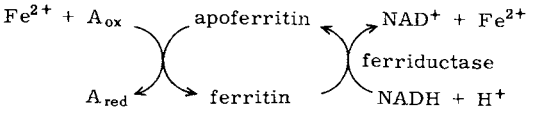

Fig. 9. The insertion of iron into apoferritin from Fe^{2+} is catalyzed by the protein itself in the presence of a suitable oxidizing agent A. Mobilization of iron as Fe^{2+} from ferritin is brought about by an enzyme designated as ferriductase which is NADH-dependent.

The possibility, outlined in Figure 9, that a complete redox system is involved both in insertion of iron into ferritin and in its mobilization from ferritin, opens the way to a detailed analysis of the regulation of these two pathways, and hence as our understanding of these processes grows, to a more rational therapeutic approach to disorders of iron storage. This is particularly crucial at a time when increasing use of transfusion therapy to combat anemia is leading to an ever-increasing number of cases of secondary iron overload (transfusion siderosis). If, as seems increasingly likely, the ferritin iron in reticulocytes is utilized for hemoglobin synthesis[65,66], it becomes even more important to understand the nature of the factors that regulate the dynamic equilibrium between the introduction of iron into ferritin and its mobilization from the

storage form. And if the mechanisms for iron introduction and removal from ferritin involve oxidation and reduction respectively, there can be little doubt that somewhere within the cell a system must exist for oxidation of Fe^{2+} to Fe^{3+} prior to, or simultaneously with, the uptake of iron by transferrin at the cell surface. This system must also be capable of reduction of the ferric iron of transferrin and its delivery within the cell as Fe^{2+}. It is tempting to speculate that the carrier system, which may or may not be enzymic in nature, is located within the cell membrane, acting as a shuttle between the outer and inner surface in the same way as *Margoliash et al.*[90] have proposed for cytochrome C in the inner mitochondrial membrane. The elucidation of this pathway will give us yet more insight into the regulation of the many processes that pass under the general heading of iron methabolism, and into the one small corner with which we have concerned ourselves here.

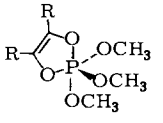
Five-Membered Cyclic Acyl Phosphates, a New Class of Extremely Reactive Phosphorylating Agents

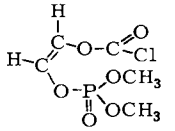
By *Fausto Ramirez, Stephen Glaser, Peter Stern, Paul D. Gillespie,* and *Ivar Ugi*[*]

In the synthesis of phosphate esters, including the polynucleotides, only phosphoryl halides and acyclic mixed anhydrides[**] of phosphoric acid, such as the mixed anhydrides with aryl sulfonic acids[1], have been used. We wish to introduce a new class of versatile, extremely reactive, phosphorylating agents, namely the five-membered cyclic acyl phosphates *(5)*. Frequently, they permit preparation of phosphoric acid esters in fewer steps than with the common reagents used previously.

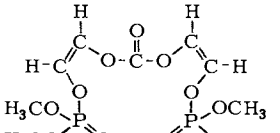


(1), R = H, CH_3, C_6H_5

The reaction of trimethyl phosphite with α-dicarbonyl compounds yields the derivatives of 1,3,2λ⁵-dioxaphosphole *(1)*[2]. *(1)* R = H, undergoes *O*-acylation by phosgene to form *(2)* or *(3)*, respectively[3], depending upon the relative amounts of the reactants, whereas *(1)*, R = CH_3, is *C*-acylated by phosgene (in hexane at 0 °C) to give *(4)* ($\delta^{31}P = +3.0$ ppm, H_3PO_4)[4].

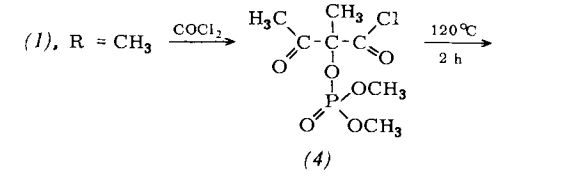


(2)

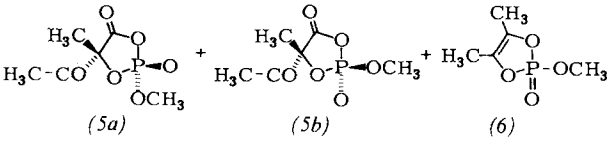


(3)

Upon heating for two hours at 120 °C *(4)* is transformed into a mixture of the diastereomeric cyclic acyl phosphates *(5a)* and *(5b)*, and the known enediol phosphate *(6)*[5] ($\delta^{31}P = -11.6$ ppm, H_3PO_4). The separation of *(5)* and *(6)* can be achieved by short-path distillation *in vacuo*. The prevalent diastereomer *(5b)* ($\delta^{31}P = -2.42$ ppm, H_3PO_4; $\tau = 7.62$, 8.23, and 6.02 ppm; $J_{HP} = 12.0$ Hz, m.p. 82—84 °C) can be obtained in crystalline form, but not the other diastereomer *(5a)* ($\delta^{31}P = -2.66$ ppm (H_3PO_4); $\tau = 7.66$, 8.13, and 6.02 ppm; $J_{HP} = 12.0$ Hz).

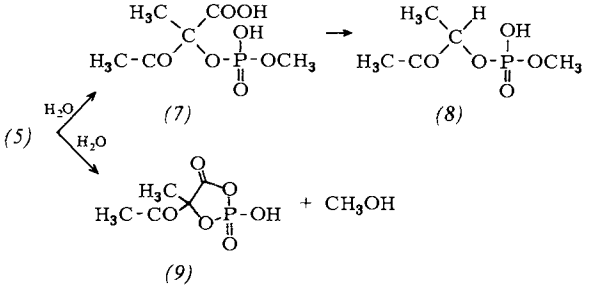


(4)



(5a) *(5b)* *(6)*

The diastereomers *(5b)* and *(5a)* interconvert in the presence of nucleophiles and form an equilibrium mixture of 70 : 30. At 150 °C *(5)* loses CO_2 to form the enediol phosphate *(6)*. In dioxane or $CDCl_3$ solution[***] *(5)* is hydrolyzed rapidly (in <15 s) by one equivalent of water, mainly *via* the intermediate *(7)*, to the acetoin derivative *(8)*; traces of the cyclic hydrogen phosphate *(9)* and methanol are also produced. The intermediate *(7)* is decarboxylated relatively slowly, and its presence can be demonstrated by esterification with diazomethane.



(7) *(8)* *(5)* *(9)*

With primary and secondary alcohols, *e.g.*, methanol, ethanol, benzyl alcohol, and isopropanol, *(5)* reacts very rapidly, with ring-opening and decarboxylation to yield the acetoin derivatives of type *(12)* [alkyl methyl (1-methyl-2-oxopropyl) phosphates]. In $CDCl_3$[***] the reaction with one equivalent of each of the above alcohols is complete in <15 s, whereas under the same conditions the reaction with *tert*-butanol proceeds with $t_{1/2} \approx 135$ s.

The reactivity of *(5)* toward hydroxyl compounds is higher than that of any previously known organophosphorus compound, including the most reactive, enediol phosphate *(6)*[5] ($t_{1/2} \approx 8$ days for the reaction with one equivalent of *tert*-butanol in $CDCl_3$[***]; $t_{1/2} \approx 150$ s for the reaction with one equivalent of water in dioxane. This pronounced reactivity is due to the fact that *(5)* contains a strongly apicophilic leaving group as part of a five-membered ring[6].

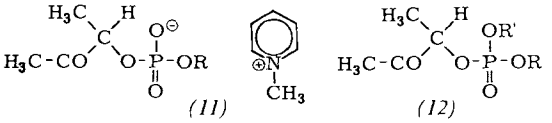
[**] *I.e.*, the P-atom does not belong to a ring.

[***] 0.1 M solution at 24 °C.

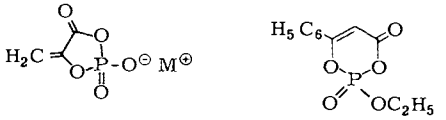
The cyclic acyl phosphate *(5)* *N*-methylates pyridine to yield the salt *(10)*. The structure of *(10)* was demonstrated by the formation of the original cyclic acyl phosphate *(5)* upon treatment with trimethyloxonium tetrafluoroborate. The nucleophilic attack of the pyridine at the methyl carbon of *(5)*—and not at the electrophilic phosphorus atom—can be attributed to the fact that the incipient formation of the C—N bond and the simultaneous rupture of the C—O bond are energetically favored over the initial formation of a P—N bond and cleavage of a P—O bond. This argument is based upon an estimate of activation energies according to *Szabo*'s method[7].



(11) *(12)*

The salt *(10)* undergoes rapid hydrolysis at 25 °C, and yields, after decarboxylation, the compound *(11)*, R = H, while alcoholysis or phenolysis gives *(11)*, R = alkyl or aryl respectively; it reacts substantially faster with primary alcohols than with secondary alcohols.

Since the phosphate esters of α-hydroxy carbonyl compounds are hydrolyzed with particular ease[6], the 3-keto-2-butyloxy groups of the phosphate esters *(11)* and *(12)* can be selectively replaced by hydrogen. Trialkyl phosphates *(12)* are obtained from the compounds *(11)* by known methods. The recyclization of compound *(7)*, and subsequent reaction with an alcohol is an attractive alternative.



(13) *(14)*

To our knowledge, *(5)* is the first isolated example of a five-membered cyclic acyl phosphate. *Clark* and *Kirby*[8] postulated the formation of the five-membered cyclic acyl phosphate *(13)* derived from the enol form of pyruvic acid. *Marecek* and *Griffith*[9] reported the isolation of the six-membered cyclic acyl phosphate *(14)*, derived from benzoyl acetic acid.

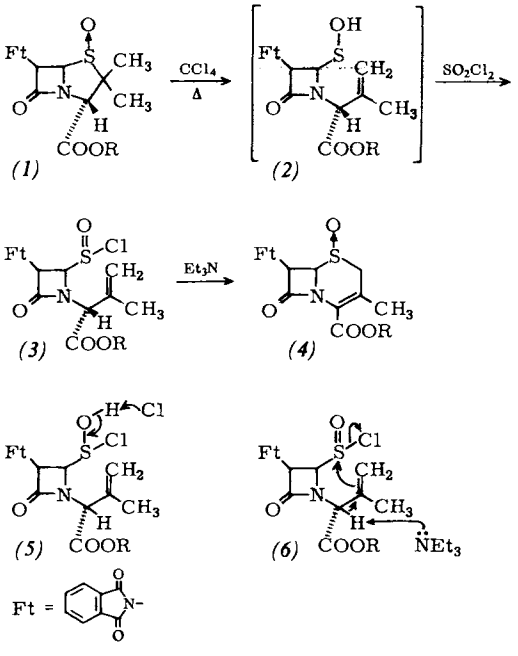
Synthesis of Deacetoxycephalosporin *S*-Oxides by Oxidative Trapping of Sulfenic Acids from Penicillin *S*-Oxides[1]

By *Stjepan Kukolja* and *S. R. Lammert*[*]

Previous studies have shown that sulfenic acids *(2)* can be generated during the heating of penicillin *S*-oxides *(1)*[2]. The high reactivity of sulfenic acids *(2)* has hitherto precluded their isolation, and only intra- and intermolecular trapping of this reactive group has thus far been accomplished. These reactions demonstrated that protonated sulfenic acids exhibit electrophilic properties. However, the sulfur atom in sulfenic acids should also possess some nucleophilic character[3]; to examine this possibility we have studied oxidative trapping of this transient functionality.



(a), R = CH_3; *(b)*, R = *p*-NO_2-$C_6H_4CH_2$

When methyl 7-phthalimidopenicillanate 1-oxide *(1a)* is heated with 1 equiv. of sulfuryl chloride in boiling carbon tetrachloride for 50 min, an inseparable mixture of two isomeric compounds is obtained in a 2 : 1 ratio. The mixture has the composition $C_{17}H_{15}ClN_2O_6$. The IR spectrum exhibits absorptions at 1075 and 1086 cm^{-1}, indicating the presence of a sulfinyl group[4], and it shows the characteristic azetidinone peak at 1800 cm^{-1}. The NMR spectrum of the mixture indicates that the isomers are closely related. The major product gives signals at 117 (s, C—CH_3), 231 (s, CO—OCH_3), 306 (2 vinylic H, and H-3, J = 1.5 Hz), 348 and 356 (d, 2 *cis*-azetidinone H, J = 5.0 Hz), and 470 Hz (4 aromatic H). The minor component shows the following NMR data: 119 (s, 3 H), 228 (s, 3 H), 313 (s, 1 H), 315 (d, 2 H, J = 1.5 Hz), 343 (d, 1 H, J = 5.0 Hz), 356 (d, 1 H, J = 5.0 Hz), and 470 Hz (m, 4 aromatic H).

These data, together with mechanistic considerations, suggest that the mixture consists of two diastereoisomers of the compound methyl 3-methyl-2-(2-chlorosulfinyl-4-oxo-

3-phthalimido-1-azetidinyl)-3-butenoate *(3a)* which are epimeric at sulfur[5].

The following reaction, which confirms the structural assignment of *(3a)*, is also significant for its synthetic utility: Treatment of *(3a)* with 1 equiv. of triethylamine in dichloromethane or benzene for 5 min at room temperature gives methyl 3-methyl-7-phthalimido-3-cephem-4-carboxylate 1-oxide *(4a)*, m.p. 215 °C, in good yield. The NMR spectrum of *(4a)*, with the characteristic AB pattern of the C-2 methylene protons at 212 and 247 Hz ($J = 16.0$ Hz) and the olefinic methyl singlet at 143 Hz, strongly supports a deacetoxycephalosporin structure. Comparison of *(4a)* with authentic sample prepared by oxidation of methyl 3-methyl-7-phthalimido-3-cephem-1-carboxylate[6] with *m*-chloroperbenzoic acid also substantiates this structure.

The reactions described above with the methyl ester *(1a)* were repeated with the *p*-nitrobenzyl ester *(1b)*. Thus, heating *(1b)* with 1 equiv. of sulfuryl chloride in boiling benzene for 55 min affords *(3b)* in almost quantitative yield. After removing the solvent, the yellow foam is redissolved in benzene, 1 equiv. of triethylamine is added, and the solution is stirred at room temperature for 5 min. The crude product, after a workup procedure, is recrystallized from ethyl acetate and yields *(4b)* as tan crystals, m.p. 198—200 °C, in good yield[7].

We believe that the nucleophilic sulfur in the sulfenic acid grouping is attacked by chlorine (electrophilic and/or a free radical) resulting in the intermediate *(5)*, which after elimination of hydrogen chloride gives *(3)*. Although the absolute configuration at sulfur is not established, the stereochemical course of the reaction is most likely controlled by the bulkiness of the neighboring phthalimido group. Cyclization of *(3)* to *(4)* can be explained by the initial abstraction of the α-proton[8] which increases the nucleophilicity of the double bond. Concomitantly the activated sulfinyl group readily undergoes nucleophilic substitution[9] resulting in formation of the S—C bond and ring closure to the six-membered ring system [see *(6)*].

Other pathways are admittedly also conceivable. Thus, expecting that *(3)* might react with the initiating base to eliminate hydrogen chloride and form the sulfine[10], we monitored the reaction of *(3a)* with triethylamine in chloroform by IR and NMR spectroscopy[11]. However, no evidence could be found for the existence of a sulfine intermediate under the applied conditions[12]. In addition, the sulfine is ruled out as a possible intermediate by the fact that 6-epicephalosporin could not be detected as a reaction product.

To our knowledge the preparation of sulfinyl chlorides by the oxidative trapping of the thermolytically-formed sulfenic acids has no precedent. The simplicity and the high yields make this a convenient preparation of sulfinyl chlorides from tertiary sulfoxides. Cyclization of sulfinyl chlorides to cephem *S*-oxides is a new synthetic method for this class of compounds. A combination of the two reactions provides a useful preparative process for deacetoxycephalosporin *S*-oxides.

[11] The sulfines give two strong IR bands at 1019—1078 and 1065 to 1128 cm^{-1} which are assigned to the C=S=O grouping; see ref. [10], p. 109.

[12] First the NMR spectrum of *(3a)* was measured in $CDCl_3$ and then two drops of triethylamine added, the sample tube was shaken for 5 seconds, and immediately the spectrum between 280 and 380 Hz was recorded. The azetidinone protons of *(3a)* disappeared and were replaced completely by those of *(4a)* in less than 1 minute.

Synthesis of 9,10:15,16-Bis(tetramethylene)cyclooctadeca-7,9,15,17-tetraene-2,4,11,13-tetrayne-1,6-dione, a Tetraalkylated Tetradehydro[18]annulenedione[1][***]

By *Koji Yamamoto* and *Franz Sondheimer*[*]

Whether fully conjugated macrocyclic diketones ("annulenediones") behave as quinones is an interesting question. Such compounds appeared to be unknown, although certain benz-fused[2] and bridged[3] [10]annulenediones have been prepared. We now describe the synthesis of the tetraalkylated tetradehydro[18]annulenedione *(5)*, the first macrocyclic example of this type of diketone.

Oxidative coupling of *(1)*[4] with cupric acetate in pyridine for 2 h at 55 °C led to the "dimer" *(2)* as light yellow crystals from chloroform-ethanol, m.p. 184—185 °C[5], in 55% yield. Reaction of *(2)* with a large excess (*ca.* 25 molar equivalents) of ethynylmagnesium bromide[6] in tetrahydrofuran for 16 h at room temperature gave in 95%

[*] Dr. K. Yamamoto [**] and Prof. Dr. F. Sondheimer

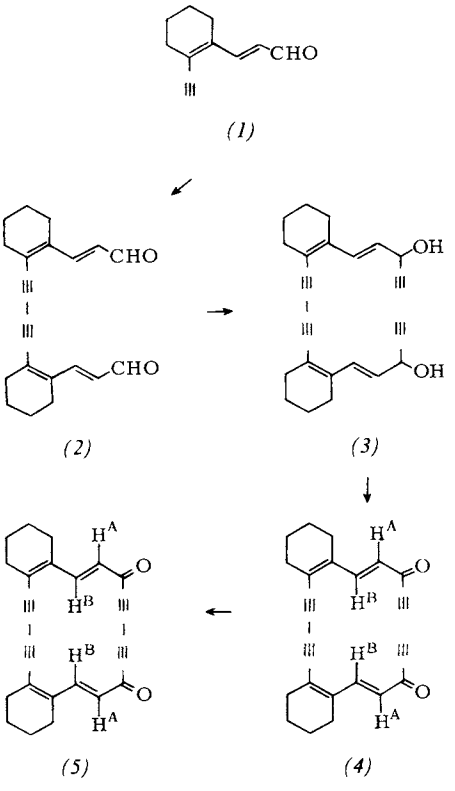
yield the light yellow diol *(3)* (isolated by chromatography on silica gel), presumably as a mixture of *meso* and racemic forms[5]. Oxidation of *(3)* with manganese dioxide[7] in ether for 1 h at room temperature yielded 60% of the diketone *(4)* as yellow prisms from chloroform-pentane, which decomposed on attempted m.p. determination; IR (KBr): 3200 m (C≡CH), 2100 m (C≡C), 1620 s cm^{-1} (C=O); λ_{max} (C_2H_5OH) 236 (ε 22900), 273 (14800), 332 (20200), 372 (19800), 383 (20000), 420 sh nm (14600); NMR (60 MHz, $CDCl_3$): τ 1.78 (2H/d, J = 17 Hz, H^B), 3.69 (2H/d, J = 17 Hz, H^A), 6.58 (2H/s, acetylenic H), 7.4—7.9 (8H/m, allylic CH_2), 8.0—8.5 (8H/m, nonallylic CH_2).



The diketone *(4)* could not be oxidatively coupled with cupric acetate in pyridine, since it is decomposed by pyridine. However, this reaction was carried out successfully by means of oxygen, cuprous chloride, and ammonium chloride in aqueous ethanol and benzene (2 h at 65 °C). Chromatography on silica gel and crystallization from chloroform-pentane then gave the cyclic diketone *(5)* in 25% yield [as well as 50% of recovered *(4)*] as relatively stable bright red needles, which decomposed on attempted m.p. determination.

The fact that *(5)* is the cyclic "monomer" was shown by the mass spectrum (strong molecular ion peak at *m/e* 364). The IR spectrum [2140 m (C≡C), 1625 s cm^{-1} (C=O)] was similar to that of *(4)*, except for the absence of the 3200 cm^{-1} (C≡CH) band. In the electronic spectrum of *(5)* [λ_{max} (C_2H_5OH) 275 (ε 9500), 293 (16900), 312 (29000), 333 (29400), 460 nm (2900), with absorption >550 nm], the most intense maxima were shifted hypochromically compared with those of *(4)*, but the highest wavelength band was shifted bathochromically.

The NMR spectrum of *(5)* (60 MHz, $CDCl_3$) showed resonances at τ 0.94 (2H/d, J = 17 Hz, H^B), 3.82 (2H/d, J = 17 Hz, H^A), 7.4—7.9 (8H/m, allylic CH_2), and 8.1—8.5 (8H/m, nonallylic CH_2). The main difference in the NMR spectra of *(4)* and *(5)* [except for the acetylenic proton band in *(4)*] is the downfield shift of *ca.* 0.8 ppm of the "inner" H^B proton resonance in *(5)* as compared to *(4)*. This is presumably due to the fact that H^B in the relatively rigid structure *(5)* is deshielded by the surrounding ethylenic and/or acetylenic bonds to a greater extent than in *(4)*, where free rotation about the single bonds can take place[8].

Experiments are now in progress to obtain information regarding the possible quinonoid nature of *(5)*.

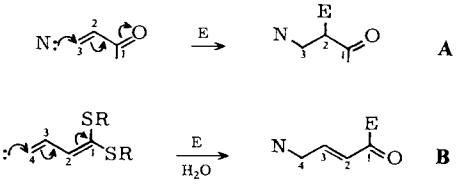
"Michael-type" Addition to Conjugated Ketene Thioacetals[**]

By *Dieter Seebach, Michael Kolb,* and *Bengt-Thomas Gröbel*[*]

By Michael addition we understand the synthetically most valuable, nucleophilic attack on C-3 of the chain of an α,β-unsaturated carbonyl compound (process **A**, where the



electrophile E is usually a proton). We here describe the first examples of the complementary process **B**, in which a nucleophile adds to C-4 of a carbonyl derivative.

The dienes *(1)*, *(3)*, *(7)*, and *(9)* can be prepared in high yields from 2-lithio-2-(trimethylsilyl)-1,3-dithiane[11] and α,β-unsaturated aldehydes (acrolein or crotonaldehyde) or ketones (methyl vinyl ketone or cyclohexenone[11]) and react with alkyllithiums in the above-mentioned sense in THF at −80 to −20 °C. In this way, by successive addition of *n*-butyllithium and methyl iodide we obtained the thioacetals of α,β-unsaturated methyl ketones *(2)*, *(4)*,

[*] Prof. Dr. D. Seebach, Dipl.-Chem. M. Kolb, and Dipl.-Chem. B.-Th. Gröbel

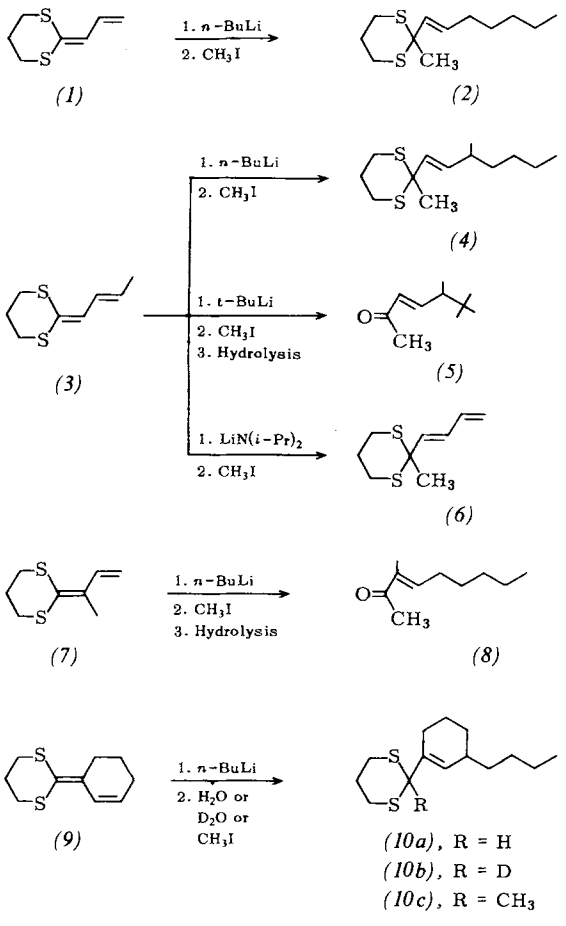
63 Giessen, Ludwigstrasse 21 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie; *B.-Th. G.* and *M. K.* thank the Studienstiftung des Deutschen Volkes for stipendia.

and *(10c)* in almost quantitative yields; protonolysis or deuterolysis of the primary adducts led similarly to the aldehyde derivatives *(10a)* and *(10b)*, respectively.



Neutral hydrolysis of the thioacetals by mercuric chloride and oxide in methanol afforded the free carbonyl compounds, *e.g. (5)* from *(3)*, *tert*-butyllithium, and methyl iodide, also *(8)* from *(7)*, *n*-buthyllithium, and methyl iodide.

Obviously, nucleophilic addition of butyllithium occurs even if, as in *(3)*, *(7)*, and *(9)*, the diene contains allylic hydrogen atoms that are removable as protons. That these atoms can be removed by a suitable base (lithium diisopropylamide) is shown by conversion of *(3)* into *(6)* which is a masked acylbutadiene of interest for Diels-Alder reactions.

The new compounds gave correct elemental analyses; according to NMR analysis (see Table 1; 16Hz-*trans*-coupling), the double bonds in the products have the *trans*-configuration shown in the formulas.

The results described are a valuable extension of the synthetic utility of metalated thioacetals: for instance, orienting experiments show that other alkyllithium compounds behave like butyllithium; the ketene thioacetals used are accessible by a reaction of large scope, and of course[2] the methyl iodide may be replaced by many other electrophiles.

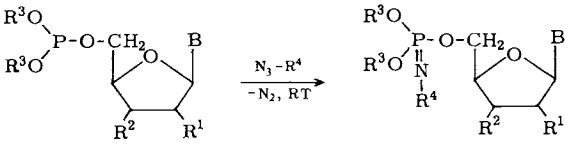
Imidophosphates as New Nucleotide Derivatives

By *Gerhard Baschang* and *Vratislav Kvita*[*]

Although phosphoric diester amides are obtained from trialkyl or triaryl phosphites and aliphatic azides[1,2], the analogous reaction with sulfonyl, phosphoryl or acyl azides gives trialkyl or triaryl imidophosphates[3]. We have prepared compounds *(2)* of this type from 5′-phosphorous esters *(1)* of uridine, cytidine, and thymidine[4] and the azides R^4N_3 (see Table 1).



(1) *(2)*

This reaction proceeds quantitatively when an excess of azide is used at room temperature. We prepared the nucleoside 5′-phosphite esters *(1)* from the corresponding protected nucleoside derivatives and chlorophosphites in the presence of 2,6-lutidine; they were not isolated but were used directly for further work. 5′-Imidophosphates of adenosine are unstable; they decompose with loss of the

phosphate group to give a salt of the adenosine cyclonucleoside.

General procedure:

2-Chloro-5,5-dimethyl-1,3,2-dioxophosphorinane or another chlorophosphite (1.5–2 equivalents) is added dropwise with cooling (10–20 °C) to a mixture of a 10% solution of the protected nucleoside in dioxane and 2 equivalents of 2,6-lutidine. After 15 h at room temperature the mixture is treated with the azide (3 equivalents; see Table 1) and set aside for a further 15 h until nitrogen evolution is complete. The precipitated lutidinium chloride is then removed, the filtrate is evaporated in a vacuum and the residue is chromatographed on silica gel 60 (Merck) with the solvent listed in Table 1.

New Derivatives of Thymidine 3′,5′-Cyclophosphate

By *Gerhard Baschang* and *Vratislav Kvita*[*]

Extension of the reaction of sulfonyl, phosphoryl, and acyl azides with trialkyl phosphites to nucleoside phosphorous esters opened a simple and mild route to new nucleotide derivatives[1] that interested us because of their presumed stability towards phosphatases. We expected the same properties from the thymidine 3′,5′-cyclophosphate derivatives *(2)*—*(5)* that we prepared from thymidine by way of its 3′,5′-cyclophosphite *(1a)*.

Thymidine was treated with $RP[N(CH_3)_2]_2$ in dioxane at 80 °C or in dioxane in the presence of CO_2 at 20—50 °C, yielding compounds of type *(1)*. If alkoxybis(dimethylamino)phosphanes are used in place of tris(dimethylamino)-phosphane, the yield of cyclophosphite *(1)* is increased from 20% to about 40% (determined spectrophotometrically). The cyclophosphites were not isolated because of their sensitivity to hydrolysis, but were brought at once into further reaction.

On oxidation with $KMnO_4$, hydroperoxides or peroxy acids (sometimes after replacement of the dimethylamino group by an alkoxy or aryloxy group), *(1a)* afforded the thymidine 3′,5′-cyclophosphates *(3)*—*(5)* or on oxidation by methylsulfonyl azide the corresponding imidophosphate *(2)* (see Table 1). Replacement of the dimethylamino group of *(1a)* by alkoxy groups on reaction with alcohols and CO_2 yielding compounds of type *(6)* by way of a carbamoyl phosphite is known[2] and occurs, as we found, also very readily with phenols.

[a] All the compounds gave correct elemental analyses and were characterized by NMR spectra (100 MHz).
[b] The UV spectra were measured with a Beckman DBG instrument.
[c] Not corrected.
[d] Total yield thymidine → *(1a)* → *(6)* → product.
[e] Preparative chromatography on silica gel 60 (Merck).

To our knowledge it was not possible to obtain nucleoside 3',5'-cyclophosphoric esters by the methods previously recorded.

The stability toward phosphatases: Compounds *(2)*—*(5)* were incubated with rat liver homogenate and tris buffer pH = 7.2 at 37 °C. *(4)* is sensitive to hydrolysis and was cleaved; *(2)*, *(3)*, and *(5)* were stable.

Thymidine 3',5'-cyclo(dimethylamino)phosphite (1a)

Tris(dimethylamino)phosphane (0.5 ml) is added to a suspension of thymidine (1.2 g) in anhydrous dioxane (50 ml), and the mixture is heated slowly with stirring to 80 °C and kept for 8 h at that temperature. The resulting solution can be treated directly with methanesulfonyl azide to afford *(2)*. For oxidation to *(3)* and *(4)* the dioxane solution is evaporated in a vacuum and *(1a)* is extracted at room temperature by ethyl acetate.

Thymidine 3',5'-cyclo(dimethylamino)-N-(mesylimido)-phosphate (2)

Methanesulfonyl azide (2 equivalents) is added to a dioxane solution of *(1a)* which is then set aside at room temperature for 15 h and finally evaporated to dryness in a vacuum. The residue is chromatographed (see Table 1); *(2)* is eluted first.

Thymidine 3',5'-cyclo(dimethylamino)phosphate (3)

m-Chloroperoxybenzoic acid (1.1 equivalents), followed after 10 min by 2,6-lutidine (1.1 equivalents), is added to an ethyl acetate solution of *(1a)*, which is then evaporated in a vacuum. The residue is chromatographed (see Table 1), *(3)* being eluted first.

Thymidine 3',5'-cyclo(p-acetoxyphenyl)phosphate (4)

p-Acetoxyphenol (3 equivalents) is added to an ethyl acetate solution of *(1a)*, into which CO_2 is then led at room temperature for about 40 h. Next *tert*-butyl hydroperoxide (1.1 equivalents) is added and the mixture is evaporated in a vacuum. The residue is chromatographed, the excess of *p*-acetoxyphenol being eluted before the *(4)*.

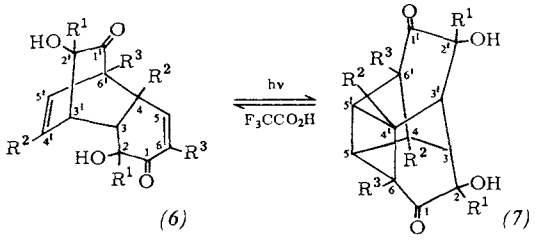
(4), probably *via* intermediate 2,4-cyclohexadienones *(2)* and subsequent $[_{\pi}4_s + _{\pi}2_s]$ and $[_{\pi}2_s + _{\pi}2_s]$ cycloadditions[1].

Although cyclohexadienones easily rearrange photochemically[2] and undergo ring opening by the addition of solvents[3], we failed to detect *(2)* as an intermediate by these reactions. However, the first direct evidence for the intermediacy of 2,4-cyclohexadienones *(2)* was provided by flash photolysis in the presence of dienophiles.

When a solution (0.4 mM) of *N*-chloroacetyltyramine *(1a)* in ethanol-water (1:9) was flash-photolyzed at room temperature[4], a transient absorption at $\lambda_{max} = 325$ nm was observed, which must be due to the 2,4-cyclohexadienone *(2a)*[4]. The decay curve followed second-order kinetics ($k = 5.3 \times 10^3$ l mol^{-1} s^{-1}). The relatively large rate constant indicates rapid thermal dimerization under steady-state irradiation without photolysis of the cyclohexadienone. Compounds *(1b)* and *(1c)* gave similar results [*(2b)*: $\lambda_{max} = 333$ nm, $k = 2.0 \times 10^3$ l mol^{-1} s^{-1}. *(2c)*: $\lambda_{max} = 339$ nm, $k = 1.1 \times 10^3$ l mol^{-1} s^{-1}].



(6) *(7)*

(6a), $R^1, R^3 = CH_3$, $R^2 = H$ [7]
(6b), $R^1, R^2, R^3 = CH_3$ [7]
(6c), $R^1 = CH_2Cl$, $R^2, R^3 = H$, m.p. 175—176 °C (dec.)
(6d), $R^1, R = CH_3$, $R^3 = H$

(7a), [1]
(7b), m.p. 246—248 °C (73%)
(7c), m.p. 228—229 °C (38%)
(7d), m.p. 226—227 °C (82%)

The second proof was chemical: When *(1b)* was irradiated with a 10-W low pressure lamp in the presence of 2 equivalents of *N*-ethylmaleimide a Diels-Alder adduct *(5b)* was isolated in 29% yield accompanied by *(4b)* (17%). The structure of *(5b)* (m.p. 161—163 °C) was easily confirmed by mass and NMR spectra.

The photolysis of *(1d)* gave unidentified products with a trace of *(4d)*, detectable by mass spectrometry [410 (M^+)]. The steric hindrance of the methyl group on C-3[5] makes *(2d)* a less reactive dienophile and renders formation of the dimer *(4d)* commensurately more difficult, though *(2d)* is detectable by flash photolysis ($\lambda_{max} = 340$ nm). Interestingly, the 2,3-dimethyltyramine *(1e)* formed two dienones *(2e)-A* and *(2e)-B*, which acted both as diene and dienophile, respectively, to give the dimer *(4e)* (m.p. 296—298 °C, dec.) in 35% yield.

The presence of *(3)* is suggested by analogy with the same type of cage compound obtainable by irradiation of a simple dienone dimer[1,6]. In addition we have now obtained *(3)* from *(4)* by a novel acid-catalyzed reversion reaction. When *(4b)* was digested with trifluoroacetic acid for 1 h at room temperature, *(3b)* (m.p. 292—295 °C) was isolated in 80% yield [^{1}H-NMR (D_6-DMSO, 120 °C[7]): $\delta = 5.14$ (1 H/s, —C=CH—), 5.94 (1 H/s, —CO—C=CH—); mass: 410 (M^+); UV (CH_3OH): $\lambda_{max} = 250$ nm ($\varepsilon = 5100$)].

Under similar conditions *(4e)* also gave *(3e)* (m.p. 315—317 °C, dec.) in 85% yield, whereas *(4a)* and *(4c)* remained unchanged after standing overnight in trifluoroacetic acid. However, on refluxing for 22 h, *(4c)* gave *(3c)* (m.p. > 320 °C) in 70% yield.

Among the model cage compounds *(7a)*, *(7b)*[6], *(7c)*, and *(7d)*[6] readily obtained photochemically from the corresponding dienone dimers[8,9], *(7b)* reverted to *(6b)* quantitatively within 5 min[10], and *(7d)* to *(6d)* in 80% yield after 30 min in CF_3CO_2H. Yet *(7a)* and *(7c)* gave no trace of *(6a)* and *(6c)*, even after refluxing for 17 h. It would appear that the stabilization of a carbonium cation at C-4' determines the ease of cleavage in this acid-catalyzed reversion reaction. In addition, a substituent at C-6 in *(7)* accelerates the reaction, probably because of steric repulsion between alkyl substituents at C-4' and C-6. A detailed kinetic analysis is now in progress.

Irradiation of the enones *(3b)*, *(3c)*, and *(3e)* regenerated the photodimers *(4b)*, *(4c)*, and *(4e)* in yields of 87, 84, and 77%, respectively. Finally, pyrolysis of *(3b)* in the presence of a ten-fold excess of *N*-ethylmaleimide gave *(5b)* in 13% yield, thus affording additional evidence for the intermediacy of the 2,4-cyclohexadienone *(2b)*.

N-Sulfenylamino Acid *N*-Carboxyanhydrides

By *Hans R. Kricheldorf*[*]

Although the attempted acylation of amino acid *N*-carboxyanhydrides (NCA's) with carbonyl, sulfonyl and phosphoryl chlorides fails and silylation leads to rearrangement of the anhydride ring[1-3], α- and β-amino acid NCA's can be rapidly and quantitatively acylated by reactive sulfenyl chlorides. In this connection particular interest attaches to *o*-nitrophenylsulfenyl (NPS) derivatives because the *o*-nitrophenylthio group can be removed under mild conditions[4-6].

Unlike the unsubstituted NCA's, the NPS-NCA's *(1)* to *(5)* (Table 1) cannot be polymerized and thus are appreci-

ably more stable on storage, but they decarboxylate more or less rapidly when melted. The electrophilic reactivity of the carbonyl group is similar to that of the parent unsubstituted NCA's. For example, NPS-amino esters *(6)* are obtained by reaction with alcohols, NPS-amino amides *(7)* from amines, and (silyloxycarbonyl) NPS-amino amides *(8)* from *N*-silylated amines. NPS-NCA's are useful for peptide synthesis because their preparation is free from racemization, their reactivity is suitable, and these activated amino acid derivatives crystallize well.

The IR spectra of all the NPS-NCA's in KBr show a usually short, broad band at 2.8—2.9 μm (3440—3540 cm^{-1}) and two carbonyl bands, these being at 5.40 μm (1850 cm^{-1}) and 5.60 μm (1785 cm^{-1}) for *(1)*, n = 1, at 5.48 μm (1825 cm^{-1}) and 5.70 μm (1755 cm^{-1}) for *(1)*, n = 2, at 5.55 μm (1800 cm^{-1}) and 5.70 μm (1755 cm^{-1}) for *(2)*—*(4)*, and at 5.63 μm (1780 cm^{-1}) and 5.75 μm (1740 cm^{-1}) for *(5)*.

NPS-L-Phenylalanine-NCA (1c)

L-Phenylalanine-NCA (0.1 mol) and *o*-nitrophenylsulfenyl chloride (0.1 mol) are dissolved in anhydrous ethyl acetate (300 ml) or THF, and triethylamine or 4-methylmorpholine (0.1 mol) is added dropwise with ice-cooling. After 30 min the solution is filtered and most of the solvent evaporated in a vacuum. Addition of carbon tetrachloride/light petroleum with ice-cooling affords crystalline *(1c)* (32 g, 93%).

NPS-D,L-Valine amide

A solution of NPS-valine-NCA *(1b)* (0.025 mol) in anhydrous ethyl acetate (100 ml) is stirred with a solution of NH_3 (*ca.* 0.03 mol) in THF (50 ml) for 5 min at 25 °C and the mixture is thereafter heated for 5 min at the boiling point. The solution is then shaken with 5% citric acid solution; the organic phase is separated, dried and evaporated, yielding a crystalline product (6.2 g, 92%) of m. p. 166 to 168 °C.

NPS-L-Phenylalanylglycine

A solution of NPS-L-phenylalanine-NCA *(1c)* (0.025 mol) in anhydrous ethyl acetate is mixed with one of *N*-(trimethylsilyl)glycine trimethylsilyl ester (0.025 mol) in anhydrous dioxane (80 ml) and the whole is boiled for 2 min. The mixture is then shaken with a concentrated ammonium sulfate solution (causing evolution of CO_2). On evaporation and cooling of the dried organic phase a crystalline product (8.8 g, 94%) separates having m. p. 185—187 °C and $[\alpha]_D^{20} = 30.5° \pm 0.5°$ (m.p. 188—190 °C, $[\alpha]_D^{20} = 32°$[4]).

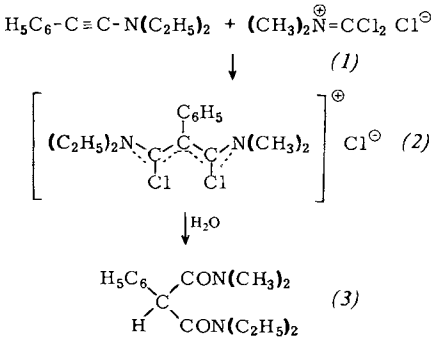
"Biuret Trichlorides" from *N*-Dichloromethylene-*N*,*N*-dimethylammonium Chloride and Dimethylcyanamide[1]

By *Zdenek Janousek* and *Heinz Günter Viehe*[*]

Electron-rich multiple bonds such as in enamines[2] and ynamines[3] very readily undergo addition reactions with *N*-dichloromethylene-*N*,*N*-dimethylammonium chloride ("phosgeneimmonium chloride") *(1)*. Thus diethylaminophenylacetylene and *(1)* form 1,3-dichlorotrimethinecyanine *(2)*[4], which on hydrolysis produces the phenyl malonic diamide derivative *(3)*.



H_5C_6-C≡C-N$(C_2H_5)_2$ + $(CH_3)_2\overset{\oplus}{N}$=$CCl_2$ $Cl^{\ominus}$ *(1)*

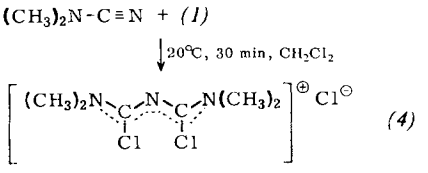
$(C_2H_5)_2N$, C_6H_5, $N(CH_3)_2$, Cl, Cl $Cl^{\ominus}$ *(2)*

H_2O

H_5C_6, $CON(CH_3)_2$, H, $CON(C_2H_5)_2$ *(3)*

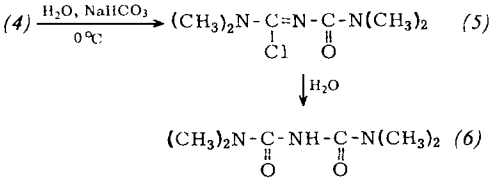
[*] Dr. Z. Janousek and Prof. Dr. H. G. Viehe
Laboratoire de Chimie Organique, Université de Louvain
96, Naamsestraat, B-3000 Louvain (Belgium)

Dialkylcyanamides are electron-rich nitriles and react with *(1)* analogously to ynamines. A smooth addition occurs even at room temperature in methylene chloride solution to give almost quantitative yields of the new 1,3-dichloro-2-azatrimethinecyanines *(4)*, which may be considered as "biuret trichlorides"

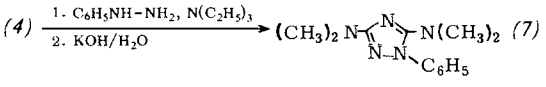


(4)

The hydrolysis of *(4)* leads under mild conditions to N^1,N^1-dimethyl-N^2-(dimethylcarbamoyl)chloroformamidine *(5)* and subsequently to the expected biuret derivative *(6)*.



Like *(2)*, the new azacyanine *(4)* is a versatile bis-electrophilic reagent, particularly for the synthesis of heterocycles. Thus reaction of *(4)* with phenylhydrazine gives the new 1,2,4-triazole derivative *(7)* in 93% yield.



N,N,N',N'-tetramethyl-1,3-dichloro-2-azatrimethinecyanine (4):

Dimethylcyanamide (1.29 g, 18.5 mmol) is added at 20 °C to a stirred suspension of *(1)* (3.0 g, 18.5 mmol) in dry methylene chloride (15 ml). The majority of the solvent is distilled off and the residue treated with about 20 ml of dry ether, whereupon 3.29 g (93%) of *(4)* precipitates as colorless crystals (m.p. 157—161 °C (dec.)) which are stable in a dry atmosphere. NMR ($CDCl_3$): $\delta = 3.59$ and 3.64 ppm; UV (CH_2Cl_2): $\lambda_{max} = 282$ nm ($\varepsilon = 32000$).

N^1,N^1-Dimethyl-N^2-(dimethylcarbamoyl)chloroformamidine (5):

Azacyanine *(4)* (2.32 g, 10 mmol) dissolved in CH_2Cl_2 (20 ml) is hydrolyzed with H_2O (4 ml) and an excess of $NaHCO_3$ for 2 h at 0 °C. The organic phase is dried over $MgSO_4$ and fractionated to give 1.26 g (71%) of *(5)* as a colorless oil (b.p. 120 °C/0.7 torr), which is soluble in water. NMR (CCl_4): $\delta = 2.86$ and 3.14 ppm (two s); IR (film): $\nu = 2925$, 1640, 1485, 1438, 1457, 1260, and 1170 cm^{-1}; mass spectrum: 177 (M^+), 133, 105, 72.

3,5-Bis(dimethylamino)-1-phenyl-1,2,4-triazole (7):

A mixture of phenylhydrazine (1.08 g, 10 mmol) and triethylamine (3.4 g) is added to a stirred solution of *(4)* (1.97 g, 8.5 mmol) in dry methylene chloride (40 ml) over a period of two hours at room temperature. After refluxing for a further hour, the mixture is cooled to −10 °C and treated with concentrated aqueous potassium hydroxide (10 ml). The organic phase is separated, dried over K_2CO_3 and the crude *(7)* distilled. *(7)* (b.p. 122 °C/0.3 torr; yield 1.83 g (93.4%)), is a colorless oil which solidifies at ambient temperature (m.p. 75—77 °C (from water)). NMR ($CDCl_3$): $\delta = 2.75$, 2.96 (12H/2 s), 7.20—7.70 ppm (5H/br); IR (film): $\nu = 1580$, 1545, 1500, 1410, 1376 cm^{-1}; mass spectrum: 231 (M^+).

Mechanism of Cleavage of Diethyl Ether by Alkyllithium Compounds: Differing Mechanisms of Decomposition of α- and β-Deuterated Diethyl Ether[**]

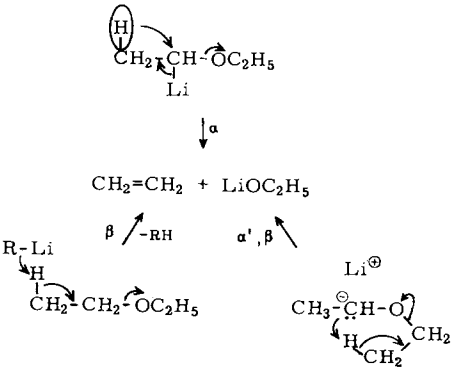
By *Adalbert Maercker* and *Wolfgang Demuth*[*]

Decomposition of diethyl ether by alkyllithium compounds primarily occurs according to eq. (1)[1]. α-Elimination has been discussed as the mechanism of this reaction, by analogy with findings for dimethyl ether, but this has not been proved[1]. We recently observed that the solution contains higher alkyllithium compounds soon after the beginning of the decomposition, these being formed in a secondary reaction[2] whereby the ethylene produced is partially inserted into the lithium-carbon bond of still unused organolithium compound [eq. (2)].

$$RLi + (C_2H_5)_2O \rightarrow RH + CH_2{=}CH_2 + LiOC_2H_5 \quad (1)$$

$$RLi + n CH_2{=}CH_2 \rightarrow R(CH_2{-}CH_2)_nLi \quad (2)$$

In principle, three mechanisms have to be considered for the primary step in the decomposition of diethyl ether by organometallic compounds: α-elimination as for dimethyl[1] and butyl methyl ether[1,3], β-elimination as for methyl 1-methylheptyl ether[4] and finally α', β-elimination



(3)

as for benzyl ethyl ether[5, 6]. All three mechanisms would lead to the same products from diethyl ether [eq. (3)], so it is not remarkable that for this ether cleavage both β-elimination[7] and primary metalation at the α-position[8] have been discussed, and recently even α', β-elimination[9].

To clarify the cleavage mechanism we have synthesized both the specifically α- and the specifically β-labeled diethyl ether in high purity and yields of up to 80%, using a specially developed apparatus[10]. In order to be able to follow the reaction by NMR spectroscopy we chose perdeuterioethyllithium as the organometallic component, which we prepared in our microapparatus[11] directly in the NMR tube from C_2D_5Br and lithium powder under argon at −35 °C in α- or β-deuterated diethyl ether. When cleavage was complete we hydrolyzed the products and studied them additionally by gas chromatography and by mass spectrometry.

It was found that α-deuterated diethyl ether was cleaved by perdeuterioethyllithium as fast as the undeuterated ether, and that this occurred by β-elimination. The ethylene produced, which had reacted almost quantitatively according to eq. (2), must have been exclusively $CH_2{=}CD_2$, as was shown by the broadened singlet signals at $\tau = 11.0$ ($-CD_2CH_2Li$) and 8.7 ($-CH_2CD_2Li$), so that α-elimination is excluded from consideration [eq. (4)].

This was confirmed by the mass spectra of the hydrocarbons produced by the cleavage—they consisted to more than 99% of *n*-alkanes with an even number of C atoms and mass numbers $[35 + n \cdot 30]$ ($n = 1$ to 12). The hydrocarbons $C_2D_5(C_2D_2H_2)_nH$ up to eicosane ($n = 9$) were also detected by gas chromatography. The alcohol obtained after hydrolysis in the aqueous phase was doubly deuterated; the appearance of worthwhile amounts of $CH_3CDHOLi$ and thus α',β-elimination were already excluded by NMR spectroscopy.

$$C_2D_5Li + (CH_3CD_2)_2O \xrightarrow{\beta} C_2D_5H + CH_2{=}CD_2 + CH_3CD_2OLi$$
$$\xrightarrow{\alpha} C_2D_6 + CH_2{=}CDH + CH_3CD_2OLi \quad (4)$$
$$\xrightarrow{\alpha',\beta} C_2D_6 + CH_2{=}CD_2 + CH_3CDHOLi$$

$$C_2D_5Li + (CD_3CH_2)_2O \xrightarrow{\beta} C_2D_6 + CH_2{=}CD_2 + CD_3CH_2OLi$$
$$\xrightarrow{\alpha} C_2D_5H + CD_2{=}CDH + CD_3CH_2OLi \quad (5)$$
$$\xrightarrow{\alpha',\beta} C_2D_5H + CH_2{=}CD_2 + CD_3CDHOLi$$

Because of the isotope effect[12], cleavage of the β-deuterated diethyl ether occurs 4 to 5 times more slowly (4 months at 35 °C), three mechanisms coming simultaneously into play [eq. (5)]. The cleavage occurs this time predominantly by an α',β-mechanism (55—60%), and the β-elimination, at *ca.* 35%, retreats far into the background. Of particular interest is the finding that 5—10% of α-elimination also occurs; this is proved by the fact that an average of one in about every ten ethylene molecules that are inserted into the lithium-carbon bond according to eq. (2) has a mass of 31 ($CD_2{=}CDH$). α- and α',β-Elimination together are about twice as strongly represented as β-elimination, since C_2D_5H and C_2D_6 are found in approximately 2:1 proportions[12].

Competitive experiments with 1:1 mixtures of, on the one hand, α- and β-deuterated diethyl ether (the α-deuterated ether being almost exclusively attacked by the perdeuterioethyllithium) and, on the other hand, of α-deuterated and undeuterated diethyl ether (the two ethers being attacked to the same extent) showed that the undeuterated ether was cleaved, like the α-deuterated ether, by β-elimination. The experiments, however, do not permit a decision whether these reactions involve only ionic processes or whether radical mechanisms also come into play. Kinetic measurements and investigations of other ethers are in progress.

Synthesis of 8,8'-Biheptafulvenyl

By *Shigeyasu Kuroda, Masaji Oda*, and *Yoshio Kitahara*[*]

We report here the synthesis of 8,8'-biheptafulvenyl which is a higher analog of heptafulvalene.

Heating ethyl 7-cycloheptatrienecarboxylate *(1)*[1] under reflux in xylene for 5 h gave the 1,5-sigmatropic hydrogen shifted product, the carboxylate *(2)* (contaminated with about 5% of 1-ester). Reduction of *(2)* with $LiAlH_4$ gave the alcohol *(3)* (b.p. 66—67 °C/1 torr) in high yield. This was easily converted into the corresponding bromide *(4)* (b.p. 69—72 °C/2 torr) in 63% yield by treatment with excess concentrated hydrobromic acid in an ice bath. Treatment of *(4)* with magnesium in ether resulted in

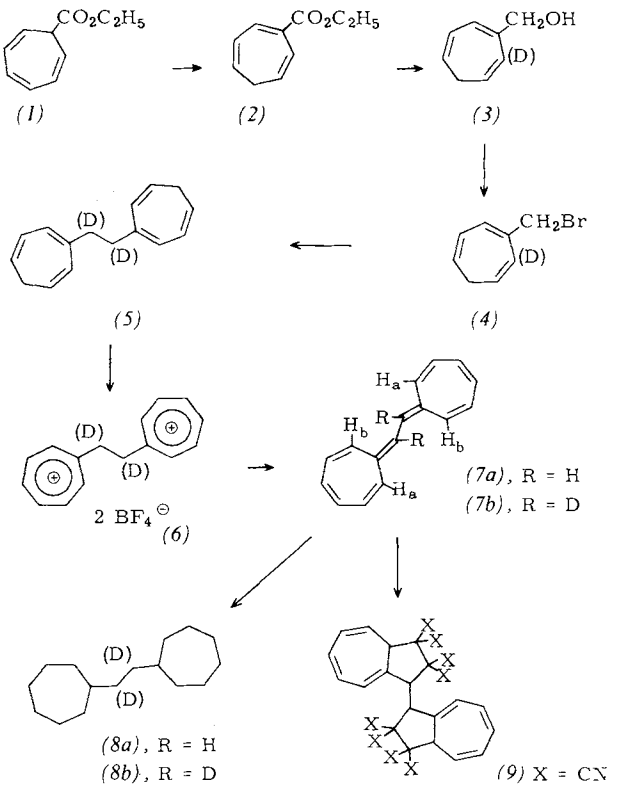
[***] To whom all correspondence should be addressed.

coupling to produce 1,2-di(3-cycloheptatrienyl)ethane *(5)* (b.p. 107—110 °C/0.2 torr, *m/e* 210) in 85% yield. Hydride-abstraction from *(5)* with triphenylmethyl tetrafluoroborate (2 equiv.) in dichloromethane afforded the corresponding salt *(6)* (m.p. 228—230 °C, 60% yield), whose structure was confirmed by the ^{1}H-NMR spectrum [60 MHz, in CF_3COOH, TMS, $\delta = 9.33$ (m), and 4.08 ppm (s), ratio 3:1].



8,8'-Biheptafulvenyl *(7a)* was easily obtained from *(6)* in 46% yield by cleavage of dehydrofluoroboric acid with triethylamine in dichloromethane. The dideuterio derivative *(7b)* could be obtained in the same way by using $LiAlD_4$. *(7a)* and *(7b)* can be isolated by chromatographing the concentrated reaction mixture through a short silica-gel column. Solid *(7a)* and *(7b)* decompose completely within one day in air at room temperature; they are, however, moderately stable in carbon tetrachloride solution and remain unchanged after one day. Compound *(7a)* crystallizes from *n*-hexane-dichloromethane at 20 °C as red brownish needles, m.p. 120—121 °C; *m/e* = 206 (M^+), 128, 115, 103, 91, and 78; IR (KBr): $\nu_{max} = 3010$ w, 1573 s, 924 m, 878 m, 744 s, and 720 cm^{-1}; UV (cyclohexane): $\lambda_{max} = 242$ (log $\varepsilon = 4.20$), 412 (4.61), and 438 nm (4.54). The intense absorption in the visible spectrum lies at about 65 nm longer wavelength than that of heptafulvalene (7,7'-bicycloheptatrienylidene)[2, 3].

The NMR signals of the ring protons of *(7a)* (Fig. 1) at $\delta \approx 5.3$ ppm appear close to those of 8-vinylheptafulvene (*ca.* 5.4)[3]; heptafulvalene absorbs at 5.91 ppm[2, 3]. In the NMR spectrum (100 MHz) of *(7b)*, the signal at $\delta = 5.39$ ppm has disappeared. The structured doublet at 5.95 and 5.70 ppm can be assigned to H_a and H_b, respectively. H_a may be more strongly deshielded by the other heptafulvene group in the molecule than H_b. In view of the large steric interaction of the two rings in the cisoid form, compound *(7)* may preferably exist in transoid form at room temperature.

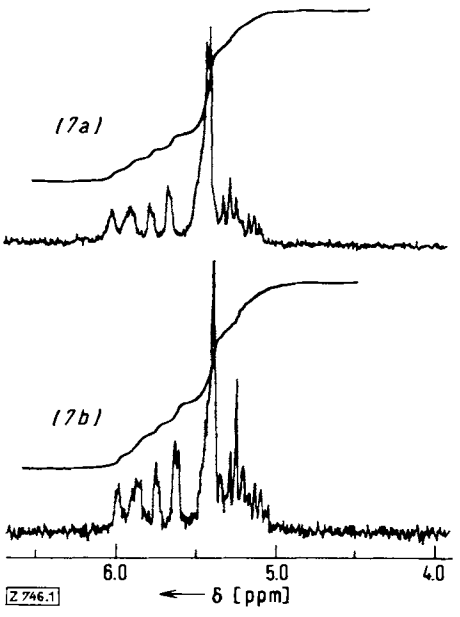


Fig. 1. 100-MHz ^{1}H-NMR spectrum (in CCl_4) of 8,8'-biheptafulvenyl *(7a)* and 8,8'-dideuterio-8,8'-biheptafulvenyl *(7b)*.

Complete hydrogenation of *(7a)* and *(7b)* on platinum oxide catalyst gave *(8a)* (*m/e* = 222) and *(8b)* (*m/e* = 224), respectively. *(7a)* easily reacts with two moles of tetracyanoethylene in dichloromethane at room temperature to give a pale yellow mixture of cycloadducts, which could not be separated. UV (268 nm) and ^{1}H-NMR spectrum of the mixture (60 MHz, $CDCl_3$, $\delta = 6.6$ (m), 5.7 (m), 4.3 (m), and 3.2 (m) in the ratio 4:1:1:1) suggest that it consists of stereoisomers of 8 + 2 cycloadducts *(9)*.

Reactions of Carbonylmetal Hydrides with Aziridine and Propylene Sulfide (2-Methylthiirane)[1]

By *Wolfgang Beck, Wolfgang Danzer*, and *Roland Höfer*[*]

Treating tetracarbonylhydridocobalt with oxirane leads to tetracarbonyl-(2-hydroxyethyl)cobalt or -(3-hydroxypropionyl)cobalt[2]. Reaction of aziridine with the carbonyl hydrides $HMm(CO)_5$, $HMn(CO)_4PPh_3$, and $HM(CO)_3(\pi\text{-}C_5H_5)$ (M = Mo or W) leads to formation of 3-aminopropionyl chelate complexes[3] according to the reaction scheme.

These reactions can be regarded formally as 1,3-insertion of aziridine into the metal-H bond, it being assumed that a 2-aminoalkyl complex arises by protonation of the nitrogen and ring opening; subsequently the alkyl group migrates to the CO ligand and the amino group becomes bonded to the metal.

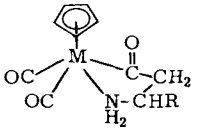
(1a), R = H
(1b), R = CH_3

(2)



(3a), M = Mo, R = H
(3b), M = Mo, R = CH_3
(3c), M = W, R = H
(3d), M = W, R = CH_3

The structure of *(1)*, *(2)*, and *(3)* as 3-aminoacyl chelate complexes follows from the IR spectra (Table 1). The complexes *(3)* show the expected two ν(M)—C≡O bands; the IR spectra of *(1a)* and *(1b)* contain the four νCO vibrations required for octahedral *cis*-$M(CO)_4L_2$ complexes. Three stereoisomers (of which one is dissymmetric) are possible for *(2)*, but they cannot be distinguished unambiguously on the basis of the IR spectrum. The amino and the keto groups are characterized by the absorptions at 3300 ($\nu_{as}NH_2$ and ν_sNH_2) and 1600 cm^{-1} (ν>C=O and δNH_2). Complexes of the same type have been obtained by *King et al.*[4] by a different route, from (2-chloroethyl)-dimethylamine and carbonylmetalates.

The compounds *(3)* deserve particular attention, as they are dissymmetric owing to the aminoacyl ligands. In *(3b)* and *(3d)* the aminoacyl ligand contains an additional chiral center at a C atom, so that two diastereoisomeric pairs could be formed. The occurrence of only one doublet for the methyl protons in the ^{1}H-NMR spectrum of *(3b)* and *(3d)* indicates that only one pair of enantiomers (DD,LL) is formed. Optically active compounds of the type π-$C_5H_5Mo(CO)_2$(L-L') with other chelate ligands were recently separated by *Brunner et al.* into their optical antipodes[5].

Table 1. IR absorptions (cm^{-1}) of aminopropionyl chelate complexes.

	ν(M)—C≡O [a]	νNH_2 [b]	ν>C=O, δNH_2 [b]

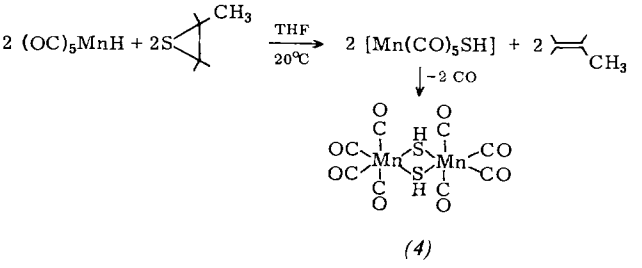
[a] Solution in CH_2Cl_2.
[b] Solid in KBr.

Propylene sulfide (2-methylthiirane) reacts with pentacarbonylmanganese in a "desulfurization reaction" with insertion of sulfur into the Mn—H bond, yielding *(4)* which is a dimeric SH-bridged complex:



(4)

Octacarbonyl-di-μ-hydrogensulfidodimanganese *(4)* (point group D_{2h} with SH as a point mass) is the first complex containing SH bridges and, like the corresponding phenylthio complex $[Mn(CO)_4SPh]_2$[6], shows four νCO bands (2077, 2018, 2004, 1972 cm^{-1}; solution in CCl_4). The observed three νSH (2571, 2531, 2481 cm^{-1}) or νSD bands (1867, 1841, 1806 cm^{-1}; solid in KBr) indicate the presence of *syn*- and *anti*-isomers (*syn* and *anti* refer to the position of the H atoms). In the mass spectrum of *(4)* the complete series of ions $H_2S_2Mn_2(CO)_n^+$ (n=0—8), $HS_2Mn_2^+$, $S_2Mn_2^+$, SMn_2^+, Mn_2^+ can be observed, as expected.

The reaction of $HMn(CO)_5$ with *trans*-2,3-dimethylthiirane (*trans*-2,3-butene sulfide) affords only *trans*-2-butene alongside *(4)*, *i.e.* the two C—S σ-bonds of the three-membered ring are opened concertedly (cheletropic reaction)[7], as in the stereospecific transfer of sulfur from butene sulfides to phosphanes.

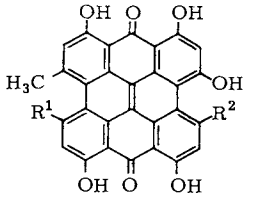
Alkaline Condensation of Emodin to Isohypericin: A Simple Synthesis of the *meso*-Naphthodianthrone (Phenanthro[1,10,9,8-*opqra*]perylene) System[**]

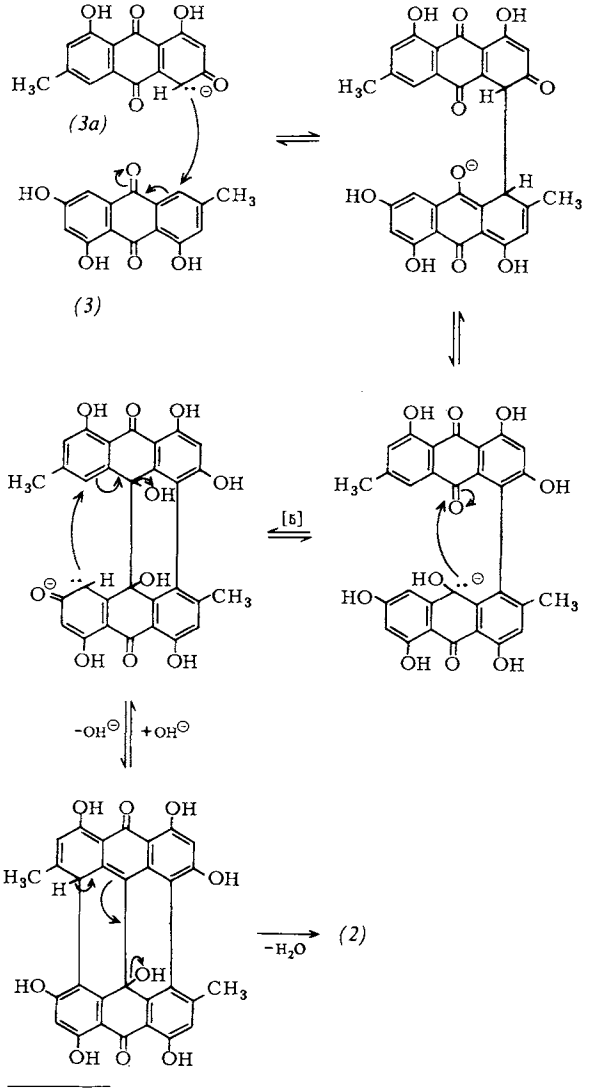
By *Wolfgang Steglich* and *Rüdiger Arnold*[*]

In their work on the structure of hypericin *(1)*, *Brockmann et al.*[1] discussed the possibility that "isohypericin" *(2)* might be formed alongside *(1)* in the oxidative dimerization of emodin-9-anthrone. We have now found that *(2)* is accessible in a facile manner from emodin *(3)*.



(1), $R^1 = CH_3$, $R^2 = OH$
(2), $R^1 = OH$, $R^2 = CH_3$

If *(3)* (0.5 mmol) is heated with hydroquinone (1 mmol) in 0.6 N KOH (3 ml) under nitrogen in a sealed tube for 3 weeks at 110 °C, dark-violet crystals can then be isolated in 35% yield by acidification, extraction with ethyl acetate, and chromatography on cellulose powder with ethyl acetate/acetone (1:1) as eluant. These crystals give red solutions in pyridine or methanol that, like those of *(1)*, exhibit intense red fluorescence. This compound is not to be distinguished from authentic *(1)* by thin-layer chromatography[2]. Since the absorption spectra of the two compounds in methanol, THF, and concentrated sulfuric acid are very similar, but differ in alkaline media[3], our compound can only be isohypericin *(2)*. This is confirmed by the mass spectrum of the orange-yellow hexaacetate which, starting from the molecular ion $m/e = 756$, shows six consecutive losses of ketene. If the synthesis of *(2)* is effected without addition of hydroquinone, then 2,5'-bisemodin and traces of norxanthorin[4] are formed as by-products.



The reaction conditions exclude an oxidative coupling step in the formation of the *meso*-naphthodianthrone system. Its appearance is explained without difficulty if Michael addition of an emodin anion *(3a)* to a molecule of emodin *(3)* is assumed as the primary step, followed by a series of simple tautomerizations, condensations, and eliminations.

We are now studying the application of the new *meso*-naphthodianthrone synthesis to simpler hydroxyanthraquinones.

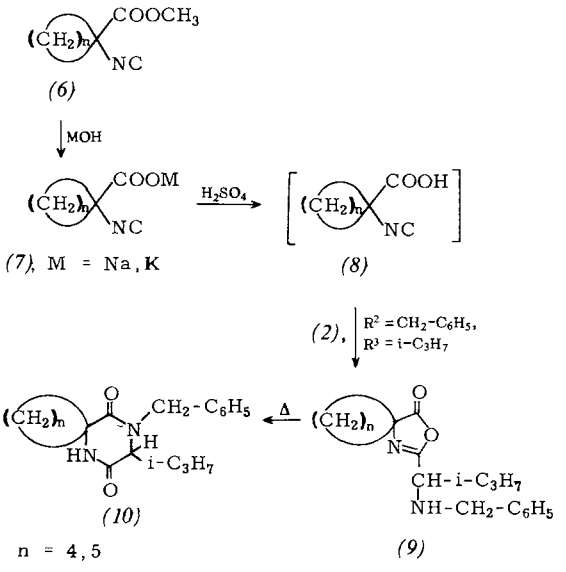
509 Leverkusen-Bayerwerk (Germany)

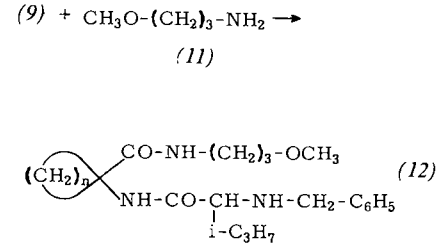
[**] Four components are obtained if the aldimine is regarded as the product from aldehyde and amine.

products *(4)* are assumed to be intermediates that undergo stabilization by rearrangement to *(5)*. We have now been able to isolate such α-adducts as stable compounds.

The readily accessible[2] 1-isocyanocycloalkanecarboxylic esters *(6)* can be easily hydrolyzed to the water-soluble salts *(7)*, which are fairly stable even in the solid state[3]. If the alkaline aqueous solution of *(7)* is neutralized by a mineral acid in the presence of an aldimine *(2)* (*e.g.* R^2 = benzyl, R^3 = isopropyl) and the mixture is then at once shaken with an inert water-immiscible solvent, the product *(9)* is obtained. If *(2)* is added only after the neutralization, then *(9)* is not formed.



The free 1-isocyano carboxylic acid *(8)* could not be isolated, but it is reasonable to assume that it is formed as an intermediate and undergoes four-component condensation with the aldimine *(2)*. Here the α-adduct must be the azlactone *(9)*, a structure in accord with the physical data[4] (Table 1). Acylation to give *(10)* (Table 1) proceeds only in the melt but then occurs almost quantitatively. Not only the intramolecular acylation of *(9)* to give *(10)*, but also the acylation of the primary amine *(11)* by *(9)* to give *(12)*, are further confirmation of the structure assumed for *(9)* [*(12)*, $n=4$, m. p. 80—81 °C; *(12)*, $n=5$, m. p. 74—75 °C; both from light petroleum]. *(9)* does not react with *tert*-butylamine in benzene solutions even on prolonged boiling, possibly due to steric hindrance.



The structure of *(12)* was confirmed both by IR and NMR data and by independent synthesis by four-component condensation of *N*-benzylvaline (as ammonium salt[5]), cyclopentanone, or cyclohexanone, and 1-isocyano-3-methoxypropane.

The remarkable stability of *(9)* can be ascribed to its spiro structure, since analogous azlactones without spiro structure (*e.g.* from 2-isocyano-2-methylpropionic acid) are indeed formed (strong band at 1810 cm^{-1}) but decompose on attempted isolation.

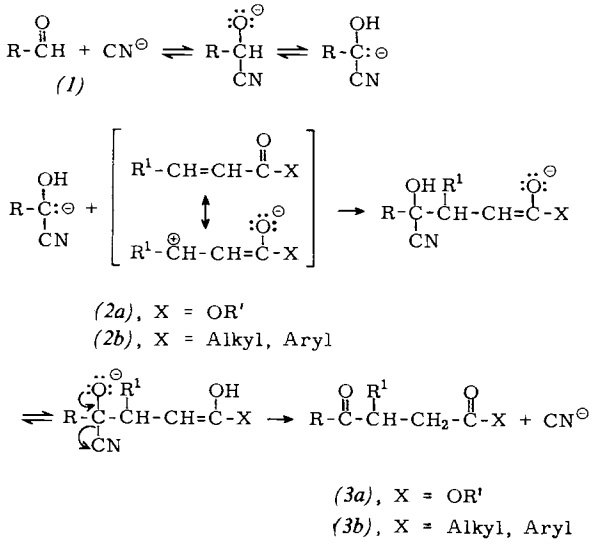
A New Method for Addition of Aldehydes to Activated Double Bonds

By *Hermann Stetter* and *Manfred Schreckenberg*[*]

Radical addition of aldehydes to α,β-unsaturated carbonyl compounds is a known process[1], but only in rare cases are the results preparatively favorable.

We have found aldehydes *(1)* to add smoothly to α,β-unsaturated carboxylic esters *(2a)*, ketones *(2b)* or nitriles under the catalytic influence of cyanide ions, whereby γ-oxo carboxylic esters *(3a)*, γ-diketones *(3b)* or γ-oxo nitriles are respectively formed.



(2a), X = OR'
(2b), X = Alkyl, Aryl

(3a), X = OR'
(3b), X = Alkyl, Aryl

The reaction can be carried out in polar solvents such as dimethylformamide and dimethyl sulfoxide. In the examples tabulated the reaction conditions were maintained as follows:

A solution of the unsaturated carbonyl compound or the corresponding nitrile (0.5 mol) in dimethylformamide (100 ml) is dropped with stirring into a solution of the aldehyde (0.5 mol) and sodium cyanide (0.1—0.5 mol) in dimethylformamide (150—250 ml) at *ca.* 35 °C, but in the case of acrylonitrile an excess of 0.35 mol is advantageous. The mixture is stirred until reaction is complete (1—4 h). Working up may be by pouring into water and extraction with chloroform.

Table 1. Examples of the reaction of aromatic aldehydes with α,β-unsaturated carbonyl compounds or nitriles:

$$R{-}CHO + R^1{-}CH{=}CH{-}R^2 \rightarrow R{-}CO{-}CHR^1{-}CH_2{-}R^2$$

R	R^1	R^2	M.p. [°C] B.p. [°C/torr]	Yield [%]
C_6H_5	H	CN	76	80
C_6H_5	CH_3	$COOC_2H_5$	119–121/0.5	33
C_6H_5	$COOC_2H_5$	$COOC_2H_5$	150–155/0.8	32
C_6H_5	C_6H_5	$COCH_3$	60–61	67
p-Cl—C_6H_4	H	CN	73	70
p-Cl—C_6H_4	CH_3	$COOC_2H_5$	34 [a]	56
p-Cl—C_6H_4	$COOC_2H_5$	$COOC_2H_5$	190/1.5	35
p-Cl—C_6H_4	C_6H_5	$COCH_3$	64	90

[a] B.p. 121 °C/0.2 torr.

Benzoins may replace benzaldehyde and Mannich bases may replace unsaturated ketones with equally good results. Table 1 contains some examples of the use of aromatic aldehydes. Examples with aliphatic and heterocyclic aldehydes will be published shortly.

Methylenebicyclo[4.2.1]nona-2,4,7-triene[1]

By *Manfred T. Reetz, Reinhard W. Hoffmann, Werner Schäfer*, and *Armin Schweig*[*]

We report here the synthesis and properties of methylenebicyclo[4.2.1]nona-2,4,7-triene *(1)* and 9-methylenebicyclo[4.2.1]nonane *(2)*. Starting from bicyclo[4.2.1]nona-2,4,7-trien-9-one[2] we obtained, by Wittig olefination in ether/THF followed by gas-chromatographic separation, a 44% yield of *(1)*: m.p. 29—32 °C; NMR (CCl_4), $\tau = 3.80$ to 4.36 m, 4.75 s, 5.33 s, 6.66 (d, $J = 6.5$ Hz) in relative intensities 2:1:1:1; IR, 3080, 2980, 1675, 1580, 1380 cm^{-1}; UV (cyclohexane), maxima at 265 nm (log $\varepsilon = 3.58$), 260 (3.59), 217 (3.57), shoulders at 275 (3.31), 245 (3.52). Compound *(2)* was prepared similarly from bicyclo[4.2.1]-nonan-9-one[2] in 37% yield: m.p. 42 °C; NMR (CCl_4), $\tau = 5.28$ s, 7.2—7.5 m, 7.8—8.9 m in relative intensities 1:1:6; IR, 2950, 2895, 1650, 1460, 1450 cm^{-1}

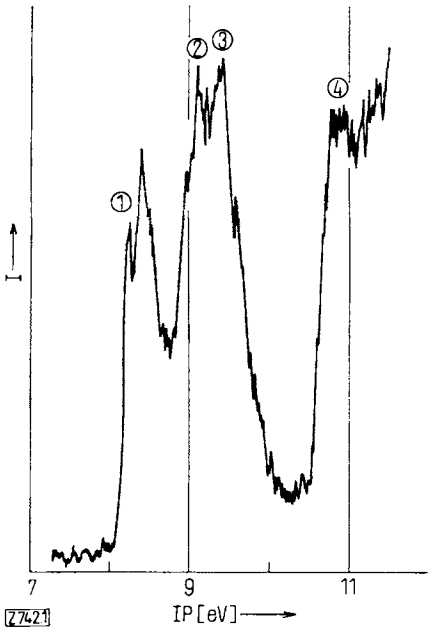

Fig. 1. Photoelectron spectrum [10] of methylenebicyclo[4.2.1]nona-2,4,7-triene *(1)*.

Compound *(1)* has three π-systems in spatial proximity of one another, these not being conjugated in the classical sense. Nevertheless, its photoelectron spectrum (Fig. 1) reveals some degree of interaction. Information about the energy levels of the "isolated" π-systems in *(1)* is provided by PE spectra of *(2)* and *(4)*[3]. From the correlation diagram (Fig. 2) it can be seen that the HOMO of the butadiene moiety in *(4)* appears energetically unchanged in *(1)* because its symmetry precludes coupling with the other π-systems. The correlation diagram also shows that the two MOs of the ethylene units in *(2)* and *(4)* accidently have the same energy and that their interaction in *(1)* leads to significant splitting. Here MINDO/2 calculations[4] lead to the assignment of π_2 in *(1)* as π-bonding and π_3 as π-antibonding, which indicates a predominant hyperconjugative (through bond[5]) interaction. A study of further models will have to precede a decision whether this bishomo-conjugative[6] interaction in *(1)* is accompanied by an additional, also symmetry-allowed interaction of π_3 with the symmetrical butadiene MO yielding a bicycloaromatic[7] system.

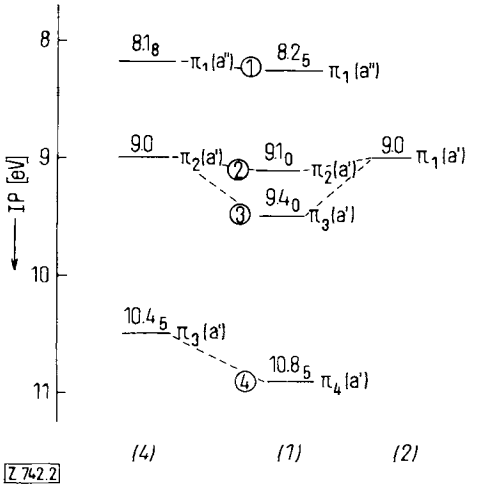

Fig. 2. Correlation diagram of the highest occupied MOs in bicyclo-[4.2.1]nona-2,4,7-triene *(4)*, methylenebicyclo[4.2.1]nona-2,4,7-triene *(1)* and 9-methylenebicyclo[4.2.1]nonane [2]. The numbers placed above the peaks are vertical ionization potentials. The MOs are classified according to the irreducible representations (*a''*, *a'*) of the C_s symmetry group.

Interaction of the π-systems could lead to polarization of the exocyclic double bond[8, 9]. We therefore studied the ^{13}C-NMR spectra of *(1)* and *(2)*. The difference in chemical shift (in ppm downfield from tetramethylsilane) between C-9 and C-10 was found to be 41 ppm for *(1)*. This difference is distinctly less than that for ω-methylenebicyclo[*n*.2.1]alkanes [50—60 ppm, cf. *(2)*], and the latter is in turn considerably smaller than that for *(3)* (99 ppm)[9]. The reason for this could be that the exocyclic double bond of *(1)*, in contrast to that of *(3)* gives up a small amount of its charge to the remainder of the π-system.

Biogenic Macromolecules of Arterial Tissue and Cartilage

By *Eckhart Buddecke*[*]

Proteoglycans are structural components of cells, of pericellular structures, and of the extracellular space in connective tissue. They have the chemical structure of graft polymers, in which polysaccharide chains are covalently linked to a central protein or polypeptide core. Chondroitin sulfate (CS), dermatan sulfate (DS), heparan sulfate, and keratan sulfate have been identified as polysaccharide components of proteoglycans of arterial tissue and cartilage.

Hyaline cartilage contains up to 40% of its dry weight of a proteoglycan whose carbohydrate content amounts to 84% and whose polysaccharide chains consist mainly of chondroitin sulfate $[(1\text{-}4)\beta$ GlcUA $(1\text{-}3)$GalNAc 4-sulfate$]_n$ bonded β-glycosidically to serine residues of the protein through the trisaccharide galactosylgalactosylxylosyl. Light scattering and viscosity measurements revealed a molecular weight of 0.5×10^6 to 1.0×10^6, the molecular shape of a stretched coil, a radius of gyration of 1400 Å, and an effective hydrodynamic volume of 200—400 ml of water per g. These figures were confirmed by electron micrographs showing an ellipsoidal molecular shape with a central protein filament of 1800—2000 Å length and 22 side chains of 520 Å length.

In a hybrid proteoglycan of arterial tissue, CS and DS are components of the same macromolecule and are present in part as copolymeric polysaccharide chains. The copolymeric structure of the polysaccharide chains was proved by isolation of a tetrasaccharide having the structure GlcUA—GalNAc sulfate—IdUA—GalNAc sulfate. On incubation of arterial tissue *in vitro* in the presence of ^{35}S-sulfate or ^{14}C-glucose, the ^{35}S or ^{14}C was incorporated into the polysaccharide chains at a constant rate for at least 6h; however, the specific radioactivity of the ester sulfate or iduronic acid groups of the DS is found to be 2—3 times greater than that of the ester sulfate or glucuronic acid groups of CS.

The chemical and metabolic heterogeneity of the polysaccharide chains of the hybrid CS—DS protein of arterial tissue is explained by the fact that biosynthesis of the carbohydrates is not subject to direct genetic coding but is controlled indirectly by the specificity and activity of the glycosyl transferases, by the substrate concentration, and by compartmenting of the pool of metabolic precursors. The metabolic heterogeneity of the copolymeric CS—DS chains is not in accordance with the generally assumed stepwise synthesis of the carbohydrate side chains of the proteoglycan molecules.

Their physicochemical properties enable the proteoglycans to bind water and Ca^{2+}. Further, in model experiments a "molecular sieve effect" could be observed: In solutions of critical concentration, proteoglycans form a gel-like macromolecular structure. Such systems are permeable to small molecules (glucose, amino acids) but inhibit the passage of larger molecules. *In vivo* this "molecular sieve effect" may be involved in control of extracellular and pericellular transport processes.

Chemical Structure and Biological Action of the Components of Bee Venom

By *E. Habermann*[*]

Bee venom contains three types of active ingredient:

1. Histamine is the most important of the biogenic amines. It causes pain, dilates the blood vessels, and increases their permeability.

2. A group of biologically active peptides is responsible for the local and general toxicity of the venom. To this group belong:

a) *Melittin*, whose primary structure is

Gly—Ile—Gly—Ala—Val—Leu—Lys—Val—Leu—Thr—Thr—
—Gly—Leu—Pro—Ala—Leu—Ile—Ser—Trp—Ile—Lys—
—Arg—Lys—Arg—Gln—GlnNH_2

The extremely irregular distribution of its amino acid residues is remarkable. Mainly hydrophobic or slightly hydrophilic neutral groups occupy the positions 1 to 20 while the C-terminal portion is strongly basic and wholly hydrophilic. This structure resembles that of an invert soap. Both the hemolytic potency of melittin and its ability to lower the surface tension of water might be explained by its primary structure. This is in accord with the almost universal action of melittin on biological structures (cell membranes, mitochondria, lysosomes, liposomes) and on pharmacological test objects (smooth and striated muscle, neuromuscular junction, sensible nerve endings, tonus and permeability of blood vessels). Since mellitin constitutes about 50% of dried bee venom, this peptide can be considered as the principal toxin.

b) *Apamin* (2 to 4% of dried venom). Its sequence is

Cys—Asn—Cys—Lys—Ala—Pro—Glu—Thr—Ala—Leu—Cys—
—Ala—Arg—Arg—Cys—Gln—Gln—HisNH_2

The four half-cystines exist in the disulfide form. Unlike the action of melittin, that of apamin is highly specific, in that it augments the spinal polysynaptic reflexes. In mice its action lasts for several days (LD_{50} : 4 to 5 mg/kg).—

c) *MCD peptide* (2 to 4% of the whole venom) degranulates rat mast cells. The histamine released lowers the blood pressure and dilates the blood vessels.

3. Enzymes. a) The structure and mode of action of *bee venom phospholipase A* has been determined recently by

[*] Prof. Dr. E. Habermann
Pharmakologisches Institut der Universität
63 Giessen, Schubertstrasse 1 (Germany)

Vernon and his colleagues[1]. b) The venom *hyaluronidase* differs appreciably from that of the hyaluronidases of other organs, *e.g.* of ox testicles.

Absorption of Light by Organic Molecules in Electric Fields—Some New Applications

By *H. Labhart*[*]

It was shown in the introduction how the change in intensity of incident polarized light on application of an electric field to a solution allows the determination of the angle between the dipole moment and the optical transition moment to an excited state[1]. Here it is briefly mentioned how several other excited state properties can be derived.

The first example concerns interpretation of the n-π^* transition of α-diketones[2]. If only the direct overlap of the atomic n-orbitals is taken into account, one expects that each of the two observed n-π^* bands results from an overlap of two transitions polarized perpendicularly to each other. On the other hand, CNDO calculations lead to the prediction that the longest-wavelength n-π^* band is due to a single transition polarized perpendicularly to the dipole moment and the shorter-wavelength n-π^* band to a transition polarized parallel to it. Measurements of the influence of an electric field on the spectrum of camphor diketone confirm the predictions of the CNDO calculations and strengthen the view that indirect interaction through the σ-orbitals of the carbon atoms determines the coupling of the n-orbitals.

A second application concerns the energetic coupling of the partial chromophores of 9,9′-spirobifluorene (SBF) and of 7,7′-dinitro-9,9′-spirobifluorene-2,2′-diamine (ANSBF)[3]. From the spectra it can be concluded that there is very weak coupling of the partial chromophores in the region of the longest-wavelength bands, and from the influence of the field on the spectrum of ANSBF it is clear that the transition moment makes an angle of approximately 45° with the dipole moment. Hence it follows that the excitation must be considered as localized on the partial chromophores. By measuring the degree of polarization of the fluorescent light it is possible to determine the degree to which energy is transferred from the initially excited to the non-excited chromophore during the time from excitation to emission. From this information one can calculate that the coupling energy U for SBF is $U = 7 \times 10^{-5}$ eV and for ANSBF is $U = 4.1 \times 10^{-3}$ eV. Since U vanishes for the equilibrium state of SBF owing to symmetry, the experimental value must be ascribed to vibrational influences.

With the same vibrational amplitude a coupling energy about ten times greater would be expected for ANSBF. The discrepancy from the approximately 60-times greater value found can be explained as due to slight twisting, which is caused by their electrostatic interaction, of the chromophores from their perpendicular positions. Estimation of the effect of spiroconjugation gave a negligibly small contribution.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Sequencing of peptides with the aid of dipeptidyl aminopeptidase I from bovine spleen is reported by *P. X. Callahan, J. K. McDonald,* and *S. Ellis.* This enzyme, which shows relatively little amino acid specificity, cannot cope with *N*-terminal arginyl and lysyl residues or with the cleavage of proline bonds. The time course of cleavage is followed by paper chromatography for small peptides, whereas larger peptides are cleaved in an ultrafiltration cell whose membrane only permits passage of the resulting dipeptides which are then identified by thin-layer or column chromatography. Difficulties are circumvented by adding an alanyl residue to the *N*-terminal end of the peptide under study or by removing a residue; the resulting peptide affords the sequence in the form of other dipeptides. Surface effects in hemostasis and thrombosis are considered by *E. W. Salzman.* In healthy individuals the blood circulates as a non-Newtonian fluid: however, contact with surfaces other than the endothelium of the blood vessels triggers off a complicated series of reactions which result in the formation of a "red clot" in stationary blood and a "white clot" in flowing blood. The latter phenomenon is designated thrombosis. Its significance is apparent from

the fact that in the USA it ranks first among the causes of death. The article summarizes the present state of knowledge regarding the effects of "foreign" surfaces on the blood. [Surface Effects in Hemostasis and Thrombosis. Chem. Biosurfaces *2*, 489—522 (1972)]; 203 references]

[Rd 582 IE—M]

The occurrence and isotope distribution of xenon in terrestrial and extraterrestrial material, the concern of the new scientific discipline of xenology, is reviewed by *H. Hintenberger*. Xe, which has nine stable isotopes, offers more scope for the study of the early history of our solar system then any other element. The significance of Xe isotopes in these studies derives from the extremely sensitive methods available for its detection and the multiplicity of the possible nuclear reactions. Shifts in the abundances of the various Xe isotopes arise from fractionation processes (especially diffusion, and also condensation and evaporation processes) and from nuclear reactions, the abundance of only one isotope usually changing (radioactive decay, neutron capture, spallation reactions, fission of heavier elements). Lunar Xe exhibits considerable differences in isotope distribution compared to meteoritic Xe. The noble gases captured from the solar wind in lunar dust provide the most accurate information hitherto available regarding the noble gas abundances on the sun. Two new synthetic methods from diazo chemistry, *viz.* transformation of aliphatic diazo compounds with retention of the diazo group and reactions in which an azide group serves as diazo precursor, are dealt with in a review by *M. Regitz*. The first reaction can take place by nitration, halogenation, acylation, metalation, and substitution *via* metal derivatives *(1)*. Such substitutions are limited to diazomethyl compounds and a number of 1,1-disubstituted

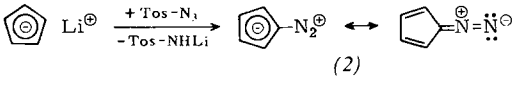
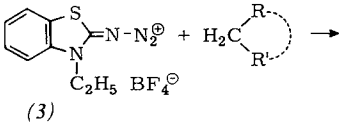
(1)

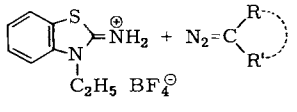
diazo alkanes. Other transformations are possible by addition of diazomethyl compounds to carbonyl compounds and electron-rich olefins, and by cleavage reactions, *e.g.* of diacyldiazomethanes to give acyldiazomethanes.— Diazo group transfer is conducted mainly with the stable and readily accessible tosyl azide. Reaction yields *e.g.* diazocyclopentadiene *(2)* and -cyclohexadiene, α-diazo carbonyl compounds, α-diazo sulfonyl compounds, α-diazo



(2)



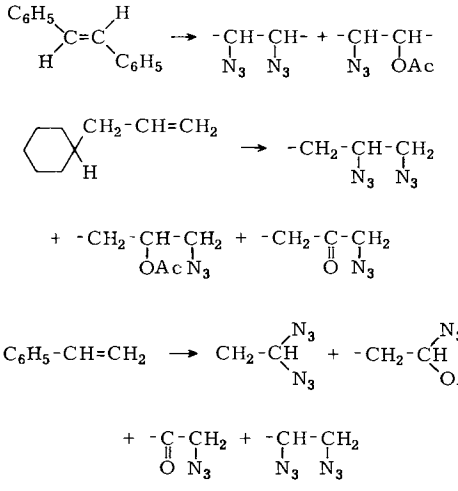
(3)



phosphono and α-diazo phosphinyl compounds. The preparative scope is considerably increased on use of azidinium salts *(3)*. [Recent Synthetic Methods in Diazo Chemistry. Synthesis *1972*, 351—373; 138 references]

[Rd 581 IE—M]

The reaction of olefins with lead(IV) acetate azides, $Pb(OAc)_{n-1}(N_3)_n$, *(1)*, a reagent discovered in 1969, is reviewed by *E. Zbira*. Compound *(1)* is produced by mixing $Pb(OAc)_4$ and $(CH_3)_3SiN_3$ in aprotic solvents at −40 to −20 °C. The olefins are added to one of the two components prior to mixing (−20 °C to room temperature). Depending on the kind of olefin, reaction yields diazido-, acetoxyazido-, and azido carbonyl compounds:



A large new range of possibilities open up in the steroid field. Bridged olefins (camphene, norbornene, benzonorbornadiene) undergo skeletal rearrangements. Triple bonds are also attacked by *(1)*, the temperature of reaction determining the product composition. The (diacetoxyiodo)-benzene/trimethylsilyl azide system reacts with olefins in a similar manner to *(1)*. [Organic Syntheses Using Lead(IV) Acetate Azides. Synthesis *1972*, 285—302; 74 references]

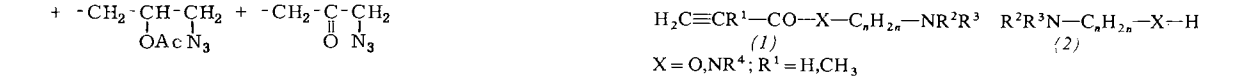
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Thermosetting molding compositions consist of a polymerizable component A of a butadiene polymer having a high vinyl content and an isobutene polymer B. Components A that are regarded as particularly suitable are butadiene polymers containing at least 65% of 1,2-polymerized units. An average viscosity molecular weight of the polymer of between 500 and 500000 is preferred. The isobutene polymer used as component B serves to regulate the shrinkage that occurs during thermosetting. Solid, liquid, or rubbery materials having a number average molecular weight of between 1000 and 100000 may be used. The isobutene polymer may also contain an admixture of up to 15 wt.% of polymers of other monomers having C=C bonds, such as vinyl acetate, styrene, and isoprene. The concentration of the isobutene polymer is 1—50%, based on the weight of the butadiene polymer. [DOS 2136435; BP Chemicals Ltd., London]

[PR 9—E IE]

For the production of dyed objects from polylactones, *e.g.* polypivalolactone, a small quantity of ethylene copolymers containing tertiary N atoms is added to the polymers, the mixture is shaped, and the objects are dyed, optionally after acid treatment. The copolymers may be prepared *e.g.* from ethylene and amino esters or amino amides of acrylic or methacrylic acid *(1)* and optionally other comonomers, or may be obtained by chemical modification of copolymers of ethylene and esters of acrylic acid, methacrylic acid, maleic acid, or fumaric acid with tertiary amines *(2)*.



(1) *(2)*

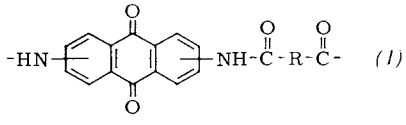
$X = O, NR^4$; $R^1 = H, CH_3$

R^2, R^3 = alkyl, cycloalkyl, aryl, aralkyl (C_1—C_8);
R^2 and R^3 may be connected together by one or more C, N, or O atoms;
$R^4 = H, R^2$; $n = 1$—4

The acid treatment can be carried out with acidic gases, mineral acids, carboxylic acids, halogen compounds liberating hydrogen halide on contact with water, boron trifluoride, esters of boric acid, and/or phenol. The dyeable plastics mixtures are characterized by higher stability during hot forming in comparison with those containing primary or secondary amino groups. [DOS 2143770; Shell Internationale Research Maatschappij N.V., Den Haag]

[PR 28 IE—C]

Quinonoid vat polymers characterized by the repeat structural unit *(1)*, where R is a bivalent aliphatic or aromatic

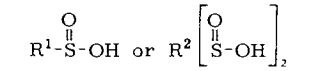


(1)

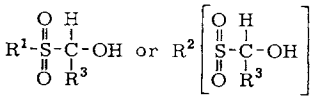
residue, are thermally very stable and are easy to process. The polymers can be dissolved by reduction (shortening) in aqueous alkali and converted into fibers, films, sheets, and coatings by reoxidation. The vat polymers are produced by polycondensation of diaminoanthraquinones with dicarboxylic acids and their amide-forming derivatives in solution or in substance at temperatures between room temperature and 350°C. [DOS 2056710; Battelle-Institut e.V., Frankfurt]

[PR 44 IE—E]

As a delayed-action accelerator for sulfur-vulcanizable rubber compositions one can use a) an organic sulfinic acid *(1)*, b) a metal salt or an amine salt of an organic sulfinic acid, or c) an aldehyde or aldehyde-amine derivative of an organic sulfinic acid *(2)*. R^1 denotes aryl, alkyl, cycloalkyl,



(1)



(2)

aralkyl, or alkaryl, R^2 denotes alkylene or arylene, and R^3 denotes hydrogen, alkyl, or aryl. Sulfinates of monovalent and bivalent metals may be used as metal salts, and salts with ammonia or primary, secondary, or tertiary amines as amine salts. The accelerators exhibit a high degree of safety against scorching when the mixing and processing operations are carried out at relatively high temperatures. [DOS 1 770905; Uniroyal, Inc., New York]

[PR 42 IE—E]

Shaped objects of nylon 4 that can be produced at temperatures well below the melting point of nylon 4 (polymer of 2-pyrrolidone) are obtainable by swelling nylon 4 with water and drying the swollen composition under pressure. The operation is carried out at a pressure of at least 3.5 kg/cm^2 and at a temperature of at least 25 °C, the temperature and the pressure being inversely related; lower temperatures are used at higher pressures, and higher temperatures at lower pressures. In this way, an integral structure is obtained without melting. Other materials such as wood pulp fiber, semisynthetic and synthetic fibers, and fillers may be blended with the swollen nylon 4. The shaped objects are produced by drying a nylon 4 pulp on a perforated support under pressure. [DOS 2142761; Alrac Corp., Stamford, Conn.]

[PR 43 IE—E]

BOOK REVIEWS

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH, Weinheim/Bergstr., 8th fully revised edition.

System No. 14: Carbon, Part D 1. Carbon-Nitrogen Compounds. Principal editor: *Dieter Koschel.* 1971. vi, xxii, 475 pp., 51 figures, Balacron DM 574.—.

Whereas the volume "Carbon C" dealt with simple C—H compounds and the physical properties of CO, CO_2, and C_3O_2, the first volume of Part D is concerned with carbon-nitrogen compounds. In addition to the compounds of these two elements, compounds that also contain hydrogen and/or oxygen are included. The volume is thus of interest both to inorganic and to organic chemists, though this classification of chemists is as open to question as the classification of substances and their reactions into inorganic and organic chemistry. The principal editor refers in the foreword to the difficulties of selecting the compounds that should be treated predominantly from the standpoint of inorganic chemistry, corresponding to the character of the Handbook. With a few exceptions, the volume contains only C—N compounds having one C atom and their oligomers. These include $(CN)_{1,2,x}$, CN^-, N_3CN, C_4N_2, $C(CN)_2$, $CH(CN)$, $C_2(CN)_4$, HCN, HNC, H_2NCN, $(NH_2)_2CNCN$, $(CNO)_{1,2}$, HNCO, HOCN, NOCN, $(CN)_2CO$, urea, semicarbazide, and guanidine.

Among the compounds discussed, most space is devoted to cyanogen $(CN)_2$, hydrogen cyanide HCN, cyanamide H_2NCN, dicyanodiamide $(NH_2)_2C{=}NCN$, isocyanic acid HNCO, urea $(NH_2)_2CO$, and guanidine $(H_2N)_2CNH$. The treatment of cyanic acid HOCN, on the other hand, takes up only a few lines, since the free acid exists only as isocyanic acid, whereas HOCN molecules can be detected only on photolysis of HNCO in Ar and N_2 matrices. On the other hand the isomeric fulminic acid HCNO, with the structure of a nitrile oxide, is so stable that very thorough investigation of this substance has been possible. Cyanuric acid and its derivatives melamine, ammeline, and ammelide are also well known.

The form of the presentation should satisfy everyone. The only evidence of lack of systematic procedure is to be found in the description of the chemical behavior of the substances toward organic compounds. Though there is no denying the difficulty of drawing a boundary line just here and preserving the character of a handbook of inorganic chemistry, it would have been preferable to show more clearly the *connection* with organic chemistry in the classical sense. At isolated points, *e.g.* in the discussion of guanidine or of hydrocyanic acid, this has been achieved informatively, and yet without wasting space, by a few sentences and references to collective works on organic chemistry, but notes on behavior toward organic compounds are totally lacking in the discussion of very many other compounds (*e.g.* semicarbazide).

The literature has been evaluated up to and in some cases beyond the end of 1970, so that on grounds of current interest, Gmelin's "Carbon-Nitrogen Compounds" should not be lacking either in an inorganic or in an organic library.

System No. 49: Niobium, Part B2. Alloys. Principal editor: *Herbert Lehl.* 1971, vi, xvi, 307 pp., 167 figures, Balacron DM 382.—.

The present volume deals with alloys of niobium with metals of System Nos. 20 to 48 (lithium to vanadium). It comes between the first volume, which was published in 1970, and which deals with the compounds of niobium up to the element bismuth, and the just published volume B 3 in which the oxoniobates of the alkaline earth metals up to those of vanadium are discussed.

Alloys of niobium with the alkali metals are of no importance. Niobium is only slightly soluble in alkali metals. Solubility and corrosion are evidently decisively influenced by the impurities in the system in question, particularly by the oxygen content. On the other hand, the niobium-beryllium equilibrium diagram shows the existence of several intermetallic phases. Most niobium-beryllium alloys are characterized by extremely high melting points. According to present-day knowledge, the alloys of niobium with the other elements of the second main group and also of the second sub-group are of minor importance. Alloys of any desired composition can be prepared by fusion of niobium with aluminum. They are often superconducting,

and indeed their superconductivity is also the most intensively studied property of the other alloys discussed in this volume. Nb_3Al melt samples have jump temperatures between 17.3 and 18.5 °K. The extensively studied alloys of niobium with titanium belong to the class of "hard" superconductors, which correspond to the type III superconductors and can conduct high current densities without loss even in strong fields. However, these are also of interest because of their mechanical properties and because of the high chemical resistance of the niobium-rich alloys. A very similar class of materials, both in their superconductivity and in their mechanical properties, are the alloys of niobium and zirconium. Finally, considerable space is devoted to the descriptions of the binary Nb-Sn and Nb-V alloys. Niobium and lead are not miscible either in the molten state or in the solid state.

The literature has been evaluated up to and in some cases beyond mid-1970 for this volume.

System No. 46: Tin, Part B. The Element. Principal editor: *Gerhard Kirschstein.* 1971. vi, xix, 423 pp., 130 figures. Balacron DM 513.—.

Whereas Part A described the history and occurrence of tin, Part B deals with the element itself. Short introductory chapters on the position of the element in the periodic system and its atomic weight are followed by a longer chapter on its industrial production, which also includes the purification of crude tin and data on purity testing. Tables give figures for the world production up to 1968 and the tin consumption for various purposes in the USA. The next chapter deals with colloidal solutions and aerosols. Considerable space is devoted to the description of the preparation, separation, and enrichment of tin isotopes, of which 10 stable and 15 radioactive ones are known at present. The properties of the atom and of the atom-ions are discussed in detail. The formation of Sn_2 molecules on evaporation of tin from a Knudsen cell is of theoretical interest. 120 pages are devoted to the crystallographic, mechanical, thermal, electrical, magnetic, and optical properties, and 96 pages to the electrochemical behavior, which is of great practical importance for the plating industry and has accordingly been very thoroughly investigated. The last large chapters in the volume describe the chemical behavior of the metal and of its ions. Little space is taken up by a chapter on the physiological behavior of tin and its compounds, which would have been better headed "Toxicity" in accordance with the marginal notes in English, particularly since there is a section entitled "Antidotes". The data on methods of detection, determination, and separation in the last chapter are largely confined to a list of references to secondary literature. A table gives the most sensitive reactions of Sn.

The volume contains a number of linguistic shortcomings with regard to chemical terminology, *e.g.* the statement on p. 1 that: "Sn^{II} oxydiert leicht zu Sn^{IV}." Terms such as "unedles Normalpotential" (p. 397), "Ammoniumhydroxidlösung" (p. 365), and "sulfidierung" (p.354) also prove disturbing. It is incorrect to state that α-tin is known as tin plague (p. 130). On the contrary, tin plague is the conversion of white β-tin into gray α-tin, since "pimples" formed from gray tin at isolated points on white tin have an "infectious" action on the surrounding areas. In the section on the transition from β-tin into α-tin (p. 131) or in connection with the preparation of gray tin (p. 37), it is interesting to note that no reference is made to pink salt, $(NH_4)_2[SnCl_6]$, which is mentioned in all the textbooks as an accelerator of the transition.

The incorrect formula NH_4CNS has been copied from the original literature, instead of NH_4SCN, for ammonium thiocyanate (p. 51).

The literature has been evaluated up to the end of 1969, and more recent publications are also included in some cases.

Ekkehard Fluck [NB 89 IE]

Episome (Episomes). By *A. M. Campbell.* Moderne Biowissenschaften, Vol. 1. Akademie-Verlag, Berlin 1971, 1st Edit., 203 pp., numerous illustrations, bound, DM *ca.* 32.—.

A review of episomes and related topics (section headings: historical introduction, temperate bacteriophages, transfer agents, bacterial plasmids, and partial diploidy) is followed by a presentation of experimental results (mode of chromosomal attachment, mechanism of chromosomal attachment, mechanism of detachment, abnormal detachment, and the formation of transducing phages, immunity and its genetic control, autonomous replication, joining and separation of ends, polylysogeny). The book ends with a general examination of the definition of the episome and a chapter on episomes as model systems, in which an attempt is made to apply the results obtained with the episome-bacterial chromosome system to the situation prevailing in the case of eukaryotic chromosomes and to fit them in the general biological framework.

The particularly well known λ phage is used extensively as an example. The operative organization of the λ genome and the regulation mechanisms that allow integration of the phage genome into the bacterial genome can also serve as a model for regulation in higher cells. Tumor viruses, whose genomes are attached to the chromosomes of eukaryotic organisms [*H. M. Temin*, Sci. Amer. *226*, no. 1, p. 24 (1972)] and the possibility of curing genetically defective human cells *in vitro* with the aid of transducing phages [*C. R. Merril, M. R. Geier*, and *J. C. Petricciani*, Nature *233*, 398 (1971)] show that the episome concept described here is not restricted to bacteria. The attachment of viral chromosomes to bacterial chromosomes by simple exchange may be regarded as a model for the crossing-over in meiosis, but could also indicate a way in which an increase of DNA in eukaryotic chromosomes could have come about through evolution. The attachment of concatemeres formed in the replication of viral DNA could have contributed to the DNA redundancy so typical of the eukaryotes. In view of these many aspects, the readership of this book should not be restricted to those interested in microbial genetics.

The monograph was originally published in English by Harper & Row in 1969. Some recent findings have been incorporated by *E. Geissler*, the editor of the present series, in the form of footnotes and figures. This translation is most welcome, if often somewhat too literal.

Günter Obe [NB 90 IE]

Spectroscopy in Inorganic Chemistry. Vol. 1. Edited by *C. N. R. Rao* and *J. Ferraro.* Academic Press, New York—London 1970. 1st Edit., xii. 410 pp., numerous illustr., bound, $ 19.50.

A very wide variety of spectroscopic methods have in recent years found increasing importance in structural

investigations. This has led the editors to present a collection of articles designed to give the inorganic chemist an understanding of modern spectroscopic methods and to provide him with some ideas about the application of these methods to his own particular problems. In the light of this avowed aim, it is understandable that practically every one of the nine contributions begins with a detailed introduction to the experimental and theoretical principles of the methods. Descriptions of special applications follow, some of them selected from the individual authors' work. The treatment is not always comprehensive, which is scarcely surprising in view of the size of the book. One exception is the article by *Ballhausen* concerning the spectroscopy of ionic crystals, in which one problem encountered in this area is examined in a highly interesting manner. Many a chemist will find this article quite difficult reading.

The present work will be found useful by anyone wishing to acquaint himself with the principles and range of application of the methods discussed. The extensive literature cited provides the reader with easy access to the original work. The specialist in this field will not find much in the way of new information.

H.-G. Kuball [NB 91 IE]

Molecular Acoustics. By *A. J. Matheson.* John Wiley & Sons Ltd., New York—London 1971, 1st Edit., xvi, 290 pp., numerous figures and tables, bound £ 5.50.

Very detailed information on the interaction between molecules in the gas phase, in liquids, in solids, and in high polymers can be obtained from investigations on the propagation of high-frequency sound waves. In addition to questions of energy transfer in gases and liquids *Matheson*'s book deals especially with problems that are of interest to the chemist, such as the determination of energy barriers in molecules exhibiting internal rotation, as well as viscoelastic properties of dilute and concentrated solutions of polymers, including the rotational isomerization of polymers and the helix-coil transitions in polypeptides. The investigations in solution, such as the association of ions by ultrasonic waves, are also discussed. A short chapter is devoted to the propagation of sound waves in solids, including semiconductors and ferromagnetics, and the influence of dislocations on the damping of sound waves.

The author deals briefly with the experimental methods used for the measurement of the velocity, dispersion, and absorption of sound. The fundamental theoretical views are presented in an easily understandable manner.

The book can be particularly recommended to those who wish a general picture of the possibilities offered by the investigation of the propagation and absorption of sound for the treatment of various chemical problems.

H. Gg. Wagner [NB 92 IE]

Pulse and Fourier Transform NMR. Introduction to Theory and Methods. By *T. C. Farrar* and *E. D. Becker.* Academic Press, New York—London 1971. 1st Edit., 115 pp., bound $ 7.50.

Two basic recording techniques are now available to the NMR spectroscopist. One is the normal continuous scanning of the Larmor frequency range of a nucleus, *i.e.* continuous wave (CW) NMR spectroscopy, and the other is the simultaneous excitation of all the Larmor frequencies of a nucleus with strong radio-frequency pulses of short duration, followed by Fourier transformations of the resulting time-dependent free induction signal, *i.e.* pulse Fourier transform (PFT) NMR spectroscopy. The PFT method is faster and more sensitive than the CW technique. These advantages, supported by the development of commercially available PFT-NMR spectrometers, have helped to open up PFT-NMR spectroscopy. The present monograph takes this into account and fills a gap in the introductory NMR literature.

Fundamental concepts such as nuclear energy states, relaxation, nuclear precession, and free induction are explained accurately and concisely. Vector calculation is briefly reviewed to allow a better understanding of nuclear magnetic processes. Two sections dealing mainly with equipment present an outline of instrumental requirements regarding the spectrometer, pulse unit, and computer. The authors describe relaxation mechanisms and refocusing and spin echo methods for the measurement of relaxation times. They thus stress the growing importance of relaxation times as structural parameters alongside chemical shifts and coupling constants. Topics touched upon in two special sections include nuclear nutation and spin echo experiments as well as possibilities for the use of the pulse technique to follow diffusion, exchange, and molecular dynamic processes.

102 sources are cited for further reading on methods. The absence of a section on pulsed homonuclear and heteronuclear double resonance, which can now be carried out as a routine method, is hardly surprising in view of the planned restriction of the book to about 100 pages, particularly since introductory monographs on nuclear magnetic double resonance already exist. The book is systematically organized and clearly and skillfully written, and should therefore present no difficulty even to the less experienced reader.

Eberhard Breitmaier [NB 93 IE]

Stereochemistry of Carbohydrates. By *J. F. Stoddart.* Wiley-Interscience, New York 1971. 1st Edit., xi, 249 pp., numerous illustrations, bound, £ 7.00.

This is a splendid book, and one for which we have been waiting a long time. It should find general acclaim not only among carbohydrate chemists but also among all those interested in questions of stereochemistry. Carbohydrate chemistry has contributed a great deal—for instance in the field of conformational analysis—that is important for all chemists working in organic chemistry and biochemistry, and it is therefore most pleasing that a systematic review of this field has at last appeared. Most chemists are unaware of the wealth of material in the form of excellent model substances that carbohydrate chemistry has to offer for the study of stereochemical and mechanistic problems. The present book should considerably facilitate access to material that can sometimes be quite tricky. For example, it is worth recalling that the problem of the anomeric effect was discussed for years among carbohydrate chemists before it became familiar to all chemists as a phenomenon generally encountered in heterocycles.

The book provides a clear survey of all the most important aspects of stereochemistry. It is divided into five chapters, an introduction being followed by a discussion of the problems of constitution and configuration, conformation, physical methods, and isomerism. The book is written in

an up-to-date manner, and every effort has been made to include the most recent results. In the circumstances, one is quite prepared to make due allowance for the odd shortcoming, brought about by the fact that one or two of the chapters were written in some haste. The new nomenclature on conformations of five- and six-membered rings in monosaccharides agreed by the British-American commissions has been used, although it has not yet been published by the IUPAC commissions. The nomenclature is simple and should help to clear up some of the confusion that has prevailed hitherto, so that it is likely to become accepted. The book may be warmly commended to carbohydrate chemists and to all those with an interest in stereochemistry.

Hans Paulsen [NB 94 IE]

Physicochemical Characteristics of Oligonucleotides and Polynucleotides. By *B. Janik*. IFI-Plenum, New York—Washington 1971. 1st Edit., vii, 213 pp., bound $ 20.—.

The title of the book is inviting, as there has been no comprehensive treatise on the physical and chemical properties of this group of substances since "Polynucleotides" by *Steiner* and *Beer*, published in 1961. However, one soon also begins to doubt whether this is possible in about 200 pages, since *Michelson* in 1963 was hard put to give even a sketchy picture of the material from 421 sources in the corresponding chapter of his book. What can one and what should one expect, therefore, from such a bold title?

It conceals a tabulated collection of data and literature in three chapters embracing the following topics: dissociation properties, spectral data, melting points. This is undoubtedly a selection of a few important physico-chemical properties of oligonucleotides and polynucleotides. However, one quickly becomes reconciled to this limitation, since the book proves to be a very handy collection of data because it is well classified and complete, and its recent data gives it an additional advantage over *Sober*'s 1968 "Handbook of Biochemistry".

The tabulated part is preceded by a chapter on its use. This chapter should be read carefully, since very extensive use has been made of symbols and abbreviations in classifying the material, *e.g.* to indicate data that were not taken directly from a publication, but were read from its diagrams.

Each chapter is preceded by a short text with definitions and special explanations to allow direct comprehension of the succeeding tables. Footnotes are also used to describe complicated situations. This arrangement allows a rapid and accurate grasp of the contents of the tables, which can be checked and if necessary expanded with the aid of the appended references. The arrangement of the tables can be illustrated by the chapter on dissociation properties, in which the material is grouped in the following columns: name of substance, measuring method, measuring temperature, medium, pK_{mono}, pK_{poly}, notes, references. *Janik* bases his book on a total of 289 references extending up to the end of 1970.

The book can be wholeheartedly recommended to anyone working in this field, since it offers a great deal of information, and hence saves work, at a reasonable price. Since it will quickly lose its up-to-date character with the passage of time, however, it is advisable to buy it soon!

Alfred Maelicke [NB 95 IE]

Fast Reactions. By *D. N. Hague*. John Wiley & Sons, New York—London 1971. 1st Edit., viii, 159 pp., numerous figures, bound £ 3 —.

The book is divided into four chapters, which are followed by four short appendixes. The first chapter deals briefly with molecular beam experiments and also presents a very short discussion of the diffusion-controlled reaction. The second chapter, on experimental methods, forms the heart of the book, both in its subject and in its size. Despite the need to deal with very diverse measuring methods in a fairly limited space, this chapter provides a good survey of the methods that have been used so far in the kinetics of fast reactions.

The last two chapters are concerned with selected results from the extensive literature on fast chemical reactions. The third chapter concentrates mainly on elementary processes (reactions of protons, electrons, and metal ions), while the examples in the fourth chapter are taken from reactions that are of biological interest (enzymes, nucleic acids). However, the section on metal complex formation could have been more comprehensive. It should also be noted that an error has crept into the discussion of the log k/pK relation in the last chapter: the slope factor α should not appear in the exponent when the equation is written in the logarithmic form.

The exercises appended to each chapter underline that this book is intended for students.

On the whole it provides a lucid introduction to the field of fast chemical reactions. It can be recommended to all students and newcomers to reaction kinetics as a primer, and to the more advanced as a useful addition to the existing literature.

Displacement Reactions of Phosphorus(V) Compounds and Their Pentacoordinate Intermediates[1]

Paul Gillespie, Fausto Ramirez, Ivar Ugi, and Dieter Marquarding[*]

Reactions of phosphorus(V) compounds involving the mutual interconversion of tetra- and pentacoordinate species are discussed in a critical review emphasizing stereochemical implications of the reaction mechanism. This discussion includes the formation and decomposition of the stable oxyphosphoranes, the Michaelis-Arbusov, Perkov, and Wittig reactions, interconversions of phosphines and their oxides, and the nucleophilic displacements on phosphonium compounds. Reactions of phosphate esters and related compounds receive particular attention. All chemical arguments are derived by considering the effect of factors determining the relative stabilities of phosphorane derivatives, their rates of formation, decomposition and rearrangement by bond deformation or rupture and recombination processes, considerations which are uniformly applied on the basis of concepts developed in a preceding communication[2]. It is shown that a comprehensive mechanistic interpretation of the foregoing reactions requires substantial addition to available conceptual foundations such that, in many cases, present concepts and mechanisms must be revised.

1. Introduction

Interest in the interconversions of tetracoordinate phosphorus compounds pervades many fields of pure and applied organic and inorganic chemistry including biochemistry. Much of this interest is due to the fact that certain phosphoric acid derivatives are essential to life processes in a great variety of ways while others inhibit some vital reactions.

The voluminous literature on the mechanistic aspects of tetracoordinate phosphorus chemistry[3–18] gives the impression that most of the fundamental problems in this field have been solved with only peripheral questions left unanswered. This review critically examines which of the published conclusions are firmly justified by the existing evidence and what additional statements can safely be made.

[*] Prof. Dr. I. Ugi and Dr. P. Gillespie
Department of Chemistry
University of Southern California
Los Angeles, Calif. 90007 (USA)
Present address:
Organisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)
Prof. Dr. F. Ramirez

[**] In this paper the following abbreviations are used:
ADP = adenosine diphosphate
AMP = adenosine monophosphate
ATP = adenosine triphosphate
BPR = Berry pseudorotation [2,38]
BE = binding energy
TBP = trigonal bipyramid(al)
TR = turnstile rotation [2,29,46]

A consistent treatment of the mechanistic problems in this field requires extension and revision of mechanistic concepts in prior use. Reactions under consideration in this review are discussed in terms of the properties of the pentacoordinate intermediates that are involved. The mutual interconversions of tetra- and pentacoordinate phosphorus compounds are interpreted by invoking facial attack of nucleophiles upon tetracoordinate species, in some cases followed by permutational isomerization of the pentacoordinate adduct, with attendant apical departure of a leaving group from the phosphorane derivative.

The various factors that determine the respective stabilities of the permutational isomers of the pentacoordinate intermediates are also discussed on the basis of concepts developed in a preceding communication[2].

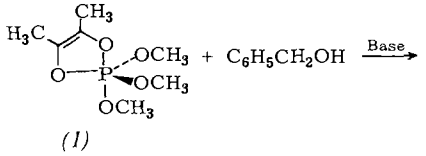
2. Some Properties of Oxyphosphorane Derivatives

The existence of stable oxyphosphoranes[19,20] provides a sound basis for the hypothesis that metastable oxyphosphoranes are intermediates in many reactions of phosphorus(v) compounds.

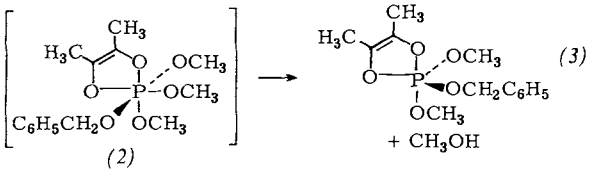
Isolable phosphorane derivatives are generally capable of rapid reorganization by bond-deformation processes, *i.e.*, "regular" permutational isomerizations.

The base catalyzed exchange of alkoxy groups that is observed when oxyphosphoranes are treated with alcohols[21] clearly shows that these systems are capable of undergoing reactions *via* hexacoordinate species (see Reaction 2.1). It follows that an analogous substitution process, involving the alcohol which corresponds to one of the alkoxy groups on the phosphorane, may result in an irregular permutational isomerization of the latter[2].

Reaction 2.1[21]



(1)



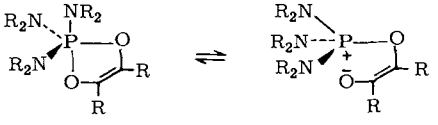
(2) *(3)*

The exchange of alkoxy groups in *(1)* proceeds with ring retention and is strongly catalyzed by 2,4,6-trimethylpyridine. It is reasonable to assume that this reaction involves the addition and subsequent elimination of alkoxy groups *via (2)*, which may be either a transition state or an intermediate. In this context, the base catalyzed hydrolysis of halogeno-amine-cobalt complexes should be mentioned; these are said to occur by the addition of water to a trigonal bipyramidal pentacoordinate cobalt complex[22].

The dissociation of phosphoranes into pairs of ions is supported by experimental evidence[23–25]. This or other related phenomena[26,27] can cause the irregular permutational isomerization of certain phosphoranes.

The rearrangement of phosphoranes *via* tetracoordinated intermediates is observed when electron donating groups stabilize the phosphonium ion and when one of the phosphorane ligands is a good leaving group. Compound *(4)* in Reaction 2.2 exists[25a,b] in two crystalline forms, the phosphorane derivative *(4a)* and the zwitterion *(4b)*. NMR data indicate that, in solution, both isomers yield the same fast equilibrium system, whose composition is solvent dependent. The ^{31}P chemical shift of *(4)* results from the chemical shifts of the phosphorane ($\delta^{31}P = +40$ ppm *vs.* H_3PO_4) and phosphonium ($\delta^{31}P = -40$ ppm *vs.* H_3PO_4) nuclei[25a,b].

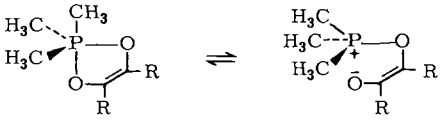
Reaction 2.2[25a,b]



(4a) *(4b)*

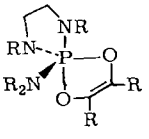
Analogous equilibria are also observed among trialkyldioxyphosphoranes[25c,d], *e.g. (5a)* ⇄ *(5b)* (cf. Reaction 2.3).

Reaction 2.3[25c,d]



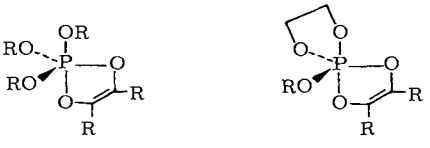
(5a) *(5b)*

Spirophosphoranes show a greater tendency to exist in the pentacoordinate state than the corresponding monocyclic systems, and only the phosphorane form of *(6)* can be observed [compare with *(4a)* ⇄ *(4b)*][25a,b].



(6)

Relatively high ligand electronegativity[28] favors the phosphorane *vs.* the phosphonium structure, and among compounds with five oxygen ligands, only the phosphorane structures *(7)* and *(8)* are observed in both monocyclic and spiro derivatives[25a,b].

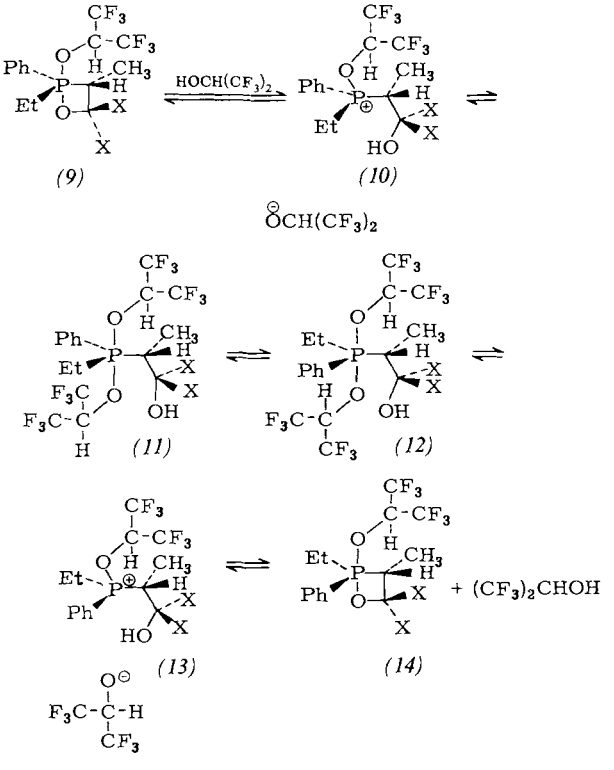


(7) *(8)*

Recently, examples of acid catalyzed irregular permutational isomerizations[2,29,30] *via* tetracoordinate intermediates have been observed. The two four-membered ring oxyphosphoranes[31] *(9)* and *(14)* are epimers which differ with respect to the configuration of the TBP center of chirality. The ^{31}P-NMR resonance of *(9)* appears at $\delta^{31}P = +30.3$ ppm, that of *(14)* at $\delta^{31}P = +21.0$ ppm. The interconversion of *(9)* and *(14)* by regular processes in neutral aprotic media is not possible because the necessary sequences of BPR or TR processes would involve species with prohibitively high energies, *e.g.*, with a diequatorial four-membered ring and apical P—C bonds[19d,31]. (The reader is referred to the footnote [**] at the beginning of this article for an explanation of the abbreviations used here and in the following text.)

The isomerization *(9)* ⇄ *(14)* is observed only in the presence of an acidic catalyst such as hexafluoroisopropyl alcohol; in the absence of the catalyst, no isomerization takes place[29]. Rapid hydrolysis of *(9)* and *(14)* occurs with formation of the acidic hexafluoroisopropyl alcohol; therefore, to avoid interconversion of *(9)* and *(14)*, moisture must be rigorously excluded. The mechanism shown in Reaction 2.4 accounts for these observations.

Reaction 2.4[29a]



The discovery of this type of *acid catalyzed irregular permutational isomerization*[29,30] emphasizes the necessity of determining the regular or irregular nature of a given process before attempting to provide mechanistic interpretations of it. The Selection Rules[5,8c-e] for phosphate ester hydrolysis do not account for this aspect of the problem and should therefore be carefully reexamined.

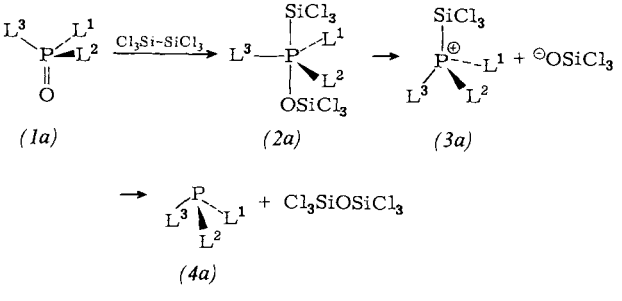
Some of the most revealing information on phosphorane derivatives has emerged from X-ray crystallographic analyses of four-membered[31b,c] and five-membered[32,33] cyclic oxyphosphoranes. The apical bonds in the TBP are longer than the corresponding equatorial bonds. The skeletal placement of the four-membered ring, as well as that of the five-membered ring, is apical-equatorial. *There is a great deal of intramolecular crowding in TBP phosphoranes*, some distances between non-bonded atoms are as short as 2.63 Å. One of the consequences of this phosphorane structural feature is that their stability is markedly increased by the presence of four- and five-membered rings. The decrease in intramolecular crowding in the TBP can outweigh the ring strain resulting on deformation of bond angles within the rings. On the other hand, ring strain rather than intramolecular crowding is the main factor in determining the stability of tetracoordinate phosphorus. This basic difference between phosphorus in its two coordination states has an important consequence for the chemistry and biochemistry of phosphate esters. Relative to the corresponding compounds in which the phosphorus is not incorporated in rings, a five-membered cyclic phosphate ester loses in stability, while the corresponding cyclic phosphorane gains in stability. Hence, there is thermodynamic and kinetic advantage in adding a nucleophile such as hydroxide or alkoxide to tetracoordinate phosphorus to form a phosphorane intermediate when a five-membered ring is present in the phosphate, or when this ring is easily formed during a reaction, in particular, if this process is rate determining[19d]. This important theme will recur often throughout this Review.

3. Steric Course of the Reduction of Phosphane Oxides and of Displacement Reactions of Phosphonium Compounds and Related Reactions

3.1. Acyclic Systems

The reduction of optically active *acyclic* phosphane oxides *(1a)* with silane derivatives (excepting trichlorosilane[34]) proceeds with inversion of configuration at the central phosphorus atom[3,13]. A plausible mechanism[3] for this reaction is shown in Reaction 3.1. Accordingly, the reduction of phosphane oxides is closely related to the displacement reactions of the phosphonium compounds.

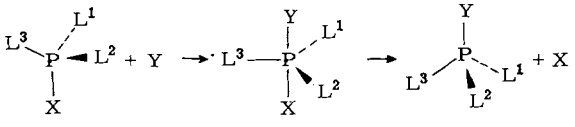
Reaction 3.1



These reactions correspond to the general pattern of Reaction 3.2, whose essential features were established *ca.* 40 years ago by *Ingold et al.*[35a,b] and formulated for the first time explicitly with an intermediate of type *(2)* by *McEwen et al.*[35c-g].

The stereochemical pattern of Reaction 3.2 applies generally to the reduction of acyclic phosphinates[36, 37] which resemble the phosphane oxides[3] and to the displacement reactions of acyclic phosphonium ions[4, 35] when the nucleophile Y attacks the tetrahedron at the face opposite the leaving group X. If this is the case, the leaving group X will appear in an apical position of the TBP intermediate *(2)*. The TBP *(2)* with apical X is favored by the "polarity rule"[2, 38–40] when X is significantly more electronegative than the ligands L^1, L^2, and L^3. The polarity rule[39,40], a semiempirical rule based upon experimental observations and theoretical deductions, will be discussed in Section 4.3. In most "normal" reactions of the type under consideration, X is substantially more electronegative[28] than L^1, L^2, L^3, and the stereochemical pattern of Reaction 3.2 is indeed observed. However, if X, L^1, L^2, and L^3 do not differ significantly in electronegativity, a different stereochemical pattern may be observed for the reaction.

Reaction 3.2



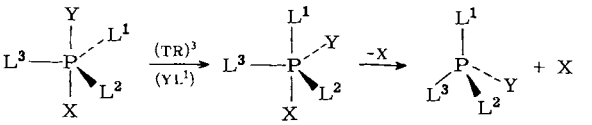
(1) *(2)* *(3)*

Any constraint that prevents the leaving group X from becoming apical, or that forces one of the ligands L^1, L^2, or L^3 to become apical while the TBP intermediate is being formed will also result in a steric course different from that of Reaction 3.2. The most important of these constraints[2,19d] originates with the presence of four- or five-membered rings. This feature forces one of the ligands that forms part of the ring into an apical position in the TBP, with consequences that will be discussed in Section 3.2. In general, nucleophiles attack the faces of skeletal tetrahedra and appear in the apical position of the TBP pentacoordinate species[2–5, 41–45]. When the tetracoordinate atom is phosphorus and the pentacoordinate TBP species is an intermediate, the next step is the decomposition of the intermediate by departure of the leaving group X from the apex of the TBP. Apical departure of X from *(2)* [without any permutational isomerization of *(2)*] gives the tetracoordinate species *(3)* which is heterochiral[30] to *(1)* if the entering and leaving groups are considered to be equivalent, *i.e.*, the displacement proceeds with inversion[3,4c,35c–e,g,36,37]. [Likewise, *(4a)* in Reaction 3.1 can be regarded as heterochiral to *(1a)*.]

A displacement of X by Y in tetrahedron *(1)* will occur with retention of configuration when the product is the optical antipode *($\bar{3}$)* of *(3)*, since *($\bar{3}$)* is homochiral[30] to *(1)* (Reaction 3.3).

The displacement with retention *(1)*→*($\bar{3}$)* *via* the TBP *(2)* requires the permutational isomerization of the latter by a triple or $(TR)^3$ process[2,29,46], or by a sequence of three single TR processes or of three BPR. One TR or BPR, or an even number of them, cannot result in displacement with retention. One of the $(TR)^3$ processes which exchange Y and a ligand L, without affecting X and the other two ligands L, is depicted in Reaction 3.3. In this illustration, Y and L^1 exchange positions to give TBP *(5)*, from which apical departure of X results in tetrahedron *($\bar{3}$)*, homochiral to *(1)* (retention).

Reaction 3.3



(2) *(5)* *($\bar{3}$)*

As a rule, the nucleophile Y (as well as the leaving group X) is more electronegative (*i.e.*, more apicophilic; see Section 4.3) than L^1, L^2, or L^3. Consequently, TBP *(2)* (which leads to inversion without permutational isomerization) is energetically favored over TBP *(5)* (which could lead to retention) by the polarity rule. All these effects then favor the pattern of Reaction 3.2, *i.e.*, displacement with inversion for acyclic systems where X and Y are more apicophilic than L^1, L^2, and L^3.

Consider now the case in which X and the ligands L^1, L^2, and L^3 do not differ substantially in apicophilicity. The situation becomes more complex, but not, we believe, for the reasons given in the previous literature[3]. As X, L^1, L^2, and L^3 become comparable in apicophilicity, the preference for the attack by the nucleophile Y at the tetrahedral face opposite X vanishes. Attack by Y on the remaining three faces opposite to L^1, L^2, and L^3, respectively, can place these ligands in an apical position of a TBP, to the extent that this is allowed by the electronegativity and the steric requirements of these ligands (the apical positions are subject to more steric hindrance than the equatorial positions). Now, the intermediate TBP can decompose by the reverse process, or can undergo certain permutational isomerizations that will bring X to the apical position from which it can then depart; cf. Reaction 3.4.

The mechanisms by which regular permutational isomerizations of TBP take place have been discussed in detail[2,29]. Here we need only summarize the conditions necessary to observe displacements with inversion or retention of tetrahedral configuration by the TR and the BPR processes, when the nucleophile Y must enter at the face opposite the leaving group X, and when Y can enter at any one of the four faces of the tetrahedron, *i.e.*, opposite L^1, L^2, L^3, or X.

If Y must enter at the face opposite X, *inversion* can result without any TR or BPR, or after $(TR)^2$, or after a sequence of an even number of single TR or BPR[46]. Retention can occur only after $(TR)^3$, or after a sequence of three single TR or BPR. Retention cannot be the result of one single TR or one BPR, because in those cases the leaving group X is transferred to an equatorial position from which it cannot depart to form a tetrahedral arrangement.

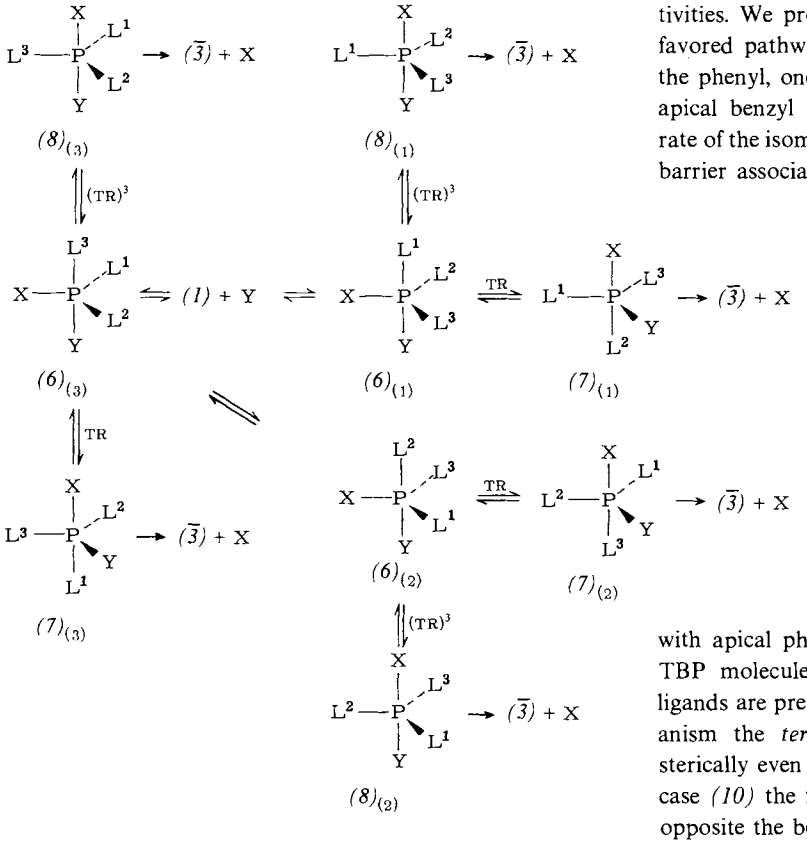
If Y can enter at the faces opposite L^1, L^2, or L^3, *inversion* can occur only after $(TR)^2$, or after a sequence of an even number of single TR or BPR. *Retention* can occur after one single TR or one BPR, (assuming that Y is able to move to an equatorial position as a result of that isomerization) or a $(TR)^3$, (see Reaction 3.4).

Table 1. Summary of the steric course of substitution reactions of tetracoordinate phosphorus compounds *via* oxyphosphoranes.

Position of entry of Y	Permutational isomerization of the TBP intermediates	Stereochemical result at the P-center
opposite X	none	inversion
opposite X	one BPR or one TR	no reaction
opposite X	two BPR or two TR or one $(TR)^2$	inversion
opposite X	three BPR or three TR or one $(TR)^3$	retention
opposite L^1, L^2, or L^3	none	no reaction
opposite L^1, L^2, or L^3	one BPR or one TR	retention[a]
opposite L^1, L^2, or L^3	two BPR or two TR or one $(TR)^2$	inversion
opposite L^1, L^2, or L^3	three BPR or three TR or one $(TR)^3$	retention

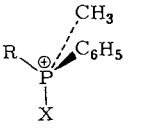
[a] Assuming that Y is able to move to an equatorial position.

Reaction 3.4



With these considerations in mind, it should be clear from Reaction 3.4 that the displacement will proceed with retention when the single TR or BPR can bring X to an apical position, *i.e.*, when the isomerization rearranges *(6)* in such a way that *(3)* is produced by the apical departure of X. On the other hand, displacement with inversion is possible only after those $(TR)^2$, or the corresponding sequences of two TR or BPR, capable of transforming TBP *(6)* into TBP *(2)* have occurred.

These concepts account for the observation that the phosphonium ion *(9a)* undergoes displacement of X by HO^- with retention[47] (Reaction 3.4), while the analogous ion *(9b)*[48], with one alkoxy ligand, undergoes displacement with inversion[48-50] (Reaction 3.2). Note that in *(9a)*, L^1, L^2, L^3, and X are of comparable electronegativities ($X = CH_2C_6H_5$), and Y can attack at the face opposite L^1 ($L^1 = C_6H_5$). In *(9b)*, L^1, L^2, and L^3 are of substantially lower electronegativity than X ($X = OC_2H_5$), and Y must attack at the face opposite it.



(9a), R = $C(CH_3)_3$, X = $CH_2C_6H_5$
(9b), R = $C(CH_3)_3$, X = OC_2H_5
(10), R = C_2H_5, X = $CH_2C_6H_5$

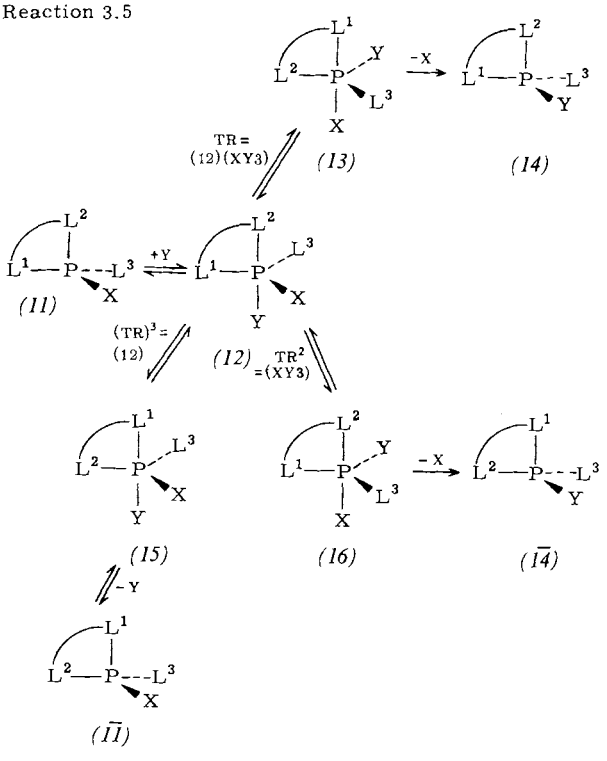
The phosphonium ion *(9a)* differs from *(10)* only in the size of one of the ligands, $(CH_3)_3C > C_2H_5$, and yet the former *(9a)* undergoes displacement with retention[47] and the latter *(10)* with inversion[4c,35c-g]. Both are examples of comparable X, L^1, L^2, and L^3 electronegativities. We propose that in the *tert*-butyl case *(9a)* the favored pathway is the attack of Y at the face opposite the phenyl, one rapid single TR or BPR, and the loss of apical benzyl (X); (retention by Reaction 3.4). The fast rate of the isomerization could be due to a very low energy barrier associated in part with the highly energetic TBP with apical phenyl and equatorial *tert*-butyl group. The TBP molecule is very crowded when relatively bulky ligands are present[19d,32,33] (see Section 4). In this mechanism the *tert*-butyl group need never move to the sterically even less favorable apical position. In the ethyl case *(10)* the favored pathway is attack of Y at the face opposite the benzyl, no permutational isomerization, and the loss of apical benzyl[4c,35c-g] (inversion by Reaction 3.2). In this case, the barrier for the TR or BPR required in the alternate pathway for retention is relatively higher.

3.2. Cyclic Systems

When the phosphorus atom of phosphane oxides and of phosphonium ions is incorporated into a small ring, *i.e.*, a four- or five-membered ring, the reduction and displacement reactions proceed, as a rule, with retention of the configuration at the reactive center[51-54] (see also ref.[55-57]), in contrast to the analogous reactions of *acyclic* systems where inversion is the normal stereochemical pattern (cf. Reaction 3.2). The reasons for this difference between four- and five-membered *cyclic* systems, on the one hand, and *acyclic* systems on the other hand, are

easily understood in terms of the TR mechanism[2,46]. Both the TR and the BPR processes are acceptable mechanistic alternatives to explain the permutational isomerizations of *acyclic* TBP phosphoranes. In four- and five-membered *cyclic* phosphoranes, the ring must always play the role of the "pair" in the single TR and the multiple $(TR)^n$ processes, and the remaining three ligands the role of the "trio". This provides the only general and consistent interpretation of the experimental data[2,29], and presumably results from the circumstance[2] that the lowest barrier for the TR is obtained when the pair angle is slightly smaller than 90°, while the trio angles are slightly larger than 90°. The analysis takes the following form in the situation under discussion[58]. Four- and, as a rule, five-membered rings are unable, for reasons of strain, to occupy the diequatorial position of a TBP molecular skeleton and must occupy the apical-equatorial position, even if this results in violation of the polarity rule. Consequently, the nucleophile Y must attack the skeletal tetrahedral face opposite one of the ligands that form part of the small ring in the cyclic tetracoordinate phosphorus compound, see *(11)*→*(12)*, and *(11̄)*→*(15)* in Reaction 3.5.

Reaction 3.5



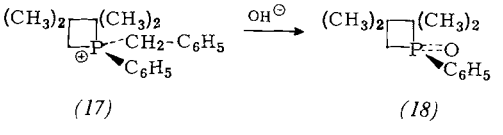
(11) *(12)* *(13)* *(14)* *(15)* *(16)* *(11̄)* *(14̄)*

Since the nucleophile Y must enter apically and one of the ring-ligands must also be apical, the leaving group X must always be equatorial; thus there must be permutational isomerization of TBP *(12)* for displacement of X by Y, if X must depart from the apical position. The cyclic TBP intermediate *(12)* is capable of undergoing a single TR, a $(TR)^2$ or a $(TR)^3$ process[46], and in general $(TR)^2$ and $(TR)^3$ processes tend to have higher barriers than the single TR process. The TR which uses the ring as the pair and which moves the leaving group X to an apical position is denoted by the permutation (1 2)(X Y 3) and transforms TBP *(12)* into *(13)*. Apical departure of X from *(13)* yields the tetrahedron *(14)* which is homochiral to *(11)* (retention).

The $(TR)^2$ which, again, uses the ring as the pair and moves X to an apical position is denoted by the permutation[2,29,30] (X Y 3)=$(TR)^2$ and transforms TBP *(12)* into *(16)*; apical departure of X from *(16)* yields *(14̄)*, the optical antipode of *(14)* and heterochiral to *(11)* (inversion). Since (TR) has, in general, a lower barrier than $(TR)^2$, retention of configuration, *(11)*→*(12)*→*(13)*→*(14)*, is the expected stereochemical pattern in cyclic tetracoordinate phosphorus compounds with small rings. Note the stereochemical consequence imposed by the ring in this case. Due to the fact that the nucleophile must enter opposite an apical ring ligand and that the ring must be the "pair", a $(TR)^3$ can only lead to inversion with no substitution, in contrast to the case for acyclic phosphoranes[2,29]. Interconversion of diastereoisomers by inversion at phosphorus in the *cyclic* system is due, in this interpretation, to the apical entry and departure of the nucleophile Y, to the occurrence of one $(TR)^3$, and to the need to involve the ring as the pair in the TR process[2,29].

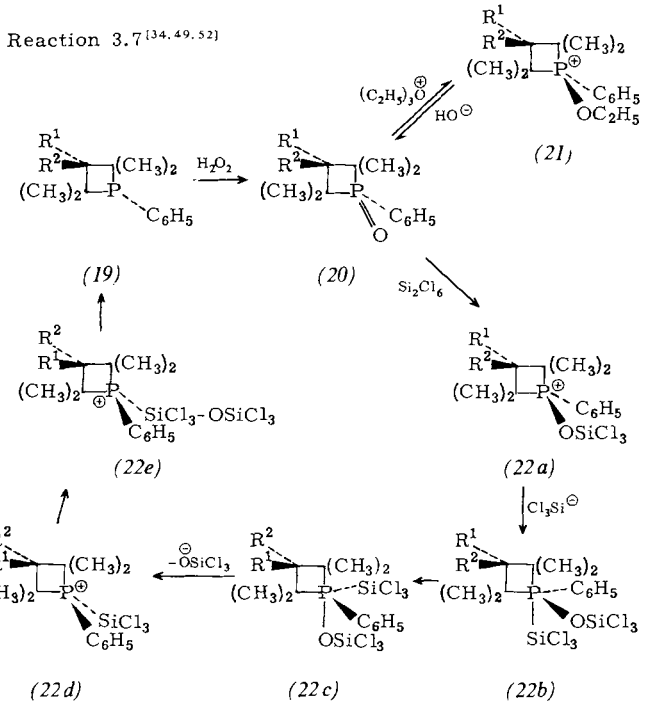
Reactions 3.6, 3.7, 3.8, and 3.9 are reported examples in which phosphonium compounds and phosphane oxides containing small rings undergo displacements and reductions, respectively, with retention of the phosphorus configuration. (In Reaction 3.7, the displacement is *(21)*→*(20)*, and the reduction is *(20)*→*(22)*→*(19)*.)

Reaction 3.6[51]



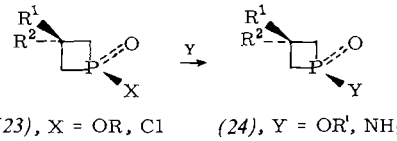
(17) *(18)*

Reaction 3.7[34,49,52]



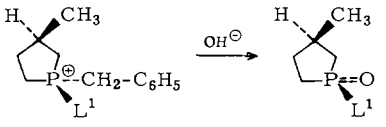
(21) *(19)* *(20)* *(22e)* *(22a)* *(22d)* *(22c)* *(22b)*

Reaction 3.8[53]



(23), X = OR, Cl *(24)*, Y = OR', NH_2

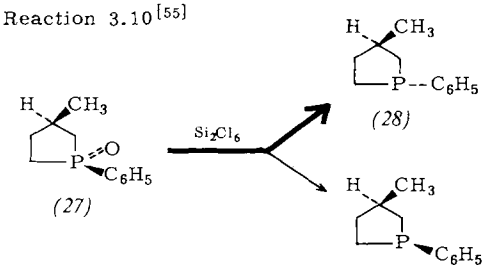
Reaction 3.9 [54, 57]



(25a), $L^1 = CH_3$ (26)
(25b), $L^1 = C_6H_5$

Reaction 3.10 describes some observations that have defied interpretation in the past[55]. The reduction of the cyclic phosphane oxide (27) proceeds to give predominantly (28) with inversion, rather than (29) with the expected retention: [(28)] ≫ [(29)].

Reaction 3.10 [55]

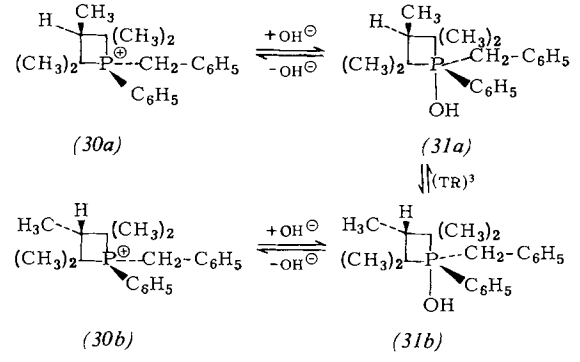


(27) (28) (29)

This anomaly can be explained in one of two ways. In the first, (28) and (29) are formed according to the pattern of Reaction 3.5, but in this case the barrier for $(TR)^2$ must be lower than that for the single TR, hence (12) ⇄ (16) ⇄ (14) is favored over (12) ⇄ (13) ⇄ (14), and inversion results[58]. A second interpretation is that the homochiral product is formed according to Reaction 3.5: (11) ⇄ (12) ⇄ (13) ⇄ (14), or (27) → (29), while the heterochiral product (inversion) is formed according to Reaction 3.1: (1a) → (2a) → (3a) → (4a), or (27) → (28). In this interpretation, the TBP intermediate (2a) must have a diequatorial five-membered ring, but the high strain associated with this situation[2] (*ca.* 40 kcal/mol) could certainly be offset by the placement of the relatively apicophilic ligand X = $OSiCl_3$ in apical position in (2a), but in equatorial position in (12); likewise the carbon = L^2 is equatorial in (2a) but apical in (12). Therefore, TBP (2a) may be favored over (12) by the effect of the modified polarity rule *vs.* ring strain, in this particular case.

Reaction 3.11 is an illustration of inversion of configuration at the phosphorus center of chirality without any substitution of one group by another. In our interpretation, the pathway is (11) ⇄ (12) ⇄ (15) ⇄ (11), of Reaction 3.5, where there is a $(TR)^3$ process with the small ring forming the pair and the other ligands the trio. This is favored because it brings back the most electronegative ligand OH to the apical position (31a) → (31b)[2].

Reaction 3.11 [3,56]

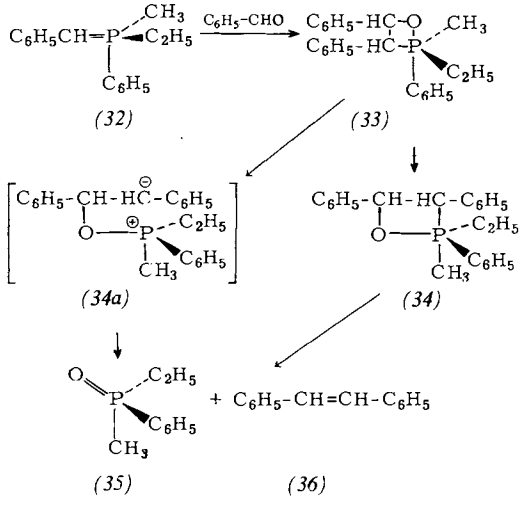


(30a) (31a) (30b) (31b)

Reaction 3.12 represents the application of these concepts to the interpretation of the retention of configuration about phosphorus during a Wittig olefin synthesis[4c, 30, 35d, f, g].

The interpretation of the Wittig reaction by invoking one or more pentacoordinate intermediates and employing the apical entry and departure concept for the formation and decomposition of the TBP requires one to force the first pentacoordinate adduct (33) to form either (34) or (34a). It is conceivable that the decomposition of (33) to products (35) and (36) is concerted with reorganization (*i.e.*, by a TR process) such that the breaking C—O and P—C bonds are already weakened in the TR barrier situation. The fact that the ring must be the pair in the TR forces retention on the reaction (see also ref.[29]).

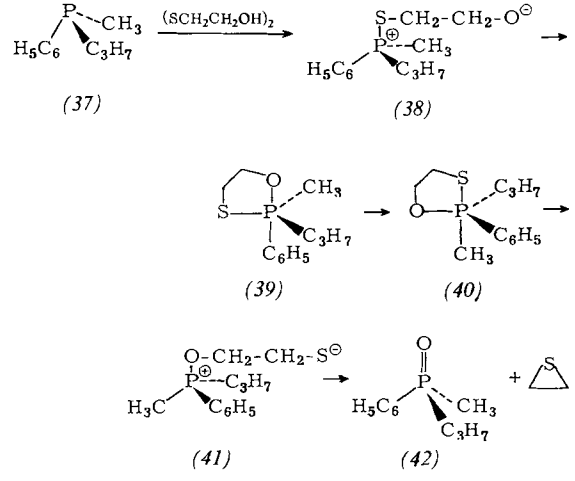
Reaction 3.12 [35d, g]



(32) (33) (34a) (34) (35) (36)

The steric course of Reaction 3.13 is an obvious consequence of apical entry and departure and a TR process with the ring as the pair.

Reaction 3.13 [13b]



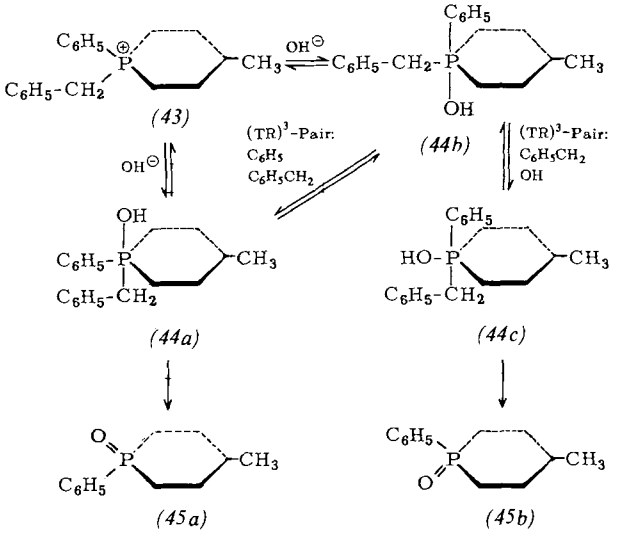
(37) (38) (39) (40) (41) (42)

Six-membered and larger rings are free of the constraints to which the small rings are subject. In general, if apicophilicity considerations so allow, the six-membered rings prefer the diequatorial placement, but can also adopt an apico-equatorial attachment. If the six-membered ring occupies the preferred diequatorial arrangement, then it functions as part of the trio in the TR processes, and in such a case, TR and $(TR)^2$ will move it into an apico-equatorial attachment, *while $(TR)^3$ will leave it diequatorial.* It should be noted that with a diequatorial six-membered ring, if one insists on invoking the BPR process, one must use a ring member as a pivot which leads to an apico-equatorial ring placement; otherwise, the ring would have to span the two apical positions of the new TBP skeletal arrangement.

If the six-membered ring occupies the apico-equatorial placement, and it functions as the pair of TR processes, then TR, $(TR)^2$, and $(TR)^3$ will necessarily leave it in the apico-equatorial placement, although the ring termini will exchange the skeletal positions as a result of TR and $(TR)^3$, but not $(TR)^2$. The participation of the ring in the trio of the TR or $(TR)^2$ can result in apico-equatorial placement with exchange of termini, or in diequatorial placement of the ring, while in the $(TR)^3$ the ring retains its placement.

In the six-membered cyclic systems, just as in the acyclic case, displacements occur normally with inversion (Reaction 3.2). An apparent exception is illustrated in Reaction 3.14 where there is some retention[57], although inversion is preferred. If one assumes here the preferred diequatorial placement and keeps the ring in that attachment, then the results can be interpreted in terms of nucleophilic displacement involving a $(TR)^3$ reorganization of the TBP intermediate *(44)*, using the ring as part of the trio. Note that in Reaction 3.14 there is not much difference in the electro-

Reaction 3.14[57]

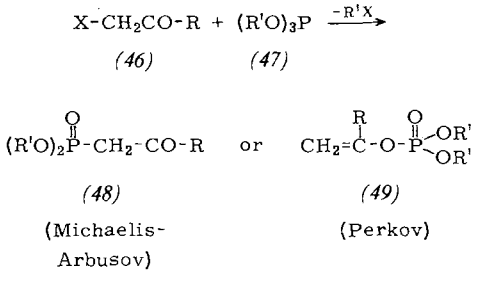


negativities of the leaving group X and of the ligands L^1, L^2, and L^3. Here, the preference is for apical phenyl (L^1), as in TBP *(44b)*, rather than apical benzyl (X) as in TBP *(44a)*. However, retention requires a $(TR)^3$, *(44b)* → *(44c)* → *(45b)*, while inversion requires no permutational isomerization, *(44a)* → *(45a)*.

3.3. A Note on the Perkov and the Michaelis-Arbusov Reactions

The reactions of trivalent phosphorus compounds with α-halocarbonyl compounds (Reaction 3.15) provide one of the most intriguing and controversial mechanistic problems in phosphorus chemistry[59]. Depending on the structure of the phosphorus(III) derivative, the nature of the halogen X, the type and degree of substitution at the α-carbon of the carbonyl compound, and the type of function (R = H, alkyl, aryl, OR, *etc.*), one obtains one or the other, or mixtures, of two products, a phosphonate *(48)* (or a phosphonium derivative) with a new P—C bond, and the thermodynamically more stable enol ester, *(49)*, with a new P—O bond.

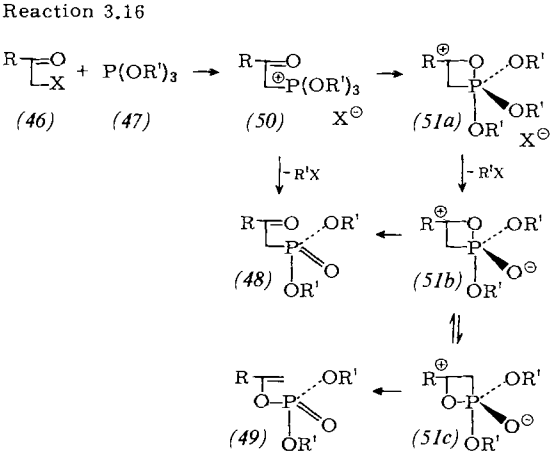
Reaction 3.15



Many mechanisms have been proposed[59] to account for various aspects of these reactions, and it has been recognized that the two reactions could proceed *via* a common intermediate or occur independently. The latter view has gained some preference over the common-intermediate hypothesis[59b].

The concepts discussed in this review lead to a further alternative for a possible solution to the problems concerning the Michaelis-Arbusov and Perkov reactions. Both reactions can result from a common phosphonium intermediate *(50)* which can either directly, or *via* *(51a)*[21b,31a,b,60] and *(51b)*, lead to the Michaelis-Arbusov product *(48)*, or through *(51c)* to the Perkov product *(49)* (see Reaction 3.16).

Reaction 3.16



The following is a statement of the Curtin-Hammett principle which may prove useful for this discussion:

In a complex kinetic system of parallel and consecutive reactions, any set of species in thermodynamic equilibrium behaves as a single kinetic entity and may be represented by any one of the species participating in the equilibrium set. This statement must be confined to systems where parallel reactions are of the same kinetic order and equilibria between participants of equilibrated species are established so rapidly relative to other participants in the kinetic system that thermodynamic equilibrium prevails at any instant of the reaction.

When the Curtin-Hammett principle applies, the ratios of the products are exclusively determined by the rate determining transition states leading to them. Such a principle is a consequence of the fact that the same type of dependence upon thermodynamic equilibrium and reaction rates exists for the free energies of the species concerned, *i.e.*, in both cases, functions of the type $\exp(-\Delta G^{\neq}/RT)$ are involved.

The dependence of the ratio of the rate of formation of the Michaelis-Arbusov product *(48)* to the Perkov product *(49)* upon the rate constants of the individual steps of Reaction 3.16 is given by Equation (3.1).

$$\frac{d[(48)]}{dt} \Big/ \frac{d[(49)]}{dt} = [k_{(50)\rightarrow(48)} \cdot k^{-1}_{(50)\rightarrow(51a)} \cdot k^{-1}_{(51c)\rightarrow(49)}] \times [-k_{(51c)\rightarrow(51b)} + k^{-1}_{(51b)\rightarrow(51c)}(k_{(51b)\rightarrow(48)} + k_{(51b)\rightarrow(51c)})(k_{(51c)\rightarrow(51b)} + k_{(51c)\rightarrow(49)})] + (k_{(51b)\rightarrow(48)} \cdot k_{(51b)\rightarrow(51c)} \cdot k^{-1}_{(51c)\rightarrow(49)}) \times (k_{(51c)\rightarrow(51b)} + k_{(51c)\rightarrow(49)})^{-1} \quad (3.1)$$

This indicates that without suitable data which permit one to cancel some of the terms in Equation (3.1), it is not possible to predict for a given α-haloketone and a set of selected reaction conditions whether the formation of *(48)* or *(49)* will prevail.

4. Mechanistic Problems Associated with the Hydrolysis of Phosphate Esters and Related Reactions

The problems associated with the hydrolysis of phosphate esters can be presented in terms of the following questions.

4.1. Are the Oxyphosphoranes Intermediates in the Hydrolyses of Phosphate Esters?

Experimental data[2, 5, 8–12, 20, 32, 61] support the assumption that oxyphosphoranes are intermediates in the hydrolysis of cyclic phosphate esters and analogous systems when the ring is five-membered. The concept of phosphorane *intermediates* in the displacement reactions of tetracoordinate phosphorus compounds originates with *McEwen et al.*[35c–g]. *Westheimer et al.*[8a] initially considered the concept of pentacoordinate *transition states* as an alternative in these reactions. Shortly thereafter, however, *Ramirez et al.*[9a, 11, 20a–d] established the former as the mechanistic interpretation for these reactions followed by a similar determination from *Westheimer et al.*[5, 8c–e, g].

The evidence for these intermediates is not as compelling in the case of phosphate esters of monofunctional aliphatic alcohols. However, the sum of all the evidence favors the general formulation of Reaction 4.1, *i.e.*, an addition-elimination mechanism where T and T′ = the tetracoordinate phosphate derivative, and N and N′ the nucleophile:

Reaction 4.1.

$$N + T \rightleftharpoons TBP \rightleftharpoons T' + N'$$

Little is known about the dynamics of this type of process; substantial differences in the relative rates of the reactions can be expected in different cases.

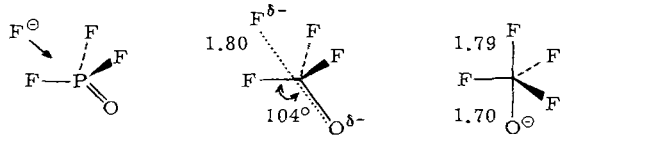
The stability of an oxyphosphorane relative to its tetracoordinate precursor or decomposition product increases with the number of P—O bonds and decreases with the accumulation of steric bulk in the immediate vicinity of the phosphorus atom. In fact, the oxyphosphoranes so far isolated contain at least two P—O bonds, and in such cases, the molecule also contains one or more four- or five-membered rings, which help reduce the local steric bulk about the phosphorus. Among acyclic oxyphosphoranes[20e–g], four or five P—O bonds are required to produce isolable but still slightly unstable oxyphosphoranes.

4.2. Is there a Well-defined and Consistent Steric Pattern for the Formation and Decomposition of the Pentacoordinate Intermediates?

All evidence points towards a mechanism in which the oxyphosphorane intermediate is formed from the tetracoordinate precursor by attack of the nucleophile at one of the tetrahedral faces, which, with regard to the skeleton of the intermediate, corresponds to an apical entry; the decomposition of the oxyphosphorane intermediate to form a tetracoordinate compound occurs *via* the departure of an apical group (see also Section 3), according to the mechanistic concept of *Ingold et al.*[35a, b] that was developed further by *McEwen et al.*[35e–g].

The postulated apical entry and departure can be supported by arguments similar to those used for the S_N2 reactions of tetrahedral carbon systems[2, 3, 4c, 5, 8, 39–44]. Moreover, this hypothesis is consistent with the observation that apical bonds in phosphorane derivatives are weaker and longer[30] than comparable equatorial bonds[33, 39, 40] having smaller force constants[31b, c].

Equatorial entry and departure has been considered as an alternative to the apical case by *Westheimer et al.*[5, 8a] and was favored by *Cram et al.*[45] for analogous processes involving sulfur compounds. An entering group approaching a molecule with a tetrahedral skeleton at one of the tetrahedral "edges" results in equatorial entry. Then, this group and two of the ligands of the tetracoordinate species become very close prior to the incoming moiety being near enough to the central atom to undergo any bonding interaction. This leads to a situation where the strong steric interactions leading to the bending motions of the two edge ligands is not compensated by a simultaneous bond formation. In the case of face attack, although the entering group now interacts with



best

Δ = -69 kcal/mol

(2d)

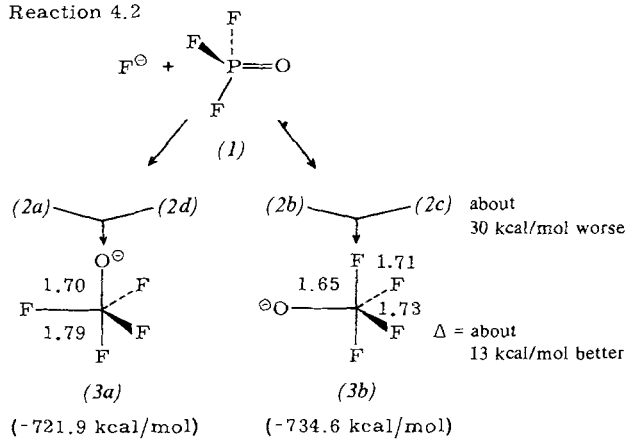
(-650.6 kcal/mol)

three ligands, this steric interaction is weaker as the route to the central atom is more open, allowing bonding to occur with less bending. This pathway, in effect, allows a more efficient rehybridization, *i. e.* less bending required, leading to more positive overlap. It would be desirable to have detailed quantitative comparisons between the apical entry-departure mechanism and its alternatives; barriers for the various types of nucleophilic attack of an $F^{\ominus}$ anion on POF_3 *(1)*, as a model system, were calculated using the CNDO/2 approximation[43b] (see also ref.[2] and literature quoted therein). Results of these calculations indicate that the barrier situations can, with some approximation, be represented by formulas *(2a–d)* shown with their binding energy in kcal/mol.

These model calculations indicate that apical attack on the FFF face *via* the barrier model situation *(2a)* is the most favorable mode of nucleophilic attack of $F^{\ominus}$ on POF_3. The latter, in comparison to attack on the OFF face [*via (2b)*] is favored by 15 kcal/mol, due in the main to increased electrostatic repulsion prior to the gain in energy upon formation of sufficient σ bond character. Equatorial attack on an FF edge *(2c)* is disfavored by 30 kcal/mol relative to apical attack *via (2a)* while FO edge attack *via (2d)* is approximately 69 kcal/mol higher in energy *vs. (2a)*.

Formation of the most stable TBP is not always favored kinetically as indicated by comparisons of *(2a)* and *(2b)* in Reaction 4.2.

Reaction 4.2



(3a)

(-721.9 kcal/mol)

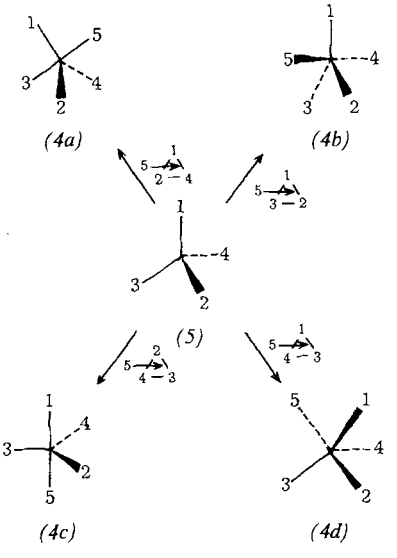
(3b)

(-734.6 kcal/mol)

By apical addition of a nucleophile, a tetracoordinate molecule *(5)* can be transformed into four different permutation isomers of a pentacoordinate intermediate, *(4a)–(4d)*.

Decomposition of a pentacoordinate molecule by the departure of an apical ligand can lead to two different

Reaction 4.3



species with a tetrahedral skeleton, which are not necessarily isomeric. In this decomposition the group with the better leaving properties departs preferentially[41–43][*].

[*] *Note added in proof:* Apical elimination and addition (re-entry of an apically eliminated ligand into one of the four "faces" of the tetracoordinate intermediate) of ligands in pentacoordinate molecules with a TBP skeleton is an irregular reorganization mechanism leading to six other (of the 20 conceivable, when all 5 ligands are different) permutation isomers. This mechanism (AEA) is resultwise equivalent to the $(TR)^2$. AEA generates the mutual interconversions of 10 each of the permutation isomers and partitions the 20 isomer set into two equivalence classes or "antipodic ensembles". For each of the species in one ensemble there exists a mirror image in the complementary emsemble. The AEA and the $(TR)^2$ are both described by the same graph consisting of two disjoint parts. These subgraphs each contain 10 points and 30 lines representing the 10 species and their 30 pairwise interactions.

4.3. Is There a Preferred Distribution of Ligands in the Oxyphosphorane Intermediate?

Quantum mechanical considerations that take into account d-orbital effects classify the ligands of a given set attached to pentacoordinate phosphorus into apicophilic and apicophobic[2]. In many cases the apicophilic ligands correspond to the most electronegative[28] ligands of the original polarity rule[39,40]. However, binding energy data (BE) of pentacoordinate phosphorus compounds calculated by the use of the CNDO/2 approximation suggest that with the aid of only one ligand property, *e.g.*, electronegativity, one can get at best a rough estimate of the relative stability of several permutation isomers[2,29]. When more than two permutation isomers are conceivable, the sequence of their relative stabilities cannot be predicted safely by the polarity rule in all cases.

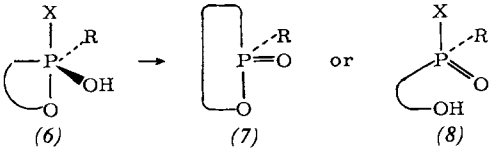
4.4. Is Apical-equatorial Placement of a Five-Membered Ring Preferred in the Pentacoordinate Intermediate of Cyclic Phosphate Hydrolysis?

Initially[8a], a pentacoordinate species with a TBP skeleton and an apico-equatorially placed five-membered ring as the activated complex was considered as one among six alternative structures for the hydrolysis of ethylene hydrogen phosphate. Reactions of the latter type were later interpreted using pentacoordinate intermediates with apico-equatorial five-membered rings as a TBP skeleton[8c], after X-ray crystallographic studies of cyclic oxyphosphorane derivatives with five-membered rings had shown that the rings are attached apically-equatorially to the TBP molecular skeleton[32]. The same is found for cyclic oxyphosphoranes with four-membered rings[31b]. A four-membered ring with a 90° TBP apical-equatorial angle is definitely less strained than that with a deformed 120° TBP diequatorial angle[2,29]. Similar arguments apply to the five-membered ring situation, as can be shown by calculations on suitable model compounds[2,29]. The total strain appears as the sum of the contributions of the deformations of all members of the ring, and includes also the conformational contributions[62]. These considerations suggest that six-membered rings should preferentially be placed diequatorially on the TBP skeleton. However, a thorough experimental and theoretical study of six-membered cyclic oxyphosphoranes is required to determine the generality of this conclusion.

4.5. Are Rings Preferentially Preserved or Opened Upon Decomposition of Cyclic Oxyphosphoranes?

There is no general answer to this question. The fate of the ring is closely dependent upon the chemical constitution of the oxyphosphorane derivative and upon the specific reaction conditions whose influence varies from case to case[*]. Much experimental evidence exists concerning the acid and base catalyzed hydrolyses of cyclic phosphate and phosphonate esters in aqueous media, and they have been extensively discussed[5,6,8,10,12]. However, this effort has not yielded a consistent and general picture of the fate of the ring in these compounds. Valuable information can be obtained from studies on the hydrolyses of cyclic phosphate esters[9a,61c,d,h], and of isolable cyclic oxyphosphoranes[9,20a,b,d,61a–d,f] with limited amounts of water in aprotic solvents; cf. Sections 6 and 7. The transformations of the five-membered cyclic oxyphosphoranes into the tetracoordinate phosphate under these conditions generally proceed with preservation of the ring[9,20a,d,61a–d,f]; cf. *(6)*→*(7)* in Reaction 4.4. Sometimes this tendency for the preservation of five-membered rings during the decrease in coordination number is obscured by rapid secondary reactions among the products that result from the primary reaction stage, *i.e.*, the initially formed cyclic phosphate ester is subsequently transformed into an acyclic phosphate *(8)*.

Reaction 4.4



4.6. What Happens to the Phosphoryl Oxygen (P=O) when the Tetracoordinate Phosphate is Transformed into an Oxyphosphorane Intermediate?

The phosphoryl oxygen of the phosphate can be transformed into an apical or an equatorial ligand of the corresponding oxyphosphorane derivative. Depending on the protonation or lack of it during the addition step, this transformation can result in a hydroxyl group or in an anionic oxygen ligand.

The calculated BE data of the mono- and dianions of various suitable polyhydroxy phosphorane models[2,29] demonstrate clearly that the $O^{\ominus}$ ligands have a pronounced tendency to occupy equatorial positions, as had been already assumed[12] from an application of the polarity rule (see Section 4.3). The equatorial hydroxyl groups of polyhydroxy phosphoranes are, by many orders of magnitude, more acidic than the corresponding apical hydroxyl groups. Hence, one should expect that oxyphosphorane derivatives arise from tetracoordinate phosphates *via* two different mechanisms.

Mechanism 4.6.1.

If sufficient protons are available in the reaction medium, and if the molecule is free from any constraint that requires the apical placement of a particular ligand[63], then the

[*] *Note added in proof:* In general, it seems that the collapse of an oxyphosphorane with the loss of *methanol* and the retention of the ring is favored over the collapse with ring opening (see Section 6). The apparent exception to this rule encountered in the hydrolysis of dimethyl acetoin phosphate (Section 5.2) may be due to the rather special nature of the corresponding oxyphosphorane intermediate; in this intermediate one of the ring carbons is a hemiacetal analog and the initial collapse of the oxyphosphorane probably involves C—O bond rupture and not the P—O rupture. The dimethyl acetoin phosphate case does not represent, strictly, a comparison of the tendency of the ring to be retained or opened in the collapse of an oxyphosphorane by departure of an oxygen ligand from TBP phosphorus. When the collapse of an oxyphosphorane involves the loss of *water* and the retention of the ring, that pathway seems to be slightly disfavored over the pathway for ring opening (see Section 5.3). These situations are further discussed in the appropriate Sections.

phosphoryl oxygen of the phosphate will appear as an apical OH in the TBP because in this process all participating components of the incipient oxyphosphorane are collinear (*i.e.*, the incoming nucleophile, as well as the P and the phosphoryl O). A hydroxyl group is also more apicophilic than an alkoxyl group.

Mechanism 4.6.2.

If there is insufficient proton supply, or if some overriding constraint in the molecule (*e.g.*, the presence of a five-membered ring) forces one of the ligands to be apical, then one should expect that the phosphoryl oxygen will appear as an $O^{\ominus}$ ligand in an equatorial position of the TBP skeleton.

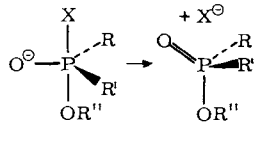
4.7. Which Conditions Promote the Formation of a Tetracoordinate Phosphorus Compound from a Pentacoordinate Oxyphosphorane Derivative?

Any set of conditions which allows the departure of an apical ligand from the TBP phosphorane *without charge separation* should facilitate the decomposition of the phosphorane. This condition can be met both in solvents that are capable of supporting a charge on a molecule, and in those that are incapable of supporting a charge on a molecule.

4.7.1. The usual media that can support a charge on a molecule are protic solvents of variable polarity, such as water and alcohols. In protic solvents one can conceive three extreme situations.

1. When there is proton deficiency, as in Reaction 4.5, the negative charge on the equatorial $O^{\ominus}$ ligand of the TBP is transferred to the departing apical ligand X, *(9)*→*(10)*.

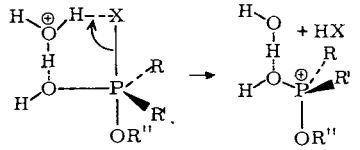
Reaction 4. 5



(9) *(10)*

2. When protons are readily available, as in Reaction 4.6, a proton from the solvent-oxonium is transferred to the decomposing oxyphosphorane, *i.e.*, the positive charge is transferred from oxygen to phosphorus, *(11)*→*(12)*.

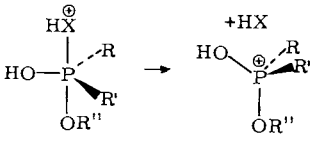
Reaction 4. 6



(11) *(12)*

3. When there is proton abundance, and when the nature of the ligand X in the phosphorane favors its protonation, one obtains the case shown in Reaction 4.7. Now the positive charge is transferred from the ligand X to phosphorus, *(13)*→*(14)*.

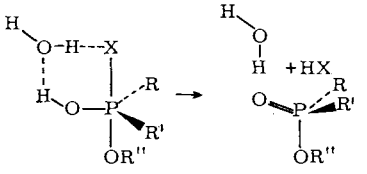
Reaction 4. 7



(13) *(14)*

4.7.2. The media that cannot support a charge on a molecule are to be found among aprotic solvents of relatively low polarity. In this situation small amounts of water may yield hydrogen bonded adducts of the oxyphosphorane involving one or more water molecules, *e.g.*, *(15)* of Reaction 4.8. Proton transfers which avoid charge separation may still occur within these adducts, *(15)*→*(16)*.

Reaction 4. 8



(15) *(16)*

In Reactions 4.5–4.8 the phosphoryl oxygen of the product originates from equatorial $O^{\ominus}$ or HO groups. In the cases of Reactions 4.6–4.8 the original hydroxyl group could have been apical in the TBP phosphorane as well.

4.8. Do the Oxyphosphorane Intermediates Undergo Permutational Isomerizations; and, if so, by what Mechanism?

To apply the principles set forth in Sections 4.1 through 4.8 one must introduce the further concept of permutational isomerization of the TBP phosphorane intermediate. It is mandatory to distinguish between *regular* and *irregular permutation isomerizations*[2,29]. Regular processes occur without bond making and breaking, with preservation of all the proximity relationships defined by the bond system and maintenance of coordination number. Regular processes are possible only in flexible molecular skeletons. Regular reorganization processes of molecules with monocentric skeletons, such as the pentacoordinate phosphoranes, correspond in principle to the conformational interconversions of molecules with polycentric skeletons, *e.g.*, the ethane derivatives; the differences are due to different types of skeletal flexibility[2,29].

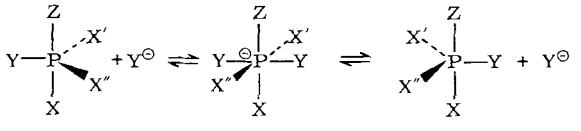
Irregular reorganization processes, in contrast to the regular ones, proceed with opening and closing of covalent bonds *via* intermediates which differ from the initial and final compounds in their coordination numbers[21,23–27,29a]. The regular permutational isomerization of stable phosphoranes and of postulated phosphorane intermediates have been the subject of recent intensive studies and discussion[2,3,5,26,27,29–31,38,45,64–68]. Of all the conceivable mechanistic alternatives which are given by the subclasses of S_5[2,29] only two can be accepted as providing reasonable pathways for the regular reorganization processes of pentacoordinate molecules with a TBP skeleton, namely *Berry pseudorotation*[38] (BPR)

and the *simple and multiple turnstile rotations*[2, 29] (TR). In some cases, the TR mechanism provides the only interpretation of the experimental data[2, 29]. Cyclic phosphorane derivatives where the phosphorus is a part of a four- or five-membered ring (except spiro compounds) undergo only such *TR processes in which the ring participates as the pair.*

The irregular rearrangement processes of phosphorane derivatives occur *via* tetracoordinate or hexacoordinate species. When rearrangement processes of phosphorane derivatives are open to investigation by NMR, it is possible, in favorable cases, to discriminate experimentally between regular and irregular processes. If, for example, there is a spin-spin interaction between a ligand and the phosphorus central atom, then this coupling is not destroyed by regular processes, but disappears during irregular processes, unless these are intramolecular and proceed extremely rapidly.

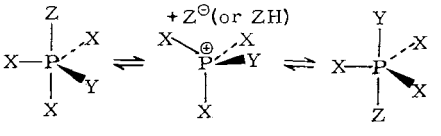
Possible irregular permutation isomerizations of oxyphosphorane intermediates in the hydrolyses of phosphate esters and related reactions should not be overlooked. There are many experimental observations that can be interpreted solely on the basis of irregular isomerizations of the intermediates (see Section 2.2). Base catalysis favors irregular processes proceeding *via* higher coordination intermediates (*e.g.*, see Reaction 4.9). Thermal or acid catalyzed reactions are more likely to involve irregular processes *via* intermediates that are lower in coordination number (Reaction 4.10).

Reaction 4.9



(17) *(18)* *(19)*

Reaction 4.10



(19) *(20)* *(21)*

It seems quite likely that under certain conditions in the hydrolyses of phosphate esters, oxyphosphorane intermediates are capable of adding hydroxide ions to form hexacoordinate intermediates (or transition states). If hexacoordinate species are indeed involved (cf. Section 2), the *Selection Rules*[5, 8c, d] postulated for the hydrolyses of cyclic phosphates lose their basis. The kinetic analysis of the hydrolysis of phosphate esters to be presented in Section 5 shows the added complexity that is introduced by the involvement of hexacoordinate species in these reactions. Even neglecting those species, the kinetic systems are quite complex, and it will be shown that kinetic observations *per se* are insufficient to justify the proposed Selection Rules[5, 8c, d] and to resolve the troublesome questions raised by the previous use of the Principle of Microscopic Reversibility[3, 5]. However, it should be emphasized that some elements of the Selection Rules, notably apical entrydeparture and ligand polarity, are quite valid and have been incorporated into the concept developed in this Review.

4.9. What is the Effect of Metal Ions on the Behavior of Tetra- and Pentacoordinate Phosphoric Acid Derivatives?

Biochemically important derivatives of phosphoric acid exist, under physiological conditions, largely as anions. These anions have little tendency to react with nucleophiles, in part due to decreased electrophilicity, in part due to the fact that in polyphosphates the leaving group porperties of the phosphate moiety are substantially decreased by the negative charge *vs.* the undissociated compounds. It is widely accepted that metal ions, such as Mg^{2+}, affect the reactivity of these phosphoric acid derivatives by neutralizing negative charges thus improving their tendency to react with nucleophiles[7, 29d, 69, 70]. Indeed, it has been suggested[7d, h] that the chief function of magnesium ion in promoting the reactions of polyphosphates is its ability to "neutralize" the negative charges of the polyphosphate. This concept, however, is not always sufficient for the interpretation of the observations; for example, Ca^{2+} and Mg^{2+} do not cause a significant rate increase in the hydrolysis of ATP[71] at pH 8.5 to 8.8.

The order of stability of the 1:1 complexes of metal ions and phosphate ligands[72] like AMP, ADP, ATP is: $Ba^{2+} \approx Sr^{2+} \approx Ca^{2+} \approx Mg^{2+} < Mn^{2+} \approx Fe^{2+} \approx Co^{2+} \approx Ni^{2+} \approx Cu^{2+} \approx Zn^{2+}$. This order is independent of the nature of the phosphate[72], as shown by the comparable stability of complexes of HPO_4^{2-} and $HP_3O_{10}^{4-}$. The nucleoside moiety in nucleotides seems to have little effect on the stability of the complexes with metal ions[72]. The oxygen-containing donor-ligands, unlike the nitrogen and sulfur analogs, do not effectively discriminate among the various metal ions, as far as complex stability is concerned[72].

For the discussion of the possible role of metal ions in phosphate and pyrophosphate chemistry, one must take into account the formation of oxyphosphorane intermediates and the effect of the polarity of the reaction medium on the interaction of metal ions with tetracoordinate and pentacoordinate phosphorus derivatives. For example, it is conceivable that the coordination of a metal cation with the anions of oxyphosphoranes, under certain conditions, could affect the relative stabilities of the various permutational isomers of the latter and their interconversion barriers.

These effects will be discussed in a subsequent review dealing with the behavior of AMP, ADP, and ATP, and related systems.

4.10. Summary of Rules

The interpretation of the available data on the hydrolysis of phosphate esters and related compounds is achieved by the consistent application of the eight postulates discussed in this Section. The interpretation of the data on reduction

of phosphane oxides and on displacement reactions of phosphonium compounds involves the same postulates, with minor variations, which depend on the circumstance that several of the ligands are carbon atoms rather than oxygen atoms. This affects primarily the relative stability of the phosphorane intermediates, the placement of ligands in the TBP, the ability of ligands to act as leaving groups, and the barriers for the permutational isomerizations of the TBP molecules; for future reference, the eight rules that evolve from the present analysis can be summarized as follows:

1. Intermediacy of oxyphosphoranes.

2. Apical entry-departure rule.

3. The polarity rule modified by taking into account d-orbital effects and ligand-ligand interactions.

4. Exclusive apical-equatorial placement of five-membered and four-membered rings in oxyphosphoranes, in contrast to the preferred diequatorial placement of six-membered rings.

5. Preferential retention of rings in decompositions of cyclic oxyphosphoranes.

6. Equatorial placement of anionic oxo ligands, apical or equatorial placement of hydroxyl groups, in oxyphosphoranes.

7. Avoidance of charge-separation in decomposition of oxyphosphoranes.

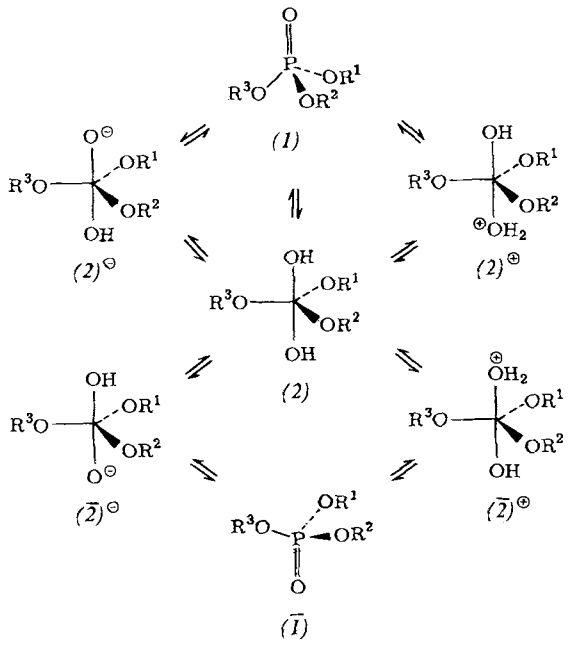
8. Permutational isomerization of oxyphosphorane by regular and irregular processes. Regular permutational isomerizations may occur by the TR or BPR mechanism for open chain systems; however, these processes must (with the exception of spiro compounds) go *via* TR for cyclic systems. We observe exclusive involvement of the four- and five-membered rings as the pair and normally the six-membered ring as the trio in the pair-trio combination of the TR-mechanism in oxyphosphoranes. Irregular permutational isomerizations occur *via* intermediates (or transition states) with coordination number six (base-catalyzed), and *via* intermediates with coordination number four (thermal or acid-catalyzed).

5. Kinetic Data in Mechanistic Studies of Hydrolyses of Phosphate Esters

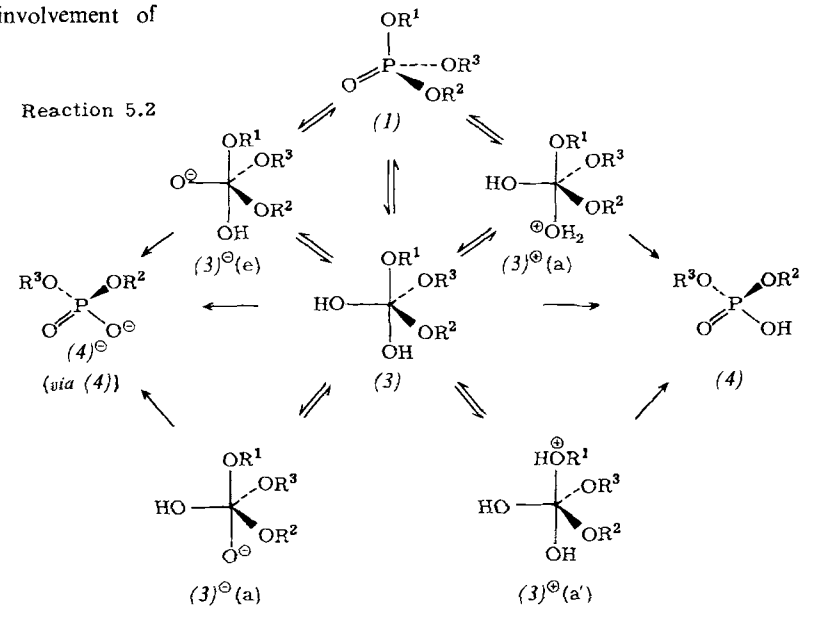
5.1. General Considerations. Hydrolyses of Trimethyl Phosphate and Ethylene Methyl Phosphate

The statements set forth in Section 4 lead to the general formulation of the hydrolyses of phosphate esters shown in Reactions 5.1 through 5.5.

Reaction 5.1

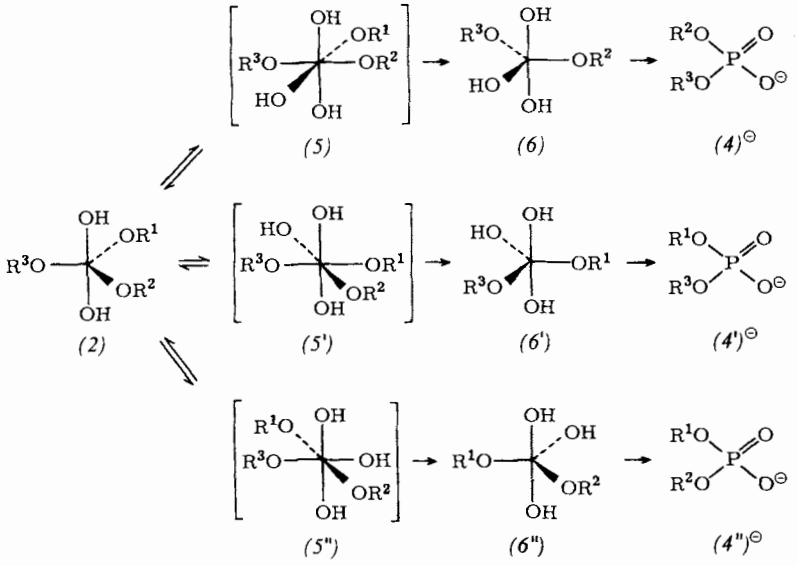


Reaction 5.2



In these reactions, hydroxide ions or water are introduced at the skeletal tetrahedral face opposite either the phosphoryl oxygen (Reaction 5.1), or protonated phosphoryl oxygen, or one of the alkoxide groups (Reaction 5.2) of the ester. The key oxyphosphoranes are *(2)* (Reaction 5.1) and *(3)* (Reaction 5.2), with two hydroxyl ligands apical, or one apical and one equatorial, respectively. Reaction

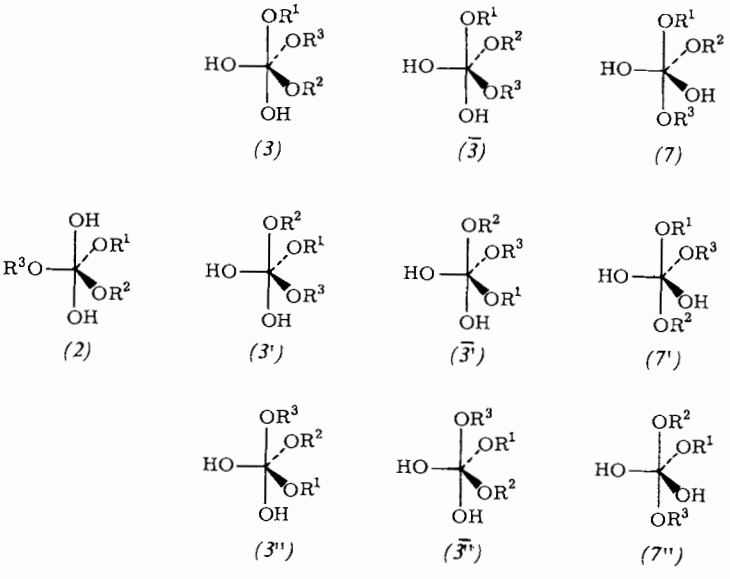
Reaction 5.3



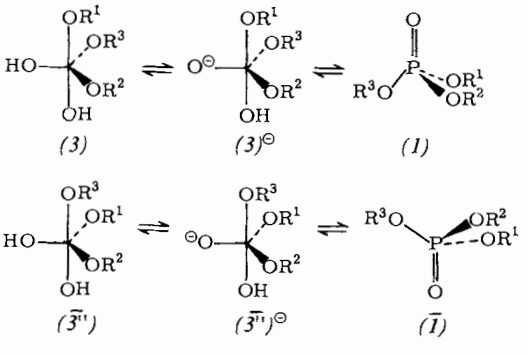
5.1 is an oxygen-exchange *(1)* → *(Ī)*, and Reaction 5.2 is a hydrolysis, *(1)* → *(4)*, $(4)^{\ominus}$. The alkaline oxygen exchange is disfavored because it requires the placement of $O^{\ominus}$ in an apical position, *(1)* → $(2)^{\ominus}$, in violation of the modified polarity rule. The ionization step, *(3)* → $(3)^{\ominus}$ (a) in Reaction 5.2 is disfavored for the same reason.

If octahedral transition states with hexacoordinate phosphorus are also involved under certain conditions, with collinear (opposed) entering and departing groups, the formation of hydrolysis products, $(4)^{\ominus}$, $(4')^{\ominus}$, $(4'')^{\ominus}$, *via* the TBP *(2)* must also include the pathways shown in Reaction 5.3. If species with hexacoordinate phosphorus are intermediates, and undergo reorganizations of their own, and/or are capable of losing either one of the various ligands to return to a TBP phosphorane, then additional steps must be included, *e.g.*, *(5')* → *(6')* → $(4')^{\ominus}$.

Reaction 5.4



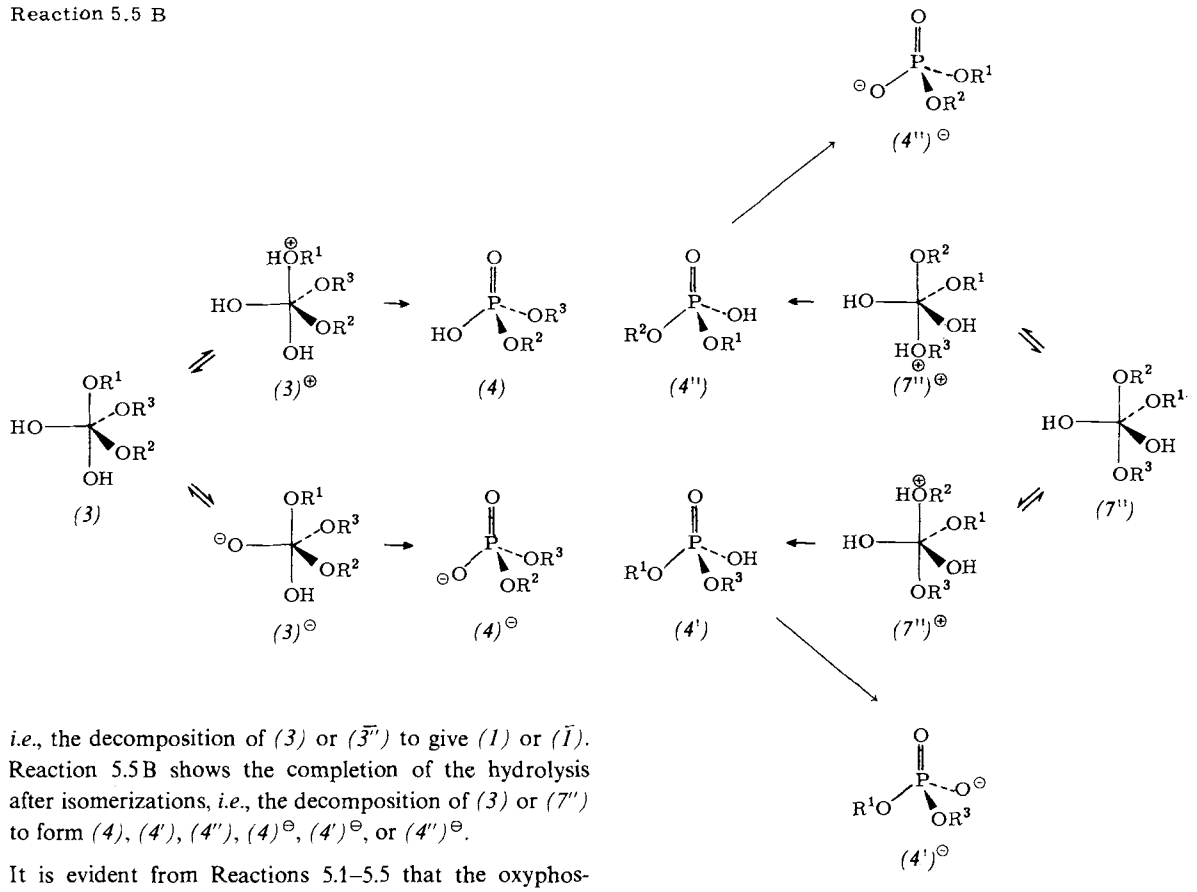
Reaction 5.5A



Reaction 5.4 represents the set of permutational isomers of the neutral TBP phosphoranes that originate from *(1)* and water. The interconversion of these isomers can occur by the simple and multiple TR processes and, if rings are absent from the TBP, also by the BPR process[2,29].

Reaction 5.5A is the completion of the oxygen-exchange after the permutational isomerizations (cf. Reaction 5.4),

Reaction 5.5 B

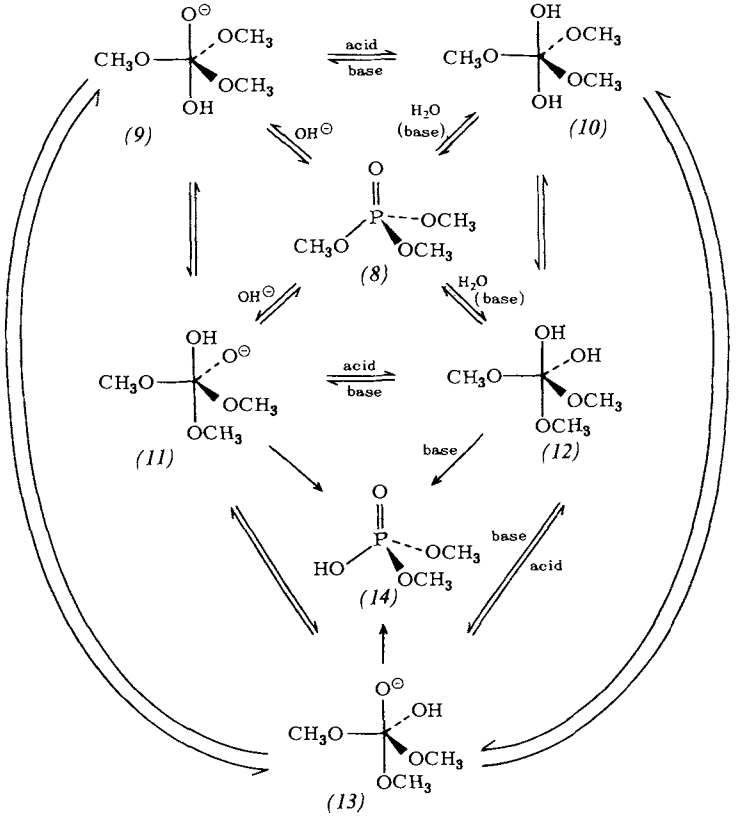


i.e., the decomposition of *(3)* or *(3‴)* to give *(1)* or *(1̄)*. Reaction 5.5B shows the completion of the hydrolysis after isomerizations, *i.e.*, the decomposition of *(3)* or *(7″)* to form *(4)*, *(4′)*, *(4″)*, $(4)^{\ominus}$, $(4')^{\ominus}$, or $(4'')^{\ominus}$.

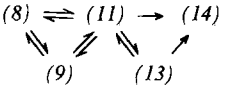
It is evident from Reactions 5.1–5.5 that the oxyphosphorane-intermediate hypothesis gives rise to a rather complex kinetic system of consecutive and parallel reactions in the hydrolyses of phosphate esters. A comparison of observed reaction rates cannot lead to valid mechanistic conclusions, unless there is reasonable assurance that, in a set of consecutive reactions, one known step is much slower than all others and hence is rate determining, and in a given set of competing parallel reactions, one of the competing sequences of reactions is much faster than all the others and hence the latter can be neglected. Without such assurances even the observed rate of such seemingly simple processes as the hydrolysis of trimethyl phosphate in weakly alkaline solution must be treated as a fairly complex function of 27 different rate processes (see Reaction 5.6A). In very strongly alkaline solution, where hexacoordinate transition states or intermediates should also be considered (cf. Reaction 5.3), the situation is even more complicated.

As a consequence of this complexity, it seems advisable to reexamine the far-reaching conclusions that have been drawn previously on the basis of comparison of the rates of hydrolysis of these compounds[5,8], in order to determine which are valid and which need modification.

Reaction 5.6A



Reaction 5.6B



Reaction 5.6C

Reaction 5.6D

Consider the *alkaline hydrolysis* of trimethyl phosphate *(8)→(14)* in the light of the premises set forth in Section 4. In this case, Reaction 5.6A is simplified to Reaction 5.6B with 10 rate constants, since the reactions with H_2O and the protonations are neglected *vs.* the reactions with $HO^{\ominus}$

The application of the Bodenstein theorem to Reaction 5.6B:

$$\frac{d[(9)]}{dt} = \frac{d[(11)]}{dt} = \frac{d[(13)]}{dt} = 0 \qquad (5.6a)$$

results in Equation (5.6b), which is still of some complexity.

$$\begin{aligned}\frac{d[(14)]}{dt} = [(8)][OH^{\ominus}]\cdot k_{hydrol,obs.} = [(8)][OH^{\ominus}][&k_{(11)\to(14)} \\ &+k_{(13)\to(14)}\cdot k_{(11)\to(13)}(k_{(13)\to(11)}+k_{(13)\to(14)})^{-1}] \\ &\times k_{(8)\to(11)}k_{(9)\to(11)}(k_{(9)\to(8)}+k_{(9)\to(11)})^{-1}[(k_{(11)\to(8)} \\ &+k_{(11)\to(9)}+k_{(11)\to(13)}+k_{(11)\to(14)}) \\ &-k_{(11)\to(13)}k_{(13)\to(11)}(k_{(13)\to(11)}+k_{(13)\to(14)})^{-1} \\ &-k_{(11)\to(9)}k_{(9)\to(11)}(k_{(9)\to(8)}+k_{(9)\to(11)})^{-1}]^{-1}\end{aligned} \qquad (5.6b)$$

Further simplifications can be achieved by neglecting one of the unfavorable TBP with an apical oxygen anion, namely *(13)*. One can now consider two alternate additional simplifications. The first is the exclusive direct formation of the other unfavorable TBP *(9)* with an apical oxide anion, followed by a permutational isomerization and decomposition to dimethyl phosphate *(14)*, as shown in Reaction 5.6C. The isomerization *(9)⇄(11)* must involve two simple TR or BPR or one $(TR)^2$, *e.g.*, with OH and OCH_3 as the pair[2,46]. The kinetic consequences would be given by Equation (5.6c):

$$\begin{aligned}k_{hydrol,obs.} = &k_{(11)\to(14)}\cdot k_{(8)\to(9)}\cdot k_{(9)\to(11)} \\ &\times[(k_{(11)\to(9)}+k_{(11)\to(14)})(k_{(9)\to(8)}+k_{(9)\to(11)}) \\ &-k_{(9)\to(11)}\cdot k_{(11)\to(9)}]^{-1}\end{aligned} \qquad (5.6c)$$

which reduces to Equation (5.6c') if *(9)⇄(11)* is rate determining:

$$k_{hydrol,obs.} = k_{(8)\to(9)}\cdot k_{(9)\to(11)}\cdot k^{-1}_{(9)\to(8)} \qquad (5.6c')$$

The second and more logical approximation is to assume an exclusive direct formation of the most stable TBP *(11)* with an equatorial oxide anion, followed by direct decomposition to dimethyl phosphate *(14)* without any intervening permutational isomerization (cf. Reaction 5.6D). The kinetic consequences are those in Equation (5.6d):

$$k_{hydrol,obs.} = k_{(11)\to(14)}\cdot k_{(8)\to(11)}\cdot(k_{(11)\to(8)}+k_{(11)\to(14)})^{-1} \qquad (5.6d)$$

If further $k_{(11)\to(14)} \gg k_{(11)\to(8)}$, one obtains Equation (5.6d'):

$$k_{hydrol,obs.} = k_{(8)\to(11)} \qquad (5.6d')$$

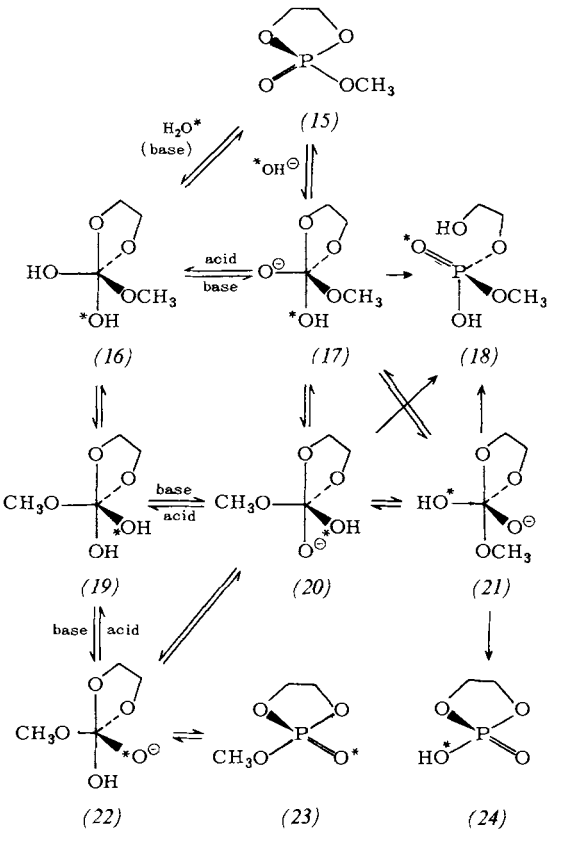
If, however, $k_{(11)\to(8)} \gg k_{(11)\to(14)}$, the result is Equation (5.6d''):

$$k_{hydrol,obs.} = k_{(11)\to(14)}\cdot k_{(8)\to(11)}\cdot k^{-1}_{(11)\to(8)} \qquad (5.6d'')$$

Evidently, even under the extreme simplifications contained in Reaction 5.6D, the $k_{hydrol,obs.}$ in the alkaline hydrolysis of trimethyl phosphate provides straightforward information only if the partition of the TBP phosphorane *(11)* between product and reactant strongly favors the product as shown in Equation (5.6d').

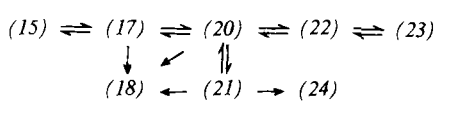
Consider now the much studied[5,8b,e] hydrolysis of methyl ethylene phosphate in *weakly alkaline solution*. Without simplifications the picture of Reaction 5.7A is kinetically quite complex.

Reaction 5.7A

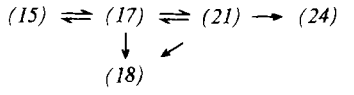


If one neglects the reaction of H_2O and the proton transfers, the picture is simplified to that of Reaction 5.7B.

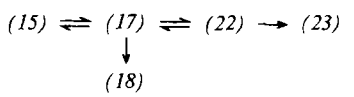
Reaction 5.7B



Reaction 5.7C



Reaction 5.7D



The kinetic expressions that give the rate of hydrolysis with ring opening, *(15)→(18)*, and with ring retention (exocyclic hydrolysis), *(15)→(24)*, and the rate of ex-

change of the phosphoryl oxygen with the solvent, *(15)→(23)*, are shown in Equations (5.7a), (5.7b), and (5.7c), respectively. These are still complex expressions as can be seen by developing the term P as shown in Equation (5.7d). No quantitative understanding of the factors that determine the rates of these hydrolyses, and the ratio of the rates of the three processes of interest, *i.e.*, the formation of *(18)*, *(24)*, and *(23)*, can be gained in this manner, *i.e.*, from $k_{(18)\,\mathrm{obs.}}$, $k_{(24)\,\mathrm{obs.}}$, $k_{(23)\,\mathrm{obs.}}$, even after the simplifications that led to Reaction 5.7 B.

$$\frac{d[(18)]}{dt} = [(15)][OH^{\ominus}]\cdot P^{-1}\cdot k_{(17)\to(18)}(P\cdot k_{(15)\to(17)}+k_{(20)\to(17)}) \times(k_{(17)\to(15)}+k_{(17)\to(18)}+k_{(17)\to(20)})^{-1} + k_{(20)\to(18)}+k_{(20)\to(21)}\cdot k_{(21)\to(18)} \times(k_{(22)\to(20)}+k_{(22)\to(23)})^{-1} \quad (5.7a)$$

$$\frac{d[(23)]}{dt} = [(15)][OH^{\ominus}]\cdot P^{-1}\cdot k_{(22)\to(23)}\cdot k_{(20)\to(22)} \times(k_{(22)\to(20)}-k_{(22)\to(23)})^{-1} \quad (5.7b)$$

$$\frac{d[(24)]}{dt} = [(15)][OH^{\ominus}]\cdot P^{-1}\cdot k_{(21)\to(24)}\cdot k_{(20)\to(21)} \times(k_{(21)\to(18)}+k_{(21)\to(20)}+k_{(21)\to(24)})^{-1} \quad (5.7c)$$

with

$$P = k_{(15)\to(17)}^{-1}\cdot k_{(17)\to(20)}^{-1}[(k_{(17)\to(15)}+k_{(17)\to(18)} + k_{(17)\to(20)})\{(k_{(20)\to(17)}+k_{(20)\to(18)}+k_{(20)\to(21)}+k_{(20)\to(22)}) - k_{(20)\to(21)}\cdot k_{(21)\to(20)}(k_{(21)\to(18)}+k_{(21)\to(20)}+k_{(21)\to(24)})^{-1} - k_{(20)\to(22)}\cdot k_{(22)\to(20)}(k_{(22)\to(20)}-k_{(22)\to(23)})^{-1}\} - k_{(17)\to(20)}\cdot k_{(20)\to(17)}] \quad (5.7d)$$

To treat this system further, one must resort to additional simplifications, for example, those which lead to the picture of Reaction 5.7C (see above). Now, one neglects the oxygen exchange *(15)→(23)*, and assumes that ring opening, *(15)⇄(17)→(18)*, occurs exclusively by the most direct pathway without permutational isomerization. Exocyclic hydrolysis, *(15)⇄(17)⇄(21)→(24)*, is assumed to occur exclusively after one reasonable permutational isomerization that preserves the equatorial placement of the oxide anion. The kinetic expressions that result from Reaction 5.7C are shown in Equations (5.7e)–(5.7g).

$$\frac{d[(18)]}{dt} = [OH^{\ominus}][(15)]R^{-1}[k_{(21)\to(18)}+(k_{(21)\to(17)}+k_{(21)\to(18)} + k_{(21)\to(24)})\cdot k_{(17)\to(21)}^{-1}\cdot k_{(17)\to(18)}] = [OH^{\ominus}][(15)]k_{\mathrm{obs.}(18)} \quad (5.7e)$$

$$\frac{d[(24)]}{dt} = [OH^{\ominus}][(15)]k_{(21)\to(24)}\cdot R^{-1} = [OH^{\ominus}][(15)]k_{\mathrm{obs.}(24)} \quad (5.7f)$$

with

$$R = k_{(15)\to(17)}^{-1}[(k_{(17)\to(15)}+k_{(17)\to(18)}+k_{(17)\to(21)})(k_{(21)\to(17)} + k_{(21)\to(18)}+k_{(21)\to(24)})k_{(17)\to(24)}^{-1}-k_{(21)\to(17)}] \quad (5.7g)$$

The ratio of the rates of ring-opening *(15)→(18)* to ring-retention *(15)→(24)* is given by Equation (5.7h)

$$k_{\mathrm{obs.}(18)}/k_{\mathrm{obs.}(24)} = [k_{(17)\to(21)}\cdot k_{(21)\to(18)} + (k_{(21)\to(17)}+k_{(21)\to(18)}+k_{(21)\to(24)}) \times k_{(17)\to(18)}](k_{(17)\to(21)}\cdot k_{(21)\to(24)})^{-1} \quad (5.7h)$$

All that can be concluded from the experimental observation that $k_{\mathrm{obs.}(18)} \gg k_{\mathrm{obs.}(24)}$ is that either $k_{(17)\to(18)} \ll k_{(17)\to(21)}$, or that $k_{(21)\to(18)} \gg (k_{(21)\to(17)}+k_{(21)\to(24)})$ where $k_{(17)\to(18)} \approx k_{(17)\to(21)}$.

Detailed knowledge concerning the complete dynamics for a system of consecutive and parallel reactions would allow one to predict the kinetic behavior of the system. Conversely, it is possible to derive detailed conclusions from observed rates of complex systems only in some exceptional cases. From this it follows that the mere comparison of observed reaction rates does not provide valuable information.

The fact that *(15)→(23)* is slow relative to *(15)→(18)* + *(24)* could, for example, be interpreted by a simplification that produces the picture of Reaction 5.7D (see above). In this interpretation, one imagines a simultaneous proton transfer and permutational isomerization, *(17)→(22)*, which results in the kinetic expressions of Equations (5.7i)–(5.7k).

$$k_{\mathrm{obs.}(18)} = S^{-1}\cdot k_{(17)\to(18)}\cdot k_{(15)\to(17)} \quad (5.7i)$$

$$k_{\mathrm{obs.}(23)} = k_{(22)\to(23)}\cdot k_{(15)\to(17)}\cdot k_{(17)\to(22)} \times S^{-1}(k_{(22)\to(17)}+k_{(22)\to(23)})^{-1} \quad (5.7j)$$

with

$$S = k_{(17)\to(15)}+k_{(17)\to(18)}+k_{(17)\to(22)}-k_{(22)\to(17)}\cdot k_{(17)\to(22)} \times(k_{(22)\to(17)}+k_{(22)\to(23)})^{-1} \quad (5.7k)$$

The ratio of the rates of hydrolysis with ring opening, *(15)→(18)*, and of oxygen-exchange, *(15)→(23)*, would be given by Equation (5.7l):

$$k_{\mathrm{obs.}(18)}/k_{\mathrm{obs.}(23)} = k_{(17)\to(18)}\cdot k_{(22)\to(23)}^{-1}\cdot k_{(17)\to(22)}^{-1} \times(k_{(22)\to(17)}+k_{(22)\to(23)}) \quad (5.7l)$$

Since it is experimentally observed that $k_{\mathrm{obs.}(18)} \gg k_{\mathrm{obs.}(23)}$, one may conclude that either $k_{(17)\to(18)} \gg k_{(17)\to(22)}$ where $k_{(22)\to(17)} \ll k_{(22)\to(23)}$, or that $k_{(17)\to(18)} \gg k_{(22)\to(23)}$ where $k_{(22)\to(23)} \ll k_{(22)\to(17)}$ and $k_{(17)\to(22)} \approx k_{(22)\to(17)}$.

This analysis shows that a mechanistic interpretation of the hydrolyses of trimethyl phosphate (Reaction 5.6) and methyl ethylene phosphate (Reaction 5.7) from the available experimental kinetic data must be based on a series of simplifications and approximations which have not been subject to test. It is even more difficult to derive sound mechanistic conclusions from a comparison of the rate data for the two reactions; *i.e.*, to *interpret the differences in the reaction rates for Reaction 5.6 and Reaction 5.7*. Let us assume that the behavior of the acyclic phosphate is well described by the approximations that give Reaction 5.6C from Reaction 5.6A, and that of the cyclic phosphate by the approximations that give Reaction 5.7C from Reaction 5.7A. In the cyclic case, ring opening is faster than ring retention, *i.e.*, $k_{\mathrm{obs.}(18)} \gg k_{\mathrm{obs.}(24)}$ and Equation (5.7f) is neglected *vs.* Equation (5.7e). The pertinent equation for the acyclic case is Equation (5.6c'), since the isomerization *(9)⇄(11)* is assumed to be rate determining in Reaction 5.6C. One could attribute the observed faster

hydrolysis with ring-opening *(15)→(18)* relative to the hydrolysis of trimethyl phosphate *(8)→(14)*, $k_{obs.(18)} \gg k_{obs.(14)}$, to the operation of one, two, or all three of the following factors:

1. The TBP intermediate is formed much faster in the cyclic than in the acyclic case; *i.e.*, $k_{(15)\rightarrow(17)} \gg k_{(8)\rightarrow(9)}$.

2. The decomposition of the TBP intermediate is much faster in the cyclic than in the acyclic case; *i.e.*, $k_{(17)\rightarrow(18)} \gg k_{(11)\rightarrow(14)}$.

3. The reaction of the acyclic ester *(8)→(14)* is much slower than that of the cyclic one *(15)→(18)* because in the former, Reaction 5.6C, the isomerization *(9)→(11)* is a necessary step, while such a step is not required in the latter, Reaction 5.7C, to realize the conversion *(15)→(18)*. In the acyclic case, either $k_{(11)\rightarrow(14)} \gg k_{(11)\rightarrow(9)}$, or $k_{(9)\rightarrow(8)} \gg k_{(9)\rightarrow(11)}$, while in the cyclic case, $k_{(17)\rightarrow(15)}$ and $k_{(15)\rightarrow(17)}$ do not differ appreciably.

It is not reasonable to attribute[5,8] the faster rate of hydrolysis with ring-opening, *(15)→(18)*, *vs.* the hydrolysis of trimethyl phosphate, *(8)→(14)*, to a particular feature of the substrates *(8)* and *(15)*, *on purely kinetic grounds*, unless it is clearly established which of these three factors is responsible for the observed rate differences. Even if ring strain[5,8] exists in the cyclic phosphate *(15)*, the kinetic data do not justify the conclusion that *(15)* hydrolyses faster than *(18)* due to ring strain in phosphate ester, because the strain affects factors *(1)*, *(2)*, and *(3)* in different ways.

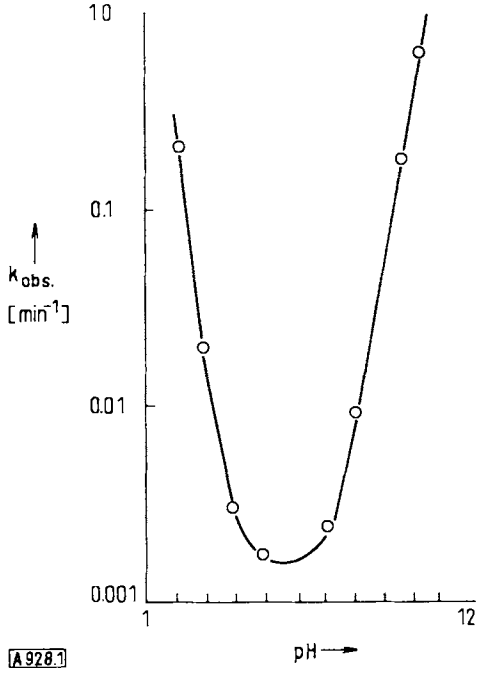


Fig. 1. The pH dependence of methyl ethylene phosphate hydrolysis rates at 25 °C.

We turn now to the observed[8e] pH dependence of the rate constants for the hydrolysis of methyl ethylene phosphate *(15)* (Reaction 5.7A). This phenomenon is depicted in Figure 1.

The observed rate constants can be expressed[8e] by Equation (5.7 m), while the various terms correspond to the different *mechanisms* discussed above.

$$k_{obs.} = k_{H^{\oplus},obs.}[H^{\oplus}] + k_{W,obs.} + k_{OH^{\ominus},obs.}[OH^{\ominus}] + k_{2OH^{\ominus},obs.}[OH^{\ominus}]^2 \quad (5.7\,m)$$

(at 25 °C: $k_{H^{\oplus},obs.} = 0.35\ M^{-1}s^{-1}$; $k_{W,obs.} = 2.3 \times 10^{-5}\,s^{-1}$; $k_{OH^{\ominus},obs.} = 64\ M^{-1}s^{-1}$)

The ratio of exocyclic hydrolysis *(15)→(24)* *vs.* ring opening *(15)→(18)* does not correlate in any simple manner with the pH-rate profile. Rather, the ratio is a complex function of the pH (cf. Figure 2)[8e].

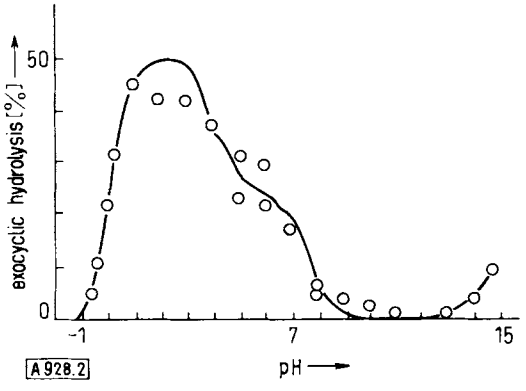

Fig. 2. Methyl ethylene phosphate hydrolysis pH-product profile.

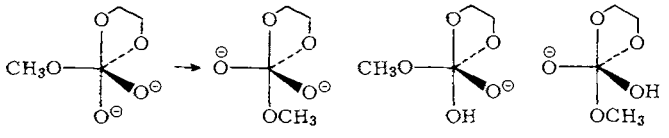
In acidic solution the hydrolysis of methyl ethylene phosphate takes place according to the mechanism which is given by the general formulation of Reaction 5.2 and by the more detailed picture of Reaction 5.7A. The falloff of the exocyclic hydrolysis in strong acid[8e] can be attributed to the fact that the rate of hydrolysis with ring opening (*(15)→(17)→(18)*, after suitable protonation) is proportional to the proton concentration, whereas the rate of permutational isomerization of the oxyphosphorane intermediate when required for exocyclic hydrolysis (*(15)→(17)→(21)→(24)*, after suitable protonation) is independent of the acidity of the medium. Therefore, at high acidities, the rate of exocyclic hydrolysis is determined by the TR processes and fails to keep pace with ring opening; consequently, the yield of exocyclic products falls towards zero.

In the region of pH = 4 – 11 the curve of Figure 2 can be expressed in terms of the fraction of reaction that occurs *via* acid and hydroxide ion catalysis, as well as the water reaction, assuming[8e] that the acid catalyzed reaction gives 50%, the water reaction 25% (the corresponding hydrolysis in aprotic solvents proceeds with 100% ring retention (see Section 6)), and the hydroxide ion reaction 0% exocyclic hydrolysis. In strong alkali (pH > 12), the $[OH^{\ominus}]^2$ dependent reaction also takes place and the fraction of exocyclic hydrolysis rises in an approximately linear fashion with the hydroxide ion concentration to about 15% exocyclic cleavage in 10 M alkali[8e]. It was suggested[8e] that this behavior resulted from the formation of the dianion *(25a)* in strong alkali, assuming

that the concentration of the dianion *(25a)* is proportional to $[OH^{\ominus}]^2$. The dianion *(25a)* is then said to undergo the BPR process to form the new dianion *(25b)*, which should be more stable than *(25a)* according to the modified polarity rule. Dianion *(25b)* can account for the exocyclic hydrolysis to *(24)*. The apical hydroxy groups of hydroxyphosphoranes are very weakly acidic[2], and it seems that this acidity should be even weaker when the first anion has already been formed and has its oxide group in the equatorial position (cf. *(17)*). If the dianion *(25b)* is to be invoked at all, it would be logical to first isomerize the monoanion *(17)* to *(21)* by the TR process and then ionize the somewhat stronger equatorial OH to give the dianion *(25b)*. However, neither of these alternatives is very plausible. The hydrolysis of methyl ethylene phosphate in a strong alkaline medium probably proceeds *via* hexacoordinate species as described in Reaction 5.3. Although it was mentioned[8e], this possibility, was not pursued further. The rate of hydrolysis *via* hexacoordinate species would be proportional to $[OH^{\ominus}]^2$ in agreement with the experiments; this mechanism also predicts approxi-

Reaction 5.7E



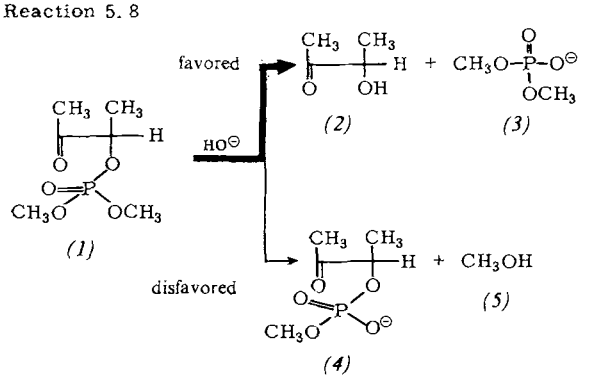
(25a) *(25b)* *(17)* *(21)*

mately equal yields of the products of exocyclic and of ring-opening hydrolyses. The mechanism *via* hexacoordinate species is also in line with the known[21] nucleophilic substitutions of oxyphosphoranes by alcohols catalyzed by bases; see Section 2.

5.2. The Fast Alkaline Hydrolyses of Dimethyl Acetoin Phosphate and Methyl Acetoin Methylphosphonate

The hydrolysis of dimethyl acetoin phosphate *(1)*, Reaction 5.8, at pH = 7.7 – 8.2, is extremely fast relative to the hydrolysis of trimethyl phosphate under comparable

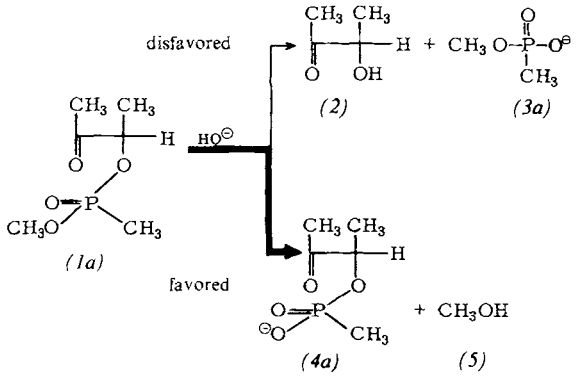
Reaction 5.8



conditions[11]. The products are mainly acetoin *(2)* and dimethyl phosphate *(3)*; ("acetoin displacement"). Very little[12] (*ca.* 3–4%) methanol *(5)* and methyl acetoin phosphate *(4)* are formed; ("methanol displacement").

The comparable hydrolysis of methyl acetoin methylphosphonate[12] *(1a)*, Reaction 5.9, is 200 times slower than that of the phosphate *(1)*, and gives mainly methanol *(5)* and acetoin methylphosphonate *(4a)* (*ca.* 95%).

Reaction 5.9



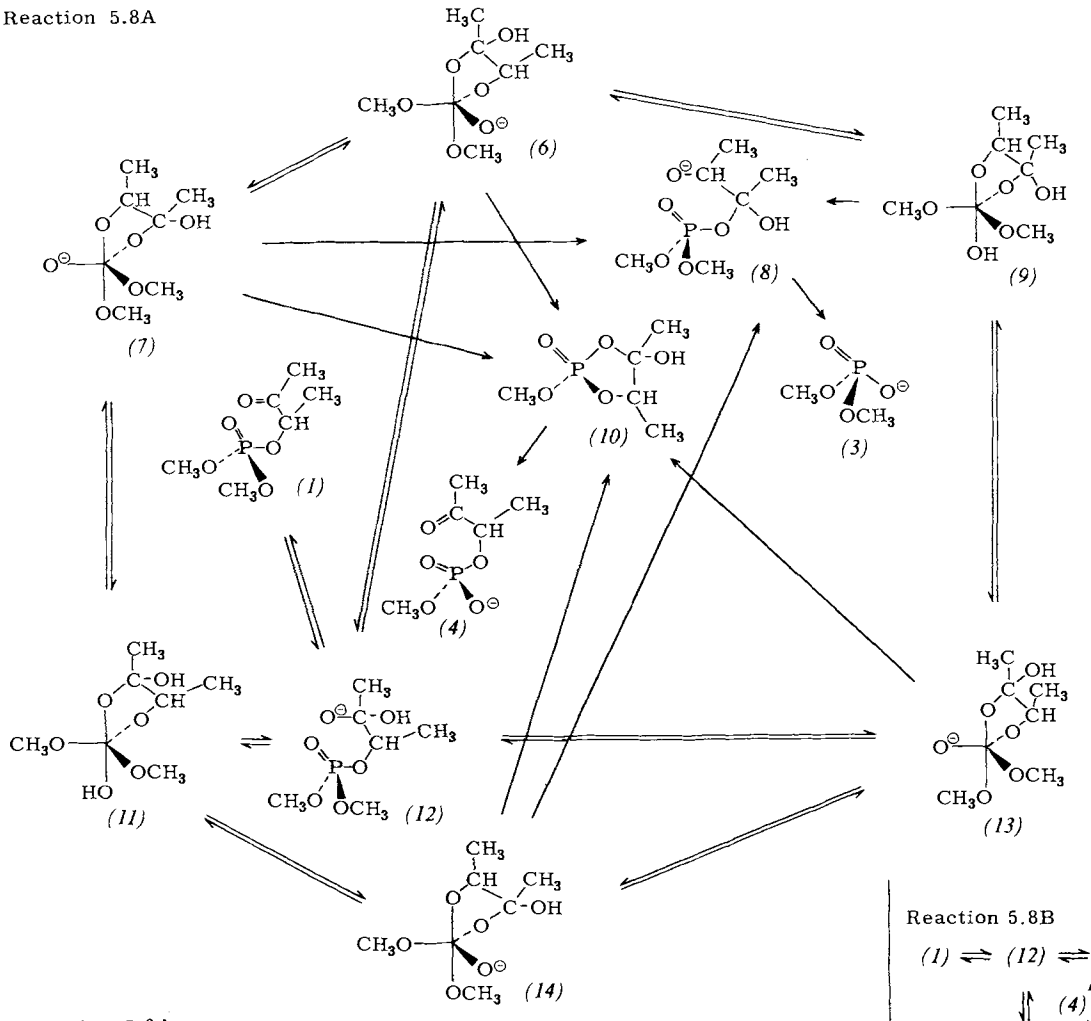
The rates[12] of the methanol-displacement reactions are of the same order of magnitude in both cases: $k_{(1)\rightarrow(4),\,obs.} \approx k_{(1a)\rightarrow(4a),\,obs.}$. However, the rate[12] of the acetoin displacement is about 600 times faster in the phosphate, *(1)*→*(2)*, than in the phosphonate *(1a)*→*(2)* ($k_{(1)\rightarrow(3),\,obs.} \gg k_{(1a)\rightarrow(3a),\,obs.}$). A available data strongly favor a mechanism involving participation of the carbonyl function in the formation of oxyphosphorane intermediates[11]. However, the data do not mandatorily eliminate mechanisms which involve the enol forms of *(1)* and *(1a)*, or the cleavage of the C_α—O bond. The reaction mechanisms 5.8A and 5.9A which are based upon oxyphosphorane intermediates whose premises are outlined in Section 4 account nicely for the observed data concerning Reactions 5.8 and 5.9. The essential differences between these two is that *the TBP intermediates (13) and (7) (Reaction 5.8A) have no counterpart in the phosphonate case (Reaction 5.9A) because in the latter case the TBP would have to carry apical* P—CH_3 *bonds in violation of the modified polarity rule.* This violation of the modified polarity rule renders the corresponding reaction pathways non-competitive relative to other allowed pathways in the phosphonate case.

To arrive at manageable kinetic expressions, Reaction 5.8A for the phosphate is simplified to Reaction 5.8B, and Reaction 5.9A for the phosphonate is simplified to Reactions 5.9B, by taking into consideration only the most probable of the competing parallel reactions, and by combining some steps in the reaction sequences.

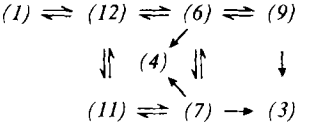
Note that *(7a)* and *(13a)* cannot be generated.

The kinetic expressions for the phosphate hydrolysis according to Reaction 5.8B are given in Equations (5.8a) to (5.8h). The corresponding expressions for phosphonate hydrolysis according to Reaction 5.9B are given in Equations (5.9a) to (5.9d). The rate ratios for methanol displacement (*i.e.*, formation of *(4)* or of *(4a)*) relative to acetoin-

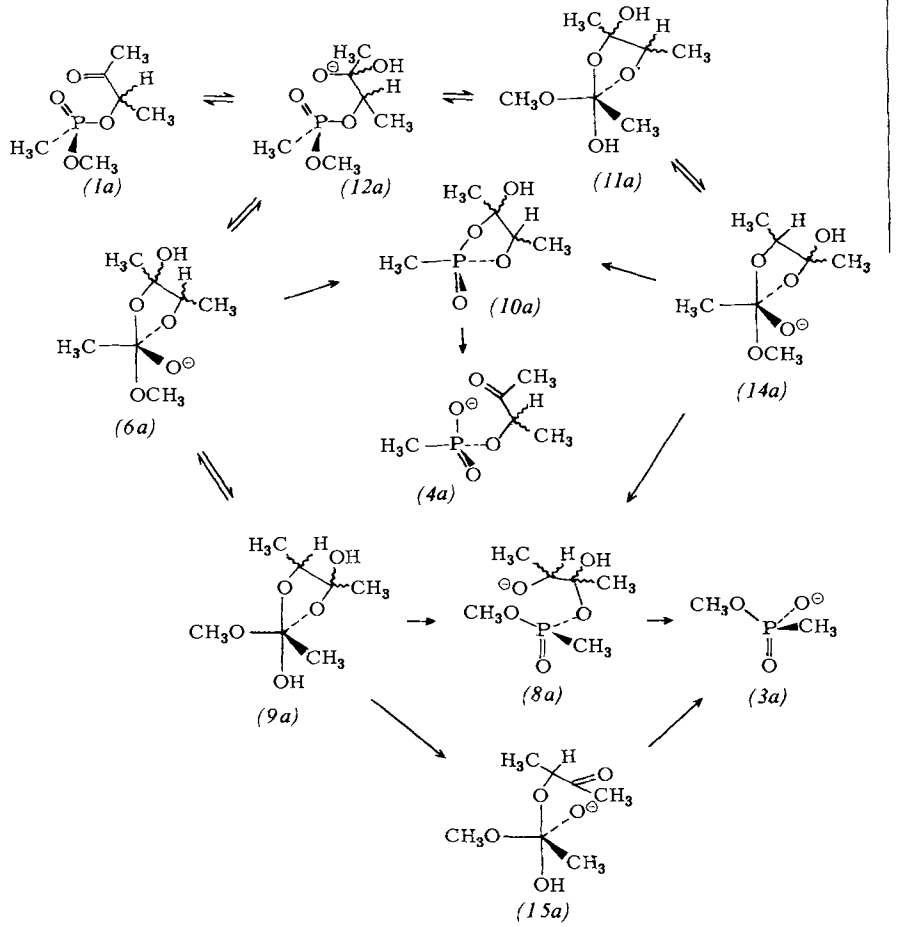
Reaction 5.8A



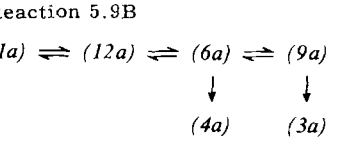
Reaction 5.8B



Reaction 5.9A



Reaction 5.9B



displacement (*i.e.*, formation of *(3)* or of *(3a)*) for the phosphate and the phosphonate, respectively, are shown in Equation (5.8c) and Equation (5.9d).

$$\frac{d[(3)]}{dt} = \frac{[OH^{\ominus}][(1)]k_{(1)\rightarrow(12)}\cdot k_{(12)\rightarrow(11)}\cdot K[k_{(7)\rightarrow(3)}\cdot L + k_{(6)\rightarrow(9)}\cdot k_{(9)\rightarrow(3)}(k_{(9)\rightarrow(3)}+k_{(9)\rightarrow(6)})^{-1}M]}{LO-MN} \quad (5.8a)$$

$$\frac{d[(4)]}{dt} = \frac{[OH^{\ominus}][(1)]k_{(1)\rightarrow(12)}\cdot k_{(12)\rightarrow(11)}\cdot K[k_{(7)\rightarrow(4)}\cdot L + k_{(6)\rightarrow(4)}M]}{LO-MN} \quad (5.8b)$$

Methanol displacement/acetoin displacement:

$$\frac{d[(4)]}{dt}\Big/\frac{d[(3)]}{dt} = (k_{(7)\rightarrow(4)}\cdot L + k_{(6)\rightarrow(4)}\cdot M)[k_{(7)\rightarrow(3)}L + k_{(6)\rightarrow(9)}k_{(9)\rightarrow(3)}(k_{(9)\rightarrow(3)}+k_{(9)\rightarrow(6)})^{-1}M]^{-1} \quad (5.8c)$$

with

$$K = [(k_{(11)\rightarrow(7)}+k_{(11)\rightarrow(12)})(k_{(12)\rightarrow(1)}+k_{(12)\rightarrow(6)}+k_{(12)\rightarrow(11)}) - k_{(11)\rightarrow(12)}k_{(12)\rightarrow(11)}]^{-1} \quad (5.8d)$$

$$L = k_{(6)\rightarrow(7)}\cdot k^{-1}_{(11)\rightarrow(7)} - k_{(11)\rightarrow(12)}\cdot k^{-1}_{(12)\rightarrow(6)}(k_{(11)\rightarrow(7)} + k_{(11)\rightarrow(12)})^{-1}(k_{(6)\rightarrow(1)}+k_{(6)\rightarrow(7)}+k_{(6)\rightarrow(9)}+k_{(6)\rightarrow(12)}) + k_{(6)\rightarrow(9)}\cdot k_{(9)\rightarrow(6)}\cdot k^{-1}_{(12)\rightarrow(6)} \times k_{(12)\rightarrow(11)}(k_{(9)\rightarrow(3)}+k_{(9\rightarrow6)})^{-1}(k_{(11)\rightarrow(7)}+k_{(11)\rightarrow(12)})^{-1} \quad (5.8e)$$

$$M = k^{-1}_{(11)\rightarrow(7)}(k_{(7)\rightarrow(3)} - k_{(7)\rightarrow(4)} + k_{(7)\rightarrow(6)} + k_{(7)\rightarrow(11)}) + k^{-1}_{(12)\rightarrow(6)}(k_{(7)\rightarrow(11)}\cdot k_{(12)\rightarrow(6)} - k_{(7)\rightarrow(6)}\cdot k_{(12)\rightarrow(11)}) \times (k_{(11)\rightarrow(7)}+k_{(11)\rightarrow(12)})^{-1} \quad (5.8f)$$

$$N = k_{(6)\rightarrow(7)}\cdot k^{-1}_{(1)\rightarrow(7)} + k_{(6)\rightarrow(11)}\cdot k_{(12)\rightarrow(11)}K \quad (5.8g)$$

$$O = k^{-1}_{(11)\rightarrow(7)}(k_{(7)\rightarrow(3)}+k_{(7)\rightarrow(4)}+k_{(7)\rightarrow(6)}+k_{(7)\rightarrow(11)}) - k_{(7)\rightarrow(11)}\cdot K(k_{(12)\rightarrow(1)}+k_{(12)\rightarrow(6)}+k_{(12)\rightarrow(11)}) \quad (5.8h)$$

$$\frac{d[(4a)]}{dt} = [(1a)][OH^{\ominus}]\cdot k_{(6a)\rightarrow(4a)}\cdot P \quad (5.9a)$$

$$\frac{d[(3a)]}{dt} = [(1a)][OH^{\ominus}]\cdot k_{(6a)\rightarrow(9a)} \times k_{(9a)\rightarrow(3a)}(k_{(6a)\rightarrow(9a)}+k_{(9a)\rightarrow(3a)})^{-1}P \quad (5.9b)$$

$$P = [k^{-1}_{(1a)\rightarrow(12a)}\cdot k^{-1}_{(12a)\rightarrow(6a)}(k_{(12a)\rightarrow(1a)}+k_{(12a)\rightarrow(6a)})(k_{(6a)\rightarrow(12a)} + k_{(6a)\rightarrow(4a)}+k_{(6a)\rightarrow(9a)}) - k_{(12a)\rightarrow(6a)}\cdot k^{-1}_{(6a)\rightarrow(12a)} + k^{-1}_{(6a)\rightarrow(9a)} \times k^{-1}_{(9a)\rightarrow(12a)}(k_{(12a)\rightarrow(1a)}+k_{(12a)\rightarrow(6a)})(k_{(9a)\rightarrow(6a)}+k_{(9a)\rightarrow(3a)})]^{-1} \quad (5.9c)$$

Methanol displacement/acetoin displacement:

$$\frac{d[(4a)]}{dt}\Big/\frac{d[(3a)]}{dt} = k_{(6a)\rightarrow(4a)}\cdot k^{-1}_{(6a)\rightarrow(9a)}\cdot k^{-1}_{(9a)\rightarrow(3a)} \times (k_{(9a)\rightarrow(6a)}+k_{(9a)\rightarrow(3a)}) \quad (5.9d)$$

The observed fact that

$$k_{\text{obs. }(1)\rightarrow(4)} \ll k_{\text{obs. }(1)\rightarrow(3)} \quad (k_{\text{Methanol}} \ll k_{\text{Acetoin}}) \quad (5.8i)$$

corresponds to

$$k_{(7)\rightarrow(4)}\cdot L + k_{(6)\rightarrow(4)}\cdot M \ll k_{(7)\rightarrow(3)}\cdot L + k_{(6)\rightarrow(9)}\cdot k_{(9)\rightarrow(3)} \times (k_{(9)\rightarrow(3)}+k_{(9)\rightarrow(6)})^{-1}M \quad (5.8j)$$

which leads to:

$$k_{(6)\rightarrow(4)} \ll k_{(6)\rightarrow(9)}\cdot k_{(9)\rightarrow(3)}(k_{(9)\rightarrow(3)}+k_{(9)\rightarrow(6)})^{-1} \quad (5.8k)$$

when

$$L \ll M \quad (5.8l)$$

with the additional assumption that

$$k_{(9)\rightarrow(3)} \gg k_{(9)\rightarrow(6)} \quad (5.8m)$$

Equation (5.8k) implies that:

$$k_{(6)\rightarrow(4)} \ll k_{(6)\rightarrow(9)} \quad (k_{\text{collapse with ring retention}} \ll k_{TR}) \quad (5.8n)$$

i.e., the permutation isomerization *(6)→(9)* is much faster than the collapse of the oxyphosphorane *(6)*. On the other hand, from Equation (5.8j) it follows that:

$$k_{(7)\rightarrow(4)} \ll k_{(7)\rightarrow(3)} \quad \begin{matrix}(\text{collapse with ring retention} \\ \ll \text{collapse with ring opening})\end{matrix} \quad (5.8o)$$

i.e., the collapse of the oxyphosphorane *(7)* with ring opening to *(8)* and thence to *(3)* is much faster than its collapse with ring retention to *(10)* and thence to *(4)*, when

$$M \ll L \quad (5.8p)$$

From Equation (5.9d) and:

$$k_{\text{obs. }(1a)\rightarrow(4a)} \gg k_{\text{obs. }(1a)\rightarrow(3a)} \quad (k_{\text{obs. methanol displacement}} \gg k_{\text{obs. acetoin displacement}}) \quad (5.9e)$$

it can be concluded that

$$(k_{(9a)\rightarrow(6a)}+k_{(9a\rightarrow(3a)})\,k_{(6a)\rightarrow(4a)} \gg k_{(6a)\rightarrow(9a)}\cdot k_{(9a)\rightarrow(3a)} \quad (5.9f)$$

which, with the assumption

$$k_{(9a)\rightarrow(6a)} \ll k_{(9a)\rightarrow(3a)} \quad (k_{TR} \ll k_{\text{collapse with ring opening}}) \quad (5.9g)$$

implies

$$k_{(6a)\rightarrow(4a)} \ll k_{(6a)\rightarrow(9a)} \quad (k_{\text{collapse with ring retention}} \ll k_{TR}) \quad (5.9h)$$

Further, since *(1)→(4)* and *(1a)→(4a)* are similar processes with similar observed rates, the *faster overall hydrolysis of (1) over that of (1a) is primarily due to the fact that the positional exchange processes of Reaction 5.8A which led to (3) have no counterparts in Reaction 5.9A.* According to Equations (5.8a), (5.8b) and (5.9a), (5.9b), the relatively high rates of alkaline hydrolysis of *(1)* and *(1a)* are mainly due to the fast formations of the intermediates *(12)* and *(12a)* from *(1)* and *(1a)* and also to the high rates of the processes *(12)→(6)*, *(11)→(7)*, *(9)→(3)*, and *(6a)→(4a)*, respectively.

The relatively fast formation of the oxyphosphorane intermediates from *(12)* and *(12a)* is due to the fact that those

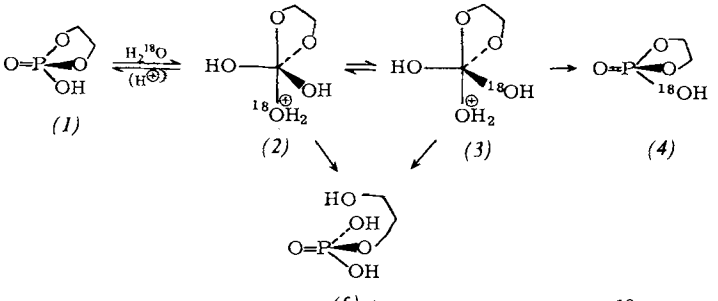
processes are first order reactions which lead to *unstrained five-membered rings*, providing a further argument against the assumption of the relief of five-membered ring strain[5,8] being responsible for the rapid hydrolyses of ethylene phosphates and related compounds. In fact, the enhancement of the rate can be said to be due to the tendency that exists for the formation of the five-membered ring in a TBP pentacoordinate phosphorane.

One of the consequences of the kinetic analysis presented above is that in the case of the reactions of oxyphosphoranes derived from dimethyl phosphoacetoin, the collapse of a phosphorane with ring opening is kinetically favored over the collapse of a phosphorane with ring retention. This is in apparent contradiction to the principle enunciated in Section 4.5 to the effect that collapse of the cyclic oxyphosphorane with ring retention is favored over collapse of a phosphorane with ring opening. However, it should be noted that formula *(9a)* of Reaction 5.9A is an unusual type of oxyphosphorane, since it has a hemiacetal function at the quasiequatorial carbon. We suggest therefore that in such cases the rupture of the hemiacetal C—O bond to the acyclic oxyphosphorane *(15a)* is favored over the rupture of the apical P—O bond of *(9a)* with the formation of *(8a)*. This interpretation retains the generality of the statement given in Section 4.5 for the non-hemiacetal oxyphosphorane.

5.3. Acid Hydrolysis and ^{18}O-Exchange of Ethylene Phosphate

One of the earliest and most significant experiments bearing on the mechanism of hydrolysis of phosphate esters is the observation of the oxygen-exchange that accompanies the acid hydrolysis of the five-membered cyclic ethylene phosphate *(1)*[5,8a], Reaction 5.10. The permutational isomerization *(2)*⇄*(3)* is simplified in this representation and probably involves deprotonation, isomerization by the TR mechanism, and reprotonation of the OH at the apical position which is more capable of sustaining the most electronegative ligand[2].

Reaction 5.10



(1) *(2)* *(3)* *(4)*

(5) (partially labeled with ^{18}O)

This experiment strongly supports the hypothesis that oxyphosphoranes are formed in these hydrolyses, and that the TBP pentacoordinate intermediates are capable of undergoing permutational isomerizations. However, one must reexamine the previous interpretation[5,8a] of the kinetic data in the light of concepts presented in this Review. Concepts in question are those pertaining to the relative rates of the permutational isomerization steps and to the mechanism, *i.e.*, BPR or TR, by which this type of isomerization takes place in *cyclic* oxyphosphorane derivatives.

The picture of Reaction 5.10 leads to the kinetic expressions given in Equations (5.10a) to (5.10c):

$$\frac{d[(4)]}{dt} = [(1)][H^{\oplus}]\cdot k_{(3)\rightarrow(4)}\cdot J \qquad (5.10a)$$

$$\frac{d[(5)]}{dt} = [(1)][H^{\oplus}][k_{(2)\rightarrow(5)}\, k^{-1}_{(2)\rightarrow(3)}(k_{(3)\rightarrow(2)}+k_{(3)\rightarrow(4)} + k_{(3)\rightarrow(5)})+k_{(3)\rightarrow(5)}]\cdot J \qquad (5.10b)$$

$$J = k_{(1)\rightarrow(2)}k_{(2)\rightarrow(3)}[(k_{(2)\rightarrow(1)}+k_{(2)\rightarrow(3)}+k_{(2)\rightarrow(5)})(k_{(3)\rightarrow(2)} + k_{(3)\rightarrow(4)}+k_{(3)\rightarrow(5)})-k_{(3)\rightarrow(2)}k_{(2)\rightarrow(3)}]^{-1} \qquad (5.10c)$$

Making the assumptions that the permutational isomerizations *(2)*⇄*(3)* occur at the same rate in both directions, $k_{(2)\rightarrow(3)}=k_{(3)\rightarrow(2)}$, and that both analogous oxyphosphoranes *(2)* and *(3)* decompose with ring opening at the same rate, $k_{(2)\rightarrow(5)}=k_{(3)\rightarrow(5)}$ (deprotonations and reprotonations are neglected in these representations) one arrives at Equation (5.10d) for the ratio of the rates of hydrolysis *vs.* oxygen exchange:

$$\frac{d[(5)]}{dt}\Big/\frac{d[(4)]}{dt} = [k_{(2)\rightarrow(5)}\cdot k^{-1}_{(2)\rightarrow(3)}(k_{(3)\rightarrow(2)}+k_{(3)\rightarrow(4)}+k_{(3)\rightarrow(5)}) + k_{(3)\rightarrow(5)}]\cdot k^{-1}_{(3)\rightarrow(4)} \qquad (5.10d)$$

Two significantly different situations can now be envisioned. The first involves the hypothesis *that the permutational isomerization among the oxyphosphoranes is faster than their decomposition to tetracoordinate phosphates:* $k_{(2)\rightarrow(3)}$, $k_{(3)\rightarrow(2)} \gg k_{(2)\rightarrow(5)}$, $k_{(3)\rightarrow(4)}$, $k_{(3)\rightarrow(5)}$. Under this assumption, the experimentally observed ratio

$$\frac{d[(5)]}{dt}\Big/\frac{d[(4)]}{dt} = 5 \quad \text{(ratio of ring opening : ring retention)} \qquad (5.10e)$$

for the rates of hydrolysis *vs.* oxygen exchange leads to Equation (5.10f). In other words, the tendency of an oxyphosphorane to lose one mole of water (where the ring is retained) is 2.5 times less pronounced than its tendency to undergo ring opening.

$$k_{(3)\rightarrow(4)} = 0.4\, k_{(2)\rightarrow(5)} \quad (i.e., \text{the rate of collapse with ring retention} = 0.4 \times \text{rate of collapse with ring opening}) \qquad (5.10f)$$

The second situation involves the hypothesis that the *permutational isomerization of the oxyphosphoranes is slower than their decomposition to tetraccordinate phosphates:* $k_{(2)\rightarrow(3)}, k_{(3)\rightarrow(2)} \ll k_{(2)\rightarrow(5)}, k_{(3)\rightarrow(4)}, k_{(3)\rightarrow(5)}$. This type of hypothesis has been recently suggested by *Westheimer et al.*[8e]; in it, with $k_{(2)\rightarrow(5)}=k_{(3)\rightarrow(5)}=\alpha k_{(3)\rightarrow(4)}$, one should obtain Equation (5.10g). Since the assumption[8e] that isomerization is much slower than decomposition ($k_{(2)\rightarrow(3)} \ll k_{(2)\rightarrow(5)}$), Equation (5.10g) is hardly compatible with the values (Eq. 5.10e) observed for the ratio of the rates of hydrolysis *(1)*→*(5)* *vs.* oxygen exchange *(1)*→*(4)*. Therefore, this assumption is untenable

and $k_{(2)\rightarrow(3)}$, $k_{(3)\rightarrow(2)}$ must be of the same order of magnitude as $k_{(2)\rightarrow(5)}$, $k_{(3)\rightarrow(4)}$, or more likely, as stated above $k_{(2)\rightarrow(3)}, k_{(3)\rightarrow(2)} \gg k_{(2)\rightarrow(5)}, k_{(3)\rightarrow(4)}$.

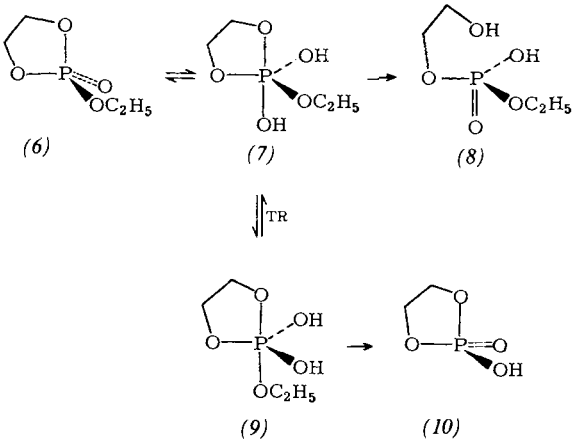
$$\frac{d[(5)]}{dt} \Big/ \frac{d[(4)]}{dt} = k_{(2)\rightarrow(5)}(1+\alpha)\cdot k^{-1}_{(2)\rightarrow(3)} \qquad (5.10g)$$

Again the slight tendency for an oxyphosphorane to collapse with ring opening instead of with ring retention is in apparent contradiction with the conclusion reached in Section 4.5. However, it should be noted that this principle refers to the loss of an alkoxyl group from an oxyphosphorane in both cases (*i.e.*, where the ring is retained and where the ring is opened). On the other hand, in Reaction 5.10 a water molecule is the leaving group in ring retention (*(3)→(4)*) while the alkoxy group is the leaving group in ring opening (*(3)→(5)*). We would suggest that the general tendency of oxyphosphoranes to undergo collapse with ring retention is offset to some extent by the higher leaving tendency of an alkoxy group, as compared with water. It is remarkable, in fact, that the ring opening is only 2.5 times greater than ring retention. It should also be emphasized that the acyclic oxyphosphorane *(15a)* of Reaction 5.9A has the option to collapse with the loss of alkoxide to give *(3a)* and acetoin or to collapse with the loss of hydroxide to give *(1a)*. This is another case of the collapse of an oxyphosphorane with loss of an alkoxide taking precedence over collapse with the loss of a hydroxide.

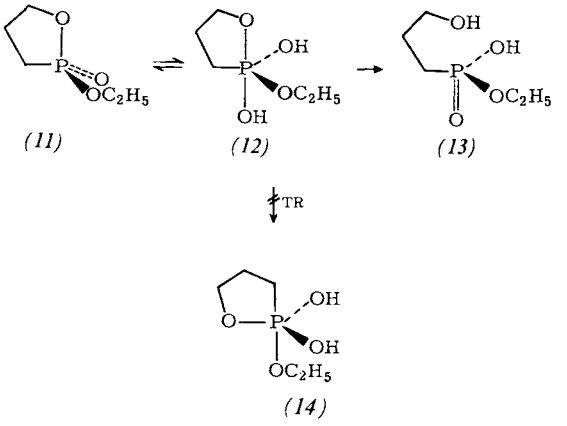
Finally, the relatively high rate of acid hydrolysis of ethylene phosphate *(1)→(5)*, Reaction 5.10, relative to the acid hydrolysis of dimethyl phosphate, $(CH_3O)_2P(O)OH$, can be interpreted by assuming that *the formation of the TBP intermediate is faster in the presence of a five-membered ring.* This is another example of the principle enunciated in Sections 2 and 4, namely, that there is a kinetic (as well as a thermodynamic) advantage in the conversion of a five-membered cyclic tetracoordinate phosphate into a five-membered cyclic pentacoordinate oxyphosphorane, for the reasons given in those Sections.

The relatively rapid permutational isomerization of the oxyphosphoranes *(2)⇄(3)*, Reaction 5.10, is understandable in the TR mechanism[2,29] using the ring as the pair of the pair-trio TR-combination.

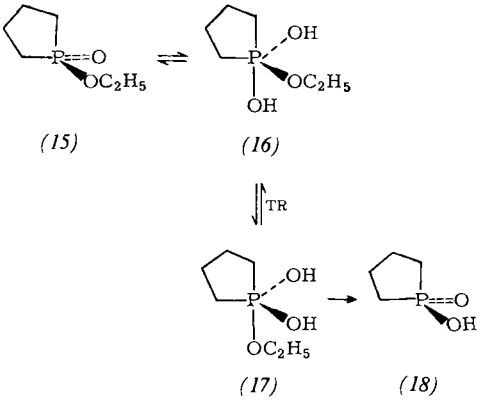
Reaction 5.11



Reaction 5.12



Reaction 5.13



5.4. Differences in the Hydrolytic Behavior of Cyclic Phosphate, Phosphonate, and Phosphinate Esters

Interpretation of behavior differences in the hydrolyses of cyclic phosphate, phosphonate and phosphinate esters where phosphorus lies incorporated in a five-membered ring[8c,e,f] follows directly from the previously mentioned TR rule for cyclic phosphoranes (see Section 4.10; 8).

In contrast to the corresponding cyclic phosphate *(6)* (Reaction 5.11) which leads to *(8)* and *(10)*, the fast hydrolysis of the cyclic phosphonate *(11)* (Reaction 5.12) proceeds exclusively with ring opening forming *(13)*. The oxyphosphorane intermediate *(12)* is incapable of rearrangement by a single TR process with the ring as the pair, since this would generate *(14)* with an energetically disfavored apical P—C bond. A $(TR)^2$ process which may lead to exocyclic hydrolysis is also disfavored for reasons given in Ref.[2].

The acid hydrolysis of cyclic phosphate *(6)* corresponds mechanistically to the analogous preceding case (Reaction 5.10).

The cyclic phosphinate ester *(15)* behaves as expected. Now, hydrolysis is possible only after the TR *(16)→(17)* in which the ring acts as the pair. In both *(16)* and *(17)* there is an apical P—C bond and hence the energies of the two TBP are of the same order of magnitude and the TR *(16)→(17)* is thermodynamically permissible. The relatively slow observed rate of hydrolysis of *(15)* can result from either one of the following factors or their combination (see Equations (5.13a) to (5.13c)): 1. The TBP intermediate

(16) is relatively energy rich due to the apical carbon (in contrast to *(7)* and *(12)*); this would make step *(15)*→*(16)* slow. 2. The TR barrier of *(16)*→*(17)* is expected to be relatively high since the two P—CH_2 groups interfere sterically with the P—O moiety. In the phosphate case, *(7)*→*(9)*, this type of interference is absent. Thus, the relatively slow rate of hydrolysis of the cyclic phosphinate *(16)* to *(18)* is accounted for.

$$k_{\text{hydrol, obs.}} = k_{(15)\rightarrow(16)} \cdot k_{(17)\rightarrow(18)} [(k_{(16)\rightarrow(15)} + k_{(16)\rightarrow(17)})(k_{(17)\rightarrow(16)} + k_{(17)\rightarrow(18)}) k^{-1}_{(16)\rightarrow(17)} - k_{(17)\rightarrow(16)}]^{-1} \quad (5.13a)$$

For the extremes, Equation (5.13b) follows with the assumption
$k_{(16)\rightarrow(17)}, k_{(17)\rightarrow(16)} \gg k_{(16)\rightarrow(15)}$:

$$k_{\text{hydrol, obs.}} = k_{(15)\rightarrow(16)} \quad (5.13b)$$

and Equation (5.13c) with the assumptions $k_{(16)\rightarrow(17)}$, $k_{(17)\rightarrow(16)} \gg k_{(16)\rightarrow(15)}$, $k_{(17)\rightarrow(18)}$, and $k_{(15)\rightarrow(16)} \approx k_{(16)\rightarrow(15)}$

$$k_{\text{hydrol, obs.}} = k_{(16)\rightarrow(17)} \quad (5.13c)$$

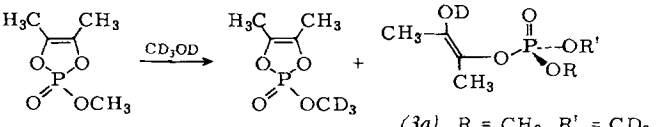
6. Hydrolyses and Rearrangements of Phosphate Esters in Aprotic Solvents and in Neutral Aqueous Solutions

In neutral media where oxyphosphorane intermediates exist neither in protonated nor anionic form, their collapse by departure of an apical ligand is accompanied by charge separation (see Section 4.7), unless rapid proton transfer from hydrogen bonded water molecules takes place. Hence it can be predicted that the lifetime of oxyphosphorane intermediates in neutral media is much longer than in acidic or alkaline solutions, and positional exchange is more likely to occur.

According to the pH-rate profile[8e] for the hydrolysis of methyl ethylene phosphate (see Section 5.1), the acid catalyzed reaction gives 50% exocyclic hydrolysis; the ring-retention process falls off to 25% for the water reaction and to 0% for the hydroxide-ion reaction. In the hydrolysis of five-membered cyclic phosphate esters in aprotic solvents with limited amounts of water[9a,61c,d,h], *there is always a remarkable tendency for exocyclic hydrolysis, and in some cases, nearly complete retention of the ring could be demonstrated*[9a,61c,d,h]. To detect this tendency toward ring retention, one must avoid the secondary reactions of the products that are formed in the first stage. It is not quite clear at this time why the cyclic oxyphosphorane intermediates in these reactions manifest such preference for collapse with exocyclic apical departure of, *e.g.*, methanol leading to hydrolysis with ring retention. Presumably the corresponding transition state is less strained than the transition state for ring opening.

The enediol cyclophosphate *(1)*, Reaction 6.1, reacts with nucleophiles in aprotic solvents at an extraordinarily rapid rate[61c,h]. The approximate half-life of the reaction with one mol. equiv. of methanol in 0.3 M CCl_4 solution amounts to one minute at 20 °C[61h]. Methanol enters and leaves the molecule with retention of the ring; this exchange is followed by the slower rupture of the ring, as can be shown by the use of CD_3OD: *(1)*→*(2)*+*(3)*. Highly selective nucleic acid syntheses seem possible employing reactions of a type which is represented by this model[*].

Reaction 6.1[61c,h]

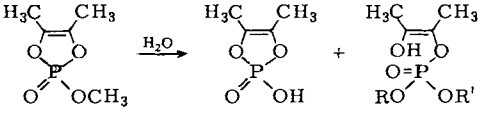


(1) *(2)*

(3a), R = CH_3, R' = CD_3
(3b), R = R' = CH_3
(3c), R = R' = CD_3

The addition of one mol. equiv. of water to a 0.6 M benzene solution of *(1)*, Reaction 6.2, gives within seconds the cyclic phosphodiester *(4)* and methanol. Subsequent reaction of the methanol thus formed with the unreacted cyclic triester *(1)* and with the cyclic diester *(4)* yield respectively the open phosphotriester *(5a)* and phosphodiester *(5b)*. There is also formed some open phosphomonoester *(5c)* which must have resulted from the reaction of water with the cyclic diester *(4)*[61h].

Reaction 6.2[61h]

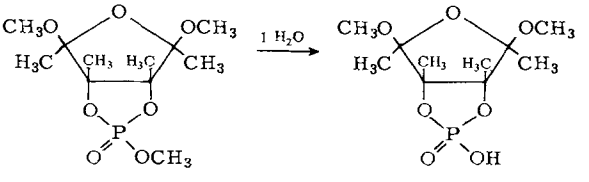


(1) *(4)*

(5a), R = R' = CH_3
(5b), R = CH_3, R' = H
(5c), R = R' = H

The furanose-2,3-cyclophosphotriester *(6)*, Reaction 6.3, undergoes rapid hydrolysis with *ca.* 100% ring retention in aprotic solvents[9a].

Reaction 6.3[9a]



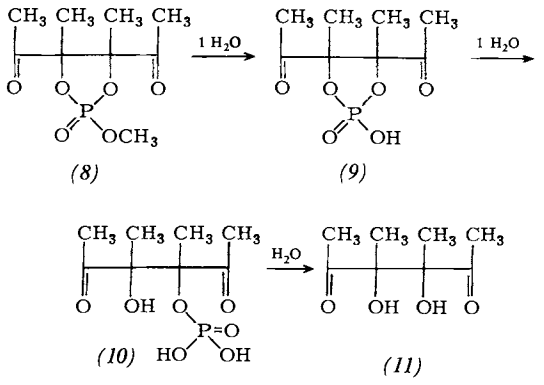
(6) *(7)*

Cyclic phosphotriesters derived from α,β-dihydroxy-γ-diketones *(8)*, Reaction 6.4, undergo hydrolysis, with *ca.* 100% ring retention *(8)*→*(9)*[9a,61]. Further hydrolytic cleavage of the ring is also rapid and gives the monoester *(10)*. The latter loses phosphoric acid quite rapidly, because the phosphate is activated by both adjacent functions, the carbonyl and the glycol-OH, *(10)*→*(11)* (see Section 5.2).

Cyclic phosphotriesters derived from α,β-dihydroxy-monoketones *(12)*, Reaction 6.5, illustrate nicely the relative activating effects of the carbonyl group and of the glycol-

[*] See also: *S. Glaser, F. Ramirez, P. Stern, P. D. Gillespie*, and *I. Ugi*, Angew. Chem. *85*, 39 (1973); Angew. Chem. internat. Edit. *12*, 66 (1973).

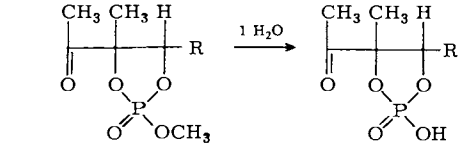
Reaction 6.4[9a,61c]



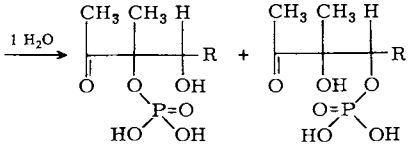
(8) (9) (10) (11)

OH group on adjacent phosphate esters[61d]. The first hydrolysis product is the cyclic phosphodiester *(13)* which undergoes subsequent hydrolytic cleavage to the α-phosphate *(14)* of the α,β-dihydroxyketone. The latter undergoes a relatively slow isomerization to the more stable β-phosphate *(15)*. The carbonyl group "pushes" the phosphate toward the β-ketol function, *(14)*→*(15)*.

Reaction 6.5[61d]



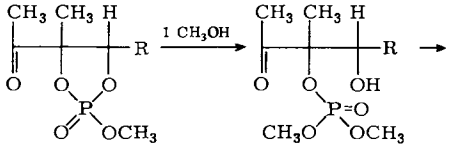
(12), R = CH_2CH_3, $CH{=}CH_2$ *(13)*



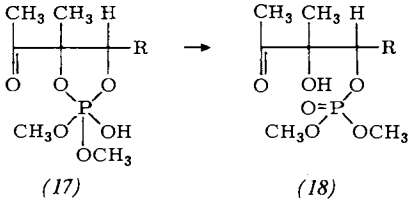
(14) *(15)*

The reactions of the α,β-dihydroxyketone-phosphotriesters *(12)*, Reaction 6.6, with methanol are very fast and give the α-phosphotriesters *(16)*. The product *(16)* undergoes an extremely rapid isomerization to the β-phosphotriester *(18)*. This isomerization is much faster than that of the monoester *(14)*.

Reaction 6.6[61d,f]



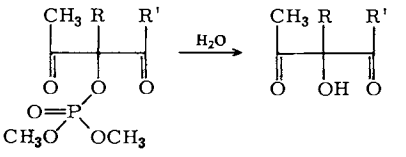
(12) *(16)*



(17) *(18)*

A phosphate ester flanked by two carbonyl groups, as in *(19)*, Reaction 6.7, represents a condition of extraordinary hydrolytic instability. This is true for phosphate esters of α-hydroxy-β-diketones *(19a)* and *(19b)*, α-hydroxy-β-ketoesters *(19c)*, and α-hydroxy-β-ketoamides *(19d)*, with and without α-hydrogens. The most reactive example is that of the phosphotriester *(19b)*, which loses its phosphate within minutes when treated with one mol. equiv. of water in ether solution at 0 °C[61e].

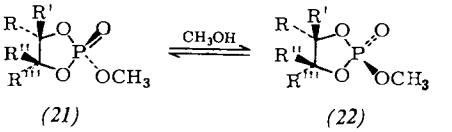
Reaction 6.7[61b,e]



(19a), R = R' = CH_3 *(20)*
(19b), R = CH_3, R' = CF_3
(19c), R = CH_3, R' = OCH_3
(19d), R = H, R' = NHR''

Diastereomeric five-membered cyclophosphotriesters such as *(21)* and *(22)*, Reaction 6.8, which differ by the configuration at the phosphorus, undergo rapid diastereomerization by inversion at the P-center under the catalytic influence of methanol[9b]. Permutational isomerization of the hypothetical oxyphosphorane intermediates by the TR with the ring as the pair accounts for these observations.

Reaction 6.8[9b]



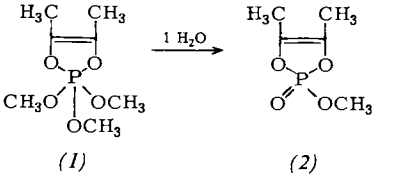
(21) *(22)*

7. Hydrolysis of Isolable Cyclic Oxyphosphoranes in Aprotic Solvents

The concept that transient oxyphosphoranes are formed in the hydrolyses of phosphate esters and related reactions, and the ideas presented in Sections 2 and 4 relative to the role of five-membered rings in those reactions, are supported by the behavior of the *isolable*, relatively stable, five-membered cyclic oxyphosphoranes toward water.

The reaction of one mol. equiv. of water with the five-membered cyclic unsaturated oxyphosphorane, Reaction 7.1, in benzene solution at 0 °C gives two mol. equivs. of methanol and the enediol cyclophosphate *(2)*.

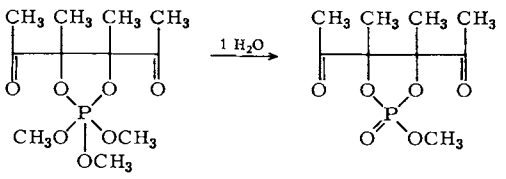
Reaction 7.1[21,61a,c]



(1) *(2)*

The oxyphosphorane *(3)*, Reaction 7.2, derived from the addition of two moles of diacetyl to one mole of trimethyl phosphite gives cyclic phosphotriesters *(4)* upon treatment with one mol. equiv. of water.

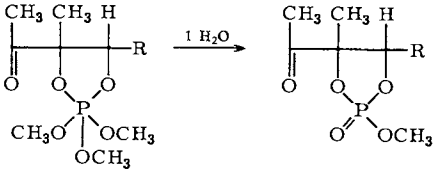
Reaction 7.2[9b,20a,b,d,61c]



(3) *(4)*

The oxyphosphoranes *(5)*, Reaction 7.3, which are made from the reaction of one mole each of diacetyl, an aldehyde, and trimethyl phosphite, show a marked tendency to undergo hydrolyses with ring-retention in aprotic media.

Reaction 7.3[61d,f]



(5) *(6)*

8. Conclusion

Nucleophilic displacement reactions of tetracoordinate phosphorus compounds, including biochemically important phosphoric acid derivatives, in general, proceed subject to the rules and concepts outlined above. These rules are primarily empirical, and based upon the known chemistry of the stable phosphorane derivatives and the experimental evidence which is available on nucleophilic displacement reactions of tetracoordinate phosphorus compounds. Moreover, some of these rules can be justified by quantum mechanical treatment[2] of the bonding properties of pentacoordinate phosphorus and its ligand sets. The latter includes the analysis of polytopal reorganization mechanisms based upon the subclasses of the symmetric permutation groups S_n[*] with respect to the skeletal symmetry subgroups[2]. The concepts presented in this and in the preceding communication[2] permit a consistent and unified treatment of an essential aspect of phosphorus chemistry. Indeed, it is possible at times to make detailed predictions of the relative rates and of the outcome of many reactions of phosphorus compounds.

[*] *Note added in proof:* In this context the reader should recall the use of the structure of the symmetric group S_5 for the classification of the rearrangements of pentacoordinate molecules, as discussed in a preceding communication of this series [2].

The permutations belonging to the symmetric group S_5 correspond to the rearrangements of pentacoordinate molecules and are the *isomerizers* of pentacoordinate molecules [2].

Definitions for the terms arising from the treatment of the problem given in ref. [2] are as follows:

Permutational Isomerization = an individual rearrangement or reorganization with a characteristic pathway of motion and result.

Mechanism = Motionwise equivalent permutational isomerizations, cf. [73].

[46] Single and multiple TR-processes have the consequences which follow from the application of the following rules[2,29]: Partition the five ligands of the TBP phosphorane into a *pair* (one apical and one equatorial ligand) and a *trio* (one apical and two equatorial ligands), and carry out the following permutations. For (TR): transpose the pair ligands; rotate the trio of ligands 120° in the direction that brings the trio-apical ligand into the original position of the trio-equatorial ligand that remains equatorial in the isomerization. For $(TR)^2$: do not change the pair; rotate the trio as for (TR). For $(TR)^3$: transpose the pairs; do not change the trio. A repetition of the TR six times with the same pair-trio combination regenerates the original bipyramid: $(TR)^6 \approx$ identity. The actual motions of the ligands in the TR process, whose consequences are given by those rules, are discussed in Refs. [2,29].

Syntheses of Heterocycles by Intramolecular Acylation of Nitrile-Hydrogen Halide Adducts

By Gerhard Simchen and Günther Entenmann[*]

Five-membered, six-membered, and seven-membered aza-, diaza-, and thiazaheterocycles can be prepared by cyclization of ω-cyano carboxylic acid halides in the presence of hydrogen halides in aprotic solvents. Nitrile-hydrogen halide adducts occur as intermediates in this novel heterocycle synthesis of wide application. The acylating cyclizations of nitriles in protonic media, which proceed *via* imidic esters or amides, are not discussed.

1. Introduction

Heterocycle syntheses with nitriles as reactants are very numerous. The nitrile group often acts only as an electrophile in these syntheses, *i.e.* only the carbon atom is incorporated into the ring system, with formation of amino-substituted heterocycles[1,2]. Ring closure reactions with incorporation of the entire nitrile group are usually preceded by the conversion of this group into an imidic ester or a carboxamide group[3–5]. Developments of the past 15 years include syntheses of heterocycles from nitriles by 1,3-dipolar cycloaddition[4] and on the basis of nitrilium salts[6–8]. These syntheses will not be discussed here.

The nitrile nitrogen is only weakly nucleophilic. Thus the presence of Lewis acids is necessary for the formation of alkylnitrilium and acylnitrilium salts[9]. Only very reactive acyl halides, such as malonyl chloride, react directly with nitriles to form heterocycles[10,11]. An intramolecular acylation leading to heterocycles is possible with hydrogen halide adducts of ω-cyanoacyl chlorides.

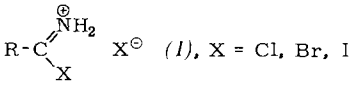
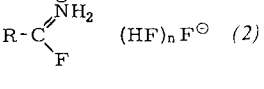
2. Nitrile-Hydrogen Halide Adducts

Reaction products of nitriles with hydrogen halides, though discovered by *Gautier*[12] in 1867, received little attention until recently. In 1964, *Allenstein et al.*[13,14] succeeded in establishing the structure of adducts of nitriles or thiocyanates with hydrogen chloride, bromide, and iodide. The isolable, thermally unstable substances (the adduct of acetonitrile and hydrogen chloride decomposes at 6 °C) were found to be compounds of the imidium acid halide halide (amide halide) type *(1)*. Their stability increases with the acidity of the hydrogen halide.



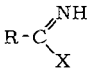
(1), X = Cl, Br, I

Adducts with complex anions are more stable, comparable with the "amide fluorides" *(2)*[15].



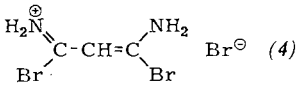
(2)

Imidoyl halides having the structure *(3)* have not so far been isolated[16,17]. The addition of one mole of HX evidently increases the basicity to such a degree that a further



(3)

mole of HX can be rapidly taken up. Imidoyl halides are postulated not only for the formation of the "amide halides" *(1)* but also for many reactions of nitriles that are catalyzed by hydrogen halides. The adduct *(4)* of malodinitrile and hydrogen bromide deserves mention[18]. In this case a 1:1 adduct is stabilized, as it were, by tautomerization to the α-bromoenamine.



(4)

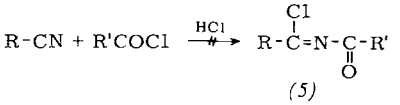
Nitrile-hydrogen halide adducts of the type *(1)* react with nucleophiles such as water, alcohols, and carboxylic acids[19]. The trimerization of nitriles to *s*-triazines may also belong to this class of reactions.

The course of the synthesis of many heterocycles from α,ω-dinitriles with hydrogen halides is uncertain. *Johnson* and *Madronero*[6] have invoked nucleophilic attack of a nitrile group on an "amide bromide" function in their interpretation.

3. Electrophilic Reactions on Nitrile-Hydrogen Halide Adducts

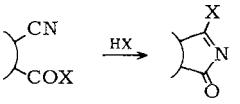
The increased nucleophilicity of the adducts in comparison with the nitriles should facilitate electrophilic reactions on the nitrogen. It should not, however, be overlooked that such addition compounds are present only in low concentrations, particularly at elevated temperatures. The isolation of *N*-acylation products therefore depends on the possibilities of stabilizing them.

Initial attempts to prepare *N*-acylimidoyl chlorides *(5)* by reaction of nitriles with acyl chlorides in the presence of hydrogen chloride[20] were unsuccessful.



(5)

When this reaction was applied to ω-cyanoacyl halides *(6)*, however, a novel synthesis of wide application was found for five-membered, six-membered, and seven-membered heterocycles. Significantly, the synthesis leads directly

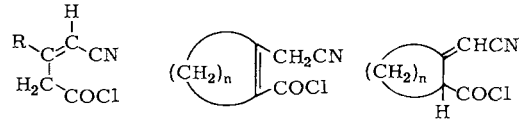


(6) *(7)*

to a heterocycle having a reactive halogen atom. The initially formed cyclic *N*-acylimidoyl halides *(7)* are stabilized in many cases by prototropy (see Section 4).

3.1. 6-Halo-2-pyridones

Non-cyclic esters of β-keto acids react with cyanoacetic acid to form esters of *cis*- and *trans*-β,γ-unsaturated γ-cyano carboxylic acids[21,22], from which the acids are obtained by hydrolysis, and the acyl chlorides *(8a)* are then obtained as crude products by reaction with phosphorus pentachloride. The corresponding cycloalkanecarboxylic acids give mixtures of the α,β- *(8b)* and β,γ-unsaturated acyl chloride *(8c)* in these reactions.



(8a), R = CH_3, C_6H_5 *(8b)*, n = 3, 4, 5 *(8c)*, n = 3, 4, 5

The acyl chlorides *(8a)* and *(8b)/(8c)* in the pure form remain unchanged in inert solvents. However, if hydrogen chloride is passed into solutions of these substances in ether/di-*n*-butyl ether, with subsequent heating to 50–80°C, one obtains 6-chloro-2-pyridones *(9a)* and *(9b)*[22,23] (Table 1)[*]. Since the ring closure does not occur in the absence of hydrogen chloride, the acylation must take place on an intermediate hydrogen chloride adduct.

Table 1. 6-Chloro-2-pyridones *(9a)* and *(9b)* from *(8a)* and from *(8b)/(8c)*.

	R/*n*	Conditions	Yield [%][a]	M.p.[°C]
(9a),	CH_3	6 h, 50°C	37	156–158
(9a),	C_6H_5	6 h, 50°C	63	166–168
(9b),	3	4 h, 60°C	35	182–184
(9b),	4	7 h, 80°C	38	187–190

[a] The yields are based on the carboxylic acids from which *(8a)* and *(8b)/(8c)* are derived.

Adducts with hydrogen bromide and with hydrogen iodide are more nucleophilic and thermally more stable than those with hydrogen chloride. This is confirmed by the extremely fast cyclization of *(8a)* and *(8b)/(8c)* (15–30 min at 0°C) in the presence of hydrogen bromide or hydrogen iodide[24]. The initial products are salt-like adducts of the hydrogen halides with 6-bromo-2-pyridones and 6-iodo-2-pyridones. The 6-halo-2-pyridones *(10a)* and *(10b)* are obtained from the adducts by treatment with aqueous sodium hydrogen carbonate solution (Table 2).

[*] It should be noted that the mixture *(8b)/(8c)* is converted exclusively into *(9b)*.

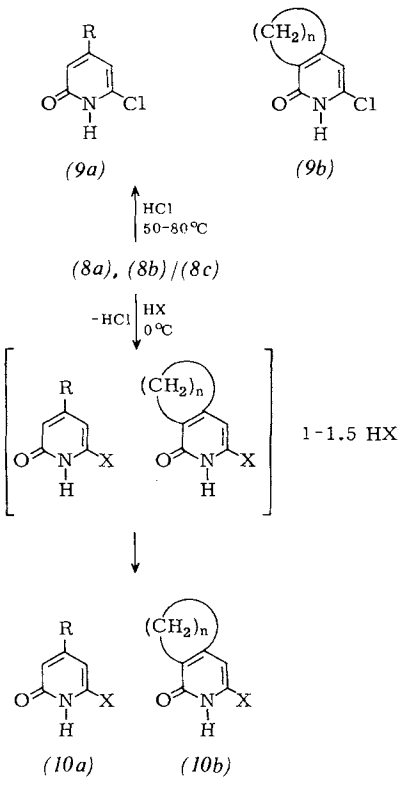


Table 2. 6-Halo-2-pyridones *(10a)* and *(10b)* from *(8a)* and from *(8b)/(8c)*.

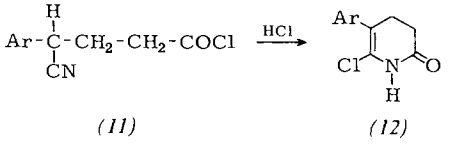
	R/*n*	X	Conditions	Yield [%][a]	M.p.[°C]
(10a),	CH_3	Br	30 min, 0°C	24	149–151
(10a),	C_6H_5	Br	30 min, 0°C	80	174–176
(10a),	C_6H_5	I	15 min, 0°C	67	199–201
(10b),	3	Br	30 min, 0°C	24	174–175
(10b),	4	Br	30 min, 0°C	38	195–196
(10b),	4	I	15 min, 0°C	40	192–193
(10b),	5	Br	30 min, 0°C	32	171

[a] The yields are based on the carboxylic acids from which *(8a)* and *(8b)/(8c)* are derived.

3.2. 6-Chloro-3,4-dihydro-2(1*H*)-pyridinones

The *N*-acylimidoyl halides formulated as precursors of the 2-pyridones *(9)* and *(10)* are stabilized by formation of the ring-conjugated pyridone system. The question whether this is essential for the ring closure can be examined in the reaction of 4-aryl-4-cyanobutyryl chlorides *(11)*[25] with hydrogen chloride. The compounds *(11)* can be distilled unchanged at temperatures above 100°C. However, if solutions of *(11)* in dioxane saturated with hydrogen chloride are heated for 6 h at 60°C, 6-chloro-5-aryl-3,4-dihydro-2(1*H*)-pyridinones *(12)* are formed in excellent yields[25] (Table 3).

The driving force of the cyclization is evidently the formation of the α-chloroenamide structure in *(12)*. If the



(11) *(12)*

Table 3. 6-Chloro-5-aryl-3,4-dihydro-2(1*H*)-pyridinones *(12)* from *(11)*.

Ar	Yield [%]	M.p.[°C]
Phenyl	80	180–184
4-Chlorophenyl	79	193–195
4-Methoxyphenyl	88	175–178
4-Nitrophenyl	85	240–245

γ-hydrogen in *(11)* is replaced by a methyl group, the ring closure does not occur[25].

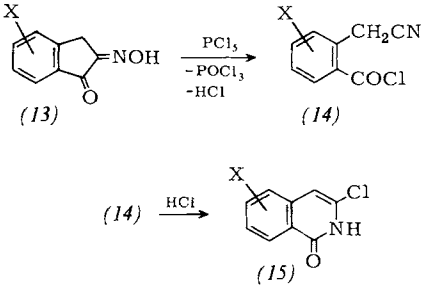
3.3. Halogenated Isoquinolines

In view of the great importance and the widespread use of isoquinolines, it would be of interest to synthesize them on the basis of the principle described. Most of the earlier isoquinoline syntheses involve intramolecular electrophilic substitution on the benzene ring. Satisfactory yields are therefore obtained only if the carbocyclic ring is activated by suitable +M or +I substituents[26–28]. An interesting method that was recently described for the preparation of 1,3-dichloroisoquinolines from arylacetonitriles and phosgene in the presence of hydrogen chloride offers no improvement[29]. Isoquinoline derivatives with activating substituents on C-8 were practically unknown in the past, since the cyclization occurs almost exclusively in position 4 with respect to the activating group[28]. Little investigation has been devoted to syntheses that give isoquinolines in good yields irrespective of the nature and position of the substituent; examples are the amidation of isocoumarins[30], the reaction of homophthalic acids with amines[27], and the cyclization of *o*-cyanomethylbenzonitriles[31] with hydrogen bromide, which leads to 1-bromo-3-aminoisoquinolines.

3.3.1. 3-Halo-1-isoquinolones

The starting materials for the cyclization are 2-cyanomethylbenzoyl chlorides *(14)*, which are obtained either from phthalides by reaction with potassium cyanide[32] and then with phosphorus pentachloride or by Beckmann rearrangement of the second kind[33] from 2-oximino-1-indanones *(13)*[34]. 2-Oximino-1-indanones are readily obtainable by nitrosation of 1-indanones with alkyl nitrites in the presence of hydrochloric acid[34].

Saturation of solutions of 2-cyanomethylbenzoyl chlorides *(14)* in dioxane with hydrogen chloride and heating for a few hours at 60—70°C leads to 3-chloro-1-isoquinolones *(15)*[34,35] (Table 4).



(13) *(14)* *(15)*

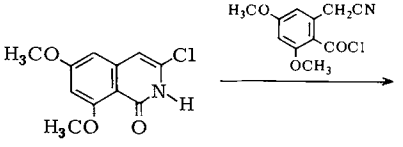
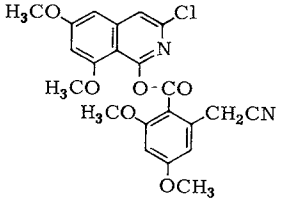
7-Nitro	100	323–325

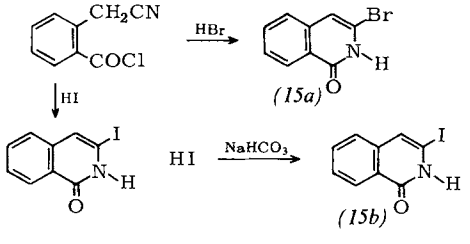
[a] The yields of *(15)* are based on 2-oximino-1-indanones *(13)*.

The rate of the cyclization increases with the hydrogen chloride concentration. If the reaction is carried out at low hydrogen chloride concentrations, *e.g.* in di-*n*-butyl ether, side reactions due to acylation of already formed *(15)* are observed in the case of inert acyl chlorides *(14)*[34].





3-Bromo-1-isoquinolone *(15a)* and 3-iodo-1-isoquinolone *(15b)* are obtained particularly readily and in quantitative yield from 2-cyanomethylbenzoyl chloride with hydrogen bromide and hydrogen iodide respectively in ether at 0 °C[34] (2 h and 20 min respectively).



3.3.2. 1,3-Dichloroisoquinolines

By analogy with the synthesis of 3-chloro-1-isoquinolones *(15)*, it seemed reasonable to attempt the preparation of 1,3-dichloroisoquinolines *(16)* by a "single-reactor method" from 2-oximino-1-indanones *(13)*. By Beckmann rearrangement of *(13)* with phosphorus pentachloride in phosphorus oxide chloride as the solvent, saturation with hydrogen chloride, and heating for a few hours at 60 °C, one obtains 3-chloro-1-isoquinolones *(15)* as intermediates. After further addition of an equimolar quantity of phosphorus pentachloride and heating at 80–100 °C, the components react to form 1,3-dichloroisoquinolines *(16)*[36]. 2-Cyanomethylbenzoic acid is used as the starting material for the preparation of 1,3-dichloroisoquinoline *(16a)* (Table 5).

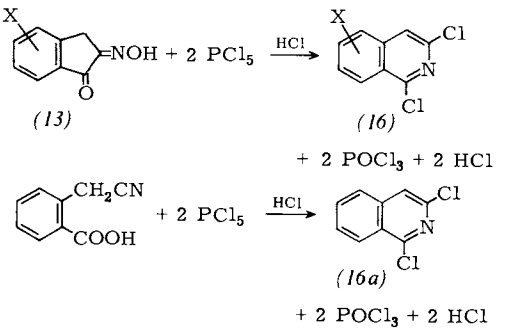


Table 5. 1,3-Dichloroisoquinolines *(16)* from 2-oximino-1-indanones *(13)*.

5-Chloro-8-methyl	70	165–166
5,8-Dimethyl	44	136–137
7-Nitro	64	176–180

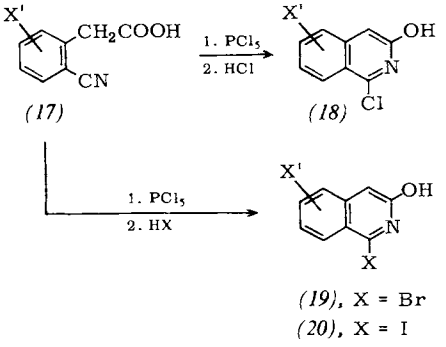
[a] *(16a)*; prepared from 2-cyanomethylbenzoic acid.

3.3.3. 1-Halo-3-hydroxyisoquinolines

A feature common to all the syntheses described so far is the electrophilic attack of chlorocarbonyl groups on hydrogen halide adducts of aliphatic nitriles, *i.e.* of compounds whose cyano groups are not directly attached to an aromatic nucleus. Whether the much less stable hydrogen halide adducts of aromatic nitriles can be acylated should be shown by corresponding reactions with (2-cyanophenyl)-acetyl chlorides. (2-Cyanophenyl)acetic acids *(17)* are obtained from oxindoles by alkaline hydrolysis followed by a Sandmeyer reaction with copper(I) cyanide, or from (2-nitrophenyl)acetic acids, which are reduced and again subjected to a Sandmeyer reaction[37–39].

If (2-cyanophenyl)acetic acids *(17)* are first converted into the acyl chlorides by reaction with phosphorus pentachloride in di-*n*-butyl ether or ether/di-*n*-butyl ether at 20 °C, followed by saturation of these solutions with hydrogen chloride and standing for about 12 h, 1-chloro-3-hydroxyisoquinolines *(18)* precipitate in excellent yields[39,40]. In the preparation of 1-bromo- *(19)* and 1-iodo-3-hydroxyisoquinolines *(20)*[39], after the reaction of *(17)* with phosphorus pentachloride, the phosphorus oxide chloride and the solvent are first distilled off and the crude product is taken up in ether. Hydrogen bromide

or hydrogen iodide is introduced at 0 °C until the solution is saturated; after a few minutes, *(19)* or *(20)* is obtained in the form of the hydrogen halide adduct (Table 6).



(19), X = Br
(20), X = I

Table 6. 1-Halo-3-hydroxyisoquinolines *(18)*–*(20)* from (2-cyanophenyl)acetic acids *(17)*.

X'	X	Yield [%]	M.p. [°C]
(18), H	Cl	79	205–206
(19), H	Br	83	179–182
(20), H	I	81	154–157
(18), 6-Methyl	Cl	84	194–196
(19), 6-Methyl	Br	82	188–190
(20), 6-Methyl	I	70	165–167
(18), 7-Methyl	Cl	94	194–196
(19), 7-Methyl	Br	84	193–195
(18), 6-Chloro	Cl	80	219–221
(19), 6-Chloro	Br	70	204–206
(18), 6-Bromo	Cl	70	226–227
(19), 6-Bromo	Br	89	197–199
(20), 6-Bromo	I	85	180–182
(18), 6-Methoxy	Cl	72	211
(19), 6-Methoxy	Br	73	191–193
(20), 6-Methoxy	I	85	180–182
(18), 7-Methoxy	Cl	70	230–232
(18), 6,7-Dimethoxy	Cl	69	226–227
(19), 6,7-Dimethoxy	Br	75	207–210
(20), 6,7-Dimethoxy	I	61	220–222

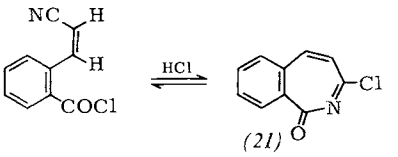
Investigations on the reaction course showed that though *(18)* is formed more slowly than the chlorine analog *(16)*, the differences are small and are not noticeable at high hydrogen halide concentrations[41].

The syntheses described in Sections 3.3.1 to 3.3.3 all give isoquinolines in equally good yields, irrespective of the nature and position of the substituents in the aromatic compounds. The isoquinoline derivatives in Tables 4–6 have not been described before or were hitherto obtainable only with considerable difficulty.

3.4. 3-Chloro-2-benzazepin-1-one

In all the ring closure reactions discussed so far the final product is stabilized by a proton shift (cf. Section 3.2).

The question whether the proton shift is a necessary criterion, *i.e.* whether cyclization does not also occur if bond systems obeying the Hückel rule are formally to be expected directly, has been investigated for the reaction of 2-(*cis*-2-cyanovinyl)benzoyl chloride with hydrogen chloride in dioxane (70 °C, 5 h). The reaction did in fact lead to the previously unknown 3-chloro-2-benzazepin-1-one (benzazatropone) *(21)*, which may be regarded as a heteroaromatic system[42,43].



(21)

Yields above 50% were unobtainable; the reaction is an equilibrium process.

3.5. Diazaheterocycles

As can be seen from the heterocycle syntheses described in the foregoing sections, nitrile-hydrogen halide adducts can be acylated on the nitrogen if stabilization of the cyclic *N*-acylimidoyl halide is possible by tautomerization (Sections 3.1 and 3.2) or by formation of a ring-conjugated 6π-electron system (Sections 3.3 and 3.4).

Substantial expansions of the synthesis result from variation of the acyl halide function. For example, stable heterocycles should also be obtained on replacement of the chlorocarbonyl group by a chlorocarbonylamino group.

3.5.1. 4-Halo-2-quinazolones

Reaction of *o*-cyanophenyl isocyanates *(22)* with hydrogen halide at room temperature in di-*n*-butyl ether leads first to carbamoyl halides *(23)*, which cyclize at about 70 °C in the presence of an excess of hydrogen halide to form 4-halo-2-quinazolones *(24)*[44] (Table 7).

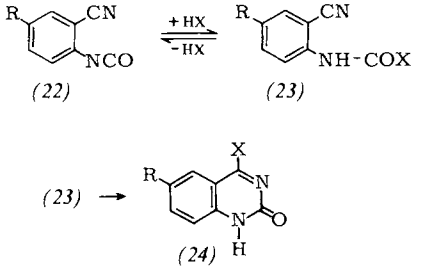


Table 7. 4-Halo-2-quinazolones *(24)* from *(22)*.

X	R	Yield [%]	M.p. [°C]
Chloro	H	87	213
Bromo	H	78	[a]
Chloro	Bromo	77–85	250–255

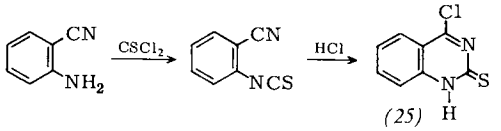
[a] The compound is susceptible to hydrolysis. The melting points found in several experiments range from 280 to 320 °C.

The synthesis of 4-chloro-2-quinazolones can also be carried out as a "one-reactor process" by introduction of phosgene into a suspension of 2-cyanoanilinium chloride in dibutyl ether at 120 °C, followed by the introduction of hydrogen chloride at 80 °C.

Reference should be made at this point to the formally similar reaction of nitriles with phosgene to form 6-chloro-2,5-disubstituted 4-pyrimidones as described by *Yanagida et al.*[45]; however, the ring closure in this case is carried out by intramolecular *C*-acylation of an enamine.

3.5.2. 4-Chloro-2-thioquinazolone

o-Cyanophenyl isothiocyanate, which is readily obtainable from *o*-cyanoaniline and thiophosgene, can be cyclized with hydrogen chloride in analogy with the reactions described above to give 4-chloro-2-thioquinazolone *(25)*. The yield is 70%[44].



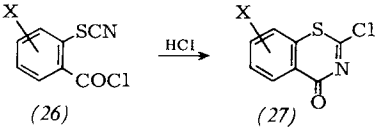
(25)

3.6. 1,3-Thiazaheterocycles

Cyclization of α,β-unsaturated β-thiocyanatoacyl chlorides with hydrogen halides should yield heterocycles that are formally derived from 3-chloro-2-benzazepin-1-one *(21)* by replacement of a vinylene grouping by sulfur.

3.6.1. 2-Chloro-1,3-benzothiazin-4-ones

When a solution of an *o*-thiocyanatobenzoyl chloride *(26)* in an ether/dibutyl ether mixture saturated with hydrogen chloride is heated (5 h, 70°C), 2-chloro-1,3-benzothiazin-4-ones *(27)* are obtained in good yields[46] (Table 8). Similarly, 2-chloronaphtho[2,3-*e*]-[1,3]-thiazin-4-one *(27a)* is obtained from 3-thiocyanato-2-naphthoyl chloride.



(26) *(27)*

Table 8. 2-Chlor-1,3-benzothiazin-4-ones *(27)* from *(26)*.

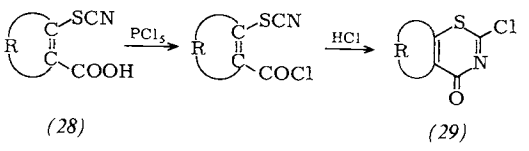
X	Yield [%]	M.p.[°C]
H	74	115–117
7-Chloro	73	149–150
6-Chloro	74	178
7-Methoxy	88	164–165
6-Methoxy	61	162
7-Nitro	73	188–190
6-Nitro	80	140–142
(27a)	76	176–178

The acyl chlorides *(26)* need not be isolated; the crude products obtained by reaction of the *o*-thiocyanatobenzoic acids with phosphorus pentachloride can be cyclized to form *(27)*.

After these investigations had been closed, we learned of a method for the preparation of 2-chloro-1,3-benzothiazin-4-ones by reaction of 2-thiocyanatobenzoic acids with thionyl chloride in the presence of catalytic quantities of dimethylformamide[47].

3.6.2. 2-Chloro-1,3-thiazin-4-ones

On reaction of *cis*-β-thiocyanatoacrylic acid *(28a)* in ether at 0°C with phosphorus pentachloride and introduction of dry hydrogen chloride into the solution, 2-chloro-1,3-thiazin-4-one *(29a)* precipitates[48]. The derivatives *(29b)* and *(29c)* are obtained in a similar manner (Table 9).



(28) *(29)*

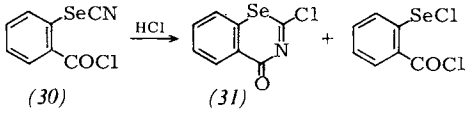
Table 9. 2-Chloro-1,3-thiazin-4-ones of the type *(29)*.

	R	Yield [%]	M.p.[°C]
(29a)	—H H—	52	95–97
(29b)	—$(CH_2)_3$—	53	77–79
(29c)	—$(CH_2)_4$—	45	78–80

cis-β-Thiocyanatoacrylic acid *(28a)* is formed by addition of potassium thiocyanate to acetylenemonocarboxylic acid in dilute sulfuric acid. The acids *(28b)* and *(28c)* are prepared by reaction of 2-chloro-1-formyl-1-cyclopentene and 2-chloro-1-formyl-1-cyclohexene, respectively, with potassium thiocyanate, followed by oxidation with chromium trioxide.

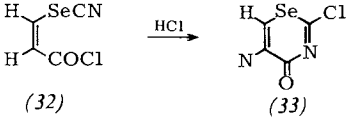
3.6.3. 2-Chloro-1,3-selenazin-4-ones

When 2-selenocyanatobenzoyl chloride *(30)* is heated for 5 hours in dioxane saturated with hydrogen chloride, one obtains 2-chloro-1,3-benzoselenazin-4-one *(31)* having a melting point of 125—126 °C in 59% yield[40,46]. 2-Chloroselenenylbenzoyl chloride is also formed by cleavage of *(30)*[46].



(30) *(31)*

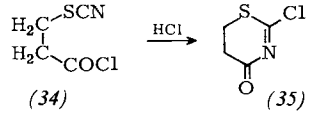
The cyclization of β-selenocyanatoacryloyl chloride *(32)* to form 2-chloro-1,3-selenazin-4-one *(33)* proceeds in poor yield with hydrogen chloride in dibutyl ether at 80°C. The main reaction here is probably the cleavage of the selenocyanate group to give selenenyl chloride and hydrogen cyanide[48].



(32) *(33)*

3.6.4. 2-Chloro-5,6-dihydro-1,3-thiazin-4-one

If hydrogen chloride is led into a solution of β-thiocyanatopropionyl chloride *(34)* in ether at 0°C, 2-chloro-5,6-dihydro-1,3-thiazin-4-one *(35)* crystallizes out after one hour[48]. It was thus possible, by acylation of a nitrile-hydrogen halide adduct, to synthesize a heterocyclic



(34) *(35)*

compound that is not stabilized by tautomerization or by formation of a 6π-electron system. *(35)* is not very stable,

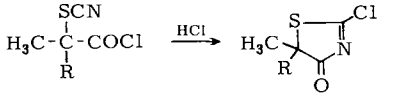
and is reconverted into *(34)* on standing for several days at room temperature. *(35)* also exhibits a number of peculiarities in its reactions. Whereas the halogen in the thiazinones *(27)* and *(29)* is smoothly replaced in reactions with nucleophiles, ring cleavage predominates in *(35)*.

Perhydro-1,3-thiazine-2,4-dione is obtained by hydrolysis of *(35)*[48] or by reaction of β-thiocyanatopropionic acid with thionyl chloride[49].

3.6.5. 2-Chloro-4-thiazolones

Though many six-membered and seven-membered heterocycles have been synthesized, it is not yet known whether smaller rings are also obtainable by cyclizing acylation of nitrile-hydrogen halide adducts. As an example we chose the cyclization of α-thiocyanatoacyl chlorides, partly because of the interesting properties of the expected 4-thiazolones.

On saturation of a solution of α-thiocyanatopropionyl chloride or of α-thiocyanatoisobutyryl chloride in absolute ether with dry hydrogen chloride at −20 to 0°C, the 5-substituted 2-chloro-4-thiazolone *(36a)* or *(36b)* crystallizes out after a short time[50] [*(36a)*, m.p. 55°C, yield 64%; *(36b)*, m. p. 81–83°C, yield 74%].

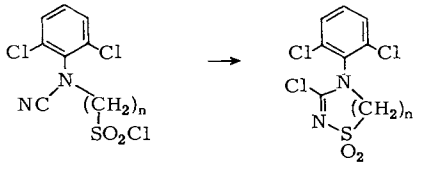


(36a), R = H
(36b), R = CH_3

5,5-Dimethyl-2-chloro-4-thiazolone *(36b)* is a stable crystalline substance; *(36a)* decomposes on prolonged standing at room temperature, with development of a yellow color.

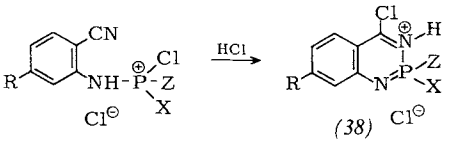
3.6.6. Ring Systems with Three Hetero Atoms

The extreme versatility of the cyclization reaction described here is underlined by syntheses of other heterocyclic systems. *Toldy* and *Sohár*[51] described the preparation of 3-chloro-5,6-dihydro-1,2,4-thiadiazine 1,1-dioxides *(37a)* and 3-chloro-5*H*-6,7-dihydro-1,2,4-thiadiazepine 1,1-dioxides *(37b)* by heating ω-(*N*-aryl-*N*-cyanamino)alkanesulfonyl chlorides. This reaction probably also proceeds *via* intermediate nitrile-hydrogen halide adducts.



(37a), n = 2
(37b), n = 3

4-Chloro-3*H*-1,3,2-benzodiazaphosphorinium chlorides *(38)* are obtained according to *Schmidpeter* and *Schindler*[52] by cyclization of 2-cyanoanilinophosphonium chlorides with hydrogen chloride.

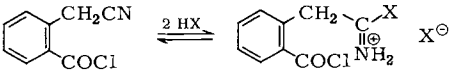


(38)

R = H, CH_3
X = C_6H_5, CH_3, Cl
Z = C_6H_5, Cl

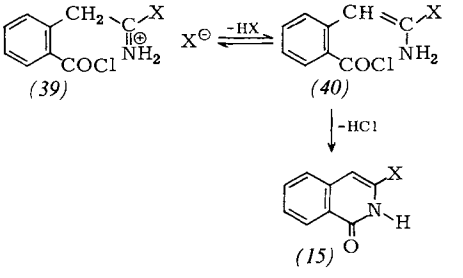
4. Course of the Reaction

Detailed investigations on the mode of formation of 3-halo-1-isoquinolones *(15)* have proved that nitrile-hydrogen halide 1,2-adducts *(39)* occur as intermediates.



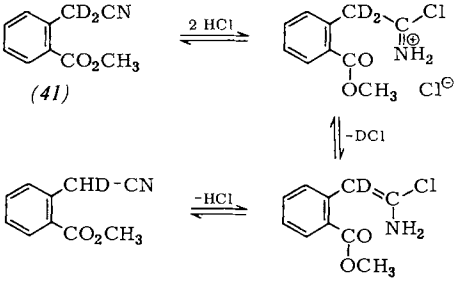
(39)

Since an electrophilic attack of the carbonyl group on the imonium group is not very probable, we assume that α-haloenamines *(40)* occur as intermediates.



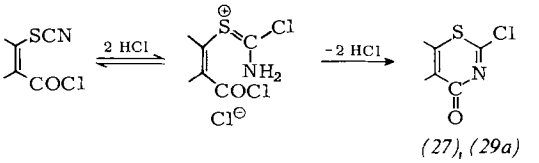
(39) *(40)* *(15)*

The existence of α-haloenamines has been detected *e.g.* by D/H exchange on methyl [α,α-D_2]-2-cyanomethylbenzoate *(41)* with dry hydrogen chloride in dioxane at 50°C.



(41)

Intermediates having an analogous structure should also be possible in the cyclization of α,β-unsaturated β-thiocyanatoacyl chlorides to form *(27)* and *(29a)*.



(27), *(29a)*

However, nitrile-hydrogen halide 1,1-adducts cannot be ruled out as the true reactive intermediates at least in the ring closure reactions leading to *(18)*, *(21)*, *(24)*, and *(25)*.

We thank Prof. Dr. H. Bredereck for his generous support of our work. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for material aid.

Chemistry and Biology of the Acylneuraminic Acids

By Roland Schauer[*]

Acylneuraminic acids occupy an outstanding position both sterically and with respect to biological functions in gangliosides and in many glycoprotein molecules. Acylneuraminic acids are *N*-acylated and partly *O*-acylated derivatives of neuraminic acid, a polyhydroxyamino keto acid that has the properties of a carbohydrate and is therefore capable of forming a glycoside linkage. The present report provides a survey of our knowledge of the chemistry and biology of the acylneuraminic acids, which occur widely in particular in the animal kingdom.

1. Discovery and Elucidation of the Structure of the Acylneuraminic Acids

The first indication of the existence of the substances under discussion was obtained in 1927 by *Walz*[1] and by *Levene* and *Landsteiner*[2] when they heated glycolipids with orcinol in hydrochloric acid containing ferric chloride and observed a red-violet color (see Section 2). In 1936, *Blix*[3] isolated a monocarboxylic acid in the crystalline form from the "submaxillary mucin", the glycoprotein of the submandibular gland (glandula submaxillaris) of the ox; this acid, whose possible composition was given as $C_{14}H_{23}NO_{11}$, also gave a red-violet color with the orcinol-hydrochloric acid reagent. In 1941, by methanolysis of gangliosides of the brain, *Klenk*[4] obtained a substance having an acidic reaction, which he named "neuraminic acid" because of its origin in the nerve tissue. It was identified a year later as "methoxyneuraminic acid" (neuraminic acid β-methyl glycoside), the derivative of a polyhydroxyamino acid, having the composition $C_{10}H_{19}NO_8$[5].

N-Acetylneuraminic acid was first isolated in the crystalline form by *Klenk* and *Faillard*[6] and by *Klenk*, *Faillard*, and *Lempfrid*[7] from bovine submaxillary mucin by acid hydrolysis and from urinary mucin by the action of influenza viruses (see Section 7). Pure *N*-glycoloylneuraminic acid was obtained by *Blix*'s research group[8] in 1956 and by *Klenk* and *Uhlenbruck*[9] in 1957 from pig submaxillary mucin. Diacetylneuraminic and triacetylneuraminic acids were obtained by *Blix*[8, 10] from bovine and horse submaxillary mucins (see Section 4; other acylneuraminic acids are also described there).

The determination of the constitution of neuraminic acid took a long time, since it occurs in nature only in the form of acyl derivatives, which are also called sialic acids after a proposal by *Blix*, *Gottschalk*, and *Klenk*[11]. Only the functional groups of neuraminic acid, *i.e.* a carboxyl group, a reducing (glycoside) group, an amino group, and five hydroxyl groups, quickly became known[8, 12]. Further light was thrown on the chemistry of neuraminic acid by the first syntheses of *N*-acetylneuraminic acid *(1)*, which was achieved by *Cornforth et al.*[14, 15] from *N*-acetylglucosamine and oxalacetic acid ("activated pyruvic acid") on the basis of *Gottschalk*'s assumption[13] that *N*-acetylneuraminic acid is an aldol condensate of *N*-acetylglucosamine and pyruvic acid. This gave a substance that was completely identical with the substance isolated from the natural products. These experiments pointed to *N*-acetylglucosamine as a structural component of *N*-acetylneuraminic acid. However, *Comb* and *Roseman*[16] obtained *N*-acetylmannosamine *(2)* and pyruvic acid *(3)* by the action of an aldolase (see Section 7) on *N*-acetylneuraminic acid *(1)*, showing that the configuration of the substituents on C atoms 5 to 8 of neuraminic acid correspond to those of *N*-acetylmannosamine (Fig. 1). The successful syntheses of *N*-acetylneuraminic acid from *N*-acetylglucosamine[14, 15] are explained by the ease of epimerization of *N*-acetylglucosamine to *N*-acetylmannosamine in alkaline media[17, 18].

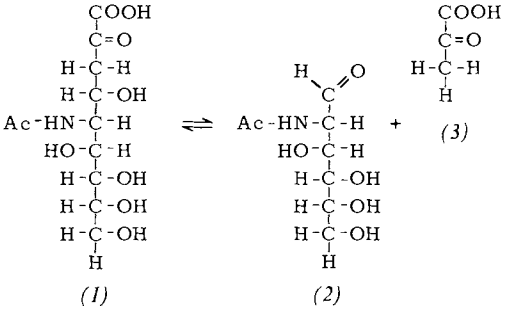

Fig. 1. Reversible cleavage of *N*-acetylneuraminic acid *(1)* into *N*-acetylmannosamine *(2)* and pyruvic acid *(3)* by the aldolase "acylneuraminate-pyruvate lyase" (see Section 7). Representation of the sugars (keto forms) in Fischer projection formulas.

After the determination of the configuration of the OH group on C-4 (on the right-hand side in the Fischer projection formula; see Fig. 1) by *Kuhn et al.*[19, 20], the stereochemistry of neuraminic acid was largely known, and it was possible to assign the following systematic name to *N*-acetylneuraminic acid: 5-acetamido-3,5-dideoxy-D-glycero-D-galactononulosaminic acid. Like all acylneuraminic acids, it occurs in the pyranose form (see Figs. 2, 6, 7)[21]. The absolute conformation of *N*-acetylneuraminic acid has recently been determined by NMR studies on the methyl ester of *N*-acetylneuraminic acid[22] and X-ray analysis of crystals of neuraminic acid β-methyl glycoside[23]. It corresponds to the 1C conformation according to the Reeves nomenclature (Fig. 2). According to these investigations, the anomeric hydroxyl group of the non-

glycosidically bound neuraminic acid is arranged axially on C-2 (Fig. 2).

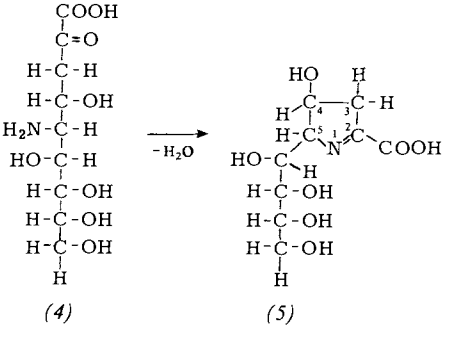
2. Properties of and Methods for the Detection of Acylneuraminic Acids

Unsubstituted neuraminic acid *(4)* is incapable of existence, since it cyclizes immediately by condensation of the amino group on C-5 with the carbonyl group on C-2 to form an internal Schiff base, 4-hydroxy-5-(1,2,3,4-tetrahydroxybutyl)-Δ^1-pyrroline-2-carboxylic acid *(5)*[24] (Fig. 3). This ring closure is prevented by the glycoside linkage *e.g.* of a methyl group to C-2 ("neuraminic acid β-methyl glycoside")[4] or by acylation of the amino group, as is the case in the naturally occurring or synthetically prepared neuraminic acid derivatives (see Sections 4 and 5).



(4) *(5)*

Fig. 3. Spontaneous cyclization of neuraminic acid *(4)*, which cannot exist, to form 4-hydroxy-5-(1,2,3,4-tetrahydroxybutyl)-Δ^1-pyrroline-2-carboxylic acid *(5)*.

The acylneuraminic acids are colorless substances that can be crystallized from mixtures of acetic acid, ethanol, or dioxane with water, are stable in the dry state, and melt with decomposition below 200 °C[21, 25]. They dissolve readily in water, and in aqueous solution they rotate the plane of polarized light to the left[21, 25]; they are sparingly soluble in methanol (with the exception of the oligoacetylneuraminic acids; Section 4) and insoluble in ether. As α-keto acids, they are relatively strong acids and, depending on the nature of the *N* or *O* substituents, their p*K* values lie between 1.8 and 2.6[26, 27].

Whereas free acylneuraminic acids decompose readily both in alkaline and in acidic solution, glycosidically bound acylneuraminic acids are moderately stable toward alkalis. In alkaline media, free acylneuraminic acids realdolize to form pyruvate and *N*-acylmannosamines or *N*-acylglucosamines[28, 29] (cf. Fig. 1), or else pyrrole derivatives are formed[30]. In a reaction typical of α-keto acids, acylneuraminic acids are decarboxylated in 12% HCl at 100 °C; with concentrated H_2SO_4 they give carbon monoxide[8]. The decomposition proceeds slowly in dilute acids[31], with gradual formation of cherry red to dark brown products[32]. The degradation begins either with deacylation of the amino group followed by intramolecular ring closure of the resulting free neuraminic acid, or else enolization, dehydration, and elimination reactions lead to cyclization and polymerization of the molecules to form brown "humin substances"[33].

The products resulting from the acid degradation of the acylneuraminic acids form the basis of the Ehrlich and of the Svennerholm/Bial methods for the quantitative determination of acylneuraminic acids. In the "direct" Ehrlich reaction, a purple-red dye is formed when acylneuraminic acids are heated in hydrochloric acid solution with *p*-dimethylaminobenzaldehyde[21, 32]: the chromogen of this reaction is presumably the 5-tetrahydroxybutyl-2-pyrrolecarboxylic acid formed from neuraminic acid[21], which is trapped by the aldehyde. In the Svennerholm/Bial method, a violet dye is formed by heating acylneuraminic acid in hydrochloric acid with resorcinol[34] or with orcinol[35] and Fe^{3+} ions. This color is probably due to a methine dye[36], which is specific for neuraminic acid and is formed from it in a complicated sequence of reactions that has not yet been fully clarified.

Both of these methods are suitable for the determination of either glycosidically bound or free acylneuraminic acids. The periodic acid/thiobarbituric acid method of *Warren*[37] and *Aminoff*[38], on the other hand, responds only to free acylneuraminic acids. In this very sensitive method of analysis (detection limit 2—5 μg of *N*-acetylneuraminic acid), which is the most commonly used, the periodate oxidation of acylneuraminic acids yields β-formylpyruvic acid (HOOC—CO—CH_2—CHO[39]), which couples with 2-thiobarbituric acid to give a red dye.

3. Isolation of the Acylneuraminic Acids

Acylneuraminic acids mainly do not occur free in nature, but are attached to macromolecules by acid-labile α-glycoside linkages (see Section 4). The glycoside linkage can be broken either under particularly mild conditions with the commercially obtainable enzyme neuraminidase (see Section 7[40, 32, 41]) or with dilute acids[21], *e.g.* with 0.05—0.1 N H_2SO_4 or HCl (80 °C, 1 h[21, 32, 42, 43]). (For the cleavage of acylneuraminic acids having very readily hydrolyzable *O*-acetyl groups, the hydrolysis conditions must be even milder: 0.01 N HCl, 70 °C, 1 h[40].) The acylneuraminic acid released is dialyzed out against water, purified by ion exchange chromatography, and fractionated on cellulose powder in butanol/propanol/water (Ref. [40], cf. Fig. 4).

The acylneuraminic acids are identified by thin layer (radio)chromatography on silica gel and cellulose in several systems[40, 44]. The number of ester groups is determined with hydroxylamine by the method of *Hestrin*[45], and their position on the neuraminic acid skeleton is found polarographically with periodic acid[40]. Good progress is being

(For further explanation see Section 4.)

made in the development of gas-chromatographic methods for the quantitative and qualitative analysis of the acylneuraminic acids[46].

The isolation of neuraminic acid as neuraminic acid β-methyl glycoside, which is used as a starting material for the synthesis of acylneuraminic acids (Section 5), is easily achieved in a yield of about 80% on the basis of well-known methods[47] by methanolysis (1 N H_2SO_4 in anhydrous methanol) of acylneuraminic acids, which occur abundantly in glycoproteins from bovine submandibular glands or from the nests of oriental swallows[25,48].

4. Naturally Occurring Acylneuraminic Acids

Acylneuraminic acids have so far been found only in animal material and in some bacteria, but never in plants[49]. They are of widespread occurrence as components of glycoproteins and glycolipids both in invertebrates and in vertebrates in cells and in body fluids[21,32] (Section 8). However, free non glycosidically bound acylneuraminic acids can be detected in the tissue only in small quantities[50,51]. The observation by *Montreuil et al.*[52] of the excretion of up to 7.2 g of free *N*-acetylneuraminic acid daily by a patient aged three years ("sialuria") is so far an isolated case.

The acylneuraminic acids generally occupy the non-reducing end of the heterooligosaccharide chains in glycoproteins[32] and in gangliosides[53], where they are bound by a glycoside linkage to hydroxyl groups of the galactose, the *N*-acetylgalactosamine, or a second *N*-acetylneuraminic acid molecule. Examples of linkages that occur are *N*-acetylneuraminic acid(2→3)-galactose[*][54–56] in 3'-sialyllactose and in gangliosides, *N*-acetylneuraminic acid(2→6)-*N*-acetylgalactosamine[57] in the submaxillary mucin of sheep, and *N*-acetylneuraminic acid(2→8)-*N*-acetylneuraminic acid in gangliosides[58] and in colominic acid (see below)[59]. In all the natural neuraminic acid glycosides investigated so far, the ketoside linkage of the acylneuraminic acids (assuming that *N*-acetylneuraminic acid belongs to the D series[54,60,61]) has the α configuration. As was mentioned in Section 3, this bond is acid-labile and is readily attacked by enzymes[61] (Fig. 5).

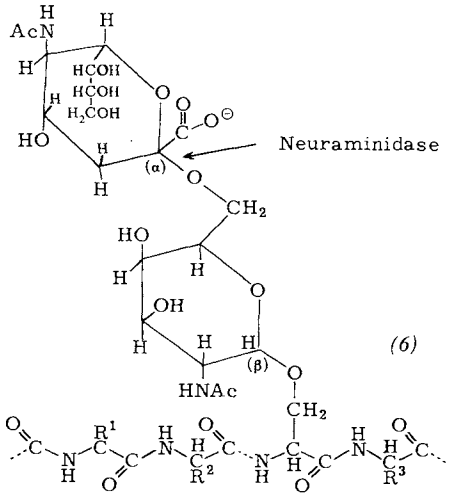


Fig. 5. Part of a glycoprotein molecule *(6)* of sheep submaxillary mucin to demonstrate the α-glycoside linkage of the *N*-acetylneuraminic acid to other carbohydrate residues, in this case to C-6 of *N*-acetylgalactosamine. The disaccharide group is attached by an *O*-glycoside linkage to hydroxyl groups of serine or threonine residues of the protein chain (from [32, 57]).

The most widely occurring natural derivative of neuraminic acid is *N*-acetylneuraminic acid *(1)*. This occurs as a polymer, known as colominic acid, in the culture filtrate of *Escherichia coli* K-235[59]. The acylneuraminic acid fraction from the submaxillary mucin of sheep[8] and from glycoproteins of human organs and erythrocytes[6,7,62] also contains mainly *N*-acetylneuraminic acid. However, a mixture of acylneuraminic acids occurs in many animal materials. Apart from *N*-acetylneuraminic acid *(1)*, which is surprisingly always present, these are mainly *N*-glycoloylneuraminic acid *(7)* (Fig. 6) and a number of more highly acetylated neuraminic acids such as *(8)—(11)* (Fig. 7). In addition to the *N*-acetyl group the latter contain one or more acetic acid residues attached by ester linkages.

N-Glycoloylneuraminic acid *(7)* is of relatively widespread occurrence. The organ having a particularly high content of *N*-glycoloylneuraminic acid is the submandibular gland of the pig, in which *N*-glycoloylneuraminic acid accounts for about 90% of the total acylneuraminic acids[43,50]. *N*-Glycoloylneuraminic acid also occurs in various quantities *e.g.* in bovine erythrocytes[21], in serum glycoproteins[63], in bovine and horse submaxillary mucin[40], in the skin of calf fetuses[64], in gangliosides from horse erythrocytes[65], and in gangliosides from the brain of the hen[66].

[*] This notation means *e.g.* linkage of the glycoside hydroxyl group on C-2 of the *N*-acetylneuraminic acid to the hydroxyl group on C-3 of the galactose.

Fig. 7. Structural formulas of some *N*-acetyl-*O*-acetylneuraminic acids: *N*-acetyl-4-*O*-acetylneuraminic acid *(8)*, *N*-acetyl-7-*O*-acetylneuraminic acid *(9)*, *N*-acetyl-8-*O*-acetylneuraminic acid *(10)*, and *N*-acetyl-7,8-di-*O*-acetylneuraminic acid *(11)*.

Rich sources of *N*-acetyl-*O*-acetylneuraminic acids are bovine and horse submaxillary mucins, whose acylneuraminic acid fraction consists of 60—70% of *O*-acetylated *N*-acetylneuraminic acid. As shown in Table 1, the diacetylneuraminic acids from bovine submaxillary glycoprotein each contain one *O*-acetyl group in position 7 or 8 [*(9)* and *(10)*][8,40,67], whereas that of the corresponding horse glycoprotein is *O*-acetylated on C-4 [*(8)*] (Fig. 7)[8,40]. The positions of the two *O*-acetyl groups of bovine triacetylneuraminic acid *(11)* are known (Table 1), whereas the position of the second *O*-acetyl group in horse triacetylneuraminic acid[40] still remains to be established. A tetraacetylated neuraminic acid (*N*-acetyl-tri-*O*-acetylneuraminic acid[68]) has been isolated in small quantities from bovine submaxillary glycoprotein. *N*-Acetyl-*O*-acetylneuraminic acids also occur in other glycoproteins of animal[69] and of human origin[70] as well as in oligosaccharides, *e.g.*

Table 1. Composition of the acylneuraminic acid fraction of bovine and horse submaxillary mucins.—means not detectable (from Ref. [68]).

Acylneuraminic acid	Submaxillary mucin Bovine [%]	Horse [%]
N-glycoloylneuraminic acid *(7)*	15	1–2
N-acetylneuraminic acid *(1)*	20–25	15–20
N-acetyl-4-*O*-acetylneuraminic acid *(8)*	—	70–75
N-acetyl-7-*O*-acetylneuraminic acid *(9)*	*ca.* 25	—
N-acetyl-8-*O*-acetylneuraminic acid *(10)*	*ca.* 25	—
N-acetyl-7,8-di-*O*-acetylneuraminic acid *(11)*	5–10	—
N-acetyl-4,?-di-*O*-acetylneuraminic acid	—	2–5
N-acetyl-?-tri-*O*-acetylneuraminic acid	*ca.* 3	—

O-acetyllactaminolactose[71]. *Wiegandt*[72] isolated *N*-acetyl-8-*O*-acetylneuraminic acid *(10)* from gangliosides of the brains of several bony fishes.

The isomeric *N*-acetyl-*O*-acetylneuraminic acids behave differently from *N*-acetylneuraminic acid *(1)* in the periodic acid/thiobarbituric acid reaction; no difference is observed, on the other hand, in the orcinol/Fe^{3+} reaction. Whereas the 4-isomer *(8)* gives practically the same color yield as *(1)* with periodic acid/thiobarbituric acid, the molar extinction of the 8-isomer *(10)* is only 47% of that of *(1)*. The 7-isomer *(9)*, on the other hand, does not react at all with this reagent (Fig. 4), a fact that was reported and explained by *Paerels*[39].

The method that has proved best for the determination of the position of the *O*-acetyl groups is the polarographically followed periodic acid oxidation (Fig. 8). The fast consumption of periodic acid is 2 moles per mole of acylneuraminic acid if the three adjacent hydroxyl groups on C-7 to C-9 are unoccupied [*(1)* and *(8)*]; it is only 1 mole if the OH group on C-7 is esterified [*(9)*]. *(10)* no longer contains vicinal OH groups, as is shown by the particularly slow oxidation with periodic acid[40].

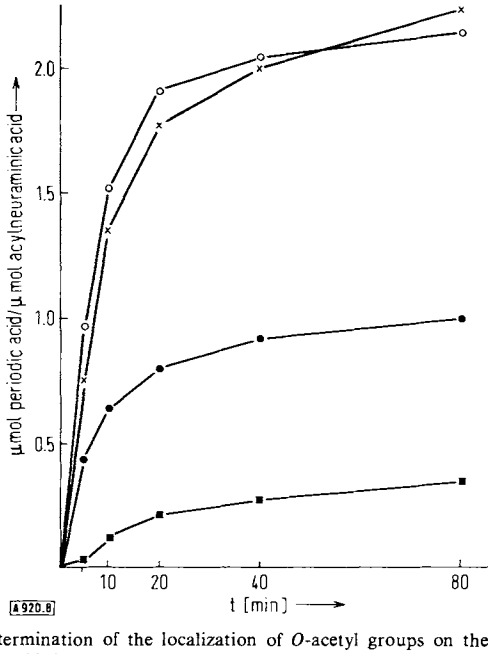

Fig. 8. Determination of the localization of *O*-acetyl groups on the neuraminic acid skeletons of several isomeric *N*-acetyl-mono-*O*-acetylneuraminic acids by polarographic measurement of the periodic acid consumption at 0 °C [40]. × — × *N*-Acetylneuraminic acid *(1)*; ○ — ○ *N*-acetyl-4-*O*-acetylneuraminic acid *(8)*; ● — ● *N*-acetyl-7-*O*-acetylneuraminic acid *(9)*; ■ — ■ *N*-acetyl-8-*O*-acetylneuraminic acid *(10)*.

Less common acylneuraminic acids are *N*-glycoloyl-8-*O*-methylneuraminic acid, which was found in the starfish *Asteria forbesi*[73], and *N*-(*O*-acetylglycoloyl)-4-methyl-4,9-dideoxyneuraminic acid (postulated structure), which was recently discovered in the egg membrane of the sea urchin[44]. *Hakomori* and *Saito*[74] have reported an *N*-glycoloyl-*O*-acetylneuraminic acid in glycosphingolipids of the membrane of horse erythrocytes, though they were unable to decide whether this was *N*-glycoloyl-4-*O*-acetylneuraminic acid or *N*-(*O*-acetylglycoloyl)neuraminic acid.

5. Synthetic Acylneuraminic Acids

The development of the synthesis of *N*-acetylneuraminic acid *(1)* from *N*-acetylglucosamine[14,15] or *N*-acetylmannosamine[75] and oxalacetate (Section 1) offered the possibility of preparing *N*-glycoloylneuraminic acid *(7)* and several *N*-acylneuraminic acids that do not occur in nature by the use of various *N*-acylated glucosamines or mannosamines (listed in Table 2). By the use of the derivatives of the above-mentioned coupling components introduced by *Kuhn* and *Baschang*[76] (4,6-benzylidene-*N*-acylglucosamine and di-*tert*-butyl oxalacetate), it was possible to obtain considerably higher yields of *N*-acylneuraminic acids (maximum 34%). A new method even gives *N*-acetyl- and *N*-glycoloylneuraminic acids in yields of 70—80%[48,25]. This method begins with the easily prepared methoxyneuraminic acid (see Section 3), which is *N*-acylated with acetic anhydride, *O*-carboxyglycolic anhydride (1,3-dioxolane-2,4-dione), or fluoroacetic or chloroacetic anhydride. The different *N*-acylneuraminic acids are liberated by subsequent glycoside cleavage in weakly acidic medium (Fig. 9, Table 2). This method is particularly suitable for the preparation of radioactively labeled *N*-[^{14}C, ^{3}H]acylneuraminic acids having high specific radioactivities, which are required for biochemical studies (Section 6).

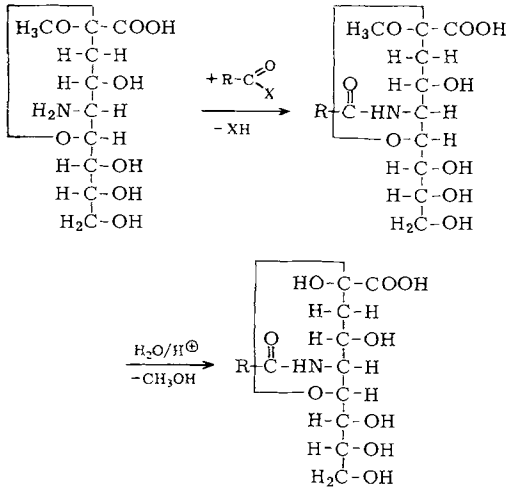

Fig. 9. Synthesis of *N*-acylneuraminic acids from neuraminic acid β-methylglycoside and acid anhydrides or acyl chlorides *via* *N*-acylneuraminic acid β-methylglycosides as intermediates.

6. Biosynthesis of the Acylneuraminic Acids

The first enzymatic synthesis both of *N*-acetylneuraminic acid *(1)* and of *N*-glycoloylneuraminic acid *(7)* was achieved in good yields by *Comb* and *Roseman*[82] from pyruvate and *N*-acetyl-D-mannosamine or *N*-glycoloyl-D-mannosamine by a reversal of the aldol cleavage of acylneuraminic acids by acylneuraminate-pyruvate lyase, which was discovered by *Heimer* and *Mayer*[83], and which was described in Section 1 (Fig. 1). However, the biological function of this enzyme, which occurs in various bacteria and in mammalian organs, consists simply in the breakdown of free acylneuraminic acids (Section 7), and not in their biosynthesis. The bacterial and the mammalian organisms follow different paths for the synthesis of *N*-acetylneuraminic acid. The simpler path is followed *e.g.* in the bacterium *Neisseria meningitidis*[84], in which *N*-acetylneuraminate is formed in one step from *N*-acetyl-D-mannosamine and phosphoenol pyruvate:

$$\text{N-acetyl-D-mannosamine} + \text{phosphoenol pyruvate} + H_2O \xrightarrow{Mn^{2+},\ -SH} \text{N-acetylneuraminate} + \text{phosphate}$$

In the mammalian organism, on the other hand (see Fig. 10), this condensation must be preceded by phosphorylation of the acetylmannosamine by a specific kinase[85]. The resulting *N*-acetyl-D-mannosamine 6-phosphate reacts with phosphoenol pyruvate under the influence of the *N*-acetylneuraminate 9-phosphate synthetase, which has been concentrated from several organs (liver, submandibular gland)[86,87], to form *N*-acetylneuraminate 9-phosphate, which is then converted by a specific phosphatase[88] into free *N*-acetylneuraminate. These reactions, which have been observed in particle-free homogenates of rat liver[86], the colonic mucous membrane of the sheep[89], and submandibular glands[51], are preceded by the biosynthesis of *N*-acetylmannosamine from *N*-acetylglucosamine by epimerizing enzymes[90,91]. The *N*-acetylglucosamine is formed from D-glucosamine and acetyl-coenzyme A[92]. Close relationships are clearly visible here between the hexose metabolism and the neuraminic acid metabolism[93].

Activation of the glycoside hydroxyl group is necessary for the transfer of the *N*-acetylneuraminic acid to glycoproteins or gangliosides. This is effected by acid-glycoside linkage of the *N*-acetylneuraminic acid with a phosphoric acid residue of cytidine triphosphate with elimination of pyrophosphate (Fig. 10). The resulting cytidine-5′-monophospho-*N*-acetylneuraminic acid *(12)* (Fig. 11) was first found in *Escherichia coli*[94], and was later synthesized with the aid of an enzyme concentrated from pig submandi-

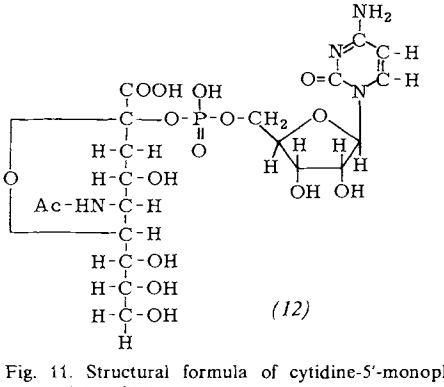
bular glands[95]. It is the substrate for sialyl transferases, *i.e.* enzymes responsible for the glycoside linkage of *N*-acetylneuraminic acid with other carbohydrates.

Sialyl transferases from various organs differ in their specificity with respect to the *N*-acetylneuraminic acid acceptor. Whereas a transferase from rat mammary glands transfers *N*-acetylneuraminate only to terminal β-galactopyranosyl groups of oligosaccharides, *e.g.* lactose[90], another sialyl transferase from the thyroid gland of the calf also links *N*-acetylneuraminate to galactose, but only if



(12)

Fig. 11. Structural formula of cytidine-5'-monophospho-*N*-acetylneuraminic acid *(12)*.

this is attached terminally to glycoproteins or glycopeptides (lactose is not an acceptor in this case[96]). In the submandibular gland of the sheep, *N*-acetylneuraminate is linked to *N*-acetylgalactosamine residues of the glycoproteins by another specific transferase, which, unlike the enzymes mentioned above, cannot transfer its substrate to galactose[97]. Further examples could easily be given.

Strict acceptor specificity for the hexoses or *N*-acetylhexosamines transferred by specific transferases is also observed throughout the biosynthesis of the oligosaccharide chain of glycoproteins. Thus according to the views of *Eylar*'s research group[99,98], the specificity of each glycosyl transferase for the sugar residue previously incorporated leads to a characteristic structure of the oligosaccharide component of a given glycoprotein, which can always be reproduced again. As assumed by *Gottschalk*[100], however, this acceptor specificity is not quite infallible, since the stepwise incorporation of the sugars, unlike in the synthesis of proteins, does not proceed by a gene-controlled template mechanism that substantially eliminates errors; the occasional incorporation of wrong carbohydrates can therefore lead to errors in the synthesis of the oligosaccharide chains of a given type of glycoprotein (microheterogeneity of the glycoproteins).

In contrast with *N*-acetylneuraminic acid *(1)*, the elucidation of the biosynthesis of *N*-glycoloylneuraminic acid *(7)* and of *N*-acetyl-*O*-acetylneuraminic acids was achieved only during the past five years. In agreement with an assumption first expressed by *Martensson et al.*[101], *N*-glycoloylneuraminic acid is formed directly from *N*-acetylneuraminic acid by oxidation[43,50,102,103]. By incubation of surviving slices of pig submandibular gland with [1-^{14}C]acetate and with several *N*-[1-^{14}C]acetylated precursors of *N*-acetylneuraminic acid and with $^{18}O_2$, it was possible to show that the *N*-glycoloyl group of *N*-glycoloylneuraminic acid is formed directly from the *N*-acetyl group by a hydroxylating enzyme[43,50,103] (Fig. 12). In addition to oxygen, this hydroxylation requires NADPH or ascorbate; in the presence of these cosubstrates, *N*-[1-^{14}C]-acetylneuraminate is converted in homogenates of pig submandibular gland into *N*-[1-^{14}C]glycoloylneuraminate, the reaction being brought about by an enzyme that is provisionally named as "*N*-acetylneuraminate, ascorbate, or NADPH : O_2 oxidoreductase (*N*-acetyl-hydroxylating)" (E.C. 1.14.1 or 2)[102].

N-Acetylneuraminic acid also functions as a precursor of *N*-acetyl-(oligo)-*O*-acetylneuraminic acids[51,68]. In bovine submandibular glands, acetyl groups are specifically transferred by acetyl-coenzyme A to the hydroxyl groups in positions 7 and/or 8 of *N*-acetylneuraminic acid, while *N*-acetyl-4-*O*-acetylneuraminic acid is formed in the corresponding gland of the horse. The experiments carried out both with surviving tissue slices and with homogenates show the existence of different position-specific *O*-acetyl transferases in both animals. These enzymes are called "acetyl-CoA : *N*-acetylneuraminate-7- and/or -8-*O*-acetyl transferase(s)" (bovine) and "acetyl-CoA : *N*-acetylneuraminate-4-*O*-acetyl transferase" (horse); (E.C. 2.3.1.?[51,68]).

The enzymes that hydroxylate or *O*-acetylate *N*-acetylneuraminic acid are largely bound on the subcellular

membranes ("microsomes") of the submandibular gland tissue[104, 105]. They belong there to a group of structure-bound enzymes that are responsible for the synthesis of the oligosaccharide chains of the glycoprotein produced in these glands. The chemical reactions of this "multi-enzyme complex" are illustrated for bovine submandibular gland (Fig. 13). The carbohydrate groups of bovine submandibular glycoprotein consist mainly of disaccharide

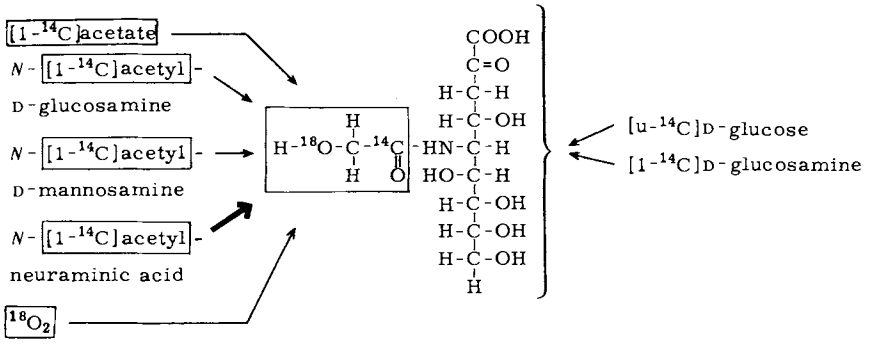


Fig. 12. Biosynthesis of *N*-glycoloylneuraminic acid *(7)* by direct oxidation of *N*-acetylneuraminic acid. The supply of radioactive acetate or of precursor substances of *N*-glycoloylneuraminic acid with *N*-[1-^{14}C]acetyl groups to surviving slices of pig submandibular gland leads to radioactive labeling only of the *N*-glycoloyl group of the neuraminic acid. $^{18}O_2$ is also incorporated specifically into the *N*-glycoloyl group, as evidence of the hydroxylation reaction. (On the other hand, the ^{14}C atoms of glucosamine or glucose can be detected after incubation both in the *N*-glycoloyl group and in the 9-C chain.)

units[106]. *N*-Acetyl-, *N*-glycoloyl-, or *N*-acetyl-(oligo)-*O*-acetylneuraminic acids (see Table 1) are bonded to *N*-acetylgalactosamine residues, which are linked to the peptide chain *via* serine or threonine[107]. In the biosynthesis of this glycoprotein (Fig. 13), *N*-acetylgalactosamine residues are first transferred by a specific *N*-acetylgalactosamine transferase[108] to protein chains, which are transported here from their ribosomal point of synthesis through "channels" of the endoplasmic reticulum (which can be isolated as a fraction of membrane-like particles that

"Multienzyme complex" in the subcellular membranes of bovine submandibular gland, which is responsible for the biosynthesis of the oligosaccharide part of the glycoprotein molecules of the submaxillary mucin. The proposed model is explained in the text. ○ *N*-Acetyl-, □ *N*-glycoloyl-, ◑ *N*-acetyl-7(8)-mono- and -di-*O*-acetylneuraminic acids: ▭ *N*-acetylgalactosamine; ▨ serine and threonine residues of the protein chain.
1: *N*-Acetylgalactosamine transferase, 2: *N*-acetylneuraminate, ascorbate, or NADPH: O_2-oxidoreductase; 3: sialyl transferase(s); 4: *N*-acetylneuraminate-7(8)-*O*-acetyl transferase(s); 5: subcellular membrane. (Abbreviations: CMP = cytidine monophosphate; UDP = uridine diphosphate; NADPH = reduced nicotinamide adenine dinucleotide phosphate.)

sediment at $10000 \times g$[105]). This is followed by the transfer (as cytidine monophosphate glycosides) of the *N*-acetylneuraminic acid and its (presumably on the membrane surface) hydroxylated or *O*-acetylated derivatives to the *N*-acetylgalactosamine residues; acylneuraminic acid-specific transferases have been suggested for this transfer[50, 51]. It is only now, as has been shown by experiments with microsomes labeled with *N*-[1-^{14}C]acetylneuraminic acid, that part of the *N*-acetylneuraminic acid molecules that have already been incorporated into the glycoprotein of the subcellular membrane are modified by the hydroxylase or *O*-acetyl transferase[104, 105, 109]. After the incorporation of the acylneuraminic acids, the completed glycoprotein is released from the membranes, stored in the cytosol[51, 109], and released as required by the salivary gland in a highly viscous solution.

In the described biosynthesis of bovine submandibular glycoprotein, we have seen a mechanism that appears to be of general validity in the biosynthesis of glycoproteins. After the completion of the protein part of the glycoproteins, the addition of the first sugars to form an oligosaccharide chain begins even on the ribosomes (in the "rough microsome" region)[110]. After its release from the ribosomes, the protein chain migrates to the region of the endoplasmic reticulum known as "smooth microsomes", where the oligosaccharide chain is built up further by transfer of hexoses or of their derivatives and completed by the attachment of acylneuraminic acids or even of fucose[98, 100, 111–115]. The specific glycosyl transferases responsible for the synthesis of the oligosaccharide portion of the glycoprotein are presumably parts of a multienzyme complex[99] that is situated in the smooth microsomes or in the Golgi apparatus[116].

7. Enzymatic Degradation of the Acylneuraminic Acids

Most acylneuraminic acids can be readily released from their α-ketoside (see Section 4) linkage to glycoproteins or gangliosides by an enzyme that *Gottschalk*[117] called "neuraminidase" (E.C. 3.2.1.18; suggested systematic name: "acylneuraminide-acylneuraminosyl hydrolase"[118]). This process introduces the degradation of the glycoproteins or gangliosides. Neuraminidase occurs widely in lysosomes of vertebrate organs[119–121] and in bacteria[122], and can be isolated and crystallized[41, 125] from culture filtrates of *Vibrio cholerae*[123] or *Clostridium perfrin-*

gens[124]. Neuraminidases also occur in some types of viruses ("myxoviruses"), *e.g.* in influenza viruses[126].

Comparative studies on the specificity of action of the neuraminidase from *Vibrio cholerae* have shown that the nature of the glycoside bonding partner of the neuraminic acid has much less influence on the ease of enzymatic cleavage of acylneuraminic acid glycosides than the size of the nitrogen substituent of the neuraminic acid or than chemical changes in the neuraminic acid in the vicinity of the glycoside linkage. Whereas synthetic glycosides of *N*-propionylneuraminic and of *N*-glycoloylneuraminic acids are more resistant to cleavage by neuraminidase than those of *N*-acetylneuraminic acid, the corresponding glycosides of *N*-benzyloxycarbonylneuraminic or *N*-butyrylneuraminic acid cannot be hydrolyzed by neuraminidase[127–129]. Esterification of the carboxyl group of the neuraminic acid blocks the action of neuraminidase completely[130], as does peracetylation of the molecule[127]. Partial *O*-acetylation of *N*-acetylneuraminic acid in positions 7 or 8, as *e.g.* in the diacetylneuraminic acids of bovine submandibular glycoprotein, reduces the rate of the hydrolytic liberation of these acylneuraminic acids by neuraminidase[40], as is shown by the fact that the Michaelis constant is greater than that of *N*-acetylneuraminic acid (Table 3). Esterification of the hydroxyl group on C-4 of *N*-acetylneuraminic acid with acetic acid even completely blocks the action of neuraminidase on the glycoside linkage (Table 3[40]). No experimental indications have been found so far for the part played by the (unoccupied) hydroxyl group on C-4 of the neuraminic acid in enzymatic catalysis by the neuraminidase. The biological significance of the resistance of *N*-acetyl-4-*O*-acetylneuraminic acid toward neuraminidase probably consists in protection of the glycoprotein molecules that contain this acylneuraminic acid against attack by neuraminidase and thus against the further breakdown by other glycosidases.

Table 3. Influence of the position of *O*-acetyl groups on the neuraminic acid skeleton in *N*-acetyl-mono-*O*-acetylneuraminic acid glycosides on the Michaelis constants of acylneuraminide-acylneuraminosyl hydrolase ("neuraminidase" from *Vibrio cholerae* [40]) and of acylneuraminate-pyruvate lyase ("neuraminic acid aldolase" from *Clostridium perfringens* [131]).

Acylneuraminic acid tested	Michaelis constants (K_M) [mmol/l]	
	Neuraminic acid aldolase	Neuraminidase [a]
N-acetylneuraminate	1.85	2.5
N-acetyl-8-*O*-acetylneuraminate	2.00	16.0
N-acetyl-7-*O*-acetylneuraminate	4.55	16.0
N-acetyl-4-*O*-acetylneuraminate	12.50	∞

[a] The acylneuraminic acids were bound to bovine or equine submaxillary glycoproteins.

The acylneuraminic acids released from their glycoside linkage are degraded by an aldolase, acylneuraminate-pyruvate lyase[131] (E.C. 4.1.3.3). This leads in reversible reactions to the formation of pyruvic acid and acylmannosamines, as was shown in Figure 1 for *N*-acetylneuraminic acid[132]. *O*-Acetyl groups sometimes also have a strong influence on this cleavage reaction. As can be seen from the K_M values given in Table 3, an *O*-acetyl group in position 8 has only an insignificant effect on the enzyme activity, whereas in position 7 it reduces the rate of cleavage by about 40%, and in position 4 by about 80%.

The investigations described were carried out with acylneuraminate-pyruvate lyase from *Clostridium perfringens*[131]. Like neuraminidase, the enzyme occurs widely; it has been detected in several bacteria and has also been isolated from mammalian organs (references can be found in[131, 133, 134]).—In the catalysis of the aldolase from *Clostridium perfringens* the participation of lysine residues forming intermediary Schiff bases between enzyme and substrate molecules and of histidine residues has been demonstrated[134].

8. Biological Functions of the Acylneuraminic Acids

The widespread occurrence of the acylneuraminic acids suggests that they are of great biological importance. A number of vital processes in which the acylneuraminic acids play a decisive part have indeed been found in recent years. Some examples are given below, grouped according to function (for reviews see Ref. [135]).

8.1 Increase in the Viscosity of Glycoproteins in Aqueous Solution ("Mucus")

Acylneuraminic acids bonded to glycoproteins are partly responsible for the high viscosity of mucilaginous secretions of the respiratory passages, the digestive tract, the urogenital tract, and the eye socket. Because of their low pK values (see Section 2), their carboxyl groups are largely dissociated at physiological pH values (approx. 7.4), so that the filamentous glycoprotein molecules are extended by abundant coverage with negatively charged, mutually repelling acylneuraminic acid residues. The result of this and of the very high molecular weight (up to several million) is a high viscosity of aqueous solutions of these neuraminic acid-rich glycoproteins, such as occur *e.g.* as secretions of mucous membranes[136].

The mucilaginous glycoprotein solutions are vital[135]. They act as lubricants for the rotation of the eyeball, and they prevent the cornea from drying out and protect it against damage by grains of dust *etc.* In the oral cavity and in the gastrointestinal tract, they envelop foods, so making them slippery and protecting the tender mucous membranes against mechanical and chemical (stomach acid, digestive enzymes, *etc.*) damage. The neuraminic acid in this way opposes the formation of stomach ulcers. The layer of mucin that is continuously transported outward on the epithelium of the respiratory passages moistens the air breathed, traps bacteria and other impurities in the air, some of which may be corrosive, and in this way keeps the lungs sterile. Similarly, a very viscous plug of mucin in the cervical canal of the uterus keeps bacteria out of the uterine cavity, and hence out of the abdominal cavity. This viscosity barrier is lowered only at the time of ovulation to admit spermatozoa. Glycoproteins rich in neuraminic acid that are secreted by mucous glands of the vagina are important to reproduction in that they facilitate both coitus and childbirth[135].

8.2. Further Functions in Reproduction

Neuraminic acid is also directly involved in the formation of a sperm reservoir in the vagina of the pig that guarantees fertilization. The ejaculum of the boar contains a high molecular weight, acidic glycoprotein (isoelectric point: pH = 1.1) containing 25% of *N*-acetylneuraminic acid, which agglutinates with a basic protein to form a network from which the spermatozoa are released over a long period[137]. Glycoproteins rich in neuraminic acid, which are known as "fertilisin", are present in the egg membranes of some animals, *e.g.* sea urchins[138], that are deposited in the water, and these glycoproteins specifically bind spermatozoa. Neuraminic acid plays a decisive role here, and allows reliable fertilization. Neuraminic acid also appears to be essential to fertilization as a component of the zona pellucida of the egg cells of mammals: after enzymatic removal of the acylneuraminic acid, the egg cell of the rabbit loses its elasticity, and spermatozoa can no longer penetrate into it[139].

8.3. Binding and Transport of Molecules and Viruses

Some types of virus can attach themselves to cells with the aid of cell-membrane-bound acylneuraminic acids. Red blood cells are agglutinated by myxoviruses[140], which include a number of types that are pathogenic to animals or to man, *e.g.* influenza viruses[32, 141, 142]. This "hemagglutination" is due to the neuraminidase, the only enzyme of these viruses, and presumably to a second specific virus protein, hemagglutinin[142], which, because of a high affinity for neuraminic acid, allow the adsorption of viruses on the erythrocytes and hence permit their agglutination. Erythrocytes treated with neuraminidase no longer exhibit this phenomenon. (In human erythrocyte membranes, part of the *N*-acetylneuraminic acid that serves as the virus receptor is a constituent of M and N blood-group substances[143].) It has been suggested[142, 144] that the cell neuraminic acid plays a part, which is not yet entirely understood, in the infection of cells with myxoviruses.

Acylneuraminic acids bound on the surface of cells are involved in the transport of potassium through cell membranes[145], and act in smooth muscle as receptors for the stimulating substance serotonin[146]. Plasmapexin, a neuraminosyl glycoprotein of blood plasma, binds the base histamine[147].

8.4. Effects on Surface Charge, Aggregation, and Shape of Cells

Negatively charged acylneuraminic acid residues impart a certain strength[148] to cell membranes because of their mutual repulsion, and influence the mutual adhesion of cells in the organ structure. Whereas neuraminic acid allows the aggregation of embryonal muscle cells of the hen, presumably *via* Ca^{2+} bridges[149], it prevents spontaneous clumping of blood platelets[150, 151], and so opposes any undesirable formation of blood clots.

8.5. Protection of Macromolecules against Proteolytic Attack

N-Acetylneuraminic acid protects the "intrinsic factor", a neuraminic acid glycoprotein secreted by the mucous membrane of the stomach, against the action of proteolytic enzymes. The intrinsic factor binds vitamin B_{12} ingested with the food and allows its absorption in the lower sections of the intestine. As was shown by *Faillard* and *Pribilla*, the intrinsic factor still retains its ability to bind vitamin B_{12} after removal of the neuraminic acid, but the absorption of the vitamin from the intestinal lumen is no longer possible[152, 153]. This loss of the biological function in the intestine is due to destruction of the neuraminic acid-free intrinsic factor by proteolytic enzymes on the way to the absorption sites for vitamin B_{12}, which can be readily demonstrated in the test tube. *N*-Acetylneuraminic acid probably protects the intrinsic factor against the proteolytic destruction only because of its relatively strongly acidic carboxyl group, since replacement of *N*-acetylneuraminic acid by polyacrylic acid vinylpyrrolidine, which is also a strong acid, prevents the rapid breakdown of the neuraminic acid-free intrinsic factor by trypsin.

Free *N*-acetylneuraminic and *N*-glycoloylneuraminic acids have an inhibitory action on the fibrinolytic enzyme plasmin, and thus delay the dissolution of fibrin and the dangerous release of blood clots[154].

8.6. Regulation of the "Normal" Behavior and of the Lifetime of Cells and Macromolecules

The rate of the invasive growth of cancer tissue also appears to be influenced by the neuraminic acid content of the cell surface. The rate at which mouse tumor cells spread in tissue cultures is greatly reduced by removal of the neuraminic acid[155]. Neuraminic acid bound on the cell membrane protects erythrocytes against rapid phagocytosis by macrophages[156]. *N*-Acetylneuraminic acid protects macromolecules occurring in blood plasma, such as α_1-glycoprotein, ceruloplasmin, haptoglobulin, lactoferrin, human chorionic gonadotropin, and follicle-stimulating hormone, from a similar fate. These glycoproteins, which have important biological functions, are rapidly removed from the blood stream by liver parenchyma cells after loss of the acylneuraminic acid[157]. The glycoproteins mentioned are adsorbed by plasma membranes of the liver cells after removal of the acylneuraminic acid[158], and are probably withdrawn from the blood stream in this way. However, this binding is possible only if the plasma membranes themselves contain acylneuraminic acids.

It may be assumed that the neuraminic acid in erythropoietin, which stimulates the formation of red blood corpuscles in the bone marrow, has a similar action in the blood circulation. Thus it has been shown that *N*-acetylneuraminic acid must remain bound to the erythropoietin if it is to exert its biological action after injection into the blood stream in the intact animal[159]; on the other hand, no *N*-acetylneuraminic acid is required for the action of the hormone in bone marrow cell cultures[160].

Neuraminic acid on the surface of lymphocytes regulates the normal distribution of these cells in the body, though the manner in which it does this is not yet known. After loss of the neuraminic acid, the cells are not accumulated in the normal manner in the lymph nodes or in the spleen, but in the liver[161].

8.7. Masking of Cellular Antigens

An observation that is probably of great biological importance is that acylneuraminic acids of the cell membranes reduce the immunochemical reactions both of healthy and of carcinomatously degenerated cells[162, 163]. A fetus in the uterine cavity, for example, is immunologically speaking a foreign body (a "transplant") as far as the mother is concerned, since the composition of its proteins is also determined by the father. A histochemically detectable glycoprotein layer on the surface of trophoblast cells, the boundary zone between mother and child, may form an immunobarrier between the two organisms, which prevents the mother from producing antibodies against the child. This assumption is based on the observation that antibodies against mouse trophoblast cells can be formed in the mother mouse only after enzymatic removal of the acylneuraminic acid from the surface of these cells. As a result of this treatment, the tissue of young animals (tested with skin transplants) is no longer tolerated by the mother organism, but is rejected[164].

If methylcholanthrene-induced mouse sarcoma cells are treated with neuraminidase and then injected into hereditarily equal mice, antibodies that prevent the development of massive tumors are formed (without this removal of neuraminic acid, reliably fatal tumors are formed[165]). Similar observations have been made with leukemia cells[166] and with Landschütz ascites tumor cells[167] in mice. Whether this phenomenon can be used for cancer therapy in man is still the subject of speculation.

Whereas some of the effects of acylneuraminic acids described here, *e.g.* the increase in viscosity, the binding of bases, and in part also protection against proteases, can be explained by their physical properties, particularly the negative charge, there are as yet no satisfactory explanations for many other biological effects of acylneuraminic acids that have been mentioned here.

It is not yet known why so many enzymes are acylneuraminosyl glycoproteins[32, 168]. It is interesting to note that hydrolases in particular, *e.g.* phosphatases from lysosomes of mammals, contain neuraminic acid, which imparts electronegativity to the enzyme molecules. (The electrophoretic mobility of these enzymes is therefore considerably altered on removal of the neuraminic acid[169, 170]). The enhanced resistance of these enzymes to proteolytic decomposition is attributed, as in the case of the intrinsic factor, to the presence of acylneuraminic acid residues[170]. Apart from the acidic phosphatase from the human prostate, which exhibits a slight increase both in the pH optimum of the enzyme activity and in the affinity for the substrate on loss of the neuraminic acid[171], no effects of the bound acylneuraminic acids on the enzyme activity have so far been found.

There is also still speculation regarding the part played by the acylneuraminic acids as well as by the other carbohydrate components in many other biologically important glycoproteins[135], *e.g.* immunoglobulins, basal membranes (these have supporting functions for cells in the organ or filtration functions as in the glomeruli of the kidney[172]), glycoproteins and gangliosides of the nerve tissue (these are mainly localized on particular elements such as microsomes and synaptosomes and maybe involved in the conduction of stimuli or even in the memory function of the brain[173, 174]), metal ion-binding glycoproteins of the blood and of the bone tissue, hormone-transporting macromolecules and protease inhibitors of the blood plasma, and components of the blood clotting system.

There is no doubt that it would be worthwhile to push ahead with the explanation of all functions of the *N*-acetyl-, *N*-glycoloyl-, and *N*-acetyl-*O*-acetylneuraminic acids that are structural elements of molecules from very diverse sources and with such different biological tasks. The same is true of the structure and function of the carbohydrate components to which the acylneuraminic acids are bound in these molecules.

My own investigations on the biochemistry of acylneuraminic acids were carried out in the laboratories of Prof. Dr. H. Faillard, to whom I am very grateful for his constant interest in my experiments. I also thank Dr. F. Wirtz-Peitz for his valuable cooperation. Special thanks are due to Frau Margret Wember for her outstanding technical assistance. The investigations were supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Chemistry and Biochemistry of Azaquinones

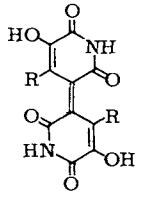
By Hans-Joachim Knackmuss[*]

The azaquinones are a new class of bacterial secondary metabolites. Investigations were necessary on the chemistry of the azaquinones, their imides, and 2,3,6-pyridinetriols and 3-aminopyridine-2,6-diols in order to obtain information about the structure and biogenesis of these natural products.

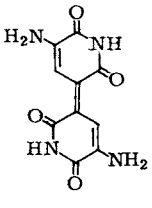
1. Occurrence of Azaquinones

Most bacteria are colorless, but species are occasionally observed having yellow to orange, or less frequently red and violet pigments. Blue bacterial pigments are a rarity. The earliest known was the blue phenazine pigment pyocyanine from *Pseudomonas aeruginosa* and *Cyanococcus chromospirans*. Bacterial indigotin is formed by *Pseudomonas indoloxidans* on nutrients containing indole.

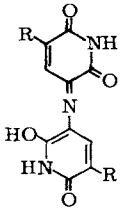
Azaquinonoid structures have recently become accepted for a group of blue bacterial pigments. With pyridinols as carbon and nitrogen sources, it is easy to grow bacteria that partly oxidize the substrate to blue pigments. The pigment deposited in large crystals by *Arthrobacter crystallopoietes* has the diazadiphenoquinone structure *(1)*[1]. A pigment formed by bacterial oxidation of isonicotinic acid or 2,6-dihydroxyisonicotinic acid is reported to have a similar structure *(2)*[2].



(1), R = H
(2), R = CO_2H



(3)



(4), R = Ribosyl
(5), R = Octanoylamino

The formation of blue, presumably azaquinonoid pigments is observed in the degradation of nicotine and of nicotinic acid by species of *Arthrobacter* and of *Pseudomonas*[3]. A component of the nicotine blue from *A. oxidans* was recently obtained in the crystalline state[4] and recognized as the monopotassium salt of *(1)*[24,25][**].

The extracellularly formed diazadiphenoquinone indigoidine *(3)* is obtainable in fairly large quantities from cultures of *Corynebacterium insidiosum*, *Pseudomonas indigofera*, *Arthrobacter atrocyaneus*, and *Arthrobacter polychromogenes* (see Section 3.1)[1]. Small quantities of *(3)* have been detected in three plant-pathogenic strains of bacteria of the *Erwinia chrysanthemi* group[5].

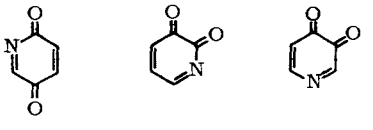
In addition to the water-insoluble indigoidine *(3)*, *Arthrobacter polychromogenes* excretes a water-soluble azaquinone, indochrome *(4)*[6]. Both pigments have also been identified in cultures of two *Arthrobacter* species, two *Corynebacteria*, and *Micrococcus flavocyanus*[7]. As early as 1900, a soluble pigment having the properties of indochrome was described, together with "colored, insoluble crystals", for a bacterium called *Bacillus polychromogenes*[8]. Indochrome consists of several components, which differ in linkage and configurations of the ribosyl residues (see Section 3.2).

The intracellularly formed blue pigment *(5)* of *Pseudomonas lemonnieri*, like indochrome, has a diazaindophenol structure[9] (see Section 3.3).

2. Formation and Reactions of the Azaquinones

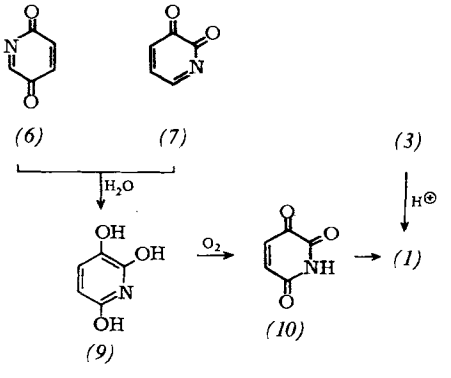
2.1. Azabenzoquinones and Their Solvation

The three isomeric azaquinones *(6)*, *(7)*, and *(8)* are formally derived from *p*- and *o*-benzoquinone by replacement of CH by N. The "pyridoquinone" having the structure



(6) *(7)* *(8)*

(6) or *(7)* described as an oxidation product of pyridinediols[10] was later found to be diazadiphenoquinone *(1)*[11]. The azaquinone *(6)* or *(7)* formed as the primary



(6) *(7)* *(3)* *(9)* *(10)* *(1)*

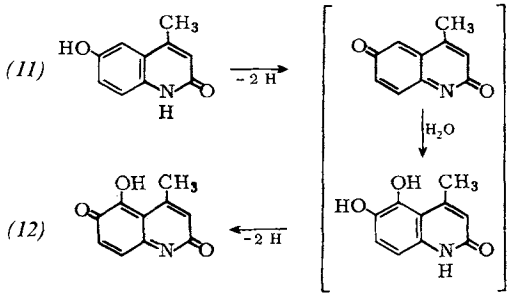
[*] Priv.-Doz. Dr. H.-J. Knackmuss
Institut für Mikrobiologie der Universität
und Institut für Mikrobiologie der Gesellschaft für Strahlen- und Umweltforschung mbH München in Göttingen
34 Göttingen, Grisebachstrasse 8 (Germany)

[**] *Note added in proof:* The second labile component of nicotine blue has now been isolated as a barium salt. Spectroscopic data indicate a structure similar to *(1)*, where one OH group is replaced by H.

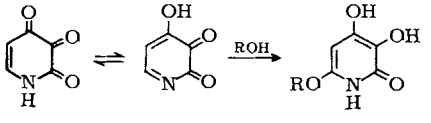
product on oxidation of 2,5- or 2,3-pyridinediol[10] or of 5- or 3-amino-2-pyridinol in strongly acidic solution[12] undergoes hydration at the C=N bond to form 2,3,6-pyridinetriol *(9)*[*]. Further oxidation leads to 2,3,6-trioxo-1,2,3,6-tetrahydropyridine *(10)*[**], which dimerizes to *(1)*.

Hydration at the C=N bond is not possible when 6-hydroxy-4-methyl-2-quinolone *(11)* is oxidized[13]. Water is added instead to the carbocyclic quinonoid ring of the intermediate. Further oxidation then leads to the azanaphthoquinone *(12)*.

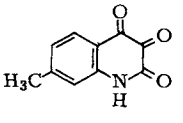
The azaquinone pyromekazone [*(13a)*⇄*(13b)*] crystallizes as colorless needles which always contain 1 mole of alcohol of crystallization [as *(13c)*][14]. Here again, solvation must have occurred at the C=N bond of the tautomer *(13b)*. On the other hand, the yellow benzo homolog



(14)[15] cannot be correspondingly solvated.



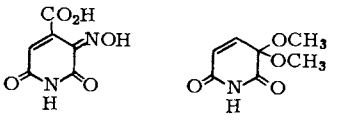
(13a) *(13b)* *(13c)*



(14)

2.2. Dimerization of 2,3,6-Trioxo-1,2,3,6-tetrahydropyridine

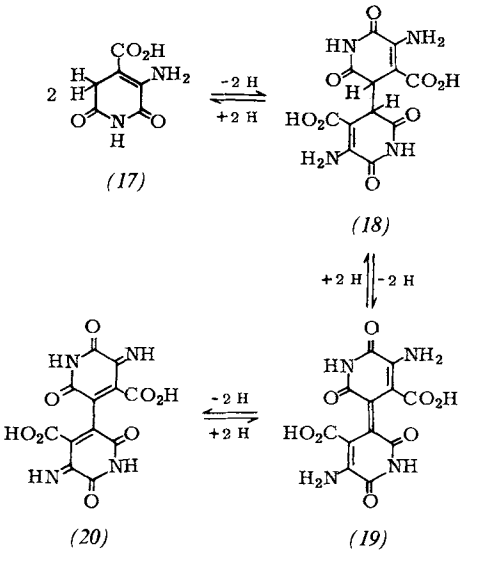
The oxidation of 2,3,6-pyridinetriols or 3-amino-2,6-pyridinediols always leads to dimers if position 5 is free. An example is the dimerization of *(10)* with formation of *(1)*. The formation of *(1)* from *(15)*[16] or *(16)*[17] on acid hydrolysis can be explained in the same way.



(15) *(16)*

2.3. Oxidation Products of 3-Amino-2,6-pyridinediols

The oxidation of aminocitrazinic acid *(17)*[18], which can be followed potentiometrically, can be described by Scheme 1[19]. Like the blue indigoidinedicarboxylic acid *(19)*[11], the colorless oxidation products, the bipyridyl



Scheme 1. Reversible oxidation of aminocitrazinic acid *(17)*.

[b] Determined for the hydrochloride after addition of Dowex 2×4 (OH^- form).

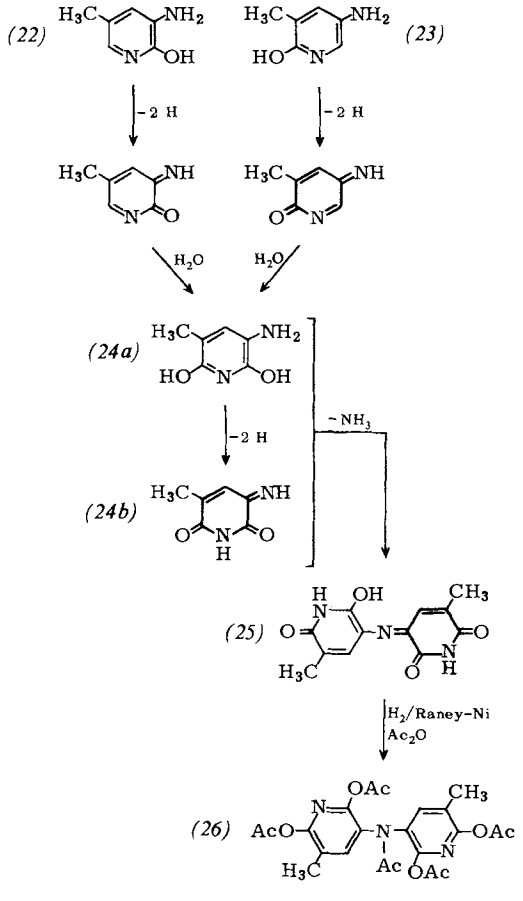
[*] 2,3,6-Pyridinetriol *(9)* actually exists, at least in DMSO, as an equilibrium mixture of 3-hydroxy-2,6-dioxo-1,2,5,6-tetrahydropyridine *(9a)* and 3,6-dihydroxy-2-pyridone *(9n)* (sse Section 2.5).

[**] Because of the easy solvation of the —CH=N group, only azaquinones in which the carbon atoms adjacent to the nitrogen are substituted by oxygen are known. In the present work, these azaquinones were represented in the tautomeric imide form (as 2,3,6-trioxo-1,2,3,6-tetrahydropyridines), as in formula *(10)*. According to their IR spectra, the azaquinones appear to exist largely in this form. However, the simple compounds *(30)*, *(31)*, *(36)*, and *(27)* in particular have electronic spectra typical of benzoquinones, from which the azaquinones are formally derived by replacement of a —CH=CH by a —CO—NH group (see Section 2.5).

derivative *(18)* and the bis(azaquinone imide) *(20)* can also be isolated in the pure form; their constitution has been confirmed by spectra[19] (cf. Table 1). All oxidation steps, and also the transition *(17)*⇄*(18)* at a suitable pH, can be reversed by hydrogenation (with Raney nickel)[19]. Corresponding to the formation of *(19)*, indigoidine *(3)* is formed quantitatively by autoxidation of 2-amino-glutaconimide *(21)*[20].

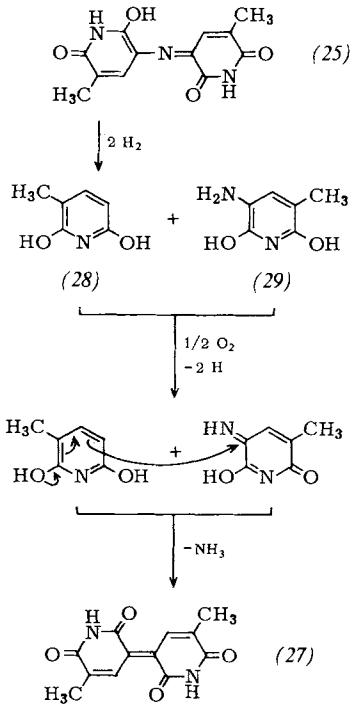
2.4. Azaquinone Imides

The oxidation of 5-substituted 3-amino-2-pyridinols or 3-substituted 5-amino-2-pyridinols, *e.g. (22)* or *(23)*, does not lead to azaquinhydrones[12] as was formerly assumed; the azaquinone imide *(24b)* formed as an intermediate is stabilized instead by condensation to form the diazaindophenol dye *(25)* corresponding to Scheme 2[21]. The dipyridylamine derivative *(26)* is formed by hydrogenation in acetic anhydride.



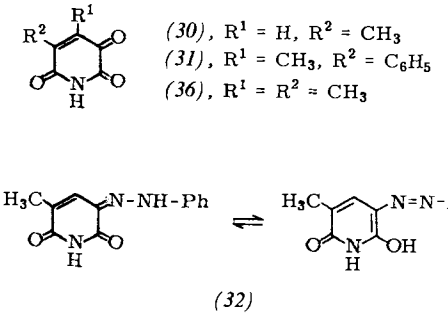
Scheme 2. Oxidation of 3- and 5-amino-2-pyridinols of the types *(22)* and *(23)*.

On hydrogenation of the dye *(25)* with Pd catalysts, *two* equivalents of H_2 are consumed. Autoxidation does not regenerate the diazaindophenol dye *(25)*; the diazadiphenoquinone *(27)* is formed instead. By trapping of the hydrogenolysis products [*(28)* as the 3-benzeneazoderivative and *(29)* as the tetraacetyl derivative], it was possible to verify the reaction represented in Scheme 3.



Scheme 3. Transformation of diazaindophenols of type *(25)* into diazadiphenoquinones of type *(27)*.

Concentrated nitric acid splits *(25)* into 5-methyl-2,3,6-trioxo-1,2,3,6-tetrahydropyridine *(30)*, which, like the homolog *(31)* described earlier[22], cannot dimerize



because of the substitution on C-5. *(30)* reacts with phenylhydrazine to form *(32)*, which is identical with the benzeneazo derivative of *(28)*.

2.5. Azaquinones from 2,3,6-Pyridinetriols

The products formerly referred to as "2,3,6-pyridinetriols"[23], which were formed by autoxidation, are shown by their absorption spectra to be homologs of the azaquinone *(30)*. The first true 2,3,6-pyridinetriols are the four recently synthesized homologs *(9)*, *(33)*, *(34)*, and *(35)*[24,25] (Table 2).

To avoid autoxidation, the synthesis was always directed toward the 2,3,6-triacetoxy derivatives. These can be hydrolyzed in concentrated hydrochloric acid in the

absence of O_2 to the hydrochlorides of the pyridinetriols, which readily lose HCl at high temperatures with sublimation of the free bases.

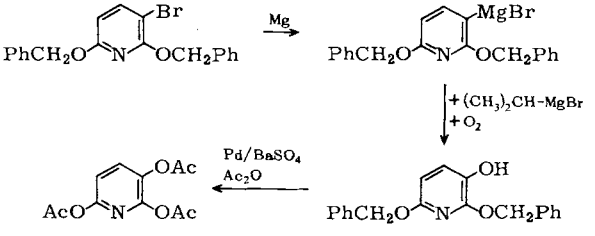
Table 2. Tautomeric equilibria of the 2,3,6-pyridinetriols in dimethyl sulfoxide.

	R^1	R^2	K_T [a]
(9)	H	H	1.75
(33)	H	CH_3	0.4
(34)	CH_3	CH_3	2.0
(35)	CH_3	H	4.2

(a) ⇌ *(b)*

[a] $K_T=[(a)]/[(b)]$.

The triacetyl derivative of *(33)* is readily obtained by hydrogenative acetylation of *(30)*. The corresponding derivatives of *(34)* and *(35)* are obtainable by hydrolysis and subsequent acetylation of the 3-diacetylamino-2,6-diacetoxypyridines. 2,3,6-Triacetoxypyridine itself was unobtainable by an analogous path, and was synthesized in accordance with Scheme 4[25].



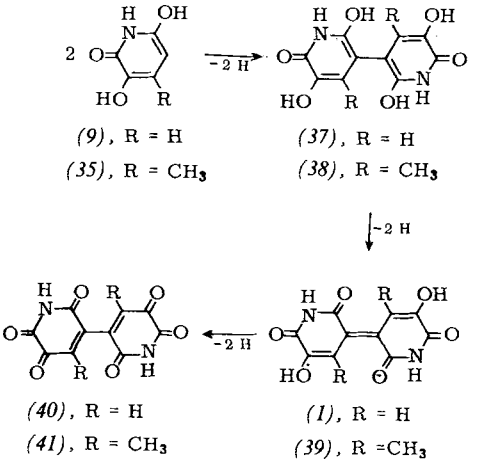
Scheme 4. Synthesis of 2,3,6-triacetoxypyridine.

The sublimed 2,3,6-pyridinetriols contain two oxo groups, corresponding to the formulas *(9a)*, *(33a)*, *(34a)*, and *(35a)*. On dissolution, these forms set up an equilibrium with the OH forms *(b)*, and this process can be followed by UV and NMR spectrometry. The K_T values given in Table 2 were determined by NMR spectroscopy. Similar values are calculated from the UV spectra in methanol. In trifluoroacetic acid and in aqueous mineral acids, the equilibrium is strongly displaced in favor of the more basic OH form *(b)*. A form having three free OH groups is unknown.

In non-acidic solution, *e.g.* in methanol, the 2,3,6-pyridinetriols are autoxidized (their OH forms *(b)* particularly readily) to azaquinones. The reactions of *(33)* and of *(34)*, in which the CH_3 groups on C-5 hinder dimerization, lead quantitatively to the monomeric azaquinones *(30)* and *(36)* respectively.

In the autoxidation of *(9)* and *(35)*, dimerization can take place *via* position 5 (see Scheme 5). The final reaction products are the bis(azaquinones) *(40)* and *(41)*. Depending on the reaction conditions chosen, it is possible to intercept the intermediates of the oxidation. Unlike the indigoidine hydrolysis product *(1)*, the diazadiphenoquinone *(39)* is unstable because of the steric hindrance of the CH_3 groups, and disproportionates into *(38)* and *(41)*.

The 2,3,6-trioxo-1,2,3,6-tetrahydropyridine structures formulated for the azaquinones *(30)*, *(31)*, *(36)*, *(40)*, and *(41)* have been confirmed by comparison of the IR spectra



Scheme 5. Autoxidation of 2,3,6-pyridinetriols.

(medium-strong carbonyl absorption at 1730 to 1745 cm^{-1}). The corresponding structure for *(30)* was verified by recording the spectrum in solution. The straw-yellow compounds (in methanol) give a typical absorption spectrum of the type found for corresponding *p*-benzoquinones, which result on replacement of —CO—NH— by —CH=CH—.

3. Azaquinones from Bacteria

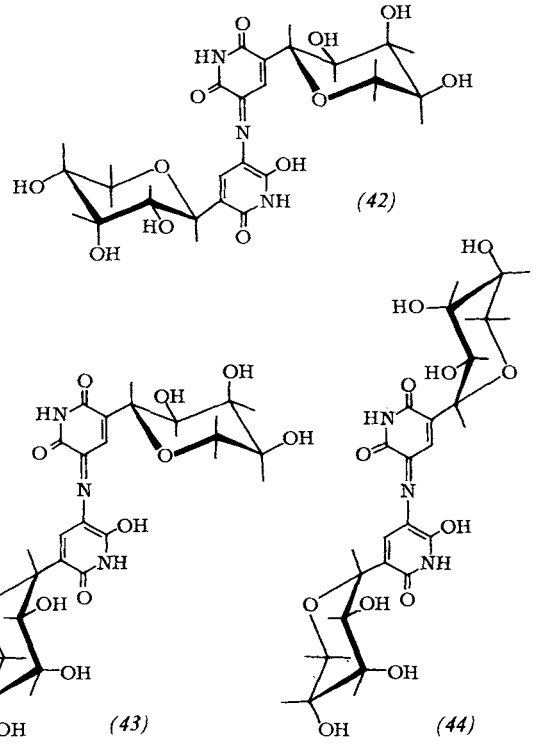
3.1. Indigoidine

Indigoidine *(3)* owes its name to its indigo-like color and vat dyeing properties. In solution and in the vat, the bacterial pigment undergoes slow partial loss of the exocyclic nitrogen, and this hindered the elucidation of the structure of the pigment, which was observed as early as 1890[26]. The decisive step in the determination of the structure was the degradation of indigoidine to the soluble bis(azaquinone) *(40)* by hydrolysis [*(3)*→*(1)*] followed by dehydrogenation with nitric acid[11]. Many syntheses have been described for the degradation products and for the pigment itself[11,20]. The synthesis of indigoidinedicarboxylic acid *(19)* and its decarboxylation to *(3)* also prove the structure of the bacterial pigment.

3.2. Indochrome

The water-soluble blue indochrome is released into the culture liquid only by indigoidine-producing bacteria. In addition to a biogenetic relationship, a structural relationship also had to be assumed between the two pigments. Indochrome consists of at least five isomeric pigments, the

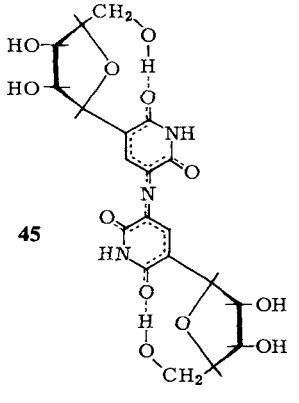
main components of which have been separated chromatographically. The structure *(42)* has been accepted for the



(42)

(43)

(44)



45

Indochrome A: *(42)*
Indochrome B I: *(43)* + *(44)*
Indochrome B II: *(45)*
Indochrome B III: contains the α-D-ribofuranosyl residue

dye acid of indochrome A, and the structure *(45)* for indochrome B II. The pigment component B I consists mainly of *(43)*, and contains small quantities of *(44)*. The minor indochrome component B III and other very weak chromatographic zones are thought to contain the thermodynamically little favored α-D-ribofuranosyl residue. On equilibration in trifluoroacetic acid, the pure pigment components regenerate the natural isomeric mixture. Indochrome is thus an equilibrium mixture. The structures of the components have been determined by UV, ORD, and NMR spectra and by degradation and synthesis[6,27]. Corresponding to the degradation of *(25)* to *(32)*, degradation of indochrome A *(42)* with nitric acid followed by condensation with phenylhydrazine yields *(46)*. From indochrome B I [*(43)* + *(44)*] the α-anomer *(47)* is obtained in addition to *(46)*.

The phenylhydrazones *(46)* and *(47)* were prepared as indicated in Scheme 6. The alcohol *(48)* obtained by condensation has been resolved into its isomers. "Deazauridine" *(49)*[28] was obtainable as an isomeric mixture by ether cleavage with BBr_3, and pure *(46)* and *(47)* were obtained by coupling with benzenediazonium chloride. Hydrogenation and autoxidation of *(46)* and *(47)* lead smoothly to indochromes, *(46)* giving indochrome A [*(42)*], and an equimolar mixture of *(46)* and *(47)* giving indochrome A *(42)* and indochrome B I [*(43)* + *(44)*] [*(42)* : *(43)* : *(44)* = 1 : 2 : 1]. If an equilibrium mixture of 3-D-ribosyl-5-benzeneazo-3,6-pyridinediol (*e.g.* a precipitated crude product that also contains the ribofuranosyls) is used instead of the pure anomers *(46)* and *(47)* for the

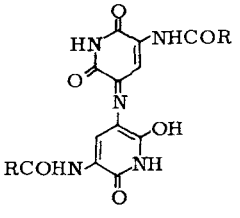
Scheme 6. Synthesis of the indochrome components *(42)* to *(44)*. *(42)* and *(46)*, Rib = β-D-ribopyranosyl; *(44)* and *(47)*, Rib = α-D-ribopyranosyl; *(43)*, Rib = α- and β-D-ribopyranosyl.

indochrome synthesis, one obtains a mixture of dyes that corresponds to the composition of natural indochrome and in which the indochromes B II and B III can also be detected. The presence of two identical α-D-ribofuranosyl residues

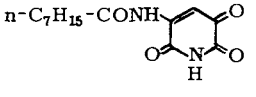
in indochrome B II is shown by the absorption and ORD spectra. The particularly deep blue color of indochrome B II in weakly basic solutions is explained, as shown earlier by the extended formula *(45)*, by strong intramolecular hydrogen bonding, which additionally stabilizes the mesomeric anion. The fixation of the chromophore plane with respect to the optically active center causes an unusually strong (multiple) Cotton effect (in DMSO).

3.3. The Pigment from *Pseudomonas lemonnieri*

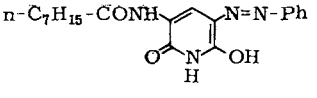
On the basis of spectral properties, degradation reactions, and syntheses, the structure *(50)* has been accepted for the dye acid of the pigment from *P. lemonnieri*[9,29]. The anion of *(50a)* is responsible for the deep blue color of the cells; the cation is unknown.



(50a), R = n-C_7H_{15}
(50b), R = CH_3



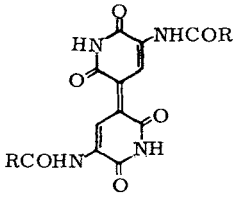
(51)



(52)

Corresponding to the degradation *(25)*→*(30)*, cold nitric acid degrades *(50a)* to the azaquinone *(51)*, which is stabilized by condensation with phenylhydrazine to form *(52)*.

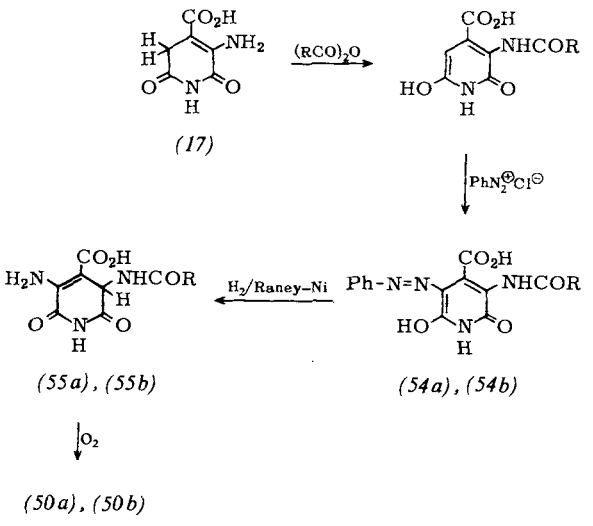
(50a) undergoes cleavage similar to that outlined in Scheme 3 on hydrogenation with Pd. Autoxidation yields *(53a)*, a homolog of diacetylindigoidine *(53b)*[1,11].



(53a), R = n-C_7H_{15}
(53b), R = CH_3

The structure of the pigment *(50a)* has been proved by synthesis of the homologous dye *(50b)* and of the pigment itself (see Scheme 7).

Acetylation or octanoylation of aminocitrazinic acid *(17)* followed by coupling with benzenediazonium chloride leads to the azo dye *(54b)* or *(54a)*. Sublimation of *(54a)* yields the phenylhydrazone *(52)*. The aminoacylaminocitrazinic acids *(55b)* and *(55a)* are obtained by hydrogenation, and readily undergo autoxidation to form *(50b)* and *(50a)* respectively. The model dye *(50b)* exhibits all the typical reactions of the bacterial dye



(17)

(55a), *(55b)*

(50a). On hydrogenolysis and autoxidation, it is converted into diacetylindigoidine *(53b)*. All the intermediates of this reaction have been trapped, and the reaction course has been shown to be similar to that indicated in Scheme 3.

4. Biogenesis of the Azaquinones

Though aminocitrazinic acid *(17)* and particularly aminoglutaconimide *(21)* readily form indigoidine *(3)* on autoxidation[20], it was not possible to detect the obvious biosynthesis path, in which glutamine is cyclized to aminoglutarimide, which is then dehydrogenated to aminoglutaconimide. Neither intact nor ruptured cells of *Corynebacterium insidiosum* were able to transform aminoglutarimide or phthalimidoglutarimide (thalidomide) into indigoidin[30].

On the other hand, 2,6-pyridinediol appears to be the common precursor in a synthesis path leading both to indigoidine and to indochrome. Feeding with 2,6-pyridinediol considerably increases the yield of indigoidine in cultures of *C. insidiosum*[31]. 3-D-Ribosyl-2,6-pyridinediol (deazauridine) *(49)* has been isolated from cultures of the wild strain of *Arthrobacter polychromogenes*, and is immediately converted into indochrome by an indochrome-free mutant of *A.polychromogenes*[32]. A monooxygenase (synthesis of indigoidine) evidently competes with a ribosyl transferase (synthesis of indochrome) for the substrate 2,6-pyridinediol. Whereas both pigments are formed in a stationary culture, the monooxygenase reaction predominates in a strongly aerated shaking culture, so that indigoidine is almost exclusively formed. Indochrome formation occurs in the shaking culture only on addition of deazauridine *(49)*. Since this effect occurs immediately on addition of the substrate, the enzymes for the parallel pathway must already be present in indigoidine-producing cells. No bacterium that produces only indochrome has either been found in nature or produced by mutation. Mutation leads either to the loss only of the ability to form indochrome or to progeny that do not form pigments at

all. The indochrome-free mutant of *A. polychromogenes* thus differs from the wild strain only in the lack of a ribosyl transferase.

In the biosynthesis of indigoidine from 2,6-pyridinediol, 2,3,6-pyridinetriol should be the further reaction product. A corresponding reaction has recently been detected in the degradation of 2,6-pyridinediol by *Arthrobacter oxydans* by identification of 2,3,6-pyridinetriol as an intermediate[25] and isolation of the corresponding monooxygenase[33]. As in autoxidation, the pyridinetriol is converted into *(1)* ("nicotine blue I")[4]. A second readily soluble pigment ("nicotine blue II") is also formed, particularly in the early exponential growth phase. This latter compound is formed *in vitro* on autoxidation of 2,3,6-pyridinetriol in the presence of 2,6-pyridinediol[34, 4]. Its synthesis agrees with the structure derived from spectroscopic data.

Direct Proof of the Non-aromaticity of Phospholes and Arsoles[1]

By *Werner Schäfer, Armin Schweig, Gottfried Märkl, Hagen Hauptmann,* and *François Mathey*[*]

Physicochemical investigations (X-ray structure analysis[2e,g], UV[2a-d,o], NMR[2a-d,f,h-k,n], dipole moment[2l,4b], and reaction kinetic measurements[2m] as well as theoretical-chemical[3a-c] and chemical[2a-d,k,o,4a,b] studies of the participation of the lone pairs of hetero atoms in cyclic conjugation (aromaticity) in phospholes and arsoles have so far had contradictory results. We now describe a direct proof of the non-aromaticity of these systems.

Figure 1 shows the photoelectron spectra[5] of 1-phenylphosphole *(1)*, 1-phenylphospholane *(2)*, 2,5-dimethyl-1-phenylphosphole *(3)*, and 2,5-dimethyl-1-phenylarsole *(5)*, and Figure 2 displays the correlation diagram for the highest occupied MO's of *(1)* to *(5)* derived from these spectra and that of 2,5-dimethyl-1-phenylphospholane *(4)*. The spectrum of *(1)* shows two bands of relative intensity 1:1 in the region of lower ionization potentials (IP). From the position (9.25 eV; $e_{1g}(\pi)$ MO in benzene, 9.24 eV[5]) and the form of the second band (no splitting) it follows that there is no interaction between the phenyl substituent and the phosphole system of *(1)*[6]. The relative intensity of the first band indicates that there must be two ionizations in this region, these being assignable only to the antisymmetric MO ($a_2(\pi)$ in cyclopentadiene, 8.57 eV[7]) and the lone pair of the phosphorus atom [8.35 eV in *(2)*]. This

assignment is wholly confirmed by comparison with the spectra of *(3)* and *(4)*. Methyl substitution in the 2,5-positions raises the π-MO to 8.0 eV[8] (as a result of the hyperconjugative coupling between the CH_3 groups and the π-MO), but the lone pair is influenced hardly at all. All the available arguments—the lone pair of PH_3 (10.59 eV)[10]

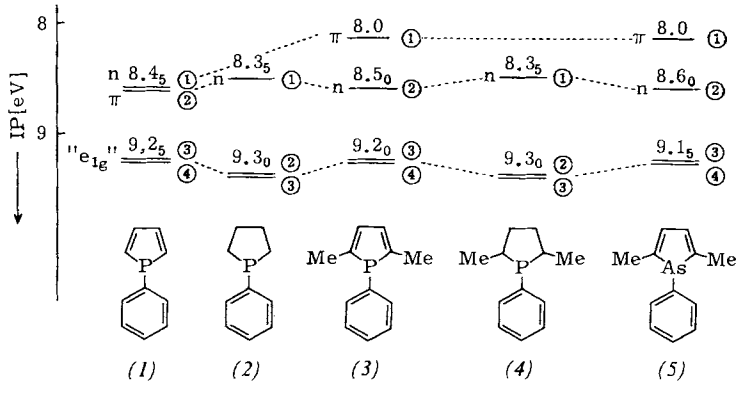

Fig. 2. Correlation diagram of the highest occupied molecular orbitals of compounds *(1)*—*(5)*.

and of AsH_3 (10.58 eV)[10] have equal energy, the π-HOMO (highest occupied MO) of *(3)* is almost a 1,4-dimethyl-*cis*-butadiene MO, and quantum-chemical approximations[3c]—make it probable that the same assignment is valid for *(5)* as for *(3)*.

Our results show that there is no conjugative interaction between the five- and the six-membered ring in any of the compounds studied [the e_{1g} (π) MO's of benzene are not split in *(1)* to *(5)* and retain almost constant energy]. Our results further show that the lone pairs in the phospholes *(1)* and *(3)*, and very probably also in the arsole *(5)*, take no part in a cyclic five-membered ring conjugation (saturation of the *cis*-butadiene system in the five-membered ring has no noticeable influence on the energy of the lone pair). Accordingly, phospholes and arsoles in their ground-state conformations consist of localized diene systems and lone pairs of hetero atom electrons. In this sense phospholes and arsoles are not aromatic.

Preparative-Scale Synthesis of (1 *R*)- and (1 *S*)-Monodeuteriopropanol by Enzymatic Exchange Reactions

By *Helmut Günther*, *Florian Biller*, *Max Kellner*, and *Helmut Simon*[*]

The optical activity of chiral compounds of the type $CRR'H^2H$ and the stereochemistry of their reactions are of considerable interest[1-4]. Chemical methods for their preparation seldom lead to high stereochemical purity[3,4]. Enzymatic reactions on a preparative scale are usually very demanding[5]. An enzyme-catalyzed exchange reaction involving no isolation of intermediates is appreciably simpler and generally applicable for preparation of (*R*)- and

[*] Dr. H. Günther, Dr. F. Biller, Dr. M. Kellner, and Prof. Dr. H. Simon
Lehrstuhl für Organische Chemie und Biochemie der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

(*S*)-enantiomers of numerous compounds[6]. Thus a diaphorase brings about exchange between the hydrogen atoms of the pyridine nucleotide coenzyme and those of water. Owing to the reversibility of the NAD-dependent dehydrogenase reactions this leads also to stereospecific exchange between the hydrogen atoms of the substrate and those of the medium.

In the present communication we describe the preparation of the hitherto unrecorded (1*R*)-[1-^{2}H]- and (1*S*)-[1-^{2}H]-propanols[7]. It seems that this is also the first time that both enantiomers of a compound that is chiral because of substitution by deuterium have been synthesized on a preparative scale.

Experimental:

In all the compounds named below the labile-bound protium was replaced by deuterium atoms before the incubation.

The following were incubated together in D_2O (290 ml) at 35 °C: phosphate buffer (pD = 8.0) 22.4 mmol, ethylenediaminetetraacetic acid 100 mg as sodium salt, albumin (recrystallized five times) 200 mg from hens' egg white, NAD^+ 50 mg, NADH 50 mg, diaphorase 5200 U[**], yeast alcohol dehydrogenase 22500 U[***], and 1-propanol 10.5 ml. The exchange of *pro-R*-protium of the propanol was determined in an aliquot portion after 25 h and again after 42 h by NMR spectroscopy and was found to be 97 ± 5%. The propanol was extracted with dry, ethanol-free ether; the solution was concentrated, whereafter 7.0 ml propanol containing 13.5 vol.-% of water were obtained by preparative gas chromatography. The 3,5-dinitrobenzoate of this propanol showed 0.97 ± 0.01 atom of deuterium per molecule on mass spectroscopy[8].

10.5 ml of [1,1-$^2H_2$]propanol were incubated analogously in H_2O for 45 h and then worked up. The water content of the product was 17.4% and the 3,5-dinitrobenzoate contained 1.29 ± 0.01 atoms of deuterium per molecule; the exchange in this case amounted to only 71.3%.

Table 1. Specific rotations [a] of the monodeuteriopropanols, calculated for anhydrous material with a ^{2}H-content of 1.0 atom per molecule.

λ [nm]	(1*R*)-[1-^{2}H]-Propanol $[\alpha]_D^{20}$ [°]	(1*S*)-[1-^{2}H]-Propanol $[\alpha]_D^{20}$ [°]
220	—	7.36 [b]
240	−5.17	5.29 [b]
257	−4.12	4.19
302	−2.65	2.70
365	−1.58	1.64
400	−1.24	1.29
500	−0.72	0.75
589	−0.50	0.51

[a] Measurements were made with a Jasco-Spectral polarimeter J 5. Unless otherwise stated, the samples contained 15 vol.-% of water.

[b] Values determined on 3.5% aqueous solutions.

Table 1 shows the specific rotations for various wavelengths. The agreement between the absolute values shows that there is no optically active impurity in the preparations, since it is extremely unlikely that these would have different signs in the two enantiomers.

The molar rotations of (1*R*)-[1-^{2}H]ethanol and of the corresponding propanol and butanol are $[M]_D = 0.14°$[5,9], −0.29°, and −0.35°[10], respectively. The difference between $[M]_D$ for ethanol and propanol is 0.43° but for propanol and butanol only 0.06° which is not with certainty significant.

Brewster[1] predicted that (1*R*)-[1-^{2}H]butanol would be *ca.* 0.33° more levorotatory than ethanol.

Boron Tris(trifluoroacetate) for Removal of Protecting Groups in Peptide Chemistry

By *J. Pless* and *W. Bauer*[*]

Boron compounds have been used for removal of protecting groups only on rare occasions[1-4].

We have found that, in CH_2Cl_2, BBr_3 and BI_3, but not BF_3 or BCl_3, effect quantitative removal, under very mild conditions, of the benzyloxycarbonyl (Z) group that is very frequently used in peptide chemistry, and do not thereby attack OH groups of serine or threonine or SH groups of cysteine. Ester groups are, however, partially hydrolyzed to acid, and a further disadvantage is the use of CH_2Cl_2 which is not a good solvent for the longer peptides.

When trifluoroacetic acid is used as solvent instead of CH_2Cl_2, BBr_3 forms boron tris(trifluoroacetate) (BTFA)[5]:

$$3CF_3COOH + BBr_3 \rightarrow B(OOCCF_3)_3 + 3HBr$$

For the cleavage experiments this reagent (BTFA) can be easily isolated (see Experimental) and can be used in CH_2Cl_2 or preferably in trifluoroacetic acid. BTFA removes Z and other acid-labile groups as smoothly as BBr_3, but does not cause hydrolysis of esters or other side reactions. Surprisingly, BTFA is also suitable for smooth removal of other side-chain protecting groups used for arginine and cysteine (see Table 1) that have hitherto required drastic conditions[6,7].

Experimental:

Equivalent amounts of BBr_3 and CF_3COOH are mixed at 0 °C in CH_2Cl_2, whereupon a precipitate is formed. The

Table 1. Protecting groups that are removable or not removable by BTFA.

Removable protecting groups	
Amino-protecting groups:	Z, Boc, Nps, Trt, or other acid-labile protecting groups
Carboxyl-protecting groups:	benzyl (also polymer bound)
Side-chain-protecting groups:	Arg(NO_2), Arg(Tos), Cys(*p*-MeO-Bzl), Ser(Bzl), Thr(Bzl), Tyr(Bzl)
Non-removable groups	
COOMe, COOEt, R—OMe (ether), —CONH—	

mixture is evaporated to dryness at 20 °C in a vacuum. The residue is dissolved in CF_3COOH and this solution is used directly for the group cleavage. For this purpose the protected compound is dissolved in CF_3COOH and treated with at least 3 equivalents of BTFA in CF_3COOH at 0 °C. For removal of nitro, tosyl or *p*-methoxybenzyl groups, 5—8 equivalents of BTFA are needed. An even greater excess of reagent becomes necessary with increasing chain length of the peptide. After 1 h the solution is evaporated at room temperature and the residue is worked up. The boron compounds can be removed by repeated evaporation with methanol or by chromatography.

The new reagent thus has a similar action to liquid HF but does not require special cautionary measures or apparatus. Biologically active peptides have already been successfully prepared using this technique.

sp^2-Hybridization on the Sulfur-substituted Nitrogen in Diethyl 2,2-(Heptasulfane-1,7-diyl)-1,1-hydrazinedicarboxylate[1]

By *Karl-Heinz Linke, Dietmar Skupin, Johann Lex*, and *Bernward Engelen*[*]

By treating diethyl 1,1-hydrazinedicarboxylate with dichlorodisulfane or dichloroheptasulfane we recently synthesized a hydrazine that was substituted on the same nitrogen atom by two sulfur atoms, namely diethyl 2,2-(heptasulfane-1,7-diyl)-1,1-hydrazinedicarboxylate *(1)*[2]. For the study of bonding in hydrazines having substituents with free d-levels it seemed important to us to have an X-ray structure analysis of *(1)*, in particular to establish the (p→d)π contribution to the N—S bonds.

[*] Prof. Dr. K.-H. Linke, Dr. D. Skupin, Dr. J. Lex, and Dipl.-Chem. B. Engelen
Institut für Anorganische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

Compound *(1)* crystallizes in the monoclinic form with lattice constants $a = 8.85_7$, $b = 31.99_2$, $c = 11.61_5$ Å, $\beta = 98.7°$. The density determined by the flotation method amounts to 1.60 g cm^{-3}, corresponding to 8 molecules per unit cell ($d_{calc.} = 1.625$ g cm^{-3}). The systematically absent reflections and the symmetry of the reflection intensities lead to the space group $P2_1/n$. For the three-dimensional X-ray structure analysis the intensities of 2288 independent reflections were determined photographically by the multi-film method from precession exposures. The structure was calculated by the direct method with the program system X-RAY 70[3] on IBM computers 360/75 and 370/165 in the Zentralinstitut für Angewandte Mathematik der Kernforschungsanlage in Jülich. The isotropic refinement by the method of least squares for the nitrogen, sulfur and carbon atoms provided an *R* value of 0.157; hydrogen atoms were not considered.

The asymmetric unit contains two molecules of *(1)*. The bond lengths, bond angles, and dihedral angles of these two molecules, determined independently of one another, show significant differences in the region of the hydrazine group. The bond lengths and bond angles of molecule I can be seen in the schematic representation of *(1)* in Fig. 1. The relatively high standard deviations (see legend) are to be ascribed to the limited accuracy with which the intensities can be determined from films and to the large number of atom parameters to be determined for each molecule.

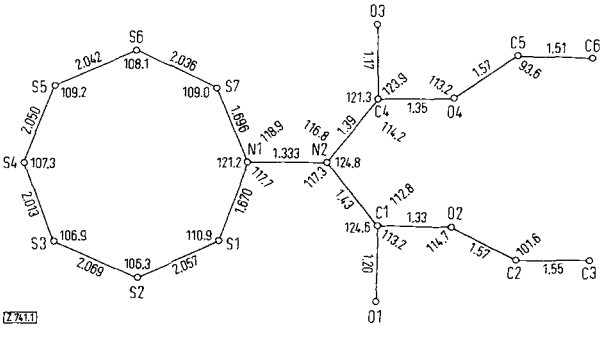

Fig. 1. Bond lengths (Å) and bond angles (°) in diethyl 2,2-(heptasulfane-1,7-diyl)-1,1-hydrazinedicarboxylate (molecule I). Standard deviation of bond lengths and angles: σ_{S-S} 0.009—0.012 Å; σ_{S-N} 0.020—0.022 Å; σ_{N-N} 0.028 Å; σ_{N-C} 0.03 Å; σ_{C-O} 0.03—0.04 Å, σ_{C-C} 0.04—0.06 Å; σ_{S-S-S} 0.5°; σ_{S-S-N} 0.8—0.9°; σ_{S-N-S} 1.3°; σ_{S-N-N} 1.5—1.6°; σ_{N-N-C} 1.8—2.2°; σ_{N-C-O} 1.9—2.3°; σ_{O-C-O} 2.3—2.5°; σ_{C-O-C} 1.9—2.8°; σ_{O-C-C} 2.1—3.3°.

The sulfur-nitrogen ring of *(1)* exists in the crown form, with the ester groups in a plane almost perpendicular to this ring. The nitrogen atom forming part of the ring in molecule I shows complete sp^2 hybridization which can be explained by formation of dative π-bonds from the nitrogen to the sulfur atoms. The angle between the planes defined by the atoms S1-N1-S7 and S1-N1-N2 is found to be 179.9°, so that a planar arrangement of the atoms around the ring-nitrogen atom N1 is proved. In agreement with this are the N—N distance and the two N—S bond lengths which are significantly shorter than the known values for corresponding single bonds, namely, *ca.* 1.45 and 2.76 Å, respectively.

In molecule II there are also strong double-bond contributions between the ring-nitrogen atom and the sulfur atoms to be observed, but sp^2 hybridization of the nitrogen is incomplete. The angles S1-N1-S7, N2-N1-S1, and N2-N1-S7 in molecule II were determined as 121.1 ($\sigma = 1.3$), 118.6

($\sigma = 1.5$) and 115.5° ($\sigma = 1.7°$), respectively; the angle S1-N1-S7/S1-N1-N2 here amounts to 154.7°. The two N—S distances are 1.64 and 1.70 Å severally, and the N—N bond length is 1.42 Å.

No simple explanation can be given for the difference between the observed N—S and N—N bond lengths in molecules I and II. Calculation of the contact separations does not show any marked intermolecular interaction, so that these differences may be due to lattice forces that perhaps lead to more favorable total positioning of the two relatively large and bulky molecules in the unit cell. Severe hindrances can be observed in the neighborhood of the hydrazine group, and these may be responsible for the poor yield of *(1)* and the difficulty in crystallizing the compound.

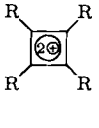
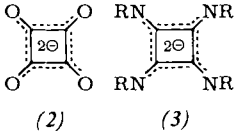
Alkylation and Redox Behavior of a Squaric Amidine[**]

By *Siegfried Hünig* and *Hermann Pütter*[*]

Cyclobutene dications *(1a)* and *(1b)* can be conclusively shown to exist as 2π Hückel aromatic compounds in strongly acidic media at low temperature[1-3], but they cannot be isolated. It would be expected that the donor action of four amino groups, as in *(1d)*, would make it possible to isolate the dication. The effect of hydroxyl groups[3] is insufficient for this.



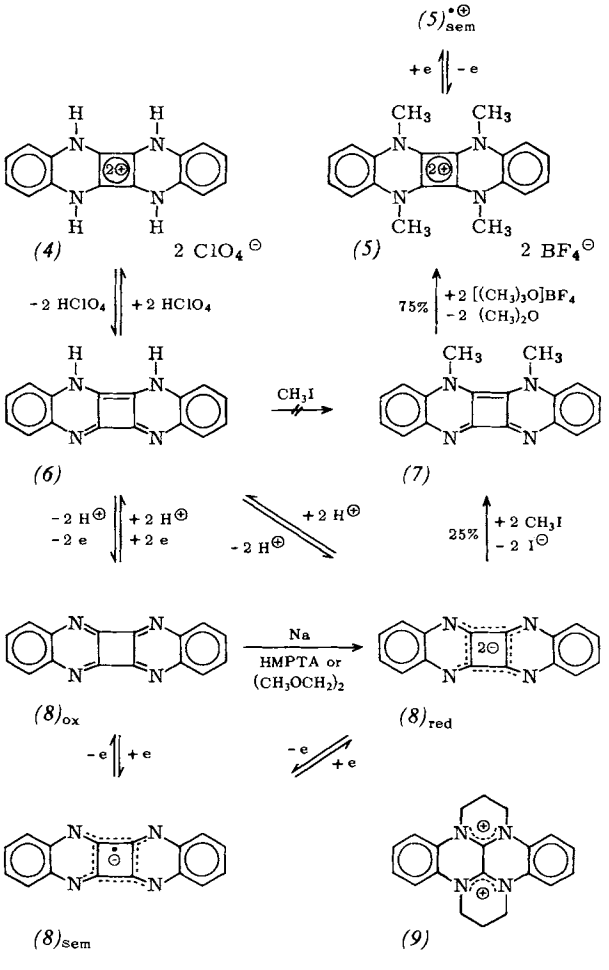
(1a), R = CH_3
(1b), R = C_6H_5
(1c), R = OH
(1d), R = NR^1R^2



(2) *(3)*

The salt *(4)* was recently described[4] and is the first representative of type *(1d)*, but because of its sparing solubility the proton distribution remained unproved.

We have now succeeded[5] in synthesizing the green tetramethyl derivative *(5)*, m.p. 262 °C (dec.)[6], whose structure follows unambiguously from the NMR spectrum [$\delta(CF_3COOH) = 3.2$ (s/12H), 6.5—7.1 ppm (m/8H)]. *(5)* is thus to be considered a salt with a stable cyclobutenium dication of type *(1d)*. Its electron spectrum is almost superposable on that of *(4)*, so that the structure of the latter is also ensured[7]. Analogously to the dication *(9)*[8] of related structure, the salt *(5)* takes up one electron at −0.67 V[9]; however, unlike *(9)*, it cannot be further reduced until −1.6 V, *i.e.* with an additional expenditure of energy amounting to 20 kcal/mol, which is a further indication of the antiaromatic destabilization energy[10] in the cyclobutadiene derivative that would result.



The synthesis of *(5)* from $(8)_{red}$ is effected by way of *(7)*, a suspension of which in ethylene dichloride is alkylated by trimethyloxonium tetrafluoroborate (4h under reflux). Although *(4)* undergoes ready reversible deprotonation to the bisamidine *(6)*[4], it cannot be methylated to yield *(7)*, even in the presence of an auxiliary base. *(7)* is formed, however, from the dianion $(8)_{red}$ by methyl iodide[11]. $(8)_{red}$ is reversibly oxidizable in two steps to $(8)_{ox}$[4], the reaction proceeding *via* the thermodynamically unusually stable $(8)_{sem}$ ($K_{sem} = 2 \times 10^{15}$!) [$(8)_{red} \rightarrow (8)_{sem}$, $E_2 = -1.47$ V, in DMF; $(8)_{sem} \rightarrow (8)_{ox}$, $E_1 = -0.57$ V, in DMF]. $(8)_{sem}$, formed as a brownish-red solution of $(6) + (8)_{ox}$ in DMF/K *tert*-butoxide[12], shows a fully resolved ESR spectrum, in which not only all the N atoms, but also all the H atoms, possess the same coupling constants (Fig. 1).

The squaric acid dianion *(2)* has been described as a typical example of the series $C_nO_n^{2\ominus}$, the aromatic "oxocarbons"[13], which are oxidizable. With nitrogen as substituent the series $C_n(NR)_n^{2\ominus}$, the aromatic "iminocarbons"[14], is to be expected[15], and $(8)_{red}$ is the first example thereof.

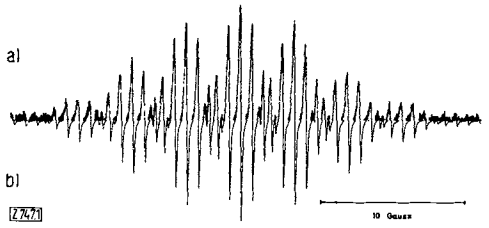

Fig. 1. a) ESR spectrum of $(8)_{sem}$ in DMF/K *tert*-butoxide. b) Simulated spectrum with $a_H = 0.80$ and $a_N = 3.75$.

The radical ion $C_4O_4^{\ominus}$ has been merely postulated[13] as formed on oxidation of *(2)*, and cyclobutanetetraone is known only as tetrahydrate[13]. However, all three oxidation states have been proved to exist for the iminocarbons *(8)* of type $C_4(NR)_4$ *(3)* described in this communication.

A New Mechanistic Concept for the Bicyclopropenyl Rearrangement[1]

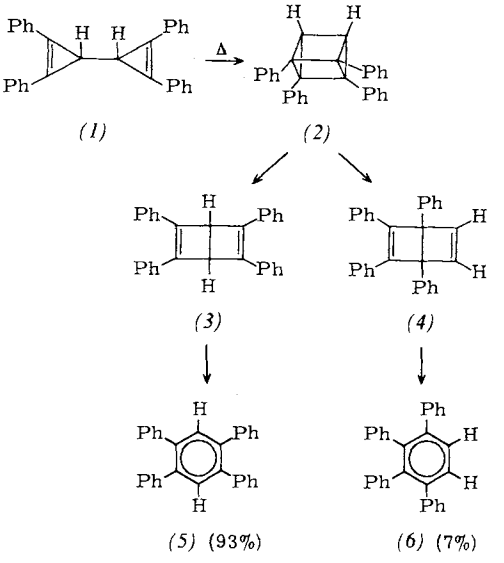
By *Robert Weiss* and *Steffen Andrae*[*]

The often cited[2, 3] study by *Breslow et al.*[4] (Scheme 1) is the only work hitherto reported on the course of thermal isomerization of the bicyclopropenyl derivative *(1)* to the benzene derivatives *(5)* and *(6)*.

Doubt is, however, thrown on the formation and/or nature of the hypothetical intermediates *(2)*—*(4)* for the following reasons:

1. The reaction *(1)*→*(2)* is forbidden by the Woodward-Hoffmann rules and also leads to an increase in strain energy.

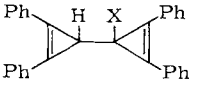
[*] Dr. R. Weiss and Dipl.-Chem. St. Andrae
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)



Scheme 1

2. From experience in prismane chemistry[2d] it would be expected that thermal isomerization of *(2)* should produce a benzvalene intermediate which, *inter alia*, should cause formation of the *meta*-isomer of *(5)* and *(6)*.

These objections, and our observation that *(3)* can be obtained from *(1)* by $Ag^{\oplus}$ catalysis[1], induced us to undertake a more detailed study of the bicyclopropenyl rearrangement including its $Ag^{\oplus}$ catalysis.



(7a), X = CH_3 [5]
(7b), X = OCH_3 [5,6]
(7c), X = CN [5,6]

According to NMR analysis the action of an equimolar amount of $AgClO_4$ on the model substance *(7a)* in anhydrous C_6H_6 at 50°C is complete in 2 h and gives exclusively *(8)* and *(9)*.

(9) (CH_3 signal at τ = 7.79) could be obtained pure from the reaction mixture by recrystallization and was identified by comparison with an authentic specimen[7].

The structure of *(8)*, which was not obtained completely free from entrained *(9)*, was proved by the following data:

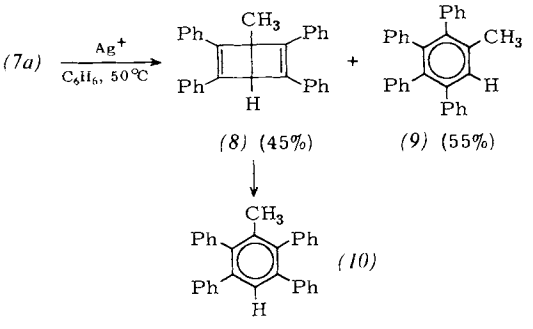
1. The UV spectrum ($CHCl_3$) exhibited $\lambda_{max} = 295$ nm with log ε = 4.33 which is characteristic of two substantially independent *cis*-stilbene chromophores[1].

2. In the NMR spectrum, *(8)* shows, besides aromatic protons, a CH_3 signal at τ = 8.22 (s) and the signal of one methine proton at τ = 5.93 (s). In particular the position of the last signal is characteristic of a Dewar-benzene of this structural type[1].

3. Finally, *(8)* was aromatized in boiling toluene with a half-reaction time of 3 h to 1-methyl-2,3,5,6-tetraphenylbenzene *(10)* [identical with an independently synthesized sample[8]: m.p. 269—270°C, NMR ($CDCl_3$): τ = 8.04 (3H/s), 2.83 (10H/s), 2.81 (10H/s), 2.26 (1H/s)].

Thermal rearrangement of *(7a)* in boiling $(CH_2Cl)_2$ (to avoid acid catalysis this solvent was previously chromatographed over basic Al_2O_3) afforded after 4 weeks the benzene derivatives *(9)* (30%) and *(10)* (70%) as sole end-products. In this reaction it is remarkable that the Dewar-benzene derivative can be shown unambiguously by NMR

spectroscopy to be an intermediate in the formation of *(10)* [composition of the reaction mixture after 331 h: *(7a)* 57%, *(8)* 9%, *(9)* 13%, *(10)* 21%]. This is the first successful[3] direct proof of a Dewar-benzene intermediate in the thermal rearrangement of a bicyclopropenyl which is due to the high stability of *(8)* [compared with that of *(3)*[1]].



Furthermore, the products and product distribution (Table 1) show that thermal and Ag^I-catalyzed rearrangements are closely related processes both in the case of *(1)* and in that of *(7a)*. In particular, the fact that for *(1)* the product composition is almost identical in the two types of rearrangement (cf. Table 1) shows that in this case the conversion of a sequence of symmetry-forbidden processes (Scheme 1) into a sequence of symmetry-allowed processes can hardly be a function of Ag^I[10]. Scheme 1 is also unable to explain the great influence of the bridgehead substituent in *(7a)* on the product distribution that results from thermal rearrangement.

Table 1. Results of thermal and Ag^I-catalyzed rearrangement of *(1)* and *(7a)* [9].

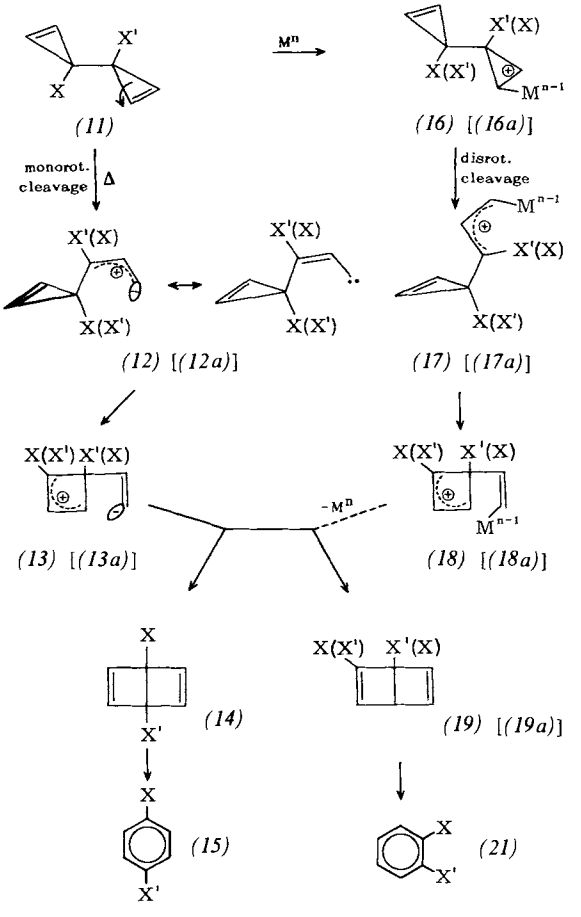
Cpd.	Rearrangement	*o*-Series [a]	*p*-Series [a]
(1)	Δ	7% *(6)* [4]	93% *(5)* [4]
(1)	Ag^I	5% *(6)* [b]	95% *(5)* [b]
(7a)	Δ	30% *(9)*	70% *(10)*
(7a)	Ag^I	55% *(9)*	45% *(10)*

[a] This assignment refers to the position of the bicyclopropenyl bridgehead substituents in the rearrangement products (benzene or Dewar-benzene).

[b] As we have now found, *(6)* is also formed to a small extent as product of the Ag^I-catalyzed rearrangement of *(1)* [1]; *St. Andrae*, Diplomarbeit, Universität München, 1972.

However, an adequate interpretation of all the experimental material on the bicyclopropenyl rearrangement can be based on the new mechanistic concept formulated in Scheme 2.

The *thermal* bicyclopropenyl rearrangement of *(11)* is, according to Scheme 2, initiated by a reversal of the formation of a cyclopropene[11], namely a retrocarbene fission[12] to afford the singlet carbene[13] *(12)* [*(12a)*]. Then follows the reaction *(12)* [*(12a)*]→*(13)* [*(13a)*] which is a ring expansion of the known cyclopropenylmethyl cation→cyclobutenyl cation type[14] that occurs with extreme ease. If the monorotatory[15] opening of the cyclopropene ring of *(11)* occurs from the transoid conformation, it leads directly to the bisected conformation of the vinylcarbene *(12)* [*(12a)*] required for the ring expansion (cf. Scheme 2). This would provide a good possibility that the ring opening and ring expansion sequence could be coupled in an energetically favorable manner, *i.e.* could occur as a concerted process (in which case *(12)* [*(12a)*] would not be a true intermediate in the bicyclopropenyl rearrangement). These reactions would be followed by final reaction of the inner ion pair *(13)* [*(13a)*] to give the isomeric Dewar-benzenes *(14)* and *(19)* [*(19a)*] in the product-determining step (see below) with, under some conditions, their aromatization.



Scheme 2

The most likely *function of* Ag^I in the rearrangement is catalysis of the retrocarbene fission (retrocarbene cleavage of cyclopropenes by Cu^I[16] and Tl^{III}[17], for instance, is known). This could consist in the (sterically favorable) *exo*-attack by Ag^I on *(11)* and rapid disrotatory opening of *(16)* [*(16a)*] to give *(17)* [*(17a)*]. With the ring expansion to *(18)* [*(18a)*] the reaction follows the same path as in the thermal case and should proceed to exactly the same result.

Application of Scheme 2 to *(1)* [*(11)*, X=X'=H] shows that in its thermolysis retrocarbene cleavage must be the rate-determining step; if its activation energy is lowered by Ag^I-catalysis then the Dewar-benzene derivative *(3)* becomes isolable. In neither type of rearrangement can the Dewar-benzene derivative corresponding to *(19)* [*(19a)*] be detected—its structure differs in type from that of *(4)* (cf. Scheme 1); presumably conversion into *(6)* is greatly facilitated by the phenyl group on the bridgehead[18]. Finally the *o*/*p*-product ratio in the thermolysis reflects the competitive situation of the cyclobutenyl cation in *(13)* [*(13a)*] (X=X'=H) *vis à vis* the vinyl anion: there nucleophilic addition to the more electrophilic 1-position with conservation of conjugation between the phenyl groups

would be expected to preponderate very largely[19], which accords with the experiment (see above). According to Scheme 2 the same situation should occur on Ag^I-catalysis since there *(13)* [*(13a)*] is again postulated as intermediate: the almost identical *o/p*-ratio (see Table 1) is visible confirmation thereof.

The influence of the bridgehead substituent in *(7a)* on the product distribution can be understood in view of the intermediate *(13)* ($X=CH_3$, $X'=H$): the CH_3 group, which stabilizes carbenium ions, acting on position 1 increases the amount of ring closure at position 3 and thus also increases formation of the representative of the *o*-series. On Ag^I-catalysis, however, this intermediate should have a statistically greater effect than in the thermolysis, because for steric reasons attack by Ag^I should be favored on the cyclopropene ring with the unsubstituted bridgehead, whereas thermal retrocarbene cleavage should occur preferentially by way of *(12)* ($X=H, X'=CH_3$; carbenium ion stabilization!). On this basis the different *o/p*-ratios formed by the two routes become intelligible (cf. Table 1).

[18] In work analogous to our previous investigation [1], *W. H. de Wolf, J. W. van Straten*, and *F. Bickelhaupt* (Tetrahedron Lett. *1972*, 3509) also found a Dewar-benzene of the type *(19)* [*(19a)*] postulated by us, but without explaining its occurrence. Thus the correctness of our views about this point in the topology of the bicyclopropenyl rearrangement is completely proven.

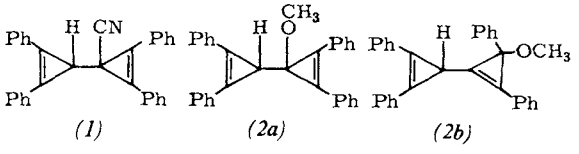
[19] The electronically very similar 2,3-diphenylcyclopropenylium ion shows a quite analogous behavior towards nucleophiles: *R. Breslow, J. Lockhart*, and *H. W. Chang*, J. Amer. Chem. Soc. *83*, 2375 (1961).

Formation of a Dewar-Anisole by Bicyclopropenyl Rearrangement

By *Robert Weiss* and *Steffen Andrae*[*]

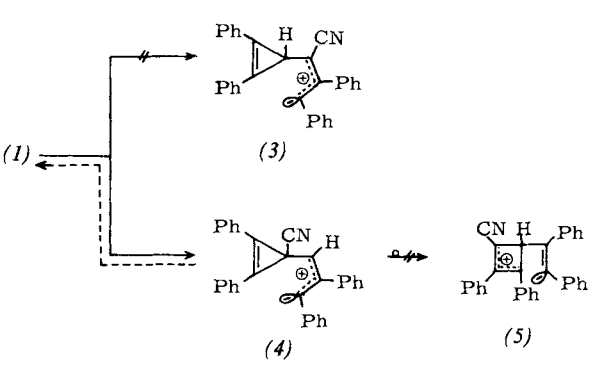
According to our mechanistic concept[1] it should be possible to influence the course of rearrangement of bicyclopropenyl systems to benzene derivatives in specific manners by means of bridgehead substituents; in particular, donor substituents should make rearrangement easier and acceptor substituents should hinder it. Because of their similar mechanisms we should expect also a general parallelism between the effects on thermal and on Ag^I-catalyzed rearrangements[1].

We have tested these hypotheses on the model substances *(1)* [1] and *(2a)/(2b)*[1,2].



(1) *(2a)* *(2b)*

The cyano compound *(1)* proved to be completely stable for days even in presence of a two-fold excess of Ag^I ions[3] in boiling anhydrous benzene. Thermally, *(1)* is stable for weeks up to 110°C in solution (at appreciably higher temperatures the substance decomposes without definite products being detectable). The lack of any tendency of *(1)* to aromatize is in striking contrast to the behavior of all previously known bicyclopropenyl derivatives[1] and, in particular, is incomprehensible on the basis of the mechanism proposed by *Breslow et al.*[1,4] for the bicyclopropenyl rearrangement. Our alternative mechanism, however, offers a simple explanation for the behavior of *(1)* (see Scheme 1): the retrocarbene fission *(1)*→*(3)* required for the thermal rearrangement of *(1)* (cf. Ref.[1]) is blocked by the CN group (α-cyano carbenium ion!). It is true that a (reversible) retrocarbene fission of the other cyclopropene ring, to give *(4)*, is possible (this point was not followed up) but then the CN group should prevent the ring expansion *(4)*→*(5)* (cf. Ref.[1]). Completely

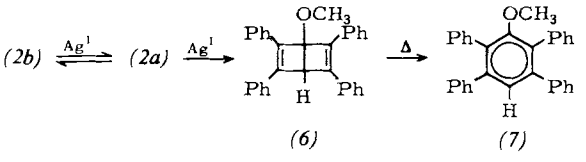


Scheme 1

analogous arguments apply to the Ag^I-catalyzed rearrangement. In this way, one CN group on the bridgehead suffices to stabilize the whole bicyclopropenyl system.

[*] Dr. R. Weiss and Dipl.-Chem. St. Andrae
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

The ether *(2a)* supplies what in our mechanism is the electronic counterpart of *(1)*. Although investigation of the thermal rearrangement of *(2a)* had to be abandoned owing to tenacious contamination by *(2b)*[2], this difficulty could be overcome by Ag^I-catalysis. The action of an equivalent amount of Ag^I ions on a solution of a mixture of *(2a)* and *(2b)* in anhydrous benzene proceeded under uniquely mild conditions (5 min at room temperature) and almost exclusively[5] according to Scheme 2.



(6) (7)

Scheme 2

If the reaction was stopped after 5 min by extracting the Ag^I ions into H_2O, two new substances *(6)* (*ca.* 70%) and *(7)* (*ca.* 30%)[5] were detected by NMR spectroscopy in place of *(2a)*/*(2b)*.

The structure of *(6)* follows from the following data: 1. NMR spectrum: $\tau = 6.60$ (3H/s); 5.43[6] (1H/s); 2. UV spectrum: λ_{max} ($CHCl_3$) = 290 nm (log $\varepsilon \approx 4.40$)[1]; 3. Quantitative isomerization with a half-reaction time of *ca.* 20 min at 50 °C, to give *(7)*[7] which was identical with an authentic specimen[8].

(7) could be isolated as the sole final rearrangement product and was formed, according to Scheme 2, in at least 95% yield[5].

The observed course of the reaction can be interpreted in the sense that a mobile equilibrium between *(2a)* and *(2b)* is set up under the catalytic influence of Ag^I (corresponding to a reversible ether cleavage) and that *(2a)* is then removed by its Ag^I-catalyzed rearrangement to *(6)*. The fact that almost exclusively a representative of the *p*-series is thus formed[1] accords with our mechanistic model of the bicyclopropenyl rearrangement. According to that (cf. Ref.[1]) under the conditions used, only the cyclopropene ring substituted by the donor group in *(2a)* should be opened on electrophilic attack by Ag^I. In contrast to the case with a CH_3 group[1], steric hindrance of this *exo*-attack[1] is not to be expected for the OCH_3 group because of its conformational mobility, and this situation should result in almost exclusive formation of *(6)* (see Ref.[1]).

Compound *(6)* is the first example of a Dewar-benzene with a donor substituent on the bridgehead. Its extremely facile aromatization is of interest in connection with the nature of orbital-symmetry forbidden processes[9, 10]. The kinetic data are at present being determined.

Influence of Ligands on Catalysts for the Heterogeneous Metathesis of Olefins

By *G. Henrici-Olivé* and *S. Olivé*[*]

In 1963 *Banks* and *Bailey*[1] reported the metathesis of olefins over molybdenum and tungsten catalysts on alumina supports. Straight-chain olefins were found to undergo conversion at 120–160 °C into homologs having longer chains and those having shorter chains, *e.g.*:

$$2CH_3{-}CH{=}CH_2 \rightleftarrows CH_2{=}CH_2 + CH_3{-}CH{=}CH{-}CH_3 \quad (1)$$

$$2CH_3{-}CH_2{-}CH{=}CH_2 \rightleftarrows CH_2{=}CH_2 + CH_3{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_3 \quad (2)$$

Meanwhile the new reaction type has attracted wide interest[2–4].

We wish to report on modifications to the conventional molybdenum catalyst which increase its activity to such a degree that much lower working temperatures are required. We have chosen the metathesis of propene and 1-butene as test reactions [cf. eq. (1) and (2)].

Pseudo γ-alumina (particle diameter *ca.* 3 mm, surface area 299 m^2/g) was impregnated with aqueous ammonium molybdate; after evaporation of the solvent the catalyst was oxidized at 500 °C in an O_2 stream for 8 hours (catalysts marked ox in Table 1). In several cases the catalyst was subsequently reduced at 500 °C in a CO stream for 3 hours and flushed with argon before use (marked red in Table 1). The reduced catalysts are considerably more active, with both propene and 1-butene, under otherwise identical conditions (see runs 1—4 in Table 1).

The alumina was impregnated with ethanolic $Ti(OC_4H_9)_4$ solutions of varying concentrations; after evaporation of the solvent and oxidation (8 hours, 500 °C, O_2), molybdenum was applied to the same carrier and oxidized as described above. Finally the catalysts were activated with CO. Table 1 shows that the activity of the catalysts containing both metals is considerably higher than that of the catalysts containing either metal alone; the synergic effect of the titanium increases with increasing Ti content for a fixed Mo charge (see runs 5—8 and 10—13).

A combination of both effects, at suitable molybdenum charge and flow rate, allows conversions close to the equilibrium values[5] at moderate temperatures (*e.g.* run 13).

Whereas reaction (1) gives only C_2 and C_4 species, considerable amounts of C_3 and C_5 compounds are in-

[d] $[Ti] = 1 \times 10^{-3}$ g-atom/g catalyst; no Mo.

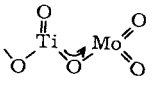
variably produced in reaction (2)[1, 6] whose formation is attributable to isomerization of both 1-butene and 3-hexene prior to metathesis. (Regarding the molecular weight distribution, see ref.[7].)

The oxidized catalysts are diamagnetic, the reduced ones paramagnetic. Table 2 and Figure 1 give the result of the magnetic susceptibility and EPR measurements.

Table 2. Magnetic data of reduced catalysts.

$[Mo] \times 10^3$ [g-atom/g cat.]	Ti/Mo	Spins/Mo	g-value
0.9	0	0.44	1.928
0.8	3.3	0.45	1.935

The magnetic data indicate that the titanium does not contribute to the paramagnetism of the catalyst, *i.e.* it is present in a diamagnetic form, presumably as Ti(IV). Evaluation of the magnetic susceptibility data gives 0.45 unpaired electrons per molybdenum in both cases, which is best interpreted assuming that about 50% of the molybdenum ions (originally present as MoO_3) are reduced to Mo(V) by the CO treatment. On the other hand, the different line shapes and g-values of the EPR signals indicate that the environment of the Mo ions changes when titanium is introduced. This, and the pronounced synergic effect of the titanium, lead to the conclusion that the active species in the bimetallic catalyst is a Ti(IV)-Mo(V) compound probably having an oxygen bridge, *e.g. (1)*.



(1)

MoO_3 is known to be strongly acidic: it dissolves readily in dilute alkali whereas TiO_2 is only poorly soluble in concentrated alkali[8]. It may therefore be assumed that TiO_2 acts as an electron donor toward the Mo(V) species. Both modification procedures (reduction of Mo(VI) to Mo(V) and formation of such a compound) would hence increase the electron density on Mo. If it is also borne in mind that the rate-determining step is not the actual metathesis between two olefin molecules coordinated to an Mo center but rather the desorption of the olefins[4], then the enhanced reactivity can be readily explained as a promotion of desorption: the increase in electron density at the Mo center weakens the coordinative bonding of the olefin[9].

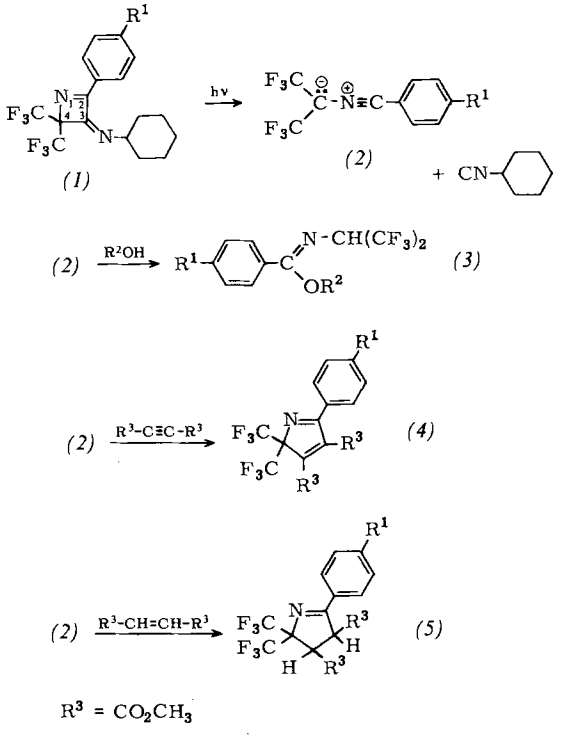
1,3-Dipolar Cycloreversion of 1-Azetines[**]

By *Klaus Burger, Willy Thenn,* and *Evi Müller*[*]

[3+1]-Cycloaddition of nitrile ylides[1] (obtained by thermolysis of 4,5-dihydro-1,3,5λ^5-oxazaphospholes[2]) to isocyanides leads to 1-azetines *(1)*[3,4]. This reaction is photochemically reversible.

On irradiation of *(1)* in benzene solution for several hours with a quartz lamp (Hanovia 450 watt) cycloelimination of isocyanide occurs. The nitrile ylide *(2)* formed can be trapped by alcohols as *N*-(hexafluoroisopropyl)benzimidic



esters *(3)*, by dimethyl acetylenedicarboxylate as 2*H*-pyrroles *(4)*, and by dimethyl maleate or fumarate as 1-pyrrolines *(5)* (Table 1).

Table 1. Compounds of types *(3)*, *(4)*, and *(5)* prepared.

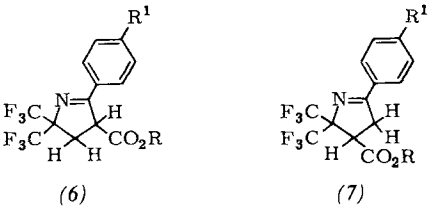
If acrylic esters are used as dipolarophile, then the ylide *(2)* yields the isomers *(6)* and *(7)*. Table 2 gives the isomer ratios determined by NMR spectroscopy. The results are comparable with those found previously on thermolysis and photolysis of 4,5-dihydro-1,3,5λ^5-oxazaphospholes in the presence of acrylic esters[1].



(6) *(7)*

Table 2. Ratios of isomers formed on reaction of *(2)* with acrylic esters.

(6)+(7)	R^1	R	*(6)*:*(7)*
(a)	H	CH_3	58:42
(b)	CH_3	CH_3	63:37
(c)	Cl	CH_3	56:44
(d)	H	C_2H_5	57:43
(e)	CH_3	C_2H_5	65:35
(f)	Cl	C_2H_5	63:37

Formation of the same products and almost identical isomer ratios indicate occurrence of the same intermediate for photolysis of 1-azetines *(1)* and thermolysis or photolysis of 4,5-dihydro-1,3,5λ^5-oxazaphospholes.

The nature of the products rules out electrocyclic ring fission (cleavage of the bond between C3 and C4) which was found for cyclobutenones[5]. Ring fission between C2 and C3 and subsequent decomposition to nitrile ylide and isocyanide — if the intermediate has a longer life — should, on reaction with methanol, give different trapping products and different ratios of the isomers produced by the addition. Thus a simultaneous or nearly synchronous bond cleavage between C2 and C3, and between C3 and C4, appears probable, which corresponds to a cheletropic [3+1]-cycloelimination on *Woodward* and *Hoffmann*'s classification[6].

Ethyl p-chloro-N-(hexafluoroisopropyl)benzimidate (3f):

2-(*p*-Chlorophenyl)-3-cyclohexylimino-4,4-bis(trifluoromethyl)-1-azetine[4] (7.9 g, 20 mmol) and anhydrous ethanol (50 ml) are irradiated in anhydrous benzene (250 ml) for 25.5 h by a quartz lamp (Hanovia 450 watt). After removal of the excess of alcohol, the solvent, and the cyclohexyl isocyanide formed, the residue is fractionated twice through a small column, giving a 43% yield (2.8 g) of *(3f)*.

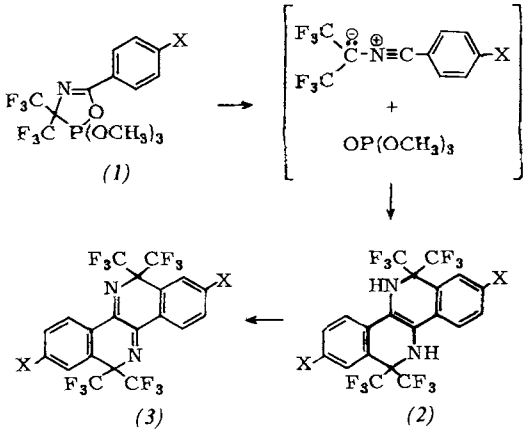
A New Type of Dimerization of Nitrile Ylides[***][1]

By *Klaus Burger*, *Kurt Einhellig*, and *Georg Süss*[*], together with *Alfred Gieren*[**]

We reported recently on cycloadditions[2] of the nitrile ylides produced by thermolysis or photolysis of 4,5-dihydro-1,3,5λ⁵-oxazaphospholes[****] *(1)*. On thermolysis of *(1)* in anhydrous xylene at 140 °C in absence of a dipolarophile, dimers *(2)* are formed with cycloelimination of phosphoric acid esters. The dimers are readily oxidized and with mercury(II) acetate afford excellent yields of 6,12-dihydro-6,6,12,12-tetrakis(trifluoromethyl)dibenzo-[*c*,*h*][1,5]naphthyridines *(3)*. The photolysis of *(1)* in benzene leads to *(3)* directly but in lower yields. IR, NMR, UV, and mass spectral data of *(3)* are available (Table 1); decision upon structure *(3)* followed from X-ray structure analysis[3].



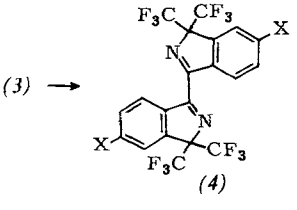
(1) *(3)* *(2)*

Table 1. Properties of *(3)* and *(4)*.

Cpd.	X	Yield [%]	M.p. [°C]	IR [cm⁻¹] [c]
(3a)	H	45[a] 90[b]	157	1628, 1600
(3b)	CH_3	36[a] 93[b]	227	1630, 1600
(3c)	OCH_3	30[a] 80[b]	213—213	1620, 1600
(4a)	H	90[d]	176	1600, 1538
(4b)	CH_3	95[d]	207	1610, 1535

[a] Yield referred to *(1)*.
[b] Yields referred to *(2)*.
[c] Measurements for KBr disks by a Perkin-Elmer Infracord instrument.
[d] Yields based on *(3)*.

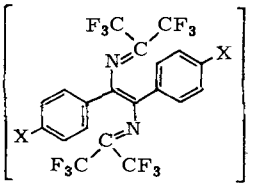
Heating the product *(3)* in methanolic KOH in a sealed tube at 120—130 °C converts it into 1,1,1′,1′-tetrakis-(trifluoromethyl)-3,3′-bi(1*H*-isoindole) *(4)* in high yields. *(3a)* and *(4a)*, and *(3b)* and *(4b)*, give barely distinguishable mass spectra. The electron band of longest wavelength appears at almost the same wavelength (for IR spectra see Table 1). The constitution of *(4)* was solved by X-ray structure analysis[4].



(3) → *(4)*

The dimerization products of nitrile ylides previously reported have been dihydropyrazines (readily convertible into pyrazines[5, 6]), 1,3-diazabicyclo[3.1.0]hex-3-enes[6, 7], imidazoles[6–8], and pyrimidines[7].

Since benzoylphenylcarbene (obtained from 4,5-diphenyl-1,3,2λ⁵-dioxaphosphole by thermolysis) dimerizes to dibenzoylstilbene[9], we postulate an analogous initial reaction step. The 2-azahexatriene system of *(5)* undergoes the thermally allowed disrotatory ring closure with subsequent [1.5]-sigmatropic H shift[10]. The reaction sequence is repeated in the other half of the molecule. The resulting enediamine *(2)* is extremely readily oxidized, so that *(2)* always contains small amounts of *(3)*.



(5)

The conversion *(3)* → *(4)* is merely an opening of the six-membered ring system and formation of the five-membered ring system; it proves the structure of *(3)*.

Experimental:

(1a) (9.85 g, 25 mmol) is heated in anhydrous xylene (50 ml) for 16 h at 140 °C. Then, after cooling, the solvent and trimethyl phosphate formed are distilled off in a vacuum. The residual yellow solid is digested with a little cold methanol, filtered off, and refluxed in methanol with an excess of mercury(II) acetate for 5 h. The mixture is then evaporated to dryness and the residue is digested in a little chloroform; most of the mercury(I) acetate remains undissolved. Recrystallization from methanol gives 45% (2.9 g) of *(3a)*.

(3a) (2.54 g, 5 mmol) is heated with methanol (200 ml) and concentrated KOH (5 ml) in a sealed tube for 48 h at 120—130 °C. After cooling, crystallization begins and is completed by addition of water. Yield 2.3 g, 90%; m.p. 176 °C (from methanol).

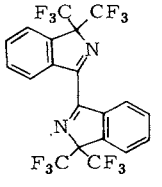
X-Ray Structure Analysis of 1,1,1′,1′-Tetrakis-(trifluoromethyl)-3,3′-bi(1*H*-isoindole)

By *Alfred Gieren*[*], together with *Klaus Burger* and *Kurt Einhellig*[**]

We have carried out an X-ray structure analysis of 1,1,1′,1′-tetrakis(trifluoromethyl)-3,3′-bi(1*H*-isoindole) *(1)* in order to solve its structure and mode of formation. The analysis led to the detection of a novel type of dimerization of nitrile ylides[1].

Suitable single crystals were obtained from methanolic solution. Space group Pbca; $a = 16.55_0$, $b = 21.76_9$, $c = 10.64_7$ Å; $d_{obs} = 1.73_7$ g cm^{-3}; 1 molecule/asym. unit ($d_{calc} = 1.74_6$ g cm^{-3}). 3631 independent reflections were measured on a Siemens diffractometer with $Cu_{K\alpha}$ radiation (695 not observed, $I \leq 2\sigma_I$; $\vartheta \leq 70°$, $\vartheta/2\vartheta$ scan, 5-point measurements).



(1)

The signs of 290 structure factors were determined by direct methods[2]. The positions of all the atoms (except H) could be seen in a *E*-Fourier synthesis. Least squares refinement, first with isotropic, then with anisotropic temperature factors, was carried out to an *R* value of 10.2%. Thereafter, the H atoms found in a difference Fourier synthesis were included in the refinement. Towards the end of the refinement all the data were corrected for absorption by an experimental method[3]. Structure factors with $|\Delta F| > 5$ (in the last cycle 43) were no longer used for calculation of shift. Convergence occurred at $R = 6.2\%$ (*R* value without 28 reflections with $\Delta F < -10$: 4.7%).

To a first approximation the molecule *(1)* (Fig. 1) has 2/m symmetry. Bond lengths and bond angles do not deviate significantly from this symmetry. The two isoindole rings are planar and only slightly twisted relative to one another around the C7—C8 bond (angle between the best planes: 2.9°). The almost planar, centrosymmetrical conformation of the 1,4-diaza-1,3-butadiene system explains the absence of the IR band at 1628 cm^{-1} ($\nu_{C=N}$)[1].

X-Ray Structure Analysis of 6,12-Dihydro-6,6,12,12-Tetrakis(trifluoromethyl)dibenzo[*c*,*h*]-[1,5]naphthyridine

By *Alfred Gieren*[*], together with *Klaus Burger* and *Kurt Einhellig*[**]

We have carried out an X-ray structure analysis of 6,12-dihydro-6,6,12,12-tetrakis(trifluoromethyl)dibenzo[*c*,*h*][1,5]naphthyridine in order conclusively to prove its structure and formation by a new type of dimerization of nitrile ylides[1].

The single crystals obtained from methanolic solution are monoclinic. Space group $P2_1/b$; $a = 13.42_9$, $b = 13.03_8$, $c = 11.10_5$ Å, $\gamma = 103.2_9°$; $d_{obs} = 1.75$ g cm^{-3}; 1 molecule/asym. unit ($d_{calc.} = 1.77$ g cm^{-3}). 3586 independent reflections (400 not observed, $I \leq 2\sigma_I$; $\vartheta \leq 70°$, $\vartheta/2\vartheta$ scan, 5 point measurements) were recorded on a Siemens diffractometer with $Cu_{K\alpha}$ radiation.

Positions of all the atoms (except H) were found in an *E*-Fourier synthesis calculated with 298 structure factors which were phased by direct methods[2]. After least-squares refinement, first with isotropic and then with anisotropic temperature factors, all the H atoms could be found in a difference Fourier synthesis at an *R* value of 10.1%. The refinement was continued with inclusion of the H atoms; towards the end an experimental absorption correction was carried out[3]. Structure factors with

Angles [°]

C16—C19—F7: 112.9	C16—C20—F10: 112.5
C16—C19—F8: 112.1	C16—C20—F11: 112.6
C16—C19—F9: 109.8	C16—C20—F12: 110.2
C17—C15—C18: 111.1	

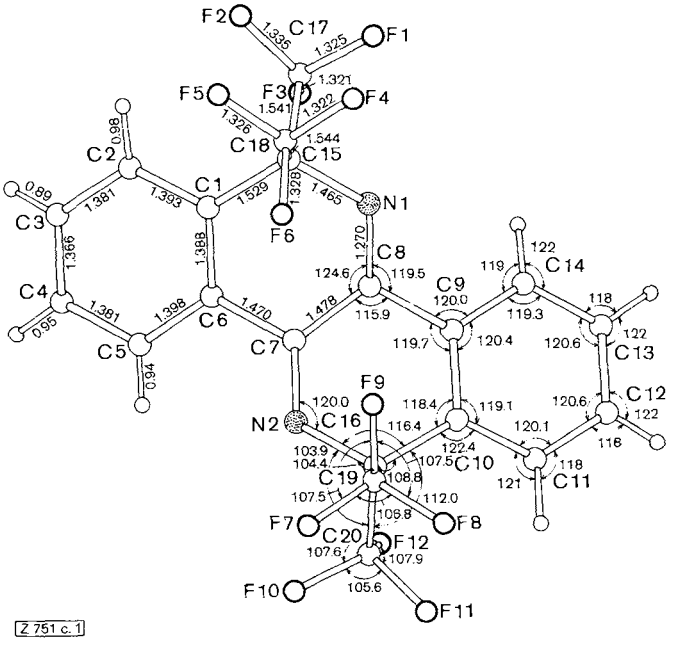

Fig. 1. Molecular structure of 6,12-dihydro-6,6,12,12-tetrakis(trifluoromethyl)dibenzo[c,h][1,5]naphthyridine *(1)*. The bond lengths and angles were determined with consideration of two-fold molecular symmetry. The standard deviations of the bond lengths and angles (without averaging on the basis of the two-fold symmetry axis) had mean values of 0.014 Å or 0.9° (without C—H: 0.11 Å, or without C—C—H: 6°).

The molecule *(1)* (Fig. 1) has a two-fold symmetry axis perpendicular to the central C7—C8 bond. The benzene rings are planar, but the heterocycles of the naphthyridine system are in boat form, which *inter alia* leads to the π-orbitals at C-6, C-7, and C-8 having a twist around C7—C8 (N2—C7—C8—N1: 164.7°) and around C6—C7 (C5—C6—C7—N2: 14.3°). Further the twist at C7—C8 explains the appearance of the IR band at 1628 cm^{-1}[1].

Crystal Structure of Allenedicarboxylic Acid[***]

By *Leslie Leiserowitz* and *Franz Nader*[*]

The interest in both the stereochemistry and chemical reactivity of cumulenes warrants thorough and systematic X-ray studies of this class of compounds. The only investigation of this kind to be published so far concerned tetraphenylhexapentaene[1] and yielded gross structural features only, because of two-dimensional diffraction data. Nevertheless, electron diffraction studies have been carried out on allene[2a,b] and butatriene[3].

We have undertaken the structure analysis of a derivative of allene, the simplest molecule in the cumulene series. We chose allenedicarboxylic acid (glutinic acid) because of its easy preparation[4] and the restricted thermal vibrations expected in the crystalline phase.

Single crystals of the compound were obtained by slow evaporation of acetic acid solutions[****]. Crystallographic data: orthorhombic; $a = 15.108$ Å, $b = 8.214$, $c = 4.527$; space group: $Pna2_1$, $Z = 4$; $d_{exp} = 1.53$, $d_{calc} = 1.514$ g/cm³.

The structure was solved by a direct method[5] using the multi-solution technique[6]. The positions of the hydrogen atoms were obtained from the difference map. The refinement with 764 independent reflections (of which 150 were treated as unobserved) yielded a final agreement factor of $R = 4.0\%$.

Bond lengths and bond angles are shown in Fig. 1. The length of the C=C double bond of the cumulene system is without doubt shorter than that of the isolated or conjugated C=C double bond (*ca.* 1.33—1.34 Å). The same conclusion was reached in the electron diffraction study of allene[2b] which yielded a C=C bond somewhat longer than that of the present X-ray study (1.311 Å *vs.* 1.298).

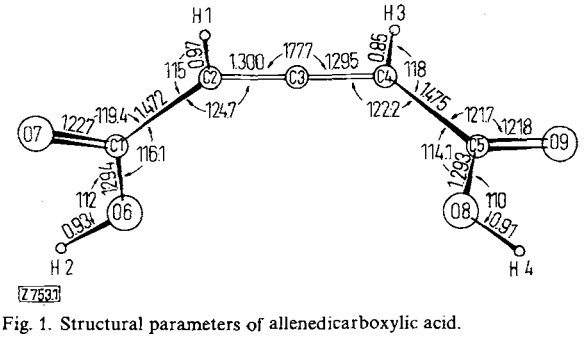

Fig. 1. Structural parameters of allenedicarboxylic acid.

That the carbonyl groups and the double bonds are in conjugation is indicated by the shortness of the carbon single bond joining them (1.474 Å). Whereas the bond lengths in the two halves are in good agreement the bond angles show distinct differences beyond the limit of probable error of 0.3°.

[***] Cumulenes, Part 1.

[****] In ethanol or water solutions partial decarboxylation combined presumably with dimerization occurs. One obtains monoclinic crystals of space group $P2_1/c$. From the measured density the molecular weight is calculated to *ca.* 172. In ethanol at −15°C however, this reaction is suppressed and one can obtain single crystals of allenedicarboxylic acid by slow evaporation.

The allene bonds are not completely linear. The small deviation (2.3°) is presumably due to steric interactions between the carboxyl groups and the central allene carbon atom (C-3). The planes of the two carboxyl groups are—as expected—perpendicular to each other. The carboxyl groups are each slightly twisted (*ca.* 2°) out of the plane of the allene system.

The conformation of the molecule surprisingly shows an *anti*-planar arrangement of carbonyl groups and allene double bonds. The *syn*-planar disposition is usually found in α,β-unsaturated carboxylic acids and derivatives thereof[7, 8].

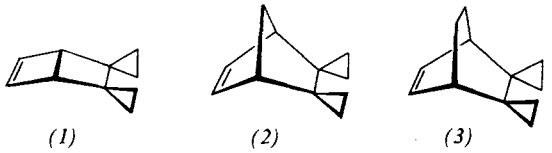
[2+2]- and [2+4]-Cycloadditions of Bicyclopropylidene[**]

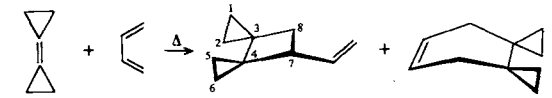
By *Dieter Kaufmann* and *Armin de Meijere*[*]

Methylenecyclopropane[1] and substituted methylenecyclopropanes[2,3] undergo thermal dimerizations in analogy to fluoroalkenes, yielding cyclobutane derivatives. Dichloromethylenecyclopropane reacts also with 1,3-butadiene exclusively by [2+2]-cycloaddition[4]. Potential [2+4]-cycloadducts such as *(1)*, *(2)*, and *(3)* of the bicyclopropylidene system *(4)* to cyclic 1,3-dienes are of particular interest with regard to possible "through-space" electronic interaction between the Walsh orbitals[5] of the cyclopropane ring and the π-electrons of the double bond. We have therefore investigated the question whether [2+4]-cycloadducts are formed on thermal reaction of *(4)* with 1,3-dienes.

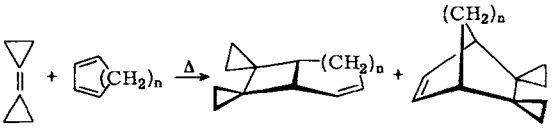


(1) *(2)* *(3)*

Bicyclopropylidene *(4)*[6] was heated with a 4- to 8-fold molar excess of 1,3-butadiene *(5)*, cyclopentadiene *(8)*, or 1,3-cyclohexadiene *(9)* and a trace of hydroquinone in sealed glass ampoules at 150–180°C. The crude mixture of products was analyzed by gas chromatography; a combination of gas chromatography and mass spectrometry (GC-MS) initially revealed the components that had molecular weights expected of the respective cycloadducts of *(4)*. The individual components were then isolated pure by preparative gas chromatography; their structural elucidation was based mainly on NMR-spectroscopic data[7]. The reaction conditions and relative yields are collected in Table 1.



(4) *(5)* *(6)* *(7)*



(4) *(8)*, n = 1; *(9)*, n = 2 *(10)*, n = 2 *(2)*, n = 1; *(3)*, n = 2

Table 1. Conditions and yields in the reaction of *(4)* with 1,3-dienes.

Diene	Reaction condns. T[°]	t[h]	Products, rel. yields [2+2]-adduct	[2+4]-adduct	Total yield [b]
(5)	180	12	*(6)* 92%	*(7)* 8%	54%
(8)	150	10	[a]	*(2)* >97%	16%[c]
(9)	170	11	*(10)* 78%	*(3)* 22%	50%

[a] It was not possible to detect a product corresponding to *(10)* but with $n=1$.
[b] Total yield of products isolated by gas chromatography.
[c] In this reaction the bicyclopropylidene did not undergo complete conversion.

Cyclopentadiene *(8)* gave only one product of mass number 146; no further component of that mass number could be detected in the crude product mixture by GC-MS. The NMR spectrum (CCl_4) of this product showed a multiplet centered at $\tau=9.88$ (8 cyclopropyl protons), $\tau=7.88$ (2 bridgehead protons) and $\tau=3.80$ (2 olefinic protons), together with an AB line system centered at $\tau=8.20$ (2 methylene protons); the number and coupling patterns of the signals indicate the structure bicyclo[2.2.1]hept-2-ene-5,6-dispirocyclopropane *(2)*[17].

When *(4)* was treated with 1,3-cyclohexadiene *(9)* two products of mass number 160 were formed as well as dimeric cyclohexadiene (also mass number 160). The NMR spectrum ($CDCl_3$) of one of the components showed multiplets centered at $\tau=9.95$ (8 cyclopropyl protons), $\tau=8.79$, 8.15 (2 protons each of the ethano bridge, respectively *endo* and *exo* to the double bond), $\tau=8.47$ (2 bridgehead protons), and $\tau=3.66$ (2 olefinic protons); these signals were identical with those of a sample of bicyclo[2.2.2]oct-2-ene-5,6-dispirocyclopropane *(3)* synthesized by an independent route[8]. The spectrum (CCl_4) of the main component, showing multiplets at $\tau=9.83$ (8 cyclopropyl protons), $\tau=8.47$, 7.98 (2 methylene protons each), $\tau=7.37$, 7.07 (1 methine proton each), and $\tau=4.48$, 4.11

[*] Dipl.-Chem. D. Kaufmann and Doz. Dr. A. de Meijere

[**] Supported financially by the State of Niedersachsen and with materials by the Deutsche Solvay-Werke, Rheinberg/Rhld., and Degussa, Frankfurt/M.

(1 olefinic proton each) is consistent only with the structure of bicyclo[4.2.0]oct-2-ene-7,8-dispirocyclopropane *(10)*.

1,3-Butadiene, which is a diene not fixed in the *cis*-configuration, gave two cycloadducts of molecular weight 134. A component forming only 8% of the total yield was, according to its NMR spectrum and gas-chromatographic retention time, identical with authentic dispiro[2.0.2.4]-dec-8-ene *(7)*[11]. The main product gives a NMR spectrum (CCl_4) with signals at $\tau = 9.75$ (m, 8 cyclopropyl protons), $\tau = 7.64$ (AB system, split into doublets, 2 cyclobutylmethylene protons), $\tau = 6.93$ (q, 1 cyclobutyl-methine proton), $\tau = 5.21$, 5.07, 4.15 (ABC line system, 3 vinyl protons), and thus has the structure 7-vinyldispiro[2.0.2.2.]-octane *(6)*.

Attempts to react *(4)* with cyclobutadiene produced *in situ*[12] in order to obtain bicyclo[2.2.0]hex-1-ene-5,6-dispirocyclopropane *(1)* have so far been without success. No unchanged *(4)* could be recovered, but no component of the expected molecular weight 132 could be detected in the crude product by GC-MS.

According to the above findings bicyclopropylidene *(4)* behaves differently from dichloromethylenecyclopropane[4] in reactions with conjugated dienes. Although it appears to add preferentially by a diradical mechanism, it can nevertheless also react by way of the transition state of a synchronous Diels-Alder reaction, as is proved by the appearance of the [2+4]-adduct *(7)*[13,14].

The question of through-space electronic interaction between the cyclopropane rings and the double bonds is being studied for compounds of types *(2)* and *(3)* by means of photoelectron spectroscopy[16].

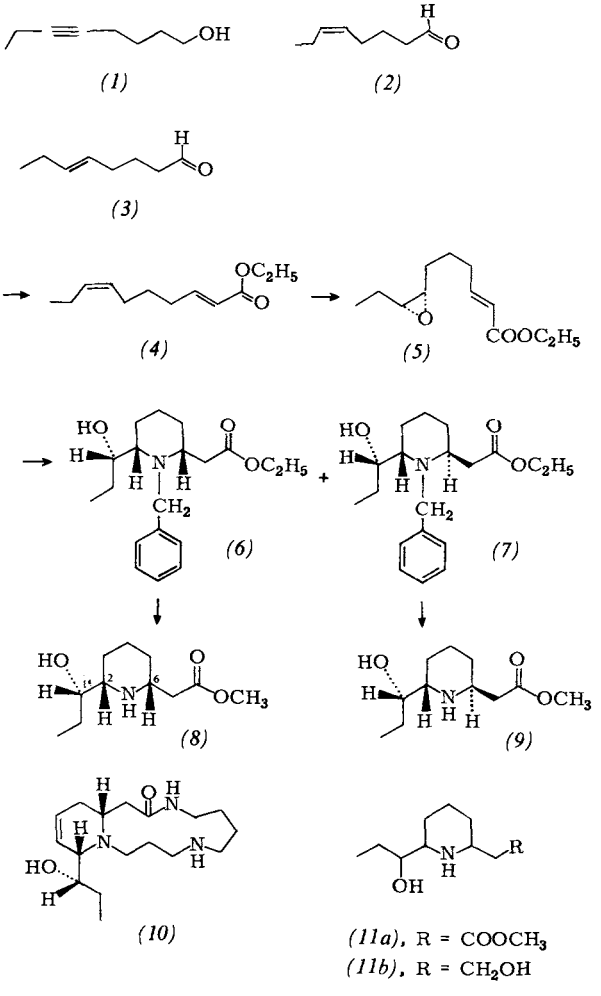
Synthesis of (±)-Dihydropalustraminic Acid

By *Peter Wälchli* and *Conrad Hans Eugster*[*]

In palustrine *(10)*, the poisonous main alkaloid of *Equisetum palustre* L. (marsh horsetail), we recognized in 1960 the first member of the spermidine alkaloids[1]. The key substance in the determination of its structure was the methyl dihydropalustraminate *(11a)* obtained therefrom by Hofmann degradation[2]. The synthesis described below confirms the constitutional formula proposed and also clarifies the steric relations:

5-Hexyn-1-ol[3] was ethylated *via* its pyranyl ether by ethyl bromide ($NaNH_2/NH_3$-ether), and the 5-octyn-1-ol *(1)* obtained was reduced catalytically and then oxidized by Collins' method[4] to *cis*-5-octen-1-al *(2)*. The ester *(4)* was then formed by olefination of the anion of ethyl (diethylphosphino)acetate (NaH-benzene) and was epoxidized on the non-conjugated double bond to give *(5)*. Treatment with benzylamine next caused opening of the oxide (*threo*-amino alcohol) and ring closure to the *cis*- *(6)* and *trans*-piperidine *(7)*, which were separated on a preparative scale by chromatography on alumina (Alox). On



hydrolysis and transesterification we then obtained the (±)-compounds corresponding to *(8)* and *(9)*, respectively. Their stereochemistry followed from NMR measure-

Organisch-chemisches Institut der Universität
Rämistrasse 76,
CH-8001 Zürich (Switzerland)

ments (cf. Ref.[5]) and lactonization experiments[6]. The synthetic (±)-*threo-cis*-methyl ester *(8)* [m.p. (hydrochloride) 176.4—177 °C] was spectroscopically and chromatographically identical with the (−)-methyl ester [m.p. (hydrochloride) 185 °C] obtained by degradation of the alkaloid.

Analogous reactions with *trans*-5-octenal *(3)* have led to synthesis of the *erythro-cis*- and the *erythro-trans*-compound *(11a)*; these stereoisomers differ significantly from *(8)* in their NMR and IR spectra.

The (2*S*,6*R*,1′*S*)-configuration of (−)-*(8)* follows unambiguously from the chiroptical data for (−)-*(8)* and (−)-*cis-(11b)*[7] together with the *threo*-configuration that has now been proved. Thus palustrine has structure *(10)*.

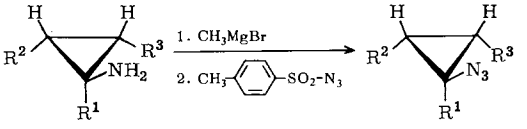
The Thermolysis of Cyclopropyl Azides[1]

By *Günter Szeimies*, *Udo Siefken*, and *Rolf Rinck*[*]

Cyclopropyl azides were unknown until very recently when some representatives of this class of compounds were synthesized by special reactions[2–4].

In the nitrogen-transfer reaction from *p*-toluenesulfonyl azides to anions of cyclopropylamines[5] we have found a more general method of preparing cyclopropyl azides.

Thermal removal of nitrogen from the cyclopropyl azides *(1)*—*(3)* can be effected between 100 and 120 °C. For example, after 2 h in boiling toluene, *(2)* yielded 76% of 2-phenyl-1-azetine[7] *(4)* [NMR signals of the four-membered ring protons in carbon tetrachloride at 60 MHz: triplets (each 2 protons) at $\tau = 6.75$ and 6.15, $J = 3.5$ Hz; IR: C=N at 1568 cm^{-1}]. Reduction by $LiAlH_4$ converts



(1) - *(3)*

Compound	Yield [%] [6, 7]	B.p. [°C/torr]

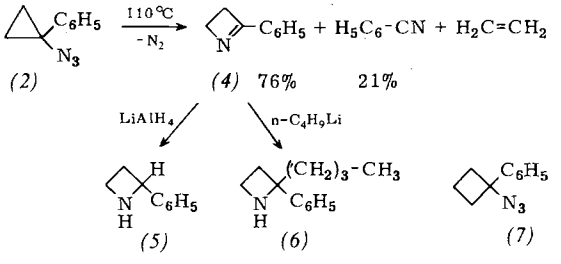
(2), $R^1=C_6H_5$, $R^2=R^3=H$	40	45—48/0.001
(3), $R^1=H$, $R^2+R^3=-(CH_2)_4-$ [8]	21	35—38/0.01

(4) into 2-phenylazetidine *(5)*[7], and addition of butyllithium into 2-butyl-2-phenylazetidine *(6)*[7]; additionally, thermolysis of *(2)* affords 21% of benzonitrile and ethylene, of which the latter was identified as 1,2-dibromoethane.



(2) *(4)* *(5)* *(6)* *(7)*

Nitrogen cleavage from *(1)* in *o*-dichlorobenzene at 110 °C gave, together with styrene (57%) and hydrogen cyanide, a rapidly polymerizing oil that we have not yet been able to purify. Thermolysis of *(3)* in carbon tetrachloride in a sealed tube at 120 °C led to 90% of cyclohexene and a small amount of a resin.

Table 1. Rate constants of the azide thermolysis in *o*-dichlorobenzene [9].

Azide	Concn. [mol/l]	Temp. [°C]	$k_1 \times 10^4$ [s^{-1}]	E_A [kcal/mol]	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [cal mol^{-1} deg^{-1}]
(1)	0.0470	112.8	3.28			
	0.0470	126.1	12.3	30.5	29.7	2.0
	0.0470	135.2	29.2

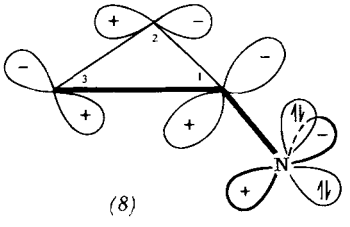
It is noteworthy that the thermolysis temperature of the cyclopropyl azides is much lower than that of alkyl azides. Table 1 gives the first-order rate constants and the activation parameters of the thermal decomposition of the azides *(1)*, *(2)*, and *(3)* and of 1-phenylcyclobutyl azide *(7)*.

[*] Dr. G. Szeimies, U. Siefken, and R. Rinck
Organisch-chemisches Laboratorium der Universität
8 München 2, Karlstrasse 23 (Germany)

An activation energy of 38.5 kcal/mol[10] is required for removal of nitrogen from isopropyl azide, and of 47.5 kcal/mol for that from cyclohexyl azide[11]. What makes cyclopropyl azides so labile thermally? Loss of the three-membered ring strain cannot explain this great acceleration of the removal of nitrogen from three-membered ring azides: assuming comparable transition states, the four-membered ring azide *(7)* should decompose faster than the corresponding three-membered ring azide *(2)* if loss of ring strain has a decisive effect on the energy of the activation complex[12] since the cyclopropane and cyclobutane rings have approximately the same ring strains of 27.1 kcal/mol and 26.2 kcal/mol, respectively[13], whilst the azetine system which is the main thermolysis product of the three-membered ring azide should be considerably more strained than the 1-pyrroline system which is the thermolysis product of the four-membered ring azide. The activation enthalpy of thermolyis of the cyclobutyl azide *(7)* is about 5 kcal/mol greater than that of the cyclopropyl azide *(2)*, corresponding to a rate ratio of 1:525 at 102.5 °C, and this indicates that the cyclopropane ring is not broken to an appreciable extent in the rate-determining step of nitrogen elimination. Removal of nitrogen from the cyclopropyl azide should thus not be wholly synchronous with ring expansion and cheletropic elimination[14], but the reactions occur one after the other.

With this in mind we see a possible explanation of the considerable facilitation of removal of nitrogen from cyclopropyl azides by the electron donor effect of the cyclopropane system to the empty p orbital of the nitrene nitrogen in the orbital combination represented in *(8)*, the transition state being able to profit therefrom: the occupied asymmetric Walsh orbital[15] of the cyclopropane can fill the electron deficiency on the nitrene nitrogen caused by nitrogen elimination[16].



(8)

This "vertical stabilization"[17] of the nitrene nitrogen by the cyclopropyl group has an analogy in the stabilization of a carbenium ion center by a cyclopropyl substituent. This interaction can also be recognized in the increased rate of solvolysis of certain cyclopropylmethyl compounds[18]: acceleration of the solvolysis and of the "nitrogenolysis" on cyclopropyl substitution should thus have similar origins. The formation of the end products can be easily explained by the interaction represented in *(8)*: charge transfer from the three-membered ring to the nitrene nitrogen weakens the bonds C^1—C^2 or C^1—C^3 in the cyclopropane and thus facilitates the rearrangement to the azetine or the cheletropic elimination of nitrile to give ethylene[21].

That the two last-mentioned compounds are not products of a subsequent thermal decomposition of the 1-azetine system can be demonstrated conclusively for pyrolysis of *(2)*: benzonitrile is formed at 102.5 °C in a first-order reaction with $k_1 = 2.91 \times 10^{-4}$ [s^{-1}], and this value is identical within experimental error with k_1 of the azide thermolysis.

A Direct Cyclobutene-Bicyclobutane Valence Isomerization[1][**]

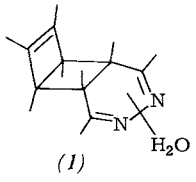
By *Günther Maier* and *Manfred Schneider*[*]

Irradiation of tricycle *(1)* leads to fission into tetramethylcyclobutadiene and tetramethylpyridazine[2]. If it were possible to prepare the heterocycle *(2)* that is valence-isomeric with *(1)*, a substance would be available whose photofragmentation might open a route to tetramethyltetrahedrane.

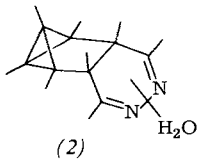
[*] Prof. Dr. G. Maier and Dipl.-Chem. M. Schneider
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We have now prepared the ozonide *(4)*, which appears to be an ideal starting material for the synthesis of *(2)*. Compound *(4)* [m.p. 142 °C; NMR (CCl_4): $\tau = 8.60$ (6H), 8.73

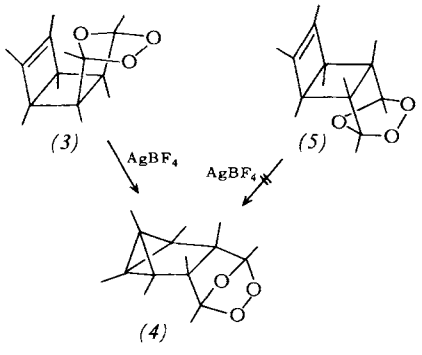


(1)



(2)

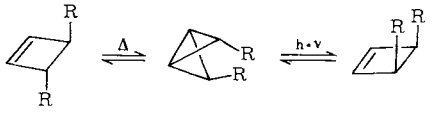
(3H), 8.77 (3H), 9.07 (6H), 9.20 (6H)] is formed surprisingly smoothly by the action of $AgBF_4$ on the valence-isomeric ozonide *(3)*[3]. Reducing *(4)* with triphenylphosphane affords the diacetyl compound, m.p. 179 °C, containing an intact bicyclobutane ring skeleton. Irradiation of *(4)* at room temperature or −70 °C effects fission into hexamethylbenzene and acetic anhydride.



(3) *(5)* *(4)*

It is noteworthy that the ozonide *(5)* having the *anti*-configuration is not rearranged under the same conditions. This is a result of the fact that the steric strain in the *syn*-isomer *(3)* is greater than that in *(5)*.

Valence isomerizations in the cyclobutene ⇌ bicyclobutane system are of interest in connection with the Woodward-Hoffmann selection rules[4]: the conversion of a cyclobutene of *cis*-configuration as in *(3)* into an *endo,endo*-disubstituted bicyclobutane such as *(4)* is thermally "forbidden", but it is "allowed" on photochemical excitation.



The rearrangement *(3)* → *(4)* described here is, to the best of our knowledge, the first example of the direct conversion of a cyclobutene into a bicyclobutane. At the same time it is a further confirmation[4, 5] that $Ag^{\oplus}$-ions can cause a reversal of the stereochemistry necessary for the thermal, non-catalyzed reaction.

9,10,11-Trioxapentacyclo[6.2.1.0^{2,7}.0^{3,5}.0^{4,6}]undecane (4)

Addition of 50 mg $AgBF_4$ to a solution of 5.00 g (0.019 mol) ozonide *(3)* in 40 ml dry acetone, stirring under nitrogen in a closed vessel for 16 h at 20 °C, evaporation of the solvent and filtration of the residue in petroleum ether through an Al_2O_3-column gives 4.50 g (90%) of bicyclobutane derivative *(4)*.

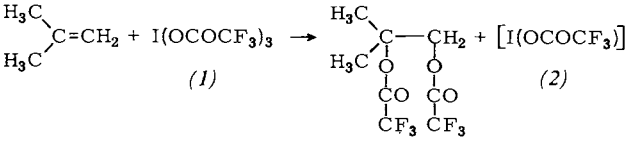
Stereospecific Oxidation of Alkenes by Iodine Tris(trifluoroacetate)

By *Joachim Buddrus*[*]

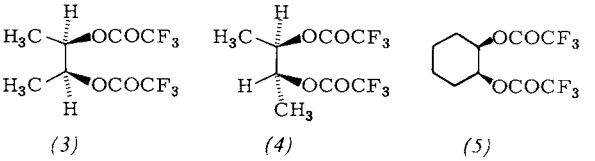
Acetates of metals in their higher oxidation states are known to act as oxidizing agents. For example, lead tetraacetate, thallium triacetate, and mercury diacetate convert alkenes into mixtures of the allylic acetates as well as the diacetates of *vic*- and *gem*-diols[1]. In such reactions the allylic acetate usually predominates. Insofar as they are formed at all, the ethylene acetates are diastereoisomeric mixtures.

It was observed that iodine tris(trifluoroacetate) *(1)*[2] also oxidizes alkenes. If it is suspended in olefin-free pentane and an alkene is then added dropwise at room temperature a rapid reaction occurs, esters of *vic*-diols being formed in yields of 50—70%. Isobutene affords 1,1-dimethylethylene bis(trifluoroacetate).



The iodine mono(trifluoroacetate) *(2)* formed simultaneously cannot be isolated, but only iodine; formation of *(2)* can, however, be demonstrated indirectly by adding an excess of alkene, which leads to the iodohydrins (as trifluoroacetate).

Oxidation of the alkene occurs largely stereospecifically. *cis*-2-Butene[3] gives mainly the *meso*-compound *(3)* [*(3)*:*(4)* = 97:3], *trans*-2-butene[3] gives mainly the *dl*-

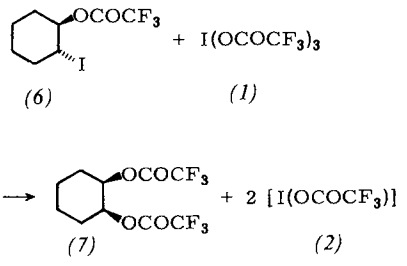


compound *(4)* [*(3)*:*(4)* = 9:91]. Cyclohexene is converted into *(5)* and the corresponding *trans*-compound in the proportion 94:6. The isomers can be separated by gas

[*] Priv.-Doz. Dr. J. Buddrus
Institut für Spektrochemie und Angewandte Spektroskopie
46 Dortmund, Bunsen-Kirchhoff-Strasse 11 (Germany)

chromatography (stationary phase: 3,3'-oxydipropionitrile). They were identified by comparing their retention times and ^{1}H-NMR spectra with those of authentic samples[4].

The degree of stereospecificity depends on the polarity of the solvent. Thus the ratio between the amounts of the isomeric 1,2-diol derivatives from cyclohexene is 94:6 in pentane, 91:9 in chloroform and 85:15 in methylene dichloride. This dependence rules out a concerted mechanism[5]. A two-step mechanism may be presumed: electrophilic *trans*-addition of *(1)* to the alkene is followed by substitution of the carbon-iodine bond by the trifluoroacetate ion with inversion at the carbon atom. An inversion of this type can be demonstrated for the reaction of *(6)* with *(1)*, which also occurs in pentane at room temperature.



(6) *(1)* *(7)* *(2)*

In this reaction the *trans*-compound *(6)* [J_{CHI} = 10.5 + 9.5 + 4.5 Hz] passes into the *cis*-compound *(7)* [*(7)*:corresponding *trans*-compound = 95:5]. The mechanism is still under study.

The oxidation of alkenes by *(1)* can be compared with that of alkenes by iodine and silver salts of carboxylic acids in aqueous acetic acid as described by *Woodward* and *Brutcher*[6]. In both cases *cis*-1,2-diol derivatives are formed.

Orientation experiments show that rearrangements occasionally occur. Whereas isobutene and tetramethylethylene give only the expected derivatives of the *vic*-diols, 2-methyl-2-butene affords not only the *vic*-compounds but also 1,2-dimethylpropylidene bis(trifluoroacetate) which is a derivative of the *gem*-diol (ratio 2:1). Styrene is converted mainly into the rearranged product 2-phenylethylidene bis(trifluoroacetate).

CONFERENCE REPORTS

Mechanism of Excitation of Photoreceptor Cells

By *Hennig Stieve*[*]

Photoreceptor cells function as interpreters that translate the light stimulus into the language of the nervous system. A receptor is an active biological transducer (amplifier).

Photoreceptor cells usually have a part containing an increased area of strongly folded surface membrane in which the photosensitive pigment, rhodopsin, is incorporated. A nerve fiber leads from the cell body carrying the excitation finally to other nerve cells. The stimulating light, which is absorbed by the photosensitive pigment, causes in the photoreceptor cells a series of reactions, which one refers to as excitation: absorption of a light quantum starts a photochemical reaction of the rhodopsin —namely, stereoisomerization of the chromophore 11-*cis*-retinal to all-*trans*-retinal—which is followed by a cascade of dark reactions. The dark reactions consist of changes in the protein portion of the rhodopsin. By some as yet not fully understood mechanism one of these reaction steps causes a transient change in the conductivity of the cell membrane and thus a transient change in the membrane potential of the photoreceptor cells. This voltage impulse, being the response to the light stimulus, is called the receptor potential.

The amplitude of the receptor potential amounts at most to 70 mV. It is larger the larger the intensity of the stimulating light. The change in conductivity of the photoreceptor cell membrane caused by the light stimulus is different in the visual cells of vertebrates from that in the photoreceptors of invertebrates. In invertebrates the conductivity at first increases on illumination, whereas in the visual cell membranes of the vertebrates it decreases transiently. The changes in the structure of the rhodopsin must be regarded as causing the opening or closing of pores in the visual cell membrane. This in turn causes changes in the ionic current through the cell membrane. Calcium ions play a decisive role in the process of opening and closing of the pores. It is assumed nowadays that a change in the calcium ion concentration due to a change in the conformation of the photosensitive pigment controls the conductivity of the visual cell membrane.

The voltage signal, called the receptor potential, spreads over the whole cell membrane and can set off a series of

nerve impulses (spikes) in the membrane portions where the nerve fiber originates or at the synapses.

Use of Deuterated Compounds in the Study of Tyrosine-Dopa Metabolism in Phenylketonuria

By *H.-Ch. Curtius*[*]

The use of radioactive isotopes for labeling of metabolic processes in man is not without risk and can be undertaken only in special cases. Non-radiating, stable isotopes such as ^{15}N, ^{13}C and deuterium have found little use so far because their measurement presented some analytical problems. The most suitable instrument for detection of stable isotopes is the mass spectrometer, but the separation and purification of the various compounds before mass spectrometry is very cumbersome and usually provides only low yields. Since the introduction of the combination of gas chromatography with mass spectrometry this problem has become much less serious. Complicated biological mixtures can now be separated by gas chromatography in amounts down to the nanogram scale and then analyzed for their isotope content in the mass spectrometer[1, 2].

We have studied the tyrosine and phenylalanine metabolism during phenylketonuria with the aid of stable isotopes. In this disease there is no conversion of phenylalanine into tyrosine, *i.e.* the phenylalanine-hydroxylase complex is defective. The causes of the symptoms of this disease (mental-retardation, neurological symptoms, partial lack of pigmentation) are still largely unknown.

Patients suffering from phenylketonuria with high plasma phenylalanine content excrete low concentrations of catecholamine metabolites in the urine. Investigations *in vitro* have shown that the conversion of tyrosine into dopa by tyrosine-hydroxylase isolated from bovine adrenal gland is inhibited by high phenylalanine concentrations[3]. To follow the conversion of tyrosine into biogenic amines in phenylketonuria patients *in vivo* we have carried out loading experiments with deuterated L-tyrosine (150 mg/kg body weight). The experiments were made with patients having high (25 to 35 mg/100 ml), moderate (15 to 20 mg/100 ml) and low plasma phenylalanine content (< 4 mg/100 ml) as well as with healthy controls. The excretion of tyrosine metabolites (dopamine, 4-hydroxy-3-methoxyphenylglycol, homovanillic acid, vanillylmandelic acid) in the urine was studied by gas chromatography linked to mass spectrometry. Patients with high phenylalanine plasma concentration showed only a very small increase in the above-mentioned metabolites, those with a medium phenylalanine concentration showed a somewhat greater increase. When the phenylalanine content was low we observed a large increase in the amounts of urinary metabolites, analogous to that in the healthy controls. These experiments show that the tyrosine-hydroxylase activity *in vivo* and thus the formation of biogenic amines and of L-dopa is dependent on the phenylalanine concentration in plasma and tissues. To confirm these results we loaded the same patients with 50 mg/kg body weight of L-dopa while their phenylalanine plasma level was high (about 30 mg/100 ml); the urinary metabolites in question were indeed excreted in appreciably higher concentrations after one administration of L-dopa.

The *in vivo* inhibition of L-dopa formation by phenylalanine could be an important factor in the pathogenesis of the neurological symptoms and the mental retardation of phenylketonuria patients.

ABSTRACTS

The lipids of mycobacteria, which are reviewed by *M. B. Goren*, play an important role for the relationship between these bacteria and the host organisms. The structural variety of the substance class became apparent only with the aid of modern analytical methods. It has not yet been established whether the compounds which are mainly isolated from *in vitro* cultures are not artifacts since the chemical structure of the bacteria depend upon their environment. In the cell the substances are probably in a defined arrangement; it was shown for the phosphatides that their immunological activity is greatly enhanced by complex formation. Some representatives of the high-molecular weight waxes D, chloroform-soluble peptidoglycolipids of the cell wall, could serve as starting materials for the eludication of the relationship between chemical structure and physiological activity of the substances by a synthetic method. [Mycobacterial Lipids: Selected Topics. Bacteriol Rev. *36*, 33—64 (1972); 268 references]

[Rd 546 IE—R]

The surface properties of calcium phosphates represents the theme of a summarizing report by *C. L. Kibby* and *W. K. Hall*. Calcium phosphates having an apatite struc-

ture, primarily hydroxyapatite, are the main components of bones and teeth. The crystals are exceptionally small and the surface area correspondingly large, *e.g.* 1 to 10 m^2/g for tooth enamel and 60 to 100 m^2/g for bone mineral. The apatite structure permits numerous ionic substitutions and defects and the number of possible modifications is so great that it is often difficult to decide whether an experimental result applies only to the sample in question or whether it is of more general validity. Changes in chemical composition naturally produce changes in surface properties. [Surface Properties of Calcium Phosphates. Chem. Biosurfaces *2*, 663—729 (1972); 183 references]

[Rd 552 IE—G]

Measurements of adsorption at electrodes are critically discussed by *H. H. Bauer*, *P. J. Herman*, and *P. J. Elving*. The authors consider the question: How can adsorption at electrodes be measured, and what information can be gained from the results? Adsorption at electrodes differs from other adsorption processes in that the electrical potential of the adsorbent can be varied independently. Furthermore, electron transfer reactions whose occurrence is potential-dependent can be superimposed on the adsorption process. [Critical Observations on Measurements of Adsorption at Electrodes. Mod. Aspects Electrochem. *7*, 143—197 (1972); 305 references]

[Rd 554 IE—G]

Transport-controlled deposition and dissolution of metals is the title of a review by *A. R. Despić* and *K. I. Popov*. Structure and appearance and the nature of the surface of a deposited metal are largely dependent upon the pathway and the rate of flow of the deposited species. Rate-determining transport processes therefore play a role in the formation of irregularities, in formation of dendrites, whiskers, and powdery deposits, as well as in the processes employed in the removal of these irregularities (electropolishing, *etc.*). The article surveys the current state of the art and the uniform theoretical treatment of the processes mentioned. [Transport-Controlled Deposition and Dissolution of Metals. Mod. Aspects Electrochem. *7*, 199—313 (1972); 131 references]

[Rd 555 IE—G]

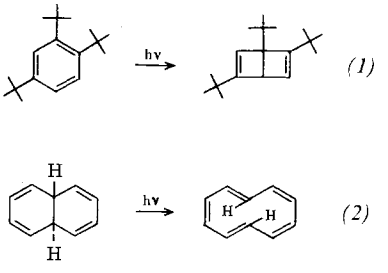
The application of ESR spectroscopy to problems of catalyst research is reviewed by *J. H. Lunsford*. The information available from ESR data ranges from the confirmation of the presence of an unknown paramagnetic species to the detailed description of bonding and orientation of a surface complex. The high sensitivity of the method makes it of particular interest in catalyst research since it permits the study of very low concentrations of active sites. Thus unexpected valence states and intermediates (for instance the anions O_2^- and O^-) have been be detected by ESR spectroscopy. [Electron Spin Resonance in Catalysis. Advan. Catal. *22*, 265—344 (1972); 174 references]

[Rd 574 IE—G]

Heat-flow microcalorimetry and its application to problems of heterogeneous catalysis is the topic of a review by *P. C. Gravelle*. Principle of the method: the inner vessel of a calorimeter is connected to its environment by a thermal conductor. If heat is evolved or consumed, a flow of heat is set up until thermal equilibrium is reestablished. The temperature difference between the two ends of the thermal conductor is measured as a function of time. The article considers: types of calorimeters; theory of the measuring technique; evaluation of the experimental results; and applications to problems of heterogeneous catalysis. It becomes apparent that heat flow calorimetry is subject to fewer theoretical and practical limitations than other calorimetric techniques. It is therefore particularly suitable for studies on surface processes on solids of poor thermal conductivity, which includes most industrial catalysts. [Heat-Flow Microcalorimetry and Its Application to Heterogeneous Catalysis. Advan. Catal. *22*, 191—263 (1972); 84 references]

[Rd 575 IE—G]

Valence bond isomers of aromatic and heteroaromatic systems are the subject of a review by *E. E. van Tamelen*. Since the synthesis of the Dewar-benzene derivative *(1)* a decade ago many other such valence bond isomers have been detected, such as the highly unstable cyclodecapentaene ([10]annulene) *(2)* that is formed from *trans*-9,10-dihydronaphthalene. In contrast, the 1,6-bridged [10]annulenes are stable. Numerous other examples, *e.g.* bullvalene, are to be found among the $(CH)_{10}$ hydrocarbons.



The author also discusses, *inter alia*, valence bond isomeric systems characterized by participation of ions and heteroaromatic compounds. [Valence Bond Isomers of Aromatic Systems. Accounts Chem. Res. *5*, 186—192 (1972); 62 references]

[Rd 579 IE—L]

Radical anions and carbanions as donors in electron-transfer processes is the title of a report by *M. Szwarc*. Rates and free energies of the reactions depend upon the form of the participating ions (free ions, ion pairs, higher aggregates). Systems with two or more ionic species are particularly interesting. Thus biphenyl anion ($Biph^{\cdot -}$) and naphthalene (Naph) equilibrate with biphenyl and naphthalene anion:

$$Biph^{\cdot -}, Na^+ + Naph \rightleftharpoons Biph + Naph^{\cdot -}, Na^+$$

Carbanions can transfer an electron to aromatic acceptors (A), *e.g.*:

$$Ph_3C^- + A \rightarrow Ph_3C^{\cdot} + A^{\cdot -}$$

The author also considers reactions of dianions and ionic aggregates and the methods of studying these reactions.

[Radical Anions and Carbanions as Donors in Electron-Transfer Processes. Accounts Chem. Res. 5, 169—176 (1972); 43 references]

[Rd 580 IE—L]

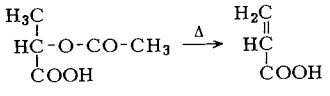
Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i.e.* provisionally published specifications as filed with the German Patent Office

***trans*-Polyalkenamers having a broad molecular weight distribution** are prepared by polymerization of cycloolefins with ring cleavage in inert organic solvents with organometallic mixed catalysts consisting of tungsten compounds, organoaluminum compounds, and possibly catalysts. The polymerization is carried out in the presence of hydrogen chloride, the molar ratio of hydrogen chloride to the tungsten compound being 0.1 : 1 to 10 : 1. The broad molecular weight distribution of the polymers is reflected in the values for the Defo hardness and elasticity. The material exhibits excellent sheet formation on the mill. Because of the good shear gradient excellent dispersion of fillers and additives occurs during processing on the mill or in the internal mixers. The polymers, which exhibit excellent vulcanization properties even in highly filled and oil-extended mixes, are used as synthetic rubber. [DOS 2056178; Farbenfabriken Bayer AG, Leverkusen]

[PR 45 IE—E]

In a new synthesis of acrylic acid, α-acetoxypropionic acid *(1)* is passed at 200—500 °C over catalysts containing phosphates of metals of group I and/or II of the periodic system, possibly on support materials such as silica, Al_2O_3, silicates, pumice stone, and charcoal. In the past, acrylic



(1)

acid was obtained, *e.g.* by thermolysis of β-hydroxypropionic or β-acetoxypropionic acid, which are difficult to obtain. In the thermal cleavage of the free acid under the conditions of the cleavage of α-acetoxypropionic acid derivatives, acetaldehyde and carbon monoxide are formed. [DOS 2046411; Farbwerke Hoechst, Frankfurt/Main-Höchst]

[PR 48 IE—B]

Novel alcohol-promoted chromium oxide-aluminum oxide catalysts for the production of aromatic hydrocarbons, particularly of *p*-xylene, by dehydrocyclization of diisobutylene or triisobutylene and/or their hydrogenation products are claimed. The catalysts have the following composition: 10 to 25% of Cr_2O_3, 1 to 5% of K_2O, 0.5 to 4% of SiO_2, 67 to 88.5% of α-Al_2O_3. A special advantage claimed for this process is the low carbon formation. [DOS 2144226; Deutsche Akademie der Wissenschaften, Berlin]

[PR 51 IE—D]

Thiazoles *(1)* can be used as condiments and flavors, particularly for foods and allied products as well as for perfumed products. Other flavoring substances, supports, stabilizers,

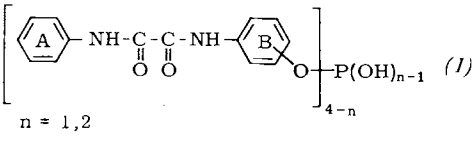
thickening agents, surface active agents, conditioners, and taste-increasing agents may be added to them. [DOS 2152557; International Flavors & Fragrances Inc., New York]

[PR 52 IE—D]

The sound absorption of soundproofing layers for motor vehicles based on castable polyester or polyether urethane foams is substantially improved by addition of a mixture of 200—400 parts by weight of barite (based on the polyol component) with 10—30 parts by weight (based on the barite) of alkanesulfonic ester, *e.g.* of phenol or cresol. The addition of this latter substance, which is itself known, and which has plasticizing properties, leads to a surprising decrease in the viscosity of the final reaction mixture. It is thus possible to obtain a large increase in the density, which is directly responsible for the effectiveness of thermal and particularly acoustic insulation. The barite may be entirely or partly replaced by other heavy fillers, and the alkanesulfonic ester may be entirely or partly replaced by other plasticizers. [DOS 2063588; Phoenix Gummiwerke AG, Hamburg]

[PR 59 IE—O]

New organic phosphorus compounds having the general formula *(1)* stabilize organic materials, in most cases simultaneously against the destructive action of UV light, visible light, air, and heat. This broad action spectrum makes them particularly valuable as stabilizers for plastics, *e.g.* polypropylene, to which they are added before processing. The benzene ring A may be substituted by alkyl,



(1)

n = 1,2

alkoxy, or hydroxyl groups; the benzene ring B may contain a methyl group. The compounds *(1)* are prepared by reaction of $4-n$ moles of a diaryloxamide *(2)* with one mole of phosphorus trichloride or tribromide; when $n = 2$, a reaction with one mole of water follows. [DOS 2150787; Sandoz AG, Basel]

Inorganic Vibrational Spectroscopy. Vol. I. By *L. H. Jones*. Marcel Dekker, Inc., New York 1971. 1st Edit., viii, 218 pp., numerous tables, bound, $ 22.50.

The contents of the present book are much narrower in scope than its title would lead one to suppose. It is restricted to an evaluation of the fundamental vibrations of those inorganic molecules and complex anions for which experimental work allows a complete calculation of the force constants. Besides diatomic and triatomic molecules, the author deals with some halides of the type XHal , as well as with mononuclear cyano and carbonyl complexes of higher symmetry, calling upon his own contributions to the spectra and force constants of these compounds. Additional parameters such as isotope frequency shifts and Coriolis force effects are taken into account in determining force constants. The possibilities of correcting for anharmonicity and its effect on the calculated force constants are demonstrated. As a rule, the author bases the force constants on the general force field, but in some cases he also uses a modified Urey-Bradley field. Some statements are made on the interpretation of force constants, especially interaction constants, although no generally applicable conclusions can be drawn at the present time.

The introduction to the special section takes the form of a brief outline of the theory of molecular vibrations, with discussions of the energy relationships for harmonic and anharmonic vibrations, G and F matrices, internal coordinates, symmetry coordinates, redundance relationships, and potential fields. This part of the book, in conjunction with the examples and tables given in the appendix, can help the advanced student to get the hang of normal coordinate calculations. On the whole, however, the restricted scope of the book makes it more likely to be useful for those working in vibrational spectroscopy for the derivation of special results and for the literature references.

H. J. Becher [NB 100 IE]

Techniques of Chemistry. Vol. I: Physical Methods of Chemistry. Edited by *A. Weissberger* and *B. M. Rossiter*. John Wiley & Sons, Inc., New York—London 1971. 1st Edit., Part I A: xi, 433 pp., numerous figures, bound £ 9.50. Part I B: xi, 330 pp., numerous figures, bound £ 8.00.

After several editions, the series "Techniques of Organic Chemistry" edited by *A. Weissberger* now appears under the title "Techniques of Chemistry". The first volume deals in five parts with the physical methods commonly used in chemistry. Parts I A and I B have now been published.

Part IA deals with the basic mechanical, electrical, and electronic components of scientific instruments. The section "Mechanical" presents the possibility of producing mechanical movements, the types of motors, and the physical layout of such systems. In the sections "Basic Electrical Principles" and "Electronic Components", the electrical and electronic components of instruments and their theoretical principles (measurement of resistances and capacities, circuits, amplifiers, current supply equipment, AD and DA converters, semiconductor electronics, *etc.*) are discussed. The nature and reproduction of electrical signals, the difference between analog and digital signals, and "digital logic" are also discussed. The last section of this volume is devoted to the production and modulation of electromagnetic waves, optical sources, and the production of acoustic signals.

The first section of Part I B presents a survey of detectors for radio waves and microwaves, for the optical range (IR, UV/visible), and for radioactive radiation, while the principles of automatic systems are described in the next two sections. The last section deals with the mathematical basis, the construction, and the functioning of analog and digital computers, as well as possibilities for their use in chemistry.

The two volumes are well illustrated. The various sections, which are written by different authors, end with very useful references to reviews and other important literature. The subject index could have been more detailed. The books appear at a time when instrumental methods are being increasingly used in all branches of chemistry. Their value cannot therefore be overestimated. To whom can they be recommended? To any chemist (or even biologist) whose electrical and electronic instruments are more to him than the infamous black box. In these volumes he can learn what was omitted from the practical physics course in many universities, and still is omitted in part; he can also learn about the functioning of a pen recorder, a photomultiplier, a semiconductor component, *etc.* He will find what he is looking for condensed to the essentials as far as he is concerned, and presented in a form that he can understand. He can also learn about the fundamentals of electronic data processing. For example, he will learn in a few lines the meaning of the 5-channel BCD code in which he punches the values for his HMO and kinetic calculations. The two volumes occupy a unique position in present-day support literature for chemists and biologists.

Egon Fahr [NB 97 IE]

Partition of Cell Particles and Macromolecules. By *P. Albertson*. Almqvist & Wiksell, Stockholm 1972. 2nd Edit., 323 pp., numerous figures, bound Sw.kr. 72.25.

The development of chemistry started with methods for the separation of low molecular weight substances; the refinement of these methods and their application to the complicated mixtures of cell components and metabolites characterized the progress of biochemistry to the stage of our present knowledge of macromolecules. The purification of enzymes, nucleic acids, and many complex cell components is now routine in the laboratory, and is even carried out semi-industrially in some cases. On the other hand, investigations on labile cell particles, viruses, and cells as well as on other multicomponent mixtures of biological colloids are still hindered by purification problems, particularly where fairly large quantities are concerned. Apart from modern centrifugation methods and separations on molecular sieve columns, partition chromatography in aqueous multiphase systems, which was developed by *Albertson*, has recently been making a name for itself.

The second edition of the present monograph is a thorough modernization and revision of the book that appeared ten years ago, with the incorporation of the more recent findings. This clearly written and skillfully arranged book begins with the Brønsted equation for partition in two-phase systems and deals with this theory from various

angles, but always in an understandable manner and with an eye to practical applications, which are illustrated by numerous examples of the fractionation of cells, mitochondria, chloroplasts, viruses, and protein/protein and nucleic acid/protein complexes. Single partitions are suitable for mixtures of macromolecules with very different molecular parameters. Others must be separated by multi-stage countercurrent partition, for which *Albertson* has designed an effective apparatus. The method is thus suitable not only for the separation of particles but also for the study of bonding between particles or molecules. The many examples and the carefully evaluated literature make this seem an attractive method for a number of outstanding problems, though patience and experience are evidently necessary for successful results. However, the beginner is given access to the theory and application through numerous tables and data on the behavior of aqueous polymer/polymer phases. The book will thus be welcomed by chemists and biologists who are concerned with the separation and the biochemical and physical behavior of cell organelles, and also as a practical guide.

L Jaenicke [NB 101 IE]

Methoden der Organischen Chemie (Methods of Organic Chemistry) (Houben-Weyl). Edited by *E. Müller*. Vol. IV/Part 4: Isocyclic Four-Membered Ring Compounds, by *D. Seebach*. Appendix: Cyclopropane and Cyclobutane Derivatives from Natural Products, by *S. Beckmann* and *H. Geiger*. Georg Thieme Verlag, Stuttgart 1971. 4th Edith., xxviii, 568 pp 47 tables, bound DM 258 —

The volume is a very comprehensive summary of the physical and chemical properties of isocyclic four-membered ring compounds. The material in the main part (444 pages) is divided into chapters on the preparation and the reactions of four-membered ring derivatives, an arrangement that has proved satisfactory in the past. The classification is mechanistically oriented, and contains ordering principles of modern structural theory. Wherever possible the author succeeds in explaining stereochemical findings in the language of orbital symmetry control without lengthy theoretical descriptions. This becomes his dominant theme with the result that the reader is not only required to note modes of reaction, but his understanding is also challenged.

The volume ends (29 pages) with an enumeration of natural products having cyclopropane and cyclobutane structural units and data on their occurrence and their structure. More detailed information on any syntheses of these substances would have been of great value to the chemist (*e.g.* information on the elegant syntheses of the bourbonenes is lacking on p. 470).

The preparation of four-membered rings is guided by formal patterns of atoms linked (p. 30), which bring some lucidity and order to the many reactions used. However, the price of excessively strict adherence to this principle is that mechanistically related or identical reactions (*e.g.* Chap. Ia, pp. 31—53 and Chap. II, pp. 119—125), which belong together, appear in different parts of the book. To help the reader to overcome this obstacle, the author consistently provides cross references, of which there are too many rather than too few.

On the whole, the main part has been presented painstakingly and well by the author and by the publishers. The expert selection of the numerous synthesis procedures and the physical data that are given for practically all the compounds mentioned ensure optimum information for the user, and the numerous references to recent literature that are incorporated into the footnotes give the volume an up-to-dateness that is sometimes lacking in the other volumes of the series because of long publication times.

The volume ends with an author index, a subject index, and an index of synthesis procedures. A new feature of the subject index is the inclusion of basic structural types of classes of compounds before the appropriate columns, so that the reader in a hurry can find the desired class of compounds simply by inspection of these basic structures. Substituents are then arranged according to the Beilstein system.

The disadvantage of this arrangement in classes of substances is that it is difficult to find a reaction type from the index. For example, the "metathesis of olefins", which is dealt with on p. 299, cannot be found from the index. Some of the treasures of the book can thus be found out only by intensive reading.

A few points that occurred to the reviewer may also be mentioned in conclusion.

The text contains very few printing errors. The presentation of the reaction mechanism with formulas on p. 305 strikes the reviewer as unnecessary, since the structure of the reaction product has not yet been verified. The preparation of the compound IIIb (pp. 242—243) requires the use of 3,4-*cis*-dichlorotetramethylcyclobutene, whose preparation should be described on p. 307. However, the preparation of the *trans* compound is described on this page. The addition of dichlorovinylene carbonate to acetylene is not described on pages 239 and 242, as it should be according to page 341. The cyclobutenediylium dyes deserve more then a mention in footnotes. The perfluoro derivatives enumerated on p. 214 do not include tetrafluorocyclobutane-1,2-dione, which has surprising properties.

Nevertheless, the book is unquestionably a very valuable addition to the Houben-Weyl series[1]. It provides the synthetic chemist with a fund of information on methods, and the theoretical chemist with a number of starting points. For example, the commonly used term "activated double bond" is defined differently on pages 185, 188, 216, and 267, and certainly could not be understood without the particular reactants; this is a wide field for those intersted in perturbation theory.

H.-D. Scharf [NB 102 IE]

[1] Cf. Angew. Chem. internat. Edit. *10*, 433 (1971).

Advanced Organic Synthesis, Methods and Techniques. By *R. S. Monson*. Academic Press, New York—London 1971. 1st Edit., xii, 230 pp., numerous figures, bound $ 7.95.

The foreword to this book announces a collection of modern reactions that have won a place in synthetic organic chemistry. The book is addressed to advanced students and postgraduate workers. It is evidently an attempt to make the important reactions, which are widely scattered in the original literature and in reviews, directly accessible with detailed experimental procedures. This would have been very useful if it had been correctly executed, since it might have helped to overcome the well-known barrier to the use of a new reaction that has not become established in the particular research group. However, the

stated objective has been satisfactorily achieved only in a few chapters. Chapters 4 (Hydroboration), 9 (Enamines), 11 (Wittig Reaction), and 12 (Reactions with Trialkylboranes) do in fact provide good, representative procedures that should be easy to apply to a range of compounds.

In the other chapters the selection is very arbitrary and not so good as it might have been. The inclusion of reactions as old as a chromic acid oxidation and the epoxidation of cyclohexene under oxidations, while the many variations of solvolytic oxidation with dimethyl sulfoxide are not mentioned, the failure to mention hydride complexes such as tri-*tert*-butoxy hydridoaluminate under hydride reductions, and the inclusion of a triviality like the ketalization of cyclohexanone in Chapter 7 (Elimination, Substitution, Addition) while many modern addition reaction, such as the regioselective and stereoselective addition of iodine azide, which leads to interesting intermediate products, are not mentioned are only three very obvious instances. Others could be added to the list.

Even the procedures selected do not always meet with approval. When *e.g.* the Wolff-Kishner reduction is described on p. 55 in its oldest form (ethylene glycol/KOH; 200 °C) while the much more active system potassium *tert*-butoxide/dimethyl sulfoxide, which has been known for some time, is not even mentioned, the stated aim has clearly not been achieved.

Finally, the reader gains the impression that organic chemistry is the chemistry of alicyclic compounds, as other fields are scarcely touched upon; however, it is a well-known fact that heterocyclic compounds are frequently rather neglected in American books. Verdict: Recommended with some hesitation.

Ekkehard Winterfeldt [NB 104 IE]

Pesticides in the Environment. Vol. 1, Part. 1. Edited by *R. Withe-Stevens*. Marcel Dekker, Inc., New York 1971. 1st Edit., xv, 270 pp., numerous figures and tables, bound $ 23.50.

According to the foreword, the editor's intention in the planned five-volume compendium is to present a comprehensive survey of the chemical, biological, and toxicological properties of the pesticides in current use, as well as their practical use and their behavior in the environment. Experts both from universities and from industry have contributed as authors of the various sections. Volume 1 (two parts) will deal with mainly scientific aspects, while Volume 2 (three parts) will be concerned with the use of the pesticides.

The present volume is divided into three chapters. In Chapter 1 "Chemistry and Biology of Pesticides" (*R. L. Metcalf*), some 600 chemicals are mentioned on 140 pages under the headings fungicides, herbicides, insecticides, molluscicides, nematocides, and rodenticides. The chemistry, structure-activity relations, mode of action, action spectrum, and toxicology are described for each group of substances. 165 references are cited, the latest being from the year 1966. This should be quite useful as a basis for the following sections, but seen in isolation it has a number of shortcomings in comparison with similar, more recent publications, most of which are more comprehensive. Thus, despite the terse form, no distinction is made between the preparations that are widely used at present and those that are only of historical interest or that never progressed beyond the development stage. The description does not correspond to the current position. It contains none of the modern fungicides against mildew and rice diseases and none of the systemic fungicides; the preparations of the amidine and triorganotin types, which are important at present in resistant areas, are not mentioned among the acaricides; and herbicides *e.g.* of the nitrodiethyl ether type are not discussed.

The second chapter "Metabolism of Insecticides and Fungicides" (*T. R. Fukuto* and *J. S. Sims*) comprises 90 pages with 344 references. Apart from the fact that the latest article cited dates from 1967, this is probably the most comprehensive account in existence of the degradation reactions of insecticides in cultivated plants, domestic animals, soil, and water, which are extremely important to the assessment of the nature and duration of their biological effects, toxication and detoxication processes, and toxicological dangers, as well as to residue analysis. The discrepancy in the description of the metabolism of insecticides (phosphorus compounds 40 pages, carbamates 12, chloro-organic insecticides 15) and that of fungicides (5 pages), which is practically limited to preparations of the thiocarbamate and captan types, is no fault of the authors, but reflects the serious gaps in the investigations.

Chapter 3 "Metabolism of Herbicides" (*J. E. Loeffler* and *J. van Overbeek*), which occupies 34 pages and includes 146 references, is unquestionably the most up-to-date section (several references from 1969). Unlike Chapter 2, it is arranged not according to chemical principles but on a broader basis. An introduction to the general principles, problems, methods, and techniques of metabolic studies (8 pages) is followed by separate discussions of the degradation reactions: photochemical transformations, nonenzymatic reactions, oxidation, conjugation, hydrolysis, and others. The metabolic principles found in nature are thus presented in a very understandable manner.

The book will be a very useful orientation aid even to the expert, not the least of its merits being the numerous references.

Klaus Sasse [NB 106 IE]

Die Prüfung thermoplastischer Kunststoffe (Testing of Synthetic Thermoplastics). By *H. J. Orthmann* and *H. J. Mair*. Carl Hanser Verlag, München 1971. 1st Edit., 163 pp., 50 figures, 43 tables, bound DM 28.—.

The methods and conditions for the testing of synthetic thermoplastics are largely described and specified in standards. The terse, dry language of standards, which arises mainly from the need to define all the conditions for a given test method as briefly as possible and with no possibility of mistake, makes the standards difficult to use as instructions for the execution of a test.

The present book fills a need in this respect. The principle of the test methods is described with reference to the corresponding standards, emphasis being placed on information that is not usually found in standards but is part of the experience of the plastics tester, such as data on the accuracy of the methods and on possible sources of error, relationships with similar methods, and the practical significance of the test results. Useful features are the list of bodies and associations that issue standards, recommendations, and quality guides, and particularly the guidance on the evaluation and statistical analysis of test results.

The book is thus a good introduction to techniques for testing synthetic thermoplastics, which offers guidance to those who wish to take up the testing of plastics, and provides those concerned with the buying and selling, processing, and use of plastics, to whom these substances are

presented with test data, with the knowledge required to interpret these data correctly.

Werner Waldenrath [NB 107 IE]

Einführung in die Immunchemie und Immunologie (Introduction to Immunochemistry and Immunology). Heidelberger Taschenbücher Vol. 79. By *E. A. Kabat*. Springer-Verlag, Berlin–Heidelberg–New York 1971. 1st Edit., viii, 322 pp., 107 figures stitched DM 18.80.

The present volume is a translation, undertaken by members of the Max-Planck-Institut für Immunbiologie in Freiburg, of the American original published in 1968. Despite the fact that recent developments in the domain of immunology have been left out of the account (literature references up to 1967), this book provides a splendid "introduction to immunochemistry and immunology." The theoretical principles of immunochemistry and immunobiology are clearly set forth in a series of well thought-out chapters, followed by a detailed description, with illustrations, of the relevant methods. The most important techniques for the detection of antigens and antibodies are described so lucidly as to enable the reader to apply them in practice without further ado.

The book is suitable not only for students, but also for physicians, biochemists, and chemists whose work requires them to use immunological techniques or confronts them with problems in the area of immunology. A detailed subject index is provided.

Gerhard Schwick [NB 110 IE]

Inorganic Reaction Mechanisms. Vol. I. Specialist Periodical Reports. Published by The Chemical Society London 1971. 1st Edit., xv, 338 pp., bound, £ 7 —

One of the innovations in the program of the Chemical Society is the series of "Specialist Periodical Reports". These volumes, which are very similar in presentation and style to the well-known "Annual Reports", are to be published at regular intervals of one to two years, and are intended to present substantially complete literature surveys of the special field of chemistry covered.

The present book covers the literature that became available to the authors between January 1969 and August 1970 on kinetics and mechanisms of inorganic reactions in solution. Including the reviews mentioned, *J. Burgess* ("Senior Reporter"), *D. N. Hague*, *R. D. W. Kemmitt*, and *A. McAuley* have evaluated more than 1700 publications. The book, which contains numerous tables and an author index, is very logically arranged and subdivided by mechanistic aspects and by substance, so that a subject index is unnecessary.

The volume contains four main parts:
1. Electron Transfer Processes; 2. Substitutions and Related Reactions; 3. Complex Formation with Labile Metals and Biochemically Interesting Reactions; 4. Organometallic Compounds (only transition metals and mercury).

At the abstractor's discretion, publications are discussed in detail or merely mentioned. The main parts and the subchapters are mostly preceded by short introductions, in which the scope of the subject matter is defined and any reviews are mentioned.

The task of presenting a succinct but readable account of a very large number of articles naturally has its problems; in the reviewer's opinion, some publications have received too much or too little attention, and the emphasis sometimes appears to have been wrongly placed in rendering the content of a report. Nevertheless, for those who are actively engaged in research, the book will prove to be of valuable assistance in overcoming the tiresome literature problems if it is accepted that the reports cannot appear until nine to twelve months after the publication of the latest articles reviewed. Those interested who are not experts in this field will find here a means of gaining a quick and reasonable insight into a relatively young field that still has many problems to be solved.

Jörn Müller [NB 105 IE]

Fluorocarbon and Related Chemistry. Vol. 1. Specialist Periodical Reports. Published by The Chemical Society, London 1971. 1st Edit., viii, 307 pp., numerous illustrations, bound £ 7 —

The present first volume of the series represents a review of the literature covering the years 1969 and 1970. It is proposed to cover the entire chemistry of highly fluorinated organic and organometallic compounds in a two-year cycle.

R. E. Banks and *M. G. Barlow*, both of whom enjoy an international reputation in the field of organic chemistry of fluorine, provide a detailed survey of work on organofluorine compounds, so that the book fully lives up to the title of the series.

This book, which is written in a clear and sober style, represents far more than the usual literature survey. In dividing the 300 pages into five chapters, the authors have hit upon a simple arrangement, but one that may well be just what is wanted for a field with so many ramifications as fluorine chemistry. Chapters 1 and 2 cover saturated fluorinated hydrocarbons and per- and polyfluorinated olefins and acetylenes. The chemistry of the carbonyl group forms the subject of Chapter 3. Chapter 4 deals with all the remaining organoelemental compounds, following the order of the Periodic Table. This somewhat unusual arrangement may admittedly make a given compound more difficult to find for an organic chemist thinking in terms of functional groups; nevertheless, it proves to be an advantageous one, especially in view of the large number of papers on organometallic compounds. The chemistry of per- and polyfluorinated aromatic compounds is sensibly given in a separate chapter. The last section of some 25 pages contains the most recent results in ^{19}F-NMR spectroscopy.

The printing and the presentation of the book are of a high standard. Numerous formulas and reaction schemes are given, together with the mechanisms and brief details of preparation. Indeed, in this form the book encourages one to leaf through and read it. An additional reference list at the end of each chapter supplements literature citations appearing on each page. The book closes with an appendix containing details of important publications, standard works in the field of fluorine chemistry, and a list of authors. There is unfortunately no index, so that in trying to solve certain problems the reader may involve himself in an intensive search.

The commendable speed with which it has been published preserves the book's topicality, and its aims make it an excellent complement to the other periodicals appearing in the field of fluorine chemistry. One of the volume's outstanding features is its presentation, which manages to avoid giving the impression of a textbook whilst retaining clarity and cohesion.

G. Büttner [NB 111 IE]

Preparative Acetylenic Chemistry by *L. Brandsma*. Elsevier Publishing Co., Amsterdam—London—New York 1971. 1st Edit., x, 207 pp., 14 figs, 3 tables, bound £ 8.20.

In a foreword written by his famous teacher, Prof. *Arens*, the author is praised for the care with which the book is written and for the usefulness of this collection of recipes, which are arranged in nine chapters as follows: 1. General practical information: 2. Preparation of metal acetylides; 3. Alkylations at the acetylene carbon and related reactions; 4. α-Hydroxyalkylation, -carboxylation, and -acylation at the acetylene carbon; 5. Direct introduction of hetero-substituents; 6. Preparation of acetylene compounds by means of elimination reactions; 7. Base-induced migration of the triple bond; 8. Various syntheses; 9. Starting compounds. Further information regarding the contents will be found in a type index and in an index of empirical and structural formulas, extending over some eight pages.

According to the author, this collection of recipes is not intended merely for the specialist in the field; however, one must mention in this context a very serious drawback, namely that, incredibly enough, the book contains practically no literature references! By way of justification it is explained in the introduction that the principles of *Raphael, Rutledge, Viehe*, and *Ziegenbein* have been adequately dealt with. There are thus practically no simple comparisons with the original literature. However, if the critical user takes the trouble to look up original works, he will often find himself wondering why changes have been made without comment or reference. Without this deplorable shortcoming this otherwise useful book would have been even more recommendable.

Heinz Günter Viehe [NB 108 IE]

Synthetic Methods of Organic Chemistry. Vol. 25. By *W. Theilheimer*. S. Karger Verlag, Basel 1971. 1st Edit., xvi, 707 pp., bound DM 296.—

"Theilheimer", which has been appearing annually for 25 years and which has now notched up 22357 selected abstracts covering all areas of preparative organic chemistry, constitutes an invaluable aid to anyone carrying out syntheses. The present volume contains abstracts of 700 original papers published during the period 1968—1970. This volume contains in addition the citations from volumes 21—24 in the text and in a comprehensive general index (161 pages), which covers methods, compound classes, and reagents. This makes the book much easier to use, especially for those readers for whom the Weygand system on which the arrangement is based represents a serious "energy barrier"!

As in the past, the seven-page section on "Trends in Synthetic Organic Chemistry", which contains a brief description of synthesis methods and information of general interest from the latest literature, is especially readable. The use of India paper has made it possible to keep the size of the current volume, which contains more information than ever before, within reasonable limits. Apart from two missing pages (550 and 551) in the reviewer's copy and some absence of care in the drawing of a few steric formulas, the printing and presentation are up to the usual excellent standard.

In view of the plethora of abstract literature available to the organic chemist at the present time, one might be tempted to question whether "Theilheimer's" continued existence is still justified. In the reviewer's opinion no other work can compare in the speed, detail, or clarity with which "Theilheimer" abstracts the literature on synthetic methods. It is therefore most desirable that students of chemistry should become acquainted with the Weygand system at the earliest possible stage.

Lutz-F. Tietze [NB 109 IE]

Organic Fluorine Chemistry. By *M. Hudlicky*. Plenum Press, New York—London 1971. 1st Edit. xiii 198 pp., numerous figures and 50 tables, bound $ 18.48.

This book appears to be based on the manual published by the same author in the late 1950's, which was translated into German in 1960 under the title: "Chemie der organischen Fluorverbindungen". The great value of this fundamental monograph on organic fluorine chemistry lay in the concise summary of methods, preparation routes, and reactions.

In comparison with the standard work, which has become a "classic", the present book contains no fundamental changes. The first few chapters deal with fluorinating agents and their use. The chapter "Analysis of Organic Fluorine Compounds" has been placed earlier in the book, and now contains brief notes on IR, mass, and fluorine NMR spectroscopy.

The longest chapter deals with the reactions of organic fluorine compounds. An introductory section on reaction mechanisms presents a discussion of the inductive, mesomeric, steric, and hyperconjugation effects for the interpretation of the reactivity of fluorinated organic compounds, which is rather superficial. The section "Hyperconjugation", for example, makes no mention of the fact that this model has no physical significance. Valid theories that should also have been used for the explanation of mesomeric effects" are not considered.

In the reviewer's opinion, any survey of this special field, however detailed, is of little value at present without a fairly profound discussion of the broader relationships. The book can therefore be recommended at best as a collection of facts.

Carbocations and Electrophilic Reactions[1][**]

By George A. Olah[*]

The general concept of carbocations encompasses all cations of carbon containing compounds which can be differentiated into two distinct classes: trivalent ("classical") carbenium ions and pentacoordinated ("nonclassical") carbonium ions. In this paper the preparation and structural study (by NMR, IR, Raman and ESCA spectroscopy) of stable carbenium ions and carbonium ions are discussed. As is well known, trivalent carbenium ions play an important role in electrophilic reactions of π- and n-donor systems. Similarly, pentacoordinated carbonium ions are the key to electrophilic reactions of σ-donor systems (single bonds). The ability of single bonds to act as σ-donor lies in their ability to form carbonium ions *via* triangular two electron, three-center bond formation. Consequently there seems to be no principle difference between the electrophilic reactions of π- and σ-bonds except that the former react more easily, even with weak electrophiles, whereas the latter necessitate more severe conditions. The role of carbocations in electrophilic reactions of π- and σ-donor systems is discussed.

1. General Concept

1.1. Definition and Differentiation of Carbenium Ions and Carbonium Ions

The concept of carbocations (it seems to be the logical name for all cationic carbon compounds since the negative ions are called carbanions), with exception of the early isolation of highly stabilized triarylcarbenium ion salts, had its origin and grew to maturity through kinetic, stereochemical, and product studies of a wide variety of reactions, especially unimolecular nucleophilic substitutions and eliminations[2]. Leading investigators such as *Meerwein, Ingold, Hughes, Whitmore, Bartlett, Nenitzescu, Winstein,* and others have contributed fundamentally to the development of modern carbenium ion theory, *i.e.* to the concept of electron deficient cationic intermediates. Direct observation of stable, long-lived carbenium ions, generally in highly acidic (superacid) solvent systems, has become possible only in recent years[3].

Based on our continuing study of carbocations by direct observation of long-lived species, it became increasingly apparent that the carbocation concept is much broader than previously realized and necessitates general definition. Such a definition is offered, therefore, based on the realization that *two distinct classes of carbocations exist*[4]:

a) *Trivalent ("classical") carbenium ions* containing an sp^2-hybridized *electron deficient* central carbon atom (with six electrons in the valence shell), which, in the absence of constraining skeletal rigidity or steric interference, tends to give a planar (or close to planar) arrangement with the three directly bound atoms. (It should be noted that sp-hybridized, linear acyl cations and vinyl cations also show substantial electron deficiency on carbon.)

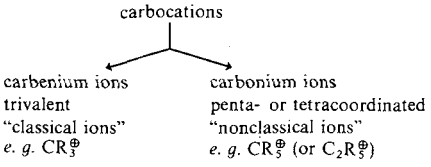
[**] This memoir will also be published as a separate brochure, copies of which can be ordered from Verlag Chemie GmbH, D-694 Weinheim, Postfach 129/149 (Germany) or John Wiley & Sons Inc., 605 Third Avenue, New York, N. Y. 10016 (USA). A German version is also available from Verlag Chemie GmbH.

b) *Penta-(or tetra)coordinated ("nonclassical") carbonium ions*, which contain five or four coordinated carbon atoms (having eight electrons in the valence shell) bound by three single bonds, and a two-electron, three-center bond (the latter being bound either to two additional bonding atoms or involving a carbon atom to which they are also bound by a single bond).

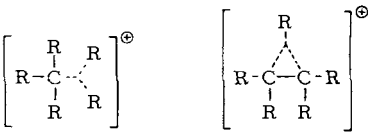


Expansion of the carbon octet *via* 3d-orbital participation does not seem possible; there can be only eight valence electrons in the outer shell of carbon[5]. Thus the covalency of carbon cannot exceed four. Pentacoordination implies a species with five or four ligands within reasonable bonding distance from the central atom[6]. The transition states long ago suggested for S_N2 and S_E2 reactions may represent such cases. However, the direct observation of stable pentacoordinated species in solution was not reported until recently when studies were carried out on long-lived "nonclassical" ions in superacid solvent systems. Moreover, in the past, S_E2 substitution reactions have been mainly restricted to organometallic compounds, *e.g.* organomercurials[7].

Interaction of neighboring groups with the vacant p-orbital of the carbenium ion center can contribute to ion stabilization *via* charge delocalization. Such phenomena can involve atoms with unshared electron pairs (n-donors), C—H and C—C hyperconjugation, bent σ-bonds (as in cyclopropylcarbenium ions) and π-electron systems (direct conjugative or allylic stabilization). Thus trivalent carbenium ions can show varying degrees of delocalization without becoming pentacoordinated carbonium ions. The limiting classes defined do not exclude varying degrees of delocalization, but in fact imply a spectrum of carbocation structures.

In contrast to the rather well-defined trivalent ("classical") carbenium ions, "nonclassical ions"[8] have been more loosely defined. In recent years, a lively controversy has centered on the classical-nonclassical carbonium ion problem[9]. The literature contains numerous contributions to the topic, but no generally accepted definition of nonclassical ions has emerged. Furthermore, no direct experimental means have been recognized for the differentiation of classical and nonclassical ions. The extensive use of "dotted lines" when writing carbonium ion structures has been (rightly) criticized by *Brown*[9d], who carried, however, the criticism to questioning the existence of any σ-delocalized (nonclassical) ion. For these ions, if they exist, he stated "...a new bonding concept not yet established in carbon structures is required".

It is suggested that unequivocal experimental evidence has since been obtained for nonclassical ions such as the norbornyl cation[10], and that the bonding concept required to define "nonclassical ions" is to consider them as penta- or tetracoordinated carbonium ions, of which CH_5^+ (the methonium ion, carbonium ion) is the parent, in the same way as CH_3^+ (methenium ion, methyl cation, carbenium ion) is the parent for trivalent carbenium ions.



For simplicity it is suggested that three-center bonds be depicted by triangular dotted lines drawn from and meeting each other between the three participating atoms; full straight lines are used to symbolize two center, two electron bonds. Such a formulation best illustrates the overlapping bonding orbitals; however, it must be remembered that the point of branching of the dotted line does not represent an additional atom.

Regarding the carbocation concept, it is regrettable that trivalent, planar ions of the type CH_3^+ are generally referred to as carbonium ions in the Anglo-Saxon literature. If the name is considered analogous to other onium ions (ammonium, sulfonium, phosphonium ions, *etc.*), then it should relate to the higher valency state carbocation. The higher valency state carbocations, however, clearly are not the trivalent but the *pentacoordinated cations* of the CH_5^+ type. In the German and the French literature the term "carbenium ion" is frequently used for naming the trivalent cations. Should we consider these latter ions as protonated carbenes, then this naming is indeed correct[11] and in agreement with IUPAC rules for the nomenclature of organic compounds and we could thus *differentiate* quite simply between *carbenium (trivalent)* and *carbonium (penta- or tetracoordinated) ions*[12]. It should be pointed out, however, that "carbenium ion" should be used only for the trivalent ions and not as a generic name for all carbocations. Owing to the wide acceptance of naming all cations of carbon, as carbonium or carbenium ions, we find the use of prefixes for differentiating trivalent and penta- or tetracoordinated is advisable. However, in the future the nomenclature must differentiate quite clearly between trivalent carbenium ions and pentacoordinated carbonium ions.

1.2. Development of Modern Theory: Kinetic and Stereochemical Studies

One of the most daring and fruitful ideas born in organic chemistry was the suggestion that carbocations might be intermediates in reactions that start from nonionic reactants and lead to nonionic covalent products. It was *Meerwein*[13] who in 1922, while studying the kinetics of the rearrangement of camphene hydrochloride to isobornyl chloride, reported the important observation that the reaction rate increased in a general way with the dielectric constant of the solvent. Further, he found that metal chlorides—such as $SbCl_5$, $SnCl_4$, $FeCl_3$, $AlCl_3$, and $SbCl_3$ (but not BCl_3 or $SiCl_4$), as well as dry HCl—which promote the ionization of triphenylmethyl chloride by formation

of ionized complexes, considerably accelerate the rearrangement of camphene hydrochloride. *Meerwein* concluded that the conversion of camphene hydrochloride into isobornyl chloride actually does not proceed by way of migration of the chlorine atom but by a rearrangement of a cationic intermediate. Thus the modern concept of carbocations was born.

In England, starting in the late 1920's, *Ingold* and *Hughes et al.* carried out detailed kinetic investigations on what later became known as nucleophilic substitution at saturated carbon and on polar elimination reactions[14]. The well-known work relating to S_N1 and later to E1 reactions established the carbocation concept. In a series of papers from 1932 onwards *Whitmore*[15] extended *Meerwein*'s rearrangement theory to many organic chemical reactions.

Kinetic and stereochemical evidence helped to establish the role played by carbocations in organic reactions. Generally, however, they were considered only as very short lived species and could not be directly detected by physical means.

1.3. Observation of Stable, Long-lived Ions

The transient nature of carbocations in chemical reactions arises from their extreme reactivity with nucleophiles. By the use of highly acidic and very weakly nucleophilic solvents, it is possible to prevent reactions leading to covalent products; in the last decade or so it has been possible in this way to observe a wide range of *stable*, long-lived carbocations.

2. Preparation and Structure of Stable Trivalent Carbenium Ions

2.1. Alkylcarbenium Ions

2.1.1. Early Unsuccessful experiments

Simple alkylcarbenium ions were, until recently, considered only as transient entities[2] and their existence has been inferred from studies on the course of certain reactions. No reliable physical or chemical method other than that of electron impact measurements were known for the detection of simple alkylcarbenium ions. The formation of organic cations in the gaseous phase by electron bombardment of alkanes, haloalkanes, and other precursors has been widely investigated by mass spectrometry[16]. An analogous direct observation of carbenium ions in solution has not been achieved.

Observation of alkylcarbenium ions (trivalent alkyl cations) such as the trimethylcarbenium ion (*tert*-butyl cation) $(CH_3)_3C^+$ or the dimethylcarbenium ion (isopropyl cation) $(CH_3)_2CH^+$ has thus been a longstanding challenge for many research workers. The occurrence of alkylcarbenium ions in systems of alkyl halides and Lewis acid halides has been inferred from a variety of observations, such as those of vapor pressure depressions of CH_3Cl and C_2H_5Cl in the presence of gallium chloride[17], the electrical conductivity of aluminum chloride in alkyl chlorides[18] and of alkyl fluorides in boron trifluoride[19], as well as the effect of ethyl bromide on the dipole moment of aluminum bromide[20]. However, in no case has a well-defined, stable ionic salt or complex been established, even at very low temperatures.

Rosenbaum and *Symons*[21] recorded the electronic spectra of alcohols and olefins in sulfuric acid. They observed, for a number of simple aliphatic alcohols and olefins, absorption maxima around 290 nm which they ascribed to the corresponding alkylcarbenium ions.

Later, *Finch* and *Symons*[22] reinvestigated the absorption of aliphatic alcohols and olefins in sulfuric acid, and showed that the condensation products formed with acetic acid (used as solvent for the precursor alcohols and olefins) were responsible for the spectra, not the simple alkylcarbenium ions. Protonated mesityl oxide was identified as the species responsible for the absorption at 290 nm in the isobutylene/acetic acid/sulfuric acid system.

Deno et al.[23] carried out an extensive study of the fate of alkyl cations in H_2SO_4 and oleum. They found that equal amounts of a mixture of saturated hydrocarbons (C_4 to C_{18}) that are insoluble in H_2SO_4 and a mixture of cyclopentenyl cations (C_9 to C_{20}) that are soluble in the H_2SO_4 layer are formed. Cyclopentenyl cations exhibit strong ultraviolet absorption at about 300 nm.

It must be concluded, therefore, that earlier attempts to prove the existence of stable, well-defined alkylcarbenium ions were unsuccessful, both in experiments with sulfuric acid solutions as well as with systems from alkyl halides and Lewis acid halides.

2.1.2. Preparation of Carbenium Ions from Alkyl Fluorides in Solutions Containing Antimony Pentafluoride

In 1962 we reported the first direct observation of stable alkylcarbenium ions in solution[24-26]. We obtained the trimethylcarbenium ion (*tert*-butyl cation) when *tert*-butyl fluoride was dissolved in excess antimony pentafluoride, which served both as Lewis acid and solvent. Later the counterion was found to be, under these conditions, primarily the dimeric anion $Sb_2F_{11}^-$[27]; whereas in SbF_5—SO_2 or SbF_5—SO_2ClF solutions, both SbF_6^- and $Sb_2F_{11}^-$ were found.

$$(CH_3)_3CF + (SbF_5)_2 \rightarrow (CH_3)_3C^{\oplus}Sb_2F_{11}^{\ominus}$$

The possibility of obtaining stable alkylcarbenium fluoroantimonate salts from alkyl fluorides (and subsequently other halides) in antimony pentafluoride solution (neat or diluted with sulfur dioxide, sulfuryl chloride fluoride, or sulfuryl fluoride) or in other superacids[28] [particularly FSO_3H—SbF_5 (magic acid®[29]), HF—SbF_5, fluoroantimonic acid, see subsequent discussion) was investigated in detail, our studies extending to all isomeric C_3, C_4 and C_5 alkyl fluorides, as well to a number of higher alkyl halides.

Propyl, butyl, and pentyl fluorides in excess antimony pentafluoride gave the isopropyl *(1)*, *tert*-butyl *(2)*, and *tert*-amyl cations *(3)* (as their fluoroantimonates).

$$C_3H_7F + (SbF_5)_2 \longrightarrow H_3C\text{-}\overset{\oplus}{C}H\text{-}CH_3 \quad Sb_2F_{11}^{\ominus} \qquad (1)$$

$$C_4H_9F + (SbF_5)_2 \longrightarrow H_3C\text{-}\overset{\oplus}{C}(CH_3)\text{-}CH_3 \quad Sb_2F_{11}^{\ominus} \qquad (2)$$

$$C_5H_{11}F + (SbF_5)_2 \longrightarrow H_3C\text{-}\overset{\oplus}{C}(CH_3)\text{-}C_2H_5 \quad Sb_2F_{11}^{\ominus} \qquad (3)$$

The secondary butyl and amyl cations can be observed at low temperatures, but they rearrange readily to more stable tertiary ions.

Generally, the most stable tertiary or secondary carbenium ions are eventually observed on starting from any of the isomeric alkyl fluorides in superacidic solvent systems. Rearrangement to these more stable ions can be studied, starting from very low temperatures.

2.1.3. NMR-Spectra

One of the most powerful tools in the study of carbenium ions is nuclear magnetic resonance spectroscopy. The main feature of the proton NMR spectra of alkyl fluorides in antimony pentafluoride is the substantial deshielding of the protons in the carbenium ions as compared with in the starting alkyl fluorides (Fig. 1 and Table 1) and the absence of H—F coupling.

In order to prove that stable alkylcarbenium ions, and not exchanging donor-acceptor complexes were obtained, we investigated the ^{13}C nuclear magnetic resonance of the potentially electropositive carbenium carbon atom in alkylcarbenium ions[30].

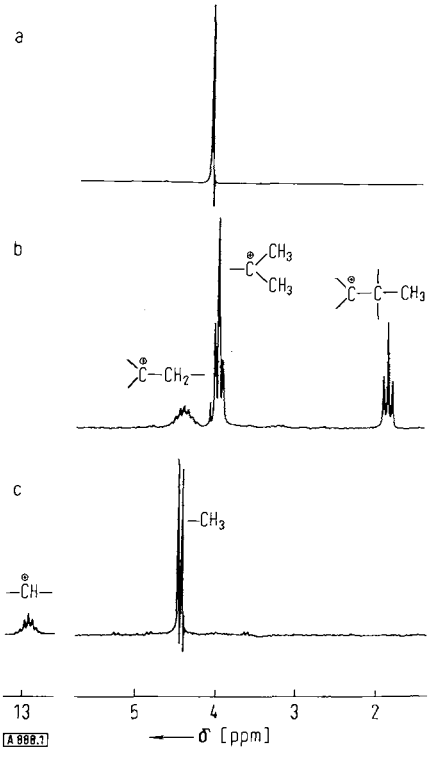


Fig. 1. ^1H-NMR spectra of: a) the *tert*-butyl cation *(2)* [trimethylcarbenium ion, $(CH_3)_3C^+$]; b) the *tert*-amyl cation *(3)* [dimethylethylcarbenium ion, $(CH_3)_2C^+—C_2H_5$]; c) the isopropyl cation *(1)* [dimethylcarbenium ion, $(CH_3)_2C^+H$]. (60 MHz, $SbF_5—SO_2ClF$ solution, $-60°C$.)

The ^{13}C chemical shift of C^+ in the *tert*-butyl cation $(CH_3)_3{}^{13}C^+$ in $SO_2ClF—SbF_5$ solution at $-20°C$ is $\delta_{^{13}C} = -135.4$ (with reference to capillary $^{13}CS_2$, as given throughout this review), the long-range coupling constant (J_{CCH}) to the methyl protons being 3.6 Hz.

Under identical conditions the ^{13}C chemical shift of the C^+ in the isopropyl cation is $\delta_{^{13}C} = -125.0$, and the long-range coupling to the methyl protons is 3.3 Hz (Fig. 2).

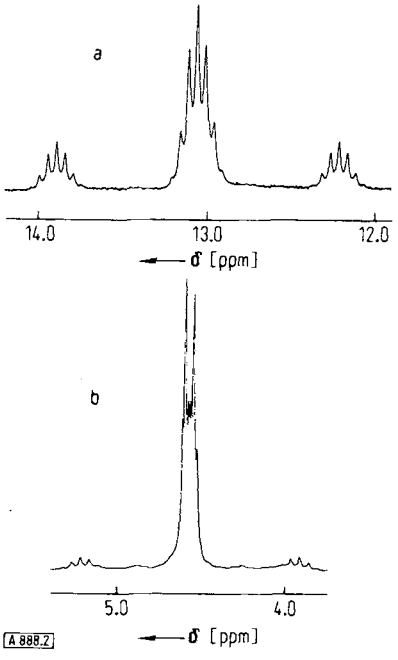

Fig. 2. 100-MHz ^1H-NMR spectrum of the isopropyl cation generated from isopropyl chloride with a 50% ^{13}C enrichment of C-2, in $SO_2ClF—SbF_5$ solution. The spectrum was recorded at $-60°C$. Figure 2a shows the methine region and consists of a septuplet ($J_{HH} = 5$ Hz) with ^{13}C satellites 84.5 Hz on either side of the main resonance ($J_{CH} = 169$ Hz). Figure 2b shows the methyl region. The ^{12}C species gives a doublet in this region while the ^{13}C-labeled ions give a doublet of doublets due to the long-range CCH coupling of 3.3 Hz. Some scrambling of the ^{13}C label into the methyl groups is apparent in this spectrum giving small pentuplets 65.5 Hz on either side of the main resonance. The structure of these satellites arises from the fact that the three- and four-bond proton-proton coupling constants are similar in magnitude (5 and 6 Hz).

The direct $^{13}C—H$ coupling is 169 Hz (a good indication of the sp^2 hybridization of the carbenium carbon atom is obtained from the apparent linear relation of the coupling constant with the hybridization; the electron-deficient carbon atom shows 33.8% s-character). The long-range, proton-proton coupling constant is 6.0 Hz (see Fig. 3).

Substitution of the methyl group in the *tert*-butyl cation by hydrogen thus causes a shielding of the C^+ (upfield shift of the $^{13}C^+$ signal of about 10.4 ppm). If a direct relation between ^{13}C shifts and electron density at C^+ exists, then it could be taken that the central carbon atom in the *tert*-butyl cation is slightly more positive than that in the isopropyl cation. Otherwise the difference can be accounted for in terms of a substituent effect (*i.e.* CH_3 *vs.* H).

The ^{13}C chemical shift of C^+ in the *tert*-amyl cation $[C_2H_5C^+(CH_3)_2]$ is $\delta_{^{13}C} = -139.4$, *i.e.* C^+ is more strongly deshielded (shift downfield of *ca.* 4 ppm) than C^+ in the

tert-butyl cation. This shift difference is much smaller than the 17 ppm found in the case of the related alkanes, although the shift observed is in the same direction.

It should, however, be pointed out that other factors than electron density can also affect the chemical shifts; thus no quantitative conclusion relating to charge densities can be established from the NMR data.

in the *tert*-butyl cation, than on the carbenium center of the isopropyl cation (naturally, this relates only to the gas phase).

It is difficult to interpret the observed large deshieldings and coupling-constant values in any way other than as a direct proof that (i) the central carbon atoms involved in the carbenium ion are sp^2-hybridized, and (ii) that,

Table 1. Characteristic NMR parameters of alkylcarbenium ions in SbF_5—SO_2ClF solution at −70 °C.

Ion	^{1}H-NMR (δ [ppm]) $CH^{\oplus}$	$J_{\oplus CH}$	$J_{\oplus CCH}$	α-CH_2	α-CH_3	β-CH_3	^{13}C-NMR (δ [ppm]) $C^{\oplus}$	α-CH_3

$H_3CC^{\oplus}(C_2H_5)_2$ (4)				4.44	4.16	1.87	−139.4	150.8

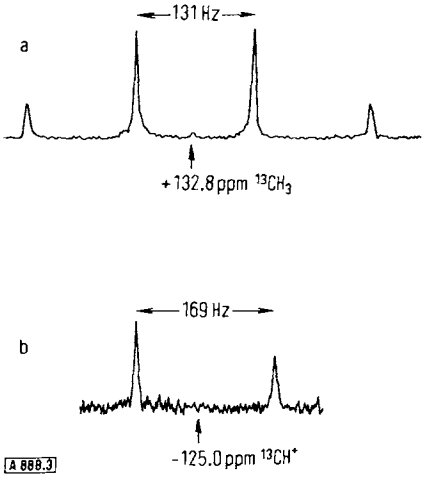

Fig. 3. 25-MHz ^{13}C-INDOR spectrum [30a] of the isopropyl cation. The spectra were obtained at −20 °C by monitoring the signal intensity of the ^{13}C satellites shown in Figure 2 while sweeping the irradiating frequency. The peaks observed are the result of splitting of the satellite due to "tickling" of connected ^{13}C transitions. Figure 3a shows the quartet corresponding to the methyl ^{13}C and Figure 3b the doublet from the methine ^{13}C. The latter spectrum was obtained from the low-field ^{13}C satellite in the proton spectrum. The low-field ^{13}C transition is connected regressively and the high-field ^{13}C transition connected progressively to this transition leading to the observed asymmetry of the ^{13}C-INDOR spectrum. This asymmetry is particularly apparent in C-INDOR spectra obtained using a low-amplitude "tickling" field.

The total shielding constant σ for a particular nucleus can be regarded as the sum of three terms

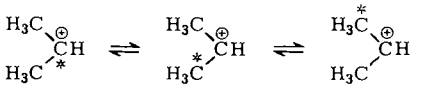
$$\sigma = \sigma_d + \sigma_p + \sigma'$$

where σ_d is the diamagnetic term, σ_p the paramagnetic term, and σ' the term arising from neighboring groups. For a carbon nucleus the dominant paramagnetic contribution is affected principally by charge polarization, variation in bond order, and the average excitation energy. The relative significance of each factor must be considered.

It is interesting to note that theoretical calculations indicate higher positive charge density on the carbenium center at the same time, the carbon atom carries a substantial positive charge.

Table 1 lists the parameters of the ^{1}H- and ^{13}C-NMR spectra of the cationic centers of a few secondary and tertiary carbenium ions. The main points to be noted are the downfield chemical shifts ($\delta_{^{13}C}$) which point to extensive positive character and the coupling constants (J_{CH}) indicative of sp^2-hybridization.

When the isopropyl cation was generated from 50%-labeled [2-^{13}C]-2-chloropropane by dissolution in SO_2ClF—SbF_5 at −60 °C, equilibration of the ^{13}C labeling occurred with a half-life of 1 hour; after several hours the ^{13}C labeling was distributed equally among the three carbons ("scrambling"). This observation suggests involvement of protonated cyclopropanes in the carbon scrambling process (see below). Similar scrambling was observed in the *sec*-butyl and *tert*-amyl cations (*Saunders*[31]).



2.1.4. Infrared and Raman Spectra

Infrared and Raman spectra of the stable alkylcarbenium ions were also recorded[25, 32] and are in complete agreement with the carbenium structure of the ions. The IR spectra of these ions and of their deuterated analogs correspond to the spectra predicted by calculations based on selected molecular models and force constants. Thus, vibrational spectra can also be used in the identification of stable carbenium ions.

Laser Raman spectroscopy is another powerful tool in the study of carbocations. Since Raman spectra give valuable information on symmetry, these spectra help to establish in detail the structures of the ions and their configurations. Raman spectroscopic data provide strong evidence,

for example, that the trimethylcarbenium ion in magic acid[29] prefers a conformation leading to overall C_{3v} point group symmetry (Table 2). Thus, the $\overset{+}{C}(CH_3)_3$ ion possesses a planar $C^+(C_3)$ carbon skeleton with one hydrogen atom of each CH_3 group above the plane of the carbon atoms. The other two hydrogen atoms are arranged symmetrically below this plane to the right and left of the C_3 axis. Raman spectra observed for the *tert*-amyl cation (dimethylethylcarbenium ion), the pentamethylethyl cation (dimethyl-*tert*-butylcarbenium ion), and the dimethylisopropylcarbenium ion also show similar structure (Fig. 4). Raman and IR spectroscopic studies thus provide, in addition to ^{13}C-NMR data, direct evidence for the planar (or near planar) carbenium center of alkylcarbenium ions.

Table 2. Raman and IR frequencies of the *tert*-butyl cation and [D_9]-*tert*-butyl cation and their correlation with those of $(CH_3)_3B$ and $(CD_3)_3B$.

	$\nu_1, \nu_{12}, \nu_7, \nu_{19}$	ν_2, ν_{13}	ν_{21}	ν_{14}	ν_{15}	ν_{17}	ν_5	ν_{16}	ν_6	ν_9	ν_{10}	ν_{18}
$(CH_3)_3C^{\oplus}$ (2)	2947	2850		1450		1295			667		347	306
$(CH_3)_3B$	2975	2875	1060	1440	1300	1150	906	866	675	973 (486?)	336 [a]	320
$(CD_3)C^{\oplus}$	2187	2090		1075		980			720		347	300
$(CD)_3B$	2230	2185		1033	1018	1205			620	870	(289) [b]	(276) [b]

[a] IR frequency.
[b] Calculated.

to condensation products or cyclic allylic ions and not to the simple alkylcarbenium ions[34].

2.1.6. ESCA Spectra

ESCA spectroscopy[35] is an extremely useful method for the investigation of carbocations[36]. Within such molecules the positive charge is generally unequally distributed over different atoms of the carbon skeleton. Consequently, the core electrons of these atoms are differently screened

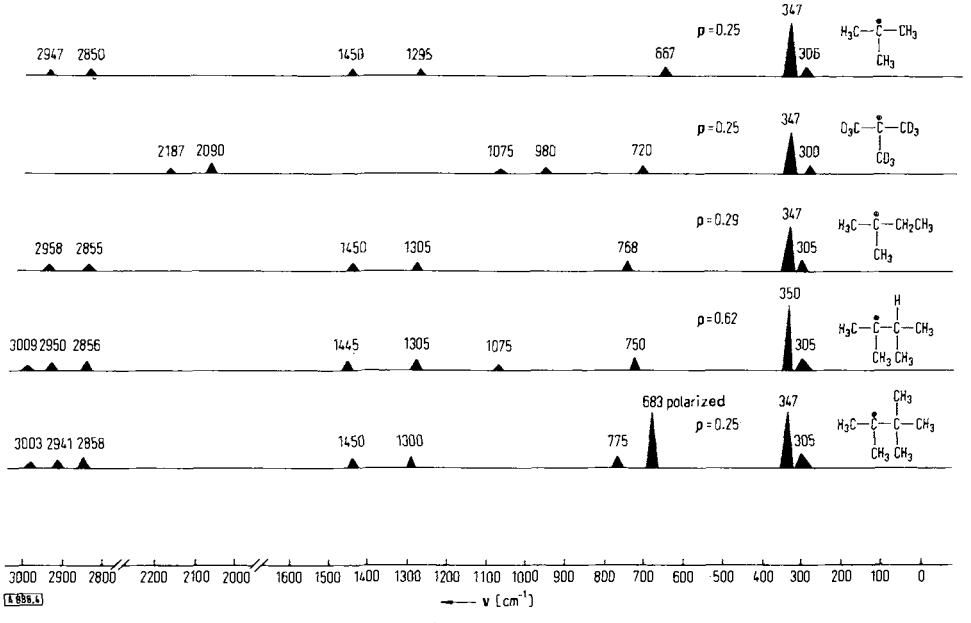

Fig. 4. Schematic representation of Raman spectra of alkyl cations

Evidence for planarity or near planarity of the sp^2 center of trivalent alkylcarbenium ions thus comes from the combined results of NMR (^{1}H and ^{13}C), IR, and Raman spectroscopy[30,32].

2.1.5. UV Spectra

The observation of stable alkylcarbenium ions in antimony pentafluoride and related superacid solutions also opened up the possibility of investigating the UV and visible spectra of such solutions. *Waack*, *Pittman*, and *I* reported[33] that solutions of alkylcarbenium ions in FSO_3H—SbF_5 solutions at −60 °C showed no absorption maxima above 210 nm. In view of this observation, it is highly probable that previous claims relating to a 290 nm absorption of alcohols and olefins in sulfuric acid solutions were due

and show increasing binding energies with increasing positive charge on the C atoms. With correspondingly large positive charge on the carbocationic center the energy differences are large enough to give rise to separate 1s-level photoelectron lines.

In contrast measurements of carbon 1s electron binding energies in several hydrocarbons yielded a rather narrow range of chemical shifts. For instance, one cannot distinguish between the carbon atoms of neopentane and those of benzene, for their 1s binding energies are virtually the same (290.4 eV). Ethane (290.6 eV), ethylene (290.7

eV), and acetylene (291.2 eV) carbon 1s binding energy differences are well below the presently attainable resolution with ESCA measurements.

These results are in agreement with theoretical expectations. Core electrons are barely affected unless their screening against nuclear attraction is modified by a significant change in the outer (valence) electron shell. In other words, core electron binding energies are mainly dependent on the formal charge of the corresponding atom and on the electronegativity of attached atoms or groups of atoms. The fact that such factors are minimal in hydrocarbons accounts for the small differences described above.

Since ESCA spectroscopy is a 'surface' method the recording of the spectra of the carbenium ions was carried out on frozen superacid solutions or on isolated salts; they were recorded at liquid nitrogen temperature[36].

The binding energies E_b (defined as differences between the Fermi level and the 1s atomic level energies) are given by the equation

$$E_b = E_{h\nu} = E_{kin} - \Phi_s$$

where $E_{h\nu}$ is the energy of the exciting radiation (*e.g.* $Al_{K\alpha}$ X-rays), E_{kin} is the measured kinetic energy of the photoejected electron, and Φ_s is the spectrometer work function (the energy necessary to bring the electron from the Fermi level to the free-electron level). The 1s-electron spectrum (ESCA spectrum) of the *tert*-butyl cation is shown in Figure 5.

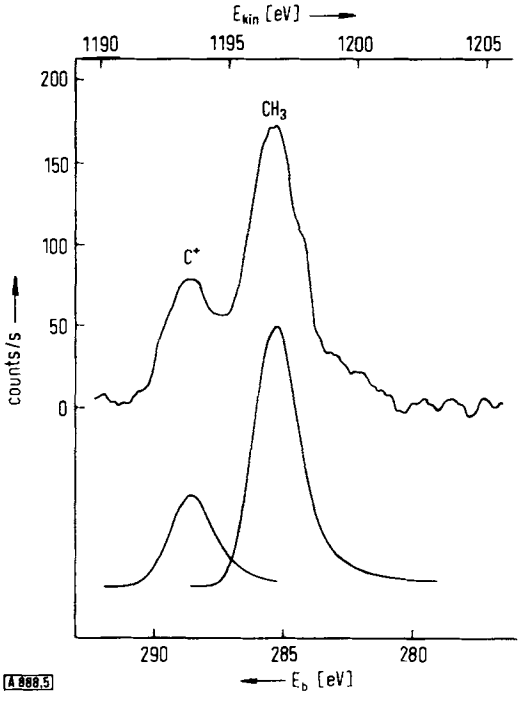

Fig. 5. Carbon 1s electron spectrum (ESCA) of the *tert*-butyl cation (*2*). E_b = binding energy, E_{kin} = kinetic energy.

The upper trace in Figure 5 exhibits two clearly separated peaks with a separation of $dE_{b+C-C} = 4 \pm 0.2$ eV. The lower trace represents the result given by a curve resolver. The peak area ratio is 1:3.

The experimentally determined carbon 1s binding energy difference between the carbenium ion center and the remaining three carbon atoms lies within the limit of that predicted by *ab initio* quantum mechanical calculations (4.45 eV). Comparable results were obtained in experiments carried out in collaboration with *Mateescu* on a series of other alkylcarbenium ions, such as the *tert*-amyl cation (*3*) ($dE_{b+C-C} = 4 \pm 0.2$ eV).

2.1.7. Preparation of Carbenium Ions from Other Precursors

Alkylcarbenium ions can be formed not only from halides (the earlier investigation of generation from alkyl fluorides was later extended to alkyl chlorides, bromides, and even iodides) but also from other precursors such as olefins in superacids like HF—SbF_5 and FSO_3H—SbF_5[37, 38].

$$RCH{=}CH_2 \xrightarrow[HF\text{-}SbF_5]{FSO_3H\text{-}SbF_5} \overset{\oplus}{R}CH\text{-}CH_3$$

Tertiary and reactive secondary alcohols in superacids like FSO_3H—SbF_5 (magic acid®[29])[34], FSO_3H, and SbF_5—SO_2—(SO_2ClF) also ionize to the corresponding stable carbenium ions[39]. The generation of alkylcarbenium ions from alcohols indicates the great advantages of increasing acidity and of using acid systems with low freezing points. *Deno*[23] showed that the use of sulfuric acid and oleum results in formation of cyclized allylic ions from simple aliphatic alcohols. If the extremely strong acid FSO_3H—SbF_5 ("magic acid"®) is used these alcohols can be ionized to the corresponding tertiary and secondary alkylcarbenium ions without further rearrangements taking place.

$$(CH_3)_3C\text{-}OH \xrightarrow[-H_2O]{FSO_3H\text{-}SbF_5} (CH_3)_3C^{\oplus}$$

Primary and less reactive secondary alcohols are protonated in FSO_3H—SbF_5 solution at low temperatures (−60 °C) and show very slow or no proton exchange with the superacid[40].

$$H_3C\text{-}CH_2\text{-}CH_2OH \underset{-H^{\oplus}}{\overset{+H^{\oplus}}{\rightleftharpoons}} H_3C\text{-}CH_2\text{-}\overset{\oplus}{C}H_2OH_2$$

$$H_3C\text{-}\underset{OH}{CH}\text{-}CH_3 \underset{-H^{\oplus}}{\overset{+H^{\oplus}}{\rightleftharpoons}} H_3C\text{-}\underset{\oplus OH_2}{CH}\text{-}CH_3$$

Temperature-dependence studies of the NMR spectra allow the kinetics of dehydration of protonated alcohols to the corresponding carbenium ions to be followed[41].

$$H_3C\text{-}CH_2\text{-}CH_2\text{-}CH_2OH \xrightarrow[-60\,^{\circ}C]{FSO_3H\text{-}SbF_5\text{-}SO_2} H_3C\text{-}CH_2\text{-}CH_2\text{-}\overset{\oplus}{C}H_2OH_2$$

$$\xrightarrow{\Delta,\ H^{\oplus}\ /\ -H_3O^{\oplus}} [H_3C\text{-}CH_2\text{-}CH_2\text{-}CH_2^{\oplus}] \rightarrow (CH_3)_3C^{\oplus}$$

Antimony pentafluoride itself (neat or in SO_2 or SO_2ClF solution) ionizes alcohols smoothly to alkylcarbenium ions.

$$R{-}OH \xrightarrow{SbF_5} R^{\oplus}SbF_5OH^{\ominus}$$

We have found that difficulties in the ionization of primary (and less reactive secondary) alcohols at low temperatures can be overcome, in some cases, if the alcohols are first converted with thionyl halides or carbonyl halides into the corresponding haloformates *(5)* or halosulfites *(6)*, which then readily ionize in SbF_5—SO_2 solution and lose CO_2 or SO_2 (fragmentation ionization)[37,42].

$$ROH \xrightarrow{COX_2} \underset{(5)}{RO{-}\overset{\overset{O}{\|}}{C}{-}X} \xrightarrow{SbF_5\text{-}SO_2} R^{\oplus}SbF_5X^{\ominus} + CO_2$$

$$ROH \xrightarrow{SOX_2} \underset{(6)}{RO{-}\overset{\overset{O}{\|}}{S}{-}X} \xrightarrow{SbF_5\text{-}SO_2} R^{\oplus}SbF_5X^{\ominus} + SO_2 \qquad X = Cl, F$$

Aliphatic ethers such as *(7)* are protonated in strong acids, and subsequently cleaved (at higher temperatures) to alkylcarbenium ions[43].

$$\underset{(7)}{H_3C{-}O{-}CH_2{-}CH_2{-}CH_2{-}CH_3} \xrightarrow[-60\,^{\circ}C]{FSO_3H\text{-}SbF_5} H_3C{-}\overset{\overset{\oplus}{H}}{\underset{|}{O}}{-}CH_2{-}CH_2{-}CH_2{-}CH_3 \xrightarrow[H^{\oplus}]{\Delta} H_3C\overset{\oplus}{O}H_2 + [H_3C{-}CH_2{-}CH_2{-}CH_2^{\oplus}] \longrightarrow (CH_3)_3C^{\oplus}$$

The protonation and subsequent ionization of mercaptans (thiols) and sulfides have been studied in a similar way[44].

Superacids such as FSO_3H—SbF_5 act as very effective hydrogen abstracting agents, allowing the generation of carbocations from saturated hydrocarbons[45].

$$H_3C{-}\underset{\underset{CH_3}{|}}{CH}{-}CH_3 \xrightarrow[SO_2ClF]{FSO_3H\text{-}SbF_5} (CH_3)_3\overset{\oplus}{C} + H_2$$

Antimony pentafluoride itself (without addition of FSO_3H or HF) also ionizes alkanes to the corresponding alkylcarbenium ions. Since SbF_5 always contains traces of HF, however, it is questionable whether the reaction is effected by the Lewis acid itself.

Carbenium ions can also be generated by decarbonylation of *tert*-alkyloxocarbenium ions, such as the *tert*-butyloxocarbenium ion (pivaloyl cation) *(8)*[26].

$$(CH_3)_3CCOF + SbF_5 \rightleftharpoons \underset{(8)}{(CH_3)_3CCO^{\oplus}SbF_6^{\ominus}} \overset{\Delta}{\rightleftharpoons} (CH_3)_3C^{\oplus}SbF_5^{\ominus} + CO$$

This reaction corresponds to the reverse of the Koch-Haaf acid synthesis, which is known to involve reaction of carbenium ions with carbon monoxide. Indeed, the pivaloyl cation can be obtained by reaction of the tertiary butyl cation with carbon monoxide[26,46].

Thiols and thioesters (sulfides), like their oxygen analogs, can also be used as starting substances for preparation of alkylcarbenium ions[47]; their ionization in superacids generally necessitates more forcing conditions (higher temperatures). *S*-Alkyl halothioformates *(9)* also form carbenium ions *via* fragmentation ionization[48].

$$RSH \xrightarrow[HF\text{-}SbF_5,\ FSO_3H\text{-}SbF_5]{SbF_5 \text{ or}} R^{\oplus}SbF_5SH^{\ominus}$$

$$\underset{(9)}{RS{-}\overset{\overset{O}{\|}}{C}{-}Cl(F)} \xrightarrow{SbF_5\text{-}SO_2ClF} R^{\oplus}SbF_5Cl^{\ominus}(F) + COS$$

Amines also can be used as precursors for the generation of alkylcarbenium ions. The classical method of deaminative formation of carbenium ions involves some type of diazotization reaction producing an equimolar amount of water.

$$RNH_2 \xrightarrow[-H_2O]{HNO_2} [RN_2^{\oplus}] \longrightarrow R^{\oplus} + N_2$$

This difficulty can be overcome by first converting the amine into the corresponding sulfinylamine *(10)* or isocyanate *(11)*, which is then reacted with stable nitrosyl (NO^+) salts to give the related carbenium ion with evolution of N_2 and SO_2 (or CO_2) instead of water[49].

$$RNH_2 \xrightarrow{SOCl_2} \underset{(10)}{RNSO} + NO^{\oplus}SbF_6^{\ominus} \longrightarrow R^{\oplus}SbF_6^{\ominus} + N_2 + SO_2$$

$$RNH_2 \xrightarrow{COCl_2} \underset{(11)}{RNCO} + NO^{\oplus}SbF_6^{\ominus} \longrightarrow R^{\oplus}SbF_6^{\ominus} + N_2 + CO_2$$

2.1.8. Preparation of Alkylcarbenium Ions in Superacids Not Containing Antimony Pentafluoride

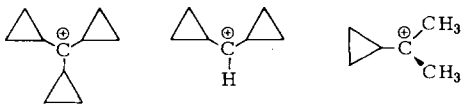
Whereas superacids (such as HF—SbF_5, FSO_3H—SbF_5, CF_3SO_3H—SbF_5 *etc.*) containing antimony pentafluoride are the preferred solvents for obtaining stable alkylcarbenium ions, other superacids such as HF—BF_3, HF—TaF_5 or fluorosulfuric acid can, on occasions, also be used successfully. The stability of carbocations—with exception of tertiary ions—in these solvents is, however, generally lower.

2.2. Cyclopropylcarbenium Ions

Solvolysis studies carried out by *Roberts*[50] and *Hart*[51] showed both the unusual stability of cyclopropylcarbenium ions and the facility with which such ions rearrange.

Cyclopropyl groups bound to the carbocation center have a strong stabilizing effect and effectively delocalize charge. The direct observation of cyclopropylcarbenium ions by NMR spectroscopy provides clear indication of charge delocalization.

The first cyclopropylcarbenium ion observed directly was the tricyclopropylcarbenium ion *(12)*[52]. Its NMR spectrum in H_2SO_4 consists of a single sharp line at $\delta = 2.26$. In the 300 MHz spectrum of a solution in SbF_5—SO_2ClF, however, the signals of the methine and methylene cyclopropyl protons are well resolved[53] (Fig. 6a).



(12) *(13)* *(14)*

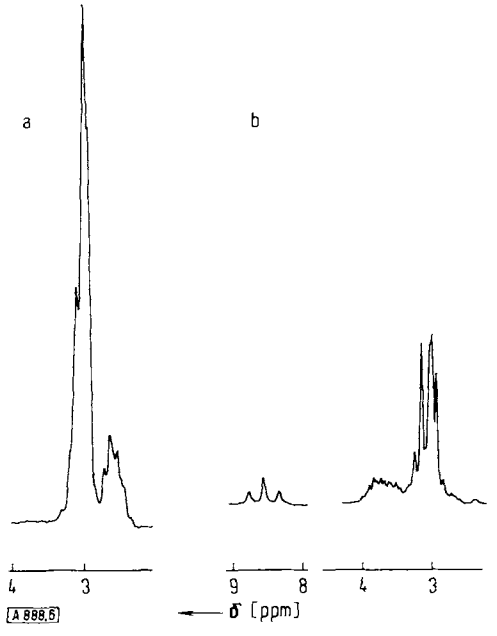


Fig. 6. a) 300-MHz ^{1}H-NMR spectrum of the tricyclopropylcarbenium ion *(12)*; b) 60-MHz ^{1}H-NMR spectrum of the dicyclopropylcarbenium ion *(13)*.

Pittman[54] and *I* have observed several tertiary and secondary cyclopropylcarbenium ions, such as the dicyclopropylcarbenium ion *(13)* (Fig. 6b). The solvent used was usually SbF_5—SO_2 or FSO_3H—SbF_5—SO_2. The ring protons are resolved in the NMR spectrum of each of these ions. Most interesting of these ions is the dimethylcyclopropylcarbenium ion *(14)* (Fig. 7). The two methyl groups are non-equivalent and are separated by 0.54 ppm. Since in uncharged systems the hydrogens lying in the face of the cyclopropane ring experience an upfield shift of 0.3 to 0.5 ppm, we concluded that the cyclopropane ring lies in a plane perpendicular to the plane of the dimethylcarbenium ion center (bisected form).

The plane of the cyclopropane ring lies parallel to the axis of the vacant p orbital of the carbenium carbon atom. In this configuration, one methyl group is *cis* to the cyclopropane ring and the other is *trans*. The *cis* methyl group now experiences the diamagnetic anisotropy of the cyclopropane ring; this accounts for its observed position 0.54 ppm upfield from the *trans* methyl group. The methyl bands do not coalesce at $-30\,^\circ C$, at which temperature

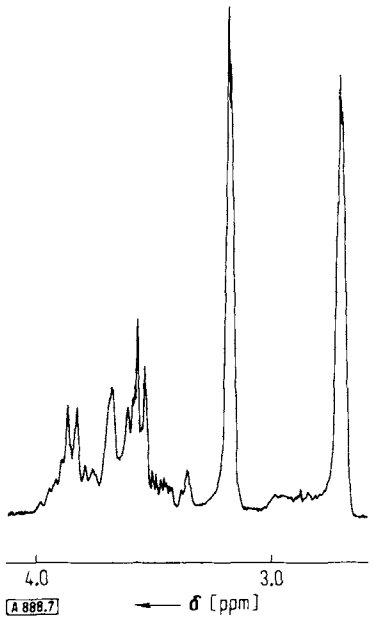

Fig. 7. 100-MHz ^{1}H-NMR spectrum of the dimethylcyclopropylcarbenium ion *(14)*.

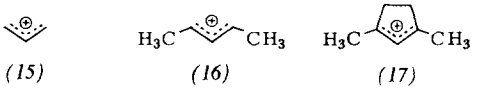
ring opening takes place in FSO_3H—SbF_5 solution and the ion undergoes subsequent decomposition reactions. This shows that the cyclopropane ring does not rotate at this temperature, and that the rotational barrier is at least 10 kilocalories per mol. Recently, *Kabakoff* and *Namanworth*[54a] succeeded, using double resonance experiments, in determining the barrier as 13.7 kcal/mol (in SbF_5—SO_2ClF).

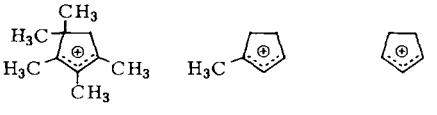
In contrast to the "classical" tertiary and secondary cyclopropylcarbenium ions *(12)*—*(14)* (showing of course substantial charge delocalization over the cyclopropane ring but maintaining the identity of the trivalent ions), primary cyclopropylmethyl cations show entirely different non-classical carbonium ion character (see Section 3).

2.3. Alkenyl Cations

A large number of alkenyl cations has been directly observed, particularly by *Deno* and *Richey*[23,55], *Sorensen*[56], and *Olah*[57] and their co-workers. *Deno* reviewed the chemistry of these ions[23] and the number of known examples has since then increased substantially. Cations of the allylic type are particularly stable. Representative examples which have been observed are the ions *(15)* to *(25)*.



(15) *(16)* *(17)*

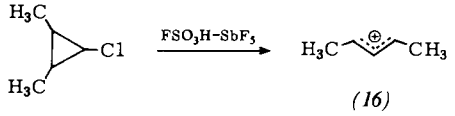


(18) *(19)* *(20)*

(21) (22)

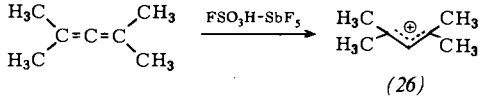
(23) (24) (25)

The opening of halocyclopropanes with the formation of allyl cations such as *(16)* has also been investigated[58-61].



(16)

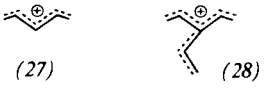
Protonation of certain allenes also leads to allyl cations which are otherwise difficult to obtain from allylic precursors[62,63].



(26)

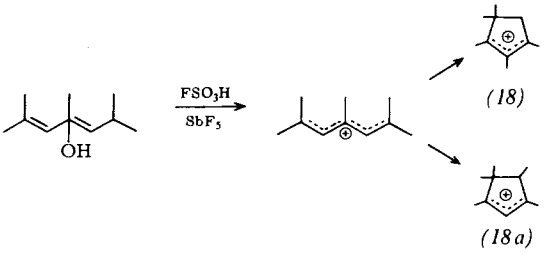
2.4. Alkadienyl and Polyenyl Cations

Deno, *Richey*, and their co-workers[23] have investigated a substantial number of alkadienyl and polyenylic cations. *Sorensen*[64] has reported the observation of the divinyl- *(27)* and trivinylcarbonium ions *(28)*.



(27) (28)

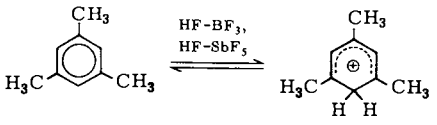
Alkenyl cations show a substantial tendency to cyclize to the more stable cyclic allylic ions such as *(18)* and its isomers *(18a)*. *Pittman*, *Sorensen*, and *I* were able to follow these cyclizations by NMR spectroscopy[65].



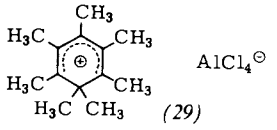
(18) (18a)

2.5. Arenium Ions

Cycloalkadienyl cations, particularly cyclohexadienyl cations (benzenium ions), show remarkable stability. They can be obtained by protonation of aromatic hydrocarbons by strong acids[66-68] and studied advantageously by ^{1}H- or ^{13}C-NMR spectroscopy[69].

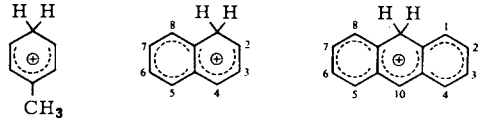


Doering and *Saunders* described the very stable heptamethylbenzenium ion *(29)*[70].



(29)

Figures 8, 9, and 10 show the ^{1}H-NMR spectra of the *p*-toluenium ion *(30)*[69], the naphthalenium ion *(31)*[71] and the anthracenium ion *(32)*[72] as representative examples of arenium ions (which are also of importance as intermediates, usually called σ-complexes, in electrophilic aromatic substitutions).



(30) (31) (32)

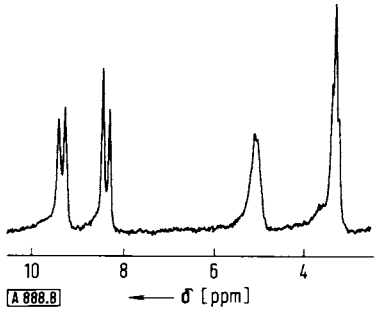


Fig. 8. 60-MHz ^{1}H-NMR spectrum of the *p*-toluenium ion *(30)* at −97 °C.

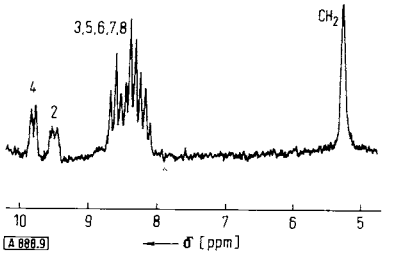

Fig. 9. 100-MHz ^{1}H-NMR spectrum of the naphthalenium ion *(31)* at −90 °C.

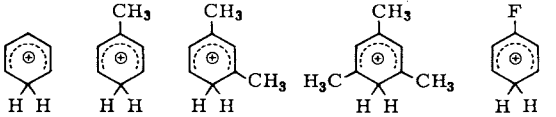
Even the parent benzenium ion ($C_6H_7^+$) *(33)* has been observed[73], as have also the isomeric monoalkylbenzenium ions[71,74] and most di-, tri-, tetra- and pentaalkyl



(33) (30) (34) (35) (36)

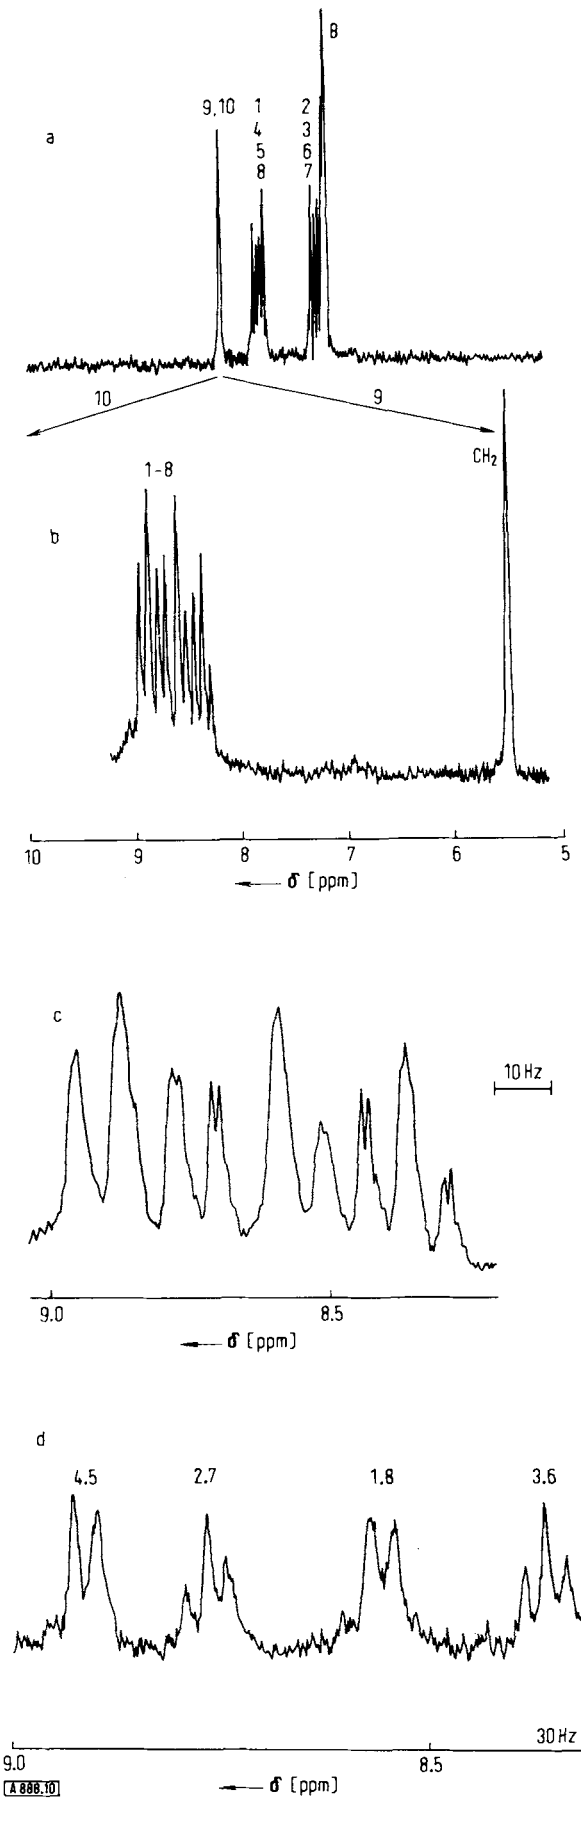


Fig. 10. (a) 100-MHz ^{1}H-NMR spectrum (−55°C) of anthracene in C_6D_6 and (b) of the anthracenium ion *(32)*, B = C_6H_6; (c) part of (b); (d) first order pattern of the 300-MHz ^{1}H-NMR spectrum of the anthracenium ion.

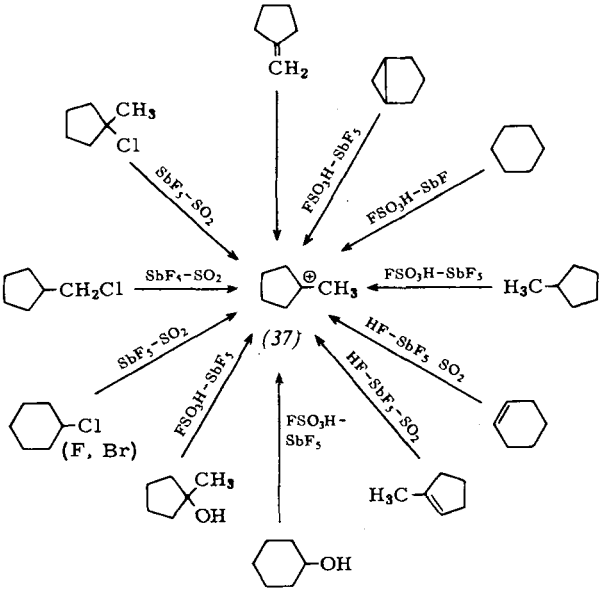
and halobenzenium ions[74]. Some representative ions are *(34)*—*(36)*.

2.6. Cycloalkyl Cations

Tertiary cycloalkyl cations, like the 1-methyl-1-cyclopentyl cation *(37)*, show high stability in superacid solutions. The ion *(37)* can be obtained from a variety of starting substances[75].



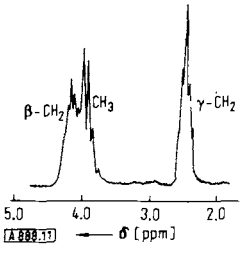


Fig. 11. 60-MHz ^{1}H-NMR spectrum of the 1-methyl-1-cyclopentyl cation *(37)* at −60°C.

It is worthwhile mentioning that not only cyclopentyl but also cyclohexyl compounds give the 1-methyl-1-cyclopentyl cation. This indicates that the tertiary methylcyclopentyl cation is more stable than the secondary cyclohexyl cation, from which it is formed by isomerization.

The cyclopentyl cation shows in its proton magnetic resonance spectrum in SbF_5—SO_2ClF solution, even at 100°C, only a single absorption line at $\delta = 4.68$[38,73]. This observation indicates a completely degenerate ion in which there are only low energy barriers to the consecutive secondary-secondary hydrogen shifts (see below).

The secondary cyclobutyl cation undergoes immediate rearrangement *via* σ-bond delocalization into the equilibrating non-classical cyclopropylmethyl ion system[76] (see Section 3.4). Similar behavior is also observed with the 1-methylcyclobutyl cation. The 1-phenylcyclobutyl cation *(38)* (Fig. 12) on the other hand is a classical tertiary carbenium ion[76].

(38)

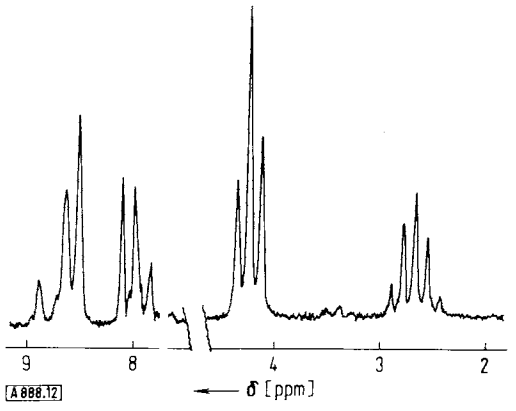

Fig. 12. 60-MHz ^{1}F-NMR spectrum of the 1-phenyl-1-cyclobutyl cation *(38)* at −65°C.

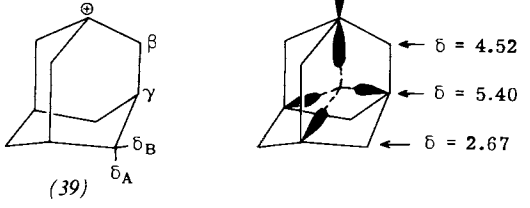
2.7. Bridgehead Carbenium Ions

Bredt's rule in ts original form[77] seems to exclude the possibility of fo mation of positive carbenium ion centers at bridgehead carbon atoms of bicycloalkanes. Indeed, bridgehead halides, such as apocamphyl chloride, proved extremely unreactive under solvolytic conditions[78]. However, 1-bromoadamantane very readily gives the bridgehead carboxylic acid under the usual conditions of the Koch-Haaf acid synthesis[79]. 1-Fluoroadamantane is ionized in SbF_5 to give the stable bridgehead 1-adamantyl cation *(39)*[80,81].



(39)

The ^{1}H-NMR spectrum of the adamantyl cation *(39)* in SbF_5 solution consists of resonances at $\delta = 5.42$, $\delta = 4.50$ and $\delta = 2.67$ with peak areas of 3:6:6. The γ-CH hydrogens are more deshielded, *i.e.* have their resonance at a lower field, than those of the three β-CH_2 groups even though they are farther from the positive carbon. This could be explained by a "cage effect", *i.e.* the lobe of the empty p-orbital overlapping with the backlobes of the three bridgehead C—H bonds, causing their deshielding, or by σ-π hyperconjugation.

A similar effect is indicated in the ^{13}C-NMR spectrum of the 1-adamantyl cation (Fig. 13).

Mateescu, Sipos, Schleyer, and *I* have also observed a series of methyladamantyl cations[81]. The bridgehead "congressane" (diadamantane) cation has also been observed recently[75,81]; it likewise shows the cation cage effect. Although the bridgehead 1-norbornyl cation could not be observed directly, the stable 2-norbornyl cation can be obtained from 1-chloronorbornane in SbF_5—SO_2

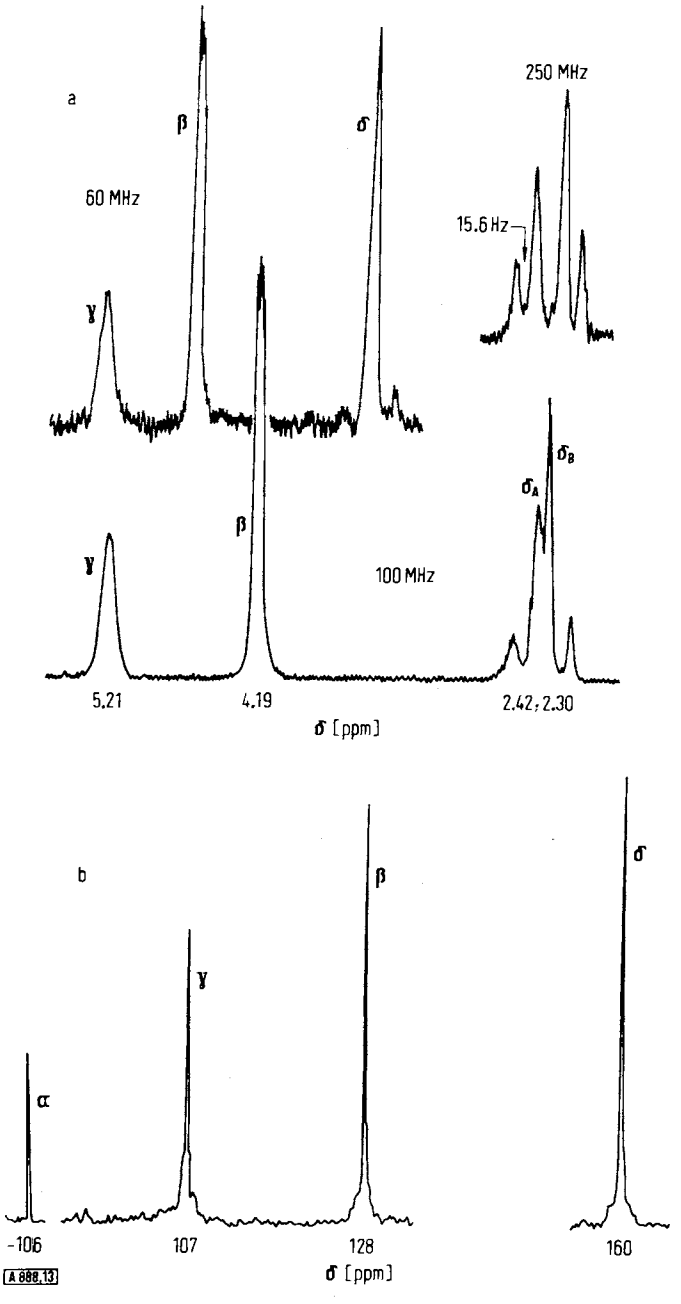


Fig. 13. a) ^{1}H-NMR spectrum of the 1-adamantyl cation at 60 MHz, 100 MHz, and 250 MHz; b) Fourier-transform ^{13}C-NMR of the 1-adamantyl cation (in FSO_3H—SbF_5).

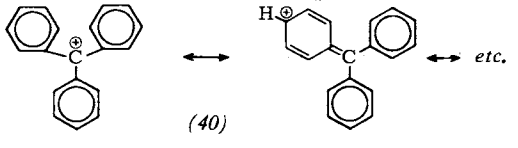
solution[82]. Thus, ionization to the bridgehead carbenium ion must be followed by a fast shift of hydrogen from C-2 to C-1, the driving force for which is obviously the tendency to relieve strain in the carbenium ion.

2.8. Aryl and Alkylarylcarbenium Ions

The first stable long-lived carbenium ion to be observed was the triphenylcarbenium ion *(40)*[83–85] (Fig. 14a).



(40)

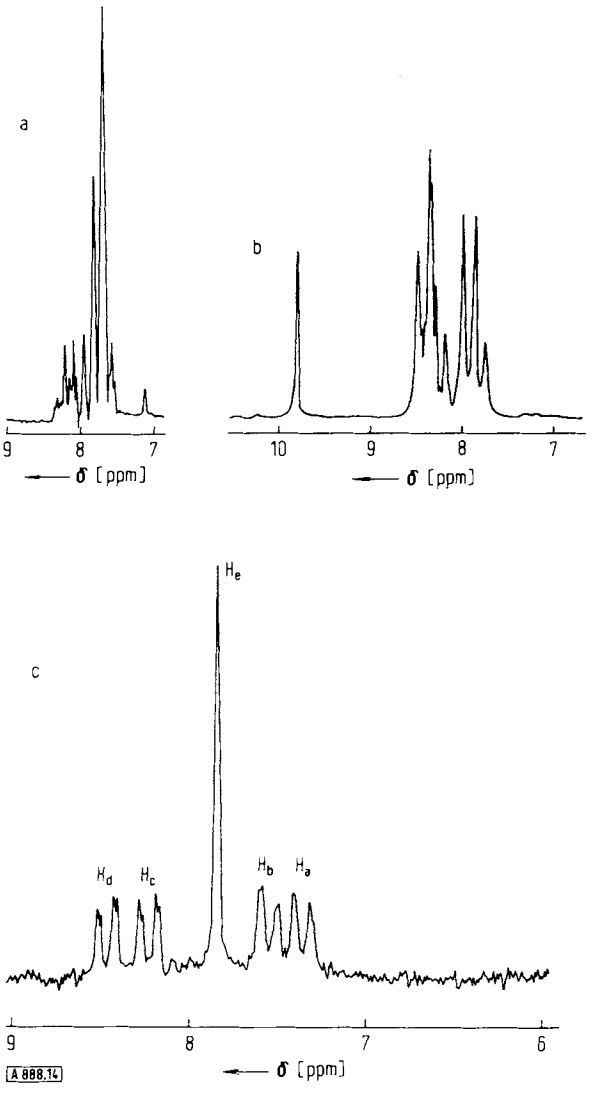


Fig. 14. a) 60-MHz ^{1}H-NMR spectrum of the triphenylcarbenium ion *(40)* (trityl cation); b) 60-MHz ^{1}H-NMR spectrum of the diphenylcarbenium ion *(41)* (benzhydryl cation); c) 100-MHz ^{1}H-NMR spectrum of the 4-methoxyphenylcarbenium ion (*p*-methoxybenzyl cation).

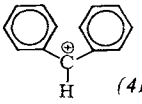
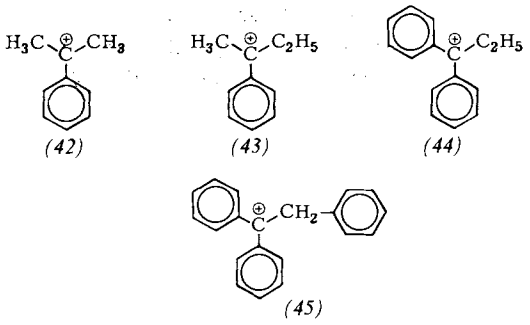
This ion remains the most-investigated carbocation[2] and its propeller-shaped structure has been established beyond doubt. Strong contribution from *para* (and *ortho*) quinonoidal resonance forms in the ion make it probable that these reactive secondary forms contribute strongly to the reactivity of the ion. Diphenylcarbenium ions (benzhydryl cations) are considerably less stable than their tertiary analogs. Although their ultraviolet spectra have been obtained in dilute sulfuric acid solutions[86] the benzhydryl ion *(41)* has only recently been observed in higher concentrations in acid solutions ($ClSO_3H$[87], FSO_3H[88], and FSO_3H—SbF_5[89]) (Fig. 14b).



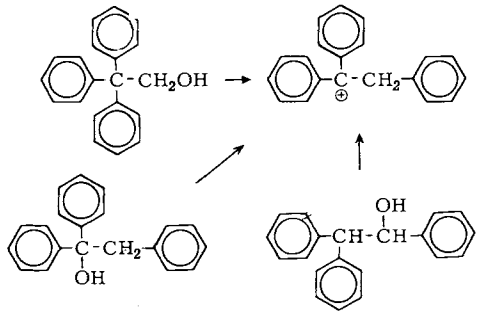
(41)

Solutions of mono- and dialkylarylcarbenium ions can be readily obtained from the corresponding alcohols, olefins, or halides in strong acid media such as H_2SO_4[86], FSO_3H—SbF_5[89], $ClSO_3H$ and FSO_3H[87], and oleum[88]. Representative examples of the cations are *(42)*—*(45)*.

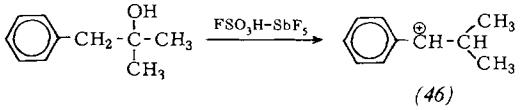


(42) *(43)* *(44)* *(45)*

Because of the high stability of the tertiary ions, these are preferentially formed in the strong acid systems from both tertiary, secondary, and even primary precursors[90].

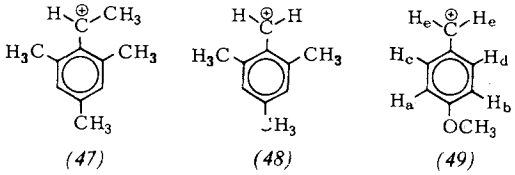


Non-benzylic, tertiary arylalkylcarbenium ions, on the other hand, rearrange to secondary, benzylic ions such as *(46)*.



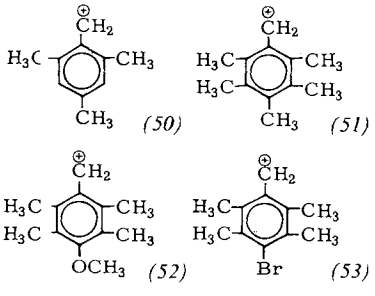
(46)

Suitable substituent groups (which also prevent transalkylations) stabilize even secondary [*e.g. (47)*] and primary benzyl cations [*e.g. (48)*[91,92] and the *p*-methoxybenzyl cation, Fig. 14c].



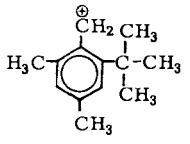
(47) *(48)* *(49)*

The observation of benzyl cations in superacid solutions was only recently achieved[91]. Although the unsubstituted benzyl cation is still elusive, we have observed a number of substituted derivatives such as *(50)*—*(53)*.



(50) *(51)* *(52)* *(53)*

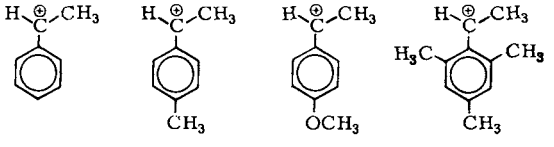
As NMR studies have shown, in benzyl cations like 2,4-dimethyl-6-*tert*-butylphenylcarbenium ion *(54)* a high rotational barrier is observed around the $H_2^+C—C_1$ bond.



(54)

This means that the methylene protons are magnetically non-equivalent[92]. Rearrangement of benzyl cations to tropylium ions, which is claimed to take place in the gas phase (mass spectroscopic measurements) has not been observed in acid solution.

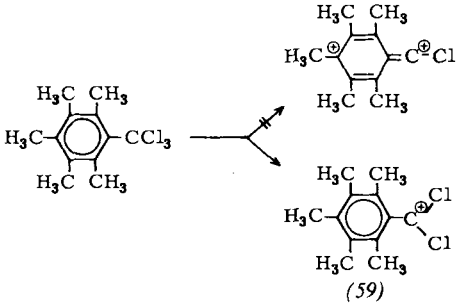
The styryl cation (methylphenylcarbenium ion) *(55)*[93] and a number of substituted methylphenylcarbenium ions *(56)*—*(58)*[85] have also been observed.



(55) *(56)* *(57)* *(58)*

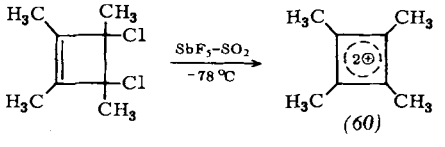
2.9. Dicarbenium Ions

Earlier reports[94] that a dicarbenium ion had been obtained from pentamethyltrichloromethylbenzene have turned out to be incorrect. The species in question is the benzylic dichloropentamethylphenylcarbenium ion *(59)*[95–97].



(59)

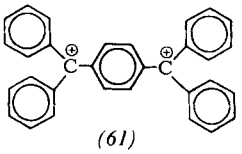
The 1,2,3,4-tetraphenylcyclobutadiene dication has also been reported[98]. However, there is evidence that the ion actually observed was only an equilibrating cyclobutenyl monocation. X-ray crystallographic investigation of the isolated crystalline complex confirm this conclusion[99].



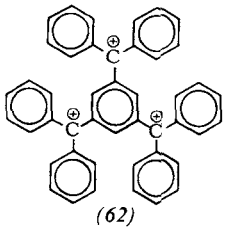
(60)

Recently *Bollinger*, *White*, and *I* succeeded in obtaining the 1,2,3,4-tetramethylcyclobutadiene dication *(60)*[100] and with *Mateescu* we obtained the *bona fide* tetraphenylcyclobutadiene dication[101]. ^1H and ^{13}C nuclear magnetic resonance studies confirmed its structure and the 2π electron aromatic nature, which is similar to the cyclopropenium cations previously prepared by *Breslow*[102].

Hart and *Volz* have shown that if two carbenium centers are separated by a phenyl ring, then a wide variety of di- and tricarbenium ions such as *(61)* and *(62)* can be obtained[103, 104].

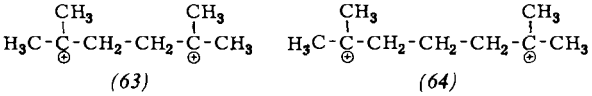


(61)



(62)

We have also prepared simple alkyldicarbenium ions[105], in which the two carbenium ion centers are separated by two or three methylene groups. These ions [*(63)* and *(64)*, Fig. 15] are stable entities in the strongly acidic solvent system ($SbF_5—SO_2$) at low temperature (−60 °C).



(63) *(64)*

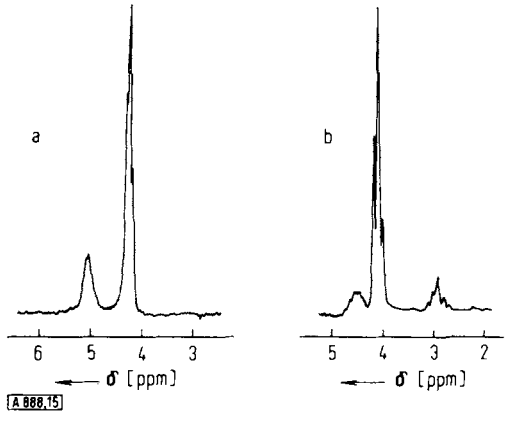


Fig. 15. 60-MHz ^1H-NMR spectra of the alkyldicarbenium ions, a) *(63)* and b) *(64)*.

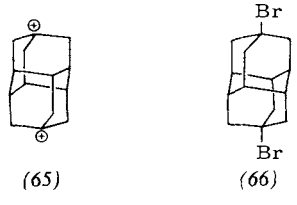
Dicarbenium ions have also been observed in more rigid cage systems, such as the apical,apical diadamantane dication *(65)*[81] (Fig. 16).



(65) *(66)*

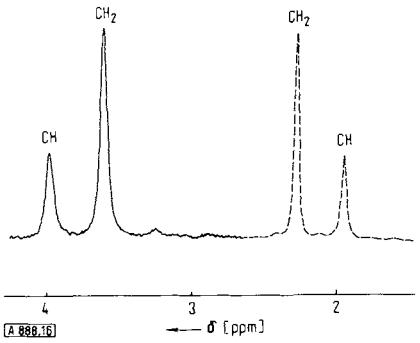


Fig. 16. 100-MHz ^{1}H-NMR spectrum of the apical,apical diadamantane dication *(65)* (———) and the precursor dibromoadamantane *(66)* (– – –).

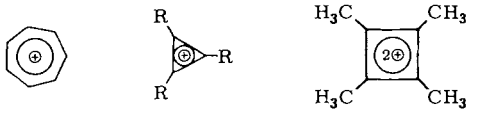
2.10. Aromatically Stabilized Carbenium Ions

If a carbenium ion is also a Hückeloid aromatic system, resonance causes substantial stabilization. The best known examples of aromatically stabilized carbenium ions are the cycloheptatrienyl cations *(67)* (tropylium ions)[106–108], cyclopropenium ions[102], and the tetramethyl- and tetraphenylcyclobutenium dications[100, 101].



(67) *(68)* *(60)*

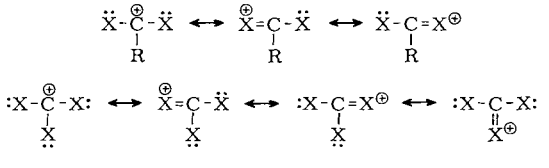
Because of their aromatic character, these ions are highly stable. Other examples of aromatically stabilized carbenium ions are also known.

2.11. Heteroatom-Stabilized Carbenium Ions

In contrast to hydrocarbon cations, heteroatom-substituted carbenium ions are strongly stabilized by electron donation from the non-bonded electron pairs of the heteroatoms adjacent to the cationic carbon center:

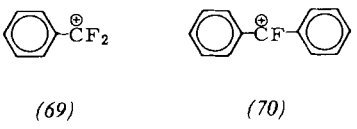
$R_2\overset{\oplus}{C}-\ddot{X} \leftrightarrow R_2C=X^{\oplus}$ X = Br, O, N, S, F, Cl

The stabilizing effect is enhanced when two, or even three, electron-donating heteroatoms coordinate with the electron-deficient carbon atom.



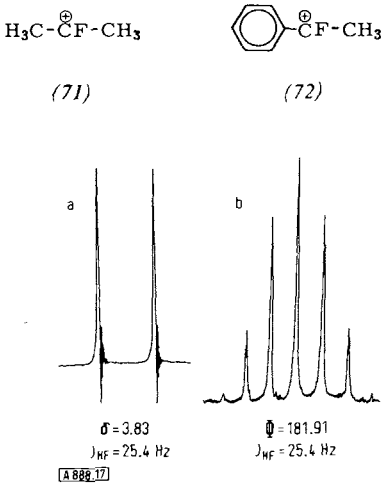
2.12. Halogen as Heteroatom

In 1965, *Cupas, Comisarow*, and *I* reported the first fluorocarbenium ions[109], the phenyldifluorocarbenium ion *(69)* and the diphenylfluorocarbenium ion *(70)*.



(69) *(70)*

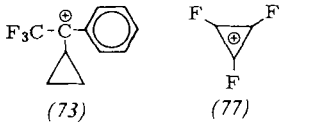
Fluorine has a particular ability to stabilize carbenium ions *via* back-coordination of its unshared electron pairs into the vacant p orbital of the carbon atom. Since ^{19}F magnetic resonance offers an excellent possibility for structural investigations of these ions, extensive work was initiated[110] in this regard. The dimethyl- *(71)* and phenylmethylfluorocarbenium ions *(72)* were *inter alia* prepared and thoroughly investigated[111].



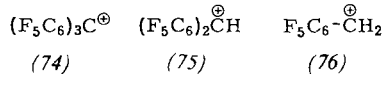
(71) *(72)*

Fig. 17. a) ^{1}H-NMR spectrum of the dimethylfluorocarbenium ion *(71)* at 60 MHz: J_{HF} = 25.4 Hz; b) ^{19}F-NMR spectrum of the same ion at 56.4 MHz: J_{HF} = 25.4 Hz.

Trifluoromethylcarbenium ions such as *(73)*[112] and perfluorophenylcarbenium ions *(74)*—*(76)*[113, 114] have also been investigated. The trifluorocyclopropenium ion *(77)*[115] is also known.



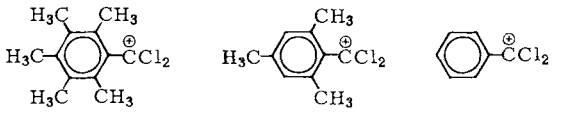
(73) *(77)*



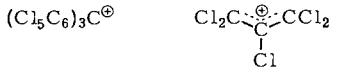
(74) *(75)* *(76)*

Because of the relatively large fluorine resonance shifts, anisotropy and ring current effects play a relatively much smaller role in ^{19}F-NMR spectroscopy than they do in the case of proton resonance. Therefore, as is also true of ^{13}C-NMR spectroscopy, a better correlation between charge distribution and chemical shifts can be obtained than with ^{1}H-NMR spectra.

A series of chlorocarbenium ions, including phenyldichlorocarbenium ions such as *(59)*, *(78)* and *(79)*[95–97, 116] and the perchlorotriphenylcarbenium ion *(80)*[117] *(Ballester)* have also been described. *West* observed the perchloroallyl cation *(81)*[118].

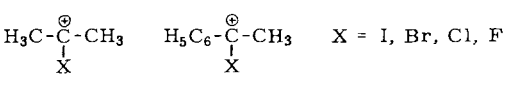


(59) (78) (79)



(80) (81)

Comisarow and *I* observed[119] a series of chloro-, as well as bromo- and iodocarbenium ions, and showed the general stabilizing ability of halogen attached to carbenium ion centers. [See also the fluoro compounds *(71)* and *(72)*.] *Halpern, Mo,* and *I* were subsequently able to study these effects in more detail using ^{13}C-NMR spectroscopy[120].



Closely related to the halocarbenium ions are the halonium ions in which the positive charge is to be found predominantly on the halogen atom. In our work with *Bollinger*[121] and *Peterson*[122], we reported on the three- and five-membered halonium ions of the type *(82)* and *(83)*.

(82) (83) (82a)

X = I, Br, Cl

R = H or Alkyl

Illustrative is the ^{1}H-NMR spectrum of propylenebromonium ion *(82a)* shown in Fig. 18.

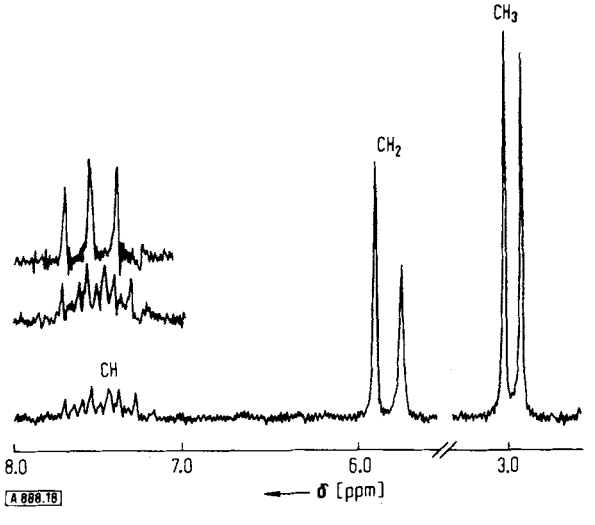


Fig. 18. ^{1}H-NMR spectrum (at 60 MHz) of the propylenebromonium ion *(82a)*. Left: Signal of the methine protons, decoupled.

In our work with *DeMember*[123] we were able to obtain not only ring halonium ions, but also a series of open-chain dialkylhalonium ions such as:

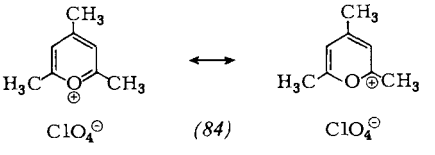
$[H_3C{-}I{-}CH_3]^{\oplus}$	$[[(CH_3)_2CH]_2Br]^{\oplus}$	$[H_3C{-}I{-}C_2H_5]^{\oplus}$
$[H_3C{-}Br{-}CH_3]^{\oplus}$	$[[(CH_3)_2CH]_2Cl]^{\oplus}$	$[H_3C{-}Br{-}C_2H_5]^{\oplus}$
$[H_3C{-}Cl{-}CH_3]^{\oplus}$	$[[(CH_3)_2CH]_2I]^{\oplus}$	$[H_3C{-}Cl{-}C_2H_5]^{\oplus}$
$[(C_2H_5)_2Br]^{\oplus}$	$[(n\text{-}C_3H_7)_2I]^{\oplus}$	$[CH_3{-}Cl{-}CH(CH_3)_2]^{\oplus}$
$[(C_2H_5)_2Cl]^{\oplus}$	$[(n\text{-}C_3H_7)_2Br]^{\oplus}$	
$[(C_2H_5)_2I]^{\oplus}$		

Dialkylhalonium fluoroantimonate salts can be isolated; they are versatile, very reactive alkylating agents, surpassing in many cases the selectivity and utility of *Meerwein*'s trialkyloxonium salts.

2.13. Oxygen as Heteroatom

Crystalline addition compounds of alcohols, ethers, aldehydes, and ketones with Brønsted and Lewis acids have been known since the middle of the last century. They were long considered as unstable "molecular compounds"[124]. *Collie* and *Tickle*[125] were the first (1899) to assign "oxonium salt" character to the acid complexes, *i.e.* they considered the compounds as containing a tetravalent oxygen, analogous to the ammonium salts in which nitrogen at that time was assumed to be pentavalent.

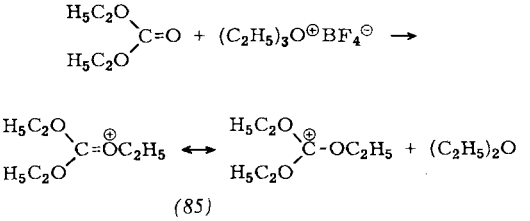
Hantzsch[126] proved, as early as 1922, that the pyrylium salts were clearly ionic. Pyrylium salts react with strong nucleophiles to give phenols. This behavior toward strong nucleophiles shows that the carbenium ion form contributes significantly to charge delocalization in pyrylium salts.



$ClO_4^{\ominus}$ (84) $ClO_4^{\ominus}$

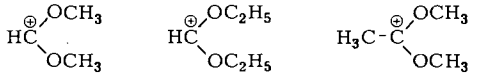
2.13.1. Alkoxy- and Hydroxycarbenium Ions

Resonance, similar to that in the pyrylium salts, was shown by *Meerwein*[127] to exist between tri- and dialkyloxonium and alkoxycarbenium ion forms in the fluoroborates obtained by alkylation of ketones, esters, and lactones with trimethyl- or triethyloxonium fluoroborates, such as *(85)*.



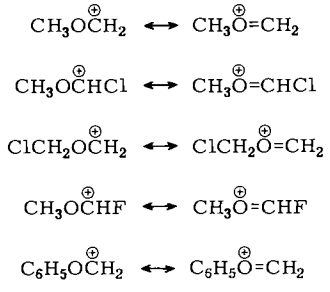
(85)

Taft and *Ramsey*[128] investigated a series of secondary and tertiary alkoxycarbenium ions *(86)*—*(88)* ^{1}H-NMR spectroscopically.



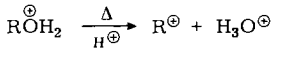
(86) *(87)* *(88)*

Bollinger[129] and *I* prepared primary alkoxycarbenium ions such as the methoxy- and phenoxycarbenium ions and their halogenated derivatives, and investigated their ^{1}H-, ^{13}C-, and later ^{17}O-NMR spectra.



Acidic oxonium ion can be studied particularly well in superacid solvent systems. With *Sommer* and *Namanworth*[41] we showed that primary and secondary alcohols are protonated in FSO_3H—SbF_5(SO_2,SO_2ClF) solution at −60 °C, and that well-resolved NMR spectra of the protonated species can be obtained.

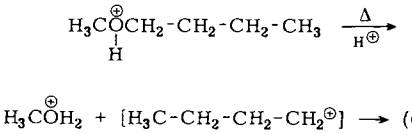
At higher temperatures they cleave to carbenium ions; the kinetics of these cleavage reactions could be followed by NMR spectroscopy.



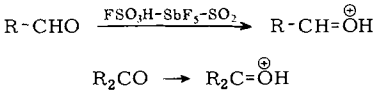
Tertiary alcohols (with the exception of the ones containing strongly electron-withdrawing groups like CF_3) generally dehydrate very fast in the acid media, and the intermediate protonated species cannot be observed, even at low temperature.

Ethers are also protonated in superacid media[43].

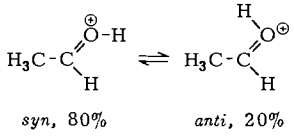
Once again the subsequent cleavage reactions can, as in the case of methyl *n*-butyl ether *(7)*, be followed by NMR spectroscopy.



Aldehydes and ketones are protonated on the carbonyl oxygen atom, and in superacid media at low temperatures the protonated species can be directly observed[130–134].

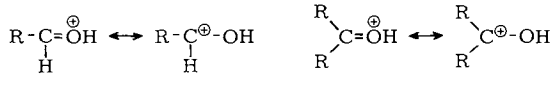


Even protonated formaldehyde has been prepared. Protonated acetaldehyde was observed in two isomeric forms, the proton on oxygen being *syn* or *anti* to the hydrogen of the aldehyde group.



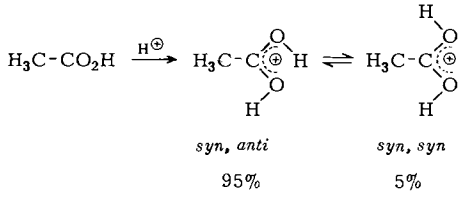
syn, 80% *anti*, 20%

The hydroxycarbenium ion forms of protonated ketones and aldehydes (obtained in strong acid solutions) contribute to the resonance hybrid, the degree of contribution of each form being quite accurately estimable by ^{13}C-NMR spectroscopy[135].



Carboxylic acids are protonated in superacid media such as FSO_3H—SbF_5—SO_2, HF—SbF_5, or HF—BF_3[136].

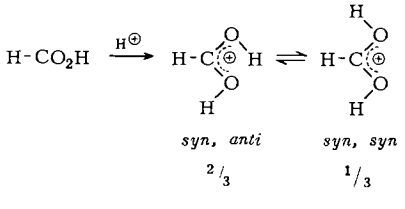
The NMR spectrum of acetic acid in such media at low temperatures shows two OH resonances. This indicates (i) that protonation of the carbonyl group is favored, and (ii) that rotation about the resultant C—OH bonds is hindered. The predominate conformer observed is the *syn,anti* isomer; but about 5 percent of the *syn,syn* isomer has also been observed.



syn, anti *syn, syn*

95% 5%

Formic acid is also protonated under the same conditions, two conformers being formed in the ratio 2:1; the *syn,anti* isomer predominates.

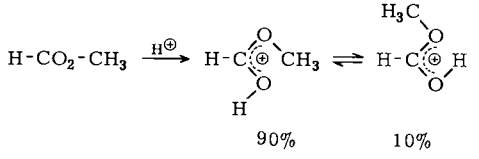


syn, anti *syn, syn*

$^2/_3$ $^1/_3$

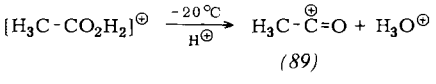
These isomers can be readily identified from the magnitudes of the vicinal coupling constants in the ^{1}H-NMR spectrum; thus in the *syn,anti* isomer, the methine proton gives a doublet of doublets (J_{HH} = 15 Hz and 3.5 Hz) while in the case of the *syn,syn* isomer a triplet is observed (J_{HH} = 3.5 Hz). No evidence for the *anti,anti* isomer has been found in either protonated carboxylic acids, esters, or their thio analogs.

Esters behave in an analogous fashion. Once again the oxygen atom of the carbonyl oxygen takes place. Thus, protonated methyl formate is present in FSO_3H—SbF_5—SO_2 solution as two isomers in a ratio of 90 to 10[137].



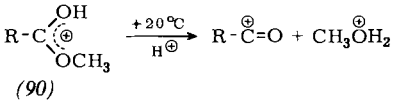
By raising the temperature of solutions of protonated carboxylic acids and esters, their cleavage reactions can be observed. These reactions can be considered within the framework of the two unimolecular reaction pathways for acid-catalyzed hydrolyses of esters, either involving alkyl- or acyl-oxygen cleavage. Studies of these reactions in superacid media have the advantage over those carried out under the usual solvolytic conditions in that the cleavage step can be isolated and studied in detail, since the cleavage products generally do not undergo further reaction.

For example, in the case of protonated acetic acid in FSO_3H—SbF_5—SO_2 solution, a reaction analogous to the rate-determining step in the unimolecular cleavage of esters is observed; this leads to formation of the acetyl cation *(89)* and the hydronium ion.

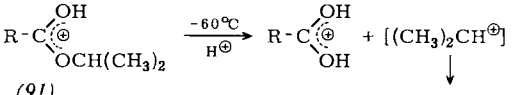


(89)

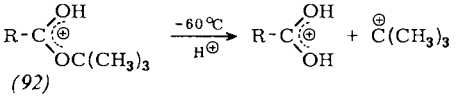
Unimolecular cleavage in this case corresponds to dehydration of the acid. In the case of protonated esters, however, the cleavage pathway depends on the nature of the alkoxy group, as is shown in examples *(90)*—*(92)*.



(90)

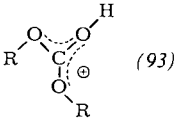


(91)



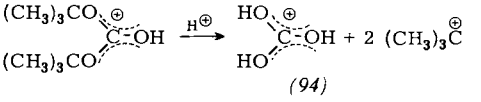
(92)

Dialkyl carbonates have been studied in FSO_3H—SbF_5 solution and have been shown to be protonated on the carbonyl oxygen giving the dialkoxyhydroxycarbenium ions *(93)*[138].



(93)

Di-*tert*-butyl carbonate cleaves spontaneously at −80 °C. Alkyl-oxygen fission takes place giving the *tert*-butyl cation and the protonated form of carbonic acid *(94)*, whose structure has been established from the ^{13}C-NMR spectrum (see Fig. 19). The quartet with a coupling constant of 4.5 Hz shows coupling of the carbon to three equivalent hydroxyl protons[138].



(94)

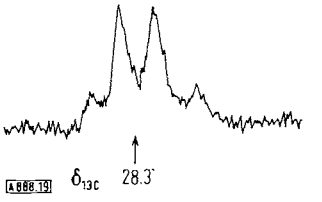


Fig. 19. ^{13}C-INDOR spectrum of the 56% ^{13}C-enriched protonated carbonic acid *(94)* (trihydroxycarbenium ion).

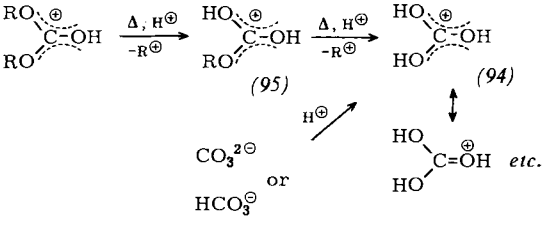
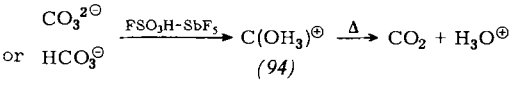
Di-isopropyl and diethyl carbonate cleave at a higher temperature, also *via* alkyl-oxygen cleavage, with initial formation of the protonated monoalkyl hydrogen carbonates *(95)*, which can also be obtained by protonation of their sodium salts. Upon further heating cleavage takes place to give protonated carbonic acid.



Protonated carbonic acid *(94)* can also be obtained by dissolving inorganic carbonates and hydrogen carbonates in FSO_3H—SbF_5 at −80 °C. It is stable in solution to about 0 °C, when it decomposes to the hydronium ion and carbon dioxide. Protonated carbon dioxide (CO_2H^+) may be an intermediate.



(94)

It is worthwhile to point out the close similarity between protonated carbonic acid *(94)* (the trihydroxycarbenium ion) and its nitrogen analog the guanidinium ion. Both are highly resonance stabilized through their onium forms.

The existence of protonated carbonic acid as a stable chemical entity with substantial resonance stabilization may have major implications in our understanding of some of the more fundamental biological carboxylation processes. Obviously the *in vitro* observation in specific, highly acidic, solvent systems cannot be simply extrapolated to different environments (biological systems). However, it is possible that on the active receptor sites of enzyme

systems (for example, those of the carbonic anhydrase type) local hydrogen ion concentration may be very high compared with the overall "biological pH". In addition, on the receptor sites a very favorable geometric configuration may help to stabilize the active species, a factor which cannot be reproduced in model systems *in vitro*.

2.13.2. Acyl Cations

In 1943 *Seel*[139] characterized the first stable acyl cation. Reaction of acetyl fluoride with boron trifluoride gave a complex (decomposition point 20 °C) which was characterized as the acetyl tetrafluoroborate salt.

$$H_3C{-}COF + BF_3 \rightleftharpoons H_3C{-}CO^{\oplus}BF_4^{\ominus}$$

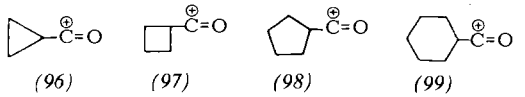
The identification was based on analytical data and chemical behavior. Only in the 1950's was further characterization of the complex by physical methods possible, namely by infrared and NMR spectroscopy. A series of acyl cations[140-142] (oxocarbenium ions) has been isolated and identified. The hexafluoroantimonate and hexafluoroarsenate complexes were found to be particularly stable[142]. *Deno et al.* investigated solutions of carboxylic acids in sulfuric acid and oleum[143]. They observed protonation at lower acid concentrations, and dehydration to give acyl cations at higher acidities.

$$R{-}CO_2H \xrightleftharpoons{H_2SO_4} R{-}\overset{\oplus}{C}O_2H_2 \xrightleftharpoons{\text{Oleum}} R{-}\overset{\oplus}{C}{=}O + H_3O^{\oplus}$$

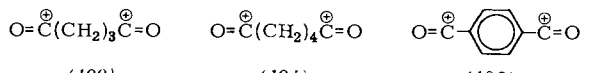
The investigation of acyl cations like the acetyl, propionyl, butyryl, isobutyryl, pivaloyl and benzoyl cation was substantially helped by NMR studies. Not only ^1H, but also ^2H, ^{13}C, and ^{19}F resonance studies established the structure of these ions[142,144]. The ^{13}C- and ^1H-NMR spectra showed that in the case of acyl cations, such as the acetyl cation *(89)*, a resonance hybrid of the oxonium ion, oxocarbenium ion, and of the ketene-like form is involved.

$$H_3C{-}C{\equiv}O^{\oplus} \longleftrightarrow H_3C{-}\overset{\oplus}{C}{=}O \longleftrightarrow \underset{H^{\oplus}}{CH_2{=}C{=}O}$$

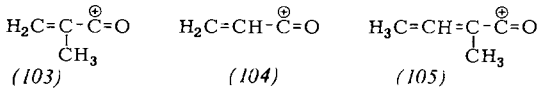
Recent x-ray crystallography studies of the $CH_3CO^+{-}SbF_6^-$ complex substantiated this suggestion and provided convincing evidence for the linear structure of the crystalline complex[145].



(96) *(97)* *(98)* *(99)*



(100) *(101)* *(102)*

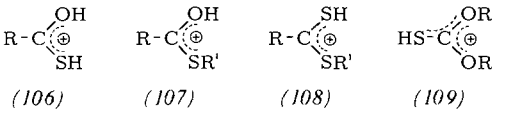


(103) *(104)* *(105)*

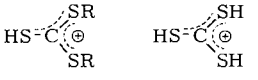
Investigation of acyl cations has been extended to the study of acyl cation, *i.e.* cycloacyl cations such as *(96)* to *(99)*[146], unsaturated acyl cations such as *(103)* to *(105)*[147], and diacyl cations such as *(100)*—*(102)*[148].

2.14. Sulfur as Heteroatom

Thiols and sulfides are protonated on sulfur and give, in superacid media, the stable mono- and dialkylsulfonium ions respectively[47]. Thiocarboxylic acids, *O*- and *S*-alkyl thioesters, dithioesters, and thiocarbonates also form stable thiohydroxy or thioalkoxycarbenium ions[158]. Examples are the ions *(106)*—*(111)*.



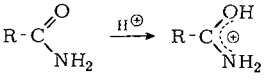
(106) *(107)* *(108)* *(109)*



(110) *(111)*

2.15. Nitrogen as Heteroatom

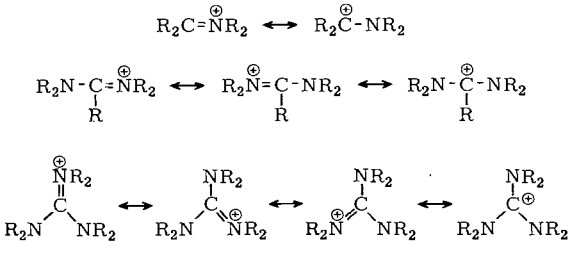
Amides are protonated in superacid media at low temperatures on the carbonyl oxygen atom, as was first shown by *Gillespie*[149].



It has been claimed[150] that protonation of ethyl *N,N*-diisopropylcarbamate, a hindered amide, takes place on nitrogen and not on oxygen. A reinvestigation, however, established that at low temperature *O*-protonation first takes place (kinetic control) and that the *O*-protonated amide subsequently rearranges to the more stable *N*-protonated form (thermodynamic control)[151].

The possibility of observing the protonated amide linkage in strong acid media has particular relevance in the study of peptides and proteins[152,153].

Since nitrogen is a much stronger electron donor than oxygen, the contribution of carbenium ion structures in acid salts of imines, amidines, and guanidines is small[154].



However, even in protonated nitriles contribution from the iminocarbenium ion resonance form must also be considered[155,156].

$H_5C_2-C\equiv\overset{\oplus}{N}H \leftrightarrow H_5C_2-\overset{\oplus}{C}=NH$

Ions such as the triazocarbenium ion, $(N_3)_3C^+SbCl_6^-$, have also been reported[157].

The field of protonated heteroaliphatic compounds has been studied in detail; interested readers are referred to a recent review[158] for more information.

3. Equilibrating Carbenium Ions or Static Carbonium Ions? The Classical-Nonclassical Ion Controversy

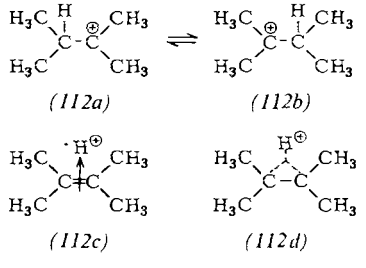
Some carbocations show great tendency to undergo fast degenerate rearrangements, leading through intramolecular hydrogen or alkyl shifts to the related identical structures[2]. The question arises, whether these processes are equilibrations between the limiting carbenium ("classical") ion intermediates separated by low energy level transition states or whether intermediate hydrogen or alkyl bridged carbonium ions are involved. Extensive discussions regarding the kinetic and stereochemical results in these systems have already appeared in the literature and it is considered outside the scope of this review to recapitulate the arguments. The reader is referred to reviews, such as *Schleyer*'s[2], and the original literature.

As direct observation of long-lived carbocations, generally in superacid media, became possible in recent years it was as a logical extension of our work to apply the developed spectroscopic and chemical studies of direct observation to the study of equilibrating or bridged carbocation systems. Differentiation between these two possibilities by NMR spectroscopy is difficult; because of the "slow time scale" of the NMR method, rapidly equilibrating or bridged ions can be expected to give similar ^{1}H-NMR spectra.

^{13}C-NMR spectra can, however, be used advantageously[30] for investigation of the structure of carbocations in which the possibility exists for degenerate rearrangements to occur which are fast with respect to the NMR time-scale and which lead to average shifts and coupling constants being observed. "Rapid" methods such as IR, Raman, and especially ESCA spectroscopy are therefore particularly useful for investigating these systems.

3.1. Equilibrating Alkylcarbenium Ions

The dimethylisopropylcarbenium ion is an example of a rapidly equilibrating alkylcarbenium ion. Its ^{1}H-NMR spectrum, shows four equivalent methyl groups and does not permit a clear distinction to be made between a rapidly equilibrating system or a static ion [which may be formulated as involving hydrogen bridging, *i.e.* a π-complex *(112c)* or alkenonium ion *(112d)*].



(112a) ⇌ *(112b)*

(112c) *(112d)*

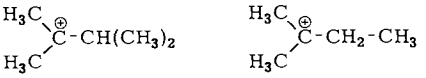
The average ^{13}C chemical shift observed for the two central carbons of the dimethylisopropylcarbenium ion is $\delta = 3.4$. The INDOR spectrum consists of a, doublet ($J_{CH} = 65$ Hz)[27]. In the case of an equilibrating system the average value of the shifts at the two sites, *i.e.* C^+ and $HC<$, would be observed as the chemical shift. A suitable model for estimating these shifts is the *tert*-butyl cation; the average value of the ^{13}C chemical shift of the methyl group and of the central C^+ atom is $\delta_{^{13}C} = 6.2$. The effect of the two additional methyl groups in *(112)* should cause additional deshielding of both shifts compared with those in the model compound, and thus there is excellent agreement between the observed shift and the chemical shift expected for the rapidly equilibrating ion. The coupling constant can also be estimated (again using the *tert*-butyl cation as a model compound) from the direct and long-range C—H coupling constants J_{HC} and J_{HCC}. The average of these values (assuming the long-range coupling to be negative, as is usual in three-bond CCH coupling) is 64 Hz, again in excellent agreement with the observed value. The agreement of both the coupling constants and the chemical shift with the values predicted for the rapidly equilibrating ion are so good as to leave little doubt as to the nature of this ion. IR and Laser Raman spectroscopic studies of the ion also confirm this conclusion. Whereas NMR studies of rapidly equilibrating ions are thus possible, clearly the relatively slow time-scale of the NMR experiment does not allow direct, separate observation of individual species, but gives information through analysis of *average* chemical shifts and coupling constants of the equilibrating species. Thus it is clear that the study of these ions necessitates the use of physical methods whose time scale is not affected by even the fastest chemical equilibrating processes.

Consequently we carried out a study of the infrared and Raman spectra[25, 32] of the isopropyldimethylcarbenium ion and, for comparisons, those of a series of alkylcarbenium ions with known "static" structure, such as the *tert*-butyl, *tert*-amyl, and isopropyl cations. The nearly identical spectra of the ions and the evident planarity (or near planarity) of the carbenium centers suggest that the dimethylisopropylcarbenium ion is "classical", similarly to the static ions used for comparison.

Finally, the most decisive physical method yet applied to the study of carbocations in the condensed state is perhaps that of x-ray photoelectron spectroscopy (ESCA)[36], which allows one to differentiate between equilibrating carbenium ions and bridged carbonium ions. This method allows direct measurement of carbon 1s electron binding energies. As the charge distribution within carbocations causes increasing binding energies with increasing positive charge localization, highly electron deficient classical alkyl and cycloalkyl carbenium centers (as in *tert*-butyl and *tert*-amyl cations) show at least 4 eV binding energy differences from the remaining less electropositive carbon atoms.

In the ESCA spectra of bridged carbonium ions, such as the norbornyl cation (see Section 3.3), there is no indication

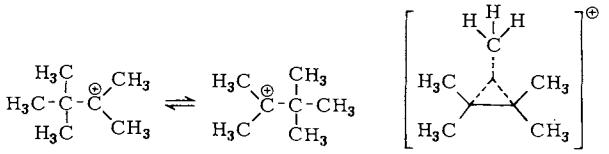
of such a highly electron deficient carbon center with high binding energy. The ESCA spectra of the dimethylisopropylcarbenium ion *(112)* and of the dimethylethylcarbenium ion *(113)* show practically the same difference in the 1s bonding energies (ΔE_b) between C^+ and adjacent C atoms ($\approx$4.2eV).



(112) *(113)*

Since ESCA spectra represent observation of the ejected core electron from a single species, no time scale limitation related to possible chemical equilibration phenomena can exist. The ESCA spectra thus clearly indicate that the ion studied is a classical carbenium ion and not a bridged tetramethylethyleneprotonium ion *(112d)*.

An example for differentiating between an equilibrating and a methyl bridged ion is the dimethyl-*tert*-butylcarbenium ion *(114)* (the triptyl cation or pentamethylethyl cation). The ^{1}H-NMR spectrum of this ion consists of a single signal at $\delta = 2.90$[45]. The position of this chemical shift was considered indicative of a rapidly equilibrating structure [*(114a)*$\rightleftharpoons$*(114b)*] rather than a bridged structure *(114c)*, although the fact that only a single proton

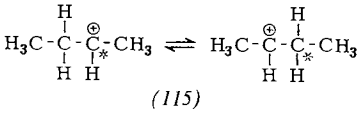


(114a) *(114b)* *(114c)*

resonance is observed does not necessarily enable these structures to be distinguished since in the methyl bridged carbonium ion intramolecular equilibration of the methyl groups could take place. As in the case of the dimethylisopropylcarbenium ion the ^{13}C-NMR spectral data can give additional evidence about the structure[30].

The average ^{13}C chemical shift for C-2 and C-3 was found to be $\delta_{^{13}C} = -11.5$; this is consistent only with the rapidly equilibrating structure. The norbornyl cation (see Section 3.3), which has been experimentally observed, provides a good model for a methyl bridged ion. The bridged carbon atoms in this ion have a chemical shift $\delta_{^{13}C} = 70$. If the dimethyl-*tert*-butylcarbenium ion is similar in nature to the norbornyl cation we would expect the C-2 and C-3 shifts in the former compound to be 81.5ppm further upfield than they actually are. The near zero coupling between the methyl protons and carbon-13 is also revealing. Since this ion rapidly equilibrates, the observed coupling will be the average of the two and three bond carbon-hydrogen coupling constants. The two bond coupling constant in the *tert*-butyl cation is 6.5 Hz. A similar value is to be expected for the methyl bridged ion. Since the observed coupling constant is zero, the three bond coupling must have the same magnitude but opposite sign. So far the signs of only a few such couplings have been determined. However, such a sign alternation has been reported by *Karabatsos*[31a], the two bond coupling being negative and the three bond coupling positive.

The ^{1}H-NMR spectrum of the 2-butyl cation *(115)* at -120 °C consists of two signals at $\delta = 3.2$ and 6.7, the



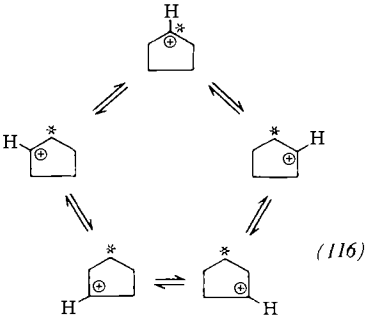
(115)

intensity ratio being 2:1[159]. This is the result of a degenerate 1,2 hydrogen shift, which at this temperature is fast with respect to the NMR time-scale.

In the ^{13}C-NMR spectrum the two central carbons give a quartet at $\delta_{^{13}C} = 21.2$ with a carbon-hydrogen coupling constant of $J_{CH} = 70 \pm 2$ Hz[30]. Using the difference of the ^{13}C shifts observed in the dimethylisopropyl ion *(112)* and the dimethyl-*tert*-butylcarbenium ion *(114)* as a measure of the effect of methyl substitution on the ^{13}C chemical shift in equilibrating ions (8 ppm) then a ^{13}C chemical shift of $\delta_{^{13}C} = 13$ is to be expected. This is in reasonable agreement with the observed value. Using the isopropyl cation as a model gives an estimated coupling constant of 72 Hz. As in the two previous examples the ^{13}C-NMR values clearly demonstrate that the 2-butyl cation is an equilibrating "classical" carbenium ion rather than a bridged "non-classical" carbonium ion. Both Raman and ESCA spectroscopic studies of the pentamethylethyl and 2-butyl cations clearly indicate the classical carbenium ion nature of the ions. The 1s binding energies of the carbenium centers and the remaining carbon atoms differ in the case of the tertiary ions by about 4.0—4.8 $\pm$ 0.2 eV.

3.2. The Equilibrating Cyclopentyl Cation

As already mentioned the ^{1}H-NMR spectrum of the cyclopentyl cation *(116)* in SbF_5—SO_2ClF solution at -70 °C consists of a singlet at $\delta = 4.68$. The ^{13}C satellites of this



(116)

peak show a J_{CH} coupling constant of 28.5 Hz and have an intensity five times that normally observed. This results from the degenerate rearrangements that occur in this ion which, on the NMR time-scale, lead to equivalence of the nine protons and five carbon atoms. The ^{13}C-

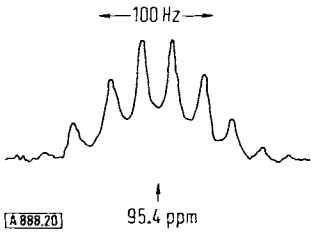


Fig. 20. 25 MHz ^{13}C-INDOR spectrum of the cyclopentyl cation obtained in natural abundance from cyclopentyl chloride in SO_2ClF—SbF_5 solution. The ten-line multiplet (J_{CH} = 28.5 Hz) is a result of the degenerate rearrangements in this ion leading to complete scrambling of the nine protons among the five carbons on the NMR time scale. The observed shift and coupling constant are thus average values.

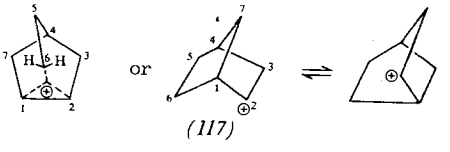
INDOR spectrum shows a 10 line multiplet at $\delta_{^{13}C} = 95.4$ with a coupling constant of 28.5 Hz[30] (Fig. 20).

Once again the ESCA spectrum[36], which is not affected by the time scale of equilibration, shows that the ion *(116)* is a secondary carbenium ion. The binding energies of the carbenium carbon atom and remaining carbon atoms differ by about 4.8 eV.

3.3. The Norbornyl Cation

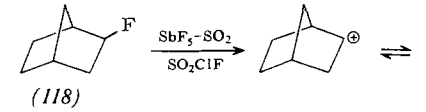
The cyclopentyl cation *(116)* leads us to the discussion of one of the most controversial of all carbocations, the



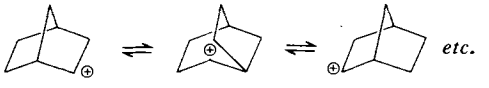
(117)

norbornyl cation *(117)*, whose structure has been the central point of many discussions regarding the much publicized classical-nonclassical controversy of "carbonium ions"[9].

The methods worked out in our laboratories to generate and study stable carbocations in solution were successfully applied to the direct observation of the norbornyl cation and the clarification of its structure[10].



(118)



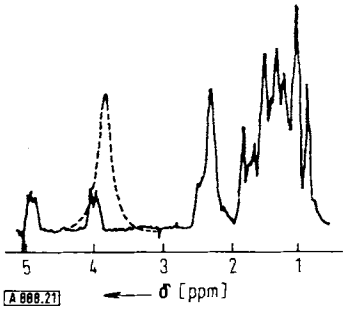


Fig. 21. 60-MHz ^{1}H-NMR spectrum of the norbornyl cation *(117)* (- - -) and the 2-*exo*-fluoronorbornane *(118)* (——) at 35 °C.

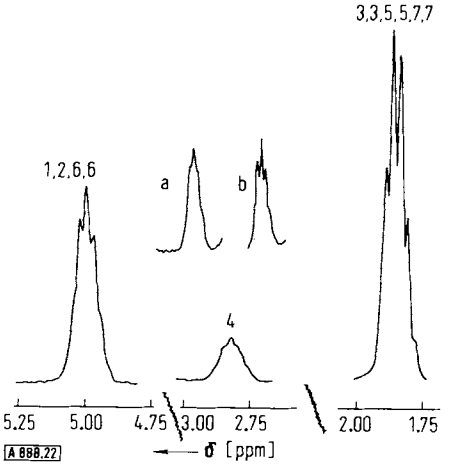

Fig. 22. ^{1}H-NMR spectrum (100 MHz) of the norbornyl cation *(117)* in SbF_5—SO_2 solution at −80 °C. The insert shows the effect of irradiating the low-field septuplet on the one-proton peak at δ = 2.82. a is the spectrum without irradiation and b is with irradiation.

In 1964 *Saunders, Schleyer,* and *I* first investigated[160] the ion prepared from 2-*exo*-fluoronorbornane *(118)* in SbF_5—SO_2 and recorded its ^{1}H-NMR spectrum. At room temperature it consists of a single broad band at δ = 3.75 (Fig. 21) due to scrambling of all hydrogen atoms. The contrast between this single band and the complex spectrum of the starting compound is striking. The equilibration of the hydrogen atoms is caused by the fast 3,2- and 6,2-hydrogen shifts and the Wagner-Meerwein rearrangement.

Similarly at room temperature the ^{13}C-NMR spectrum of the ion shows a single broad absorption line centered at $\delta_{^{13}C} = 134$[10].

When the temperature is lowered to −60 °C the ^{1}H-NMR spectrum of the 2-norbornyl cation is resolved into three different peaks (intensity ratio 4:1:6). The spectrum does not change when the temperature is lowered to −120 °C[10] (Fig. 22).

The spectrum was interpreted as evidence that the 3,2-hydrogen shift could be frozen out, but the 6,2-hydrogen shift and the Wagner-Meerwein rearrangement are still fast even at the low temperatures used (−120 °C). The rate constant of the slow 3,2-hydrogen shift was established from temperature-dependence studies, and the activation energy of this shift was found to be 12 kcal/mol. In studies with *White*[10] we subsequently succeeded in "freezing out" on the NMR time scale even the fast 6,2-hydrogen shift. Using a mixed solvent system (SbF_5—SO_2ClF—SO_2F_2) it was possible to observe the 100 MHz spectrum at temperatures down to −156 °C. At −120 °C, the spectrum was identical to that described previously; however, in the temperature range −128 to −150 °C significant changes occur. The most deshielded peak due to the four equilibrating "protonated cyclopropane" ring protons broadens and then separates into two signals at δ = 3.05 and 6.59 with relative intensities 2:2. The high field resonance, due to the six methylene protons, also broadens and develops a shoulder at δ = 1.70. The signal at δ = 2.82 due to the single bridgehead proton remains unchanged (Fig. 23).

The temperature dependence of the low field resonance was used to calculate the rate constants based on the

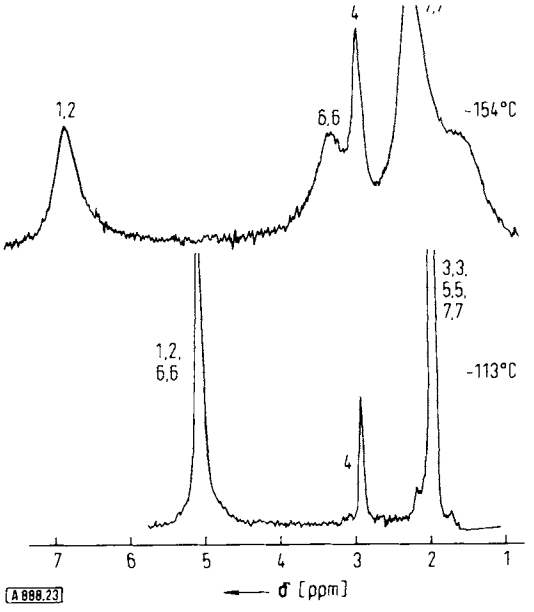

Fig. 23. 100-MHz ^{1}H-NMR spectrum of the "norbornyl cation" in SbF_5—SO_2ClF—SO_2F_2 solution at temperatures between −113 and −154 °C.

Gutowsky-Holm equations. The activation energy from the Arrhenius plot is 5.9 ± 0.2 kcal/mol^{-1} and the pre-exponential factor $10^{12.7}$ s^{-1}.

These observations could signify either: (a) that the ion is "classical" and that the temperature dependence corresponds to the "freezing out" of the 6,1,2-hydrogen shift, the Wagner-Meerwein rearrangement still being fast at −156 °C, or (b) that the ion is "non-classical", all rearrangements have been "frozen out" and thus the structure is that of a methylene bridged ion with a pentacoordinated carbon atom.

In order to differentiate between these two possibilities the Raman and ^{13}C-NMR spectra of the ion were studied[10]. As Raman spectroscopy is a rapid physical method (assuming that vibrational transition rates are faster than any of the hydrogen or alkyl shifts) the question of possible equilibration *versus* bridged ion becomes unimportant. The previously discussed technique of average ^{13}C-NMR shifts should be also applicable in this case for differentiating a static nonclassical bridged ion from rapidly equilibrating classical carbenium ions.

The Raman spectroscopic investigation of the stable norbornyl cation was carried out at −70 °C in FSO_3H—SbF_5—SO_2 solution using a helium-neon laser. In the C—C stretching frequency region there is only one strong line at 972 cm^{-1} ($\rho = 0.35$). The C—H stretching frequency region shows five lines, one of which is at 3110 cm^{-1}. The skeletal vibrations of the ion and their comparison with those of model compounds suggest a structure closer related to nortricyclene, but not to norbornane, *i.e.* under the conditions of the investigations (−70 °C, where, as the NMR spectra show, the ion rapidly equilibrates) an ion having protonated nortricyclene nature is present.

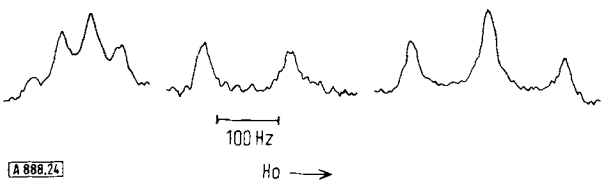

Fig. 24. ^{13}C-INDOR spectrum of the norbornyl cation *(117)* generated in SbF_5—SO_2 solution from *exo*-2-chloronorbornane and recorded at −70 °C. The spectrum was obtained by observing the ^{13}C satellites in the 100-MHz ^{1}H-NMR spectrum while irradiating the sample with a swept 25-MHz frequency. ^{13}C shifts indicated are with respect to $^{13}CS_2$.

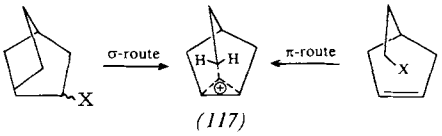
As mentioned, the ^{13}C-NMR spectrum of the ion at room temperature shows a single broad absorption. On lowering the temperature to −70 °C, three well resolved absorptions are observed (Fig. 24). The chemical shift of the triplet due to the equivalent methylene carbon atoms C-3, C-5 and C-7 is at $\delta_{^{13}C} = 162.5$ ($J = 140.2$ Hz) and that of the bridgehead carbon atom C-4 at $\delta_{^{13}C} = 156.1$ (doublet $J = 153$ Hz). The 53.3 Hz pentuplet observed at $\delta_{^{13}C} = 101.8$ (from $^{13}CS_2$) using the INDOR method (on irradiation of the satellites of the lowest field peak) corresponds to the three equivalent carbons C-1, C-2 and C-6 associated with the four equivalent equilibrating protons.

Subsequently we were also able to obtain the ^{13}C-NMR spectrum of the "frozen out" norbornyl cation at −156 °C. Whereas the use of the INDOR method is generally based on observing the effects of irradiation on the ^{13}C satellites in the proton spectrum, these satellites could not be observed at −156 °C due to a poor signal-to-noise ratio at this very low temperature. Enhancement of the C-1, C-2-proton resonance (due to a collapse of the ^{13}C satellites and possibly a nuclear Overhauser effect) proved to be possible on irradiation at 25.1 MHz, however, even at −156 °C. The low-field proton resonance (at $\delta = 6.59$) was enhanced on irradiation at $\delta_{^{13}C} = 70 \pm 2$ while the more shielded proton resonance (at $\delta = 3.05$) was enhanced on irradiation at a frequency corresponding to $\delta_{^{13}C} = 173 \pm 2$.

We were unable to obtain the C—H coupling constants and peak multiplicities in this manner. Recently, however, it has been possible by use of the rapid Fourier Transformation Method to obtain the complete ^{13}C-NMR spectrum, and all the coupling constants and peak multiplicities. Table 3 lists the corresponding values of the carbon atoms participating in the three center bond.

It should also be mentioned that both the "σ-route" from 2-norbornyl halides and the "π-route" from β-Δ^3-cyclopentenylethyl halides lead to the same norbornyl cation *(117)*.



(117)

Recently *Mateescu, Riemenschneider*[36], and *I* succeeded in recording the ESCA spectrum of the norbornyl cation and compared it with that of the 2-methylnorbornyl cation and other trivalent carbenium ions, such as the cyclopentyl

and methylcyclopentyl cations *(116)* and *(37)*. The 1s electron spectrum (Fig. 25) of the norbornyl cation *(117)* shows no high binding energy carbenium center and a maximum separation of less then 1.5 eV between the two "cyclopropyl" type carbons, to which bridging takes place, from the other carbon atoms (including the pentacoordinated bridging carbon). In contrast the 2-methylnorbornyl cation shows, like other trivalent carbenium ions, a high binding energy carbenium center that is only slightly delocalized, as indicated by the binding energy difference of 3.7 eV from the other carbon atoms.

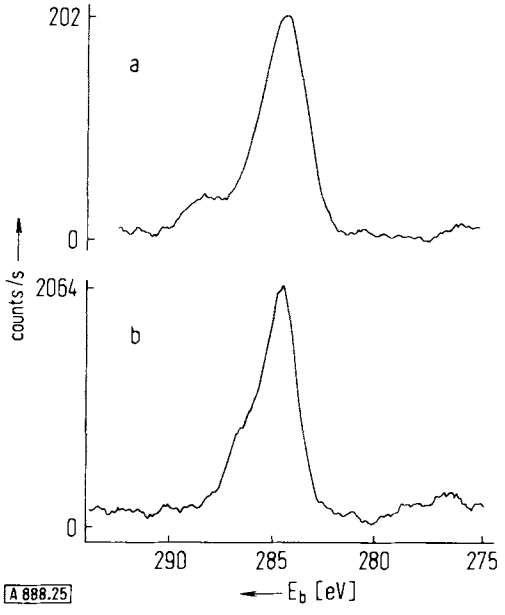


Fig. 25. Carbon 1 s electron spectrum (ESCA spectrum) a) of the 2-methylnorbornyl cation and b) of the norbornyl cation *(117)*. E_b = binding energy.

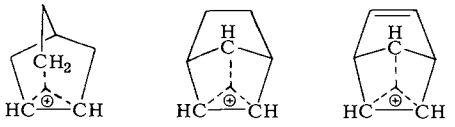
Since in electron spectroscopy the time scale of the measured ionization processes is of the order of 10^{-16} s, definite ionic species can be characterized, regardless of possible intra- and intermolecular interactions (*e.g.* Wagner-Meerwein rearrangements, hydrogen shifts, proton exchange, *etc.*), which have no effect. Thus, ESCA spectroscopy gives an undisputable, direct answer to the long debated question of the "nonclassical" nature of the norbornyl cation independent of any possible equilibration process.

The bridging methylene carbon atom C-6 of the norbornyl ion is pentacoordinated. It is bound to two hydrogen atoms and to the carbon atom C-5 by three two-electron single bonds. The remaining sp^3 orbital is involved in two-electron three-center bonding with C-1 and C-2. Thus the pentacoordinated carbonium ion center is similar to CH_5^+ and the norbornyl ion is a carbonium ion.

Other examples of directly observed long-lived carbonium ions in which pentacoordinated carbonium centers were identified by ^{13}C and ^1H-NMR spectroscopy are the 7-norbornenyl *(119)* and the 7-norbornadienyl cation *(120)*[10,161].

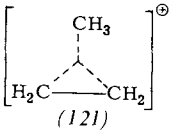
Winstein[162] and *Richey*[163] have shown that the 7-norbornenyl cation *(119)* can be obtained *via* both the "σ-route" and the "π-route".

The carbonium centers in the norbornyl cation *(117)*, the 7-norbornenyl cation *(119)*, and the 7-norbornadienyl cation *(120)*[10,164] are similar and related to the ethylene-



(117) *(119)* *(120)*

methonium ion *(121)*, although strain differences in the ions are obviously significant. All these ions contain a two electron three-center bond. The bridging carbon atoms are pentacoordinated, whereas the carbons to which they bridge are tetracoordinated carbonium atoms.



(121)

Comparison of the characteristic ^{13}C-NMR parameters of the carbonium centers in these ions with those of trivalent carbenium centers in related tertiary classical ions (Table 3) shows the very significant differences which allow clear differentiation. The carbenium centers are highly electron deficient and therefore deshielded, whereas the carbonium centers show much higher shielding (up to 300 ppm) on account of their higher coordination.

It can be concluded that the original views of *Winstein*[165] on the nonclassical nature of the norbornyl cation, based on kinetic and stereochemical results, have been fully substantiated by direct spectroscopic studies of the long-lived ion[10]. Whether the ion is completely formed under solvolytic conditions (S_N1 type) or the reaction has more S_N2 character, cannot be decided at the present time. Investigation of the norbornyl cation, however, contributed substantially to our general understanding of carbonium ions as being distinct and well differentiated species from carbenium ions. Carbonium ions cannot only be formed intramolecularly, but also in intermolecular reactions and represent the key for electrophilic reactions on single bonds (see following discussion).

3.4. Cyclopropylmethyl and Cyclobutyl Cations

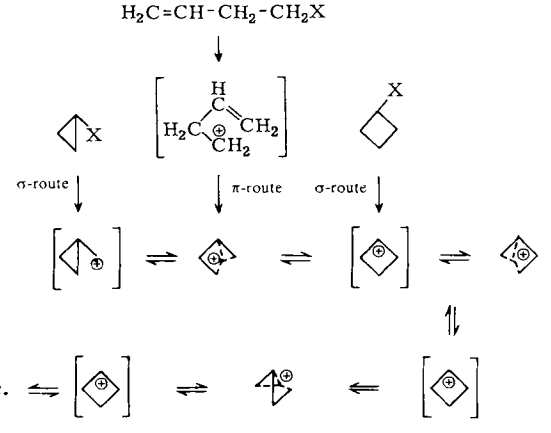
The solvolytic reactions of the cyclopropylmethyl—cyclobutyl—allylmethyl system has been studied extensively by *Roberts*[166], *Wiberg*[167], and other authors. In these studies and in recent spectroscopic investigations of the long-lived ions in superacids[76], the nonclassical nature of the common ions could be established. Rapid equilibration between the so-called unsymmetrical bicyclobutonium ions is in agreement with all data.

Table 3. Comparison of the ^{13}C-NMR parameters of the carbocation centers in carbonium and carbenium ions.

Ion	Carbonium ions δ[ppm]	J_{CH}[Hz]	$\delta_{^{13}C}$[ppm]
 *(117)*	$H_A = 3.05$ $H_B = 6.59$	$H_A = 145.8$ $H_B = 184.5$	$C_A = 171.4$ $C_B = 68.5$
 *(119)*	$H_A = 3.25$ $H_B = 7.04$	$H_A = 218.9$ $H_B = 193.8$	$C_A = 159.8$ $C_B = 67.9$
 *(120)*	$H_A = 3.24$ $H_B = 7.48$	$H_A = 216.4$ $H_B = 192.3$	$C_A = 157.6$ $C_B = 78.9$

Ion	Carbenium ions Solvent T[°C]	$\delta_{^{13}C}$[ppm]
	$FSO_3H—SbF_5—SO_2$ −80	C-1 = +113.0 (J = 169.5 Hz) $C^{\oplus}$-2 = −77.3
 *(37)*	$SbF_5—SO_2$ −60	$C^{\oplus}$-1 = −142.0
$(CH_3)_3C^{\oplus}$ *(2)*	$SbF_5—SO_2ClF$ −60	$C^{\oplus}$ = −135.4
$(CH_3)_2CH^{\oplus}$ *(1)*	$SbF_5—SO_2ClF$ −60	$C^{\oplus}$ = −125.0
	FSO_3H −35	C-1 = +134.0 (J = 158.4 Hz) $C^{\oplus}$-2 = −63.5
	FSO_3H −20	$C^{\oplus}$-1 = −74.6
$(CH_3)_2\overset{\oplus}{C}C_6H_5$ *(42)*	$FSO_3H—SbF_5—SO_2$ −60	$C^{\oplus}$ = −61.1

Stable, long-lived cyclopropylmethyl and cyclobutyl cations were studied in $SbF_5—SO_2ClF$ solution at low temperature by ^{1}H- and ^{13}C-NMR spectroscopy. Structural assignments were based on the data obtained and on comparison with model compounds. The cyclopropylmethyl cation *(122)* (Fig. 26) and for comparison the



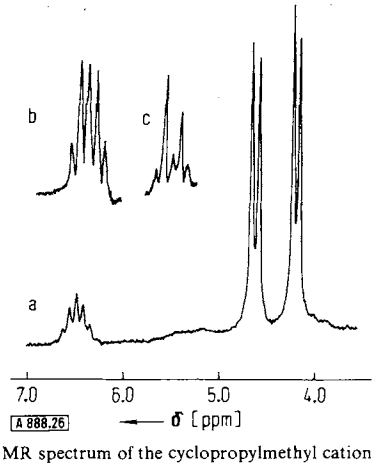


Fig. 26. a) 100-MHz ^{1}H-NMR spectrum of the cyclopropylmethyl cation *(122)* in $SbF_5—SO_2ClF$ solution at −80 °C. b) 60-MHz spectrum in the region of the CH signal; c) 60-MHz spectrum the CH signal of the α,α-dideuteriocyclopropylmethyl cation.

methyl substituted cations *(123)* and *(14)* were examined under comparable conditions. The NMR parameters are summarized in Table 4.

Table 4. NMR parameters of cyclopropylmethyl cations.

Ion	CH_3	^{1}H-NMR, δ [ppm] (J_{H-H} [Hz]) CH_2	CH	$^{\oplus}$CH
(122)		4.21 (6.5) 4.64 (8.0)	6.50 (6.5, 8.0)	
 *(123)*	3.34 (6.2)	4.32 4.45	4.58	9.6 (6.2)
 *(14)* [a]	2.70 3.18 (1.25)	3.57 3.68	3.83	

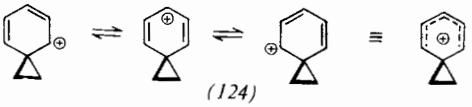
Ion	^{13}C-NMR, δ [ppm] ($J_{^{13}CH}$ [Hz]) CH_3	CH_2	CH	$C^{\oplus}$
(122)		+138 (180)	+ 85	
(123)	+160	+136	+126	−59.1
(14)	+154 (125) +163 (125)	+140	+134	−86.8

[a] See also Fig. 7.

All of the cyclopropylmethyl cations show charge delocalization by the cyclopropyl ring, but only with the primary system is the unique behavior observed which puts it in a class distinct from the secondary and tertiary ions. Comparison with model compounds, including the previously discussed norbornyl type cations, established the nonclassical carbonium ion nature of the cyclopropylmethyl cation *(122)*. A set of equilibrating cyclopropylcarbonium ions is involved, with equilibration occurring *via* the puckered cyclobutenium ion (cyclobutyl cation).

3.5. Ethylenearenium Ions

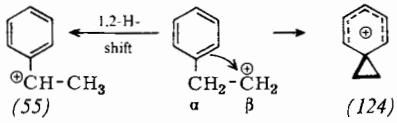
The classical-nonclassical ion controversy also included the question of the so-called "ethylenephenonium" ions. *Cram*'s extensive studies[168], based on kinetic and stereochemical evidence, clearly established the bridged-ion nature of β-phenylethyl cations in solvolytic systems. Spectroscopic studies (particularly ^{1}H- and ^{13}C-NMR)[169] of a series of stable long-lived ions proved the symmetrically bridged structure, and at the same time showed that these ions do *not* contain a pentacoordinated carbonium ion center (*i.e.* they are not "nonclassical ions"). They are spiro[2.5]octadienyl cations *(124)* (spirocyclopropylbenzenium ions) or, in other words, cyclopropylmethyl cations in which the carbenium center belongs to a cyclohexadienyl cation (benzenium ion).



(124)

The nature of the spiro carbon atom is of particular importance in determining the structure of these carbocations. ^{13}C-NMR spectroscopic studies clearly established the aliphatic tetrahedral nature of this carbon, thus ruling out a "nonclassical" ethylenephenonium ion.

The formation of the ethylenebenzenium ion *(124)* from β-phenylethyl precursors can be depicted as cycloalkylation of the aromatic π-system and not, as such, of the C_{Ar}—C_α bond which would give the tetracoordinated ethylenephenonium ion. Rearrangement of the β-phenylethyl to α-phenylethyl cations on the other hand is a regular 1,2-hydrogen shift involving the C_α—H bond.



(55) *(124)*

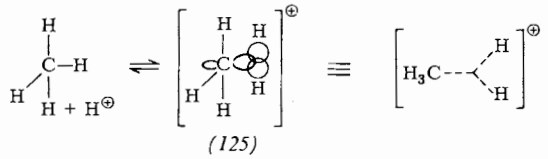
4. The Role of Carbocations in Electrophilic Reactions

4.1. General Considerations

Trivalent carbenium ions, as recognized in the pioneering work of *Meerwein*, *Ingold*, and *Whitmore*, play an important role in acid-catalyzed rearrangements of hydrocarbons (isomerization, alkylation, cyclization, polymerization, *etc.*), as well in a large variety of electrophilic reactions including those of the generalized Friedel-Crafts type. These reactions and their mechanisms are well reviewed[170] and will not be discussed here. It is suggested, however, (see subsequent discussion) that only ionization of lone (non-bonding) electron pair donor precursors (n-bases) or protonation of singlet carbenes can lead directly to carbenium ions. Other (π- or σ-) donors always interact first *via* their bonding electron pairs with the electrophilic reagents, forming two electron three-center bound carbonium ions (transition states or intermediates) which subsequently yield the trivalent carbenium ions.

4.2. Formation of Methonium Ion (the Simplest Carbonium Ion) from Methane

The bonding of a carbonium center is considered to involve three covalent, two-electron bonds with the fourth bond being a two-electron three-center bond[12]. This type of bond occurs, similarly as in the norbornyl cation *(177)*[10], in alkonium ions like CH_5^+ *(125)*. The existence of the methonium ion CH_5^+ is based not only on mass spectrometric studies[171] but also on the chemistry of methane in superacids and with strong electrophiles[172]. Thus, the interaction involves the main lobes of the covalent bonds (frontal attack). Since an electrophile will attack the points of highest electron density, attack will occur on the covalent bonds themselves and not on the relatively unimportant back lobes.

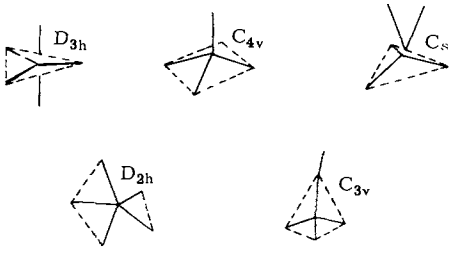


(125)

It should be remembered that the dotted lines symbolize the bonding orbitals of the three centered bonds and that

their point of junction does not represent an additional atom.

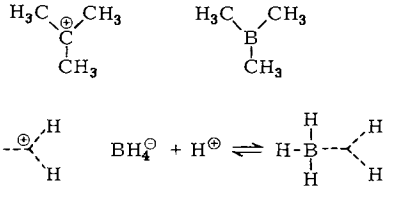
Of the possible structures for the methonium ion (D_{3h}, C_{4v}, C_s, D_{2h} or C_{3v} symmetry) *Olah*, *Klopman*, and *Schlosberg*[173] suggested preference for the C_s front-side protonated form. Preference for this form was based on consideration of the observed chemistry of methane in superacids (hydrogen-deuterium exchange and, more significantly, polycondensation indicating ease of cleavage to CH_3^+ and H_2) and also on the basis of self-consistent field (SCF) calculations[173]. More extensive calculations[174], including *ab initio* calculations utilizing an "all-geometry" parameter search[175], confirmed the favored structure with C_s symmetry. This structure is about 2 kcal/mol energy-poorer than the structure with C_{4v} (or D_{2h} or C_{3v}) symmetry, which in turn is about 8 kcal/mol energy-poorer than the structure with trigonal bipyramidal D_{3h} symmetry.



At the same time it should also be recognized that ready interconversion of stereoisomeric forms of CH_5^+ is possible by a pseudorotational-like process. *Muetterties* recently suggested naming stereoisomerization processes of this type in pentacoordinated compounds as "polytopal rearrangements"[176] (sometimes called "polyhedral rearrangements"). We, however, prefer to call intramolecular carbonium ion rearrangements as "bond to bond rearrangements" since these are not limited to equivalent bonds in the case of higher homologs of CH_5^+ (see subsequent discussion). Hydrogen-deuterium scrambling observed in superacid solutions of deuterated alkanes strongly indicate such processes.

4.3. Boron Analogs of Carbocations

It is of interest to note that isoelectronic boron compounds can be used as model compounds for both carbenium and carbonium ions. Trimethylboron has already been compared with the trimethylcarbenium ion (see Table 2) and it has recently been suggested that BH_5 may similarly be used as a model for comparison with CH_5^+[12].



BH_5 is formed in the acid hydrolysis of tetrahydroborates[177,178]. When the hydrolysis is carried out with deuterated acid, not only HD but also H_2 is formed. In strong acids the isotopic distribution is statistical. This is indicative of D^+ attacking the B—H bond (similarly to the attack of H^+ on methane) and of polytopal (bond to bond) rearrangement of BH_4D taking place, before subsequent cleavage occurs. The ease with which diborane exchanges hydrogen for deuterium when treated with deuterium gas[179] also indicates the formation of the three center bound analog, BH_3D_2.

$$B_2H_6 \rightleftharpoons 2\ BH_3$$

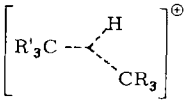
$$BH_3 + D_2 \rightleftharpoons H\text{-}B(H)(H)\text{---}D \rightleftharpoons H\text{-}B(H)(D)\text{---}H \rightleftharpoons BH_2D + HD$$

$$\Downarrow\Uparrow$$

$$B_2H_4D_2\ \textit{etc.}$$

4.4. Steric Effects in the Formation of Carbonium Ions

It should be emphasized that if steric interference (as is the case in interaction of tertiary C—H bonds in isoalkanes with tertiary carbonium ions) is substantial, the three-center bond of carbonium ions must be highly unsymmetrical, although the attack of the tertiary carbenium ion on the tertiary hydrogen of the isoalkane still cannot be considered to lie along an extension of the C—H bond (*i.e.* in a linear fashion)[180].



Similarly the protonation of sterically hindered C—C (and C—H) bonds can also only proceed *via* highly unsymmetrical carbonium ion states (see following discussion).

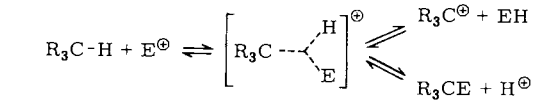
The preferred direction of attack by the electrophile should thus not be considered to be always the same and may very well vary from compound to compound (according to the reaction conditions). Since the possible configurations of pentacoordinated carbon do not differ very much in stability (as is also the case in CH_5^+), with exception of the "back-side" substituted trigonal bipyramid, which must be considered the least favorable form, it is unlikely that there is any "inherently" preferred pathway: it will depend on the individual reaction conditions; the electrophilic attack, however, always takes place on the appropriate bonds *via* "frontal" interaction.

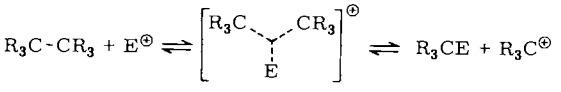
4.5. Electrophilic Reactions at Single Bonds: σ-Donor Systems

Pentacoordinated carbonium ions play an important role not only in connection with the structure of nonclassical ions, but more importantly in the general area of electrophilic reactions at single bonds, *e.g.* in the aliphatic substitution of alkanes and cycloalkanes. Such reactions include acid-catalyzed hydrocarbon isomerizations, fragmentations, cyclizations, and other transformation reac-

tions, electrophilic substitutions of alkanes and cycloalkanes and related electrophilic reactions.

We have in recent years obtained evidence for the general reactivity of covalent C—H and C—C single bonds of alkanes and cycloalkanes in various electrophilic substitution reactions such as protolytic processes, hydrogen-deuterium exchange[181], alkylation[180], nitration[182], halogenation[183] *etc.* This reactivity is due to what we consider, alongside n- and π-donor ability, the third major type of electron donor ability, *i.e.* the σ-donor ability (sigma basicity) of *bonded* electron pairs (*i.e.* single bonds) to share their electron pairs with an electron deficient reagent *via* two-electron, three-center bond formation. The reactivity of single bonds thus stems from their ability to participate in the formation of pentacoordinated carbonium ions. Subsequent cleavage of the three-center bond results in formation of trivalent carbenium ions and substitution products, or hydrogen (alkyl) transfer takes place.





$E^{\oplus} = D^{\oplus}, H^{\oplus}, R^{\oplus}, NO_2^{\oplus}, Hal^{\oplus}$

As to the nature of the transition state of the electrophilic reactions at single bonds, the experimental product compositions strongly favor pentacoordinated carbonium ion-type transition states involving carbocation centers with three regular covalent two-electron bonds and one two-electron three-center bond, which, in contrast with the linear or "back-side" attack, is formed *via* "frontal" attack[12, 180].

Frontal attack involving a trigonal transition state would lead to retention of optical activity if reactions were carried out at an optically active carbon center. Experiments presently being carried out in our laboratories appear, in part, to prove this, but there are many experimental difficulties in carrying out such reactions under controlled conditions. We have also been able to carry out electrophilic substitution reactions (deuteration, alkylation, nitration, chlorination) at bridgehead positions of rigid systems, such as adamantane, where back-side attack and olefin formation is impossible (for back-side attack the electrophile would need to pass through the cage structure). These reactions give direct experimental evidence for the frontal direction of the electrophilic attack and the nature of the pentacoordinated carbonium ion-type transition state[181, 182, 184].

4.6. Protolysis and Hydrogen-Deuterium Exchange

With superacids, alkanes readily undergo protolytic reactions involving tertiary, secondary, and primary C—H as well as C—C bonds[172, 181]. In the case of isoalkanes, tertiary C—H bond reactivity exceeds that of C—C bonds and secondary (and primary) C—H bonds. In *n*-alkanes, the C—C bond reactivity is generally found to exceed that of the C—H bonds. It is also apparent that steric factors affect σ-basicity as they do π- or n-basicity.

Bartlett, Condon, and *Schneider*[190] were the first to recognize that in aluminum halide catalyzed intermolecular hydrogen abstractions, the electrophile (carbenium ion or proton) can remove a tertiary hydrogen atom together with its bonding electron pair (the so-called hydride transfer reaction).

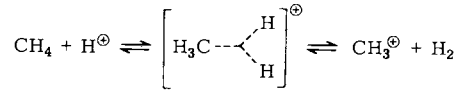
$$R_3C{-}H + R^{\oplus} \text{ (or } H^{\oplus}) \rightleftharpoons R_3C^{\oplus} + H{-}R \text{ (or } H_2)$$

In subsequent literature the assumption has generally been made that the hydrogen atom is removed with its electron pair through what amounts to a linear transition state.

Lewis, Hawthorne, and *Symons*[185] must be given credit for having first suggested that the transition state in hydrogen abstraction could be considered triangular instead of linear: "...electrophilic reagent attacks the C—H bond and the reasonable mode of attack is on the electrons of the bond. A triangular transition state is therefore proposed." This suggestion, however, went relatively unnoticed, mainly because there were no experimental data available to substantiate it and because it was considered that steric hindrance, particularly in the interaction of a tertiary carbenium ion with a tertiary isoalkane, would allow only linear interaction.

The question of the mechanism of the hydride abstraction was not further considered until 1967, when, with *Lukas* we reported on the protolytic ionization and hydrogen-deuterium exchange of alkanes and cycloalkanes in superacids such as FSO_3H—$SbF_5(SO_2ClF)$[45, 172a]. *Hogeveen,* in independent work, also made similar observations in HF—SbF_5 solutions[172c].

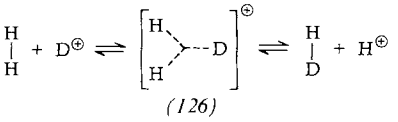
These studies demonstrated that in the new superacid systems not only tertiary and secondary, but also primary C—H bonds as well as C—C bonds undergo facile protolytic cleavage. To account for the observed protolytic reactions of alkanes, we suggested with *Klopman* and *Schlosberg*[173] that protolyses preferentially involve "front-side" attack through formation of triangular carbonium ions as shown in the case of protonation of methane to CH_5^+.



It appears, therefore, more reasonable to call these processes hydrogen abstractions (transfer) and not hydride abstractions, since *de facto* hydride ion is not involved in these processes.

Subsequently, we were able to show with *Shen* and *Schlosberg*[186] that molecular hydrogen (deuterium) itself readily undergoes hydrogen-deuterium exchange in superacids.

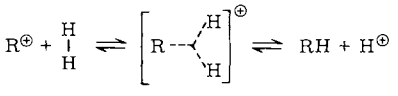
The reaction takes place even at room temperature, and we assume that a triangular H_3^+-transition state *(126)* is involved in the protolytic process.



(126)

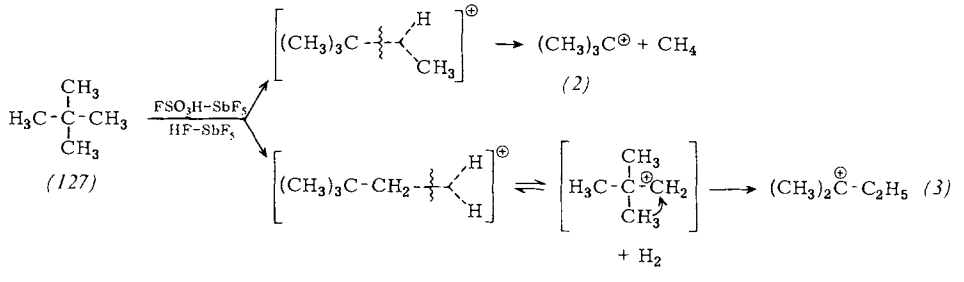
By way of contrast, *Hogeveen*[187a] initially rejected triangular transition states in hydride abstractions by arguing that such transition states would suffer considerable strain. Subsequently however, in collaboration with *Brouwer*, he favored bridged, unsymmetrical transition states[187b]. He also stated that he found no evidence for exchange of molecular hydrogen (deuterium) with the superacid system used (generally SbF_5 in a large excess of HF, which is a weaker acid system than the 1:1 acids used in our work), which he considered as further evidence against triangular transition states. At the same time he described the reaction of carbenium ions with molecular hydrogen[188]. He could not distinguish the nature of the transition state (linear *vs.* triangular) but considered the reaction to involve a linear transition state since no hydrogen-deuterium exchange was observed with molecular hydrogen (deuterium) itself.

$$R^{\oplus} + H{-}H \rightleftharpoons (R\cdots H\cdots H)^{\oplus} \rightleftharpoons R{-}H + H^{\oplus}$$



According to our studies of the hydrogen-deuterium exchange in superacids and the reaction of carbenium ions with hydrogen *i.e.* hydrogenolysis by carbenium ions, we suggested that they take place at the H—H bond, *i.e.* they represent alkylation of H—H by alkylcarbenium ions.

In our continued investigations it became obvious that protolysis of single bonds, including C—H as well as C—C bonds is a general reaction[181]. As example, the protolysis of neopentane *(127)* may be mentioned, where there is both C—C and C—H bond reactivity.



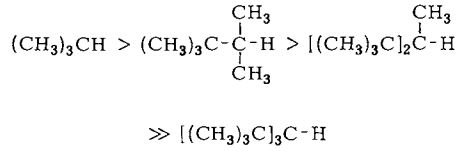
(127)

(2)

(3)

In FSO_3H—SbF_5 or SbF_5 (which generally always contains HF) C—H cleavage is favored at low temperatures (−80 °C). At higher temperatures or in HF—SbF_5, on the other hand, C—C cleavage predominates. This difference could be explained by the differing nature of the solvated proton ($H_2SO_3F^+$ or H_2F^+) which in superacids must be considered as a well defined, stable species.

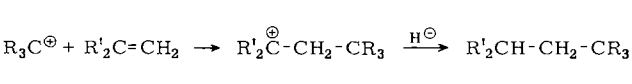
As is well known for of n- and π-basicities, steric hindrance can also influence the σ-basicity. If in isobutane the methyl groups are substituted by the much larger *tert*-butyl groups the reactivity of the tertiary C—H bond towards electrophilic reagents decreases rapidly. In the case of tri-*tert*-butylmethane this bond is already shielded to such a high degree that the tertiary C—H bond shows no reactivity at all, and electrophilic reactions, therefore, only occur on the C—C and the primary C—H bonds.



Due to the oxidizing ability of antimony pentafluoride (which is subsequently reduced to SbF_3), the possibility of one electron transfer redox processes must always be kept in mind when dealing with systems containing SbF_5. In superacids and particularly at low temperature the equilibrium concentration of SbF_5, for example in a HF—SbF_5 system, is low. Furthermore the protolytic reactivity of alkanes is well demonstrated using deuterated superacids. Electron transfer from an alkane single bond is a relatively high energy process necessitating 4—5 eV (*i.e.* > 100 kcal/mol) more activation energy then a comparable electron transfer process from a related alkene π bond and consequently is not very probable in low temperature solution chemistry. It is worth mentioning that many of the protolytic reactions discussed can also be carried out with acid systems other than those containing SbF_5. HF—TaF_5 and HF—BF_3 are, for example, useful superacids in such reactions. Since the redox potentials in these systems are high, it seems a well established fact that alkanes react in superacid solutions *via* single bond protolytic processes.

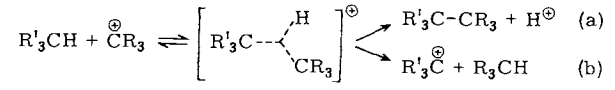
4.7. Alkylation

Despite frequent literature references to electrophilic alkylation of alkanes by olefins, from a mechanistic point of view these reactions must be considered as alkylations of the olefin by the carbenium ion formed from the isoalkane by intermolecular hydrogen transfer. Thus the alkane just serves as a reservoir for the alkylating agent.



The suggested reaction mechanism (*Schmerling*[189]) is reflected by the products formed in the reaction of propylene and isobutylene with isobutane. The products do not contain 2,2,3-trimethylbutane or 2,2,3,3-tetramethylbutane. These compounds would be expected as primary alkylation products in the direct alkylation of isobutane with propylene and isobutylene, respectively. As already discussed, in intermolecular hydrogen abstraction from a tertiary isoalkane by a carbenium ion, described by *Bartlett*, *Nenitzescu*, and *Schmerling*, the transition state could be considered either linear or triangular (from frontside attack on the C—H bond). The latter would under no circumstances be symmetrical because of steric interaction between the carbenium ion and the tertiary isoalkane. Even with a strongly distorted triangular transition state (*i.e.* assuming that the reaction takes place on the C—H bond itself and not at the back-lobe of the hydrogen atom), it becomes obvious that subsequent cleavage can result not only in intermolecular hydrogen transfer, but also, *via* proton elimination, in direct alkylation.

It should be emphasized that there is no necessity in suggesting a common transition state for hydrogen abstraction and alkylation, but only that triangular states of related nature are formed. As to which products are formed depends on the nature of the reactants, the reaction conditions, and the stability of the products, besides other factors such as strain in the formation of transition states, which affects the ratio of reactions (a) and (b).



R, R' = Alkyl

In the case of tertiary-tertiary systems (reaction of an isoalkane system with a *tert*-alkyl cation) a close to symmetrical trigonal three-center transition state would be too highly strained for its formation to be possible. However, it is unnecessary to consider a symmetrical transition state in the reactions. The tertiary carbenium ion could easily approach the tertiary C—H bond in such a way as to form an unsymmetric transition state, which can account for the great preference of intermolecular hydrogen transfer over alkylation in the reaction.

The possibility of preparing stable alkylcarbenium ions, permitted these reactions to be investigated under controlled "pure" conditions.

The reaction of stable, alkylcarbenium ions with alkanes can be advantageously studied in sulfuryl chloride fluoride solution at low temperatures (generally as low as $-78\,^{\circ}C$). A small amount ($\approx 2\%$ of C_8 fraction) of 2,2,3,3-tetramethylbutane was detected in the reaction of *tert*-butyl fluoroantimonate with isobutane[180].

$$(CH_3)_3C^{\oplus} + HC(CH_3)_3 \rightleftharpoons (CH_3)_3C{-}C(CH_3)_3 + H^{\oplus} \quad (128)$$

This observation is, however, of substantial importance since no other way than direct alkylation of the C—H bond of isobutane by the *tert*-butyl cation can account for formation of hexamethylethane *(128)*. That direct alkylation of alkanes indeed can be carried out with ease is further shown when isobutane is reacted with the less bulky isopropyl fluoroantimonate, or when propane is reacted with *tert*-butyl fluoroantimonate. The primary alkylation product 2,2,3-trimethylbutane is formed in up to 12% yield[180]. As intermolecular hydrogen transfer is faster than alkylation, and the isopropyl cation more reactive than the *tert*-butyl cation, the alkylation reaction in the system is considered to be mainly the propylation of isobutane.

$$(CH_3)_2CH_2 + \overset{\oplus}{C}(CH_3)_3 \rightleftharpoons (CH_3)_2CH^{\oplus} + HC(CH_3)_3$$
$$(CH_3)_3CH + H\overset{\oplus}{C}(CH_3)_2 \rightleftharpoons (CH_3)_3CCH(CH_3)_2 + H^{\oplus} \quad (129)$$

The alkylation products obtained are not only those derived from the starting alkanes and carbenium ion, but also those from the alkanes and carbenium ions formed by intermolecular hydrogen transfer. Generally this transfer reaction is a faster reaction than alkylation. Since carbocations also undergo isomerization, and since intermolecular hydrogen transfer produces new alkanes from these ions, it is obvious that increasingly more complex mixtures are going to be obtained. Generally the bulkier tertiary carbenium ions can attack the more shielded tertiary C—H bonds only with great difficulty. The processes mentioned, however, readily produce secondary and even incipient primary ions in the systems, which then substitute C—H bonds ("alkylation") or react with C—C bonds ("alkylolysis"). The alkylation reactions of alkanes produce a variety of products which, however, can be quantitatively analyzed by today's methods (gas chromatography, mass spectrometry). Since olefins are formed only to a minimal degree, if at all, under the reaction conditions when stable carbenium ion salts in low nucleophilicity solvents are used and since at low temperatures ($-78\,^{\circ}C$) and short reaction times (<30 sec), isomerizations are considered of lesser importance, we feel that indeed, for the first time, we have been able to study direct alkylation of alkanes. Product compositions, which indicate hydrogen transfer as well as primary and secondary alkylation but insignificant olefin formation or isomerization, support this claim. No similar product compositions have been observed in previous acid-catalyzed olefin alkylations. The alkylation of alkanes in competition with simultaneous hydrogen transfer can also be effected with the recently described $CH_3F{\rightarrow}SbF_5$[191] and $C_2H_5{\rightarrow}SbF_5$[192] complexes (which show incipient methyl and ethyl cation properties) and dialkylhalonium ions[193]. It is also reasonable now to suggest that in conventional Friedel-Crafts system direct alkylation can play a role, although in systems where olefin formation is possible, alkene reactivity vastly exceeds that of alkanes.

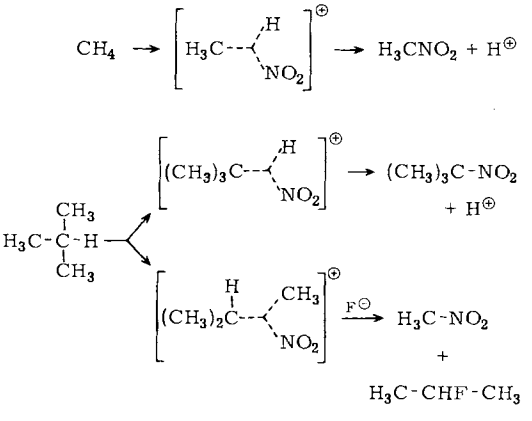
4.8. Nitration

The general concept of electrophilic reactivity of single bonds (σ donors) can be further demonstrated with a typical electrophilic reaction such as nitration. To avoid

the possibility of any free radical reaction resulting from the use of nitric acid and to avoid acid cleavage of reaction products, nitrations were carried out with stable nitronium salts, such as $NO_2^{\oplus}PF_6^{\ominus}$, in aprotic solvents such as methylene chloride-sulfolane[182]. In the case of methane and ethane (where the nitration product—nitromethane and nitroethane—is not acid-sensitive) anhydrous HF or FSO_3H were also used as solvents.

$$R{-}H \xrightarrow[CH_2Cl_2\text{-sulfolane}]{NO_2^{\oplus}PF_6^{\ominus}} R{-}NO_2 + H^{\oplus}$$

So far our studies have been directed primarily to mechanistic aspects. In methylene chloride-sulfolane solutions (which as n-bases compete with hydrocarbon σ-bases, such as methane) the yields are low (ranging from 1% nitration of methane at 25 °C through 2—5% nitration of higher alkanes, to 10% nitration of adamantane). In HF or HSO_3F solutions much higher yields of nitration of methane and ethane are obtained, but in the case of secondary and tertiary reaction products extensive protolytic cleavage reactions occur in acid media. In the electrophilic aliphatic nitronium ion nitration of alkanes the C—H and C—C bonds are once again the sites of attack; this results in substitution (*i. e.* nitration) or nitrolysis.



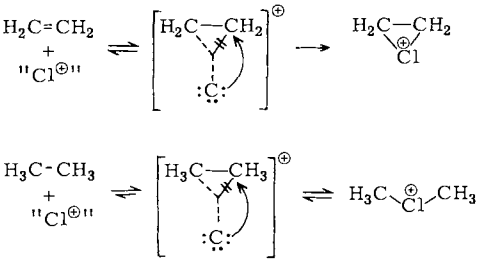
Since tertiary and secondary nitroalkanes are cleaved with ease by strong acids, aliphatic electrophilic nitration is affected by protolytic cleavage of products and therefore generally cannot be carried out in strong acid media without giving complex reaction mixtures.

4.9. Chlorination

Chlorination of alkanes can also be carried out under electrophilic conditions, *i. e.* Friedel-Crafts type acid-catalyzed chlorination, which takes place even at −78 °C in the dark[183].

In contrast to other electrophiles, the nature of positive halogens has not yet been sufficiently defined. We were able to carry out the chlorination of methane, ethane, propane, and higher alkanes in Cl_2—SbF_5—SO_2ClF solution at −78 °C in the dark. In this reaction, substitution products *(chlorination)* are formed as well as C—C cleavage products *(chlorolysis)*. The products formed can once again be explained as resulting from attack of the electrophile on the corresponding bonds with formation of a two-electron three-center bonded transition state. In the reaction of ethane with Cl_2—SbF_5 in SO_2ClF solution at low temperatures (*i. e.* under conditions favoring stable ions), for example, the main reaction products are the dimethylchloronium ion (chlorolysis) and the diethylchloronium ion (chlorination with subsequent formation of the chloronium ion).

Interestingly, in the case of electrophilic halogenations (such as chlorination) alkanes and alkenes act similarly as electron pair donors. The difference between the paraffins and the olefins in their reactions with "positive" chlorine, in which the unshared electron pairs of chlorine are also involved, is reflected in the type of reaction products formed. In the alkenes, where the σ-bonds are not involved in the reaction, three-membered cyclic halonium (chloronium) ions are formed whereas in the case of alkanes, where the C—C σ-bonds are involved directly in the reaction, open chain dialkyl chloronium ions are formed (chlorolysis).

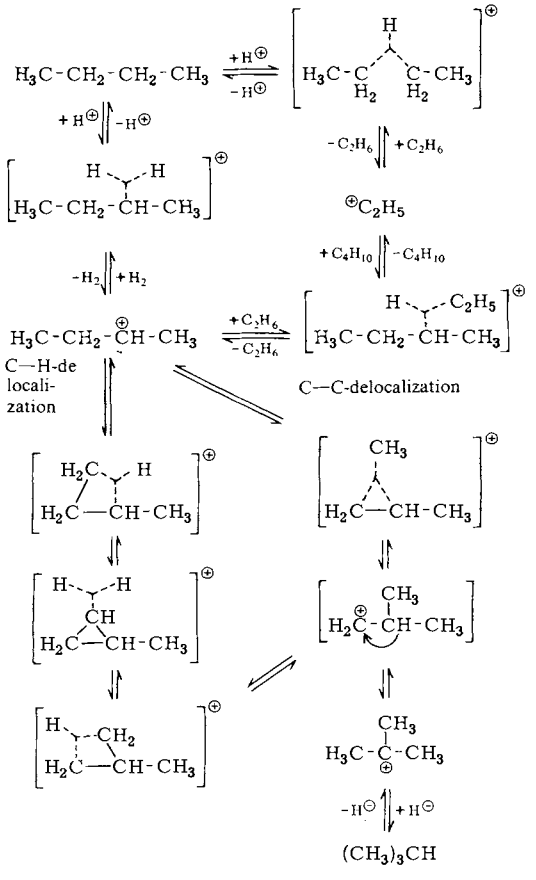


Alkanes also react in general (*i. e.* under conditions where the intermediate products are unstable) with chlorine in the presence of catalysts such as aluminum chloride, ferric chloride, and antimony pentachloride. Under the mild reaction conditions, these chlorides themselves show no chlorinating ability and are considered to act as true catalysts. (At higher temperatures and in the presence of light or free radical initiators ferric chloride, antimony pentachloride, and phosphorus pentachloride are chlorinating agents.) The reaction conditions used are not considered to favor radical formation, although it must be pointed out that electrophilic chlorine (Cl^+ or more probably Cl_2^+) can be considered as a radical cation (*i. e.* the triplet state). At the same time, the chlorine atom (Cl·) is a strong electrophile. Hence the differentiation between ionic and radical chlorine is not as clear as in the case of other substituting agents. Further, some catalysts such as PCl_5 coordinate weakly with molecular chlorine and could facilitate subsequent homolytic cleavage and thus radical chlorination.

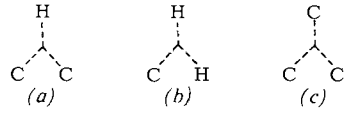
The Friedel-Crafts type chlorination of alkanes affords varying yields (2—5% in the case of methane but up to 55—60% in the chlorination of higher alkanes, including neopentane) and fairly high selectivity. In the chlorination of methane only methyl chloride is obtained (no methylene chloride or chloroform could be detected by gas chromatography). Stronger Lewis acid catalysts ($AlCl_3$, $FeCl_3$, *etc.*) cause increased dehydrochlorination of secondary and tertiary alkyl chlorides with subsequent chlorine addition leading to vicinal dichlorides.

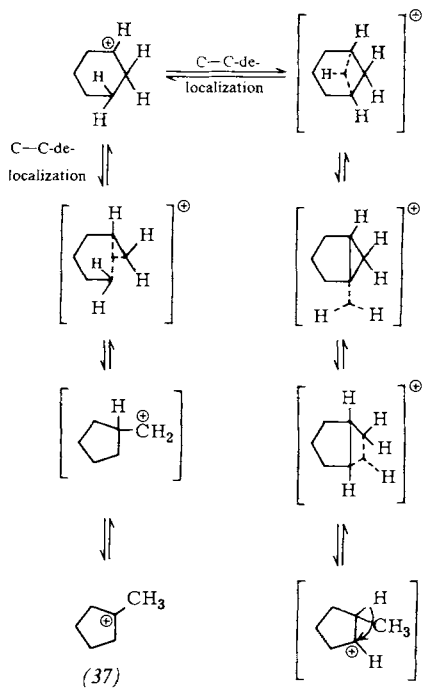
4.10. Rearrangements and Related Transformations

With a knowledge of the electron donor character of single bonds which leads to pentacoordinated carbonium ions it is now possible to explain the mechanisms of acid-catalyzed saturated hydrocarbon transformation reactions in those cases where no π- or n-donor reagents are involved which could themselves readily produce the needed initial carbenium ions. In such systems, for example in the isomerization of alkanes, the primary step is protolysis of a C—H or a C—C bond with formation of the corresponding carbonium ion transition state. (We have recently presented a detailed account of the mechanism of protolysis of alkanes[181].) In the following reaction step, with simultaneous cleavage of molecular hydrogen or of an alkane of lower molecular weight, an alkylcarbenium ion is formed which can subsequently undergo intra- or intermolecular processes (alkylation, alkyl or hydrogen shift, hydrogen transfer). These can all be considered to involve interaction of the electron-deficient carbenium center[194] with a C—C or C—H bond with formation of a new carbonium ion transition state. The typical carbocation processes can be shown, for example, in the isomerization of butanes[195].



A decisive role is played by protonated cyclopropanes in the rearrangement of the *sec*-butyl cation into the *tert*-butyl cation. The edge- and corner-protonated forms with three-center bonds of type *(a)* and *(b)*, respectively, can be differentiated from the methyl-bridged form [type *(c)*].



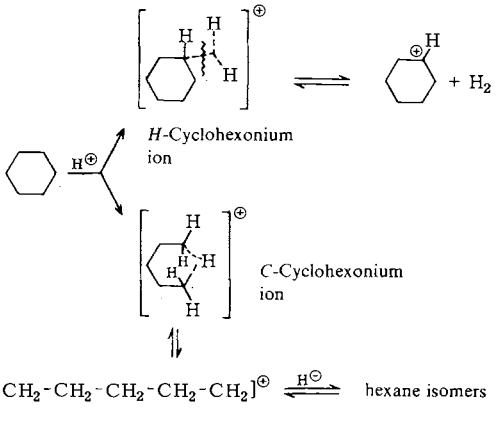


(37)

The skeletal rearrangements, however, must always take place with participation of the incipient primary isobutyl cation. Protonated cyclopropanes alone can not account for it, even though they are known to be involved in the hydrogen and carbon exchange (scrambling) processes.

Intramolecular alkylation processes (we have previously discussed well-defined intermolecular alkylations of alkanes by stable alkylcarbenium ions[180]) involving C—C or C—H bonds play a decisive role in ring contraction (or expansion) isomerizations, as, for example, in the isomerization cyclohexane ⇌ methylcyclopentane. Again, either C—H delocalized protonated cyclopropanes or C—C delocalized carbon bridged carbonium ion transition states can be involved.

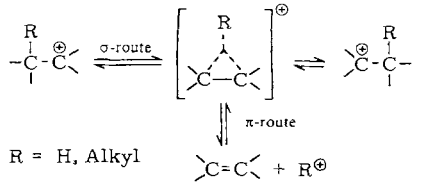
Whereas the cyclohexane-methylcyclopentane isomerization[196] involves initial formation of the cyclohexyl (methylcyclopentyl) cation (*i.e.* protolysis of a C—H bond) it should be mentioned that in the acid-catalyzed isomerization of cyclohexane up to 10% hexanes are also formed[196, 197]. This is indicative of C—C bond protolysis.



The observed protolytic behavior of cycloalkanes (and polycycloalkanes) in superacid solutions is indicative of either C—H or C—C bond protonation[198].

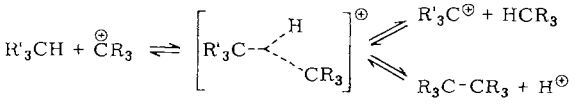
1,2-CH_3(alkyl) or hydrogen shifts (or the similar 1,3-, 1,4- or 1,5-shifts) in alkylcarbenium ions can also be considered as intramolecular alkylation of the C—C or C—H bonds by the carbenium ion center which leads to alkenonium ions. Hydrogen and alkyl bridged alkenonium ions are not observed in superacid solutions of rapidly equilibrating alkylcarbenium ions (*i.e.* by NMR, IR, Raman and ESCA spectroscopy[25, 30, 32, 36]); they are therefore probably only transition states or short-lived intermediates. However, it cannot be decided, as yet, whether alkenonium ion intermediates can exist.

Protolytic or alkylative three-center bond formation in carbonium ion processes can also explain cleavage and elimination reactions, particularly when the cleaving entity is a tertiary carbenium ion or proton; however, secondary and even primary ion cleavages are also observed. The close relationship between substitution, addition, and elimination reactions is thus obvious. Common (or closely related) carbonium ion transition states leading to carbenium ion intermediates are involved, which can be formed either by σ- or π-routes.



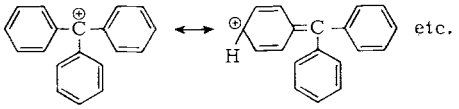
The β-cleavage reactions and deprotolytic olefin formations described by *Whitmore*[199] can also be considered as examples of three-center bound carbonium ion cleavages. *Schleyer*[200], as well as *Brouwer* and *Hogeveen*[201], have called attention to the importance of orientation of adjacent C—H or C—C bonds relative to the vacant p-orbital of carbenium ion centers in intramolecular carbocation reactions (such as 1,2-shifts and β-cleavages). In our opinion the orientation of the vacant p-orbital should be considered with regard to formation of a two-electron three-center bonded carbonium ion transition state.

As already discussed we were recently able to show that the fundamental intermolecular hydride transfer process described by *Bartlett*, *Nenitzescu*, and *Schmerling*[189, 190] involves a three-center bound carbonium ion transition state[181] and not, as has been generally assumed, a linear transition state[202]. Even in the sterically highly unfavorable reaction of isobutane with the *tert*-butyl cation, in addition to fast intermolecular hydrogen transfer, formation of small amounts of the alkylation product 2,2,3,3-tetramethylbutane *(129)* was also observed[180]. This



(129), R = CH_3

strongly indicates the triangular nature of the transition state. In the frequently used hydrogen abstractions with triphenylmethyl cations[203] (such as in the preparation of tropylium salts from cycloheptatriene[204]) the hydride abstracting agent may not always be the tertiary carbenium ion site. When perdeuteriotriphenylmethyl cation was allowed to react with cycloheptatriene to form tropylium ion, the triphenylmethane formed in the reaction showed protium substitution in the *para* (and *ortho*) ring positions. Hence, not only the tertiary carbenium ion center, but also secondary benzenium ion centers contributing to the stabilization of triarylmethyl cations, participate in the reaction[205].



(40a) *(40b)*

A somewhat similar situation has emerged from recent reinvestigation of *Gomberg*'s triarylmethyl radicals[206].

4.11. The Question of Hyperconjugation

Finally one can raise the question just how much a partially developed intramolecular three-center carbonium ion bond participates in hyperconjugation and the stabilization of carbenium ions. C—H and C—C hyperconjugation are simply explained by this term (where C—C hyperconjugation should play a more important role than C—H hyperconjugation). It should be clear, however, that in three-center bond formation the relative positions of the nuclei involved in this bond (compared to the starting compounds) must change *i.e.* there are indeed new bonding states developed which subsequently can lead to bridging.

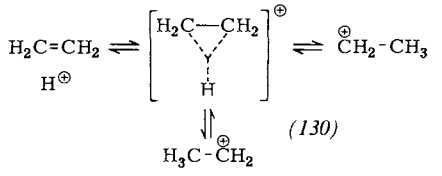
In contrast the stabilization of carbenium centers can also take place by σ-π electronic interaction without changes in bond lengths and angles, *i.e.* without extensive motion of the nuclei. This situation was described by *Traylor*[209a] as vertical stabilization (in the Frank-Condon sense). There is, however, no reason to believe that a dichotomy should exist between participation with and without bridging. The hyperconjugative interaction will always be accompanied by some geometrical change, but the extent of that deformation may be small or large (depending on the specific system).

4.12. Concerning the Mechanism of Electrophilic Reactions of π-Donor Systems

The reactivity of olefins, acetylenes, and aromatic hydrocarbons toward electrophiles in addition and substitution reactions is based on the π-electron donor ability of the unsaturated C=C or C≡C bonds and the π-aromatic systems[170a, 207].

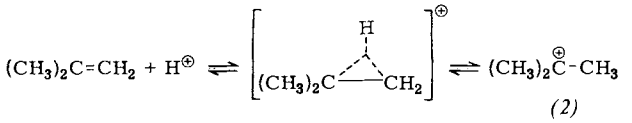
In the reactions discussed so far we have emphasized the importance of formation of two-electron, three-center bonds in pentacoordinated carbonium ion formation utilizing the electron pair of single σ-bonds. Two-electron, three-center bond formation is also considered to be involved in the initial step of electrophilic reactions of π-bonded systems.

Protonation of olefins, the essential first step in acid-catalyzed isomerizations, alkylation, hydration, and related addition and substitution reactions, is considered to involve the initial overlap of the two carbon atom p-orbitals (of the π-bond) with the empty s-orbital of the proton forming the two-electron, three-center bond of the ethyleneprotonium ion *(130)*, a hydrogen bridged carbonium ion[208].



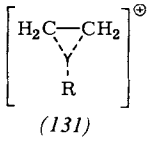
(130)

In protonated higher olefins the three-center bond formation should, because of electronic and steric effects, be unsymmetrical (oriented). Furthermore, both theoretical calculations[209] and lack of experimental observation indicate that bridged alkeneprotonium ions (as well as "alkenealkonium" ions) can exist only as high energy transition states, not as intermediates, but no decision can be made on this point as yet[209]. Subsequent opening of the three-center bond gives the carbenium ion intermediates of highest stability (which explains the empirical Markownikoff rule).

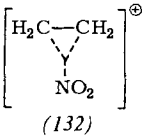


(2)

Alkylation, nitration, *etc.* of π-bonds is also considered to involve similar interactions with formation of tetracoordinated carbonium ion transition states *(131)* and *(133)* with three-center bonds.

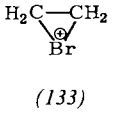


(131)

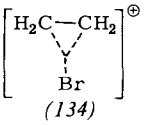


(132)

In contrast the long-lived ethylenebromonium ion *(133)* and other alkenehalonium ions are not three-center bound ions, but three-membered cyclic halonium ions with covalent C-halogen bonds[210]. These ions are clearly intermediates and the three-center bound halonium ions such as *(134)*—similar to previously discussed ions—could

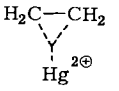


(133)



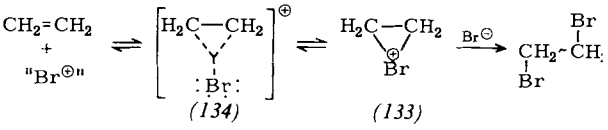
(134)

be the transition states leading to them; however, the existence of three-center bonded halonium ion intermediates cannot be ruled out. Distinction between the two different types of alkenonium ions is not always clear, although it could be, for example, in the case of observable intermediates by comparison of the NMR spectra. NMR data of the observed three-membered ring halonium ions and the three-center bound ethylenemercurinium ion *(135)*[211] (which can serve as model compounds) are quite different. [*(134)*, $\delta_H = 5.53$, $\delta_{^{13}C} = 120.8$; *(135)*, $\delta_H = 7.68$, $\delta_{^{13}C} = 57$.] Even if in the latter case the bonding is somewhat different (due to additional d-orbital participation) to what would be the case in a three-center bound halonium ion, increased p-character of the carbon atomic orbitals in a tetracoordinated carbonium ion should be reflected by substantial deshielding of the chemical shifts (caused also by higher charge density on these atoms).



(135)

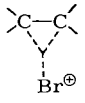
In electrophilic halogen additions to olefins the electrophilic halogen is considered to interact through its vacant atomic orbital with the π-electron pair of the olefin to form a two-electron three-center bonded ion (or probably transition state). Opening of the three-center bond and simultaneous participation of the halogen non-bonded electron pairs then gives the three-membered halonium ion intermediate (which can be spectroscopically observed and also isolated). Subsequent displacement by halide ion from the back-side results in the generally observed *trans* stereospecificity of the addition.



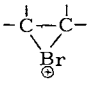
(134) *(133)*

An alternate route can be considered for the initial interaction between olefin and bromine: polarized molecular bromine reacts with the π-bond through overlap of the back-lobe of the antibonding molecular orbital of the bromine to give the three-center bound transition state.

Strating, Wieringa, and *Wynberg*[212] recently isolated a bromonium ion salt of adamantylideneadamantane. Recent studies by with *Schilling, Westerman,* and *Lin*[212a] by ^1H and ^{13}C-NMR spectroscopy have shown that the Br_2 and Cl_2 complexes of adamantylideneadamantane, as the Ag^+ complex, are indeed three-center bound



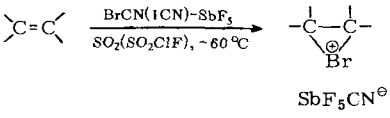
π-complex



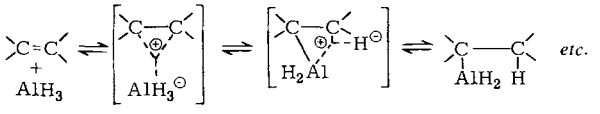
σ-complex

alkenonium ions (π-complexes), whereas the H^+ complex (in superacids) is the rapidly exchanging (equilibrating) alkenium ion (σ-complex). Thus, for the first time a direct differentiation of alkenium (σ-complex) from alkenonium ions (π-complexes) was achieved in electrophilic reactions of alkenes (even if highly hindered ones).

We have also been able to achieve the first direct preparation of cyclic three-membered σ-bound halonium ions by electrophilic halogenation of less hindered olefins by reacting tetramethylethylene and ethylene, respectively, with cyanogen iodide (bromide) in presence of SbF_5 in SO_2 or SO_2ClF solution at −78 °C.



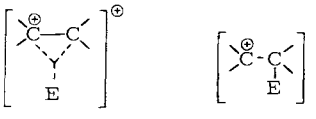
In electrophilic reactions of various π-bonded systems the electrophiles can be defined in a broad sense according to the generalized Lowry-Brønsted concept. Addition reactions, for example, are equally well carried out with various cationic reagents or Lewis acids, such as BH_3[213] or AlH_3[214] (*Brown* hydroboration[213] or *Ziegler* hydroalanation[214]).



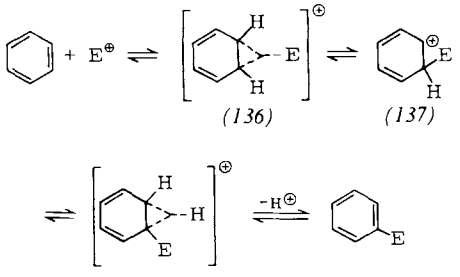
Since the B—H or Al—H bonds act as internal nucleophile during opening of the three-center bond it is clear why hydroboration and hydroalumination show *cis* stereospecificity whereas halogen additions generally proceed by *trans* addition.

Electrophilic reactions by Lewis acid type reagents on σ-bonds are considered less favorable, since the weaker electron donor σ-electron pair is generally not able to form carbonium ions *via* electron pair sharing with Lewis acids (which frequently are dimeric or polymeric halogen bridged reagents like aluminum or antimony halides, and become electron deficient reagents only on breaking the halogen bridges). That is the reason why Friedel-Crafts catalyzed hydrocarbon reactions generally need co-catalysts to provide protic or carbocationic reactivity.

Electrophilic additions to olefins can be considered, in accordance with the Hammond postulate[215], to involve transition states resembling either the intermediate trivalent carbenium (or, in the case of halogenation, three-membered ring halonium) ions or starting olefins. In the first case the new covalent bond is more developed in the transition state than in the latter. Thus the position of the transition state is not fixed and can vary along the reaction path and can resemble either starting olefin or carbenium ion intermediate.



A similar situation is found in aromatic electrophilic substitutions[216]. Once again, in these reactions we must assume the electron donor ability of a π-electron pair towards the electrophile will result in formation of a tetracoordinated three-center bonded benzonium ion *(136)* (π-complex type transition state). Subsequent cleavage of the three-center bond gives a trivalent benzenium ion *(137)* (σ-complex intermediate). The transition state, once again, can either resemble starting aromatics (when it lies early on the reaction coordinate) or be of arenium ion nature (in case of late transition states). For a more detailed discussion of the mechanism of electrophilic aromatic substitution see a recent review [216].



π-Electron pairs are, of course, stronger electron donors than σ-electron pairs. In systems containing both π- and σ-bonds, therefore, the π-system is generally the reactive site. For example, in toluene, electrophilic reactions lead to substitution at the ring and not at the methyl group. However, if we make the π-system less available (either by deactivating groups or by steric crowding) the σ-bonds of the methyl group can become more reactive. Thus pentafluorotoluene undergoes electrophilic reactions on the methyl group[217].

Similar considerations are also valid for the reactivity of deactivated or sterically hindered olefins and other π-donor systems.

Dewar[218] should be credited with having advanced the concept of "π-complex" interaction of electrophiles with π-donor systems as far back as in the 1940's. π-Complexes were, however, generally regarded only as weak donor/acceptor interactions between the π-donor system and the electron-deficient reactant. *Dewar*, however, considered them as much stronger "molecular bonds", the π-electron pair overlapping with the electron-deficient species' empty orbital. In 1965, when discussing "nonclassical ions" as π-complexes, *Dewar* and *Marchand*[219] stated, "...in a true π-complex, the π-donor and acceptor are linked by a covalent bond, not by weak forces of van der Waal's type." Dewar's π-complexes indeed are carbonium ions (alkonium ions) involving two-electron, three-center bonds, with the π-system supplying the electron pair for the bond.

It should be emphasized that the chemical literature contains in many instances suggestions for bridged (symmetrical or unsymmetrical) cationic intermediates, besides Dewar's π-complexes. For example, *Taft*[208] suggested that the protonation of olefins leads first to a separate π-bonded species which subsequently can transform into a carbenium ion. *Ingold*[220], *Winstein*[221], *Bartlett*[222], *Cram*[223], *Stiles*[224], *Berson*[225], *Allen*, *Schleyer*, and *Pople*[226] as well as other investigators have on different occasions discussed in considerable depth the question of bridging in carbocations. Only our recent studies, however, have

shown that the unifying principle of all electrophilic reactions is indeed the general donor ability of the bonded electron-pairs of either π- or σ-bonds to form, with the vacant orbital of the electrophile, triangular two-electron three center bound carbonium ions (transition states or intermediates), which subsequently can give trivalent carbenium ions or lead to substitution (addition) products[12].

5. Outlook

In conclusion, the differentiation of trivalent carbenium from penta- or tetracoordinated carbonium ions, based on their direct observation, showing marked differences, for example, in their NMR and ESCA spectra, should put an end to much of the "myth" surrounding organic cations and to the so-called "classical-nonclassical ion controversy". In defining limiting categories of carbocations it must be clearly understood, of course, that there exists the possibility of a whole spectrum of ions or intermediate degrees of delocalization (or partial "nonclassical" nature) and therefore division in strictly limiting categories frequently is arbitrary. Whereas the norbornyl cation itself, for example, is a completely symmetrically delocalized nonclassical carbonium ion, the 2-methylnorbornyl cation shows partial delocalization. More importantly, the concept of pentacoordinated carbonium ion formation *via* electron sharing of single bonds with electrophilic reagents in three-center bond formation promises to open up a whole new important area of chemistry. Whereas the concept of tetravalency of carbon obviously is not affected, carbon penta- (or tetra-)coordination as a general phenomenon must be recognized. Trivalent carbenium ions play a major role in electrophilic reactions of π- and n-donors, whereas pentacoordinated carbonium ions play an equally important similar role in electrophilic reactions of σ-donor saturated systems. Accordingly electron donors can be categorized into the following types:

Types of electron donors

π-Donors bonded (shared) electron pair donors	σ-Donors	n-Donors non-bonded (unshared) electron pair donors
alkenes alkynes aromatics	alkanes single bonds of all types, such as C—H, C—C, H—H, *etc.*	hetero-atoms, such as O, S, N, Hal *etc.* carbanions

The realization of the electron donor ability of shared (bonded) electron pairs (single bonds) could one day rank equal in importance with *G. N. Lewis*' realization[227] of the importance of the electron donor unshared (non-bonded) electron pairs. We can now not only explain the reactivity of saturated hydrocarbons and single bonds in general in electrophilic reactions, but indeed use this understanding to explore many new areas and reactions of carbocation chemistry.

Finally, I would like to point out that my review deals primarily with the structural problems of carbocations based on the direct (spectroscopic) observation of long-lived ions and the role carbocations play in the course of electrophilic reactions. No attempt has been made to give a complete survey of this very large and active field. I would, therefore, like to apologize to all those colleagues working in this field whose important contributions have not been mentioned. The choice of material was strongly influenced by limitations of space and my own interests and should not be assumed as a critical evaluation. Our own studies were inevitably strongly emphasized and served as a basis for development of the general concepts presented.

Support of our work by the National Science Foundation, the Petroleum Research Fund administered by the American Chemical Society, the U.S. Army Research Office, and the National Institutes of Health, US Public Health Service is gratefully acknowledged. My particular thanks go to all members of my research group (past and present) whose enthusiastic hard work really made our studies possible. Their names are found in the references.

The John Simon Guggenheim Memorial Foundation is thanked for a fellowship which greatly facilitated the preparation of this manuscript.

Polar Cycloadditions[**]

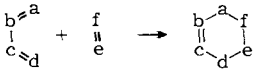
By Richard R. Schmidt[*]

Cycloadditions with ionic components are known as "polar cycloadditions" to distinguish them from cycloadditions with dipolar and uncharged components. The structural requirements, the manner in which "polar" intermediates capable of addition are produced and their reactivity with activated and nonactivated multiple bonds, the many peculiarities of the course of the cycloaddition, and the favorable synthesis of heterocyclic systems by this reaction principle makes such a terminological distinction useful and necessary if the existing data are to be brought into order. The present review, which is the first on a field of chemistry that has not yet been very extensively investigated, deals initially with cationic and then with anionic polar cycloadditions.

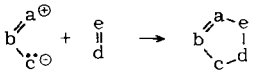
1. Introduction

1.1. Polar Cycloadditions—Definition

Cycloadditions with uncharged [eq. (1)] and dipolar components [eq. (2)] are widely known synthetic principles. Between these there are cycloadditions with positively and negatively charged ionic components, whose reactivity is



(1)



(2)

due primarily to their electrophilic or nucleophilic character. These reactions will be classified as "polar cycloadditions" [eq. (3a) and (3b)][*][1]. They are of interest in particular for the feasible synthesis of heterocycles, the inclusion of nonactivated multiple bonds in the scope of the reaction, and the numerous questions raised by following this synthetic route.

It is suggested that the number of ring atoms contributed by the ionic or "polar" components[**] and also the charge on the reactive centers should be indicated by descriptions such as $[4^{\oplus}+2]$ and $[3^{\ominus}+2]$ cycloadditions[***].

However, this tells us nothing about the reaction mechanism. The intermediate position of polar cycloadditions between those with uncharged components and those with dipolar ones is not merely formal. Thus transitions from synchronous (*i.e.* simultaneous, though not necessarily equally fast) to non-synchronous formation of the new σ bonds to give the cycloadduct are often observed here;

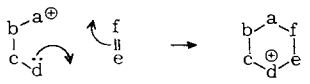
[*] Doz. Dr. R. R. Schmidt
Institut für Organische Chemie der Universität
7 Stuttgart 1, Azenbergstrasse 14 (Germany)

[**] Note added in proof: The importance of this reaction principle has recently been further demonstrated by *Eschenmoser* [148], *Ghosez* [149], *Huisgen* [150], *Schöllkopf* [151], *Corey et al.* [152], and some other research groups.

[*] A few examples were compiled earlier and their peculiarity stressed; see Ref. [7], pages 607, 608.

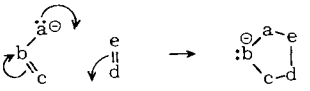
[**] The number of ring atoms contributed by the individual components has been used by *Huisgen* [2] for the classification of cycloadditions.

[***] Cycloadditions with uncharged components, such as Diels-Alder reactions, can then be described, as in the past [2], as [4+2] cycloadditions, and *e.g.* dipolar 1,4-cycloadditions are distinguished from these by designation as $[4^{\oplus}+2]$ cycloadditions; see also [3].



(3a)

$[4^{\oplus} + 2]$-Cycloaddition



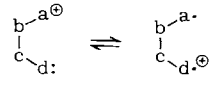
(3b)

$[3^{\ominus} + 2]$-Cycloaddition

the "conservation of orbital symmetry"[4] as an energy factor for the occurrence of the reaction is then outweighed by other energy factors, and the new σ bonds, as in many electrophilic and nucleophilic additions, are formed consecutively. For mechanistic differentiation, therefore, in synchronous reactions controlled by orbital symmetry after *Woodward* and *Hoffmann*[4], the type of orbital, the number of electrons present, and the steric participation in the reaction are indicated, insofar as they have been investigated and discussed; the course of the reaction, *i.e.* electrophilic or nucleophilic addition, is also denoted.

The polar systems capable of cycloaddition frequently cannot be isolated, but must be produced *in situ* from neutral molecules. If the formation of the new σ bond begins when the bond to the leaving group is still only partly broken, cationoid or anionoid instead of free polar systems occur as intermediates of the cycloadditions. Contact ion pairs and solvent-separated ion pairs are therefore possible intermediates of these reactions and the influence of the solvent on the course of the reaction should be large.

The polar systems may also form diradical-cations; an example is shown in eq. (4). This possibility, which has so far been considered mainly theoretically (see Section 2.5 and Ref.[133]), will not be discussed here.



(4)

In this review, the reaction principle of "polar cycloaddition" will be derived for the case of $[4^{\oplus} + 2]$ cycloadditions and then extended to other types of reactions. Mechanistic criteria cannot be used for the subdivision of the subject matter, owing to the many possibilities available. The structural variation of polar systems having the same charge and the same number of centers yield important knowledge for the understanding of these reactions; this is therefore taken as the essential basis for the subdivision of the material. The variation of the number of centers of polar systems having comparable structures and equal charges also has interesting aspects; this is illustrated by an example in Section 2.5.

1.2. Cycloadditions with Uncharged and Dipolar Components

Before discussing polar cycloadditions, let us briefly consider thermal cycloadditions with uncharged and dipolar components.

The synthesis of three-membered and four-membered rings is limited to the cycloaddition of sextet centers[5] (carbenes and nitrenes) and the cycloaddition of particularly reactive enes and heteroenes[4,6] (ketenes, isocyanates, *etc.*) to multiple bonds. Many five-membered heterocycles are obtainable by 1,3-dipolar cycloadditions[7]. The dimerization of 1,3 dipoles is only of limited use for the synthesis of six-membered heterocycles. The Diels-Alder synthesis has not attained the same importance for heterocycles[8] as for carbocycles. An important synthetic principle for heterocycles is the 1,4-dipolar cycloaddition[9,10]. Larger rings can be prepared by cycloadditions with uncharged components or dipoles only in isolated cases[4].

The main factors that determine this situation are as follows:

a) Uncharged systems with more than two conjugated multiple bonds (*e.g.* conjugated trienes) and particularly dipolar species with more than four centers (*e.g.* 1,5 dipoles) frequently change into the ring form in an irreversible electrocyclic reaction. Moreover, cycloaddition reactions are hindered by the molecular geometry of such systems.

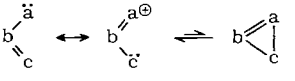
b) In cycloadditions, new σ bonds are generally formed at the cost of energy-rich π bonds. Most hetero-multiple bonds are in comparison poorer in energy than the corresponding CC multiple bonds (see Table 1); they are therefore less suitable for cycloadditions to nonpolar components.

Table 1. Average bond energies in kcal/mol[a].

C—C	83	C—N	69.7	C—O	84.0
C=C	147	C=N	147	C=O	164
C≡C	194	C≡N	207		

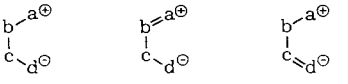
[a] *L. Pauling:* The Nature of the Chemical Bond. Cornell University Press, Ithaca, N.Y.

c) Of the dipolar intermediates, only the 1,3 dipoles are ideal cycloaddition reactants, since the valence-tautomeric three-membered ring, because of its high ring strain, is often richer in energy than the 1,3 dipole, which is comparable to the conjugated dienes [eq. (5)][7,11].

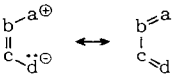


(5)

On the other hand, the production of 1,4-dipolar species is subject to very strict structural conditions. The two charges must be separated by quaternary centers, so that the energy-rich 1,4 dipole [of the type (6)] cannot change into the diene [of the type (7)], which is poorer in energy. The localization of the charges generally leaves little room for cycloaddition reactions between the irreversible intramolecular cyclization and the excessive stabilization of the



(6)



(7)

charges by appropriate substituents. The isolation of 1,4 dipoles that are capable of addition is therefore particularly important[10][*].

d) With the exception of carbenes and nitrenes the above mentioned cycloaddition components generally react only with activated multiple bonds[7].

However, as is well known, electron withdrawing and electron releasing substituents promote cycloadditions and Lewis acids are good catalysts for some of these reactions. Therefore, the more electrophilic or nucleophilic positively or negatively charged cycloaddition components should react with nonactivated multiple bonds. The polar cycloadditions demonstrate this valuable extension of the reaction scope to less reactive π-systems in many instances.

2. Cationic Polar Cycloadditions

2.1. [$4^{\oplus}+2$] Cycloadditions

2.1.1. The Structure of Polar 1,4 Systems

A cationic polar 1,4 system is defined as a compound a—b—c—d that has a sextet of electrons and a positive formal charge on a. There is at least one lone pair of electrons on d, or there is a pair of π electrons between c and d. The polar 1,4 system can form a cycloadduct with a multiple bond system e=f or e≡f. Center d or c then carries a positive formal charge in the cycloadduct.

The delocalization of the charge over several atoms is an important energy factor in the occurrence of these reactions. However, the cycloadduct is frequently stabilized by rearrangement or removal of a positive residue. The definition of the term "cycloaddition" by *Huisgen*[2], which excludes the elimination of small molecules or ions in the cycloaddition step, marks some of the polar cycloadditions discussed below as limiting cases.

The above definition allows at least the seven structurally different polar 1,4 systems *(1)* to *(7a)*. The two reactive centers a and d in these systems will generally react independently of each other (unless the relatively small interaction of orbitals *via* σ bonds[12] provides a reaction-determining energy contribution, for which there is as yet no experimental evidence in polar systems[13]):

a) The orbitals on a and d available for the formation of the new σ bonds are separated by tetragonal centers in *(2)*, *(3)*, *(5)*, and *(7)*.

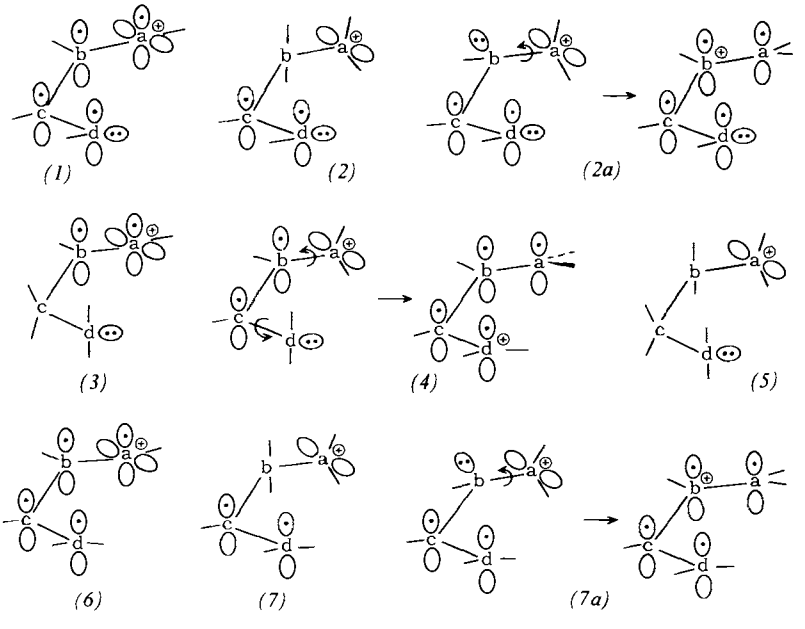
b) Though there is a conjugated 4π system in *(1)* and *(6)*, the empty vinyl cation orbital on a, which is orthogonal to the 4π system and to the non-bonding electron pair on d, is more reactive.

The situation is changed in the system *(4)* and in the systems *(2)* and *(7)* if b represents an atom with a non-bonding pair of electrons [≙ *(2a)* or *(7a)*]:

The orbitals available on a and d for the formation of the new σ bonds are coupled by π-electron resonance, and the system as a whole is stabilized by charge delocalization, so that Diels-Alder-like components are present. Synchronous cycloadditions, which follow the Woodward-Hoffmann rules[4], may now be energetically favored.

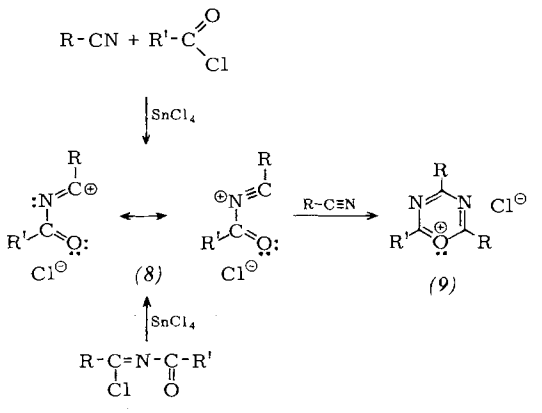
2.1.2. [$4^{\oplus}+2$] Cycloadditions *via (1)*

The reaction of acyl chlorides with nitriles in the presence of Lewis acids leads to 1,3,5-oxadiazinium salts *(9)*[14,15]. Since *N*-acylimidoyl chlorides also give *(9)* with nitriles and tin(IV) chloride[15], these reactions may, according to *Meerwein et al.*[16], be assumed to involve *N*-acylnitrilium ions *(8)* as intermediates. The cations *(8)* generally cannot

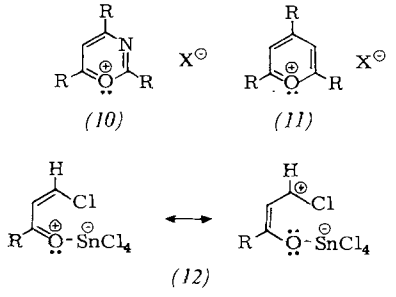


be isolated; they add to further nitrile to form the heteroaromatic compound *(9)*[15].

[*] 1,1 and 1,2 dipoles that are capable of cycloaddition cannot be produced, unless *e.g.* singlet-sextet centers are designated as 1,4 dipoles.



This reaction has been extended to cyanates[17] and cyanamides[18]. Acetylenes can also be used as cycloaddition partners; the 1,3-oxazinium salts *(10)* obtained in this way[15,19,20] are interesting intermediates for syntheses[21].



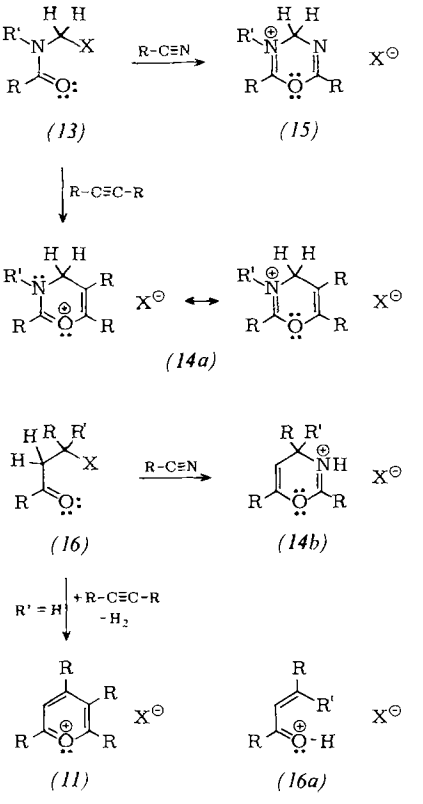
The reactions of the β-chlorovinyl ketones are formally comparable. With acetylenes they lead to pyrylium salts *(11)*[15,22,23], and with nitriles they give moderate yields of 1,3-oxazinium salts *(10)*[19]; the pyrylium salts *(11)* can also be obtained directly from acyl chlorides, acetylenes, and tin(IV) chloride[23].

Though the cycloaddition step in these reactions is reversible and subject to thermodynamic control, the formation of energy-rich vinyl cations from β-chlorovinyl ketones must be regarded as doubtful. IR-spectroscopic findings[20,24] are compatible with the formation of the undoubtedly strongly electrophilic complex *(12)*, which reacts with systems containing triple bonds to give the adducts *(10)* and *(11)*.

The reasons for the fact that numerous Diels-Alder reactions can be catalyzed by Lewis acids[25] are probably similar. Thus an increase in the electrophilic (or nucleophilic, see Section 3) strength of a cycloaddition partner by charge transfer considerably widens the scope of such reactions (see Section 1.2).

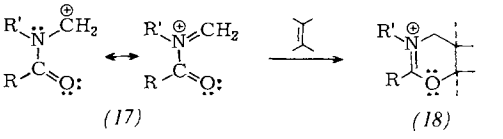
2.1.3. [4⊕+2] Cycloadditions *via (2)*

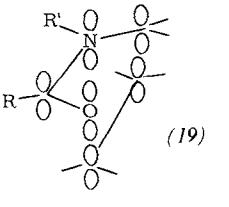
The carbonyl compound *(13)* can be converted into a polar system having the structure *(2)* by loss of the nucleofugal group X; this process is generally facilitated by suitable substitution and by acid catalysis[15,26–28]. Thus *(13)* reacts with acetylenes to give the 4*H*-1,3-oxazinium salts *(14a)*[15,29], and with nitriles to give the 4*H*-1,3,5-oxadiazinium salts *(15)*[30]. The latter reaction is reversible with excess nitrile[31]. The reaction with acetylenes can also be carried out as a multicomponent reaction with acyl chlorides, aldimines, and tin(IV) chloride[29].



Similarly, the pyrylium salts *(11)* are formed from *(16)* and acetylenes *via* unstable dihydropyrylium salts[24,29] by spontaneous dehydrogenation[15,19], and the 4*H*-1,3-oxazinium salts *(14b)* from *(16)* and nitriles by prototropy[26–28]. The polar system *(16a)*, which is structurally related to *(4)*, may be an intermediate in these last reactions.

The orientation in these additions is regiospecific; it corresponds to the rules of electrophilic addition. However, this tells us, *a priori*, nothing about the time sequence of the bond formation in the addition. The *N*-substituted amide *(13)* loses the nucleophilic group X to form the amidomethylium ion *(17)*; *(17)* is a polar system having the structure *(2)*, whose b center is an atom with a lone pair of electrons. In a planar arrangement, the two reactive centers interact *via* π bonds, and the conditions are favorable for a thermally allowed synchronous reaction.





Because of the two hetero atoms and the positive formal charge, however, the reactivity of the amidomethylium ion *(17)* could be changed in such a way that the synchronous action of the two reactivity centers with multiple bonds is overtaken by the two-step electrophilic cycloaddition.

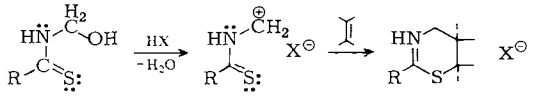
The reaction course was investigated for the cycloaddition of *(17)* to activated and nonactivated olefins, which leads in excellent yields to variously substituted 5,6-dihydro-4*H*-1,3-oxazinium ions *(18)*[32-35]. A two-step course was first deduced from the directional specificity[32]. The *cis* stereospecificity, the weak substituent effect, the inverse addition to methacrylic esters, the formation of a single product on addition to norbornene, and the results of an investigation on the geometry of the transition state in this cycloaddition support the multicenter process[33-35]. According to *Huisgen*[36], however, it is conceivable that the new σ bonds differ in the extent to which they have been formed in the transition state.

The orbital interaction and its importance to the reaction in such unsymmetrical systems has not yet been discussed. However, all the facts are compatible with a $[{}_{\pi}4_s + {}_{\pi}2_s]$ process with *(19)* as the transition state, this being the most probable of several possible[4,12] cyclic transition states.

The addition of chiral amidomethylium ions [*e.g. (17)*, R = C_6H_5—$CH(OCH_3)$] to olefins having no plane of symmetry in the plane of the π bond is a diastereogenic reaction. The determination of the ratio of the diastereoisomers (*e.g.* by NMR spectroscopy) provides information about the kinetic or thermodynamic control of the new σ bonds. Investigations of this kind show that in additions to electron-richer olefins, as even to α-methylstyrene, the kinetically controlled synchronous addition of *(17)* is accompanied by a slow two-step reaction, and that the bond between O and C-6 in the cycloadduct *(18)* is reversibly broken[37].

The synthesis of the oxazinium ions *(18)* can also be carried out as a three-component process by reaction of carboxamides, formaldehyde or formaldehyde derivatives, and olefins in glacial acetic acid/sulfuric acid[35,38-40] or of carbonyl chloride, *N*-alkylaldimine, and olefin in the presence of tin(IV) chloride[35]. The cycloaddition of the amidomethylium ions *(17)*, with R = alkyl and aryl, to 1,3-dienes yields 6-vinyl-substituted oxazinium ions[32,35]; according to *Merten* and *Müller*[41] and to *Petersen*[42], tetrahydropyridines can be prepared with alkoxy-substituted amidomethylium ions [*(17)*, R = alkoxy] by [$2^{\oplus}+4$] cycloaddition (see Section 2.3.1.).

Thioamidomethylium ions *(20)* can be produced *in situ* from hydroxymethyl compounds by acid catalysis and added in a similar manner to olefins to form 5,6-dihydro-4*H*-1,3-thiazinium salts *(21)*[30]. The addition is directionally specific and stereospecific; the yields are lower than in the reaction of amidomethylium ions *(17)*[30].

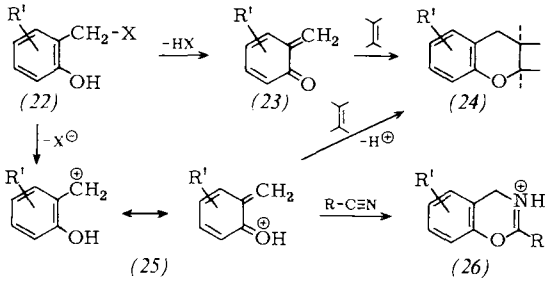


(20) *(21)*

2.1.4. [$4^{\oplus}+2$] Cycloadditions *via (4)*

In these systems the reactive centers are coupled by π-electron resonance, so that conditions are favorable for thermally allowed synchronous reactions.

The reactions of *o*-hydroxybenzyl alcohols, *o*-hydroxybenzylamines, and *o*-hydroxybenzyl halides [*(22)*, X = OH, NR_2, Hal] are particularly interesting. Unstable *o*-quinonemethides *(23)* can be produced *in situ* by thermal cleavage[44-46] or by the action of bases[47], and these react with olefins in a [4 + 2] cycloaddition to give moderate yields of chromans. The [$4^{\oplus}+2$] cycloaddition of the more electrophilic protonated *o*-quinonemethides *(25)* to olefins allows a distinct improvement of the yield[47,48]. Not unexpectedly, the addition is *cis*-stereospecific, and is also directionally specific if the olefin substituents are sufficiently different[48]; the time sequence of the bond formation has not yet been investigated[*].

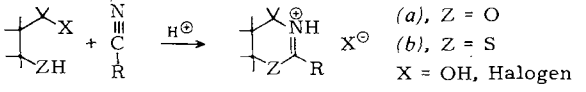


(22) *(23)* *(24)* *(25)* *(26)*

The protonated *o*-quinonemethides *(25)* add smoothly to nitriles to form 4*H*-1,3-benzoxazinium ions *(26)*[19,50] The synthesis of 1,4- and 3,4-dihydroquinazolines from α-chloromethylanilines, nitriles, and tin(IV) chloride[51] is comparable with this reaction.

2.1.5. [$4^{\oplus}+2$] Cycloadditions *via (5)*

The linkage of the reactive centers in the system *(5)* *via* tetragonal centers suggests *a priori* that the formation of the new σ bonds in the cycloaddition should be independent of time. Representative examples are the synthesis of 5,6-dihydro-4*H*-1,3-oxazinium salts *(27a)* from 1,3-diols[52-54] or 3-halopropanols[55] and nitriles by the action of acids, as well as the synthesis of 5,6-dihydro-4*H*-1,3-thiazinium salts *(27b)* from mercapto alcohols and nitriles[55-58] and the synthesis of 6*H*-1,3-thiazines from β-mercapto ketones and nitriles[59] by the action of acids.



(a), Z = O
(b), Z = S
X = OH, Halogen

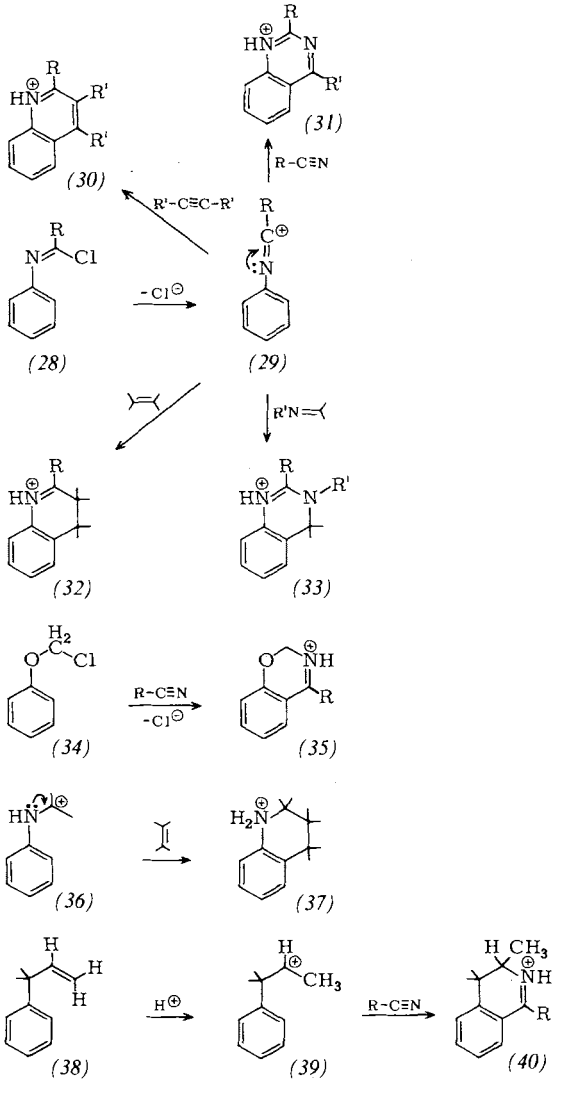
(27)

2.1.6. [$4^{\oplus}+2$] Cycloadditions *via (6)* and *(7)*

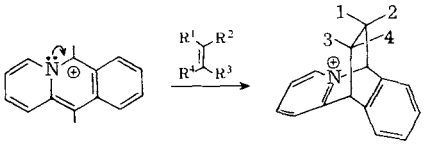
The cycloaddition of the systems *(6)* and *(7)* to multiple bonds leads to a formal positive charge at the c center; the resulting energy-rich intermediate is then often stabilized by loss of a positive residue.

[*] Enol ethers [47] and enamines [49] undergo [4 + 2] cycloadditions.

N-Arylimidoyl chlorides *(28)* can thus be converted with Lewis acids into isolable, resonance-stabilized cations *(29)*, which undergo cycloaddition with alkynes, nitriles, olefins, and electron-deficient imines to give quinolines *(30)*[60], quinazolines *(31)*[61,62], 3,4-dihydroquinolines *(32)*[19], and 3,4-dihydroquinazolines *(33)*[1] in good yields. The reaction of α-chloromethyl phenyl ether *(34)* with nitriles similarly leads to 2*H*-1,3-benzoxazines *(35)*[19], the reactions of the *N*-arylimonium ions *(36)* with olefins to tetrahydroquinolines *(37)*[63], and the reaction of allylaromatic compounds *(38)*, and of many starting compounds that give arylethyl cations *(39)* under the action of acids, with nitriles to 3,4-dihydroisoquinolines *(40)*[64–69]. Comparable reactions can also be carried out with unsaturated aliphatic systems[69]. The stereochemistry of the olefin reactions mentioned above has not yet been investigated. For simplicity, the products are shown in the protonated form.



The cycloadditions of acridizinium systems *(41)* to olefins to form the adducts *(42)–(45)*[70–73] should also be mentioned. The polar 1,4-system *(41)* is formally identical with *(36)* in the occupation of the centers. On thermodynamic grounds, however, the reaction stops at the cycloadduct stage in this case, whereas the intermediate adduct in the reaction of *(36)* with olefins undergoes cleavage of a C—H bond to give the system *(37)*.



(41) *(42)–(45)*

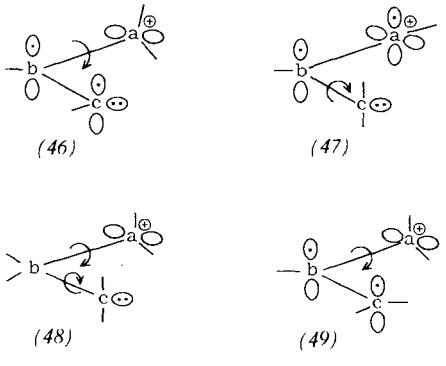
	1	2	3	4
(42)	R^1	R^2	R^3	R^4
(43)	R^2	R^1	R^4	R^3
(44)	R^1	R^2	R^4	R^3
(45)	R^2	R^1	R^3	R^4

The acridizinium ion *(41)* is a polar system having the structure *(7)*, with a lone pair of electrons on the atom at the b center; the conditions are therefore favorable for a synchronous cycloaddition (see Section 2.1.1.). The addition is substantially direction-specific, but generally only diastereoselective (the diastereoisomers *(42)* and *(43)* are formed in different quantities). Moreover, the adducts *(44)* and *(45)* of the olefin rotamers are formed on addition to electron-deficient olefins; this points to a two-step process[71]. Whether this is also true of electron-richer olefins remains to be answered by further investigations.

(41) also reacts with acetylene derivatives[74]; moreover, analogous adducts are formed from isoquinolinium salts[75], 7a- and 11a-azoniabenz[*a*]anthracene[75,76], 9a-azoniabenzo[*b*]triphenylene[76], 5a-azonianaphthacene[76] and 4a, 8a-diazoniapentaphene[76].

2.2. [3⊕ + 2] and [3⊕ + 4] Cycloadditions

Polar 1,3 systems occur chiefly in the forms *(46)–(49)*.



(46) *(47)*

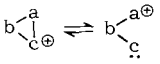
(48) *(49)*

The two centers a and c will react independently of each other in the systems *(46)–(48)*. The orbitals available on a and c for the formation of the new σ bonds are separated by a tetragonal center in *(48)*, and no low-energy mesomeric 4π system is to be expected from *(46)* and *(47)* even on suitable rotation about single bonds (see Section 2.1.1.); a 4π system of this type could be present in *(48)* if b is an atom having a lone pair of electrons. Mesomeric 2π allyl cation systems are present in *(46)* and partic-

ularly in *(49)*, so that synchronous supra-suprafacial additions to 4π systems should be possible. Some examples of the systems *(46)*, *(48)*, and *(49)* are mentioned below.

A preferred method for the production of such systems is the cleavage of three-membered rings with acids. Thus the valence tautomerism described by *Greene* and *Hecht*[11] between the three-membered rings and the corresponding 1,3-dipoles is strongly dependent on the groups representing a, b, and c. In the case of the three-membered ring cations, however, there is generally a distinct preference for the open-chain polar 1,3 system.

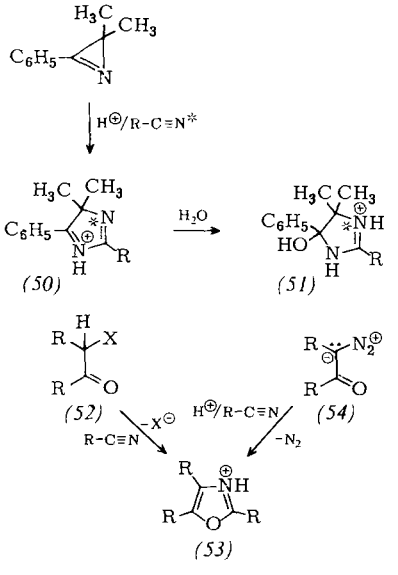
(8)



(9)

2.2.1. [3⊕+2] Cycloadditions *via (46)*

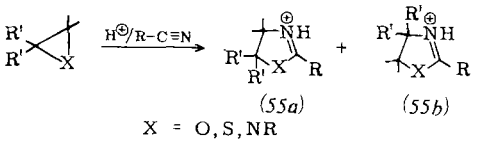
Azirines add to nitriles in acidic solution. The imidazolium ions *(50)* are formed as intermediates, and have been isolated as water adducts *(51)*[77]. The position of the cleavage of the azirine ring has been established by labeling of the nitrile nitrogen atom.



Oxazolium ions *(53)* are readily obtained by reaction of α-halo ketones *(52)*, X = halogen, with nitriles in the presence of Lewis acids[78,79]. α-Hydroxy ketones *(52)*, X = OH[80], and α-diazo ketones *(54)*[19] react similarly in the presence of protonic acids. On the other hand, the 1,3 dipole formed from *(54)* generally adds to nitriles only in very modest yields[81]. Oxazolones are obtained from α-hydroxy carboxylic acids[82–84] or cyclopropenylcarboxylic acids[85] with nitriles.

2.2.2. [3⊕+2] Cycloadditions *via (48)*

Epoxides are converted into the oxazolinium ions *(55)*, X = O, in the presence of nitriles under the action of acids[77,86,87]. Similarly, episulfides are converted into thiazolinium ions *(55)*, X = S[88,89]. The episulfide ring cleavage takes place stereospecifically with inversion; it may be assumed, therefore, that neither a free carbenium ion nor an ion pair occurs as an intermediate in the ring cleavage. Intermediates of this type are, however, formed in the analogous reaction of allylthiols or 2-mercapto alcohols in the presence to acids. Addition to nitriles also leads to thiazolinium ions[90,91]. The acid-catalyzed additions of epoxides to ketones, aldehydes, isocyanates, SO_2, SO_3, and CO_2[92], for example, may also be included in this group.

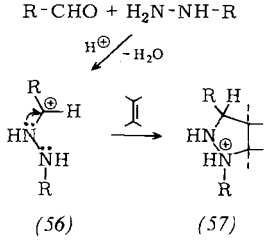


(55a) *(55b)*

X = O, S, NR

Aziridines are converted by protonation or alkylation into aziridinium salts, which readily undergo ring cleavage[93]. The resulting reactive intermediates add to nitriles to form imidazolinium ions *(55)*, X = NH or NR[77,94–97] and to aldehydes and ketones to form oxazolidinium ions[93,96,98–100]. The two new σ bonds are formed independently of each other in two steps[93].

The described ring cleavage of aziridines, epoxides, and episulfides always leads to the more stable carbenium ion as an intermediate[102]; the isomers *(55a)* and *(55b)* are formed together if the stabilities of the corresponding intermediates are comparable.

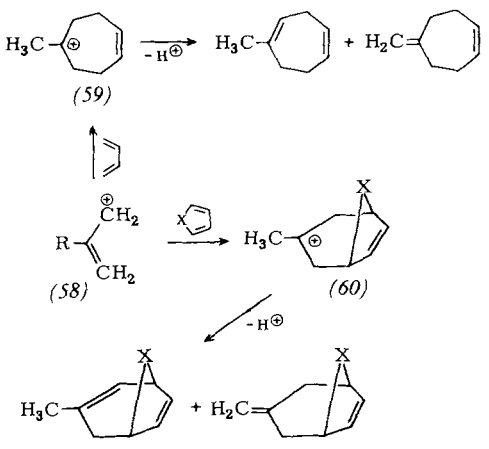


(56) *(57)*

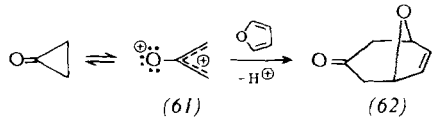
A particularly interesting [3⊕+2] cycloaddition was described by *Hesse*[101]. The *N*-aminoimonium ions *(56)* formed as intermediates from aldehydes and hydrazines can add to olefins with formation of pyrazolidinium ions *(57)*. The polar 1,3 system *(56)* may undergo a synchronous $[_\pi 4_s + _\pi 2_s]$ cycloaddition with olefins because of the nonbonding pair of electrons on the b center; so far as we know, however, the course of the reaction has not yet been investigated.

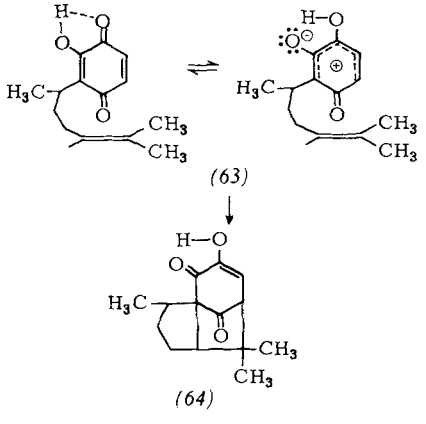
2.2.3. [3⊕+4] Cycloadditions *via (49)*

Allyl cations *(58)* are ideal examples of polar systems having the structure *(49)*, since the interaction between a and c is not disturbed by differences in the electronegativities of the centers. The conditions are therefore favorable for a synchronous addition to dienes in the form of a $[_\pi 4_s + _\pi 2_s]$ cycloaddition. 2-Methylallyl cations *(58)*, R = CH_3, can in fact add *cis*-specifically to open-chain and cyclic conjugated dienes. The reaction leads *via* positively charged cycloheptenes *(59)* and branched cycloheptenes *(60)* by deprotonation to cycloheptadienes and methylenecycloheptenes or the corresponding bridged compounds[103–106].



Cyclopropanones react with conjugated dienes, *e.g.* furan, to form adducts of the type *(62)*[107-109]. Possibly the cyclopropanone exists in equilibrium with a dipolar species *(61)*. *(61)* could react as a 2π-electron system and combine with dienes in a $[_\pi 4_s + _\pi 2_s]$-process[4]. This interpretation of the reaction course by *Woodward* and *Hoffmann*[4] presupposes the detection of this ring cleavage; a $[_\pi 4_s + _\sigma 2_s]$-process, without prior opening of the cyclopropane σ bond, could also explain the reaction.

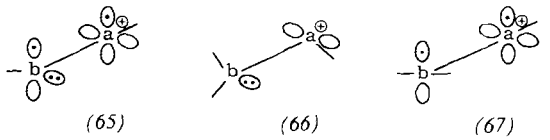




The formulation of polar systems by localization of π electrons of uncharged π systems would suggest that the formation of the pipitzols *(64)* from perezone *(63)*[110] involves a $[5^{\oplus} + 2]$ cycloaddition[4], and ultimately leads to the classification of the addition of ketenes to 2π systems as the cycloaddition of a vinyl cation[4,111] to a 2π system (see Section 2.3).

2.3. $[2^{\oplus} + 2]$ and $[2^{\oplus} + 4]$ Cycloadditions

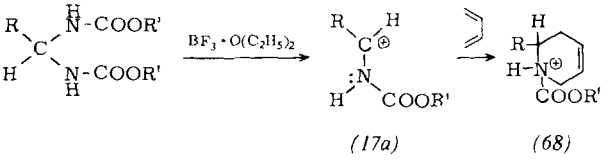
Polar 1,2 systems can occur mainly in the forms *(65)*–*(67)*.



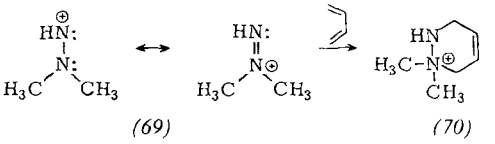
The two reactive centers a and b in the systems *(65)* and *(66)* interact *via* 2π electrons, so that with 1,3-dienes $[_\pi 4_s + _\pi 2_s]$ processes are possible. No such interaction occurs in the system *(67)*. Synchronous processes are possible, if at all, only with the aid of the π bond between a and b, *e.g.* as $[_\pi 2_a + _\pi 2_s]$ processes[4,109-111]. Examples of the systems *(66)* and *(67)* are given below.

2.3.1. $[2^{\oplus} + 4]$ Cycloadditions *via (66)*

Alkoxycarbonylamidomethylium ions *(17a)*, as was mentioned earlier (see Section 2.1.3), add *cis*-stereospecifically to conjugated dienes to form tetrahydropyridines *(68)*[40,41]. This reaction was successfully used by *Huisman*[112] for the synthesis of azasteroids.

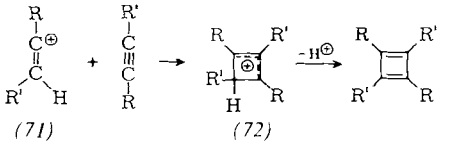


The azalog of *(17a)* behaves similarly. Thus the diazenium ion *(69)* reacts smoothly with conjugated dienes to form tetrahydropyridazines *(70)*[113,114]. The reaction mechanism has not yet been verified for either reaction.



2.3.2. $[2^{\oplus} + 2]$ Cycloadditions *via (67)*

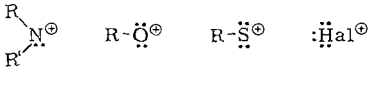
The most important example here is the formation of cyclobutenyl cations *(72)* from vinyl cations *(71)* and acetylene derivatives[117-119], which led to the synthesis of the first stable cyclobutadiene[118]. The discussion of the reaction mechanism is probably not yet closed[4,111]. The ketene-olefin addition (see Section 2.2.3) should not be included in this reaction scheme because of formal considerations.



Whether [2+2] cycloadditions catalyzed by transition metal ions[115] and a number of other reactions[*] should be mentioned as $[2^{\oplus} + 2]$ cycloadditions must be left for further investigations to decide.

2.4. $[1^{\oplus} + 2]$ and $[1^{\oplus} + 4]$ Cycloadditions

Polar 1,1 systems capable of cycloaddition consist of positively charged centers with a non-bonding occupied and an unoccupied orbital. Examples of such systems are the following cations:



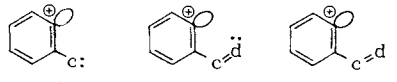
[*] See *e.g.* the formation of pyridylcyclobutanes by acid-catalyzed cycloaddition of enamines to vinylpyridines[116].

Numerous groups having a corresponding electronic structure are also to be found among the transition metal ions.

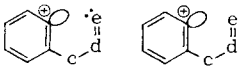
Though $[1^{\oplus}+2]$ and $[1^{\oplus}+4]$ cycloadditions of these positively charged sextet centers to 2π and conjugated 4π systems are generally accepted[120], details are still under discussion[121-124]. Two-electron three-center bonds between 2π systems and the unoccupied orbitals of protons or carbenium ions (with formation of non-classical carbonium ions) may be included here[125,126].

2.5. Cycloadditions *via* Phenyl Cations

The ionic components capable of cycloaddition that were mentioned in Sections 2.1 to 2.4 have an alkyl cation or vinyl cation structure or a comparable structure on the a center. Thus there still remains the questions of phenyl cations capable of cycloaddition. According to the structural requirements discussed above for polar systems they should have *e.g.* the structures *(73)–(77)*.



(73) [≙*(47)*] *(74)* [≙*(1)*] *(75)* [≙*(6)*]



(76) *(77)*

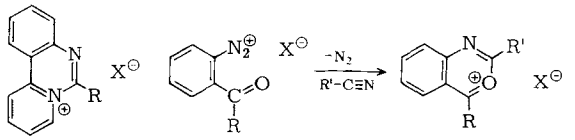
Cationic species of this nature can be formally produced by thermolysis of benzenediazonium ions, since the thermal decomposition of diazonium ions is the prototype of the aromatic S_N1 reaction[127-129].

Investigations of this type are significant for the discussion of the interaction of orbitals that are separated by one or more σ bonds and whose preferred direction is in the plane of the σ skeleton[12,13]. Some examples will be given here to allow the discussion of the variation of the number of centers of polar systems having the same structure and charge.

Thus cycloadducts are formed *via* the intermediate *(74)* on thermolysis of 2-(α-pyridyl)benzenediazonium salts in nitriles, which serve both as reactants and as the reaction medium. Derivatives of pyrido[1,2-*c*]quinazoline *(78)*[13,43,130] are formed in excellent yields. Instead of a CN group, a CO double bond *ortho* to the diazonium group can act as a functional group. Thus the analogous reaction of the *o*-carbonyl-substituted benzenediazonium salts *(79a)–(79d)* yields benzoxazinium salts *(80)*[13,130,131].

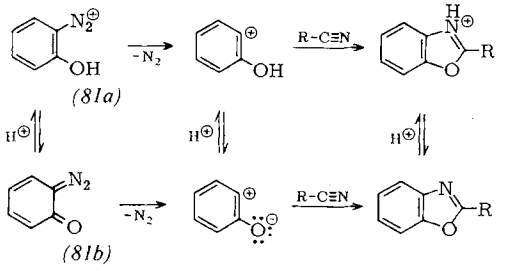
The *o*-carboxybenzenediazonium salt *(79e)* behaves quite differently from the corresponding acid *(79d)*[13,131]. This has a parallel in the behavior of the *o*-hydroxybenzenediazonium ion *(81a)* and the corresponding diazo ketone *(81b)*[130]. Whereas the thermolysis of *(81b)* in nitriles generally leads in modest yields to benzoxazoles in accordance with the 1,3-dipolar cycloaddition scheme[81], the reaction of *(81a)* can be directed *via* an intermediate of the type *(73)* to give benzoxazolium ions in good yields[130].

The two nitrogen-free species thus react differently. The unprotonated form, despite the fact that a dipolar structure can be formulated[81], reacts more slowly with the nitrile than to form competing products; the protonated form, on the other hand, reacts faster with the nitrile (for α-diazo ketones, see Section 2.2.1).



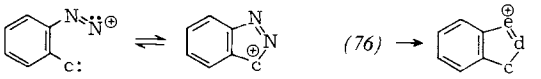
(78) *(79)* *(80)*

(a), R = Aryl; *(b)*, R = Alkyl; *(c)*, R = NR_2; *(d)*, R = OH; *(e)*, R = $O^{\ominus}$



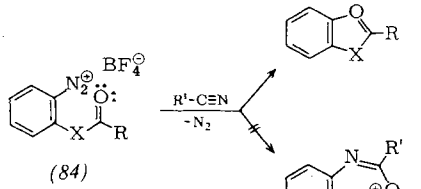
(81a) *(81b)*

All investigations have shown that the diazonium ion must be present in the free state. Intramolecular cyclizations with *ortho* substituents as in equilibrium *(82a)*⇌*(82b)* interfere with the cycloadduct formation after the liberation of nitrogen (free-radical intermediates presumably occur[132]). Because of the low electrophilic strength of the diazonium group, therefore, the best results are obtained in a weakly acidic medium[19].



(82a) *(82b)* *(83)*

An increase in the number of ring atoms, as in *(76)* and *(77)*, suppresses the intramolecular cyclization of the diazonium compound in accordance with *(82a)*⇌*(82b)* on steric grounds, but facilitates the intramolecular reaction of the phenyl cation *(76)* to form the system *(83)*[130]. Thus in the thermolysis of the diazonium salt *(84)* in nitriles, the reaction leading to the five-membered heterocycle is accelerated at least to such a degree that the intermolecular reaction with a nitrile to form the seven-membered heterocycle is no longer important[130].

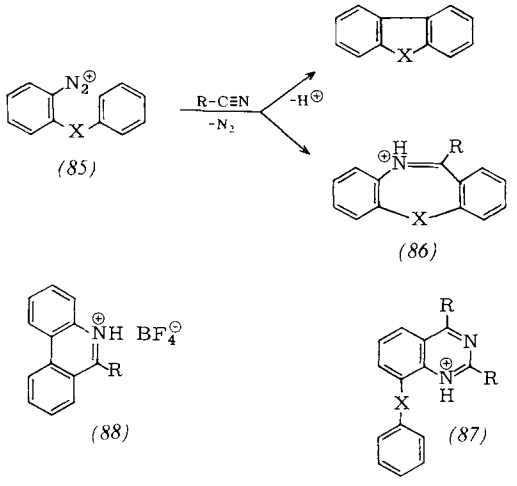


(84)

(a), X = N-CH_3, R = C_6H_5
(b), X = CH_2, R = OH

If the reactivity of the e center of *(76)* is reduced by transition to systems having the structure *(77)*, the intramolecular reaction is retarded.

This case is found in the thermolysis of diazonium ions having the structure *(85)*[13,130,133]. The main products are the morphanthridines *(86)*, X=CH_2, dibenz[*b*,*f*][1,4]oxazepines *(86)*, X=O, and dibenzo[*b*,*f*][1,4]thiazepines *(86)*, X=S. However, the products of the intramolecular reaction are also formed in small quantities by a Pschorr ring closure, as well as the quinazolines *(87)* by twofold reaction with the nitrile. If there are no functional groups *ortho* to the diazonium group, *(87)* becomes the main product[16]. The synthesis of phenanthridines *(88)* from *o*-phenylbenzenediazonium salts[13,133-135], which is derived from system *(75)*, proceeds without appreciable by-products, since the intramolecular reaction of the intermediate would lead to energy-rich four-membered ring systems. *(85)*–*(87)* are shown as cations for the sake of simplicity.



(85) *(86)* *(88)* *(87)*

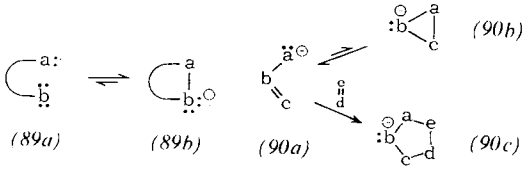
In addition to nitriles, isocyanides can also be successfully used as addition partners for ionic components of this type, and [4⊕+1] and [5⊕+1]-cycloadducts are obtained[13,136].

3. Anionic Polar Cycloadditions

Anionic intermediates that are capable of cycloaddition are much less known than cationic intermediates. There may be two reasons for this:

1. Systematic investigations on reactions of this type have only recently been carried out[137-140].

2. Systems with negative charges on the reactive center a and a sextet of electrons on the second reactive center b, as in *(89a)*, probably change irreversibly into the cyclic form *(89b)*. The remaining polar intermediates capable

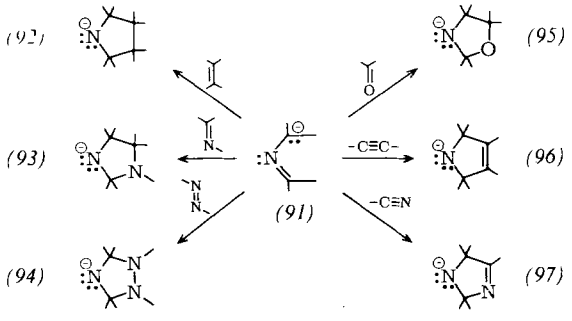


(89a) *(89b)* *(90a)* *(90b)* *(90c)*

of cycloaddition are thus mainly systems having the structure *(90a)* with a multiple bond between b and c. On intramolecular cyclization to form *(90b)* or on cycloaddition to form *(90c)*, the center b accepts a lone pair of electrons and also the negative charge. If b is more electronegative than a or if the tendency for the π bond in the addition partner d=e to disappear is great, the cycloaddition will be favored on thermodynamic grounds.

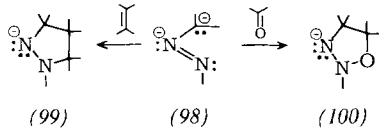
3.1. [3⊖+2] Cycloadditions

Outstanding examples in accordance with the scheme *(90a)*→*(90c)* are the cycloadditions of the 2-azallyl[137,139,140] and 1,2-diazallyl anions[138] *(91)* and *(98)* to 2π systems by *Kauffmann*[137-140]. Thus *(91)* can add smoothly to olefins, azomethines, azo compounds, ketones, acetylenes, and nitriles, the electronegative nitrogen atom of *(91)* taking over the negative charge. The corresponding five-membered heterocycles can be obtained from the anions *(92)*–*(97)*. The diazallyl anion *(98)* similarly adds to olefins and ketones with formation of the five-membered heterocycles *(99)* and *(100)* (shown as anions) respectively. The two reactive centers in the allyl anion system interact with each other *via* π electrons, so that the observed stereospecific *cis*-addition is not surprising and a [$_{\pi}4_s+_{\pi}2_s$] process seems likely.



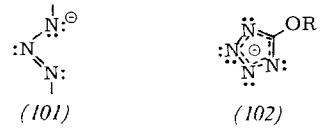
(92) *(93)* *(94)* *(91)* *(95)* *(96)* *(97)*

The localization of the negative charge on a more electronegative atom suggests that *(98)* should have less tendency than *(91)* to undergo addition; the nucleophilicity of the reactive component is reduced as a whole[139]. Cycloadditions to the even more inert triazallyl anion *(101)* are unknown.



(99) *(98)* *(100)*

Strong stabilization of the cycloadduct by delocalization of the negative charge occurs on addition of the azide ion to cyanate to form tetrazolyl anions *(102)*[141]. The lower nucleophilicity of the azide ion is compensated for by the energy gain on formation of the heteroaromatic compound.

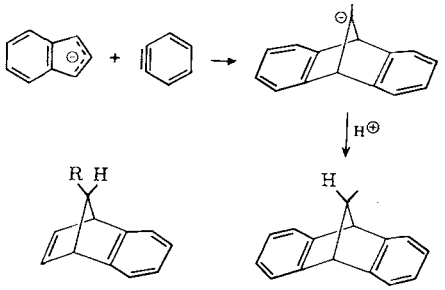


(101) *(102)*

The stabilization of a cycloadduct anion by localization of the negative charge on a more electronegative atom or by delocalization is also responsible for the addition of transition metal complex anions *e.g.* to olefins[142].

Questions of this nature are of minor importance in the case of particularly reactive addition partners. The energy for the localization of the negative charge on a less favored center is supplied by the reactive addition partner.

Thus allyl anions (or their metal compounds as anionoids) such as the indenyl anion and the cyclopentadienyl anion add smoothly to dehydrobenzene to form dibenzonorbornadiene *(103)*[142-144] or benzonorbornadiene *(104)*[145].



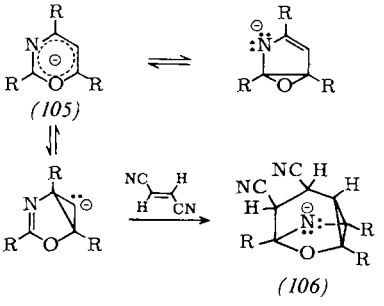
(104) *(103)*

3.2. $[4^{\ominus}+2]$ Cycloadditions

Cycloadditions of anionic components having more than three centers are practically unknown, though there are in principle many possibilities. This will be illustrated by two examples of $[4^{\ominus}+2]$ cycloadditions.

Anionic intermediates formed *in situ* from acetylide ions and nitriles give pyridines or pyrimidines on addition of a further molecule of acetylene or nitrile[146].

Heterocyclic 8π systems having the structure *(105)* are electronically destabilized[147]; they can escape from this state by valence tautomerism. Cycloaddition reactions may also be included in this process; thus *(105)* reacts with fumarodinitrile *via* the anion to give the heterotricycle *(106)* together with other products[19].



(105) *(106)*

4. Closing Remarks

The survey of polar cycloadditions has shown that besides carbocycles, very many heterocycles can be synthesized from ionic components by this reaction principle. Some of these ionic components can be isolated, while sometimes they occur in the form of reactive intermediates. In the first case the driving force for the reaction lies in the particular stability of the end products, and in the second case in the enhanced reactivity of the intermediates.

The number of unused reaction possibilities is undoubtedly very large, and the number of mechanistic questions that have not been clarified is equally large. This latter statement refers both to the structure of the polar intermediates and to the nature of the addition to multiple-bond systems. The clarification of these mechanistic questions is particularly interesting in that boundary cases between synchronous and non-synchronous formation of the new σ bonds are very often found. Moreover, some of these polar systems are good examples for the investigation of orbital interaction *via* σ bonds[12,13]

There are two main characteristics that distinguish the polar from the non-polar and dipolar cycloaddition components:

1. The high electrophilic or nucleophilic strength makes them ideal cycloaddition partners for hetero-multiple bonds and all kinds of olefins.

2. The tendency toward irreversible intramolecular cyclization is much weaker than in the dipolar cycloaddition components.

The importance of cycloadditions with polar components, therefore, is probably no less than that of cycloadditions with uncharged and with dipolar components.

I thank Professor R. Gompper for valuable discussions, and am grateful to Frau G. Falkner, Fräulein H. Vatter, Dipl.-Chem. A. R. Hoffmann, and Dipl.-Chem. W. Schneider for their active assistance. Thanks are due also to Prof. H. Bredereck, the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support of this work.

Spectroscopic Properties of Organic Azo Compounds

By Hermann Rau[*]

Azo compounds are characterized by a low-energy $^1(n,\pi^*)$ electronic state, which gives rise to a weak band at long wavelengths in the absorption spectrum. Coupling of this state with other low-lying molecular states is responsible for the high intensity of the "azo band" compared to other forbidden transitions, for its lack of vibrational structure, and for the inability of nearly all organic azo compounds to fluoresce.

1. Introduction

Although the azo group —N=N— has given its name to a large class of organic dyes, spectroscopists have shown comparatively little interest in this atomic grouping. The reason may lie in the effects of two rules characterizing the spectroscopic behavior of the azo compounds:

1. the azo group has a "structure-destroying effect"[1];

2. azo compounds do not emit.

The information that can be gleaned from absorption and emission spectra is therefore very limited.

By searching for exceptions to these rules, however, it is possible to clarify the spectroscopic properties in molecular terms. This involves the extensive use of theoretical considerations, and because of the shortage of experimental data the conclusions are necessarily somewhat speculative.

Only one field of the spectroscopy of azo compounds has been investigated in depth, *i.e.* their photochemistry, in particular the *cis-trans* isomerization of aromatic azo compounds and the photodecomposition of aliphatic azo compounds. These two processes will be considered in

[*] Doz. Dr. H. Rau
Abteilung für Physikalische Chemie der Universität
Hohenheim (LH)
7 Stuttgart 70, Postfach 106 (Germany)

the following discussion only insofar as they are relevant to the coupling of the lowest excited states.

2. Fundamentals

2.1. Molecular States

2.1.1. Pure Stationary States

It is known from spectroscopic experiments that a molecular system can absorb or emit radiation only in characteristic quanta $h\nu$, and that in so doing it passes from one energy state into another (Fig. 1a). The spin state must remain the same in this process ($S_0 \rightarrow S_1$), any change in multiplicity ($S_0 \rightarrow T_1$) being forbidden.

This leads to an energy level diagram as shown in Figure 1b in which electronic states are combined with vibrational states $v_0, v_1, v_2 \ldots$, the individual properties of the states being retained.

2.1.3. Nonstationary States

The independence of the coordinates is really only an approximation, which is satisfied to a greater or lesser degree by any real system. Electronic and vibrational states may be coupled among themselves and with one another.

Since the molecular states have the properties of oscillators, interaction between two states leads to two new states, one of higher energy and another of lower energy (Fig. 1c). The splitting ΔE depends on the extent of coupling.

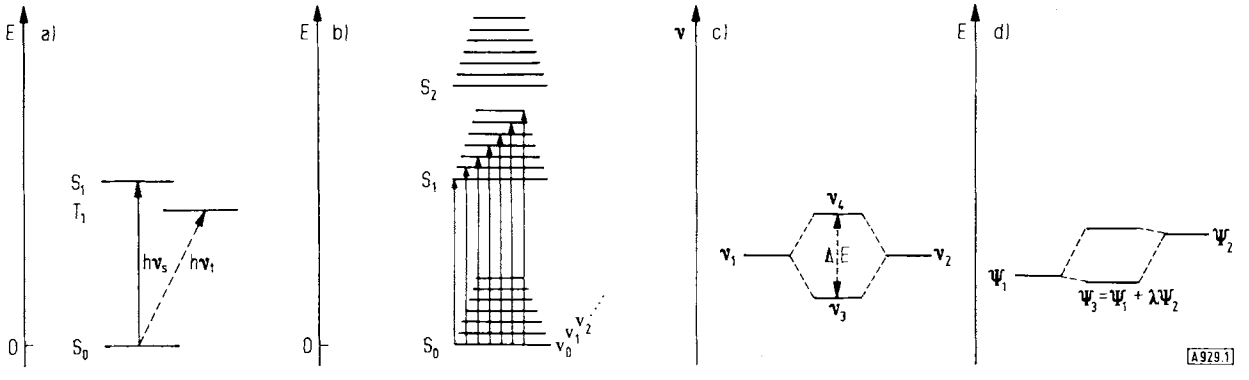

Fig. 1. a) Stationary states; b) Born-Oppenheimer states; c) coupled classical oscillators; d) coupled molecular states.

These states are characterized in that the molecular system does not spend only a short time in them. They are described by standing matter waves, the wave function containing all the information about the state. The spectroscopist is interested in energy, symmetry, and lifetime. A state in which the molecule remains is a pure stationary state.

2.1.2. Quasistationary States

States observed by spectroscopic means cannot be pure stationary states, for spectroscopy registers only transitions. However, the states that can be detected spectroscopically are normally so long-lived that they may be regarded as quasistationary and described by a single wave function.

The Born-Oppenheimer (BO) functions are particularly suitable for describing such states. In the BO approximation the internal coordinates of the molecule are resolved into three independent sets corresponding to electronic motion, vibration, and rotation. For molecules in solution, the rotational structure can be observed only in very rare cases; we shall therefore disregard rotation. The complete function of the vibronic state can then be represented in the BO approximation as the product of the electronic and vibrational functions.

$$\psi = \theta(r,q) \cdot \varphi(q) \qquad (1)$$

where r is the set of electronic coordinates and q the set of vibrational coordinates.

In wave-mechanical formalism, coupled states are described by mixing of wave functions (Fig. 1d):

$$\psi = \psi_1 + \lambda\psi_2 = \psi_1 + \frac{\int \psi_1 \mathbf{V} \psi_2 d\tau}{E_1 - E_2} \psi_2 \qquad (2)$$

The mixing coefficient λ is the ratio of the coupling energy between the states ψ_1 and ψ_2 under the interaction $\mathbf{V}$ to the energy difference $E_2 - E_1$. The BO approximation is valid as long as $\lambda \ll 1$.

Another property of coupled states can be illustrated by the behavior of two identical coupled pendulums. If one pendulum is set in motion, the other soon starts to swing, and takes over the energy of motion to such a degree that the first pendulum comes to rest, whereupon the process starts anew with the roles reversed. A molecular system moves to and fro between coupled states, so that the individual state is no longer stationary.

The time τ_p required by the system to return to a certain state depends on the intensity of coupling and on the complexity of the system. The weaker the coupling and the greater the number of coupled states, the longer the system will take to return to its original state, *i.e.* the greater is τ_p[12].

2.2. The Azo Group

The azo group consists of two nitrogen atoms linked by a double bond, each of these atoms carrying a non-bonding

pair of electrons. The chemical and photochemical stability of azo compounds increases with increasing resonance and inductive interaction with the rest of the molecule[3]. Azo compounds are characterized spectroscopically by a low-energy $^1(n,\pi^*)$ state, which is manifested as a weak absorption band at long wavelengths (*e.g.* Fig. 2).

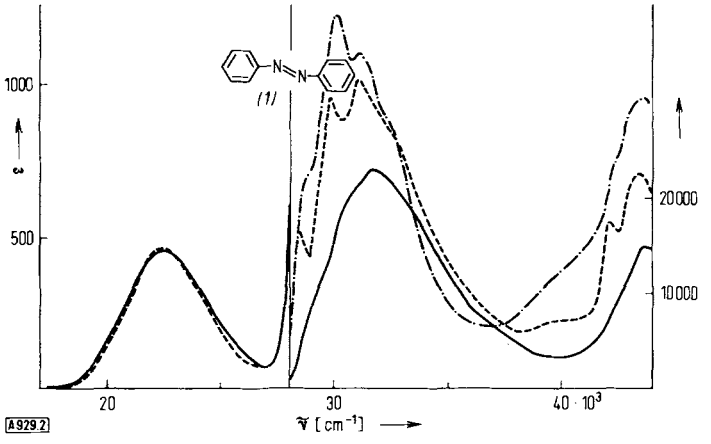

Fig. 2. Absorption of *trans*-azobenzene in methylcyclohexane/isopentane (3:1): ——— at room temperature, – – – – at 77 °K; –·–·– in polyethylene film at room temperature.

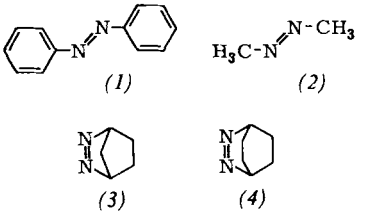
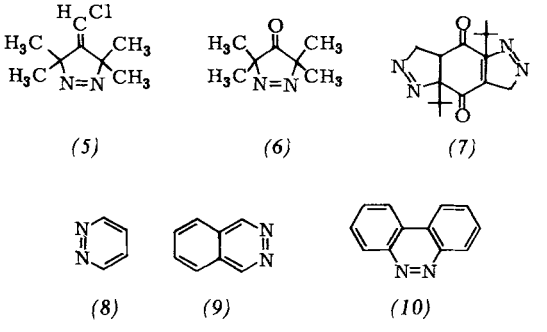
The bond lengths in the azo group are approximately equal in aromatic and in aliphatic azo compounds. The N=N distance is 1.23 Å in azobenzene *(1)*[4] and in azomethane *(2)*[5], and the length of the N—C bond is 1.41 Å in *trans*-azobenzene[6], 1.46 Å in *cis*-azobenzene[7], and 1.47 Å in azomethane[5] (this is practically the length of a resonance-free C—N bond[8]).



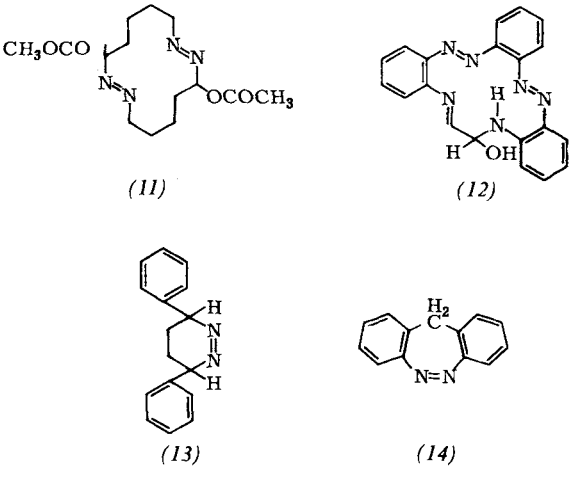
The bond angles at the nitrogen atom are close to 120°[5,6]. This geometry results in *cis-trans* isomerism (cf. *(1)* and *(2)* with *(3)* and *(4)*). The *trans* form is always the more stable of the two isomers. In the case of azobenzene, the energy difference is 12 kcal/mol[9] and the activation energy for the *cis-trans* transition is 23 kcal/mol in solution[10] and 31 kcal/mol in the solid[11], so that the two isomers can be separated at room temperature. For azomethane, this is possible only at low temperatures[12]. Aromatic *cis* azo compounds cannot be planar because of the steric hindrance of the *o*-hydrogen atoms. *cis*-Azobenzene has a planar azo group, but the phenyl rings are parallel to each other and are twisted by 56° out of the plane of the azo group[7].

The azo group in the *cis* configuration can also be part of an aliphatic or aromatic ring system, as in 2,3-diazabicyclo[2.2.1]-2-heptene *(3)*, the corresponding diazabicyclooctene *(4)*, pyrazolines such as *(5)*, *(6)*, and *(7)*, or *o*-diazines such as pyridazine *(8)*, phthalazine *(9)*, or benzo[*c*]cinnoline *(10)*.

These compounds naturally cannot isomerize. Only a few molecules are known which contain a *trans* azo group



in a ring system (*e.g.* *(11)*[13] and *(12)*[14]), and only few spectroscopic data are presently available for the cyclic *trans* azo compounds.



An important factor in the spectroscopy of *cis* and *trans* azo compounds is that they belong to different symmetry groups; the *cis* compounds have C_{2v} symmetry and the *trans* compounds C_{2h}. For aliphatic azo compounds, one need only consider the local symmetry[15] (*e.g.* for *(3)*).

3. Spectral Characteristics of Azo Compounds

3.1. Position of the n→π* Band in the Absorption Spectrum

The position of the n→π* band depends on the groups attached to either end of the azo group[3]. It appears at about 28000 cm^{-1} for aliphatic azo compounds (Table 1) and at 22000 to 23000 cm^{-1} for the aromatic representatives. Surprisingly, the position of the n→π* band is practically unaffected by substitution in aromatic azo compounds, whereas the π→π* bands in the spectrum are shifted considerably (Table 2). This is particularly noticeable for the *trans* diarylazo compounds in Table 3.

Table 1. $n \rightarrow \pi^*$ bands and fluorescence yields of aliphatic azo compounds.

3.2. Intensity of the $n \rightarrow \pi^*$ Band in the Absorption Spectrum

The intensities of the $n \rightarrow \pi^*$ bands of substituted azobenzenes are also only slightly affected by the nature of the substituent (Table 2); for the diarylazo compounds in Table 3, the intensity of the $n \rightarrow \pi^*$ band depends only on the nature of the substituent, and not on its position in the aromatic ring.

The intensity of the $n \rightarrow \pi^*$ band of *trans*-azobenzene decreases with falling temperature (Fig. 2).

The intensities are generally greater for the *cis* azo compounds than for the *trans* isomers (Tables 1, 2, and 4). The oscillator strength of *cis*-azobenzene is of an order of magnitude that is normally restricted to $\pi \rightarrow \pi^*$ transitions.

3.3. Vibrational Structure of the Electronic Bands

3.3.1. Vibrational Structure of the $n \rightarrow \pi^*$ Band

Vibrational structures of electronic bands are normally most pronounced in gas spectra, and the $n \rightarrow \pi^*$ bands usually have a more sharply defined structure than the $\pi \rightarrow \pi^*$ bands[28]. However, the $n \rightarrow \pi^*$ band of gaseous azobenzene[29], and also the long-wave bands of the azoalkanes, are without structure[17,30]; on the other hand, the structures of the $n \rightarrow \pi^*$ band are extremely sharp in *(3)* and *(4)*[20] (Fig. 3a).

Structured $n \rightarrow \pi^*$ bands have not been found in solution for *trans*-azobenzene or *cis*-azobenzene. Even low-temperature spectra (Figs. 2 and 4) and the spectrum of a solution in polyethylene show only continuous $n \rightarrow \pi^*$ bands[29]. Attempts to influence the shape of the $n \rightarrow \pi^*$ band by fixation of the molecule on surfaces have also been unsuccessful[31].

The solution spectra of the acyclic *trans* azo and *cis* azo aliphatic compounds (Table 1) also contain only unstructured bands (Fig. 3b)[16,17]. In contrast, the cyclic aliphatic azo compounds *(3)* and *(4)* in apolar solvents exhibit very sharp structures (Fig. 3b)[20,32]. Distinct structures are observed in the low-temperature spectra of the pyrazolines *(5)* and *(7)*, whereas *(6)* gives a smooth $n \rightarrow \pi^*$ band even under these conditions (Fig. 5)[18].

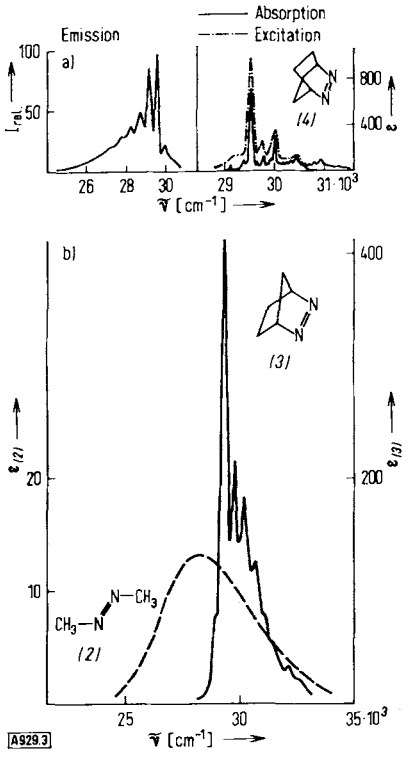

Fig. 3. a) Gas spectra of *(4)* [20]; b) absorption of ——— *(3)* in isooctane [32], --- *trans-(2)* in hexane.

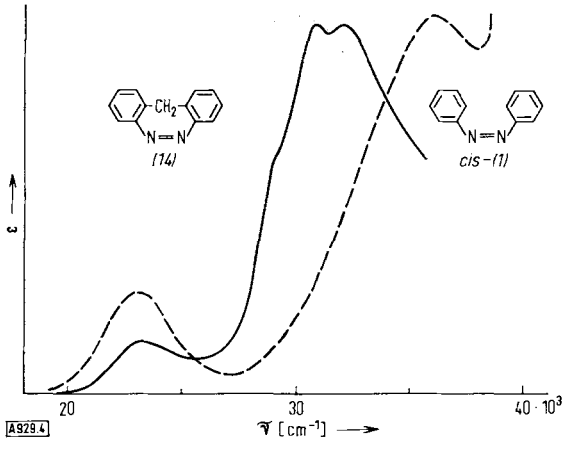

Fig. 4. Absorption of *cis*-azobenzene - - - - - and *o,o'*-azodiphenylmethane ——— in methylcyclohexane/isopentane at 77 °C.

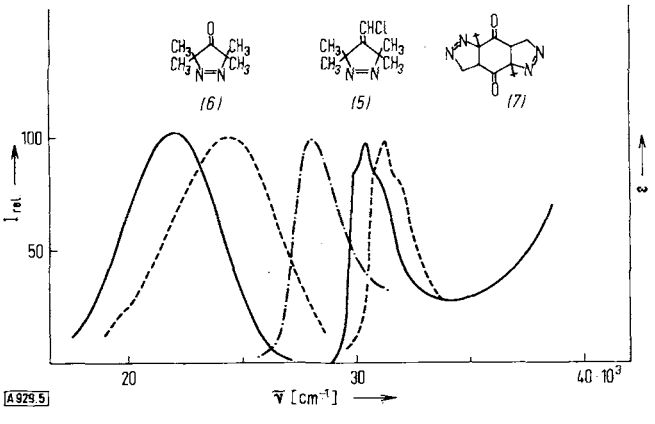

Fig. 5. Absorption and fluorescence of *(7)* - - - - - and *(5)* ——— and absorption of *(6)* -·-·-.

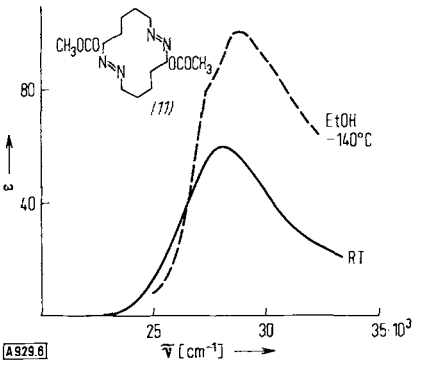

Fig. 6. Absorption of *(11)*.

The *o*-diazines *(8)*, *(9)*, and *(10)* give distinctly structured n→π* bands in apolar solvents, even at room temperature[33-35].

Owing to its solubility properties, a low-temperature spectrum can be recorded for the cyclic *trans* azo compound *(11)* only in polar solvents. In ethanol and ether-ethanol-ethyl acetate mixtures, a shoulder (Fig. 6)[36] appears on the n→π* band at low temperatures.

The crystal spectrum of azobenzene (transmission at 298 and 77 °K and reflection at room temperature) shows only a continuous n→π band[29]. A hint of a structure was found in the low-temperature spectrum of azobenzene in a stilbene host crystal at 77 °K[37], while the n→π* band in the spectrum of azobenzene in a bibenzyl crystal at 20 °K is unstructured[38].

3.3.2. Vibrational Structure of the Low-Energy π→π* Band

The π→π* bands behave quite differently from the n→π* bands with regard to their vibrational structure. The gas spectrum of azobenzene contains a sequence of vibrational bands separated by intervals of 220 cm^{-1}[39,40] and of 1300—1400 cm^{-1}[29].

The π→π* band of *trans*-azobenzene shows a hint of structure in apolar solvents, and this structure becomes sharp for solutions in polyethylene or in solid glasses at 77 °K (Fig. 2)[29].

The π→π* band of *cis*-azobenzene shows no structure even at 77 °K[20], whereas the bridged *o,o'*-azodiphenylmethane *(14)*, in addition to a large red shift and an increase in intensity, gives a structured π→π* band with intervals of 1400—1600 cm^{-1} between the maxima (Fig. 4, Table 4)[19].

The π→π* bands of *o*-diazines are strongly structured; the aromatic character of these compounds is dominant in this respect.

3.4. Emission of Azo Compounds

3.4.1. *trans* Azo Compounds

At present hardly any[*] acyclic *trans* azo compounds are known that exhibit emission, even under conditions that normally promote such behavior, such as deuteration,

[*] Some exceptions are being investigated at present. The reason for the emission of these compounds seems to be the exchange of the $^1(n,\pi^*)$- and $^1(\pi,\pi^*)$-states on the energy scale [31, 41].

incorporation in a vitreous matrix, incorporation in a solid solution, low temperatures, *etc.*

The cyclic *trans* azo compound *(11)* does not fluoresce, even at low temperatures[36], either in solution or in the crystalline state where the azo groups are planar[42]. In ethanolic solution *(12)* fluorescences weakly at room temperature and fairly strongly at low temperatures. Closer investigations lead, however, to the conclusion that it is not the azo form of the molecule that is the emitting species but probably some other tautomeric form[36].

3.4.2. *cis* Azo Compounds

The acyclic aliphatic or aromatic azo compounds in the *cis* configuration do not emit, nor do the nonplanar molecules *o,o'*-azodiphenylmethane *(14)* and *o,o'*-azobibenzyl[19], which are related to *cis*-azobenzene.

Among the cycloaliphatic compounds in Table 1, the rigid bicyclic molecules have higher fluorescence quantum yields than the planar pyrazolines. Diazacyclohexene *(13)* does not fluoresce.

3.4.3. *o*-Diazines

Emission is the rule rather than the exception for these compounds. Pyridazine *(8)*[33] and benzo[*c*]cinnoline *(10)*[35] fluoresce, and phthalazine *(9)*[43,44] phosphoresces.

3.4.4. Protonated Azo Compounds

Azo compounds dissolve readily in strong acids with asymmetric protonation[45,46] and concomitant disappearance of the n→π* band in the absorption spectrum. Almost without exception, the protonated azo compounds fluoresce[47]. Without the low-lying ^{1}(n,π*) state, however, the protonated molecules are spectroscopically no longer azo compounds.

3.4.5. Hydroxy Azo Compounds

Another class of azo compounds that can fluoresce embraces the *o*- and *p*-hydroxy derivatives. However, this fluorescence is due to the tautomeric hydrazone form[48,49].

3.5. Position of the Triplet States in Azo Compounds

Triplet states have not so far been observed for any normal azo compound by the usual spectroscopic methods.

For pyridazine[50] and benzo[*c*]cinnoline[51] it was possible to identify the lowest triplet states, from the crystal absorption spectrum at 4.2 °K, as the ^{3}(n,π*) and the ^{3}(π,π*) states, respectively; phthalazine phosphoresces[44].

In addition to spectroscopic measurements, photosensitized reactions can also provide information about the position of the triplet levels. Azobenzene can undergo photosensitized isomerization, thus revealing that the triplet state lies below 21000 m^{-1}[52]. Azoalkanes quench the phosphorescence of acetone and biacetyl[53]; the singlet-triplet difference is 3000 to 4000 cm^{-1}. A similar split of about 2500 cm^{-1} is found for *(3)*[54]. These results are of the expected order of magnitude[30].

4. Electronic States of the Azo Compounds

4.1. (π,π*) States

The bands of the azo compounds that are attributable to π→π* transitions are very similar to those of the analogous hydrocarbons. Useful methods based on molecular orbital (MO) theory are available for calculation of the π orbitals and π→π* transitions.

One approach using the MO model proceeds according to the "molecules in molecule" (MIM) concept starting from the assumption that the azo compounds consist of more or less strongly coupled electronic subunits; azobenzene, for example, is regarded as two benzene systems and the azo group[55]. This approach is favored by the molecular geometry (Section 2.2). It can be seen from Figure 7 that there is only a small difference between the MO and the MIM energy level diagrams in the simple Hückel-MO approximation.

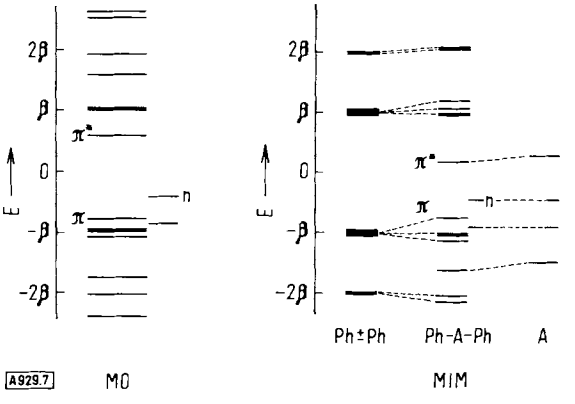

Fig. 7. Energy level diagram of azobenzene in the Hückel MO and MIM approximations.

cis Azo compounds are mostly nonplanar. When this is taken into account, it is possible to simulate the observed solution spectra[25,56]. The effect of steric factors[54,57-59] on the π→π* bands is clear from Figure 4.

4.2. (n,π*) States

4.2.1. MO Model

The n orbitals of the azo group have a symmetry property of the σ-bond skeleton: unlike the π orbitals, they are symmetrical on reflection in the plane of the molecule. If two n orbitals are situated close enough together, as in the azo group, MO theory predicts that they can combine in the same way as the p_z orbitals of the C atoms in conjugated molecules. The two n orbitals then split up into a group orbital having a higher energy and one having a lower energy (Figs. 1d and 8). The functions of the new states, which have definite symmetry properties that differ in the *trans* and in the *cis* isomers, can be expressed in this method as a linear combination of the original n orbitals. Since the group orbitals n_a and n_s are both doubly occupied, they contribute practically nothing to the bond energy.

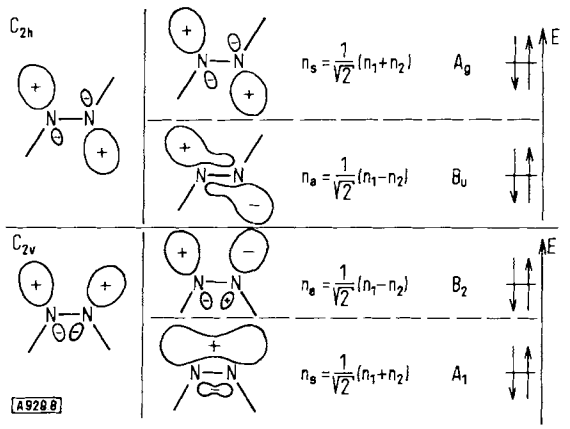

Fig. 8. The n orbitals of the *trans* and *cis* azo compounds in the MO model.

The magnitude of the n_a—n_s splitting has been the subject of a series of theoretical studies within the MO concept. Small values[60] and values of the order of 10000 cm^{-1}[25,37,61] have been calculated for aromatic azo compounds and *o*-diazines. An *ab-initio* calculation even gives 30000 cm^{-1} for diimine HN=NH[30].

In the MO model, the selection rules for *trans* and for *cis* azo compounds are different. For *trans*-azobenzene, the low-energy n→π* band belongs to a forbidden transition, whereas the transition to the higher $^1(n_a,\pi^*)$ state, with the polarization direction perpendicular to the plane of the molecule, is allowed. The situation is reversed for *cis*-azobenzene; the transition to the lowest $^1(n_a,\pi^*)$ state is allowed, again with the polarization direction perpendicular to the plane of the molecule.

In the MIM modification the n_a—n_s splitting is retained on symmetry grounds.

4.2.2. Exciton Model

When an electron localized in an n orbital of a hetero atom is excited into a π* orbital, a positive hole remains behind on the hetero atom, and this must influence the negative charge in the delocalized π* orbital. The charge distributions in the (n,π*) and (π,π*) states will therefore be fundamentally different. If the attraction between the electron and the hole is very strong, the (n,π*) state may be described essentially by an electron-hole pair, *i.e.* an exciton[62].

In molecules such as the *o*-diazines and the azo compounds, two such exciton centers are sufficiently close together for the interaction of the equally large transition moments M_a and M_b to lead to splitting of the exciton states[62,63]. Even when M is small, the splitting can be considerable in azo compounds and *o*-diazines because of the short distance d_{ab} between the centers in a molecule, according to[64]

$$\Delta E = \frac{2M_aM_b}{d_{ab}}.$$

In the exciton model, the selection rules for *cis* and *trans* azo compounds are the same. The position of the transition moments leads to the selection rules for "card-packed dimers"; the low-energy exciton transition is always forbidden, and the other transition is allowed[62–64].

A first theoretical approach has been made to find a model for the n→π* excitation that attempts to combine the elements of the MO and exciton models[65]. However, it has not yet been adapted for azo compounds.

4.2.3. *Ab-Initio* Calculations

The semiempirical MO and exciton models start with the assumption that the n orbitals are localized on the nitrogen atoms. This basis appears uncertain from *ab-initio* calculations. Calculations by various methods for pyrazine lead to the conclusion that the highest occupied n orbital of the ground state has a large share in σ orbitals of other atoms[66,67]. A geometry-dependent participation of the s electrons of the hydrogen in the n orbitals of the azo group is also found from calculations on diimine[30].

This result throws much greater doubt on the applicability of the exciton model than on that of the MO model, since the symmetry properties of the group orbitals at least are retained in the latter case.

4.2.4. Comparison of the Models with Experiment

The correct model must first reproduce correctly the following properties of the spectra of azo compounds: similar energy of the $^1(n,\pi^*)$ states in most of the azo compounds (Tables 1—3), splitting of the n orbitals, and the selection rules.

A constant position of the n→π* bands in the spectrum is compatible with the exciton and the MIM models. The exciton transitions are localized on the nitrogen atom, and they are little influenced by the groups at either end of the azo moiety. A critical comparison of exciton and MO calculations favors the MO theory, since this agrees better with the experimental results[68].

In the MIM modification of the MO model, the π* orbital is a perturbed orbital of the azo group (Fig. 7). On substitution in the aromatic subsystem, therefore, the lowest unoccupied π* orbital is displaced relatively little, whereas the highest occupied π orbital, an orbital of the aromatic subunits, is sensitive to substituents. Thus the π→π* band is displaced on substitution in the phenyl groups of azobenzene or on replacing the benzene by naphthalene moieties, whereas the n→π* band is not. The n→π* transition is localized in the azo group, *i.e.* it is not a charge transfer transition. However, the n→π* band is displaced if the substituent on the phenyl group also carries azo groups, as in bisazobenzene, trisazobenzene, tetrakisazobenzene, *etc.*, since the n orbitals of the individual azo groups can then interact with one another.

The strange similarity of the intensities (Table 3) of the n→π* bands of *trans*-1,1'- and -2,2'-azonaphthalene (symmetry C_{2h}) and *trans*-1,2'-azonaphthalene (symmetry C_s) can also be reconciled with the MIM model. The intensity of the n→π* band is determined only by the nature of the residues on the azo group, and not by the total symmetry of the molecule, as long as the configuration of the azo group itself is not altered. If the configuration is altered, the probability of transition is greatly increased in the *cis* isomer (Table 1). These selection rules provide the strongest argument in favor of the MO model.

Experimental checking of the splitting of the n orbitals as required by the models is hindered by the fact that only the one low energy n→π* band can be satisfactorily assigned in the azo compounds. Numerous attempts have been made to identify weak bands in the spectra of aromatic and aliphatic azo compounds as the second n→π* transition[16,69,70], but these assignments can hardly be regarded as final. However, the splitting of the n orbitals of the ground state is clearly recognizable in the photoelectron spectrum[71], where it has a magnitude of 26000 cm^{-1}

On the other hand, measurements on diazines point to several weak transitions in the region of the long-wave n→π* band[62,72,73]. However, the results are partly contradictory, and the identification of these transitions has not been verified[94].

4.3. Interactions of the Lowest $^1(n,\pi^*)$ State with Other Molecular States

4.3.1. Vibrational Coupling with the Lowest $^1(\pi,\pi^*)$ State

According to the MO theory, which we now favor, the n→π* transition is forbidden in the *trans* azo compounds. The observed intensity is nevertheless unusually high, and for *trans*-azobenzene it is actually higher than for the closely related benzo[*c*]cinnoline, for which the transition is allowed. The reason for this must be that the $^1(n,\pi^*)$ state is not pure (Section 2.1) but is coupled with other states. Such coupling is possible, *e. g.* through a deformation of the molecular field of a certain symmetry by corresponding vibrations or deviations from the planar arrangement of the atoms.

The transition moment $M_{00}^{i\mu}$, which corresponds to the intensity of the transition from the vibrationless electronic ground state $(\theta_0^{(0)}\cdot\varphi_0^0)$ to the μ-th vibrational state of the electronically excited state *i* $(\theta_i^{(0)}\cdot\varphi_\mu^i)$, is

$$M_{00}^{i\mu} = e\int\theta_0^{(0)} r \theta_i^{(0)} d\tau \times \int\varphi_0^0\varphi_\mu^i dq = m_0^i \langle\varphi_0^0|\varphi_\mu^i\rangle \qquad (3)$$

and taking into account the vibrational coupling[74]:

$$M_{00}^{i\mu} = m_0^i \langle\varphi_0^0|\varphi_\mu^i\rangle + \sum_{j\neq i} m_0^j \frac{\int\theta_i^{(0)}\mathbf{V}_\mu\theta_j^{(0)}}{E_j^{(0)} - E_i^{(0)}} d\tau \times \int\varphi_0^0 q_\mu \varphi_\mu^i dq \qquad (4)$$

$\mathbf{V}_\mu$ is the operator of the perturbation of the nuclear field by the vibration μ, q_μ is its normal coordinate, and $E_i^{(0)}$ is the position of the pure electronic level *i* in the energy level diagram. If the transition to the state is electronically forbidden, $m_0^i = 0$, and the observed intensity must be "stolen" from states *j* whose m_0^j is large.

The integrals conceal the selection rules, which can be determined by the use of the character tables; the transition is allowed only if the sign and magnitude of the integrand are unchanged by any symmetry operations that are possible for the molecule in question.

For the *trans* azo compounds, coupling between the $^1(n,\pi^*)$ state and the neighboring allowed $^1(\pi,\pi^*)$ state is possible through an out-of-plane deformation vibration. This brings the polarization direction of the n→π* transition into the direction of the transition moment $m_0^{(\pi,\pi^*)}$. Both bands of *trans*-azobenzene are in fact polarized in the plane of the molecule[17,29,37]. This rules out any possibility that this n→π* transition is allowed, and hence also rules out the applicability of the exciton theory.

An interaction of this type must influence both of the coupled states. This can be seen directly on comparison of the vibrational bands of the π→π transition in the low-temperature spectrum of stilbene and of azobenzene in the bibenzyl host lattice. The bands are about 15 times as broad in the case of azobenzene[38]. The effect of coupling can also be demonstrated by the influence of increasing deviations from a planar molecular structure on the allowed n→π* transition of the *cis* azo compounds. Table 4 shows the correlations between molecular geometry and vibrational structure, intensity of the n→π* band, and fluorescence yield.

Table 4. Correlation between molecular geometry and spectroscopic properties of *cis* azo compounds.

Molecule	n→π*-band structure	ε_{max}	π→π*-band structure	ε_{max}	Fluorescence yield [%]
 *(10)*	pronounced 350 500 cm^{-1}		sharp 500, 1250 cm^{-1}	1500	0.7
 *(14)*	none	970	RT: none 77 °K: weak 1400 cm^{-1}	9900	—
 *(2)*	none	1470	none	5200	—

Benzo[*c*]cinnoline is actually an azo compound rather than a diaza-aromatic compound. The absorption and emission properties[75] can be satisfactorily described by the MIM model.

4.3.2. Interaction with Other States

There is no doubt that the intensity of the n→π* band in the *trans* azo compounds is "stolen" from the π→π* transition. However, this does not necessarily lead to loss of the vibrational structure, as is shown by the sharply structured benzene band at 40000 cm^{-1}.

The overlap integral of the vibrational functions, the so-called Franck-Condon (FC) factors in equation (3), differs from zero only for vibrations of the same symmetry. It is therefore expected that only totally symmetrical vibrations μ determine the structure of the electronic bands. This is observed for the benzene band, and for *trans*-azobenzene one also finds the totally symmetrical N—N stretching vibration at 1400 cm^{-1} in the π→π* band and the totally symmetrical in-plane deformation vibration at 220 cm^{-1}[76]. The n→π* band, however, is structureless.

A band form of this type may be due to a quasi-continuum or to a true level broadening.

A quasi-continuum is observed when the distance between discrete bands is smaller than their half-width. This is possible *e. g.* for polyatomic molecules of low symmetry, where very many vibrations may be stimulated with the

electronic transition. The molecules of azobenzene or azomethane on the other hand, are too small and their symmetry too high for this to occur.

True level broadening is to be expected if, according to the Heisenberg uncertainty relation

$$\Delta t \times \Delta E = 5.25 \times 10^{-12}\ [\mathrm{cm}^{-1}\,\mathrm{s}]$$

the true lifetime $\tau = \Delta t$ of an excited vibronic state is sufficiently small. Line widths of 220 and 1500 cm^{-1} correspond to lifetimes of 2.5×10^{-14} and 3×10^{-15} s respectively.

The intrinsic lifetime of a state, τ_0, which is determined by the rate of the resonance fluorescence, can be calculated from the intensity of the corresponding absorption band[77], and is $\tau_0 = 5 \times 10^{-7}$ s for the $^1(n,\pi^*)$ state of *trans*-azobenzene. This lifetime may be shortened by radiationless processes, which are faster than the emission of light. However, a radiationless transition between two states is possible only if the states are coupled.

The degree to which the states retain their individuality and can be identified in the spectrum is dependent upon the strength of coupling. If the energy of a system capable of vibrating is removed by very tight coupling before the characteristic vibrational motion can develop, the actual lifetime drops to below one vibrational period, and the individuality of this vibration is no longer recognizable. In molecular systems this means that the BO approximation is no longer valid. One interpretation of the lack of structure of the n→π* band of azo compounds would be the assumption of particularly tight coupling of the vibrations in the $^1(n,\pi^*)$ state. However, this is opposed by theoretical considerations[73] and the spectroscopic findings.

The fact that azo compounds do not fluoresce indicates that the coupling of electronic states is responsible for the shape of the n→π* band of the azo compounds. The processes that are important to the deactivation of an excited molecule are outlined in Figure 9.

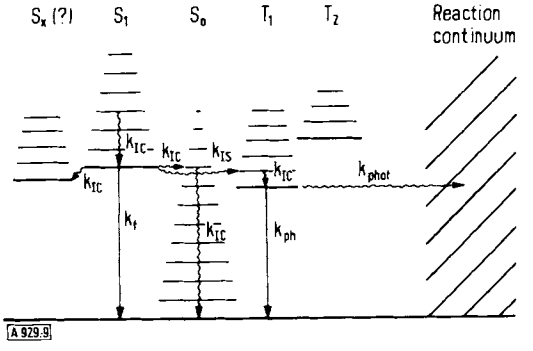

Fig. 9. Deactivation processes.

Transitions in the energy level system can be characterized by first order rate constants; k_f and k_{ph} are the constants for fluorescence and for phosphorescence respectively, k_{IC} is the constant for vibrational relaxation within a multiplicity, and k_{IS} and k_{phot} are the constants for the multiplicity change and for photochemistry.

The most extensively used model of radiationless deactivation[78–81] is based on coupling of the lattice vibrations of the solvent ψ_f, whose number is very large, with the vibrationless excited electronic state ψ', which is assumed to lose its energy non-radiatively (Fig. 10).

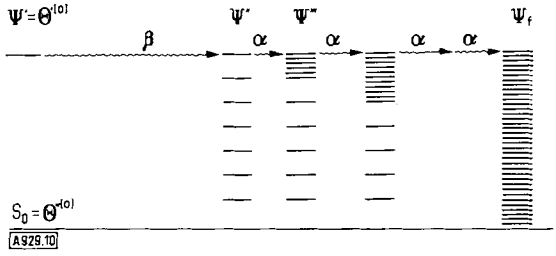

Fig. 10. Coupling in radiationless deactivation.

If only the initial state $\psi' = \theta_1 \cdot \varphi_0^1$ and the final state $\psi'' = \theta_0 \cdot \varphi_\mu^0$ (Fig. 10), a highly excited vibrational state of the electronic ground state, were coupled by a low interaction energy β, the molecular system would oscillate between the two states with a frequency of

$$\frac{1}{\tau} \approx \frac{\beta}{\hbar} = \frac{1}{\hbar} \int \theta_1 \mathbf{H}' \theta_0 \mathrm{d}\tau \, \langle \varphi_0^1 | \varphi_\mu^0 \rangle \qquad (5a)$$

where $\mathbf{H}'$ is the coupling operator. However, the final state is in interaction α with the environment, *i.e.* with the thermal vibrations of the solvent. According to spectroscopic findings, α is much greater than β, and the states ψ'', ψ''' *etc.* coupled with the final state are very numerous. The energy is very rapidly partitioned from the "hot" final state ψ'' over so many low excited vibrations of the solvent that the chance of an accumulation of energy to regenerate the final state ψ'' and reversion to the initial state ψ' is extremely small ($\tau_p = \infty$).

The BO approximation is assumed to be valid in Figure 10. The greater the coupling β, the faster is the radiationless deactivation. This is true even when the vibronic states ψ' and ψ'' have largely lost their identity, and one can therefore hardly expect a vibrational structure in the n→π* band.

There must thus be at least one vibronic state in the azo compounds at approximately the same energy as the $^1(n,\pi^*)$ state, with which the $^1(n,\pi^*)$ state can interact.

The first possibility would be a highly excited vibrational state of the ground state, as shown in Figure 10. However, the values of the FC factors, which can lie between 1 and 10^{-20} in the various cases[79], decrease roughly exponentially with the difference in the vibrational quantum numbers in the initial and in the final state[76]. Owing to the large energy difference $\psi' - S_0$ (Fig. 10), the FC factors are very small. Deuteration of the molecule, which causes the FC factors to decrease further and thus normally increases the fluorescence quantum yield[63,82], has no influence on the band shape and fluorescence in the case of azobenzene. This points to a small difference between the coupling vibrationless electronic states[83].

Optimal coupling would be offered by a singlet state S_x (Fig. 9) in the vicinity of the $^1(n,\pi^*)$ state. There need not be any measurable absorption corresponding to this state. However, there is no evidence of such a state for azo compounds, though evidence is found in the low-temperature spectra of the *o*-diazines[62]. The existence and identity of such a singlet state has yet to be confirmed.

The spectroscopic behavior of the azo compounds could also be explained by tight coupling of the $^1(n,\pi^*)$ state with a triplet state T_1 (Fig. 9). The prohibition of intersystem crossing would have to be overcome in this case. The $^3(n,\pi^*)$ state is situated only slightly below the $^1(n,\pi^*)$ state, and this leads to favorable FC factors. The coupling between singlet and triplet states corresponds to the spin-orbit interaction of the electrons, and the coupling energy is

$$\beta = \int {}^3\theta_i \mathbf{H}_{s.o.} {}^1\theta_i d\tau \langle \varphi_b^i | \varphi_\mu^i \rangle \qquad (5b)$$

The spin-orbit coupling operator $\mathbf{H}_{s.o.}$ has the symmetry properties of a rotation[84]; there are consequently also symmetry-dependent selection rules for the radiationless S→T transitions. Coupling between similar states, *e.g.* $^1(n,\pi^*)$ and $^3(n,\pi^*)$ states, is forbidden in *cis* azo compounds, but allowed in the *trans* isomers[44]. On the other hand, transitions between singlet and triplet states of different kinds are allowed. However, this electronic selection rule is strictly valid only if the configuration of the molecule is planar. Structured n→π* absorption bands and n←π* fluorescence can therefore be expected only for planar *cis* compounds where deactivation *via* the $^3(n,\pi^*)$ state is prevented, and this is in agreement with the experimental findings. The more resistant the skeleton to out-of-plane deformation vibrations, the sharper is the structure and the higher the fluorescence yield (Tables 1 and 4).

However, the energy of the $^3(\pi,\pi^*)$ state can be lower than that of the $^1(n,\pi^*)$ state for aromatic compounds. The probability of fluorescence would then be small. It is in fact found that benzo[*c*]cinnoline, for which the lowest triplet state is regarded as a $^3(\pi,\pi^*)$ state on the basis of vibrational analysis[51], has a fluorescence quantum yield of only 0.7%[75,85].

A possible objection lies in the question whether the mixing of states having different multiplicities can be sufficiently strong. Coupling is usually determined experimentally from quantum yield measurements; no answer can be given for the azo compounds concerned, owing to the absence of emission. However, the spin-orbit coupling depends on the gradient of the nuclear field, and because of their s character, the n electrons are much more exposed to this field than π electrons[81]. This coupling is also favored by any deviations from planarity of the molecule. A pathway *via* the triplet system is accepted for the photoisomerization[52,53,86].

A final possibility is the coupling of the lowest excited state with a dissociative molecular state. This is undoubtedly an important case for the aliphatic azo compounds. Both the vibrational structure and the fluorescence are more pronounced for the more photostable chloromethylenepyrazoline *(5)*[87] than for the more labile ketopyrazoline *(6)*. The weak shoulder observed for the n→π* absorption band of *(11)* could also be due to the very much higher photostability of this compound in relation to *trans*-azomethane[88].

The azobenzenes, and under certain conditions azoalkanes[82,86], are photostable apart from *cis-trans* isomerism. However, the molecule is not necessarily destroyed by a photoreaction. A transition of the excited molecule into a different form, *e.g.* a more extended form as an intermediate of the isomerization due to inversion at the nitrogen atom[89,90] before the totally symmetrical deformation vibration can become fully developed, may also be described by coupling of the $^1(n,\pi^*)$ state of the angular molecule with a state of the molecule having the transition geometry. The FC factors in equation (5) will become increasingly favorable with increasing difference in geometry between the coupling states.

The quantum yields of the isomerization of azobenzene are high[91], and the kinetic analysis calls for intermediate states[91,92]. The decrease in the quantum yield of the *trans-cis* isomerization[93] with falling temperature does not necessarily mean that the intermediate state is not reached, as long as the step that requires an activation energy takes place from this state.

Vibrational structure and fluorescence are therefore to be expected only for azo compounds that are stabilized in the *trans* or *cis* form. This is also largely in agreement with experimental results.

The last two possibilities are not mutually exclusive. The state that couples with the $^1(n,\pi^*)$ state is probably a triplet state with modified molecular symmetry. If the existence of such a state is accepted, the spectroscopic and photochemical results as a whole can be logically explained, particularly the kinetic analysis of the *cis-trans* isomerization[91] and the sensitization of this reaction[54,58].

5. Conclusion

The absorption spectrum of the azo compounds is best explained with the aid of an MO model in which the molecules are assumed to be built up from coupled electronic subunits. The electronic system of the azo group is significantly perturbed in the aromatic compounds, but the n→π* transitions are determined primarily by the local symmetry of the azo group, and not by the molecular geometry.

The $^1(n,\pi^*)$ states of the azo compounds exhibit unusual coupling properties. By vibrational coupling, the n→π* transition, which is forbidden for the *trans* isomers, "steals" its high intensity, which may exceed that of the corresponding allowed transition in a closely related *cis* molecule, from the neighboring allowed π→π* transition. The inability to fluoresce and the absence of a vibrational structure in the n→π* band for most azo compounds is due to the tight coupling of the $^1(n,\pi^*)$ state with a somewhat lower-lying molecular state, which is determined by symmetry-dependent selection rules for electronic states and by geometric factors. The identity of this state has not

yet been established; however, the experimental data point to a triplet state, probably with a molecular geometry that is strongly modified in relation to the configuration of the ground state.

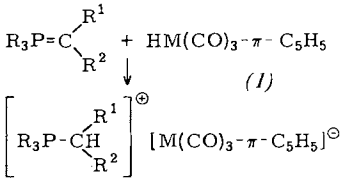
Onium Salts Containing Carbonylmetalate Anions[1]

By *Wolfgang Malisch*[*]

Ylide chemistry has so far provided hardly any information regarding the reactivity of ylide systems toward transition metal complexes. While looking for metalate reagents suitable for the synthesis of metal-metalloid bonds, we have found that an acid-base reaction according to the following scheme occurs on treatment of carbonylmetal hydrides *(1)* with alkylidene or imino derivatives of phosphorus, arsenic or sulfur.

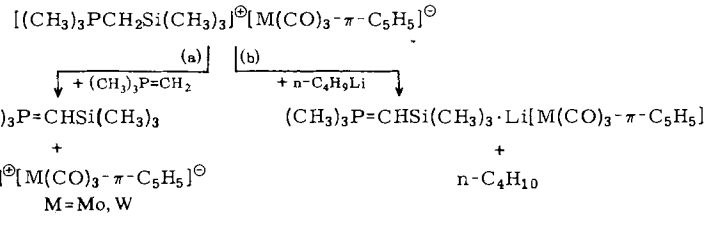


$R = CH_3, C_2H_5, C_6H_5$

$M = Cr, Mo, W$

With ylides of slight basicity, such as the compounds $(CH_3)_2S(O)CHSi(CH_3)_3$ or $(CH_3)_3PNSi(CH_3)_3$, the addition is followed by loss of the trimethylsilyl group, so that silyl-free onium salts result. The most strongly acidic representative of the carbonyl hydride derivatives of VIb transition metals, namely, $HCr(CO)_3$-π-C_5H_5, also undergoes desilylation even on reaction with the phosphorus-silyl ylides[2].

The structures of the products, which are pale yellow salts, sensitive to oxygen, can be proved by analysis and NMR and IR spectroscopy[5]. Their behavior towards organometallic bases in transylidation and deprotonation processes [(a) and (b), respectively] is comparable with that of onium halides[6].



M = Mo, W

Of the onium salts studied so far, a few are extremely reactive. Their use for transfer of the complex metalate ion, with formation of metal-metalloid bonds[1,7] is particularly advantageous in apolar solvents, for with some cat-

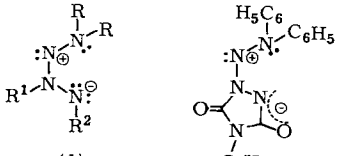
Structure of Aminoazimines

By *J. E. Weidenborner, Egon Fahr, Monika J. Richter*, and *K.-H. Koch*[*]

Addition of aminonitrenes to azo compounds yields aminoazimines *(1)*[1,2]. Conclusive proof of the structure[3] of this new class of compounds has now been provided by X-ray structure analysis of the aminoazimine *(2)*[4].



(1)

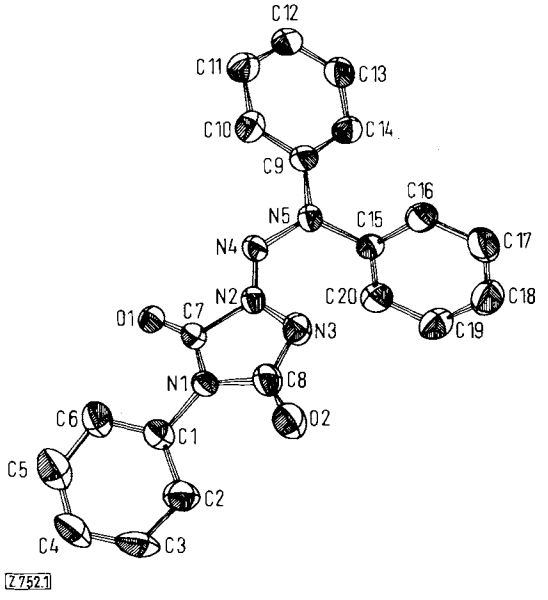
(2)

The compound crystallizes in the triclinic space group $P\bar{1}$ with $a = 12.503 \pm 0.004$, $b = 8.100 \pm 0.006$, $c = 9.610 \pm 0.003$ Å, $\alpha = 96.24 \pm 0.03°$, $\beta = 95.04 \pm 0.02°$, $\gamma = 115.63 \pm 0.03°$; d_{exp} (aqueous NaBr solution) $= 1.373$ g cm^{-3}, d_{calc} $(Z = 2) = 1.376$ g cm^{-3}.

Single crystal intensity data were measured on a CCXD four-circle computer-controlled X-ray diffractometer[5] and a total of 1717 non-zero independent reflections were recorded. The usual Lorentz-polarization corrections were applied and normalized structure factors (E-factors) were calculated using the scale factor and overall temperature factor obtained by *Wilson*'s method[6]. The structure was solved by the symbolic addition procedure[7], implemented with a version of the SORTE program[8,9] written for the IBM 360/91 computer. Three symbols were introduced and a total of 333 signs were generated for reflections with $E > 1.45$. The eight possible E-maps were synthesized and only one of these revealed clearly the positions of the 27 non-hydrogen atoms. This trial structure gave a value of

$$R = \frac{\Sigma ||F_o| - |F_c||}{\Sigma |F_o|} = 34\%.$$

Refinement was accomplished by the method of least squares. Hydrogen atoms were located on a difference Fourier map and their positions included in the refinement which was terminated at $R = 6.1\%$. The molecular structure is shown in Figure 1.



Z 7521

Fig. 1. Structure of 2-(diphenylaminoaminylio)-3,5-dioxo-4-phenyl-1,2,4-triazolidin-1-ide *(2)*. The interatomic distances and bond angles (estimated standard deviations in parentheses are in units of the last place) are as follows:

C 1—N 1 = 1.435(8) Å	N 4—N 5 = 1.340(7) Å
C 7—N 1 = 1.333(7) Å	C 9—N 5 = 1.429(8) Å
C 7—N 2 = 1.497(7) Å	C 15—N 5 = 1.447(8) Å
N 2—N 3 = 1.360(7) Å	C 7—N 1—C 8 = 110.2(9)°
C 8—N 3 = 1.344(8) Å	N 1—C 7—N 2 = 102.0(7)°
C 8—N 1 = 1.445(8) Å	C 7—N 2—N 3 = 112.3(8)°
C 7—O 1 = 1.197(7) Å	N 2—N 3—C 8 = 105.1(8)°
C 8—O 2 = 1.211(8) Å	N 3—C 8—N 1 = 110.3(8)°
N 2—N 4 = 1.269(7) Å	N 2—N 4—N 5 = 116.9(9)°

X-ray structure analysis demonstrates, surprisingly, that the molecule is separated into two isolated conjugated

The Wittig Reaction of Alkylidenetriphenylphosphoranes with Sodium α-Hydroxy Sulfonates

By *Gerhard Koszmehl* and *Bodo Bohn*[*]

In the Wittig olefin synthesis from alkylidenetriphenylphosphoranes and aldehydes[1] the aldehydes may be replaced by sodium α-hydroxy sulfonates (aldehyde hydrogen sulfite adducts) of the aliphatic, aromatic or heterocyclic series. Compared with the normal Wittig reaction, the new reaction, which is carried out under the same conditions, has the advantages of generally higher yields and purer products. The products are formed in one sterically favored form, if not actually stereospecifically, and are often precipitated immediately with the melting point of the pure *trans*- or all-*trans*-compound. The steric course of the reaction is strongly dependent on the solvent and on the nature and amount of the base used. Mechanistic studies are in progress.

$$(C_6H_5)_3\overset{\oplus}{P}\text{-}CH_2\text{-}R\ X^{\ominus} + R'\text{-}\underset{OH}{CH}\text{-}SO_3Na$$

$$\xrightarrow[-KX,\ -2\,C_4H_9OH]{+2\,KOC_4H_9} R\text{-}CH{=}CH\text{-}R' + (C_6H_5)_3PO + NaKSO_3$$

The best results with respect to steric course and yield are obtained by reaction for 1 to 2 hours at 60 °C in anhydrous DMF with addition of 2.2 mol of K *tert*-butoxide. The proportion of *trans*- or all-*trans*-compound is determined, not only by comparison of melting points, but also by IR and NMR spectroscopy as well as gas chromatography.

In some cases a sterically more favorable or stereoselective course of the normal Wittig reaction can be achieved by adding $NaHSO_3$. Such a sterically more favorable reaction is also possible up to a certain extent by addition of Li salts[2,3].

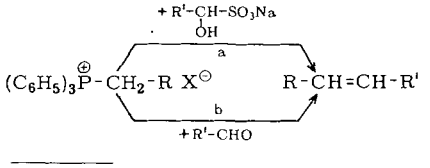

Table 1 shows that treating alkyltriphenylphosphonium salts with sodium α-hydroxy sulfonates gives higher crude yields and higher melting points of the crude products than are obtained from the aldehydes.

Table 1. Reactions of alkylidenetriphenylphosphoranes with a) sodium α-hydroxy sulfonates and b) aldehydes. Conditions: 1—2 hours at 60 °C in DMF under N_2.

5-Amino-1,2,4-thiadiazoles from 1-Amino-3-iminoisoindolenines

By *Klaus Leverenz*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

1-Amino-3-iminoisoindoleninium thiocyanates *(3)*, which can be prepared from the dinitriles *(1)* by way of 1-imino-3-

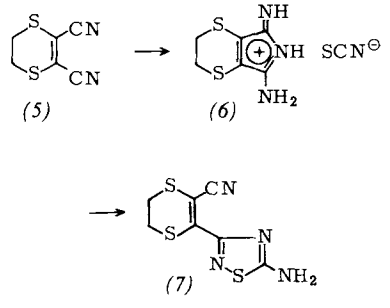
[*] Prof. Dr. G. Koszmehl and Dipl.-Chem. B. Bohn
Institut für Organische Chemie der Freien Universität
1 Berlin 33, Thielallee 63—67 (Germany)

[*] Dr. Klaus Leverenz
Farbenforschung 1
Bayer AG, 509 Leverkusen (Germany)

methoxyisoindolenines *(2)*[1], can be converted into 5-amino-1,2,4-thiadiazoles *(4)* by simultaneous action of bromine and sodium methoxide. It was not possible to separate the thiadiazoles *(4)* with $R = OCH_3$ or C_6H_5 into isomers even by thin-layer chromatography.

	R	M.p. (°C)
(4a)	H	240
(4b)	OCH_3	236—238
(4c)	C_6H_5	225—228

The thiadiazole *(7)*, m.p. 223—224 °C, is formed by a similar reaction sequence from the dinitrile *(5)* by way of the thiocyanate *(6)*.



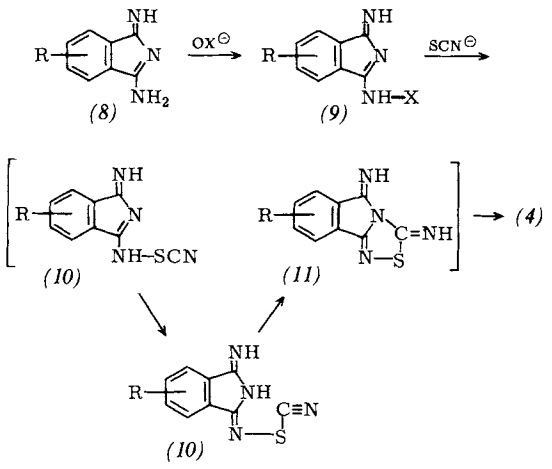
The thiocyanates *(3)* and *(6)* thus behave like open-chain amidinium thiocyanates in the thiadiazole synthesis discovered by *Goerdeler*[2]. It appears that the present reaction probably also proceeds *via* the *N*-bromo compound.

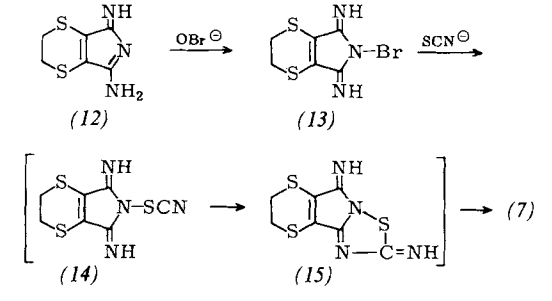
Experimentally, the 1-amino-3-iminoisoindolenines *(8)* and *(12)* can be converted by hypohalites into *N*-halo derivatives of the probable constitutions *(9)* and *(13)*, respectively, which react with alkali-metal or alkaline-earth thiocyanates in alcohols, dimethylformamide, or pyridine even at room temperature.

Since the 1-amino-3-iminoisoindolenines *(8)* and *(12)* are produced on a technical scale ("phthalogenes") and the above reactions can be conducted without intermediate isolation this reaction sequence provides a simple synthesis of the new 5-amino-1,2,4-thiadiazoles which in turn can find application in the production of azo dyestuffs[3].

General procedure:

1-Amino-3-iminoisoindolenine (1 mol) is added with stirring to a solution of KOH (1.15 mol) in methanol (1 liter) at 0—5 °C. Bromine (1 mol) is then added dropwise over *ca.* 2 h at −5 to −2 °C; this should not cause the pH to fall below 7, and, if it does, methanolic KOH should be added. The mixture is stirred for a further 2 h at *ca.* 0 °C, after which KSCN (1 mol) is introduced portionwise over *ca.* 15 min, starting at *ca.* 10 °C and without further





R = H, OCH_3, C_6H_5; X = Cl, Br

	R	X	M.p. (°C)
(9a)	H	Cl	310—315 (dec.)
(9b)	H	Br	331—334
(9c)	OCH_3	Cl	250 (dec.)
(9d)	OCH_3	Br	250—251
(9e)	C_6H_5	Br	209—211
(13)	—	Br	166—167 (dec.)

cooling. The temperature rises to 35—40 °C. To complete the reaction, the mixture is warmed for 2 h at 45—50 °C, after which the *N*-bromo compound should be no longer detectable by KI-starch paper. After a further 12 h at 20 °C the precipitate is collected and washed with methanol and finally with water until salt-free. The yields amount to 60—85%. For further purification, the 5-aminothiadiazoles can be reprecipitated from pyridine/water (2:1).

Nitrile/Amine Conproportionation to Two Imines[**]

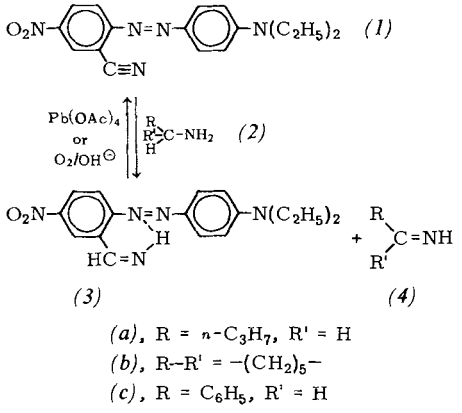
By *Hans-Dieter Scharf* and *Ludwig Kamm*[*]

On refluxing the violet azo dye 2-[*p*-(diethylamino)-phenylazo]-5-nitrobenzonitrile *(1)*[1] with *n*-butylamine *(2a)*, cyclohexylamine *(2b)*, or benzylamine *(2c)* we

[*] Prof. Dr. H.-D. Scharf and Dipl.-Chem. L. Kamm
Institut für Organische Chemie der Technischen Hochschule Aachen, Prof.-Pirlet-Strasse 1 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

observed a surprising reaction involving uncatalyzed hydrogen transfer from these amines containing α-hydrogen atoms to the aromatic nitrile group with formation of two imine groups. Besides *(1)*, it is so far known that 5-nitroanthranilonitrile (2-amino-5-nitrobenzonitrile) and its *N,N*-dibenzoyl derivative undergo this reaction.



(a), R = n-C_3H_7, R' = H
(b), R–R' = $-(CH_2)_5-$
(c), R = C_6H_5, R' = H

Good yields of the orange-red imino dye *(3)* and the imines *(4a)*, *(4b)*, and *(4c)* are formed respectively, the latter being identified as 2,4-dinitrophenylhydrazones after hydrolysis.

The structure of *(3)* was proved by IR (KBr) and mass spectroscopy[2] as well as by Stephen reduction[3] of *(1)*. Hydrolysis of the resulting immonium hexachlorostannate affords the imine *(3)*. The CN stretching vibration at 2230 cm^{-1} for *(1)* is absent for *(3)*. In its place, three bands appear in the region of N—H stretching frequencies at 3450, 3300 and 3130 cm^{-1} that are to be ascribed to the influence of hydrogen bonding[4]. The IR spectrum (KBr) of *(3)* exhibits the C=N stretching vibration at 1630 cm^{-1} in front of the aromatic bands at 1600 cm^{-1} [in *(1)* and *(3)*][5]. The position of this C=N band is typical of aldimines containing NO_2-substituted phenyl rings[6, 7] and indicates an intramolecular hydrogen bond[8].

The mass spectrum of *(3)* contains, besides the molecular ion $M^+ = 325$, very intense peaks *m/e* 149^+ ($C_7H_5N_2O_2$) and 148^+ ($C_6H_{14}N$) corresponding to the two half-molecules left on removal of N_2. In addition, 149^+ undergoes further loss of 28 mass units (HC=NH). Thus all the relevant structural elements have been recognized.

The dyestuff imine *(3)* extremely difficultly hydrolyzable and reacts with $Pb(OAc)_4$[9] or with atmospheric oxygen[10] in alkaline solution with re-formation of the dyestuff *(1)*.

Investigations of the dependence of the reaction on structural features of the molecules are in progress. It is expected that the influence of the nitro group in *(1)* and the formation of the hydrogen bond in *(3)* are prerequisites for the reaction.

Experimental

The dye *(1)* (1 g)[1] ($\lambda_{max} = 537$ nm, $\varepsilon = 4.3 \times 10^4$ in acetonitrile) is refluxed for 2 h with anhydrous benzylamine (40 ml). After cooling, the mixture is acidified with 20% hydrochloric acid, and the benzaldehyde is removed by steam distillation and converted into its 2,4-dinitrophenylhydrazone which was identified by a mixed melting point with an authentic sample and by its IR spectrum. The imine *(3)* was precipitated from the residue by basification with 4 N sodium hydroxide solution [m.p. 295°C (acetonitrile). $\lambda_{max} = 420$ nm, $\varepsilon = 1.0 \cdot 10^4$ in acetonitrile (yield 65%)].

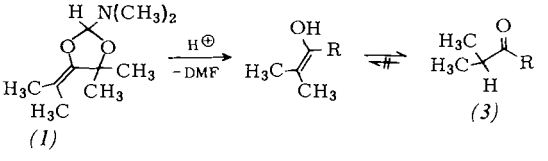
A Simple Dialkylated Enol[**]

By *H. M. R. Hoffmann* and *E. A. Schmidt*[*]

The reaction of 4-isopropylidene-5,5-dimethyl-2-dimethylamino-1,3-dioxolane *(1)* with weak acids has recently been shown to produce trialkylated enols of general structure *(2)*. Under favorable experimental circumstances these thermodynamically unstable compounds were obtained not only in substantial concentrations (up to 1 M), but also found to survive up to 3 weeks at room temperature before rearrangement into the corresponding ketone *(3)* was complete[1].



(2a), R = $C(CH_3)CH_2$ *(2c)*, R = $C(CH_3)_2OAc$
(2b), R = $C(CH_3)_2OCH_3$ *(2d)*, R = $C(CH_3)_2OH$

In view of the surprising kinetic stability of these enols the question is inevitable whether other enols, which are structurally even more simple, can be generated and identified under these conditions. A suitable precursor for such a study appeared to be 4-ethylidene-5,5-dimethyl-2-dimethylamino-1,3-dioxolane *(4)*, since it contains one methyl group less than its homolog *(1)*.

When *(4)*[2] was allowed to react with weak anhydrous acids under conditions previously shown to be optimum for obtaining the fully alkylated enols *(2)* the results were disappointing. For instance, treatment of a 1.1 M solution of *(4)* in CCl_4 with a 0.3 M equivalent of *tert*-butyl alcohol gave the α-amino ether *(6)* (80%) after 8 days at room temperature, and after another 14 days the 3(2*H*)-furanone *(7)*[4] was formed as the ultimate product. In commercial dimethyl sulfoxide (DMSO), which has proved a useful solvent for stabilizing transient enols[1], the rearrangement into *(7)* was found to be much more rapid, being complete after the solution of *(4)* had been left overnight at room temperature. Apparently, the potential enolate moiety of *(4)* is more nucleophilic and less basic than that of *(1)*;

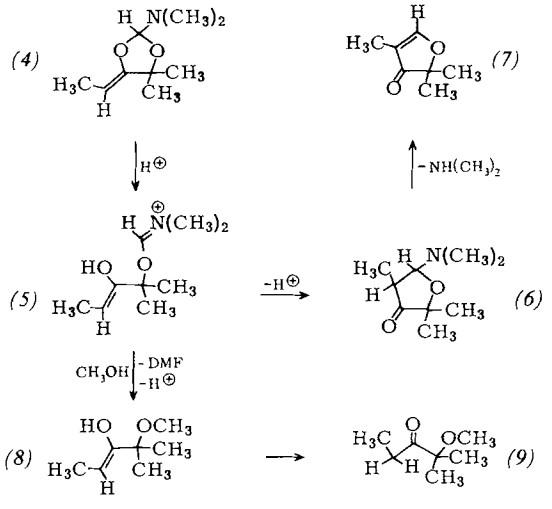
as a consequence, intramolecular alkylation of carbon with formation of *(6)* will be facile, especially in a polar aprotic solvent such as DMSO.



Interestingly, the reactions of heterocycle *(4)* proved to be very sensitive to the experimental conditions. Whereas a 1.1 M solution of *(4)* and catalytic amounts of benzoic acid (2.5×10^{-3} mol/l) at three different temperatures (−5, 27, 37 °C) gave the α-amino ether *(6)* once more, addition of two equivalents of methanol to *(4)* at 10 °C reduced the amount of *(6)* formed to 40% and gave 2-methoxy-2-methyl-3-pentanone *(9)*[5] as the major product (60%). In all experiments the formation of *(9)* was accompanied by release of an equimolar amount of dimethylformamide (DMF). Monitoring of the reaction by NMR was relatively difficult, since the spectra changed quickly and in addition to the starting material *(4)* and methanol, several compounds were present and formed simultaneously including *(6)*, *(9)*, and DMF. However, by scanning consecutive spectra, the rise and decline of three singlets at δ = 1.26 (6H), 3.08 (3H), and 7.00 ppm (1H) could clearly be discerned. As these signals disappeared, those of the ketone *(9)* grew in intensity. The comparison of the observed fleeting pattern with that of compound *(2b)*[1b] established beyond doubt that the intermediate was the enol *(8)*, the concentration of which reached a maximum (0.1 M)[6] after 10 min, then remained nearly constant for another 5 min while all precursor *(4)* disappeared. Only after *(4)* had vanished completely did the concentration of enol decrease; after a further 15 min rearrangement into the ketone *(9)* was generally complete.

When the same reaction was carried out at higher temperature (37 °C instead of 10 °C), the proportion of enol formed was actually greater (75% in place of 60%). Presumably, cleavage of the additional σ bond in going from *(5)* to the desired enol *(8)* requires a higher activation energy than closure to heterocycle *(6)*. However, the enol was more short-lived at the higher temperature as expected, reaching its maximum concentration after 5 min and disappearing completely after 15 min.

Treatment of *(4)* (1.1 M solution in CCl_4) with two equivalents of *O*-deuteriomethanol at 37 °C furnished the α-amino ether *(6)* (35%) and the *O*-deuterioenol *(8)-D* [NMR *inter alia* δ = 1.26 (s/6H), 3.07 (s/3H)], which rearranged into the corresponding deuterioketone *(9)-D*[7] (65%). In this instance the enol was sufficiently long-lived to reach a maximum concentration of 0.2 mol/l.

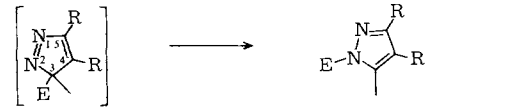
1,3-Dipolar Addition of Cyclic Diazo Ketones to Alkynes and Cyclopropene. Synthesis of Heterocycles by [1,5]-Acyl Migration

By *Michel Franck-Neumann* and *Christiane Buchecker*[*]

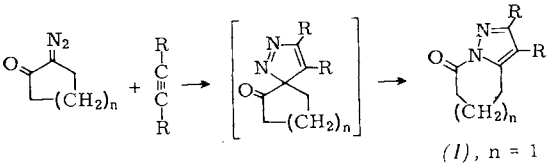
Dedicated to Professor Rudolf Criegee on the occasion of his 70th birthday

We recently found[1] a spontaneous [1,5]-group migration by which 3-acyl-, 3-alkoxycarbonyl-, or 3-cyano-3*H*-pyrazoles were converted into *N*-substituted pyrazoles at room temperature.



R = CO_2CH_3, E = $COCH_3$, $CO_2C_2H_5$, CN

These results have led us to a new synthesis of heterocycles. Cyclic α-diazo ketones such as 2-diazo-cyclopentanone or -hexanone[2] react with dimethyl acetylenedicarboxylate in boiling benzene to give *(1)* (m.p. 109 °C) or *(2)* (m.p. 82 °C), respectively, directly; the 3*H*-pyrazoles formed as intermediates were not isolated.



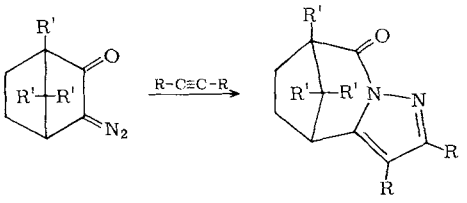
(1), n = 1
(2), n = 2

In these cases the acyl group is compelled to migrate directly to the nearest nitrogen atom since other possibilities (1,3-shift to N-1 or multiple 1,5-shifts over C-4 and C-5) would contradict Bredt's rule.

Bridged cyclic α-diazo ketones such as diazonorbornanone[3] and diazocamphor[4] react similarly but more slowly to give *(3)* (5 hours' heating in benzene, 63%

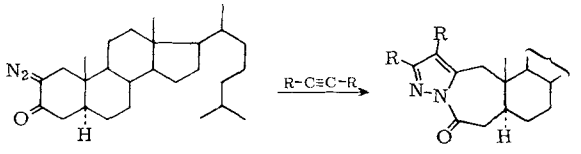
[*] Dr. M. Franck-Neumann and Dr. C. Buchecker
Laboratoire Associé au CNRS n° 31
Institut de Chimie de l'Université Louis Pasteur
1, rue Blaise Pascal, F-67 Strasbourg (France)

yield, m. p. 106 °C), and *(4)* (125 hours' heating in benzene, 73% yield, m. p. 86 °C), respectively.



(3), R' = H
(4), R' = CH_3

Steroidal diazo ketones also undergo this rearrangement. Thus in 2 h at 40 °C, 2-diazo-5α-cholestan-3-one[5] and a large excess of dimethyl acetylenedicarboxylate afford the steroidal pyrazole *(5)* (m. p. 204 °C) in 61% yield.

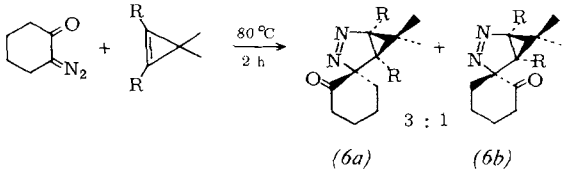


(5)

The heterocycles *(1)*—*(5)* form colorless crystals and show no N=N absorption in the ultraviolet region but only a shoulder at 235 nm (ε = 6000—7000). The NMR spectra (δ/TMS) of *(1)*, *(2)*, and *(5)* indicate two different methyl ester groups (two singlets near 3.90 ppm) and one CH_2 group α to the amide and another α to the pyrazole: *(1)* 2.77 and 3.38 ppm (broad triplet, $J = 6$ Hz); *(2)* 2.96 and 3.35 ppm (complex multiplet); *(5)* strongly shielded protons at 3.0 and 3.5 ppm (4 H), together with the typical steroid portion of the spectrum.

The spectra of the bridged heterocycles *(3)* and *(4)* resemble those of *(1)* and *(2)*, each having only two or one CH group: *(3)* 3.44 and 4.24 ppm (complex multiplets); *(4)* 3.79 ppm (1 H, broad doublet, $J = 6$ Hz).

Since cyclopropanopyrazolines resemble 3*H*-pyrazoles[6], we have also used a cyclopropene which is very reactive in 1,3-dipolar cycloadditions[7] (benzene solution). In this case the reaction stops at the primary products *(6a)* and *(6b)*. The total yield amounts to 70%. The main isomer *(6a)* (m. p. 99 °C) can be obtained pure by recrystallization from ether/light petroleum.



(6a) *(6b)*

In its NMR spectrum, *(6a)* ($\lambda_{max} = 335$ nm, $\varepsilon = 150$; $\nu(N{=}N) = 1540\ cm^{-1}$) shows two different methyl ester groups (3.72 and 3.88 ppm) and two methyl groups attached to the three-membered ring (singlets at 0.56 and 1.55 ppm). *(6b)* differs in its NMR spectrum only in respect of the signal of a methyl group attached to the three-membered ring (0.95 instead of 0.56 ppm).

With *(6a)* and *(6b)* no acyl group migration occurs; when warmed above 100 °C both isomers lose nitrogen quantitatively with formation of isomeric $C_{15}H_{20}O_5$ compounds.

This [1,5]-acyl migration, which is the basis of the heterocycle synthesis described here, thus occurs only when aromatization to a pyrazole is possible.

Dimethyl 8,11,11-trimethyl-7-oxo-5,6-diazatricyclo-[6.2.1.$0^{2,6}$]undeca-2,4-diene-3,4-dicarboxylate (4):

Diazocamphor (3.56 g, 20 mmol) and dimethyl acetylenedicarboxylate (2.82 g, 20 mmol) are mixed in benzene (45 ml) and heated under reflux for 125 h. After removal of the solvent the residue is taken up in ether/light petroleum (1:1) and chromatographed on silica gel (40 g). The first fractions (starting material) are followed, on elution with ether/light petroleum (3:1), by colorless, viscous, analytically pure *(4)* (4.70 g). Crystallization is effected by dissolution in diisopropyl ether and evaporation of the solvent.

^{13}C Shifts in Biphenylene and Analogous Compounds[1]

By *Alan J. Jones*, *P. J. Garratt*, and *K. Peter C. Vollhardt*[*]

Recent observations that diamagnetic ring current contributions to ^{13}C shifts are insignificant relative to total range[2] suggest that the so-called paramagnetic ring current contribution to ^{13}C shifts in biphenylene *(1)*[3] be reassessed. It is our contention that an isolated molecule such as biphenylene cannot be used as a model to assess the paramagnetic ring current effect. A more correct approach is to compare the difference in chemical shifts for systems in which the current may be "*on*" or "*off*", and between which geometry does not unduly differ[2]. With the advent of syntheses for the biphenylene analogs *(2)*—*(5)*[4-7] these criteria could be satisfied. Our particular interest is, therefore, in benzocyclobuta[1,2-*c*]thiophene *(2)*, (2-thianorbiphenylene)[4], and its dioxide, the sulfone *(3)*. Com-

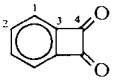
pound *(2)* is isoelectronic with biphenylene. Relative to the potential cyclobutadiene ring *(1)*, compound *(2)* therefore represents the "current-on" and compound *(3)* the "current-off" case, respectively.

The ^{13}C chemical shifts[8] of the compounds *(1)*—*(3)* are given in Table 1 along with supporting data on the model compounds *(6)*—*(8)*.

(6)

(7)



(8)

Table 1. ^{13}C chemical shifts in biphenylene and related compounds [a]. Unless indicated otherwise, assignments were confirmed using conventional techniques [9].

Compound	C-1	C-2	C-3	C-4	C-5	Total range of chemical shift
(1)	117.8_3	128.4_7	151.7_7			33.9_4
(2) [b]	118.1_3	128.4_4	145.5_6	146.6_8	112.5_1	34.1_7
(3) [c]	134.3_0	124.7_5	145.2_4	142.3_4	111.9_0	33.3_4
(6)	122.2_9	126.5_0	146.3_1	33.0_7		24.0_2
(7)	145.8_7		149.7_6		94.5_6	
(8)	135.4_5	122.3_7	173.2_0	194.2_8		

[a] All spectra were determined for solutions in deuteriochloroform. Shifts are given relative to internal TMS.

[b] Assignment of C-1 and C-2 is made by analogy with biphenylene. C-3 and C-4 are not distinguished.

[c] Assignment of C-1 and C-2 is based on analogy with the dione *(8)* and styrene. C-3 and C-4 are not distinguished.

A number of features in these data should be noted. (a) The remarkable similarity in the ^{13}C shifts and their total range[10] exhibited by the potential $4n\pi$-cyclobutadiene type molecules *(1)* and *(2)*. (b) The above similarity in shift range does not differ significantly in the cyclobutane-substituted benzenes *(3)* and *(6)*. (c) The shifts of the quaternary carbon, C-3, common to the junction of the benzene and four-membered rings in *(1)*, *(2)*, *(3)*, and *(6)* are similar (average value 147.2 ppm) and resemble that for the C-3 carbon in 3,4-dimethylenecyclobutene *(7)* (149.8 ppm). Finally, (d) the similarity in the shift at C-5 in *(2)* and *(3)* warrants consideration.

The similarity in the ^{13}C shifts and ranges in *(1)* and *(2)* suggest close electronic resemblance and justify our comparison of *(1)* and *(2)* with *(3)*. Other similarities noted in (b) through (d) suggest that we consider the data in terms of substituent additivity effects. It is clear that the low field shifts (average value 148.0 ppm) at the quaternary centers C-3 and C-4 in *(1)* and *(2)* are *not* exceptional, since the parent compound *(6)*, the sulfone *(3)*, and the dimethylenecyclobutene *(7)* exhibit similar shifts (average value 147.1 ppm). However, the upfield shifts (5—6 ppm) at C-4 in *(3)* compared to *(2)* and the high field shift at C-5 in *(3)* (111.9 ppm), which is similar to that for the analogous position in styrene (113.6 ppm)[11], do suggest that the 4,5-bond may be relatively localized in *(3)*.

Considering benzocyclobutene *(6)* as the parent compound for this series it is instructive to compare the shifts for the carbon atoms C-1 and C-2 in *(1)*, *(2)*, *(3)*, and *(8)*. Thus, upfield shifts (4.5 and 4.2 ppm) and downfield shifts (2.0 and 1.9 ppm) occur at C-1 and C-2 in compounds *(1)* and *(2)*, respectively. In compounds *(3)* and *(8)* downfield shifts (12.0 and 13.2 ppm) and upfield shifts (1.7 and 4.1 ppm) occur at C-1 and C-2, respectively. These comparisons, and the earlier considerations relating to C-3 and C-5 in *(3)* lead to the suggestion that the compounds *(3)* and *(8)* are electronically similar and, consequently, that they may be considered as benzocyclobutenes substituted by relatively localized double bonds at C-4.

It remains to reconcile the chemical shifts between the compounds *(2)* and *(3)*. The similarity noted in the shifts at C-5 in *(2)* and *(3)* may be a consequence of either (i) that the double bonds in the heterocyclic ring of *(2)* are relatively localized, and *(2)* has substantial dimethylenecyclobutene character, or (ii) the presence of a paramagnetic shielding current in the four-membered ring of *(2)*, which effectively compensates for the diamagnetic current induced in the thiophene ring. This latter mechanism seems unfavorable since it is recognized[2, 12] that magnetic effects induced by diamagnetic currents change from deshielding to shielding immediately upon crossing from locations outside to locations inside the ring. Consequently, the diamagnetic contribution of the thiophene ring at C-5 is expected to be zero. The downfield shift at C-5 (0.6 ppm) in *(2)* compared to *(3)* is, therefore, in the wrong direction for an expected "dominant" paramagnetic effect. Further, cancellation of possible diamagnetic and paramagnetic effects in *(2)* would be expected to give rise to upfield shifts at both C-1 and C-2 in *(2)* compared to *(3)*. A large upfield shift (16.2 ppm) is observed at C-1 but the downfield shift (3.6 ppm) at C-2 cannot be reconciled with a ring current model.

We suggest, therefore, that the upfield shift at C-1 and the downfield shifts at C-2 and C-5 in *(2)*, as compared to *(3)*, are the consequence of some contribution from the delocalized thiophene structure to *(2)*. Further, the similarities and difference in shifts at C-1 through C-4 in compounds *(1)*, *(2)*, and *(6)* suggest that *(1)* and *(2)* are benzene and thiophene substituted benzocyclobutenes, respectively.

We conclude that additivity relationships account adequately for the ^{13}C chemical shifts in the compounds studied. On the basis of the similarities noted in (a) through (d) compounds *(1)* and *(2)* must be considered as annelated benzocyclobutenes, while *(3)* is a dimethylenebenzocyclobutene. However, it is noteworthy that all of the stable polycyclic systems containing a potential cyclobutadiene ring so far isolated [*e.g. (1)*, *(2)*, *(4)*, *(5)*] have the common feature of being able to accommodate the four-membered ring in either the dimethylenebenzocyclobutene or dimethylenecyclobutene form with only partial disruption of the aromatic system with which it is associated[13]. As expected this feature gives rise to a high reactivity in addition reactions[5]. The contrast provided by the proton chemical shifts in *(2)* and *(3)* may still be reconciled by the paramagnetic ring current postulate. However, the effect of this "current" on the ^{13}C shifts is considered to be insignificant (1—3 ppm) relative to the ^{13}C shift range[14].

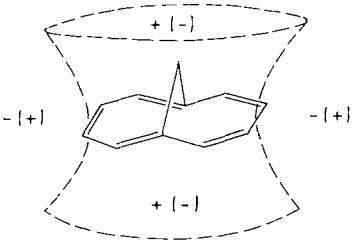
Does a "Ring Current Effect" Exist for ^{13}C-Nuclear Magnetic Resonance? A Study of Bridged Annulenes[**]

By *Harald Günther, Hans Schmickler, Heinrich Königshofen, Klaus Recker*, and *Emanuel Vogel*[*]

Theoretical studies and previous experimental evidence[1] show that the magnetic shielding constant σ of the ^{13}C nucleus is influenced mainly by the immediate electronic environment and by the paramagnetic contribution to the shielding[2]. Thus in ^{13}C-resonance spectroscopy only secondary importance attaches to the neighboring group effects (magnetic anisotropy, field and van der Waals effect) which are so important[3] for interpretation of the chemical shifts in proton resonance spectroscopy.

In annulene chemistry particular interest centers on the magnetic anisotropy of cyclic conjugated $[4n]$- and $[4n+2]$-π-electron systems which, as paramagnetic or diamagnetic (respectively) "ring current effect", now ranks as the most important physical characteristic of annulenes[4]. The increasing significance of ^{13}C-resonance spectroscopy for structural elucidation and characterization of unsaturated systems made it important to investigate the extent to which ring current effects influence chemical shifts of the ^{13}C nucleus, particularly as previous studies[5-8] failed to clarify this situation convincingly.

Particularly suitable for such an investigation are the bridged annulenes such as *(1)*, *(3)*, *(5)*, and *(8)*[9], whose bridging C atoms lie in the diamagnetic [*(1)*, *(3)*, *(5)*] or paramagnetic [*(8)*] region of the anisotropy cone of the π-electron cloud (Fig. 1)[10]. Since one cannot expect



2766.1

Fig. 1. Diamagnetic (paramagnetic) ring current effect in bridged annulenes.

a comparison with substituent constants measured for open-chain[11,12] or alicyclic compounds[13] to reveal a possible ring current effect for ^{13}C-resonance, suitable reference compounds also have to be analyzed. In that respect, because of the sensitivity of ^{13}C-resonance to steric factors[1], it is important to choose systems that are closely related in their geometry to the annulenes in question. In the ideal case the only difference from the annulene should be the absence of a dia- or paramagnetic ring current. The present investigation, whose results are shown in Figure 2, is thus confined to the systems *(1)*—*(8)*[14]. Previous ^1H-NMR studies[15-17] enable us to start the present discussion from the fact that the [10]- or [14]-annulenes *(1)*, *(3)*, and *(5)* show a diamagnetic ring current effect whilst for the [12]annulene *(8)* the positions of the proton resonances [$\delta(H_{ring})=5.4$—5.8, and $\delta(CH_2)=6.1$ ppm] permit recognition of a paramagnetic ring current. Comparison with the model substances *(2)*, *(4)*, *(6)*, and *(7)* (for which no ring current is induced in the magnetic field) then shows (Fig. 2) that the strongest influence on the ^{13}C-resonance of all fully conjugated π-systems is due to strain effects arising on introduction of the remaining double bonds. This is already clear from the position of the ^{13}C signal in the spectrum of the 1,6-methano[10]annulene *(1)*[18]; here the absorption of the quaternary carbon atoms was found at highest field although, according to known substituent effects[11], these nuclei should experience the least shielding. The aromatization, *i.e.* conversion of *(2)* into *(1)*, thus leads to an upfield rather than a downfield shift of the C(c) resonance. Since such effects are known to extend over several C

[**] Applications of ^{13}C-Resonance Spectroscopy, Part 3.—Part 2: *H. Günther, B. D. Tunggal, M. Regitz, H. Scherer*, and *T. Keller*, Angew. Chem. *83*, 585 (1971); Angew. Chem. internat. Edit. *10*, 563 (1971). We thank the Deutsche Forschungsgemeinschaft for a grant.

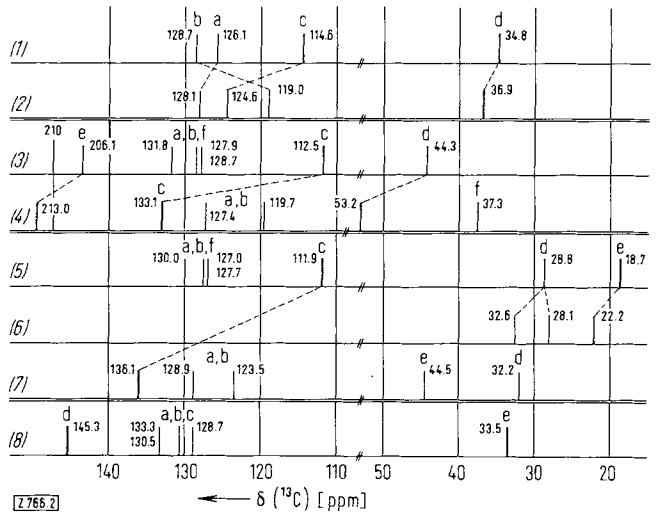

Fig. 2. Schematic representation of the ^{13}C-resonance spectra of the systems *(1)—(8)*. The ^{13}C-resonance in tetramethylsilane served as internal standard. Conditions of measurement: *(2), (5)—(7):* room temperature, in CCl_4; *(1):* room temperature, in CS_2; *(3), (4):* $-80\,^{\circ}C$, in CD_2Cl_2. Concentration in all cases *ca.* 1 mol/l or less. Experimentally proved assignments are denoted by thick lines.

atoms, sometimes with change of sign, it is impossible to reach a conclusion about the existence or non-existence of a diamagnetic ring current effect by means of the shifts for the other peripheral C atoms of which one pair is deshielded. Thus also the shielding observed for the methylene-carbon provides no information relevant to our problem.

For the pair of compounds *(3)/(4)* the influences of the geometrical changes expected with aromatization on the ^{13}C-resonance can be considered to be smaller than those for *(1)/(2)* since the structure of the periphery differs only little between the two systems. Thus the C=O stretching vibration, which is sensitive to angle deformation, is $1730\,cm^{-1}$ for both compounds[16]. Hence it is interesting that in this case—independently of the correct assignment—both the outer peripheral C atoms C(a) and C(b) are deshielded on going from *(4)* to *(3)*, whereas the same change produces considerable shielding of the bridging C atoms. For the carbonyl carbon, whose resonance should be least affected by other factors, one finds a shift of +7 ppm. This observation clearly provides positive evidence for the existence of a diamagnetic ring current effect on the ^{13}C-resonance[19].

This interpretation is supported by the results for the pair of compounds *(5)/(6)*. Here too the differences in geometry are certainly small, and the downfield shift of the bridging C atoms on transition from *(5)* to *(6)* can be ascribed to the decrease in the ring current effect that is unambiguously proved by ^1H-NMR investigations[20]. Only for the resonance of C(d') can (slight) shielding be observed, whose cause may be seen to lie in the anisotropy effect of the benzene ring. The corresponding proton is also strongly shielded. A ring current effect is further indicated by the fact that C(d) in *(5)* is shielded in comparison with C(d) in *(7)* to the extent of 3.4 ppm, for deshielding would normally be expected on replacement of a hydrogen atom by a CH_2 group[11,12].

On the other hand, no paramagnetic ring current effect could be demonstrated for the ^{13}C-resonances in the [12]annulene *(8)*. Here the methylene-carbon should be deshielded, yet no effect of this kind could be recognized either in comparison with the $[4n+2]$-π-system *(1)* or in that with the olefinic system *(2)*[21].

In conclusion, it can be stated that a diamagnetic ring current effect does exist also for the ^{13}C-resonances but that it is masked in most cases by other factors that affect the ^{13}C-resonance appreciably more strongly. No paramagnetic ring current effect could be detected in our case. These findings are in clear contradiction to the influence observed on ^1H-resonance, whose shift is unambiguously determined by the ring current effect for the pairs of compounds discussed here (Fig. 3). ^{13}C-resonance is thus not

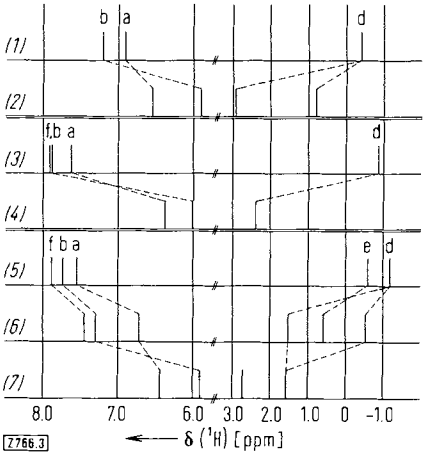

Fig. 3. Schematic representation of the ^1H-resonance spectra of the systems *(1)—(7)* (according to [15–17, 20, 22]).

suitable as a probe for the magnetic properties of cyclic π-systems. Incidentally our observations confirm other findings[1], according to which steric effects such as ring strain and angle deformations play a dominant role in determining the position of the ^{13}C-resonance signals[23].

[10] No theoretical prediction does exist for the sign of the induced secondary field at the position of the peripheral C atoms. Results for the ^1H-resonance cannot be simply adopted because of the different positions of the nuclei. The simple model of a current loop or coil (consideration of two ring currents corresponding to the π-electron distribution in the carbon-$2p_z$ orbitals) indicates that the secondary field on the carbon nucleus disappears for planar systems. Indications of the existence of a ring current effect are thus to be expected primarily from the resonances of the bridging C atoms.

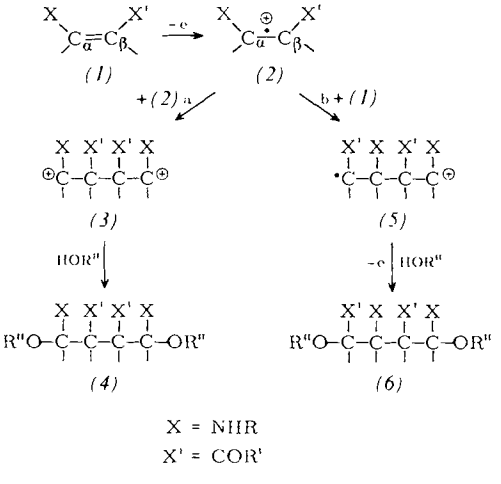
One-Step Synthesis of Pyrroles by Anodic Dimerization of Enamino Ketones or Esters[**][1]

By *Dietrich Koch* and *Hans Schäfer*[*]

Anodic dimerization has previously been achieved only for olefins with electron-donating substituents[2]. We have now electrolyzed vicinally disubstituted olefins *(1)* with one electron-donating (X) and one electron-attracting substituent (X'), in order a) to extend the preparative usefulness of the dimerization and b) to decide, from the structures of the dimers, whether the C—C linkage by way of the radical cation *(2)* occurs by radical dimerization (route a) or by electrophilic addition (route b).



Route a should lead to the dication *(3)* in which the two positive charges are stabilized by the substituents X; solvolysis of *(3)* should afford the symmetrical dimers *(4)*. The radical cation *(5)* should be formed by route b[3], and its oxidation and solvolysis should lead to the unsymmetrical dimers *(6)*.

For the enamino ketones or esters *(1a)—(1e)* the half-wave potentials on voltammetry in a methanolic $NaClO_4$ solution at a rotating vitreous carbon or gold electrode are found between +1.0 and +1.2 V (*versus* Ag/AgCl). Controlled-potential preparative electrolysis at graphite electrodes yields the pyrroles *(7a)—(7e)* (Table 1).

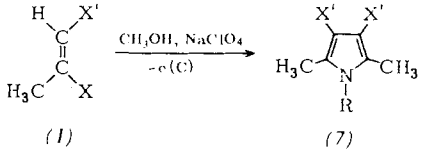


Table 1. Yields and melting points of the pyrroles *(7)* prepared from *(1)*.

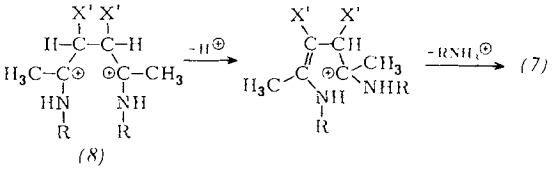
	X	X'	R	*(7)* [a] M.p. [°C]	Yield [%] [b]
a	NH_2	CO_2CH_3	H	120—121 (118—119[6])	34 (22)
b	$NHCH_3$	CO_2CH_3	CH_3	149.5—150	36 (33) [c]
c	NH_2	$COCH_3$	H	178—179 (180—181[7])	16 (15)
d	$NHCH_2C_6H_5$	CO_2CH_3	$CH_2C_6H_5$	105—106	45 (47)
e	NHC_6H_5	CO_2CH_3	C_6H_5	86—87 (87—88[8])	12 (9)

[a] The structures of the pyrroles are proved by IR, NMR, and mass spectroscopic data, as well as by C,H analyses and comparison of the melting points with those of authentic compounds.
[b] The yields of the pyrroles *(7)* separated by thin-layer chromatography relate to the amounts of olefin *(1)* used (material yields); the figures in parentheses are current yields. Electrolysis and workup conditions were not optimized.
[c] In dichloromethane/methanol (20:1, v/v).

Formation of the symmetrically substituted pyrroles indicates radical dimerization of the radical cations (route a) formed as primary products from *(1a)—(1e)*. This process leads to the dications *(8)* from which the pyrroles *(7)* can be formed by cyclization and elimination of amine.



This new pyrrole synthesis supplements their preparation by 1,3-dipolar cycloadditions of azlactones to alkynes[8,9].

Dimethyl 1-benzyl-2,5-dimethyl-3,4-pyrroledicarboxylate (7d):

Methyl 3-(benzylamino)crotonate (19.5 g, 95 mmol) is electrolyzed in 0.3 N methanolic $NaClO_4$ solution (45 ml) with

Polyvinyl Alcohol Substituted by Nucleotides as Carrier for Liquid Phase Oligonucleotide Synthesis[**]

By *Herbert Schott*[*]

Polystyrenes[2], polyethylene glycols[3], and Sephadex LH 20[3] have been used as carriers in the synthesis of oligonucleotides by *Merrifield*'s method[1]. The nucleotide chain remains bound to polystyrene during the synthesis by means of trityl or benzyl groups[4]; in polyhydroxy compounds covalently bound 5'-ribonucleotides serve as anchors. Polyhydroxy compounds can be more easily obtained than polystyrene carriers and have the advantage of an almost complete absence of the side reactions observed with polystyrenes, particularly during removal of the chain[5]. Since the maximum loading of the carriers named above is about 0.3 mmol of nucleotide per gram of polymer, oligonucleotide syntheses have thus far been practicable only in μmol batches.

We have now found that one gram of polyvinyl alcohol can be loaded with up to 10 mmol of mononucleotide. Polyvinyl alcohol is soluble in mixtures of pyridine and hexamethylphosphorotriamide. Condensations in the presence of this latter amide have been described[6]. Thus all reactions with this carrier can be carried out in the liquid phase.

For condensation with the carrier we used 5'-thymidyl-, 5'-uridyl-, or 5'-ribo-guanylic acid in a protected form and, after completion of the reaction, removed the protecting groups by short treatment with alkali. The condensations were carried out by means of 2,4,6-triisopropylbenzenesulfonyl chloride (TPS) in hexamethylphosphorotriamide/pyridine and produced more than 90% yields. For removal of lower-molecular products and unattached nucleotides the reaction mixture can be dialyzed, precipitated, or separated by column chromatography on Sephadex or DEAE-cellulose. Substituted polyvinyl alcohol passes through a Sephadex-G-50 column in the eluant and is bound to DEAE cellulose as a polyanion. Retardation is so strong that complete elution is only possible with 7 M urea/1 M sodium chloride. The column-chromatographic separations prove indirectly the covalent bonding of the nucleotides and permit unbound nucleotides to be recovered. The nucleotide content of the dissolved polymers can be determined by UV measurements and checked gravimetrically on precipitated material.

Experimental:

Polyvinyl alcohol (1 g, MW *ca.* 70000) is dissolved with stirring in hot anhydrous hexamethylphosphorotriamide (40 ml). Anhydrous pyridine (40 ml) is added to the clear, pale yellow solution which is then cooled to room temperature. Subsequently pyridinium 2',3'-di-*O*-acetyluridine 5'-phosphate (5 g, *ca.* 10 mmol) is added to the mixture, followed by TPS (9 g, *ca.* 30 mmol), with continuous stirring. After this mixture has been stirred for 24 h at room temperature, water (10 ml) is added and the whole is dialyzed for 12 h against water. For removal of the protecting groups sodium hydroxide solution is added until a 1 M NaOH solution results. After standing for 10 minutes at room temperature the solution is neutralized with HCl and then concentrated in a vacuum to a syrup from which the polymer is precipitated by addition of ethanol (*ca.* 200 ml). The precipitate is dissolved in water and dialyzed for 12 h against water. 97000 absorption units were measured in the dialyzed solution by spectral photometry (262 nm). The extinction ratios were 250/260 = 0.85 and 280/260 = 0.32. The solution is concentrated in a vacuum and lyophilized, yielding a yellow powder (4.1 g).

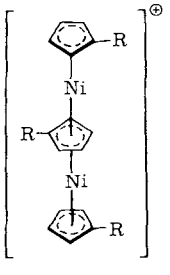
Preparative and Mechanistic Aspects of the Reactions of Cyclopentadienylmetal Complexes: The Route to the Triple-Decker Sandwich

By *Helmut Werner*[*]

Reactions of sandwich complexes of the type $M(C_nH_n)_2$ ($n = 5$ or 6) with Lewis acids and Lewis bases have attracted increasing interest in recent years[1]. Marked reactivity is exhibited by compounds such as $Co(C_5H_5)_2$ and $Ni(C_5H_5)_2$ in which the metal atom possesses a formal excess of one or two electrons, respectively, beyond the 18 electron shell (noble-gas configuration).

The action of *Lewis bases* [*e.g.* tertiary phosphites $P(OR)_3$] on the above-mentioned bis(η-cyclopentadienyl)metal compounds can lead to fission of only *one* metal-ring bond or to fission of *both* $M—C_5H_5$ bonds[2, 3]. Products are formed such as $C_5H_5Co[P(OR)_3]_2$ and $Ni[P(OR)_3]_4$ which can undergo unexpected reactions on thermolysis. Mechanistic studies of the reaction of $Ni(C_5H_5)_2$ and $P(OR)_3$ have led to isolation of compounds such as $Ni(C_5H_5)_2 \cdot MA$ (MA = maleic anhydride), $C_5H_5Ni[P(OR)_3]Cl$, and $C_5H_5Ni[P(OR)_3]P(O)(OR)_2$.

The behavior of $Co(C_5H_5)_2$ and $Ni(C_5H_5)_2$ towards *Lewis acids* is characterized by a one-electron transfer as primary step[4]. $Co(C_5H_5)_2$ reacts with $[C(C_6H_5)_3]^+$, $[C_7H_7]^+$, or H^+ (as HF or HBF_4) very rapidly with formation of the stable cation $[Co(C_5H_5)_2]^+$[5]. The less stable cation $[Ni(C_5H_5)_2]^+$ undergoes subsequent reactions that lead under suitable conditions to the binuclear complex $[Ni_2(C_5H_5)_3]^+$[6]; its formation is very probably to be interpreted in terms of an ion-molecule reaction. Ring-substituted derivatives $[Ni_2(C_5H_4R)_3]^+$ (R = CH_3 or *tert*-C_4H_9) are also very easily obtained from the system $Ni(C_5H_4R)_2/HBF_4$/propionic anhydride[7]. Both spectroscopic data and chemical properties of the complex cations $[Ni_2(C_5H_4R)_3]^+$ indicate that these represent a new structural type *(1)*, which in accord with previous proposals[8] we name "triple-decker sandwiches".



(1)

The reactions of the complexes $[Ni_2(C_5H_4R)_3]BF_4$ with a series of uni- and multi-dentate Lewis bases L or L—L afford quantitative yields of $Ni(C_5H_4R)_2$ and new ionic mono(η-cyclopentadienyl)nickel compounds $[C_5H_4RNiL_2]BF_4$ or $[C_5H_4RNi(L—L)]BF_4$[9, 10], of which the representatives with L—L = diolefin are worthy of particular mention.

Prebiotic Evolution of Enzyme-Like Systems

By *Klaus Dose*[*]

Model experiments have indicated that the lower-molecular building units of the first living systems could have arisen by the action of various forms of energy (electric discharges, solar UV light, ionizing radiation, volcanic heat) on the components of the primitive atmosphere of the primordial earth. This secondary atmosphere was of volcanic origin and probably contained the elements C, H, O, N, and S, mainly in the form of CO_2, CO, CH_4, H_2O, N_2, and H_2S. Thus the composition of this atmosphere was different from that of the H_2- and He-rich intergalactic cloud from which our solar system was formed almost 5 billion years ago. Free oxygen was formed in the terrestrial atmosphere only in the last 3 billion years, after the appearance of photosynthetic organisms. Substantial (chemical) evolution of biologically important compounds in an oxidizing atmosphere cannot occur under prebiotic conditions.

α-Amino acids usually predominate in the products formed by the action of energy on various simulated primitive atmospheres. It is assumed that they are formed mainly by hydrolysis of racemic α-amino nitriles that are obtained as intermediates from aldehydes, HCN, and NH_3. Mixtures of α-amino acids, particularly when containing substantial proportions of acidic amino acids, can condense to protein-like polymers (proteinoids) when heated for several hours at 100 to 185 °C. These proteinoids give a positive biuret reaction and yield free amino acids on hydrolysis. Proteinoids are, however, only partially degraded by proteases since they contain non-physiological cross-linkages. Remarkable is the selectivity with which the amino acids condense to specific kinds of proteinoid with definite structures (small range of molecular size and charge distribution). The proteinoids have various catalytic properties.

[*] Prof. Dr. K. Dose
Institut für Biochemie der Universität
65 Mainz, Postfach 3980 (Germany)

For instance, proteinoids have been synthesized that accelerate the decarboxylation of pyruvate or oxaloacetate. Catalysis of hydrolyses (of esters), reductive aminations (of α-keto acids), oxidative deaminations (of α-amino acids) and peroxidatic reactions were also observed. Peroxidatic activity [oxidation of an (organic) substrate by H_2O_2] is shown by proteinoids that are linked with hemin. These hemoproteinoids may have made possible a first oxidative metabolism at a time when the atmosphere was still oxygen-free; the H_2O_2 necessary for this process could have been continuously regenerated by the action of UV light or ionizing radiation on the primitive hydrosphere.

Lecture at Saarbrücken, July 7, 1972 [VB 357 IE]

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The mechanisms of stepwise electrode processes on amalgams are the subject of a review by *V. V. Losev*. The author presents a complete kinetic analysis of anodic dissolution and cathodic deposition of metals forming multiply charged ions so that charge transfer is a stepwise process involving intermediates bearing lower charges. Experimental difficulties attending work with solid metal electrodes are obviated with amalgams, thus accounting for the interest they attract. [Mechanisms of Stepwise Electrode Processes on Amalgams. Mod. Aspects Electrochem. *7*, 314—398 (1972); 179 references]

[Rd 556 IE—G]

The use of isotopes for kinetic studies of heterogeneous catalysis is the subject of a review by *J. Happel*. The author considers publications concerned with chemisorption, the reaction itself, and subsequent desorption, *i.e.* mass transfer and diffusion processes preceding and following these steps are not included. The results are illustrated with the aid of NH_3 synthesis, SO_2 oxidation, oxidation of CO to CO_2, and hydrogenation and dehydrogenation of C_4 hydrocarbons. [Study of Kinetic Structure Using Marked Atoms. Catal. Rev. *6*, 221—260 (1972); 100 references]

[Rd 559 IE—G]

Conformational changes and thermodynamic properties of macromolecules in ternary polymeric systems is the subject of a review by *A. V. Gevarkyan*. The author summarizes the previously reported properties of polymers in binary solvent mixtures and tries to explain a few of the anomalies between theory and experiment. Conformational changes of the macromolecule, especially the transformation from the "random form" to the "segregated form", are discussed in relation to the composition of the solvent. [Conformational and Thermodynamic Properties of Macromolecules in Ternary Polymeric Systems. Russ. Chem. Rev. *41*, 216 to 221 (1972); 61 references]

[Rd 586 IE—Q]

Loading of the Rhine with organic, especially petrochemical, pollutants is discussed in a review by *W. Kölle, H. Ruf*, and *L. Stieglitz*. An overall estimate of pollution by organic pollutants can be gained from measurement of the oxygen demand per 1 mg of organically bound carbon. Most of the substances responsible for pollution can also be determined UV spectroscopically. Radiocarbon dating can be used as an analytical method for overall assessment of pollution and for differentiation between biogenic substances and substances of petrochemical origin. Biogenic substances can be readily monitored and dated according to their ^{14}C activity whereas fossilized petrochemical substances possess practically no such activity. Traces of organic substances can be determined by a combination of mass spectrometry and gas chromatography. Approximately 100 readily extractable and vaporizable compounds (isomers not considered!) have so far been identified. The enrichment of pollutants (*e.g.* by plankton, fishes, fish-eating birds) has also been monitored. The Hg-content of fishes taken from the Rhine near Mannheim considerably exceeds the tolerated limit of 0.5 ppm for human consumption. The fish lipoid fraction contains about 200 ppm of organically bound chlorine. [Die Belastung des Rheins mit organischen Schadstoffen. Naturwissenschaften *59*, 299—305 (1972); 15 references]

[Rd 594 IE—M]

The intermediary metabolism of mycobacteria is the subject of a review by *T. Ramakrishnan, P. S. Murthy*, and *K. P. Gopinathan*. These bacteria, which resemble one another primarily in their cell wall structure, are of interest because they include pathogenic organisms. The long generation times make working with them a little difficult; nevertheless, numerous studies have been carried out on their carbohydrate and lipid metabolism. Hopes of finding variations in metabolism associated with virulence were not fulfilled; such differences are found, however, in the enzyme complement although their significance is not yet understood. Protein and nucleic acid synthesis are being investigated mainly with a view to the use of drugs; the studies are still in their infancy. The metabolism of the vitamins, which could also offer therapeutic points of attack, known modes of action of drugs, and the genetics of mycobacteria close the article. [Intermediary Metabolism of Mycobacteria. Bacteriol. Rev. *36*, 65—108 (1972); 436 references]

[Rd 547 IE—R]

The chemistry of filling materials used in dentistry is the topic of a review by *G. M. Brauer* and *E. F. Huget*. The authors show that the ideal material is not yet available for conservative dentistry since all substances used (metals, metal alloys, synthetic resins, ceramic masses, and organic/inorganic mixed phases) are held in place in the dental cavity by mechanical forces but do not undergo chemical bonding to the teeth. Such a material would be most welcome as it would greatly reduce the incidence of secondary decay and its use would reduce losses of healthy dental material during treatment. However, lack of effective *in vitro* methods for testing its suitability means that an essential prerequisite for the development of such an adhesive is not fulfilled. [Dental Adhesives. Chem. Biosurfaces *2*, 731—800 (1972); 179 references]

[Rd 553 IE—G]

The growth of mammalian cells on glass surfaces is reviewed by *C. Rappaport*. It has been known since the 1930's that some kinds of cells can grow *in vitro*, *i.e.* on glass surfaces, and modern biology makes extensive use of such cell cultures. Other kinds of cells, particularly those regarded as specialized (brain cells, liver cells) resist attempts to culture them outside the body under such simple conditions. The reason is unknown, as are the conditions under which cells multiply in the body. The author surveys papers concerned with these problems. [Some Aspects of the Growth of Mammalian Cells on Glass Surfaces. Chem. Biosurfaces *2*, 449—487 (1972); 46 references]

[Rd 558 IE—G]

The determination of the number of active centers and growth rate constants in the catalytic polymerization of olefins is described in a review by *Yu. I. Ermakov* and *V. A. Zakharov*. The following methods for the determination of these growth characteristics are described and their reliability discussed: the kinetic method (investigation of the degree of polymerization as a function of reaction conditions), the inhibitor method (calculation of the number of active centers from the amount of inhibitor required to stop the reaction), and the labeling method (radioactive labeling of the growing molecule). Values of the growth factors are given for a few catalytic systems. Interesting conclusions regarding the mechanism of polymerization and the structure of the active centers can be drawn from the dependence of such values on the composition of the catalyst, its method of preparation, and the polymerization conditions. [Determination of the Number of Active Centres and Growth Rate Constants in the Catalytic Polymerization of α-Alkenes. Russ. Chem. Rev. *41*, 203—215 (1972); 113 references]

[Rd 585 IE—Q]

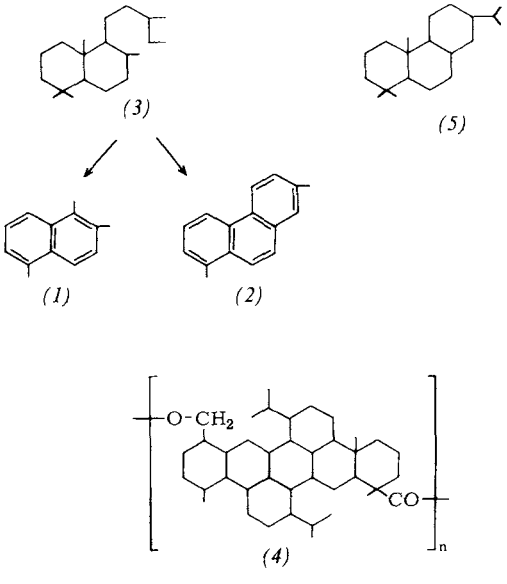
Thermogalvanic cells have been reviewed by *B. F. Markov* and *E. B. Kuzyakin*. In such cells, two identical electrodes at different temperatures are connected *via* a fused-salt electrolyte. The electromotive force of this element is a function of the temperature and the type of element. Here the authors concern themselves in particular with the theory and practice of thermogalvanic cells having metal- and halogen-electrodes and a single component fused-salt electrolyte. A few examples of how the observed characteristics and temperature dependence of the thermopotential can be utilized in the physical chemistry of fused salts are discussed. [Thermogalvanic Cells with a Single Fused Salt. Russ. Chem. Rev. *41*, 250—257 (1972); 47 references]

[Rd 588 IE—Q]

The analysis of hallucinogenic drugs is reviewed in an article by *A. Sperling*. New methods of analysis as well as old ones still in use are described. Chromatographic methods are particularly suitable. In fact, thin-layer and column chromatography are relatively inexpensive and rapid methods for the separation of LSD and LAA (lysergic acid amide). Thin-layer chromatography is used for the qualitative detection of the decomposition products formed by UV radiation; a quantitative determination can be carried out UV-spectrometrically at 312 nm. Few satisfactory results have so far been obtained with gas chromatography, whereas mass spectrometry has proved to be very useful since LSD shows three characteristic peaks ($m/e = 323, 221, 207$). Unfortunately, high investment costs restrict this method to forensic laboratories. Hallucinogenic tryptamines, such as α-methyl-, dimethyl-, diethyl-, and dipropyltryptamine are separated thin-layer chromatographically and developed by spraying with *p*-dimethylaminobenzaldehyde. This analysis could also be carried out gas chromatographically. Numerous hallucinogens can be determined by fluorescence, IR, NMR, and mass spectrometry. Several methods for the extraction of tetrahydrocannabinol are described. [Analysis of Hallucinogenic Drugs. J. Chromatogr. Sci. *10*, 268—275 (1972); 48 references]

[Rd 591 IE—X]

Amber. Recent research on amber is reviewed by *C. W. Beck*. Numerous secondary products are formed during the fractionation of the components of amber: dehydrogenation leads to agathalin *(1)* and pimanthrene *(2)*, thus indicating the presence of the diterpene of type *(3)*. Lambertinic acid and sciadopinic acid, which have been isolated from the Californian sugar pine and Japanese umbrella pine respectively, also belong to type *(3)*. Accord-



ing to another hypothesis, amber should basically contain a derivative of abietic acid, the polyester *(4)* according to *Rottländer* (model studies with diabietic acid). If such is the case the resin acid of amber would be of the type *(5)* and isopropyl groups should be detectable. [Aus der Bernstein-Forschung. Naturwissenschaften *59*, 294—298 (1972); 40 references]

[Rd 593 IE—M]

Methods for the analysis of narcotic analgesics and amphetamines are summarized by *S. J. Mulé*, particular interest being attached to the identification of these drugs after their isolation from biological material. Separation from the biological matrix is usually carried out by production of the free base and its extraction from the aqueous phase or by extraction from an Amberlite-XAD-2 column. Color reactions, like microcrystalline determinations and UV spectrometry, are not specific and sensitive enough for the identification of drugs, since in all cases extensive purification of the extract obtained from the biological material must be resorted to. Gas chromatography could very well be the most suitable method. It permits determination of drugs in the μg to ng range. Fluorescence spectroscopy appears to be very promising for the future, since it combines sensitivity and specificity with low time requirements. [Methods for the Analysis of Narcotic Analgesics and Amphetamines. J. Chromatogr. Sci. *10*, 275—282 (1972); 84 references]

[Rd 592 IE—X]

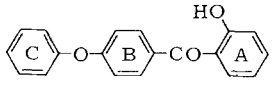
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

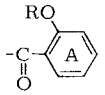
Porous, heat-cured resins with low densities are produced by formation and subsequent hardening of a water-in-resin emulsion, whose resin phase consists of an unsaturated polyester resin and/or a vinyl ester resin and monomers that can be copolymerized with these resins. A polyalkylene oxide block copolymer with a hydrophobic component having a molecular weight of at least 1000 is added to the emulsion as a nonionic surface active agent. Because of this addition, the cured resin emulsion gives off water even at room temperature, and can be readily dehydrated without the formation of cracks or fissures or other damage in the porous mass. The heat-cured resin can be worked *e.g.* like wood. It can be sawn, drilled, nailed, and screwed. [DOS 2046575; Dow Chemical Co., Midland, Mich.]

[PR 40 IE—E]

The novel use and production of 2-hydroxy-4'-phenoxybenzophenones *(1)* as stabilizers for organic material such as polyvinyl chloride, polyethylene, and polypropylene against the action of O_2, heat, and light is claimed. The benzene nucleus A may be substituted with CH_3, and nuclei B and



(1)



(2)

C may be substituted by halogen or substituted alkyl or alkoxy residues. The compound *(1)* is prepared by a Friedel-Crafts reaction of a diphenyl ether with a compound containing the residue *(2)* at $\leq 50\,^{\circ}C$. In the second step, R (lower alkyl) can be replaced by H by heating (acid hydrolysis with HBr). The new compounds may be incorporated into light-sensitive substances or applied as a protective layer. [DOS 2142353; Sandoz AG, Basel].

[PR 47 IE—B]

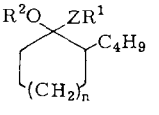
Scrap from polyoxymethylene plastics may be used as a source of formaldehyde in the production of reaction products of formaldehyde with aliphatic hydroxy compounds. The reaction proceeds in the presence of an aqueous acidic catalyst between 60 and 150 °C. Low molecular weight alcohols and diols or dihydrates of aldehydes are particularly suitable for use as hydroxy compounds. Examples of suitable catalysts are sulfuric acid, perchloric acid, phosphoric acid, and potassium hydrogen sulfate. The process is suitable for the production of formals and particularly of cyclic formals such as 1,3-dioxolane and 1,3,5-trioxolane. [DOS 2064100; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

[PR 56 IE—I]

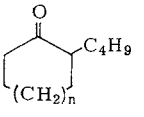
Flame-resistant plasticized polyvinyl chloride is obtained by the addition of the plasticizer tribromophenyl 2,3-dibromopropyl ether. The incombustibility of raw polyvinyl chloride, which is a valuable property, is greatly reduced by the usual additives, particularly plasticizers. The plasticizer mentioned, on the other hand, acts as a flameproofing agent without limiting the cold strength of the plasticized PVC mix or necessitating additional synergists such as antimony compounds. [DOS 2049188; Chemische Fabrik Kalk, Köln]

[PR 73 IE—T]

New carbocyclic perfumes *(1)* and their production are claimed.



(1)



(2)

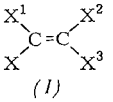
(3)

R^1 = H, methyl; R^2 = H, lower alkanoyl;
Z = $-C\equiv C-$, $-CH=CH-$, $-CH_2-CH_2-$;
n = 0,1,2; M = alkali metal, MgHal

They are prepared by reaction of compounds *(2)* with an organometallic compound *(3)*. The hydroxyl group of the reaction product may be alkanoylated, and a triple or double bond may be hydrogenated to a double or single bond. [DOS 2155671; L. Givaudan & Cie. S.A., Vernier-Genève]

[PR 53 IE—D]

Modified olefin and diolefin homopolymers and copolymers containing polar groups, which exhibit very good technical properties, are produced by reaction of the polymers, *e.g.* 1,4-*cis*-polyisoprene, with an unsaturated compound of the type *(1)*, *(2)*, or *(3)* between 40 and 200 °C in the



(1)

(2) *(3)*

X to X^3 = H, COOH, COOR, CN, CHO, $CONH_2$, SO_3H, CH_2Cl; at least one of the residues X to X^3 is not H; the *cis* substituents of the C=C double bond may be bivalent residues, which react with ring formation;
R = alkyl, aryl

presence of free-radical catalysts, *e.g.* azodiisobutyronitrile, antioxidants, and aliphatic or cycloaliphatic hydrocarbons and/or ketones containing at least 5 C atoms, *e.g. n*-heptane and cyclohexanone, as a solvent.

Examples of suitable unsaturated compounds are allyl chloride, acrolein, acrylic acid, acrylonitrile, tetracyanoethylene, azodicarboxamide, and particularly maleic anhydride. The products can be made into curable objects having good green strength. [DOS 2143804; Snam Progetti S.p.A., Milan]

[PR 30 IE—C]

Deuterated, saturated, acyclic C_4—C_8 hydrocarbons containing functional groups (ethers, alcohols, monocarboxylic, dicarboxylic, or polycarboxylic acids or their ester or amide derivatives) and having boiling points of at least 100 °C for the liquids are prepared as follows: Saturated or unsaturated hydrocarbons containing one or more functional groups are brought into contact in the liquid state with deuterium gas in the presence of a metal catalyst of Group VII or VIII until the desired fraction of the hydrogen atoms has been replaced by deuterium atoms. The catalyst is advantageously held on a support, and the reaction temperature is up to about 300 °C. The compounds are used in research work, as high-temperature solvents, as lubricating oils, or as base fluids for lubricating greases. [DOS 2162535; Merck Sharp & Dohme (I.A.) Corp., New York]

[PR 54 IE—I]

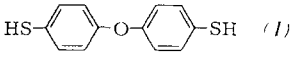
Cyanuryl chloride can be prepared by catalytic trimerization of cyanogen chloride in the gas phase with an aluminum silicate catalyst $Na_2O \cdot Al_2O_3 \cdot nSiO_2$ having pore sizes of about 6 to 15 Å and a molar ratio of silicon dioxide to aluminum oxide of at least 2.2 : 1 in the original and/or modified ion-charged form after treatment at a high temperature, preferably between 550 and 570 °C. The catalyst may also be subjected to carbon deposition; it can be used in a fixed bed or in a fluidized bed. [DOS 2159040; VEB Chemiekombinat Bitterfeld, Bitterfeld]

[PR 57 IE—I]

A new, greatly weakened living vaccine for rubella can be obtained by further growth of the rubella virus over at least ten passages in a tissue culture containing primary kidney cells of the guinea pig. The vaccine can be used for vaccination against German measles, and does not lead to the side effects observed in the past, even in adults. [DOS 2132911; Takeda Chemical Industries Ltd., Osaka]

[PR 90 IE—N]

4,4'-Dimercaptodiphenyl ether *(1)* can be used as a vulcanizing agent for natural and synthetic rubbers. This compound is obtained by reduction of diphenyl ether 4,4'-bis(sulfonyl chloride) with Zn/conc.HCl. The quantity of *(1)* required for vulcanization is not critical; it is preferably 1.5 to 4 parts by weight per 100 parts by weight of rubber. It is generally also necessary to add sulfur in a proportion of 0.05 to 0.5 part by weight as an activator. The types of rubber that can be vulcanized with *(1)* include all those that can be vulcanized in the usual manner as well as polychloroprene and silicone rubbers. [DOS 1643556; Uniroyal, Inc., New York]



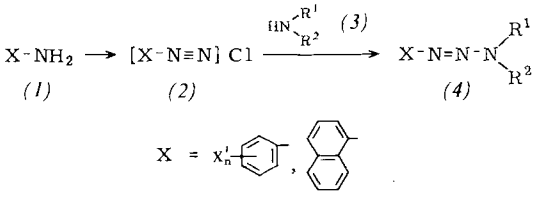
(1)

[PR 38 IE—E]

Readily biodegradable carboxylated polyalkenes, which are very desirable from the standpoint of protection of the environment, are obtained by irradiation of a monomeric or polymeric hydrocarbon, *e.g.* polyethylene, polypropylene, or polybutadiene, in CO_2 under pressure. Ionizing radiation such as γ-radiation, X-rays, or high-energy electrons from any source may be used. The physical properties of the material, which is used *e.g.* as a packaging film or as fibers, are largely unaffected. Carboxylated polyalkene fibers having a sufficiently high degree of carboxylation can also be readily dyed. [DOS 2148927; Standard Research Institute, Menlo Park, Calif.]

[PR 72 IE—T]

Viricidal, insecticidal, and miticidal agents contain triazene derivatives *(4)* as active ingredients. The agents are not phytotoxic, and can be used in agriculture and horticulture to combat several types of viruses that attack useful and ornamental plants (such as rice, grain, vegetables, potatoes, fruit, and flowers). The agents can also be used against harmful insects and against red spider. The triazene compounds *(4)* can be prepared by diazotization of an aromatic amine *(1)* and reaction of the diazonium chloride *(2)* with an aliphatic or cyclic amine *(3)*.



X' = H, CH_3, OCH_3, Cl; n = 1, 2; R^1, R^2 = —CH_2—CH=CH_2, lower alkyl; $R^1 + R^2$ = (CH_3-substituted) heterocyclic group (C_4—C_6) containing N

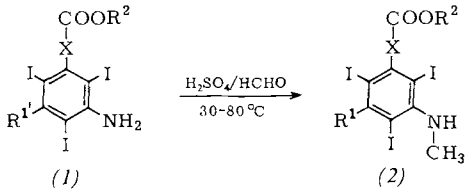
[DOS 2147259; Farbenfabriken Bayer AG, Leverkusen]

[PR 87 IE—N]

Living polymers are obtained by addition of a monomer having the general formula H_2C=CXX' (where X is hydrogen or an organic substituent and X' is an organic substituent, and the sum of the Hammett substituent constants of X and X' lies in the range between −0.2 and 0.1) to a mixture of alkali metals having a large surface at a temperature in the range between −100 and 30 °C in an inert atmosphere. Aromatic hydrocarbons, for example, are added as activators in a stoichiometric excess to the alkali metal and a Lewis base. [DOS 1595048; Nippon Soda K.K., Tokyo]

[PR 83 IE—E]

Monomethylaminotriiodophenyl compounds *(2)* or their salts with physiologically acceptable bases are valuable X-ray contrast media and are characterized by favorable elimination *via* the bile and by a low toxicity. The compounds can also be converted by *N*-acylation into known X-ray contrast media, *e.g.* metrizoic acid. The compounds are prepared by reaction of the amines *(1)* with a mixture



R^1, $R^{1'}$ = *e.g.* H, I, (cyclic) acylamino; R^2 = *e.g.* H, lower alkyl; X = *e.g.* —CO—N(C_6H_5)-alkylene, single bond

of concentrated sulfuric acid and (excess) formaldehyde. [DOS 2050217; Schering AG, Berlin and Bergkamen]

[PR 88 IE—N]

In a new process for the production of chloropyridines, in which there is no need to start with a preformed pyridine ring, cheap ε-caprolactam or cyclohexanone oxime is allowed to react with chlorine in the vapor phase at a temperature of least 250°C (400 to 600°C). The chlorine and the caprolactam or cyclohexanone oxime are preferably preheated separately. The starting materials may be diluted with inorganic diluents (N_2 or steam) or with organic diluents that are inert to chlorine (CCl_4). The new method is particularly suitable for the preparation of pentachloropyridine, but chloropyridines having less than five chlorine atoms can also be obtained, the proportion of these products depending on the quantity of chlorine, the reaction temperature, and the residence time. In general, at least 5 mol of chlorine should be used per mol of caprolactam or cyclohexanone oxime. If pentachloropyridine is desired as the main product, 15—30 mol of chlorine are used per mole of starting material. The preferred residence times for the mixture in the reaction zone are between 10 and 30 seconds. In one example, ε-caprolactam is allowed to react with 18 mol of chlorine per mol of caprolactam at 530°C, with a residence time of 20 seconds. In addition to 2,3,4,6- and 2,3,5,6-tetrachloropyridines, the product contains pentachloropyridine in a yield of 86%. [DOS 2141632; Imperial Chemical Industries Ltd., London]

[PR 75 IE—U]

Hydrogenation catalysts for the hydrogenation of polymers in viscous solution at low temperatures and low hydrogen pressures consist of a reaction product of at least one metal chelate of the metals nickel, cobalt, and iron, the chelating agent being bonded to the metal *via* a nitrogen atom and an oxygen atom, with at least one reducing agent having the formula MR_n, where M is lithium, magnesium, or aluminum, R is a hydrocarbon or alkoxy group containing 1 to 12 carbon atoms or hydrogen, and *n* is the valency of M. The catalyst can be obtained by dissolution or dispersion of the metal chelate in an inert solvent and reaction with the reducing agent; however, the catalytic components may also be mixed with the polymer solution to be hydrogenated. The catalyst is used for the hydrogenation of polymers that contain C=C double bonds, C≡C triple bonds, and C≡N triple bonds. [DOS 1767832; Bridgestone Tire Co. Ltd., Tokio]

[PR 37 IE—E]

BOOK REVIEWS

Aromaticity. By *P. J. Garratt.* McGraw-Hill Book Co., London 1971, 1st. Edit., viii, 184 pp. numerous figures, bound £ 3.40.

In the course of a century the concept of aromaticity has greatly promoted the synthetic and theoretical development of organic chemistry. This process is described in the present work, which is intended as a textbook. It first explains in detail, by a discussion of the classic pair benzene and cyclooctatetraene, the physical and chemical differences between Hückel systems with closed and with open shells. This is followed by the treatment of annulenes, monocylic aromatic and antiaromatic ions, annulenones, and fulvenes. The other chapters are devoted to heterocycles, polycyclic compounds, homoaromatic π systems, and finally the aromatic transition states of pericyclic reactions.

A very large volume of material is presented within this broad framework, often with the welcome inclusion of spectroscopic, magnetic, kinetic, and structural data, and the field is covered in part up to 1971. In line with the textbook style, the references are mainly confined to lists of secondary literature at the ends of chapters. The consistent use of the Frost-Musulin formalism or the Dewar PMO method for the determination of delocalization energies is didactically commendable, as it makes these parameters, which are fundamental to the understanding of aromaticity, accessible even to students and chemists with no mathematical background. On the other hand, the treatment of aromatic transition states in four pages, where (incorrectly in this context) even homoaromatic ions are found as solvolysis intermediates, is simply too short. This chapter, which is certainly not out of place, should be rewritten and expanded in a new edition. The opportunity should then be taken to rid the book of errors.

The book is well written and abundantly provided with reaction schemes. It will provide advanced students and chemists specializing in other fields with a good survey of the field that has benefited from the concept of aromaticity. Moreover, it also represents a reasonably priced reference work for those who are already conversant with this field.

Wolfram Grimme [NB 1121E]

Carbene Chemistry. By *W. Kirmse.* Academic Press, New York—London 1971. 2nd Edit. xi, 615 pp., numerous figures and tables, bond $ 33.—.

One of the heuristic principles of the last few decades in organic chemistry (which is certainly not short of ideas) is the carbene concept, which was introduced in the early

1950's and rapidly blossomed into a classical field of research. *Kirmse's* book, which first appeared in 1964, provided a first comprehensive survey and soon became *the* book on this subject; it was also the prelude to a distinguished series of monographs on organic chemistry edited by *A. T. Blomquist* (now with *H. Wasserman)*, which now comprises 23 volumes. The rapid further development of carbene chemistry, which is impressively reflected in the fact that the number of publications on the topic has now trebled, is undoubtedly a consequence not only of the many mechanistic problems and preparative possibilities but mainly (in the author's opinion, which is surely correct) of the emotional impact of the concept of bivalent carbon. The present second edition, though identical in its external presentation, is a completely rewritten book, with twice as many pages as the first edition, and with 2500 references extending up to 1970.

To allow a coherent presentation of the extensive material in its many aspects, *Kirmse* has (very skillfully in the reviewer's opinion) divided the book into two main parts; in the first part (entitled Methylene Transfer Reactions), consisting of the four chapters Introduction, Photochemical and Thermal Methylene Transfer Reactions, Organometallic Methylene Transfer Agents, and Base-Induced α-Eliminations, the emphasis is on the ways in which carbenes and carbenoids are formed, while the second part deals with their structure and reactivity and is divided into the following eight chapters: Structural Theory of Carbenes (written by *J. F. Harrison*), Spectra of the Carbenes, Reactions with C—H Bonds, Additions to Alkenes, Additions to Alkynes, Additions to Aromatic Compounds, Reactions Involving Hetero Atoms, and Rearrangements. Another chapter, which was written by *P. P. Gaspar* and *B. J. Herold*, deals with silicon, germanium, and tin structural analogs of carbenes (the authors offer didactic objections to the more usual term "carbene analogs").

The book is fluently, clearly, and concisely written. A number of omissions and instances of personal emphasis are hardly to be avoided in view of the abundance of material, and are of little consequence owing to the many references to original literature. The index and numerous cross references in the text enhance the value of the book as a reference work. All in all, the second edition will carry on the role of the first edition as an authoritative book on carbene chemistry, and is a must for any chemical library and for the bookshelves of any scientist who is interested in this subject.

Gert Köbrich [NB 103 IE]

Models in Chemical Science. An Introduction to General Chemistry. By *G. S. Hammond, J. Osteryoung, T. H. Crawford*, and *H. B. Gray*. W. A. Benjamin, Inc., New York, 1971, 1st Edit., xiii, 422 pp., numerous figures, bound *ca.* DM 38.—.

Teaching Guide for Models in Chemical Science. By *R. L. Keiter*. W. A. Benjamin Inc., Menlo Park, Calif. 1971. 1st Edit. x, 491 pp., bound.

Because of the curricula followed in many schools, the background knowledge of those embarking on a chemistry course often leaves much to be desired. An introduction to the basic principles of chemical thought, with a very limited range of subject matter, can be of great assistance in such cases. There is no shortage of textbooks of this type in English-speaking countries. However, these are often aimed at the American high-school level, and are too simple for German university entrants. The present book by *Hammond et al.* is an exception. The beginner is presented here with the essential ideas of chemistry, with a clarity that is often exemplary. The axiomatic nature of these ideas is never concealed. On the contrary, the fundamental aim of the authors is to demonstrate clearly the model character of all our chemical views. This is further emphasized by *Keiter's* excellent supplement, which is a valuable aid to tutors in the tutorial treatment of the material in the textbook.

More than half of the book is devoted to the development of the concept of chemical structure and bonding in molecules, liquids, and solids. It is a pity that the concept of symmetry, which is so important nowadays, is not introduced here.

A chapter on solutions, which provides the first contact with thermodynamic concepts, is followed by a detailed treatment of equilibrium in chemical reactions and a very brief chapter on the various reaction types. After a chapter on chemical kinetics the book ends with an example of chemical taxonomy from the field of carbon and silicon compounds.

A feature that the reviewers feel to be very valuable is the list of chemical concepts discussed, with dictionary-like definitions, after each chapter and at the end of the book.

Nowhere is it easier to find omissions than in an introduction to general chemistry. It is to the authors' credit, in our opinion, that they did not yield to the temptation to introduce more material at the expense of clarity and detail.

The treatment of the diversity and classification of chemical reactions is admittedly too short, but a course in chemistry is largely devoted to this topic in any case. This book is unmatched as an introduction to the main concepts of modern chemistry for course entrants. The text is excellently arranged, and is supported by clear diagrams that make a lasting impression.

Guido Hartmann and *Siegfried Hünig* [NB 113 IE]

The Alkaloids. Vol. 13, Chemistry and Physiology. Edited by *R. H. F. Manske*. Academic Press, New York—London 1971, 1st Edit., xv, 457 pp., numerous figures, bound $ 24.—.

In this new volume, the editor has again managed to find important specialists to write the nine chapters.

K. W. Bentley (283 references) has collected a large number of general and special reactions of morphinan derivatives. This contribution covers articles on mass-spectrometric fragmentations as well as the numerous synthesis, degradation, and rearrangement reactions. 26 new morphinan alkaloids are presented, substances having the hasubanonine skeleton also being listed here. *M. Shamma's* article on the small group of spirobenzylisoquinoline alkaloids (26 references) deals mainly with problems of their structural elucidation and synthesis. *A. Brossi, S. Teitel*, and *G. V. Perry* (97 references) present a concise survey of the principal chemical, biosynthetic, and pharmacological discoveries in the field of ipecacuanha alkaloids. The number of pages required has increased from 2 in Volume 7 to 20 in the present volume. *B. Robinson* reviews recent syntheses of the physostigmine skeleton and publications on the determination of the absolute configuration and the pharmacology of the Calabar bean alkaloids (28 references).

The elucidation of the complicated structures of the Galbulimima alkaloids is largely due to the authors of the 5th chapter, *E. Ritchie* and *W. C. Taylor*, who review the analytical works that have appeared since the publication of their last article in Volume 9 (1967). *R. S. Kapil* (44 references) outlines the publications since 1964 on a new subgroup of the indole alkaloids, *i.e.* the carbazole alkaloids. *M. Curcumelli-Rodostamo* correlates the 30 or so new bisbenzyltetrahydroisoquinolines isolated in the last four years (up to 1970) with the previously known compounds, and adds further important information (124 references). An abundance of recent syntheses, stereochemical investigations, and physiological and pharmacological findings explain the renewed discussion of the tropane alkaloids (*G. Fodor*, 194 references). The last chapter, "Alkaloids Unclassified and of Unknown Structure" (116 references), was written by *R. H. F. Manske*.

The favorable overall impression given by this alkaloid volume is only very slightly weakened by the few errors (mainly in the first chapter): pentavalent carbon (formula X), missing or incorrect reaction arrows (p. 155), a formula scheme under an incorrect heading (p. 155), and irregularities in the characterization of stereoisomerization and ^{14}C labeling (p. 374).

Spot checks show that the references are fairly free from errors (though one should read 1965 for 1925 in reference 3, p. 156). After reading this book, the reader will be in no doubt as to the unsuitability of Roman numerals for numbering chemical formulas. The very short subject index gives only a hint of the abundance of information presented.

All the articles show impressively the important part played by the proper use of modern physical methods in the successes that have been achieved. They also show how youthful alkaloid chemistry has remained, despite its long history.

The book can be unreservedly recommended to all chemists, botanists, and pharmacologists who are interested in the alkaloid field. It should certainly find a place in any library.

Volker Teetz [NB 117 IE]

Gel Permeation Chromatography. Edited by *K. H. Altgelt* and *L. Segal*. Marcel Dekker Inc., New York 1971, 1st Edit., xvii, 646 pp., numerous figures bond $ 24.75.

The book contains the lectures from a symposium on this topic held by the American Chemical Society at the beginning of 1970, which were published in 1970/71 in "Separation Science". The editors have tried to take account of the wide range covered by the fields of interest of the lecturers by division of the material into the following chapters: Fundamental Introduction; Survey of Theories and Evaluation Methods; New Developments; Application to Polymer and Petrochemical Problems. The specialist will find here a great deal of valuable advice for his own theoretical and experimental work, *e.g.* on the gel permeation chromatography (GPC) of high molecular weight polyethylene and polypropylene with an IR detector and with tetrachloroethylene as a solvent at high temperatures; on corrections required in the evaluation; on the use of the universal calibration after *H. Benoit*; on the GPC methods known up to 1970 for the investigation of copolymers.

From the title of the book, one would expect a substantially complete description of the GPC technique, the theories, and its uses; the book by *Determann* [Gelchromatographie (Gel Chromatography). Springer-Verlag, 1967] on general gel chromatography might serve as a pattern in this respect. A coherent and (to the chemist) more readily comprehensible introduction to the physical material would also be possible within this framework. However, the contributions presented are well able to widen and deepen the knowledge of those who are familiar with GPC.

Manfred Unbehend [NB 118 IE]

Spectroscopic Properties of Inorganic and Organometallic Compounds. Vol. 4. Specialist Periodical Reports. Published by The Chemical Society, London 1971, 1st Edit., xviii, 604 pp., numerous figures bound £ 10.00.

Volume 4 presents a survey of the literature published in 1970 in the following fields: nuclear magnetic resonance (185 pages); nuclear quadrupole resonance (10 pages); microwave spectroscopy (13 pages); vibrational spectra (260 pages); and Mössbauer spectroscopy (95 pages). The collection of literature is complete, and is presented in such a way that all the significant developments in these fields are specially picked out. Not only are the results reported, but possibilities for using spectroscopic information are also shown.

Each chapter is complete in itself, and provides an insight into the range of applications that have been found for the various methods. The books and reviews that have been published are discussed in the introduction to each chapter and the main subjects of the investigations are emphasized. Each chapter contains sections arranged according to the lements. This arrangement facilitates rapid scanning.

This volume can be warmly recommended to everyone concerned with these methods. The series is particularly valuable for those who wish to familiarize themselves with this field (degree and doctorate candidates). One obtains here a large, ordered literature survey in a very short time with a minimum of work.

Chemistry and Biosynthesis of the Hypothalamic Releasing and Inhibiting Neurohormones[**]

By Karl Folkers, Nils-Gunnar Johansson, Fred Hooper, Bruce Currie, Hans Sievertsson, Jaw-Kang Chang, and Cyril Y. Bowers[*]

The hypothalamus secretes hormones which in turn affect the release of hormones from the anterior lobe of the pituitary gland. Evidence has so far been adduced for the existence of seven hypothalamic releasing hormones and three inhibiting hormones. These neurohormones are all oligopeptides and occur in only nanogram amounts in the hypothalamus. The study of synthetic analogs has provided valuable information regarding their mechanism of action.

1. Summary

1.1. Background

The hypothalamus is a region of brain tissue which has significant functions in mammalian physiology and particularly influences the secretion of hormones of the anterior lobe of the pituitary gland. The tentative list of hypothalamic neurohormones consists of seven releasing hormones and three inhibiting hormones.

The thyrotropin releasing hormone (TRH) and the luteinizing hormone releasing hormone (LRH) have been isolated and structurally elucidated. TRH is a tripeptide, pGlu-His-Pro-NH_2, and LRH is a decapeptide, pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2. TRH and LRH have been synthesized by various combinations of classical reactions and solid-phase procedures.

It has been commonly considered that there is a "unitary" hormone relationship between the hypothalamus and the pituitary, *i.e.*, one hypothalamic hormone regulates one pituitary hormone. However, this "unitary concept" may not be invariant.

LRH releases the luteinizing hormone (LH) and the follicle stimulating hormone (FSH), and has been designated as the gonadotrophin releasing hormone for both LH and FSH. TRH releases thyrotropin and prolactin; current investigations should reveal whether it is the intrinsic regulator of both these pituitary hormones.

A peptide isolated from the hypothalamus, Val-His-Leu-Ser-Ala-Glu-Glu-Lys-Glu-Ala, has been proposed as the growth hormone releasing hormone. However, its essential failure to release growth hormone by radioimmunoassay appears to invalidate this claim.

Two peptides displaying the activity of a melanocyte release inhibiting hormone have been isolated, *viz.* Pro-Leu-Gly-NH_2 and Pro-His-Phe-Arg-Gly-NH_2. Pro-Leu-Gly-NH_2 did not inhibit release of MSH in tests by other investiga-

tors who concluded that the nature of MRIH is uncertain, but for the rat may be tocinoic acid

or a related peptide. Tocinoic acid does not inhibit the release of MSH in amphibian pituitary tissue. The pentapeptide H-Cys-Tyr-Ile-Gln-Asn-OH, on the other hand, does act as MSHRH.

According to data obtained with labeled amino acids, biosynthesis of TRH and LRH in systems from hypothalamic tissue appears to involve soluble enzymes and not DNA-dependent RNA-directed reactions.

The tetrapeptide pGlu-Tyr-Arg-Trp-NH_2 was the first synthetic peptide having LRH activity, which is remarkable since the positions of Tyr- and Trp- in this tetrapeptide differ from those in LRH. Both the π-electrons and the basicity of protonated His- of TRH may be functional for the release of TSH, release possibly resulting from both complexing and an ionic mechanism involving a negatively charged receptor site. The Arg^8- moiety of LRH is apparently important to hormonal activity and potency. The positive charge of protonated Arg- in LRH could play an ionic role in release comparable with that of protonated His- in TRH.

Differences in activities of analogs of TRH and LRH at dosages up to 100-fold that of the hormone may arise predominantly from the structures of the analogs. Differences in activities of analogs at dosages of 10000-fold and higher may be due to a combination of molecular variations of both the hormone and that of the receptor site.

Substance P has been characterized as Arg-Pro-Lys-Pro-Gln-Gln-Phe-Gly-Leu-Met-NH_2, and the partial structure of neurokinin is reported as pGlu-, 1 Lys-, 2 Arg-, 1 Asp-, 1 Glx-, 2 Pro-, 1 Ile-, 2 Leu-, 2 Tyr-. Although these two peptides have not been classified as hypothalamic neurohormones, they are derived from hypothalamic and other tissue of the mid-brain, and neurokinin has an initial pGlu- moiety. Substance P has sialogogic activity and neurokinin has hypotensive and other physiological activities.

New therapeutic advances can be anticipated from these new hypothalamic neurohormones.

1.2. Hypothalamus and Pituitary Gland

The hypothalamus is a small section of tissue of the diencephalon, the posterior part of the prosencephalon[1]. Apart from the hypothalamus, the prosencephalon consists of the thalamus, metathalamus, and epithalamus. The hypothalamus is not considered as an organ with boundaries, but rather as a region of brain tissue which has significant functions in many aspects of mammalian physiology.

This tissue is apparently responsible for hormonal regulation of many basic functions of life and also affects behavior. While the hypothalamic region of the brain is only a part of a complex anatomical system, the functions of this region are so strategic that derangement can have profound effects. The hypothalamus must be regarded as part of the series of complex neural systems involving the brain stem, cerebral hemispheres, and other parts of the diencephalon. The hypothalamus is presumably influenced by the great sensory systems of the brain including thalamic and cortical influences for behavioral and autonomic expressions.

The hypothalamus and the pituitary gland are separated by a further region of tissue (median eminence)[1].

The hypothalamus influences the secretory activities of the anterior lobe of the pituitary gland. This hypothalamus-pituitary relationship influences the thyroid gland, adrenal gland, testis, ovary, bone, *etc.*

The hypothalamus and the pituitary interact *via* neural secretions or neurohormones. Fibers of hypothalamic origin, which are estimated to number 100000 in man, terminate in the posterior lobe of the pituitary where they release the nonapeptides vasopressin and oxytocin. Other fibers of hypothalamic origin terminate in the median eminence close to capillaries that are connected to the portal blood vessels of the anterior lobe of the pituitary. The blood flowing through this system transports the releasing and inhibiting hormones discussed in this report.

To summarize, the nonapeptides vasopressin and oxytocin are neurohormones which are released by nerve cells and function in the posterior lobe of the pituitary. The releasing and inhibiting hormones are transported by a network of capillaries and act upon the anterior lobe. Vasopressin, oxytocin, thyrotropin releasing hormone, and luteinizing hormone releasing hormone are peptides of relatively low molecular weight, *i.e.* containing nine, nine, three, and ten amino acids, respectively.

2. Hypothalamic Releasing and Inhibiting Neurohormones

The hypothalamic neurohormones which act upon the anterior pituitary were postulated by *Hinsey*[2] and by *Green* and *Harris*[3] and were studied by many other investigators between 1937 and 1949. During the following 20 years or so, seven hypothalamic hormones were proposed on the basis of biological data concerning the release of corresponding anterior hormones. Three additional hypothalamic factors or hormones were also proposed which appear to inhibit the release of their corresponding hormones from the anterior pituitary. For many years it was commonly thought that one hypothalamic hormone controls one hormone of the anterior pituitary; recently, this "unitary concept" may have been breached since a single hypothalamic hormone appears to release the two pituitary hormones LH and FSH and another one seems to release both TSH and PRL. However, the evidence proving the two dual releases may yet be incomplete, and the "unitary concept" is not necessarily excluded.

The neurohormones of the hypothalamus have been designated as factors, but since their chemistry and biology comply with the definition of a hormone, the early nomen-

Table 1. Tentative list of hypothalamic releasing and inhibiting hormones (see text for relevant literature).

Releasing hormones Name	Abbreviation
1. Thyrotropin releasing hormone	TRH, TRF
2. Luteinizing hormone releasing hormone	LRH, LHRH, LRF
3. Follicle stimulating hormone releasing hormone	FRH, FSHRH, FRF
4. Corticotropin releasing hormone	CRH, CRF
5. Growth hormone releasing hormone	GRH, GHRH, GRF
6. Prolactin releasing hormone	PRH, PRF
7. Melanocyte stimulating hormone releasing hormone	MRH, MSHRH, MRF
Inhibiting factors or hormones	**Abbreviation**
1. Growth hormone inhibitory factor	GIF
2. Prolactin inhibitory factor	PIF
3. Melanocyte inhibitory factor	MRIF, MIF, MRIH

clature should be updated and the designation "hormone" adopted.

Table 1 lists the seven proposed releasing hormones, as studied by many investigators. This particular list is based on the concept of one hypothalamic hormone releasing one pituitary hormone. One can anticipate that further hypothalamic hormones may be added as they become biologically characterized. The three hypothalamic inhibiting hormones are also listed in Table 1, again assuming one hypothalamic inhibiting hormone for one hormone of the anterior pituitary.

2.1. Hypothalamic Releasing Hormones of Established Chemistry

2.1.1. Isolation

The isolation of even the first of these hypothalamic releasing hormones in pure form involved many years of effort. At least two major sources of difficulty were encountered. Only nanogram quantities of the releasing hormones appear to be present in the hypothalamic tissue of a single animal, and the hypothalamic fragment of one pig weighs at most 500 mg. Consequently, hundreds of thousands of the correct and minute pieces of tissue had to be knowingly removed from equivalent numbers of pigs, sheep, or other farm animals at slaughter houses. The isolation of milligram quantities of a pure hormone required for structural elucidation from these hundreds of thousands of hypothalami was a tedious task.

Associated with this difficulty of isolation were the problems of *in vivo* and/or *in vitro* assays for biological monitoring of the chemical isolations. These assays had to be devised and improved; they were frequently complicated and sometimes of questionable significance and even of doubtful specificity. It had been correctly predicted that the first hypothalamic releasing hormone to be chemically elucidated would be the thyrotropin releasing hormone (TRH) because a good assay had been evolved from the studies of many investigators which could guide the isolation of this particular hormone.

The final isolation of the porcine thyrotropin releasing hormone was reported by *Schally et al.*[4], and that of the corresponding ovine hormone by *Burgus* and *Guillemin*[5]. Porcine luteinizing hormone releasing hormone was isolated by *Schally et al.*[6], and ovine LRH by *Amoss et al.*[7].

Present knowledge of the organic chemistry of two hypothalamic releasing hormones should facilitate the continuing chemical and biological research directed toward the elucidation of other hypothalamic hormones, not only in the planning stage, but also in the laboratory. While the multiple chemical steps and countless biological assays required to obtain additional hormones may be somewhat less laborious than for TRH and LRH, it is still evident that the isolation of these additional hormones will involve truly prodigious efforts and many potential pitfalls. Also, the budgets required to sustain such efforts represent a financial problem.

2.1.2. Chemical Structure

The chemical structures of the two hypothalamic releasing hormones established so far are shown in Figure 1. The thyrotropin releasing hormone (TRH) is a tripeptide. TRH releases thyrotropin from the anterior pituitary which in turn acts on the thyroid gland. TRH was later discovered to release prolactin (see Section 4). The second hypothalamic releasing hormone to be characterized is the luteinizing releasing hormone (LRH or LHRH).

Interestingly, one hypothalamic releasing hormone is a tripeptide and another a decapeptide, and both have a

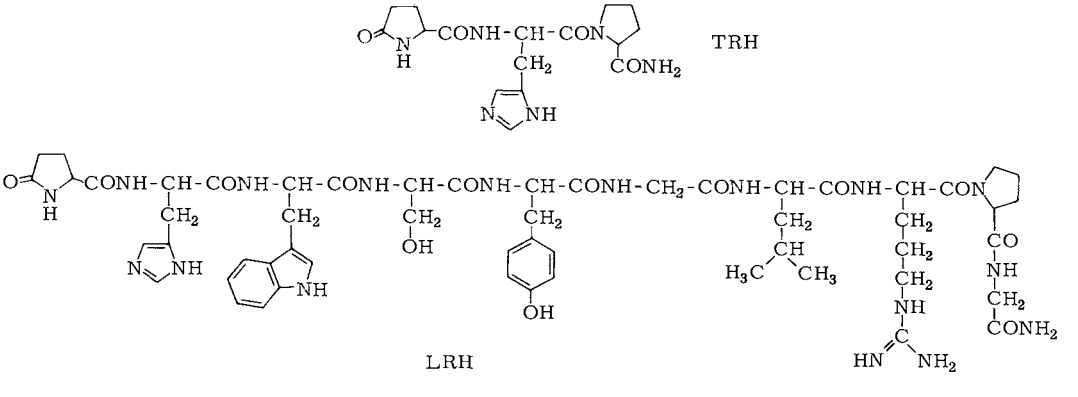

Fig. 1. Hypothalamic releasing hormones having established structures. Above: Thyrotropin releasing hormone (TRH), pGlu-His-Pro-NH_2. Below: Luteinizing hormone releasing hormone (LRH), pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2.

pGlu- moiety at the N-terminus. No species specificity has yet been reported for either TRH or LRH. The discovery that a releasing hormone such as TRH could have the structure of only a "simple" tripeptide initially seemed hardly credible. When the next releasing hormone, LRH, was proposed to have the structure of a nonapeptide and then of a decapeptide renewed unbelief was aroused—such has been the challenge and excitement in this field. Possibly, new surprises are in store for future research into the remaining hypothalamic hormones.

The structures of TRH and LRH in Figure 1 have been emphasized as established. This situation contrasts with that in Figure 2 where structures are proposed for a hypothalamic inhibitory hormone and a releasing hormone; some of the data on the chemistry and hormonal activities are ambiguous, and certain artifacts appear to have been possible.

2.2. Proposed Structure of an Inhibitory Hormone

A proposed structure of melanocyte release inhibitory hormone (MRIH) is reproduced in Figure 2.

2.3. Proposed Structure of a Growth Hormone Releasing Hormone

Figure 2 also shows a structure proposed for the hypothalamic growth hormone releasing hormone (GHRH).

Whereas the structures of TRH and LRH are certain, those proposed for MRIH and GHRH apparently have not been confirmed. In the case of MRIH and GHRH, it is implied that although certain data may be correct, the identification of the MRIH is not clear, and the decapeptide proposed for GHRH is possibly an artifact, at least on the basis of published evidence. These statements are made in an effort to be both fair and objective in appraising the available information on MRIH and GHRH.

2.4. Chemical Structure of the Established Thyrotropin Releasing Hormone

It is now appropriate to survey in more detail the structures established for TRH and LRH and those proposed for MRIH and the GHRH. However, neither the step-by-step structure determination of TRH and LRH nor the protecting groups used in their syntheses will be considered in detail. Instead an overview is provided of the chemistry of these four hormones as known at this time.

The structure of the thyrotropin releasing hormone from both porcine[8,9] and ovine tissue[11] was established as that of pyroglutamyl-histidyl-prolinamide. It appears that

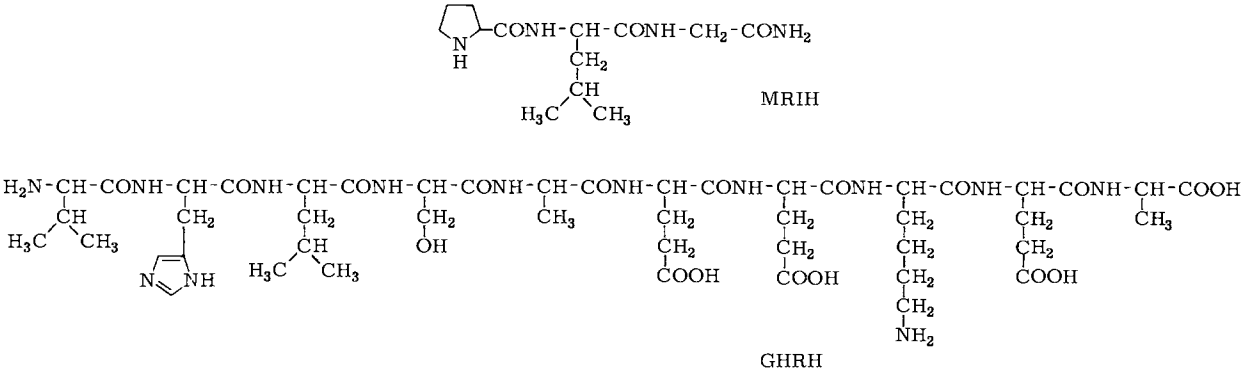

Fig. 2. Proposed structures for two hypothalamic hormones. Above: Melanocyte release inhibitory hormone (MRIH), Pro-Leu-Gly-NH_2. Below: Growth hormone releasing hormone (GHRH), Val-His-Leu-Ser-Ala-Glu-Glu-Lys-Glu-Ala.

this hormone has the same structure in other mammalian species, including man.

The synthesis of TRH was uniquely and unexpectedly achieved as a part of the structural study of porcine TRH in 1969[8,9], and it was concomitantly found that the biological properties of the porcine hormone and the synthetic pGlu-His-Pro-NH_2 are identical[10]. Syntheses of TRH

by various routes, and with unprotected and protected amino acids in classical reactions, and by the solid-phase procedure of *Merrifield*, were achieved over the period of 1969—1971 by six groups of investigators. The six relevant publications[8,9,12–15][*] include the pioneering syntheses with the closely following and related synthetic studies (see Table 2).

2.5. Chemical Structure of the Established Luteinizing Releasing Hormone

The decapeptide shown in Figure 1 was provisionally proposed as the structure of LRH by *Matsuo et al.*[16] in 1971. This structure was based on data from a micro-scale degradation by a combined Edman-dansyl procedure, and a selective tritiation method for C-terminal analysis. The degradations were carried out directly on the digestion products of the hormone with chymotrypsin and thermolysin without separation of the fragments. Their proposed structure is correct, and they subsequently confirmed the structure by another sequence of degradation reactions[17]. It appears that *Matsuo et al.*[16] established this structure with 100 to 200 µg of the hormone isolated from porcine tissue.

Matsuo et al.[16] first published their proposed amino acid sequence for LRH with the comment that the evidence for the linkage pGlu-His- "is not very strong" and that "the mode of blocking at C-terminal Gly- still remains to be solved". It is nevertheless evident that their proposal of a decapeptide with "N-pGlu-" and a C-amide terminus was indeed reasonable, and provided a basis for synthesis of this decapeptide so that the synthetic peptide could be compared with the isolated hormone from porcine tissue and tested in the various bioassay systems for the appropriate hormonal activities.

Ovine LRH was isolated by *Amoss et al.*[7]. The primary structure, established by *Burgus et al.*[18,19], was reported in 1971–1972 to be identical to the decapeptide which had been previously established as the structure of porcine LRH. *Burgus et al.*[19] had at their disposal about 40 µg of the ovine hormone which represented about one-half of the total material derived from side fractions reserved from the early stages of the isolation of TRH. Altogether, their isolation of ovine TRH and LRH was said to utilize about 300000 sheep hypothalamic fragments.

2.6. Syntheses of Luteinizing Releasing Hormone

LRH has been synthesized by classical reactions, by the Merrifield procedure, and by combinations of classical and solid-phase techniques. The thirteen relevant publications[20–32] describe syntheses of pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 (cf. Fig. 1). There was essential agreement concerning the LH-releasing activity of the synthetic decapeptide.

Matsuo, Arimura, Nair, and *Schally*[24] reported that their synthetic decapeptide showed the same physico-chemical and biological properties as their isolated natural porcine hormone.

Many workers in the pharmaceutical industry have now synthesized LRH. For example, *Immer, Nelson,* and *Gotz* of Ayerst Laboratories in Montreal have announced their use of synthetic LRH in studies of animal and human fertility control.

2.7. Proposed Chemistry of Melanocyte Release Inhibiting Hormone

Kastin et al.[33] reported in 1968 on the extrapigmentary effects of the melanocyte-stimulating hormone in amenorrhoeic women. A highly purified preparation of MSH was administered to six women with secondary amenorrhoea. There was menstrual bleeding which might have represented a "rebound effect". The administration of MSH may have directly resulted in stimulation of the ovary. There were statistically significant changes in the concentrations of several components of the serum. The melanocyte-stimulating hormone darkens the skin of amphibians and permits adaptation to environment. It was considered that during the course of evolution, this pituitary hormone may have acquired extrapigmentary functions in mammals.

Celis et al.[34,35] had proposed that the C-terminal fragment of oxytocin (see Fig. 3), Pro-Leu-Gly-NH_2 is the natural MSH-release-inhibiting hormone.

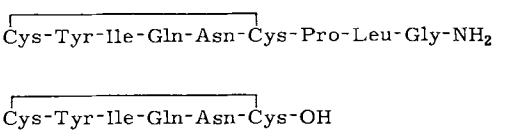

Fig. 3. Above: Oxytocin. Below: Tocinoic acid.

Nair et al.[36] isolated two MRIH-active peptides from bovine hypothalamic extracts, and found one of the peptides to show high MRIH activity and the other peptide to show much weaker activity. They determined the structure of the "main MRIH-active peptide" as Pro-Leu-Gly-NH_2, and synthesized this peptide. *Kastin et al.*[37] found that 10 ng of synthetic Pro-Leu-Gly-NH_2, when applied directly to the pituitary, resulted in lightening of the skin of a frog which had previously been darkened by the destruction of the hypothalamus. They recommended this modified assay for future studies with MRIH, because of its simplicity. The structure of the second MRIH peptide, with lower activity, was subsequently elucidated as H-Pro-His-Phe-Arg-Gly-NH_2[40].

A pentapeptide H-Cys-Tyr-Ile-Gln-Asn-OH was found by *Celis et al.*[38] to act like MSH-RH, because nanogram dosage of this peptide decreased the MSH content of the rat pituitary and increased the MSH concentration of plasma. This peptide also stimulated the release of MSH in animals with a lesion in the median eminence, which indicated a direct action of the peptide on the pituitary. Oxytocin has no effect on the MSH content of the pituitary.

Bower et al.[39] found that the synthetic tocinoic acid (see Fig. 3), which is the ring structure of oxytocin, inhibited

[*] Publications on tentative aspects of TRH structure and subsequent more detailed papers *etc.* will not be considered here.

the release of MSH from rat pituitaries *in vitro* at less than nanogram levels. However, this activity could not be demonstrated on the amphibian pituitary. In contrast to the report of *Kastin et al.*[37] Pro-Leu-Gly-NH_2 did not inhibit the release of MSH from either a rat or a frog system *in vitro*. *Bower et al.* believed that the differences could not be ascribed to differences in the techniques of assay. They concluded[39] that the exact nature of MRIH appears to be uncertain and suggested that, for the rat, tocinoic acid or a closely related structure may be a likely candidate as a natural MRIH.

2.8. Uncertain Chemistry of the Growth Hormone Releasing Hormone

Schally et al.[41] reported the isolation of the growth hormone releasing hormone (GHRH) from porcine hypothalami in 1969. The assay for GHRH activity was based on the depletion of the content of GH in the pituitary of rats and by other assays. In 1971, *Schally et al.*[42] reported the amino acid sequence of the isolated peptide to be Val-His-Leu-Ser-Ala-Glu-Glu-Lys-Glu-Ala, which is a decapeptide.

Veber et al.[43] observed a striking similarity between this decapeptide and a proposed amino-terminal sequence of the beta chain of porcine hemoglobin. Nevertheless, *Veber et al.*[43] synthesized the above decapeptide. *Schally et al.*[42,44] assayed the synthetic decapeptide and found that it stimulated the release of growth hormone, both *in vivo* and *in vitro*, by procedures in which the released growth hormone was measured by the tibia test method of *Greenspan et al.*[45] or by the assay for the sulfation factor. However, the synthetic decapeptide and the isolated peptide were essentially inactive in tests where the release of growth hormone was measured by a radioimmunoassay for rat growth hormone. It has not yet been reported whether mono-, di-, or tri-Gln- modifications of the decapeptide show GHRH activity on radioimmunoassay.

3. Biosynthesis of the Hypothalamic Hormones

In 1971 *Mitnick* and *Reichlin* reported[46] on the biosynthesis of the thyrotropin releasing hormone (TRH). They utilized hypothalamic fragments from the rat and examined the stalk median eminence and the ventral and dorsal sections. Labeled amino acids were added to the incubation system and after purification with the aid of carrier TRH and ^{125}I-TRH, labeled TRH was apparently obtained. However, no bioassays were reported.

From their results they deduced that only Glu-, His-, and Pro- were incorporated. Glu- is cyclized to give the pGlu- moiety and Pro- becomes Pro-NH_2 during the biosynthesis. It appeared that the biosynthetic mechanism involved soluble enzymes and not DNA-dependent RNA-directed reactions.

Johansson, *Hooper*, *Sievertsson*, *Currie*, and *Folkers*[47] at the University of Texas, in collaboration with *Cyril Bowers* of Tulane University, are also studying the mechanism of biosynthesis of the hypothalamic releasing hormones. We have utilized slices of porcine tissue and have added ^{14}C-Glu- to the incubation system. After several steps of purification and the utilization of synthetic LRH as carrier, it was concluded that labeled LRH had been biosynthesized. This conclusion is based on the observation that the LRH-Pauly spot was associated with radioactivity, and that hydrolysis of the radioactive spot yielded ^{14}C-Glu-. The radioactive spot was biologically active for the release of LH in the rat. It seems likely that the biosynthesis of LRH is by soluble enzymes, as reported for the biosynthesis of TRH by *Mitnick* and *Reichlin*.

4. The "Unitary Concept"

Early in this survey, reference was made to the "unitary concept" which has been based on the general idea that one hypothalamic releasing hormone controls one hormone of the anterior pituitary gland, and it was indicated that this "unitary concept" may have been breached. During the tedious and lengthy isolation of the luteinizing releasing hormone from porcine tissue, it was continuously observed that the releasing activities for both LH and FSH did not separate during the fractionations. Finally, *Schally et al.*[48] reported the isolation of LRH in an apparently homogeneous state, and stated that the hormone also has FSH releasing activity. The statement was based on the observation that partition chromatography in ten different solvent systems did not separate FSHRH activity from LHRH. The isolated hormone stimulated the release of both FSH and LH, *in vivo* as well as *in vitro*.

Subsequently, *Schally et al.*[49] were apparently convinced that the decapeptide intrinsically regulates the secretion of both luteinizing and follicle stimulating hormones, and they designated it as the "gonadotrophin-releasing hormone". It appeared to them that the overall control of FSH and LH secretion and the preferential release of one or the other of these gonadotrophins may be mediated by interactions between the decapeptide and steroids.

Additional information on the release of two pituitary hormones by one synthetic hypothalamic hormone has come from studies by *Bowers et al.*[50] who showed that synthetic pGlu-His-Pro-NH_2 (TRH) releases not only thyrotropin in man but also prolactin at all dose levels which have been tested. In fact, injection of only 10 μg of the synthetic tripeptide in man increased the serum levels of both thyrotropin and prolactin. There was no consistent release of GH, LH, or FSH, but the release of prolactin was invariable. This dual release of thyrotropin and prolactin raised the question of whether this synthetic tripeptide hormone is also a "natural regulator" of prolactin in man. The question is still being experimentally studied.

5. Discovery of LRH-Activity of pGlu-Tyr-Arg-Trp-NH_2

Turning now to the subject of the luteinizing releasing hormone, we shall describe the discovery of the first synthe-

tic peptide having the biological activity of LRH. *Bogentoft et al.*[51] studied concentrates of bovine and porcine LRH by chemical and enzymatic inactivations coupled with bioassays. They reported evidence for the presence of arginine, tyrosine, and tryptophan. *Amoss et al.*[52] and *Currie et al.*[53] had previously reported LRH to have a blocked N-terminus in the form of a pGlu- moiety.

Chang et al.[54] synthesized the six tetrapeptides which are possible for pGlu-, Arg-, Trp-, and Tyr-, and *Bowers et al.*[55] found that only one of the six is biologically active. Dosage in the range of 50–200 μg of pGlu-Tyr-Arg-Trp-NH_2 released LH *in vivo* under the conditions for the assay of LRH. It was obvious that this tetrapeptide is not the naturally occurring luteinizing releasing hormone.

On the basis of this LRH-active tetrapeptide, it was possible for *Bogentoft et al.*[51], *Chang et al.*[54], and *Bowers et al.*[55], to predict that LRH is a decapeptide and not a nonapeptide according to reports by *Schally et al.*[48]. This prediction was correct.

Recently, *Guillemin et al.*[56] confirmed that at comparable dosage the tetrapeptide pGlu-Tyr-Arg-Trp-NH_2 and synthetic LRH exhibit the same LRH activity *in vivo* and *in vitro*. It was also observed that pGlu-Tyr-Arg-Trp-NH_2 releases FSH with the same potency ratio as synthetic LRH. They also reported *in vivo* assay data which demonstrated that with pGlu-Tyr-Arg-Trp-NH_2, as well as LRH, a significant release of LH may be effected without a corresponding significant release of FSH. *Bowers et al.*[55] reported LH release without FSH release with as little as 50 μg and up to 600 μg of the tetrapeptide. *Guillemin et al.*[56] reported that at a dose of 500 μg a significant release of LH occurs without a release of FSH, but FSH was released (95% confidence) at a dose of 4 mg. The significance of FSH release at a dosage of 4 mg for this tetrapeptide is not clear.

6. Conformation-Sequence-Activity Relationships and Mechanism of Activity

When the sequence of the luteinizing releasing hormone became known, it was evident that the position of Tyr- and Trp- in the tetrapeptide and in LRH are reversed. Consequently, the hormonal activity of pGlu-Tyr-Arg-Trp-NH_2 *in vivo* is of additional interest with regard to conformation-sequence-activity relationships.

Sievertsson et al.[57] have reported on the role of the histidine moiety in the structure of the thyrotropin releasing hormone. Towards this objective, they synthesized the four analogs of pGlu-His-Pro-NH_2 (TRH) listed in Table 3. pGlu-Phe-Pro-NH_2 is remarkably active for the release of thyrotropin in mice, as measured by the T_3 method. A dose of 100 ng of this analog released nearly as much thyrotropin as 9 ng of TRH. They considered that both the π-electrons and the basicity of protonated His- may be functional for release of thyrotropin in the hormonal mechanism. It also appeared that release may result from both complexing and an ionic mechanism involving a

Table 3. Role of the histidine moiety in thyrotropic releasing hormone. Assay of tripeptides by the T_3 method in mice for release of thyrotropin.

Tripeptide	Dose [ng]	Counts/min ^{125}I
pGlu-His-Pro-NH_2 (TRH)	9	5612
pGlu-Phe-Pro-NH_2	100	3534
pGlu-Trp-Pro-NH_2	50000	204
pGlu-Tyr-Pro-NH_2	50000	100
pGlu-Phe-3Hyp-NH_2	50000	8

negatively charged group in the receptor site. Further studies of TRH analogs have been summarized by *Bowers et al.*[58].

We are also studying the conformation-sequence-activity relationships of the luteinizing releasing hormone. An advantageous new synthesis of pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 was achieved by "classical reactions" by *Chang et al.*[30,31,59]. In principle, the 1—6 sequence, pGlu-His-Trp-Ser-Tyr-Gly-, and the 7—10 sequence, Leu-Arg-Pro-Gly-NH_2, were synthesized separately and then coupled to give the decapeptide. The synthesis employed appropriate protective groups, good yields, and helpful stepwise purifications.

Since the Arg^8- moiety of the decapeptide is presumably important to hormonal activity and potency, this new synthesis provided the flexibility needed to replace Arg^8- with other moieties in the relatively small 7—10 sequence.

Table 4. Activity of analogs of luteinizing hormone releasing hormone.

Compound	Rel. dose
pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 (LRH)	1
Lys^8-LRH	5 – 50
His^8-LRH	200
Nva^8-LRH	100 – 300
Des-Arg^8-LRH	2000

The data in Table 4[30,31,59] reveal that Lys^8-LRH is a relatively active peptide. The other peptides tested were far less active than LRH, but a valid release at the high dosage levels recorded in Table 4 was still observed.

A molecular model of a possible conformation of the decapeptide LRH reveals that the planar indole and benzenoid moieties of Trp- and Tyr- could be in approximately parallel positions, because of possible π-bond interactions. Such parallel planarity may bestow some structural specificity for hormonal activity upon this molecule. The guanidino moiety of arginine could be relatively extended and exposed in this conformation of the decapeptide. Because of the basicity and exposure of the guanidino moiety, the positive charge of protonated Arg- could participate in the mechanism of the releasing activity. This ionic role of Arg- may be comparable with that of His- in TRH.

Continuing their studies on analogs of the luteinizing releasing hormone with a view to elucidating the release mechanism, *Chang et al.*[60] described seven new analogs of LRH, which were synthesized and assayed. Five of these seven analogs are listed in Table 5. Des-Leu^7-LRH and Des-Leu^7-Arg^8-Pro^9-Gly^{10}-LRH were active at a high dosage range. Des-Leu^7-Arg^8-LRH and Des-Arg^8-Pro^9-Gly^{10}-LRH were inactive at such dosages. The 7—10

sequence, Leu-Arg-Pro-Gly-NH_2, of the decapeptide was interesting for bioassay, because it contains the unique Arg- moiety. However, this tetrapeptide proved to be inactive.

Table 5. Activity of analogs of luteinizing hormone releasing hormone.

Compound	Rel. dose
pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 (LRH)	1
Des-Leu^7-LRH	20000
Des-(Leu^7-Arg^8)-LRH	50000, inactive
Des-(Arg^8-Pro^9-Gly^{10})-LRH	20000, inactive
Des-(Leu^7-Arg^8-Pro^9-Gly^{10})-LRH	20000—40000
Leu-Arg-Pro-Gly-NH_2	20000, inactive

The bioassays of the synthetic analogs described in Tables 4 and 5 led to further considerations concerning the mechanism of hormone release. The proximity of the positive charge of protonated Arg- in LRH and a companion negative charge on the receptor site may be important for an ionic reaction proposed as part of the release mechanism. This proposal is supported by the low activity of Des-Leu^7-LRH which could have a positive charge too remote for a normal ionic reaction.

In contemplating the conformation-sequence-activity relationships of LRH and its analogs, *Chang et al.*[60] observed that a division of the analogs into two categories provides help in understanding the obviously complex and overlapping relationships. The first category could include analogs of LRH which show significant release of LH at dosages up to 100-fold that of LRH. In this first category, differences in activities may arise predominately from the structures of the analogs. The second category could comprise those analogs which show significant release of LH at dosages of about 10000-fold and higher than the reference dosage levels of LRH. In this second category, differences in activities may be due to a combination of molecular variations of both hormone and release site. These enormous differences in the range of valid hormonal activity are observable because of the extraordinary potency of the hypothalamic hormones at picogram and nanogram levels.

Vale et al.[61] and *Monahan et al.*[62] have described two analogs of LRH modified at the His^2-position which were tested for release of LH in cultures of dispersed rat anterior pituitary cells. The analog in which glycine was substituted for His^2-, *i. e.* Gly^2-LRH, behaved as a partial antagonist: less than 50% of LH was released at maximum concentrations of LRH. Des-His^2-LRH had no significant activity for release. When added to the culture cell system at molar ratios of 10^3—10^4 times that of LRH, Gly^2-LRH and Des-His^2-LRH decreased the amount of LH secreted in response to LRH.

7. Substance P and Neurokinin

S. E. Leeman reported in June, 1972, at the 55th Canadian Chemical Conference in Quebec city, on the chemistry of two peptides which may have some relationship to the hypothalamic releasing hormones. While these peptides are not now classified as hypothalamic releasing hormones, they are derived from hypothalamic tissue and other tissue of the mid-brain.

Leeman and *Hammerschlag*[63] detected the presence of a sialogogic peptide in extracts of bovine and rat hypothalami while studying the activity of CRF (corticotropin releasing factor) in these extracts. *Chang* and *Leeman*[64] isolated this peptide and showed the presence of 1 Lys-, 1 Arg-, 2 Glx-, 2 Pro-, 1 Gly-, 1 Leu-, 1 Met-, and 2 Phe-. The total number of amino acids in the peptide is eleven and the molecular weight is about 1340. During the studies, it became evident that the peptide and the previously described Substance P are identical. Substance P was first detected in 1931 by *von Euler* and *Gaddum*[65] and found to have many interesting biological properties[66], but prior to this report[64] had never been obtained in pure form. Through cooperative studies with *Niall*[67] the sequence of the peptide was determined as Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH_2.

A peptide having this sequence was then synthesized by *Tregear et al.*[68] and was found to possess all the chemical and biological properties of the native peptide. Approximately 100000 bovine hypothalamic fragments were used to ascertain the chemistry of this peptide. A radioimmunoassay for Substance P has now been developed. Using this method, the concentration of Substance P found in substantia nigra tissue of human brain is estimated as 500 ng/g.

In further observations of the pharmacological activities of bovine hypothalamic extracts, *Leeman* observed the presence of a peptide that produced a characteristic vasodilation of the exposed cutaneous regions of anesthetized rats within seconds following intravenous injection. *Carraway* and *Leeman*[69] isolated the peptide responsible and found its activity to be associated with a transient hypotension. This peptide has now been found to contain 13 amino acids consisting of: 1 Lys-, 2 Arg-, 1 Asx-, 2 Glx-, 2 Pro-, 1 Ile-, 2 Leu-, and 2 Tyr-.

Of potential relationship to the hypothalamic releasing hormones, the structural studies showed that this peptide has a pGlu-moiety as do the thyrotropin and luteinizing releasing hormones; its structure would then be: pGlu-, 1 Lys-, 2 Arg-, 1 Asp-, 1 Glx-, 2 Pro-, 1 Ile-, 2 Leu-, 2 Tyr-.

This substance was tentatively designated neurokinin as in addition to its hypotensive activity it causes contraction of guinea pig ileal tissue while producing relaxation of the rat duodenum. In large doses it causes rats to become cyanotic.

8. Outlook

The chemistry of the hypothalamic releasing and inhibiting hormones is now clearly established as a new area in the field of biologically active peptides and signals a new era in the physiology of neurohormones. The chemical aspects of this new field are already attracting broad attention on the part of organic chemists, medicinal chemists,

biochemists, and enzymologists. Corresponding therapeutic advances in medicine can be anticipated from these advances in basic science.

Repair Processes on Deoxyribonucleic Acid

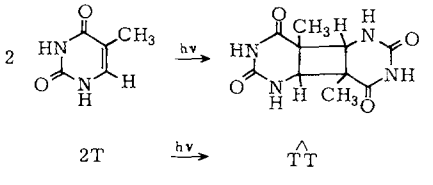
By J. Berndt[*]

Many cells have the ability to recognize and eliminate damage to their DNA, particularly thymine dimers formed by UV light. The elimination of this damage may be achieved by enzymatic, light-dependent cleavage of the dimers into the monomers (photoreactivation) or more frequently by dark repair, in which the damaged part is completely removed from the DNA. In this repair process, the DNA is incised by an endonuclease in the immediate vicinity of the thymine dimers. Oligonucleotides containing the thymine dimer are removed hydrolytically from the DNA by the 5→3′ exonuclease activity of DNA polymerase I (Kornberg enzyme). The resulting gaps are immediately closed by a *de novo* synthesis with the aid of the same DNA polymerase I, the complementary strand serving as a template (excision repair). The final step is the formation of the phosphodiester bond between the newly synthesized DNA fragment and the old DNA strand by a DNA ligase. Xeroderma pigmentosum patients lack the endonuclease as a result of a genetic defect; they therefore cannot eliminate thymine dimers from their DNA, and are extremely sensitive to sunlight. All information so far suggests that genetic recombination and DNA repair are performed by the same enzyme system.

1. Introduction

The genetic material of all cells consists of deoxyribonucleic acid (DNA). Two complementary DNA strands are held together by hydrogen bonds, and in this way they form a DNA double helix. The complementarity of the two strands is due to the fact that the adenine bases (A) of one strand form hydrogen bonds with the thymine bases (T) of the other, and hydrogen bonds are also formed between guanine (G) and cytosine (C). Until recently it was assumed that any modifications in the DNA due to external agents (UV light, X-rays, mutagens) must lead to the death of the cell, or in "favorable" cases to mutated daughter cells. Surprisingly, however, this is not the case, and many cells survive such harsh treatment. These cells possess a machinery by which damage to the DNA can be eliminated and the original form of the DNA double helix restored. This process is generally known as DNA repair.

Beukers and *Berends*[1] found that UV-irradiated, frozen thymine solutions contain dimers of thymine in which two thymine molecules are linked together by C—C bonds to form a cyclobutane ring. These dimers are relatively stable, and can be isolated *e.g.* by chromatography.



2T $\xrightarrow{h\nu}$ $\widehat{TT}$

The irradiation of DNA with UV light (260 nm) also leads to the formation of thymine dimers within a DNA strand at points where two thymine bases are neighbors in the same strand[2]. These dimers are the main reason for the biological action of UV light on the DNA[2,3]. They block DNA replication *in vitro*[4] and *in vivo*[5]; they are mainly responsible for the bactericidal action of UV light. The greater the number of thymine bases in the DNA of a bacterium, the more sensitive is this strain to the action of UV light.

In addition to the formation of thymine dimers in the DNA, UV irradiation can also lead to linkage of two cytosine molecules and/or a thymine and a cytosine mole-

Institut für Biochemie, Zentralabteilung
8 München 2, Landwehrstrasse 61 (Germany)

cule[6,7], though this happens to a smaller extent[*]. *Setlow* and *Carrier*[8] found the following (relative) quantities of dimers in *Escherichia coli (E. coli)*: $\widehat{TT}$ 50%, $\widehat{CT}$ 40%, $\widehat{CC}$ 10%. After exposure to high doses of radiation, the quantity of $\widehat{TT}$ is greater, especially when short wavelengths have been used. Dimerization of thymine molecules lying opposite each other in two neighboring DNA strands does not appear to occur[9].

As a result of DNA repair, therefore, thymine dimers and similar modifications are eliminated from the DNA. This can be achieved by two different mechanisms:

1. Photoreactivation

2. Dark repair.

These processes are discussed below.

2. DNA Repair

2.1. Photoreactivation

In 1949 *Kelner* observed that cultures of *Streptomyces griseus*[10], *Penicillium notatum*, and yeast cells[11] survived UV irradiation much better if they were subsequently exposed to visible light. This "photoreactivation" was then found to occur in a large number of microorganisms[12]. Light having a wavelength of 220—300 nm is most effective for the UV irradiation (dimer formation), whereas visible light having a wavelength of 310—440 nm is required for the photoreactivation process[13].

The first observation of an *in vitro* photoreactivation of UV-irradiated, purified DNA by an *E. coli* extract[14] was followed by similar investigations by *Rupert*[14-18] with yeast extracts. The results clearly showed for the first time that photoreactivation is an enzymatic process.

Yeast and *E. coli* extracts possessing photoreactivating activity have very similar spectra, with absorption maxima at 355 and 385 nm, but until recently it was not certain whether these are in fact the maxima of the "photon-absorbing unit" of the enzyme or of the enzyme-substrate complex[19]. A DNA-photoreactivating enzyme was recently purified seventy-thousand-fold from yeast and the properties of the enzyme were studied in detail[20]. The molecular weight was found to be 53000 and the enzyme had an excitation maximum at 385 nm and a fluorescence emission maximum at 485 nm. These two maxima correspond to the chromophoric groups of the enzyme, but these groups have not been characterized so far.

Obviously, the specificity of the enzyme for a cleavage of dimers is not very high, but the rate of cleavage is greatest for thymine dimers[13].

The photoreactivating enzyme acts by energy transfer, splitting the nucleotide dimers (particularly those of thymine) into monomers; normal adenine-thymine pairing is then again possible, and the function of the DNA is restored.

UV-damaged RNA is not attacked by the photoreactivating enzyme, but dimers of the single-stranded DNA of the phage ΦX174 can also be split into the monomers[13]. The double-stranded structure of the DNA thus does not seem to be a necessary condition for the activity of the enzyme.

The photoreactivation is found mainly in microorganisms, but is not restricted to this group of organisms. A similar photoreactivation has also been observed in mammalian cells[21-24], and photoreactivating activity was recently detected in tissue cultures from the (American) opossum and from the rat kangaroo[25]; however, the enzyme was not characterized further.

Since a much simpler enzyme assay is now available[25a], it should be possible to study the mechanism of the photoreactivating process in greater detail.

2.2. Dark Repair

A much more important repair process is that known as dark repair. This name does not mean that it occurs only in the dark, but simply that light plays no role in the process. This type of repair is capable of eliminating not only dimers of the pyrimidine derivatives, as in photoreactivation but also other types of damage to the DNA.

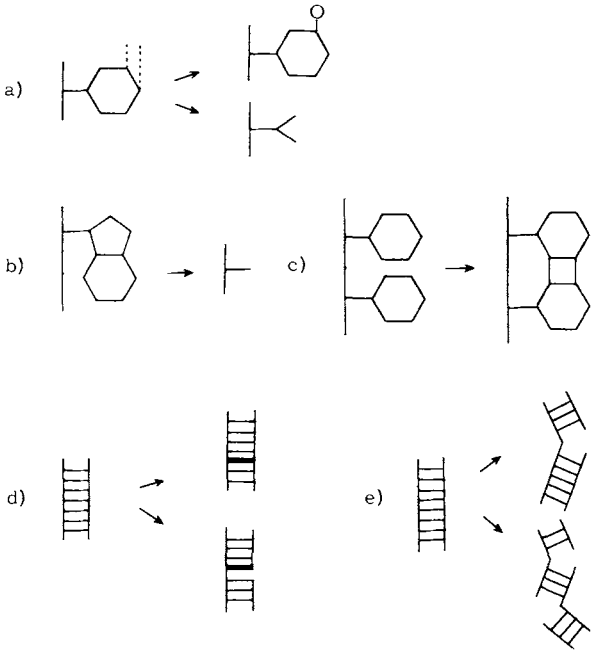

Fig. 1. Modifications which inactivate DNA (according to ref. [26]). (a) Modification of base, caused by hydroxylamine, hydrazine, methylene blue, acridine orange. (b) Removal of base, caused by hydroxylamine, hydrazine, high temperature, alkylation, alkali. (c) Dimer formation, caused by UV light. (d) Crosslinks, caused by nitrous acid, UV light, mitomycin, Nitrogen Lost, low pH. (e) Single-chain breaks, caused by ^{32}P, X-rays, methyl methanesulfonate, radicals in general.

Figure 1 shows modifications in DNA leading to an inactivation, *i.e.* inability to reduplicate. Unlike the effects of mutagenic substances, the modifications inactivating the DNA can be lethal unless repaired or compensated. In this respect it should be mentioned that many of the substances causing modifications inactivating the DNA are known to be carcinogenic.

[*] $\widehat{TT}$, $\widehat{CT}$, and $\widehat{CC}$ are referred to collectively as "dimers" in the present article.

In 1958, *Hill*[27] isolated a mutant B_{s-1} from the radiation-resistant *E. coli* B/r that is 50 to 100 times more sensitive to UV light (see Fig. 2) than the parent strain. Another UV-sensitive strain was isolated by *Howard-Flanders et al.*[29] from *E. coli* K 12. These strains are unable to eliminate damage (dimers) caused by the action of UV light on the DNA. The nature of the biochemical defects in these UV-sensitive mutants was established independently by *Setlow* and *Carrier*[30] and by *Boyce* and *Howard-Flanders*[31] in their classical experiments. The bacteria were grown on a culture medium containing ^{3}H-thymine, and this was incorporated into the DNA. The cells were then irradiated with UV light, whereupon equal quantities of thymine dimers were formed in the wild type and in the mutant. On further growth of the bacteria (now on a medium containing no ^{3}H-thymine) it was found that the radioactivity decreased in the DNA of the wild type and appeared in low molecular weight fractions. Hydrolysis and chromatographic separation of these low molecular weight fractions yielded thymine dimers. These dimers were undetectable in the case of the UV-sensitive mutants, *i.e.* the mutants lacked the enzyme for the elimination of the thymine dimers from the DNA.

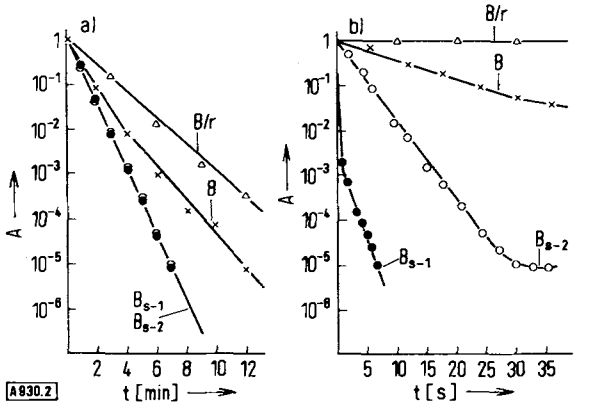

Fig. 2. Fraction A of survival rates of several *E. coli* strains (a) after exposure to X-rays and (b) after UV irradiation (according to ref. [28]).

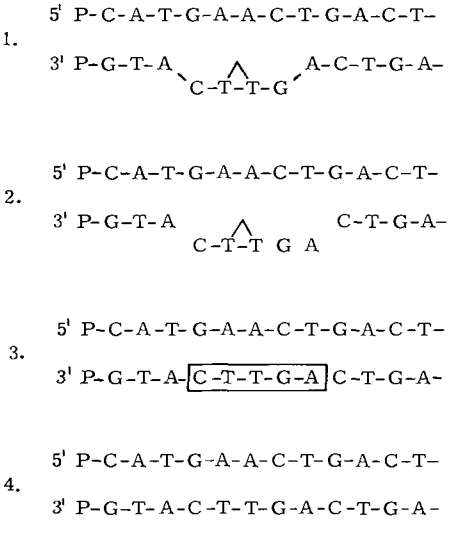

Fig. 3. Scheme of the dark repair of DNA (cut and patch mechanism); for explanations see text.

In the dark repair process the damaged part is completely removed from the DNA, whereas in the photoreactivation process the dimers are split within the DNA molecule into the monomers. Dark repair therefore involves the following steps:

1. Incision of the DNA strand at the damaged position (endonuclease reaction);

2. Excision of the damaged part (exonuclease reaction);

3. Insertion of nucleotides into the resulting gap, with the complementary undamaged DNA strand as a template (polymerase reaction, repair replication);

4. Joining of the phosphodiester bonds in the repaired DNA strand (ligase reaction).

2.2.1. Endonuclease Reaction (Incision)

Extracts from *Micrococcus lysodeikticus* and *Neurospora crassa*[32] cause the formation of single-stranded breaks in DNA containing dimeric pyrimidine derivatives; the number of chain breaks formed roughly corresponding to the number of dimers[33]. The number of endonucleases isolated from *E. coli* alone has now increased to about 4 or 5[34-40,40a,69]; however, not all of them are absolutely specific for a DNA containing dimeric pyrimidine derivatives.

An endonuclease which in fact appears to play a role in repair processes on DNA was isolated by *Kaplan et al.* from *Micrococcus luteus (M. luteus)*[41], and its properties were investigated[41]. The enzyme seems to be specific for UV-irradiated double-stranded DNA in *in vitro* experiments, and has a Michaelis-Menten constant (K_m) of 1.25×10^{-5} mol/l for this substrate. Native DNA, irradiated denatured DNA, and unirradiated denatured DNA are not attacked by this enzyme. On the other hand, native DNA irradiated with γ-rays (^{60}Co) is an appropriate substrate[41a]. With this DNA it was demonstrated for the first time that the enzyme is not absolutely specific for UV-damage only. The molecular weight of the enzyme is 15000. In the UV dose range of 10^4 to 10^5 erg/mm^2, a linear relation exists between the number of dimers formed and the number of single-chain breaks, *i.e.* one chain break is formed per dimer. The curve is very similar for DNA from *E. coli* and from *M. luteus*; the only difference seen is in the reaction rate (Fig. 4), possibly as a result of a lower dimer content in the *M. luteus* DNA.

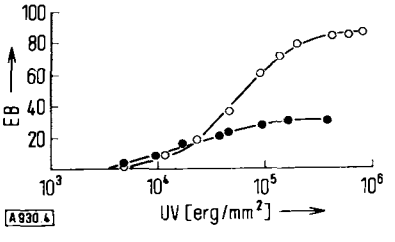

Fig. 4. Formation of single-chain breaks (EB) by the endonuclease from *M. luteus*, expressed as pmoles of phosphodiester bonds cleaved. The substrate was ^{32}P-labeled, UV-irradiated *E. coli* (o — o) and *M. luteus* DNA (• — •) (according to ref. [42]).

This UV endonuclease hydrolyzes a single phosphodiester bond in the 5′ position to form the photoproduct. This gives a free 3′-phosphate group on the DNA and a 5′-OH group either on the photoproduct itself or one nucleotide away from the photoproduct. However, hydrolytic cleavage does not split off any nucleotides from the DNA chain; for this a UV exonuclease is required (see Section 2.2.2). The purification of the UV-specific *M. luteus* endonuclease was recently also described by *Nakayama et al.*[43]. These findings provide substantial support for the required ability of the enzyme to "recognize" modifications in the DNA.

Very similar properties are shown by an endonuclease from T4-infected *E. coli*[39]. This enzyme is also specific for UV-irradiated DNA; native or denatured DNA are not attacked. The enzymes from *E. coli* and from *M. luteus* are activated by Mg^{2+}, but are not strictly dependent on these ions[39,42].

The UV-specific endonuclease is necessary for the *in vivo* repair processes on the DNA, as was recently shown with *M. luteus* mutants[44]. Whereas the wild type exhibited a 100% survival rate after UV irradiation, the survival rate for the mutant $Uvr_7^-end^-$ was about 0.01%; no endonuclease activity was detectable in this mutant (Fig. 5). However, there are also mutants that exhibit 100% survival rates despite low endonuclease activities or (for other *M. luteus* mutants[45]) low UV sensitivity despite a total absence of endonuclease activity.

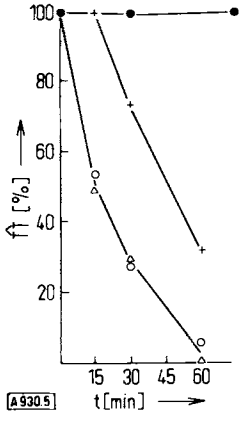

Fig. 5. Removal of thymine dimers from the DNA of the *M. luteus* mutants $Uvr_7^-end^-$ (●···●), $Uvr_{170}^-end^-$ (+—+), $Uvr_{200}^-end^+$ (△—△) and of the wild type (○···○). The strain $Uvr_7^-end^-$ has no endonuclease and does not remove dimers; the wild type and $Uvr_{200}^-end^+$ removed practically all dimers within 60 min (according to ref. [44]). *t* is the time after UV irradiation.

Though the UV endonuclease is specific for UV-irradiated native DNA, it is not known what special region on the irradiated DNA is recognized by the enzyme. If dimers are absolutely necessary for the activity of the enzyme, it is difficult to understand the repair processes observed after the action of *e.g.* methyl methanesulfonate, mitomycin, and HNO_2, unless there are other endonucleases for this purpose. An endonuclease II from *E. coli* that attacks only alkylated DNA, but not irradiated DNA, has in fact been detected[46]. It is more probable, however, that the endonucleases recognize the steric deformations caused by the agents mentioned in the DNA. They would thus have a more general function in the dark repair.

2.2.2. Exonuclease and Polymerase Reaction (Excision Repair)

After the single-chain break has been inserted (incision), the thymine dimer or the modified base is split off by an exonucleolytic reaction. An exonuclease isolated from *M. luteus*[41,42] particularly degrades those DNA sections in which single-chain breaks have been formed by endonucleases. The enzyme hydrolyzes unirradiated and irradiated, heat-denatured DNA from *E. coli in vitro*; native DNA, irradiated native DNA, and RNA are not attacked. K_m for irradiated denatured DNA is 4.5×10^{-6} mol/l[42]. Unlike the UV endonuclease, the activity of the UV exonuclease depends on the presence of Mg^{2+} ions. For each single-chain break, about seven nucleotides are split off by hydrolysis in *E. coli* DNA, and about ten in a DNA from *M. luteus*. Oligonucleotides are liberated first, and these are then degraded by the same enzyme to 5′-mononucleotides (see Fig. 6). Such oligonucleotides (containing the thymine dimers) were also detected by *Setlow* and *Carrier*[30] for the first time in their fundamental experiments.

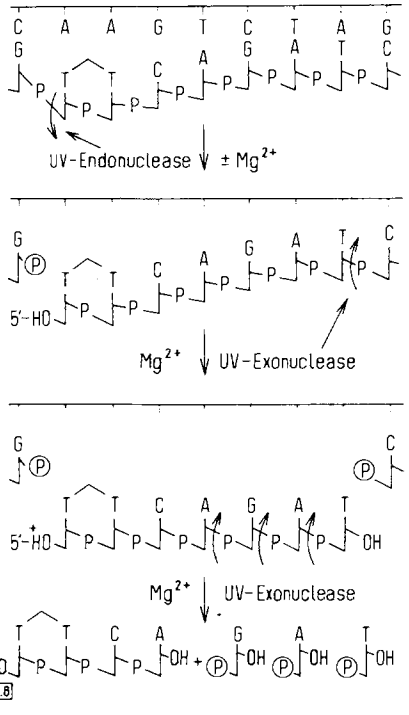

Fig. 6. Mode of action of the UV-specific endonuclease and exonuclease from *M. luteus* (according to ref. [42]).

In the gap left in the DNA by the exonuclease reaction, a free 3′-phosphate group is formed on one side (by the endonuclease reaction), and a 5′-phosphate group on the other side. The degree of degradation of the DNA differs widely among various bacteria and their mutants. In the extremely radiation-resistant *Micrococcus radiodurans* (100% survival rate even after 500 krad of X-rays), up to 20% of the DNA may be degraded (cf.[28]). Despite this considerable degradation, single-stranded DNA has not been detected in any strain of bacteria. The gap formed in the DNA by the combined action of endonuclease and exonuclease is obviously repaired immediately *in vivo* by a *de novo* DNA synthesis.

There are several known exonucleases[47,69] which degrade DNA from various sources, but according to recent investigations of the DNA polymerase, it is doubtful whether the exonuclease reveals its action in the repair process separate from the polymerase.

Thus *Kelly et al.*[48] have shown that the DNA polymerase from *E. coli* contains an exonuclease activity, which is an integral component of the polymerase and not that of an accompanying exonuclease. This DNA polymerase, which was used in the Kornberg laboratory, exhibited a 5′→3′ exonuclease activity on irradiated polydeoxythymidylic acid as a model substrate, the thymine dimers being removed in the form of oligonucleotides.

Oligonucleotides were also found after treatment of an irradiated *E. coli* DNA with DNA polymerase. After formation of a "nick" by a pancreatic DNase[48] the action of DNA polymerase liberated oligonucleotides with a chain length of 3—8 which contained the thymine dimers. An exonucleolytic activity has also been detected in the *M. luteus* DNA polymerase[49]; the exonuclease also attacks the DNA from the 5′ end, and in this case dinucleotides are formed.

In the Kornberg laboratory it was possible to separate the exonucleolytic activity from the *E. coli* DNA polymerase by partial proteolysis of the highly purified polymerase[50,51,51a,51b]. The complete enzyme has a molecular weight of 109000. Two fragments are formed after proteolysis: a large fragment (mol.wt. 76000) which retains the polymerase activity and a 3′→5′ exonucleolytic activity, and a small fragment (mol.wt. 36000) which retains only the 5′→3′ exonuclease activity[51a,51b].

The large fragment carries out DNA synthesis on nicked double-stranded DNA without degradation of the strand ahead of the growing point. It further catalyzes a 3′→5′ exonuclease action on both single- and double-stranded DNA with production of mononucleotides. Hence, this large fragment has the polymerase activity to fill the gap.

The small fragment has the 5′→3′-exonuclease activity to produce the gap in the nicked DNA. The enzyme excises mismatched DNA regions such as thymine dimers, and it can degrade DNA to mono- and oligonucleotides. Nucleoside triphosphates, which support polymerization, fail to stimulate the exonuclease. At a locus of the nick in DNA, the two fragments bind adjacent to one another to perform the coordinated exonuclease-polymerase function that characterizes the intact enzyme.

It is suggested[51c] that the 3′→5′ exonucleolytic activity of the large fragment is to remove mispaired nucleotides which have been incorrectly incorporated into the repaired DNA. Therefore, the 3′→5′ exonuclease may serve a proofreading or error correcting function; this would promote the polymerase to a wonder enzyme.

After excision of the damaged part of the DNA by the exonuclease, the appropriate nucleoside triphosphates are inserted in the resulting gap in the DNA in the 5′→3′ direction by the DNA polymerase in an almost simultaneous reaction[52]. The complementary strand acts as a template. This replication process has been described in detail by *Kornberg*[52], and will not be discussed again here.

The above-mentioned process of almost simultaneous excision and repair (excision repair, cut and patch[53,54] (Fig. 7)) seems to correspond well to the repair processes *in vivo*, and would explain the non-occurrence of single-stranded DNA in this process. The polymerase-free UV exonuclease isolated by *Kaplan et al.*[41,42] also appears to be part of an exonuclease-polymerase enzyme complex *in vivo*. *Harwood et al.*[49] detected dinucleotides as products of an exonucleolytic activity of the *M. luteus* DNA polymerase, and *Miller* and *Wells*[49a] could demonstrate and characterize an exonucleolytic activity in the *M. luteus* polymerase. It is possible that during the earlier[41,42] isolation and purification procedures this complex had dissociated into its components.

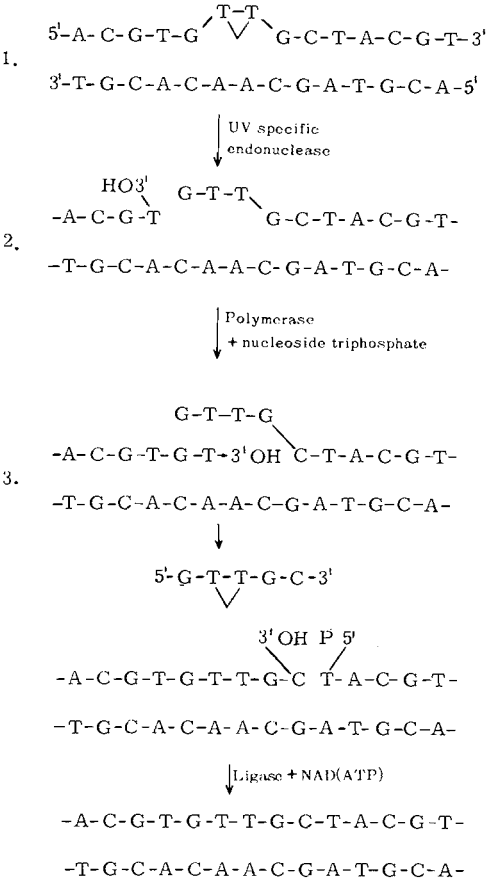

Fig. 7. Scheme of the cut and patch mechanism (cf. also Fig. 3). The gap formed in the DNA is immediately refilled.

A discovery by *DeLucia* and *Cairns*[55] first raised doubts as to whether the Kornberg polymerase is actually necessary for genetic replication and whether this enzyme might have the function of a repair enzyme *in vivo*. *DeLucia* and *Cairns*[55], and somewhat later other groups[56-61], were able to isolate mutants of *E. coli* that contained no DNA polymerase activity (measured by the incorporation of nucleoside triphosphate into DNA). These mutants (pol A1) grow quite well without DNA polymerase and reproduce their DNA in the normal way. They do this with DNA polymerase II[62-64] or DNA polymerase III[62,65] but without polymerase I (Kornberg enzyme). These mutants exhibit a strikingly greater sensitivity to UV light than the parent strains[55,58-60] (see Fig. 8).

This higher UV sensitivity is therefore due, at least in some cases[58-60], to the fact that these mutants lack parts of the enzyme system (particularly polymerase I) by which dimers are eliminated from the DNA. It seems that the DNA polymerase I is not essential for the normal replication of DNA, and actually plays the role of the repair enzyme.

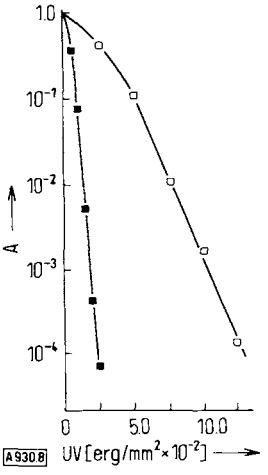

Fig. 8. Fraction A of surviving rates of *E. coli* wild type W 3110 (□—□) and mutant P 3478 (■—■), which has no polymerase I (=Kornberg enzyme) (according to ref. [59]).

2.2.3. Ligase Reaction (Joining)

The final step of the repair process is a formation of the phosphodiester bond between the newly inserted DNA segment and the old DNA strand (see Fig. 7). An enzyme which links preformed polynucleotides to one another by phosphodiester linkages was discovered in bacteria in 1967 almost simultaneously by several groups: linkage of a covalent bond and hence formation of circular DNA in *E. coli* infected with λ phages[66], healing of single-chain breaks in T4-infected *E. coli*[67], and finally enrichment of a "polynucleotide-joining enzyme" from *E. coli*[68]. This enzyme, which is usually referred to as DNA ligase, has now been detected in several organisms and purified[69], and its mode of action has been elucidated. Whereas all the ligases investigated so far are specific for the same DNA substrates and form the same DNA end products, there is an interesting difference between the enzyme from *E. coli* and the other ligases in their cofactor requirement. While the *E. coli* enzyme requires nicotinamide adenine dinucleotide (NAD)[70,71], the phage-induced ligases and the mammalian ligases require adenosine triphosphate (ATP) as a cofactor[72-74].

The mode of action of the DNA ligase is shown in Figure 9. In the first step of the reaction, the enzyme reacts with ATP or NAD, with formation of the enzyme-adenosine monophosphate complex (E-AMP) and inorganic pyrophosphate (PP_i) or nicotinamide mononucleotide (NMN). In the second step, E-AMP reacts with a DNA chain to form a pyrophosphate linkage, the 5'-phosphate group of the DNA reacting with the phosphate group of the AMP. In the final step, the bond is formed by the enzyme, and AMP is liberated.

The ligase-AMP complex (E-AMP in Fig. 9) has been identified by normal separation methods in *E. coli* and in T4-infected *E. coli*[73,75-77]. The bond between the enzyme and the AMP is covalent; *Gumport* and *Lehman*[78]

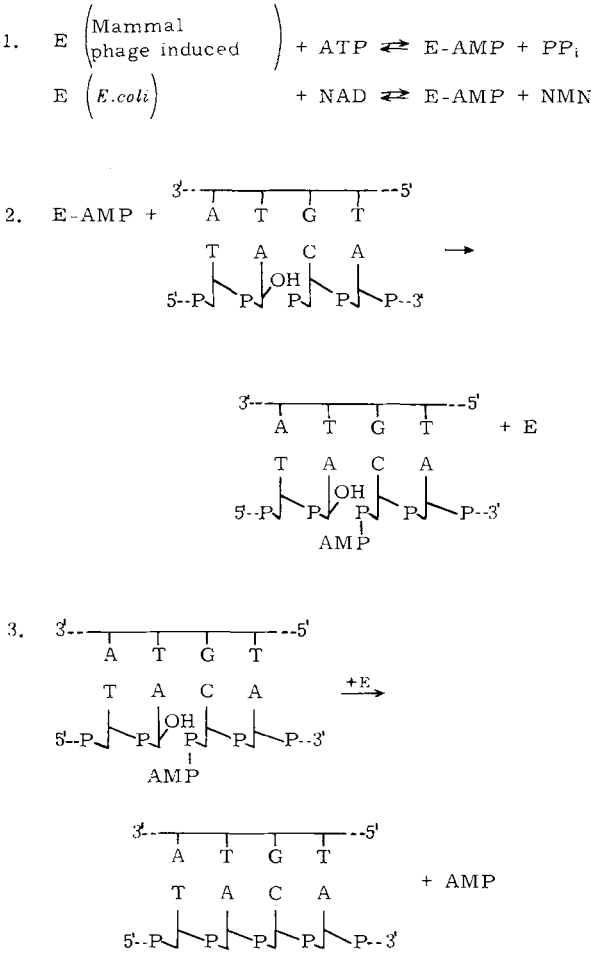

Fig. 9. Mode of action of DNA ligase (according to ref. [69]).

were recently able to show that the AMP is linked *via* its phosphate group to an ε-amino group of lysine on the ligase molecule *(E. coli)*.

In a strain of *E. coli* that requires NAD for its growth, but was grown for 2.5 h without NAD, the ligase activity is normal[78a], but the DNA synthesis is disturbed. Addition of NAD to the culture medium immediately normalizes the DNA synthesis.

The DNA-AMP intermediate has also been detected, though with some difficulty[79].

A double-helix structure of the DNA with a single-chain break is necessary for the ligase to reveal its enzymatic activity, and a 3'-OH and a 5'-phosphate group must be in adjacent positions[68,71,73]. There is apparently no specificity for a particular nucleotide[80]. The enzyme can repair all kinds of single-chain breaks, independently of how they were formed[69], provided that the above conditions are satisfied. These conditions are apparently also satisfied if two complementary DNA strands are linked to form a circular DNA[66,81,81a], as shown in Figure 10. Finally it should be mentioned that the ligase played

an outstanding role in the excellent syntheses of the alanine transfer RNA (t-RNA^{ala}) in *Khorana*'s laboratory (cf.[82]).

A series of mutants with more or less highly modified ligase activity have recently been isolated. *Pauling* and *Hamm*[83,84] isolated a heat-sensitive and radiation-sensitive *E. coli* mutant that can remove dimers from its DNA

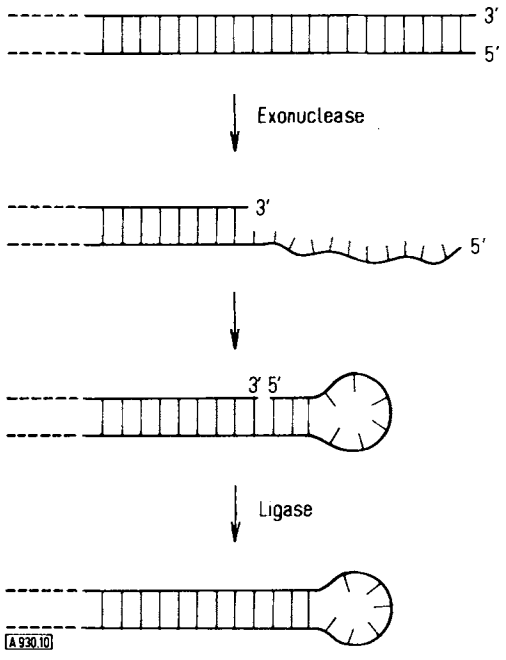

Fig. 10. Formation of circular DNA by exonuclease and ligase in *E. coli* infected with T4 phages.

and refill the gap; however, this does not give normal DNA, but relatively small DNA fragments[84]. This mutant lacks the DNA ligase. Three other *E. coli* mutants[85] contain ligase activities of 40—150% at 30 °C, but only 4—14% at 42 °C. In two of these mutants, the quantity of the enzyme-AMP complex (see Fig. 9) was decreased, and the third mutant (150% activity at 30 °C, 4% at 42 °C) was UV-sensitive at 42 °C. As was found by *Modrich* and *Lehmann*[86], a thermolabile ligase is formed in heat-sensitive mutants. Thus, not only the quantity, but also the quality of the enzyme can vary.

2.2.4. *In Vitro* Repair of a DNA

One of the (rare) prized moments in the life of a biochemist is the complete *in vitro* simulation of an *in vivo* process. A group of Dutch workers[87] recently succeeded in carrying out the entire repair process *in vitro* with the aid of the purified enzymes: ^{3}H-labeled DNA from *Bacillus subtilis* was exposed to UV radiation *in vitro*, with the result that dimers were formed in the DNA. This damaged DNA was incubated with UV-specific endonuclease from *M. luteus* (see Section 2.2.1), whereupon the DNA was incised on the 5' side of the dimers. The DNA was then incubated with DNA polymerase from *E. coli*, the triphosphates of the four DNA bases, and DNA ligase from *E. coli*. The DNA was subsequently either assayed for biological activity (transforming ability), or it was hydrolyzed and the quantity of dimers removed in the repair process was determined by chromatography.

With this *in vitro* repair, it was possible to restore 50% of the biological activity of the irradiated DNA; about 25% of the dimers were removed from the DNA under these conditions. The entire process could be performed despite the fact that the components of the *in vitro* repair system originated from different sources (*B. subtilis*, *M. luteus*, *E. coli*). When pancreatic DNase was used instead of the UV-specific endonuclease for the endonuclease reaction, no biological reactivation of the DNA occurred, *i.e.* no dimers were removed from the DNA; this is an indication of the specificity of the endonuclease.

2.3. DNA Repair in Mammalian Cells

Mammalian cells were also investigated for their DNA repair capacity. Though only few investigations have been published, the observations so far leave no doubt that this process also occurs in cells of higher organisms.

DNA breaks induced by X-rays in leukemia cells[88,88a], UV-induced DNA changes in "Chinese hamster cells"[89,90,92], and DNA damage induced by UV and X-rays in HeLa cell cultures[93], mouse fibroblasts[94], lymphoma cells[95], and human cell cultures[96,97,97a,97b] are repaired. Alkylated DNA from HeLa cells can also be repaired[91]. The processes involved in these repairs in mammalian cells appear to be fundamentally the same as in microorganisms. Dimers were removed from UV-irradiated DNA with the aid of DNA exonuclease III and IV from rabbit cell nuclei[98]. ATP-dependent ligase from lymphoma cells[74] repairs the DNA in the same manner as does the *E. coli* enzyme.

2.4. DNA Repair in Man (Xeroderma Pigmentosum)

The repair of DNA in man is clearly of special interest. The fact that this process actually occurs in man was indirectly demonstrated in a rare disease, xeroderma pigmentosum. This disease is hereditary; xeroderma pigmentosum patients are extremely sensitive to sunlight or UV light. After brief exposure to sunlight they exhibit symptoms similar to those observed in normal skin after strong irradiation with X-rays, very often associated with skin tumors. The disease is not caused by the accumulation of light-sensitive products such as hematoporphyrins in the skin. It is now known to result from a genetic defect in the DNA repair apparatus.

The nature of the biochemical damage in xeroderma pigmentosum has been elucidated in particular by the investigations by *Cleaver*[99-101]. In the crucial experiment[100], the DNA repair in skin fibroblasts of xeroderma pigmentosum patients was investigated after two types of DNA damage:

1. The fibroblasts were irradiated with UV light; this leads to the formation of dimers, especially thymine dimers, but no chain breaks.

2. The fibroblasts were first irradiated with X-rays, which cause chain breaks but no dimers, and then with UV light, which in addition gives dimers.

In the first case all three repair steps, *i.e.* incision of the DNA (Section 2.2.1), exonuclease and polymerase reaction (Section 2.2.2), and ligase reaction (Section 2.2.3), are necessary for the repair of the resulting damage. The first step is unnecessary in the second case, since the incision (= chain breakage) has already been effected by the X-rays.

It was found that the only fibroblasts that can perform a DNA repair are those in which chain breaks have been produced as well as thymine dimers (case 2). Fibroblasts in which only dimers have been produced (case 1) cannot repair their DNA.

It was thus shown (a) indirectly that DNA repair occurs in man and (b) directly that xeroderma pigmentosum patients lack the UV-specific endonuclease.

The same results were obtained somewhat later by *Setlow et al.*[102]. These authors were able to show that normal fibroblasts remove 70% of the dimers from the DNA in 24 hours, with simultaneous appearance of single-chain breaks, which then disappear again. In fibroblasts from xeroderma pigmentosum patients, less than 10% of the dimers are removed from the DNA; the appearance and disappearance of single-chain breaks was not observed in this case. Meanwhile, the technique for the measurement of DNA repair in human cells has been developed to a considerable degree of perfection[103].

It has been mentioned that skin cancer occurs very readily in xeroderma pigmentosum patients. It is possible that the accumulation of dimers and other products in the DNA of the skin cells leads directly or indirectly to the transformation of these cells into cancer cells or predisposes them for this transformation[102]. In any case, it was possible to show here for the first time that dimers *per se* have something to do with carcinogenesis.

3. Genetic Recombination

The investigation of repair processes on DNA is not merely a hobby for radiologists; they also appear to make possible another process that occurs widely in nature, *i.e.* genetic recombination. In this process, two chromosomes break and rejoin crosswise (see Fig. 11). For this process to occur, chain breaks must be produced, parts of the DNA must be removed and new parts synthesized, and phosphodiester linkages must be formed. The processes involved are thus fundamentally the same as in the repair process, of course without the removal of dimers.

It is uncertain how the breaks occur in the DNA (chromosome) during the recombination. Breaks of this type evidently cannot be repaired immediately by the ligase. Endonucleases may play a role here[104]. On the other hand, it has been found that an exonuclease (phage λ) participates in the recombination process[69, 105]. Likewise, all experimental data so far[69] also suggest that the gaps that occur in the recombination process (see Fig. 11) are filled by a synthesis of new DNA (on the complementary strand). The phosphodiester bond is evidently formed, as the final step of the recombination process, by the same DNA ligase as in the repair of UV-damaged DNA[69]. Though there are only a few experimental results supporting the idea that DNA repair and genetic recombination are catalyzed by the same enzyme system, no data have

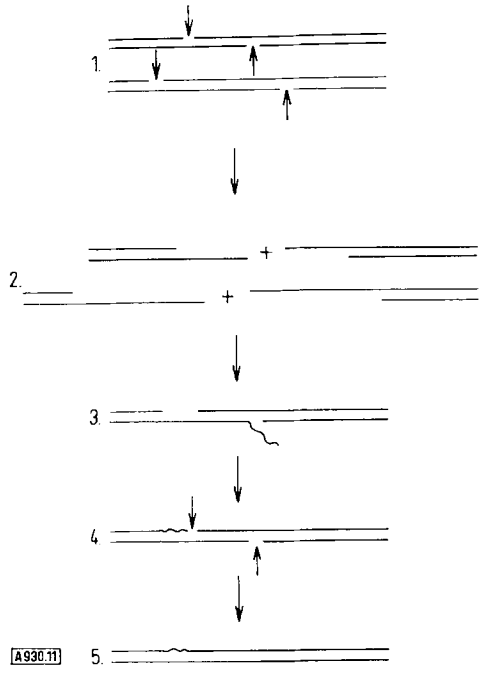

Fig. 11. Scheme of genetic recombination. A chain break is formed in the first step (cause unknown). In the second step, the double helix unwinds, and complementary nucleotide sequences are exposed. In the third step, homologous regions of the two DNAs join to form recombined double strands, which still have gaps and overlapping segments. The gaps are refilled (repair replication) and the overlapping segments are split off by hydrolysis (exonuclease) in the fourth step. The remaining single-chain breaks are repaired in step 5 by formation of a phosphodiester linkage (ligase). The recombined molecule is a DNA double helix consisting of parts of the two parent DNAs.

so far accrued which principally contradict this concept. This view is further supported by the fact that recombination-negative mutants (rec$^-$) are much more sensitive to UV light[7] than the parent strains.

4. Closing Remarks

Though most of the observations described here came from *in vitro* experiments, there is no doubt that the *in vivo* DNA repair is performed by the same mechanism. It appears however—at least in *E. coli*—that there are two DNA repair systems, only one of which requires the polymerase I (Kornberg enzyme)[106]. The *E. coli* mutants (pol A1) isolated by *DeLucia* and *Cairns*, which have no polymerase I, are more sensitive to UV light than the parent strain, but still show considerable survival rates after the irradiation process. These mutants have a second repair system, which is genetically defined as the "recA pathway" and is also necessary for genetic recombination[7]. With this system, pol A1 mutants can eliminate UV-induced dimers from their DNA. The nature of this gene product is unknown; it must be an enzyme that differs from polymerase I. The investigations by *Cooper*

and *Hanawalt*[107] support the concept that polymerase I (Kornberg enzyme) is involved in the short patch repair process of damaged DNA, while the rec-system produces predominantly large patches. Either of these systems is capable of completing the excision-repair process in the absence of the other. This could explain the survival rates of some pol Al strains on UV irradiation.

Of course, geneticists tried to produce a double mutant, pol Al rec A^{-}[108], but without success; such a mutant is apparently not viable. Thus either polymerase I or the rec A gene product is absolutely essential to growth. This means[108] that gaps occur in DNA strands during normal growth and normal division of *E. coli*, and are immediately filled.

Besides the numerous problems concerning genetic regulation of the repair process, it is not clear how the DNA-repairing system "recognizes" that there is damage to be repaired on the large DNA molecule. Probably the enzyme recognizes a structural deformation on the DNA molecule. Does a mechanism exist which transports the repair enzyme back and forth on the DNA molecule? Considering the high degree of coiling of the DNA within the cell, however, this idea would overtax the imagination even of molecular biologists.

The repair system operates with an extremely high degree of fidelity but there is evidently some tolerance for errors as no mutations would otherwise occur and this would lead to an evolutionary dead end. The repair process on the DNA is apparently also subject to selection during evolution.

Toxicological Problems Relating to Changes in the Environment[**]

By D. Henschler[*]

Assessment of the toxicological risk from foreign substances in the environment is based on the determination of action thresholds below which effects injurious to health no longer occur, even with life-long intake. According to the latest theories it is likely that such thresholds exist even for "irreversible" (carcinogenic, mutagenic) effects. However, the difficulties besetting the determination of threshold values by experimental or epidemiological methods still appear to be virtually insuperable. The problems are both quantitative (excessive numbers of animals and observations required) and qualitative (poor predictability of effects owing to substantial differences in biological reactivity between species). Neither animal experiments nor experience with human subjects can guarantee total security from toxic effects. Legislative measures designed to restrict the introduction of chemical substances into the environment must therefore be based on compromise. Scientists must be consulted, but ultimately the decisions must be political, and politicians have to assume the responsibility for them.

1. Introduction

Civilization and progress unavoidably interact with the turnover of substances in nature. According to recent estimates[1], chemical synthesis adds some 250000 new chemical compounds each year to the two million already in existence. Roughly 300 of these new compounds are released every year into the environment, some controlled, some not. Many of them are biologically active, sometimes not intentionally, but often as the deliberate and desired result of the chemical synthesis, *e. g.* in the case of pesticides, disinfectants, food additives, cosmetics, and, by no means least, drugs.

In addition to these planned, or at any rate conscious, chemical changes in the environment, there are many unwanted ones: waste products from power stations and domestic fuel, from traffic and chemical plants are discharged primarily into the atmosphere, water, and soil. Many of these waste products have characteristics that are potentially harmful to man. Contamination is widespread in some cases, even global in others, and control measures are either ineffective or only partially successful.

However, in the course of its development mankind has always been exposed to toxic substances in the environment, and in many instances the progress of civilization has in fact led to a reduced uptake of such ancient poisons. Consider, for example, the amounts of carbon monoxide inhaled by cavemen in prehistoric times—considerably greater than those to which today's traffic policeman is exposed in the city center; think back to those clouds of street dust, the smoke from badly drawing stoves, the putrefaction products invariably present in foodstuffs, or the uncontrollable contamination of drinking water in even small settlements by organic and mineral pollutants.

[*] Prof. Dr. D. Henschler
Institut für Pharmakologie und Toxikologie der Universität
87 Würzburg, Koellikerstrasse 2 (Germany)

[**] Based on a lecture presented on the occasion of the Chemistry Day during the 107th Congress of the Gesellschaft Deutscher Naturforscher und Ärzte on October 10, 1972 in München (Germany).

In other words, progress has not brought about any fundamentally new situation as regards the effect of environmental poisons on man. If one recalls that the most powerful toxic substances are of natural rather than synthetic origin, then one finds that from the toxicological standpoint the present environmental situation is characterized essentially by a shift in the circumstances. Any toxicological assessment of environmental changes must proceed from the starting point. Moreover, a substantial proportion of precisely the most widespread, supposedly purely man-made, environmental poisons have recently been shown to be natural constituents of the environment, in particular of the atmosphere: for example, nitrogen oxides (NO and NO_2), ozone, sulfur dioxide, carbon monoxide; indeed, traces of the latter are produced in the course of human metabolism. As regards carcinogenic substances, the most active are produced in nature and not in the laboratory. It is still difficult to say whether the march of civilization has on balance increased or decreased the hazards to human life and health from the environmental poisons.

What is certain is that the continuing large-scale introduction of new synthetic materials has multiplied the *number* of potential dangers, and is still doing so all the time. Therefore, in attempting to redress the balance and control the adverse effects of progress, we must begin by analyzing the nature and the extent of the risks to health from individual substances as well as their combined effect.

It is the function of toxicology to detect and quantify damage to health produced by chemical substances, thus paving the way for systematic preventive measures. This branch of science therefore assumes a key position in the study and protection of the environment. Animal experiments constitute its most important tool. The detection and quantitative determination of poisons are also pursued by the techniques of analytical chemistry. Experience with patients and with healthy human subjects is indispensable to confirm, or indeed cast doubt on, the results of animal experiments. Some time ago toxicology was concerned almost exclusively with the investigation of acute poisoning and the development of effective methods of treatment.

In purely quantitative terms this type of work is today outweighed by analyses of chronic poisoning effects, although its practical importance is now if anything greater than ever before.

2. Improvements in the Detection and Treatment of Acute Poisoning

A rise in the incidence of accidental intoxication has been observed for some decades as a result of the industrial and domestic use of countless cleaning and maintenance agents and adhesives, the large-scale application of pesticides, and—by no means least—the liberal recourse to therapeutic drugs. Spurred on by the good examples set abroad, the Federal German authorities have also come to recognize that a determined effort to improve diagnosis and therapy can bring about a decisive fall in the number of fatalities. Since 1965 the Federal Health Bureau's commission on the "Detection, treatment, and prevention of poisoning" has been systematically seeking out potentially toxic household products and classifying them according to the active principles. At the same time intensive-care units have been established, which can provide immediate advice to physicians handling emergencies, and if necessary take over the treatment. A confidential file compiled by the above-mentioned commission contains a list of household products and active substances, together with information on symptoms, toxic doses, recommended treatment, and chemical detection methods[2].

In the modern approach to the treatment of poisoning, *nonspecific measures* such as anti-shock therapy, oxygen, hemodialysis, and forced diuresis are more important than the administration of specific antidotes. Nevertheless, the latter are still essential in some types of poisoning that take a particularly rapid and serious course, where they

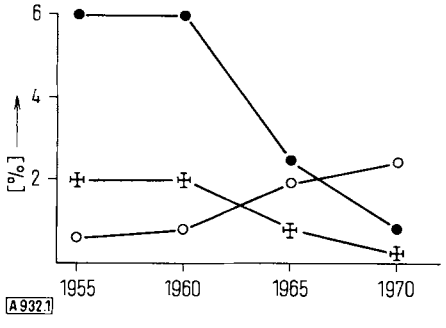

Fig. 1. Frequency of poisoning in children and the results of treatment (○—○): percentage of approx. 4000 hospitalizations per annum; (●—●): permanent injury; (✠—✠): fatal outcome (Universitäts-Kinderklinik Freiburg/Br., 1955—1970). After [3].

represent the sole life-saving remedy, for instance in poisoning due to cyanide, alkyl phosphates, or many heavy metals. Intensive care is costly in terms of both staff and equipment, and it is no doubt for this reason that many treatment centers in the German Federal Republic have not yet attained the desirable and internationally accepted standard of equipment. This situation is due to a failure on the part of authorities responsible for health policy, and must be quickly put right. Nevertheless, the decision to steer a course including both counsel and action has proved right. The fatalities due to acute poisoning (Fig. 1) have fallen to a low level, a gratifying reduction being noted particularly in delayed complications and permanent damage. It is thus possible to make satisfactory headway in this area, provided that adequate funds can be made available.

3. Long-Term Effects of Small Amounts of Environmental Poisons

It is much more important, and at the same time also far more difficult, to evaluate the long-term effects of very small doses or concentrations of potentially toxic environmental substances on large populated areas. This has in fact become the principal task of modern toxicology. A selected listing from among the large number of man-made environmental pollutants with largely known toxic action potential is presented in Tables 1 and 2. The latter give substances which are distributed widely or even globally, and which are or may be responsible for particular forms of injury to health.

It would be outside the scope of the present paper to attempt an exhaustive survey of the current status of toxicological knowledge concerning each substance, and the reader is referred to the literature for such details[4]. Mention must, however, be made of the distinction between the suspected and certain toxic effects of the individual substances under the currently prevailing environmental conditions, a distinction that emerges from a critical analysis of the present state of knowledge. Only in the case of a few of the substances listed can injury to the health of at least some of those exposed be regarded as certain. In this context no account is taken of isolated and limited cases of poisoning due to accidental contamination of the environment. Even where the effects are certain, they may show extreme variations in magnitude, not only as regards the frequency of occurrence, but also their nature: For example, a measurable, but quantitatively insignificant formation of methemoglobin due to nitric oxides, or of carbon monoxide hemoglobin due to carbon monoxide, represent no real pathological threat under normal environmental conditions, whereas the slightest rise in the incidence of cancer is of the gravest importance. However, it will be seen from the tables that, with the one exception of asbestos, suspected carcinogenic effects have not been confirmed (occupational cancer due to chemicals is not taken into account here).

There is no sound scientific basis for the statement recently made by a cancer researcher[5]—and incidentally widely misquoted and misinterpreted in the lay press—to the effect that 90% of all cancers in man are attributable to chemical carcinogens and 50% to environmental factors. It is also worth pointing out that closer scrutiny of findings relating to the effects of pollution on man frequently produces surprising results: For instance, the concentration of mercury in the Atlantic off the coast of North America has not changed for centuries[6]; a survey carried

Table 1. Effects of man-made inorganic environmental poisons.

Substance	Occurrence [c]	Toxic effects suspected	Toxic effects confirmed	Trend in environmental loading
Arsenic [a]	F, D, O	carcinogenic		↓
Asbestos	A, F, D, O		carcinogenic	↑
Lead [a]	A, F, O	blood damage, neurotoxic, mutagenic		↑
Cadmium [b]	F, O	nephrotoxic, hypertensive, carcinogenic		↑
Fluoride [b]	A, D, O	bone hardening	dental damage	→
Carbon monoxide [a]	A, O	neurotoxic	blocking of blood pigment	↑
Nitrate/nitrite [a]	F, D	formation of carcinogenic *N*-nitroso compounds		↑
Nitrous fumes (NO,NO_2)	A, O	lung damage, carcinogenic	formation of Met-Hb	↑
Ozone, oxidizing agents [a]	A, O	lung damage		↑
Mercury [a]	F, O	neurotoxic		→
Sulfur dioxide [a]	A, O	lung damage		↓
Vanadium [b]	A, O	carcinogenic		↑

[a] Occurring naturally.
[b] Essential.

Table 2. Effects of man-made organic environmental poisons.

Substance	Occurrence [a]	Toxic effects suspected	Toxic effects confirmed	Trend in environmental loading
Aldehydes (automotive exhaust gases)	A	lung damage, mutagenic	eye irritation	↑
Antibiotics	F		interference with bacterial ecology	↑
Benzene	A, O	leukemogenic, mutagenic		↑
Carcinogens				
polycyclic hydrocarbons	A, F	carcinogenic, mutagenic		↑
aromatic amines	F, O			
epoxides	A, F, O			
N-nitroso compounds	F			
Hormones	F	metabolic modifications		↑
Insecticides				
chlorinated cyclic hydrocarbons (DDT)	F	carcinogenic, hepatotoxic		↓
organophosphates	F	neurotoxic		↑
Polychlorinated biphenyls	F	hepatotoxic		↑
Herbicides				
2,4,5-T (dioxine)	F	teratogenic, mutagenic		?

[a] A = Air, F = Food, O = Occupational.

out in the USA even shows that the mercury content of human organs has been falling in recent years[7].

The value of such schematic surveys may be questioned, and in some points different interpretations could be advanced. However, no attempt is being made to present a comprehensive study. They merely serve to underline the fact that at the present time suspected toxic effects vastly outnumber those confirmed. On the other hand, it is of course quite impossible to *rule out* the possibility of toxic risk in the case of the suspected effects. Moreover, even where injury to health has been demonstrated with certainty, it has been difficult to *quantify* its extent satisfactorily. Such uncertainties characterize not only environmental toxicology, but also many other areas of environmental research. It is hoped that the following attempt at an analysis of the causes will facilitate an understanding of the situation, as well as providing a basis for the development of effective measures to improve it.

4. Epidemiological Investigations

One method of establishing the risk is by epidemiological statistical analysis. This technique has brought to light a number of important, often unexpected relationships pertaining to the intensity of the exposure of man to envi-

ronmental substances, especially those which accumulate in the body, *e.g.* DDT, vanadium, mercury, lead, and so on. With one exception—namely lung cancer in smokers—these investigations have hitherto yielded little valid information concerning the nature and the extent of the actual danger to health. This has not prevented many people from making false claims as to causal relationships allegedly demonstrated in the course of epidemiological environmental research. The mistake made by authors, and even more so by those who interpret their work, resides in an assumption that their factor analysis is flawless. In reality for the investigation of large population groups factor limitations are arrived at in a more or less arbitrary manner; in fact, their admissibility can be neither demonstrated nor refuted. However, even where a relationship appears plausible, or indeed compelling, as in the case of smoker's cancer, it has still been impossible to prove causality in a scientific sense. As we know only too well, we are still far from identifying the constituent or constituents of tobacco smoke that are carcinogenic in man.

Basically, a causal relationship between the long-term action and a toxic effect can in the case of most environmental poisons be demonstrated only in model experiments under fully controlled conditions. This requirement can as a rule be satisfied only by animal experiments. The latter are in any case essential, since they provide the sole means of determining quantitative dose/effect relationships which can be used as a basis for calculating the risk. Long-term animal experiments are associated with numerous problems, particularly when it comes to toxicological investigation of the environment, and it is essential to know their possibilities and limitations if the results are to be valid. In considering them no attempt will be made at a systematic presentation of experimental details, which are fully described in the literature[8].

5. Determination of Risk by Means of Chronic Animal Experiments. The Problem of "Threshold Values"

Chronic animal experiments are organized and evaluated on the basis of two assumptions:

1) The occurrence and the magnitude of toxic effects are dose-dependent and can therefore be calculated

2) There is a threshold dose below which no toxic effect occurs. The essential aim, then, is to demonstrate the *absence* of an effect, an approach that has aptly been described as "non-toxicology". In its way, this is unique in the life sciences, for whereas researchers in other fields seek out and analyze real states and changes in these states, we are trying to determine the absence of changes, as it were the demonstration of something negative. The toxicological threshold value is used to lay down tolerance levels designed to prevent injury to human health. The determination of a threshold value for toxic effects involves problems which shake the very foundations of toxicology:

The toxic effect is dependent on the concentration (c) at the biological receptor and on the duration of exposure (t). If the product is a constant magnitude (W), we obtain a hyperbolic dependence:

$$c \times t = W$$

If the product, now taken as a variable dose, is plotted on the familiar dose/effect graph, then—because of the asymptotic approach of W to t in the above equation—the curve obtained passes through the origin. This means that neither mathematically nor fundamentally is it possible to derive a dose level at which no effect occurs. This would mean that no threshold value exists.

This concept received support through experimental investigations with ionizing radiation, which were used in the derivation of the "hit theory"[9], and through experiments with chemical carcinogenesis, in which the action product remained the same over a large concentration or dose range[10]. Further support was sought in the postulate that all that was needed was that just a single reactive molecule had to hit a "target" molecule in a biological system, as a rule in the cell, and trigger a biological effect. Hence it would be possible for no lower dose or concentration limit to exist for biological effects.

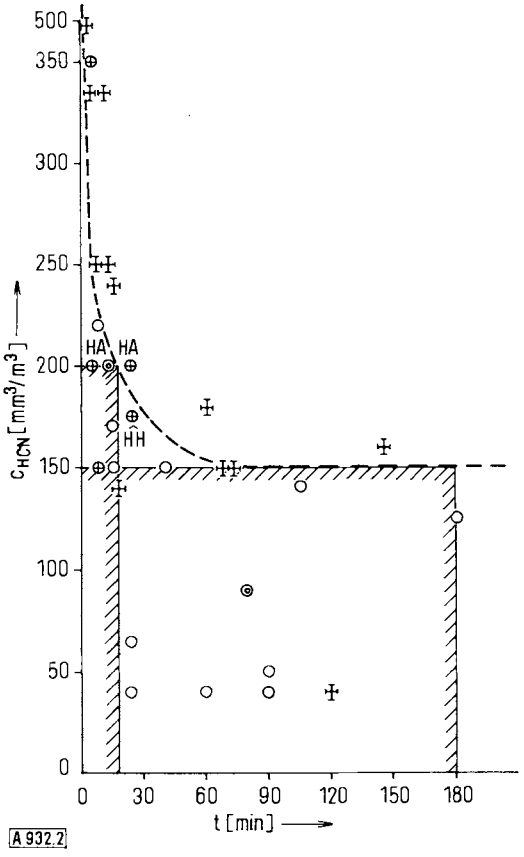

Fig. 2. Fatal effect of inhaled hydrogen cyanide as a function of the active concentration and inhalation time. Demonstration of a threshold concentration.
H = dog, A = monkey, ✣ = fatal poisoning, ○: animal survives, ◎: two animals survive, ⊕: one animal dies, one survives. After [12, 13].

On the other hand, empirical considerations and sound common sense tell us that thresholds and concentration regions with no toxic effects must exist. *Paracelsus* was

probably the first to give a clear enunciation of the action threshold in the third of his seven Carinthian defenses[11]:

"what is it that is not poison? all things are poisons/ and none that are not/ Only the dose decides that a thing is not poisonous".

The first experimental proof of the existence of a threshold of action was adduced by *Flury* and *Heubner*[12], who used hydrogen cyanide, showing that below a certain concentration the gas could be inhaled almost indefinitely without fatal results (Fig. 2). They were thus able to refute *Haber*'s rule of the constancy of the action product

$$c \times t = W = \text{const.}, \quad (1)$$

formulated on the basis of the results of experiments with phosgene. *Flury*[13] explained the later results in terms of an elimination (e) of the foreign substance or its effect, which counteracts the absorption by the body and must be subtracted from the concentration:

$$(c-e) \times t = W = \text{const.} \quad (2)$$

This elimination was later shown to be enzymatic detoxication of cyanide to thiocyanate[14].

A plausible theoretical basis for the existence of an inactive concentration, which would justify the assumption of threshold values, was recently formulated with an interesting deduction, relating also to "irreversible" (carcinogenic and mutagenic) effects[15], for which it had been emphatically rejected[16]. It is possible to estimate the proportions of

Table 3. Concentrations and estimated probability (P) of reactive atoms in liver cells. After [17].
Elements printed in bold type are essential, others are not.

Element	Atoms/cell	P
H, O	$>10^{14}$	1.0
C, N	10^{12}—10^{14}	1.0
S, P, Na, K, Mg, Cl, Ca, Fe, Si	10^{10}—10^{12}	≈0.9
Zn, Li, Rb, **Cu, Mn**, Al, Br, **F**	10^{8} —10^{10}	≈0.4
Sn, Ti, Mo, **Co, I**, Pb, Ag, B, Sr, Ni, Sc, Cd, Cr, **Se**	10^{6} —10^{8}	≈0.3
V, Hg, Be	10^{4} —10^{6}	≈0.1
40 others	10^{2} —10^{4}	≈0.1
Ra	10^{0} —10^{2}	

atoms and molecules in body cells by weight or number (Table 3)[17]. The lower limit of biological activity for trace elements is 10^4 atoms/cell. It is a dogma of biochemistry that these elements act through highly specific bonding or reaction sites. In contrast, on the basis of what we know about toxicological action mechanisms, foreign substances always have in addition nonspecific reaction sites whose number increases with the reactivity of the substance. This has been demonstrated in the case of heavy metals acting on SH enzymes[18], and for reactive carcinogens[19]. It is deduced from this that for foreign substances, as for trace elements, a certain minimum number of molecules must be present in order to give rise to a biological effect. In fact, it may be assumed that this number will be higher in the case of foreign substances than in that of trace elements. A man weighing 70 kg is made up of 6×10^{13} cells, and hence needs 8.6×10^{15} molecules/kg of cell mass as a minimum concentration of foreign substances to produce a biological effect, or, expressed in equivalents, 1×10^{-8} mol/l. Action thresholds derived on this basis for certain highly active carcinogens all range between 10^{13} and 6×10^{17} molecules/kg[20].

It must be admitted that no abstract proof can be adduced in support of a comparison of the biological effect of trace elements with the toxic effect of molecules of a foreign substance, but such comparison is acceptable on the basis of the theoretical principles of biochemistry and toxicology. This does not, of course, eliminate the fundamental difficulty of establishing action thresholds in each individual case. The deduction does, however, provide a sound basis for the acceptance of threshold values and tolerance limits in the practical assessment of risks.

The philosophy of threshold levels below which foreign substances pass through the body harmlessly, in the case also of "irreversible" effects, is further strengthened by the fact that all biochemical structures undergo permanent renewal, so that there is a possibility of changes being repaired, even when they occur in the genetic material of the cell. Moreover, all biological processes, including the restoration processes, are homeostatically controlled, so that changes can be compensated provided they do not exceed a certain magnitude. As soon as a process opposed to the biological change comes into play, the existence of an effect-free zone of concentration or dose can in fact be mathematically derived, in the sense of eq. (2).

Furthermore, there is a fundamental difference between the "value" of biological and toxic effects which is not allowed for by the "single-molecule theory": A biological process induced by foreign substances only becomes toxic when the change produced in the structure and/or function has an adverse effect on the stability and renewal of the body as a whole.

6. Predictive Value of Chronic Animal Experiments

Long-term animal experiments must satisfy three criteria: 1) the number of animals must be sufficiently large to ensure that rare effects do not escape detection; 2) toxic effects must be clearly discernible, so as to be susceptible to measurement; 3) the mode of action of the tested substance on the experimental animal and on man must be largely or completely identical if valid inferences are to be drawn from one to the other. In this connection problems arise which restrict the validity of the results of animal experiments. Although the three requirements mentioned above are satisfied in the vast majority of the substances and their effects, there are important exceptions. Difficulties arise especially where the evaluation criterion is not the strength of the effect on the individual but the incidence of an event in a group, *e.g.* the occurrence of cancer or of mutations. With an upper limit to the frequency of occurrence of only 2‰, about 1000 animals would be required for a confidence level of 90%, and about

30000 animals for 99.9%. The practical inference of this is obvious: taking the population of West Germany, two in every thousand of those aged 45 or more would mean some 40000 additional cases of cancer, or nearly 2000 per annum. The scope of the experiments, and hence the information they provide, is governed by practical limitations.

Special problems are encountered in the simulation of the manner in which the foreign substance is absorbed by man. For example, in animals it is quite impossible to reproduce the inhalation of cigarette smoke satisfactorily. Inhalation experiments with aerosols and gases are always problematic, owing to the much more effective nasal filter that animals have, the different type of breathing, and the different breathing intensity, the latter resulting from the animals' peculiar heat regulation system which is due to their fur. Hence research into the effects of atmospheric pollution suffers in many respects from the lack of suitable models.

7. Differences in the Sensitivity of Man and of Experimental Animals

The differences in the *manner* in which man and animals react to foreign substances are far more important. There are two main reasons for this: 1) the target organs vary in their susceptibility to the action of foreign substances; or 2) the foreign substance reaches the target site in a different concentration or in another form, or perhaps even not at all, because its chemical changes in the body are different. Apart from a few insignificant examples, we know practically nothing about the mechanisms of the first type. The first explanation is often advanced if the search for evidence of the alternative proves inconclusive. However, tremendous strides have been made in this area in recent times, and the study of the change of foreign substances in the metabolism and of their pharmacokinetic behavior has developed into one of the most promising fields of research in experimental toxicology. With the aid of sophisticated separation and determination techniques employing chromatography, mass spectrometry, and radiochemistry it is in some cases possible to follow the fate of foreign substances step by step as they pass through the body. Since such investigations can often be conducted even in man with safe, very low, doses or concentrations, it has been possible to establish comparability between man and experimental animals. This in turn has provided a rational basis for chronic tests and hence also substantially improved their practical usefulness. At the same time, the information acquired so far has revealed unsuspected qualitative and quantitative differences between individual species of animals, as well as between animals and man, and it is only now that the magnitude of the problem is apparent. Space does not permit a systematic discussion, and the reader is referred to the specialized literature[21]. However, the amount of work and time needed to obtain an uninterrupted pharmacokinetic profile is so huge that a systematic investigation of all environmental poisons is not likely to be completed in the foreseeable future.

The problem is further complicated by the fact that many poisons do not release toxic effects in their original form but in a chemically altered one. Although metabolic transformations often represent detoxication reactions, in many cases also inactive precursors are converted into reactive derivatives. These can be difficult to detect, especially if the proportion of the amount converted is very small in relation to that ingested; detection is frequently only possible by indirect means, owing to the instability of the chemical species concerned in the biological medium associated with their high reactivity. The limited possibility of detection restricts the predictability of the occurrence of a toxic effect, leaving an uncertainty, a question mark against the value of the toxicity test. If *pharmacogenetic* peculiarities, *i. e.* changes of the metabolic pattern in only a few genetically determined exceptions in the human group, are involved, then animal experiments must of necessity fail.

8. Carcinogenic, Teratogenic, and Mutagenic Effects

The metabolic activation mechanisms assume special importance in the case of carcinogenic, teratogenic, and mutagenic substances. The *malignant tumors* observed hitherto in man following the action of chemical substances, practically without exception occupational cancer, either form at the site of action or else, when they occur after absorption of the substance, are characterized by strict organotropism. The cancer types produced by chemical substances in the course of animal experiments are also governed by organotropism, but if we go by their localization and histological structure they are to a large extent unknown or rare in man. The organotropism can vary from one animal species to another with one and the same substance; certain compounds are carcinogenic in some species, but not in others; for example, the strongest known carcinogen, aflatoxin, has practically no effect on sheep[22]. The type of tumor frequently observed in feeding experiments involving the administration of foreign substances to mice—the officially recommended and most widely used rodent—namely a particular kind of hepatoma, is practically unknown in man. Extreme variations are observed in the frequency and indeed in the appearance of tumors at all between different series of experiments involving similar animals and substances, when the latter are administered at doses close to the threshold, since in such cases nonspecific influences of the experiment mask the effect of the foreign substance[23]. In many animal species and breeds benign and malignant tumors occur quite spontaneously, the only effect of "carcinogenic" substances being to accelerate their formation. The significance of such an acceleration with respect to the risk of cancer in man is not clear.

As long as the causes of organotropism remain unexplained, it will be impossible to *predict with certainty* that a substance shown to be carcinogenic in animal experiments can also give rise to tumors in man. Conversely, a negative finding in animal experiments *cannot rule out with certainty* the risk of cancer in man. Risk assessments relating to carcinogenic effects must therefore be reduced

to compromises not resting on a rigorous scientific basis. A committee of experts in the USA has worked out a recommendation[24] which has been adopted in many countries. According to this, every substance that has definitely given rise to tumors in animals should be regarded as carcinogenic and therefore representing a potential cancer threat to man.

Such a rule is unsatisfactory as long as the risk remains unquantified, and until its relationship with the permanent, definite carcinogens in the environment, say the 100 or more carcinogenic substances in "pure" food[25], is clarified. There is an obvious possibility, indeed a probability, of underestimating real risks and overestimating negligible ones. In tending to militate against a more accurate assessment of the situation, the recommendation also distracts our attention from the most pressing concern, namely the pinpointing of the carcinogenic substances that have no effect on rats or mice, the routinely used experimental animals.

Only exceptionally have *teratogenic* risks been associated with environmental poisons at the concentrations encountered in practice. One such instance is 2,3,7,8-tetrachlorodibenzo-*p*-dioxine, occurring as an impurity in the herbicide 2,4,5-trichlorophenoxyacetic acid[26]. The thalidomide tragedy has lent powerful impetus to the experimental investigation of teratogenesis and has led to the careful development of experimental techniques that have been subjected to scrutiny[27]. Nevertheless, the substantial biological differences between the embryonal development in man and in experimental animals means that the *predictive* value of the test methods is limited. The thalidomide case provides a good illustration of this: the malformation syndrome observed in man cannot be reliably reproduced to the same extent in animals under comparable conditions. In other words animal experiments cannot at present be used to rule out teratogenic risk with certainty.

The situation in the domain of *chemical mutagenesis* is even more problematic. Tests on primitive organisms, developed successfully for the investigation of the molecular biology principles of mutagenesis, are quite unusable for risk evaluation, since they do not take into account the pharmacokinetic behavior of the foreign substances, which can have a decisive influence on whether or not mutagenic changes occur. This applies particularly to cases in which the effect is produced not by the substances themselves but by metabolites. Lower organisms do not have the activation mechanisms found in mammals. This situation, which has long been obvious to toxicologists, was until recently totally ignored by geneticists. Indeed the general policy was to carry out routine tests on foreign substances with primitive organisms and to demand a ban on their use in the event of a positive finding[28]. With this in mind, the Deutsche Forschungsgemeinschaft established a testing laboratory. Its activities were justified among other things with the argument that the results obtained with *in vitro* methods are 99% transferable to man[29]. This claim is quite untenable, being totally bereft of all scientific basis. The fact is that on the basis of tests on lower organisms many substances are pronouncedly mutagenic which are manifestly not mutagenic in man, whereas numerous highly toxic, carcinogenic, and probably also mutagenic principles are overlooked. At this point a danger comes to light which also inhibits progress in other areas of research into toxic effects: In making things too easy for ourselves with oversimplified demands we are losing sight of the real dangers, and the analysis of the overall situation becomes distorted.

Mutagenicity tests on intact mammals have a certain value. However, they have not yet advanced to the stage where one could expect reliable data for the assessment of the risk of mutagenesis in man. In particular, further investigations are needed into the usefulness of the methods in the case of the prolonged action of low concentrations of foreign substances. Scarcely any work has been done into dose/effect relationships in this area, which is of primary importance for environmental toxicology. Systematic mutagenesis research has hitherto been carried out mainly with high, acute toxic doses of alkylating agents. The mutagenic potential of these substances is well known; after all, they have been used medically with the precise object of cell damage. The data so far available concerning the mutagenic effects of the real and important environmental poisons on man thus represent conjecture rather than scientific evidence.

9. How Safe is "Safe"?

The above discussion of the limitations of epidemiological methods and animal experiments shows plainly that it is impossible to predict with absolute certainty whether a toxic effect in man must be expected or can be ruled out with particular substances. Despite this, the authorities expect, the press demands, and many manufacturers promise "safety" from injury to health through environmental poisons. Legislators use the term "harmlessness" in laws and regulations. Both "safety" and "harmlessness" imply a guarantee, and inevitably persuade the layman that it can in fact be given. Unfortunately, biological experiments are fundamentally incapable of providing such a guarantee. In Germany, the layman's understandable desire for security is also nurtured by a linguistic misunderstanding, to which journalists are particularly prone: The English "safety" is glibly translated by "Sicherheit". In actual fact, by "safety" we mean that it is sure or likely that no harm will result[30], whereas the German "Sicherheit" denotes "an absence of danger, protection from any threat"[31].

The toxicological assessment of foreign substances must therefore always involve a greater or lesser, but never completely calculable residual risk. Toxicity tests can measure only relative safety, which must be defined according to the prevailing fund of scientific knowledge. Scientists, the press, and legislators should have the courage to acknowledge this fact and to enlighten the public as to the true state of affairs, eschewing all simplification. Laymen must learn something about biological variability and quantitative relationships, and they must realize that the use of chemicals is fundamentally inseparable from risk. Only in this way will the public be able to assume a proper share of the responsibility that the progress of civilization imposes upon us.

All the same, toxicology finds itself permanently compelled to act: Judgments have to be made under the pressure of the gravity and complexity of the problems to be solved, and frequently on the basis of inadequate data. These externally imposed shackles on the quality of judgments cast a stigma on the discipline. Compared with the clarity with which results can be obtained and interpreted in other scientific domains, the situation in toxicology gives little cause for satisfaction. Similar problems are encountered in the assessment of the environmental hazards associated with nuclear reactors. The need to compromise, to calculate the incalculable, was recently described by *Weinberg*[32] as "trans-scientific elements". Nevertheless, pessimism would be out of place. We are at the present time experiencing a period of extraordinary improvements in toxicological methods leading to better and earlier detection of toxic risks. Success in this endeavor depends, now and in the future, on a joint effort by both scientists and legislators, even though their roles are quite distinct.

10. Solutions

1. The prevention of damage to the environment and of danger to human health from pollution calls for *restrictive legislation*. The nature and scope of the latter is a purely *political* matter, but the political decisions in this area must be based on scientific advice concerning the measures that can be taken to avert a danger to health. Such advice must be confined to a statement of strictly *scientific* facts. Examination of the economic benefits and burdens associated with restrictive measures falls entirely within the province of the politician. Such considerations must not influence scientific judgment. Experience shows that if the scientist changes his mind by permitting economic factors to affect scientific decisions, legislators and press alike will be quick to discredit him. And rightly so. Yet the politician, too, should be honest enough to acknowledge the political motivation behind his decisions and not seek to cloak them in pseudoscientific arguments. Take one example: The German Federal government justifies the law banning the use of DDT by stating that whereas damage to health had not been demonstrated, it could not be excluded[33]. As already explained, however, such an exclusion cannot be demonstrated, for DDT as for any everyday food or "harmless" environmental factor. The justification is neither plausible nor practicable.

2. *Recommendations* and *decisions* on possibly toxic environmental substances should not be made by heterogeneous committees containing a small minority of members with direct practical experience of the problems of toxicity tests and their value. Majority decisions can in such circumstances be erroneous. For instance, the advisory committee which recommended the ban on DDT in the USA outvoted the argument that the animal experiments performed to test for a carcinogenic effect were grossly defective in both organization and evaluation[34]. Today everyone feels called upon to pronounce on toxic effects and the risk to health from environmental pollution; why cannot this task be left to the genuinely knowledgeable specialists working to unravel the complexities of the field, as is the case in nuclear physics or oceanology?

3. A *total prohibition* on substances whose harmful effect has not been demonstrated is not, as a rule, likely to eliminate health risks. On the contrary, it may very well increase them. For the ban leaves a gap in supply, and, in its efforts to meet the demand, industry switches to less thoroughly researched materials, concerning whose effects on man little or no experience has been gathered. These materials can therefore conceal a greater risk—or at any rate one more difficult to appraise—than the prohibited substance. Following the ban, efforts to throw light on the causal relationship are broken off, and the uncertainty in the identification of real poisons increases. Our interests are better served by effective control of the use of the incriminated substance and its restriction to the economically necessary extent, *i.e.* by *prevention of misuse* with simultaneous intensification of research into the material's ecological behavior and toxicological properties.

4. Restrictive measures should be based on a *quantitative* assessment of the risk, especially in the case of potentially carcinogenic and mutagenic substances. A substance should not be banned automatically because of evidence of a carcinogenic effect. The decision should be based on a comparative examination of the strength of this effect with due regard to the nature, intensity, duration, and frequency of action. Very weak or doubtful carcinogenic and mutagenic effects produced by man-made substances must be carefully weighed against the potential dangers of "natural" substances.

5. Discussions and judgments on questions of environmental toxicology must remain *free from emotional arguments* and global claims confined to individual disciplines. What sense can there be in, say, inflating the relative importance of mutagenetic research with statements such as: "We must not wait until the lunatic asylums are overflowing with abnormal children", or claiming, as someone did recently[35], that problems of environmental toxicology should and could be solved exclusively by mutagenicity tests?

6. Judgments in the field of environmental toxicology and the legislative measures based on them should be *re-examined at certain intervals*, and if necessary amended, to allow for progress made in the intervening period. The initial decisions should in no way inhibit subsequent correction. The soundest policy is to impose restrictions—and issue authorizations—step by step, maintaining constant surveillance to check whether the existing measures are working well.

7. Owing to the vast scope of the problems encountered in environmental toxicology, optimal use must be made of present and future *research capacity*. A comprehensive study of the toxicological action of a foreign substance can only be successfully carried out by teamwork involving not only toxicologists, but also biochemists, analytical chemists, geneticists, and if necessary also microbiologists, epidemiologists, and specialists in various aspects of general and industrial medicine, backed by all the technical resources of these domains. The interdisciplinary character

of toxicology creates a need for large and well equipped research facilities. If individual aspects of projects are assigned to laboratories with conventionally limited specialization, there is a strong risk of distorted and unqualified judgments in the interpretation of the results from the health standpoint. Whether a biological effect is a state of disease or not can in the final analysis only be evaluated by a physician. In arriving at its final verdict on a toxicological problem, a competent team would thus be led by a toxicologist combining qualifications in experimental toxicology, pharmacology, and pathophysiology with experience in clinical medicine. Regarded in this light, environmental toxicology emerges not as a conventional discipline but as a task that must be tackled jointly by the classical fields of medicine, chemistry, and biology.

8. In the interests of better comparability of the results, toxicological laboratories should be subjected to standardization and *quality control*, like in the areas of analytical and clinical chemistry. Such a policy would greatly reduce or even eliminate duplication of work.

9. The *information flow from laboratories in industry*—which is undertaking its own independent toxicological research on a growing scale, spurred on by the legislation of responsibility of the originator—represents a trickle rather than a torrent. Environmental research would benefit from an improvement in this respect. This lack of cooperation may be partially attributed to misunderstandings between representatives of the controlling authorities and industrial scientists, resulting from their different outlook on toxicological problems: on the one hand we have the primarily or exclusively administrative official with a decidedly political position, on the other a scientific expert brought up on practical experimental problems and possessing high qualifications, perhaps even international renown. One way of resolving such misunderstandings and building up mutual confidence would be to remove the discussion of both fundamental and day-to-day problems from the province of officialdom into the scientific arena, as is the widespread practice in other countries. It is particularly desirable that toxicologists employed by the authorities should participate actively in scientific debates, their understanding of methodological problems being augmented wherever possible by their own practical contributions.

10. Minimum requirements should be stipulated for toxicity tests, although detailed rules as to procedures and evaluation entail some risk. Chronic experiments involving large numbers of animals of different species which receive doses in the vicinity of the threshold level usually proceed uneventfully. They yield great numbers of data relating to normal findings, and vigilance becomes blunted, so that if eventually an apparently slight—but decisive—change occurs, it tends to be overlooked. A decision as to whether importance should be attached to an effect that may not even rate statistical significance can only be reached properly after rapid and thorough consideration of all the experimental parameters, including molecular-biology relationships. Qualified scientists naturally shy away from the strict regimentation of chronic animal experiments and good trainees are hard to recruit. *Work in environmental toxicology should therefore be made more attractive.* The best way of achieving this is to do away with inflexible test procedures, such as have already become established in many fields, *e.g.* food additives, cosmetics, and drugs. Greater attention should be given to the more interesting clarification of the *mechanism of action* of foreign substances, an aspect that is neglected in current testing regulations. This would simultaneously raise the efficiency of the researcher, for study of mechanisms has contributed far more to our present knowledge of the relationships in environmental toxicological systems than has mere routine testing. In particular, emphasis should be placed on *fundamental research* and the *development of new methods* which will help us to obtain more meaningful results more quickly and at reduced cost. A principle of "more research, less testing" will help to recruit better candidates for an urgent task: conquest of the dark side of chemical progress.

Quartz Crystals and Their Colors

By Gerhard Lehmann and Hans Ulrich Bambauer[*]

The many colors found in quartz crystals are always due to the presence of impurity atoms, whose concentrations rarely exceed 0.1 wt.%. The impurity atoms occupy either silicon sites in the lattice or interstitial sites in the channels parallel to the *c* axis of the quartz structure; very fine precipitations of foreign phases are sometimes also observed, though this is less common. In addition to intrinsic colors of transition metal ions, one also finds color centers produced by ionizing radiation. Regular distributions of impurity atoms and colors may develop in the crystals as a result of some factor connected with its growth. Most of the natural quartz colors, as well as others that do not occur in nature, have been produced in synthetic quartzes.

1. Introduction

Colored varieties of quartz crystals, which are colorless in the pure state, are of widespread occurrence, and have been valued from time immemorial as jewelry stones. This mineral was therefore classified in very early times on the basis of its color, and trivial names (Table 2) have been introduced to distinguish different types of quartzes. Attention was naturally given to the origin of the many colors. Apart from early, purely speculative interpretations, the first partial answers resulted from the determination of the trace contents and their correlation with the intensity of the colors, and often also from comparison with similar colors in glasses of known composition. Special mention should be made of the work carried out by *Holden*[1] and by *Wild et al.*[2] in the 1920's. It was possible to determine the trace element responsible for the color in most cases, but the structure of the lattice defects that give rise to the color[**] was still uncertain, since the experimental and theoretical principles required for their investigation had not yet been developed.

Decisive impetus was provided around the middle of this century above all by electron spin resonance and the ligand field theory. Assisted by other, mainly spectroscopic, methods of investigation, they led to the elucidation of the structure of the color centers in many minerals having no color of their own. At the same time, interest in color centers shifted from practical to scientific questions.

In general, the causes of color can be divided into three groups:

1. Ions of transition metals or rare earth metals that are incorporated in a state of atomic dispersion into the crystal structure, and cause selective absorption in the visible region of the spectrum because of their ligand field or electron transfer bands.

2. Electronic defects, which are preferentially formed at structural faults in crystals (impurities, vacancies or interstitial atoms) by ionizing radiation; by transfer of electrons, this always leads to complementary pairs of electron and hole centers. The assignment of absorption bands and other properties to one of these centers is usually difficult, and cannot be achieved by correlation of only two parameters. Electronic defects not associated with impurities are of minor importance with regard to the colors in quartzes; on the other hand, they form a large number of color centers in the alkali halides[3].

3. Heterogeneous inclusions, which can cause selective absorption and scattering of light; in many cases these simply produce turbidity in the crystals.

In the majority of cases, therefore, the color of quartzes is associated with the presence of foreign atoms.

[**] The name "color centers" has been generally adopted for lattice defects of this type, even where they have no appreciable absorption in the visible region of the spectrum.

2. Crystal Structure of Quartz and Possibilities for the Incorporation of Trace Elements

The nature and amount of impurities that can be incorporated into a crystal under otherwise ideal conditions depend on the structure of the host and its dimensions.

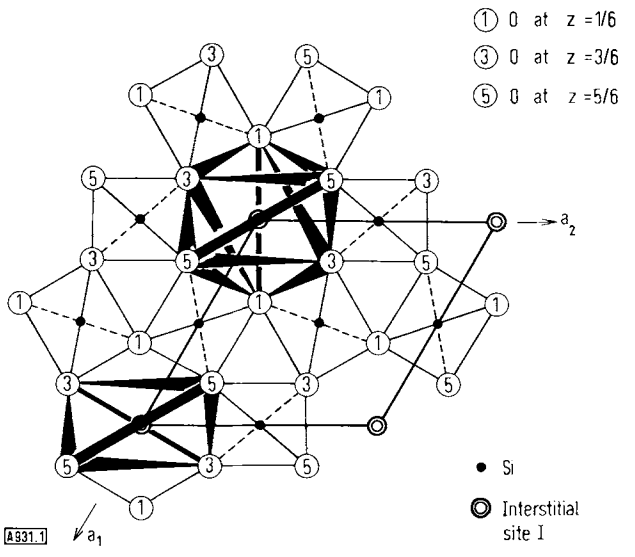

Fig. 1. Projection of the (average) crystal structure of high quartz on (0001). (The structure of low quartz differs from this only in small displacements of the parameters.) The two types of interstitial sites that occur in the channels parallel to the c axis, with distorted tetrahedral and distorted octahedral environments, are emphasized by the indication of spatial coordination in one example each: I_4 on $z = 4/6$ and I_6 on $z = 3/6$. After [38].

These in turn are determined by the nature and valency of the atoms from which it is formed. Figures 1 and 2 show the structural principle of quartz: $[SiO_4]^{4-}$ tetrahedra are linked by their corners to form three-dimensionally crosslinked Si—O—Si "chains", leaving relatively wide channels between the chains along the c and a axes of the unit cell. For clarity, the diagrams are based on the (average) high quartz structure (hexagonal point group D_6-622), which is stable above 573 °C. The structure of low quartz (trigonal point group D_3-32) differs from this only in small displacements of the parameters. In the channels along the (optical) c axis there are interstitial sites I_6 with distorted octahedral coordination and I_4 with distorted tetrahedral coordination, which are separated from one another by $c/6$. Si lattice sites occupied by foreign atoms will be denoted by S in the following discussion[*].

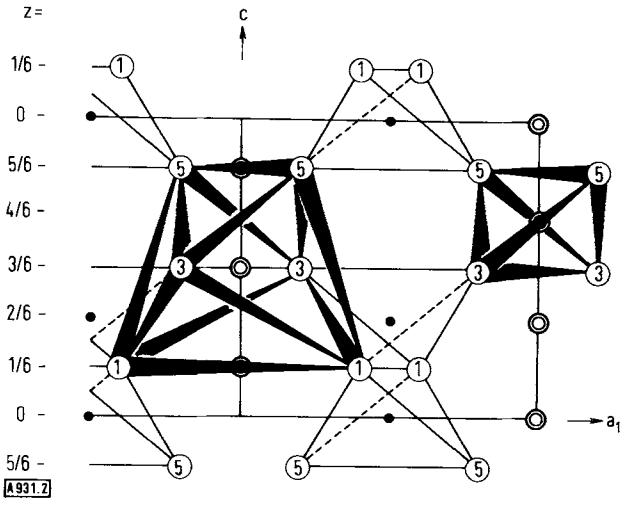

Fig. 2. Projection of the (average) crystal structure of high quartz on (01$\bar{1}$0); otherwise as in Figure 1. Only the interstitial sites I_6 are indicated in the channel parallel to the c axis on the left, and only the I_4 on the right. After [38].

Table 1 presents a survey of trace element contents in natural quartzes from recent literature data. These values can be illustrated with the aid of Figure 3. It should be noted that the upper limits indicated are extremely rare. One can see that the trace element content practically never exceeds 0.1%. Another interesting point is that elements forming tetrahedrally coordinated anions, such as S, P, and As, have not yet been found in natural quartzes, though the size of these complexes is such that they could replace $[SiO_4]^{4-}$ tetrahedra. That this is not entirely due to geochemical factors can be seen from the failure to incorporate these groups[23] or borates into synthetic quartzes. There must therefore be some kinetic inhibition that prevents the incorporation of negatively charged groups.

Table 1. Trace elements in natural quartzes. Table from [56] corrected according to more recent literature. The maximum values indicated are mostly rare, and values given in brackets are uncertain. Other elements are not indicated, either because their concentrations are too low, or because the number of analyses is too small or the analyses are uncertain.
The values are given a) in ppm (parts per million); b) as the number of atoms per 10^6 silicon atoms (often denoted by "ppm Si" in the literature).

Substitution of the tetravalent silicon by other ions, particularly those of the transition and rare earth metals, is possible

[*] I from "interstitial", S from "substitutional".

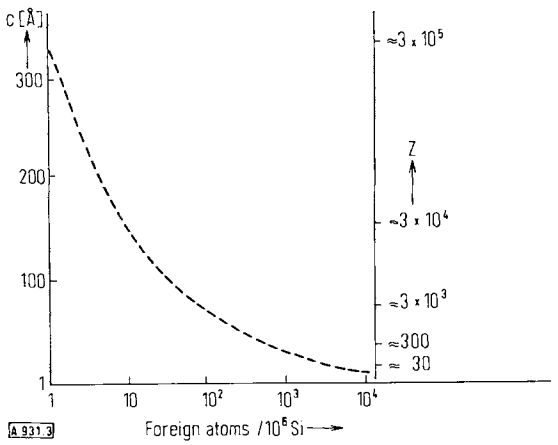

Fig. 3. Illustration of the concentration data for foreign atoms in Table 1. As values *averaged* over the analyzed range, Z is the number of unit cells and c is the edge length of the cube per foreign atom (which is also the shortest distance between two foreign atoms). (We are grateful to Prof. *Laves*, Zürich, for this diagram.)

only to a very limited extent, if at all, because of its high valency and its small ionic radius. This substitution has so far been observed for Al^{3+}[4], Fe^{3+}[5–7], Ti^{4+}[8], and Ge^{4+}[9–11]. One can understand, therefore, why quartz is one of the purest of all minerals. A series of additional ions have been found in interstitial sites: alkali metal ions, which can be replaced by one another or by hydrogen (or deuterium) by electrolysis or high-temperature diffusion[50], and the transition metal ions Co^{2+}, Co^{3+}[12], Fe^{2+}[7], Fe^{3+}[13], and almost certainly also Ti^{3+}[14]. The surprising ease with which the transition metal ions with higher valencies are incorporated into interstitial sites is evidently due to their d electrons[*]. Another influencing factor is the ligand field stabilization energy, as a result of which the octahedral coordination is energetically favored when the d shell is only partly filled, this effect being particularly strong in the case of Cr^{3+}. The almost exclusive incorporation of this ion into distorted octahedrally coordinated interstitial sites in $AlPO_4$[19] with a quartz superstructure[20] is a particularly striking example of this influence. It is possible to determine the coordination of this interstitial site (and the valency of the transition metal ion) from the optical spectrum on the basis of the ligand field theory.

Apart from the capacity of the quartz structure for the incorporation of ions, the incorporation of impurities is limited by their solubility in the hydrothermal growth solution and the partition coefficient between solution and crystal. At present there are few known quantitative data on either of these factors, in comparison with the large number of systems. It is occasionally found that the incorporation of one ion is strongly influenced by the presence of another. Thus distinctly more Co^{2+} is incorporated into synthetic quartz if the growth solution also contains beryllium salts[21]. It is also known that the incorporation of Al^{3+} is strongly favored if the solution contains alkali metal ions that can be incorporated. To dope synthetic quartzes with iron ions, it was necessary to use potassium carbonate solutions instead of sodium carbonate, since the sparingly soluble acmite $NaFe[Si_2O_6]$ is formed with Na^+[22]. In the case of the transition metals, which can exist in solution in various valency states, the redox equilibrium is shifted to the least soluble valency state. This explains the striking reducing action of alkaline hydrothermal solutions on transition metal ions[23], if one assumes that, contrary to the situation at room temperature, the solubility of the higher valency state increases with rising temperature, *e.g.* as a result of the formation of anionic complexes[14].

[*] It is well known that alkali metal halides exhibit Schottky defects, with vacancies in both sublattices, while the silver halides exhibit Frenkel defects, with vacancies and interstitial ions of Ag; similarly in the n conductor ZnO, the excess of zinc is achieved by the incorporation of additional Zn in interstitial sites, and not by vacancies in the oxygen sublattice. The factor responsible for the incorporation of metal ions into interstitial sites is the fact that the energy required is less than for the formation of vacancies in the anion sublattice. Thus the enthalpy of formation of the Frenkel defects in AgCl is only about 14 kcal/mol [15], whereas the enthalpy of formation of Schottky defects in alkali metal halides is around 23 kcal/mol or more [16—18].

3. Color-Producing Trace Elements

The colored varieties of quartz (cf. Table 2) can be classified from various points of view, the choice of which depends on the state of knowledge about the causes of color and the detection or synthesis of new varieties. Thus a differentiation based on the nature of the color or the mineralogical trivial name no longer seems appropriate, since several very different causes often produce similar colors, which are difficult to distinguish, and it would be necessary to introduce new trivial names for colors that have been obtained synthetically.

If there were no gaps in our knowledge of the structures of all color centers, these structures would form a suitable basis for differentiation. Our knowledge at present is adequate for a classification according to the nature of the color-producing trace element, and this is the basis that will be used here. It avoids the difficulty arising from the fact that the same crystal often contains different color centers in varying ratios, so that there may be doubt in a given case, from the mineralogical point of view, as to whether a crystal should be referred to as amethyst or as smoky quartz. On the other hand, further differentiation is necessary in cases where the same element produces different colors according to its valency, coordination, or degree of dispersion. This is particularly noticeable for iron.

3.1. Color Centers of Iron

This element was recognized at an early date as the source of the violet color of amethyst[1d, 2b]. The incomplete correlation between the iron content and the depth of color was also discovered in these investigations, but the reasons for this, as well as the nature of the color centers, remained unknown until very recently. The formation of the color centers by ionizing radiation and their low thermal stability point to an anomalous valency as their cause. ESR investigations[5, 24] showed the presence of trivalent iron in silicon sites of the lattice, with alkali metal ions in adjacent interstitial sites to compensate for the missing positive charge.

Table 2. Colored varieties of quartz.

Trivial name	Color	Color-producing trace element	Color center (scattering center)	Stability limit of color [°C]	Artificial preparation	Naturally occurring
Rock crystal	colorless	—	—	—	+	+
Smoky quartz	brown	Al	AlO_4^{4-} + electron center	*ca.* 200	+	+
	light yellow [a]	Al	AlO_4^{4-} + electron center	*ca.* 150	–	(+)
Amethyst	violet	Fe	$Fe^{4+}(S) + Fe^{2+}(I_4)$	*ca.* 350	+	+
Citrine	yellow-brown	Fe	Fe_2O_3-precipitations	*ca.* 600	–	+
—	yellow-brown	Fe	$Fe^{3+}(I_4)$	*ca.* 600	+	–
"Prasiolith"	green	Fe	$Fe^{2+}(I_6)$	*ca.* 600	+	(+)
Rose quartz	pink	Ti	$Ti^{3+}(I_6)$ (+ rutile needles)	*ca.* 575	–	+
Blue quartz	grey-blue	Ti	(rutile needles)	?	–	+
—	light-blue	Co	$Co^{2+}(I_4)$	?	+	–
—	red-brown	Co	$Co^{3+}(I_6)$	*ca.* 450	+	–

[a] Radiation color of certain rock crystals (see Section 3.4).

This S_1 center does not contribute to the color of amethyst itself, since the ligand field bands of trivalent iron have only a low intensity in the visible region of the spectrum, comparable with that in $AlPO_4$, $GaPO_4$, and $AlAsO_4$[25], and the first strong electron transfer band, as in $AlPO_4$ and $GaPO_4$, lies well above the visible region, with a maximum at 46000 cm^{-1} (see Fig. 4). Since the concentration of the S_1 centers increases on decoloration and decreases on discoloration, these must be regarded as precursors of the amethyst centers.

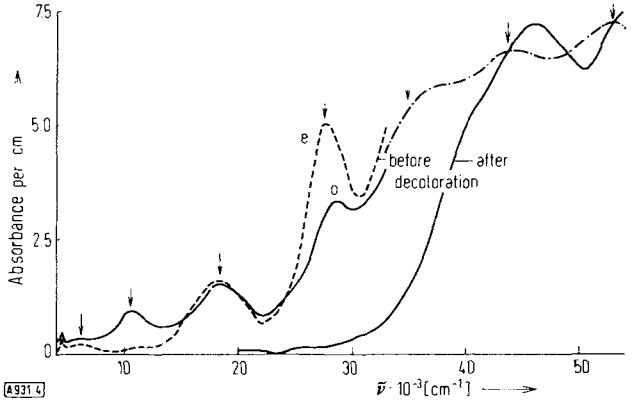

Fig. 4. Absorption spectra of amethyst (Four Peaks, Arizona) and their variation on thermal bleaching; o: light polarized perpendicular to the c axis (σ or o spectrum), e: light polarized parallel to the c axis (π or e spectrum).

A very similar center, but with a proton on one of the four oxygen ions of the $[FeO_4]^{5-}$ tetrahedron instead of the alkali metal ion in an interstitial site (S_2 center), is formed on discoloration as a by-product of the irradiation in concentrations that vary according to the hydrogen content of the quartz[7]. Its absorption in the visible and ultraviolet regions of the spectrum must be substantially similar to that of the S_1 center.

The first attempts at the hydrothermal synthesis of iron-doped quartzes led to a different incorporation of trivalent iron, as was shown by the completely different ESR spectrum of the centers, which were again atomically dispersed[26,27], and by the much higher optical absorption in the visible region, which leads to a pronounced yellow color in the crystals at concentrations of only about 0.01 at %. The analysis of this optical spectrum (Fig. 5) showed that the trivalent iron in this case is accommodated in inter-

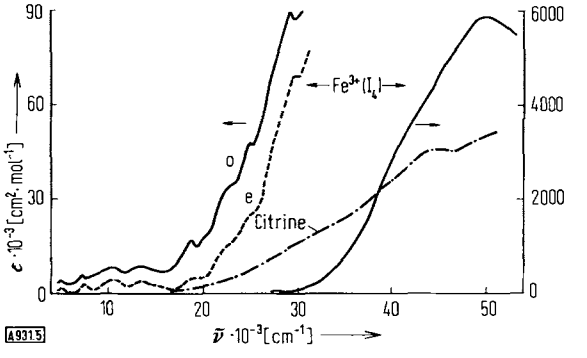

Fig. 5. Absorption spectra of yellow quartzes containing iron (arbitrary scale in the case of citrine).

stitial sites with approximately tetrahedral symmetry[13,28]. There are striking similarities between the optical spectra of this I_4 center and of the Fe^{3+} in alkali metal silicate glasses[29], in which Fe^{3+} also has a tetrahedral coordination as shown by Mössbauer investigations[30,31].

Analogies of this nature are also found for other transition metal ions, and transition metal ions in interstitial sites in the quartz structure generally have the same coordination as in silicate glasses rich in alkali metals[28]. The I_4 center is also found in bleached amethysts, but almost completely disappears on sufficiently long exposure to ionizing radiation if the concentration of S_1 centers predominates[27]. Conversely, in synthetic amethysts with more I_4 than S_1 centers, practically all the S_1 centers disappear on irradiation. An amethyst center thus consists of one S_1 and one I_4 center, which change their valency in opposite directions on irradiation. The depth of color attainable is therefore limited by the center that is present in the lower concentration, and if only I_4 centers are present (a situation so far found only in synthetic quartzes), irradiation does not lead to the formation of amethyst centers. The incomplete correlation between the iron content and the depth of color of amethyst can thus be explained as follows. Only in the ideal case of equal concentrations

of S_1 and I_4 centers and vanishingly small hydrogen contents (no conversion $S_1 \rightarrow S_2$) can all the Fe^{3+} be converted into amethyst centers, provided that the radiation dose is sufficiently high. The resulting model of the color centers as tetravalent iron in lattice sites and bivalent iron in interstitial sites[7][*] is supported by the optical spectra of amethysts (Fig. 4)[39]. Bands attributable to tetrahedral Fe^{2+} appear in the far UV and in the IR at 1600 nm, so that the color of the amethysts is due almost exclusively to the contribution of the Fe^{4+}. This explains the small variation of the colors of amethysts in comparison with other minerals colored by impurities[32]. The high intensity of the bands at 545 nm and shorter wavelengths[7] identifies them as transitions with charge transfer character in the sense of the MO theory, similar to the bands of the MnO_4^- and CrO_4^{2-} ions[34].

According to this model, crystals in which Fe^{3+} is incorporated exclusively in S_1 sites should also be incapable of discoloration to give amethyst, but such crystals have not so far been found as minerals or synthesized. The occasional occurrence of amethysts with abnormal properties (*e.g.* decoloration by daylight) indicates that other defects as well as the I_4 centers may act as electron acceptors.

By the use of suitably oriented crystal plates as seeds, partial incorporation of trivalent iron into S_1 sites has been achieved in sectors of the positive rhombohedron[22]. The synthesis of amethysts has thus been achieved in principle; however, the depth of color obtained is still low in comparison with that of natural amethysts, since a much greater proportion of the S_1 centers are converted into S_2 centers because of the high hydrogen concentration, and thus become unavailable for the formation of amethyst centers.

Strongly colored regions of natural amethysts turn brown when heated to about 500 °C; the color is very similar to that of natural citrines. Both give a broad isotropic ESR absorption at a g value of 2[7,33]. The lack of dependence of the line width on the microwave frequency[28] points to heterogeneous inclusions of Fe_2O_3, corresponding to the precipitation of $MnCl_2$ in alkali metal halides[35]. The optical spectrum of citrine is also isotropic (Fig. 5),

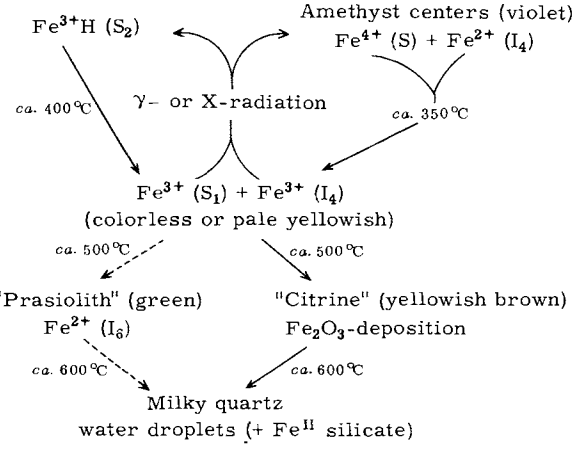

Fig. 6. Scheme of the observed changes in quartzes containing iron.

[*] The opposite arrangement is very unlikely for several reasons.

and its similarity to the absorption of Fe^{III} hydroxide sols was pointed out at an early date[1c].

Some amethysts turn green when heated to temperatures of about 500 °C; the optical spectrum[36] agrees with that of bivalent iron in I_6 interstitial sites in synthetic quartzes[7]. The cause of this thermal reduction is unknown. Temperatures around 600 °C produce a milky turbidity in amethysts, which is also known in other varieties of quartz, including synthetic quartzes with Z growth (cf. Section 4), where it has been traced to the separation of water droplets[37,58]. Milky quartz is occasionally also found in nature. It must also be assumed that under these conditions an Fe^{II} compound of unknown structure, probably an iron(II) silicate, is formed in amethysts and iron-doped synthetic quartzes[27].

The scheme in Figure 6 shows a survey of the possible transformations in amethysts. Because of the large number of reactions and migration processes that occur, this system is also of interest for kinetic measurements.

3.2. Cobalt

Doping with bivalent cobalt yields blue quartzes. The absorption spectrum (Fig. 7) practically agrees with that of Co^{2+} in silicate glasses that are rich in alkali metals[21]. It is typical of tetrahedral coordination of this ion, and can only be explained by incorporation in interstitial sites I_4[12], since occupation of the lattice sites (which are also tetrahedral) would cause a strong displacement of the bands to shorter wavelengths because of compression. Reddish-brown quartzes are obtained on doping with trivalent cobalt. Evaluation of the optical spectrum (Fig. 7) indicates that this ion occupies the interstitial site I_6[12].

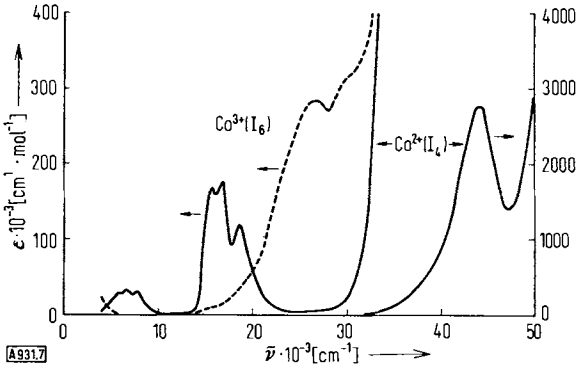

Fig. 7. Absorption spectra of synthetic quartzes doped with Co.

On heating to about 450 °C, the cobalt is reduced to the bivalent state, and this process is accompanied by a change of position from I_6 to I_4, as is shown by a comparison of the optical spectra. The activation energy for migration in the channels parallel to the c axis cannot therefore be very high, in agreement with the strongly preferred diffusion of monovalent cations along these channels[40]. On thermal reduction of Fe^{3+} to Fe^{2+} in the rare amethysts that can be turned green, a migration from I_4 to I_6 is observed (cf. Section 3.1). The occurrence of the migration

and its direction are determined purely by the preference for a certain coordination of the ion having the lower valency, which results from the differences in the ligand field stabilization energies. The reduction of the trivalent cobalt is reversible if the heating is carried out for only a short time, but becomes irreversible on prolonged heating; this is an indication of diffusion processes with participation of the oxygen formed during the reduction.

3.3. Titanium

This element is responsible for the color of rose quartz, which is found mainly in cloudy, compact pieces, and rarely in small, well-formed crystals. The pink color is due to a band at 20400 cm^{-1} (Fig. 8), is not changed by radiation, and is also thermally very stable. It can be explained only by trivalent titanium in interstitial sites I_6[14]. The surprising formation of the trivalent state, which is sensitive to oxidation, can be attributed to the reducing action of the growth solutions, which was mentioned earlier. A small proportion of the titanium is incorporated in the tetravalent state into silicon sites in the lattice; this can be reduced to the trivalent state by ionizing radiation[43]. The turbidity is, at least in part, due to precipitated rutile needles, which are up to 0.1 mm long and have a very uniform diameter of about 0.05 to 0.07 µm[41,42]. Attempts to grow rose quartz hydrothermally have so far been unsuccessful[44].

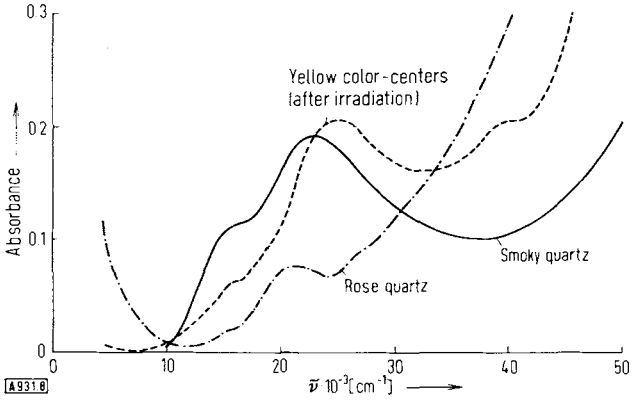

Fig. 8. Absorption spectra of quartzes with hole centers of aluminum and of rose quartz.

The gray-blue colored blue quartz also contains rutile needles, which are larger on average but less uniform than those in rose quartz[42].

3.4. Aluminum

Aluminum is the commonest impurity in natural quartz; Table 1 shows the range of variation found. Unlike the paramagnetic transition metal ions, this ion gives ESR and optical spectra that yield information on the manner in which it is incorporated only after the formation of electronic defects. The smoky quartz centers can be regarded as a defect electron on one of the four oxygen ions of substitutional $[AlO_4]^{5-}$ tetrahedra[4,46,47,53]; the elucidation of the structure was made possible by the hyperfine splitting of the ESR signal as a result of interaction with the nuclear spin of ^{27}Al. It is not yet known what becomes of the electron split off; *Mitchell* and *Paige* attribute absorption bands in the far UV to electrons in oxygen vacancies[48]. It seems quite possible that bands at longer wavelengths in smoky quartz (Fig. 8) are actually due to electron centers of this or of another kind, in analogy with the F centers in alkali metal halides and alkaline earth metal oxides[3,49]. The smoky quartz centers can be destroyed by UV radiation or by temperatures above 200 °C, and are thus less stable than amethyst centers.

In the region of Alpine deposits, the colorless quartzes (rock crystals) can be divided into two groups[51,56,59] according to trace element content (see Table 1) and macroscopic crystal defects[64]: 1. "ordinary rock crystals", with relatively low trace contents and a typical linear structure (Fig. 11) and 2. "lamellar quartzes", with relatively high trace contents and made up of a framework of low symmetry lamellas (Figs. 12 and 13)[57]. Natural smoky quartzes fit readily into the first group. Both groups are also found in deposits outside the Alps.

Most rock crystals assume a smoky quartz color under the action of ionizing radiation[56]. Much less common is a pale yellow color[22,50], which is thermally less stable than the smoky quartz color. The optical spectrum (Fig. 8) shows small band displacements compared to the spectrum of smoky quartz, and an additional band at 38500 cm^{-1}. Differences from smoky quartz are also found in the hydrogen content and in the ESR spectrum. The hydrogen content, with a value of *e.g.* about 10^2 H/10^6 Si, is distinctly higher than in typical smoky quartzes and near the lower limit of the values for "lamellar quartz". The content of other trace elements (Al, Li), in contrast with the "lamellar quartzes", appears to be no higher than in smoky quartzes and ordinary rock crystals. The ESR spectrum, as in the case of smoky quartz, shows the presence of holes on $[AlO_4]^{5-}$ groups. Irradiated "lamellar quartzes" frequently contain lamellar regions with a visually "normal" smoky color separated by regions with a brownish-yellow to yellowish color. This yellowish color could be the same as that mentioned above. No explanation has been found as yet for the differences between the corresponding color centers and the smoky quartz centers, and the assignment of the optical absorption bands to electron and hole centers has not yet been possible.

3.5. Color Centers Associated with Other Ions

The irradiation of germanium-doped quartzes leads to the formation of a series of electron centers with absorption bands in the near UV[52]. ESR studies[9,54,55] were again the principal aid to the elucidation of their structures.

New colors have been achieved by doping with other transition metal ions. The relationships to alkali metal silicate glasses that were mentioned earlier, in conjunction with the ligand field theory, allow a fairly reliable prediction of the coordination of a given ion and of the resulting color. Thus trivalent chromium is expected to be incorpo-

rated only in interstitial sites I_6, with production of a green color, as in $AlPO_4$[19]. However, the knowledge of such rules does not overcome the experimental difficulties associated with any attempt to dope with another foreign ion.

4. Non-Uniform Distributions of Impurities and Color Centers

It is extremely rare for the trace element concentration in quartz to be constant over the entire crystal. The anisotropy of the rate of growth and the kinetics of the deposition process (variations of temperature and concentration with time and with location) lead to sector and zonal structures in the real crystal.

a) *Natural Quartzes:* Their morphology is essentially described by the rhombohedron and the prism (Fig. 9). One finds mainly growth sectors of the positive rhombohedron $\{10\bar{1}1\}$, the negative rhombohedron $\{01\bar{1}1\}$, and the prism $\{10\bar{1}0\}$.

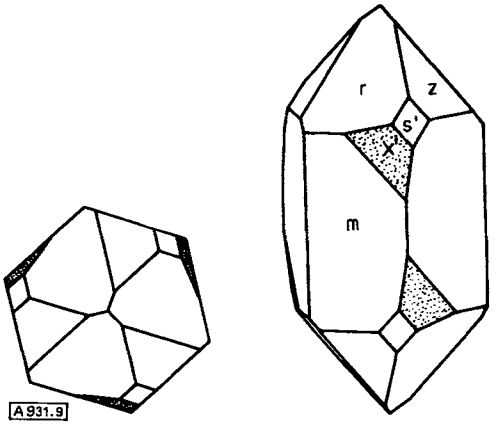

Fig. 9. Morphology of right-handed quartz; r = positive rhombohedron $\{10\bar{1}1\}$, z = negative rhombohedron $\{01\bar{1}1\}$, m = prism $\{10\bar{1}0\}$.

In the group of ordinary rock crystals and of smoky quartzes, the following relation is usually satisfied for the content of Al, Li, Na, and H: $r(10\bar{1}1) > z(01\bar{1}1) > m(10\bar{1}0)$[56]. Since the intensity of the smoky color due to irradiation is approximately proportional to the total content of trace elements, the sector

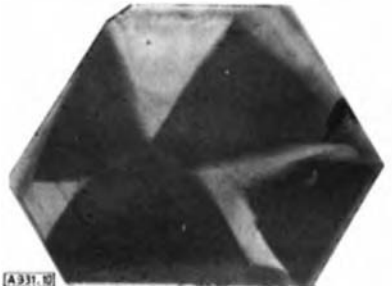

Fig. 10. Plate perpendicular to the *c* axis of originally light smoky quartz, diameter ≈ 3 cm. Sector structure appearing after γ irradiation: positive rhombohedron dark, negative rhombohedron light, outermost prism light. Dark region in the light sector on the right: Growth sector following positive rhombohedron in twinning position (Dauphiné law). Source: P. di Grandinagia, Swiss Alps [60].

Fig. 11. Plate parallel to the *c* axis of originally colorless "ordinary" rock crystal, approx. 3 cm wide. Visible after γ irradiation: zonal structure following positive rhombohedron (a roughly vertical Dauphiné twinning boundary runs through the middle of the section), as well as less strongly colored outer zones of the prism. The crystal defects characteristic of "ordinary quartzes" can be seen from the fan-like branching of the subindividuals. Source: Druckstollen Sta. Maria-Nalps, Swiss Alps [60].

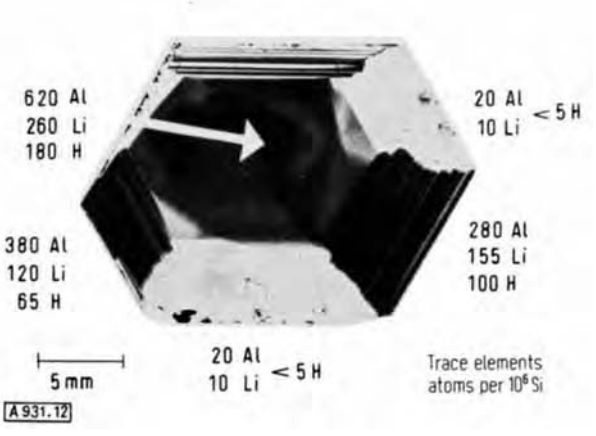

Fig. 12. Plate perpendicular to the *c* axis of originally colorless "lamellar quartz". After irradiation with neutrons: three outer sectors with radiation-colored lamellas alternating with optically homogeneous, practically undiscolored sectors: central part lamellated after the two rhombohedra. Source: Madagascar [57].

Fig. 13. Section parallel to the *c* axis of radiation-discolored "lamellar quartz" as in Fig. 11, 9 mm wide. Boundary line of the lamellas parallel to negative rhombohedron and parallel to prism (running vertically) with dovetailing [57].

and zonal structure is easily recognizable in irradiated crystals, as can be seen from the examples in Figures 10, 11, and 14. Unlike the color produced artificially by

radiation, the (natural) smoky color of smoky quartzes exhibits exactly the opposite relationship for the color shades[56]. The lamellar structure of lamellar quartzes is also clearly shown by the irradiation color (Figs. 12 and 13). Amethysts (like irradiated rock crystals) are most deeply colored in sectors following the positive rhombohedron $(10\bar{1}1)$.

Irregularity in the distribution of foreign atoms and color can also be caused by twinning and macroscopic imperfections, as is also clear from the examples in Figures 10 and 11.

b) *Synthetic Quartzes:* Synthetic quartzes generally also tend toward the morphology shown in Figure 9. An additional factor here, however, is the shape and orientation of the seed introduced, causing planes that do not normally occur in the crystal, such as (0001), to grow. This is illustrated in Figure 14 for a synthetic quartz grown from a rod-shaped seed (so-called Y bar), whose long edge is perpendicular to the prism face. A plate was cut from the crystal in the plane of the X and Z axes (the a and c crystallographic axes), *i.e.* parallel to the prism. Neither X or Z is a normal growth direction. The following relationships have been found for the enrichment of foreign atoms in various sectors in such crystals: $(0001) < (2\bar{1}\bar{1}0) < (11\bar{2}1) < (51\bar{6}1)$[63] and $(0001) < (10\bar{1}1)$[61]. The polar directions $+X$ and $-X$ differ not only in growth rate but also in capacity to accommodate impurities: $(0001) < (2\bar{1}\bar{1}0) < (\bar{2}110)$, *i.e.* more foreign atoms can be accommodated in direction $+X$[62]. The depth of the smoky color produced by radiation accordingly also increases. Correlations between impurities that are incorporated in different ways have been demonstrated in the zonal structure in the Z direction on a Z seed crystal[58].

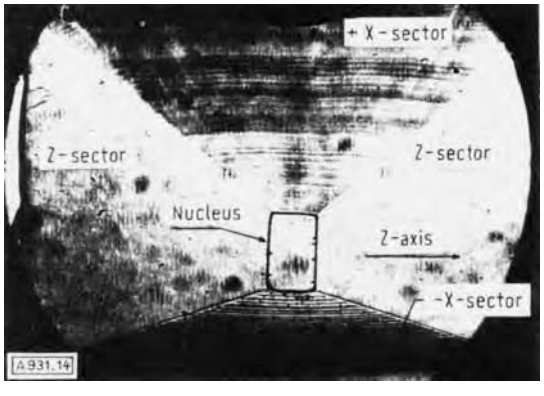

Fig. 14. Section parallel to the X—Z plane (a—c plane) through synthetic quartz (Y bar), γ-irradiated, approx. 2 cm wide. Growth sectors with zonal structure following Z and the polar directions $+X$ (rapid growth) and $-X$ (slow growth), hence eccentric position of the seed [45].

Another type of non-uniform distribution of color centers can be detected in certain amethysts. The Fe atoms substitute the three equivalent Si positions in the cell to very different extents. Amethysts of this type exhibit pleochroism in three mutually perpendicular directions (trichroism). Annealing at 600 °C leads to a random distribution of the centers, and after irradiation a dichroism corresponding to a trigonal symmetry is found[5].

An ordered distribution of foreign atoms (mainly Al, Li, H) has also been assumed to explain the nature of the similarly pleochroitic, smoke-colored lamellas in lamellar quartz after irradiation[57].

Synthetic Precious Stones[**]

By Josef Liebertz[*]

The first industrially feasible process for the synthesis of rubies was developed by *Verneuil* around the turn of the century. Progress in growing single crystals led in time to numerous other processes, some of which can be applied to the production of precious stones. In this way it became possible to synthesize the most important precious stones. Even crystals that do not occur in nature, but were originally of interest in other connections, have acquired importance for jewelry in recent years.

1. Introduction

True precious stones are minerals that usually occur as crystals and are characterized by beauty of color, play of light, and brilliance. This visual impression is considerably enhanced by skillful cutting. A high degree of hardness is required to avoid wearing away during use; the hardness of most precious stones exceeds 7 (hardness of quartz) on the Mohs' scale, but it can also be as low as about 5, particularly for polycrystalline material such as lapis lazuli. In addition to the aesthetic factors, a precious stone must be rare, and therefore valuable. The values can easily be as high as, and even exceed, 10^5 DM/cm^3.

Synthetic precious stones, on the other hand, are industrial products that agree crystallographically, physically, and chemically with the natural precious stones. The agreement almost self-evidently does not extend to the value, since the purpose of the synthesis is precisely to overcome the rarity. The favorable price of synthetic precious stones and the possibility of growing large crystals have opened up a wide field for technical use in addition to the use in jewelry.

The synthetic precious stones have the same names as the corresponding natural stones, preceded by "synthetic". It is accordingly incorrect, for example, to speak of a synthetic tourmaline. Really it would be a tourmaline-colored synthetic spinel. Some synthetic jewelry stones cannot be strictly referred to as precious stones, since no corresponding mineral exists. Compounds of this class were in most cases originally prepared for the sake of their physical properties, and their use for jewelry followed later.

With progress in growing single crystals, the number of processes for the production of synthetic precious stones has greatly increased. It therefore seems appropriate to present a survey of these processes first, and then to deal

with the particular precious stones and jewelry stones. Their principal properties are summarized in Table 1.

Table 1. Properties of precious stones and jewelry stones.

Crystal	Composition	Point group	Hardness (Mohs')	Refr. index	Dispersion	Growth process[a]
Diamond	C	m3m	10	2.42	0.04	Hp
Corundum (ruby, sapphire)	Al_2O_3	$\bar{3}$m	9	o 1.77 e 1.76	0.01	Ve, Cz, Fl, Hy *etc.*
Spinel	$MgAl_2O_4$	m3m	8	1.73	0.01	Ve, Cz, Fl
Beryl (emerald)	$Al_2Be_3Si_6O_{18}$	6/mmm	7.5–8	o 1.58 e 1.57	0.01	Fl, Hy
Quartz	SiO_2	32	7	o 1.54 e 1.55	0.01	Hy
Rutile	TiO_2	4/mmm	6–6.5	o 2.62 e 2.90	≈0.18	Ve
Strontium titanate (Fabulite)	$SrTiO_3$	m3m	6–6.5	2.41	0.10	Ve
Yttrium aluminum oxide (YAG)	$Y_3Al_5O_{12}$	m3m	8–8.5	1.83	0.03	Cz, Fl
Lithium niobate	$LiNbO_3$	3m	5–5.5	o 2.30 e 2.21	≈0.13	Cz

[a] Abbreviations: Hp = high-pressure method; Ve = Verneuil method; Cz = Czochralski method; Fl = flux method; and Hy = hydrothermal method.

2. Growing Methods

2.1. Verneuil Process

Around the turn of the century, *Verneuil*[1–4] developed the process that bears his name for growing rubies in the oxyhydrogen flame. The Verneuil synthesis may be regarded as a classic synthesis in that it was the first industrial method for growing precious stones, and is still used for the production of corundum, spinel, and other high-melting compounds. Its undiminished importance can be seen from the fact that the present annual world production is around 2000 tonnes of corundum and spinel.

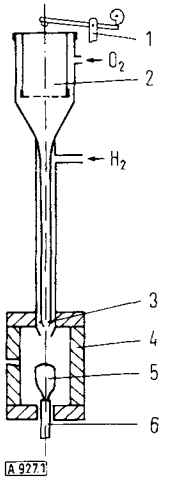

Fig. 1. Verneuil apparatus: 1, tapping apparatus; 2, powder container with perforated base; 3, burner jets; 4, ceramic muffle; 5, crystal; 6, sintered corundum crystal support.

The procedure of the Verneuil process can be seen from Figure 1. Hydrogen and oxygen are led through the outer and the inner tube respectively to the oxyhydrogen burner, whose jet is directed downward. The finely powdered starting material (<20 μm) is held in a container with a perforated base, and a tapper or vibrator is used to introduce it into the oxygen stream, and hence into the flame. A sintered corundum rod projects upward into the flame to act as the crystal support. Thermal insulation of the flame is provided by a ceramic muffle with a small peephole.

The flame temperature is initially adjusted so that the powder forms a sintered cone on the rod, and the tip of the cone is then fused. For nucleus selection a thin neck is first allowed to grow, and this rapidly widens to form the actual crystal as the supply of material and of gas is increased. The initial stage can be appreciably shortened by the use of a seed crystal. The top of the crystal is covered with a film of molten material up to 1 mm thick. The crystal holder is lowered at a rate of 5 to 10 mm/h, corresponding to the rate of growth, so that the position of the growing crystal surface in the flame remains constant. The gas consumption is about 1.2 m^3/h of H_2 and 0.4 m^3/h of O_2. For industrial production, about 50 units are combined to form a battery, and one man supervises three batteries.

The crystals produced in this way generally have a diameter of 10 to 20 mm and a length of 50 to 80 mm, though considerably greater dimensions are possible in special cases.

2.2. Czochralski Process

Whereas the Verneuil method was actually developed for the synthesis of precious stones, the Czochralski method[5] was originally used for the crystallization of metal filaments. It was introduced into semiconductor technology in a modified form; it is now one of the most important methods for growing crystals from the melt, and has a wide range of applications.

The principle of the method can be seen from Figure 2. The molten material from which the crystal is to be grown

is held in a crucible, which is usually induction heated by a high-frequency generator. This has the advantage that the maximum temperature attainable is limited only by the crucible material and the power of the generator. Platinum, rhodium, iridium, molybdenum, and tungsten are mainly used as crucible materials. The seed fixed in the base of the drawing shaft is in contact with the melt, and is brought to the desired diameter by adjustment of the temperature.

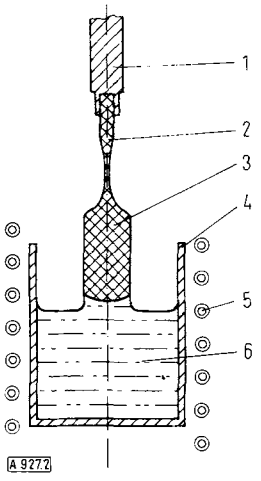

Fig. 2. Czochralski technique: 1, drawing shaft; 2, seed with tapered neck; 3, growing crystal; 4, crucible; 5, high-frequency inductance coil; 6, melt.

The temperature of the melt and the diameter of the crystal are then kept substantially constant. The crystal grows from the melt at a rate corresponding to the drawing rate, which can vary between 1 and 50 mm/h. The drawing shaft generally rotates at a rate of 30 to 150 rpm to keep the temperature and the distribution of impurities in the melt uniform and to reduce the diffusion boundary layer. The danger of constitutional supercooling can be avoided in this way.

The crystals produced by the Czochralski process are in the form of rods. Their diameters range up to about 50 mm, and their length up to about 1 m.

2.3. Flux Method

In the flux method, the desired compound is crystallized from a molten mixture consisting of the dissolved compound and the flux. The choice of the flux is naturally strongly dependent on the nature of the crystal to be grown; borates, molybdates, fluorides, and lead oxide have proved to be particularly suitable. The vessel is usually made of platinum. Depending on the system chosen, the temperature can be between 600 and 1300 °C. In the flux method, therefore, the crystals are grown from solution at high temperatures.

To produce the supersaturation required for crystallization, the initially slightly undersaturated melt is slowly cooled, possibly with a seed suspended in it; cooling rates of 0.1 to 1 °C/h are usual. The temperature difference principle described in Section 2.4 is occasionally also used for the crystallization.

Since growing times of several weeks must be expected and the size of the crystals is generally restricted to a few cm or less, the flux method cannot compete with melt methods. In general, it is used only if the crystal modification melts incongruently or undergoes a destructive phase transition in the solid state, so that the growing must be carried out below the temperature in question.

2.4. Hydrothermal Process

An alternative to the cases just mentioned is offered by the hydrothermal process, which is carried out between 300 and 600 °C, usually in the range above the critical temperature. Additives known as mineralizers are introduced into the water used as the solvent to increase the solubility. To ensure that the liquid or fluid solution phase has an adequate density of about 0.7 g/cm^3 (corresponding to 70% filling at room temperature) the *P-V-T* diagram of H_2O[6] shows that pressures between 200 and 3000 b are required in the temperature range mentioned. This means that the growing must be carried out in autoclaves. Because of the comparatively low solubility (<1%), only the temperature difference principle is used.

Figure 3 shows a diagram of the usual arrangement. The solution space, which is at a high temperature, is partly filled with lumps of feed material. A few seed crystals are suspended in the upper growth space at a lower temperature.

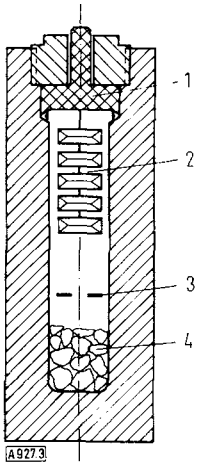

Fig. 3. Autoclave for hydrothermal growing: 1, self-sealing cover with delta ring; 2, growing space with crystals (T_0); 3, baffle; 4, solution space with feed material ($T_u > T_0$).

The saturated solution rises from the bottom, is supersaturated at the top, and thus supplies material to the growing crystals. To obtain favorable transport and flow conditions, a baffle is placed between the two regions.

Because of the serious corrosion problems, it is usually necessary to protect the autoclave *e.g.* with a silver or gold lining. Alternatively, the actual reaction vessel may be a sealed tube fitting loosely into the autoclave. To prevent the tube from breaking open, provision must be made for pressure equalization in the intervening volume.

3. Precious Stones

3.1. Diamond (C)

The name diamond is derived from the Greek word "adamas", which means the invincible. This refers primarily to the hardness of 10, but for a long time it might equally have referred to the synthesis, which was achieved only in 1955 at General Electric in the USA[7,8] and independently at ASEA in Sweden[9].

Direct transformation of graphite into diamond requires pressures of more than 120 kb at temperatures around 3500 °C[10]. The conditions for the catalytic synthesis are much more favorable, being 1500 to 2500 °C and 50 to 80 kb. The industrial production of diamond is therefore carried out only in this range, with transition metals as catalysts.

Several designs have been proposed and executed in order to realize the extreme pressure-temperature conditions in industry; the most important of these are the belt apparatus[10,11] and the tetrahedron apparatus[12]. (For further information see *e.g.*[13].)

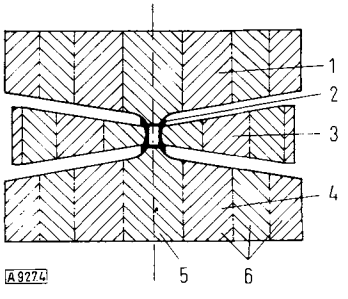

Fig. 4. *Hall*'s belt apparatus [10]: 1, upper ram; 2, sample chamber with pyrophyllite lining; 3, belt; 4, lower ram; 5, tungsten carbide; 6, various steels.

The belt apparatus (Fig. 4) is a modification of the ram-cylinder arrangement commonly used for lower pressures. The load is applied uniaxially with a press to the two rams, which taper very rapidly on the high-pressure side. The crucial feature is the lateral support ring (belt) surrounding the sample chamber. To even out mechanical stresses, the rams and the belt are made from several layers of material shrunk on to one another, with tungsten carbide inside and steel outside. The sample chamber is lined with the aluminum silicate pyrophyllite, which serves both as a pressure transfer medium and for electrical and thermal insulation. Since heating is carried out by direct passage of current, metal or graphite heating elements must be inserted in the pyrophyllite body. The operating times are usually less than 30 minutes, the pressure being increased first and then the temperature, whereas at the end of the operation, the pressure is released after cooling.

The tetrahedron apparatus consists of four rams in a tetrahedral arrangement, each of which is driven by its own hydraulic system. With a suitable conical arrangement of three rams and application of the pressure to the fourth, however, a normal high-pressure press can also be used for laboratory purposes[14]. Reference should also be made to an apparatus developed by a Japanese group[15], again on the basis of the multiaxial principle, with a hexahedral arrangement of rams; this apparatus has the advantage that it is self-adjusting.

The synthetic diamonds generally have dimensions of a few tenths of a millimeter and are therefore suitable only for industrial purposes at present. Nevertheless, about 40% of the industrial requirements are supplied by synthetic diamonds. The main producers are General Electric and De Beers. Diamonds that satisfy the size and quality criteria for jewelry stones are also produced in exceptional cases, but at a cost that could never be recovered. Thus 3/4 ct water-clear diamonds having the face combination (111)+(100) have been obtained at General Electric[16].

3.2. Corundum (Al_2O_3)

The industrial production of corundum crystals is still carried out almost exclusively by the Verneuil process, which was described in Section 2.1. The fine, free-running powder required as the starting material is obtained by calcination of ultrapure ammonium aluminum alum at about 1100 °C; it consists of a mixture of α-Al_2O_3 and Al_2O_3 transition phases.

For colored stones, the transition metal oxide used for doping is added to the alum in the form of the sulfate. Concentrations of between about 0.1 and 2%, based on the oxides, are usual. The most important additive is chromium oxide, which gives the red color of ruby, though Cr_2O_3 is itself green. This behavior, which seems surprising at first sight, is explained by the slight shift of the otherwise practically unchanged Cr^{3+} absorption spectrum toward shorter wavelengths in ruby[17]. The striking color change is thus primarily physiological in origin. A mixture of TiO_2 and Fe_2O_3 is used for the blue sapphire. Less important additives are NiO (yellow), Co_2O_3 (green), CoO (blue), and V_2O_3 (alexandrite-colored).

Linde[18,19] have been producing star rubies and star sapphires since 1947, and the production of these stones was later also started by Wiedes Carbidwerk[20,21]. A small quantity (about 0.3%) of TiO_2 is added to the starting powder, and dissolves in the corundum lattice at the high growing temperature. Prolonged annealing of the crystals in an oxidizing atmosphere between 1100 and 1500 °C leads to supersaturation with TiO_2; thin, oriented needles of rutile separate out, and these cause the asterism.

Only a small proportion of the synthetic corundums are intended for the jewelry industry, in which mainly colored crystals are used. The crystals for industrial use, on the other hand, are mostly colorless, apart from laser rubies and the traditionally red bearing stones for watches. Because of their excellent mechanical and thermal properties, synthetic corundums are used mainly as bearings and knife edges for instruments, pickup styli, thread guides in the textile industry, high-stress optical windows, mortars, and recently scratch-resistant watch "glasses" and substrates for semiconductor components.

In the case of ruby crystals, the quality and size requirements are frequently higher for industrial purposes. Thus

for laser rubies[22], a very homogeneous distribution of the Cr ions (concentration approx. 0.05%) is required. Moreover, with lengths of up to about 300 mm, these crystals must contain few dislocations, be free from mechanical stresses and scattering centers, and be strictly oriented (0°, 60°, or 90° between the *c* axis and the rod axis). The required uniformity of growth is achieved in particular by automation of the Verneuil process[23,24]. Shapes different from the usual boule or rod shape can be produced by appropriate movement of the seed crystal. With a crystal rotating perpendicular to the axis of the flame, one obtains circular disks (diameter about 80 mm), while eccentric rotation of the crystal gives tubes[25–28].

The Verneuil industry is concentrated mainly in Europe, apart from Linde (Union Carbide) in the USA, where production was started in 1940 because of the war. Important manufacturers include Djevahirdjian, Sadem, and Swiss Jewel Co. in Switzerland, Baikowski and Rubis synth. des Alpes in France, and Wiedes Carbidwerk in the German Federal Republic.

Attempts have also been made to grow corundum by other methods. Special mention should be made of the Czochralski process, which was described in Section 2.2, and which, at best, may offer an economical alternative to the Verneuil process. On grounds of cost, however, it is confined at present to laser rubies, which are produced by several firms and laboratories[29–32] with good results.

The EFG (edge-defined, film-fed growth) process, which was recently developed by *LaBelle et al.*[33–35], and which is partly based on the Czochralski principle, seems very promising. An important feature of this method is a molybdenum tool situated in the Al_2O_3 melt, the top edge of the tool projecting above the surface of the melt in the crucible, but still being covered with a film of melt because of the surface tension. This film is continuously replaced during crystallization, which takes place immediately above it, so that the growth front always remains in the same place. Figure 5 illustrates the arrangement for a tube. The shape

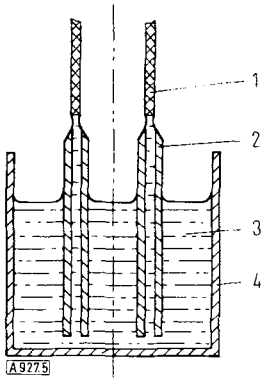

Fig. 5. EFG process after *LaBelle et al.* [33–35] for growing profiled single crystals, *e.g.* tubes: 1, tubular corundum crystal; 2, molybdenum tool; 3, Al_2O_3 melt; 4, molybdenum crucible.

of the crystal is determined by the design of the tool, and in addition to filaments, rods, and strips, single crystals with practically any desired profile can be produced from usually colorless corundum by the EFG process, examples being square tubes or tubes with several bores. The lengths reached are up to 115 m in the case of filaments and 150 cm for other profiles, the latter having transverse dimensions of up to 25 mm. The growth rates are surprisingly high, and exceed the values normally found in the Czochralski process by a factor of more than 100; they are between 2.5 and 5 cm/min, and even up to 20 cm/min for crystals oriented along the *c* axis.

Another process for growing corundum from the melt[36] is reminiscent of *Stöber*'s method[37]. The aluminum oxide is melted in a vacuum furnace with a graphite heating element (Tammann furnace). The crucible, which is made of molybdenum, is cooled at the center of the base by an adjustable stream of helium gas. The crystallization begins here and proceeds toward the wall of the crucible and upward. The monocrystalline growth can be reinforced by the use of a seed. The largest disk-shaped crystal obtained in this way has a diameter of 150 mm and a thickness of 68 mm.

The last method to be mentioned for growth from the melt is vertical zone melting, which is of limited interest in connection with laser rubies. The zone can be melted by the focused light of CO_2 lasers[38], arc lamps[39], or xenon lamps[40]. The crystals are considerably smaller than the rods produced by the Verneuil and Czochralski processes.

The natural genesis conditions are most closely approached in growth from fluxes or hydrothermal growth. Crystals obtained in this way are always idiomorphic, and are more difficult to distinguish from natural crystals. Because of the disadvantages mentioned earlier, however, these methods are of little importance for the production of corundum, which is easy to grow from a melt. It is reported that Chatham in San Francisco is to market rubies crystallized from fluxes that are of outstanding quality for jewelry. Mixtures of PbO, PbF_2, and B_2O_3 have proved suitable as fluxes[41–43]. The temperature range for growing extends from 1250 to 950 °C, and the cooling rate is about 1 °C/h. The hydrothermal synthesis of corundum[44,45] is best carried out in 1 M to 2 M K_2CO_3 or Na_2CO_3 solutions between 400 and 500 °C, and has led to crystals measuring up to 60 mm.

3.3. Spinel ($MgAl_2O_4$)

The industrial synthesis of spinel is carried out exclusively by the Verneuil process[46], the production conditions being almost the same as for corundum. Since the spinel with the stoichiometric composition presents great difficulties, a molar ratio of Al_2O_3:MgO greater than 1, and generally equal to 3.5, is always used to facilitate growth. An excess spinel of this type may be formally regarded as a solid solution of $MgAl_2O_4$ and γ-Al_2O_3, which also crystallizes in the spinel lattice. The powder is prepared from ammonium aluminum alum and magnesium sulfate. The spinel boules often have an approximately square cross-section, whereas the corundum pears are rarely polygonal.

Since jewelry is by far the predominant use of synthetic spinels, the color is important. The current aim is to simulate the colors of precious stones that cannot yet be

synthesized, such as aquamarine and tourmaline. As in the case of corundum, the crystals are doped with bivalent and trivalent ions of the transition metals, which can occupy tetrahedral magnesium sites or octahedral aluminum sites in the spinel lattice. An interesting phenomenon is the incorporation of Cr^{3+}[17], which produces the visual color red in the stoichiometric spinel, but leads in stages to pure green in the excess spinel beyond a molar ratio of 3. Thus the natural (stoichiometric) spinel containing chromium is red, whereas the usual synthetic spinel containing chromium is the same green as Brazilian tourmaline.

Spinel has also been successfully grown in the laboratory by the Czochralski method[47] and from PbO/PbF_2 mixed melts[41]; crystals having the stoichiometric composition can be obtained in this way.

3.4. Beryl ($Al_2Be_3Si_6O_{18}$)

The synthesis of beryl, for understandable reasons, is applied mainly to the most valuable variety, the chromium-containing emerald. According to general experience, beryl melts incongruently at about 1475 °C, and on slow cooling, it does not form a melt having the same composition even as a subsidiary phase[48]. The synthesis of beryl from the melt mentioned by *Gentile et al.*[49] and *Wilson*[50] is therefore extremely doubtful. The only growing methods worth considering are the methods based on crystallization from solution (Sections 2.3 and 2.4).

Large emerald crystals measuring up to 30 mm were first grown at the former I. G. Farbenindustrie, and were called Igmeralds. Production was stopped in 1942 because of the war. The process is based on the diffusion of the oxide components into a lithium molybdate melt with reaction to form beryl; BeO and Al_2O_3 are situated at the base of the crucible, and SiO_2 glass floats on the melt[51]. Of the present-day producers, Chatham (San Francisco), Gilson (Pas de Calais), and presumably also Zerfass (Idar-Oberstein) also use melts containing fluxes, as can be deduced from comparative investigations[52]. Their precise growing conditions are kept secret. The literature[52-55] contains reports of numerous fluxes, among which the systems Li_2O-MoO_3, Li_2O-WO_3, and PbO-V_2O_5 appear to be particularly suitable. The temperature range extends from about 700 to 1200 °C. The crystallization is carried out either by slow cooling or by transport in a temperature gradient.

It is only in the last few years that good results have been obtained in the hydrothermal synthesis of emerald. *Lechleitner* (Innsbruck) first confined his attention to the application of strongly colored epitactic emerald layers to previously polished, pale natural beryls, but since 1962 he has also been producing completely synthetic emeralds. Linde[52,56] also uses the hydrothermal process, with temperatures of 500 to 600 °C and pressures of 1000 to 1500 b. NH_4Cl is very effective as a mineralizer in concentrations of up to 11 mol/l. In another publication[57], 5% solutions of H_3BO_3 or $Na_2B_4O_7$ are reported to be advantageous. The pressure and temperature conditions correspond to those mentioned above.

3.5. Quartz (SiO_2)

Apart from the varieties amethyst, citrine, and smoky quartz, quartz finds very little use as a precious stone. On the other hand, colorless quartz is of great industrial importance for piezoelectric applications, particularly as resonators. About one third of the requirement for this purpose is currently supplied by synthetic crystals.

Because of the phase transition to β-quartz at 575 °C, the growing of quartz must be carried out below this temperature; the only method that can be used is therefore the hydrothermal method, which can now be carried out industrially[58-61]. Autoclaves up to 3 m high (capacity about 500 l) are used. The temperature is about 400 °C, the packing is about 85%, and the pressure is therefore about 1500 b. 1 N NaOH or Na_2CO_3 is used as the mineralizer. Since the growth rate is greatest in the direction of the *c* axis, basal plates are generally used as seed crystals. In this way, 40 crystals weighing more than 1 kg each can be grown in one autoclave within three weeks. The synthetic quartz crystals offer important advantages in preparation, since they are always untwinned and of uniform shape and size, so that the examination and orientation required for natural material is unnecessary.

Colored quartzes can be grown hydrothermally with suitable doping, particularly with cobalt (blue)[62,63] and iron (amethyst, green, yellow)[64-66], but little use has so far been made of these in the jewelry industry.

4. Jewelry Stones

4.1. Rutile (TiO_2)

Natural rutile crystals are always dark because of the presence of impurities, and are therefore unsuitable for use in jewelry. However, pure TiO_2 crystals were grown by the Verneuil process in 1948 at the National Lead Co.[67] and Linde. Though the flame is operated with an excess of oxygen, *e.g.* by an additional external supply of O_2 in a tricone burner[68], the crystals obtained are black because of a deficiency of oxygen. On subsequent annealing at lower temperatures in oxygen, however, they become almost colorless, with a very light yellow hue.

The fact that synthetic rutile has a higher refractive index and dispersion than diamond suggests its use as a substitute for diamond. On the other hand, the resulting play of color is so striking that large cut stones look artificial or even trashy. Moreover, the edges of the facets look washed-out because of the high birefringence.

4.2. Strontium Titanate ($SrTiO_3$)

Strontium titanate, which is structurally a perovskite, is even more favorable than rutile for the replacement or simulation of diamond. It is completely colorless and optically isotropic, and its refractive index agrees very closely with that of diamond; only the dispersion is too high. Like

rutile, however, the hardness (approx. 6) leaves something to be desired.

Strontium titanate is grown by the Verneuil process, and as in the case of rutile, the oxygen deficit must be made up by subsequent annealing in oxygen[69]. The only manufacturer is the National Lead Co., which markets the $SrTiO_3$ crystals under the name Fabulite.

4.3. Yttrium Aluminum Oxide ($Y_3Al_5O_{12}$)

Yttrium aluminum oxide, whose formula is $Y_3Al_5O_{12}$, has the garnet structure, and is therefore often referred to as YAG (yttrium aluminum garnet). $Y_3Al_5O_{12}$ is derived from normal garnet $M^{II}_3Al_2Si_3O_{12}$ by coupled replacement of the bivalent cation by yttrium and of the silicon by aluminum, the yttrium occupying dodecahedral sites and the aluminum octahedral and tetrahedral sites. (For further information on the crystal chemistry of garnets, see [70].)

YAG was first used in industry. Crystals doped with lanthanides, particularly with neodymium, are suitable for lasers in continuous operation[71]. Because of isomorphism, YAG crystals can also be used as substrates for ferrimagnetic garnets of the type $Y_3Fe_5O_{12}$. Even better is $Gd_3Ga_5O_{12}$, whose lattice constants are the same as those of $Y_3Fe_5O_{12}$[72].

Now that economical growth is possible by the Czochralski process, yttrium aluminum garnet is also used in jewelry applications, where its relatively high hardness of about 8.5 is advantageous. Though the refractive index is not very high, YAG has been offered by Linde in recent years as a substitute for diamond. Colored crystals can be obtained by the incorporation of lanthanide ions into yttrium sites or of transition metal ions into aluminum sites.

The best growing method is the Czochralski method[31,72-74], but growing from fluxes[75,76] is also possible. The conditions are similar to those for growing corundum in both cases.

4.4. Lithium Niobate ($LiNbO_3$)

Lithium niobate is of interest mainly because of its ferroelectric and optical properties[77]. However, its high refractive index and strong dispersion suggests that it might also be used as a jewelry stone, though its hardness (5–5.5) is not entirely satisfactory. $LiNbO_3$ crystals are grown exclusively by the Czochralski technique. Very attractive colors can be obtained by the addition of oxides of the transition metals, particularly Cr_2O_3 (green), Fe_2O_3 (red), and CoO (blue)[78].

I am very grateful to Mr. P. Balmer of Djevahirdjian for his valuable advice and remarks. I am also grateful to Union Carbide for further advice.

Direct Quantitative Photometry on Thin Layer Chromatograms

By Ute Hezel[*]

The principal methods for the direct photometric evaluation of thin layer chromatograms are discussed with the aid of examples. Since light is strongly scattered by TLC adsorbents, absorption measurements in reflection are preferable to transmission measurements. In the reflection measurements, an approximation method for the Kubelka-Munk function leads to satisfactory straight calibration lines. The working range for quantitative reflection measurements is in the µg range, and the detection limit is of the order of 10^{-8} g. The standard deviation for spots of equal concentration is less than $\pm 1\%$. The signal-to-background ratio is improved by simultaneous measurement of reflection and transmission. The measurement of diminution in fluorescence ("fluorescence quenching") is found to be less sensitive than the reflection at the absorption maximum. However, combined measurement of the reflection and the diminution of fluorescence gives an increase in sensitivity as compared to pure reflection measurements. As in solution photometry, fluorescence measurements are generally much more sensitive than absorption measurements. The working range is normally in the ng region, and the detection limit is around 10^{-11} g. All the investigations described in this paper were carried out on the Zeiss chromatogram spectrophotometer.

1. Introduction

Since the development of thin layer chromatography (TLC) into a microseparation method that is widely used in all fields of chemistry, there has been a growing need for a quantitative investigation of TLC spots. Purely visual, subjective comparison of the spots, whether according to intensity of color or fluorescence intensity[1-4] or simply according to spot size[5], gives only an accuracy of at best 10—20%. A possible objective method is to scrape the individual spots from the plate, elute the substances from the stationary phase, and determine them by absorption photometry or fluorimetry. An accuracy of about 3% can be achieved by this method[6]. It has the disadvantage, however, that about 50—100 µg of substance per spot must be applied in order to attain a normal sensitivity and this accuracy; with quantities as large as these, the plate is often supersaturated, and one obtains badly separated, tailed spots. Moreover, the scraping and elution are time-consuming and subject to interference, and cannot be carried out accurately for overlapping spots[7]. These difficulties can be avoided if the spots are evaluated on the plate itself by absorption photometry or fluorimetry; one then speaks of "*in situ*" measurements[8-13].

2. Absorption Measurements in Incident Light (Reflection)

TLC spots appear colored because they absorb a certain characteristic range of wavelengths from the incident polychromatic visible light. Less light is therefore reflected than from the white, non-absorbing background. This decrease in reflection as a result of absorption in the visible and also in the UV region can be used for the quantitative evaluation of the TLC spots. The relation between the degree of reflection and the concentration is not linear, but is best described by the Kubelka-Munk function[14-17]:

$$\frac{(1-R_{abs})^2}{2R_{abs}} = \frac{\varepsilon \cdot c}{s} = \frac{k}{s}$$

R_{abs} = absolute reflection
ε = extinction coefficient
c = concentration
s = scattering coefficient
k = absorption coefficient

For reflection measurements of this kind, the theory demands a uniform distribution of the sample within the measuring area. To satisfy this condition for measurements on TLC spots (here the concentration is greatest in the center), one can use a small measuring area (*e.g.* 1 mm²) in relation to the spot size. The total quantity of substance in a spot is then found by moving the spot in a meandering fashion over the measuring area. Care must be taken to ensure that each part of the spot is actually measured exactly once, *i.e.* that no part is measured twice or not measured at all. After this scanning operation, the experimental values are converted into Kubelka-Munk values and added. This gives a satisfactory straight calibration line, as shown in Figure 1, curve 1, for 0.1—2.0 µg of Sudan Red.

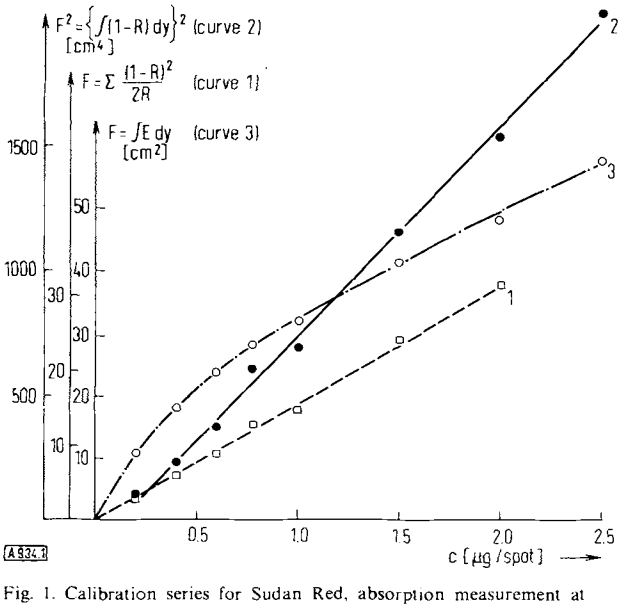

Fig. 1. Calibration series for Sudan Red, absorption measurement at $\lambda = 500$ nm.
Curve 1: reflection, point measurement and evaluation by means of the Kubelka-Munk function; curve 2: reflection, scanning with measuring slit and evaluation with the square of the area; curve 3: transmission, scanning with measuring slit and evaluation with the area in extinction units.

However, this method is very time-consuming, and efforts were therefore made to find a simplification that could be used in practice. If the TLC spots are scanned with a measuring area in the shape of a slit whose width is adjusted to correspond to the dimensions of the spot, one obtains *e.g.* the curve shown in Figure 2 for the reflection as a function of position. The square of the area between this curve and the baseline is plotted *versus* the concentration. Good straight calibration lines can be obtained in this way in the µg range (*e.g.* Fig. 1, curve 2)[18-23]. The concentration range for which this approximation is valid is perfectly adequate in practice, and generally covers approximately one power of ten. We thus have a method whose deviations from linearity (correlation coefficients generally >99.5%) are smaller than the fluctuations due to plotting and to the chromatographic parameters. The overall error of the method is reported to be 3—4%[24]. The area between the reflection-location curve and the baseline can be closely approximated in most cases by a triangle. As can be seen in Figure 2, this graphic integration is reasonable even if the baseline is sloping. Correction for the reflection background, which varies slightly from spot to spot, can also be easily made by normalization of the interpolated average reflection background R_u at the spot to 100% reflection:

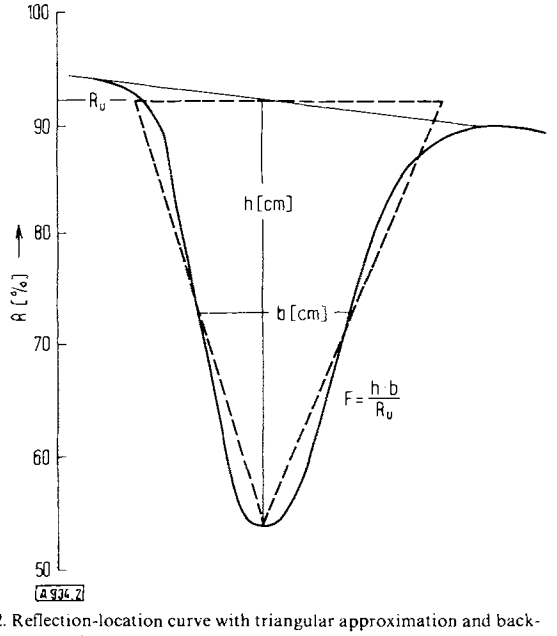

Fig. 2. Reflection-location curve with triangular approximation and background correction.

$$\text{Area } (F) = \frac{\text{Height } (h) \cdot \text{half band width } (b)}{\text{Average reflection background } (R_u)}$$

An important point here is that unlike in the double-beam method discussed below, the interpolated reflection background at the spot itself is taken into account. It has therefore been possible to achieve a standard deviation of 0.8% for the single value by this method (Table 1).

To eliminate background fluctuations, attempts have been made to apply the double-beam measuring principle, which is recommended in solution photometry, to measurements

Table 1. Reproducibility of eight Sudan Red spots containing 2 μg each on Merck commercial silica gel plates, solvent: benzene, measuring wavelength 500 nm.

h [mm]	b [mm]	R_u [%]	$F=\frac{h \cdot b}{R}$ [mm²]
107	36.5	94.5	41.3
107	36.5	94.5	41.3
107	36.5	93.5	41.8
108	36.5	94.5	41.7
107.5	36.5	94.5	41.5
105.5	36.5	93	41.4
106	36.5	93.5	41.4
104	36.5	93	40.8
		mean value	41.4
	standard deviation of single value		0.3 ≙ 0.73%
	standard deviation of mean value		0.1 ≙ 0.25%

on TLC plates[25-27]. However, this is effective only if the background in the track of the spot is identical with that in the reference track. This requirement is not satisfied in particular at the edge of the plate; differences of the order of 2 to 3% are not unusual. Such differences appear in full in the experimental value as systematic errors, and adversely affect the reproducibility in comparison with that of single-beam measurements. Moreover, the measuring track and the reference track must be separated from each other by lengthwise grooves in the separation direction. This is to prevent the TLC spots from diffusing into the reference track at higher R_f values. The result is a substantial change in the chromatographic conditions. In the first place, the spots become elongated, and the effectiveness of the separation thus deteriorates; secondly, unsymmetrical and dumb-bell shaped spots readily appear, probably as a result of interference with evaporation by the grooves, and the reproducibility and effectiveness of separation are further decreased. Moreover, the need for additional reference tracks reduces the sample capacity per plate.

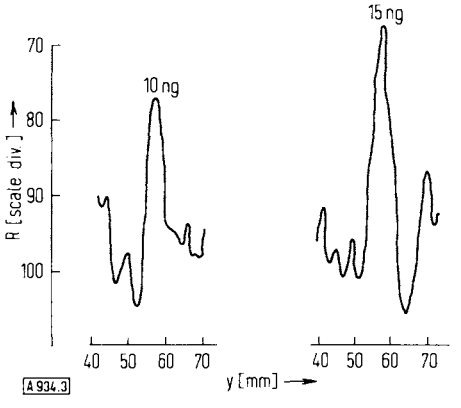

Fig. 3. Detection limit for caffeine on Merck commercial silica gel plates (without fluorescence indicator). Solvent: benzene/ether/glacial acetic acid (40:50:10); height of ascent 10 cm; reflection measurement, $\lambda = 275$ nm, measuring area 2×3.5 mm².

With single-beam reflection measurements, for example, 10 ng of caffeine can be detected directly at $\lambda = 275$ nm (Fig. 3). The signal corresponds to a change in reflection from 100% to approximately 99%. This small effect can be missed in the double-beam method because of the differences in the measuring and reference beams, which are of the same order of magnitude.

3. Absorption Measurements in Transmitted Light

It seemed reasonable to suppose that the transmission method commonly used in solution photometry should also be suitable for use, preferably in a double-beam arrangement, for the quantitative evaluation of TLC plates[25-27]. Unlike true solutions, however, TLC plates are strongly scattering media, for which the Beer-Lambert law is not obeyed. Figure 1, curve 3, shows clearly, for the case of Sudan Red, that the extinction-concentration line is strongly curved, particularly in the low concentration range; it can be approximated by straight lines only over narrow concentration ranges, and since these lines do not pass through the origin, they do not reproduce the linear relation between the extinction E and the concentration c that one would expect if the Beer-Lambert law were valid ($E = \varepsilon \cdot c \cdot d$). An approximation formula that straightens this curvature can be deduced from the Kubelka-Munk theory[27]. However, the empirically determined correction parameters are valid only for silica gel of a given quality, and are therefore not universally applicable. Reflection measurements with evaluation of the square of the area, on the other hand, give a satisfactory straight calibration line in the same concentration range (Fig. 1, curve 2). Above all, however, transmission measurements on TLC plates are possible only in the visible region, since most of the support materials used, such as glass or aluminum foil, completely absorb the measuring light in the UV, and since the layer itself has a considerable UV absorption, particularly in the short-wave UV range.

A further argument in favor of reflection measurements is provided by comparison of the signal-to-background ratios for measurements in reflection and in transmission. Faults in the plate, such as differences in grain size and in layer thickness, lead to greater background fluctuation in transmission measurements than in reflection measurements[7] (Fig. 4). Moreover, the evaporation of the solvent from the surface of the TLC plate during development leads to a flow of solvent, which pushes the spot against the surface[28] (Fig. 5). Reflection occurs almost exclusively on the surface layer, so that the relative concentration of the substance in the measuring area is greater than in transmission measurements, in which the total thickness of the adsorbent layer is included in the measurement. This is why the measured signal in transmission measurements is only insignificantly stronger than in reflection measurements, contrary to theoretical expectations[25,27]. Because of the lower background deviations, reflection measurements always give a better signal-to-background ratio than transmission measurements. It can be seen from Figure 6 that *e.g.* for Butter Yellow at $\lambda = 440$ nm on commercial silica gel plates, the signal-to-background ratio in reflection is better by a factor of 1.7 than in transmission.

Because of the strong background fluctuation in transmission measurements, a background correction is a pressing need. The double-beam method is of little value in this respect, since the background fluctuations in the paths of the measuring beam and of the reference beam are by no means identical. With a difference of *e.g.* 2% (which is quite possible) in the transmission background between

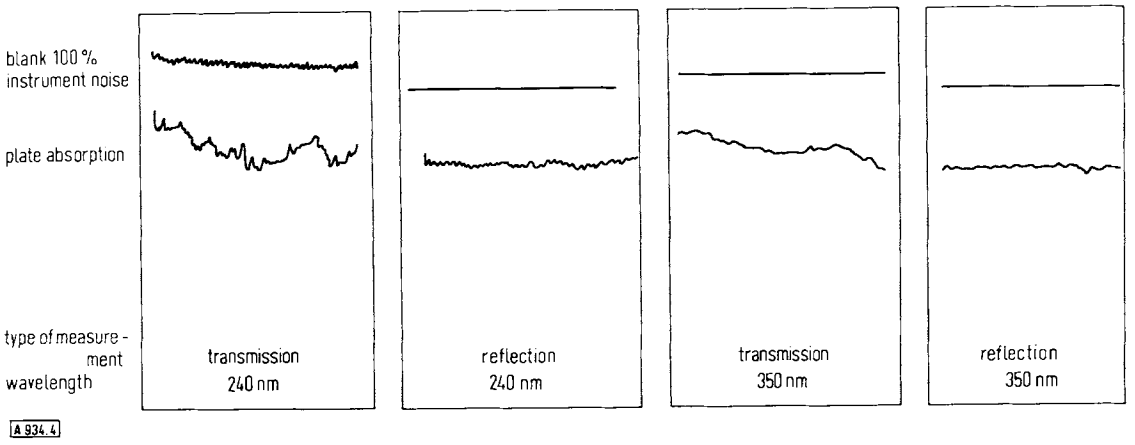

Fig. 4. Comparison of the plate background for reflection and transmission. Measurements on the same track, silica gel layer on quartz supporting plate.

the measuring beam and the reference beam in a double-beam arrangement, this difference appears additively in the result, and hence with an absolute value of $\Delta E = 0.009$.

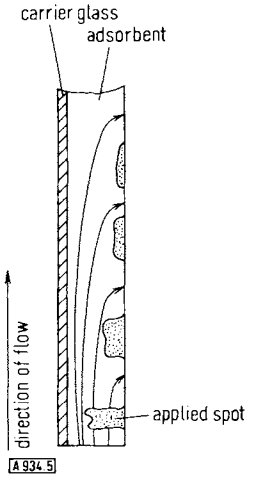

Fig. 5. Schematic representation of the spot penetration depth as a function of the R_f value of the spots [28].

This leads to considerable relative errors, particularly at low concentrations. For 0.2 µg of Sudan Red, one obtains a maximum extinction of about 0.1, and an error of 9% would therefore have to be expected in the above example.

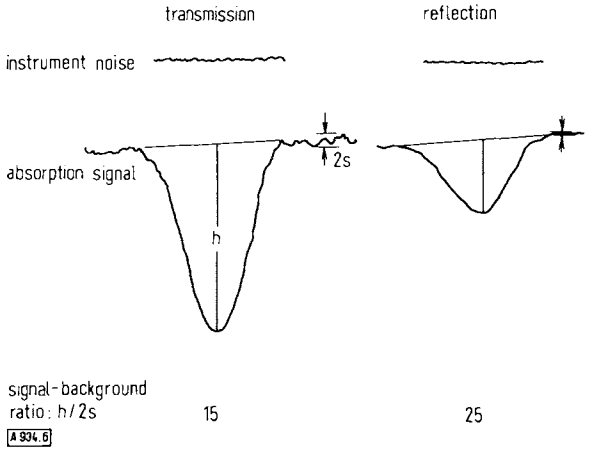

Fig. 6. Comparison of the signal-to-background ratios in reflection and in transmission for 1.25 µg of Butter Yellow at $\lambda = 440$ nm.

4. Determination of Absorption by Simultaneous Reflection and Transmission Measurements[29]

As can be seen from Figure 7, the detection limit in the direct photometric evaluation of TLC plates is determined not by the equipment noise but by the inhomogeneities in the adsorbent layer, which produce differences in scattering from place to place. It is found, however, that for reflection and for transmission measurements, these fluctuations from place to place will be exactly complementary;

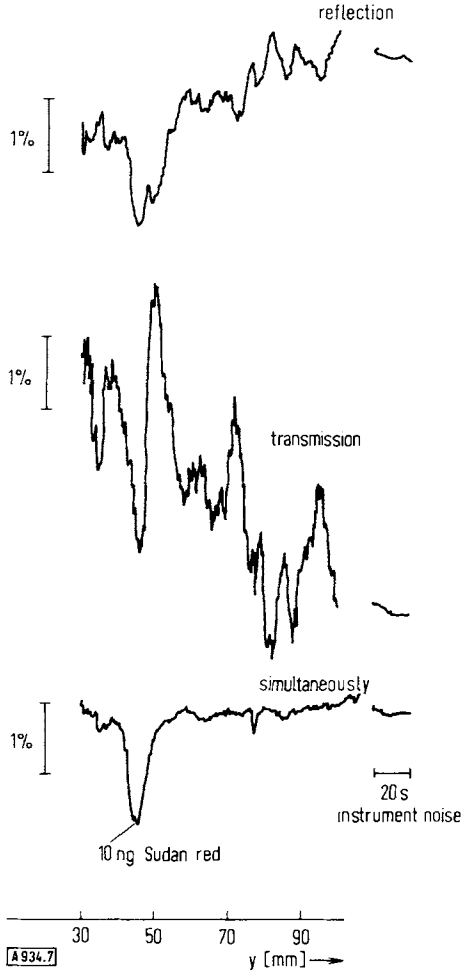

Fig. 7. Absorption measurement on 10 ng of Sudan Red on Merck commercial silica gel plate, solvent: benzene; measuring wavelength 500 nm, slit: 0.1 × 10 mm².

a decrease in transmission due to scattering on the unspotted and hence non-absorbing plate background means an increase in reflection. True absorption, on the other hand, *e.g.* due to a TLC spot, reduces the measured value both in reflection and in transmission. If the reflection signal and the transmission signal are added together, therefore, the baseline is smoothed out at a certain ratio of the magnitudes of these two signals, and at the same time the measured absorption value for the TLC spots becomes greater than in the pure reflection measurement (Fig. 7). This greatly improves the signal-to-background ratio; thus as little as 5 ng of Sudan Red can be detected directly by this method.

The quantitative evaluation of 10—100 ng of Sudan Red is shown in Figure 8. In this range of very small absorptions, the area between the absorption curve and the baseline varies linearly with the concentration.

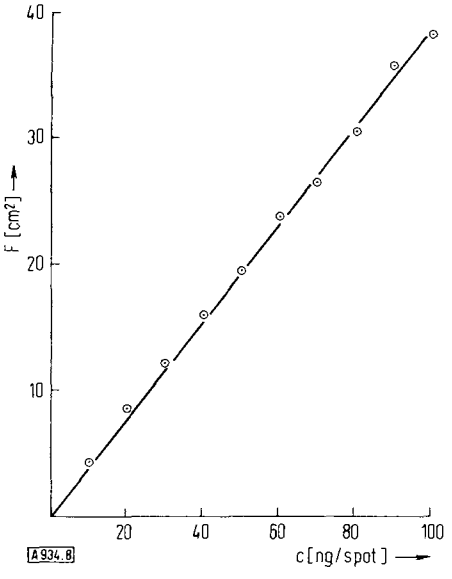

Fig. 8. Simultaneous measurement of reflection and transmission on 10—100 ng of Sudan Red; measuring wavelength 500 nm; amplification ratio reflection:transmission = 10:4, slit: 0.1 × 7 mm².

The method of simultaneous measurement is particularly effective in the visible region of the spectrum, since considerable penetration of the measuring radiation into the plate material occurs in this range.

An important feature of this method is that unlike in the double-beam method, the background is corrected at the actual point of measurement as a result of the retention of the single-beam principle.

5. Indirect Absorption Measurements by Diminution of Fluorescence in Reflection and Transmission

The diminution of fluorescence (often erroneously referred to as fluorescence quenching) is used in the visual investigation of TLC spots that absorb only in the UV region. This diminution of fluorescence is not a quenching phenomenon but an absorption effect[30, 31], generally for the 254 nm mercury line. The effect will be discussed below for the usual F_{254} plates (Fig. 9).

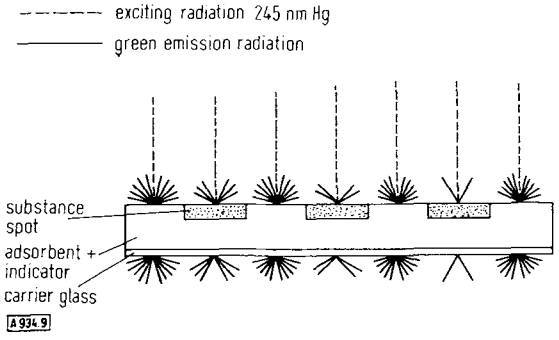

Fig. 9. Schematic representation of the diminution of fluorescence.

The adsorbent layer contains a fluorescence indicator, which fluoresces green on excitation (with 254 nm mercury line). If there is a spot on the TLC plate that absorbs the 254 nm radiation, it acts as a filter; this means that the quantity of exciting light falling on the indicator is reduced, with the result that less fluorescence light is produced at this point. The UV-absorbing spot therefore appears darker against the intensely green fluorescent background. The filter effect becomes stronger with increasing concentration of the substance, so that the spots appear correspondingly darker. This effect can also be used for the direct quantitative determination of UV-absorbing substances.

For non-scattering objects, the decrease of the green fluorescence, in transmission, would obey the Beer-Lambert law. The glass support of the TLC plate generally acts as a barrier filter for the exciting radiation in transmission measurements. The result of such a measurement is shown in Figure 10, curve 1, in which $\int E\,dy$ for the individual

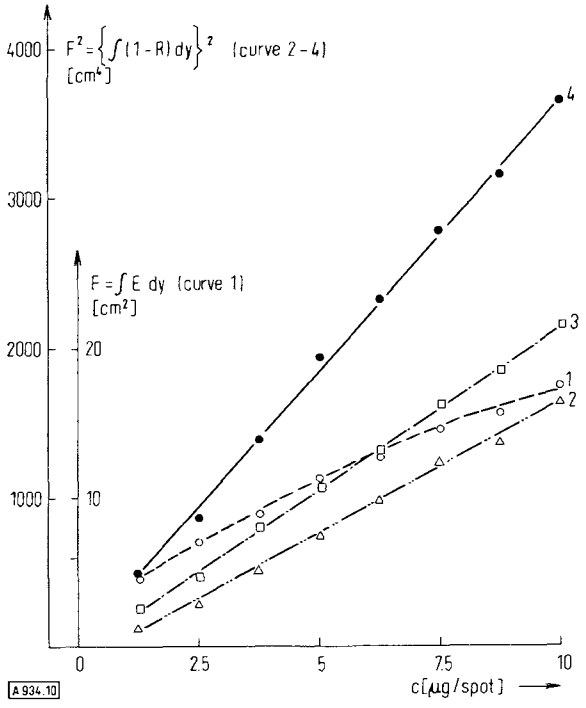

Fig. 10. Calibration series for caffeine, absorption measurement. Curve 1: diminution of fluorescence at 254 nm Hg in transmission, evaluation from the area in extinction units; curve 2: diminution of fluorescence at 254 nm Hg in reflection, evaluation from the square of the area; curve 3: reflection at 275 nm, evaluation from the square of the area; curve 4: combined reflection and diminution of fluorescence at 275 nm, evaluation from the square of the area.

spots is plotted *versus* the concentration. As in transmission measurements in the visible region of the spectrum (Fig. 1, curve 3), it can again be seen that the Beer-Lambert law is not obeyed because of scattering, and curved calibration lines are obtained. On the other hand, if the diffusely reflected fluorescent light is measured, a straight calibration line is again given by a plot of the square of the area (Fig. 10, curve 2). The scattered exciting radiation is cut off in this case by a secondary filter. As expected transmission measurements again offer no advantages over reflection measurements for evaluation based on the diminution in fluorescence. It still remains to check whether the measurement of the diminution in fluorescence is advantageous in comparison with absorption measurements in reflection.

The diminution in fluorescence measures only the absorption of the TLC spots at the wavelength at which the indicator is excited, *i.e.* generally at 254 nm. Normally, for substances whose absorption maximum does not happen to correspond to this wavelength, the measurement of diminution in fluorescence means a loss in sensitivity in relation to reflection measurement at the wavelength of maximum absorption. This effect is demonstrated in Figure 11, curves 1 to 4, for a mixture of drugs, whose

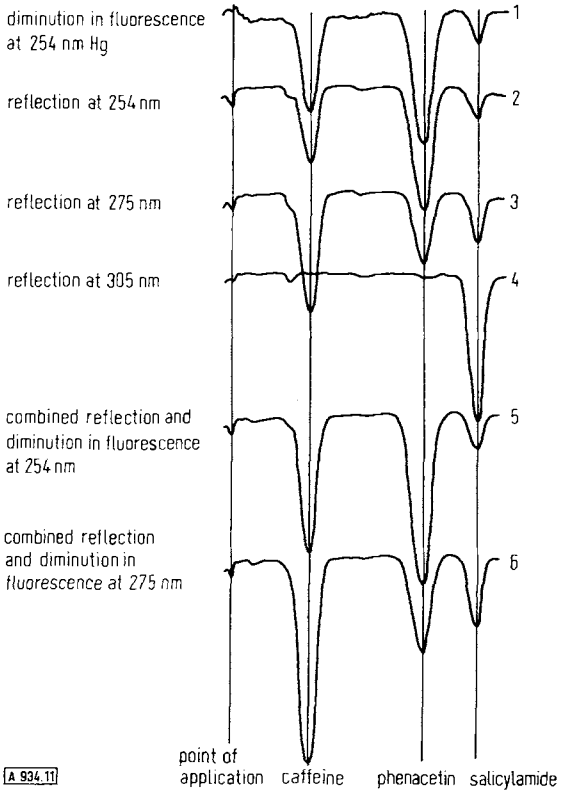

Fig. 11. Absorption-location curves for a mixture of drugs in reflection, diminution of fluorescence, and combined reflection and diminution of fluorescence.

principal components are caffeine ($\lambda_{max} = 275$ nm), phenacetin ($\lambda_{max} = 250$ nm), and salicylamide ($\lambda_{max} = 305$ nm) (spectra: Fig. 12). The reflection-location curves measured at various wavelengths are compared with the curve obtained by measurement of the diminution of fluorescence. The loss of sensitivity is particularly pronounced in the case

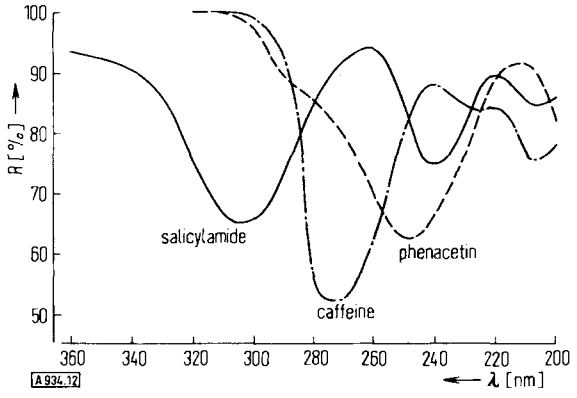

Fig. 12. Reflection spectra for 4 µg of caffeine, phenacetin, and salicylamide, based on silica gel.

of salicylamide. The value recorded on measurement of the diminution of fluorescence with excitation at 254 nm is only one sixth of the value recorded by a reflection measurement at the absorption maximum of 305 nm.

Determinations based on the diminution of fluorescence are therefore comparable with measurements using a filter photometer that allows measurements at only one wavelength, *e.g.* 365 nm, for all colored substances.

Though the measurement of the diminution of fluorescence offers no advantages as such, F_{254} plates are preferred in practice, since they allow a fast visual check on the chromatography. In addition to the less effective method based on the diminution of fluorescence (Fig. 10, curves 1 and 2), there are two methods for the quantitative evaluation of samples of this type.

The first method is monochromatic detection of the reflection with polychromatic radiation. In this case the measured value is practically unaffected by the fluorescence of the indicator. This pure absorption measurement in reflection satisfies the Kubelka-Munk law and is evaluated as the square of the area, as explained earlier (Fig. 10, curve 3; Fig. 11, curves 2—4).

The other method is to expose the plate to monochromatic radiation at the wavelength of the characteristic UV absorption of the substance in question. This light is reflected. Since the F_{254} plates not only exhibit fluorescence on excitation with 254 nm light, but can be excited over the entire UV range down to about 235 nm, this measuring arrangement also leads to the production of long-wave fluorescent radiation, which also falls on the photomultiplier. The reflected and the fluorescent light are both weakened by absorption in the spot in accordance with the Kubelka-Munk law. Since the absorption occurs at the same wavelength in both cases, the extinction coefficients ε are identical, but the scattering coefficients s for the short-wave reflected radiation and the long-wave fluorescent radiation are different. For this reason, combined measurement of the reflection and the diminution of fluorescence gives a stronger measured signal than pure absorption measurements in reflection. Theoretically the combined reflection and fluorescence measurements do not satisfy the Kubelka-Munk function. It is found in practice, however, that satisfactory straight calibration lines can also be obtained for this method by the approximation based on the square of the area (Fig. 10, curve 4).

6. Fluorescence Measurements

Fluorescent substances can also be investigated directly on the TLC plate. Just as in solution, the fluorescence intensity is directly proportional to the quantity of substance in the spot if the absorption is sufficiently low. A uniform distribution of the substance is no longer necessary, and the total fluorescence of the spot can be recorded all at once[32]. This can be achieved with a circular measuring area slightly larger than the TLC spots to be investigated.

In analogy with fluorescence photometry in solution, the fluorescence intensity obeys the law[13]:

$$I_{fl} \sim I_0(1-10^{-\varepsilon c d})$$

I_{fl} = fluorescence intensity
I_0 = intensity of incident light
ε = extinction coefficient
c = concentration
d = effective optical path in substance

For small extinctions $E=\varepsilon \cdot c \cdot d$ (roughly for $E<0.02$), the above equation can be approximated[13,32-35], within the accuracy of the measurements, by

$$I_{fl} \sim E \sim c$$

This linear relation between the fluorescence intensity and the concentration is used in quantitative fluorimetry. The validity of the laws can be demonstrated *e.g.* for Rhodamine B. The maximum excitation occurs at 546 nm Hg, and the emission maximum is found at 580 nm. Figure 13 shows calibration curves for 0.02—4 µg of Rhodamine

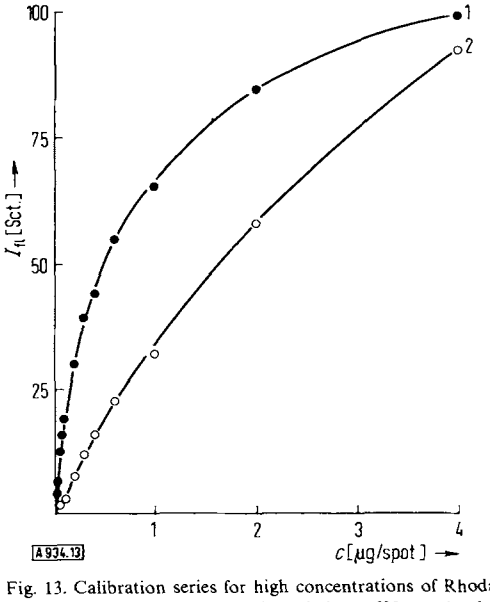

Fig. 13. Calibration series for high concentrations of Rhodamine B on excitation with 546 and 365 nm Hg, emission at 600 nm, circular measuring area.
Curve 1: excitation with 546 nm Hg; curve 2: excitation with 365 nm Hg.

B for excitation with various mercury lines. On excitation with 546 nm light, the linear range extends to approximately 0.1 µg per spot. For 365 nm light, the extinction coefficient, and hence also the extinction, of Rhodamine B is lower by a factor of about 10 than at 546 nm. The measuring sensitivity at 365 nm is accordingly lower by a factor of 6, but the extinction is so low even for 1 µg that the linear relation is valid up to this concentration.

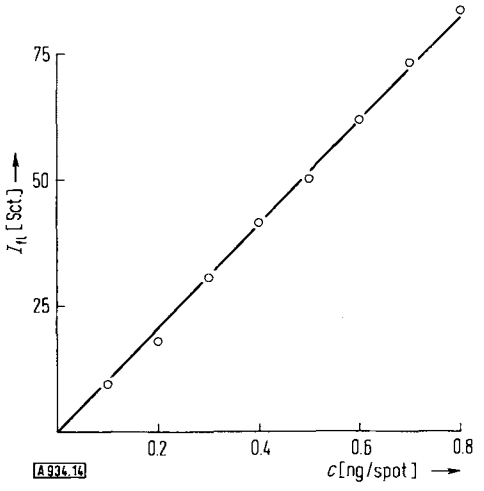

Fig. 14. Calibration series for low concentrations of Rhodamine B on excitation with 546 nm Hg, emission at 600 nm, circular measuring area.

In practice, the lower absorption is achieved with low concentrations. Thus on excitation with 546 nm light, for example, an excellent straight calibration line is obtained for 0.1—0.8 ng of Rhodamine B (Fig. 14). The detection limit is approximately 10^{-2} ng of Rhodamine B (Fig. 15).

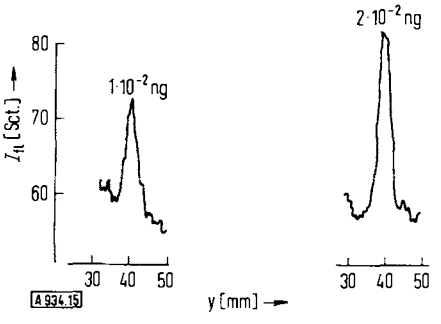

Fig. 15. Detection limit for Rhodamine B; fluorescence measurement on Merck commercial silica gel plate. Solvent: *n*-butanol/acetic acid/water (40:10:50); flow distance 7 cm; excitation at 546 nm Hg, emission at 590 nm, measuring area: $0.3 \times 6\,mm^2$.

The location resolution with a circular measuring area is limited by the diameter of the area. Measurement with a slit is therefore preferable for overlapping spots. Figure 16 shows the plot of fluorescence *versus* location as recorded with a measuring area in the form of a slit for aflatoxins B_1, B_2, G_1, and G_2. The quantitative evaluation must naturally be based on the area under the curve in this case. This gives a straight calibration line as shown in Figure 17 for aflatoxin B_1, with the aid of which it was possible to determine 1.22 ng of aflatoxin B_1/µl of sample solution with an accuracy of 4%[*].

[*] I am grateful to Mr. *Lorenzen*, Landwirtschaftliche Untersuchungs- und Forschungsanstalt, Bonn, for the aflatoxin samples.

7. Equipment

All the measurements were carried out with a Zeiss chromatogram spectrophotometer in combination with a Servogor recorder (Metrawatt) or a logarithmic integrating recorder W + W 3218 (Kontron).

The setup generally used for reflection measurements is a follows (Fig. 18a). Light from a tungsten or hydrogen lamp passes through a quartz monochromator and an achromatic imaging lens system to the sample. The light scattered here is measured at an angle of 45° with a photomultiplier. The measured value is amplified and passed to a pen recorder. The slit-shaped measuring area is produced by a 1:1 image of the entry slit of the monochromator on the sample. The slit is adjusted to the size of the spot by means of slip-in diaphragms (3.5—14 mm) fitted in the monochromator. The TLC plate is placed on a motorized stage; the chromatogram track can then be passed under the slit-shaped measuring area, and one thus obtains the reflection-location curve for the quantitative evaluation. Reflection measurements down to $\lambda = 190$ nm are possible with this arrangement.

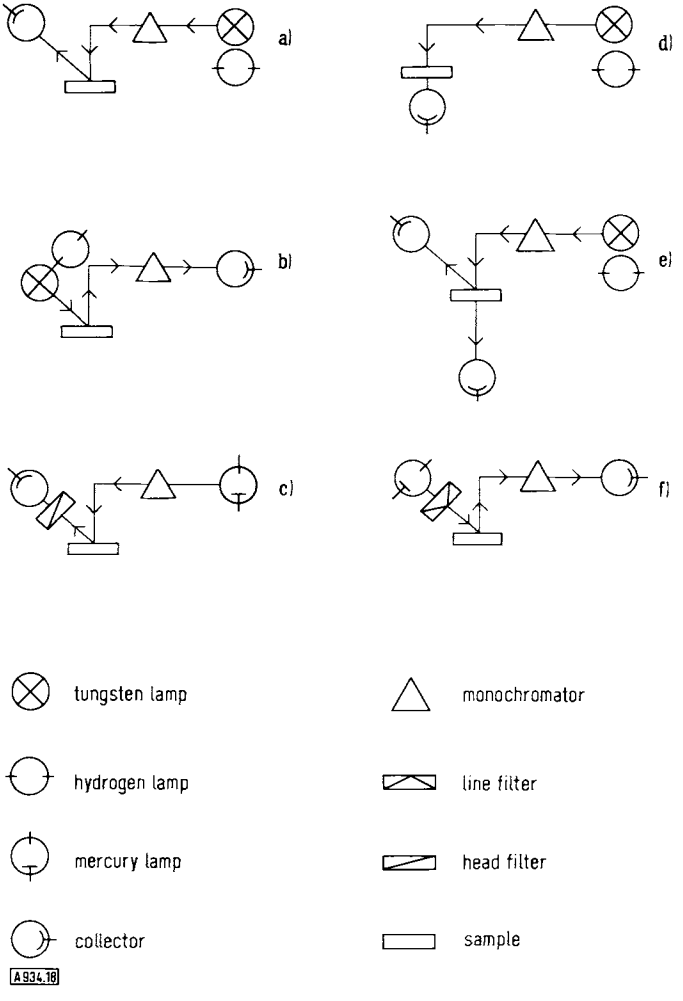

Fig. 18. The most important measuring arrangements for the Zeiss chromatogram spectrophotometer.
a) Absorption measurement in reflection and in combined reflection and fluorescence diminution; b) absorption measurement in reflection with interference by fluorescence; c) absorption measurement by diminution of in fluorescence, excitation preferably at 254 nm Hg; d) absorption measurement in transmission; e) simultaneous absorption measurement in reflection and in transmission; f) fluorescence measurement on excitation with Hg lines.

For reflection measurements where it is desirable to exclude fluorescence, *e.g.* fluorescence from the spot itself or the fluorescence of the plate background, the beam path is reversed (Fig. 18b). The sample is now irradiated with

polychromatic light, but only light of the desired reflection wavelength reaches the detector through the monochromator.

For measurement of the diminution of fluorescence (Fig. 18c), an medium-pressure mercury lamp type St 41 is fitted in the lamp-house to the right of the monochromator instead of the tungsten lamp. The Hg resonance line at 254 nm is selected with the monochromator. To cut out the exciting radiation, a secondary barrier filter ($\lambda_{barrier} \approx 460$ nm) is inserted between the sample and the detector.

For combined measurement of the reflection and the diminution of fluorescence on F_{254} plates, the same arrangement is used as for normal reflection measurements (Fig. 18a).

For transmission measurements, the sample is illuminated perpendicularly from above, and the detector is placed under the plate (Fig. 18d).

For the simultaneous measurement of reflection and transmission, the sample is again illuminated perpendicularly from above; the diffusely reflected light is measured at an angle of 45°, and the transmitted light at an angle of 0° under the sample (Fig. 18e).

For fluorescence measurements, the sample is illuminated with an Hg medium-pressure mercury lamp type St 41 at an angle of 45° (Fig. 18f). The mercury lines are selected by primary filters. An interchangeable lens in the measuring head, combined with an iris diaphragm, is used to obtain a circular measuring area, so that the total fluorescence of the TLC spot can be measured with direct integration. Only the emission radiation reaches the receiver through the monochromator. Where separation of the spots is poor, the slit-shaped measuring area is used because of its better location resolution.

8. Preparative

The caffeine/phenacetin/salicylamide mixture, Sudan Red, Butter Yellow, and Rhodamine B were chromatographed on Merck commercial silica gel plates. Merck Uvasols were used as solvents and developers. The aflatoxins were determined on Macherey and Nagel commercial silica gel plates.

The solutions were applied with a gas-tight 250 µl syringe (Hamilton) in combination with an Agla micrometer screw.

I am very grateful to Dr. W. Tausch, Oberkochen, for discussions and for his interest in the work.

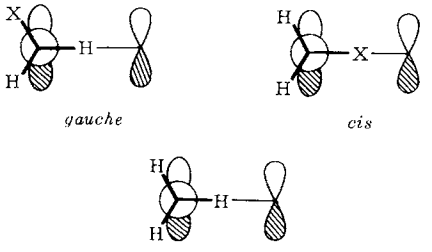
Semiquantitative Proof of Hyperconjugation[1]

By *Hartmut Schmidt* and *Armin Schweig*[*]

In recent years hyperconjugation[2] has again come much into the foreground of chemical research[3]. Using photoelectron (PE) spectra of allyl halides, we here describe the first semiquantitative proof of hyperconjugation.



Allyl halides CH_2=CH—CH_2X (X = F, Cl, Br or I) exist as *gauche* and *cis*-conformers[4]. However, because of the different populations of the two isomers, only the *gauche* form can be observed in the PE spectra[4d,e].

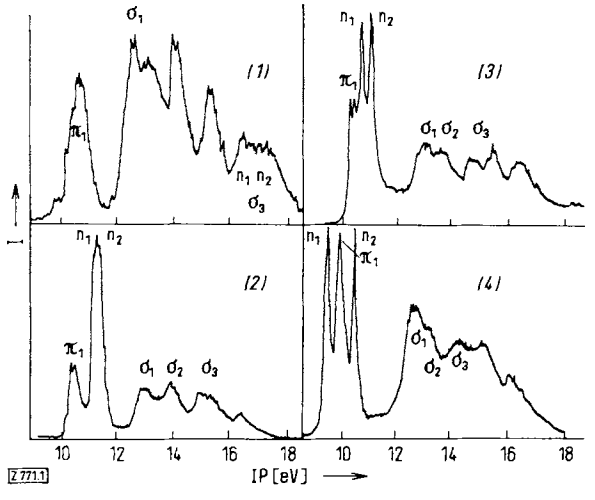


Fig. 1. Photoelectron spectra of allyl fluoride *(1)*, allyl chloride *(2)*, allyl bromide *(3)*, and allyl iodide *(4)*.

Figure 1 shows the PE spectra of the allyl halides, and Figure 2 shows the correlation diagram derived therefrom and from the PE spectrum of propene[3c]. π_1 is the highest occupied π-MO (antibonding combination of vinyl-π-MO and a π-combination of the CH_2X bonds). σ_1 couples the vinyl moiety to the substituents CH_2X. σ_2 and σ_3 are mainly localized in CH_2X, σ_3 being the C—X bonding MO. n_1 and n_2 are the MO's of the lone pairs of the halogen atoms; they are split by spin-orbit coupling[5].

We consider now the π_1-MO's. The electronic interactions between the vinyl-π-MO and the substituents CH_2X can be described, from models, by the hyperconjugative effect of the C—X and the C—H bonds (in the *cis*-conformation only the C—H bonds) and by the inductive effect of the halogen atoms.

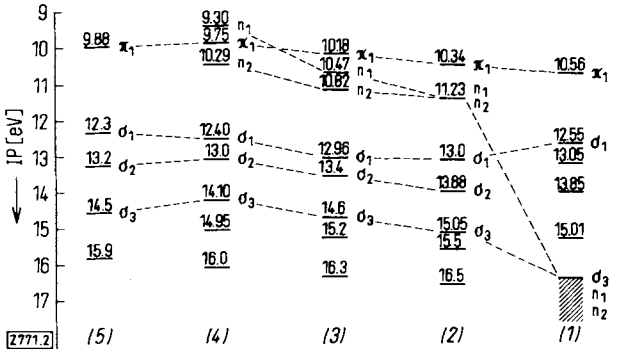

Fig. 2. Correlation diagram of the highest occupied MO's in propene *(5)* and the allyl halides *(1)* to *(4)*. The numbers above the levels denote vertical ionization potentials.

The hyperconjugative effect destabilizes π_1 (antibonding π-CH_2X combination), and the inductive effect stabilizes π_1 (F, Cl, Br and I are more electronegative than H). Our experimental results (Figs. 1 and 2) show that π_1 in allyl chloride *(2)*, bromide *(3)* and iodide *(4)* are destabilized (hyperconjugative interaction predominant) relative to the vinyl-π-MO (we selected as unperturbed vinyl-π-MO the $\pi(b_{1u})$-MO of ethylene, energy = −10.51 eV[6]); π_1 is stabilized only in allyl fluoride *(1)* (the particularly high inductive effect of the fluorine atom preponderates). The two interactions cannot be separated for allyl compounds. The inductive effect of the halogen atoms can, however, be estimated separately for the $\pi(a_2)$-MO[7] of the corresponding phenyl halides Ph—X (F = −0.58, Cl = −0.45, Br = −0.43, I = −0.18 eV[6]). If these inductive effects are subtracted from the observed total shifts of the π_1-MO's in the allyl compounds CH_2=CH—CH_2X (F = −0.05, Cl = 0.17, Br = 0.33 and I = 0.76 eV) there remain the bare hyperconjugative effects of the CH_2X substituents (F = 0.53, Cl = 0.62, Br = 0.76 and I = 0.94 eV).

In the allyl halides (*gauche* conformation) hyperconjugation is effective between the ethylene-π-MO on the one hand and one C—X and one C—H bond (both in *gauche* position) on the other. The hyperconjugative effect of the CH_3 substituent on π_1 in propene *(5)*, which exists only in one conformation[8], amounts to 0.63 eV[3c]. We can thus ascribe a value of 0.31 eV to the hyperconjugative effect of a C—H bond in the *gauche* position. If we subtract this C—H contribution from the hyperconjugative effects already determined for the CH_2X substituents, we finally obtain the hyperconjugative effects δE of the C—X bonds (F = 0.22, Cl = 0.31, Br = 0.45, and I = 0.63 eV)[9].

If hyperconjugation is a conjugation that can be described by the same bonding models as, for example, π-conjugation, then, applying the rules of simple perturbation theory, we must expect that δE will be indirectly proportional to the energy difference ΔE between the interacting MO's (basis MO's). As basis MO's we select, alongside the $\pi(b_{1u})$-MO of ethylene, the $\sigma(a_1)$-MO's (C—X MO's) of the methyl halides CH_3X (energies: F = −16.2[10], Cl = −14.4, Br = −13.5, I = −12.5 eV[6]).

355 Marburg, Biegenstrasse 12 (Germany)

Plotting δE against $1/\Delta E$ gives a straight line which, as it must, passes exactly through the origin (Fig. 3). On the assumption that the interaction integrals between the various C—X bonding MO's and the $\pi(b_{1u})$-MO of ethy-

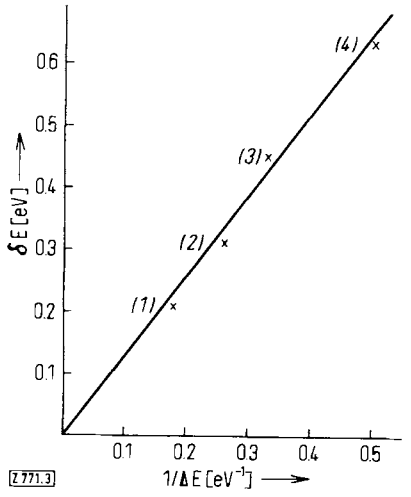

Fig. 3. A plot of δE against $1/\Delta E$.

lene do not differ much[11], this result provides a consistent confirmation of hyperconjugation as a conjugation mechanism that can be described by the same model as π-conjugation, and further provides an independent proof of the existence of hyperconjugation. From Fig. 3 we can also extract the series of hyperconjugative ability: C—F < C—Cl ≈ C—H < C—Br < C—I.

Photoionization Cross Sections: Differing Relative Band Intensities in He-I and He-II Photoelectron Spectra[1]

By *Peter Dechant, Armin Schweig,* and *Walter Thiel*[*]

In the transition from He-I to He-II photoelectron spectra (photon energies 21.22 and 40.81 eV, respectively) intensity shifts often occur[2] (cf. Fig. 1) which are theoretically described by the energy-dependence of the corresponding photoionization cross sections. Within the framework of certain approximations (dipole approximation, *Koopmans'* theorem, description of the ionized molecular orbital (MO) by a valence-electron-LCAO—SCF—MO and of the orbital of the free photoelectron by a plane wave) the photoionization cross section σ_n of the n-th ionization process[3,4] is given by:

$$\sigma_n = A\, p_n \left[\sum_a Q_a^n + \sum_{a<b} Q_{ab}^n\right]/E_{ph} \qquad (1)$$

where A is a constant, p_n the momentum of the free photoelectron, and E_{ph} the irradiating photon energy. The one-center terms Q_a^n and the two-center terms Q_{ab}^n are composed of the contributions of the individual basis atomic orbitals (AO) $\phi_{a\nu}$ and their combinations $\phi_{a\nu}/\phi_{b\lambda}$ (atoms a, b; AO numbers ν, λ). They are dependent on the LCAO coefficients $c_{a\nu}$ of the ionized MOs, on the AO transition moments $M_{a\nu}$ (measure of the transition probability between the $\phi_{a\nu}$ AO and the orbital of the free photoelectron; conjugate complex $M_{a\nu}^*$) and on the interference terms $I_{\nu\lambda}$[4]:

$$Q_a^n = \sum_\nu c_{a\nu}^2\, M_{a\nu}\, M_{a\nu}^* \qquad (2)$$

$$Q_{ab}^n = 2\sum_\nu \sum_\lambda c_{a\nu}\, c_{b\lambda}\, M_{a\nu}\, M_{b\lambda}^*\, I_{\nu\lambda} \qquad (3)$$

In order to find the energy-dependence of the photoionization cross section it is generally necessary to investigate each quantity p_n/E_{ph}, Q_a^n and Q_{ab}^n of eq. (1) separately. In ionization processes with similar ionization potentials IP_n the quotients p_n/E_{ph} are of approximately the same size. This is true particularly for high photon energies ($E_{ph} \gg IP_n$), so that in this case there is only a slight effect on the relative values of the photoionization cross sections. The two-center terms Q_{ab}^n are usually considerably smaller than the one-center terms Q_a^n (*inter alia*, for ionizations of lone pairs and for π-ionizations at high photon energies). Thus intensity shifts in photoelectron spectra can often be explained to a first approximation by variation in the one-center terms Q_a^n alone, as will be shown by the following examples:

Table 1 contains the calculated[5] and the experimental[6] values for the relative intensities of the highest bands in the He-I and He-II spectra of cyclopentadiene, pyrrole, furan, and phosphane. Figure 1 illustrates a section of the He-I and the He-II spectra of furan.

For the heterocycles among the five-membered rings investigated[7] it is found that, in agreement between theory and experimental investigations, the second band (π-MO with non-zero coefficient at the hetero atom, symmetry

	a_1	19.0	—	—	—	10	—	<15

b_1) in the He-I spectra is less intense than the first band (π-MO with node at the hetero atom, symmetry a_2) but that its intensity increases significantly on going to the He-II spectrum. Because of the symmetry of the MOs the 2p-AO of the hetero atom provides a one-center contribution [eq. (2)] to the photoionization cross section only for the b_1- and not for the a_2-MO. As shown in Figure 2, this contribution increases relatively sharply on transition from the He-I to the He-II spectrum, since M_{av} M^*_{av} of the 2p-AO transition moments for nitrogen and oxygen in the He-I energy region is considerably less than for carbon but in the He-II energy region is approximately the same. The differing intensities of the two uppermost π-bands in the He-I and the He-II spectra of pyrrole and furan are thus to be ascribed to the differences in the one-center contributions from the hetero atom. As is to be expected theoretically, there is no corresponding intensity shift with the homologous cyclopentadiene.

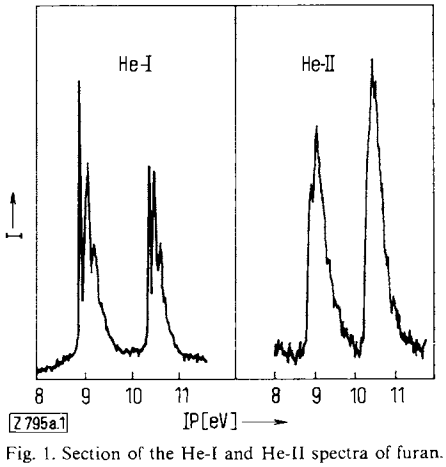

Fig. 1. Section of the He-I and He-II spectra of furan.

For phosphane[2b, 8], a decrease in intensity of the highest band (a_1, lone pair on the phosphorus) and a very low intensity of the lowest band (a_1, PH-bonding) is observed on transition to the He-II spectrum. The two a_1-MOs each have high 3s coefficients whereas for symmetry reasons the e-MO (PH-bonding) has no 3s component. According to Figure 2 the low intensity of the a_1 bands in the He-II spectrum can be ascribed to the great decrease in the transition moments of the phosphorus 3s AO at higher kinetic energies of the photoelectron.

The two cases discussed demonstrate how, to a first approximation, band intensities in photoelectron spectroscopy can be interpreted by means of the LCAO coefficients (electron density distribution) in the ionized MO and of

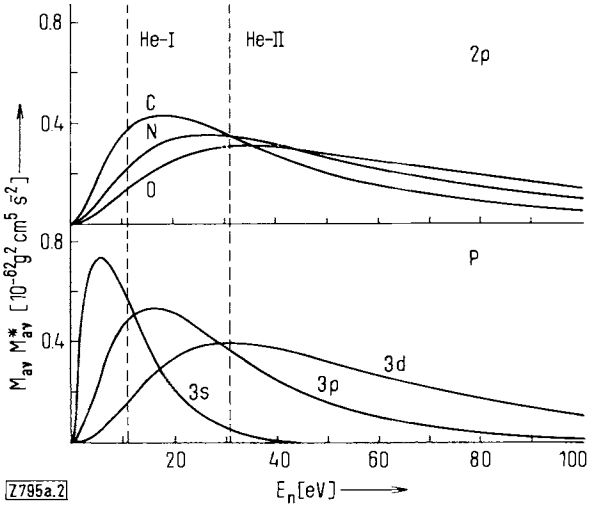

Fig. 2. Squared amounts $M_{av}M^*_{av}$ of the transition moments of some basis AOs as a function of the kinetic energy E_n of the free photoelectron ($E_n = E_{ph} - IP_n$). The two broken lines show the photoelectron energies that appear on He-I and He-II excitation at an ionization potential of 10 eV.

the energy-dependent transition moments of the basis AOs. Since, qualitatively, the intensity shifts (He-I/He-II) are correctly predicted, the procedure appears useful as an aid in assignments.

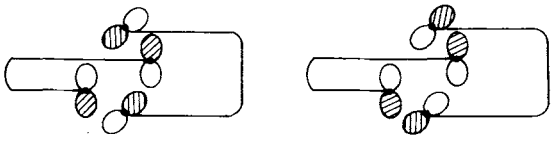
Spiroconjugation[1]

By *Armin Schweig, Ulrich Weidner, Dieter Hellwinkel,* and *Wolfgang Krapp*[*]

When two π-systems are perpendicular to one another and linked by one tetrahedral atom, interaction by spiroconjugation[2] can occur between those MOs of the two systems whose terminal $2p_\pi$-AOs ($2p_\pi$-AOs on the atoms next to the tetrahedral atom) are each antisymmetric to one another[3]. These antisymmetric $2p_\pi$-AOs in each of the two partial systems can adopt either of two arrangements with respect to each other: (A) spiroantibonding and (B) spirobonding. The difference between the energies of the spiroantibonding (A) and the spirobonding (B) combinations is called "spiro splitting".



(A) *(B)*

The concept of spiroconjugation was originally developed for spiro compounds. In previous papers[4] we provided, by photoelectron spectroscopy, the first evidence for spiroconjugation in the structurally similar but non-spiro compounds tetravinylmethane $(CH_2{=}CH)_4C$ *(5)* and tetravinylsilane $(CH_2{=}CH)_4Si$ *(6)*. For these compounds we had to rely on assumptions concerning molecular geometry (D_{2d} symmetry), since this is not fixed by ring formation as it is for spiro compounds. In addition, problems arise with assignment, since in the π-systems of dimethyldivinylmethane $(CH_3)_2C(CH{=}CH_2)_2$ and dimethyldivinylsilane $(CH_3)_2Si(CH{=}CH_2)_2$ the energy separation of the HOMO ("highest occupied MO") not capable of spiroconjugation and the MO immediately below this which takes part in spiroconjugation is smaller than the splittings that occur (Jahn-Teller splitting of the HOMOs and spiro splitting of the lower MOs). These problems can be avoided by studying spiro compounds of suitable structure (the HOMOs of the two rings are capable of spiroconjugation and lie sufficiently far above the other π-MOs). We have thus been able to provide direct, unambiguous evidence for spiroconjugation by means of the photoelectron (PE) spectra of 9,9-dimethylfluorene *(1)*, 9,9-dimethyl-9-silafluorene *(2)*, 9,9′-spirobifluorene *(3)*, and 9,9′-spirobi(9-silafluorene) *(4)*.

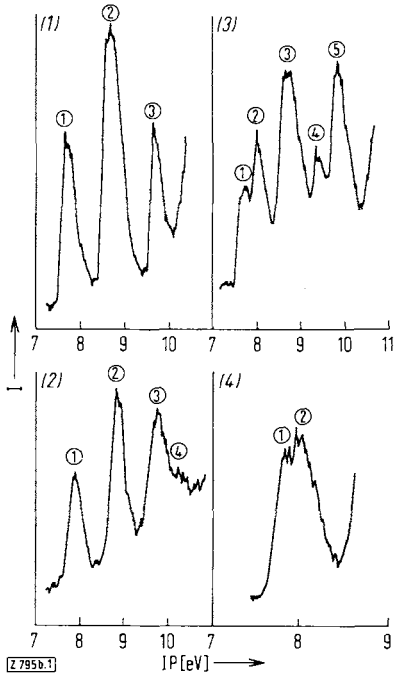

Fig. 1. Photoelectron spectra [9] of 9,9-dimethylfluorene *(1)*, 9,9-dimethyl-9-silafluorene *(2)*, 9,9′-spirobifluorene *(3)*, and 9,9′-spirobi(9-silafluorene) *(4)*. The vertical ionization potentials (in eV) and relative intensities are: For *(1)*: ① 7.8/1, ② 8.75/1.8, ③ 9.75/1.0; for *(2)*: ① 7.9/1, ② 8.80/1.5, ③ 9.7, and ④ 10.25/2.7; for *(3)*: ① 7.7/1, ② 8.0/1.3, ③ 8.7/3.2, ④ 9.4/1.3, and ⑤ 9.9/3.0; for *(4)*: ① 7.85 and ② 8.0/2, ③ 8.85 and ④ 9.1/3.7, ⑤ 9.85/2, and ⑥ 10.25/3 [10].

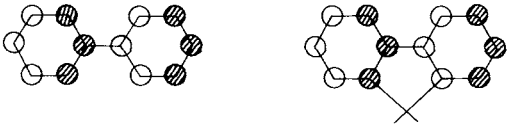
Figure 1 shows the PE spectra of *(1)* to *(4)*. The spectra of *(1)* and *(2)* show the same signal structure (intensities of ①:②:③ = 1:2:1) as for biphenyl *(7)*[5]. It follows that the highest occupied MOs of *(1)* and *(2)* are closely related to the corresponding MOs in *(7)* and thus in particular that the HOMO in *(1)* and *(2)* is capable of spiroconjugation (the $2p_\pi$-AOs of the atoms 8a and 9a next to the tetrahedral atom are antisymmetric) [cf. the representation of the HOMOs of *(7)* and *(1)* or *(2)*].



As thus anticipated, we observe splitting of signal ① in the PE spectra of *(1)* and *(2)* into two signals ① and ② in the PE spectra of *(3)* and *(4)*. It amounts to 300 meV for *(3)* and 180 meV for *(4)*. Since the splitting is in each case smaller than the separation of signal ① from signal ② in the spectra of *(1)* and *(2)* no problem of interpretation or assignment arises.

The ratio of the spiro splittings for compounds *(4)* and *(3)* amounts to 180/300 = 0.60 and is thus almost the same as the corresponding ratio for compounds *(6)* and *(5)* 450/730 = 0.62[4]. So the spiro splitting decreases by about 60% on replacement of the tetrahedral C atom (the spiro atom in the spiro compounds) by an Si atom.

If the tetrahedral atom remains the same, the spiro splitting of two different MOs capable of spiroconjugation should

behave as the square of the $2p_\pi$-AO coefficients of the atoms next to the tetrahedral atom. The observed ratio of the spiro splittings for compounds *(3)* and *(5)* (*i.e.* in the carbon series) is 300/730 = 0.41. The analogous ratio in the silicon series, 180/450 = 0.40, is in good agreement with that. The ratio estimated from MINDO/2 coefficients[6] is $(0.34)^2/(0.47)^2 = 0.52$.

(8)

After these results we expect for the newly synthesized spiro[4.4]nonatetraene *(8)*[7] an HOMO splitting of $[(0.56)^2/(0.34)^2]\cdot 0.3\,\text{eV} = 0.8\,\text{eV}$ or $[(0.56)^2/(0.47)^2]\cdot 0.7\,\text{eV} = 1.0\,\text{eV}$, *i.e.* about $0.9 \pm 0.1\,\text{eV}$[8].

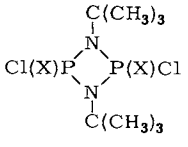
Crystal Structure of 1,3-Di-*tert*-butyl-2-*trans*-4-dichloro-2,4-dioxo-1,3,2λ⁵,4λ⁵-diazadiphosphetidine; Stereochemistry of Oxidation at Phosphorus(III) by Dimethyl Sulfoxide

By *Rodney Keat*, *Ljubica Manojlović-Muir*, and *Kenneth W. Muir*[*]

The oxidation of phosphorus(III) compounds by dimethyl sulfoxide constitutes a useful route to oxophosphoranes[1], although nothing is known of its stereochemical features. To shed more light on this aspect of the oxidation process and on the structure of a dioxocyclodiphosphazane, for which no detailed structural information is available[2], we have examined the crystal structure of 1,3-di-*tert*-butyl-2,4-dichloro-2,4-dioxo-1,3,2λ⁵,4λ⁵-diazadiphosphetidine *(2)*.



(1), X = lone pair
(2), X = O

[*] Dr. R. Keat, Dr. Lj. Manojlović-Muir, and Dr. K. W. Muir
Chemistry Department, University of Glasgow
Glasgow G 12 8QQ (Great Britain)

Compound *(2)* was obtained as a crystalline, air-stable solid (m.p. 139—140 °C) by oxidation of the analogous phosphorus(III) compound *(1)* by dimethyl sulfoxide in methylene chloride solution at −78 °C. A ^{31}P-NMR spectrum of the reaction products showed only one signal at +7.5 ppm (from external H_3PO_4), indicating that only one isomer was formed. No evidence has obtained for the presence of a second isomer.

Compound *(2)* crystallizes in the tetragonal space group $P4_2/n$; a cell of dimensions $a = 13.428$, $c = 8.152$ Å contains four molecules, each of which is required to possess C_i symmetry. The intensities of all reflections with $\theta(Mo_{K\alpha}) \leq 30°$ were measured on a PDP 8-controlled Hilger and Watts Y 290 diffractometer. Least squares refinement (841 observations significantly above background, 110 parameters) converged with $R = 0.036$ and $R_w = 0.042$. The results are summarized in Table 1 and Figure 1. Since there are no significant differences between chemically equivalent bond lengths or interbond angles, appropriate average values are presented in the Table.

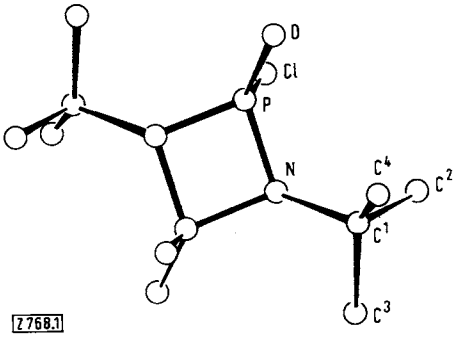


Fig. 1. Perspective view of one molecule of *(2)* (hydrogen atoms omitted for clarity).

Table 1. Mean bond lengths [Å] and interbond angles [°] in the diazadiphosphetidine *(2)*.

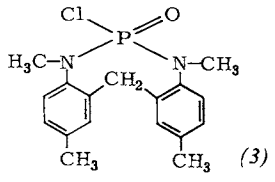
P—Cl	2.007(2)	Cl—P—O	109.5(1)
P—O	1.448(3)	Cl—P—N	108.2(2)
P—N	1.661(5)	O—P—N	121.5(8)
N—C	1.507(5)	N—P—N′ [a]	85.5(2)
C—C	1.518(7)	P—N—P′ [a]	94.5(2)
C—H	1.00(2)	P—N—C	131.9(18)

[a] Primed atoms are related to corresponding unprimed atoms by an inversion center.

The most striking feature of the structure of *(2)* is that the chlorine atoms are arranged *trans* to each other, whereas they are mutually *cis* in the precursor *(1)*. Thus the oxidation of *(1)* to *(2)* is, within experimental error, stereospecific and involves both inversion and retention of configuration at phosphorus. We are at present unable to decide whether this unusual result has kinetic or thermodynamic origins. In contrast, retention of configuration at phosphorus was observed on oxidation of cyclic phosphites by HNO_3 and by N_2O_4[3].

The P—Cl and P—N distances in *(2)* are respectively 0.098(9) and 0.028(7) Å shorter than the corresponding distances of 2.105(9) and 1.689(5) Å in *(1)*[4]. It has recently been shown that a similar slight shortening of P^{III}—N bonds occurs on formation of a P^V-sulfide[5]. Comparison with the bond lengths about the approximately tetrahedral phosphorus atom in the heterocycle *(3)*[6] is interesting in that the exocyclic P=O and P—Cl bonds (respectively 1.492(5) and 2.069(3) Å) are appreciably longer than the corresponding bonds in *(2)*, while the P—N distance in

(3) of 1.644(6) Å is comparable with that in *(2)*. This implies a strengthening of the P=O and P—Cl bonds when the N—P—N angle is decreased; in fact these bonds in *(2)* are comparable in length with those in $POCl_3$ (1.456(10) and 1.976(7) Å respectively)[7] and in $Cl_2P(O)$—$NC_6H_5P(S)Cl_2$ (1.449(6) and 1.969(6) Å respectively)[5], where the phosphorus atoms are highly electrophilic. However, in view of these differences, it is surprising that the P—N bond length in *(3)* is not reduced more significantly relative to that in *(2)*.



(3)

The ring system in *(2)* is planar, whereas in *(1)* it was slightly puckered. This may be as much a function of the mutual orientation of the chlorine atoms as of the oxidation state of phosphorus, since the *trans* isomer of the structurally related dithiocyclodiphosphazane $[C_6H_5(S)P—NC_2H_5]_2$ has a planar ring, but in the *cis* isomer the ring is puckered[8].

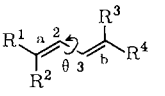
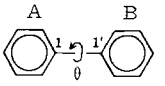
Ionization Potentials of Deformed π-Bonds[1]

By *Christopher Batich, Otto Ermer, Edgar Heilbronner*, and *John R. Wiseman*[*]

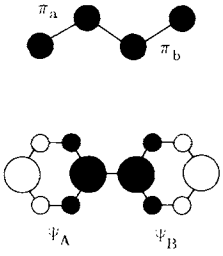
If two conjugated π-systems, each individually planar [*e.g.* the double bonds a, b in the diene *(1)* or the benzene rings A, B in biphenyl *(2)*] are twisted with respect to each other by an angle θ, then there is a noticeable effect on the position of the π-bands in the photoelectron (PE) spectrum of the compound in question[1-4]. If, in the sense of *Koopmans'* theorem[5], the vertical ionization potentials I_v are interpreted as negative orbital energies,



(1)



(2)



i.e. $I_{v,J} = -\varepsilon_J$, then it can be shown that the splitting Δ of the orbitals

$$\pi_+ = (\pi_a + \pi_b)/\sqrt{2}$$
$$\pi_- = (\pi_a - \pi_b)/\sqrt{2}$$

in *(1)* or the orbitals (1)

$$\psi_+ = (\psi_A + \psi_B)/\sqrt{2}$$
$$\psi_- = (\psi_A - \psi_B)/\sqrt{2}$$

in *(2)* can be described within the framework of a first order perturbation calculation referred to a simple LCMO model, by the relationships

$$(1):\ \Delta = \varepsilon(\pi_-) - \varepsilon(\pi_+) = -\beta_{23}\cos\theta$$
$$(2):\ \Delta = \varepsilon(\psi_-) - \varepsilon(\psi_+) = -\tfrac{2}{3}\beta_{11'}\cos\theta \quad (2)$$

The resonance integrals $\beta_{23} = \langle\phi_2|\mathscr{H}|\phi_3\rangle$ and $\beta_{11'} = \langle\phi_1|\mathscr{H}|\phi_{1'}\rangle$ are defined as usual for the 2p atomic orbitals of the coplanar system *(1)* or *(2)*, *i.e.* for θ = 0°. Calibration by means of the PE spectra of substituted compounds of types *(1)* and *(2)* whose angles of twist θ are known or can be estimated (substituted butadienes[2], cycloalkadienes[3], substituted biphenyls[4]) affords $\beta_{23} \approx \beta_{11'} \approx -2.5$ to -2.8 eV.

These successful applications of photoelectron spectroscopy to determination of the dependence on the angle of twist θ of the coupling between conjugated π-systems might lead one to suppose that this method would prove an ideal probe for characterizing twisted or otherwise deformed double bonds. We shall show that this is not the case or only so within very narrow limits.

Within a HMO model the resonance integral $\beta_{12} = \langle\phi_1|\mathscr{H}|\phi_2\rangle$ between the two 2p atomic orbitals ϕ_1, ϕ_2 of a two-center π-bond has a β_{12} value of at least ≈ -3.6 eV, as calculated from the above values with $\beta_{12} = \beta_{23}S_{12}/S_{23}$, where S_{12} and S_{23} are the overlap integrals for $R_{12} = 1.33$ and $R_{23} = 1.48$ Å. If one twists ϕ_1 and ϕ_2 by an angle θ, while keeping the distance R_{12} constant, the orbital energy $\varepsilon(\pi) = \alpha + \beta_{12}$ of the planar system (θ = 0°) is shifted by

$$\Delta\varepsilon(\pi) \approx 3.6(1 - \cos\theta)\,\text{eV} \quad (3)$$

For θ = 10, 20, 30 and 40° expression (3) gives the values $\Delta\varepsilon(\pi) \approx 0.05$, 0.22, 0.48 and 0.84 eV.

However, when applying formula (3) it must be remembered that non-planar deformations of the double bond of a system $R^1R^2C{=}CR^3R^4$ can be effected not only by a pure twist but also by out-of-plane (oop) bending, *i.e.* deformations with loss of coplanarity of the three σ-bonds that originate from each of the two C atoms. Thus, to characterize the deformation it is necessary to define both the twist angle (defined as the arithmetical mean of the

[*] Prof. Dr. E. Heilbronner and Dr. Ch. Batich

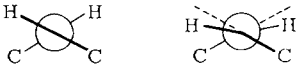
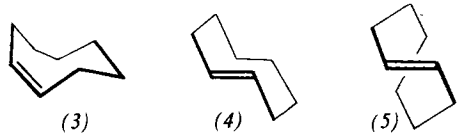
two *cis* torsion angles of a double bond) and two "oop-bending" parameters χ_1 and χ_2[6,7]. *Mock*[8], and also *Radom*, *Pople*, and *Mock*[9] have shown by theoretical calculations that both types of deformation must occur in conjunction if, for instance, a *trans*-C—CH=CH—C unit is twisted around the double bond, because the C—H bonds are then oriented as shown in (B) and not as one would have expected *i.e.* as in (A).



(A) (B)

It follows that the influence of χ_1 and χ_2 on $\Delta\varepsilon(\pi)$ must be complex, since apart from additional changes in β_{12} the amount of σ,π-interaction and the s-character of the basis orbitals ϕ_1, ϕ_2 also will change.



(3) (4) (5)

cis-cyclooctene
$I_a(\pi)$ = 8.82 eV
$I_v(\pi)$ = 8.98 eV

trans-cyclooctene
$I_a(\pi)$ = 8.53 eV
$I_v(\pi)$ = 8.69 eV

The most favorable conformation of *cis*-cyclooctene is very probably *(3)*[6,10,11] which can be derived from the chair-tub conformation of cyclooctane. In this case the π-bond is only minimally twisted if at all. The preferred conformation of *trans*-cyclooctene is not known with complete certainty. An electron diffraction study carried out recently by *Gavin* and *Wang*[12] was interpreted by the authors as showing that in the gas phase *trans*-cyclooctene has the chair conformation *(4)* with a C—C=C—C torsion angle of 23°, but other results favor the conformation *(5)* of C_2 symmetry that is related to the eight-membered ring crown conformation. X-ray analyses of two *trans*-cyclooctene derivatives afforded C—C=C—C torsion angles of 138°[13] and 134°[14]; energy minimization calculations yield the corresponding values of 138°[6] and 149°[11]. (Inserting these C—C=C—C torsion angles, which are certainly much too large for the free molecules, into eqn. (3) yields $\Delta\varepsilon(\pi)\approx 0.5$ to 1.1 eV, *i.e.* values that are unrealistically high.)

For the free molecules, energy-minimization calculations afford twist angles (as defined above) of 19.8°[6] and 16.3°[11], respectively, in which, however, *(5)* is predicted to be the more stable conformer. Independently of which conformation is the preferred one, if one uses $\theta\approx 16$ to 23° in eqn. (3), one obtains $\Delta\varepsilon(\pi)=0.14$ to 0.29 eV. However one should note that formula (3) is only a very crude approximation and leaves the influence of "oop-bending" deformations out of account. The observed difference in vertical (adiabatic) ionization potential $I_v(\pi)(I_a(\pi))$ between *cis*- and *trans*-cyclooctene amounts to 0.29 eV, which by eqn. (3) corresponds to an angle θ in our model of ≈23°, in agreement with expectation.

To obtain further insight into the dependence of the π-ionization potential on deformation of the π-bond, we have determined the PE spectrum of cyclooctyne *(6)*. In this compound the C_{sp}—C_{sp} bonds depart by *ca.* 21.5° from colinearity with the axis of the triple bond[15]. This should

(6)

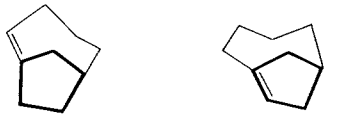
cyclooctyne
$I_a(\pi)\approx 8.9$ eV
$I_v(\pi)$ = 9.2 eV

noticeably lift the degeneracy of the two π-orbitals, but to a first approximation this is not the case. The spectrum of *(6)* shows a simple intense π-band, with little fine structure, at $I_v(\pi)=9.20$ eV with a halfwidth (HW) of 0.6 eV and no recognizable marked splitting [for comparison: diethylacetylene: $I_v(\pi)=9.25$ eV (HW = 0.5 eV); di-*n*-butylacetylene: $I_v(\pi)=9.06$ eV (HW = 0.5 eV)[16]]. From this result it must be concluded that the splitting of the two π-orbitals induced in *(6)* has a value of at most one vibrational quantum of the ionized C≡C bond, *i.e. ca.* 0.2 eV.

On the basis of these results it is not surprising that the PE-spectroscopic study of "anti-Bredt" hydrocarbons such as the pair of isomers bicyclo[4.2.1]non-1(2)ene *(7)* and bicyclo[4.2.1]non-1(8)ene *(8)*[17] provides little information. From energy calculations with an optimized valence force field (including important cross terms)[6] the conformations here schematically represented as *(9)* and *(10)* appear to be the most advantageous. The calculations give twist angles of 18.4 and 16.6°, respectively.

(7) *(8)*

$I_v(\pi)$ = 8.45 eV $I_v(\pi)$ = 8.37 eV



(9) *(10)*

From formula (3) and in view of our experience with the compounds *(3)*, *(4)* and *(5)*, the shifts here can hardly be expected to be greater than $\Delta\varepsilon(\pi)\approx 0.1$ to 0.2 eV. In fact the measured ionization potentials $I_v(\pi)=8.45$ and 8.37 eV for *(7)* and *(8)*, respectively, coincide within experimental error with the values that would be expected, on the basis of known data for unsaturated hydrocarbons, for a correspondingly substituted and fully planar π-bond.

Direct Chemical Evidence for Energy Transfer between Identical Molecules[**]

By *Peter Lechtken* and *Nicholas J. Turro*[*]

Energy transfer in the solid state, especially in crystals, is a well-known and well-studied phenomenon[1]. However, with the sole exception of some studies employing the indirect technique of fluorescence depolarization[2], there exists little information in the literature concerning energy transfer between identical molecules in *fluid solution at room temperature*[3]. The difficulty in studying energy transfer between identical molecules in fluid solution resides in the absolute identity of the reactants and the products [Reaction (1)].

$$A^* + A \rightleftharpoons A + A^* \quad (1)$$

$$A^* + A \rightleftharpoons (AA)^* \rightleftharpoons A + A^* \quad (2)$$

Evidence for the occurrence of such an "energy hopping" between identical molecules is of great interest for:

a) unraveling the question of whether excimers[4] of ketones exist [(AA)*; Reaction (2)];

b) providing a novel mechanism for "long range" energy transfer;

c) understanding the factors which determine the duration of electronic excitation in a molecule.

The ability of tetramethyl-1,2-dioxetane *(1)* to produce high yields of excited singlet and triplet acetone upon photolysis[5] provides a unique opportunity to demonstrate electronic excitation transfer between identical molecules by a *direct chemical method of analysis*. Indeed, *(1)* may be considered as a stable, "masked" electronically excited acetone molecule. Irradiation of *(1)* in deuterioacetone, under conditions such that acetone[6] is not excited by direct absorption of light (high pressure Hg lamp, 365 nm line), effects the reaction scheme shown.

The acetone singlets and triplets generated from photolysis of *(1)* were trapped with dicyanoethylene and diethoxyethylene, respectively, to give the corresponding oxetanes *(2)* and *(4)*[7]. Since the excitation energy must originally reside on a $[H_6]$-acetone ($A—H_6$) molecule, one can determine the extent of energy transfer to $[D_6]$-acetone ($A—D_6$) by simply measuring the ratio of *(2)* to *(3)* and/or *(4)* to *(5)* in the reaction products.

The analysis of the reaction mixture was executed by a combination of gas chromatography and mass spectrometry. The relative amounts of *(2)* and *(3)*, or *(4)* and *(5)*, were determined from the intensities of the relevant masses (Table 1). As standard controls, authentic mixtures

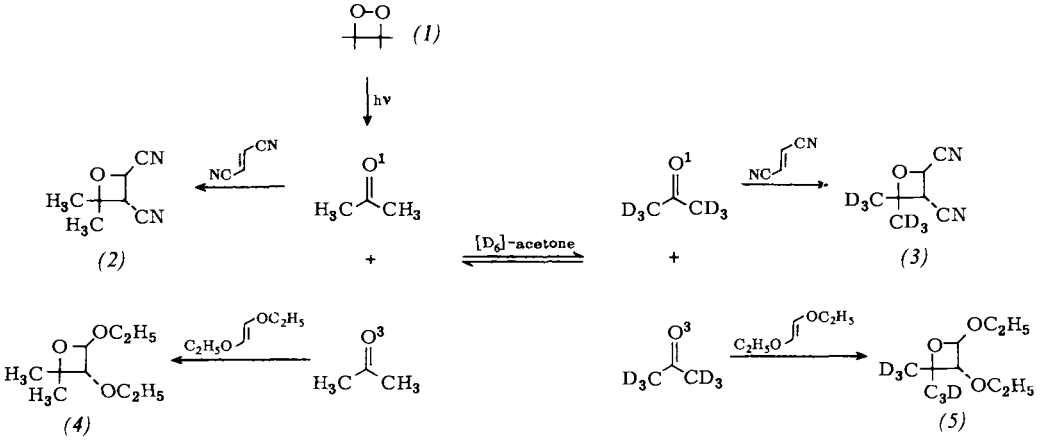

Fig. 1. Reaction scheme of energy transfer.

(Even if some anisotropy were involved in the reaction, say, initiated by excitation with polarized light, the rapid rate of tumbling of molecules in fluid solution converts the system into an isotropic one much faster than most physical measurements can be made).

of *(2)* and *(3)* [or *(4)* and *(5)*] were prepared and analyzed.

Table 1. Mass numbers for analysis of deuterium contents [8].

Fragment X=H,D	Oxetane (2)	(3)	(4)	(5)
CX_3CO	43	46	43	46
CX_3COCX_3	58	64	58	64

in the total oxetane mixture, while the corresponding deuterated oxetane *(5)* from addition of triplet acetone to diethoxyethylene accounted for $10 \pm 5\%$ of the total oxetane mixture.

Application of Stern-Volmer kinetics[9] leads to the following rate constants for energy transfer:

Singlet-Singlet: $k_q^1 = 3.5 \times 10^6\ mol^{-1}\ s^{-1}$
Triplet-Triplet: $k_q^3 = 2.8 \times 10^6\ mol^{-1}\ s^{-1}$

Thus, within the experimental error of $\pm 50\%$, the two energy transfer rate constants are equal and about three orders of magnitude smaller than the value for diffusion in acetone ($\approx 5 \times 10^9\ mol^{-1}\ s^{-1}$).

$$A_1^* \curvearrowright A_2 \curvearrowright \ldots\ A_n \rightarrow A_1\ \ A_2\ \ldots \curvearrowright A_n^*$$

$$\Phi_{HOP} = \frac{k_q}{k_q + \sum k_d}[A] \qquad \begin{matrix} n^1 \approx 1 \\ n^3 \approx 14 \end{matrix}$$

The number of energy hopping events, Φ_{HOP}, depends on the ratio of the rates of hopping to the sum of all deactivation rates ($\sum k_d$). In pure acetone at room temperature ([A] = 14 M, $\sum k_d^1 \approx 0.6 \times 10^9\ s^{-1}$, $\sum k_d^3 \approx 2 \times 10^5\ s^{-1}$)[10] the singlet makes only one hop per lifetime, while the triplet makes about 14 hops per lifetime.

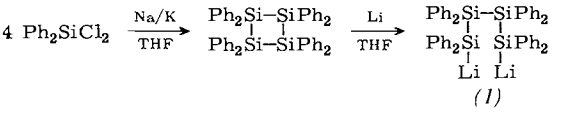
Boracyclopentasilane, a New Type of Heterocyclic Silane

By *Edwin Hengge* and *Dieter Wolfer*[*]

Only a few heterocyclic silanes with cumulated Si—Si bonds are known[1] and most of them contain, as hetero atoms, elements of the fourth, fifth and sixth main Group. Analogous cyclosilane derivatives with elements of the third main Group have so far been unknown. We here report the first synthesis of a boracyclosilane.

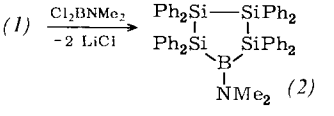
It is known that octaphenylcyclotetrasilane[2] reacts with lithium with ring fission to 1,4-dilithiooctaphenyltetrasilane *(1)*[3]:



(1)

We have been able to isolate this Li compound *(1)* as tetrahydrofuran adduct; it had previously been obtained only in solution and used therein for manifold reactions. Metalating ring cleavage in a little tetrahydrofuran leads to $Ph_8Si_4Li_2 \cdot 2THF$ being precipitated as yellowish-red, small crystals which can be recrystallized from cyclohexane: m.p. 121—123 °C (uncorr. in a sealed tube). ^{1}H-NMR (in C_6D_6): Ph multiplet at 3.25—2.08 ppm, two THF multiplets at 8.78 (THF in C_6D_6 8.47) and 6.68 (6.64) ppm. The compound is very sensitive to oxygen and hydrolysis.

First attempts to convert *(1)* by dichloro(phenyl)borane into nonaphenylboracyclopentasilane failed; we obtained only polymeric products. However, analogously to the work of *Nöth et al.*[4] who raised the electron density of a Si—B bond by dimethylamino-substitution, thus stabilizing it, it proved possible to cyclize *(1)* to 1-(dimethylamino)-2,2,3,3,4,4,5,5-octaphenyl-1-boracyclopentasilane *(2)* by means of dichloro(dimethylamino)borane:



(2)

The boracyclosilane *(2)* forms small white crystals, has an unusually low density, and is very sensitive to oxygen and hydrolysis; it is slightly soluble in benzene, toluene or xylene, still less so in cyclohexane and insoluble in pentane or ether. M.p. 261—263 °C (uncorr. in a sealed tube).

The ^{1}H-NMR spectrum (in C_6D_6; TMS standard) shows a singlet for the methyl-protons at 7.08 ppm and a phenyl multiplet at 3.16—2.17 ppm in the proportions 1 : 6.9 (calc. 1 : 6.7). In the IR spectrum the phenyl and dimethylamino vibrations are at their usual frequencies, but the νB—N at 1392 cm^{-2} lies remarkably low. In the Raman spectrum νB—N appears at 1394 cm^{-1} and a further band at 541 cm^{-1} which is presumably to be considered as a symmetrical ring vibration. The UV spectrum, compared with those of other heterocycles of the type Si_4X (with X = Si, Ge, N, P, O or S), gives a band at the particularly long-wave position 330 nm ($\varepsilon = 1700$).

Experimental

Solutions of $(Ph_2Si)_4Li_2 \cdot 2THF$ (0.044 mol) in THF (180 ml) and of Me_2NBCl_2 (0.044 mol) in benzene (250 ml)

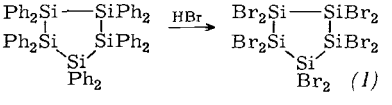
Cyclopentasilane, the First Unsubstituted Cyclic Silicon Hydride

By *Edwin Hengge* and *Günther Bauer*[*]

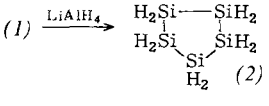
Only a few derivatives of cyclosilanes have previously been known and, except for a single chloro-derivative of uncertain structure[2], these all contained alkyl or aryl substituents[1]. Cyclic silanes containing functional groups were first obtained by removing phenyl groups from perphenylated cyclosilanes by means of HI[3], but this is not generally possible and led, for example, only to derivatives of pentaphenylcyclopentasilane $Si_5(C_6H_5)_5X_5$[4].

We have now found that decaphenylcyclopentasilane is converted quantitatively into decabromocyclopentasilane *(1)* by anhydrous HBr in a bomb tube at room temperature:



Compound *(1)*, easily prepared in this way and the first bromocyclosilane to be known, forms colorless crystals melting at 195 °C and extremely sensitive to moisture. The relative molecular masses (ebullioscopically, in benzene; mean of several measurements) are 939 (calc. 939.5). The Raman and IR spectra have very few lines, as expected; a Raman-active breathing vibration of the ring is observed at 510 cm^{-1} as well as the Si—Br bands.

As regards the reactions of *(1)* we were naturally most interested in the possibility of hydrogenation to the unsubstituted cyclosilane. This can be done by using very pure ethereal $LiAlH_4$ solution which should be added slowly to a benzene solution of the bromocyclosilane. After removal of the solvent a product could be isolated from the residue under reduced pressure (yield 80%); this proved to be the long sought cyclopentasilane *(2)*:



Si_5H_{10} is a colorless liquid with an extrapolated boiling point of ≈ 130 °C. Elemental analysis shows only silicon and hydrogen in the correct proportions. The ^{1}H-NMR spectrum (in benzene, internal standard benzene) shows a single sharp singlet at 6.57 ppm with a coupling constant J^{29}SiH of 195 Hz. The vibration spectra show few lines: IR: νSiH 2130, δSiH_2 865, 890 cm^{-1}; Raman: νSiH 2135, δSiH_2 891, 924, ring pulsation (ν_sSiSi) 382, ν_{as}SiSi 463, δ_{ring} 175 cm^{-1}. A theoretical estimate of the pulsation frequency, on the assumption that the ring is planar and with the nuclear separations and force constants of disilane, gave a value of 373 cm^{-1}[5].

The mass spectrum of *(2)* contains lines in the region of *m/e* 150 (molecular ion), 118 (Si_4 units with varying proportions of hydrogen), 88 (Si_3 units with varying proportions of hydrogen) and 60 (Si_2 units with varying proportions of hydrogen). The individual groups were split by isotope effects, as expected.

The existence of the cyclic silane C_5H_{10} can be regarded as proved by the findings described above.

Crystal and Molecular Structure of $NH_4[S_4N_5O]$—A New Sulfur-Nitrogen Cage[1]

By *Ralf Steudel*, *Peter Luger*, and *Hans Bradaczek*[*]

$NH_4[S_4N_5O]$ *(1)* is obtained as yellow water-soluble crystals on reaction of $SOCl_2$ with liquid NH_3 and subsequent hydrolysis of the reaction products[2]. As the IR and mass spectrum of this compound indicate an unusual cage structure of the anion $S_4N_5O^-$, we have carried out a single-crystal X-ray structure analysis of *(1)*.

The compound crystallizes in the monoclinic space group $C\,2/m$ with $a = 17.848$, $b = 6.232$, $c = 7.095$ Å; $\beta = 104.83°$; $Z = 4$; $d_{exp.} = 1.96$, $d_{calc.} = 2.01$ g/cm^3. 1207 reflections were measured on an automatic Siemens single-crystal diffractometer with θ between 2.4° and 30°. 82 reflections whose intensities were less than twice the statistical error were treated as unobserved. The structure was solved by the multisolution method and refined by the method of least squares. Temperature factors of the atoms S, N and O were anisotropic, but that of the H atom was isotropically refined. Because the linear absorption coefficient was small and the crystal form was nearly that of a cube, we did not apply an absorption correction. After convergence of the refinements the final *R* value amounted to 5.1%. Figure 1 shows the result of the analysis; Table 1 lists the most important intramolecular distances and angles. Two neighboring ions NH_4^+ and $S_4N_5O^-$, joined by an O—H hydrogen bridge are placed on a common mirror plane. Both ions have C_s symmetry; moreover, the NH_4^+ ion is bonded to the N^2 atoms of two further anions by way of two N—H hydrogen bridges. Only one of the four H atoms of NH_4^+ does not take part in an H bridge.

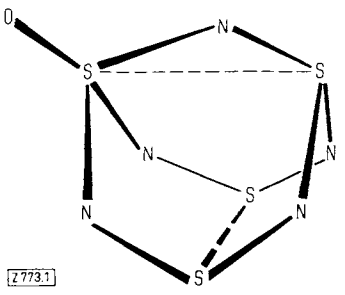

Fig. 1. Structure of the anion $S_4N_5O^-$.

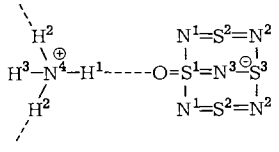
Thus the cation is not tetrahedral but instead is strongly deformed (three different N—H nuclear separations, HNH angles between 82 and 128°).



The structure of the anion can be formally derived from the cage of S_4N_4[3], one S atom (S^1) carrying an O atom and bridged to a neighboring S atom (S^3) through an N atom. This oxidized S atom is almost tetrahedrally coordinated. The S=O nuclear separation, 1.433 Å, corresponds to that in other molecules with S=O double bonds (SO_3 1.42 Å; SOF_4 1.42 Å).

The formation of *(1)* from $SOCl_2$ and NH_3 can be interpreted by a series of successive condensations with elimination of HCl, H_2O and NH_3:

$$2\,SOCl_2 + 7\,NH_3 \xrightarrow{NH_3} HN(SONH_2)_2 + 4\,NH_4Cl$$

$$2\,HN(SONH_2)_2 \xrightarrow{H_2O} NH_4[S_4N_5O] + 3\,H_2O$$

Lithium Derivatives of Silanol and Related Compounds

By *Stephen Cradock, Evelyn A. V. Ebsworth, Hans Moretto, David W. H. Rankin,* and *W. John Savage*[*]

Although disilylphosphane is relatively stable *in vacuo*, silanethiol and silaneselenol are not, while silanol is not known[1]. Alkali metal derivatives of these compounds are therefore difficult to obtain directly.

We find that methyllithium reacts smoothly in diethyl ether over a period of minutes at 227 K with $(SiH_3)_2Y$ (Y = O, S, Se)[2] or $(SiH_3)_3Z$ (Z = P, As); methylsilane is evolved in about 90% of the amount required by the equations:

$$(SiH_3)_2Y + CH_3Li \rightarrow Li[YSiH_3] + CH_3SiH_3$$

$$(SiH_3)_3Z + CH_3Li \rightarrow Li[Z(SiH_3)_2] + CH_3SiH_3$$

Table 1. Bond lengths and angles in $NH_4[S_4N_5O]$ *(1)*. Standard deviations in parenthesis.

Bond lengths [Å]					
N^4—H^1	1.03 (0.06)	S^1—O	1.433 (0.004)	S^2—S^2	2.633 (0.001)
N^4—H^2	0.98 (0.06)	S^1—N^3	1.580 (0.004)	S^1—S^3	2.717 (0.002)
N^4—H^3	0.93 (0.12)	S^1—N^1	1.591 (0.003)	S^1—S^2	2.658 (0.001)
N^2...H^2	2.00 (0.06)	S^2—N^1	1.631 (0.004)	S^2—S^3	2.741 (0.001)
O ...H^1	1.95 (0.06)	S^2—N^2	1.603 (0.003)	N^1—N^2	2.676 (0.004)
		S^3—N^2	1.651 (0.004)	N^1—N^1	2.524 (0.004)
		S^3—N^3	1.658 (0.005)	N^2—N^2	2.506 (0.005)
Bond angles [°]					
OS^1N^3	108.7 (0.2)	$N^1S^2N^2$	111.7 (0.2)	$H^1N^4H^2$	119 (5)
OS^1N^1	110.4 (0.2)	$S^2N^2S^3$	114.8 (0.2)	$H^1N^4H^3$	85 (7)
$N^1S^1N^3$	111.2 (0.1)	$S^1N^3S^3$	114.1 (0.3)	$H^2N^4H^2$	82 (5)
$N^1S^1N^1$	105.0 (0.2)	$N^3S^3N^2$	107.5 (0.2)	$H^2N^4H^3$	128 (5)
$S^1N^1S^2$	111.2 (0.2)	$N^2S^3N^2$	98.8 (0.2)		

The S—N nuclear separations in $S_4N_5O^-$ are somewhat more strongly differentiated than in S_4N_4, where they vary only between 1.596 and 1.634 Å. Nevertheless one must assume largely delocalized π-bonds within the S_4N_5 skeleton. The structural formula above can therefore be described only as a limiting structure.

As in S_4N_4, the contacts between the S atoms of one cage, being 2.7 Å, are appreciably smaller than the van der Waals S—S separations which are 3.7 Å. The smallest distances between different anions are practically in agreement with the van der Waals distances.

The lithium derivatives may be isolated as white crystalline solids by evaporation of the solvent. They have been characterized by their Raman spectra (obtained from solids and from solutions—Tables 1 and 2).

The ^{1}H-NMR spectra in general give the expected single Si*H* resonance, with satellites due to ^{29}Si in natural abundance [$^1J(^{29}SiH) \approx 200$ Hz in all cases]; we have shown by heteronuclear decoupling that in $Li(YSiH_3)$ the ^{29}Si spectrum is the expected quartet of sharp lines, whereas in $Li[Z(SiH_3)_2]$ the ^{29}Si spectrum is a quartet of quartets, the smaller splitting arising from ^3J(SiH). When Z=P, the main Si*H* resonance appears as a doublet at room temperature [^2J(PH)=15.5 Hz] and heteronuclear decoupling shows that the ^{31}P spectrum is a heptet. When Y=Se, satellites due to ^{77}Se appear at low temperatures [^2J(SeH)=11 Hz]; they collapse at temperatures above 273 K, presumably because of some exchange process, but at 253 K the ^{77}Se spectrum is a quartet.

Solutions of $Li(SSiH_3)$ and of $Li(SeSiH_3)$ react with trimethylchlorosilane to form $H_3SiSSi(CH_3)_3$ and $H_3SiSeSi(CH_3)_3$ respectively, which were characterized by their vibrational spectra. We are exploring further the synthetic potential of the lithium salts.

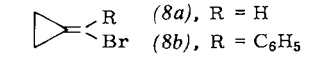
Synthesis and Solvolysis of (1-Bromo-1-cyclopropylmethylene)cyclopropane: A Particularly Stable Vinyl Cation[1][**]

By *William E. Heyd* and *Michael Hanack*[*]

Formation of vinyl cations on solvolysis of vinyl halides is particularly favored by cyclopropyl groups in the α-position[2]; for example, the chloride *(1)*[3] and the iodide *(2)*[4] are readily solvolyzed to the intermediate cation at 48.80 and 48.76 °C) is one of the highest yet found for solvolysis of vinyl halides[2].

The special additional stabilizing effect of the cyclopropane ring in *(6)* is shown by comparison of the relative rates of solvolysis of *(5)* and the vinyl bromides *(8a)* and *(8b)* (80% ethanol, 100 °C[1,5]): *(8a)* $k_{rel}=1$; *(8b)* $k_{rel}=3.6\times10^3$; *(5)* $k_{rel}=1.51\times10^5$.



(8a), R = H
(8b), R = C_6H_5

The high stability of *(6)* is shown also by the fact that it has almost no tendency to rearrange. Whereas solvolysis

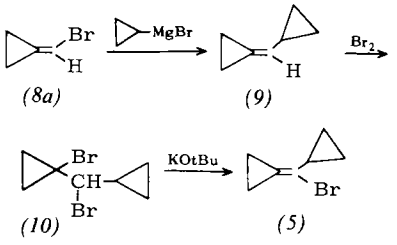
of *(8a)* affords exclusively the rearranged cyclobutanone[5], the main product in our case is dicyclopropyl ketone *(7)*.



For preparation of (1-bromo-1-cyclopropylmethylene)cyclopropane *(5)*, (1-bromomethylene)cyclopropane *(8a)*[5] was coupled with cyclopropylmagnesium bromide in THF in the presence of $FeCl_3$[8], yielding the hydrocarbon *(9)* which was then brominated in pentane at -70 °C. The resulting dibromide *(10)* was allowed to react with potassium *tert*-butoxide in dimethyl sulfoxide without further purification and the product *(5)* was isolated by preparative gas chromatography. NMR (CCl_4): $\tau = 8.30$ (1H/m, tertiary H); 8.72 (4H/AA'BB', methylenecyclopropane ring-protons); 9.12 (4H/m, cyclopropyl protons); IR (film): 1760 cm^{-1} (*exo*-methylenecyclopropane double bond); mass spectrum: $m/e = 172$, 174.

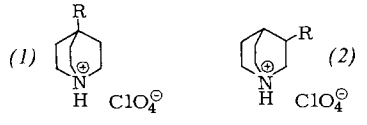
4-Substituted Quinuclidinium Perchlorates as Models for the Determination of Polar Substituent Effects

By *Cyril A. Grob, Werner Simon*, and *Dieter Treffert*[*]

Because of their structure and high symmetry 4-substituted quinuclidines are particularly suitable for the quantitative measurement of polar substituent effects by pK_a measurements[1,2]. Now that this type of compounds has become considerably more accessible[3], measurements can be carried out on a broader basis. Table 1 lists the pK_a values of some 4-substituted quinuclidinium perchlorates *(1)* and, for comparison, those of their 3-substituted analogs *(2)*[4].



[*] Prof. C. A. Grob, W. Simon, and D. Treffert
Institut für Organische Chemie der Universität
CH-4056 Basel, St.-Johanns-Ring 19 (Switzerland)

Table 1. pK_a values of 4- and 3-substituted quinuclidinium perchlorates *(1)* and *(2)*, respectively, in water at 25 °C. Mean deviation from the mean value ±0.3%.

R	*(1)* pK_a	*(2)* pK_a
$C(CH_3)_3$	11.07	11.02
$CH(CH_3)_2$	11.02	—
H	10.96	10.96
C_2H_5	10.95	10.94
CH_3	10.88	10.91
$COCH_3$	9.45	9.67
$COOC_2H_5$	9.44	9.40
CN	8.07	7.81

The following conclusions can be drawn from the values in the Table:

a) The range of pK_a values measured for the salts *(1)* of the 4-series is wide and covers three pK_a units.

b) The differences in the pK_a values of the alkyl derivatives are significant, albeit small, in both the 4- *(1)* and the 3-series *(2)*. The electron-repelling +I effect increases in the expected order $CH_3 < C_2H_5 < (CH_3)_2CH < (CH_3)_3C$.

c) A methyl group in the 4- or the 3-position is electron-attracting relative to hydrogen. Within experimental error, the ethyl group is equal to hydrogen.

d) The fact that the acetyl group is more electron-attracting in the 4-position than in the 3-position confirms the superiority of the field model of the inductive effect[5,6]. The direct distance and the orientation of the substituent dipole with respect to the nitrogen atom are clearly decisive, and not the chain length.

Between 15 and 35 °C the differences between the pK_a values of quinuclidinium perchlorate and those of its 4-methyl and 4-isopropyl derivatives remain almost constant. Thus, the 4-substituent contributes to the free enthalpy of dissociation by way of the enthalpy term[7].

The pK_a values of the 4-substituted quinuclidinium perchlorates *(1)* show a linear correlation with *Taft*'s polar substituent constants σ^*[8] (correlation coefficient $r = 0.9978$), provided that hydrogen is excluded. The particular position of the pK_a value of hydrogen [cf. c)] is not yet understood. It therefore seems advisable to use 4-methylquinuclidinium perchlorate as the basis for a linear free-energy relation of the form

$$pK_a^{(CH_3)} - pK_a^{(R)} = \rho\sigma$$

which is analogous to the *Hammett* equation.

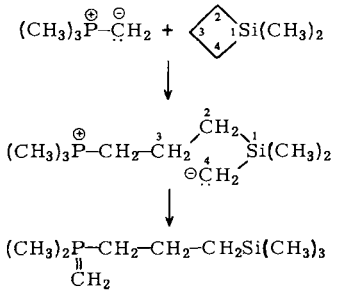
Abnormal Ring Opening of Silacyclobutanes by Trialkylalkylidenephosphoranes[1]

By *Hubert Schmidbaur* and *Walter Wolf*[*]

Present knowledge of the chemistry of silacyclobutanes[2] shows that both electrophilic[3] and nucleophilic ring-opening[4] affects only the Si—C bonds. Thus monosilacyclobutane rings are also usually opened at the "junction", *e.g.* by phenyllithium[4], and not with C—C bond cleavage. The same applies to carbene insertion by organomercury compounds[5], though the reaction is then accompanied by C—H insertion.

Attempts to silylate phosphorus ylides by silacyclobutanes revealed that the ylidic carbanion groups unexpectedly attack the strained ring system at the *C atom in position 3*. Heterolysis of the C—C bond occurs, yielding a new carbanion attached to silicon which then undergoes stabilization by prototropy to give a new phosphorus ylide. In this way dimethylmethylene[(3-trimethylsilyl)-*n*-propyl]phosphorane *(1)* is formed in almost quantitative yield from trimethylmethylenephosphorane[6] and 1,1-dimethylsilacyclobutane[2] in diethyl ether at $-10\,^{\circ}C$.

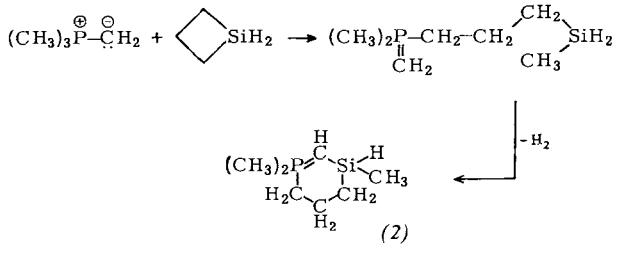
For well known reasons[7] one of the *P*-methyl groups loses a proton in the above-mentioned isomerization. *(1)*, b. p. 47 °C/0.1 torr, m. p. −10 °C, is unambiguously identifiable by analysis and spectroscopy. ^{1}H-NMR (neat, TMS ext.): $\delta CH_2{=}P$ 0.82, d, *J*(HCP) 7; δCH_3Si 0.12; δCH_3P −1.15, d, *J*(HCP) 12.5; δCH_2 at −0.48, −1.3, and −1.4 Hz ($A_2B_2M_2X$). Proton exchange induced by a trace of methanol causes $\delta CH_2{=}P$, δCH_3P, and δCH_2P (A_2) to collapse



to a common singlet; there then remain δCH_2 and δCH_2Si as the B_2M_2X portion which can be simplified to the B_2M_2 system by P-decoupling.

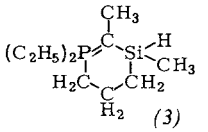
The abnormal course of the reaction is explained in terms of carbanion stabilization in the intermediate by the silicon atom. This possibility would not be provided by any alternative ring opening mode (attack at the 1- or 2-position).

When unsubstituted silacyclobutane is used, the analogous ring fission is followed by ring closure with extrusion of hydrogen.



The evolution of hydrogen is due to the presence of acidic phosphonium-hydrogen and negative *Si*-hydrogen functions in the same molecule in positions favorable to ring closure.

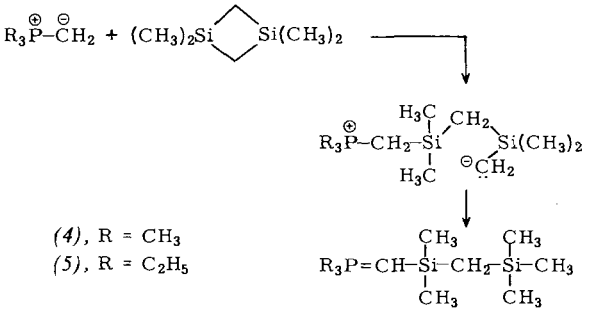
Reaction of $(C_2H_5)_3PCH_2$ and $(CH_2)_3SiH_2$ likewise affords the homologous heterocycle *(3)*. The two reactions occur rapidly and completely even at 0 °C. *(2)*, b. p. 46—47 °C/0.1 torr; ^{1}H-NMR (in C_6D_6, TMS ext.); δCH 1.2, d, J(*HCP*) 7.5; δCH_3Si −0.03, dd, *J*(*HCSiH*) 3, J(*HCSi*) 6.7, *J*(*HCSiCP*) 0.5; δCH_3P −1.13, d, J(*HCP*) 12 (broadened by the chirality center on Si); δHSi −7.73, dsex, *J*(*HSiCP*) 8.5; δCH_2 at −0.70, −1.73, and −2.63 Hz ($A_2B_2C_2X$); P-decoupling produces the expected changes. *(3)*, b. p. 63 °C/0.5 torr.



(3)

1,1,3,3-Tetramethyldisilacyclobutane is also easily cleaved by trialkylmethylenephosphoranes, but here there is no opportunity for alternative ring opening. Silylated ylides of types *(4)* and *(5)* are formed through Si—C cleavage.

In these cases nucleophilic attack on the hetero atom can also produce a stabilized carbanion, which then rearranges to the phosphorus ylide by proton abstraction from the PCH_2Si bridge[8,9].



(4), R = CH_3
(5), R = C_2H_5

That other nucleophilic reagents attack silacyclobutanes exclusively at the hetero atom is explained by the fact that in those cases the counter-ions present—*e.g.* Li^+ in the case of LiR—can assist by stabilizing the carbanion intermediate. Such assistance by counter-ions is absent in the case of salt-free ylides, and stabilization through the silicon atom therefore determines the course of the reaction.

Because of pronounced steric hindrance, reactions of triisopropylmethylenephosphorane[1] take place only slowly and incompletely. The nucleophilicity of methylenetriphenylphosphorane[10] no longer suffices for ring opening of disilacyclobutanes.

Silylated Ylides as Components for Wittig Reactions[1, 2]

By *Hubert Schmidbaur* and *Herbert Stühler*[*]

From the few reported attempts to synthesize silylated olefins from carbonyl compounds and silylated ylides it is clear that Wittig olefin synthesis with these components does not proceed according to the usual scheme but leads to unexpected products[3, 4]. Complicated mechanisms are required to explain the generally complicated product distributions[3] and it is difficult to test their validity. Only in one case[5] did the reaction conform to the classical concept[6].

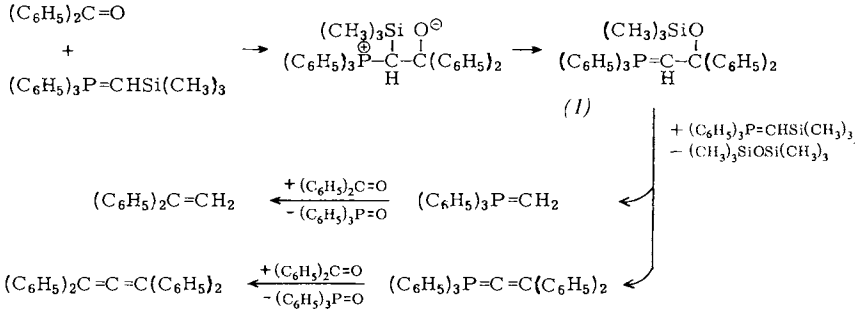
We have now found that calculable products are obtained only if the ylide and the carbonyl compound are used in the stoichiometric proportion 2:3 and if the ylide is pure and salt-free. These measures represent the only way of accommodating for the tendency to form a phosphane oxide as well as a disiloxane product.

The most important variants of the reaction course will be illustrated by three examples:

1. (Trimethylsilylmethylene)triphenylphosphorane[5, 7] and benzophenone afford tetraphenylallene and 1,1-diphenylethylene *quantitatively* along with triphenylphosphane oxide and hexamethyldisiloxane according to the following overall equation[3]:

$$3\,(C_6H_5)_2C{=}O + 2\,(C_6H_5)_3P{=}CHSi(CH_3)_3 \rightarrow$$
$$2\,(C_6H_5)_3PO + (CH_3)_3SiOSi(CH_3)_3$$
$$+ (C_6H_5)_2C{=}CH_2 + (C_6H_5)_2C{=}C{=}C(C_6H_5)_2$$

This result can be explained by a desilylation[8] of the second molecule of ylide by the primary product *(1)*; the $(C_6H_5)_3P{=}CH_2$ thus formed then reacts in the usual way:



2. On addition of $(C_6H_5)_2CO$ to $(CH_3)_3P{=}CHSi(CH_3)_3$[5, 9] the primary product *(2)* rearranges, after desilylation, by prototropy[10] in a different way, giving a *well defined phosphane oxide (3)*[11]:

$$3\,(C_6H_5)_2C{=}O + 2\,(CH_3)_3P{=}CHSi(CH_3)_3 \rightarrow$$
$$(CH_3)_3P{=}O + (CH_3)_3SiOSi(CH_3)_3$$
$$+ 2\,(C_6H_5)_2C{=}CH_2 + (CH_3)_2P(=O)CH{=}C(C_6H_5)_2$$
(3)

Mechanism:

$$(CH_3)_3P{=}C(H)-C(OSi(CH_3)_3)(C_6H_5)_2 \xrightarrow[-(CH_3)_3SiOSi(CH_3)_3]{+(CH_3)_3P=CHSi(CH_3)_3}$$
(2)

$$(CH_3)_3P{=}CH_2 + (CH_3)_2P(=CH_2)-CH{=}C(C_6H_5)_2$$
$$\downarrow (C_6H_5)_2C{=}O \qquad \downarrow (C_6H_5)_2C{=}O$$
$$(CH_3)_3P{=}O + (C_6H_5)_2C{=}CH_2 \quad (3) + (C_6H_5)_2C{=}CH_2$$

3. Similarly 2,4-dimethyl-1,3-pentadiene along with isobutene are formed from the last mentioned ylide and acetone:

$$3\,(CH_3)_2C{=}O + 2\,(CH_3)_3P{=}CHSi(CH_3)_3 \rightarrow$$
$$2\,(CH_3)_3PO + (CH_3)_3SiOSi(CH_3)_3$$
$$+ (CH_3)_2C{=}CH_2 + CH_3{-}C(CH_3){=}CH{-}C(CH_3){=}CH_2$$

A likely intermediate in this case is methallylidenetrimethylphosphorane. After desilylation, deprotonation occurs preferentially at one of the two methyl groups:

$$(CH_3)_3P{=}C(H)-C(OSi(CH_3)_3)(CH_3)_2 \xrightarrow[-\text{disiloxane}]{+\text{ylide}}$$

$$(CH_3)_3P{=}CH_2 + (CH_3)_3P{=}C(H)-C(CH_3){=}CH_2 \text{ etc.}$$

Reactions according to this new scheme make it possible to synthesize even complicated olefins under very mild

Low-temperature X-ray Structure Analysis of Ammonium Carbamate

By *Alfred Gieren*, *Walter Hoppe*, and *Klaus Fleischmann*[*]

We have carried out an X-ray structure analysis of ammonium carbamate ($NH_4^+CO_2NH_2^-$). Not only is this substance sensitive to moisture but also its relatively high volatility results in single crystals being unstable at room temperature even in dry air[1]. The analysis was therefore carried out in a low-temperature room at −50 °C while N_2 was used as protecting gas. The single crystals were obtained by passing CO_2 into liquid ammonia and then slowly evaporating the excess of ammonia.

Space group: *Pbca* with $a = 6.46$, $b = 6.66$, $c = 17.00$ Å; cell volume: 731.4 Å^3; $\rho_{exp}^{20\,°C} = 1.38$ g·cm^{-3}; $Z = 8$; $\rho_{calc.}^{-50\,°C} = 1.42$ g·cm^{-3}. The intensities were mostly measured photographically with a Weissenberg camera (oscillating procedure) but some few with a precession camera ($MO_{K\alpha}$ radiation). Evaluation afforded 1213 independent reflections (407 not observed).

The structure was solved by direct methods using the triple product rule and a program by *Hechtfischer*[2]. A Fourier synthesis calculated with the 300 largest, phased, unitary structure factors showed the positions of all the atoms (except H). Refinement, first with isotropic and then with anisotropic temperature factors, led to an R value of 10.5%.

The hydrogen atoms of the NH_2 group, but not those of the NH_4^+ group, could be seen after refinement in a difference Fourier synthesis. However, since the maxima were not sharp, these H positions were set in calculated positions (H1 parallel to C1—O2, H2 parallel to C1—O1, N—H = 1.0 Å) and only their temperature factors (isotropic) were included in the refinement ($R = 10.3\%$).

The planar carbamate ions associate to cyclic dimers (Fig. 1), which are held together by two N—H···O hydrogen bridges. The dimeric anion has a crystallographic symmetry

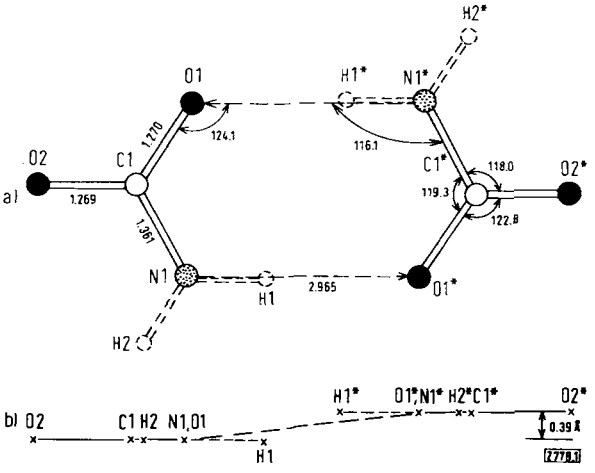

Fig. 1. Centrosymmetric dimeric anion in ammonium carbamate: a) Horizontal section: projection on N1, C1, O1; b) vertical section: projection along N1—O1. Standard deviations: 0.006 Å, 0.4°.

center. Its two portions are thus necessarily parallel but they do not lie strictly in one plane (separation of the two planes: 0.39 Å). HCO_3^- ions also form dimers in $KHCO_3$[3], but the anions in NH_4HCO_3[4] and $NaHCO_3$[5,6] and sodium sesquicarbonate ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$)[7] polymerize—the latter with inclusion of H_2O molecules. Dimers of our type are found in, *e.g.* carboxylic acids and their amides[8]. Similar cyclic hydrogen bridges play a role in base-pairing of nucleic acids[9]. The N1—O1 hydrogen bridge is 2.96$_5$ Å long, which agrees well with the mean value of the N—H···O bridge (2.94 Å[8]) for acid amides. The hydrogen bridge is asymmetric but linear within a few degrees.

The C—N (1.36 Å) and the C—O distances (1.27 Å) do not differ significantly from those in urea[10] (1.356 ± 0.007 and 1.276 ± 0.008 Å, respectively); they reflect the expected double-bond character.

The dimeric anions form buckled layers parallel to (001). On their periphery lie the NH_4^+ ions, which, mainly by hydrogen bridges, cross-link both the layers and the dimeric anions within the layers. The NH_4^+ group has four nearest O neighbors at the corners of a distorted tetrahedron (N2···O2: 2.74, 2.80 Å; N2···O1, 2.80, 2.87 Å). A fifth oxygen atom (O2) is considerably further removed (3.11 Å) but still in the range of a N—H···O bridge, even if a long one. The second hydrogen atom (H2) of the amino-group also takes part in a weak H bridge (N1···O1: 3.37 Å). But, unlike the H bridges in the dimeric anion, the bridges just mentioned show large deviations from the ideal configuration. That the two C—O distances in the dimeric anion do not differ significantly is probably to be ascribed to the fact that both oxygen atoms act to about the same extent as acceptors for hydrogen atoms.

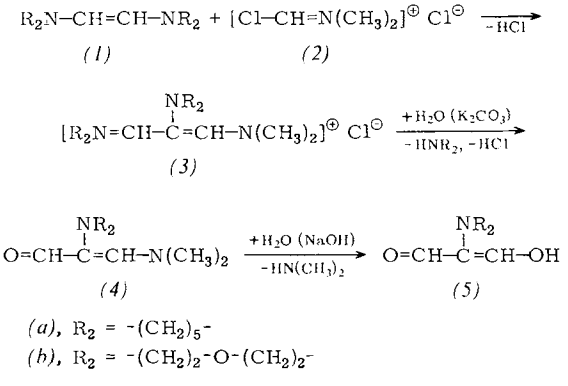
Vilsmeier Formylation of Enediamines[1]

By *Christian Reichardt* and *Klaus Schagerer*[*][**]

Whereas Vilsmeier formylation of enamines leads to formyl ketones and formyl aldehydes (dialdehydes)[2], the same reaction with enediamines should permit preparation of the hitherto inaccessible (dialkylamino)malondialdehydes.

If 1,2-dipiperidino- *(1a)* or 1,2-dimorpholino-ethylene *(1b)*[3] reacts with *N*-(chloromethylene)-*N*,*N*-dimethylammonium chloride *(2)* (produced from *N*,*N*-dimethylformamide and oxalyl chloride) in chloroform, then, after hydrolysis of the intermediate trimethinium salt *(3)*, the 2-(dialkylamino)-3-(dimethylamino)acroleins *(4)* can be isolated; their alkaline hydrolysis affords piperidino- *(5a)* and morpholino-malondialdehyde *(5b)*, respectively.



(a), R_2 = $-(CH_2)_5-$
(b), R_2 = $-(CH_2)_2-O-(CH_2)_2-$

The structures of all the new products were proved by elemental analysis and by IR, ^{1}H-NMR, and mass spectra.

The (dialkylamino)malondialdehydes *(5)* thus prepared for the first time are valuable starting materials for synthesis of dialkylamino-substituted polymethine dyes and heterocycles.

2-Piperidino-3-(dimethylamino)acrolein (4a)

Oxalyl chloride (21.6 g, 170 mmol) is added dropwise to a solution of *N*,*N*-dimethylformamide (11.9 g, 163 mmol) in chloroform (30 ml) with ice-cooling. Then a solution of 1,2-dipiperidinoethylene[3] (29 g, 150 mmol) in chloroform (30 ml) is added dropwise at −5 °C to the reaction mixture, which is next stirred for 12 h at room temperature and subsequently heated at 65 °C for 12 h. After cooling to 0 °C, this mixture is hydrolyzed first with ice-water (15 ml) and then with saturated potassium carbonate solution (180 ml) with subsequent heating at 70 °C for 2 h. Extraction with chloroform, removal of the solvent, and distillation of the residue in a high vacuum gave a forerun at 77 °C/0.03 torr, followed by the main fraction at 126 °C/0.03 torr, the latter solidifying to yellowish crystals in the receiver. Recrystallization from light petroleum (b. p. 40—60 °C) afforded colorless crystals (5.5 g, 20%) of m. p. 76—77 °C.—^{1}H-NMR ($CDCl_3$): 1.50 (m), 3.03 (m), 3.25 (s/CH_3), 6.35 (s/CH—N), and 8.78 ppm (s/CHO) (6:4:6:1:1).—Mass spectrum: $m/e = 182$ (M^+).

Piperidinomalondialdehyde (5a)

Compound *(4a)* (1.82 g, 10 mmol) and NaOH (0.5 g) in water (3 ml) were stirred together for 2 h at 100 °C. A little 1-propanol was added for homogenization and the pH was established at 4—5 by means of 2 N HCl. Extraction with ether, removal of the ether, and sublimation of the residue at 120 °C (bath temperature) and 0.1 torr yielded thin colorless crystals (0.99 g, 64%) of m. p. 195 °C—^{1}H-NMR ($CDCl_3$): 1.90 (m), 3.65 (m), 7.95 (s/OH), and 8.66 ppm (s/CH) (6:4:1:2).—Mass spectrum: $m/e = 155$ (M^+).

Morpholinomalondialdehyde *(5b)*, m. p. 205 °C (dec.), was obtained analogously.

5,6-Dihydro-4*H*-1,3-oxazines and γ-Amino Alcohols from α-Metalated Isocyanides and Epoxides[1]

By *Ulrich Schöllkopf* and *Reinhard Jentsch*[*]

5,6-Dihydro-4*H*-1,3-oxazines *(8)* without a substituent at position 2 or γ-amino alcohols *(7)* deserve attention as precursors of tetrahydro-1,3-oxazines which are of interest chemotherapeutically[2] or as intermediates in syntheses. We have found that these compounds can be obtained simply and in relatively good yield by treating α-lithiated isocyanides *(2)* with epoxides *(3)*, although other routes[3] give only poor yields. Investigations so far have shown that unsymmetrically substituted epoxides are attacked preferentially or exclusively at the less hindered carbon atom. The lithium compounds *(2)* can be obtained from alkyl isocyanides *(1)* and butyllithium.

The primary products *(4)* can be isolated as γ-isocyano alcohols by addition of one equivalent of glacial acetic acid. Depending upon the experimental conditions acid hydrolysis of these products yields, either γ-(formylamino) alcohols *(6)* or γ-amino alcohols *(7)*. 5,6-Dihydro-4*H*-1,3-oxazines are obtained by allowing ethanolic solutions of the primary adducts *(4)* or the γ-isocyano alcohols *(5)* containing sodium ethoxide to stand or by warming *(5)* with copper(I) oxide in benzene[4]. The γ-amino alcohols *(7)* or their *N*-formyl derivatives *(6)* can also be obtained from the dihydrooxazines *(8)* by acid hydrolysis.

residue is distilled (see Table 1 for b. p.). Characteristic IR bands (film): ν = 3500—3300 (OH), 2140—2150 (N≡C) cm^{-1}.

5,6-Dihydro-4H-1,3-oxazines (8)

Compound *(5)* (40 mmol) is stirred for 2—12 h with copper(I) oxide (10 mg) in boiling benzene (50 ml) until the N≡C band disappears from the IR spectrum. The mixture is filtered and the filtrate is evaporated in a rotary evaporator (crude yield almost quantitative) and the residue is distilled, giving *(8)* (see Table 1 for b. p.). *(8)* are also

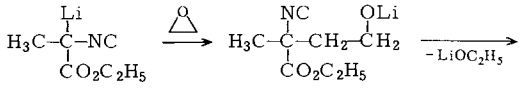
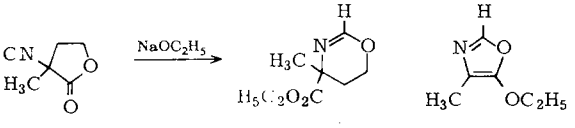
Ethyl 2-isocyano-2-lithiopropionate *(9)* and ethylene oxide afford 2-isocyano-2-methylbutyrolactone *(11)* as the first isolable product, presumably *via* the intermediate *(10)*. When treated with sodium ethoxide in ethanol, this lactone is converted into ethyl 5,6-dihydro-4-methyl-4*H*-1,3-oxazine-4-carboxylate *(12)*[5], which is the precursor of α-methylhomoserine. 5-Ethoxy-4-methyloxazole *(13)* is formed as by-product, resulting from intramolecular cyclization of *(9)*.



(9) *(10)*



(11) *(12)* *(13)*

γ-Isocyano alcohols (5)

Butyllithium (40 mmol, as a solution in pentane; precooled to *ca.* −70°) is added from a dropping funnel precooled by methanol/Dry Ice) over *ca.* 30 min to a solution of the isocyanide *(1)* (40 mmol) in tetrahydrofuran (50 ml) at −70 to −50 °C. To the resulting solution or suspension of *(2)* is added a solution of the epoxide *(3)* (40 mmol) in tetrahydrofuran (30 ml). The cooling bath is then removed and the mixture is stirred for *ca.* 10 min. at 0 °C, cooled again to −20 °C, and next treated with glacial acetic acid (40 mmol). The solvent is removed in a rotary evaporator, and the residue is shaken with water (20 ml) and methylene chloride (200 ml). The phases are separated and the aqueous phase is again extracted with methylene chloride (50 ml). The methylene chloride solutions are dried over magnesium sulfate and evaporated and the

obtained, although in lower yield, by carrying out the reaction *(2)* + *(3)* → *(4)*, adding methanol (30 ml) to the solution of *(4)* and stirring the whole at room temperature for 10 h. *(8)* are further obtained by keeping *(5)* at 40 °C in a solution of sodium (50 mg) in anhydrous ethanol (30 ml) for 4 h. Characteristic IR bands (film): ν = 3060—3080 (C—H), 1640—1650 (N=C), 1100—1150 (C—O—C); characteristic NMR signals (CCl_4): τ = 2.8—3.2 (d/H-2); $J_{H-2/H-4} \approx 2$ Hz).

γ-Amino alcohols (7) from (5) or (8)

Compounds *(5)* or *(8)* (20 mmol) are treated with 6 N hydrochloric acid (10 ml) with cooling, and the mixtures are stirred for 30 min at 50 °C. NaOH pellets (5 g) are added, and the *(7)* are extracted thrice with methylene chloride (50 ml portions). The methylene chloride solutions are dried over magnesium sulfate, the solvent is removed, and the residues are distilled; the yields of *(7)* are almost quantitative (see Table 1 for b. p.). *(7a)* can be distilled directly from the aqueous alkaline solution, without extraction.

γ-(Formylamino) alcohols (6)

Conversion of *(5)* into *(6)* can be effected as previously described[6].

A [17]Annulenyl Anion[1][**]

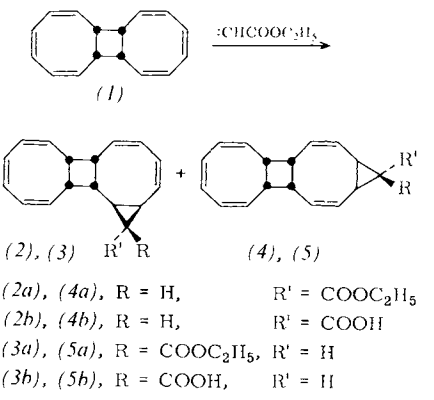
By *Gerhard Schröder*, *Günter Plinke*, *Donald M. Smith*, and *Jean F. M. Oth*[*]

Of the vinylogs of the cyclopentadienyl anion or the [5]annulenyl anion that obey the Hückel rule, the all-*cis*-[2] and the *cis,cis,cis,trans*-[9]annulenyl anion[3] have so far been reported. Also, one relatively complicated derivative each of the [17]-[4a] and [13]-annulenyl anion[4b] have been described. The aromatic character of these compounds has been convincingly proved by, *inter alia*, their ^{1}H-NMR spectra.

Now we report the synthesis and some properties of the [17]annulenyl anion, $C_{17}H_{17}^{\ominus}$, *(8)*. A suitable starting material is dimeric cyclooctatetraene *(1)*, m.p. 53 °C[5], which with diazoacetic ester in presence of copper powder at 100 °C yields the liquid adducts *(2a)*, *(3a)*, *(4a)*, and *(5a)*.

Repeated dry column chromatography (SiO_2) affords *(2a)* and *(3a)* and an inseparable mixture of *(4a)* and *(5a)* (see Table 1).

The positions of the three-membered ring and the ester group relative to the cyclobutane-protons in *(2a)*, *(3a)*, and *(4a)*/*(5a)* were determined by, *inter alia*, the paramagnetic shifts of individual proton resonance signals in the presence of europium tris(tetramethylheptanedionate). Of the crystalline acids formed on hydrolysis of *(2a)*, *(3a)*, and *(4a)*/*(5a)*, recrystallization afforded *(2b)*, *(3b)*, and *(5b)* in the pure state (see Table 1).



Photolysis of *(2a)*, *(2b)*, *(3b)*, and *(5b)* in ether at −80 °C by means of a low-pressure UV lamp led to the monosubstituted cycloheptadecaoctaenes *(6)* (having unknown configuration). In this way a red liquid *(6a)*, which according to thin-layer chromatography is homogeneous, is obtained from *(2a)*; the ester group is on the sp^3-hybridized C atom ($\bar{\nu}_{C=O}$ = 1735 cm^{-1}, 1H at τ = 5.5). The red liquid *(6b)* is formed from each of *(2b)*, *(3b)*, and *(5b)*, but nothing can be said about their homogeneity. Here too

Table 1. Data for compounds *(2)*—*(5)*.

[**] We thank Badische Anilin- und Soda-Fabrik AG for the cyclooctatetraene.

the carboxyl group is attached to the saturated C atom ($\tilde{\nu}_{C=O} = 1710\,cm^{-1}$). No isomerization with hydrogen shift has yet been observed for compounds *(6)*.

Surprisingly, *(6b)* decomposes smoothly in acetone at 20 °C to CO_2 and cycloheptadecaoctaene which can be separated into a crystalline and a liquid fraction by column chromatography (SiO_2, pentane) and fractional crystallization from pentane. For *crystalline* $C_{17}H_{18}$ (m.p. 126 °C) we propose structure *(7)*. Spectral comparison indicates that the *liquid* component is identical with a $C_{17}H_{18}$ that we had previously obtained by a somewhat different route[7] (see Table 2).

of relative intensities 2:2:1. The difference between the chemical shifts of the inner (high field) and the outer protons (low field) amounts to *ca.* 17 ppm. We therefore describe *(8)* as aromatic. Hydrolysis regenerates *(7)*.

When equimolar amounts of *(7)* and cyclopentadienylpotassium react in D_8-THF, then according to the NMR spectrum an equilibrium is set up containing *ca.* 80% of *(8)* and cyclopentadiene. However, an excess of KOH in D_8-THF is required for formation of *(8)* from *(7)* to be visible by NMR spectroscopy. The acidity of *(7)* is thus of the same order of magnitude as that of cyclopentadiene or water.

Table 2. Data for compounds *(7)*, liquid $C_{17}H_{18}$ and *(8)*.

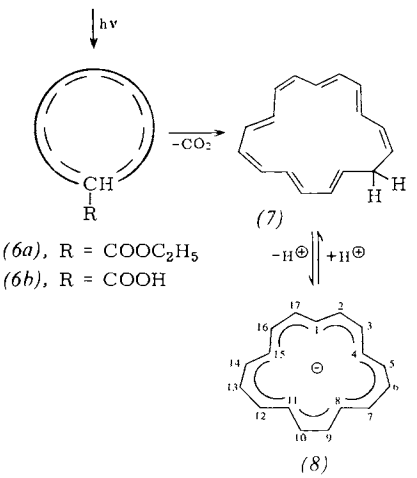
Cpd.	Yield [%]	M.p. [°C]	^{1}H-NMR, τ [ppm]	UV, λ_{max} [nm] (ε)
(7) [6]	≈32 [a] ≈90 [b]	126	2.5–3.5 (3 H/m) 3.6–4.7 (13 H/m) 7.1 (2 H/pseudo-t, $J \approx 5$ Hz) [e]	225 (16000) 260 (27000) 276 (30000) 365 (3800) [g]
$C_{17}H_{18}$ [6]	≈ 4 [a] ≈40 [c]	liquid	4.0 (16 H/m with flanks falling to 2.0 and to 4.9) 6.4–7.4 (2 H/m) [e]	225 (14000) 260 (26000) 276 (28000) 362 (3500) [g]
(8) counterion $Li^{\oplus}$	≈80 [d]		0.48 (10 outer H/m) 1.79 (H-6, H-13/t; $J = 9.5$ Hz) 17.97 (5 inner H/m) [f]	295 (53000) 426 (36000) 447 (210000) 580 (2400) 616 (2500) 673 (7700) [h]

[b] Referred to *(8)*.
[c] Referred to the methylene adduct of *(1)* [7].
[d] Referred to the amount of *(7)* used.
[e] 60 MHz spectrum in CS_2 with TMS as internal standard.
[f] 100 MHz spectrum, in D_8-THF with D-THF as internal standard; at −70 °C.
[g] In ether.
[h] In ether at −70 °C.

On catalytic hydrogenation, *(7)* and the liquid $C_{17}H_{18}$ give cycloheptadecane [m.p. 63—65 °C (64—65 °C[18]), NMR in CCl_4: τ = 8.7 (s)].

A [17]annulenyl anion is smoothly formed on treatment of *(7)* or liquid $C_{17}H_{18}$ in D_8-THF at −78 °C with a base, *e.g.* *n*-butyl- or methyl-lithium and is optically recognizable by a color change from red to dark green. The NMR spectrum (see Table 2) is in full accord with structure *(8)* (C_{2v} symmetry). Irradiation at the frequency of the signal at τ = 0.48 simplifies the triplet at τ = 1.79 to a singlet and the band at τ = 17.97 to three singlets

(2a), (2b), (3b), (5b)



(6a), R = $COOC_2H_5$
(6b), R = COOH

(7)

(8)

The thermal stability of *(7)* and *(8)* is noteworthy: *(7)* in hexachlorobutadiene, and *(8)* [from *(7)* and *n*-butyllithium] in D_8-THF, remain substantially unchanged on one hour's heating at 100 °C[19].

[8] *L. Ruzicka, W. Brugger, M. Pfeiffer, H. Schinz*, and *M. Stoll*, Helv. Chim. Acta 9, 499 (1926).

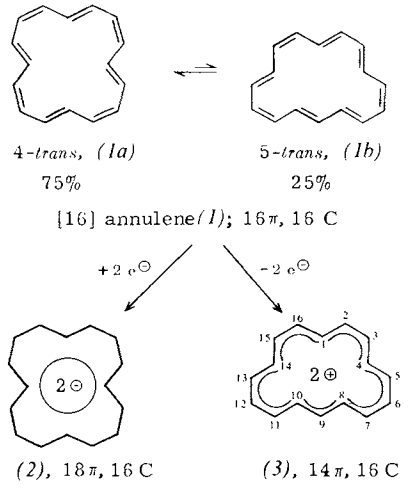
[9] The structure *(7)* proposed is based on two assumptions: a) that protonation of *(8)* occurs with the minimum of structural changes, and b) that electrocyclic reactions in a hexatriene segment containing a central *cis*-double bond of cycloheptadecaoctaene [there are two such segments in *(7)*] may not, according to model considerations, lead to relatively strain-free bi- or poly-cyclic valence isomers. Assumption b) explains the thermal stability of *(7)*.

A [16]Annulenediyl Dication[1][**]

By *Jean F. M. Oth, Donald M. Smith, Uwe Prange*, and *Gerhard Schröder*[*]

Neutral [4*n*]annulenes ($C_{4n}H_{4n}$, $n=1$, 2, 3, *etc.*) can in principle be converted in two ways into species that obey the Hückel rule [$(4n\pm2)$ π-electrons], namely a) by acceptance (reduction) and b) by loss (oxidation) of two electrons. Examples of case a) are the [8]-[2], [12]-[3], and [16]-annulenediyl dianions *(2)*[4]. No example of case b), *i.e.* formation of a dication from a [4*n*]annulene, has yet been reported[5].

We here report a surprisingly simple synthesis of a [16]annulenediyl dication *(3)* from [16]annulene *(1)*[6].



It was originally our intention to arrive at a homo[15]annulenyl cation *(5)* by proton addition to *(1)*, in analogy to the protonation of cyclooctatetraene which leads to the homotropylium ion *(4)*[7]. When FSO_3H (or FSO_3D) acts on red *(1)* in SO_2/CD_2Cl_2 at *ca.* −80 °C—a reaction that is accompanied by formation of varying amounts of polymer—there is a color change from red to violet and production of a species whose ^1H- and ^{13}C-NMR spectra (see Fig. 1) are in agreement only with those of the [16]annulenediyl dication *(3)*.

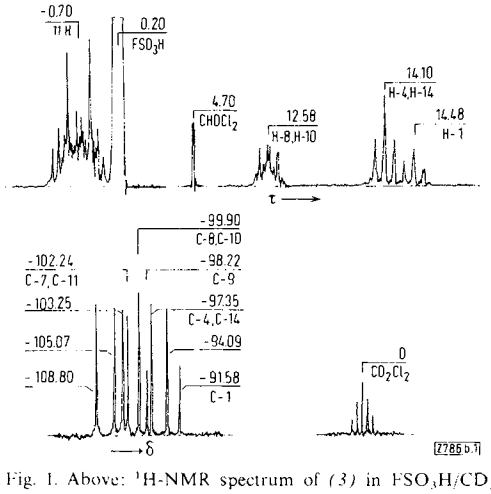


Fig. 1. Above: ^1H-NMR spectrum of *(3)* in $FSO_3H/CD_2Cl_2/SO_2$ at −25 °C and 100 MHz. Below: ^{13}C-NMR spectrum of *(3)* after heteronuclear broad-band decoupling in $FSO_3H/CD_2Cl_2/SO_2$ at −60 °C and 25 MHz. Internal standard: methylene dichloride [8].

The following arguments prove the existence of the dication *(3)*:

1. Neither the ^1H- nor the ^{13}C-NMR spectrum contains a signal that could be ascribed to a methylene group of a homo[15]annulenyl cation, *e.g. (5)*. For more detailed information the ^{13}C-NMR spectrum of *(4)* was measured (see Fig. 2). The signal of the methylene carbon atom of *(4)* appeared at +12.20 ppm.

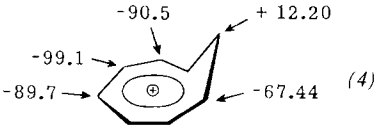

Fig. 2. ^{13}C-NMR data for *(4)* in $FSO_3H.CD_2Cl_2/SO_2$ at −60 °C and 25 MHz. Internal standard: CD_2Cl_2 [8]. δ-values are shown.

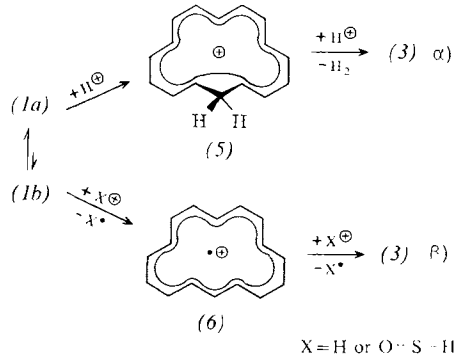
2. The ^1H-NMR spectrum indicates that the magnetic field in *(3)* induces a diamagnetic ring current: five inner protons appear at high field, and eleven outer ones at low field; the two triplets at $\tau=14.10$ (2H) and 14.48 (1H) ($J=12.5$ Hz), which we assign to the protons H-4/H-14 and H-1, respectively, also prove a system with cyclic delocalized π-bonds. The complex triplet at $\tau=12.58$ (2H) is the X part of an AA'BXX' system. Finally, the signals for the inner protons simplify to three singlets on irradiation at the absorption band at $\tau=-0.70$.

3. The center of gravity of the nine ^{13}C-absorption signals of *(3)* lies at $\delta=-100.7$ ppm with CD_2Cl_2 as standard (or at $\delta=-24.7$ with benzene as standard). The former value lies exactly on the straight line obtained when the ^{13}C signals of monocyclic neutral or charged aromatic compounds are plotted against the corresponding electron density per C atom[9].

4. The relative intensities of the ^{13}C signals (2:2:2:2:2:1:2:2:1) proves a structure with C_{2v} symmetry. The individual ^{13}C signals were assigned by selective ^1H-decoupling.



At least two possibilities can be discussed for formation of *(3)* from *(1)*[10]. By route α) a homo[15]annulenyl cation *(5)* is first formed, and subsequent protonation of a C—H bond of the methylene group can bring about production of *(3)* with loss of H_2. In route β) the proton or the conjugate acid of sulfur dioxide ($OSOH^{\oplus}$) acts as oxidizing agent, and the radical cation *(6)* is thus an intermediate. In α) molecular hydrogen is formed, but

in β) (X=H) elemental hydrogen. It proved impossible to detect hydrogen gas during formation of *(3)* in spite of a careful search.

Attempts to trap *(3)* by $NaOAc/CH_3OH$ have so far led only to indefinite polymeric products.

We plan to convert *(1)* into *(5)* by weaker acids and in other solvents, as well as to oxidize *(1)* electrochemically.

An Aza[13]annulene[1][**]

By *Gerhard Schröder, Günter Frank,* and *Jean F. M. Oth*[*]

Oxa- and aza-[13]annulenes are isoelectronic with the aromatic [14]annulene[2]. They belong to the group of higher-membered heteroannulenes (C_nH_nX, *e.g.* $n=8$, X=O or NR[3], or $n=16$, X=O or NR[4]). For several reasons, *e.g.* π-electron structure and intramolecular rearrangements, this class of compound has been studied for

[**] We thank the Badische Anilin- und Soda-Fabrik for the cyclooctatetraene.

several years past[3-5]. We here report the synthesis and properties of an *N*-(ethoxycarbonyl)aza[13]annulene *(8)*.

The tricyclic hydrocarbon $C_{12}H_{12}$ *(1)*[6] reacts with *N*-(ethoxycarbonyl)nitrene [from *N*-(*p*-nitrobenzenesulfonyloxy)urethane and triethylamine[7]] in CH_2Cl_2 at 10—20 °C, yielding the adducts *(2)*—*(5)* which can be separated and obtained pure by repeated dry column chromatography (SiO_2; pentane/ether 30:1 to 4:1) and recrystallization (Table 1) [the numbering *(2)*—*(5)* follows the order of retention volume on column chromatography].

and a brilliant yellow crystalline constitutional isomer of *(6)* to which we provisionally assign structure *(7)*, this being in accord with the NMR and UV spectra (see Table 2) and with the IR spectrum (in CS_2; *no* carbonyl band at 1700 cm^{-1}; bands of medium strength at 1750, 1645, 1285, 1045, 1000, and 750 cm^{-1}; strong absorption at 1200 cm^{-1}).

Irradiation of *(4)* affords a yellow oil (50—60% after chromatography) which could be crystallized from a little methanol. This yellow crystalline compound is an

Table 2. Data for compounds *(7)*, *(8)*, and *(9)*.

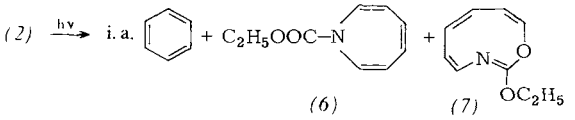
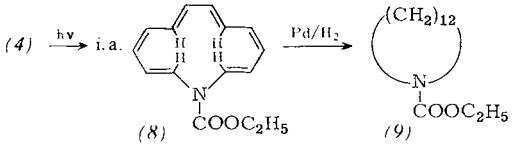
The NMR spectra indicate that *(3)* is an asymmetric molecule but that *(2)*, *(4)*, and *(5)* have a plane of symmetry. If the addition of *N*-(ethoxycarbonyl)nitrene occurs analogously to epoxidation[9], the aziridine ring in *(3)* and *(4)* is *syn* and in *(5)* is *anti* to the cyclobutyl protons. The formation of *(5a)* with the *syn*-arrangement of the three-membered ring is demonstrable only indirectly through *(2)*. *(2)* is formed from *(5a)* by a Cope rearrangement as shown by the arrows[10].

The chromophoric seven-membered ring system in *(2)* and the eight-membered ring system in *(4)* are suitable for photolysis, and this was carried out with *ca.* 500 mg each of *(2)* and *(4)* in *ca.* 1.2 l of ether at −70 °C by means of a low-pressure UV lamp. Working up and purification were by chromatography (−10 to 0 °C, pentane/ether), and subsequent recrystallization. From *(2)* we isolated benzene (*ca.* 90%), *N*-(ethoxycarbonyl)azepine *(6)*[11] (*ca.* 45%), an unidentified yellow liquid (*ca.* 3%),





aza[13]annulene to which we assign configuration *(8)*, this proposal being based on the assumption that the two multiplets at τ=5.0 and 5.45 are indicative of four inner protons and thus of four *trans*-double bonds [see Table 2 for the data pertinent to *(8)*].

In the range 40 to −60 °C the NMR spectrum of *(8)* shows only slight temperature-dependence of the olefinic proton signals. Below 0 °C the quartet and triplet of the methylene and methyl protons, respectively, undergo at least a doubling with different intensities[12], which appears to indicate the presence of various conformers.

The residue in the mother liquor from crystallization of *(8)* is oily and yellow and, according to thin-layer chromatography, contains only one component; its NMR spectrum shows, alongside traces of *(8)*, only absorptions for olefinic (τ=3.1—4.4) and ethyl protons (τ=5.75 and 8.7). Catalytic hydrogenation (Pd/C) of both *(8)* and the residue from the mother liquor yields the same liquid monocyclic urethane *(9)* (see Table 2). *(8)* is unusually sensitive to air and in solution is thermally moderately stable; changes in the NMR spectrum become evident after 1 hour's heating at 50 °C. We are currently occupied in elucidating the structures of the rearrangement products.

A Macroisopolyanion of Molybdenum: $Mo_{36}O_{112}^{8-}$

By *Karl-Heinz Tytko*, *Bernd Schönfeld*, *Bruno Buss*, and *Oskar Glemser*[*]

In continuation of our study of the reactions occurring on acidification of molybdate or tungstate solutions[1] we have investigated a series of aqueous molybdate solutions ($c = 0.1$—1 M[2]) at increasing degrees of acidity Z[3]. With $Z \approx 1.8$, we have found a new, uniform, unusually large species, namely the macroisopolyanion $Mo_{36}O_{112}^{8-}$, to exist in both the solution and the solid state. To our knowledge, this is *the largest uniform discrete ion yet proved to exist in solution or to have been isolated as a salt in the solid state.* Our conclusion is based, as described below, on Raman-spectroscopic measurements, determination of molecular masses by ultracentrifugation, X-ray crystallography, and mathematical analysis of potentiometric equilibrium curves for the system H^+/MoO_4^{2-}, the mode of formation being:

$$36\,MoO_4^{2-} + 64\,H^+ \rightarrow Mo_{36}O_{112}^{8-} + 32\,H_2O$$

Raman spectrum[4]: Intensity difference diagrams[5] (Fig. 1) show that in the region $Z > 1.6$ there are two reactions, one of which is to be ascribed to the formation and the other to further reaction of a new uniform polymolybdate species with a formation maximum in the region $Z \approx 1.8$. These two reactions can also be recognized by the appearance of isosbestic points.

In the intensity difference diagram there is a sharp transition between the two straight lines along which the two reactions proceed; from the sharpness of the intersection, which corresponds to the formation maximum in the solution, we can estimate that the new polymolybdate species reaches a molybdenum fraction[7] of >0.95 and that the role of precursors and subsequent products is no longer

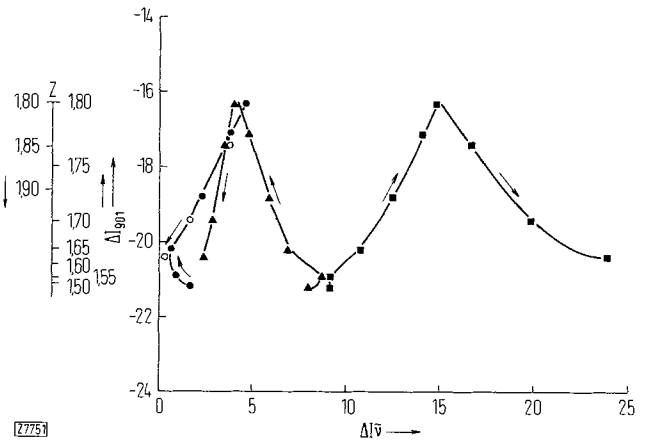

Fig. 1. Intensity difference diagram for the system H^+/MoO_4^{2-} ($c = 0.2$ M), relative to the MoO_4^{2-} spectrum in the region $Z > 1.5$ for three pairs of wave numbers: ■ 955/901, ▲ 971/901, ● ○ 983/901 cm^{-1}.

or not yet significant. The Raman spectrum of this solution (Fig. 2) can thus be regarded as identical with that of the new species in solution. Equilibration on formation of this species is complete after about 30 min at most and no further slower reaction follows.

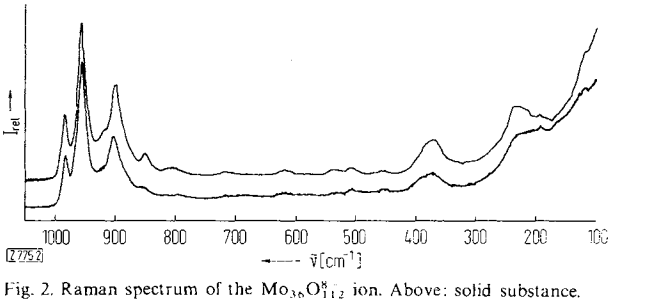

Fig. 2. Raman spectrum of the $Mo_{36}O_{112}^{8-}$ ion. Above: solid substance. Below: solution.

Crystallization of salts, which despite varying acid/base ratios (MoO_3/M_2O, where M = Na, K, NH_4, Ba/2), all give the same Raman spectrum identical with that of the solution (Fig. 2), occurs shortly after acidification from highly concentrated solutions having $Z \approx 1.8$ (the limiting concentration depends on the cation used). This proves that the solution and the crystalline solid both contain the same polymolybdate ion. Such behavior was previously found in the system H^+/MoO_4^{2-} only for the monomolybdate ion MoO_4^{2-} ($Z^+ = 0$[8]) and the 8,7-heptamolybdate ion $Mo_7O_{24}^{6-}$ ($Z^+ = 8/7 = 1.14$). A proof of this kind is very important for clarification of the mechanism of formation of polymetalate ions since results obtained on the solid (*e.g.* analysis or structure determination) thus can be used for statements about the thermodynamically most stable species in solution formed by a specific mechanism under defined conditions (degree of acidity, time, concentration)[9].

Analysis: Analysis of the salts gave the ratio Na/Mo = 0.20—0.22, K/Mo = 0.22—0.24 and NH_4/Mo =

[*] Dr. K. H. Tytko, Dipl.-Chem. B. Schönfeld, Dr. B. Buss, and Prof. Dr. O. Glemser
Anorganisch-Chemisches Institut der Universität
34 Göttingen, Hospitalstrasse 8–9 (Germany)

0.22–0.28. *Lindqvist*[10] had previously found a ratio Na/Mo = 0.23–0.29 for samples obtained by a method similar to ours, but without recognizing the nature of the species or, especially, its uniformity. The salts, which readily effloresce, contain a high proportion of water of crystallization, amounting to 2.2 H_2O/Mo, inclusive of any OH groups that may be present (they would be determined as H_2O).

The value of Z^+ derived from the above mentioned base/acid ratio amounts to 1.72—1.80, average 1.77. As we have explained, this value also applies to the new polymolybdate species in solution. The structure of the system H^+/MoO_4^{2-} in the region $Z > 1.6$ leads us to expect numerical agreement between the Z value of the solution at the formation maximum and the Z^+ value of the new polymolybdate.

Aggregation state: To determine the state of aggregation of the new polymolybdate species we have used the ultracentrifuge[17] and the sedimentation equilibrium procedure (schlieren optics) to measure the molecular masses in 0.2 M solutions at various degrees of acidity in the presence of 0.4 M Na(Cl) as inert electrolyte. We found a maximum at $Z \approx 1.8$ and determined for this in 0.1—0.2 M solutions an apparent molecular mass M_{app}[11] of ≈ 5620. Assuming that the species has a Z^+ value close to 1.8 and contains no OH group, the best approximation to the observed molecular mass would be a 38-molybdate ion $Mo_{38}O_{118}^{8-}$ ($Z^+ = 68/38 = 1.79$) with M = 5540. However, the uncertainties in the assumptions and the difference between M_{app} and M make it necessary to reckon with an error of about 5%. Control measurements on the heptamolybdate ion $Mo_7O_{24}^{6-}$ by a similar method of evaluation gave M_{app} about 10% too high. Thus aggregation states of 34—40 appear possible.

X-ray investigation: The sodium salt crystallizes in monoclinic prisms with space group $Cc—C_s^4$ or $C2/c—C_{2h}^6$ and the following lattice constants: $a = 40.2$; $b = 19.4$; $c = 33.4$ Å; $\beta = 139.2°$; $V = 16460(\pm 170)$ Å^3. In agreement with theoretical considerations of structure, the space groups exclude 34-, 35-, 37-, 38- and 39-molybdates. For a 36-molybdate the formula would be $Na_8Mo_{36}O_{112} \cdot 80H_2O$ ($Z^+ = 64/36 = 1.78$) and for a 40-molybdate $Na_8Mo_{40}O_{124} \cdot 88H_2O$ ($Z^+ = 72/40 = 1.80$). The density was determined pycnometrically (benzene or acetonitrile) as $d_{exp} = 2.72$ g/cm^3. The number of formula units in the unit cell is thus $z = 4$. For a 36-molybdate the calculated X-ray density is $d_{calc} = 2.77$ g/cm^3, and for a 40-molybdate is $d_{calc} = 3.06$ g/cm^3. If one assumes further that the O atoms are in closest spherical packing[12], as is found for all polymolybdates of known structure, one arrives at a packing density of 20.6 Å^3/O atom for a 36-molybdate and 18.7 Å^3/O atom for a 40-molybdate; the former value agrees very well with the packing densities of isopolymolybdates of known structure. The 40-molybdate is excluded by both these arguments. The new polymolybdate species is thus a 36-molybdate[14].

Structural considerations and a structural proposal: On the basis of our theoretical studies of the modes of formation and structures of polytungstate and polymolybdate ions[9], we can exclude the formation of such a large aggregate as a 36-molybdate ion by successive association of octahedron to octahedron. An 18-molybdate ion, which could dimerize to a 36-molybdate ion, is also too large to be built up in this way. Not till we reach the 12-molybdate ion, which could afford a 36-molybdate ion by trimerization, is formation by such a successive association of octahedra possible; however, structural considerations exclude any trimerization in principle (this would lead to structures of lower symmetry that would represent a section from a more symmetrical structure that could be obtained by tetramerization). The next possibility is tetramerization of four 9-molybdate ions which would lead to an ion with, in the ideal case, T_d symmetry (dimerization of two 9-molybdate ions to an 18-molybdate and dimerization thereof to the 36-ion is also conceivable). Fig. 3 shows a structure with a $Mo_{36}O_{112}$ skeleton built on this principle. In view of the terminal O atoms present and the pH range at which it exists, this species could take up at most approximately twelve negative charges and does not need to contain OH groups for structural reasons.

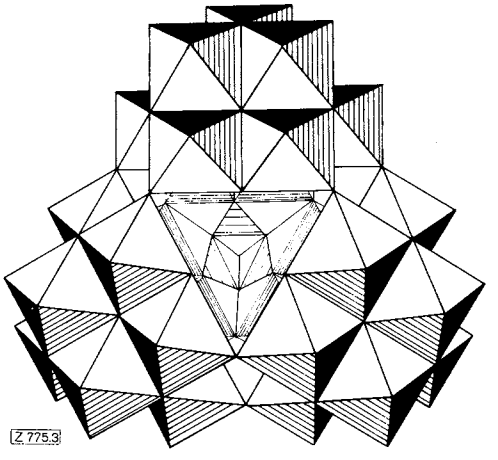

Fig. 3. Structure proposed for the $Mo_{36}O_{112}^{8-}$ ion.

It requires a minimum Z^+ value (no OH group) of 64/36 = 1.78, which affords a maximum charge of 8− and thus (charge $\lesssim 12-$) again it may not contain an OH group. The formula of the ion shown in Fig. 3 therefore is $Mo_{36}O_{112}^{8-}$ ($Z^+ = 64/36 = 1.78$).

Table 1. Overall formation constants β and standard deviation σ_Z for two sets of molybdate species according to EMF data of *Sasaki* and *Sillén*.
I: Set according to *Sasaki* and *Sillén*; II: Same set except species 64,36 in place of species 34,19.

Species	log β I	log β II
1,1	3.89	3.89
2,1	7.50	7.50
8,7	57.74	57.74
9,7	62.14	62.14
10,7	65.68	65.68
11,7	68.21	68.21
34,19	196.30	...
64,36	...	373.69
5,2	19	19
σ_Z [a]	0.0078	0.0089

[a] To prevent equalization of the σ_Z values, we used, for the calculation of σ_Z, only those runs in which a species 34,19 or 64,36 can occur, *i.e.* the runs for which data with $Z > 1.5$ were available.

Because of the symmetry (absence of a symmetry center) the four 36-molybdate ions per unit cell can be placed only on two-fold axes (the $\bar{4}$ tetrahedral axes coincide with the two-fold rotational axes). With the lattice constants given above each anion has six nearest neighbors

at a distance of *ca.* 16.5 A. The volume occupied by the anion in the direction of the six neighboring ions (determined on a model of the structure here proposed) is sufficiently small to avoid any overlap therewith. The macroisopolyanion takes four molecules of water of crystallization into its interior, while the remaining 76 molecules of water of crystallization fill the space between the anions.

Mathematical analysis of potentiometric equilibrium curves for the system H^+/MoO_4^{2-}: By a mathematical analysis of the $Z, \log h$[16] equilibrium curves for the system H^+/MoO_4^{2-}, *Sasaki* and *Sillén*[15] deduced for large values of Z the existence of a large anion of probable formula $Mo_{19}O_{59}^{4-}$ ($Z^+ = 34/19 = 1.79$). Using their data we have calculated that a set of species in which the 34,19-ion is replaced by a 64,36-ion would give only slightly less good standard deviation of Z (Table 1); and in this connection it should be noted that the calculations become increasingly better for the 64,36-ion as the concentration is increased. *Sasaki* and *Sillén*'s measurements thus do not run counter to the results of our investigations.

[14] X-ray investigation of the Ba, Na, and NH_4 salts of the 36-molybdate ion gave a triclinic unit cell for the Ba salt. For the Na salt (the NH_4 salts are isotypic) several monoclinic species were found whose diffraction patterns were the same or very similar. Analogous calculations and considerations (see above and the structural proposal) lead to an almost identical distribution of the 36-molybdate ions in the unit cell. Further investigation is in progress.

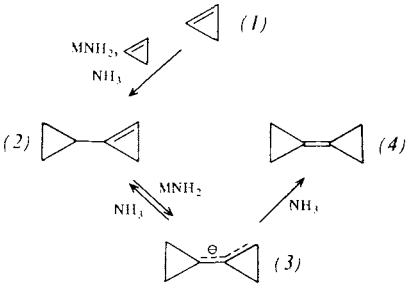
Eliminations from Three-Membered Rings: Cyclopropylcyclopropene and Bicyclopropylidene from 1-Chlorobicyclopropyl[**]

By *Lutz Fitjer* and *Jean-Marie Conia*[*]

Bicyclopropylidene *(4)* has a key position in the chemistry of polycyclopropylidenes ([*n*]-rotanes)[1] as the direct precursor of tricyclopropylidene ([3]-rotane)[2] and tetracyclopropylidene ([4]-rotane)[3].

(4) can be obtained by cyclopropanation of dimethyleneallene[3] or by anionic dimerization of cyclopropene *(1)* by metal amides in liquid ammonia with subsequent isomerization of the cyclopropylcyclopropene *(2)* by way of the allylic anion *(3)*[4].



The preparative value of the isomerization of *(2)* to *(4)* remained, however, limited because of the poor availability of cyclopropene *(1)*[5] and the poor yield in the dimerization[4].

We have therefore tried to prepare *(2)* by elimination of hydrogen chloride from 1-chlorobicyclopropyl *(12)*.

[**] This work was supported by the Deutsche Forschungsgemeinschaft through award of a research grant (L. F.).

The sodium amide used in this reaction could effect both the elimination to give *(2)* and the subsequent isomerization to *(4)*[6].

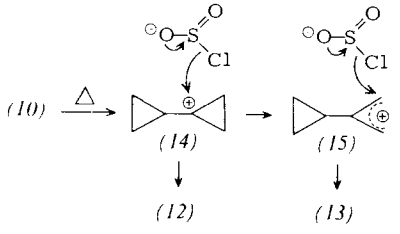
Starting from cyclopropyl methyl ketone *(5)*, we have made 1-chlorobicyclopropyl *(12)*[8] accessible by two independent routes:

1. By geminal dihalogenation to give (1,1-dichloroethyl)cyclopropane *(7)*[10], elimination to give (1-chlorovinyl)cyclopropane *(9)*[11], addition of dibromocarbene, with phenyl(tribromomethyl)mercury as carbene precursor[12] to give 2,2-dibromo-1-chlorobicyclopropyl *(11)*, and selective reduction with tri-*n*-butylhydridotin[13] to give *(12)*; and

2. by reaction of the sodium enolate of *(5)* with trimethylsilyl chloride to give [1-(trimethylsilyloxy)vinyl]cyclopropane *(6)*[14], cyclopropanation by a modified Simmons-Smith reaction[15] to give 1-(trimethylsilyloxy)bicyclopropyl *(8)*, conversion into the chlorosulfite *(10)* (not isolable but detectable spectroscopically), and pyrolysis to give *(12)*. The 2-cyclopropylallyl chloride *(13)* contaminating *(12)* can easily be removed by addition of bromine.

The reaction sequence *(8)* → *(10)* → *(12)* is, to our knowledge, the first example of replacement of a trimethylsilyloxy group by chlorine.

The formation of a preponderant amount of *(12)* rather than of *(13)* in the pyrolysis of *(10)* is further evidence of the relative stability of the 1-cyclopropylcyclopropyl cation *(14)*. This ion undergoes only slight ring opening to 2-cyclopropylallyl cation *(15)*[16].



The subsequent elimination of hydrogen chloride from 1-chlorobicyclopropyl *(12)* can be effected without any side reaction by using sodium amide in liquid ammonia and leads to bicyclopropylidene *(4)* *via* cyclopropylcyclopropene *(2)*. In agreement with this interpretation the product ratio *(4)*/*(2)* increases greatly on prolongation of the reaction time; after 18 h we obtained 15% of *(2)* and 52% of *(4)*. Subsequent distillation afforded 40% of pure bicyclopropylidene *(4)*, b.p. 101 °C, with complete polymerization of *(2)*. It is to be expected that the yield of *(4)* can be further increased[18].

(2) could be unambiguously identified in admixture with *(4)* by means of its characteristic methine-proton signal [$\tau = 4.10$ ppm, $J = 3$ Hz (pentane)]. The spectroscopic data for *(4)*[3], *(7)*[10b], *(9)*[10a] and *(12)*[9] were in accord with those reported in the literature.

All the new compounds gave satisfactory analytical values. Their most important physical and spectroscopic data are collected in Table 1.

We prefer the synthesis by way of *(6)*: it permits *(4)* to be obtained on a preparative scale by use of commercially available reagents.

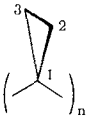
[18] *Note added in proof* (March 15, 1973): A 55% yield of pure *(4)* could be obtained by treatment of *(12)* with potassium *tert*-butoxide in DMSO.

Tricyclopropylidene ([3]-Rotane)[**]

By *Lutz Fitjer* and *Jean-Marie Conia*[*]

Polycyclopropylidenes ([*n*]-rotanes) *(1)*[1] are of particular interest because of the question whether their cyclopropane rings, which are linked to one another in *s-cis* fashion without interruption, could lead to an electron system delocalized over the central ring.

A qualitative assessment on the basis of the "bent-bond" model for cyclopropane[2] shows that this delocalization becomes the more probable the smaller the angle (β) between the planes of two neighboring cyclopropane rings and the greater the p contribution to the cyclopropane hybrid orbitals directed from C-1 to C-2 and from C-1 to C-3.



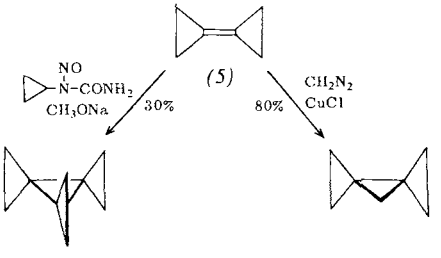
(1), n = 3, 4, 5...

Thus the conditions for a possible delocalization are most favorable for hexacyclopropylidene ([6]-rotane) *(1)*, $n=6$ ($\beta=60°$, hybridization C-1, C-2=C-1, C-3=sp^5) and least favorable for tricyclopropylidene ([3]-rotane) *(1)*, $n=3$ ($\beta=120°$, C-1, C-2=C-1, C-3=sp^3)[3][4].

We report here the synthesis of tricyclopropylidene *(1)*, $n=3$, and show, by spectroscopic comparison with dispiroheptane *(2)*, spiropentane *(3)*, and cyclopropane *(4)* that for *(1)*, $n=3$, a delocalization of the cyclopropane hybrid orbitals over the central ring is to be excluded.

Tricyclopropylidene *(1)*, $n=3$, could be obtained by spiroalkylation of bicyclopropylidene *(5)*[5] with 1-cyclopropyl-1-nitrosourea[6] as source of cyclopropylidene. Spiroalkylations of that type are known[7] but have hitherto been carried out in presence of a large excess of olefin. We, however, used an excess of 1-cyclopropyl-1-nitrosourea and obtained a 30% yield of the desired tricyclopropylidene *(1)*, along with allene.

The compounds *(2)*[8] and *(3)* required for comparison were prepared by CuCl-catalyzed reaction of *(5)* with diazomethane[10] and according to ref. [11], respectively.



(1), n = 3 *(2)*

In spite of the expected high strain energy, pure tricyclopropylidene *(1)*, $n=3$ (m. p. 29—31 °C), is thermally extremely stable. Heating for an hour at 300 °C does not lower its melting point, and the substance decomposes only at about 350 °C. Its structure is proved by spectroscopic data (see Table 1).

Table 1. Spectroscopic data for the compounds *(4)*, *(3)*, *(2)*, and *(1)*, $n=3$.

[a] Measured for CCl_4 solutions, except for *(4)* (capillary).
[b] Measured for CCl_4 solutions with TMS as internal standard.
[c] Proton decoupled spectra; measured for $CDCl_3$ solutions with TMS as internal standard. The chemical shifts obtained were converted to CS_2 as standard by using the relation $\delta(CS_2)=\delta(TMS)+192.8$ [18].
[d] Taken from non-decoupled ^{13}C-NMR spectra; the relatively large range of error is ascribed to the complexity of the spectra caused by $^{13}C-C-H$ long-range couplings.
[e] Measured for cyclohexane solutions; sh = shoulder.
[f] Center of an AA'BB' line system with $\nu_A - \nu_B \approx 0.20$ ppm.
[g] $(J^{13}C-H)_a$; $(J^{13}C-H)_b$ could not be determined because the number of accumulations was too small.

Because of the low intensity of the molecular ion (< 1%) we have determined the exact mass of $M-1$, which is characteristic for many cyclopropane derivatives[12]. Calculated (119.086) and experimental values (119.086 ± 0.002) showed the expected agreement.

Whether tricyclopropylidene *(1)*, $n=3$, possesses a delocalized electron system can be decided by comparison of

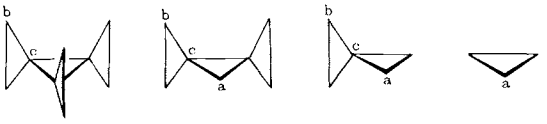
[**] Etude des Rotanes, Part V. – Part IV: [1e]. This work was supported by the Deutsche Forschungsgemeinschaft by award of a research grant (L. F.). We thank Jeolco Ltd., Grove Park-Edgware Road, London, N.W. 9, for determining the ^{13}C-NMR spectra.

the spectroscopic data for *(4)*, *(3)*, *(2)*, and *(1)*, $n=3$ (see Table 1).



(1), n = 3 *(2)* *(3)* *(4)*

Whilst the approximate agreement of the C—H stretching frequencies and ^{13}C—H coupling constants is not surprising and is no argument for or against the existence of conjugative interaction of the cyclopropane rings in *(1)*, $n=3$, the almost identical UV spectra of *(1)*, $n=3$, and *(2)* can be regarded as evidence that *(1)*, $n=3$, represents no exception in the series *(4)*, *(3)*, *(2)*, *(1)*, $n=3$.

This is shown still more clearly by comparison of the ^1H- and ^{13}C-NMR data. As would be expected if only inductive effects were operative, the ^1H- and ^{13}C-resonance signals are shifted by almost constant amounts along the series *(4)*, *(3)*, *(2)*, *(1)*, $n=3$: $\tau(CH_2)_a$ and $\delta(^{13}C)_a$ consecutively by about 0.5 and 9 ppm, respectively, downfield, and $\tau(CH_2)_b$ and $\delta(^{13}C)_b$ consecutively by about 0.05 and 0.6 ppm, respectively, upfield[19]. Only the ^{13}C-resonance signals of the quaternary carbon atoms that would be intimately concerned in delocalization of the C-1, C-2 and C-1, C-3 hybrid orbitals deviate slightly from the additivity observed elsewhere for the shifts; thus the difference $[\Delta\delta(^{13}C)_c]$ found on passing from *(3)* to *(2)* is 2.5 ppm but increases to 3.9 ppm on passing to *(1)*, $n=3$; yet this deviation is too small to suggest delocalization of the cyclopropane hybrid orbitals in *(1)*, $n=3$.

We therefore expect that the strain energy of *(1)*, $n=3$, will not fall much below the value 135.1 kcal/mol calculated from the strain energies of cyclopropane (27.15 kcal/mol[20]) and spiropentane (63.13 kcal/mol)[20, 21].

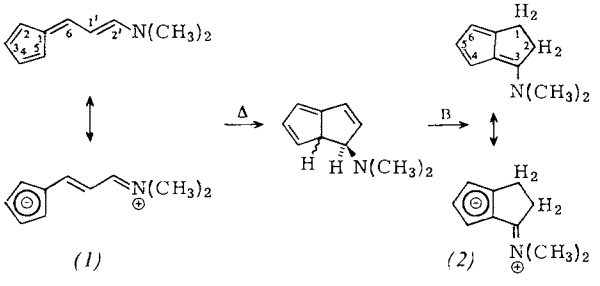
A Simple Synthesis of 1,5-Dihydropentalenes[**]

By *Reinhard Kaiser* and *Klaus Hafner*[*]

Dedicated to Professor B. Eistert on the occasion of his 70th birthday

Dihydropentalenes are important as precursors for a synthesis of pentalene and its derivatives[1]. We recently reported a simple synthesis of 1,2-dihydropentalenes *(2)* by thermolysis of 6-(2'-dimethylaminovinyl)fulvenes *(1)* in the presence of bases[2]. The reaction extends the general principle previously reported by us for the preparation of bi- and poly-cyclic conjugated π-electron systems[3].



(1) *(2)*

When applying this ring-closure reaction to derivatives of *(1)* carrying alkyl or aryl substituents in the side chain we observed that the cyclization and subsequent reactions were strongly dependent on the nature, number, and position of the substituents. Whereas fulvenes of type *(1)* with 6-alkyl or 6-aryl substituents afforded 1-alkyl- or 1-aryl-1,2-dihydro-3-dimethylaminopentalenes[4], the expected 1-alkyl- or 1-aryl-1-dimethylamino- or 1-ethoxy-1,2-dihydropentalenes *(4)* were not formed from terminally alkylated or arylated 6-(2'-dimethylamino- or -ethoxy-vinyl)fulvenes *(3)*[5] in boiling piperidine; the only products isolated were 1-alkyl- and 1-aryl-1,2-dihydro-3-piperidinopentalenes *(6)* which are resonance-stabilized and have lower energy than *(4)*.

These products *(6)* may have been formed in a thermodynamically controlled reaction by nucleophilic attack of the piperidine on the electrophilic center[6] of an initially

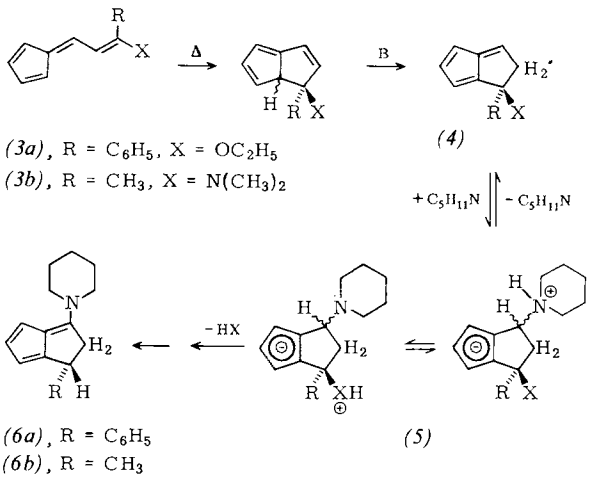
formed intermediate *(4)* and subsequent loss of dimethylamine or ethanol from *(5)*.



(3a), R = C_6H_5, X = OC_2H_5
(3b), R = CH_3, X = $N(CH_3)_2$

(4)

(6a), R = C_6H_5
(6b), R = CH_3

(5)

On the other hand, 6-(2'-dimethylaminovinyl)fulvenes *(7)*[5] alkylated at position 1' or dialkylated at positions 6 and 2' cyclize even below 20 °C and in the absence of a base. However, no derivatives of 1,2-dihydropentalene are formed, as by the ring closure of *(1)* or *(3)*, but instead the reaction yields the thermally rather unstable 1,5-dihydropentalenes *(9)*[7] which can be isomerized by bases, *e.g.* by piperidine, to the thermodynamically more stable fulvenoid 1,2-dihydropentalenes *(10)* or *(11)*. In

1,5-H shifts

(10)

(9)

(11)

the formation of *(9)* an electrocyclic reaction of *(7)*, giving *(8)*, is probably followed by a double 1,5-H shift characteristic for cyclopentadienes[8]. Consideration of models and UV spectra of *(7)* show that in *(7a)* there is steric hindrance between the substituents in positions 6 and 2' and in *(7b)* between R' on C-1' and the H atom at position 2 or 5; this would be relieved by rotation of the enamine portion around the C(6)—C(1') bond so as to move it out of the plane of the molecule. In the sterically most favored case the p_z-orbitals of C-6 and C-1' form an angle of 60 to 90°. In this process the p_z-orbitals of C-2' and C-5 come so close together that an electrocyclic reaction occurs even below 20 °C, presumably by a conrotatory 8 π-electron process[9]. These conditions favoring cyclization do not arise with *(1)* and *(3)*, for which the transoid conformation of the exocyclic group is favored instead, hence their cyclization requires a higher activation energy. However, under the conditions necessary for this cyclization neither the cyclization products *(8)* (R = R' = H, R'' = H, alkyl, or aryl) nor the 1,5-dihydropentalene derivatives *(9)* (R = R' = H, R'' = H, alkyl, or aryl) expected as a result of 1,5-H shifts are stable; in the thermal cyclization in the presence of bases they are rapidly converted into the more inert, tautomeric, resonance-stabilized, fulvenoid 1,2-dihydropentalenes *(2)* or *(6)*.

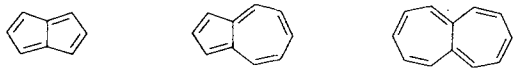
Concerning Pentalene, 2-Methylpentalene, and 1,3-Dimethylpentalene[**]

By *Klaus Hafner, Reinhard Dönges, Ernst Goedecke*, and *Reinhard Kaiser*[*]

In the series of non-alternant bicyclic hydrocarbons, pentalene *(1)* has, unlike azulene *(2)*[1] and heptalene *(3)*[2],



(1) *(2)* *(3)*

withstood attempts at synthesis that have extended over decades[3]. Each of the three compounds contains a peripheral π-electron system perturbed by a central σ-bond; in the case of azulene *(2)*, isomeric with naphthalene and having 10 π-electrons, the system has "aromatic" character, whereas heptalene *(3)* with 12 π-electrons behaves as a cyclopolyolefin. According to the Hückel rule, pentalene, with 8 π-electrons, should not have "aromatic" properties, but quantum-chemical calculations have given contradictory results[4]. Since it is not permissible to draw conclusions about the parent compound from the few known benzo-annelated or highly substituted pentalene derivatives, it is of interest to test the theoretical predictions by synthesis of *(1)* or its simple alkyl derivatives.

Starting from 1,2- and 1,5-dihydropentalene derivatives, for which we have described a simple method of preparation[5-7], we have now been able to detect pentalene *(1)*,

[a] TMS as internal standard.

1,3-dimethylpentalene *(4)*, and 2-methylpentalene *(5)* directly or by formation of their dimerization products.

Treating 1-(dimethylamino)-1,5-dihydro-1,3-dimethylpentalene *(6)*[6, 7] with methyl iodide in ether at −25 °C affords the methiodide *(7)* (yield 92%, dec. >75 °C). At 25 °C *(7)* undergoes 1,4-elimination in ethanol in the presence of a base yielding 1,3-dimethylpentalene *(4)*[8], whose existence as a short-lived intermediate is strongly suggested by isolation of dimerization products of structures *(8)* and *(9)* that are formed rapidly under the experimental conditions[6]. For each of *(8)* and *(9)* four configurations around the cyclobutane ring are possible and, of these, three stereoisomers were isolated for *(8)* [*(8a)*, *(8b)*, and *(8c)*] and two for *(9)* [*(9a)* and *(9b)*] (see Table 1).

On photolysis[9] of the dimer *(8a)* in a methylcyclohexane/2-methylbutane matrix (1:4) at −196 °C by means of monochromatic light of wavelength 254 nm, the extinctions of the maxima of *(8a)* were observed to decrease whilst a new maximum was formed at 336 nm (Figure 1).

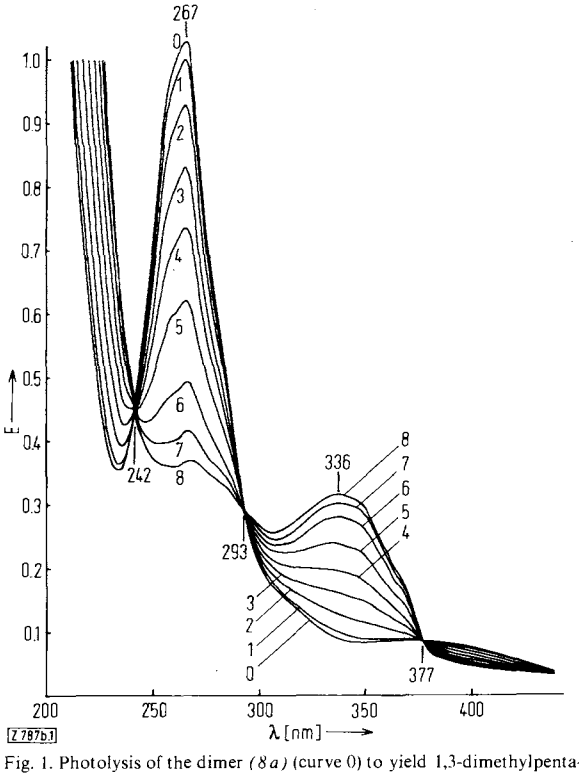

Fig. 1. Photolysis of the dimer *(8a)* (curve 0) to yield 1,3-dimethylpentalene *(4)* (curve 8). The absorption curves 1 to 8 were measured after 15 min, 1, 2, 4, 6, 10, and 25 h, respectively.

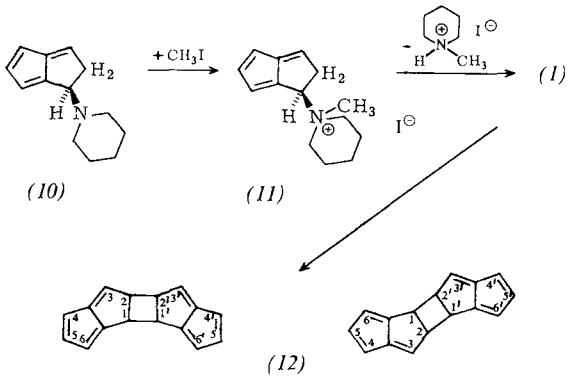
When the matrix was warmed to 20 °C this photochemical rearrangement, characterized by three isosbestic points, was seen to be thermally largely reversible. The absorptions of the product from *(8a)* are in excellent agreement with the values determined quantum-chemically for absorption by *(1)*[4d] and accord with the data of *de Mayo et al.* for 1-methylpentalene[10]. Thus the photochemical conversion of the dimeric 1,3-dimethylpentalene *(8a)* may be a [2+2]-cycloreversion with formation of 1,3-dimethylpentalene *(4)*.

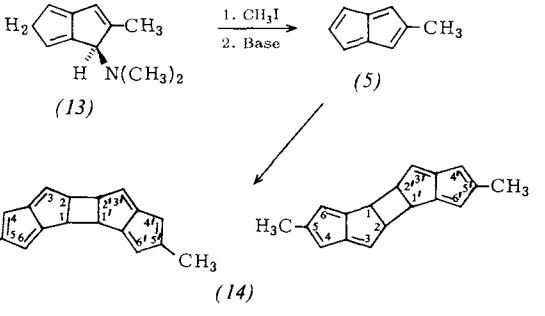
For preparation of pentalene *(1)* 1,2-dihydro-1-piperidinopentalene *(10)*[11] [a yellow thermolabile oil; λ_{max} (log ε) = 257 (3.98), 260 (3.97), 264 (3.94), 275 (3.65), 340 nm (3.08) in *n*-hexane; NMR spectrum (in CCl_4): multiplets



centered at τ = 3.28 (H-5), 3.44 (H-3), 4.00 (H-4, H-6), 6.01 (H-1), 6.97 (2H-2), 7.62 and 8.57 ($C_5H_{10}N$)] was converted into the methiodide *(11)* (yield 47%, dec. >100 °C) by methyl iodide in ether at −25 °C. In ethanol in the presence of a base this underwent Hofmann degradation at a temperature as low as 20 °C, after which two pentalene dimers of structures *(12)* were isolated in 22 and 10% yield, respectively; they are stereoisomers of *(12)* with respect to the cyclobutane ring fusions[11, 12] (see Table 1).

The results of photolysis of the dimers *(12a)* and *(12b)* under the same conditions as for the dimer *(8a)* indicate a fission of the dimers here too.

Analogously to the formation of the dimers of 1,3-dimethylpentalene *(4)*, two dimers *(14)* (or their stereoisomers with respect to the cyclobutane ring fusions) (Table 1) of the presumed intermediate 2-methylpentalene *(5)* were isolated from 1-(dimethylamino)-1,5-dihydro-2-methylpentalene *(13)*[7].



Experiments are at present being carried out in an attempt to identify the pentalene *(1)* and its derivatives *(4)* and *(5)*.

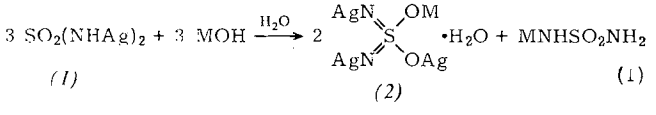
[11] Reduction of 1,2-dihydro-1,3-dipiperidinopentalene (pale yellow crystals, m. p. 99 °C) by lithium tetrahydridoaluminate gave *(10)* in 65% yield. The starting material can be prepared by condensation of sodium cyclopentadienide with 3-(dimethylamino)-3-ethoxy-*N*,*N*-dimethylpropen-2-aldimonium tetrafluoroborate, which gives 6-(2'-ethoxy-2'-dimethylaminovinyl)fulvene (red needles, m. p. 54 °C, yield 70%), with final cyclization in boiling piperidine (yield 46%).

[12] Primary formation of pentalene *(1)* before formation of the dimers is also indicated by isolation of the dimer *(12a)* on dehydrogenation of 1,2-dihydropentalene [5] at 480 °C in presence of a Pd/C catalyst *in vacuo*.

Dinitridodioxosulfate(VI), $SN_2O_2^{4-}$: A New Derivative of the Sulfate Ion

By *Edgar Nachbaur* and *Alois Popitsch*[*]

Reaction of sulfuric diamide with silver nitrate in aqueous solution followed by neutralization with ammonia gives the sparingly soluble, white *N*,*N'*-diargentosulfuric diamide *(1)*[1]. This is converted by alkali hydroxide or ammonia solution in excess into yellow products with a higher silver content. For example, *(1)* and 2 N NaOH at room temperature give monosodium trisilver dinitridodioxosulfate(VI) monohydrate *(2)* (M = Na) and *N*-sodiosulfuric diamide; the former is also only sparingly soluble, but the latter remains in solution.

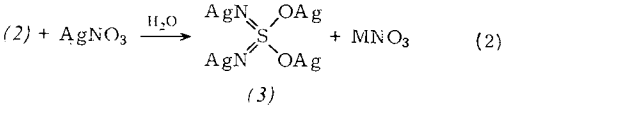


(1) *(2)* (1)

M = Li, Na, K, NH_4

Reaction of *(2)* with hydrogen sulfide in anhydrous methanol affords a mixture of sulfuric diamide and sodiosulfuric diamide, as can be demonstrated spectroscopically, and this confirms the stoichiometry of eq. *(1)*.

On digestion of *(2)* with an excess of warm aqueous silver nitrate solution one obtains the insoluble dark red tetrasilver dinitridodioxosulfate(VI) *(3)*:



(2) *(3)* (2)

If *(3)* is treated in the same way with H_2S, then sulfuric diamide is quantitatively regenerated. The composition of *(2)* and *(3)* is proved by elemental analysis. The IR spectra accord with the tetrahedral structure (C_{2v}) assumed for the $SN_2O_2^{4-}$ ion: IR spectrum of *(3)* (KBr; cm^{-1}): 1080 ν_{as}(S=N) vs; 935 ν_s(S=N) vs; 890 ν_{as}(S—O) vs; 785 ν_s(S—O) vs; 670 s, 620 s, 580 s, 375 s.

The silver salts *(2)* and *(3)* are insoluble in all the usual solvents and are thermally unstable, particularly compound *(3)* which in the dry state decomposes explosively on mechanical shock (rubbing, impact) with deposition of metallic Ag.

Experimental:

Concentrated NH_3 solution (100 ml) is added to $SO_2(NH_2)_2$ (4.8 g, 0.05 mol) and $AgNO_3$ (17 g, 0.1 mol) under red light, and the mixture is concentrated to 10 ml in a rotary evaporator. The white crystalline precipitate *(1)* is filtered off and washed with water; when heated with 5% NH_3 solution in excess it changes almost quantitatively to the pale yellow trisilver salt *(2)*.

The salt *(2)* (1 g) is digested with $AgNO_3$ (5 g) in H_2O (100 ml) in a beaker protected from light and heated on a water-bath. Dark red tetrasilver salt *(3)* is then formed and can be washed with water, alcohol, and ether and stored under an inert solvent. Yield almost 100%.

$^{13}C^{13}C$ Coupling Constants of 1,3-Butadiene[**]

By *Georg Becher*, *Wolfgang Lüttke*, and *Gerd Schrumpf*[*]

The bonding in 1,3-butadiene is of fundamental importance in the question of the extent of delocalization of the π-electrons of unsaturated molecules. Increased interest attaches to $^{13}C^{13}C$ coupling constants for the study of CC bonding[1]. There exists a direct relation[2], which also has a theoretical foundation[3], between the extent of this coupling and the properties of the C atoms participating in the bonding. Thus, we have determined the $^{13}C^{13}C$ coupling constants of 1,3-butadiene[4]. Since it is not possible, even with the techniques available today, to measure these constants precisely for compounds with their natural ^{13}C content, we have analyzed the spectra of several ^{13}C-labeled butadiene molecules. Butadienes were therefore prepared containing one or two ^{13}C atoms enriched to *ca.* 90%.

The coupling constant between non-equivalent ^{13}C atoms can be determined on introduction of only one ^{13}C atom by measuring its coupling with the other ^{13}C atoms left in their natural abundance. The coupling constants are obtained from such ^{13}C-NMR spectra by simultaneous decoupling of all the protons.

It becomes necessary to introduce two ^{13}C atoms when the coupling constant between chemically equivalent ^{13}C nuclei is to be measured. The coupling constant can be determined from the spectrum only if the two ^{13}C nuclei couple with other nuclei, *e.g.* with protons. For such spin systems all the coupling constants can be found from both the ^{13}C- and the ^{1}H-NMR spectrum[5].

To avoid too complicated spectra, as few protons as possible were left in the ^{13}C-labeled molecule; the unnecessary hydrogen atoms were replaced by deuterium, and the spectra were observed under D-decoupling conditions.

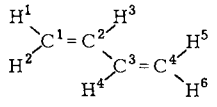
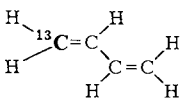
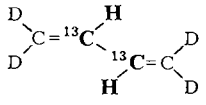
[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. *F. Bär* for determining the ^{13}C-NMR spectra.



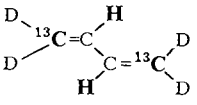
(1)



(2)



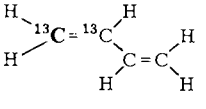
(3)



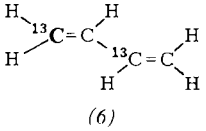
(4)

With these points in mind we have synthesized the following compounds: [1-^{13}C]-1,3-butadiene *(2)*, [1,1,4,4-$^{2}H_4$][2,3-$^{13}C_2$]-1,3-butadiene *(3)* and [1,1,4,4-$^{2}H_4$][1,4-$^{13}C_2$]-1,3-butadiene *(4)*. Formula *(1)* shows the numbering. The spectra of these compounds afforded all the CC and most of the CH coupling constants.

Analysis of the ^{1}H-NMR spectrum of *(2)* has already been reported[6]. The ^{13}C-NMR spectrum of *(2)* was obtained by the Fourier technique with proton decoupling. Because of the natural abundance of ^{13}C, about 1% each of the doubly labeled compounds *(5)* and *(6)* existed alongside *(2)*, and their spectra are superposed on that of *(2)*.



(5)



(6)

From the AX spectrum of *(5)* one obtains $J_{C^1C^2}$ at 68.8 Hz. The two doublets of the AX system of *(6)* could not be resolved. Their half-width yielded only an upper limiting value of 1 Hz for $J_{C^1C^3}$.

We obtained the coupling constants of the AA'XX' spin systems of *(3)* and *(4)* not from the ^{13}C spectra, but from the ^{1}H spectra with decoupling of the deuterons because of the considerably greater accuracy of the latter measurements. Numerical analysis of the spectrum of *(3)* gave $J_{C^2C^3}$ and that of *(4)* led to $J_{C^1C^4}$.

$J_{C^2H^3}=152.74$ and $J_{C^2H^4}=4.07$ Hz, as well as $J_{C^1H^3}=0.01$ and $J_{C^1H^4}=4.42$ Hz, were also obtained. Table 1 lists all the chemical shifts and coupling constants.

The magnitude of the CC coupling constants $^1J_{CC}$ across one bond is primarily determined by the hybridization of the carbon orbitals that form the bond[2]. Thus, the numerical value of $^1J_{CC}$ in the series ethane (sp^3-sp^3), ethylene (sp^2-sp^2), and acetylene (sp-sp) increases from 34.6, by way of 67.6, to 171.5 Hz[7]. The value 68.8 Hz found in this work for $J_{C^1C^2}$ in 1,3-butadiene lies in the double-bond region, as expected.

Table 1. Chemical shifts and coupling constants of the ^{13}C atoms of 1,3-butadiene [a].

	C^1	C^2	C^3	C^4
C^1	−10.40	68.8	<1	9.05
	(0.04)	(0.4)	(0.4)	(0.03)
C^2		10.06	53.70	<1
		(0.04)	(0.05)	(0.4)
C^3			10.06	68.8
			(0.04)	(0.4)
C^4				−10.40
				(0.04)

[a] See *(1)* for the numbering of the atoms. All the coupling constants (non-diagonal elements) are in Hz; the chemical shifts (diagonal elements) are in ppm relative to C_6D_6. Data in parentheses are standard deviations.

We presume that the exact value of $^1J_{CC}$ also depends on the number of carbon-substituents on the double bond. This is indicated by the increase of this coupling from unsubstituted ethylene by way of propene with 70.0 to isobutene with 72.6 Hz[8]: $^1J_{C=C}$ increases by 2–3 Hz per carbon substituent. Styrene with $^1J_{C=C}=70$ Hz fits into this series[2].

The influence of hybridization and an additive effect of carbon-substituents cannot fully explain the exact value of $J_{C^1C^2}$ of butadiene. In comparison with propene, for example, this coupling is shifted to lower values, although both molecules are monosubstituted ethylenes. Therefore it is probable that this decrease in $J_{C^1C^2}$ arises from a decrease in the π-bond order of the double bond in butadiene when compared with that in propene[2]; for even with benzene, where the bond order of each C—C bond is 0.67, one observes a decrease, here indeed of more than 10 Hz ($^1J_{CC}=57.0$ Hz)[9].

The magnitude of $J_{C^2C^3}$ of the formal single bond in butadiene supports this view: $J_{C^2C^3}$ at 53.70 Hz is distinctly lower than in benzene. Thus the π-character of this bond is lower than in benzene; it will hardly exceed a value of *ca.* 0.2. This is in agreement with the electron distribution as determined by theory[10] and with the experimentally observed properties of butadiene[11]. A more precise numerical value for the π-bond order of the two CC bonds in butadiene cannot be determined from our data or from those in the literature: although in all the molecules available for comparison both of the C atoms concerned in the bonding under consideration are sp^2-hybridized, they differ from butadiene in their degree of substitution and in their conformation. In spite of this last limitation we come to the conclusion that the neglect of the π-electron contribution to $^1J_{CC}$, as in a recent publication on CC coupling constants[12], seems to be unjustified. How strongly $^1J_{CC}$ depends on the individual factors discussed above is to be more closely examined by means of the various methylethylenes.

Kinetic Investigations of Anodic Oxide Layers on Niobium and Tantalum

By *K. E. Heusler*[*]

Non-porous oxide layers of uniform thicknesses between about 50 Å and 0.5 μm can be deposited on niobium or tantalum by anodic oxidation in electrolyte solutions. The glass-like oxides have the composition $M_2O_{5(1-x)}$. The oxygen deficiency creates oxygen vacancies whose concentration may approach several percent of the oxygen sites available.

The concentration of vacancies is increased by dissolution of oxygen from the oxide into the underlying metal and is decreased by reaction of the vacancies with molecular oxygen. Below 400 °C these reactions do not alter the thickness of the layer or its crystallinity.

When studying these reactions, the fact that the anodic oxides on niobium and tantalum are impurity semiconductors[1,2], whose electronic conductivity is a measure of the concentration of oxygen vacancies, was utilized. The electronic conductivity of oxide layers on niobium measured at a constant temperature increases by up to nine powers of ten during heat treatment in vacuum for several hours at temperatures between 100 and 250 °C. This effect is partly due to an increase of the concentration of vacancies. There is also a substantial contribution from the lowering of the activation energy of electronic conductivity with increasing concentration of vacancies. However, the activation energy remains constant in certain ranges of concentration. There the experiments show the concentration of vacancies to rise at a constant rate. The rate-determining step is the transfer of oxygen atoms through the interface from the oxide into the metal[3].

The reaction of oxygen vacancies in niobium oxide with oxygen is also determined by the phase-boundary reaction. Its rate is proportional to the oxygen pressure and to the square of the vacancy concentration. The mechanism suggested is that in a first, rapid step an oxygen molecule occupies a vacancy on the surface and that two normal oxygen ions are formed in a second, slow step by reaction of a second vacancy with the intermediate, involving cleavage of the oxygen-oxygen bond.

The reaction between oxygen vacancies in anodic tantalum oxide and oxygen was investigated with a quartz frequency balance[2]. The frequency of a quartz oscillator decreases linearly with the mass per unit area[4]. The quartz crystals were coated on both sides by anodized tantalum layers. The accuracy of the measurements was about 10^{-9} g $cm^{-2} d^{-1}$. Vacancies were generated by heating the sample *in vacuo*. The kinetics of the increase of mass observed after exposure to oxygen is typical of a reaction whose rate is determined by the phase-boundary reaction at low oxygen pressures and short times, but by diffusion of vacancies toward the surface of the oxide at high oxygen pressures and long times. The rate of the phase-boundary reaction is proportional to the oxygen pressure. The dependence of the rate on the concentration of vacancies also supports the view that the reactions of the oxygen with oxygen vacancies in anodic oxides of tantalum and niobium are described by the same mechanism.

Molecular Structure and Biosynthesis of the Fatty Acid Synthetase-Multienzyme Complex of Yeast

By *Eckhart Schweizer*[*]

The fatty acid synthetase complex of the yeast *Saccharomyces cerevisiae* is coded by two unlinked, complex gene loci, *fas*1 and *fas*2[1,2]. Whereas *fas*1 could be localized on chromosome XI of the revised gene map of yeast (formerly chromosome fragment 5), the position of *fas*2 is so far unknown[3].

Genetically and biochemically pleiotropic mutants of both *fas*-gene loci are known[2]. As a rule, they do not synthesize material (CRM) that cross-reacts immunologically with specific fatty acid synthetase antiserum. Synthetase-analogous CRM is, however, formed *in vitro* when cell extracts of suitable CRM-negative, pleiotropic *fas*-mutants are mixed. This *in vitro* complementation indicates that the two *fas*-gene loci are read off independently of one another, and shows further that the native, biologically active conformation of these components are formed only on their association to the total complex. This explains the hitherto unsuccessful attempts to dissociate the complex into enzymatically active partial enzymes.

By feeding radioactive pantothenic acid to various *fas*-mutants it could be shown that in *fas*2 one of the two gene regions responsible for the condensation reaction obviously controls the synthesis of the acyl carrier protein. Mutants of this region contain a pantothein-free fatty acid synthetase complex, which *in vitro* lacks only the condensation reaction.

SDS-polyacrylamide gel electrophoresis permits separation of the fatty acid synthetase complex into two components differing slightly in molecular weight (170000 to 190000). In some mutants one of these two protein bands can be shifted to a different position corresponding to a lower molecular weight. It is thus unlikely that these two bands represent two groups of proteins, each containing different components of the same molecular weight. Rather, the experiments indicate that the two gene loci *fas*1 and *fas*2 each code for a single but polyfunctional peptide chain. Individually, the two chains are obviously enzymatically inactive but on association to the complex undergo a conformational change forming the active sites of the partial enzymes. This association perhaps also yields the active sites of the three acyl transferases for which no individual structural genes have yet been identified.

[*] Prof. Dr. E. Schweizer
Institut für Biochemie der Universität
87 Würzburg, Röntgenring 11 (Germany)

Contrary to the structure of bacterial multienzyme complexes, it is probable that multifunctional peptide chains participate in the structure of a series of eukaryotic multienzyme complexes. According to this concept, during the course of evolution an increasing functional structuring of the cell interior would lead not only to formation of multienzyme complexes but also to complexes with multifunctional peptide chains. It is clear that their biosynthesis is favored, both kinetically (by abolition of association) and by regulation (no stoichiometric problem), over the association of the individual partial enzymes.

Lecture at Karlsruhe on January 18, 1973 [VB 364 IE]

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Enzymes insolubilized on inorganic supports are surveyed by *H. H. Weetall* and *R. A. Messing*. Enzyme derivatives that are insoluble in water have the advantage that they can be used as columns or suspensions and can readily be added to, or removed from, reaction mixtures. Moreover, they can be used repeatedly. Such derivatives are obtained by adsorption or covalent binding of enzymes onto supports. The article describes the available methods, lists the supports used, and considers the properties of some of the resulting preparations. [Insolubilized Enzymes on Inorganic Materials. Chem. Biosurfaces *2*, 563—595 (1972); 101 references]

[Rd 549 IE—G]

Interactions between normal and malignant cells are the subject of a review by *L. Weiss*. It describes the nature of the surface of the cell and the events occurring on cellular contact and subsequently on the surface and in the interior of cells. Interactions with malignant cells are then considered which appear to be responsible for the phenomenon of metastasis, on the one hand, and for tumor resistance, thanks to the destruction of malignant cells by the lymphocytes of the host organism, on the other. [Interactions between Normal and Malignant Cells. Chem. Biosurfaces *2*, 377—447 (1972); 371 references]

[Rd 557 IE—G]

The use of X-ray analysis in studies on amorphous catalysis is surveyed by *P. Ratnasamy* and *A. J. Léonard*. Numerous industrial catalysts (SiO_2,Al_2O_3,SiO_2/Al_2O_3, ultramarines are considered in the present article) possess a large surface area and a high porosity, but are not crystalline and therefore give diffuse X-ray diagrams. However, with the aid of two complementary methods, even such diagrams can provide information about atomic distances and coordination numbers. The methods are described, and the reader is provided with indications regarding experimental techniques. [X-Ray Scattering Techniques in the Study of Amorphous Catalysts. Catal. Rev. *6*, 293—322 (1972); 45 references]

[Rd 561 IE—G]

The role of solvated electrons in electrode processes is dealt with in a review by *B. E. Conway*. Solvated electrons can be formed by photoinjection from the cathode under certain irradiation conditions, by direct injection from the cathode if a sufficiently large potential difference is present at the interface between cathode and solution, and by dissolution of basic metals in solvents such as ammonia and some amines. The article treats experimental proofs of the occurrence of solvated electrons as intermediates in cathodic and photocathodic processes in various media. The electroorganic chemistry of reductions with solvated electrons is considered only in so far as it provides an indication of cathodic production of solvated electrons. [Solvated Electrons in Field and Photo-Assisted Processes at Electrodes. Mod. Aspects Electrochem. *7*, 83—142 (1972); 118 references]

[Rd 563 IE—G]

The IR spectroscopy of nucleic acids is the subject of a review authored by *G. P. Zhizhina* and *E. F. Oleinik*. The article contains IR and Raman data for DNA and RNA as well as their components and deals with the assignment of IR bands to individual bond vibrations. An approach to the theoretical treatment of the normal vibration of the nucleic acid skeleton is described. The authors show how IR provides information about the interactions of heterocyclic bases and about the secondary structures of nucleic acids, as well as their interactions with proteins, metal ions, and a few biologically active substances. [Infrared Spectroscopy of Nucleic Acids. Russ. Chem. Rev. *41*, 258—280 (1972); 218 references]

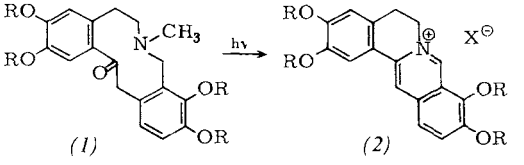
[Rd 589 IE—Q]

The reactivity of cyclic organic phosphorus compounds is reviewed by *R. F. Hudson* and *C. Brown*. The review is based on considerations of the rules of pseudorotation and on the postulates that ring strain decreases a) in the reaction of cyclic phosphoryl or phosphonium compounds with nucleophiles, and b) in the reaction of cyclic P^{III} compounds with nucleophiles to give pentacoordinated

intermediates (with the lone pair of electrons as "phantom ligand"), whereas it increases in the reaction of cyclic P^{III} compounds with electrophiles to give tetracoordinated intermediates. These postulates have been checked experimentally; in almost all the cases studied they have proved to be correct. [Reactivity of Heterocyclic Phosphorus Compounds. Accounts Chem. Res. 5, 204—211 (1972); 57 references]

[Rd 597 IE—L]

The photochemical synthesis of isoquinoline alkaloids is discussed in a review by *T. Kametani* and *K. Fukumoto*. Photolytic electrocyclic reactions are employed *inter alia* for the preparation of aporphine, protoberberine and benzophenanthridine alkaloids. Also of interest is the photochemical transannular reaction in which compounds of the protopine series *(1)* are readily converted into those



(1) *(2)*

of the berberine series *(2)*. The authors also deal with the Pschorr photoreaction (synthesis of alkaloids of the benzyl- and phenylethylisoquinoline series *etc.*) and photolytic cyclodehydrohalogenation (synthesis of aporphine, morphinandienone, proaporphine, and amaryllidaceae alkaloids *etc.*). [Photochemical Synthesis of Isoquinoline Alkaloids, Accounts Chem. Res. 5, 212—219 (1972); 42 references]

[Rd 600 IE—L]

Insolubilized antigens and antibodies are the topic of a review by *H. H. Weetall*. Such antigens and antibodies are also called immunoadsorbents because they serve to isolate, purify, and quantitatively determine the respective antibody or antigene. Furthermore, they are suitable as models for the study of antigene-antibody interactions. The author describes the supports used, the methods of linkage of antigenes or antibodies to these supports, and applications and properties of the resulting products. [Insolubilized Antigens and Antibodies. Chem. Biosurfaces *2*, 597—631 (1972); 130 references]

[Rd 550 IE—G]

The recording of weak IR signals is dealt with by *M. J. D. Low, J. C. McManus*, and *L. Abrams*. It is frequently considered impossible to obtain informative spectra from almost "black" samples. The authors have been disproving this notion for several years with commercially available spectrophotometers and in the present review they show just *what* can be measured under such unfavorable conditions, and *how* one should go about the measurements. [Recording Infrared Spectra at Low Signal Levels. Appl. Spectrosc. Rev. *5*, 171—210 (1972); 33 references]

[Rd 570 IE—G]

Chemisorption complexes and their role in catalytic reactions on transition metals are discussed in a report by *Z. Knor*. The energy of the metallic bond in transition metal crystals lies between 5 and 10 eV, the bond energy of most simple molecules is of the same order of magnitude, and the energy of a chemisorption bond is between 2 and 10 eV. It is therefore difficult to decide whether the interaction between the metal surface and a gas molecule should be described as a perturbation of the crystal by the gas molecule or whether it should be regarded as a surface complex which is perturbed by the crystal. The author favors the second possibility and indicates the consequences for catalysis research. [Chemisorption Complexes and Their Role in Catalytic Reactions on Transition Metals. Advan. Catal. *22*, 51—73 (1972); 85 references]

[Rd 577 IE—G]

Spin-spin coupling constants between geminal and vicinal protons are, as illustrated in a review by *V. F. Bystrov*, sensitive detectors of conformation and structure of molecules. Very slight changes in the structure of the molecule lead to characteristic changes in the coupling constants. The influences of bond length, bond angle, valence, electronic structure and orientation of substituents on the coupling constants is investigated. Unfortunately, present *a priori* calculations do not permit an exact description of the relationships. The author discusses semiempirical approximations that are promising on the basis of general relations from quantum mechanical calculations. [Spin-spin Coupling between Geminal and Vicinal Protons. Russ. Chem. Rev. *41*, 281—304 (1972); 293 references]

[Rd 590 IE—Q]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Polymer masses containing fibrous electrically conducting material can be obtained by the use of glass fibers coated with silver, copper, or nickel as fillers. The compositions may consist of up to 50 wt.% of glass fibers, which have a diameter of 1 to 30 μm and a metal coating 0.025 to 0.25 μm thick. The metal is applied to the glass fibers by immersion in a metal coating bath. Heat-curable resins such as phenolformaldehyde and urea-formaldehyde resins, thermoplastic resins, and rubbers such as polyamides, polyesters, polycarbonates, silicone rubber, natural rubber, and ABS rubber may be used as the polymer. It is possible in this way to avoid the high concentrations of fillers that have been necessary until now in order to obtain appreciable conductivities. [DOS 1720977; Imperial Chemical Industries, Ltd., London]

[PR 39 IE—E]

In a novel production of 3,5-dimethylpyridine, 2-methylene-1,3-propanediol and/or its monoester or diester (acetates) is allowed to react with at least 1/2 equivalent of NH_3, NH_2CH_3, and/or $NH(CH_3)_2$ in the presence of a polar solvent such as H_2O and/or CH_3OH and an acidic catalyst (0.1—10% mineral acid and/or sulfonic acid and/or carboxylic acid) at 200—300 °C and 10—200 atm. The diol can be produced by alcoholysis of the corresponding

diacetate, and can be used as a crude product with a content of 1—30% of monoacetate and/or diacetate. 3,5-Dimethylpyridine is obtained with a purity of 85 to 95%, and can be used in this form *e.g.* for the production of dicarboxylic acids by oxidation. Known processes, on the other hand, lead to mixtures of pyridine derivatives or cause considerable corrosion of the autoclave. [DOS 2045880; Farbenfabriken Bayer AG, Leverkusen]

[PR 49 IE—B]

A new catalyst for the simultaneous production of 1,3-butadiene and methacrolein by treatment of mixtures of *n*-butenes and isobutylene with molecular oxygen can be represented by the following general formula:

$Ni_aCo_bFe_cBi_dX_eMo_fO_gZ_h$

X = phosphorus, arsenic, boron
Z = potassium, rubidium, cesium
$a + b = 1$ to 15, $c = 0.5$ to 7, $d = 0.1$ to 4, $e = 0$ to 4, $f = 12$, $g = 36$ to 98, $h = 0.01$ to 1

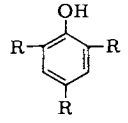
The new catalyst leads to a substantial increase in the yield of 1,3-butadiene and methacrolein in comparison with previously known methods. [DOS 2155109; Nippon Kayaku Co. Ltd., Tokyo]

[PR 50 IE—D]

The racemization of optically active α-amino-ε-caprolactam by microbiological means and a process for the production of L-lysine from D-, L- or DL-α-amino-ε-caprolactam by this racemization method in combination with a microbiological hydrolysis method are claimed. The racemization has previously been achieved only by chemical or physiochemical methods. In accordance with the invention, it is carried out with a microrganism from the genera *Achromobacter*, *Flavobacterium*, and/or *Alcaligenes* or with an enzyme formed by such a microorganism, or with the enzyme aminolactam racemase. Microorganisms from the genera *Cryptococcus*, *Candida*, and/or *Trichosporon* can be used as hydrolytic microorganisms; enzymes formed from such microorganisms or the enzyme L-α-aminolactam amidohydrolase may also be used. [DOS 2163018; Toray Industries, Inc., Tokyo]

[PR 55 IE—I]

Agents for the extermination of rodents contain trialkylphenols *(1)*. They are particularly suitable for use against rats, and are characterized by a cumulative effect. Phenols with *tert*-alkyl substituents are preferred; these can be used alone or in combination with agents for reducing blood platelet formation and for increasing capillary permeability and blood pressure or in conjunction with anticoagulants



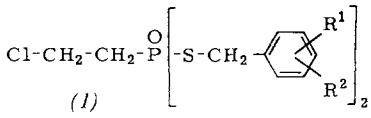
(1)

R = *sec*-, *tert*-alkyl (C_3—C_6)

for the formulation of the bait. [DOS 2145907; Imperial Chemical Industries Ltd., London]

[PR 86 IE—N]

Esters of phosphonodithiolic acids *(1)* can be used to regulate the abscission of fruits. They cause simultaneous ripening of all unripe fruits (berries, stone and kernel fruits, nuts, citrus fruits) without causing leaf fall or resin flow in fruit



(1)

BOOK REVIEWS

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH., Weinheim/Bergstr., Germany. Eighth fully revised Edition.

System No. 61: *Silver*, *Part A 3*. Chemical behavior. Detection and determination. Toxicity. Colloidal silver. Principal editor: *Karl-Christian Buschbeck*. 1971. xi, x, 224 pp., 14 figures, Balacron DM 281.—.

Whereas the first two volumes of Part A[1] dealt with the history, geochemistry, and occurrence and the preparation and physical properties of silver, the present volume is concerned with the chemical behavior of the metal and its ions, their detection, and their determination. A brief chapter is devoted to the toxicity of the metal and its compounds and to the treatment of acute silver poisoning. The closing chapter on colloidal silver, which covers 41 pages, is very long; the most important part of this section describes the hydrosols. The data on organosols, aerosols, crystal sols, vitreosols, and silver mirrors are not very comprehensive.

A topic of special importance to the processing of metallic silver is the scaling phenomena that occur on contact with halogens and chalcogens. One would have expected this chapter to contain a section giving condensed data on scale removal. The behavior of silver toward the other elements and their compounds and toward less well-defined substances such as "open air", "kitchen atmosphere", "laboratory atmosphere", or foodstuffs (*e.g.* coffee, tea, must, wine, *etc.*) has also been very intensively studied,

as one might expect from the wide range of uses to which silver is put. A surprising result is that a 1955 Oberingelheimer white wine dissolved 30 mg of silver/m^2 in 7 days, but it is reassuring to find that this had no adverse effect on the quality of the wine! Moreover, silver is practically non-toxic, both as the metal and in the form of the ion. There is thus no reason against the use of silver goblets. Silver compounds are toxic only when taken orally in large quantities. There are, however, a series of special silver compounds particularly complexes, that exhibit considerable toxicity; these include the sodium dithiosulfatoargentate formed during the fixing process in photography.

In the sections on the behavior of Ag^+ and Ag^{2+} ions, it is interesting to note the large number of recent studies on Ag^{2+}. The plan of the chapter on detection and determination is very successful, and ought to be retained. The only criticism concerns the presentation of the references to the survey of the most sensitive reactions for silver (p. 107), which should have been given individually.

The literature has been evaluated up to and in some cases beyond 1969. The contents will be of interest not only to chemists and physicists, but undoubtedly also to the silver-processing industry.

System No. 61: Silver, Part B 2. Compounds with bromine, iodine, and astatine. Principal editor: *Rudolf Keim.* 1972. vi, xviii, 481 pp., 118 figures, Balacron DM 578.—.

The second volume of Part B completes the treatment of the silver halides, of which the silver fluorides and particularly silver chloride occupied most of the first volume[2]. Though there are very few compounds in the silver-bromine system (only AgBr and $Ag_mBr_n^{(m-n)+}$ are known, while the Ag_2Br and $AgBr_2$ postulated earlier do not exist), the discussion of this system occupies 185 pages.

The reason for the almost countless investigations is the importance of silver bromide to the photographic process. As can be seen from the many very recent references cited, the problems concerned with the effects of light have not all been solved. Considerable space is occupied by the description of structural and crystallographic properties, since crystal faults are of decisive importance to photographic sensitivity.

The only silver-iodine compound whose existence has been satisfactorily demonstrated is AgI. This exists in three modifications at normal pressure. Three high-pressure modifications are also known. As in the case of AgBr, the crystallographic properties are very important to the use of this compound in photography, and have therefore been very extensively studied. The high-temperature form of AgI exhibits good electrolytic conductivity, and is used as a solid electrolyte.

In a departure from the Gmelin system, the alkali metal and alkaline earth metal double compounds with common anions, such as KAg_4I_5, are each described in this volume after the corresponding simple silver compound.

Industrial importance is again the reason for the intensive investigation of colloidal silver iodide, which is used as aerosol and hydrosol. AgI hydrosols are also important as model substances for investigations on colloid-chemical behavior in general.

The silver-astatine system occupies only a few lines. A final chapter is devoted to the applications of the photochemical decomposition of silver halides. However, this treatment is confined to the explanation of fundamental concepts and a list of examples from recent literature.

The readability of the text is enhanced by the fact that as in some of the other recent volumes, contrary to earlier practice, the references are collected at the end of each section. The literature is evaluated up to mid-1970, and even more recent publications are also mentioned in a few cases.

Eckehard Fluck [NB 114 IE]

[1] Cf. Angew. Chem. internat. Edit. *10*, 204 (1971).
[2] Cf. Angew. Chem. internat. Edit. *11*, 69 (1972).

Analyse von Tensiden (Analysis of Surfactants). By *H. König.* Springer Verlag, Berlin—Heidelberg— New York 1971, 1st Edit., vii, 239 pp., 125 figures, stitched DM 58.—.

Ten years have now elapsed since the appearance of "*Hummel*". It was with some eagerness, therefore, that practical workers awaited *König*'s book; however, their hopes have been disappointed. Nevertheless, the book may be a welcome aid to newcomers to the field who wish to acquire a general grasp of the subject. The arrangement of the subject matter is such that anionic, amphoteric, nonionic, and cationic surfactants are discussed in order. For each class of surfactants, the separation methods are described first, and these are followed by the methods of identification. The sections on ion-exchange methods and the detailed description of paper and thin layer chromatography save a tedious search in the widely scattered literature. A chapter then deals with methods for the quantitative determination of surfactants.

As far as the identification of the separated species is concerned, the reviewer feels that the chapters on IR spectrometry present no essential advances over those in "*Hummel*". The spectra show, moreover, that the author has not yet a really good IR preparation technique (*e.g.* pressing the substances between two rock salt plates). NMR spectroscopy offers very little advantage over IR spectroscopy, which yields its information more rapidly and more cheaply (exception: ethylene oxide-propylene oxide mixed condensates).

In the quantitative part, considerable space is devoted to the author's own publications on the investigation of the half-esters of sulfosuccinic acid. On the other hand, practical workers will note the absence of guidance on the investigation of ether sulfates of fatty alcohols and alkylphenols, which are more important surfactants.

Finally, a word of caution: It has evidently escaped the author's notice that the "Comprehensive separation procedure" that he proposes (p. 43 *et seq.*) cannot be successful, since fatty alcohols and their ethylene oxide condensates cannot be extracted with ether in the presence of sulfonated surfactants. An inaccuracy in the text is that the liquid obtained by ion exchange is normally referred to as a filtrate, and not as an eluate. Confusion arises from the fact that the terms eluate and elute are occasionally also used in the normal sense.

Reinhold Wickbold [NB 119 IE]

Carotenoids. Edited by *O. Isler.* Birkhäuser Verlag, Basel—Stuttgart 1971, 1st Edit., 932 pp., numerous figures (some in color) and tables, bound Sw. Fr. 118.—.

The editor of the present book, which is in English, defines its aims in the introductory chapter. It is intended, as a continuation and extension of the monograph on carotenoids published by *Karrer* and *Jucker* in 1948, and partly

also of *Goodwin*'s "The Comparative Biochemistry of the Carotenoids", to summarize the results of chemical and biochemical research during the last two decades. The literature is covered up to about the middle of 1970. The book is in the form of a joint work by several authors. The editor, *O. Isler*, who is well known as the initiator of the first industrially used vitamin A synthesis for Hoffmann-La Roche, has managed to obtain the services of distinguished university research workers as well as workers from his own group as authors of the various sections.

In agreement with the dual aim, Sections II—VI deal mainly with chemical results, and Sections VII—XI mainly with biochemical results. Thus Chapter II describes the natural occurrence of carotenoids in plants and animals, and is thus closely related to Chapter VII, in which the biosynthesis of the carotenoids in these organisms is discussed in detail. Chapter III presents a survey of isolation methods, reactions, and relationships of the carotenoids with one another. The centerpiece of Chapter IV, spectroscopic methods, consists of comprehensive tables of NMR spectroscopic and mass-spectrometric data. Chapter V deals with stereochemistry, from *cis-trans* isomerism to the absolute configuration of chiral groups. A special appendix explains the application of the *R* and *S* convention.

Chapter VI will undoubtedly be of the greatest use to the preparative chemist. There he will find all the known total syntheses of carotenoids, as well as the syntheses of the fragments used, arranged according to synthesis schemes and summarized from time to time in tables. The thoroughness with which even the entire patent literature has been evaluated and arranged is unusual. In the past it was difficult to obtain a survey even of synthesis methods, since a large proportion of the research results has been published only in patents, and is widely scattered.

Chapter VIII, under the heading "Metabolism" deals with the degradation and transformation of the carotenoids in the organism; a separate section is devoted to the carotenoid-protein complexes, which are steadily gaining in interest. The function of the carotenoids and their metabolites are discussed in Chapter IX. The most important metabolite, vitamin A, is the subject of a separate Chapter X, where among other things, its largely verified role in the process of seeing and its as yet unexplained action mechanism in other parts of the body are discussed. The practical use of carotenoids as coloring agents and provitamins in foods and animal feeds is discussed in Chapter XI.

All the known naturally occurring carotenoids are listed in Chapter XII, together with literature references. However, the principle according to which they are arranged is to be found, not here, but in Chapter I. A suitable guide would be helpful where time is short.

The book is completed and rounded off by the IUPAC recommendations on nomenclature.

Despite the difference in style and approach in the various articles, they all have one thing in common, *i.e.* the critical care with which a large volume of material has been handled. Spot checks failed to reveal any serious omissions from the references. The book is strongly made and almost free from printing errors.

International cooperation has resulted here in a book that satisfies even high expectations, and that will, in a short time, become part of the essential equipment of all laboratories concerned with research on natural products and polyenes.

Wilhelm Sarnecki [NB 120 IE]

Progress in the Chemistry of Fats and other Lipids, Vol. 11. Edited by *R. Holman*, Pergamon Press, Oxford 1971, 1st Edit., xiii, 424 pp., numerous figures and tables, bound £ 11.00.

The present volume consists of several self-contained chapters on quite different subjects. The range of subjects in this volume is thus particularly wide, in contrast with some earlier volumes. Thus the chapter "Phospholipids, Liquid Crystals, and Cell Membrane" by *R. M. Williams* and *D. Chapman* deals with the physical properties of phospholipids and phospholipid-solvent systems and the consequent possible functions of phospholipids in biological membranes. In the two articles "Chemistry and Metabolism of Fatty Aldehydes" by *V. Mahadevan* and "The Chemistry of Sulfolipids" by *T. H. Haines*, the emphasis is placed on the chemical properties, the structural elucidation, and the synthesis of the substances of this class, for which these are the first detailed surveys. *C. R. Smith, Jr.*, in "Occurrence of Unusual Fatty Acids in Plants", presents an exhaustive synopsis of the structures of all fatty acids found in plants that do not have the polyallyl structure. In the article "Insect Lipids", *P. G. Fast* discusses both the composition and structure and the metabolism of these substances, and leads over in this way to the purely enzymatic section by *R. G. Jensen*, "Lipolytic Enzymes". This article describes the occurrence, the isolation, and the properties of the lipases that break down monoglycerides or triglycerides. There is also a chapter on the very topical subject "Pesticide Residues in Fats and other Lipids", by *A. M. Parsons*.

As in the earlier volumes, the author has succeeded in obtaining outstanding specialists in each of these fields as authors. This is reflected in particular in the excellent arrangement and the understable language. The volume will be of great interest not only to readers seeking an introduction to the special fields, but also to specialists who wish to brush up their knowledge. The extensive lists of references with all the articles also provide an opportunity for further study of the material discussed in the primary literature.

The favorable overall impression made by this volume is unfortunately weakened by the fact that apart from a very few references from 1970, some of the articles cover the literature only up to and including 1968, and others up to and including 1969. In the chapter by *A. M. Parsons*, the references listed stop at the end of 1967. Thus depending on the particular chapter, the literature from the last two to four years is missing, and the book is thus not as up-to-date as it might be. In the interests of the series as a whole, the articles in the later volumes should close on a single date and should be published quickly.

Wolf-H. Kunau [NB 124 IE]

Inorganic Titrimetric Analysis—Contemporary Methods. Vol. 1. By *W. Wagner* and *C. J. Hull*. Edited by *L. Jordan*. Marcel Dekker, Inc., New York 1971. 1st ed., xii, 225 pp., bound $ 13.50.

The book, which is described in the preface as unconventional, aims to provide the chemist who is occasionally faced with the need to determine an element (or simple inorganic ions and compounds, such as azide, hydrazine, cyanide, or dithionite) with a suitable titration method in a form such that it can be carried out in a normally equipped laboratory (*e.g.* electric and photometric indication, coulometric titration) with good prospects of success.

It also aims to eliminate the need to consult handbooks of analytical chemistry or the indexes of analytical periodicals or abstracting journals before carrying out such work.

To live up to this very pragmatic aim, well known and currently used titration methods, acidimetric, complexometric, precipitation, and redox methods are described for the determination of each element; their suitability, selectivity, accuracy, and susceptibility to interference are indicated, and the necessary aids are mentioned. Details of procedures are deliberately omitted, and the reader is referred instead to a number of important recent publications in every case.

The arrangement of the book, in which convenience is the main consideration, is clear, as is that of each of its chapters. It is based on the periodic system of the elements (including the transuranium elements and the inert gases), and a survey of classical (pre-1950) and up-to-date (mostly post-1960) possibilities is followed in every case by brief descriptions of the selected methods.

The attempt to provide the chemist who is not primarily an analyst with a volumetric vade mecum may be said to have been accomplished in full. The book can only be recommended to all amateur analysts, but is also a rich source of information for the professional analyst.

Günther Kraft [NB 133 IE]

Polymer Science and Materials. Vol. 1. By *A. V. Tobolsky* and *H. F. Mark*. John Wiley and Sons, Inc., New York–London 1971. 1st ed., x, 404 pp., numerous figures and tables, bound £ 10.05.

The book is intended mainly for younger students and for scientists and technologists wishing to enter the field of polymer science or seeking a first introduction. The material presented covers a wide field. The present first volume of the planned two-volume work deals with the essential physicochemical principles of polymers in solution, as well as with the physics of the solid state of synthetic macromolecules, and finally in three chapters with the technical properties and the processing of rubbers, plastics, and fibers.

This breadth of material was possible only through the deliberate omission of all mathematical derivations. One result of this is that the numerous formulas used occasionally appear rather abruptly. It would have been preferable in such cases to present plausible explanations for the most important formulas. The aim of providing such an urgently needed book for the beginner has therefore been achieved only in part.

In addition to providing an introduction to polymer science, the book also strives to consider the fundamental science and the industrial application from a common standpoint. It may be regarded as successful in this respect, and it thus stands out from other works, which favor either one point of view or the other. The book benefits from the fact that the conception is essentially determined only by the two principal authors.

However, the level is not always constant. A very good and enthusiastic introduction is followed by a chapter on molecular weight and molecular weight distribution that is unsatisfactory and out of date with regard to material. Solid knowledge is presented in most of the chapters. Two contributions can be described as outstanding. These are the chapters "Equilibrium Polymerization" and "Liquid and Plastic Crystals". This last article in particular is unconventional, opens up new aspects, and should provide a stimulus even to the specialist in the polymer field.

Walther Burchard [NB 137 IE]

Molekulare Prozesse des Lebens (Molecular Processes of Life). By *D. E. Green* and *R. F. Goldberger*. Springer-Verlag, Berlin–Heidelberg–New York 1971. 1st ed., x, 240 pp., 93 figs., bound DM 38.—.

The aim of this book is unusual, *i.e.* the description of selected fundamental biochemical processes in living systems and of important molecular reaction courses that are identical or very similar in numerous organisms in very different stages of development. By the omission of individual facts and the stressing of common fundamental mechanisms, the reader is shown the principle of biochemical life processes and made aware of the essential points.

In addition to the structure of the cell and its components, the discussion deals mainly with enzymes and their mode of action, control mechanisms of cell metabolism, and the structure and function of macromolecules (polysaccharides, proteins, nucleic acids, phospholipids). A very large amount of space is rightly given to the discussion of the energy balance of the cell (energy-supplying processes, energy-dependent syntheses, and energy transfers). However, the chapter "DNA, RNA, and Protein Synthesis" is very brief and the material is very greatly simplified in places; stronger emphasis in this area would surely have been desirable in view of the central position within the field of molecular biology. The structure of the book is such that it contains no data on methods and literature. The translation from the English is good. The book is written in an easily understandable manner, the material is clearly and logically arranged, and details and special knowledge are mentioned only where they contribute to a better understanding of fundamental biochemical mechanisms.

This book is thus not intended as a conventional textbook. It is aimed at a broader readership, and may be regarded as a very successful attempt to present fundamental molecular processes in living systems clearly and understandably.

Jürgen Niessing [NB 134 IE]

Lactic Acid. By *C. H. Holten*, with chapters on Biochemistry (by *D. Rehbinder*) and on Analytical Chemistry (by *A. Müller*). Verlag Chemie, Weinheim 1971. 1st Edit., pp. 566, 98 figures, 181 tables, bound DM 135.—.

The book is the first large monograph on lactic acid to be written. It covers all aspects of the subject: history; applications; physical and chemical properties; derivatives; biochemistry; and analytical chemistry. Its writing has been supported by an international research association of four European producers of lactic acid. This association (called Stichting Ilra) has further assisted by making inside information on the subject available to the authors.

The literature is covered up to June 1968. About 3000 publications have been studied. Publications in languages not commonly understood have been evaluated from the original and not from summaries written in another language. The over 2000 publications entered as references have been selected critically, so that the book is not a mere compilation. References are with full titles and the number of pages of each publication is given. Among the references is a number of dissertations, some of which have remained unpublished.

The book has been written with great care over a period of eight years, and its usefulness cannot be questioned. The specialist will study it again and again. Apart from this, and perhaps contrary to what many would expect, most chapters are also interesting reading to chemists working outside the lactic acid field. The reviewer believes that the book will retain its value for many years. It is therefore recommended to every chemist or organization working with lactic acid or its derivatives, as well as to all organic chemical laboratories in general.

Niels Clauson-Kaas [NB 154 IE]

Properties of Polymers. Correlations with Chemical Structure. By *D. W. van Krevelen*. Elsevier Publishing Company, Amsterdam—London—New York 1972, 1st Edit., xi, 427 pp., numerous figures and tables, bound, $ 22.—.

The book deals with the thermophysical properties of polymers, their behavior in mechanical and electrical force fields, transport phenomena such as flow processes, diffusion, and permeation, and crystallization and degradation processes. The discussion is therefore based on the chemical constitution of polymers, with particular emphasis on the additivity principle. The author demonstrates most convincingly, drawing extensively on his own work, how it is possible to calculate, or at any rate estimate, many of the characteristics of a polymer from the physical data for the monomers, and even for the groups of molecules forming them. For this procedure the book offers a large number of clearly arranged tables and diagrams with the various monomer and polymer characteristics. At the same time, the author points out the limitations of the additivity principle, *e.g.* in the case of strength data and in the domain of crystalline polymers.

Quantitative relationships are given without derivations —the reader will find detailed references to the literature— but in a form such that they can be used directly for calculation. The many approximation formulas and rules of thumb should prove particularly useful in practice. Applications are illustrated in the form of problems, and the reader can test his knowledge by referring to the solutions. Whereas defined physical properties always receive detailed treatment, technological characteristics such as readiness to pick up an electrostatic charge, slip-stick behavior, or abrasion resistance take up relatively little space, no doubt a clear sign of the limited extent of our present knowledge concerning these aspects, despite their practical importance.

The book is obviously not intended primarily as an introduction to polymers: for example, the reader is assumed to possess a knowledge of the most important measuring methods. Anyone acquainted with the field will, however, find the book very much to his liking, for it is concise, well formulated, clearly laid out—each chapter begins with a summary of its contents—and the printing is of a high standard. In short, this is a monograph that will not only be read, but also used.

Ulrich Zorll [NB 125 IE]

The Condensed Chemical Dictionary. By *G. G. Hawley*. Van Nostrand Reinhold Comp., London 1971, 8th Edit., ix, 971 pp., bound £ 13.75.

It should be stated at the outset that this "dictionary", which first appeared over 70 years ago has the character of a handbook listing materials (defined compounds, commercial products, alloys), specialized terms, and potted biographies of prominent chemists from the past. The book contains a total of 18000 entries.

The explanations are sufficiently detailed and lucid. Against compounds the reader will find—where known—synonyms, linearized structural formula, properties (color, state, m.p. and/or b.p., solubility), occurrence or preparation, transportability, and hazards (toxicity, flammability). The composition of commercial products is described and the supplier is named. A list of suppliers is given at the end of the book. Examination of this list shows that it consists almost exclusively of American-based companies. The brief description of "leading" scientific societies are restricted to American organizations, and the biographies of deceased chemists fail to include Nobel Prize Winners such as *Wallach*, *Werner*, *Willstätter*, and others. The technical terms listed are intended primarily for the practical chemist. One does not find the specialized terms used in theoretical chemistry and process technology. The 8th edition devotes particular attention to chemical and biological aspects of environmental pollution and its control.

On the inside cover the book is recommended as an indispensable aid to all chemists. This assertion may be questioned, in view of the shortcomings referred to. However, anyone interested in the American market will undoubtedly find useful information in it. The practical chemist, too, may find this book a useful addition to his reference library.

The Origin of Life[**]

By Mella Paecht-Horowitz[*]

The theory of the evolution of the species, which is today widely accepted, requires a starting point. It is postulated that the biological starting point could have emerged only if chemical evolution had preceded it. Experiments are described which show the formation of organic substances from inorganic gases under conditions which prevailed on earth in the prebiotic era; also demonstrated is the polymerization of such organic substances into biological macromolecules. Hypotheses are discussed whereby these macromolecules could be transformed into dynamic structures which might finally lead to self-reproduction.

1. Introduction

With the development of space research, the problem of the "Origin of Life", although a very ancient one, has suddenly become extremely modern. Researchers are very anxious to detect whether there is any form of life in extraterrestrial space. As it is most improbable that extraterrestrial life forms (if any!) would be the same as those on our planet, it has become necessary to define life, to determine its characteristics and how it appeared.

There are many definitions attempting to describe life. One enjoying widespread acceptance by biologists is that a system is "alive" when it is able to reproduce itself at the expense of its internal energy; in other words, when it is able to self-reproduce with the help of its inbred memory and mechanisms.

But the problem of the origin of life is already mentioned in the earliest scriptures. The search for the "starting point" was one of the first problems ever treated by the philosophers of ancient times. The scholars of India, Babylon, and Egypt, under the strong influence of religious legends and traditions, believed that life started by autogenesis, as a result of the creative will of supernatural powers.

The Greek philosophers, from about 600 B. C. onwards, approached the problem by "scientific" methods. Nevertheless, they believed strongly in autogenesis and brought forth numerous experiments intended to prove this theory. This belief in autogenesis continued throughout the Middle Ages and into Modern Times. *Francis Bacon*[1], *Descartes*[2], and their contemporaries considered spontaneous generation as beyond question and it was only in 1668 that *Redi*[3] described a series of experiments proving that flies can generate only from flies' eggs. Still, even *Redi* believed that though flies indeed generated from eggs of their species only, autogenesis might take place in other cases. The final definitive proof that a species cannot generate save from another specimen of its own family was provided only by *Louis Pasteur*[4–10]. Yet this brings us back to the original question, namely, if an organism can be created only by another organism, how did life start at all?

Nowadays there is just one logical answer to this question, namely, that chemical evolution must have preceded biological evolution, and that the latter could have ensued only as a result of the former. Actually, this was already recognized by *Darwin* who stated that if, at the present time, a protein substance capable of experiencing further, more complex transformation were created, it would be

[**] It was intended that this discussion be written by Professor *Aharon Katzir-Katchalsky* and myself. Because of his tragic death at the Lod Airport massacre, I have had to write it alone; all I can do is dedicate it with deep sorrow to his memory—the memory of a great scientist, an outstanding teacher, and a most wonderful personal friend.

consumed or absorbed—which could not happen in the period preceding the formation of living creatures[11]. This statement brings us face to face with the first difficulty in the investigation of the origin of life—primordial formation of life under natural conditions is now impossible due to the very fact of the existence of life. This impossibility leads us into the situation that whatever experiments we conduct, however conclusive they may be, can only show possibilities that life could have started under certain specific conditions; we shall never be able to know precisely the actual conditions under which life started. Even if—by some very unfortunate event—all life on earth were to be extinguished, save for some scientist remaining to study the eventual new formation of life, the situation would not be the same as in primordial times. Earth, now deprived of life, would be like a person who has lived but is now dead, whereas in the primordial era it was like an unborn, even unconceived child.

2. The Primordial Broth

What do we know about the period preceding life on earth? According to geochemical investigations, life started on earth between one and two thousand million years ago. But whereas up to two thousand million years ago the atmosphere contained no oxygen, a thousand million years ago it was already very rich in that element. The interval between these times is the transition period, during which life on earth started. With the development of life, the atmosphere became more and more enriched in oxygen, and the more oxygen there was, the more highly developed creatures emerged.

Although nowadays lack of oxygen might stop life, it was apparently its very absence which enabled life to be formed in the prebiological era. Because of this feature, the amount of short-wave radiation reaching the surface of the earth was much greater than it is now. The 30 km deep ozone screen presently surrounding the earth considerably increases the wavelengths of radiation reaching its surface. Thus the possibilities for abiogenic photochemical syntheses were far greater than they are now. Of course, the lack of oxygen created a situation in which reduced carbon compounds could not become highly oxidized; living organisms did not exist, thus precluding the synthesis of a vast number of organic compounds by metabolic processes.

Because of all this, and because the period we are discussing left practically no geological traces, it is extremely difficult to reconstruct prebiotic situations in the laboratory, especially if these situations have to stay constant for prolonged periods of time. Nevertheless, some experiments worth mentioning have been carried out.

3. Prebiotic Synthesis

3.1. Formation of Organic Compounds under Prebiotic Conditions

Before going into details it should be mentioned that not everyone is of the opinion that the origin of life is a subject which should be treated at all by physicists or chemists. Those who hold this negative viewpoint believe that physical methods are *a priori* antihistorical, as they deal with situations which tell what can be predicted, according to physical laws, when the starting conditions are known. Thus they are indicated for predicting the future, and not for reconstructing the past. Not only do the laws of physics not teach us anything about the past, but the laws of thermodynamics tell us that natural phenomena tend to approach an equilibrium state and the description of a state does not include anything about the way it has been reached. What physicists and chemists can do is build models and test to what extent these models are consistent with the findings of biologists, geologists, anthropologists, and cosmologists. All these efforts might together come up with the right answers. The following experiments give some of them:

In 1955 *Miller*[12] passed electric discharges through a gaseous mixture of methane, ammonia, hydrogen, and water vapor and thus obtained various organic compounds, notably amino acids. By the same method, and also adding phosphoric acid to the reaction mixture, *Gulick*[13] obtained high energy phosphorus compounds similar to phosphocreatine. *Scott*[14] even synthesized complicated compounds like porphyrins in this way. *Oró* and his collaborators[15–19] heated simple hydrocarbons with hydrocyanic acid and its derivatives—hydrocyanic acid was believed at that time (1961) to have been carried to the earth by comets—and obtained amino acids, peptides, aliphatic acids, purine and pyrimidine bases, imidazoles, and pentoses. In 1962, *Palm* and *Calvin*[20] bombarded methane, ammonia, water vapor, and hydrogen with high energy electrons and obtained the same products as *Oró*'s group, and in addition HCN. Thus it was no longer necessary to postulate that this substance came from extraterrestrial sources. The formation of HCN is, according to certain investigators in this field, extremely important, because it and its derivatives might have been some of the key components in prebiological synthesis, as they are dehydrating agents *par excellence*. Later, *Ponnamperuma* and his collaborators[21,22] described the formation of ATP, still under prebiotic conditions, and *Bar-Nun et al.*[23] again produced amino acids and peptides from inorganic gases with shock waves as energy donors.

All these experiments show clearly that the formation of organic substances out of inorganic ones, even in the absence of oxygen, is possible and one may safely assume that gases like those mentioned above were the prebiotic molecular compounds on earth. There is good reason to believe that the first organic substances were formed from them with any of the natural energy sources then available.

Yet the way from here to a living cell, or even only to an organized macromolecule with a well defined sequence of monomers, is still very long.

3.2. Formation of Macromolecules under Prebiotic Conditions

It is logical to assume that life orginated in several stages. The first would be the formation of organic substances as described in the previous section, the second would be the arrangement and combination of monomers into macromolecules, the third would be the transformation

of such a lifeless macromolecule into a living one, and finally, we would have the evolutionary development of higher living forms out of the very simple ones.

There are investigators who believe that the second stage preceded the first one. *Mathews* and *Moser*[24] showed that when HCN is mixed with dry NH_3 and exposed to an electric discharge, protein-like molecules are obtained, which, on hydrolysis, give amino acids. Yet up to now, most investigators try to build biopolymers out of their monomeric units. *Schramm et al.*[25] showed that when metaphosphate esters of various compounds are heated in non-aqueous media, high polymers of the respective compounds are obtained. In this way they prepared polynucleotides, polypeptides, and polyglycosides. *Schramm* relates these findings to prebiological synthesis by the fact that orthophosphates are not stable above 300 °C; therefore he assumes that large deposits of condensed phosphates existed in water-free regions after the earth cooled down. These phosphates might have been esterified by reactions with organic compounds and produced condensations inside coacervates as has been proposed by *Oparin*[26], or in other aggregates protected by water-proof membranes.

Oparin's reasoning that condensations occurred inside coacervates was based on the following set of experiments: When adenine is polymerized *in vitro* in a polypeptide medium droplets, called coacervates, begin to separate out from the solution as soon as the molecules reach a certain size. On formation of the droplet the reaction equilibrium experiences a sharp shift towards synthesis[27]. Thus *Oparin* reasons that, if prebiological systems were subject to the same physical rules as present-day systems, production of two polymeric species would be followed by formation of a coacervate inside which reaction would continue.

We have here an assumption which should be approached carefully. While we have to assume equal laws of nature in the prebiotic era and now, for no working hypothesis would otherwise be possible, this biases our concepts of structures and forms of life and makes us project the conditions of the present into the past. To do this might be perfectly logical, as there is no reason to believe that the prebiotic chemical and physical laws were different from those of today; but we should not forget that the validity of this argument has not been proved.

Another experiment which strongly supports *Oparin*'s theory is that performed by *Evreinova et al.*[28]. This group showed that when droplets formed from gelatin and gum arabic are present in an amino acid medium, the amino acids become concentrated ten- to hundred-fold inside the coacervates. This is true of other components also, the high concentrations depending on the composition of the droplet as well as on the type of the substance absorbed. Tempting as *Oparin*'s theory might be, we have to keep in mind that such a droplet cannot serve as a convincing model for a living system, as a state of equilibrium is very soon set up between the droplet and the surrounding medium. The droplet reaches a thermodynamically stable state and becomes thus a static system.

Yet the characteristics of the stability of a living system is that it is in a state of flux and produces a steady-state system. Throughout the whole of its life any cell or multicellular organism is in a state of continuous interaction with its environment—an interaction known by the biological term "metabolism". In physical terms, the case of the droplet in thermodynamical equilibrium could be defined as a state in which there is no change in free energy ($dF=0$), while in a living organism or cell the change in free energy occurs continuously, but at a steady rate ($dF=\text{const}\neq 0$). When a living cell reaches a state where $dF=0$, the cell has ceased to live and has become a dead cell.

However, steady state conditions can be created in the laboratory. The problem is to create systems which will work in the expected way. One of the most important properties required is that the system should be able to grow in a solution of substances expected to have been present in the "primeval broth" of the earth. For instance, if we had a polymerization reaction linked to redox and phosphorylation processes, this would require the coacervate droplets which were previously developed to be capable of synthesizing polymers and of creating conditions under which the redox reaction and the polymerization linked to it could proceed more quickly than in the external medium. Such conditions could easily have arisen in droplets able to absorb strongly from the surrounding medium, so that the droplets would contain a constantly increasing concentration of substances which would act as catalysts for further polymerization. Such continuous polymerization would increase the mass of the droplet and the reaction would go on faster and faster, leading to a sort of mechanism which could explain the first catalytic reactions, analogous to metabolic reactions.

Furthermore, one could imagine that after reaching a certain size the droplets would split up into fragments of identical consistency with the parent droplet and one would thus obtain some sort of division, analogous to cellular division, although the system would still not be alive.

Calvin[29] pointed out that the development of biological catalysts from such simple catalytic systems of coacervates could have emerged by natural selection. Such a selection would be possible only when the catalyst was incorporated into a synthetic system. If the catalyst was simply in solution, no selection could occur with respect to a specific reaction because individual components of a catalytically active system, when dissolved in the surrounding medium, might, in themselves, be almost entirely lacking in this activity. When selectively absorbed, however, they would combine within the absorption medium to form a catalytically active complex which would increase the rate of reaction relative to the surrounding medium. The readiness to form such a complex would be the very factor which could determine the flowing nature of the system, its dynamic stability, and its ability to grow. It is clear that the more suited the molecular structure of the complex is to its catalytic function, the more the system will maintain itself and the more it will grow and multiply.

The theory of the coacervates calls for already existing polymers which would interact with each other and would form the droplets. But as we do not know how these polymers could have been formed in the prebiotic era we have to look for some means of concentration of the monomers. As all biological reactions and also many of

the chemical ones proceed in aqueous solutions we have to assume, for reasons of continuity and equality of conditions, that the primary synthesis occurred in aqueous solution as well. We can imagine that some of the reactants, after having been formed, fell into the oceans where they were able to react with each other. However, the primary difficulty in imagining the polymerization process to have taken place in the free ocean lies in the extreme dilution of the system.

Bernal suggested that concentration of the products, which would be an absolute necessity for evolution, could be attained by adsorption on very fine clay deposits in marine and fresh water[30]. Following this assumption, we dissolved an amino acid adenylate—the starting material for protein formation in the living cell—in water at pH 7.8 and room temperature in the presence of finely dispersed montmorillonite. This mineral is a rather interesting clay. It consists of three-layered sheets of SiO_2—Al_2O_3, $Al(OH)_3$—SiO_2 (Fig. 1) and is able to swell, expanding

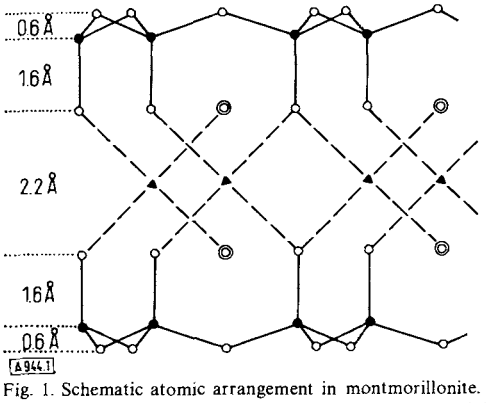

Fig. 1. Schematic atomic arrangement in montmorillonite. ○, oxygen; ◎, hydroxyl; ▲, aluminum; ●, silicon. The upper and lower layers are tetrahedral, the center layer is octahedral.

enormously in the process. We may therefore assume that monosheets of very large surface area are obtained at low concentrations. Furthermore, the aluminum ion may be replaced by other cations. In the particular montmorillonite we have been working with, every sixth aluminum ion was replaced by a magnesium ion[31]. Since aluminum is trivalent and magnesium divalent, this exchange produces strong negative centers arranged in a sort of lattice. These negative centers are presumably the active adsorption centers of the clay. While montmorillonite at pH 7 adsorbs neither amino acids nor adenylic acid, it strongly adsorbs the amino acid adenylates which undergo polymerization to polypeptides while in the adsorbed state. Polymerization in the absence of clay and in a homogeneous medium produces low molecular weight peptides having a continuous molecular weight spectrum and which are free of adenylic acid[32, 33]. Heterogeneous polymerization in the presence of montmorillonite, in contrast, results in a very interesting non-continuous distribution of molecular weights (Fig. 2)[34].

Not only is the molecular weight distribution different, the polymerization mechanism itself differs from that of homogeneous polymerization. While the latter mechanism involves a primary hydrolytic step and only the free amino acid is able to interact with a molecule of amino acid adenylate, the resultant free dipeptide released on hydro-

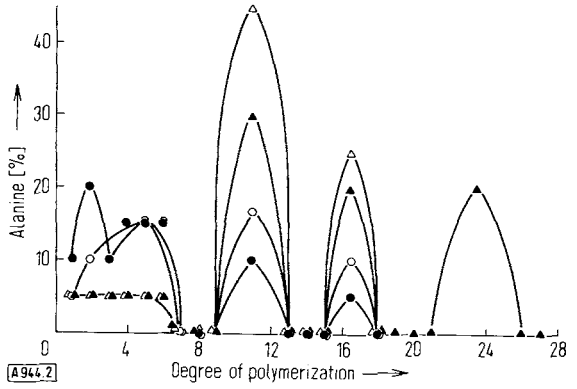

Fig. 2. Distribution of the molecular weights of polyalanines obtained when D,L-alanine adenylate is introduced into an aqueous solution at pH 8.5 in the presence of various amounts of montmorillonite ●, 20; ○, 80; △, 220; ▲, 480 mg montmorillonite/l.

lysis undergoing further reaction with another molecule of amino acid adenylate to give a tripeptide, *etc.*, the dominant reaction in heterogeneous polymerization is interaction between two active adenylates resulting in a still active higher peptide. The mechanism of homogeneous polymerization can be represented by the following scheme:

$$A \sim P \xrightarrow{h} A + P$$
$$A + A \sim P \xrightarrow{k} A_2 + P$$
$$A_2 + A \sim P \xrightarrow{k} A_3 + P$$
$$\vdots$$
$$A_n + A \sim P \xrightarrow{k} A_{n+1} + P$$

Where $A \sim P$ is the active amino acidadenylate, A the free amino acid, A_n the peptide of the n-th degree of polymerization, P free adenylic acid, h the hydrolytic constant, and k the polymerization constant.

Heterogeneous polymerization, on the other hand, can be represented as follows:

$$A \sim P + A \sim P \xrightarrow{k} A_2 \sim P + P$$
$$A_2 \sim P + A_n \sim P \xrightarrow{k} A_{n+2} \sim P + P$$
$$A_n \sim P + A_m \sim P \xrightarrow{k} A_{n+m} \sim P + P$$

The reaction scheme shows that homogeneous polymerization is a one-by-one step reaction and would therefore result in peptides having a continuous spectrum of chain lengths. Furthermore, we would not expect very high molecular weights since hydrolysis is necessary for the reaction to take place and is, in fact, the dominant reaction. In the case of heterogeneous polymerization, hydrolysis is not only unnecessary, but is actually almost completely suppressed by the protective action of the clay.

The fact that the peptides obtained by heterogeneous polymerization have a discrete molecular weight spectrum is very intriguing and we believe that it could explain some of the selectivity problems of the prebiotic era. From a purely chemical point of view, we have here a superposition of several reactions. The polymerization process liberates free adenylic acid which inhibits polycondensation by preventing the non-reactive ammonium group from dissociating. It is this dissociation with release of a proton which produces the highly reactive terminal amino group. Thus we can readily envisage that a pulse of rapid polycondensation will produce a high local concentration of acid molecules which will stop the process until the adenylic acid diffuses out.

After this diffusion a second pulse will occur which will again be stopped after several steps by the accumulated acidity. The joint operation of reaction and diffusion flows might very well give dissipative structures as described by *Prigogine*[35]. We shall see in Section 4 that such a combination of flows is very decisive also in structure formation. Incidentally, the pH range of about 4 produced by the accumulation of free adenylic acid most effectively stabilizes the amino acid adenylate, and this might be the reason for the protection of the adenylates from hydrolysis by montmorillonite.

While the main reason for the termination of homogeneous polymerization is hydrolysis, in the case of montmorillonite as polymerization template the reaction is terminated by transfer of the peptide chain from the phosphoric acid group to the ribose of the adenylate[31] (Fig. 3). In this case, the adenylic acid remains bound to the peptide, but the latter is no longer active and thus unable to grow and combine with other peptides.

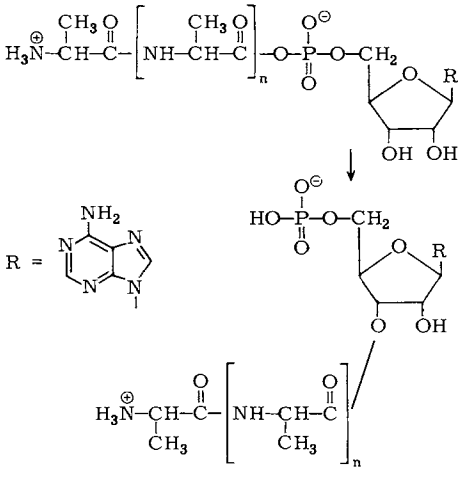

Fig. 3. The termination reaction in the heterogeneous polymerization of D,L-alanine adenylate.

But the importance of clays as related to prebiotic synthesis lies, in our opinion, not only in the fact that some of them are able to adsorb adenylates and thus produce local high concentrations of the reactants and specific chain lengths of polypeptides. It was again *Calvin*[23] who pointed out that the selection of chains of certain molecular weights from a large number of possibilities is typical of living processes, and here we have such a selection. Yet it seems to us that the importance of clays lies also in their various combination possibilities. Since the metal ions can be exchanged in the configurational layers themselves, not only can the adsorption capacities be varied, but also the spacing between active centers. This might bring about a sort of prebiotic template that might further produce a code, which, by due evolutionary development, could lead to the selective survival of such sequences which might ultimately become "alive".

Cairns-Smith[36] postulated that mica or other clays might have served as templates for prebiotic gene formation due to their regular configuration and spacings into which amino acids would fit. We would not go so far, because such a theory would require a rigid pattern of amino acid sequences. Our preliminary experiments on copolymerization of amino acid adenylates in the presence of montmorillonites have shown that indeed there are certain preferences, with some pairs of amino acids copolymerizing more readily than others, but even on the same clay there is a certain amount of fluctuation in this respect. In our opinion, clays by virtue of their various adsorption possibilities might bring the various reactants near to each other within a limited pattern, but the reactants would still have some degree of liberty to choose their interaction partners. Otherwise, we would always obtain the same sequences in copolymerization, which obviously is not the case. We believe that the well defined sequences of amino acids which exist nowadays in proteins were formed only later on, as a result of selectivity of survival processes.

There is another possibility which clays might offer. We have seen that important local pH changes occur in the course of the reaction. These changes allow us to speculate whether, under the right conditions in the presence of mixtures of suitable clays, adenylates of amino acids might not only be the forerunners of polypeptides, but at the same time also of polynucleotides. For many years researchers have asked themselves, what preceded what—the proteins the nucleic acids, or *vice versa? Eigen*[37] showed that for the formation of life, both were actually necessary. Figure 4 shows the formation of polyamino acid adenylate and the hypothetical formation of polyadenylic acid, with an amino acid still linked to one end of the molecule.

On paper at least, it is easy to see that both could be formed at the same time, starting with the same precursor. Yet while the formation of polypeptides has actually been observed[31] no polymerization of adenylic acid could be detected in the same circumstances.

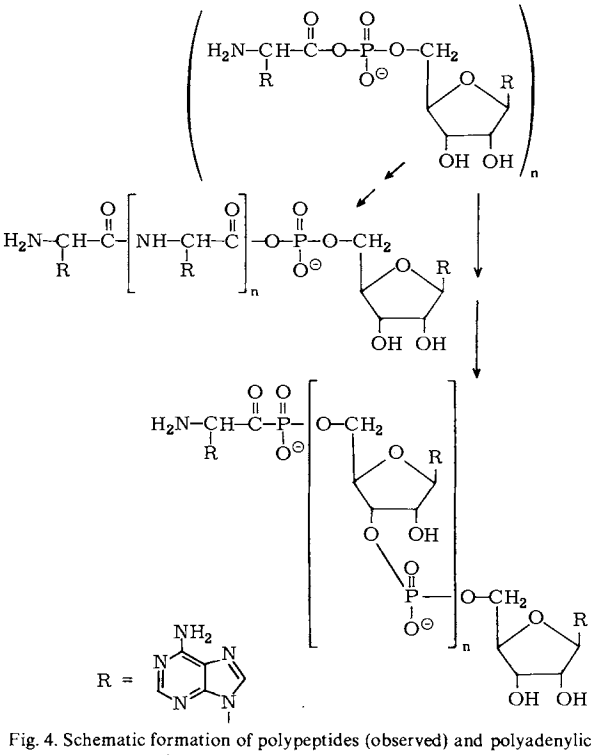

Fig. 4. Schematic formation of polypeptides (observed) and polyadenylic acid (hypothetical) from the same precursor.

3.3. Formation of Active Monomers under Prebiotic Conditions

Among the various catalytic properties of clays and minerals there is one which might have strong bearings

on prebiotic synthesis. We have seen in the previous section that amino acids must be activated in order to be able to polymerize. The need for activation of biomonomers for the polymerization process was pointed out by *Lipman* as long ago as 1941. In order to activate an amino acid, *i.e.* to transform it into a mixed anhydride with adenylic acid or with another nucleotide, the carboxylic group of the amino acid has to be in its free form and not in the ionized carboxylate form. Usually such is the case only at very low pH values, which, however, cause fairly rapid decomposition of ATP, the nucleotide donor of the mixed anhydride. Besides, it is unlikely that such low pH values (about 1—2) would occur in nature. Here another family of minerals, the zeolites, might provide a solution. Zeolites are alumino-silicate minerals well known in chemistry as molecular sieves. Some of them also exhibit very good ion exchange properties; hydrolysis produces a large number of $\geqslant$SiOH groups:

$$\geqslant SiO^{\ominus}Na^{\oplus} + H_2O \rightarrow NaOH + \geqslant SiOH$$

The SiOH groups would react with the amino acids under neutral conditions in the following way:

$$\{\geqslant SiOH + H_3N^{\oplus}—CHR—COO^{\ominus}\} \rightarrow \geqslant SiO^{\ominus}H_3N^{\oplus}—CHR—COOH$$

The latter form of the amino acid would be able to react with ATP to give the mixed anhydride which allows the amino acid to polymerize. This idea has been tested with an artificial zeolite called Decalso F[39]. Decalso F strongly adsorbs amino acids and ATP but the amino acyl compound formed is not adsorbed and passes readily into the aqueous phase. Since the amino acyl compound is hydrolyzed rather rapidly, its formation can be detected only by the increased rate of decomposition of ATP while the measurable content of amino acid remains constant. If montmorillonite, the "polymerization catalyst" is added, the free amino acid content also decreases due to polymerization, and after a certain period polypeptides are obtained with the same molecular weight distribution pattern as those produced when amino acid adenylates are polymerized in the presence of montmorillonite. Figure 5 shows the process; the starting point is adsorption of zwitterionic amino acids and ATP from the aqueous bulk solution by the zeolite and the final step is polypeptide formation on the montmorillonite, where the active anhydride formed on the zeolite transfers to the montmorillonite surface.

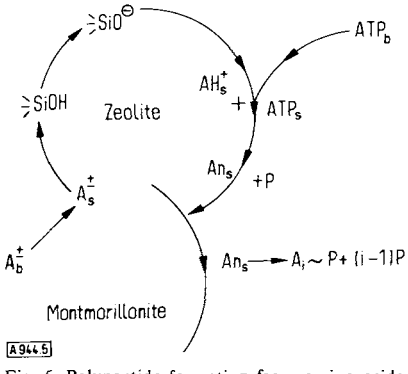

Fig. 5. Polypeptide formation from amino acids and ATP on zeolites and montmorillonites. $A^{\pm}$, amino acid; AH^{+}, free carboxyl form of the amino acid; An, mixed anhydride of amino acid and ATP derivative; $A_i \sim P$, polypeptide; P, free ATP derivative; the subscripts b and s mean that the amino acids are in solution and adsorbed, respectively.

4. Precellular Organization

Fox et al.[40] put a mixture of dry amino acids containing large amounts of aspartic and glutamic acid in the depression of a piece of lava; the lava with the amino acids was then placed in an oven at 170 °C, and after several hours the rock was removed and washed with hot 1% NaCl solution. The liquid contained large numbers of microspherical units, consisting of high polymers of amino acids. The same reactions can be observed when meteorites are used instead of lava. These microspherical units are called protenoids and they are able to swell or to shrink in hypotonic or hypertonic solutions respectively, although these responses are less marked than those of biocells. They retain their shape for an apparently indefinite time and when centrifuged at 3000 rpm retain their integrity. They also have sectionability properties and are stable even after division.

Later, *Fox* showed that the polymerization of amino acids can be accomplished at as low a temperature as 70 °C when polyphosphoric acid is present in the reaction medium[41]. Even orthophosphoric acid reduces the polymerization temperature, though less so than polyphosphates, provided the medium is completely anhydrous. *Young et al.* have shown that in the presence of the ethyl ester of polyphosphoric acids, the amino acids polymerize at 25 °C; on cooling the polymerization products slowly from 25—0 °C, they obtained protenoid microspheres[42]. These microspheres were able to coagulate and showed typical interactions with polymers of opposite charge. After interaction with a polymer of opposite charge such microspheres are seen to resemble a "blastule" with a double membrane under the microscope. pH, salt concentration, pressure, and temperature also have an effect on the morphology of the microspheres.

Formation of such microspheres requires a water-free reaction medium, which is contradictory to biological processes. Yet aqueous structure formation, based on physical phenomena, also exists.

As long ago as the beginning of this century, *Bénard* showed that when a homogeneous liquid is heated slowly at the bottom of its container certain geometrical structures are obtained at a certain critical temperature.

These structures, at first ring-like, become honeycomb-like on further heating[43-45]. The range of critical temperatures is very narrow, and with further increase in temperature, the liquid becomes homogeneous again. Figures 6 (a—c) show an oil at various stages of such a heating procedure[46].

The structures are the result of the reciprocal interaction of two types of flows, heat flow in an upward direction, and convective flow in a downward direction. Such phenomena can also be observed in crystallization processes. Often the individual crystals conglomerate into macroscopic cellular forms having a very regular structure. For the formation of these structures, various flow processes must take place; such structures could never be obtained in equilibrium states. They are dynamic structures, like those of living cells, but they are obtained by purely physical processes.

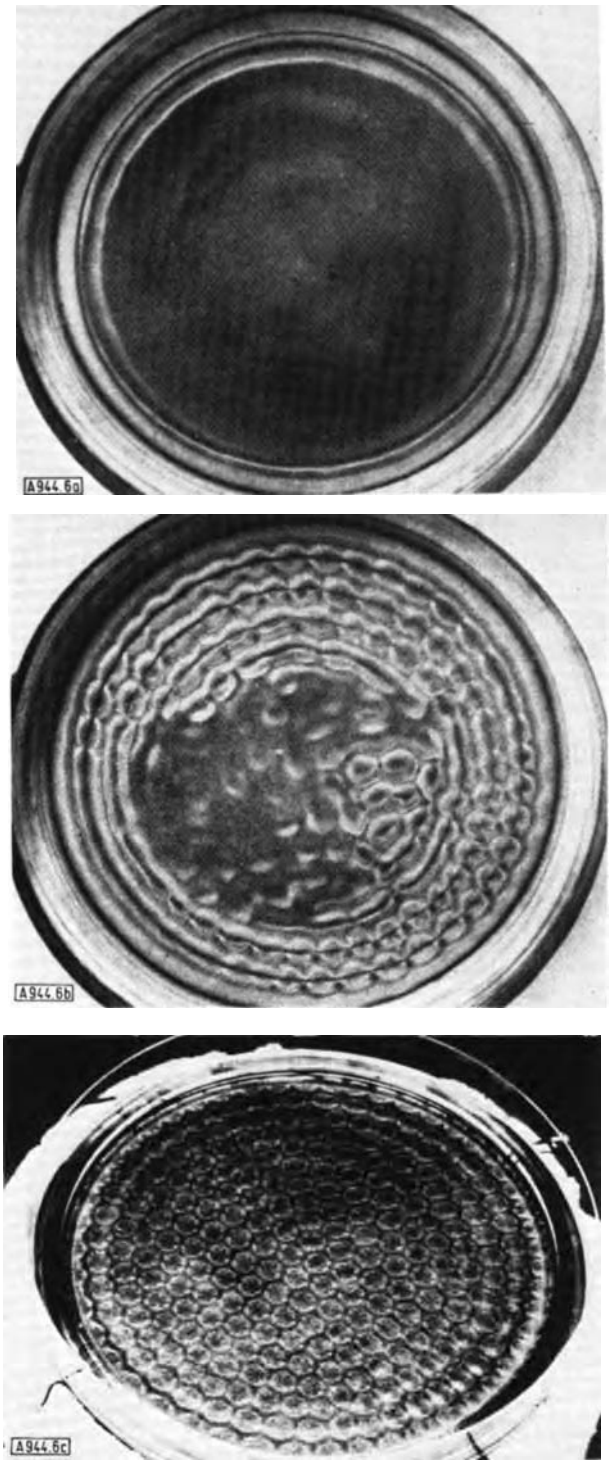

Fig. 6. Structure formation in a fluid heated from below. Diameter of vessel ≈20 cm. a) The beginning of heating with formation of circular structures. b) Continuation of heating and the beginning of cell formation. c) Further heating and formation of regular hexagonal cells.

Many astronomers and cosmologists now believe that stellar systems were formed on the same principle. A galaxy is an amorphous mass, which is subjected to cosmic flows. These flows might be the result of nuclear reactions and of convective flows determined by cosmic temperature gradients, or of atoms moving from high to low density centers. The sum of all these flows is considered to be responsible for structure in the galaxies.

Turing calculated that there would be a range of critical rates of reactions where structure was bound to appear if chemical flows, such as a chemical reaction involving diffusion through a tissue, were substituted for physical flows[47]. He called this phenomenon the chemical basis of morphogenesis. Chemical engineers working on catalytic gas cracking found to their dismay that *Turing*'s calculations were correct, and that at a certain rate of reaction structural forms appeared which deposited themselves on the walls of the cracking tubes, thus strongly impairing their catalytic properties.

Zhabotinskii[48,49] detected another type of structure formation, namely, a time dependent one. He observed that on oxidative decarboxylation of malonic acid with potassium bromate in the presence of cerium(III) sulfate, a colored intermediate was obtained whose concentration changed periodically. He postulated the following reactions:

$$Ce^{3+} \xrightarrow{BrO_3^-} Ce^{4+}$$

$$Ce^{4+} \xrightarrow{HOOC-CHBr-COOH} Ce^{3+} + Br^-$$

The latter reaction is of second order and the first one is autocatalytic. In the reaction with malonic acid, the initial concentration of Ce^{4+} decreases slowly with time due to the build-up of Ce^{3+}. As soon as enough Ce^{3+} accumulates, the mechanism becomes periodic. Thus *Zhabotinskii* obtained chemical reactions which produce chemical waves as a function of time; in other words, chemical reactions which appear and disappear in an oscillatory manner. Translated into biological processes, these reactions might well be the principle governing biological clocks. In the experiments on heterogeneous polymerization (Section 3.2) we had practically the same sort of phenomena. A wave of acid molecules emerges, it diffuses out, another wave appears, and so on. We might even—if we are very optimistic—translate the termination reaction into a fixation of the structure, like the poisoning of the catalyst which ensues according to *Turing*'s mechanism.

5. The Transition to Self-Reproduction

In Section 4 we dealt with dynamic structures resulting from flow interactions. The number of such dynamic structures is practically unlimited and their forms depend on the nature of the flows, their rates, the background against which they take place, *etc.* The transition from one such structure to another is not continuous but proceeds by discrete jumps based on all-or-none reactions, as do many biological transitions; those of the nervous system, for instance. It might be, and we make this postulate with the greatest reservations, that after the first macromolecules were created they formed a number of dynamic structures, due to the various flows around them, and some of these structures possessed catalytic activity. Such catalytic activity, after operation of various selection steps, could finally lead the molecule to a state that would bring about its self-reproduction.

6. Conclusion

While we might consider the formation of organic molecules out of the primordial broth as more or less proven,

all the other sequences of the formation of life still need much investigation in order to provide us with a comprehensive picture. However, as more data become available from year to year we may be justified in hoping that in the not too distant future at least some of the problems will be resolved.

What we can safely say now is that nature is controlled by the entirety of its laws, that these laws interact with each other, and that the scientific world emerges as a unity in which each particle has its own well defined place, time, and function.

Molecular Hysteresis and Its Cybernetic Significance

By Eberhard Neumann[*]

The general foundations for a thermodynamic analysis of hysteresis phenomena in solutions and suspensions of polyelectrolyte systems are presented using examples of molecular hysteresis in biopolymers and membranes. The fundamental cybernetic significance of metastable states and molecular hysteresis for a physical interpretation of phenomena of life such as memory recording and biological rhythms is discussed.

1. Introduction

"*I believe that the ultimate goal of biological study is to 'translate' the phenomena of life into meaningful physical concepts*".—*Aharon Katchalsky*[**]

Modern physical chemistry of biological macromolecules has its roots in classical colloid chemistry. Because of their colloid properties high molecular weight constituents of biological cells and tissues have been called biocolloids. However, it was soon recognized that many cellular components thus classified were not colloidal aggregates of small molecules but large polymers of colloidal dimensions[1].

[**] "Wer ist's", Nachr. Chem. Techn. *20* (13), 247 (1972).

The majority of biological macromolecules are linear polymer chains whose constituent monomer residues are electrically charged under physiological conditions of pH (about pH 7 to pH 8) and ionic strength (about 0.15 mol/l). Thus, for instance, all nucleic acids and acidic mucopolysaccharides are strong polyelectrolytes. The "surfaces" of many structural proteins, enzymes and biomembranes are densely covered with electrically charged groups and hence may be considered as polyelectrolyte systems.

In recent decades increased attention has been devoted to the electrochemical properties of biopolymers and biopolyelectrolyte organizations such as membranes. It has been recognized that various aspects of the specific organization and function of these cellular components are determined by the electrical interactions between them and their environment. Thus changes in structure and function of such systems may be regulated and controlled by electrical influences of the environment[2]. This cybernetic aspect gains particular interest in connection with another remarkable property of many "biocolloids": the capability of developing long-lived *metastable states.*

It is known from colloid chemistry that colloids of high electric charge may frequently exist in states that are not thermodynamically stable; such systems may undergo irreversible phase changes[3]. Thus it is not surprising that polyelectrolyte organizations of biopolymers and biomembranes are also capable of developing long-lived metastable states. In a variety of cases such metastabilities are reflected in pronounced hysteresis phenomena.

Perhaps the most familiar examples of long-lived metastabilities are the hysteresis loops displayed by ferromagnetic materials. But hysteresis phenomena are also seen in other fields of physics and chemistry; for instance, in melting-crystallization cycles of ammonium salts or in adsorption-desorption processes on porous materials. In these cases hysteretic behavior has been macroscopically interpreted in terms of domain and pore structures[4].

The term hysteresis was coined by *Ewing* in order to describe the (history-dependent) reaction of magnets to changes of the external electric field[5]. The word is derived from the Greek ὑστερεώ = to lag behind; for instance, in a magnetization-demagnetization cycle the magnetic polarization lags behind the applied magnetic field intensity.

In contrast to the classical macroscopic hysteresis phenomena in and on condensed phases, microscopic hysteresis of individual molecules in homogeneous solution has been discovered only recently. In 1956, *Cox*, *Jones*, *Marsh*, and *Peacocke* found that the potentiometric acid-base titration of ribosomal ribonucleic acid (rRNA) does not yield an equilibrium curve, but exhibits hysteresis in the degree of proton binding as a function of the pH value[6]. It was later shown that the rRNA hysteresis is an intramolecular phenomenon[7].

The result of a spectrophotometric acid-base titration of rRNA is shown in Figure 1. The hysteresis loop is practically time-independent (see Section 2) and can be traced several times. The direction of cycling, however, is fixed: titration of a neutral solution with acid always yields the lower branch, subsequent titration of the acidic solution with base always follows the upper branch of the limiting loop. Within the boundary loop we may obtain scanning

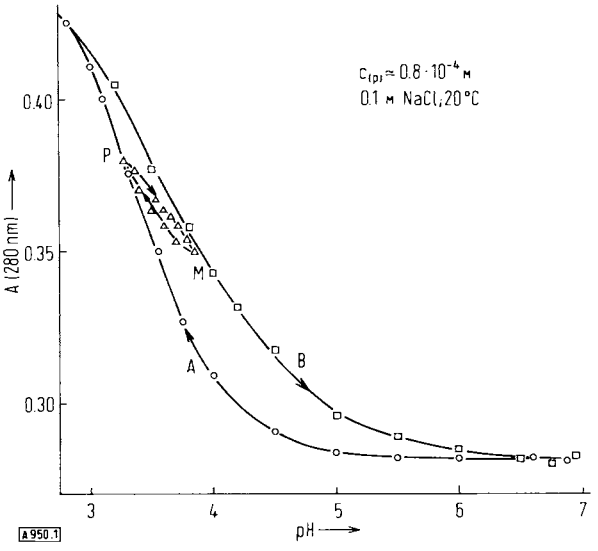

Fig. 1. Spectrophotometric titration of ribosomal RNA. Absorbance (A) at 280 nm as a function of pH; ○, acid titration (curve A); □, subsequent base titration (curve B); △, scanning loop. After [7].

curves similar to those observed in magnetic hysteresis. Because these inner curves reflect intermediary states of the system, scanning can in principle be used to scrutinize these states. The analysis of scanning curves is therefore a (novel) method of studying structural subunits in biopolymers such as rRNA in solution[8].

Numerous examples of hysteresis in solution and suspension are now known. Less numerous, however, are attempts to analyze these nonequilibrium phenomena and to elucidate the molecular origin of the underlying metastabilities. Indeed, for some time, hysteresis seems to have been considered by physicists and chemists as a curiosity that had to be avoided. That cycling of the loop is directional appears inconsistent with the time-independence of stable hysteresis loops. Directionality and changes with time are properties of irreversible (natural) processes whereas time-independence is the criterion for the limiting case of equilibrium (or of stationary states). Time-independent irreversibility, as reflected in long-lived hysteresis, apparently could not be treated either by the methods of classical thermostatics or by those of nonequilibrium thermodynamics.

It is the merit of *Aharon Katchalsky* to have contributed to a conceptual clarification of this apparent contradiction and, furthermore, to have recognized the important role which metastabilities and hysteresis may play in central phenomena of life, such as memory recording or biological rhythms[9,10]. Hysteresis is a well known expression of physical memory; thus modern computer technology utilizes hysteresis cycles of ferromagnetic and ferritic materials as memory devices for information storage.

In biology the mechanism of memory recording is still an unsolved problem. We may, however, conclude from biochemical and pharmacological studies that in the multistage process of biological memory formation there could plausibly be a physical step which is based on the directionality of hysteresis in macromolecules or membranes[11]. As a further dynamic aspect of hysteresis, circulation around a hysteresis loop presents in principle a possibility of producing periodicity on a molecular level by chemico-diffusional coupling[10,12]. This recognition is of great interest not only for the dynamics of enzyme catalysis

but also for the attempts to interpret biological rhythms[13] in terms of oscillatory chemical reactions.

Particularly challenging is the observation of hysteresis in nerve membranes[14, 15]. There is no doubt as to the fundamental role of electrochemical excitability of membranes for communication and control in all living organisms. However, the elementary processes of generation and conduction of bioelectric impulses are not well understood. It is remarkable that, according to *Adam*'s molecular theory of nerve excitability, the release of action potentials proceeds *via* short-lived metastable states of the nerve membrane[16].

These short remarks may indicate that the study of metastability and molecular hysteresis, as observed in macromolecules and membranes in solution and suspension, may be classed as an effort to "*translate*" some "*biological phenomena to physical-mechanistic concepts*"[9].

2. Thermodynamics of Hysteresis

2.1. Hysteresis and Metastability

In order to understand the special dynamic properties of hysteresis, we must delve into the nature of metastable states. Wherever long-lived hysteresis is observed, it indicates thermodynamically metastable states and cooperative nonequilibrium transitions. As is the case for macroscopic hysteresis phenomena in and on condensed phases, molecular hysteresis in solution and suspension also seems to be linked with domain structures. A domain may be defined as a structural unit or a structural region whose elementary units are able to change their state cooperatively, *i.e.* as a whole. Cooperative structural transitions in biopolymers and membranes may be thermodynamically classified as "diffuse" phase transitions and may be treated to a good approximation as first-order phase transitions[17–20].

It is frequently observed that phase changes encounter energy barriers which may hinder nucleation or/and propagation processes. These barriers must be reduced (*e.g.* by establishing nucleation centers) if the system is to pass through equilibrium states during the transition. If this is not possible under given experimental conditions, the system will pass instead into metastable states. Superheating and supercooling phenomena in thermal phase changes are manifestations of such transition barriers.

Thermodynamically the transition behavior of cooperative systems with metastabilities may be described by a state function $y(x)$ of the van der Waals type[21]. Figure 2a schematically shows such a function for the transformation of a domain between two states I and II. Between the two stable branches of this state function there is a (dotted) non-realizable range of instability. The equilibrium path, between B and D for I⇄II, may be traced at $x = x(G)$. If sufficiently high energy barriers prevent an equilibrium transition, changes in state can only occur *via* metastable regions. State I is metastable between B and 2 (region III), state II is metastable between D and 4 (region IV). The phase changes are unidirectional and irreversible, and take place at different x-values. At $x(I)$ the transition from I to II (between 2 and 3) occurs; the transition from II to I (between 4 and 1), however, occurs at $x(II)$. Thus, the irreversible phase changes fix a direction of cycling the hysteresis loop: 1→2→3→4→1.

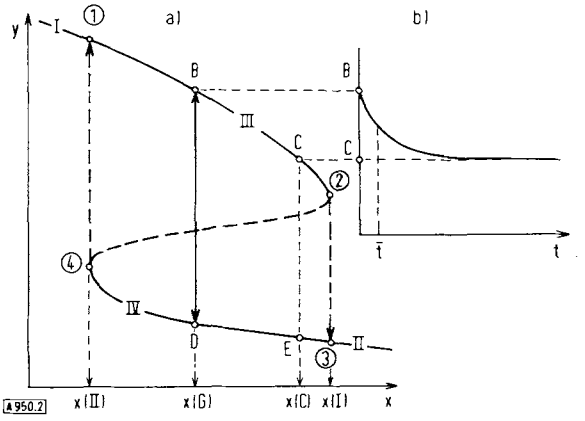

Fig. 2. a) Schematic representation of a phase transition: I, II stable states; III, IV, metastable states. y, internal parameter, *e.g.* volume or extent of reaction; x, external parameter, *e.g.* temperature or pH value. Cf. text. b) Time course $y(t)$ after a change from $x(G)$ to $x(C)$; see text.

In order to obtain hysteresis it is not necessary that both states I and II be metastable. It is sufficient that only one state develops metastability, *e.g.* state II in the region IV. In this case the transition IV to I would be irreversible whereas the change from I to II would occur along the equilibrium path at $x(G)$.

It may be seen from Figure 2 that in the hysteresis region between the transition points the internal parameter y is not a single-valued function of the external variable x. Thus, in contrast to equilibrium curves, hysteresis implies *two* values for y at *one* given value of x. Depending on the initial state, I or II, and depending on the direction of the change in x, the system may be either on the upper or on the lower branch of the $y(x)$ cycle. In the region of hysteresis the system "remembers" the history of tracing, the path by which the actual state change has been reached. It is this simple type of memory of path that distinguishes hysteresis from thermodynamic equilibrium. A state of equilibrium is "memoryless". Equilibrium may be reached by various routes; but once equilibrium is established, the system "forgets" preceding events. The memoryless state of equilibrium is the dead end of all directional, irreversible processes[9].

Abrupt, irreversible transitions characterize the dynamic behavior of a single domain. In an assembly of domains which have different stabilities, the distribution of transition points (along the x-axis) leads to an apparently smooth hysteresis curve, in which the consecutive irreversible transitions of individual domains cannot be distinguished (within experimental accuracy). Scanning curves may arise in systems having domains of different size and stability. Whereas hysteresis is a general indicator of cooperativity and metastability, scanning curves imply the existence of "polycrystallinity" or domain structures. Thus, the very observation of scanning curves classifies the rRNA molecule as such a "polycrystalline" multidomain system.

2.2. "Time-Independence" of Stable Hysteresis

As mentioned above, hysteresis is ascribed to thermodynamically metastable states[22], the lifetime of which may differ from one system to another.

Figures 2a and 2b illustrate how a hysteresis domain may react to a change of the environment. Suppose the system is in state I at point B and x is changed from x(G) to x(C). In typical examples one observes that the internal parameter, after an initial fast change (halftime $\bar{t}$), levels off to an apparently constant value C. If, within the limits of experimental accuracy, this value remains constant for long observation times $t \gg \bar{t}$, we attribute longevity to the underlying metastability. When the apparent temporal invariance holds only for short observation times, one speaks of short-lived metastable states. In the limit of an extremely small transition probability for the conversion from C to equilibrium at E, the extent of transition ξ remains apparently constant (*i.e.* $d\xi/dt = 0$) in spite of a non-zero affinity A. Hence the domain state C is comparable with a state of hindered equilibrium ($A > 0$; $d\xi/dt = 0$) such as the (metastable) mixture of H_2 and O_2 at room temperature, which reacts immeasurably slowly to give the thermodynamically stable H_2O vapor. It is a consequence of the apparent time-independence, that long-lived metastable states can be described by thermodynamic state functions, in the same way as equilibrium states.

The behavior of a domain is apparently reversible as long as external perturbations are restricted to the regions of metastability. If in our example the system at B is subjected to a displacement of x from x(G) to x(C) and then back to x(G), the domain will first change to point C and then will return from C to B. If, however, the external change proceeds beyond x(I), so that the irreversible transition to state II can occur, then—due to the directionality of the transition 2→3—the system remains in state II, even when the original condition of x(G) is reestablished. Only a change of x in the opposite direction, going beyond x(II), can bring the system back to its original condition in state I at point B. This nonequilibrium behavior means that such a domain may serve as a matrix for a permanent record of directed chemical or physical changes of the environment.

A cyclic variation of x, extending beyond both transition points x(I) and x(II), generally leads to hysteresis loops whose size depends on the cycling rate. Short-lived metastability results in relaxation hysteresis which, in the limit of very slow cycling, shrinks to the equilibrium curve. Stable hysteresis, however, does not decrease in size when the cycling velocity is diminishing (within the definition of time-independence for the underlying long-lived metastable states).

2.3. Entropy Production

The direction of rotation around a hysteresis loop is fixed by the entropy increase which accompanies directional (irreversible) changes of state. The entropy change dS of such a reaction system is correlated with changes in the internal energy dU, the work term dW and the chemical contribution $A d\xi$, through the Gibbs equation for chemical reactions (or phase changes) that proceed irreversibly at the (absolute) temperature T[23]:

$$T dS = dU + dW + A d\xi \tag{1}$$

In the equations defining the affinity and the variation of the advancement of reaction, respectively

$$A = -\sum_j \nu_j \mu_j; \quad d\xi = \nu_j dn_j \tag{2}$$

μ_j denotes the chemical potential, ν_j the stoichiometric coefficient, and n_j is the number of moles of component j (or of a component in phase j).

In nonequilibrium thermodynamics, the entropy change of a reaction system is divided into the two terms d_eS and d_iS[24]. Thus

$$dS = d_eS + d_iS \tag{3}$$

The term d_eS gives the contribution of the entropy which can be exchanged (as heat d_eQ) with the environment, $d_eS = d_eQ/T$, whereas d_iS represents the irreversible contribution created internally within the system. By definition d_iS is positive, $d_iS \geq 0$. If we now utilize the first law, $dU = d_eQ - dW$ and insert Eq. (3) into Eq. (1), we obtain

$$T d_iS = A \cdot d\xi \tag{4}$$

This relationship states that there is entropy production ($d_iS > 0$) in a reaction system only if the reaction or phase change proceeds irreversibly (*i.e.* if $A > 0$).

The entropy production accompanying a hysteresis cycle, Δ_iS, is derived by cyclic integration of Eq. (4):

$$\Delta_iS = \oint d_iS = \oint \frac{A}{T} d\xi \tag{5}$$

As noted earlier, the intrinsic directionality of hysteresis offers the possibility of recording "information" (and of erasing the record by continuing the cycle). This information (=negentropy) is based on entropy production of the recording matrix. The cost of storing as well as of erasing the imprint is "paid for" by investing work. That entropy production means loss of useful work can be derived directly from Eq. (1). For a closed cycle we have (at constant T)

$$T \oint dS = \oint dU + \oint dW + \oint A d\xi \tag{6}$$

Since the state variables S and U depend only on the state of the system, (for a variation which returns to the original state) the cyclic integrals $\oint dU$ and $\oint dS$ equal zero. Thus Eq. (6) reduces to

$$-\oint dW = \oint A d\xi \tag{7}$$

With Eq. (5) we obtain:

$$\Delta_i S = -\frac{1}{T}\oint dW \tag{8}$$

For $\Delta_i S > 0$, it follows that $\oint dW < 0$; *i.e.*, in order to close an irreversible cycle, work must be invested in the system.

2.3.1. Isothermal-Isobaric Hysteresis

The change in free energy dG accompanying a chemical reaction that proceeds irreversibly at constant temperature and at constant pressure p, is given by

$$(dG)_{p,T} = -A d\xi < 0 \tag{9}$$

We now denote the product $-T(\Delta_i S)_{p,T}$ as $(\Delta_i G)_{p,T}$, being the amount of free energy which is lost during an isothermal-isobaric hysteresis cycle.

$$(\Delta_i G)_{p,T} = -T(\Delta_i S)_{p,T} \tag{10}$$

This energy dissipation results from all processes k which occur irreversibly. Comparing Eq. (5) and Eq. (10) we may write:

$$(\Delta_i G)_{p,T} = -\sum_k \int_0^{\xi_k} A_k d\xi_k \tag{11}$$

In Eq. (11), ξ is normalized and, being the relative extent of reaction or degree of transition, varies between $\xi = 0$ and $\xi = 1$.

2.3.1. Calculation of $\Delta_i G$

Following the scheme of Figure 3, the calculation of $\Delta_i G$ may be performed in a general way. Using the symbols

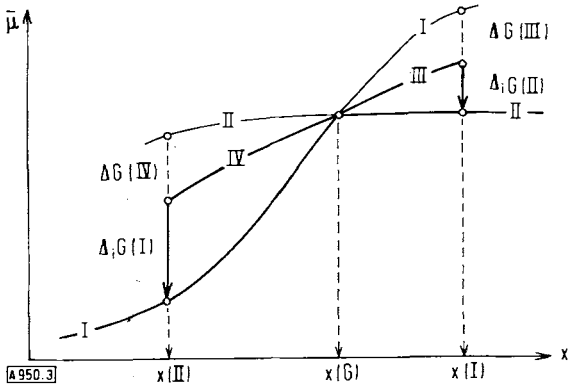

Fig. 3. Projection onto a μ-x plane of the mean chemical potentials μ̃, associated with the components or states. Cf. text and Fig. 2a.

given in Figure 2a we may choose the states I and II as reference states. The difference in free energy $\Delta G(\mathrm{II})$ between the states II and I at $x(\mathrm{II})$ is formally equal to the sum of the free energy changes $\Delta G(\mathrm{IV})$ accompanying the transition II→IV at $x(\mathrm{II})$ and the irreversible portion $\Delta_i G(\mathrm{I})$.

$$\Delta G(\mathrm{II}) = \Delta G(\mathrm{IV}) + \Delta_i G(\mathrm{I})$$

At $x(\mathrm{I})$ we have correspondingly:

$$\Delta G(\mathrm{I}) = \Delta G(\mathrm{III}) + \Delta_i G(\mathrm{II})$$

Since $\Delta_i G = \Delta_i G(\mathrm{I}) + \Delta_i G(\mathrm{II})$, the total dissipation of free energy during a hysteresis cycle is given by

$$\Delta_i G = \Delta G(\mathrm{II}) + \Delta G(\mathrm{I}) - \Delta G(\mathrm{IV}) - \Delta G(\mathrm{III}) \tag{12}$$

2.3.3. Thermal (Isobaric) Hysteresis

Provided that for thermal hysteresis the degree of transition ξ can be determined as a function of temperature, we derive from Eq. (5) a relationship for the measurement of the entropy production $(\Delta_i S)_p$.

$$(\Delta_i S)_p = \oint \left[\sum_k \frac{A_k}{T}\left(\frac{d\xi_k}{dT}\right)\right] dT \tag{13}$$

2.4. Energy Dissipation of Potentiometric Hysteresis

The hysteresis loops obtained in isothermal-isobaric potentiometric acid-base titrations are a direct measure of the energy dissipation and entropy production[25]. In a potentiometric hysteresis (cf., *e.g.*, Fig. 4) the mean degree of protonation $\bar{\alpha}$ corresponds to the internal parameter y and the pH value corresponds to x (in the notation of Fig. 2). The degree of protonation is defined as the ratio between the number of moles of bound protons and the number of moles of protonation partners.

The usual condition of such an acid-base titration is the retention of constant ionic strength during the titration cycle. This can be achieved by using a neutral salt whose concentration is large as compared to the concentrations of the reactants. If in addition the acid anion and salt anion are identical, *e.g.* are Cl^- ions, we may consider the chemical potential of the anions to be constant, and obtain, for instance, for the combination of HCl and NaCl: $d\mu_{HCl} = d\mu_{H^+} + d\mu_{Cl^-} \simeq d\mu_{H^+}$. Under this condition, the contribution of protonation to the change of the chemical potential of the (protonated) reactant j, is related (to a good approximation) to its degree of protonation α_j and the pH value by

$$\left(\frac{\partial \mu_j}{\partial \mathrm{pH}}\right)_{n \neq n_{HCl}} = -2.3\,RT\alpha_j \tag{14}$$

The notation $n \neq n_{HCl}$ means constant n except for n_{HCl} (cf.[8]).

The contribution of component j to the change of the free energy ΔG_k of the k-th protonation reaction in an acid-base cycle can be derived by cyclic integration of Eq. (14).

$$\Delta G_k = \oint \left(\frac{\partial \mu_j}{\partial \mathrm{pH}}\right)_k d\mathrm{pH} = -2.3\,RT \oint \alpha_{jk}\, d\mathrm{pH} \tag{15}$$

Since by definition

$$\Delta G_k = -\int_0^{\xi_k} A_k d\xi_k; \quad (\Delta_i G)_{p,T} = \sum_k \Delta G_k \tag{16}$$

we obtain from Eq. (11) and with $\alpha = \sum_j \sum_k \alpha_{jk}$ for the total dissipation of free energy

$$(\Delta_i G)_{p,T} = -2.3\,RT \oint \bar{\alpha}\,\mathrm{dpH} \tag{17}$$

The integral $\oint \bar{\alpha}\,\mathrm{dpH}$ is geometrically the area of the potentiometric hysteresis loop. Thus $(\Delta_i G)_{p,T}$ and the entropy production

$$\Delta_i S = 2.3\,T \oint \bar{\alpha}\,\mathrm{dpH} \tag{18}$$

can be experimentally determined.

Calculation of $\bar{\alpha}$. The number of bound protons is conveniently calculated from the difference in the amounts of acid or base which are necessary to bring the solution or suspension of the system to the same pH value as a "blank" solution. Since the investigation of hysteresis phenomena requires more than one acid-base cycle, more detailed relations (as usually needed) have to be used in order to calculate $\bar{\alpha}$. Such general equations have been given by *Revzin*, *Neumann*, and *Katchalsky*[7].

2.5. Protonation Energy of Polyelectrolyte Systems

In those regions of the hysteresis in which protonation is reversible or apparently reversible (as in the metastable regions), the formalism of protonation equilibrium may be applied. For polyelectrolyte systems, the pH dependence of the degree of protonation α_j of the group j is given by

$$\log \frac{1-\alpha_j}{\alpha_j} = \mathrm{pH} - \mathrm{p}K_j^0 - \Delta\mathrm{p}K_j \tag{19}$$

In Eq. (19), $\mathrm{p}K_j^0$ is the pK value of the single monomer residue and the polyelectrolyte contribution to the pK shift is defined by the relation

$$\Delta\mathrm{p}K_j = \frac{z_j \cdot e \cdot \psi_j}{2.3\,kT} \tag{20}$$

In Eq. (20), e is the (positive) elementary charge, k is the Boltzmann constant, ψ_j is the electrical potential at the site of protonation j, and z_j is the charge number (with sign) of the groups which give rise to ψ_j. The value of ψ_j depends on the geometry of the system, the mean degree of protonation and on the ionic strength of the medium.

The thermodynamic analysis of potentiometric hysteresis cycles often requires a knowledge of the free energy of protonation $\Delta_p G$. For the residue j, the standard value of this quantity is given by

$$\Delta_p G_j^0 = -2.3\,RT(\mathrm{p}K_j^0 + \Delta\mathrm{p}K_j) \tag{21}$$

Provided the pK value of the monomer residue is known, $\Delta_p G_j$ can be determined by calculating $\Delta\mathrm{p}K_j$ (cf. [26]).

2.6. Aim of Thermodynamic Hysteresis Analysis

The thermodynamic relations discussed in Section 2 provide the general framework for the analysis of hysteresis phenomena in chemical reactions or phase changes. The central task of such an analysis comprises the identification of those processes which occur irreversibly. For this purpose a comparison of measured and calculated values for $\Delta_i G$ may be useful.

Especially in polyelectrolyte systems, the thermodynamic analysis of temperature and ionic strength dependences may give hints as to the nature of the energy barrier which causes the metastable states and forces the system to hysteretically circumvent this barrier.

From a comparison of the Eqs. (8) and (10) we see that $(\Delta_i G)_{p,T}$ is a measure of the energy investment for an isothermal-isobaric hysteresis cycle. Therefore the thermodynamic analysis leads in principle to the determination of the free energies which must be invested in the system in order to re-establish the metastable states. The role of metastable states in triggering directed processes, at low expenditures of energy, is discussed in Sections 7 and 8.

3. Hysteresis in Nucleic Acids

3.1. Synthetic Polynucleotides

Especially pronounced hysteresis phenomena have been observed in potentiometric and spectrophotometric titrations of complexes composed of homogeneous synthetic nucleic acids. As a representative example, the result of a potentiometric acid-base titration of the polynucleotide complex poly(A)·2poly(U) is shown in Figure 4 (cf. [8]).

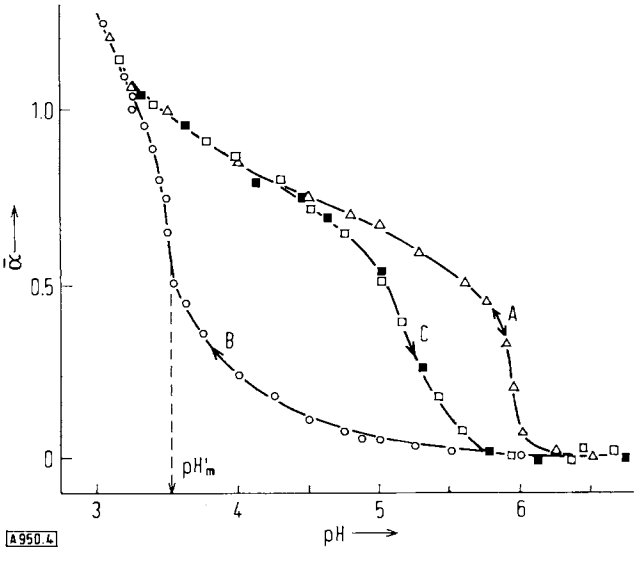

Fig. 4. Potentiometric titrations (degree of protonation $\bar{\alpha}$ as a function of pH) at 20 °C: a) 0.1 M NaCl solution of poly(A) and poly(U) mixed in the molar ratio of the polymers 1:2; ○: acid titration (curve B); □, subsequent base titration (curve C). b) 0.1 M NaCl solution of poly(A); △, (curve A). Polymer concentrations at pH 7: a) $c = 3.24 \times 10^{-4}$ M (A·2U); b) $c = 3.2 \times 10^{-4}$ M (A).

The three-stranded (A · 2 U) complex is formed when polyriboadenylate, poly(A), and polyribouridylate, poly(U), are mixed at neutral pH and sufficiently high ionic strength in the molar ratio of the polymers 1 : 2[27]. The double-stranded complex poly(A) · poly(U) may be obtained upon mixing the single strands in the molar ratio 1 : 1[28]. In these helical multistranded complexes the heterocyclic bases adenine and uracil are specifically associated by way of H-bonds and regularly stacked upon each other. Due to the cooperatively stabilized base stacking such systems may be considered as "unidimensional" crystals. (Because of their polyelectrolyte nature the stability of multistranded polynucleotide complexes is strongly dependent on the ionic strength of the medium.)

The first indications of metastable forms in the A-U system are seen in the results of *Warner* and *Breslow*: the (A · U) complex, apparently stable at pH 5.5 with respect to the single strands, is formed only to a small extent if the polymers are first separately brought to pH 5.5 and then mixed together[28]. Similar results were obtained by *Steiner* and *Beers*[29]. Later, *Cox* discovered that the size of the hysteresis loops observed in spectrophotometric titrations of (A · U) complexes are dependent on temperature[30]. Poly(A), too, shows dependence on previous history[29, 31]. The partially protonated double helix poly(A) · poly(A) that is formed at acidic pH values, has a tendency to aggregate with increasing proton concentration. At a given pH, the extent of this aggregation depends on the ionic strength. Furthermore, the actual state of the system is determined by the sequence in which the parameters pH and ionic strength are changed. The aggregation of poly(A) occurs relatively slowly at pH values which are not too low, so that this aggregation does not seriously disturb experimental studies on the acid-base hysteresis in the A-U-system. (Aggregation of larger extent can be checked by the measurement of sedimentation coefficients.)

3.1.1. The (A · 2 U) Model System

The first thermodynamic analysis of molecular hysteresis was performed by *Katchalsky*, *Oplatka*, and *Litan* using *Cox*'s results for the A-U system[25]. In contradistinction to the original interpretation, however, neither the (A · U) double helix nor the (A · A) complex can here develop long-lived metastability, but only the (A · 2 U) triple strand[8].

The hysteresis in the acid-base titration of the A-U system accompanies the "transcrystallization" reaction between the (A · 2 U) triple helix and the (A · A) double strand. The overall reaction may be written (in terms of the reactive chain residues or segments) as

$$2(\mathrm{A}\cdot 2\mathrm{U}) \underset{\curvearrowright}{\overset{\curvearrowleft}{\mathrm{H}^+}} (\mathrm{A}\cdot\mathrm{A}) + 4(\mathrm{U}) \qquad (22)$$

In the pH range 3 to 7, the measured quantity $\bar{\alpha}$ (as shown in Fig. 4) reflects protons bound to (A) residues. In the course of the acid titration the (A · 2 U) complex does not directly transform to the protonated (A · A) helix, but is first (partially) protonated. (This conclusion is supported by the similarity of the sedimentation coefficient distributions between pH 7 and pH 4.) Thus, the measured quantity $\bar{\alpha}$ is a sum of two contributions, one from protons bound to the (A · A) double helix (degree of protonation α_2) and the other from protons bound to the triple helix (degree of protonation α_3). If ξ denotes the extent of the conformational change described in Eq. (22), we obtain for each pH value:

$$\bar{\alpha} = \xi\alpha_2 + (1-\xi)\alpha_3 \qquad (23)$$

The value of α_2 can be measured independently by titration of poly(A), whereas α_3 may be calculated using a relation analogous to Eq. (19); see Eq. (35).

In a similar way UV-spectroscopic titration data can be used to determine the pH-dependence of ξ. Figure 5 shows

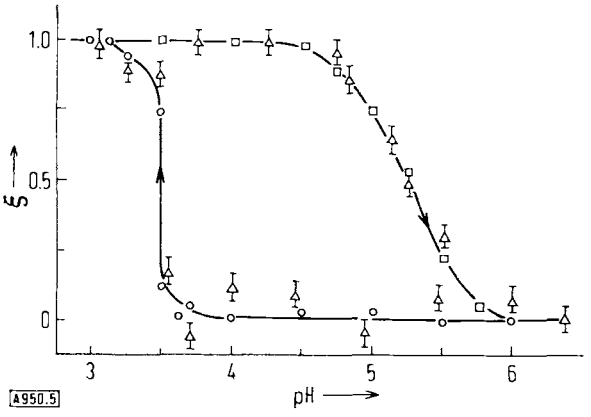

Fig. 5. Extent of reaction ξ as a function of pH. Experimental conditions as in Figure 4. ○, □: data of potentiometric and △: data of spectrophotometric titrations. Cf. [8].

that the same ξ(pH) is obtained irrespective of whether the quantity measured is $\bar{\alpha}$ or UV absorbance[8]. Furthermore, it is clearly seen that, along the acid branch, (A · A) formation occurs only at pH values near to pH 3.5. The transition on the acid branch is abrupt, whereas the smooth base branch points to an equilibrium transition.

a) Molar state variables. The measured (apparent) state variables of high molecular weight polynucleotides are independent of polymer concentration c_j[18, 32]. Therefore the polymer activity coefficients may be taken as constant and thus can be incorporated into the standard potentials μ_j^0. Thus

$$\Delta G = \sum_j \nu_j \mu_j = \sum_j \nu_j \mu_j^0 + RT \sum_j \nu_j \ln c_j \qquad (24)$$

For unit stoichiometric conversion, *i.e.* all $c_j = 1$ mol/l, it follows that

$$\Delta G^0 = \sum_j \nu_j \mu_j^0 \qquad (25)$$

and with Eq. (16) we obtain:

$$(\Delta_i G)^0 = \sum_k \left(\sum_j \nu_{jk} \mu_j^0 \right) \xi_k \qquad (26)$$

If we relate the state parameters to the number of moles of (A) chain segments, the measured $\bar{\alpha}$(pH) curve of Figure 4 directly yields the free energy loss, per mole of (A), for one isothermal-isobaric hysteresis cycle:

$$(\Delta_i G)^0_{p,T} = \sum_k \Delta G_k^0 \, \xi_k = -2.3\, RT \oint \bar{\alpha} \, \mathrm{d}\,\mathrm{pH} \qquad (27)$$

b) Calculations of $(\Delta_i G)^0$. As mentioned above there are indications that the base branch of the hysteresis in the A-U system is the equilibrium curve[8, 33]. Consequently our model system appears to have only *one* region of metastability. In this region the partial protonation of the triple helix represents a metastable pre-equilibrium. This equilibrium comprises the opening of (A·2U) segments

$$(A \cdot 2U) = (A) + 2(U) \qquad (28)$$

and the protonation of open (A) segments, according to $(A)+H^+=(AH^+)$.

The protonation equilibrium corresponds to state IV in Figure 2a. Thus, state II represents the (A·2U) triple helix, whereas state I represents the (A·A) double helix. If we now choose the chemical potentials of the separated single strands as reference, the calculation of $(\Delta_i G)^0$ becomes particularly simple. For our model system the general case as represented in Figure 3 is reduced to the scheme shown in Figure 6[8].

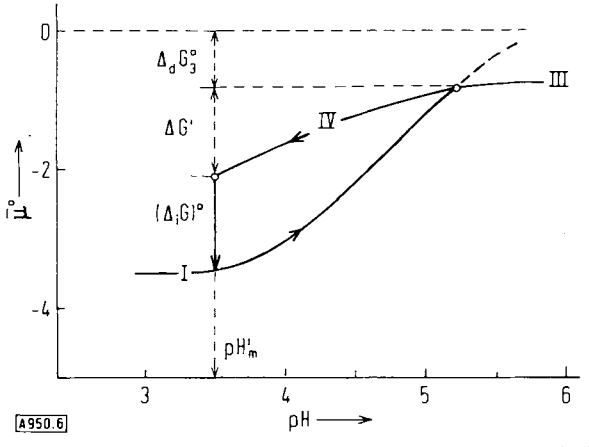

Fig. 6. Projection onto a potential-pH plane of the mean molar standard potentials $\bar{\mu}^0$ associated with the nucleotide segments; $\Delta G' = \alpha'_3 \cdot (\Delta_d G_3^0 + \Delta_p G_3^0)$, see Eq. (29).

By use of Eqs. (25) and (26) we can derive an expression for $(\Delta_i G)^0$ which corresponds to Eq. (12).

$$(\Delta_i G)^0 = \Delta_b G_2^0 + \Delta_d G_3^0 + \alpha'_3(\Delta_d G_3^0 + \Delta_p G_3^0) \qquad (29)$$

In Eq. (29), $\Delta_b G_2^0$ is the change in the free energy accompanying the reaction $(A)+H^+=\frac{1}{2}(AH^+ \cdot AH^+)$ at pH'_m (corresponding to x(II) in Fig. 3), $\Delta_d G_3^0$ is the free energy of the helix-coil transition (Eq. (28)), $\Delta_p G_3^0$ is the free energy change for the protonation of (A) segments in the triple helix (and may be calculated with Eq. (21)), and α'_3 is the extent of protonation at pH'_m.

It has been shown that, based on the assumptions underlying Eq. (29), the calculation and measurement of $(\Delta_i G)^0$ are in agreement[8]. Under the experimental conditions of Figure 4 we find that

$(\Delta_i G)^0_{p,T} = -1.4\ (\pm 0.1)$ kcal/mol (A)
$(\Delta_i S)^0_{p,T} = 4.9\ (\pm 0.1)$ cal/mol (A) deg

The agreement of the measured and the calculated $\Delta_i G$ value supports the interpretation of the hysteresis behavior, which was the basis of the calculation leading to Eq. (29). Accordingly, the hysteresis in our model system implies that a metastable protonation equilibrium exists as an intermediary during the acid titration.

It may be added that the energy loss in this hysteresis system is a rather small energy investment as compared to the average energy of stabilization of a chemical bond (≈ 50 kcal/mol).

3.1.2. (I·C) and (dC·dG) Complexes

It appears that three-stranded polyribonucleotide complexes (as opposed to double-stranded helices) tend to develop long-lived metastabilities. Polymer associates similar to the (A·2U) complex occur also in complexes of homopolymers of inosinic(I)-, cytidylic(C)-, and guanylic (G) acids. *Guschlbauer* and co-workers found that in the system poly(I)·poly(C) there are two hysteresis regions which are separated from each other by an equilibrium range[34]. A partially protonated triple strand of type (I·C·C) can be identified as an intermediate in the course of the (I·C) conversion[35]. (This is similar to the (A·2U) intermediate in the (A·U) conversion to (A·A) base pairs[8].)

Extended regions of metastability are observed in polydeoxyribonucleotides. Thus, the acid-base hysteresis in poly(dG)·poly(dC) covers about 6 pH units (between pH 2 and 8). This type of base pairing exhibits metastability in the physiologically relevant neutral pH range. Since it is known that rather long (dG·dC) stretches exist in DNA, we have here a possibility for a regulatory mechanism which could be specifically based on metastabilities in clustered (dC·dG) base pairs[34].

The energetics of such a mechanism could be estimated by a thermodynamic analysis of the hysteretic behavior of the (dG·dC) complex. In principle such an analysis can be performed in a similar way as in the (A·2U) system.

3.1.3. Thermal Hysteresis in Biopolymers

The UV-absorbance of some complexes composed of poly(dA) and polymers of substituted uridylic acids changes along a hysteresis loop during a heating-cooling cycle[36]. Similar thermal hysteresis has been observed in thio derivatives of the copolymer poly(dA-T) in solutions of high salt concentration (2 M NaCl)[37]. The hysteresis in this copolymer accompanies conformational changes between different helix types.

The capability of developing metastable states is apparently not restricted to complexes composed of several polyelectrolyte strands. For instance, the complex poly(A)·poly(1-vinyluracil) in which only poly(A) is an electrolyte, shows thermal hysteresis within a relatively broad temperature range[38].

There is a series of examples where hysteresis is due to unspecific aggregation and disaggregation of molecules. This category probably includes all the thermal hysteresis loops which have been found for a series of synthetic nucleic acids in water-methanol mixtures at lower temperatures[39].

Since optical parameters like UV absorbance at certain wavelengths are a measure of the degree of transition ξ of conformational changes, we may use Eq. (13) as a starting point for a thermodynamic description of thermal hysteresis in those biopolymers in which structural changes can be followed by optical methods.

3.2. rRNA Hysteresis

Long-lived metastabilities can be developed not only by long polynucleotides but also by shorter multistranded structured regions in nucleic acids. An example of such a system is the hysteresis of rRNA (cf., *e.g.*, [40]). Recent studies have shown that the rRNA hysteresis is clearly an intramolecular phenomenon[7]. The formation of metastable states in this biopolymer is linked with the presence of Mg^{2+} ions. Furthermore, the metastabilities occur only along the base branch of the boundary loop and along the scanning curves, whereas the acid branch represents the equilibrium curve. From the high thermal stability of the metastable forms and from the analysis of the UV spectrum as a function of pH, it was concluded that structured domains comprising mainly protonated G·G base pairs are the cause of the long-lived metastabilities in rRNA.

Questions concerning the possible role of metastable states in rRNA structures and in the regulation of ribosomal processes are the subject of further investigations[7].

4. Hysteresis in Proteins and Membranes

Hysteresis is also observed for structural changes in "globular" polyelectrolyte systems such as proteins, and lipoprotein and lipid vesicles. The hysteresis obtained in polyglutamic acid is considered representative for metastability in polypeptides. In this case the acid-base hysteresis has been interpreted in terms of specific aggregation-disaggregation processes[41].

For proteins, acid-base titrations are frequently used in order to determine type and number of buried groups[42]. However, the metastability indicated in the titration curves has rarely been thermodynamically analyzed. It should be stressed that the dissipation of free energy, $\Delta_i G$, of such systems represents a direct measure of the free energy stabilizing buried groups within the biopolymer.

An example of functional hysteresis in proteins has been discovered in the halophilic enzyme malate-dehydrogenase isolated from halobacteria of the Dead Sea[43]. The change of the catalytic activity of this enzyme with decreasing and increasing salt concentration follows a hysteresis loop (see Fig. 7).

Besides the hysteresis in nerve membranes[14, 15], metastabilities are also observed in suspensions of lipid vesicles. The thermal hysteresis found for such a spherical membrane system is bound to the presence of di- or trivalent ions or acetylcholine[20].

The acid-base titration of membrane fragments of the cell envelopes prepared from Dead Sea halobacteria yields a hysteretic proton binding curve (see Fig. 8). The size

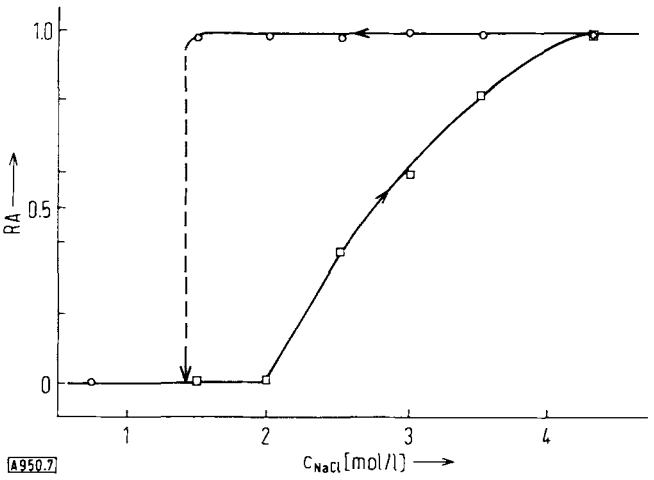

Fig. 7. Relative enzymatic activity, RA, of the haloenzyme malate-dehydrogenase at 30 °C; ○, values measured at decreasing and □, values measured at increasing NaCl concentration C_{NaCl} [43].

of this membrane hysteresis is dependent on the salt concentration; at a NaCl content smaller than 1 M, the hysteresis shrinks to give the equilibrium curve. If, at constant pH, the salt concentration is decreased and increased in a cyclic mode, one also obtains a hysteresis loop[44].

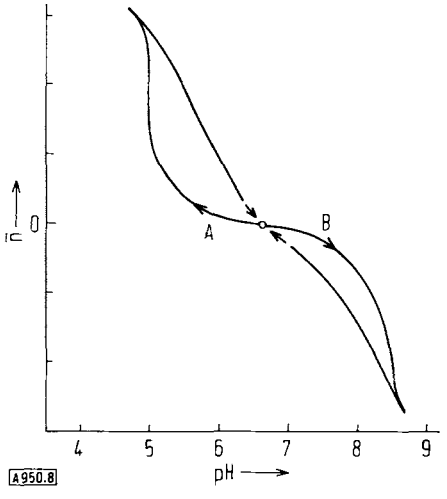

Fig. 8. Proton binding curve of suspended membrane fragments prepared from cell envelopes of Dead Sea halobacteria; $\bar{n}$, mean number of protons bound (in arbitrary units) as a function of pH.
