It is seen from Figure 8 that the nonequilibrium transitions indicated in the acid-base hysteresis occur in pH ranges which include the pK values associated with primary amino- and carboxyl groups of membrane proteins (at 3 M NaCl at about pH 8.5 and pH 5). The hysteresis in these membrane fragments is probably due to metastabilities in the "ion pairs" of electrostatically associated side groups. It appears that electrostatic interactions also contribute to the existence of hysteresis in the activity of our haloenzyme. In this protein, hysteresis derives from long-lived metastable states in the association-dissociation reaction between the dimer subunits of the tetrameric enzyme complex[43].

The cybernetic significance of hysteresis in membranes and catalytically active proteins will be discussed in Section 8.

5. Molecular Field Theory of Hysteresis

A general thermodynamic description of hysteresis cannot, of course, answer the question of the physical origin of this nonequilibrium phenomenon.

In the molecular hysteresis of nucleic acid complexes, long-lived metastability appears to be due to the cooperativity of base stacking and to the electrostatic interactions between the polyanions. Indeed, the first attempts at a molecular interpretation of the hysteresis in the A-U system include the assumption of an electrostatic nucleation barrier to the formation of protonated (A·A) sequences[25,8]. In this approach, however, only a qualitative interpretation has been given.

Recently, a molecular field theory of hysteresis has been developed[45]. According to this approach, a large energy barrier prevents opening of (A·2U) segments within the partially protonated triple helix. (The increased protonation in the acid titration compensates a part of the electrostatic repulsion energy arising from the phosphate residues of opposite strands, such that further opening of (A·2U) sequences is more difficult before a critical pH is reached.)

We may formally write the mean free energy $\bar{G}$ for the stabilization of an associate such as the (A·2U) segment as a sum of two terms:

$$\bar{G} = -\bar{A} + \bar{R} \tag{30}$$

The term $\bar{A}$ comprises all attraction contributions, primarily short range forces such as van der Waals- and hydrophobic interactions. The second term, $\bar{R}$, accounts exclusively for (long range) electrostatic *repulsion forces* between charged groups. We may further specify our "molecular field" model for the triple helix by defining the completely separated (non-interacting) single strands as a reference state for which $\bar{R}=0$. (Thus $\bar{R}$ is the relative mean free energy of the dissociated nucleotide residues in the triple helix.)

In our model the energy barrier for the separation of associated chain residues arises from the different manner in which $\bar{A}$ and $\bar{R}$ depend on the average distance, $\bar{d}$, between the opposite association partners. We may assume that $\bar{A}$ is zero for $\bar{d}>d_0$, where d_0 is the distance of maximum attraction. In the simple case of Coulomb repulsion, $\bar{R}$ is proportional to $1/\bar{d}$. Figure 9 schematically shows these correlations of $\bar{R}$ and $\bar{A}$ with $\bar{d}$.

Suppose now that the experimental conditions are such that only a few base residues within the cooperatively stabilized organization of the stacked (A·2U) triple helix could dissociate. The dissociated chain residues could not separate very far because their closed neighbors prevent them from moving apart from each other. A small distance between dissociated residues, however, means a high value of the $\bar{R}$ term. Thus dissociation of only a few associates would create an energetically unfavorable state, *i.e.* dissociation encounters a nucleation barrier.

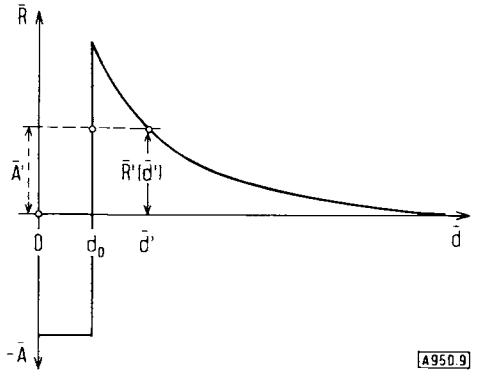

Fig. 9. Mean free energies $\bar{A}$ and $\bar{R}$ as a function of the mean distance $\bar{d}$ between the association partners in polyelectrolyte structures; see text.

This barrier can be decreased if $\bar{d}$ is increased. Such a decrease may be achieved by an increase in $\bar{A}$ (for instance, by a change in pH) thereby decreasing $\bar{R}(\bar{d})$. The thermodynamic condition for the onset of separation is given by

$$\bar{G}(\bar{d}) \geq 0.$$

If separation occurs at $\bar{d}=\bar{d}'$, we have at this point $\bar{A}'=\bar{R}(\bar{d}')$; see Fig. 9. Since now, however, $\bar{G}(\bar{d}')=\bar{A}'>0$, the dissociation of the entire assembly and the separation of the strands proceed irreversibly. All states for which $0<\bar{A}\leq\bar{A}'$ thus are metastable.

Since $\bar{R}$ depends on $\bar{d}$, it is obvious that $\bar{R}(d)$ is a function of the mean fraction, $\bar{f}$, of closed (A·2U) segments within a triple helix. We assume that this dependence is linear. Denoting the proportionality factor of this approximation by B, we may write

$$\bar{R} = B\cdot\bar{f} \tag{31}$$

It is easily seen that the term $\bar{R}$ has its maximum value if $\bar{f}=1$, while $\bar{R}=0$ for $\bar{f}=0$.

Since any chain segment in the triple helix is subject to the long-range electrostatic forces (or to the molecular field) of all segments, we may call Eq. (31) the molecular field approximation for our model.

In the range of experimental conditions, in which $\bar{G}$ depends on $\bar{d}$ and thereby on f, we may calculate the total free energy G_{tot} as a function of f by the following relation:

$$G_{tot} = -\bar{A}\cdot f + (1-f)\cdot B\cdot f + RT[f\ln f + (1-f)\ln(1-f)].$$

It can be shown that for $B>2RT$, the state function G_{tot} has two minimum values, one being associated with the metastable state and the other with the thermodynamic equilibrium state. Such an energy diagram containing two minima has already been used by *Borelius* in order to interpret long-lived metastability and hysteresis[22].

An important result of the theory is a condition for the existence of thermodynamically metastable states:

$$B > 2RT \tag{32}$$

For our (A·2U) model system, the inequality (32) holds for lower temperatures (<50 °C), whereas for the (A·U) double helix $B<2RT$. At the Curie temperatur T_c, we have $B=2RT_c$; that is, for $T \geq T_c$, the hysteresis disappears and one obtains only the equilibrium curve[8].

The hysteresis loops obtained in membranes and protein complexes of high surface charge densities may be molecularly interpreted with a molecular field approach in a manner similar to the polynucleotide systems.

6. Hysteresis as an Analytical Method

The extreme longevity of the metastabilities in some biopolymers and membrane structures permits the use of hysteresis as an analytical method for the investigation of distributions of structural subunits. As already mentioned, the occurrence of scanning curves implies domain structures. The analysis of these scanning curves can, in principle, reveal the distribution function of the domains and their characteristic transition points. Once this function is known, the scanning behavior can be predicted[46,47].

Such an analysis is based on the Preisach model[48] which underlies *Everett*'s domain theory. In the simple model of independent domains, the domain distribution function $\phi(x)$ can be determined in a relatively simple way from a limited number of scanning curves. This requires, however, that the mean extent ξ_i of the irreversible changes (*i.e.* the fraction of transformed domains) be measured as a function of the external parameter x. Let us attribute to each domain a lower transition point x_l and an upper one x_u (corresponding to x(II) and x(I) in Fig. 2). From the relationship

$$\phi(x) = -\frac{\partial^2 \xi}{\partial x_u \, \partial x_l} \tag{33}$$

the function $\phi(x)$ can be derived using experimental $\xi_i(x)$ values[46].

By assigning a lower and an upper x-limit for each scanning step we may describe scanning processes in a simple way. Thus, the paths by which a point of the hysteresis can be reached are represented by a domain complexion[46]. This function describes the path-dependent history of a domain system in a manner analogous to the after-effect function introduced in 1876 by *Boltzmann* for the description of elastic after-effects depending on the previous history of deformation[49]. Thus, *Everett*'s domain complexion is a type of memory function, and the domain distribution function describes the "memory capacity" of a multidomain system.

In order to check whether a system of independent domains is present, one may use a key theorem of *Everett*'s theory. For independent domains the areas of $\xi_i(x)$ scanning loops between the same x-limits have to be congruent. If the ξ_i values cannot be evaluated, we may use a modification of this theorem due to *Enderby*[47]. In this case the *measured* scanning loops (*e.g.*, $\bar{\alpha}$(pH) curves) between the same x_l- and x_u values are compared. In a system in which the state of a domain does not depend on the states of the other domains, the intercepts at the same x value between each scanning loop are equal.

If we utilize this theorem for the scanning loops in an (A·2U) system with a relatively broad molecular weight distribution, we obtain the picture represented in Figure 10. It is seen that the "loop intercepts" $\Delta\bar{\alpha}$(pH) are equal to within 10% accuracy. Thus the (A·2U) complexes apparently behave independently.

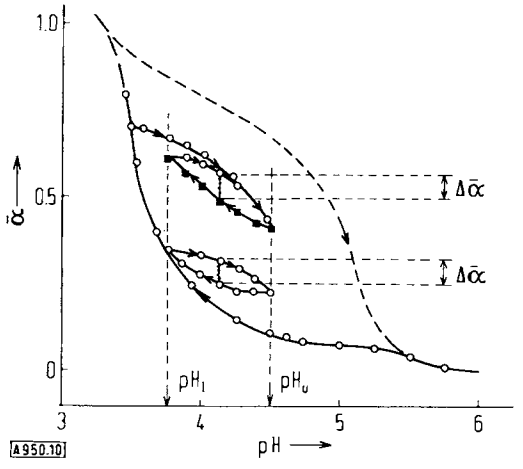

Fig. 10. Scanning loops in an (A·2U) system of broad molecular weight distribution; pH_l is the lower and pH_u is the upper pH limit of the loops. Comparison of the differences $\Delta\bar{\alpha}$ between the loops at the same pH value; cf. Figure 4 and see text.

Assuming that (A·2U) complexes of different molecular weight have different stabilities, the differentiation of the hysteresis boundary curve should yield the relative distribution of these stabilities and the relative amount of triple helices of different molecular weights along the pH scale. Thus, the analysis of the scanning behavior is in principle a method of determining the distribution of molecular weights in biopolymer mixtures.

7. Conformational Changes Induced by Electric Impulses in Polyelectrolyte Systems

Acid-base titrations are a standard technique for studying the thermodynamics of structural changes in ionizable systems. When the titrations are performed at different ionic strengths, it is possible to determine the electrostatic contributions to the energetics of structural changes. Such electrostatic contributions are particularly large in polyelectrolyte systems.

Eqs. (19) and (20) show that, for homogeneous polyelectrolyte systems:

$$\log\frac{1-\alpha}{\alpha} = \mathrm{pH} - \mathrm{p}K^0 - \frac{z\,e\,\psi}{2.3kT} \tag{34}$$

In this relationship we see that α may be changed by a variation in pH or by a change of the electrical potential

term ψ. In general, ψ is determined by the intramolecular field. This inner field may be influenced by the degree of ionization (protonation) and by the ionic strength of the medium, but also by external electric fields to which the system may be exposed.

In our hysteresis model system, the protonation pre-equilibrium of the (A·2U) complex in the pH-range above the irreversible transition at pH'_m may be described by the following relation:

$$\log\frac{1-\alpha_3}{\alpha_3} = pH - pK^0_{AMP} + \frac{e\psi}{2.3kT} + \frac{\Delta_d G_3}{2.3kT} \qquad (35)$$

In Eq. (35), pK^0_{AMP} is the pK value of adenosine monophosphate and $\Delta_d G_3$ corresponds to the pK shift due to the fraction of the (A) segments which dissociate from (A·2U) segments during protonation (cf. Eq. (28)). (ψ is negative, since it arises primarily from the negatively charged phosphate residues.) At $\alpha = \alpha'_3$ corresponding to $pH = pH'_m$, irreversible formation of (A·A) sequences occurs.

A change in ψ which leads to $\alpha > \alpha'_3$ may be achieved at constant pH by a change in the ionic strength. Indeed, the irreversible formation of the (A·A) double helix may be triggered by decreasing the salt concentration in a solution of metastable (A·2U) triple strands[33]. Recently, we have found that electric impulses (of an initial intensity of about 20 kV/cm and decaying exponentially with a relaxation time of about 10 μs) directly induce this conformational transition[50].

A polarization mechanism has been proposed to explain the electric induction of such conformational changes. In accordance with this idea, the external electric field shifts the ionic atmosphere of the polyelectrolytic (A·2U) complex and thereby induces a dipole moment. At the negative pole of the induced macro-dipole, the screening by the ion cloud of the negative phosphate residues is reduced. This, in turn, causes repulsion between the ends of the polyanions and leads finally to the unwinding of the triple helix[50].

A similar mechanism has been suggested to account for the induction of permeability changes in vesicular membranes of high surface charge density by electric impulses. Thus the displacement of the screening ionic atmosphere increases the mean distance between equally charged ionic groups on the membrane surface. The result is a permeability increase in the membrane. In this way we have interpreted the observation that electric impulses release biogenic amines from suspended chromaffin granules[51].

The electric impulses applied to solutions of the (A·2U) complex and to vesicle suspensions are comparable to the voltage pulses of the action potentials in nerve membranes. During excitation the electric field present across the nerve membrane changes in direction and intensity from about −70 kV/cm to about +50 kV/cm. We may assume that large electric fields act not only across the membrane but also in close proximity to it and (transiently) across the synaptic junction. Hence, any polyvalently charged system exposed to these fields could be affected in a similar way as the (A·2U) complex or the chromaffin granules.

Electrically induced conformational changes in macromolecules and membranes have been discussed as a possible mechanism for electrically controlled regulatory processes in general and for a recording of electric signals in particular. With this in mind we may consider directed structural transitions induced by electric impulses in metastable polyelectrolyte systems as *model reactions* for the process of imprinting nerve impulses in the neuronal structures involved in a possible physical record of memory.

It is known from physiological and biochemical studies that nerve stimulation accelerates the metabolism of innervated cells; nerve activity, for instance, enhances RNA and protein synthesis. The mechanism of coupling between electrical activity and chemical reaction is still unknown. In view of the hysteresis capacity of rRNA which might be electrically affected in a similar way as in the A-U system, the question is raised whether ribosomal activity may be regulated *via* rRNA metastabilities by the electrical activity of the cell.

Other cellular processes, too, are influenced by nerve activity. Thus the secretion of hormones and neuroeffectors (transmitter substances) is appreciably increased during nerve stimulation. The depolarization voltage which leads to increased hormone secretion in the chromaffin cell is comparable to the initial intensity of the voltage pulses which *in vitro* cause outflow of neuramines from the suspended chromaffin granules. It is therefore suggestive to assume a mechanism according to which nerve activity controls directly the intensity and the extent of neurosecretion by permeability changes in the membranes of the storage vesicles transiently attached to the nerve membrane.

Furthermore, it is suggested that the elementary processes of synaptic facilitation in the functional development of the central nervous system involve permeability changes combined with neuroeffector release induced by nerve impulses in membranes.

It is worth mentioning that a threshold value of the impulse intensity of about 18 kV/cm was observed for the release of conformational transitions in the (A·2U) model system as well as for the induction of permeability changes in the vesicle membrane. The threshold value of the depolarization voltage necessary to release action potentials in nerve membranes is about 20 mV; for an average membrane thickness of 100 Å, 20 mV correspond to a field intensity of 20 kV/cm. The similarity of these threshold voltages has revived the discussion on the chemical control of the ion flows underlying the action potentials. In line with this idea, conformational changes induced by impulses in membrane components are suggested as a mechanism for the activation of acetylcholine[53]. The relatively large amounts of heat accompanying the action potential imply the participation of chemical reactions in nerve activity. We note that chemical reactions and conformational changes which proceed irreversibly are accompanied by heat evolution due to dissipation of free energy. In this context it is of interest that during a depolarization-polarization cycle of the nerve membrane there is net heat production[53]. It is a moot question whether this heat is caused by membrane components which change their conformation along a hysteresis loop (cf. the hysteresis observed by *Tasaki* in squid axon membranes[14]).

8. Hysteresis as a Basis of Chemical Oscillations

The circular-vectorial property of hysteresis can be the basis for chemical oscillations. Microscopic chemical oscillations are of fundamental importance for a mechanistic interpretation of biological clocks[10,54].

The principle of molecular hysteresis-based periodicity is the coupling of a chemical reaction flux with a diffusional process. The condition for the development of oscillation in this case is hysteresis, either in the reaction flux or in the diffusional flux. For instance, a periodic change in the concentration of a reaction product will be caused by a substance which participates both in a chemical reaction catalyzed by a "hysteretic" enzyme, and in a diffusion process (which may be controlled by a membrane). (Theoretically, coupling between auto-catalysis and enzyme reaction can also lead to oscillations; cf., *e.g.*, [55].)

Periodic changes based on chemico-diffusional flow coupling have been known for a long time in the heterocatalysis of gas reactions on metal surfaces (see, *e.g.*,[56]). However, it has only recently been considered likely that such periodic processes may also occur on the level of single catalytically active molecules in homogeneous solution. In the halophilic malate-dehydrogenase we encounter an example of such a hysteretic catalyst[43].

Periodic changes in diffusional flows can be caused by membranes which change their permeability along a hysteresis loop. The cell envelopes of Dead Sea halobacteria could change their permeability as a function of salt concentration in this way, if the structural change indicated in the proton binding hysteresis could cause permeability changes in the cell membrane. The experimental results of *Ginzburg et al.*[57] indicate that the Dead Sea halobacteria periodically change their salt content. Further studies may elucidate whether there is a correlation between membrane hysteresis and the hysteretic activity of the enzymes, causing the "salt clock" of these organisms.

The principle of hysteretic chemico-diffusional coupling may be (qualitatively) described with the aid of an enzyme which becomes active by substrate binding at a critical substrate concentration S_2. The substrate S is assumed to flow at a constant rate in the reaction space; *i.e.*, the diffusional flow, J_d, of S is constant.

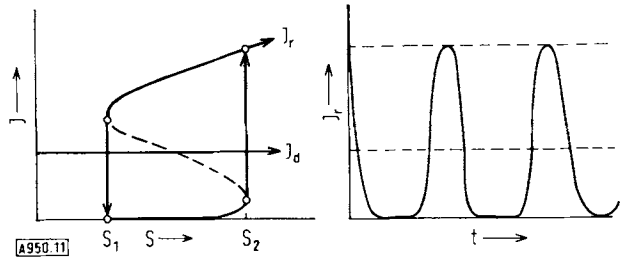

Fig. 11. Coupling scheme of transforming stationarity into periodicity by hysteretic chemico-diffusional coupling. S, substrate concentration; J_d, diffusional flux; J_r, reaction flux.

In the schematic representation of Fig. 11, it is seen that for $S > S_2$ the reaction flux $J_r(S)$ is larger than J_d. The breakdown of substrate is therefore faster than the influx of S. Thereby the substrate level in the reaction cell will sink until, at a critical concentration S_1, the enzyme becomes inactive. Now the reaction flux is smaller than the diffusional influx and substrate may accumulate until $S > S_2$. At S_2 the cycle can start again. The result is a periodic change of the reaction flux and therefore an oscillation in the product concentration[10].

In a similar way, a hysteretic permeability change in a membrane may transform a stationary flow into a periodic one. In this transducer function lies the fundamental significance of hysteretic macromolecules and membranes.

Whereas classical biology characterizes living organisms by stationary states (homeostasis), modern theories attempt to come closer to the actual dynamic behavior of biological organizations by a description which involves a quasi-stationary condition, with oscillations around a steady average[58]. Hysteresis represents a simple and energetically favorable mechanism for transducing stationarity into periodicity on a molecular level.

9. Closing Remarks

The discovery of conformational metastability in nucleic acids, proteins, and membranes has led to a new cybernetic approach to a dynamic interpretation of cellular behavior. It is worth noting that the dynamics of biological organization and function may be described by a general network theory recently developed by *Oster*, *Perelson*, and *Katchalsky*. In this approach, called network thermodynamics, "transducers" have been introduced as the coupling units between the network elements. It appears that macromolecules and membranes whose structure and function involve metastable states are particularly suited to act as elementary cybernetic units for "transducing" processes in general and for regulatory and memory reactions in particular. Metastable polyelectrolyte systems capable of storing "information" imprinted by ionic fluxes or electrical "activity" would be of significance for fast information processing with low energy expenditures.

In a dynamic picture of cellular organization and function there seems to be little room for perfect stability characterizing ideal equilibrium states. Even simple stationarity appears to be insufficient for a general description of central biological processes such as regulation and control of enzyme catalysis or membrane transport, information processing, or selforganization[60,61]. I believe that nonequilibrium approaches involving metastable states and molecular hysteresis may contribute to a better understanding of the complex dynamics of fundamental phenomena of life.

I would like to thank Arnold Revzin for critical comments regarding the manuscript and the Stiftung Volkswagenwerk for a research grant at the Weizmann Institute of Science in Israel.

The Cytochalasans: A New Class of Biologically Active Microbial Metabolites

By Michael Binder and Christoph Tamm[*]

A series of cytostatically active metabolites have been isolated from microorganisms in recent years. These compounds, which are chemically closely related, are of a new structural type. A highly substituted hydrogenated isoindolone unit is fused to an 11- to 14-membered macrocycle. The large ring may be carbocyclic or heterocyclic (lactone or carbonic diester). The absolute configurations of two cytochalasans (phomin and a cytochalasin D derivative) have been established by X-ray analysis. The biogenesis of phomin (cytochalasin B) is broadly known, and it is probable that all cytochalasans have a common biogenetic scheme. All the compounds of this class have a more or less pronounced specifically cytostatic action.

1. Introduction and Nomenclature

Under the title "The Cytochalasins as Research Tools in Cytology" *Carter*[1] recently published a review on the biological effects of a class of substances that has only been known since 1966, *i.e.* the cytochalasans. Ten members of this group have been isolated so far, and we felt it appropriate, as a complement to the above-mentioned article, to collect the chemical facts on the cytochalasans, elucidation of their structure, stereochemistry, and biogenesis in the form of this progress report. The biological properties of the cytochalasans are summarized in the last section. For detailed information, the reader is referred to the review cited.

All cytochalasans are metabolic products of microorganisms, and in some cases of molds. The isolation of these compounds resulted from the observation that culture filtrates of certain microorganisms have a cytostatic action on cell cultures *in vitro*[2].

The isolation of the first two substances of this class and the determination of their structure was achieved at about the same time, and independently of each other, in Basel[3] and by *Aldridge et al.*[4] in the research laboratories of ICI Ltd. in England.

The compounds isolated in Basel from culture filtrates of the microorganism *Phoma*, strain S 298, were named phomin *(2)* and dehydrophomin *(3)* from the name of the microorganism, while those obtained at ICI from cultures of *Helminthosporium dematioideum* were called cytochalasin A *(3)* and B *(2)*. This latter name refers to the biological activity of the two metabolites, and is derived from κύτος, meaning cell, and χάλασις, meaning relaxation. A direct comparison showed that phomin *(2)* is identical with cytochalasin B, and dehydrophomin *(3)* with cytochalasin A.

The British research group soon afterward reported the elucidation of the structures of two other cytochalasans, which had been isolated from cultures of *Metarrhizium anisopliae*[5]. These two compounds, which are chemically closely related to cytochalasins A *(3)* and B *(2)*, but belong to a different basic group of cytochalasans, were unfortunately also named cytochalasin C *(4)* and D *(5)* because of their biological action.

(10), $\Delta^{4,5}$

Precisely as in the case of phomin *(2)*, the structure of cytochalasin D *(5)* was also established on a second occasion, when *Minato et al.*[6] described a new antibiotic isolated from cultures of *Zygosporium masonii* in the research laboratories of Shionogi & Co. Ltd., Japan; these workers gave it the name zygosporin A *(5)*, after the microorganism. From data on zygosporin A *(5)* published before its structure was established, *Aldridge* and *Turner*[7] deduced that it was identical with cytochalasin D *(5)*; this was disputed

Table 1. List of natural cytochalasans.

Cpd.	Trivial name	Systematic name	Microorganism	Ref.
		24-Oxa-[14]cytochalasans		
(1)	Cytochalasin F	(7*R*,16*R*,20*R*)-7,20-Dihydroxy-16-methyl-10-phenyl-24-oxa-[14]cytochalasa-4(5),13',21'-triene-1,23-dione	*Helminthosporium dematioideum*	[10]
(2)	*Phomin* = Cytochalasin B	(7*S*,16*R*,20*R*)-7,20-Dihydroxy-16-methyl-10-phenyl-24-oxa-[14]cytochalasa-6(12),13',21'-triene-1,23-dione	*Helminthosporium dematioideum*, *Phoma* spec. S. 298	[3, 4, 12, 14]
(3)	*Dehydrophomin* = Cytochalasin A	(7*S*,16*R*)-7-Hydroxy-16-methyl-10-phenyl-24-oxa-[14]cytochalasa-6(12),13',21'-triene-1,20,23-trione	*Helminthosporium dematioideum*, *Phoma* spec. S. 298	[3, 4, 12, 14]
		[11]Cytochalasans		
(4)	Cytochalasin C	(7*S*,16*S*,18*R*,21*R*)-21-Acetoxy-7,18-dihydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-5(6),13',19'-triene-1,17-dione	*Metarrhizium anisopliae*	[5]
(5)	*Cytochalasin D* = Zygosporin A	(7*S*,16*S*,18*R*,21*R*)-21-Acetoxy-7,18-dihydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-6(12),13',19'-triene-1,17-dione	*Metarrhizium anisopliae*, *Zygosporium masonii*	[5, 6, 8]
(6)	Zygosporin D	(7*S*,16*S*,18*R*,21*R*)-7,18,21-Trihydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-6(12),13',19'-triene-1,17-dione	*Zygosporium masonii*	[9]
(7)	Zygosporin E	(7*S*,16*S*,18*R*)-21-Acetoxy-7-hydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-6(12),13',19'-triene-1,17-dione	*Zygosporium masonii*	[9]
(8)	Zygosporin F	(7*S*,16*S*,18*R*,21*R*)-7,21-Diacetoxy-18-hydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-6(12),13',19'-triene-1,17-dione	*Zygosporium masonii*	[9]
(9)	Zygosporin G	(16*S*,18*R*,21*R*)-21-Acetoxy-18-hydroxy-16,18-dimethyl-10-phenyl-[11]cytochalasa-6(7),13',19'-triene-1,17-dione	*Zygosporium masonii*	[9]
		21,23-Dioxa-[13]cytochalasan		
(10)	Cytochalasin E	7,18-Dihydroxy-16,18-dimethyl-10-phenyl-21,23-dioxa-[13]cytochalasa-4(5),13',19'-triene-1,17,22-trione	*Rosellinia necatrix*	[10]

at first by the Japanese workers, but was later confirmed by an independent elucidation of the structure[8].

A number of metabolites that were formed in small quantities, *i.e.* zygosporins D *(6)*, E *(7)*, F *(8)*, and G *(9)*, all of which are variants of cytochalasin D *(5)*, were also isolated from the fermentations of *Zygosporium masonii*[9].

In 1972, *Aldridge et al.*[10] published the structures of the last two cytochalasans known at that time. Cytochalasin F *(1)*, which is obtained from cultures of *Helminthosporium dematioideum*, is a double-bond isomer of phomin *(2)*. Cytochalasin E *(10)*, a metabolic product of *Rosellinia necatrix*, is the first member of the third group of cytochalasans.

The numbering of the basic skeletons of the cytochalasans differed as much as their names. To resolve the resulting total confusion, we recently suggested, together with the two other groups, a uniform systematic nomenclature for all cytochalasans[11], by which the three types and their derivatives can be easily designated as derivatives of a single basic type. The rules underlying the new nomenclature will now be briefly explained.

(I) The hydrogenated isoindole, including the macrocycle and carbon substituents on the isoindole except for the phenyl ring, is given the name cytochalasan. This name, which is derived from cytochalasin, seemed preferable to the corresponding name phoman derived from phomin (which should have received priority for historical reasons), since the name cytochalasin B is used in the majority of biologically oriented publications. (II) The size of the macrocycle is indicated by the number of ring members given in square brackets immediately in front of the name "cytochalasan". (III) The stereochemistry of the ring fusion sites is fixed. It is the same for all cytochalasans, and so need not be specially indicated. This is also largely true of the carbon substituents on the isoindole portion. (IV) Inserted hetero atoms, with the exception of the isoindole nitrogen, are indicated by the corresponding prefixes. Other features (further substituents, double bonds, absolute configuration) are indicated in accordance with the usual rules. The new system has the advantage that numbering differs only in those parts of the molecules that are chemically different.

The ten cytochalasans isolated so far are given in Table 1 with their trivial names, the systematic names, and the microorganisms from whose cultures they were isolated.

Because of the length of the systematic names, which are largely important only to specialists, the trivial names given in Table 1 are used whenever reference is made in the text to a specific cytochalasan. Where a cytochalasan has been given more than one trivial name, we shall use the chronologically earlier name, which is given in italics in the table, though no significance should be attached to this preference.

To facilitate comparisons between the various cytochalasans, only the new uniform numbering will be used. This numbering in accordance with[11] does not agree with that used in the existing publications[3-10,12-14,16-21], and so cannot be applied to these articles.

2. Elucidation of the Structures

2.1. Phomin *(2)*, Dehydrophomin *(3)*, and Cytochalasin F *(1)*

The reactions carried out by the two groups of workers in the determination of the structure of phomin *(2)* are

summarized in Figure 1. In both cases, the molecular weight and the molecular formula of phomin *(2)* were determined by mass spectrometry. The spectral data showed the presence of a five-membered lactam ring, an ester group, two hydroxyl groups, two *trans*-disubstituted olefinic double bonds, and an exocyclic methylene group. The base peak in the mass spectrum at *m/e* 91 is characteristic of a benzyl group (tropylium ion).

In the first case[3, 12], phomin was subjected to ozonolysis with reductive work-up ($NaBH_4$); the two γ-lactams *(11)* and *(12)* and the aliphatic triol *(14)* were isolated. The triol *(14)* reacted with periodate, and therefore contained a glycol grouping. From the mass spectrum and the NMR spectrum, it was deduced that this fragment was 6-methyloctane-1,2,8-triol *(14)*, and this was confirmed by degradation to (3*R*)-3-methylpimelic acid *(17)*. This substituted pimelic acid could also be synthesized from (+)-pulegone *(18)*, and was identical with the degradation product. Since the absolute configuration of the chiral center in (+)-pulegone *(18)* is known, this fixed the stereochemistry at C(16) in phomin *(2)*.

The structures of the two γ-lactams *(11)* and *(12)* were determined mainly by double resonance experiments. The lactam *(11)* reacted with periodate, and it followed that the hydroxyl group in the six-membered ring was situated α to the exocyclic methylene group.

Atoms 22 and 23 of phomin *(2)* are not present in *(12)* or in *(14)*. The postulated cleavage product, probably glycolic acid *(15)*, could not be detected.

In dehydrophomin *(3)*, one of the two hydroxyl groups of phomin *(2)* is replaced by a keto group. It was clear from the NMR spectra that the hydroxyl group in question was that situated on C(20). The ene-dione, *i.e.* the partial sequence C(20)—C(23), gives a characteristic absorption in the UV spectrum. Finally, dehydrophomin *(3)* could be prepared from phomin *(2)* by treatment with CrO_3/pyridine. Under the action of light, the compound isomerizes to 21-*cis*-dehydrophomin, which exists in equilibrium with the *trans* form.

The manner in which the partial structures fit together to give the formula *(2)* for phomin was again established on the basis of NMR data and irradiation experiments.

Very much more material was available in the second case[14], and it was therefore possible to use drastic degradation methods.

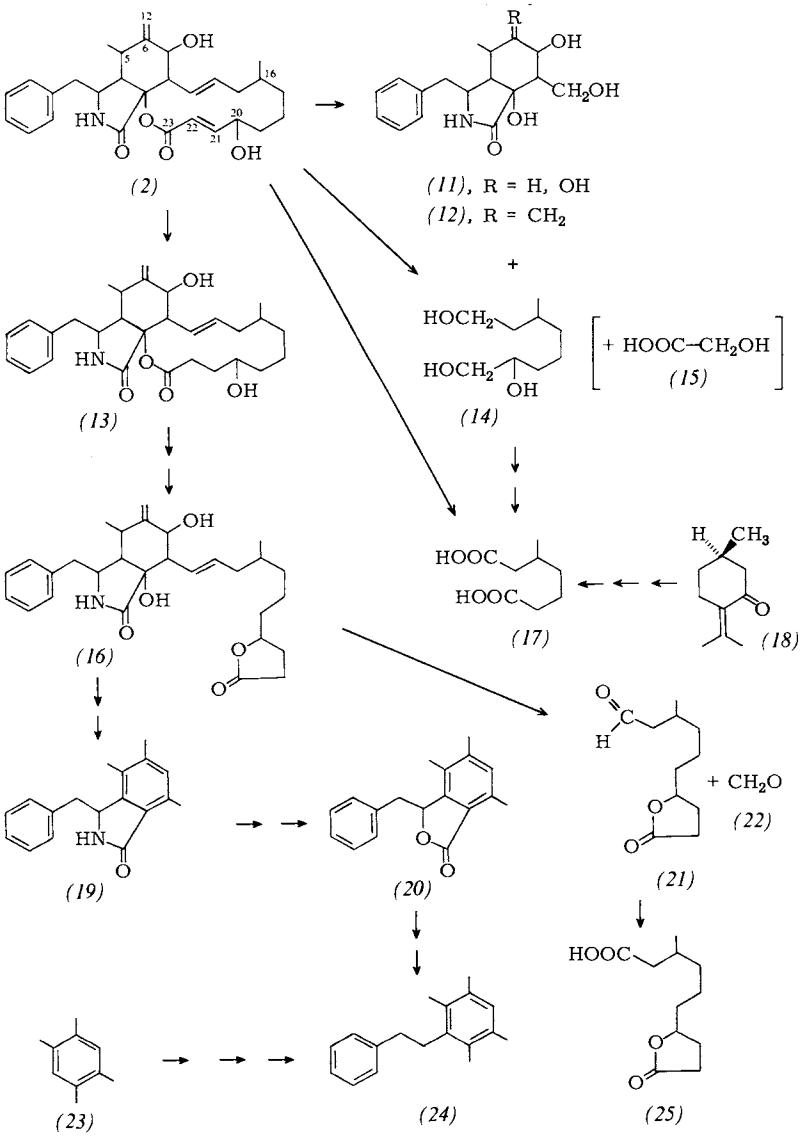

Fig. 1. Reaction sequences for the determination of the structure of phomin *(2)*.

Vigorous oxidation of phomin *(2)* with nitric acid again gave 3-methylpimelic acid together with other products. Reaction of phomin *(2)* with $NaBH_4$ led to the 21,22-dihydro derivative *(13)*, from which the hydroxy acid formed by cleavage of the macrocycle, or its lactone with the 20-hydroxyl group *(16)*, was obtained by hydrolysis. It was therefore concluded that one of the two *trans*-disubstituted double bonds must have been part of the large ring. The position of the other double bond was found by ozonolysis of the lactone *(16)*. On treatment of the ozonolysis mixture with H_2/Pd, it was possible to isolate two products, the aldehyde-lactone *(21)* and formaldehyde *(22)* (from C(12)), but no fragment corresponding to the lactams *(11)* or *(12)*. The structure of the aldehyde-lactone *(21)*, from which the carboxylic acid *(25)* was obtainable by oxidation was conclusively shown by mass and NMR spectra.

The structure of the lactam portion of phomin was established by alkali fusion of the lactone *(16)*. The resulting phthalimide derivative *(19)* was converted *via* the phthalide *(20)* in several steps into the penta-substituted benzene derivative *(24)*, whose structure was demonstrated by synthesis from 1,2,4,5-tetramethylbenzene *(23)*.

The correct arrangement of the partial structure was again established on the basis of NMR data.

Cytochalasin F *(1)*[10], according to the NMR spectrum, which contains the signal of a vinyl methyl group instead of the signal of the exocyclic methylene group, is a double-bond isomer of phomin *(2)*. From the simplification of the C(3) proton signal, it was concluded that the double bond is situated in the 4(5) position. Cytochalasin F *(1)* can be converted *via* the $\Delta^{5(6)}$ isomer into phomin *(2)* by treatment with acid. These isomerizations are irreversible.

2.2. Cytochalasin D *(5)*

As was mentioned earlier, two independent routes were followed in the determination of the structure of cytochalasin D *(5)*; the principal steps in these determinations are shown in Figure 2.

In one case[5], alkaline hydrolysis of cytochalasin D *(5)* led to the acid *(30)*, whose structure was established by comparison with the NMR spectra of phomin *(2)*. Apart from the missing hydroxyl group on C(9), this acid corresponds to the partial sequence of atoms 1—16 in phomin *(2)*. The evidence for the remainder of the molecule is indirect, since no other hydrolysis fragment was obtained. The missing sequence C(18)—C(21) was determined by comparison of the NMR spectra of the acid *(30)* and of the intact molecule of cytochalasin D *(5)*, as well as by double resonance experiments. On the basis of the NMR data and a further degradation experiment, it was possible to fit this partial structure into the structure *(5)*. The dodecahydro derivative of cytochalasin D *(5)* was converted with $NaBH_4$ into the 17-hydroxy product *(26)*, from which the keto-aldehyde *(28)* was obtained with periodate. The formation of this methyl ketone rules out the reverse arrangement of the sequence C(18)—C(21), since such a molecule would give a dialdehyde.

The determination of the structure of cytochalasin D *(5)*[8] was more difficult for the Japanese workers. They did not have the experience from the determination of the structure of phomin *(2)*, nor was a comparison with the spectra of the 24-oxa-[14]cytochalasans possible. As in the previous case, the molecular weight and the molecular formula were determined by mass spectrometry. Acetylations and deacetylations provided information on the position and character of the hydroxyl groups in cytochalasin D *(5)*. Reduction with $NaBH_4$ led to the 17-hydroxy derivative *(27)*, from which the keto-aldehyde *(29)*, the unsaturated analog of *(28)*, was obtained with periodate. The structure of the sequence C(18)—C(21) was deduced from the NMR spectra of *(29)*. Oxidation of cytochalasin D *(5)* led to the 7-oxo derivative, an α,β-unsaturated ketone, which showed that the 7-hydroxyl group is α to the exocyclic methylene group C(12) in *(5)*.

The alkaline hydrolysis of cytochalasin D *(5)*, was carried out under milder conditions here than in[14], and led to the thermodynamically controlled mixture of two acids *(30)* that were epimeric on C(9). One of the two acids (the stereochemistry on C(9) was not discussed) was converted into the methyl ester and acetylated on the C(7) hydroxyl group. Ozonolysis of the resulting compound *(33)* gave two aldehydes. According to the NMR data for their semicarbazones, one of these aldehydes is methyl 3-formyl-2-methylpropionate *(32)*, while the other has the structure *(31)*. It was possible to hydrogenate the exocyclic methylene group selectively in the ester *(33)*. The resulting dihydro derivative *(35)* was converted into the diol *(34)* with osmium tetroxide, and cleavage with periodate then gave the aldehydes *(32)* and *(36)*. The structure of the aldehyde *(32)* was already known. Reduction of the aldehyde *(36)* with $NaBH_4$ gave two products, the diol *(37)* and the allyl alcohol *(38)* resulting from the elimination of water. When heated at 300 °C over Pd/C, both *(37)* and *(38)* gave the two aromatic derivatives *(39)* and *(40)*, which were identical with authentic preparations (from *Aldridge et al.*[14]).

2.3. Cytochalasin C *(4)* and Zygosporins D *(6)*, E *(7)*, F *(8)*, and G *(9)*

Cytochalasin C *(4)*[14] is a double-bond isomer of cytochalasin D *(5)*. In the NMR spectrum, the signals of two vinyl methyl groups replace the signal of the exocyclic methylene group and the doublet of the C(11) protons; it can therefore be concluded that the double bond is situated in the 5(6) position. This assumption is supported by the identity of the hydrogenated derivatives of cytochalasins C *(4)* and D *(5)*. Isomerization of cytochalasin C *(4)* to cytochalasin D *(5)*, corresponding to that carried out for cytochalasin F *(1)*, could not be achieved.

Zygosporin D *(6)* is 21-deacetylcytochalasin D, as was readily shown by deacetylation of cytochalasin D *(5)*.

Zygosporin E *(7)* is 18-deoxycytochalasin D. This was shown by treatment of the 7-*O*-acetyl derivative of cytochalasin D *(5)* with $SOCl_2$ in pyridine. The 18-chloro derivative was dehalogenated with zinc in glacial acetic acid. The product was identical with 7-acetylzygosporin E.

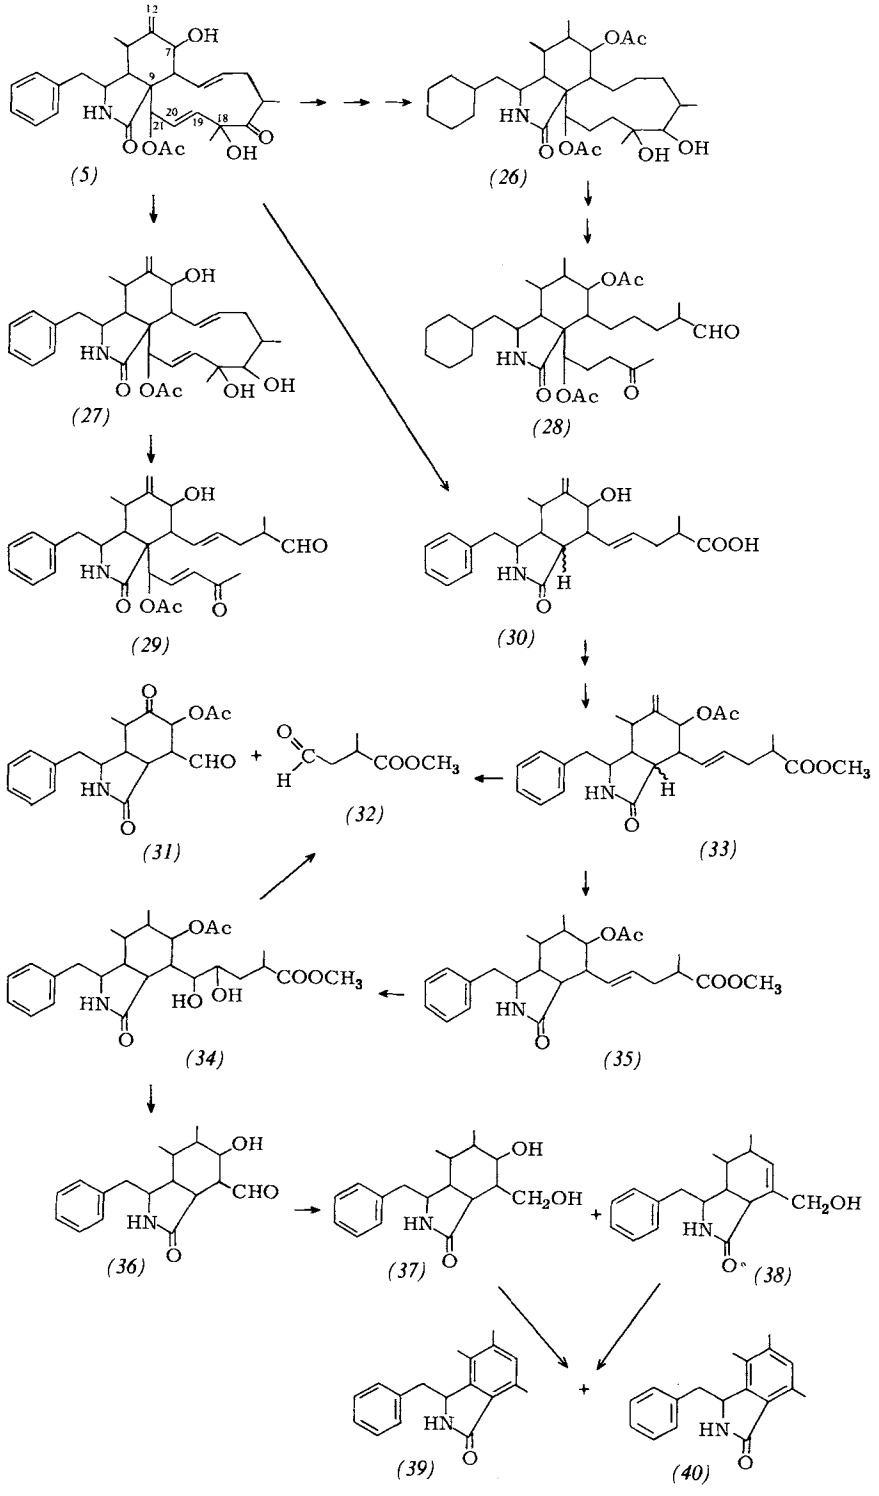

Fig. 2. Reaction sequences for the determination of the structure of cytochalasin D *(5)*.

Zygosporin F *(8)* is 7-*O*-acetylcytochalasin D.

The NMR spectrum of zygosporin G *(9)* contains the signal of a vinyl methyl group, two methyl doublets (C(11) and C(16)-methyl), and a methyl singlet (C(18)). The signal of the exocyclic methylene group has disappeared, as has that of the hydroxyl group on C(7). It follows that zygosporin G *(9)* is 7-deoxy-$\Delta^{6,7}$-cytochalasin D. Proof of this was provided by oxidation of cytochalasin D *(5)* to the 7-oxo derivative and reduction of the latter with ethanedithiol and Raney nickel to zygosporin G *(9)* and 6,7-dihydrozygosporin G.

2.4. Cytochalasin E *(10)*

A comparison of the NMR spectra of cytochalasin E *(10)* and cytochalasin F *(1)* shows that the partial structures are identical up to C(16). The $C_6H_6O_5$ unit that is missing according to the molecular formula found by mass spectrometry is shown by NMR data to contain a tertiary methyl group, a tertiary hydroxyl group, and a *cis*-disubstituted double bond[10]. The IR spectrum shows the presence of a carbonyl group and of a vinyl carbonate residue. Reduction of the 19(20) double bond gives the

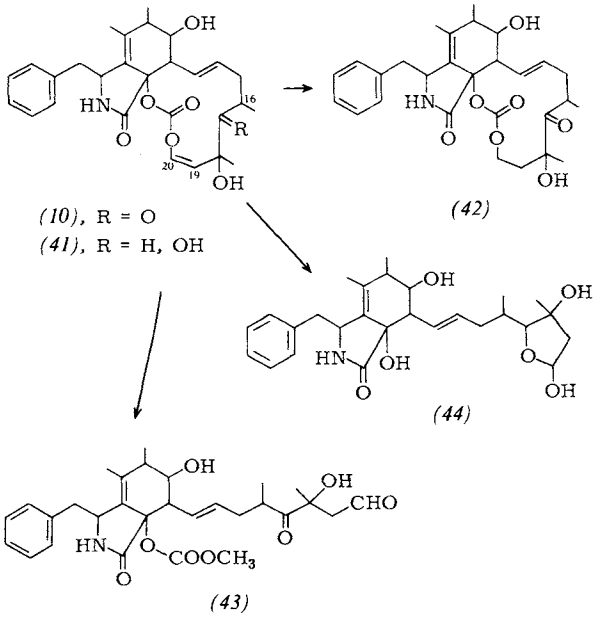

Fig. 3. Reactions of cytochalasin E *(10)*.

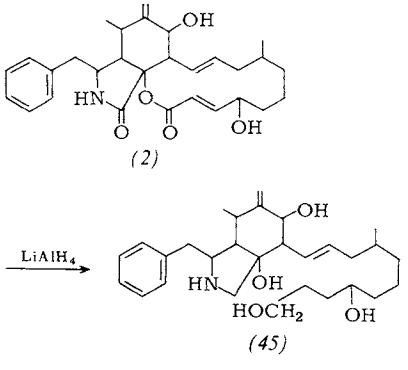
saturated carbonic diester *(42)*. Alkaline hydrolysis of cytochalasin E *(10)* leads to the aldehyde *(43)*; treatment of *(10)* with $LiAlH_4$ yields the alcohol *(41)* and the lactol *(44)*. The structure *(10)* for cytochalasin E agrees with these data. The reactions are summarized in Figure 3.

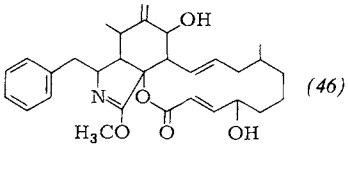
3. Other Reactions of Cytochalasans, Particularly of Phomin *(2)*

In this section we shall present a brief survey of some other reactions of the cytochalasans that were not mentioned in connection with the elucidation of their structures.

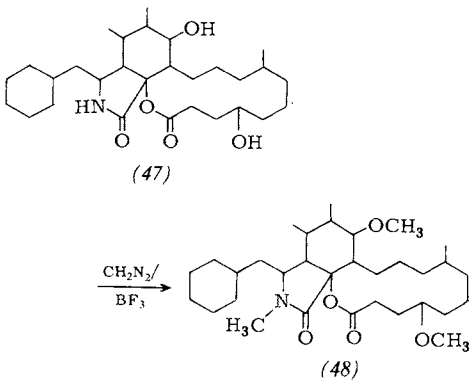
On treatment with $LiAlH_4$, phomin *(2)* first gives the known lactone *(16)*, while with a large excess of reagent and a longer reaction time, the amine *(45)* is obtained[12].



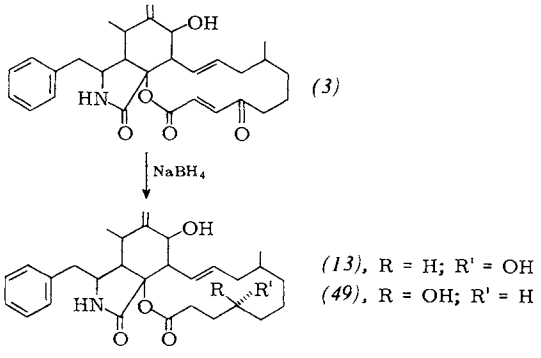
The attempted methylation of the hydroxyl groups of phomin *(2)* with Ag_2O/CH_3I in dimethylformamide yielded the phominimino methyl ether *(46)*[15].



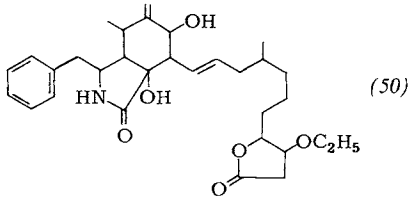
The dodecahydro derivative *(47)* of phomin *(2)* was converted with diazomethane/BF_3 into *N*-methyldi-*O*-methyldodecahydrophomin *(48)*[15].



The C(20) epimer *(49)* of dihydrophomin *(13)* was obtained together with *(13)* on treatment of dehydrophomin *(3)* with $NaBH_4$[15].



The hydrolysis of phomin *(2)* with aqueous-ethanolic alkali is accompanied by addition to the 21(22) double bond to give the product *(50)*[14].



Depending on the catalyst, phomin *(2)* can be hydrogenated to hexahydrophomin (only the olefinic double bonds are reduced) or to dodecahydrophomin *(47)*. Analogous reactions are also found for the other cytochalasans.

4. Stereochemistry of the Cytochalasans

Phomin *(2)* and cytochalasin E *(10)* each contain eight chiral carbon atoms, and cytochalasin D *(5)* contains nine; six of these are situated in the hydrogenated isoindole unit, and two or three in the macrocycle. Thus if one considers only the six chirality centers in the isoindole unit, there are 32 possible pairs of diastereoisomers, with four conformations for each of these pairs, since the six-membered ring may have the chair, boat, inverse chair, and inverse boat conformations. This gives a total of 128

possible steric arrangements. If the two or three centers of asymmetry in the macrocycle are also taken into account, this figure is multiplied by a factor of four or of eight.

The NMR data for phomin *(2)* allowed a first approximation to the solution of the problem[3, 12].

By appropriate quantitative application (with the necessary care) of the relation found by *Karplus* between the dihedral angle and the NMR coupling constant for vicinal protons[16] to the γ-lactam *(12)* obtained in the elucidation of the structure of phomin *(2)*, it was possible to reduce the 32 pairs of diastereoisomers to four, and three of the four conceivable conformations were also ruled out. The remaining four possible configurations, which are shown in Figure 4, could not be distinguished on the basis of the NMR spectra alone.

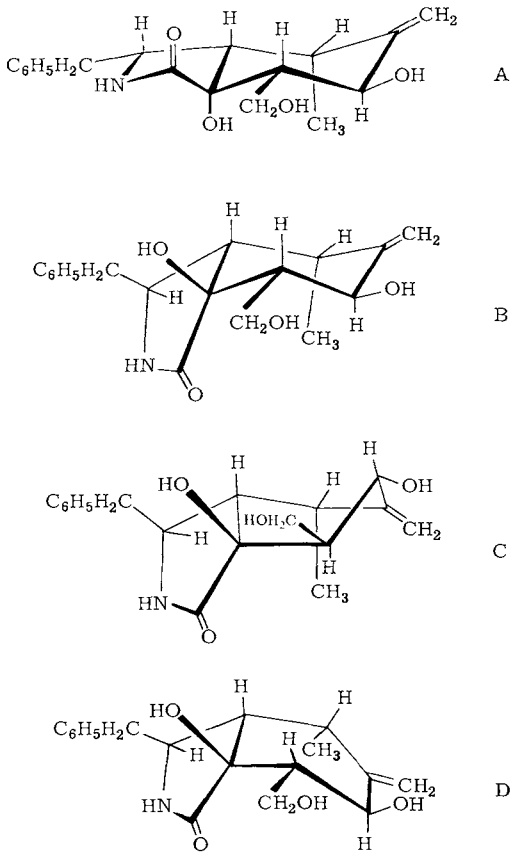


Fig. 4. Possible configurations of the γ-lactam *(12)*.

The absolute configuration at C(16) in phomin *(2)* was known by the correlation of the degradation product 3-methylpimelic acid *(17)* with (+)-pulegone *(18)*.

Similar considerations for cytochalasin C *(4)* gave two configurations for the partial structure in question; these corresponded to possibilities B and D in the case of phomin *(2)*[5].

The only possibility for the solution of the stereochemistry problem appeared to be offered by X-ray analysis, and it was therefore necessary to prepare suitable crystalline derivatives of the cytochalasans containing heavy atoms.

The first derivative of this type was the 18-*p*-bromobenzoic ester of 7-acetyl-21-deacetylcytochalasin D *(51)*[17] (cf. Figure 6) but the X-ray analysis of this compound gave only the relative configuration of cytochalasin D *(5)*; as

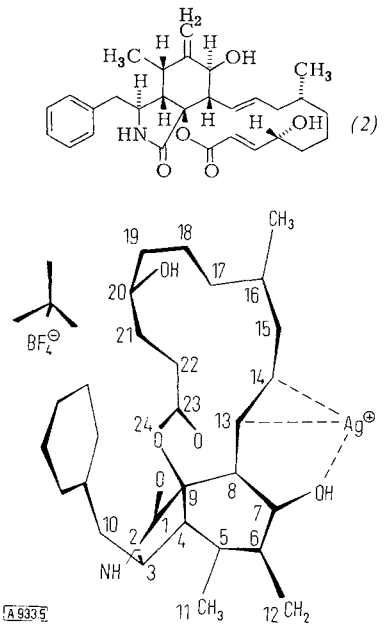

Fig. 5. Structure of the $AgBF_4$ complex of phomin *(2)* and absolute configuration of phomin *(2)*.

was later found, this was the mirror image of the actual configuration.

The second derivative was the silver tetrafluoroborate complex of phomin *(2)*[18]. From the known stereochemistry on C(16), it was possible in this case to give the absolute configuration of phomin *(2)* directly. The steric structure of the complex and the stereochemistry of phomin *(2)* are shown in Figure 5.

The assignment of the absolute configuration based on correlation with (+)-pulegone was also confirmed independently by the calculations. The stereochemistry found in this way corresponds to possibility D in Figure 4; this shows the correctness of the spectroscopic considerations.

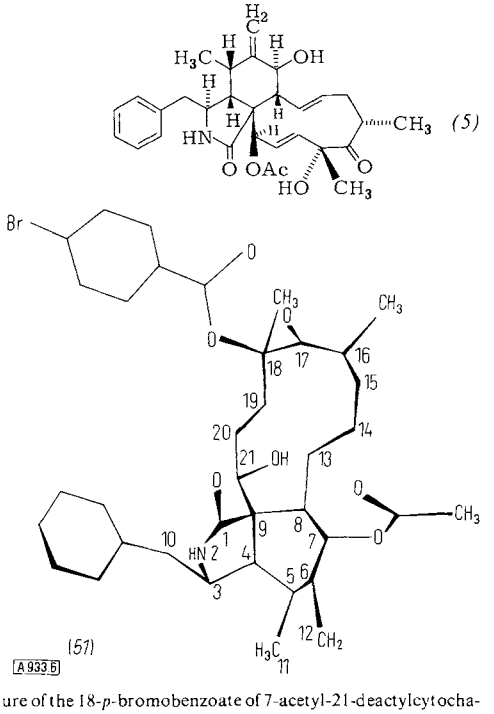

Fig. 6. Structure of the 18-*p*-bromobenzoate of 7-acetyl-21-deactylcytochalasin D *(51)* and absolute configuration of cytochalasin D *(5)*.

Detailed calculations[191] finally also led to the correct absolute configuration for the cytochalasin D derivative *(51)*. The steric structure of the derivative *(51)* and the stereochemistry of cytochalasin D *(5)* are shown in Figure 6.

The fusion of the five-membered and the six-membered rings of the isoindole part of the molecule is *cis* in both cases. The six-membered ring is in a flexible boat form. This allows two conformations for the bicyclic system, which differ only slightly and probably have very similar energies; one of these conformations is found in the crystal of the $AgBF_4$ adduct of phomin *(2)*, and the other in the derivative *(51)* of cytochalasin D *(5)*. The NMR spectra of some phomin derivatives suggest that these two conformers can readily change into one another in solution.

The stereochemistry of cytochalasin F *(1)* is probably the same as that of phomin *(2)*; nothing can be said about the configuration of the additional center of asymmetry C(6).

The configuration of the isoindole part of the molecule is probably also the same in cytochalasin E *(10)* as in cytochalasin F *(1)* and phomin *(2)*. The stereochemistry on C atoms 16 and 18 is not yet known; it could correspond to that in cytochalasin D *(5)*.

As is shown by the structural determinations, the stereochemistry of cytochalasin C *(4)*, and of zygosporins D *(6)*, E *(7)*, F *(8)*, and G *(9)* is identical with that of cytochalasin D *(5)*. The only exception is C(18) in zygosporin E *(7)*, whose configuration has not been determined. The configuration of this center of chirality cannot be deduced from the reaction sequence in which cytochalasin D *(5)* was converted into zygosporin E *(7)*.

5. Biogenesis of the Cytochalasans

Biosynthetic studies as carried out nowadays are typical "*in-vitro*" experiments. The general technique of isolation of the microorganism, cultivation on synthetic media, and incubation with special biogenetic precursors (usually radioactively labeled or labeled with isotopes) hardly corresponds to the conditions enjoyed by the organism in nature. Further problems are presented by the instant of incubation with the precursor, the form in which it is supplied, and the ability of the cell to absorb it. The optimization of such problems is difficult, and it is surprising that very good results are obtained even under conditions that could be quite unrealistic. It should be noted, however, that the result of a biosynthetic investigation must always be carefully formulated, *e. g.* as follows: Under

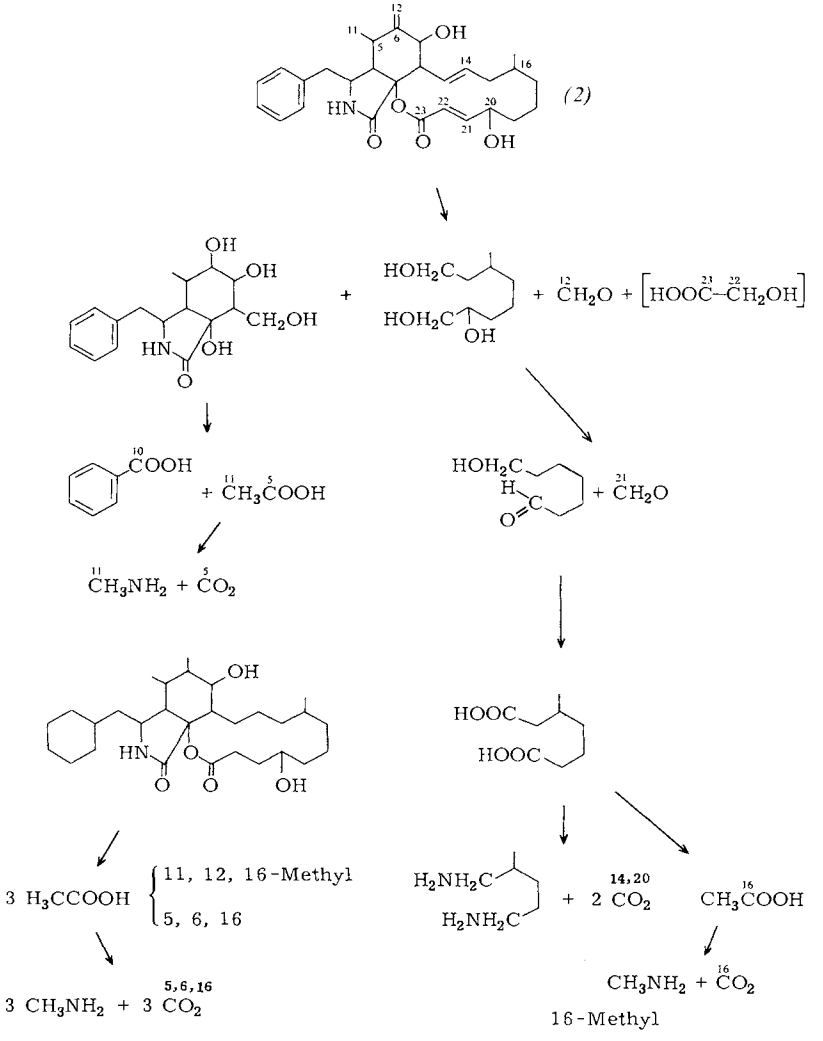

Fig. 7. Degradation reactions of phomin *(2)* for the localization of the radioactive C atoms.

the particular conditions used by us, the organism X can synthesize the molecule Y from the precursor Z, though this does not necessarily mean that it does so in nature.

Experimental data on the biogenesis of cytochalasans are available at present only for phomin *(2)*[20]. Investigations with cytochalasin D *(5)*[21] are in progress.

The procedure was as follows. The supposed, radioactively labeled precursors[*] were each added to nutrient solutions for the microorganism *Phoma* S 298, and the solutions were sterilized, inoculated with a suspension of the fungus spores, and incubated for 12 days. The cultures were then "harvested", and the phomin *(2)* present in the culture broth was isolated. The precursors used were selected on the basis of a working hypothesis on the possible biogenetic synthesis of phomin *(2)*, which was ultimately confirmed. The precursors, their radioactivity and the percentage incorporation into the phomin preparations are shown in Table 2.

Table 2. Data on the precursors and percentages (absolute) incorporated into the phomin preparations.

Precursor	Activity [mCi]	Incorporation in phomin (absolute) [%]
[1-^{14}C]-DL-phenylalanine	0.1	4.9
[2-^{14}C]-DL-phenylalanine	0.1	6.7
[U^{14}C]-L-phenylalanine	0.1	10.4
[4'-T]-L-phenylalanine	1.0	10.4
[1-^{14}C] Na propionate	0.1	0.29
[2-^{14}C] Na propionate	0.1	0.4
[1-^{14}C] Na malonate	0.1	0.33
[2-^{14}C] Na malonate	0.1	1.04
[1-^{14}C] Na acetate	1.0	0.123
[methyl-^{14}C]-L-methionine	0.1	1.96
[2-^{14}C]-mevalonate	0.25	0.007

To localize the radioactive atoms incorporated into the molecule, phomin *(2)* was subjected to specific chemical degradation; the reaction schemes are indicated in Figure 7.

The degradation first involved reactions that had been carried out in the determination of the structure of phomin *(2)*[3, 12], and was then confined to methods, such as cleavage with periodate, Kuhn-Roth oxidation, and Schmidt degradation of acids, that proceed specifically in high yields. The small quantity of radioactive material and the small quantities incorporated were limiting factors. The atoms in phomin *(2)* that were detected by the degradation are indicated in Figure 8.

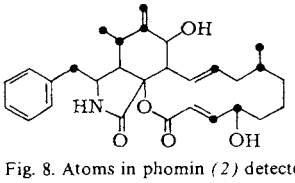

Fig. 8. Atoms in phomin *(2)* detected by the degradation.

The results obtained in this way will not be described individually, but are summarized in Figure 9.

Phomin *(2)* is thus synthesized biogenetically from one molecule of phenylalanine (including the carboxyl group),

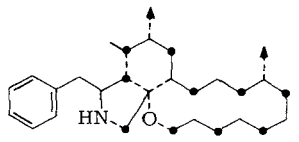

Fig. 9. Basic structural units for the biogenesis of phomin *(2)* (for explanation see text).

nine acetate units or one acetate unit and eight malonate units, and two C_1 residues from methionine. A nonaketide[*] is probably first formed from the acetate or malonate units, and this, attached by an amide linkage to phenylalanine, could then be fitted together to form a carbocyclic precursor of phomin *(2)*. The lactone ring of phomin *(2)* would be formed only later from the large carbocyclic ring by insertion of an oxygen atom after the fashion of a Bayer-Villiger oxidation.

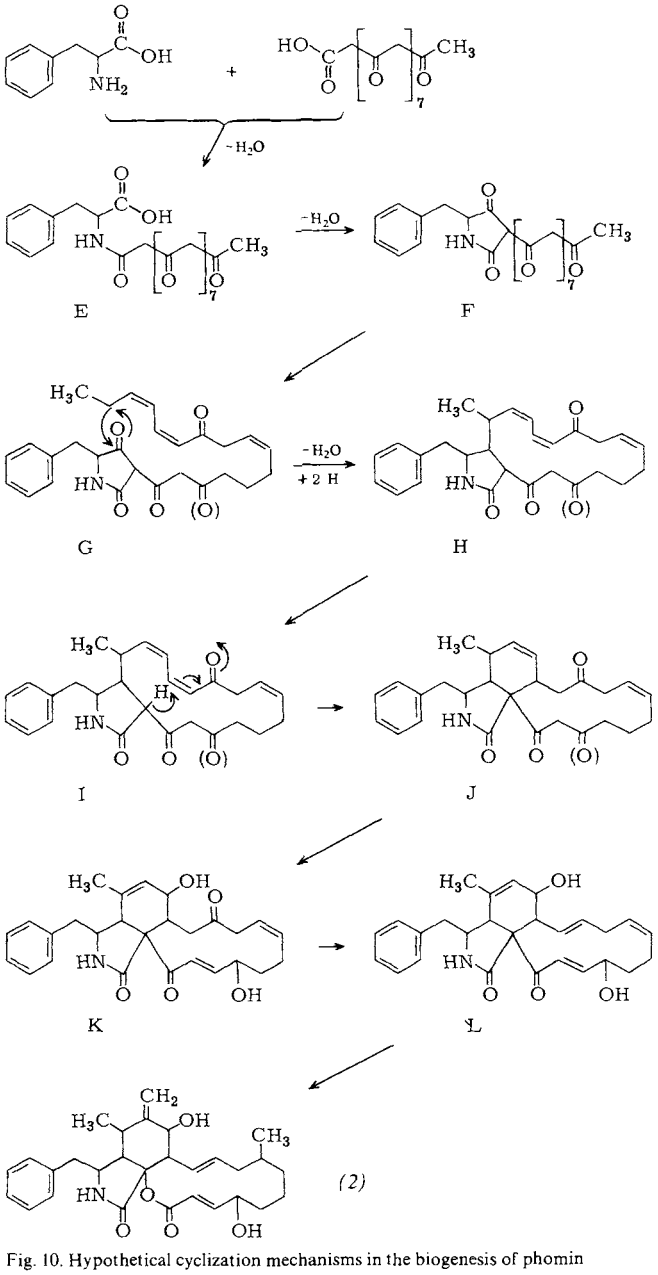

Fig. 10. Hypothetical cyclization mechanisms in the biogenesis of phomin *(2)*.

[*] Since only small quantities of the precursor were incorporated in some cases, it was not possible to use [^{13}C]-labeled compounds.

[*] The term "ketide" is applied here to compounds having β-keto groups.

It is known that instead of the hypothetical polyketide, a saturated or unsaturated fatty acid would also be a possible direct precursor of a secondary metabolite derived from acetate[22]. Experiments with Na [1-^{14}C]-linolenate and Na [16-^{14}C]-palmitate (as an equivalent of an octaketide) gave negative results in this respect[23]. The degradation showed that the low activity incorporated was distributed homogeneously over the molecule. It is thus probable that the acetogenin part of phomin *(2)* is derived from a higher oxidation state, *i.e.* the polyketide or a biogenetic equivalent, rather than from the largely reduced form, *i.e.* the fatty acid. We can only guess at present about intermediates and cyclization mechanisms in the biogenesis of phomin *(2)*.

A scheme of this nature is shown in Figure 10. The individual steps, some of which are interchangeable in their order, all correspond to known reactions.

As was mentioned above, the amide linkage of the nonaketide to phenylalanine may be regarded as the initial step. The subsequent condensation of E leads to the five-membered ring of the lactam F, one of whose carbonyl groups reacts with the penultimate C atom of the ketide after reduction to G with formation of the 4,5 bond. Partial reductions and water eliminations yield the intermediate H, in which, after allylic oxidation on C(14) to form I, the bond C(8)—C(9) is formed by condensation (J). The rearrangement of the double bond from the 6(7) position into the 5(6) position and a further allylic oxidation on C(7) and (after reduction and elimination of water) on C(20) lead to the intermediate K, from which phomin *(2)* is formed *via* L by further reduction with elimination of water, two methylations on C(6) and C(16), *e.g.* with *S*-adenosylmethionine, and an oxygen insertion after the manner of a Bayer-Villiger oxidation. It need hardly be mentioned that all these steps are hypothetical.

The experiments with cytochalasin D *(5)*[21] have so far shown that the same precursors have been incorporated to a similar degree as in phomin *(2)*.

The great structural similarity of the three basic types of cytochalasan, *i.e.* the 24-oxa-[14]cytochalasans, [11]cytochalasans, and 21,23-dioxa-[13]cytochalasans enables us to postulate a common biogenetic scheme for all cytochalasans, which is shown in Figure 11.

The fundamental units of the biogenesis of the cytochalasans are the primary metabolites phenylalanine and a nonaketide or octaketide or their biogenetic equivalents. Phenylalanine is formed from shikimic acid, and is thus derived ultimately from sugars; the nonaketide or octaketide is formed from acetate units by a process similar to the synthesis of fatty acids, but without the reduction steps.

The linkage of phenylalanine to the nonaketide leads by path I to the 24-oxa-[14]cytochalasans, while linkage to the octaketide leads by path II to the [11]cytochalasans and to the 21,23-dioxa-[13]cytochalasans. The sequence of the next few steps has already been discussed. At some point (arbitrarily taken as different here from that in Figure 10), the oxidative insertion of oxygen atoms could occur in path I and path IIb, with formation of the lactone group on the one hand and the carbonic diester group on the other.

After the further steps mentioned, this would lead us to the structures that are finally isolated, *i.e.* the end products of the secondary-metabolic reaction sequences.

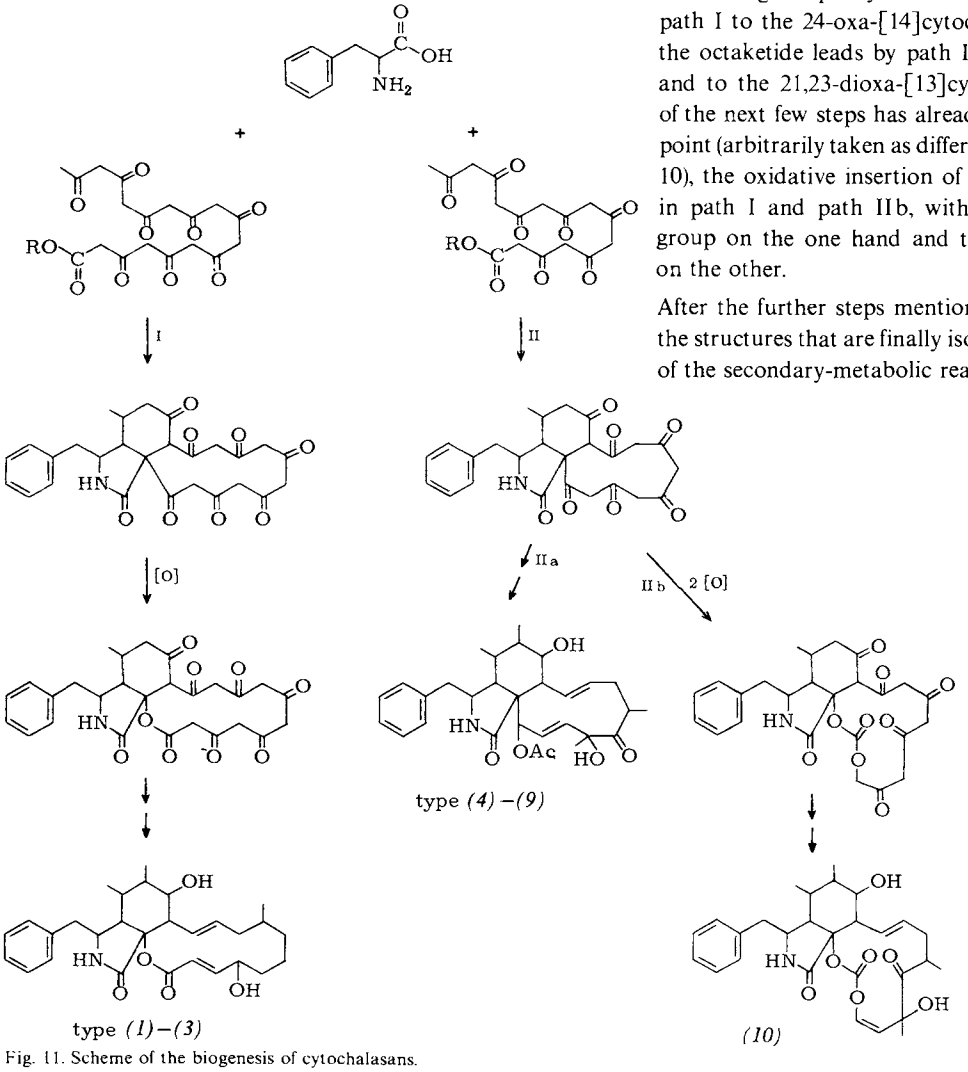

Fig. 11. Scheme of the biogenesis of cytochalasans.

The proposed scheme could be confirmed by elucidation of the biogenesis of cytochalasin D *(5)* and cytochalasin E *(10)*.

On the basis of the biogenetic scheme, we would venture to postulate the existence of further basic types of cytochalasans, possibly from block mutants of the microorganisms mentioned. One possibility would be a [13]cytochalasan, *i.e.* phomin *(2)* without the inserted oxygen[*], or a 28-oxa-[12]cytochalasan, *i.e.* cytochalasin D *(5)* with only one inserted oxygen.

Another question that would have to be answered is whether the carbocyclic cytochalasans are direct precursors of the heterocyclic cytochalasans.

6. Biological Effects of the Cytochalasans

All cytochalasans inhibit cytoplasmic cleavage in mammalian cell cultures, but differ in the intensity of their action.

In the presence of phomin (cytochalasin B) *(2)* (1 μg/ml), normal mitosis occurs in mammalian cells, but cytokinesis, *i.e.* the cleavage of the cell plasma, is blocked[12, 24].

Prolonged contact with phomin *(2)* leads to the formation of large multinucleate cells. It is interesting to note here that instead of doubling the number of nuclei per cell, each mitosis gives only one new nucleus.

High concentrations of phomin *(2)*, around 10 to 20 times the quantity required for the inhibition of cytokinesis, leads to ejection of the cell nucleus. Provided this process is not yet complete, it can be reversed in exactly the same way as cytostasis by removal of the cytochalasan; the processes are reversible.

Another general effect of the cytochalasans is their action on cell movement. Phomin *(2)* inhibits the movement of L cells. The cell margins become quiescent, and the cell ultimately assumes the shape of a thin disk. In the case of cytochalasin E *(10)*, the cells assume a broad scalloped margin.

The range of further biological activities of the cytochalasans is considerable. Phomin *(2)* blocks the development of tubular glands in the chick oviduct[25] and influences the development of normal branching in the salivary gland of the mouse[26].

Other processes affected included phagocytosis[27, 28] platelet aggregation[29, 30], breakdown of blood clots[29–31], production of cytoplasmic streaming[32], tail resorption in tunicate larvae[33], contraction of the myocardium[32], thyroid secretion[34], and the release of growth hormones[35].

Because of the strong anti-edemic and abscess-inhibiting properties of cytochalasin D *(5)* in rats, the Japanese workers have patented the production of the compound (from the microorganism mentioned) and its use in therapy[36]. Application in human medicine does not appear to be ruled out.

Finally, one might ask how the chemistry of the cytochalasans will develop in the future.

Unsolved problems include the biogenesis of the [11]cytochalasans and the 21,23-dioxa-[13]cytochalasans, as well as the isolation of larger intermediate products in the biogenesis of phomin *(2)*. Other points of interest (admittedly purely academic) would be attempted total syntheses and above all the discovery of new cytochalasans, possibly with the as yet unknown basic skeletons postulated above.

We thank the Schweizerischer Nationalfonds für Förderung der wissenschaftlichen Forschung (Project No. 2.460.71) and Sandoz AG, Basel, for support of this work.

Mechanistic Analysis of Solution Reactions by Non-Isothermal Calorimetry

By Erhard Koch[*]

For the rapid kinetic and energetic analysis of reactions in solution ($\tau_{20\,c} > 10^{-4}$ s) by differential thermal analysis (DTA), the following thermogram parameters are defined as characterizing the start of the reaction: 1. initial temperature, 2. activation energy of the initiation reaction. In conjunction with the shape index (asymmetry of the DTA curve) and the half width of the DTA curve referred to standard physical conditions (cell constant, heating rate, and temperature difference), these quantities allow a simple distinction between one-step reactions of first and second order and composite reactions. It is possible to recognize whether a process involves parallel, successive, or equilibrium reactions, or combinations of these. The reaction mechanism can be clarified in many cases by measurements at various concentrations and heating rates and by discussion of the enthalpy values. The shortened method described in this report for the evaluation of the thermograms was derived with the aid of an analog computer and checked experimentally.

1. Introduction

Non-isothermal thermal measuring methods have the advantage over many other investigation methods of universal applicability. In one measurement they cover both the energetic and the kinetic aspects of any system investigated. The non-isothermal thermal analysis of reactions is therefore an ideal complement, in principle, to all methods involving the analysis of substances, and its result, the thermogram, is a sort of "reaction-analytical placard".

However, thermal measurements in solution have not so far been extensively used, one reason being that the relations between the reaction parameters and the measured temperature are not simple, and the time that had been saved was therefore lost again because of the complicated evaluation.

The most common thermal investigation method is differential thermal analysis (DTA)[1]. However, the use of this method for the precise kinetic analysis of solution reactions calls for calorimetric operating conditions[2-4]:

1. dilute solutions,

2. stirring of the sample solution and of the reference solution to avoid temperature differences within the solutions,

3. temperature measurement in both solutions.

Equipment designed with these factors in mind lead, for one-step reactions, to thermograms that satisfy an equation derived by *Borchardt* and *Daniels*[2,3]:

$$k = \left[\frac{V|\Delta H|}{C_p}\right]^{n-1} \frac{c \cdot \theta + \frac{d\theta}{dt}}{\left[c \int_t \theta\, dt - \theta\right]^n} \qquad (1)$$

k = reaction rate constant
n = reaction order
V = volume of sample solution
ΔH = molar enthalpy of reaction
C_p = heat capacity
θ = temperature difference between sample solution and reference solution
c = kinetic cell constant

For fractional values of n, the evaluation with the aid of this equation yields formal activation energies and frequency factors, but no information on the manner in which the individual processes are linked. It cannot be applied to more complicated processes. An evaluation method for such processes is described below. This method is based on breakdown into individual processes, and allows the accurate and fast interpretation of many types of complicated thermograms without the use of complicated mathematics. Its basic principles are also applicable to other non-isothermal investigation methods.

2. Thermograms and their Characterization

The evaluation of the DTA curves ($\theta = f(t)$, $T = T_0 + \alpha \cdot t$) presents a number of problems, since both physical equipment parameters and chemical parameters are involved in a mathematically complicated combination. However, the chemist will be interested only in the chemical consequences. To study the effects of all the parameters, we developed an analog computer program, which allows the investigation even of complex mechanisms (up to four simultaneous reactions)[5]. The results of these investigations suggest the use of five independent curve parameters for the characterization of each individual thermogram signal (cf. Fig. 1):

1. total area,

2. initial temperature,

3. initial activation energy,

4. shape index,

5. half width.

[*] Dr. E. Koch
Max-Planck-Institut für Kohlenforschung
Abteilung Strahlenchemie
433 Mülheim/Ruhr,
Stiftstrasse 34—36 (Germany)

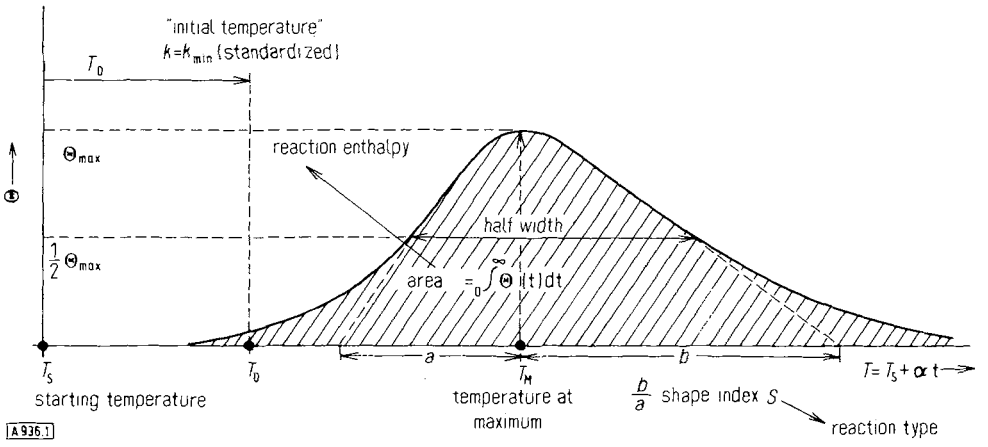

Fig. 1. Characteristic parameters of thermograms with one signal.

2.1. Total Area $\int_0^\infty \theta\,dt$

The total area between a DTA curve $\theta=f(t)$ and the zero line is used for the calculation of the heat of reaction[1,4], while the area after a time t until the curve has reached the base-line ($t=\infty$, integral in eq. (1)) is a measure of the concentration of reactive substance(s) still present.

The kinetic conditions at the start of the reaction are especially clear, since the time-dependent partial integral practically still agrees with the total integral, and because of the resulting constancy of the denominator in eq. (1), the reaction order does not yet have any effect. As will be shown later, it is also advantageous for other reasons to define the kinetic parameters in this region of the curve.

2.2. Initial Temperature T_0

At the first strong deviation of the curve from the zero line, a reaction should generally be strongly favored. Whereas in isothermal kinetics the reactivity of a substance is normally described by a reaction rate constant, a more suitable description for non-isothermal kinetics is a temperature that corresponds, *via* the Arrhenius equation, to a fixed standard rate constant[5]. Since the rate constant at the beginning of a DTA curve is always of the same order of magnitude ($k=10^{-6}$ to $10^{-4}s^{-1}$)[*], we took as our reference value $k_{min}=10^{-5}s^{-1}$. For pseudo-unimolecular processes, this value must be divided by the concentration of the reactant that is present in excess in order to obtain the true bimolecular constant. In comparison with the "peak temperature" T_m at the maximum, which is easier to determine, such an initial temperature has the advantage that it is independent of the thermal conductivity in the initial region and allows direct comparison of reactivities[5]. For the range of solution reactions, therefore, a temperature defined in this way would facilitate the comparison[6,7] and the documentation of results obtained with different DTA equipment.

For apparatus of the calorimetric "Borchardt-Daniels type", the initial temperature for the "k_{min}" defined above is found purely empirically from the temperature T_0' for the first strong deviation of the curve from the zero line and from the signal height L to be

$$T_0 \approx T_0' - 7 + 0.12 \cdot L - \frac{32}{L} - \frac{0.18}{c} \qquad (2)$$

(maximum error ± 3°K), L = signal height in mm

2.3. Initial Activation Energy

At the beginning of the DTA curve, eq. (1) gives a simple relation for the activation energy from two points on the curve ($T_1, \theta_1, d\theta_1/dt$ and $T_2, \theta_2, d\theta_2/dt$):

$$E_0 = R \cdot \frac{T_1 \cdot T_2}{T_2 - T_1} \ln \frac{c\,\theta_2 + d\,\theta_2/dt}{c\,\theta_1 + d\,\theta_1/dt} \qquad (3)$$

From T_0 and the E_0 calculated from eq. (3), the "initial frequency factor" ($k_{\infty 0}$) is obtained *via* the Arrhenius equation:

$$\lg k_{\infty 0} = \frac{\lg e}{R\,T_0} \cdot E_0 + \lg k_{min} \qquad (4)$$

2.4. Shape Index S

This quantity describes the asymmetry of the curve[8], and is related to the type of reaction taking place (Fig. 1). For the case of constant heating rate, *Kissinger* derived the relation

$$S = 0.63\,n^2 \qquad (5)$$

but this becomes increasingly inaccurate for DTA in solution and at n values >1[5,8-11]. The shape index also depends on the cell constant c and on the heating rate[5,12]. If the S value is to be used as a criterion of the (apparent!) reaction order, therefore, it must be corrected to standard conditions with regard to these quantities and to a vanishingly small temperature difference between the sample solution and the reference solution. Suitable correction tables can be constructed with the aid of an analog computer[5]. However, the measuring technique can also be designed to maintain this latter condition by additional heating as in the "differential scanning calorimeter".

[*] The following statements are valid for the heating rate 1.5°C/min.

Under the standard conditions chosen here, *i.e.* $c=0.18\ \mathrm{min}^{-1}$, $dT/dt=1.5\,^{\circ}\mathrm{C/min}$, $\theta_{max}\rightarrow 0$, S assumes a value of 0.65 for a first-order reaction, but the value of 1.2 found for a second-order reaction is only about half of the value expected from eq. (5). However, measurements on numerous one-step reactions have shown that this value is evidently typical of second-order reactions.

2.5. Half Width *h*

This last curve characteristic can be read off directly. For a constant sample heating rate, it can also be used for the determination of the reaction type.

3. Half Width in One-Step Processes

Our numerous experiments and model calculations show that the following characteristic relation exists between activation energy, action constant, and the half width corrected to standard conditions for a first-order reaction

$$M_1 = \frac{E}{h(\lg k_x - \lg \tilde{k})^2} \approx \text{const.} = 4.2 \cdot 10^{-3}\ \text{kcal/mol} \cdot {}^{\circ}\text{K} \qquad (6)$$

$\log \tilde{k}$, with a value of -3, roughly corresponds to the rate constant at the time of the maximum of θ. The relation can also be derived purely mathematically.

On introduction of the temperatures T_1 and T_2 for which $\theta = {}^1/_2\,\theta_{max}$ and the corresponding rate constants k_1 and k^2 into the Arrhenius equation (4), gives $T_2 - T_1 = h$ and, after some rearrangement,

$$\frac{E}{h(\lg k_x - \lg k_1)(\lg k_\infty - \lg k_2)} = \frac{R}{\lg e \cdot \lg \frac{k_2}{k_1}} \qquad (7)$$

It can be shown that $\log k_2/k_1$ is practically independent of E and $\log k_\infty$. For this purpose, the Arrhenius equation is combined with the solution of the differential equation (8), which describes the balance between heat produced and heat dissipated[13]:

$$\frac{d\theta}{dt} = \frac{1}{C_p} \cdot \frac{dq}{dt} - c \cdot \theta \qquad (8)$$

For $\theta(t)$ one obtains an explicit expression with integrals, which become soluble only with the introduction of justified simplifications[11], and finally give the equation (6).

For first-order one-step reactions, the activation energy can be calculated directly *via* eqs. (4) and (6) from the half width and the initial temperature.

In second-order reactions, it has been found that M_1 is no longer constant for the same range of frequency factors, but the following quantity derived from M_1 becomes a constant whose value is approximately twice as large:

$$M_2 = M_1 \cdot \sqrt{\lg k_x} \approx \text{const.} = 9 \cdot 10^{-3}\ \text{kcal/mol} \cdot {}^{\circ}\text{K} \qquad (9)$$

The M_1 and M_2 defined in this way are auxiliary quantities derived from h, which are evidently similar to the shape indices in the mechanistic information that they provide. As will be shown later, however, they do not repeat the information given by the shape indices, but lead to further specification. We therefore suggest the names "reaction type index" for M_1 and "second reaction type index" for M_2.

4. Influence of a Second Reaction

Let us confine our attention for the moment to two reactions having the same enthalpy. Let one of these begin somewhat earlier in the DTA, *i.e.* have a lower T_0. The second reaction may then be regarded as a perturbation of the first, so that it can be disregarded at the beginning of the curve, and E_0 can be calculated from eq. (3) for the first reaction.

As the process continues, the second reaction will become either increasingly important or, if its activation energy is lower, increasingly unimportant. In the former case, it may be assumed that the half width and/or the shape index will be different from those of the first reaction. For a consecutive reaction that is not yet so much slower that it gives a second signal, for example, broadening of the signal is to be expected. For a condensation reaction between the product and the educt, on the other hand, the additional consumption of the starting material leads us to expect a decrease in h, *i.e.* an increase in M_1 or M_2 as against the constant values indicated in Section 3.

All reaction mechanisms can be built up from first-order one-step processes or processes of the bimolecular type $A+B\rightarrow C$. To include all conceivable reactions, we therefore constructed sets of model curves for all combinations of two first-order or second-order one-step processes (cf. legend to Fig. 2). As a standard reaction, we stored a reaction with the following data in the analog computer:

$$E = 15\ \text{kcal/mol}, \quad k_x = 10^{10.2}\ \text{s}^{-1}$$

$\alpha = dT/dt$, c, and θ_{max} corresponded to the standard conditions. For the second reaction, E and T_0 were varied within the following ranges for all mechanisms:

$$6 < E_2 < 20\ \text{kcal/mol}, \quad -30 < T_{02} - T_{01} < +30\,^{\circ}\text{C}$$

Abnormally high or low frequency factors ($\log k_x > 15\,\text{s}^{-1}$ or $< 5\,\text{s}^{-1}$) were disregarded. Bimolecular initiation reactions were programed for the initial concentration of 1 mol/l.

We thus obtained a set of 20—40 individual curves for each mechanism, and the shape indices and reaction type indices were calculated for these curves. To illustrate the dependence on the basic types of mechanism, we choose a diagram with the shape index S as the linear abscissa and M_1 as the linear ordinate (see Fig. 2, lower left field). For M_1 values that are lower by more than the error limit ($\approx 5\%$) than the typical value for first-order reactions, M_1 is replaced by M_2 in a downward continuation

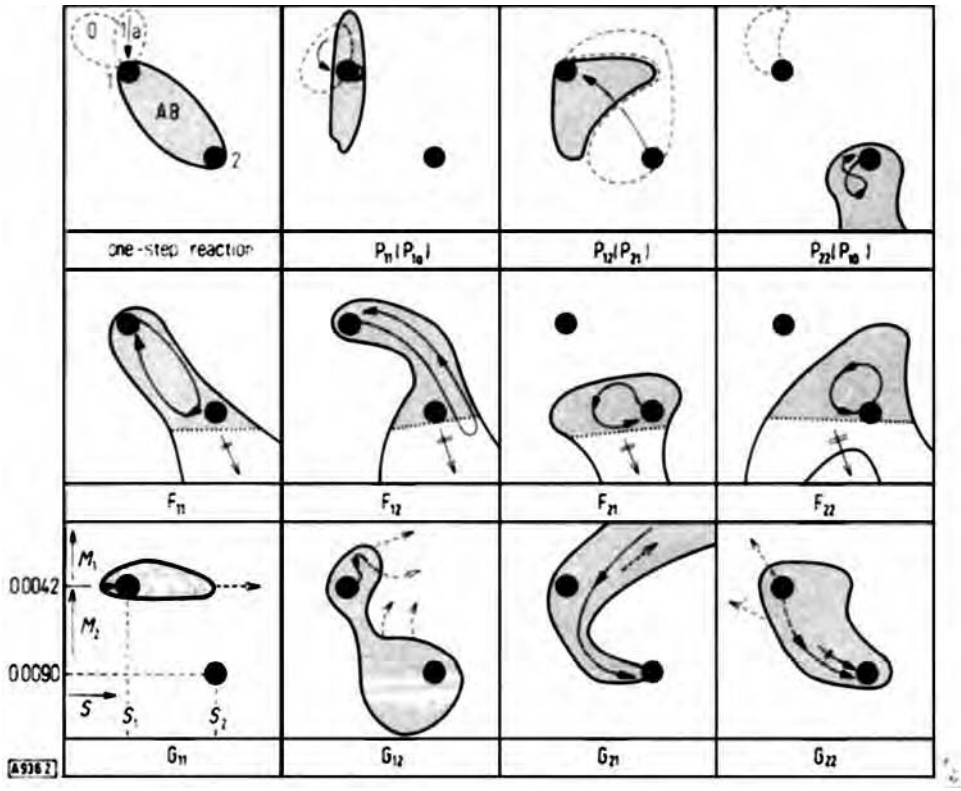

Fig. 2. Mechanistic analysis of thermograms.
⇸ splitting into two signals;
⇢ disappearance of signals;
→ curves for $k_{,2}=10^{10.2}\ s^{-1}$;
┈ boundaries of the "mechanistic regions";
( ) the same, mechanism designation in parentheses, *e.g.* (P_{21}).

Designation of mechanism types involving two reactions

0: Formal zeroth order reaction (*e.g.* catalytic).
1: First-order individual reaction.
1a: Autocatalytic reaction $A \xrightarrow{+B} 2\,B$ (ideal type).
AB: Bimolecular reaction $A+B \rightarrow C$.
2: Second-order individual reaction ($[A]=[B]$).

P_{pq}: Parallel reactions $A \begin{matrix} \nearrow B \\ \searrow C \end{matrix}$.

First index = Order of reaction with lower T_0 (=0, 1, or 2);
second index = order of reaction with higher T_0 (=0, 1, or 2);
index *a* = bimolecular condensation of B with A;
index *x* (possibly also *y*) first or second order.

F_{pq}: Successive reactions $A \rightarrow B \rightarrow C$.
Indices as above, but first index always corresponds to the initial reaction.

G_{pq}: Equilibrium reactions $A \rightleftharpoons B$.
First index always corresponds to the forward reaction.

U_{pq}: Kinetically independent reactions $A \rightarrow C$, $B \rightarrow C$ or D.
Indices as for parallel reactions.
The regions here are similar to those for successive reactions. Reaction types in parentheses are not very pronounced.

of the same scale. The ranges for the various basic mechanisms are given in Figure 2. The curve for $k_{,2}=k_{,1}=\text{const.}=10^{10.2}\ s^{-1}$ with a continuous increase in E_2 are also shown in the figure. As one moves along these curves in the direction of the arrow, the second reaction makes a steadily decreasing contribution to the overall process; as is to be expected, the curve for parallel reactions (= P) finally arrives at the point for the corresponding first-order or second-order one-step initiation reaction. For secondary reactions (= F) it also emerges from this point for the other extreme case of a much faster second reaction, and finally, after the splitting of the thermogram into two signals, returns to it for the first signal.

For a thermogram that has not yet been interpreted, this gives a clear criterion of whether or not a pure one-step reaction is involved. T_0, S, and h are found from the thermogram, E_0 is calculated, S and h are corrected, and the M_1 (or M_2 if $M_1<0.004$) calculated *via* $\log k_{x0}$ is plotted as a function of S. If the point obtained in this way lies in the regions for a first-order or second-order one-step reaction, which are slightly oval because of the error limits, the observed reaction is not appreciably perturbed by side reactions. In this case the initial activation energy E_0 is also identical with the overall activation energy calculated from h and T_0 or by other methods, *e.g.* computer simulation. If the point lies outside the one-step regions, however, one can see immediately which basic mechanisms are possible and which are not.

The situation for two reactions with different enthalpies can also be simulated by calculations. Kinetically and qualitatively, on the basis of eq. (4), an increase in the enthalpy of the second reaction has an effect similar to that of a depression of its initial temperature T_{02}.

5. Hints for Practical Use

The diagnosis method described here can be applied to any individual signal of a thermogram, but because of the overlap of the "regions" (Fig. 2) it very often leaves several possible mechanisms open. The following methods may be used to obtain more specific information[4, 5]:

1. Analyses are carried out at a lower heating rate. For secondary reactions (= F), equilibria (= G), and independent reactions (= U), this causes the points in the diagram to move toward the lower diagram border at first, and

Table 1. Asymptotic behavior of the mechanism coordinates of the basic mechanisms with increasing heating rate or concentration (cf. Figs. 2 and 3).

	End type	Parallel reactions 11	12	21	22	1a	Secondary reactions 11	12	21	22	Equilibria 11	12	21	22	Independent reactions 11	12	21	22

	2								⊙				●			⊙	⊙	

nc: No change
● appropriate mechanism;
⊙ appropriate mechanism, but signal splitting;
○ behavior of the second signal formed;
+ disappearance of the signals.

this is followed by signal splitting and a movement back into the corresponding one-step regions. For parallel reactions (= P), on the other hand, the points converge toward the region of the initiation reaction (Table 1).

2. The measurements are carried out at a higher concentration. Second-order reactions are favored in this way, and their initial temperatures are depressed. The convergence behavior shown in Table 1 is thus found for the various types.

Superimposed equilibria (= G) can be considered only if the first signal clearly runs into a second. If the reverse reaction has a much lower T_0 than the initiation reaction, the measured effects may be partly compensated. Since ΔH_1 and ΔH_2 must have different signs but practically equal absolute values, the temperature differences may be very small, but they can be increased again by separation of the reactions (reduction of the heating rate).

For more complicated mechanisms, several signals usually appear in the thermograms. The results of the single-signal analysis just described also provide the basis for a reaction separation based on the principles mentioned for each isolated group of signals, *i.e.* splitting into further individual signals.

Further aids in the reaction analysis are the addition of interceptor reagents (introduction of bimolecular reactions) and the replacement of a solvent that takes part in the reaction by an inert solvent (elimination of pseudo-unimolecular reactions).

After extensive separation of the reactions and establishment of the individual types, the overall reaction mechanism can be built up from parallel-step and one-step reactions.

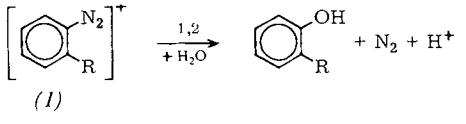
Since the thermodynamic data of all the individual steps can be obtained with the aid of an analog computer after the mechanism has been elucidated, it is then possible to confirm intermediates whose structures have been formulated both by means of thermograms of model substances and by comparison of the kinetic and energetic data.

6. Examples

Systems whose behavior is known will now be used to illustrate the application of the analytical method in accordance with the arrangement of Table 2. The positions of the examples in the mechanism diagram can be seen from Figure 3.

6.1. First-Order Reactions

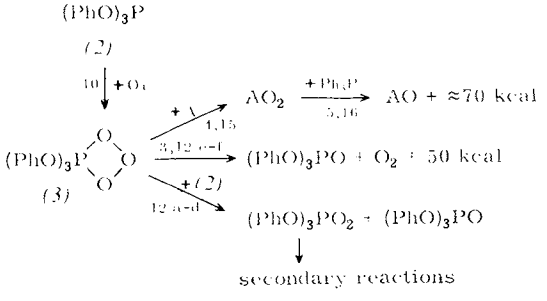
A test reaction that is repeatedly used for DTA investigations is the decomposition of arenediazonium salts with elimination of N_2 in dilute acids[2, 3, 5, 14, 15] (examples 1 and 2).



(1)

As Figure 3 shows, the positions of the points in the M/S diagram correspond, within the error limits, to an only slightly perturbed first-order reaction.

The unstable ozonide *(3)* obtainable from ozone and triphenyl phosphite *(2)*[16, 17] (Scheme 1) acts as an oxidizing agent at low temperatures[18, 19] and converts olefins into hydroperoxides, some of which have so far been obtainable only by photosensitized oxygenation[20–23].



Scheme 1.

Its decomposition (example 3) proceeds exclusively as a first-order process at sufficiently low concentrations.

On addition of a large excess of tetramethylethylene *(4)* at −90 C, this acts as a scavenger, and only the bimolecular reaction 4 with hydroperoxide formation then occurs.

Table 2. Kinetic and mechanistic analysis of thermograms.

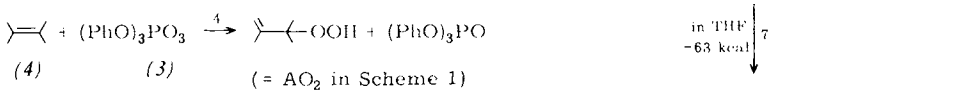
E_0: initial activation energy [kcal/mol];
S: corrected shape index;
M_1, M_2: reaction type indices [10^{-4} kcal/mol·K].
Types: See legend to Fig. 2.

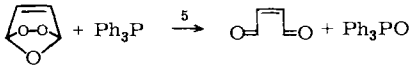
Because of the pseudo-unimolecular character of the reaction, a first-order reaction is observed in practice:



(4) *(3)* (= AO_2 in Scheme 1)

(= A in Scheme 1)

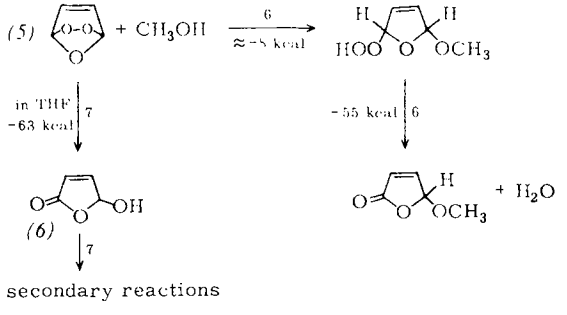
If triphenylphosphane is added to a photochemically or thermally prepared compound AO_2, *e.g.* the epidioxydihydrofuran *(5)*, the bimolecular redox reaction[4, 20, 24] (cf. Scheme 1) can also be observed (example 5).



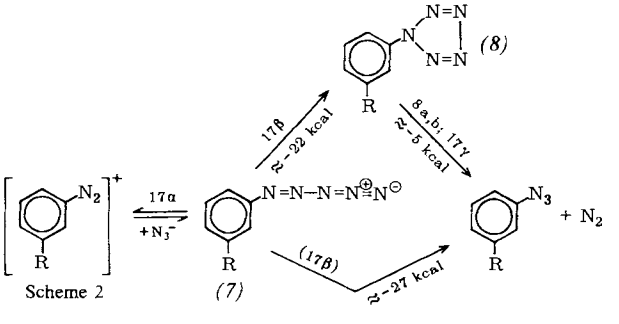
(5) (= AO_2) (= AO)

Another example of a pseudo-unimolecular reaction is the addition of methanol to the ozonide-like peroxide *(5)*, which is followed by an immeasurably fast elimination of water[3, 4, 24] (example 6).

The reaction begins much later in tetrahydrofuran (example 7). Because of the perturbed course of the decomposition, *(6)* is no longer the only end product; secondary reactions, such as the formation of dimers, also occur.



The pentazole *(8)* formed from diazotized aminobenzene and azide[25], after isolation and dissolution in methanol, exhibits an almost unimolecular decomposition (example 8a; Scheme 2).



Scheme 2 (7)

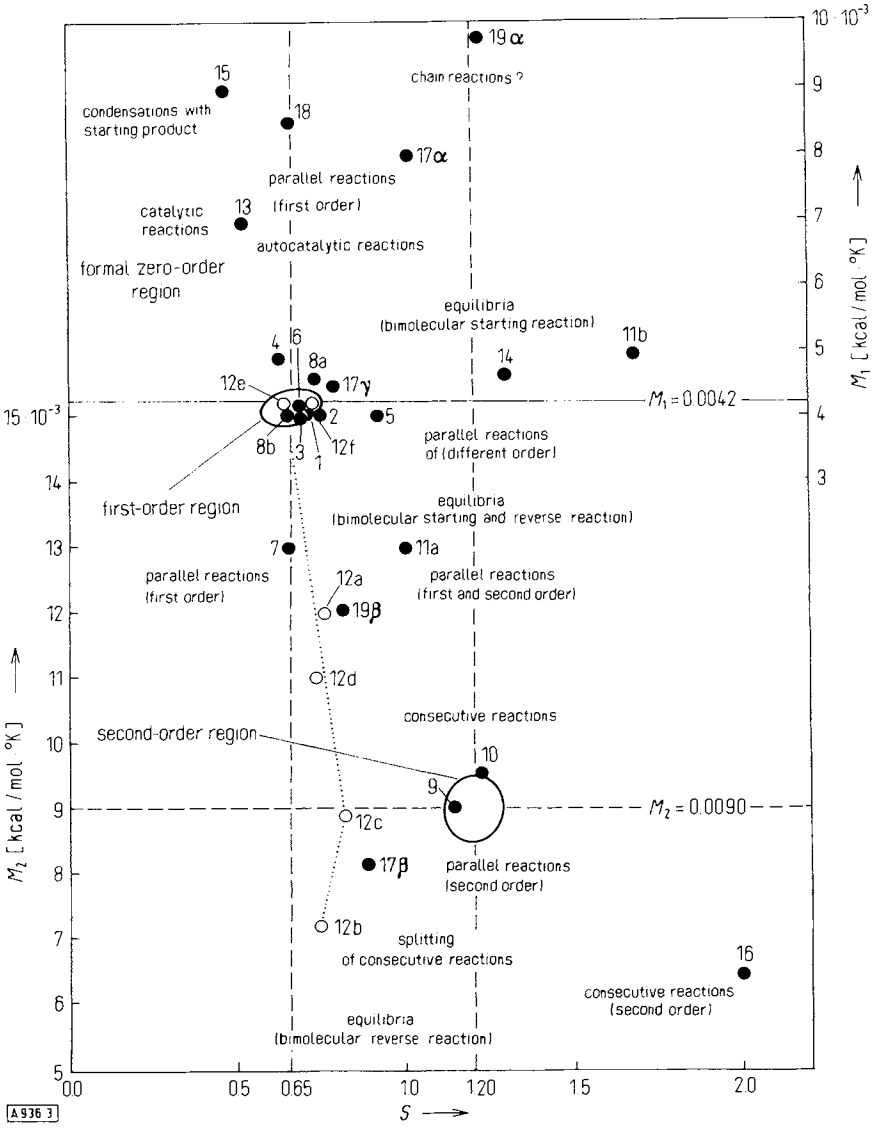


Fig. 3. Positions of systems investigated in the mechanism diagram. Numbering of examples as in Table 2 and by the reaction arrows. The explanatory text can only indicate the positions of typical regions from Fig. 2.

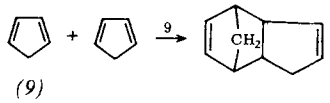
If instead of isolating the pentazole one examines the reaction mixture itself (example 8b), the purer course of the decomposition reaction indicates that the *p*-ethoxyphenylpentazole used in example 8a had evidently undergone partial rearrangement during isolation.

6.2. Second-Order Reactions and Bimolecular Reactions (Type AB) with Non-Equimolar Ratios of the Components

The dimerization of cyclopentadiene *(9)*[26,27] can be followed thermally in solution (example 9).

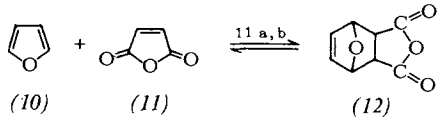


(9)

It is evidently not perturbed under these conditions by further condensation or cleavage back into the monomer.

The formation of the above-mentioned triphenyl phosphite ozonide *(3)* (Scheme 1) can be observed directly in solvents that allow investigation temperatures below −120 °C. With an equimolar ratio of the reactants, it practically follows second-order kinetics (example 10).

In bimolecular reactions, the influence of the molar ratio may be so strongly distorted by perturbations that the resulting M/S point no longer lies in the AB region of Figure 2 (examples 11a, b).



(10) *(11)* *(12)*

The formation of the Diels-Alder adduct *(12)*[28,29] is reversible, so that with an equimolar ratio of the reactants in dilute solution, the back-reaction already influences the first reaction signal.

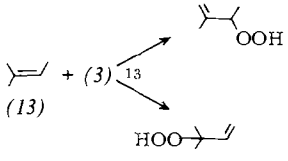
The influence of the molar ratio of the reactants on the type of reaction can be investigated in the system triphenyl phosphite/ozone (examples 12a—f, cf. Scheme 1). With much less than the stoichiometric quantity of O_3 (12a), the decomposition of the ozonide *(3)* is preceded by its

bimolecular reaction with excess phosphite *(2)* (cf. example 4, Scheme 1), but by further reaction steps (dimerization of the $(PhO)_3PO_2$ formed and disproportionation) *(3)* is ultimately regenerated, so that a second and a third signal appear. The activation energy of this interception reaction is only about 5.5 kcal/mol. With increasing addition of O_3 (examples 12b, c), the "mechanistic point" in Figure 3 approaches the second-order region. Because of the decrease in the concentration of *(2)* through the interception reaction, however, the start of this reaction is displaced toward higher temperatures (example 12d), so that the first maximum moves into the region of the unimolecular decomposition reaction (example 3). Finally, if ozone is present in excess (examples 12e, f), this reaction alone controls the process, and the first-order region is reached. The initial activation energy accordingly increases from about 8 to 15.6 kcal/mol, *i.e.* to roughly the value for the decomposition reaction (example 3).

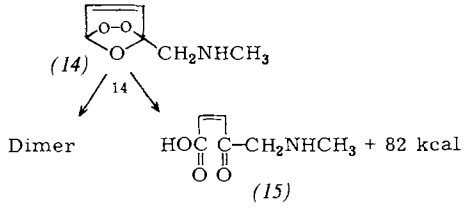
The following examples of *complex reaction types* are concerned with nearly all regions of Figure 3.

6.3. Complex Reactions

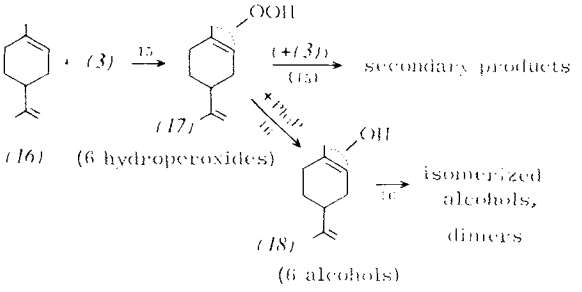
Two parallel first-order reactions give only one signal. The initial activation energy E_0 does not agree with activation energies in other parts of the curve. The half width h assumes anomalous values, while the shape factor S differs only slightly from the value for first-order reactions. This is shown by example 13, which has also been investigated preparatively[30, 31].



Parallel first-order and second-order reactions. The decomposition of the ozonide-like peroxide *(14)* of *N*-methylfurfurylamine (example 14) yields (*N*-methyl)glycylacrylic acid *(15)*[4, 32]. However, the direct formation of an isolable dimer is observed in the concentration range chosen here.



More than two parallel first-order reactions. The parallel formation of up to six hydroperoxides *(17)*, which undergo partial isomerization, by thermal oxidation of *d*-limonene *(16)*[20, 31, 33, 34] is a test case for the extension of the foregoing example to more than two processes. Because of the large excess of *(16)* (example 15), several parallel first-order reactions are to be expected. However, the "mechanistic point" appears in the upper limiting region of the P_{11} area, which is typical of condensation reactions with the educt or of autocatalytic processes. Secondary condensation steps cannot be ruled out in this example.



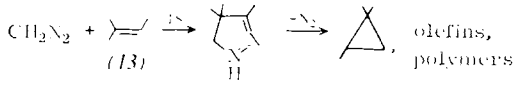
Six parallel reactions of type AB with secondary reactions. The hydroperoxides *(17)* formed in example 15 can be reduced with triphenylphosphane (example 16). A displacement from the P_{12}/AB region into the region of lower M but higher S values (Fig. 3) confirms that the reduction products isomerize or dimerize.

Equilibrium followed by parallel and secondary reactions. The formation and the decomposition of pentazoles *(8)* (Scheme 2) can be observed directly in solution. With a sufficiently low starting temperature (≈ 190 K), the thermograms of diazotized aniline salt solutions in methanol/water after addition of excess NaN_3 show three maxima, which are evidently due to the formation of the linear diazoazide *(7)* (example 17α), the cyclization of *(7)* to form the pentazole *(8)* (17β), and the decomposition of *(8)* (17γ = 8a, b).

Mechanistic analysis shows that the formation of *(7)* is probably an equilibrium reaction, and that a first-order or second-order reaction (which leads directly to the phenyl azide[25]) competes with the step leading to the pentazole *(8)* so that the yields of *(8)* do not nearly correspond to the feed. This can also be investigated quantitatively by measurement of the heat effect in the third step.

6.4. Occurrence of Free-Radical Steps and Chain Reactions

Example 18, the addition of diazomethane to the olefin *(13)* and the subsequent decomposition of the resulting pyrazoline[35, 36], leads into the boundary region of free-radical processes.

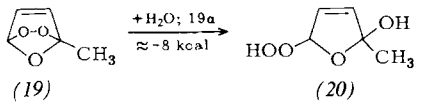


This raises the question, as yet unanswered, how far the arguments so far can be applied to free-radical mechanisms. The type determination leads in example 18 to condensation mechanisms, whereas pure consecutive reactions should be expected because of the excess of olefin. However, only one signal is present.

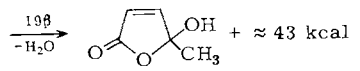
A further example raises a similar problem.

The addition of methanol to the unstable, ozonide-like epidioxydihydrofurans[4, 34] (cf. example 6), which has

become established even in preparative work in many cases, cannot be applied directly to water. In the example of the ozonide *(19)* (and also for *(5)*), instead, of a simple bimolecular step leading to the compound *(20)*, one finds a complicated sequence that evidently possesses chain character (example 19):



(19) *(20)*



(21)

Whereas the second maximum behaves normally, the first ascends so steeply that simple evaluation on the basis of the initial activation energy gives an unrealistically high frequency factor. The condition that the kinetics of the process must be determined initially by a single reaction is evidently no longer satisfied; even with the first strong deviation from the zero line, there is a reaction feedback, which must be considered by the methods of polymerization kinetics[138].

It has generally been found that abnormally high k_{r0} values (above 10^{16} s^{-1}) are always due to chain reactions or physical disturbances, *e.g.* separation of material. An extension of the model described here to chain reaction mechanisms seems conceivable.

7. Outlook

Two years ago, this journal published a report on the possibilities offered by low-temperature DTA, particularly in photochemistry, for the detection and investigation of unstable intermediates[4]. For all reacting systems, this method also yields numerous parameters, whose importance can be fully recognized by a mathematical analysis. In conjunction with the use of hybrid analog simulators, it presents ideal conditions for a complete reaction analysis even of systems whose reactions are still unknown.

The two-reaction model presented here leads to an evaluation method that is universally applicable and that should be particularly suitable for use in the search for new synthesis routes and in their optimization. Even for complicated processes, an analysis provides information about the conditions under which the thermodynamic data for the individual processes can be obtained by further experiments. The current rapid development of electronic measuring methods and of computer technology enables us to foresee where this road may finally lead, *i.e.* to the fully automatic reaction analyzer, which, after feedback between computer results, sample preparation, and reprograming of the measurement for each sample introduced, will print out the prevailing reaction scheme, with the data for all the steps. It will then remain for the chemist to insert the appropriate structural formulas for intermediates and final products, and to check whether and to what extent his proposed synthesis can be achieved.

I am grateful to the Directors of the Institute, Prof. Dr. D. Schulte-Frohlinde and Prof. Dr. O. E. Polansky, for their support of the investigations, and to Dr. G. von Bünau, Dr. C. von Sonntag, and Dr. G. Koltzenburg for valuable discussions. Thanks are also due to M. Barthels, R. Frings, G. Lindner, H. Queck, H. Siepmann, and B. Stilkerieg, for their assistance with technical and preparative preliminary work and with the DTA measurements, as well as to Dr. H. Hermann and K. Sandmann for their help with the analog computer studies.

Iron-Sulfur Proteins: Structural Chemistry of Their Chromophores and Related Systems

By Ronald Mason and J. A. Zubieta[*]

Intensive studies of iron-sulfur proteins were begun only a decade or so ago but many biological and physicochemical data have since been accumulated and summarized[1-5]. As a result of the very recent X-ray analyses of the structures of rubredoxin[6], ferredoxin (*Peptococcus aerogenes*)[7] and the *Chromatium vinosum* high potential iron protein (Hipip)[8], it has become possible to review our understanding of the nature and function of the inorganic chromophores in these proteins; to relate these findings to 'model' systems of varying relevance; but of more general interest, to comment on redox processes in biological systems particularly with respect to what might be termed electron transfer—allosteric effects in metalloenzymes.

1. Summary of Iron-Sulfur Proteins and Their Properties

The proteins which will be discussed here are distinguished from other iron-containing proteins[9] in so far as the metals are not coordinated by the complex organic ligands found, for example, in heme-proteins[10] and the siderochromes[11]. In rubredoxin, the single iron atom is coordinated by four cysteine-sulfur atoms; the ferredoxins from plants and bacteria have iron atoms coordinated by cysteine-sulfurs and by 'inorganic' sulfide (labile sulfur).

The biological role of rubredoxin has not been completely clarified; that of the ferredoxins is electron transfer in processes as diverse as nitrogen fixation, photosynthesis, hydroxylation of steroids[12], reduction of sulfite by hydrogen[13] and the reduction of NADP by formate in *Sarcina ventriculi*[14]. More generally, iron-sulfur proteins are implicated in pyruvate reduction[15] and in succinate dehydrogenase from heart-muscle particles[16] (see Table 1).

Those relatively low-molecular weight iron-sulfur proteins with two to eight iron atoms and an equal number of labile sulfide ions per molecule are known as the ferredoxins and have redox potentials which allow them to function as cellular electron carriers on the hydrogen side of NAD or NADP[12]. This fact, together with their particular amino-acid composition, has formed the basis for the speculation that they were amongst the earliest of proteins to have evolved chemically[24,62]. The known amino-acid sequences of many plant and bacterial ferredoxins are such that, separately, they show strong homologies. More recently, and interestingly, the photosynthetic bacteria of the *Chromatium* type have yielded ferredoxins whose sequences and compositions are intermediate between bacterial and plant proteins. Thus the ferredoxin from *Desulfovibrio gigas* shows[43] a strong homology with bacterial ferredoxins for the residues 1—29 but the remaining part of the chain shows some resemblance to the sequences which define the plant ferredoxins; this protein is important, therefore, as a possible link between the ferredoxins derived from anaerobic fermentative bacteria and plants. It is assumed that the bacterial ferredoxins may have evolved through gene duplication from a proto ferredoxin of 29 residues[63], a speculation also relevant to the fairly precise twofold symmetry of the eight-iron ferredoxin molecule from *P. aerogenes* (see Section 2.3).

2. Structural Chemistry of the Redox Centers in Iron-Sulfur Proteins

2.1. Rubredoxin

Through one of the most accurate structural analyses of a protein, *Jensen et al.*[6,64] have defined the nature and geometry of the redox center in rubredoxin (*Peptococcus aerogenes*) (Fig. 1). The oxidized protein can be regarded as a simple high-spin ferric thiol complex but the distortions from tetrahedral coordination geometry would not have been anticipated from the structural chemistry of simple four-coordinate complexes of iron(III). The ground state

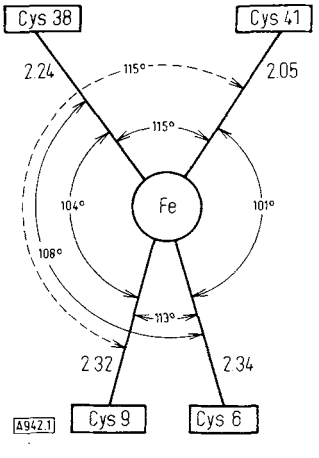

Fig. 1. Geometry of the iron-cysteine chromophore of rubredoxin (*P. aerogenes*) as determined from the 1.5 Å X-ray data (after *Jensen*, 1972; see Ref. [64]).

Table 1. Summary of iron-sulfur proteins and their properties [a, b].

[b] *Tsibris* and *Woody* [3] present a discussion of the physicochemical properties of the iron-sulfur proteins.
[c] The EPR data for these complexes is fully discussed by *Bearden* and *Dunham* [5].

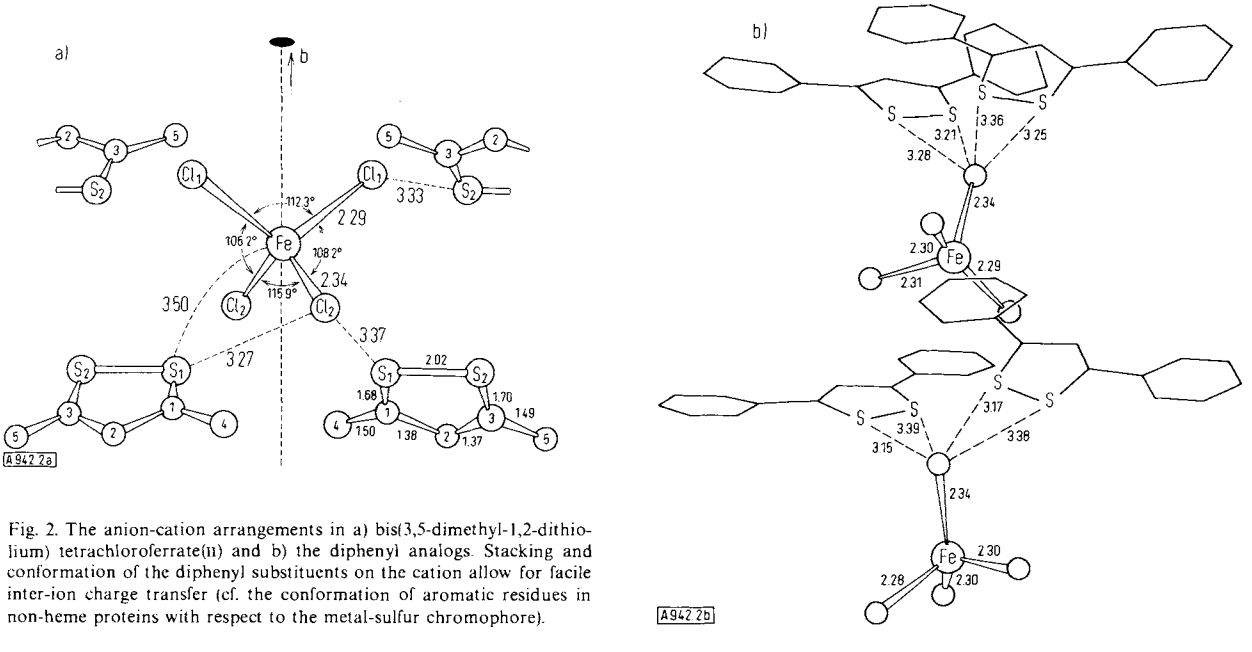

Fig. 2. The anion-cation arrangements in a) bis(3,5-dimethyl-1,2-dithiolium) tetrachloroferrate(II) and b) the diphenyl analogs. Stacking and conformation of the diphenyl substituents on the cation allow for facile inter-ion charge transfer (cf. the conformation of aromatic residues in non-heme proteins with respect to the metal-sulfur chromophore).

of a d^5 ion in a tetrahedral, high-spin complex is the orbitally non-degenerate $^6A_1$; thus simple crystal field theory predicts no Jahn-Teller distortion of the complex from T_d symmetry. High spin d^6 ions in a tetrahedral field have orbitally degenerate ground terms and the geometrical distortions from regular T_d symmetry are angular ones only, a feature which is also imposed on orbitally-non-degenerate ions by crystal packing effects[65]. The angular

distortions in the iron coordination sphere of oxidized rubredoxin must largely reflect the steric and electronic demands and constraints of the polypeptide chain. Isolated four-coordinate complex ions of Fe^{II} and Fe^{III} do not exhibit significant variation in the metal-ligand bond lengths but the variation in the Fe—S bond lengths in rubredoxin remind one, albeit qualitatively, of the situation in bis(3,5-dimethyl-1,2-dithiolium) tetrachloroferrate(II) and the diphenyldithiolium analogs of $[FeCl_4]^{2-}$ and $[HgCl_4]^{2-}$[66,67]. In these cases, the metal-ligand bond lengths vary by up to 0.08 Å and in a way which reflects *local* charge transfer interactions between the complex anions and the adjacent dithiolium cations (Fig. 2). The very short Fe—S bond length of 2.05 Å in rubredoxin may thus be due to some strong interaction with an adjacent electronegative group, a point to which we return in Section 3 in connection with the mechanism of the electron transfer processes.

The geometry of the chromophore in the oxidized rubredoxin is already, in the sense of angular distortions, intermediate between that which could be anticipated for isolated high-spin ferrous and ferric complexes; as such, it is relevant to discussions of the entatic theory[68,69] of enzyme catalysis. But the major stereochemical distortion is caused by specific non-valence interactions which could not have been anticipated by any considerations *ab initio*. Possible changes in the chromophore geometry during redox are discussed in Section 3.

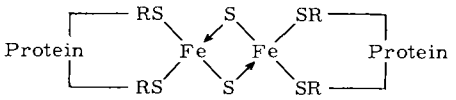

Fig. 3. Proposed structure for the redox centers in 2Fe-2S* proteins.

In the oxidized protein, each iron is in a pseudo-tetrahedral ligand field; they are both high spin ferric ions (S = 5/2), antiferromagnetically coupled to give a total spin, S, of zero[5]. Intuitively, this is not a surprising result but the spectroscopic data on the reduced protein provide convincing evidence that the two iron atoms are now, respectively, high spin ferric and high-spin ferrous ions (S = 2), antiferromagnetically coupled, giving a net total spin S = 1/2 for the dimeric iron-sulfur chromophore. It has been suggested that one electron reduction populates a metal orbital lying along the metal-metal bond axis and that electronic repulsion between the iron atoms may explain the low redox potentials of the binuclear chromophore. But a more general assessment of the electronic structure of the chromophore and the question of electron localization in the reduced protein can be developed from the structural data on other sulfur-bridged binuclear iron complexes (Table 2).

Table 2. Structural data of sulfur-bridged binuclear iron complexes.

Complex	Fe—Fe [Å]	Dihedral angle (between FeSS and Fe'SS) of the Fe_2S_2 bridge and formal oxidation state of the iron atoms		Electronic configuration (Fig. 4) and approximate Fe—Fe bond order		Ref.

2.2. Plant Ferredoxins: 2Fe-2S* Proteins

No crystallographic data are available yet to provide unequivocal information on the structure of the redox centers in two iron—two labile sulfur proteins but there is now much spectroscopic and magnetic evidence for the arrangement shown in Fig. 3, particularly as analyses of the bacterial proteins (see Section 2.3) reveal that the labile sulfur is indeed inorganic sulfide rather than cysteine persulfide.

The bonding scheme formulated[77] for these and other bridged binuclear and polynuclear complexes is summarized in Figure 3. The metal d_{z^2}, d_{xz} and d_{yz} orbitals, the sulfur lone pair orbital, which is essentially directed towards the center of the metal-metal axis, and sulfur filled 'p' orbitals are utilized in bridge bonding; of the remaining metal orbitals, *n* are directed towards the (*n*) terminal ligands and $9-(3+n)$ are assumed to be non-bonding (an adequate description except when strongly π-accepting ligands such as carbon monoxide are present). Use of the theory can be illustrated by a consideration of the complexes $[(\pi C_5H_5)Fe(CO)(SC_6H_5)]_2$ and $[(\pi C_5H_5)Cr(NO)(SC_6H_5)]_2$ where the metal-metal bond lengths are 3.39 Å[78] and 2.95 Å[76] respectively. The electronic configuration of the chromium complex is $(XZ_b)^2(Z_b^2)^2(XZ^*)^2(Z^{2*})^2(YZ)^2$(non bonding)^8 whereas it is $(XZ_b)^2(Z_b^2)^2(XZ^*)^2(Z^{2*})^2(YZ)^2$(non bonding)$^8(YZ^*)^2$ in the iron

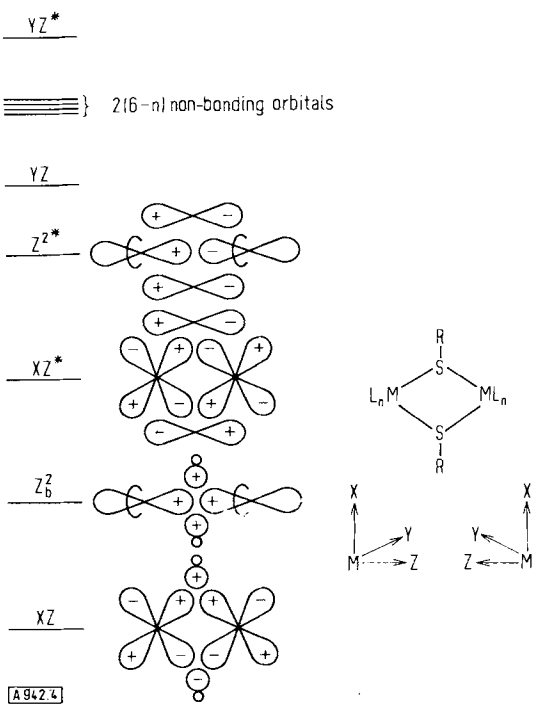

Fig. 4. Schematic representation of the bridge orbitals in sulfur-bridged dimeric species.

complex; thus the metal-metal bond order is approximately unity for the chromium complex and zero for the iron species.

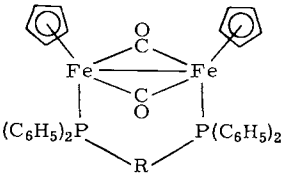
This theory provides also a rationale for the shorter metal-metal bond length in the cationic species $[Fe(\pi C_5H_5)(CO)(SCH_3)]_2^+$ where the YZ* orbital, which is antibonding with respect to the metals, is populated by one electron, compared to the neutral binuclear species in which this orbital is doubly filled. In the case of those complexes with unit bond order, the variation in metal-metal distances reflects the Lewis acidity of the terminal ligands, that is, their ability to accept electron density from those bridge orbitals which are antibonding with respect to the metal-metal bond.

The changes in the metal-metal distances in mercapto-π-cyclopentadienyliron carbonyl and its cation have been interpreted[75] as implying that the geometries of the reduced and oxidized plant ferredoxins differ significantly with respect to the iron-iron distance. However, other workers take the view that the iron-sulfur chromophore geometry remains invariant during the redox process as a result of the steric constraints imposed by the polypeptide chain[79]. Our views on the redox-induced changes are based on the schematic molecular orbital scheme of Figure 3 and an inspection of the variation of metal-metal distances and bridge geometries of Table 2. There is a correlation between the non-planarity of the bridges in the iron-sulfur bridged dimers and the metal-metal distances. For metal-metal distances in the vicinity of the iron covalent diameter (*ca.* 2.5 to 2.6 Å), interelectron repulsions are very sensitive to further reduction of the bond length. The energy of the system will be reduced on bending the Fe_2S_2 framework across the S—S line. As the Fe_2S_2 ring becomes increasingly non-planar, the energies of the bonding orbitals XZ and Z^2 will change only slowly, those orbitals involving the sulfur p_z orbital will change more dramatically; the orbitals XZ*, Z^{2*} and YZ* become less anti-bonding in character. The usual postulate of bent metal-metal bonds in these complexes reflects, in molecular orbital language, a structural change which lowers the total energy of the system; our argument is entirely similar to that established for simpler molecules by *Walsh* and other workers[80].

All the binuclear systems discussed above contain iron in the low spin state, whereas in the plant ferredoxins it is high spin. This fact alone must result in an increase in the covalent radius of about 0.1 Å. The bonding scheme (Fig. 4) indicates that in the reduced state of the plant chromophore the iron-iron bond order is at least one, the (YZ*) antibonding orbital being unfilled. One could suggest therefore a metal-metal distance of about 2.7 Å in the case of coupled high spin ions. Oxidation would remove an electron from the XZ* or Z^{2*} orbital (the relative ordering of these is not known), the net result of which will be a shortening of the metal-metal bond by *ca.* 0.15 Å together with a development of non-planarity in the bridge. That at least would follow from results on model systems. The major qualification that must be made is that bending of the bridge is a very low energy distortion—it could be enhanced or prevented by the steric requirements of the protein chain[*].

The spectroscopic data on the chloroplast ferredoxins all point to a certain degree of charge localization on one iron center following reduction, that is to an Fe^{2+}/Fe^{3+} system. Further studies by *Phillips*[83] on the contact shifts of cysteine protons in a variety of reduced plant ferredoxins shows that the environment about the reduced (ferrous) iron remains invariant whereas that about the ferric iron differs from species to species. It is reasonable to anticipate that the coordination geometry about the 'ferrous' iron is more nearly planar than tetrahedral.

Only one series of complexes is known to us which bears directly on the argument concerning the possibility of bridge conformational changes upon redox reactions in the Fe_2S_2 ferredoxins and a resultant non-equivalence of the iron atoms in the reduced plant proteins: the molecules $[\{(\pi\text{-}C_5H_5)Fe(CO)\}_2(C_6H_5)_2PRP(C_6H_5)_2]$ and their monocations (see Table 3).



[*] Many other dimers of the type $(MX)_2$ containing a variety of transition metals and bridging ligands (X = S, N or O) are known, and have been discussed elsewhere [67, 81]. Variations in M—M bond lengths can be related to the electronegativity of the bridging groups, a fact reflecting the contribution of the 'p' orbitals on the bridging ligands to the bridge molecular orbitals. The qualitative correlation noted earlier between the Fe—Fe bond length and dihedral angle in sulfur bridged binuclear species is not a general one. *Dessy* [82] has recently calculated activation parameters for a series of phosphido-bridged iron dimers and found that inversion of the Fe_2P_2 system is characterized by an activation enthalpy of only 2.2 kcal/mol. Steric effects may contribute significantly to the stabilization of a particular conformer in the case of amido- and phosphido-bridged compounds.

Table 3. Mossbauer data for the series $[\{(\pi\text{-}C_5H_5)Fe(CO)\}_2(C_6H_5)_2\text{-}PRP(C_6H_5)_2]^n$, $n=0, 1+$.

—R—	Chemical isomer shift	Quadrupole splitting Δ [mm s^{-1}]
neutral complexes		
$-CH_2-$	0.30 ± 0.01	1.84
$-N(C_2H_5)-$	0.29 ± 0.01	1.89
$-CH_2-CH_2-$	0.31 ± 0.01	1.88
cations		
$-CH_2-$	0.28	1.98
$-N(C_2H_5)-$	0.28	1.77
$-CH_2-CH_2-$	0.30	1.70

These cations have room temperature magnetic moments corresponding to one unpaired electron per two Fe atoms. Mossbauer studies indicate that the two iron atoms are non-equivalent, suggesting charge localization, that is an Fe^{2+}/Fe^{3+} system as exists in reduced ferredoxin (Table 3).

Not unexpectedly, in view of the difference of the ligands in these complexes and in reduced ferredoxin, the absolute values of the Mossbauer parameters are quite different: for oxidized ferredoxin $\delta=0.25$, $\Delta=0.60$; while in the reduced ferredoxin these values are 1.29 and 2.18 mm s^{-1} respectively. The significant point is the suggestion that non-equivalence of the iron atoms can be produced by low-energy deformations of the bridge geometry in these binuclear complexes. For the neutral complex, a metal-metal bond order of unity is predicted from our earlier theory—not an unlikely presumption on the basis of the iron-iron distance of 2.60 Å in the analogous $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ complex[84]. The (YZ*) antibonding orbital is unpopulated, but oxidation again results in the removal of an electron from the Z^2* or XZ* antibonding orbitals. The resulting cationic species should have a shorter metal-metal bond length and a non-planar bridge. This is in keeping with the IR data; the carbonyl stretching frequencies suggest that the bridge is non-planar in the complexes $[\{(\pi\text{-}C_5H_5)Fe(CO)\}_2(C_6H_5)_2PRP(C_6H_5)_2]^+X^-$, the deviation from planarity, based only on the ratio of the A_1 and B_1 mode intensities following the series $R = -N(C_2H_5)- \ll -(CH_2)_2- < -CH_2- < -(CH_2)_3- < -CH=CH-$. This trend parallels the relative rates of oxidation of the derivatives by iodine and $Ag^{\oplus}$.

One final general point should be made concerning the redox behavior of binuclear complexes. The presence of metal-metal bonds correlates well with the ability to yield stable radical anions although many species undergo irreversible two-electron reductions. *Vlček* points out[85] that a negative redox potential can be expected for high spin systems, and assumes that the greater the similarity in the electronic and atomic configuration of the two forms of the redox system, the higher the rate of electrode reaction: in cases where the internuclear distances change considerably, the redox process must have a relatively high activation energy. This offers some support to the views we have developed above for ferredoxins, that redox changes involving Fe^{2+}/Fe^{3+} dimeric systems may be accompanied by bridge angular deformations and that the values of the redox potential may be very sensitive to the capacity of the system to undergo low energy distortions which in turn will reflect its overall stereochemical freedom.

2.3. Polynuclear Iron-Ferredoxins: $Fe_4S_4^*$ and $Fe_8S_8^*$ Systems

Several models for the chromophores in these proteins have been postulated. Recent X-ray analyses of the high potential proteins from *Chromatium* and of ferredoxin from *P. aerogenes* have established that the iron and labile sulfur atoms are arranged in a 'cubane' cluster, the first coordination sphere of the iron atoms being completed by cysteine-sulfurs (Fig. 5). Structural parameters for the biological clusters and related iron-sulfur cubane complexes are collected in Table 4.

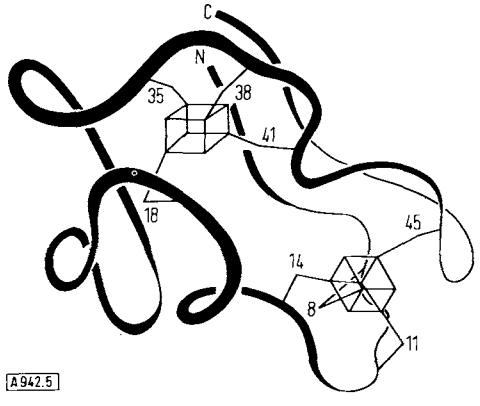


Fig. 5. Course of the main chain of ferredoxin (*P. aerogenes*) (after *Jensen*, 1972; see Ref. [64]).

Only one eight-iron protein has been analyzed completely but there are several lines of evidence pointing to the arrangement in *P. aerogenes* being representative of all the bacterial ferredoxins. The possibility of two separated clusters was recognized by crystallographic studies[7] on ferredoxin (*C. acidi-urici*) and by dithionite titration-reduction as monitored by the EPR spectra of two ferredoxins[93, 101]. The established homologies in the amino acid sequences of several bacterial ferredoxins[43], particularly in and around the eight cysteine residues, argue for closely related structures.

In ferredoxin from *P. aerogenes*, the two iron-sulfur chromophores are separated by 12 Å (Fig. 5). Each cubane cluster is surrounded by hydrophobic residues (Ile, Val, Pro, Gly); unlike structural expectations based on the sequence of cysteine residues, a cross-over of cysteine ligands occurs so that the terminal cysteine sulfur atoms of cluster 1 belong to residues 8, 11, 14 and 45, cluster 2 being formed from cysteine residues 18, 35, 38 and 41.

As discussed in Section 3, of particular significance are the two tyrosine residues, 28 and 2, which are arranged parallel to an Fe—S—Fe—S face of each cluster and separated by an average distance of 3.5—4.0 Å[64]. There is an invariance of aromatic amino acid residues at these positions in the sequences of all bacterial ferredoxins and their implication in the electron transfer process was hinted at earlier by observations of the loss of characteristic EPR and electronic absorption spectra of the ferredoxin on

Table 4. Structural parameters of biological clusters and related cubane-form iron-sulfur complexes.

acetylation of the tyrosine hydroxyl groups[94] and by changes in the ORD-CD spectra around 250 nm on reduction[95]. The overall conformation of the molecule is such that it possesses a fairly good two-fold rotation axis of symmetry.

The structural parameters of Table 4 can be rationalized in a fairly straightforward way which allows a definite view to be taken of the structural consequences of one-electron redox processes in the biological chromophores. The D_{2d} symmetry of $[(\pi\text{-}C_5H_5)FeS]_4$, with only one Fe—Fe bond per iron atom[86, 87], is consistent with an eighteen electron configuration around each iron (the π-C_5H_5 anion is assumed to be a six electron donor to the (formal) ferric ion (d^5); six electrons are donated to the irons by the sulfur atoms, the remaining one electron being used for the formation of one metal-metal bond per iron). For four-electron donor terminal ligands, such as the substituted alkene-1,2-dithiol tetranuclear complexes of *Balch*[96], two essentially equivalent metal-metal bonds per iron are to be expected. These complexes are, however, different in one important respect from the remaining tetranuclear species; the alkene-1,2-dithiol ligand is a powerful Lewis acid so that one or two electron reduction of the complex must leave its geometry essentially invariant, the added electrons being largely associated with the ligands. A nice demonstration of this lies in the magnetic circular dichroism (MCD) spectra of $[(\pi\text{-}C_5H_5)FeS]_4$, $[(CF_3CS)_2FeS]_4$, ferredoxin *(M. lactilyticus)* and their monoanions (Figure 6); the MCD spectra of the π-cyclopentadienyl complex and ferredoxin change on reduction; this establishes localization of the electron on the cluster in these two cases.

The thiolate-containing and biological clusters are much more symmetrical. This is to be anticipated: For a cluster

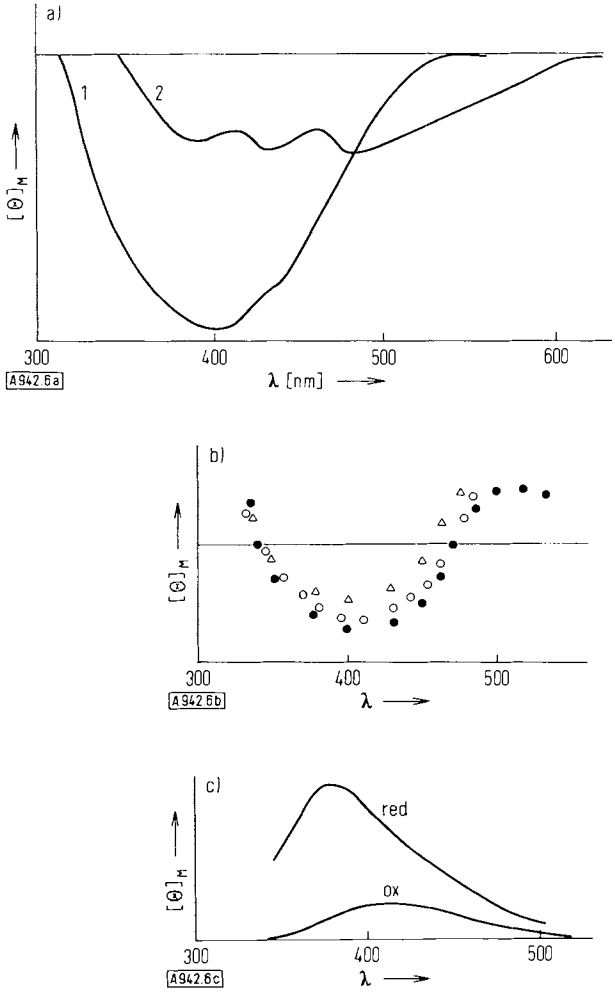

Fig. 6. MCD spectra of iron-sulfur complexes. a) 1: $[(\pi\text{-}C_5H_5)FeS]_4$; 2: $[(\pi\text{-}C_5H_5)FeS]_4^+$. b) $[(CF_3CS)_2FeS]_4^n$; △: $n=0$; ●: $n=1-$; ○: $n=2-$. c) oxidized (ox) and reduced (red) ferredoxin *(M. lactilyticus)*.

of zero net charge, the two electron donor terminal ligands and bridging sulfides provide a sixteen electron configuration around each (formal) ferric ion having three metal-metal bonds per iron. Reduction of these clusters will not change their geometries to any significant extent, the added electrons going to orbitals which are not strongly antibonding with respect to metal-metal bonds (one has still not reached, even in the case of the dianion, an effective 18 electron configuration for the metal).

3. Some Remarks and Speculations on Electron Transfer Processes in Metalloproteins

The available structural results on iron-sulfur proteins and cytochrome c proteins are beginning to pose some interesting problems and questions:

1. How does the $[RSFeS]_4$ cluster cover a range in redox potential of nearly 1 volt?

2. Given that the $[RSFeS]_4$ unit can accept up to two electrons, why have two one-electron transfers to separate clusters in the eight-iron proteins?

3. How is the function of a redox protein related to its total conformation?

4. Why does Nature require a range of iron-sulfur proteins based on mononuclear, binuclear and tetranuclear chromophores?

The range in redox potential of 0.7 V between the high potential protein and the bacterial ferredoxins implies that Nature discovered an effective ligand system for both di- and trivalent iron when sophisticated alternatives (heme) were unavailable. Three groups of redox systems involving iron-based chromophores may be delineated: cytochrome c_3, flavoproteins and iron-sulfur proteins with potentials around -0.3 V; flavoproteins, iron-sulfur proteins and cytochrome b with potentials around 0.0 V; and cytochrome c_1, c and a and copper- and iron-sulfur proteins with potentials up to $+0.25$ V. The electron transfer chain involves movement from one group to another through electron transfer components of alternating redox potential; moreover, potentials must be adjusted to those of the acceptor and donor groups—but in what manner?

The essential structural identity of the redox centers in HIPIP and ferredoxin makes, at first sight, an answer to the first question very difficult. But the difficulty really relates to the question as to whether the redox processes in HIPIP and ferredoxin are equivalent. There seems to be fairly conclusive evidence, particularly from magnetic susceptibility and magnetic resonance data[90], for the following oxidation state equivalences in the clusters:

$$[(C_6H_5CH_2S)FeS]_4^{2-} \equiv [\text{Reduced HIPIP}(Fe_4S_4)] \equiv [\text{Oxidized Fd}(Fe_4S_4)]$$

That the natural oxidation states of the biological clusters differ by one or two units must be related, presumably, to variations in the incidence of acidic and basic residues in and around the active site and hence to the overall protein makeup. The positive redox potential in HIPIP and the potential of -0.5 V in ferredoxin refer to electron transfer to clusters of quite different electronic configuration and are not comparable in any sense. The positive potential of the HIPIP protein is, of course, suggestive that, in so far as it is useful to talk about formal oxidation states, the iron is in the ferrous state; ESCA measurements appear to confirm this and also that ferric iron is present in oxidized ferredoxin[97].

Three separate points need to be made on the general observation that multi-electron transfer in enzymes or enzyme systems appears to require the appropriate number of one-electron acceptor chromophores (probably six Fe_4S_4 clusters in the case of nitrogenase as is discussed later). The first is the obvious truism—that the electron affinity of the monoanion cluster will be very low; the redox processes[90]

$$[C_6H_5CH_2SFeS]_4^{1-} \xleftarrow[-0.2\,V]{} [C_6H_5CH_2SFeS]_4^{2-} \underset{-1.2\,V}{\rightleftharpoons} [C_6H_5CH_2SFeS]^{3-}$$

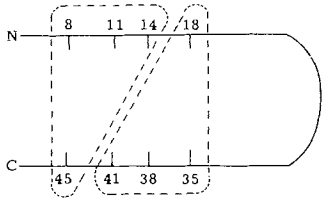
are well illustrative of this fact. The necessity for the biological system to operate around the hydrogen electrode potential implies that two-electron acceptor chromophores would have to exist naturally in a strongly oxidized state.

Secondly, and more importantly, we need to return to the question of the mechanism of the electron transfer and concomitant structural changes. The detailed X-ray analyses of oxidized and reduced cytochrome c by *Dickerson et al.*[98] demonstrate the remarkably general structural implications of one electron transfer reactions in so far as residues very far removed from the heme site change their conformation considerably. Of particular interest is the observation that the tyrosine residue—which sits over the redox center in the oxidized protein—is removed from any obvious interaction with it in the reduced enzyme. There are aromatic residues in close contact with the chromophores in both rubredoxin and ferredoxin and their role can be imagined to be one of 'one-electron trap-doors'. In oxidized ferredoxin, the interplanar separation between the tyrosine residues and a face of the tetranuclear cluster is *ca.* 3.5 Å; one would not necessarily postulate a strong charge-transfer contribution to the ground state non-valence interactions between these atoms. The aromatic residues may readily form radical anions—they are more generally exposed to the surface of the protein compared with the clusters which are located in hydrophobic pockets. The strong Lewis basicity of the aromatic radical anion coupled with good overlap of its antibonding orbital with a cluster orbital could obviously lead to facile one-electron transfer from the aromatic to the inorganic chromophore. Further electron transfer to one cluster is prevented by general conformational changes[*].

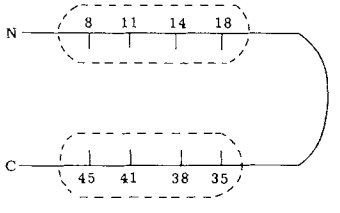
[*] *Note added in proof:* We have overlooked pulse radiolysis experiments which, *inter alia*, implicate aromatic amino acid residues as sites of transient radical intermediates in the reactions of OH radicals and e_{aq}^- with enzymes and metalloproteins [*e.g. N. N. Lichtin, J. Ogden*, and *G. Stein*, Biochim. Biophys. Acta *276*, 124 (1972); *M. Faraggi* and *I. Pecht*, J. Biol. Chem. (in press)]. RM is grateful to Professor *Stein* and Dr. *Pecht* for bringing these results to his attention. More directly ^{13}C magnetic resonance studies of the tyrosyl residues of ferredoxin (*C. acidi-urici*) implicate them in the electron transfer process [*E. L. Packer, H. Steinlicht*, and *J. C. Rabinowitz*, Proc. Nat. Acad. Sci. *69*, 3278 (1972)] although these authors imagine that the radical anion is produced by electron transfer *from* the iron-sulfur cluster. This suggestion may not be consistent with the MCD data of Figure 6.

We have previously emphasized the essential constancy of the tetranuclear cluster geometry to one-electron transfers; but this assertion now needs closer examination. Simple electron counting predicts, as we have seen, symmetrical clusters for $[RSFeS]_4^n$ and for the simple complexes, $[C_6H_5CH_2SFeS]_4^{n-}$ ($n=0,1,2$). But the thiolate cluster dianion has a small D_{2d} distortion. The simple rationale of the small distortion is to assume that in a regular cluster with equivalent metal-metal bonds, the highest lying energy level is orbitally degenerate and that the molecule is therefore subjected to the first order Jahn-Teller effect. A similar proposal has been made by *Frisch* and *Dahl* to explain the C_{2v} distortion of $[(\pi\text{-}C_5H_5)_3Co_3S_2]^+$ from the D_{3h} geometry of the uncharged Co_3S_2 fragment[99]. Thus redox coupled changes of the iron-iron bond lengths in the tetranuclear clusters ranging up to 0.1 Å or so can be anticipated and, as in cytochrome c, considerable overall conformational changes in the protein may result.

In this connection, it should be noted that on anaerobic reduction titration of the eight-iron ferredoxins, two different EPR signals arise which suggest two somewhat different paramagnetic sites—the redox properties of one cluster are connected with the oxidation state of the other although direct electron-electron interaction is surely unlikely. One may speculate that the need to have general allosteric changes in the protein following one-electron transfers is the reason for the crossover arrangement, A, rather than the sequential structure, B. Intuitively, structural changes would be more localized in the sequential structure and, functionally, the protein becomes less adaptable and flexible.



A



B

It will be of considerable interest to discover whether, as one might predict, crossover occurs in the four iron—four labile sulfur—six cysteine sulfur proteins. Here, as was mentioned earlier, the protein chain is a hybrid of the bacterial and plant protein sequences. The plant proteins have five cysteine residues and one may ask why they do not have a corresponding tetranuclear redox center? The much larger and more sophisticated plant protein chain must have evolved in response to such requirements as incorporation in membranes and lamellae; it can be imagined that the particular positioning of the cysteine residues is determined by criteria other than their potential for the formation of a tetranuclear cluster and that the binuclear structure is adequate over a more limited redox range.

4. Other Iron-Sulfur Proteins

Two enzyme systems are worthy of final mention. The structure and function of xanthine oxidase has been reviewed recently[54]; steric and functional interrelationships between the molybdenum-containing chromophores, the flavin groups and the iron-sulfur centers will become clear only through a complete structural analysis. That is just feasible whereas the characterization of the enzyme complex known as nitrogenase is only just beginning.

Apart from certain surfaces of transition metals, nitrogenase is probably the most versatile catalyst, reducing substrates as various as dinitrogen to protons. Nitrogenase from *C. pasteurianum*, *A. vinelandii*, and *K. pneumoniae* are identical in being made from two proteins (known variously as fraction I and fraction II; molybdoferredoxin and azoferredoxin; azofermo and azofer). The first has a molecular weight of 200,000—250,000 and contains 1—2 molybdenum atoms and *ca.* 20 iron and labile sulfur atoms; the second has a molecular weight of approximately 65,000 (two electrophoretically identical sub-units) with four iron and labile sulfur atoms (Table 1). The ESR spectrum of the smaller protein is very similar to those of the plant ferredoxins, the obvious implication being that each subunit has a binuclear chromophore rather than the four irons being arranged in a tetranuclear cluster.

There are sufficient biological analogs for the plausible suggestion that the two proteins are redox coupled in some way. It is attractive also to suggest that the 20—24 iron—labile sulfur atoms in molybdoferredoxin are in six tetranuclear clusters and to correlate this speculation with the six-electron reduction of nitrogen to ammonia[100]. But the basic premise of these speculations needs emphasis—it is that one could have simultaneous transfer of six electrons to the substrate from what must be considerably separated chromophores (the presently available evidence on the mechanism of biological nitrogen fixation is that it is a concerted process). Our view is that the correlation (if it exists) is coincidental; binuclear iron-sulfur chromophores in molybdoferredoxin cannot be excluded at this point. The structural implications of electron transfer in enzymes have been discussed earlier; a plausible speculation for nitrogenase would be that six-electron transfer to molybdoferredoxin is required to produce the overall conformation necessary for activity but that it is not necessary to envisage subsequent concerted electron transfer from the separated chromophores to the substrate. In this model electrons from solvent molecules would be conveyed to the molybdenum-iron reducing center *via* intervening aromatic residues in an entirely equivalent way to that which has been discussed for the cytochrome and ferredoxin proteins. This suggestion can be posed as a general question, "What is the evidence that electron-transfer enzymes actually transfer electrons to a substrate which is being reduced?" At present, the evidence is negligible if not non-existent.

We are grateful to G. Heath, R. Haines, and J. Postgate for many informative discussions and permission to quote unpublished material.

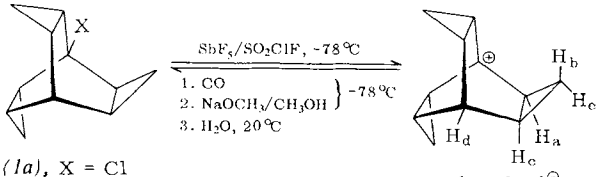
Stabilized Bridgehead Carbenium Ions: 1-Trishomobarrelyl and 1-Trishomobullvalyl Cations[**]

By *Armin de Meijere* and *Otto Schallner*[*]

Bridgehead carbenium ions which, due to ring strain, cannot assume the favored planar configuration are as a rule considerably destabilized compared to *tert*-alkyl carbenium ions[1]. Correspondingly, bridgehead halides of bicyclo[2.2.2]octane solvolyze at least 10^7 times more slowly than *tert*-butyl halides[2], but in contrast 1-chlorotrishomobarrelene and 1-chlorotrishomobullvalene react more than 10^2 and 10^4 times, respectively, faster than *tert*-butyl chloride[3]. Thus it was to be expected that in superacid media[4,5] the free carbenium ions of the latter systems should be stable and spectroscopically detectable.

If a cooled solution of SbF_5 in SO_2ClF is added with stirring to a suspension of 1-chlorotrishomobarrelene *(1a)* in SO_2ClF at -78 °C, a clear solution is formed whose ^{1}H-NMR spectrum shows four groups of lines for deshielded protons at $\delta = 2.34$ (q/3 H_c), 3.14 (q/3 H_c + H_d), 3.47 (q/3 H_b), and 3.72 ppm (q/3 H_a). In view of the number, intensity, and coupling of these NMR signals the solution contains

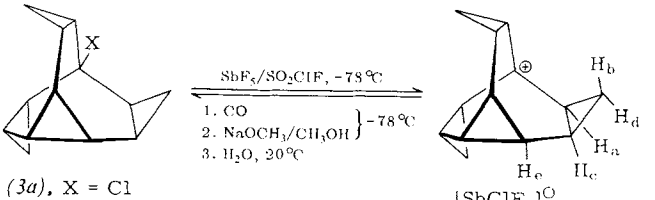


(1a), X = Cl
(1b), X = CO_2H
(1c), X = OCH_3

(2)

the free 1-trishomobarrelyl cation *(2)*. This solution can be warmed in the spectrometer stepwise to -10 °C without change in the spectrum; only at 0 °C does slow polymerization of the cation *(2)* set in. If, as a first step, carbon monoxide is fed into the solution of *(2)* at -78 °C, and the solution is then added dropwise to a cooled methanolic sodium methoxide solution and finally treated with water, 1-trishomobarrelenecarboxylic acid *(1b)*[6] and 1-methoxytrishomobarrelene *(1c)*[6] can be isolated in 53% and 24% yield, respectively.

The free cation *(4)* can be generated from 1-chlorotrishomobullvalene *(3a)* analogously to *(2)*. In this case the ^{1}H-NMR spectrum contains signals at $\delta = 1.66$ (broad s/3 H_c), 2.09 (broad s/3 H_d), 3.18 (2 broad s/3 H_b + 3 H_c), and 3.58 ppm (m/3 H_a). The solution of *(4)* is stable only up to -40 C; polymerization sets in at -30 C even after a few minutes.



(3a), X = Cl
(3b), X = CO_2H
(3c), X = OCH_3

(4)

The ion *(4)* can also be trapped without rearrangement; under the same conditions as for *(2)*, 1-trishomobullva-

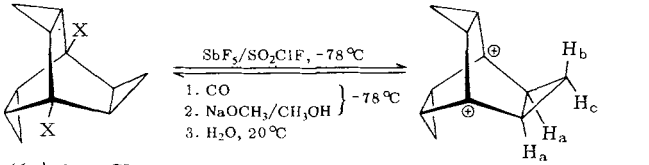
lenecarboxylic acid *(3b)*[6] and 1-methoxytrishomobullvalene *(3c)*[6] are formed in 9% and 65% yield, respectively.

The NMR signals of *(2)* and *(4)* are assigned by comparison of the spectra with those of the hydrocarbons trishomobarrelene and trishomobullvalene[7,8] and of a series of bridgehead derivatives of these systems[3,8]. On comparing the NMR data for *(2)* and *(4)* with those of the 1-bicyclo[3.2.2]nonyl cation *(5)* which has recently been investigated[5], one notices two important differences (cf. Fig. 1). The deshielding of the bridgehead proton in *(2)* and of the three "skeletal" cyclopropyl protons in *(4)* is appreciably less than that of the bridgehead proton in *(5)*. In contrast, all the "wing" cyclopropyl protons in *(2)* and *(4)* are relatively strongly deshielded, whereas in *(5)* the protons in the β-position to the carbenium ion center are notably less deshielded than those in the α-position. *Olah et al.*[5] have attributed the strong deshielding of the bridgehead proton in *(5)* to a charge delocalization which can take place on the one hand through the C—C σ-bond orbitals arranged parallel to the bridgehead p-orbitals and on the other hand directly through space ("cage effect"). It is readily understood that because of the more rigid geometry of *(2)* the distance between the two bridgehead C atoms is larger than for *(5)* and thus the charge delocalization through space is smaller for *(2)*. Apparently, in *(2)* and *(4)* the charge delocalization transmitted through the cyclopropyl-C—C bonding orbitals on to the opposite bridgehead must also be considerably less than that through the C—C σ bonds in *(5)*. The cyclopropane rings in the α-position to the carbenium ion center in *(2)* and *(4)* act, as a whole, so well as electron-donors that the positive charge is delocalized approximately equally on to all the centers of these "wing" cyclopropane rings[9].

The surprisingly high stability of *(2)* led us to treat 1,5-dichlorotrishomobarrelene *(6a)*[11] with SbF_5 in SO_2ClF at −78 °C. A smooth reaction occurred affording a clear solution whose ^{1}H-NMR spectrum showed three groups of lines at δ = 2.55 (q/3H_c), 3.41 (q/3H_b), and 3.75 ppm



(6a), X = Cl
(6b), X = CO_2H
(6c), X = OCH_3

2 $[SbClF_5]^{\ominus}$

(7)

(t/6H_a). Double resonance measurements revealed that upon irradiation at δ = 2.55 ppm the signals at 3.41 and 3.75 were simplified to a triplet and a doublet, respectively. The solution can be warmed stepwise to 0 °C without change in the NMR spectrum[12].

In view of these findings the solution might contain the 1,5-trishomobarrelyl dication *(7)*, which would be stabilized both thermodynamically and kinetically by the "wing" cyclopropane rings in the α-position to the carbenium ion centers, exactly as in *(2)*. Supporting chemical evidence was obtained, as for *(2)* and *(4)*, by trapping with carbon monoxide and sodium methoxide in methanol; 1,5-trishomobarrelenedicarboxylic acid *(6b)*[6] and 1,5-dimethoxytrishomobarrelene *(6c)*[6] were isolated in 74% and 5% yield, respectively.

However, the ^{1}H-NMR spectroscopic and chemical observations would also be consistent with the presence of a 5-chlorotrishomobarrelyl monocation in which the chlorine substituent undergoes a rapid intermolecular exchange reaction[14].

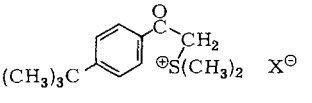
[14] Preliminary ^{13}C-NMR spectroscopic data indicate that in solution there exists a temperature dependent equilibrium between three cationic species, probably a monocation-monochloride, a monocation-monochloride-SbF_5 complex and the dication *(7)*.—Dr. *G. D. Mateescu*, Case Western Reserve University, Cleveland, Ohio (USA), has called our attention to the fact that he recently characterized the congressane dication [cf. Diss. Abstr. Int. *B 32*, 3223 (1971); Chem. Abstr. *76*, 98566f (1972)].

The Tetraphenylborate Ion as NMR-Shift Reagent for Sulfonium Compounds[1]

By *Günter Paulus Schiemenz* and *Hans Peter Hansen*[*]

Sulfonium salts such as *(1a)* and *(1b)* associate in only slightly polar solvents to short-lived contact ion pairs in which the charge centers are as close together as possible.



(1a), X = Br
(1b), X = $B(C_6H_5)_4$

If $B(C_6H_5)_4^-$ is the counter-ion then protons, particularly those in the α-position to the onium center, take up positions *above* one of the benzene rings of the anion; their NMR signals are thus strongly "shielded"[2]. The S—CH_3 signal of *(1b)* in CD_2Cl_2 is shifted upfield by 1.8 ppm with respect to the bromide *(1a)*, and the S—CH_2—CO— signal by 3.1 ppm (cf. Table 1). In the less polar solvent $CDCl_3$ the effects are even more pronounced, especially for S—CH_3 (2.3 and 3.3 ppm upfield shift respectively).

Institut für Organische Chemie der Universität
23 Kiel, Olshausenstrasse 40—60 (Germany)

Table 1. ^{1}H-NMR data for sulfonium salts *(1)*.

	δ in CD_2Cl_2 [ppm] [a]				δ in $CDCl_3$ [ppm] [a]			
	Concn. [b]	S—CH_3	S—CH_2CO	C—CH_3	Concn. [b]	S—CH_3	S—CH_2CO	C—CH_3
(1a) [c]	0.068	3.355	6.270	1.340	0.080	3.480	6.180	1.315
(1b) [d]	0.071	1.595	3.190	1.350	0.034	1.190	2.865	1.340
(1a)/*(1b)* *ca.* 1:1	0.069	2.240	4.325	1.350				

[a] Instrument: Varian A-60; relative to $(CH_3)_4Si$ as internal standard.
[b] Mol of salt per kg of solvent.
[c] From *p-tert*-butylphenacyl bromide and dimethyl sulfide in benzene at room temperature; m.p. 120—121 °C.
[d] Almost quantitative precipitation from equimolar aqueous solutions of *(1a)* and $Na[B(C_6H_5)_4]$; m.p. 156 °C.

The $(CH_3)_3C$-protons, however, no longer lie *above* the benzene ring but with free rotation around the C—C_{arom} bond approach to within a minimum distance from them approximately *in* the plane of the ring. Thus, as with *p-tert*-butylbenzylammonium salts[1, 3], these signals suffer a *slight downfield* shift; here too the anion effect is greater in $CDCl_3$ than in CD_2Cl_2 (cf. Table 1).

Mixtures of *(1a)* and *(1b)* show complete averaging. So, by choice of the appropriate concentrations, the signals can be shifted, without broadening, to any desired position within the limits set by the pure salts. $B(C_6H_5)_4^-$ is thus an effective nuclear magnetic resonance shift reagent for sulfonium cations.

Conversion of Vicinal Diols into Dicarbonyl Compounds by Manganese Dioxide

By *Günther Ohloff* and *Wolfgang Giersch*[*]

Methods for oxidative cleavage of vicinal diols have considerable preparative interest[1]. We here report a new procedure for almost quantitative fragmentation of these compounds in the heterogeneous phase under extremely mild conditions. We have found that treating 1,2-diols of varying degrees of substitution with an excess of activated MnO_2[2] and CH_2Cl_2 affords dicarbonyl fragments at room temperature[3].

As Table 1 shows, only 1,2-*cis*-diols and analogous *trans*-compounds with a flexible arrangement of their hydroxyl groups undergo this new type of fragmentation. Even diols subject to extensive sterical hindrance give the expected fragments quite smoothly (see the last example in Table 1). On the other hand, 9,10-*trans*-decalindiol[4] remains inert even if the reaction time is considerably prolonged.

If the hydroxyl groups are secondary, dehydrogenation is observed in isolated cases instead of complete fragmentation. For example, dodecanedial[5], as a fragmentation product of 1,2-*cis*-cyclododecanediol[6] is accompanied by 14% of 1,2-cyclododecanedione[7] and traces of 2-hydroxycyclododecanone[8].

Table 1. Products of oxidation of 1,2-diols by manganese dioxide.

Starting material	Product	Time [h]	Conversion [%]	Yield [%]
 [6]	 [5]	4	100	85
 [9]	 [10]	2	100	70
 [4]	 [4]	1	100	90
 [11]	 [4]	72	0	
		5	100	70
 [12]		1	100	60
 [13]		2	100	90

Experimental

9,10-*cis*-Decalindiol (1 g)[4] is stirred in CH_2Cl_2 (50 ml) with activated MnO_2 (20 g)[2] at room temperature. Thin-layer chromatographic analysis showed the diol to have reacted completely after 1 h. The MnO_2 was then filtered off on Celite, the solvent was removed at water-pump vacuum in a rotary evaporator, and the residue was distilled, affording 1,6-cyclodecanedione, m.p. 92—95 °C (from acetone) (0.9 g, 90%)[4]. The spectral data for gas-chromatographically pure dione accord with those of the authentic product[4].

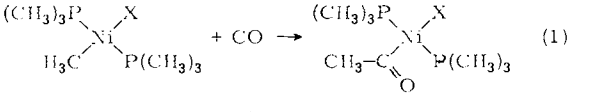
Acetylnickel Halides by Insertion of CO into Ni—C σ-Bonds

By *Hans-Friedrich Klein*[*]

The insertion of carbon monoxide into the nickel-carbon bond of an intermediate is seen as the main principle in many catalytic reactions[1]. However there has hitherto been no proof of such a step since acetylnickel compounds could not be isolated as intermediates in these processes.

We have found that solutions of methylnickel halide complexes[2] with sterically undemanding trimethylphosphane ligands absorb CO even at normal pressure.



(1)

(1), X = Cl: golden-yellow needles, m.p. 98–99 °C

(2), X = Br: orange-yellow needles decomp. > 88 °C

(3), X = I; brick-red crystals, decomp. > 95 °C

The bis(trimethylphosphane)acetylnickel halides thus formed in smooth reactions (in pentane at 20 °C; quantitative yield) can be isolated in crystalline form and show considerable thermal stability compared with other acetyl derivatives of transition metals[3]. Decarbonylation, by reversal of eq. (1), occurs only to a limited extent, even under drastic conditions: *(1)* can even be transported *in vacuo* (80 °C, 0.1 torr).

The IR spectra of all three complexes contain a very strong, broad C=O stretching vibration band (1635—1650 cm^{-1}) of the acetyl group attached to the nickel. In the region of the Ni—C stretching vibration there are strong bands at 538 *(1)*, 537 *(2)*, and 530 cm^{-1} *(3)*.

The ^{1}H-NMR spectra become deceptively simple at 30 °C owing to rapid ligand exchange: the resonances of the PCH_3 and $COCH_3$ protons appear as singlets with relative areas 6:1; only at low temperature does one observe the PCH_3 resonance as a pseudotriplet, which is typical of the $H_9PP'H_9'$ spin system of *trans*-trimethylphosphane ligands. Under these conditions (5% in CH_2Cl_2, −40 °C) the $COCH_3$ protons appear as triplet ($^4_{cis}J(PH) = 1.4$—1.7 Hz) owing to long-range coupling with two equivalent ^{31}P nuclei. Therefore the products of the CO insertion reaction also adopt a *trans*-square-planar structure in solution. A mode of reaction has thus been realized for nickel that has been known for quite a long time for organo-palladium and -platinum complexes[4].

The only evidence that this CO insertion reaction is reversible is supplied by the reaction of *(1)* with tetrakis(trimethylphosphane)nickel(0) in the course of which a CO ligand is actually mobilized from the acetylnickel group:

$$L_2Ni(COCH_3)Cl + L_4Ni \rightarrow L_2Ni(CH_3)Cl + L_3NiCO + L \qquad (2)$$
$$L = (CH_3)_3P$$

This CO enters as superior ligand into the Ni^0 system in place of a phosphane ligand which in turn is taken up as additional ligand by the methylnickel complex[2].

It is thus not surprising that in the oxidative addition of acetyl chloride to $[(CH_3)_3P]_4Ni$[5], with its complicated course, the complexes expected from eq. (2) are found experimentally as the main products.

It is thus now clear why decarbonylation always occurs in the oxidative addition of acyl halides to phosphane-substituted Ni^0 compounds[6], whereas the acyl stage can be observed only with Ni^0 complexes containing the CO-like isocyanide ligands[7].

Transannular π-π Interaction in Cyclophanes[1]

By *Roberto Boschi* and *Werner Schmidt*[*]

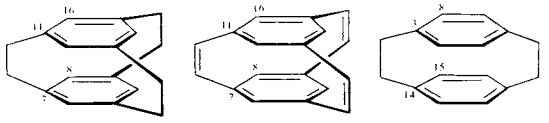
Cyclophanes are distinguished by unusual physical and chemical properties whose origin has been the subject of lively discussion in the last two decades[2]. Three qualitative models—π electron repulsion between the benzene units[3], hyperconjugation with the bridging CC bonds[4], and nonplanarity of the benzene rings[5]—have been

[*] Dr. W. Schmidt [**] and Dr. R. Boschi [***]
School of Molecular Sciences, The University of Sussex
Brighton BN1 9QJ (England)

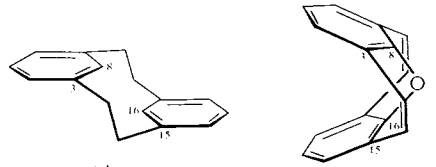
[**] New address: Institut für Organ. Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[***] New address: TWP-Sandoz AG, CH-4053 Basel
Dornacherstrasse 210 (Switzerland)

employed to rationalize these effects. In order to discriminate between these alternatives, we have determined the interaction of the benzene e_{1g} orbitals in the highly strained cyclophanes *(1)*—*(5)* by photoelectron (PE) spectroscopy.



(1) *(2)* *(3)*



(4) *(5)*

Table 1. Vertical ionization energies *IE* and energy differences ΔIE between the s and a components of the benzene e_{1g} levels [6] in [2.2.2](1,3,5)cyclophane *(1)*, [2.2.2](1,3,5)cyclophane-1,9,17-triene *(2)*, [2.2]paracyclophane *(3)*, [2.2]metacyclophane *(4)*, and 8,16-oxido-*cis*[2.2]metacyclophane-1,9-diene *(5)*.

Compound	*IE* (eV)	ΔIE_s	ΔIE_a
(1), D_{3h}	7.70 e″ 8.75 e′	1.05	1.05
(2), D_{3h}	8.06 e″ 9.24 e′	1.18	1.18
(3), D_{2h}	8.08 b_{3g} ≈8.6 b_{2g} ≈8.6 b_{2u} 9.53 b_{3u}	0.5	0.9
(4), C_{2h}	8.24 b_u 8.44 a_u 8.75 b_g 9.25 a_g	1.01	−0.3
(5), C_{2v}	7.95 b_2 8.62 b_1? 8.84 a_1? 9.45 a_2	0.2	1.50

Ionization energies *IE* as obtained from the PE spectra are given in Table 1. ΔIE_s denotes the energy difference between the out-of-phase and the in-phase linear combination of the e_{1g}(s) orbitals; ΔIE_a refers accordingly to the e_{1g}(a) components.

$$e_{1g}(s) = 1/2\sqrt{3}(2\varphi_1 + \varphi_2 - \varphi_3 - 2\varphi_4 - \varphi_5 + \varphi_6)$$
$$e_{1g}(a) = 1/2(\varphi_2 + \varphi_3 - \varphi_5 - \varphi_6)$$

For symmetry reasons, both splittings are identical in *(1)* and *(2)*.

The strong transannular interaction, which is expressed in the ΔIE_s and ΔIE_a data, is surprising in view of the relatively large intramolecular distances between the benzene rings: only in *(5)* is this distance considerably smaller than the sum of the Van der Waals radii.

The ΔIE splittings found for *(3)* and *(4)* exceed earlier estimates[3], which were based on UV data, by nearly one power of ten. It should be noted at this point that the direct transannular π-π interaction of the e_{1g} orbitals is partly compensated, in the case of the e_{1g}(a) components of *(4)* even over-compensated, due to the admixture of occupied σ levels of the CC bridges. The ΔIE values in *(1)* and *(2)* are even larger than those in *(3)* and *(4)*; the former pair must consequently be classified as the most strained compounds of the series.

Of greater relevance than the ΔIE splittings are the individual π-π resonance integrals which can be deduced from the ionization energies with the aid of a simple ZDO model[11]. As can be seen from Table 2, they correlate

Table 2. Resonance integrals, $\beta_{\mu\nu}$, of the transannular interaction, and interatomic distances, $R_{\mu\nu}$.

Compound	Centers	$\beta_{\mu\nu}$(eV)	$R_{\mu\nu}$(Å)
(1)	7,11 8,16	−1.6	—
(2)	7,11 8,16	−1.5	2.80 [7]
(3)	3,14 8,15	−1.5 −0.9	2.778 [8] 3.093
(4)	8,16 3,15	−3.2 −0.1	2.69 [9] 3.02
(5)	8,16 3,15	−2.3 ≈0	2.113 [10] 3.075

well with the intermolecular distances and the relative orientation of the interacting π-AOs; *i.e.*, the greater the σ-type overlap at a given distance, the greater is $\beta_{\mu\nu}$.

Whereas π electron delocalization in *(1)*—*(3)* extends over the carbon atoms of *both* benzene units, it is confined in *(4)* and *(5)* to C-8 and C-16; the absolute value of the resonance integral corresponds to that of a normal aromatic π bond. This finding provides the basis for an understanding of the tendency toward transannular ring closure which is commonplace in [2.2]metacyclophane chemistry. Thus, in *(4)* even the mild conditions of electrophilic substitution (or of irradiation in the presence of I_2, or reduction[12] with K) are sufficient to effect elimination of the intra-annular hydrogen atoms to give the 4,5,9,10-tetrahydropyrene system. In the case of *(5)* either oxygen expulsion and subsequent aromatization to pyrene (CF_3COOH/30 °C; benzene/214 °C) occurs, or a 1,3 shift of the oxygen atom affords 1-pyrenol (CH_3OH/123 °C)[13].

Moreover, it may be concluded from the present data that the unusual molecular geometries[7–10] of cyclophanes (distortion of the benzene rings, extremely short H···H contacts) are a consequence, rather than the origin, of the transannular π-π interaction.

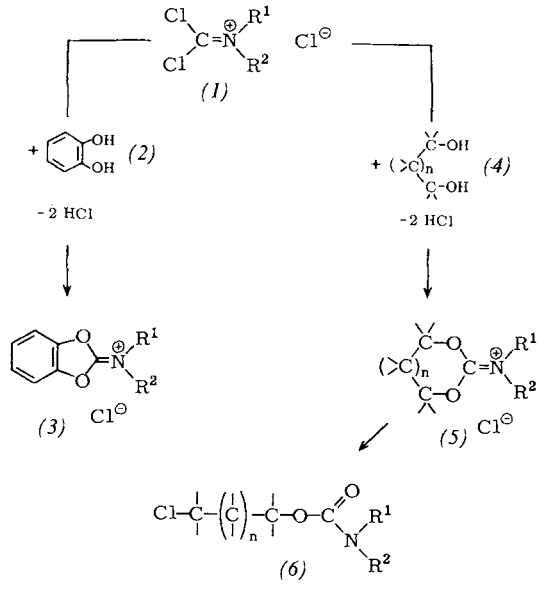
Synthesis of Chloroalkyl Carbamates from Diols and Phosgeneimmonium Salts[1]

By *Brigitte Le Clef, Jacques Mommaerts, Bernard Stelander*, and *Heinz Günter Viehe*[*]

(Dichloromethylene)ammonium chloride (phosgeneimmonium chloride) *(1)* condenses with *o*-dihydroxybenzene *(2)* to give the 1,3-benzodioxol-2-ylideneammonium chlorides *(3)*[2]. Aliphatic diols *(4)* have now been found to undergo a similar reaction giving chloroalkyl carbamates *(6)* *via* the thermally unstable immonium chloride *(5)*. Generally high yields are obtained for symmetrical 1,2-; 1,3-; and 1,4-diols (Table 1). Chloroalkyl carbamates were previously accessible only by multistep syntheses with phosgene, isocyanates, or carbamoyl halides[4-6].

The reaction of pinacol (2,3-dimethylbutane-2,3-diol) with *(1)* stops at the immonium carbonate *(5)*, which can be isolated as a thermally stable compound. This stability probably arises from steric hindrance to attack by the chloride ion which would lead to ring opening. This concept is well substantiated by the observation that *cis*-cyclohexane-1,2-diol forms the *trans*-chlorocyclohexyl carbamate and that unsymmetric diols preferentially give products resulting from attack by the chloride ion at the least hindered side of the ring in *(5)* (Table 2).



In the presence of HCl, diols react with cyanogen chloride to give chloroalkyl carbamates bearing no substituent on the nitrogen *(6)*, $R^1=R^2=H$[3], and chloroalkyl carbamates having a secondary nitrogen atom *(6)*, $R^2=H$, can be obtained from isocyanide dichlorides and HCl, presumably also *via* an intermediate of type *(5)*[7] (Table 3).

Experimental:

Synthesis of 2-chloroethyl N,N-dimethylcarbamate: 3.1 g (0.05 mol) of glycol is added dropwise at 25 °C to a stirred suspension of *(1)* (8.1 g, 0.05 mol) in dichloromethane solution. Stirring is continued until *(1)* is completely dissolved. The solvent is then evaporated off and the residue is distilled (90 °C/13 torr). 7.5 g (*ca.* 100%) of 2-chloroethyl *N,N*-di-

Heterocycles from Compounds Containing Two Nucleophilic Centers and Phosgeneimmonium Salts[1]

By *Françoise Hervens* and *Heinz Günter Viehe*[*]

N-(Dichloromethylene)-*N,N*-dimethylammonium chloride ("phosgeneimmonium chloride") *(1)* possesses three very mobile chlorine atoms and is therefore suitable as a starting material for condensation reactions[2–6]. We now wish to report that *(1)* reacts readily with dinucleophiles such as unsymmetrically substituted arylhydrazines *(2)*, amidrazones *(3)*, hydrazides *(4)*, or *o*-phenylene derivatives *(5)* to give high yields of indazoles *(6)*, triazoles *(7)*, oxadiazoles *(8)*, and benzoxazoles *(9)*, X = O, or benzothiazoles *(9)*, X = S. No intermediates have been isolated, although the reaction was followed by NMR spectroscopy until formation of the heterocycles was complete. The structures of the products synthesized were confirmed by NMR, IR, and mass spectrometry.

[a] These compounds have also been synthesized by *K. Nagarajan* and *V. Ranga Rao*, Indian J. Chem. 7, 964 (1969).

Thus phosgeneimmonium salts prove to be at least as useful for the synthesis of heterocycles as the related thioformamide chlorides[7], which suffer from the disadvantage that they can eliminate either HCl or HSR.

Experimental:

Synthesis of (6): 1 mol of *(1)* and 1 mol of *(2)* are boiled under reflux in chloroform for 2 hours until evolution of HCl stops. The solvent is evaporated off and the residue is treated with 2 N KOH and extracted with methylene chloride. The extract is dried over sodium sulfate, the solvent evaporated off, and the residue distilled at 150 °C/0.1 torr.

Synthesis of compounds (7) to (9): 1 mol of *(3)*, *(4)*, or *(5)* and 1 mol of *(1)* are boiled under reflux in chloroform for 1—2 hours until evolution of HCl stops. The solvent is then evaporated off and the residue washed with ether, treated with a solution of 2 N KOH, and then extracted with methylene chloride. The extract is dried over sodium sulfate, filtered, and the solvent finally evaporated off.

Formation of 1,2,4-Triazolin-5-ones from *tert*-Butylnitroacetylene and Phenylhydrazines[1]

By *Cécile Derycke, Volker Jäger, Jean Paul Putzeys, Maurice Van Meerssche*, and *Heinz Günter Viehe*[*]

Electron-poor nitroacetylenes[2] react with amines and hydrazines to give β-nitroalkenylamines *(2)* and β-nitroalkylidenehydrazines *(3)*, respectively. Surprisingly, however, the reaction of *tert*-butylnitroacetylene *(1)* with phenylhydrazine *(4a)* in ethereal solution at 0 °C gives a new condensation product *(5a)* by loss of water.

The IR spectrum of *(5a)* shows an absorption at 2265 cm^{-1} which is attributed to the —C≡N→O function. *(5a)* can be reduced to the corresponding nitrile *(6a)* by triethyl phosphite in refluxing benzene[3]. On standing for three days at 0 °C, *(5a)* undergoes isomerization, the rate of which can be increased by refluxing in $CHCl_3$. X-Ray analysis shows the isomer to have the structure 3-*tert*-butyl-1-phenyl-1,2,4-triazolin-5-one *(7a)*.

The substituted phenylhydrazines *(4b)* and *(4c)* likewise afford the compounds *(7b)* and *(7c)*.

The nitrile oxides *(5)* and the triazolinones *(7)* can also be obtained from 3,3-dimethyl-2-iodo-1-nitrobutene *(8)* and the phenylhydrazines *(4)* with KOH.

Experimental:

Synthesis of (5a) from (1): Compound *(1)* (258 mg, 2.03 mmol) in ether (5 ml) is added over 5 min with stirring

(7c)	87 [a]	220	1685	1.4(9H,s); 2.3(3H,s); 7.15,7.85(4H,m); 12.1(1H,s)

[a] From *(1)* and *(4)*.

to *(4a)* (216 mg, 2 mmol) in ether (5 ml) at 0 °C. The solvent is immediately evaporated off and the residue recrystallized from ether/petroleum ether (b. p. 40—60 °C) to give 385 mg (88%) of *(5a)*.

Synthesis of (7a) from (8): Compound *(8)* (510 mg, 2 mmol) in ether (5 ml) is added with stirring to *(4a)* (216 mg, 2 mmol) in ether (5 ml) and KOH (200 mg) at 0 °C. After the reaction mixture has stood for three days the solvent is evaporated off and compound *(7a)* is obtained by recrystallization of the residue from $CHCl_3$/petroleum ether (b. p. 60—80 °C); yield 91 mg (42%).

Reduction of (5a) to (6a): Triethyl phosphite (665 mg, 4 mmol) is added to *(5a)* (225 mg, 1.04 mmol) in dry benzene (10 ml) over 5 min at room temperature. After 15 minutes' heating on a water bath the mixture is diluted with its own volume of benzene and shaken with 5% H_2SO_4 (20 ml) to decompose excess phosphite. As soon as the characteristic odor of this compound has disappeared the organic layer is washed four times with water and the solvent is evaporated off. The remaining oil is crystallized from ether/pentane to yield 123 mg (62%) of *(6a)*.

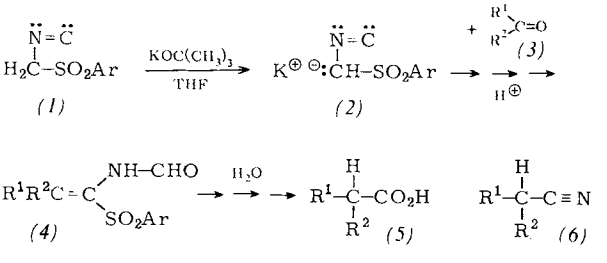
Conversion of a Ketone or an Aldehyde into the Next Higher Nitrile[1]

By *Ulrich Schöllkopf* and *Rolf Schröder*[*]

In a previous communication[2] we described the synthesis of *N*-(1-arenesulfonyl-1-alkenyl)formamides *(4)* from α-metalated arenesulfonylmethyl isocyanides *(2)* and carbonyl compounds *(3)* and their conversion into the next higher carboxylic acid *(5)* by acid or alkaline hydrolysis. The metalated isocyanides were obtained by reaction of arenesulfonylmethyl isocyanides *(1)* with potassium *tert*-butoxide in tetrahydrofuran[2]. At that time we did not engage in a detailed study of the question of which intermediates are involved in the hydrolysis step *(4)*→*(5)*[2]. The observation[3] that 2-cyanoadamantane is formed in the reaction of adamantanone with tosylmethyl isocyanide in ethanol/dimethoxyethane in the presence of sodium ethoxide suggested the intermediacy of the nitriles *(6)* during alkaline hydrolysis and their general accessibility from *(4)*.



This is actually found to be the case. As we have shown (Table 1) the nitriles *(6)* are formed in good yields when *N*-(1-arenesulfonyl-1-alkenyl)formamides *(4)* are refluxed

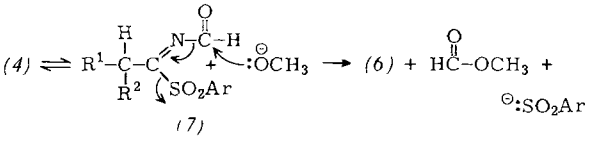
[1] Nitroacetylenes, Part 4.—Part 3: *V. Jäger* and *H. G. Viehe*, Angew. Chem. *82*, 836 (1970); Angew. Chem. internat. Edit. *9*, 795 (1970).

[2] *V. Jäger* and *H. G. Viehe*, Angew. Chem. *81*, 259 (1969); Angew. Chem. internat. Edit. *8*, 273 (1969).

[3] *C. Grundmann* and *H. D. Frommeld*, J. Org. Chem. *30*, 2077 (1965), and references cited therein.

[*] Prof. Dr. U. Schöllkopf and Dr. R. Schröder
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

for 15 min with sodium methoxide in methanol. Subject to a detailed study we would tentatively formulate the conversion *(4)*→*(6)* as proceeding *via* the formylimino compounds *(7)* that are tautomeric to *(4)*, their formyl group undergoing nucleophilic displacement from the nitrogen by the methoxide ion with concomitant elimination of an arenesulfinate ion.



(7)

Table 1. Nitriles *(6)* prepared from substituted formamides *(4)*, Ar = *p*-CH_3—C_6H_4.

R^1	R^2	*(6)*	Yield [%]	B. p. [°C/torr]
C_6H_5	H	benzyl cyanide	81	107/12
—$(CH_2)_5$—		cyclohexanecarbonitrile	85	185/760
$(CH_3)_3C$	H	neopentanecarbonitrile	72	135/760
C_6H_5	CH_3	α-methylbenzyl cyanide	69	108/12
CH_3	CH_3	isobutyronitrile	93 [a]	

[a] Crude yield; product identified by gas chromatographic comparison with an authentic sample.

Thus a method is now available for transforming the substituted formamides *(4)*, accessible by "formylaminomethylenation"[2] of carbonyl compounds *(3)*, into either the next higher carboxylic acid *(5)* or the next higher nitrile *(6)* according to choice.

General procedure for the conversion (4)→(6):

A piece of sodium (0.46 g, 20 mmol) is dissolved in methanol (30 ml). *N*-(1-Tosyl-1-alkenyl)formamide *(4)*, Ar = *p*-CH_3—C_6H_4[2], (10 mmol) is added to the resulting gently boiling solution (85 °C bath temperature) and the reaction mixture is refluxed for a further 15 min. After cooling the solvent is removed at 25 °C in a rotary evaporator *in vacuo*. Water (25 ml) is then added and the ethereal solutions obtained on ether extraction (2 × 30 ml) are dried ($MgSO_4$) and worked up in the customary manner. The nitriles *(6)* were distilled (cf. Table 1).

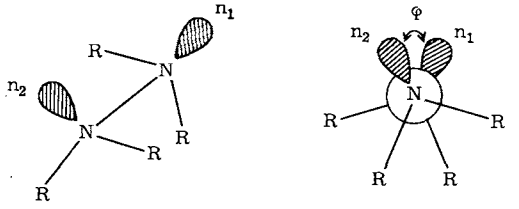
Photoelectron Spectra and Conformation of Hydrazine Derivatives[1]

By *Paul Rademacher*[*]

Photoelectron (PE) spectroscopy permits quantitative determination of the interaction of molecular orbitals[2]. Since in hydrazine derivatives R_2N—NR_2 the extent of interaction between the two nitrogen lone pairs n_1 and n_2 should vary considerably with the dihedral angle φ between the two halves of the molecule, PE spectroscopy should provide relatively simple access to the conformation of these compounds.



Calculations by the MINDO/2 procedure[3] showed that the energy of the two lone-pair molecular orbitals $E(n_+)$ and $E(n_-)$ varies continuously with φ[4]. Thus at φ = 0° n_- lies 1.45 eV above n_+, at φ = 80° n_- and n_+ have the same energy, and at φ = 180° n_- lies 2.41 eV below n_+. This change of $\Delta E = E(n_-) - E(n_+)$ with φ should be sufficient to determine the dihedral angle from the vertical ionization potentials $I_v(n_+)$ and $I_v(n_-)$ for hydrazine derivatives of different conformations.

By use of *Koopmans'* theorem[5], which states that the orbital energy equals the negative vertical ionization energy, the data in Table 1[6] were obtained in the following way: First, the $\Delta E = f(\varphi)$ curve calculated by the MINDO/2 method was calibrated by means of compounds *(1)*, *(11)*, and *(12)* whose dihedral angles φ were previously known. The value of φ could then be read off from the new curve for each of the molecules listed provided that $I_v(n_+)$ and $I_v(n_-)$ had been assigned in the photoelectron spectra. The assignments were made by MINDO/2 calculations.

Table 1. Vertical ionization potentials (*I*), orbital energy differences (Δ*E*), and dihedral angles (φ) of hydrazine derivatives.

Compound	$I_v(n_-)$ [eV]	$I_v(n_+)$ [eV]	*E* [eV]	φ [°]
Hydrazine *(1)* [7]	10.70	10.02	−0.68	90 [8]
1,2-Dimethylhydrazine *(2)*	9.65	9.02	−0.63	88
Tetramethylhydrazine *(3)*	8.77	8.38	−0.39	79
1,2-Diethylhydrazine *(4)*	9.46	8.88	−0.58	86
1,2-Diisopropylhydrazine *(5)*	9.91	8.34	−1.57	125
Pyrazolidine *(6)*	8.85	7.90	−0.95	101
Piperidazine *(7)*	9.52	8.72	−0.80	95
1,1'-Biaziridine *(8)*	11.18	8.65	−2.53	180
1,1'-Bipiperidine *(9)*	8.37	8.05	−0.32	77
1,5-Diazabicyclo[3.3.0]octane *(10)*	7.90	9.47	+1.57	12
3,4,4,5-Tetramethyl-4*H*-pyrazole *(11)*	10.12	11.93	+1.81	0
Acetaldehyde azine *(12)*	11.63	9.11	−2.52	180

The results for compounds *(2)* to *(4)* show that methyl and ethyl substituents have a negligible influence on the *gauche*-conformation — a finding in agreement with vibrational spectroscopic investigations of *(3)*[9] and electron-diffraction measurements of *(2)*[10], which indicate the *gauche*-conformation for these compounds. In *(5)* the hydrazine skeleton is clearly more twisted by the larger substituents.

The cyclic derivatives *(6)* and *(7)* also exist in the *gauche*-conformation.

[*] Dr. P. Rademacher
Organisch-Chemisches Institut der Universität
44 Münster, Orléansring 23 (Germany)

The dihedral angle $\varphi = 180°$ for 1,1'-biaziridine *(8)* agrees with the results of vibrational spectroscopic[11] and electron-diffraction studies[12] which indicated the centrosymmetric *s-trans*-conformation for this molecule. The six-membered ring homolog *(9)*, however, possesses the *gauche*-conformation analogous to the open-chain compounds *(1)* to *(4)*.

In the bicyclic compound *(10)* the repulsion between n_1 and n_2 clearly prevents the molecule from assuming the conformation with minimal ring strain ($\varphi = 0°$), in agreement with IR and Raman spectra of *(10)* which exclude a structure with C_{2v} symmetry.

The results so far with symmetrical compounds suggest that the dihedral angle and thus the conformation of hydrazine derivatives can be determined accurately from the splitting of the two lone-pair molecular orbitals.

Polymeric Octamolybdate Ions in the Crystal Structure of $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$[**]

By *Irene Böschen, Bruno Buss, Bernt Krebs*, and *Oskar Glemser*[*]

From 0.20—0.25 M aqueous[1] or acidified ammonium heptamolybdate solutions, the latter containing NH_4Cl[2], there separate after about two to three weeks colorless needles of an octamolybdate of the composition $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$. We have now elucidated its structure. The compound forms monoclinic crystals belonging to space group $P2_1/c$ with $a = 9.519 \pm 0.005$, $b = 11.309 \pm 0.006$, $c = 15.049 \pm 0.008$ Å; $\beta = 109.50 \pm 0.03°$, $Z = 2$, $d_{X\text{-ray}} = 3.00$, $d_{exp} = 3.01 \pm 0.02$ g cm^{-3} (cf. [1]).

For the determination of the structure the intensities of 3020 non-equivalent reflections were measured with $Mo_{K\alpha}$ radiation on a Hilger-Watts four-circle diffractometer. The structure could be completely solved by Patterson and Fourier methods. The parameters of all the atoms except H were refined by the method of least squares to an R value of 6.4% (anisotropic temperature factors). The X-ray structure analysis revealed one molecule of water of crystallization per molecule of octamolybdate more than was originally[1] assigned on the basis of analysis.

Figure 1 shows the anion of the structure in an idealized form established in this way. Compact octameric units are linked in each case through a common oxygen atom to give endless chains. The octameric unit is built up of distorted MoO_6 octahedra linked *via* edges and corners, edge sharing predominating in agreement with the structural principles of other isopolymolybdates. Unlike all

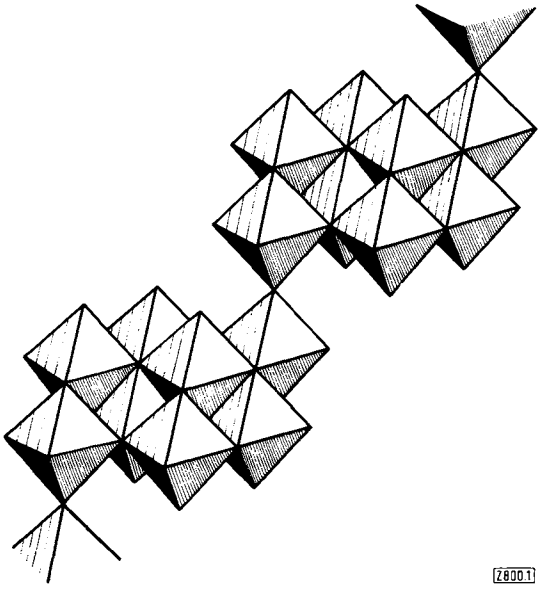

Fig. 1. Polymeric octamolybdate ion $[Mo_8O_{27}]^{6-}$

the other isopolysalts so far known as crystallizing from aqueous solution, the present compound displays polymeric units in its structure. Chain formation was previously observed only for isopolysalts obtained from melts. Interestingly, the octameric unit corresponds in structure to that in the salt $K_2Mo_4O_{13}$ crystallized from melts[3,4]. However, the units in $K_2Mo_4O_{13}$ obtained from melts polymerize *via* shared octahedral edges, whereas the units in $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$ obtained from solution are linked by shared corners.

The Mo—O bond lengths are in the range 1.697 to 2.401 Å with values of 1.697 to 1.732 Å for the terminal bonds. The Mo···Mo distances amount to 3.258 to 3.472 Å for edge linkage and 3.779 to 3.969 Å for corner linkage. The Mo atoms are shifted towards the free corners and edges of the MoO_6 octahedra owing to Mo/Mo Coulomb repulsion and the differing Mo—O bond strengths. In the crystal the anion chains are linked by hydrogen bonds to NH_4^+ ions and water molecules.

Further details of the structure will be reported elsewhere[5].

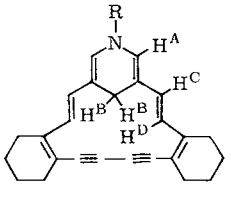
Synthesis of a Methylene-Bridged Didehydroaza[21]annulene, a Diatropic Heteroannulene[1] [***]

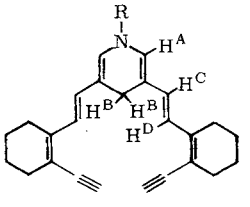
By *Philip J. Beeby* and *Franz Sondheimer*[*]

We have recently described the synthesis of the methylene-bridged didehydroaza[17]annulenes *(1a)*—*(1d)*[2,3]. Comparison of the ^{1}H-NMR spectra of these 18π-electron systems with those of the models *(2a)*—*(2d)* clearly showed the aza[17]annulenes to possess a diamagnetic ring current (=diatropic)[4], these being the first aromatic macrocyclic heteroannulenes of the pyrrole type to be obtained. This type of synthesis appeared to be applicable to the preparation of vinylogous methylene-bridged didehydroaza[19]- and [21]annulenes. These were required in order to discover whether the same alternation of electromagnetic properties between $(4n+2)$ and $4n$ π-electron systems occurs in these heteroannulenes as has already been demonstrated in the carbocyclic annulene series[4]. This synthetic objective has been realized in practice.

The preparation of the methylene-bridged didehydroaza[21]annulene *(7)* is described in the present communication, and that of the corresponding aza[19]annulene in the following one.

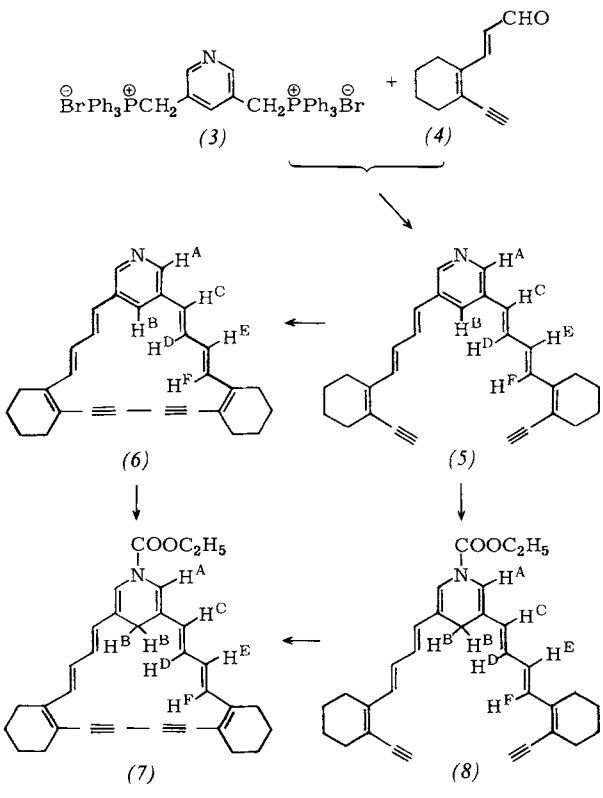


(1a), R = CH_3
(1b), R = H
(1c), R = $COOC_2H_5$
(1d), R = $COCH_3$



(2a), R = CH_3
(2b), R = H
(2c), R = $COOC_2H_5$
(2d), R = $COCH_3$

Wittig reaction of *(3)*[2] and 2 molar equivalents of *(4)*[5] in dimethylformamide with ethanolic lithium ethoxide at 70°C led to *ca.* 65% of the three possible stereoisomeric products, which could not be separated by chromatography. Treatment of the mixture in ether with a small amount



of iodine at room temperature gave a *ca.* 3:1 mixture of the *trans,trans* isomer *(5)* and the corresponding *cis,trans* isomer, which on chromatography on alumina yielded 33% [based on *(3)* and *(4)*] of pure *(5)*[6] as pale yellow crystals; NMR spectrum, see Table 1.

Table 1. ^{1}H-NMR parameters of compounds *(5)*—*(8)* in $CDCl_3$ at 100 MHz (τ values, internal standard TMS) [a].

[***] We are indebted to the Science Research Council for financial support.

spectrum of *(6)*, the "inner" H^B, H^D, and H^F protons have shifted appreciably downfield as compared with *(5)* [Table 1, $\Delta(6)-(5)$]. This is presumably due to the fact that these protons in the relatively rigid macrocyclic structure *(6)* are deshielded by the ethylenic and/or acetylenic bonds to a greater degree than in *(5)*, where free rotation about the single bonds can occur.

Reduction of *(6)* with lithium aluminum hydride in tetrahydrofuran at room temperature led to the corresponding 1,4-dihydropyridine (dark crimson solution), which could not be isolated due to its ready oxidation to *(6)*[8]. The dihydropyridine under nitrogen was therefore treated directly with ethyl chloroformate and pyridine to give 50% of the stable *(7)* as orange-red crystals [*m/e* 463; $\lambda_{max}(CHCl_3)$ 346 (ε 83000), *ca.* 380 sh (37000), *ca.* 406 sh (17000), 429 (16000), 452 (12000), and *ca.* 510 sh nm (2800); NMR spectrum, see Table 1].

Similar reduction of *(5)* with lithium aluminum hydride, followed by treatment with ethyl chloroformate and pyridine, yielded 45% of the model *(8)* as light yellow crystals [$\lambda_{max}(CHCl_3)$ 329 (ε 80000), 339 (85000), 380 (24000), 398 (25000), and *ca.* 424 sh nm (14000); NMR spectrum, see Table 1].

The urethane *(8)* was more stable than the pyridine *(5)*, and its oxidative coupling with cupric acetate in pyridine at 55—60 °C proceeded much better than that of *(5)*. The resulting *(7)*, obtained in 25% yield, proved to be identical with that derived from *(6)*, and this is the preferred route to *(7)*.

Comparison of the NMR spectra of *(7)* and *(8)* [Table 1, $\Delta(7)-(8)$] clearly shows the didehydroaza[21]annulene *(7)* to be diatropic, as expected of a 22 π-electron system, the outer protons being deshielded and the inner protons shielded[9]. This effect is less marked than in the corresponding didehydroaza[17]annulene *(1c)* [Table 1, $\Delta(1c)-(2c)$], showing that diamagnetic ring current effects in $(4n+2)$ π-electron systems become less as the size of the macrocyclic ring is increased.

[6] UV, IR, and NMR spectra, as well as elemental analyses, compatible with the assigned structures were obtained for all new compounds. All substances were isolated by chromatography on Woelm neutral alumina (activity III), and consisted of crystals which decomposed on attempted melting point determination.

[7] By comparison, the previously described lower vinylog of *(5)* could be coupled to the corresponding cyclic "monomer" [the precursor of *(1a)—(1d)*] in 85% yield [2].

[8] The corresponding *N*-methyl derivative (dark violet crystals), obtained by successive treatment of the 1,4-dihydropyridine with sodium hydride and methyl iodide, also proved to be quite unstable. The instability of these substances is in contrast to the relative stability of the corresponding derivatives *(1b)* and *(1a)* in the aza[17]annulene series [2].

[9] As already discussed for *(1a)—(1d)* [2], the shielding of the inner protons in *(7)* is actually greater than indicated, since the corresponding protons in NMR spectrum of the model *(8)* are at higher field than they would be in the conformation indicated in the formula [see Table 1, $\Delta(6)-(5)$].

Synthesis of a Methylene-Bridged Didehydroaza[19]annulene, a Paratropic Heteroannulene.—The Alternation of Electromagnetic Properties between Hetero[4*n*+1]annulenes and Hetero[4*n*−1]annulenes[1][***]

By *Philip J. Beeby* and *Franz Sondheimer*[*]

We have previously reported the synthesis of the methylene-bridged didehydroaza[17]annulene *(1)*[2,3] and didehydroaza[21]annulene *(3)*[1]. Both of these hetero[4*n*+1]annulenes are $(4n+2)$ π-electron systems, and, as expected, comparison of their ^{1}H-NMR spectra with those of the models *(2)* and *(4)* showed them to possess a diamagnetic ring current (= diatropic)[4]. We now describe the synthesis of the methylene-bridged didehydroaza[19]annulene *(19)*, a hetero[4*n*−1]annulene containing $4n$ π-electrons. It was of considerable interest to investigate whether this substance possessed a paramagnetic ring current (= paratropic)[4], a finding which would show that alternation of electromagnetic properties between $(4n+2)$ and $4n$ π-electron systems occurs in these heteroannulenes, as has already been found in the carbocyclic annulene series[4,5].

Reduction of dimethyl pyridine-3,5-dicarboxylate[2] with lithium aluminum hydride in ether, followed by a treatment of the crude 3,5-bis(hydroxymethyl)pyridine[2] with a limited amount of benzoyl chloride in pyridine, gave 30% (based on the diester) of the monobenzoate *(5)* (m.p. 62—63 °C)[6], which was oxidized to the aldehyde *(6)* (m.p. 78—79 °C) in 75% yield with chromium trioxide in pyridine. Reduction of the aldehyde *(7)*[7] with lithium aluminum hydride in ether led to the alcohol *(8)* (liquid), which was converted into the bromide *(9)* (liquid) by means of phosphorus tribromide in ether, and thence to the triphenylphosphonium salt *(10)* [m.p. 240—242 °C (decomp.)] with triphenylphosphane in boiling benzene (overall yield, 85%)[8]. Wittig reaction of *(6)* and *(10)* in dimethylformamide with ethanolic lithium ethoxide at 70 °C (with concomitant hydrolysis of the benzoate group) gave 80% of a *ca.* 1:1 mixture of *(11)* and the correspond-

ing *cis* isomer, which was oxidized with manganese dioxide in ether to a *ca.* 1:1 mixture of *(12)* and the corresponding *cis* isomer (48% yield). The stereochemical composition of these mixtures is based on their NMR spectra. Separation by chromatography proved to be difficult, and the synthesis was continued without separation.

The aldehyde *(13)*[9] was transformed to the triphenylphosphonium salt *(16)* (m. p. 170—174 °C) *via* the unstable alcohol *(14)* and bromide *(15)*, in 60% overall yield, by the same route as used for the lower vinylog *(10)*. Wittig reaction of *(12)* (admixed with the corresponding *cis* isomer) and *(16)* in dimethylformamide with ethanolic lithium ethoxide at 70 °C led to *ca.* 80% of the three possible stereoisomeric products, which were difficult to separate. However, careful chromatography on alumina gave material in 25% yield [based on *(16)*], which consisted of *ca.* 75% of the all-*trans* isomer *(17)* as estimated from the NMR spectrum (Table 1).

pure) was converted, through reduction with lithium aluminum hydride and subsequent treatment of the resulting 1,4-dihydropyridine with ethyl chloroformate and pyridine, into the urethane *(18)* [30% yield; yellow crystals which decomposed on attempted melting point determination; *m/e* 439; λ_{max} ($CHCl_3$) *ca.* 300 sh (ε 31000), 315 (51000), 328 (57000), 390 (19000), and *ca.* 414 sh nm (10000); NMR spectrum, see Table 1].

Finally, oxidative coupling of *(18)* with cupric acetate in pyridine at 60 °C gave in 40% yield the aza[19]annulene derivative *(19)* [deep red crystals which decomposed on attempted melting point determination; *m/e* 437; λ_{max} ($CHCl_3$) *ca.* 303 sh (ε 36000), 321 (62000), and 332 nm (65000), with absorption >550 nm; NMR spectrum, see Table 1].

The NMR chemical shift differences for each proton on passing from the model *(18)* to the aza[19]annulene *(19)*

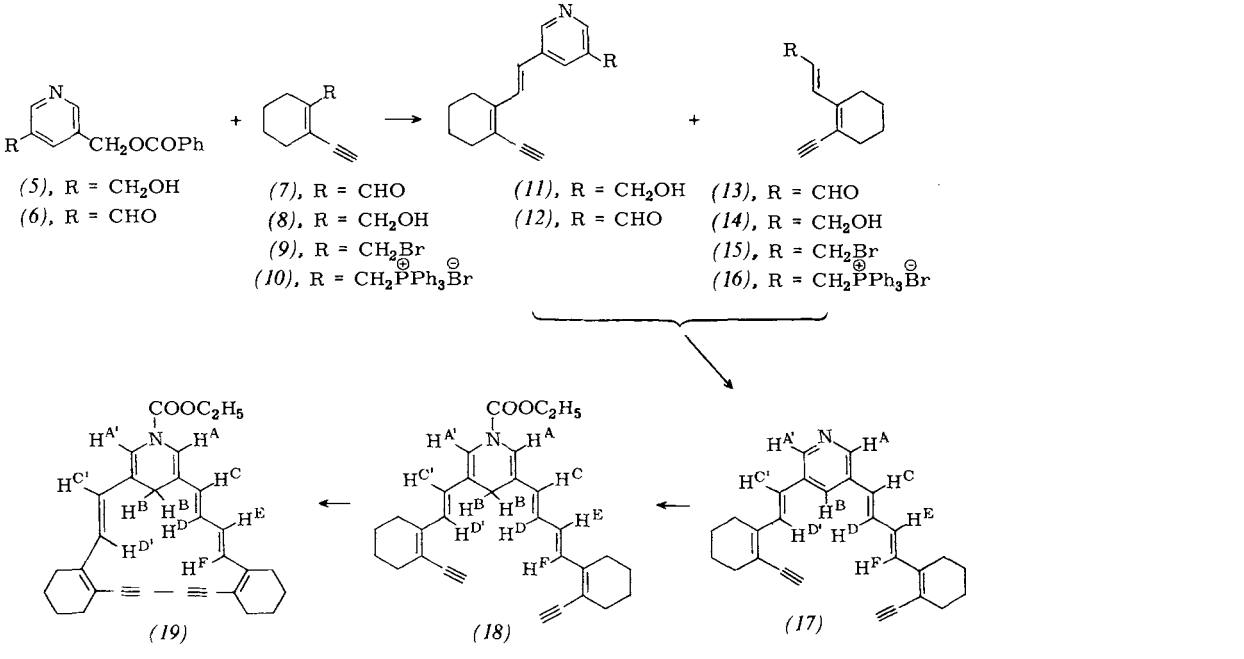
[a] In addition, all compounds showed a multiplet at *ca.* τ 8.0—8.6 (aliphatic protons).
[b] In addition, *(17)* showed singlets at τ 6.62 and 6.66 (≡CH).
[c] J = 2.4 Hz.
[d] J = 16 Hz.
[e] J = 16 and 11 Hz.
[f] In addition, *(18)* showed singlets at τ 6.64 and 6.71 (≡CH).
[g] degenerate.
[h] J = 7 Hz.
[i] The assignments of the olefinic protons were established by nuclear Overhauser and decoupling experiments.
[j] At 60 MHz.

Attempts to couple *(17)* to the corresponding cyclic "monomer" with cupric acetate in pyridine were unsuccessful. Advantage of our experience in the aza[21]annulene series[1] was now taken, and the pyridine *(17)* (*ca.* 75%

are given in Table 1 [Δ *(19)—(18)*]. It is evident that the aza[19]annulene *(19)* is paratropic, all the outer protons being shielded and the inner protons deshielded[10] This is a reversal of the behavior of the diatropic



aza[17]annulene *(1)* [Table 1, $\Delta(1)-(2)$] and aza[21]annulene *(3)* [Table 1, $\Delta(3)-(4)$], which are the lower and higher vinylogs of *(19)*, respectively. The alternation of electromagnetic properties between the hetero[$4n+1$]annulenes *(1)* and *(3)* and the hetero-[$4n-1$]annulene *(19)* is thereby clearly established.

[1] Unsaturated macrocyclic compounds, Part 101.—Part 100: *P. J. Beeby* and *F. Sondheimer*, Angew. Chem. *85*, 404 (1973); Angew. Chem. internat. Edit. *12*, 410 (1973).

[2] *P. J. Beeby* and *F. Sondheimer*, J. Amer. Chem. Soc. *94*, 2128 (1972).

[3] See also *P. J. Beeby* and *F. Sondheimer*, Angew. Chem. *84*, 896 (1972); Angew. Chem. internat. Edit. *11*, 833 (1972).

[4] *F. Sondheimer*, Accounts Chem. Res. *5*, 81 (1972).

[5] The only previously known example of a paratropic heteroannulene is a dioxido-bridged oxa[15]annulene (*H. Ogawa*, *M. Kubo*, and *H. Saikachi*, Tetrahedron Lett. *1971*, 4859). However, the structure of this substance is too different from the diatropic *(1)* and *(3)* to make a meaningful comparison impossible.

[6] UV, IR, and NMR spectra, as well as elemental analyses, compatible with the assigned structures, were obtained for all pure stable compounds.

[7] *P. Schiess* and *H. L. Chia*, Helv. Chim. Acta *53*, 485 (1970); *G. M. Pilling* and *F. Sondheimer*, J. Amer. Chem. Soc. *93*, 1970 (1971).

[8] The transformation of *(7)* to *(10)* (in *ca.* 40% overall yield) was first carried out by Dr. *Gwenda M. Pilling* (Ph. D. Dissertation, Cambridge, 1968; personal communication). The presently reported yield was obtained by Mr. *J. M. Brown* (personal communication).

[9] *R. H. McGirk* and *F. Sondheimer*, Angew. Chem. *84*, 897 (1972); Angew. Chem. internat. Edit. *11*, 834 (1972).

[10] The actual deshielding of the inner protons in *(19)* is presumably smaller (by *ca.* 0.4 ppm) than indicated, since the corresponding protons in the model *(18)* are at higher field than they would be in the conformation indicated in the formula (see reference [1], footnote 9, and reference [2], footnote 9).

μ-Phosphinodiborane

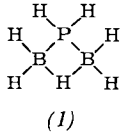
By *Helmut Hofstötter* and *Erwin Mayer*[*]

Although μ-aminodiborane and many of its derivatives substituted on boron or nitrogen have long been known[1], the analogous compounds with phosphorus as bridging element have not yet been described. Pentaborane(9) appears to be the only boron hydride into which phosphorus has hitherto been introduced at a bridging position[2].

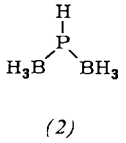
We have found that μ-phosphinodiborane is formed in the reaction of $H_2P(BH_3)_2Na$ with dry HCl in diethyl ether at −96 °C:

$$H_2P(BH_3)_2Na + HCl \rightarrow B_2H_5(PH_2) + NaCl + H_2 \quad (1)$$

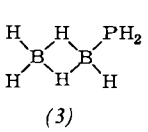
According to the stoichiometry of this reaction, besides μ-phosphinodiborane two other products of molecular formula B_2PH_7 are conceivable, namely bisboranephosphane *(2)* and τ-phosphinodiborane *(3)*.



(1)



(2)



(3)

[*] Dr. H. Hofstötter and Univ.-Doz. Dr. E. Mayer
Institut für Anorganische und
Analytische Chemie der Universität
A-6020 Innsbruck, Innrain 52a (Austria)

However, from the ^{11}B-NMR spectrum of a diethyl ether solution we conclude that only the compound *(1)* is formed (Fig. 1). The four doublets have a spin-spin coupling con-

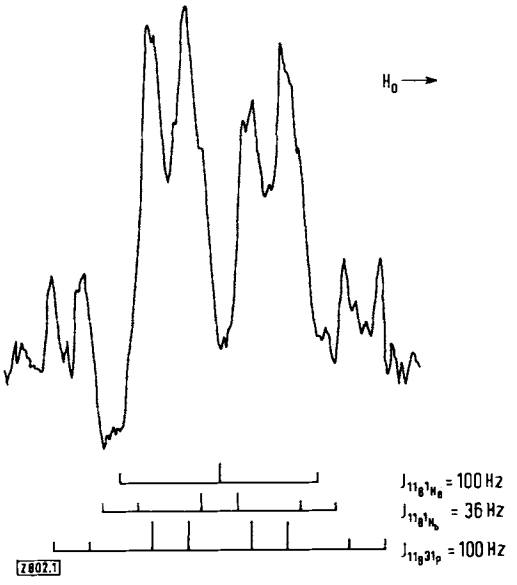


Fig. 1. ^{11}B-NMR spectrum (28.8 MHz) of μ-phosphinodiborane *(1)* in diethyl ether at room temperature [6].

stant of 36 Hz which is typical of systems with B—H—B bridges[3]. The spectrum can be interpreted for μ-phosphinodiborane as a triplet which is further split into doublets by the bridging H and by the P atom. The resulting very similar coupling constants for coupling of ^{11}B with the terminal hydrogen and with phosphorus appear surprising but were found also by *Burg et al.*[2] for various phosphinopentaboranes. τ-Phosphinodiborane *(3)* can also be ruled out as reaction product because it would give a considerably more complicated ^{11}B-NMR spectrum owing to its lower symmetry.

Dilute solutions of *(1)* in diethyl ether are stable below −20 °C. The compound is, however, considerably less stable thermally than μ-aminodiborane[4] and cannot be transcondensed without decomposition or isolated. If the solvent is evaporated off under reduced pressure or if the solution is kept for some time at room temperature, diborane(6) is formed together with a white amorphous residue whose IR spectrum shows the characteristic absorptions of B—H and P—H stretching vibrations at 2400 cm^{-1}. From the amount of diborane that results, decomposition probably involves formation of polymeric phosphinoborane:

$$B_2H_5(PH_2) \rightarrow 1/n(H_2BPH_2)_n + 1/2\,B_2H_6 \quad (2)$$

Experimental:

All the reactions must be carried out in a vacuum or under nitrogen. 90% of the stoichiometric amount of HCl (0.73 mmol) is condensed on $H_2P(BH_3)_2Na$ (68 mg, 0.81 mmol; from H_3BPH_3 and $NaBH_4$[5]) in diethyl ether (20 ml) at −196 °C. Evolution of H_2, which begins at −96 °C, is complete after *ca.* 3 h (0.68 mmol, 93% calculated on HCl used). The precipitate formed is filtered off at −96 °C and characterized as NaCl by its Debye-Scherrer diagram; its IR spectrum contains a weak band at 2400 cm^{-1} which is ascribed to a small proportion of a substance

containing B—H or P—H. B_2H_6 is slowly evolved from the ethereal solution of the boron hydride product *(1)* above 0°C; evolution of B_2H_6 is complete (0.32 mmol, 87%) after 100h at room temperature. Neither PH_3 nor H_2 was found to be formed during this decomposition.

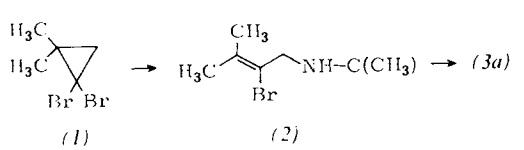
Methyleneaziridine-Cyclopropanimine Valence Isomerization[**]

By *Helmut Quast* and *Wolfgang Risler*[*]

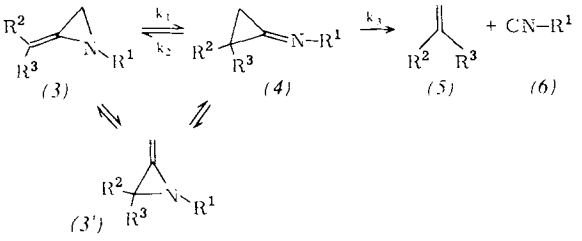
As part of our study of the thermal reorganization of nitrogen analogs of methylenecyclopropane[1,2] we report here the synthesis of a methyleneaziridine substituted at the double bond and also the first proof of the methyleneaziridine-cyclopropanimine valence isomerization that has been repeatedly postulated[3].

Methyleneaziridines unsubstituted on carbon have been known for a long time, but more highly substituted representatives of this class of compounds have not yet been described[4]. By reaction of the bromoallylamine *(2)* [readily accessible by prolonged heating of *(1)* with *tert*-butylamine at 150°C[5]; yield 67—69%, b. p. 89—89.5°C/15 torr] with $NaNH_2$ in liquid NH_3 we obtained 1-*tert*-butyl-2-isopropylideneaziridine *(3a)* (yield 50—60%; b.p. 48°C/14 torr), whose structure follows from elemental analysis and spectroscopic results. IR (CCl_4): 3025 (CH_2), 1792 cm^{-1} (C=C). NMR (CCl_4, 90 MHz): 1.00 (9H/s), 1.70—1.77 ppm (8H/m). MS: 139 (M, 40%), 124 ($M-CH_3$, 11%), 83 ($M-C_4H_8$, 55%), 82 ($M-C_4H_9$, 100%).



(1) *(2)*

(3a) decomposes slowly above 120°C and rapidly at 190°C, *(5a)* and *(6a)* being formed quantitatively. These products can, however, arise only by cheletropic decomposition of the cyclopropanimine intermediate *(4a)*; and this is indicated especially by the fact that the cyclopropanimine *(4b)* also thermolyzes quantitatively in this manner above 140°C[2,6]. If the thermolysis of *(3a)* is followed by NMR spectroscopy, transient signals appear that belong to the isomer *(3'a)* (3.84, 4.06 ppm, >C=CH_2) and, very probably, to the cyclopropanimine *(4a)* (at 1.1 1.3 ppm).



(3) *(4)* *(5)* *(6)* *(3')*

	R^1	R^2	R^3
(a)	$C(CCH_3)_3$	CH_3	CH_3
(b)	$[(CH_3)_2CH]_2CH$	$C(CH_3)_3$	H
(c)	CH_3	H	H
(d)	C_2H_5	H	H
(e)	$C(CH_3)_3$	H	H

Whereas in the case of *(3a)* there is in principle a three-component system [*(3a), (3'a), (4a)*], the kinetics of the thermolysis of the *C*-unsubstituted methyleneaziridines *(3c)*—*(3e)* are expected to be simpler since there the possible transformation *(3)* → *(3')* degenerates to a valence topomerization. We therefore studied the thermolysis of *(3c)*—*(3e)* by NMR spectroscopy[7]. The intensities of the olefinic proton signals of *(3c)*—*(3e)* decreased in a first-order reaction during several half-lives, with $[(3)]=[(3)]_0\exp[-k_1t]$ (Table 1).

Table 1. Rate constants k_1 and activation parameters (for 150°C) of the isomerization *(3)* → *(4)*.

	$10^5 \times k_1$ [s^{-1}]			$\Delta H^{\neq}$	$\Delta S^{\neq}$
	150.0°C	170.0°C	190.0°C	[kcal mol^{-1}]	[cal mol^{-1} deg^{-1}]
(3c)	3.50 ±0.03	21.4 ±0.1	127.5 ±0.8	34.1 ±0.8	1.0 ±1.7
(3d)	1.561 ±0.008				
(3e)	0.085 ±0.002	0.510 ±0.006	3.29 ±0.04	34.8 ±0.2	−4.8 ±0.5

The cyclopropanimines *(4c)*—*(4e)* were always the primary products, undergoing *slow* conversion into ethylene and the isocyanides *(6c)*—*(6e)* (maximal yield 20—25%) and, as thermolysis proceeded, further into unidentified products[8]. For example, from *(3c)* we obtained after 5.5 min at 190°C (half-life 9 min) a mixture containing 71% of *(3c)*, 28% of *(4c)*, 1% of ethylene, and 1% of *(6c)* which remained unchanged at room temperature. The structure of the cyclopropanimine *(4c)* is proved by the AA'BB'X_3 spectrum (AA'BB' part at 1.2 ppm, X_3 part at 3.24 ppm) and decoupling experiments. These results show that the experimentally determined rate constants are to be assigned to the isomerization *(3)* → *(4)* and that here $k_1 \gg k_2$[9], as also for *(4b)*[2,6].

Considering the notorious instability of cyclopropanones[10], it is surprising how stable the corresponding

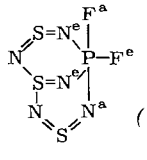
A Bicyclic Phosphorus Trisulfur Pentanitride

By *Herbert W. Roesky* and *Olaf Petersen*[*]

We have isolated a phosphorus-containing sulfur nitride of the composition $S_3N_5PF_2$ (complete elemental analysis) and the unusual structure *(1)* from the products of reaction of phosphorus pentafluoride with *N,N'*-bis(trimethylsilyl)-sulfur diimide[1]. Since the sulfur diimide is in excess at the beginning of the reaction we assume that $F_2P[N{=}S{=}N{-}Si(CH_3)_3]_3$ is first formed and then reacts further with PF_5 to yield *(1)*, $(CH_3)_3SiF$, and $(NPF_2)_n$ in the ratios $1:3:1/n$. It is known that similar reactions of PF_5 do not lead to $(NPF_2)_n$ rings but that derivatives of PF_6^- are formed.



(1)

(1) is a crystalline, golden-yellow solid, extremely sensitive to moisture and sublimable at room temperature in an oil-pump vacuum. The most probable configuration for the pentacoordinated phosphorus is assumed to be a trigonal bipyramid. From ^{31}P- and ^{19}F-NMR studies the fluorine atoms are not exclusively axial (a) and the nitrogen atoms exclusively equatorial (e), as is usual[2]; instead, one finds two doublets in the ^{31}P- and also two doublets in the ^{19}F-NMR spectrum: $\delta_P = +11.5$ ppm; $J(PF^e) = 1008$, $J(PF^a) = 925$, $J(F^aF^e) = 86$ Hz; $\delta_{F^a} = 85.4$, $\delta_{F^e} = 46.8$ ppm (measured at 35 °C; $CFCl_3$ as solvent and internal standard for ^{19}F-NMR, and 85% H_3PO_4 as external standard for ^{31}P-NMR). This accords with the proposed structure *(1)*, in which one fluorine atom is in an axial and another in an equatorial position. The nitrogen atoms assume differing positions for steric reasons. $S_2N_3PF_2$ is found as the ion with the highest mass number ($m/e = 175$, 8%) in the mass spectrum; this fragment arises by loss of NSN from *(1)* and can be regarded as a six-membered ring system; elimination of SN is known to occur in mass-spectrometric investigation of sulfur-nitrogen rings[3]. Other characteristic fragments are: $m/e = 161$ $S_2N_2PF_2$ (48.4%), 129 $NSNPF_2$ (5.1%), 115 $SNPF_2$ (23.7%), 92 S_2N_2 (4%), 78 SNS (9.6%), 69 PF_2 (38.5%), 64 NPF (3.5%), 50 PF (3.7%), 46 SN (100%), 45 NP (1.3%), 32 S (21.8%), 28 N_2 (6.2%). Absorptions (cm^{-1}) were observed in the IR spectrum at 1185 vs, 1138 vs, 1020 w, 1002 m, 960 s, 935 s, 835 s, 728 s, 707 s, and 662 s.

Experimental:

A slow stream of PF_5 is introduced, with stirring, into $[(CH_3)_3SiN]_2S$ (5 g, 0.025 mol) contained at 0 °C in a two-necked flask (250 ml) fitted with a gas inlet tube (not dipping into the liquid) and a final condensation trap (acetone/Dry Ice). When reaction is complete (*ca.* 4 h), unchanged PF_5 can be observed at the exit from the trap, and the flask containing the reaction mixture is then slowly warmed to room temperature. $(CH_3)_3SiF$ collects in the trap, and the product *(1)* (yield 1—5%) sublimes from the dark brown residue at room temperature under oil-pump vacuum.

A New, Unusually Stable Type of Organo-copper and -silver Compounds

By *Hubert Schmidbaur*, *Jürgen Adlkofer*, and *Wolfgang Buchner*[*]

Replacing simple alkyl groups by trimethylsilylmethyl groups sometimes effects considerable stabilization of organometallic compounds[1,2]. We have now found that this effect of the $(CH_3)_3Si{-}CH_2$ group is greatly exceeded by that of the isoelectronic[3] phosphonium group $(CH_3)_3P^+{-}CH_2$, and that even extremely weak bonds such as the Cu—C and the Ag—C unit[4] become capable of existence under normal conditions when this ligand is used.

Treating anhydrous copper(I) chloride with salt-free trimethylmethylenephosphorane[5] (molar ratio 1:2) in benzene or toluene under an inert gas at room temperature leads, in a homogeneous reaction, to tetramethylphosphonium chloride and a metalated ylide of composition and structure *(1)*.

Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)

$$2\ CuCl + 4\ (CH_3)_3P{=}CH_2 \rightarrow$$

$$2\ [(CH_3)_4P]\ Cl + \ominus[H_3C{-}P^{\oplus}(CH_3){-}CH_2{-}Cu{-}CH_2{-}P^{\oplus}(CH_3){-}CH_3]\ominus$$

(1)

The analogous silver compound *(2)* is better formed from the tetrameric (trimethylphosphane)silver chloride[6] and $(CH_3)_3P{=}CH_2$, and then also in quantitative yield.

$$[(CH_3)_3PAgCl]_4 + 8\ (CH_3)_3P{=}CH_2 \rightarrow$$

$$4\ [(CH_3)_4P]\ Cl + 4\ (CH_3)_3P$$

$$+\ 2\ \ominus[H_3C{-}P^{\oplus}(CH_3){-}CH_2{-}Ag{-}CH_2{-}P^{\oplus}(CH_3){-}CH_3]\ominus$$

(2)

(1) and *(2)* are colorless, crystalline compounds, m.p. 136—138 and 154—155 °C, respectively, soluble in benzene, toluene, CH_2Cl_2, and $CHCl_3$ and sublimable in a vacuum (subl. temp. 100—120 and 150—155 °C/0.1 torr, respectively). They can be recrystallized from toluene/light petroleum (1:1).

The molecular ion M^+ and the fragment ion $(M-15)^+$ appear in the mass spectrum with great intensity and with the isotope distribution characteristic of the metals[7]. The IR spectra (nujol) contain, in addition to the vibrations of the methyl and methylene groups bound to phosphorus, bands at 557 and 509 and at 518 and 470 cm^{-1}, respectively, that can be assigned to $C_2Cu(Ag)$ stretching vibrations. In the ^1H-NMR spectrum[8] of *(1)* two doublets appear with relative areas 3:2, broadened by long-range interactions. P-decoupling simplifies these doublets to two singlets. In the ^1H-decoupled ^{31}P spectrum only one line appears, its position corresponding to that for other phosphonium centers[9] (Table 1). Furthermore, selective decoupling enabled the relative signs of the $J(HCP)$ coupling constants to be determined: $^2J(H_3CP)$ and $^2J(H_2CP)$ are found to have the same sign in the product *(1)*, in contrast to the situation with the free ylide[5,10]. This observation proves rehybridization ($sp^2 \rightarrow sp^3$) of the ylide carbanion upon coordination to the metal[10,11].

Table 1. ^1H- and ^{31}P-NMR spectra of *(1)* and *(2)* (in C_6D_6 and $C_6D_5CD_3$; TMS and H_3PO_4, respectively, as external standards, 35 °C).

	(1)	*(2)*
^1H, δCH_3 [ppm]	− 0.5, d	− 0.5,d
δCH_2	+ 0.08, d	0.0, dd
^{31}P, δP [ppm]	−24.2, s [a]	−28.6, t [a]
$^2J(H_3CP)$	−11.6 Hz	−11.6 Hz
$^2J(H_2CP)$	−13.4 Hz	−12.0 Hz
$^4J(H_3CPCH_2)$	+ (small)	+ (small)
$^2J(AgCP)$	—	± 9.7 Hz [b]
$^2J(AgCH)$	—	± 9.8 Hz [b]

[a] ^1H decoupled.
[b] $J(AgCP)$ and $J(AgCH)$ have the same sign. The relation to the other coupling constants is not yet known.

The NMR spectra of *(2)* correspond to those of *(1)* but an additional effect provides new structural proof: the CH_2 resonances appear here as a doublet of doublets (1:1:1:1), on P-decoupling as a doublet, and the ^{31}P resonance appears as a 1:2:1 triplet. These multiplicities result from the $^1H{-}C{-}^{109,107}Ag$ and $^{31}P{-}C{-}^{109,107}Ag$ interactions, which to our knowledge have not been observed previously[12].

For both ring systems we assume linear C—Cu(Ag)—C units and tetrahedral PC_4 units as components of an eight-membered ring.

[12] *C. W. Alegranti* and *E. L. Mutterties* [J. Amer. Chem. Soc. *94*, 6386 (1972)] have observed direct $^{31}P{-}^{109,107}Ag$ coupling. In that case the coupling in $^1J(^{31}P{-}^{109}Ag)$ and $^1J(^{31}P{-}^{107}Ag)$ could be resolved because of the larger absolute values. The factor amounts to only 1.149.

Phosphorus Ylides as Structural Units in Organogold Compounds[**]

By *Hubert Schmidbaur* and *Rainer Franke*[*]

Organometallic gold(I) compounds are generally not very stable and can be isolated only if they contain stabilizing ligands[1]. In a study of the ligand function of ylides we have now shown that not only the first but also a second Au—C σ-bond is stabilized to an unexpectedly great extent by a neighboring onium center. In this way it has been possible to synthesize compounds containing a structural unit $R{-}Au{-}R^{\ominus}$, which is isoelectronic with the R—Hg—R group.

Treating (trimethylphosphane)gold chloride with trimethylmethylenephosphorane[2] in benzene or toluene affords, depending upon the molar proportions of the reactants, the gold-phosphonium salts *(1)* and *(2)* in quantitative yield. In the second stage of the reaction the phosphane ligand is removed from the gold atom.

(1), m.p. 178—181 °C, is readily soluble in CH_2Cl_2 and in that solvent at −60 °C shows the expected ^1H- and ^{31}P-NMR spectra. Structural evidence is provided especially by the coupling constants $J(^{31}P{-}Au{-}C{-}^1H) = +9$ Hz and $J(^{31}P{-}C{-}^1H_2) = -14.5$ Hz. The signs of the PCH_2 interaction[3] prove the rehybridization $sp^2 \rightarrow sp^3$ of the ylidic C atom on coordination. With *(2)*, m.p. 170 °C (dec), the ^1H spectrum shows the CH_2

[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. R. Franke
Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)

[**] Part 14 of Organogold Chemistry.—Part 13: *H. Schmidbaur* and *K. C. Dash,* J. Amer. Chem. Soc., in press.

doublet with evident broadening due to long-range $^4J(^{31}PCAuC^1H)$ and $^4J(^1HCAuC^1H)$ coupling. The IR spectra contain characteristic bands of Au—C stretching vibrations at 561/550 *(1)* or 549 cm^{-1} *(2)*.

$$(CH_3)_3P{\rightarrow}Au{-}Cl + (CH_3)_3P{=}CH_2$$

$$\downarrow$$

$$[(CH_3)_3P{\rightarrow}Au{-}CH_2{-}\overset{\oplus}{P}(CH_3)_3]\ Cl^{\ominus} \quad (1)$$

$$+(CH_3)_3P{=}CH_2 \;\Big|\; -(CH_3)_3P$$

$$\downarrow$$

$$[(CH_3)_3\overset{\oplus}{P}{-}CH_2{-}\overset{\ominus}{Au}{-}CH_2{-}\overset{\oplus}{P}(CH_3)_3]\ Cl^{\ominus}$$

$$(2)$$

Even the more weakly basic ylides mono- and bis-(trimethylsilyl)methylenetrimethylphosphorane[4] form one and two Au—C bonds, respectively, and yield the aurated onium salts *(3)*, *(4)*, and *(5)*.

$$(CH_3)_3P{\rightarrow}Au{-}\underset{\oplus}{C}H(Si(CH_3)_3){-}P(CH_3)_3\ Cl^{\ominus}$$

$$(3)$$

$$(CH_3)_3Si{-}\underset{\oplus}{C}H{-}\overset{\ominus}{Au}{-}\underset{\oplus}{C}H{-}Si(CH_3)_3\ (P(CH_3)_3,\ P(CH_3)_3)\ Cl^{\ominus}$$

$$(4)$$

$$(CH_3)_3P{\rightarrow}Au{-}\underset{\oplus}{C}(Si(CH_3)_3)_2{-}P(CH_3)_3\ Cl^{\ominus}$$

$$(5)$$

Introducing the large organosilicon ligands increases the solubility of the substances in weakly polar solvents, so that high concentrations can be achieved. The decomposition temperatures for *(3)* to *(5)* are at or above 150 °C.

The ^{31}P-NMR spectrum of *(5)* contains an AB system with $\delta P^{III} = -2.82$, $\delta P^{V} = -23.4$, and $^3J(^{31}PAuC^{31}P) = 17$ Hz[5].

When an excess of the ylide reacts with $(CH_3)_3PAuCl$, or with *(1)* or *(2)*, dehydrohalogenation and precipitation of $[(CH_3)_4P]Cl$ occur, with formation of the novel eight-membered heterocycle *(6)*, m. p. 216—218 °C.

Like its copper and silver analogs[6], this dimeric gold(I)-dimethylphosphonium bismethylide is soluble in organic solvents such as CH_2Cl_2 and $CHCl_3$ and is volatile in a vacuum. In the mass spectrum[7] the molecular ion

$$H_3C{-}\overset{\oplus}{P}(CH_2{-}\overset{\ominus}{Au}{-}CH_2{-}CH_3)(CH_2{-}Au{-}CH_2{-}CH_3)\overset{\oplus}{P}{-}CH_3 \quad (6)$$

appears with great intensity at $m/e = 572$; νAuC occurs as a strong IR band at 551 cm^{-1}. *(6)* is remarkably insensitive to air and moisture. ^{1}H-NMR: $\delta CH_3P = -1.65$ ppm (d, 3 H), $J(HCP) = -11.9$ Hz; $\delta CH_2P = -0.93$ ppm (d, 2 H), $J(H_2CP) = -12.3$ Hz. ^{31}P-NMR: $\delta P = -32.2$ ppm (s, ^{1}H decoupled)[8].

Column-Chromatographic Separation of Neutral Sugars on a Dihydroxyboryl-Substituted Polymer[*]

By *Konrad Reske* and *Herbert Schott*[*]

The separation of ribo- and deoxyribo-nucleic acid units on dihydroxyboryl-substituted polymers ("boric acid gels") was reported recently[1]. Meanwhile we have been able to separate mixtures of mono- and oligo-saccharides by means of this gel (Figs. 1 and 2).

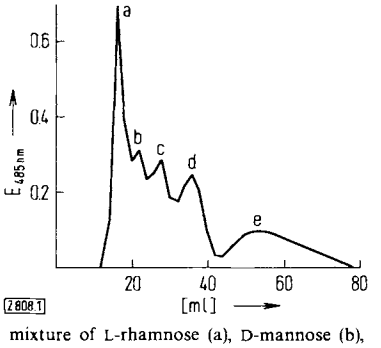

Fig. 1. Elution profile of a mixture of L-rhamnose (a), D-mannose (b), D-galactose (c), D-glucose (d), and D-ribose (e) on "boric acid gel"; for conditions see Experimental.

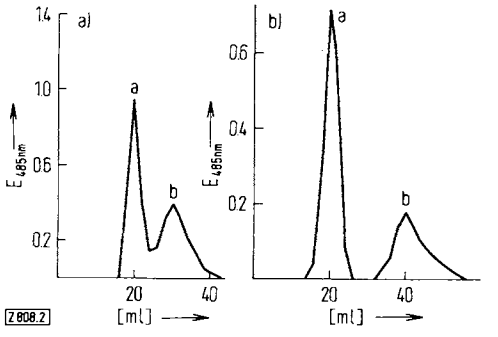

Fig. 2. a) Separation of maltose (a) and isomaltose (b) and b) of lactose (a) and raffinose (b) on "boric acid gel"; for conditions see Experimental.

We have found the complexes of the sugar with the gel matrix to correspond to the sugar-borate complexes in solution; their formation is pH-dependent. Optimal separation is obtained at pH > 9. The configuration of the sugar hemiacetal ring is of special importance for complex formation as it is well known that sugars form borate complexes preferentially in their furanose form[2]; Fig. 1 confirms this finding. Furanose formation of the terminal glucose also provides an explanation for the separation of maltose from isomaltose (Fig. 2a). An increase in the number of *cis*-hydroxyl groups leads to more extensive complex formation; thus lactose and raffinose can be separated quantitatively (Fig. 2b). The disaccharide pairs maltose and cellobiose, and maltose and lactose, however, show only very slight differences in their elution maxima since none of them yields a furanose form and they all contain the same number of *cis*-hydroxyl groups.

Compared with the procedures used hitherto[3-5], chromatography on "boric acid gels" offers the following advantages:

1. The use of volatile buffers permits rapid working up of the fractions since the separated sugar components can be isolated quantitatively in high purity without desalting. Also the absence of borate residues is of particular importance in structural chemical work with oligosaccharides[6].

2. By suitable choice of gel and gel volumes both mono- and oligo-saccharides can be optimally separated, even if they differ only very slightly in complex formation constants.

Experimental:

A chromatographic column (1/20 cm) is filled with swollen "boric acid gel"[1], then washed with 0.5 N HCl, and finally washed neutral. The sugar mixture (each 1 mg per mono- or oligo-saccharide) is dissolved in the eluant (0.2 ml), placed on the column and eluted with 0.1% aqueous ammonia (pH = 10.5), fractions of 4 ml per hour being collected. Aliquot parts (0.2 ml) of the fractions are monitored by the phenol/sulfuric acid reagent for presence of sugars[7] (test batch: 0.2 ml of fraction solution + 0.1 ml of 90% phenol + 1 ml of H_2O, shake, then add 3 ml of concentrated H_2SO_4). The sugars that are separated are identified by borate electrophoresis.

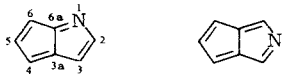
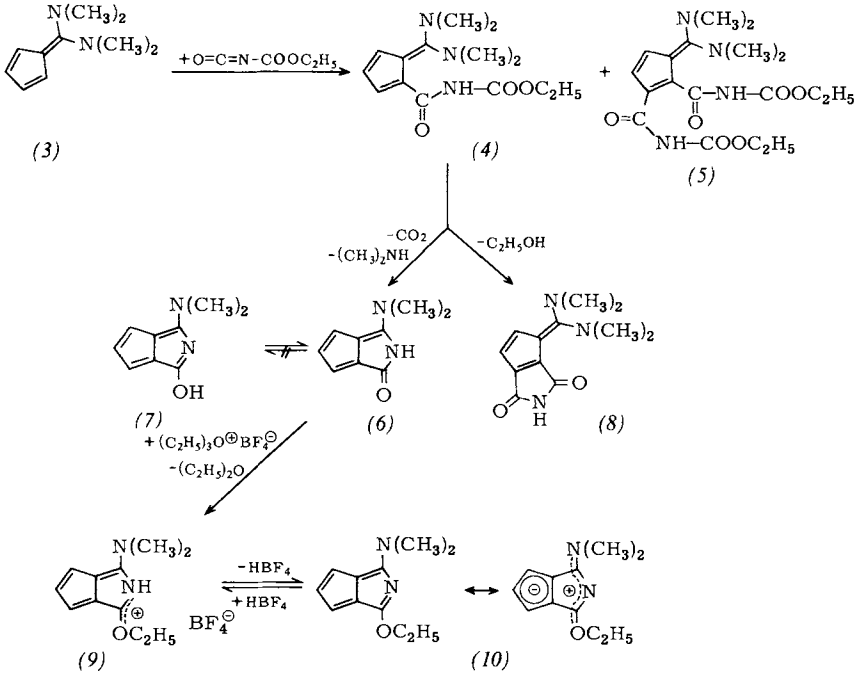
A Stable 2-Azapentalene[**]

By *Klaus Hafner* and *Frank Schmidt*[*]

After the synthesis of simple carbocyclic pentalenes[1] the aza analogs attract particular interest because their properties are likely to depend markedly on the position of the nitrogen atoms. As 8π-electron systems 1- *(1)* and 2-azapentalene *(2)*, as well as polyazapentalenes with C-fusion of the two five-membered rings, should not be "aromatic". In spite of many attempts no such bicyclic azapentalene has hitherto been prepared. The thermal instability of benzo[*b*]- and benzo[*f*][1]azapentalene precludes their



(1) *(2)*



(3) *(4)* *(5)* *(6)* *(7)* *(8)* *(9)* *(10)*

[*] Prof. Dr. K. Hafner and Dr. F. Schmidt

der Technischen Hochschule
61 Darmstadt, Schlossgartenstrasse 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

isolation[2]. Neither the various known azapentalene anions[3] nor the "aromatic" 1,3a,4,6a-tetraazapentalenes[4] and 3a,6a-diazapentalenes[5] allow valid conclusions about the properties of *(1)* and *(2)*. Both the structures *(1)* and *(2)* formally combine a pentafulvene and an azapentafulvene system, and this consideration led us, starting from 6,6-bis(dimethylamino)fulvene *(3)*[6], to synthesize the first stable 2-azapentalene.

(3) reacts with ethyl isocyanatoformate in acetonitrile at 20 °C, yielding 6,6-bis(dimethylamino)-1-[*N*-(ethoxycarbonyl)carbamoyl]fulvene *(4)*[7] [yield 22%; yellowish crystals, m. p. 150—151 °C; UV (dioxane): λ_{max} (log ε) = 258 (4.25), 335 (3.93), 369 nm (4.13); 60-MHz-NMR ($CDCl_3$): τ = 2.14 (broad, NH); double doublet centered at 3.37 (J = 3.5 Hz and J = 2.0 Hz) and 3.77 (J = 3.5 Hz and J = 2.0 Hz, 2-H, 4-H), 3.96 (t, J = 3.5 Hz, 3-H), 5.79 (q, CH_2), 6.96 (s, $2N(CH_3)_2$), 8.71 (t, CH_3)], and 7% of 6,6-bis(dimethylamino)-1,2-bis-(*N*-ethoxycarbonyl)carbamoyl]fulvene *(5)* (pale yellow crystals of m. p. 172—174 °C).

In boiling pyridine/H_2O (80 h), *(4)* undergoes intramolecular cyclization with loss of CO_2 and $(CH_3)_2NH$, yielding 3-(dimethylamino)-2*H*-2-azapentalen-1-one *(6)* [yield 47%; orange needles, dec. > 250 °C; UV (CH_3OH): λ_{max} (log ε) = 217.5 (4.39), 252 (4.14), 360 (4.02), 444 nm (3.44); IR (Nujol): 3180 (NH), 1685 cm^{-1} (CO); 60-MHz-NMR ([D_6]DMSO): τ = 0.42 (broad, NH); A_2B system: τ_A = 3.75 (4-H, 6-H), τ_B = 3.96 (5-H) (J_{AB} = 3.4 Hz), 6.71 (s, N—CH_3), 6.78 (s, N—CH_3)]. In addition, 0.5% of 6,6-bis(dimethylamino)fulvene-1,2-dicarboximide *(8)* was isolated (yellow crystals, m. p. 174—175 °C). The IR and UV spectra of the lactam *(6)* give no evidence for an equilibrium with the pentalenoid lactim *(7)*.

As expected, *(6)* can be converted by triethyloxonium tetrafluoroborate in CH_2Cl_2 at 0 °C by *O*-alkylation into the tetrafluoroborate *(9)*. The deprotonation of *(9)* by 50% aqueous K_2CO_3 solution leads to the lactim ether, 3-(dimethylamino)-1-ethoxy-2-azapentalene *(10)*, isolated as bluish-violet needles of m. p. 78—79 °C (yield 37%). The 100-MHz-NMR spectrum (in $CDCl_3$) of *(10)*, which proves its structure, resembles that of 1,3-bis(dimethylamino)pentalene[8] regarding the chemical shifts of the five-membered ring protons and provides no evidence for an induced ring current. [ABX system at $\tau_{A,B} \approx 3.85$ (4-H, 6-H) and τ_X = 4.15 (5-H), 6.66 (s, N—CH_3), 6.76 (s, N—CH_3), 5.57 (q, OC_2H_5), 8.57 (t, OC_2H_5).] The UV spectrum of *(10)* (in *n*-hexane) agrees reasonably with the values obtained by an SCF—CI calculation[9] and shows absorption maxima at 221 (log ε = 4.36), 274 (4.03), 281 (sh), 393 (4.16), and 598 nm (2.75). The spectrum resembles that of 1,3-bis(dimethylamino)pentalene. However, as with azulenes[10], replacing a methine group of a pentalene by nitrogen at a position of high charge density causes a hypsochromic shift of the longest-wavelength maximum.

In atmospheric oxygen *(10)* is stable for some days at room temperature, and shows a marked basicity (dissolves in 0.1 N acetic acid). It is converted by proton acids, in a quantitatively reversible reaction, into the conjugate acid *(9)* [perchlorate, carmine-red needles, dec. > 195 °C; UV (CH_2Cl_2): λ_{max} (log ε) = 260 (4.00), 267 (4.01), 272 (3.87), 372 (4.08), 381 (4.11), 522 nm (3.24); 100-MHz-NMR (CD_3CN): τ = 0.91 (broad NH), ABX system with $\tau_{A,B} \approx 3.15$ (4-H, 6-H) and τ_X = 3.60 (5-H), 6.63 (s, N—CH_3), 6.70 (s, N—CH_3), 5.40 (q, OC_2H_5), 8.48 (t, OC_2H_5)].

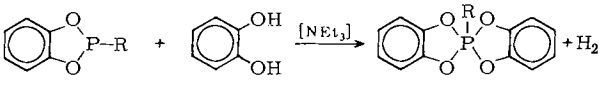
Alkyl- and Aryl-hydridobis(*o*-phenylenedioxo)-phosphate(1−), a Stable Spiroanion Containing Hexacoordinated Phosphorus[**]

By *Markus Wieber* and *Keywan Foroughi*[*]

Reactions of derivatives of quinquevalent phosphorus often occur by way of an intermediate containing a hexacoordinated phosphorus atom[1]. When converting trivalent into quinquevalent phosphorus by the reaction[2]

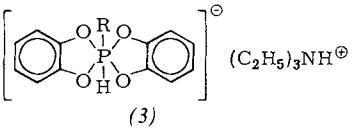


(1) *(2)*

R = CH_3, C_6H_5

we have isolated the first stable intermediate containing hexacoordinated phosphorus.

Hydridomethyl (or phenyl)bis(*o*-phenylenedioxo)phosphate(1−) can be obtained as its triethylammonium salt *(3)* by treating 1,3,2-benzodioxaphospholes *(1)* with pyrocatechol and triethylamine in the molar ratio 1 : 1 : 1.



(3)

R = CH_3, C_6H_5

As shown by the NMR spectra (Table 1), the products exist, even in polar solvents, in the spiro form with coor-

Anion Structure of Tributylammonium Decatungstate $[HN(C_4H_9)_3]_4W_{10}O_{32}$

By *Joachim Fuchs, Hans Hartl*, and *Wolfgang Schiller*[*]

When a tungstate solution is acidified, the oxide hydrate $WO_3 \cdot 2H_2O$ is formed. The aggregation process leads through numerous intermediates (polyanions), some of which can be demonstrated by physicochemical methods. In weakly acid solutions the hexameric paratungstate A[1], $W_6O_{20}(OH)^{5-}$ or $W_6O_{19}(OH)_3^{5-}$, dominates, but in more strongly acid solution the decatungstate ion $W_{10}O_{32}^{4-}$[2] The structures of these acidification products have so far been unknown; the only structures clarified are those of the polytungstates formed during more protracted aging processes (paratungstate Z[3], metatungstate[4], *etc.*).

The tributylammonium salt $[HN(C_4H_9)_3]_4W_{10}O_{32}$[2] was the first crystalline decatungstate to be obtained. It is formed by precipitation from a freshly acidified tungstate solution ($1.6\,H^+/WO_4^{2-}$) with tributylammonium acetate or by treating $WO_3 \cdot H_2O$ with a solution of tributylamine in acetone or by hydrolysis of tetraethyl tungstate(VI), $WO(OC_2H_5)_4$, in the presence of tributylamine. It can be recrystallized from methanol.

The structure of $[HN(C_4H_9)_3]_4W_{10}O_{32}$ has now been elucidated by three-dimensional diffractometer data with evaluation of 4973 independent reflections ($R=7.7\%$). The unit cell, of space group $P2_1/c$ with $a=12.159\pm0.006$, $b=13.185\pm0.006$, $c=24.849\pm0.013$ Å, and $\beta=95.36\pm0.10°$, contains two formula units. Figure 1 shows the idealized structure of the polyanion with the symmetry 4/mmm (D_{4h}).

Two W_5O_{18} units are bonded mirror-symmetrically through four common oxygen atoms with formation of an octahedral space. The polyanion contains four differing groups of oxygen atoms: 10 terminal O atoms (O_t), 16 O atoms (O_k) each bridging two W atoms to each other through edges of octahedra, 4 O atoms (O_e) bridging two W atoms through corners of octahedra, and 2 O atoms (O_c) each coordinated to five W atoms. The W—O distances within the polyanion are: W—O_t = 1.68—1.76 Å; W—O_k = 1.86—2.01 Å; W—O_e = 1.88—1.94 Å; and W—O_c = 2.28—2.34 Å.

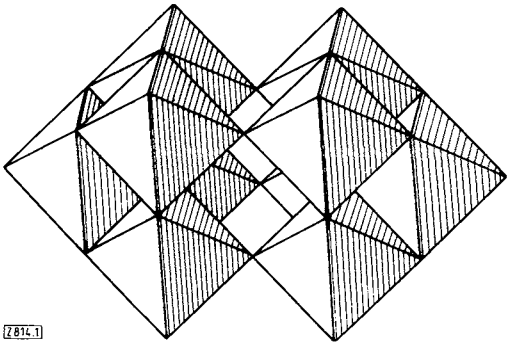

Fig. 1. Structure of the decatungstate ion $W_{10}O_{32}^{4-}$.

[*] Prof. Dr. F. Seel and Dipl.-Chem. H.-J. Güttler
Institut für Anorganische Chemie der Universität des Saarlandes
66 Saarbrücken (Germany)

[**] The results of this investigation were first reported in a lecture at Erlangen (Germany) on January 12, 1973.

green), S_3^- (blue), S_4^- (red), as colored particles in solutions of polysulfides(−2) in superheated water, electron pair donor ("EPD") solvents such as dimethylformamide (DMF), dimethyl sulfoxide, and hexamethylphosphorotriamide, melts of potassium thiocyanate and borate glasses, as well as of doped alkali-metal halides and as colored species of ultramarine[1]. Most authors, however, failed to assign the color and charge of the particles correctly. We have now found that one can solve this problem convincingly by quantitative spectrophotometric titration of 1 to 4×10^{-3} molar solutions of *disodium tetrasulfide* in DMF[2] with milligram portions of sulfur under *absolute* exclusion of oxygen.

100 ml of polysulfide solution was placed in a "two-bulb" apparatus with a connection to a vacuum line; to this apparatus was fused a quartz cuvette 1 mm thick (d) and a glass tube with a magnetic closure. The glass tube also held 20 small glass beakers each containing 1 mg of sulfur (see Fig. 1).

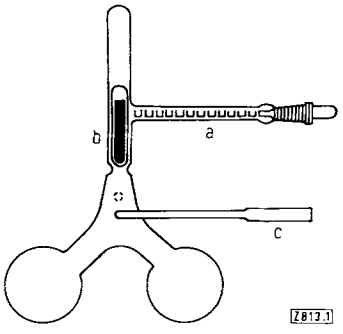

Fig. 1. Apparatus for titration of solutions with solid substance with exclusion of air. a, small beakers; b, magnetic closure; c, cuvette.

The extinction curves in the range 12000 to 30000 cm^{-1} show successive development of three absorption maxima, at 25300, 16200, and 19500 cm^{-1}, with two isosbestic points, at 23300 and 18100 cm^{-1}, which impressively demonstrate the changes $S_2^-\rightarrow S_3^-\rightarrow S_4^-$. A disproportionation equilibrium $4S_2^-\rightleftarrows 2S_3^- + S_2^{2-}$ explains why the *bluish-green* solutions of pure sodium tetrasulfide already display the band at 16200 cm^{-1}. Solutions with S : Na = 1.9 contain only *green* S_2^- alongside polysulfide(−2). *Blue* S_3^- is formed almost quantitatively when S : Na = 3. (Cf. Fig. 2.) Here the value of the quotient $E_{16200}/d\cdot c_{Na}$ ($\approx$4800) is almost independent of the concentration c_{Na} of sodium ions when $c_{Na}<10^{-3}$ g-atom/l. This means that in very dilute solution S_3^- is only slightly associated to S_6^{2-}. The association S_n^- to S_{2n}^{2-} is also indicated by the finding that the two isosbestic points are no longer so well developed in more concentrated solutions.

An argument for the correctness of the assignment is that the band due to S_3^- at 16200 cm^{-1} in a solution as well as the band due to S_3 at 24400 cm^{-1} in a matrix[3] show a vibrational structure. That, on addition of still more sulfur, S_3^- is actually replaced by *red* S_4^- is shown by the tangent placed in Figure 2 near the maximum of the curve for E_{16200} and leading to the point S/Na = 4 on the abscissa. However, addition of sulfur in excess of S/Na = 4 does not lead to even approximately quantitative formation of S_4^- ($E_{19500}/d\cdot c_{Na}\approx 2200$). Clearly an equilibrium sets in between S_4^- and S_3^- plus free sulfur. At very high sulfur concentrations the proportion of S_3^- decreases faster than that of S_4^- increases. It must be assumed that under these conditions polysulfide(−2) ions, S_n^{2-} ($n>8$), are formed and that these do not dissociate to radical ions $S_{>4}^-$. The explanation of this is that normal polysulfide(−2) ions form a structurally homologous series of chain molecular ions and not the radical ions S_2^-, S_3^-, S_4^-, as already shown by the various colors. Evidently

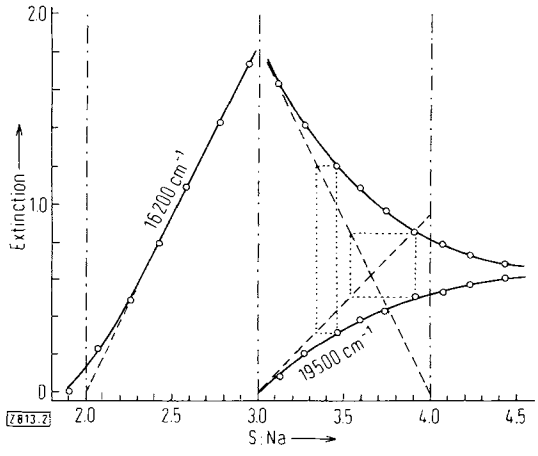

Fig. 2. Change in the maximal extinction of S_3^- and S_4^- in the visible region on titration of a 2.05×10^{-3} M solution of disodium tetrasulfide in dimethylformamide at 25 °C (layer thickness 1 mm).

only those radical fragments are formed that are stabilized by electron delocalization effects. (The ESR signal of S_4^- indicates that the four sulfur atoms form a ring[4].)

As expected, the equilibrium $nS_4^-\rightleftarrows nS_3^- + S_n$ is concentration-dependent. That it is also temperature-dependent is shown by the fact that violet solutions, which contain both S_3^- and S_4^-, become pure blue when warmed to 100 °C and red when cooled to 0 °C. Cooling to near the melting point of dimethylformamide (−61.0 °C) leads to *yellow* polysulfide(−2) solutions which are characterized by a first extinction maximum at 21000 cm^{-1}. The square of the quotient of the extinction values of S_4^- and S_3^- is proportional to the concentration of excess sulfur to a very good approximation in the range Na : S = 3 to 3.5; this is an indication that in EPD solvents the cleavage of S_8-sulfur to S_2 molecules is catalyzed by nucleophilic attack of sulfide.

In agreement with other authors[4,5] we have found no hyperfine splitting in the ESR signals of anionic sulfur radicals due to formation of long-lived ionic associates with Na^+ (*g* factor of S_3^-: 2.0280). That the signal width is very large particularly in dilute solutions (110—120 G) indicates a rapid exchange of electrons within larger, short-lived ionic associates with at least two S_n^- ions:

$$S_n^-\,Na^+\,S_n^- \rightleftharpoons S_nNa \qquad S_n^- \rightleftharpoons S_nNa^+S_n^{2-}$$

or rapid equilibration between polysulfide(−1) ions on the one hand and polysulfide(−2) ions and small sulfur molecules on the other.

π-Ionization Potentials of Alkylfulvenes, or the Limitations of Koopmans' Theorem[**]

By *Franz Brogli, Patricia A. Clark, Edgar Heilbronner,* and *Markus Neuenschwander*[*]

The so-called Koopmans' theorem states that vertical ionization potentials $I_{v,j}$, taken as negative, can be equated to the Hartree-Fock-SCF orbital energies ε_j:

$$\varepsilon_j = -I_{v,j} \tag{1}$$

where ε_j denotes the SCF orbital energy of that orbital ψ_j in the neutral singlet molecule M which loses the electron e^- in the (photo)ionization process

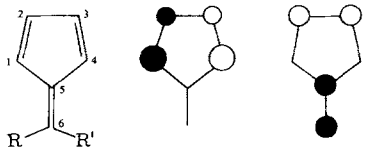
$$M \xrightarrow{h\nu} M^+(\psi_j) + e^- \tag{2}$$

That theorem (1) must fail in many cases was discussed in detail already by *Koopmans* in his fundamental paper[1] (cf. [2]). Photoelectron spectroscopy has recently provided numerous examples showing that, in particular, reorganization of the electrons remaining in the radical cation $M^+(\psi_j)$ results in considerable corrections. An extreme example is provided by bis(π-allyl)nickel, whose first ionization potential $I_v = 7.85$ eV[3] corresponds to the removal of an electron from the $9a_g$ orbital of the neutral molecule. This is an almost pure Ni-3d orbital[4], which, however, is not the highest occupied molecular orbital, but the 13th orbital (!), counted from the highest occupied orbital $7a_u$. *Ab initio* calculations by *Rohmer* and *Veillard*[5] showed that $\varepsilon(9a_g) = -18.3$ eV, whereas they obtained only $\Delta E(M^+(9a_g)) = -7.9$ eV for the energy of $M^+(9a_g)$ after relaxation of the electrons, this value being in good agreement with experiment.

In spite of the well known and well understood shortcomings of eq. (1) it is nevertheless often implicitly assumed that Koopmans' theorem is valid at least in the weakened form

$$\delta\varepsilon_j = -\delta I_{v,j} \tag{3}$$

i.e. that, for example, changes $\delta I_{v,j}$ in the ionization of a parent compound M due to substitution can be predicted from orbital energy shifts $\delta\varepsilon_j$ calculated by perturbation theory (cf. *e.g.* [6]). The following example of alkyl-substituted fulvenes *(1)* (R,R') will show that even this is true only under quite definite conditions.



(1) (R, R') $1a_2$ $2b_1$ (4)

The PE spectrum of fulvene *(1)* (H,H) shows two bands, at $I_{v,1} = 8.55$ and $I_{v,2} = 9.54$, which according to eq. (2) are to be correlated with the π-orbitals $1a_2$ and $2b_1$[7]. The π-orbital diagrams shown in (4) for $1a_2$ and $2b_1$ are those obtained from an HMO model.

Since $1a_2$ possesses a nodal plane through centers 5 and 6, the influence of the substituents R,R' would not be expected to cause any shift $\delta I_{v,1}$, whereas $\delta I_{v,2}$, because of the finite value of the π-orbital $2b_1$ at positions 5 and 6, should differ distinctly from zero and should be negative. This expectation is supported from a theoretical standpoint by calculations employing EHT[8], MINDO/2[9], SPINDO[10], and INDO[11] procedures[12] and assuming eq. (1) or (3) to be valid. In sharp contrast, however, the experiment (see Table 1) shows that $\delta I_{v,1}$ is of the same order of magnitude as $\delta I_{v,2}$.

Table 1. π-Ionization potentials of alkyl-substituted fulvenes *(1)* (R,R') in eV.

(1) (R,R') R	R'	$I_{v,1}$	$I_{v,2}$	$-\delta I_{v,1}$	$-\delta I_{v,2}$
H	H	8.55	9.54	0.00	0.00
H	Me	8.31	9.09	0.24	0.45
H	Et	8.27	9.03	0.28	0.51
H	*n*-Pr	8.23	8.95	0.32	0.59
H	*i*-Pr	8.25	8.97	0.30	0.57
H	*n*-Bu	8.24	8.96	0.31	0.58
H	*i*-Bu	8.17	8.91	0.38	0.63
H	*t*-Bu	8.11	8.88	0.44	0.66
Me	Me	8.08	8.75	0.47	0.79
Et	Et	7.99	8.63	0.56	0.91
n-Pr	*n*-Pr	7.92	8.53	0.63	1.01
$-CH_2(CH_2)_2CH_2-$		7.93	8.57	0.62	0.97

From the values in Table 1 one calculates that (in eV)

$$\delta I_{v,2} = (-0.0694 \pm 0.0297) + (1.503 \pm 0.071)\,\delta I_{v,1} \tag{5}$$

The correlation coefficient $r = 0.989$ shows that $\delta I_{v,1}$ and $\delta I_{v,2}$ are strictly linearly dependent on one another. The standard deviation from the regression line (5) amounts to only 0.042 eV. Since the regression line (5) does not significantly by-pass the origin on a 95% confidence level we can write for all the derivatives *(1)* (R,R'):

$$\delta I_{v,2}/\delta I_{v,1} = 1.5 \tag{6}$$

The reason why $\delta I_{v,1} \neq 0$ is at once evident if one carries out an SCF calculation for the radical cation produced from *(1)* (H,H) according to process (2) in one or the other of the two states $^2A_2$ (ground state; single occupation of $1a_2$) and $^2B_1$ (first excited state; single occupation of $2b_1$). The results collected in Table 2 have been obtained by the INDO procedure[11,12]. It can be seen that for the ground state $^2A_2$ the "Koopmans process" gives rise to changes $\Delta Q(1a_1)$ in the positive charge at positions 1, 2, 3, and 4 [cf. the orbital diagram (4)] and to zero change at positions 5 and 6. Relaxation of the electrons in the radical cation leads to the positive "holes" being filled by a drift of π- and σ-electrons. As a consequence removal of electrons from the exocyclic double bond causes a positive charge of $Q_6^+(1a_2) = 0.234$ unit charge at position 6. Taking the electron relaxation into consideration one finds, on comparing $Q_6^+(2b_1)$ with $Q_6^+(1a_2)$, that

$$Q_6^+(2b_1)/Q_6^+(1a_2) = 1.61 \tag{7}$$

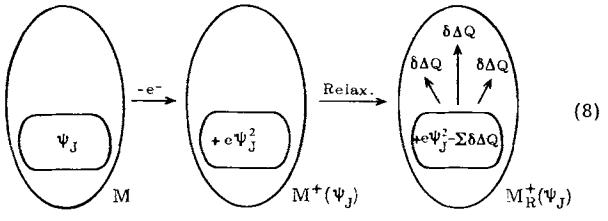
i.e., a value that agrees closely with the ratio of the observed shifts given in (6).

Table 2. Theoretical calculation of the electron relaxation in fulvene radical cations. All charges and changes of charge are given in $e/1000$ (e = unit charge) to the nearest whole number. Method of calculation: INDO [11]. Q = charge in the neutral fulvene *(1)* (H,H). $Q^+(1a_2)$, $Q^+(2b_1)$ = charge in the fulvene radical cation after relaxation has been taken into account. $\Delta Q(1a_2)$, $\Delta Q(2b_1)$ = change in charge due to removal of one electron from the orbitals $1a_2$ and $2b_1$, respectively ("Koopmans ionization process"). $\delta\Delta Q$ = change in charge due to relaxation of the π- or σ-electrons. Note: $Q^+(\psi) = Q(\psi) + \Delta Q(\psi) + \delta\Delta Q_\pi + \delta\Delta Q_\sigma$, within rounding off error.

		Ground state $^2A_2$				1st Excited state $^2B_1$			
		Ionization from $1a_2$; 1st band				Ionization from $2b_1$; 2nd band			
Position	Q	$\Delta Q(1a_2)$	$\delta\Delta Q_\pi$	$\delta\Delta Q_\sigma$	$Q^+(1a_2)$	$\Delta Q(2b_1)$	$\delta\Delta Q_\pi$	$\delta\Delta Q_\sigma$	$Q^+(2b_1)$
2, 3	−3	168	−34	16	147	164	31	−4	188
1, 4	−35	332	3	−63	237	12	−42	74	9
5	50	0	−104	49	−5	262	48	−131	229
6	25	0	164	45	234	386	−26	−9	376

From this result the general conclusion can be drawn that Koopmans' theorem is not always a valid approximation, even in the form (3), *i.e.* as a basis for perturbation calculations. It must fail in particular when, for example, for symmetry reasons, the orbital ψ_J that is vacated by the electron e^- in process (2) is localized only in one part of the molecule M (cf. (8)). According to the assumptions under which Koopmans' theorem was derived [same SCF orbitals ψ_J for M and $M^+(\psi_J)$] first a positive charge increase described by ψ_J^2 will be produced, which is necessarily localized [cf. $M^+(\psi_J)$]. The subsequent relaxation process spreads the positive charge into the region of



(8)

the system where $\psi_J^2 = 0$ [cf. $M_R^+(\psi_J)$]. The resultant charge equalization stabilizes the radical cation (*Pauling*'s electroneutrality rule). If M is substituted in a region where $\psi_J^2 = 0$, then clearly one must take into account the changes $\delta\Delta Q_\pi$ and $\delta\Delta Q_\sigma$ caused by electron relaxation since they give rise to first-order perturbations. Similar considerations apply also to orbitals whose "localization" is not due to symmetry, such as those of "lone pairs". On the other hand, the usual procedures within the framework of Koopmans' theorem may be expected to give reasonable results when ψ_J extends more or less uniformly over the whole molecule M.

Crystal and Molecular Structure of Cyclooctasulfur Oxide, S_8O[1]

By *Ralf Steudel*, *Peter Luger*, *Hans Bradaczek*, and *Michael Rebsch*[*]

S_8O is formed on condensation of $SOCl_2$ with "crude sulfane" (H_2S_n; $n = 3,4,5\ldots$) by the dilution technique; it crystallizes from CS_2 in yellow needles[2]. We have carried out a single-crystal X-ray structure analysis of such crystals at 10 °C.

The crystals belong to space group $Pca2_1$ with $a = 13.197$, $b = 7.973$, $c = 8.096$ Å, $d_{calc.} = 2.11$, $d_{exp.} = 2.13\ g\,cm^{-3}$. 1008 reflections with θ between 3° and 27° were measured on an automatic Siemens single-crystal diffractometer. 128 reflections whose intensity was less than twice the statistical error were regarded as unobserved. As the substance decomposed gradually the intensity measurements were effected with three different crystals. Scaling was achieved by a reference reflection. We determined the phases by the tangent formula[3]; the structure was refined by the method of least squares with anisotropic temperature factors for all atoms. After convergence of all the parameters the final R value amounted to 5.0%.

Figure 1 shows the result. Table 1 contains the intramolecular nuclear distances and angles. The molecule of S_8O belongs to the point group C_s. The S atoms form a crown-shaped ring in which each set of four atoms lies approximately in one plane. The two planes are almost parallel. The O atom is in an axial position to the ring. The S—O internuclear distance of 1.483 Å corresponds to the value of 1.49 Å calculated from the valence force constant[2].

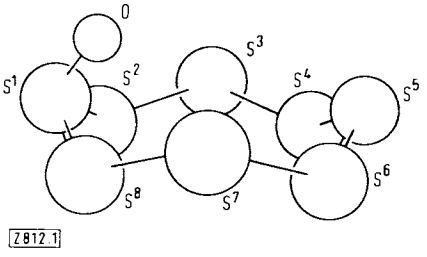

Fig. 1. Structure of the molecule of S_8O.

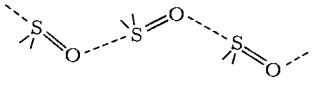
The intramolecular S—S distances show more pronounced variations than in the S_8 ring of rhombic α-sulfur where they vary between 2.042 and 2.050 Å[4]. Very striking are the two unusually large S—S distances involving the thionyl group (S^1S^2 and S^1S^8: 2.20 Å); these S—S bonds are to be regarded as partial bonds and their ready cleavage probably accounts for the ease of decomposition of S_8O at room temperature. SO_2 and polymeric sulfur are produced in this decomposition[2]; elimination of SO_2 can occur without diffusion or rotation of the S_8O molecule in the crystal since the packing is such that the SO groups of molecules stacked next to and above each other form a planar zig-zag chain:



The unit cell contains two such chains parallel to the *c*-axis. Within each chain the intermolecular S—O distance amounts to 2.935 Å (van der Waals bond length: 3.2 Å); the OSO and SOS angles amount to 175 and 131°, respectively. Such intermolecular interaction of the S_8O molecules was supposed previously on the basis of the IR spectrum[2].

The smallest intermolecular S—S distance of 3.388 Å accords with findings for rhombic sulfur[4] (van der Waals distance: 3.6 Å).

In the S_8O ring the dihedral angles, much discussed in connection with the stability of sulfur rings, vary within relatively large limits. The mean value 101.4°, however, is only slightly greater than that (99°) found for rhombic cyclooctasulfur[5].

Tetrasulfur Tetranitride—A New Insertion Reagent[**]

By *Herbert W. Roesky* and *Michael Dietl*[*]

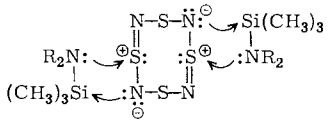
Cleavage of silicon-nitrogen or tin-nitrogen bonds by halides RX has proved to be a versatile synthetic procedure[1,2], but insertion reactions with S_4N_4 have not hitherto been reported.

We have now treated SiN (and also SnN) compounds of type *(1)*[3] with tetrasulfur tetranitride *(2)* in the molar ratio 2:1, and obtained products containing an S_2N_3 skeleton *(3)*, *e.g.*:

$$2\ (CH_3)_3SiNR_2 + S_4N_4 \rightarrow 2\ (CH_3)_3Si{-}N{=}S{=}N{-}S{-}NR_2$$

(1) *(2)* *(3a)*, R = CH_3 : b.p. 29 °C/0.01 torr; *(3b)*, R = C_2H_5: b.p. 37 °C/0.01 torr

The reaction appears to involve nucleophilic attack by the amino nitrogen on a sulfur atom of the S_4N_4 ring, leading to electrophilic cleavage of the metal-nitrogen bond[4].



In this connection particular interest attaches to the reaction of $S_3N_2Cl_2$ *(4)* with SiN compounds. For example, if *(4)* is allowed to react with *(1a)* in the molar ratio 1:2, then S_4N_4 *(2)* is formed as intermediate.

$$4\ (1a) + 2\ S_3N_2Cl_2 \rightarrow (2) + 4\ (CH_3)_3SiCl + 2\ (CH_3)_2N{-}S{-}N(CH_3)_2$$

(4)

Anorganisch-chemisches Institut I der Universität
6 Frankfurt, Robert-Mayer-Strasse 7—9 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

In such circumstances *(2)* exists in a particularly reactive form, being converted completely into *(3a)* by further reaction with *(1a)* according to the first mechanism above.

The compounds *(3)* are intensely red[5], oily liquids that distil unchanged under reduced pressure and react with halides[6].

In its ^{1}H-NMR spectrum, *(3a)* shows the expected two singlets, with intensity ratio 3:2, at $\delta_{(CH_3)_3Si} = -0.33$ and $\delta_{(CH_3)_2N} = -2.93$ ppm relative to $(CH_3)_4Si$ (external). The IR spectrum contains absorptions at 2990 w, 2980 s, 2890 w, 1452 s, 1255 vs, 1187 vs, 1037 w, 962 vs, 850 vs, 760 s, 673 s, 633 s, and 471 w cm^{-1} (capillary between KBr disks). The bands at 2900 are assigned to the C—H stretching and those at 1452 cm^{-1} to the corresponding deformation vibration. The strong bands at 1255 and 1187 cm^{-1} belong to S=N stretching vibrations.

Insertion reactions of S_4N_4 with other organometallic derivatives are at present under study.

General experimental procedure:

$S_3N_2Cl_2$ (0.05 mol) or S_4N_4 (0.1 mol) is suspended or partly dissolved, respectively, in CH_2Cl_2 contained in a two-necked flask with an attached dropping funnel and reflux condenser. $(CH_3)_3SiNR_2$ (0.2 mol) is added dropwise to this mixture at a rate such that the methylene chloride just boils. At the end of the reaction the solvent is removed and the product distilled at oil-pump vacuum. The reaction gives an almost quantitative yield of *(3)*[7].

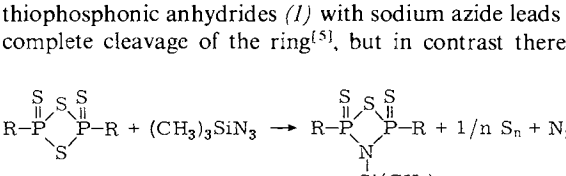
A Novel Covalent Azide Reaction in Phosphorus Chemistry[**]

By *Herbert W. Roesky* and *Michael Dietl*[*]

The best known reaction of azides for preparation of phosphazenes is connected with the names *Staudinger* and *Horner*: it consists in treating phosphane derivatives with alkyl, aryl, or acyl azides[1–4]. Reaction of cyclic alkyldithiophosphonic anhydrides *(1)* with sodium azide leads to complete cleavage of the ring[5], but in contrast thereto



(1) *(2)*

(3a), R = CH_3: m.p. 114 °C
(3b), R = C_2H_5: oil

heterocycles of type *(3)* are formed quantitatively from trimethylsilyl azide *(2)* and *(1)*.

The removal of sulfur and nitrogen begins already at room temperature and no further nitrogen is evolved if an excess of *(2)* is used.

(3a) is colorless, sublimes, and can be unambiguously identified by means of its ^{1}H-NMR and mass spectrum[6]. For the $(CH_3)_3Si$ group the ^{1}H-NMR spectrum shows a singlet at $\delta = -0.53$ ppm and for the CH_3P groups a doublet at $\delta = -2.52$ ppm with $J_{HCP} = 14.5$ Hz [relative to $(CH_3)_4Si$, external; solution in CH_2Cl_2]. In the mass spectrum the following characteristic fragments can be seen as well as the molecular ion 275 (58%): *m/e* = 260 [67%; $M-CH_3$], 245 [1%; $M-2CH_3$], 228 [3%; $M-SCH_3$], 211 [7%; $M-2S$], 196 [10%; $M-S_2CH_3$], 182 [5%; $(CH_3)_3SiNPS_2$], 170 [12%; $(CH_3)_2P_2S_2N$], 164 [10%; $(CH_3)_3SiNP_2CH_3$], 150 [100%; $(CH_3)_3SiNPS$], 138 [10%; $(CH_3)_2P_2SN$], 118 [26%; $(CH_3)_3SiNP$], 73 [62%; $(CH_3)_3Si$] 63 [11%; PS], 45 [20%; PN], and 32 [65%; S].

The IR spectrum of *(3a)* (KBr disk) shows bands at 2970 w, 2910 w, 1398 vs, 1300 vs, 1295 vs, 1286 s, 1255 vs, 985 vs, 910 vs, 845 vs, 770 vs, 758 vs, 700 vs, 620 vs, 541 s, 430 vs, 412 vs, 340 s, and 320 w cm^{-1}. It differs from the spectrum of *(1a)* particularly in the region of the (HCSi) deformation vibration.

Experimental:

$(CH_3)_3SiN_3$ (11.5 g, 0.1 mol) is added dropwise with stirring to a suspension of $(CH_3PS_2)_2$ (22 g, 0.1 mol) in CH_2Cl_2 (300 ml). Vigorous gas evolution sets in at once. At the end of the reaction the mixture is warmed for a short time and then filtered from the deposited sulfur under nitrogen. The solvent is removed in a vacuum and the residue is either recrystallized from CCl_4 or sublimed at oil-pump vacuum. The yield is quantitative (27 g).

Chemiluminescent Paracyclophanes[**]

By *Karl-Dietrich Gundermann* and *Klaus-Dieter Röker*[*]

Some time ago, *White et al.*[1] synthesized chemiluminescent compounds of type *(1)* containing a hydrazide group in a part of the molecule that is not itself luminescent or at most slightly so; the electronic excitation energy produced by their oxidation is transferred to another part of the same molecule that fluoresces strongly in the visible region; *(1)* chemiluminesces with the fluorescence emission of *N*-methylacridone. That the energy transfer is *intra*-molecular is shown, *inter alia*, by the fact that a mixture of

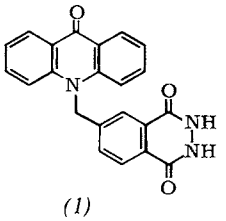
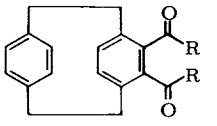
[**] Constitution and Chemiluminescence, Part 5.— Part 4: [5].

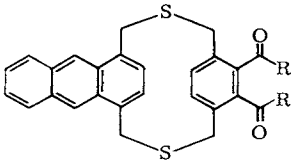
phthalhydrazide and *N*-methylacridone does not emit under the same conditions.



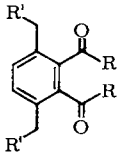
(1)



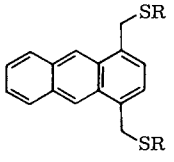
(2), -R R- = -NH-NH-
(3), R = OCH_3



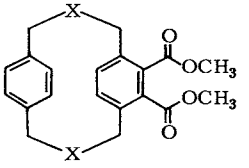
(4), -R R- = -NH-NH-
(5), R = OCH_3



(6), R = OH, R' = H
(7), -R R- = -NH-NH-, R' = H
(8), R = OCH_3, R' = Br



(9), R = H
(10), R = CH_3



(11), X = S
(12), X = SO_2

The methylene group in *(1)* and similar compounds precludes mesomeric interaction between the energy-producing and the emitting parts of the molecule; the two partial structures cannot assume the parallel positions particularly favorable for energy transfer (cf. [2]). Considerable parallel fixation between the phthalhydrazide and the fluorescing group should, however, be present in the corresponding paracyclophanes.

We have synthesized [2.2]paracyclophane-4,5-dicarboxylic hydrazide *(2)* and 2,15-dithia[3.3](1,4)anthraceneparacyclophane-18,19-dicarboxylic hydrazide *(4)* by *Vögtle*'s method[3]. In both these compounds the hydrazide portion resembles an ω,ω'-disubstituted derivative of 3,6-dimethylphthalic acid *(6)*, whose hydrazide *(7)* shows no chemiluminescence on hemin-catalyzed oxidation by aqueous alkaline hydrogen peroxide and extremely little in the system DMSO/*tert*-butoxide/oxygen. In *(4)* a substituted 1,4-bis(mercaptomethyl)anthracene *(9)* acts as a group that fluoresces in the visible region.

(4) (5.1×10^{-4} mol/l) chemiluminesces on oxidation by oxygen/potassium *tert*-butoxide (2.3×10^{-2} mol/l) in dimethyl sulfoxide at $\lambda_{max} = 450$ nm [fluorescence of *(10)*: 423 nm] with about double the amount of light emitted by 2,3-anthracenedicarboxylic hydrazide[5]. A mixture of *(10)* and the hydrazide *(7)* emits only about 1/25 as much light as *(4)* under the same conditions.

The paracyclophane derivative *(2)* fluoresces although formally only a *p*-xylene residue that cannot fluoresce is present as acceptor of excitation energy: *Vala*, *Haebig*, and *Rice*[2] previously noted the ability of unsubstituted [2.2]paracyclophane to fluoresce ($\lambda_{max} = 355$ nm). The emission of *(2)* in the system DMSO/*tert*-butoxide/oxygen ($\lambda_{max} = 395$ nm) is considerably weaker than that of *(4)* but nevertheless exceeds that of *(7)* in the same system by an order of magnitude.

(2) was obtained by conversion of disodium *p*-phenylenedi(methanethiolate) by *(8)* into *(11)* by the dilution method[3] (yield *ca.* 30%; m.p. 147 °C), oxidation of *(11)* by acetic acid/perhydrol to the disulfone *(12)* [yield 65%; m.p. 320 °C (dec.)], pyrolysis of *(12)* to *(3)* (yield 25%; m.p. 100 °C) and reaction of *(3)* with hydrazine hydrate in methanol. When heated, *(12)* affords only traces of *(3)* (cf. [4]); only the addition of a 12-fold amount of *p*-terphenyl, which clearly exerts a matrix-like short-range ordering effect, leads to yields around 25% of *(3)* on pyrolysis at 325 °C [*(3)*: ^{1}H-NMR ($CDCl_3$), $\tau = 6.50$—7.20 (m, benzyl-H) 3.32, 3.43 (phenyl-H), and 2.92 (phthalyl-H)].

We obtained *(4)* analogously. Simultaneous dropwise addition of *(8)*, *(9)*, and sodium hydroxide to a large volume of ethanol gave *(5)* (yield 31%; m.p. 230 °C) whose reaction with hydrazine led to *(4)*. We have not yet succeeded in oxidizing *(5)* to the disulfone. *(5)*: ^{1}H-NMR ($CDCl_3$), $\tau = 5.69$—6.05 (m, benzyl-H), 3.09, 2.23, 1.48 (anthracenyl-H), and 3.56 (phthalyl-H). This shift to higher field in comparison with the phthalyl protons of *(3)* proves the presence of the *anti*-isomer (cf. [6]).

Macromolecular Colloquium

The Macromolecular Colloquium—arranged by the Institut für makromolekulare Chemie der Universität Freiburg—was held at Freiburg/Br. (Germany), March 8—10, 1973.

From the lectures:

Polymerization Induced by Field Ionization and Field Emission in Various Liquid Monomers

By *Marcel Brendle*[*]

It was recently shown that polymerization reactions in bulk can be brought about purely by the action of very high electric fields, with no catalyst[1].

The ions or radical-ions are formed by field emission or field ionization of the monomer. This reaction requires very high electric fields ($>10^6$ V/cm). The most frequently used electrode system consists of a fine tungsten tip and a flat polished counterelectrode with an electrode separation d of 0.5 cm and an applied voltage V of 30 kV. Depending on the polarity of the tip, cationic, anionic, and in most cases also free-radical polymerizations can be initiated.

Since the currents are limited to an order of a few μA, very low concentrations of water or other deactivating impurities are sufficient to prevent ionic polymerization. In fact, a current of 1 μA for one hour corresponds to only 3.74×10^{-8} mole, *i.e.* 7×10^{-7} mole of water in a volume of 50 ml.

Ionic polymerizations can therefore occur only in very carefully dried monomers. There are probably no counterions; the lifetime of the ions is probably no greater than the time taken to migrate from one electrode to the other.

On the basis of this view, we have shown that the Faraday yield

$$R_F = \frac{\text{quantity of polymer formed}}{\text{quantity of charge introduced}}$$

should be

$$R_F = k_p m \frac{d^2}{\mu V} M$$

k_p = growth constant, m = concentration of monomer, M = molecular weight of monomer, μ = migration velocity of the ions.

In the case of styrene, we were able to show that the voltage V and the distance between the electrodes d correspond to this equation if the influence of the water that is always present is taken into account.

To determine the ratio of the ions deactivated by impurities to the electrically discharged ions, we compared the lifetimes of the growing ions τ_p to the time of migration τ_m. μ was determined by two independent methods[2].

In the cationic polymerizations of styrene, of cyclopentadiene, and of isobutyl vinyl ether, the τ_p and τ_m values agree to some extent.

Ultradry monomers (obtained by the method of *F. Williams* and *D. Metz*) and a more accurate determination of the migration time are necessary for the satisfactory determination of the constant k_p for ionic polymerizations without counterions. Experiments with this purpose are in progress.

Determination of the Configuration of Polybutadienes and Poly-α-methylstyrenes by ^{13}C-NMR Spectroscopy

By *K.-F. Elgert* (lecturer), *H.-J. Cantow*, *B. Stützel*, and *P.-J. Frenzel*[*]

High-resolution ^{1}H-NMR spectroscopy allows the determination of the tacticity of poly-α-methylstyrenes from the resonances of the methyl group, and independently also from those of the *o*-phenyl protons on deuteration of the *p* and *m* ring protons. A variation of the tacticity with the molecular weight has been detected in this way in products obtained by anionic polymerizations with butyllithium in THF[1]. In polybutadienes, on the other hand, the *cis*-1,4 and the *trans*-1,4 resonances are situated close together and are difficult to separate while no tacticity effect can be detected in the 1,2 sequences[2]. This invariance of the spectra with respect to the configuration of the 1,2 units allowed the quantitative analysis of the succession of chemically different sequences in α-methylstyrene-butadiene copolymers from proton resonance spectra[3].

On the other hand, the ^{13}C-NMR spectra found for polybutadienes at 22.7, 25.2, and (with a superconducting system) 67.9 MHz are satisfactorily resolved with regard to *cis*-1,4 and *trans*-1,4 resonances and the tacticity of 1,2 linkages. By measurements on products obtained by various polymerization mechanisms, it was possible to show from the resonances of the ^{13}C nuclei of the vinyl and aliphatic resonance region that the positions of the signals are influenced not only by the different isomeric structural units but also by their neighboring groups. Investigations on the isomerization of *cis*-1,4-polybutadienes were also included in the discussion.

Determination of configurational sequences is also possible in poly-α-methylstyrenes. The dependence of the tacticity

Asymmetric Stereoselective Polymerization of the *N*-Carboxy Anhydrides of D,L-Leucine

By *Heinrich G. Bührer* and *Hans-Georg Elias* (lecturer)[*]

N-Carboxy-D,L-leucine anhydride was polymerized in dioxane, benzene, tetrahydrofuran, butanone, or dimethylformamide between 10 and 55 °C with 15 primary and secondary amines as initiators. The optical yield of polymer can be satisfactorily described for conversions between 3 and 94% by an ideal copolymerization equation

$$d[L]/d[D] = R([L]/[D])$$

The highest R (= 1.30) was found for initiation with L-proline methyl ester in dioxane at 25 °C. The ideal copolymerization equation can be derived for ten models, depending on the assumptions regarding homopropagation, heteropropagation, homo-absorption, and/or hetero-absorption. The most likely answer, according to all the observations, is a pure or at least strongly predominant homopropagation ($k_{LL}=k_{DD}$; $k_{LL}[P_L^*] \gg k_{DL}[P_D^*]$ and $k_{DD}[P_D^*] \gg k_{LD}[P_L^*]$), with a constant concentration of active chain ends in the D and in the L configuration ($[P_L^*]=$ const.; $[P_D^*]=$ const'.; $[P_L^*]/[P_D^*] \neq 1$).

Supports Containing Diazonium Groups for Biologically Active Compounds

By *J. Exner* (lecturer), *M. Křiváková*, *J. Labský*, *M. Bleha*, *O. Wichterle*, and *J. Čoupek*[*]

Suspension copolymerization of hydrophilic monomers with a comonomer that contains a primary amino group leads, in an inert solvent in the presence of a crosslinking agent, to macroporous aerogels having well-defined pore size distributions and with large internal surface areas. These properties allow the use of the copolymers as supports for biologically active compounds for catalytic processes and for affinity chromatography. The biologically active component is covalently bonded to the surface of the highly crosslinked matrix.

Because of the physical properties of the gel, the support possesses outstanding mechanical strength and good flow-through properties with minimal non-specific adsorption.

The relations between the properties of the support skeleton, the diazotization conditions, and the concentration of diazonium groups and their reactivity with passive coupling components, model amino acids, and model enzymes have been followed. At the same time, the influence of the modifying reactions on the physical structure of the gel and the influence of the unreacted ionic groups on the activity of the bound enzyme were studied. Possible applications of these macroporous hydrophilic supports based on hydroxyalkyl methacrylate were discussed.

Plant Structural Polysaccharides: Structure and Biosynthesis

By *W. W. Franke* (lecturer) and *W. Herth*[*]

The characteristic morphology of plant cells and tissues is determined by the cell wall, and in particular by the structural polysaccharides. The latter are characterized by their mechanical stability, their high degree of polymerization, their fibrillar superstructure, and their chemical stability (in particular toward alkalis).

Over the past decade, it has been shown that in addition to the typical representatives of this group (cellulose and chitin) some other polysaccharides are also capable of fulfilling these functions. These polysaccharides include β-1,3-glucans, β-1,3-xylans, β-1,4-mannans, and also xyloglucans, glucomannans, and glucogalactans. The algae in particular show wide variations in this respect. In some cases it has been possible to demonstrate that the membrane-bound biosynthesis of these polymers occurs not outside but inside the cells, in the sacs of the Golgi complex, the polymeric product being released from the cell by membrane fusion processes taking the form of exocytosis. In the course of such a secretion even the crystallization stage can take place intracellularly.

Chemical analyses show that such structural polysaccharide fibrils are not pure polyglycans, but contain a stable and probably covalently bound peptide portion with a very characteristic pattern of amino acids (in particular, a high proportion of OH-amino acids). It has recently been suggested that this peptide portion may have a particular significance in controlling the synthesis of structural polysaccharides, and the analogies to the formation of animal and bacterial peptidoglycans and the more alkali-labile cell-wall substances are emphasized.

Kinetic and Morphological Studies on the Free-Radical Grafting of Styrene on Polybutadienes

By *J. P. Fischer*[*]

The kinetics of the free-radical grafting of styrene on polybutadienes is investigated with the aid of fractional precipitations. It is possible in this way to describe the dependence of the nature and quantity of the graft copolymers formed on the structure of the polybutadienes and the conditions of the thermal and initiated polymerization of styrene.

Kinetically derived equations allow the separation of the grafting into the polymer-radical and initiator-radical contributions. Different initiators give very different grafting reactivities. Thermal graft polymerization shows only a polymer-radical contribution, which increases in particular with the 1,2 vinyl content of the polybutadiene and with rising temperature.

The length of the grafted chains is determined by the kinetics of the styrene polymerization, and can be adjusted

[*] Dr. J. P. Fischer
Farbwerke Hoechst AG
6230 Frankfurt 80 (Germany)

particularly readily by chain transfer agents. The average number of grafted chains per grafted polybutadiene molecule increases from a value of 1 with increasing monomer conversion in a manner that can be described kinetically.

The influence of the nature and quantity of the graft copolymer on the adjustment of the morphology in the graft polymerization of styrene on polybutadiene is determined independently of the normally coupled effects, *e.g.* of the viscosity of the polystyrene matrix, by experiments with additions of graft copolymer. Within certain molecular weight limits, the emulsifier effectiveness is proportional to the length of the grafted chain. Consequently, the graft efficiency (% of grafted styrene with respect to total polystyrene) is found to be a good combination measure for describing the effect of graft copolymers on the dispersity of the multiphase system in question.

A Method for the Investigation of Stress-Induced Rearrangement Processes in Polymers: Crystal Transition II to I of Poly-1-Butene by Mechanical Stresses

By *G. Goldbach*[*]

The rate of transition of the tetragonal modification II of poly-1-butene into the hexagonal crystal form I can be considerably increased by mechanical stresses. Investigations on the stress-induced crystal transition II to I over a wide temperature range showed that a noticeable transition begins only when the yield stress is reached (uniaxial tensile tests). Since the yield stress corresponds essentially to the shear strength of the material, one could assume that the transition from modification II to modification I is induced by shear stresses rather than by tensile stresses. Measurements were carried out in a multiaxial stress field to establish which stress component is decisive for the transition.

The experimental arrangement chosen was a film with a hole (modification II) under tensile stress, from whose geometry the stress fields can be calculated from elasticity theory. The degree of transition from II to I was measured by IR spectroscopy along specific lines at the edge of the hole where the maximum shear and principal stresses are known. The evaluation of the results showed that in tensile tests the II to I-transformation is induced by a tensile deformation of the crystals and not by a shear deformation.

Polymeric Reagents

By *M. L. Hallensleben*[*]

The use of polymeric reagents instead of low molecular weight reagents in preparative organic chemistry offers a number of important advantages. Linear polymeric reagents can be easily separated from the product after a reaction because of the difference in solubility in certain solvents; crosslinked polymeric reagents considerably simplify the isolation of products from the reaction mixture[1, 2]. Use in a column considerably increases the yields in many cases, since the substrate in the column always follows a large concentration gradient of the reagents.

Investigations were carried out on a number of polymeric reagents that satisfy the essential conditions for economical use of such compounds. These conditions are that reactions on the reagents should proceed polymer-like, so that there is no loss of the above advantages as a result *e.g.* of chain degradation, and in particular there is no change in the flow properties in a column in the case of gels; polymeric reagents must be capable of being regenerated, since their synthesis is generally more expensive than that of low molecular weight analogs.

These conditions are satisfied by poly-*p*-styryl iodide chloride[3, 4] and by poly-*p*-iodosostyrene diacetate[4, 5], which can be used for chlorinations[6] and for oxidations and acetylations[7] respectively. The use of poly-*p*-vinylbenzoyl chloride and of poly-4-vinylpyridinium tetrahydridoborate as polymeric reagents was also studied. From the above points of view, the only polymeric metalating agents that can be used and regenerated are those with complexed metal.

Use of Polymerization Kinetics for the Investigation of Homogeneous Catalytic Processes

By *G. Henrici-Olivé* (lecturer) and *S. Olivé*[*]

The activation of molecular oxygen on soluble transition metal centers is a topic of current interest. On the one hand, low molecular weight model substances should help to provide an understanding of the processes that occur on the respiratory pigments, while on the other it is hoped that access will be gained to selective oxidation of suitable substrates with homogeneous catalysis.

We investigated cobalt complexes of the general form $X_2R_4Co(II)$ (X = organic anion, R = primary aliphatic amine), which eagerly take up oxygen to form diamagnetic μ-peroxo complexes: $X_2R_3Co—O—O—CoR_3X_2$. The latter decompose when heated, with formation of a paramagnetic Co(II) species, which is again able to take up oxygen (catalysis), and with oxidative modification of amine ligands.

The thermal decomposition of the complexes leads to free radicals that initiate the polymerization of styrene. From the kinetics of the polymerization, it was possible to calculate the decrease in the concentration of the radical-producing species with time. The magnetic changes in the system also allowed direct kinetic investigation of the decomposition of the μ-peroxo complex. A first-order course was found in both cases, with equal rate constants. This shows that the free radicals are formed in connection with the decomposition of the complex.

The reaction products of the amines suggest the intermediate occurrence of alkyl free radicals.

Ring-opening Polymerization of Cycloolefins in the Presence of Metathesis Catalysts

By *Hartwig Höcker* (lecturer), *Rüdiger Musch*, *Frank R. Jones*, and *Ingo Lüderwald*[*]

The metathesis reaction of acyclic monoolefins leads to transalkylidenation products, whereas cyclic olefins react by the same mechanism to give oligomers and polymers which should have a cyclic structure.

To allow the conclusive demonstration of the cyclic structure of these oligomers, the reaction conditions were optimized for the oligomerization of cyclooctene and the oligomers up to the decamer were separated by gel permeation chromatography and investigated spectroscopically. The IR, the NMR, and particularly the mass spectra which show the molecular ion peak of the oligomer in question, up to the nonamer, with a peak-free field in front, confirm the cyclic structure.

The catalyst for the reaction consists of a transition metal halide, an activator in certain cases, an alkylating or a reducing agent, and an aluminum halide. In particular, the systems $WCl_6/C_2H_5OH/C_2H_5AlCl_2$, $WCl_2(OC_6H_5)_4/BuLi/AlBr_3$, and $WCl_6/BuLi/AlBr_3$ were investigated. The results of the polymerization of cyclooctene in the presence of the systems mentioned lead, with consideration of the yield and the structure of the polymers obtained, to the following conclusions:

1. An activator is necessary only if a relatively weak alkylating agent is used.

2. Two ligands of the transition metal are replaced by alkyl groups.

3. An aluminum halide is required as a complexing agent.

Quaternary Structure and Activity of Enzymes

By *Rainer Jaenicke*[*]

The definition of the quaternary structure of enzymes contains implicitly the assumption of inactive subunits according to the reaction

$$M_n \text{ (active)} \rightleftharpoons n \cdot M \text{ (inactive)}.$$

This correlation of quaternary structure and activity cannot be understood from the point of view of evolution, since association is preferably considered to cause *regulation* rather than causing *activity* itself.

Normally, determinations of particle weight and of enzymatic activity are carried out in concentration ranges differing widely from each other. On carrying out a systematic study of the particle weight of some glycolytic enzymes under conditions identical to those used in the enzymatic test ($c \leqq 1$ µg/ml), the correlation of molecular weight and activity to the parameters of the solution turns out to be different for different enzymes. In general conditions which lead to complete splitting into subunits concomitantly cause deactivation. This effect can be accounted for by denaturation (without dissociation), since denaturation in general precedes dissociation.

[*] Prof. Dr. R. Jaenicke
Fachbereich Biologie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

In the case of lactate dehydrogenase the concentration-dependent reactions of dissociation and deactivation run parallel; at the same time, the kinetics of reassociation after dissociation and deactivation at pH < 3 are shown to be slow in comparison with the kinetics of renaturation[1].

The apoenzyme of glyceraldehyde-3-phosphate dehydrogenase occurs in a partially dissociated state under standard conditions of the enzymatic test; depending on the concentration, dissociation gives both dimers and monomers. In the presence of the coenzyme (NAD) the equilibrium is shifted to the tetrameric state.

In the case of aldolase, splitting in 8 M urea and subsequent reactivation by dialysis or dilution points to active subunits[2]; in this case decreasing protein concentration as well as increasing ionic strength do not lead to dissociation under any conditions of the experiment.

It may thus be concluded that under certain circumstances subunits are capable of showing enzymatic activity. Basically, the enzyme is stabilized by association, just as it is by coenzyme binding. Under the conditions *in vivo* the enzymes under consideration should be regarded as associated, since even in the case where the effective concentration of the enzyme is low, other proteins or polyelectrolytes inhibit dissociation as well as deactivation.

International Molecules

By *Rolf Hosemann*[*]

Interesting, novel, rubbery-elastic phenomena have been observed for linear and branched polyethylenes; these phenomena allow conclusions to be drawn regarding the molecular structure, and appear to be typical for a large class of synthetic and biological linear high polymers.

In the case investigated, necking on drawing leads to a drawing factor that is characteristic of the material. If the material is subsequently crosslinked with small doses of radiation (*e.g.* 15 Mrad of ^{60}Co) and then maintained not too high above its melting point for not too long, the original form is restored in every detail, down to colloidal dimensions. Large-angle and small-angle X-ray studies show that the original crystal structure of the material crystallized from the melt was completely altered on drawing. The "memory" lies in the "international" molecules, which join these individual crystal regions that are distorted and deformed in the drawing process.

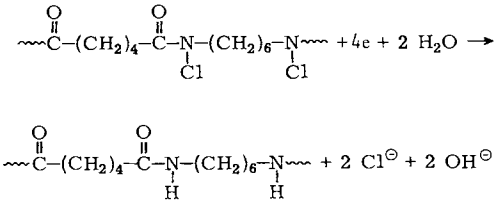
1. the oxidative action of *N*-chloro-polyamides, *e.g.* N—Cl-nylon 66:



Numerous organic and inorganic substances can be oxidized in accordance with this scheme. The substances whose standard potentials are known can be arranged in order of increasing potential up to the system:

$$Br_2 + 2e \rightleftarrows 2Br^{\ominus}$$

2. The *N*-chloro-polyamide is reduced in accordance with the above redox equation to the polyamide, from which the oxidizing agent can be regenerated by *N*-chlorination. An aqueous solution of HOCl is very suitable for use as the *N*-chlorinating agent.

3. Various methods can be used to bring the *N*-chloro-polyamide into a favorable form for the kinetics of a heterogeneous redox reaction in aqueous systems. We polymerized *N*-substituted acrylamides into ion exchange resins and obtained a snake-cage configuration. After *N*-chlorination, products of this type can exert an oxidizing action and can exchange ions to a greater or lesser extent, depending on the starting substances.

The Quasi-Static Elasticity Moduli of Semicrystalline Copolymers of Ethylene

By *H. G. Kilian* (lecturer) and *D. Klattenhoff*[*]

The elasticity moduli of random copolymers of ethylene at 1 Hz were measured as a function of the temperature and of the composition of the copolymers. From knowledge of the main superstructure parameters of the semicrystalline systems, and taking energy-elastic and entropy-elastic contributions into account, we calculate moduli that are determined by "crystal crosslinking" and by "physical" crosslinking in the noncrystalline regions. The theoretical elastic properties of systems with different degrees of crystallinity depend on the model used. Characteristics of the superstructure must be taken into consideration.

Partial Miscibility of Polymer Solutions

By *R. Koningsveld* (lecturer) and *W. H. Stockmayer*[*]

If a polymer solution separates into two liquid phases, one of these phases is usually extremely dilute, while the other is relatively concentrated. Extensive thermodynamic studies have been carried out on the latter state, in which the macromolecular coils overlap considerably, as well as on the dilute solution, in which the coils are separated from one another by regions of pure solvent.

To describe such phase equilibria, one requires an expression for the free enthalpy of mixing, which covers the two concentration ranges continuously. A suitable semi-empirical equation is proposed, which has the advantage of containing no additional adjustable parameters. The values of the parameters can be found from independent experimental data on dilute and on concentrated solutions.

It is shown that this function can at least partly explain the discrepancy found by *Breitenbach* and *Wolf*[1] in certain phase relations in the polystyrene-cyclohexane system. The effect of the dilute solution is generally evident only to a small extent in the phase separation.

Determination of the Radius of Gyration of Polymethylmethacrylate in the Vitreous State by Neutron Diffraction

By *R. G. Kirste*, *W. A. Kruse* (lecturer), and *J. Schelten*[*]

Light diffraction and X-ray diffraction yield little information regarding the morphology of filament molecules in the pure, amorphous phase. A new procedure has been devised for this purpose. Dilute solid solutions of the normal polymer in the fully deuterated polymer are prepared. Because of the large difference between the coherent scattering cross sections of D and of H, the neutron diffraction experiments can be evaluated in the same way as light diffraction and X-ray diffraction experiments on dilute solutions of polymers in low molecular weight liquids. As the background, one subtracts the scattering of a polymer preparation containing D and H in the same ratio as the solid solutions, but with the protons and the deuterons randomly distributed over all the molecules.

The method was first used for the investigation of vitreous polymethyl methacrylate (PMMA). The specimens were prepared by dissolution of the calculated quantity of a fractionated normal PMMA (*i.e.* a PMMA containing protons) in deuterated monomeric MMA and subsequent polymerization of the deuterated monomer. Equilibration is ensured by annealing at 130 °C. For $M_w = 250000$, one obtains a Zimm plot, from which the second virial coefficient of the osmotic pressure was found to be $A_2 = 0$ and the radius of gyration to be $r_z = 130$ Å ($r_w = 116$ Å). The radius of gyration is almost the same as in a low molecular weight θ-solvent.

The Deformation of Single Spherulites

By *M. Kryszewski*[*]

In a number of articles we have discussed the deformation of single spherulites and considered several inconsistencies

[*] M. Kryszewski
Polska Akademia Nauk
Centrum Badań Molekularnych i Makromolekularnych
Łódź 40, ul. Prędzalniana 72 (Poland)

in the literature in this connection. Our theory dealt with the deformation of two-dimensional spherulites; a flat, two-dimensional structure consisting of radially distributed two-dimensional individual elements with a definite anisotropy of the mechanical properties was assumed.

This model was then extended to a three-dimensional spherulite, which consists of two-phase volume elements with transverse anisotropy of the mechanical properties in the radial direction. On the assumption of a definite distribution of the mechanical stress, the deformation of these individual volume elements can be calculated. By summation of their translation, it is possible to calculate the dimensions of spherulites deformed by external mechanical forces. These results can be compared with direct results from optical microscopy. The distribution density of the structural elements in the deformed spherulite was also calculated and taken into account in the theory of small-angle light scattering by spherulites (*Samuels* approximation).

Determination of the Lengths of Grafted Chains and Incompatibility of Graft Polymers

By *Rainer Kuhn* (lecturer), *Heiner Alberts*, and *Herbert Bartl*[*]

The molecular weights M_w of the grafted chains in graft polymers and the incompatibility of the grafted chains with the backbone polymer can be determined by light-scattering measurements in solution if the solvent used in these measurements is isorefractive with the backbone polymer and if the content of grafted chains by weight is known.

The method is illustrated for fractions of graft polymers in which styrene is grafted on ethylene-vinyl acetate copolymer. From the anomalous Zimm diagrams at 90 °C in toluene, which is isorefractive with ethylene-vinyl acetate copolymers at this temperature, almost regardless of the vinyl acetate content, one obtains the molecular weights M_w of the grafted polystyrene chains if one molecule contains only one grafted chain, irrespective of whether ungrafted backbone polymer is still present.

The anomalous Zimm diagrams also provide a measure of the incompatibility of the grafted chains with the backbone polymer, both through the virial coefficients and through the radii of gyration of the grafted chains. Also from the anomalous Zimm diagrams, it is possible to define a θ concentration at which the length of the grafted chains M_w can be determined by light scattering at only one concentration.

After calibration, the molecular weight of the grafted chain can be deduced simply from the phase separation determined by turbidimetric measurements.

By combination of light-scattering and phase-separation measurements for molecules having more than one grafted chain per molecule, it is possible to estimate the molecular weights and the number of grafted chains per molecule.

After suitable fractionation, the chain-length distribution of the grafted chains in graft polymers can also be obtained by the light-scattering method described.

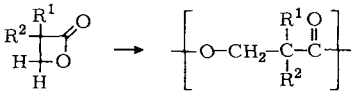
Preparation, Structure and Mechanical Properties of Block Copolyesters from β-Lactones

By *R. W. Lenz*[*]

The ring-opening polymerization of two 2,2-dialkyl-β-propiolactones to form linear polyesters (initiated by ammonium carboxylates) was studied:



PL, $R^1 = R^2 = CH_3$
MPL, $R^1 = CH_3$, $R^2 = n\text{-}C_3H_7$

Initial investigations on the polymerization of MPL showed that this anionic polymerization reaction formed polymers having very narrow molecular weight distributions, indicating the existence of a "living polymer" system. As a result, AB and ABA block copolymers of PL (as the A unit) and MPL were prepared and characterized for crystallinity, melting point, and stress-strain properties as films. Unusual crystallinity and melting point behavior was observed by DSC in both the block copolymers and the MPL homopolymers, and both PL and MPL polyesters are believed to exist in interchangeable helix and linear zig-zag crystalline unit cells (possibly as a function of elongation) as indicated by X-ray diffraction studies. The tensile properties of the ABA block copolymers were believed to be dependent upon the quality of phase separation between PL and MPL blocks. Phase separation behavior was investigated by dynamic-mechanical methods.

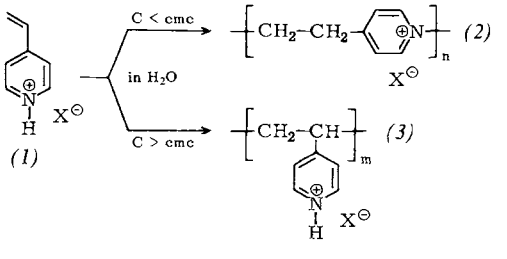
Polymerization Reactions of 4-Vinylpyridinium Salts in Aqueous Solutions

By *Volker Martin* (lecturer), *Helmut Ringsdorf*, *Helmut Ritter*, and *Wolfgang Sutter*[*]

The "spontaneous" polymerization of 4-vinylpyridinium salts *(1)* in water leads to polymers having different structures according to the monomer concentration. The change of product is explained by aggregation of the monomers *(1)* above the critical micelle concentrations (cmc). Polyadducts *(2)* are formed below these concentrations by a nucleophilic addition reaction, and polymers *(3)* at higher concentrations, probably by a free-radical mechanism.



[*] Dipl.-Chem. V. Martin, Prof. Dr. H. Ringsdorf, Dipl.-Chem. H. Ritter, and Dr. W. Sutter
Organisch-Chemisches Institut der Universität
65 Mainz, Johann-Joachim-Becher-Weg 18—20 (Germany)

The critical micelle concentrations (cmc) of 4-VP salts are strongly dependent on the counterion. They can be lowered by addition of foreign salts. At the same time, the "critical polymerization concentrations" (cpc), the concentrations at which polymer formation starts, are also lowered.

Mixtures of *(2)* and *(3)* are found in the region of the critical micelle concentrations. The width of the transition range increases with decreasing tendency for the monomer to form micelles.

The effects of CO_2, SO_2, O_2, and NO on the polymerization behavior below and above the critical micelle concentration were investigated. Anionic (CO_2) and free-radical (O_2, NO) inhibitors have no influence on the formation of the polyadduct *(2)*. The formation of the polymer *(3)*, on the other hand, is strictly inhibited by O_2 and NO.

Light-Induced and Free-Radical Initiator-Induced Cationic Polymerization of *N*-Vinylcarbazole in the Presence of CBr_4

By *O. F. Olaj* (lecturer), *J. W. Breitenbach*, and *H. F. Kauffmann*[*]

On irradiation ($\lambda = 365$ nm) or addition of azobisisobutyronitrile (AIBN) to a benzene solution of *N*-vinylcarbazole (NVC) and CBr_4, a rapid polymerization begins. The conversion-time curves have a sigmoid shape in every case; termination processes are of minor importance at least in the light-induced polymerization, since after the light source is switched off, the polymerization continues for a long time at the rate prevailing at this instant. The polymerization is brought to a stop only by a side reaction with formation of a colored substance or by exhaustion of the monomer.

A kinetic approach, that is based on the absence of a termination reaction and takes into account the consumption of monomer as the reaction proceeds, leads to the equation

$$-\ln(1-U) = Kt^2$$

(U = conversion in fractions, t = reaction time)

which is excellently satisfied by the experimental data. The composite quantity K in the photo-initiated polymerization is proportional to $I^{\frac{1}{2}}$ at low intensities I, and to I at high intensities; no equivalent trend with respect to the initiator concentration can be detected for the AIBN-initiated polymerization, for which K is roughly proportional to $[\text{AIBN}]^{0.75}$.

The termination-free character of the polymerization points to an ionic mechanism; in copolymerizations with styrene or methyl methacrylate as comonomers, NVC is almost exclusively incorporated into the polymer. This is typical of a cationic polymerization mechanism.

The cationic character of the AIBN-initiated polymerization can be explained by the assumption that the free radicals formed by decomposition of the initiator are converted after a few free-radical growth steps into 1-bromo-1-carbazylalkyl structures by transfer reaction with the highly efficient chain-transfer agent CBr_4, and these structures then function as centers of *cationic* chain growth (with Br as the counterion).

The photoinitiation leads first to radical-cations, whose ionic function is probably already capable of growing, while the free-radical function is again converted into a cationic 1-bromo-1-carbazylalkyl derivative by chain transfer with CBr_4.

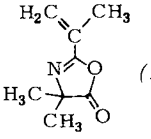
Inhomogeneous Polymer Networks through Incompatibility

By *Gerhard Markert* (lecturer) and *Horst Pennewiss*[*]

Copolymers of 4,4-dimethyl-2-isopropenyl-5-oxazolone *(1)*[1] with acrylic or methacrylic esters are crosslinked with diamines and investigated by torsional vibration experiments.



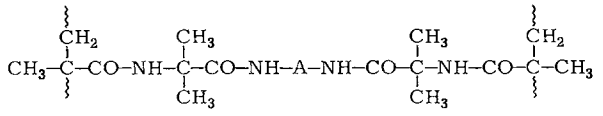
(1)

With increasing content of *(1)* (5 to 30 mole-%), increasing mechanical inhomogeneity is observed. There are two possible reasons for this:

a) a nonuniform distribution of the oxazolone groups,

b) a difference in the degree of intramolecular crosslinking.

In connection with the question of chemical inhomogeneity, the mechanical measurements are compared with calculations for the copolymerization. By variation of the



A = $(CH_2)_6$, $(CH_2)_{20}$, $(CH_2{-}\underset{CH_3}{CH}{-}O)_{\bar{n}-1}{-}CH_2{-}\underset{CH_3}{CH}$ with $\bar{n}$ = 4, 8, 16

crosslink length A, it is possible to influence the degree of intramolecular crosslinking, as can be seen from the determination of the conversion at the gel point.

Polymerization and Copolymerization of 1,2-Dimethoxyethylene

By *Norbert Vollkommer*[*]

1,2-Dimethoxyethylene is prepared from trimethoxyethane by elimination of methanol in the gas phase in a fixed-bed catalyst.

Whereas no polymer is obtained with free-radical and anionic initiators, the polymerization can be initiated with

[*] Dr. N. Vollkommer
Dynamit Nobel AG, Zentrallabor I
521 Troisdorf (Germany)

cationic initiators. Organometallic compounds containing halogen and syncatalytic initiator systems are used in addition to Friedel-Crafts catalysts, perchlorates, and oxonium salts. Organoaluminum compounds containing chlorine, such as diethylaluminum chloride and ethylaluminum dichloride, have proved to be the most favorable group of cationic initiators.

The polymerization of dimethoxyethylene with this last group of initiators can be carried out particularly advantageously in the region around -50 °C with liquefied low-boiling aliphatic hydrocarbons as the suspension medium. The effects of the initiator concentration, the polymerization temperature, and the content of suspension medium on the polymerization conversion and molecular weight are investigated. Polydimethoxyethylenes having molecular weights ($\bar{M}_w$) of around 290000 can be obtained in almost quantitative conversions.

The principal properties of polydimethoxyethylene are reported, particularly the behavior in aqueous solution in the presence of electrolytes or water-soluble polymers, the absorption of water from the atmosphere at various atmospheric humidities, and a number of physical and mechanical properties.

Copolymerization experiments with monomers that polymerize with ring cleavage, such as six-membered ring carbonates and four-membered and seven-membered ring lactones, were also carried out.

Analysis of the Tacticity of Polymers by ^{19}F-NMR Spectroscopy

By *W. Regel* (lecturer), *L. Westfelt*, and *H.-J. Cantow*[*]

The ^{1}H- and ^{19}F-NMR spectra of monomeric *p*-fluoro-α-methylstyrene were discussed. The measured spectrum of the type AA'BB'X (X = ^{19}F) is in complete agreement with the calculated spectrum.

In cationically synthesized—predominantly syndiotactic—polymers, splitting of the α-proton signals at 220 MHz, and of the fluorine signals at 94.1 Hz, takes place according to the tacticities; the degree of splitting was found to be greater in the ^{19}F-NMR spectrum. The proportions of syndio- (83%) and of hetero-tactic triads (17%) calculated from the ^{19}F resonance are in agreement with those determined from the resonances of the α-methyl protons.

A heteronuclear decoupling technique (protons) especially developed for the Varian HA-100 spectrometer (100 MHz) led, as expected, to a single peak for the fluorine in monomers and to a splitting into pentads in the case of the polymers.

It could thus be shown that ^{19}F-NMR spectroscopy makes very good resolution of the *p*-fluorine nucleus possible in a short measuring time, even when the fluorine nucleus is far removed from the skeletal chain.

Model Calculations for the Hydrolytic Polymerization of Caprolactam

By *Ferdinand Hafner*, *J.-C. Heilig*, and *Paul Wittmer* (lecturer)[*]

Caprolactam can be polymerized in various ways; the most important reaction from the industrial point of view is polycondensation or hydrolytic polymerization. Three equilibrium reactions occur together in this process (hydrolytic ring cleavage, polycondensation, and monomer addition). Amide groups also undergo transamidation.

We use kinetic equations for the formal description of the complete reaction. The constants required for numerical calculation were taken from the literature. One constant was changed from the literature value to obtain better agreement between the calculated values and the experimental results. Regulation by amine or carbonyl groups is taken into account.

The kinetic equations can be used together with formal patterns for reactors, *e.g.* residence-time spectra, for the mathematical simulation of the course of polymerization in given feed mixtures and reactors. This is a great help in the planning and optimization of reactors.

The equations are also suitable for the calculation of the rate of remonomerization on fusion of the delactamized polymer.

The Initial Stage of the Oxidative Degradation of Native Cellulose by Molecular Oxygen

By *G. V. Schulz* (lecturer), *S. Jovanović*, and *A. Palma*[*]

Native Cellulose: Cotton bolls grown in a greenhouse are harvested immediately before or after they open, extracted with organic solvent, and boiled with 2% sodium hydroxide solution containing added Na dithionite. Result: A material that is completely soluble in cuprammonium solution or, after nitration, in acetone, contains no gel particles according to light scattering (LS) measurements, and consists to an extent of about 90% of molecules having a uniform degree of polymerization of 14000.

Degradation: 1. Treatment with 20% NaOH in the strict absence of oxygen at 20 °C. 2. The resulting alkali metal cellulose is exposed to molecular oxygen, and the decrease in the molecular weight (M_w) is followed by LS and [η] measurements. The molecular weight distributions of the nitrates were determined continuously during these treatments.

Result: The treatment with alkali alone leads to a considerable decrease in viscosity, whereas LS measurements show that M_w remains constant, the radius of gyration decreases, and the second osmotic virial coefficient A_2 increases. Other physical properties (density, refractive index) also change. Fractionation experiments show that these property changes occur practically uniformly in all the molecules. They may be regarded phenomenologically as a sort of molecular shrinkage process. The same effect is observ-

[*] Prof. Dr. G. V. Schulz, Doz. Dr. S. Jovanović, and Dr. A. Palma
Institut für physikalische Chemie der Universität
65 Mainz, Jakob-Welder-Weg 15 (Germany)

ed in the cuprammonium solutions of the cellulose as well in the acetone solutions of the nitrate. It thus has considerable chemical resistance. The nitrates of the original cellulose and of the shrunk cellulose have equal nitrogen contents.

Interpretation: We assume that this shrinkage is due to intramolecular chemical crosslinking of the cellulose chains during the alkali treatment. More or less large rings are introduced into the dissolved molecule in this way, and these reduce the radius of gyration in solution. This interpretation is supported by the fact that oxidative cleavage of glucoside linkages in the alkali-treated material first leads to an increase in the intrinsic viscosity, while the molecular weight found by LS measurements remains unchanged; this means that after prolonged treatment with alkali, nearly all the glucose units are situated in the rings, whose cleavage increases the radius of gyration without reducing the molecule. The purely intramolecular nature of the crosslinking is shown by the fact that the molecular weight distribution of the alkali-treated material has no detectable component with a degree of polymerization higher than 14000.

Conclusion: The cellulose molecules must be folded in the elementary fibrils.

Growth of Crystals of Polyoxymethylene during Equilibrium Polymerization of Trioxane

By *Rosa Mateva* and *G. Wegner* (lecturer)[*]

It has long been suggested that polymerization and crystallization are coupled in the cationic polymerization of trioxane. We have therefore investigated the growth of the hexagonal platelets of POM formed immediately after addition of the catalyst (BF_3Et_2O) with the aid of electron-microscope methods. The results can be correlated with measurements of the conversion, the molecular weight, the specific gravity, the melting behavior, and the thermal stability of the polymers obtained.

At the end of the nucleation period, lamellar single crystals about 80—150 Å thick and about 1 µm in diameter are present. The chains are folded in the usual manner in these lamellas. It is surprising to note that these crystals increase both in thickness and in diameter with increasing conversion. This growth continues even after the limiting conversion imposed by the prevailing ceiling equilibrium has been reached. The driving force of this reaction is the minimization of the free surface energy of the microscopic crystals present, which are in equilibrium with one another *via* the polymerization-depolymerization equilibrium in the presence of the catalyst; thus smaller crystals redissolve, while larger crystals continue to grow.

The lateral growth of the crystals takes place by the normal polymerization reaction. The increase in thickness, on the other hand, results from the insertion of monomer into the chain folds of the surfaces of the lamellas. This reaction proceeds uniformly from the crystal-chemical point of view, with formation of growth spirals. The thickness of the crystals increases to an average of about 3000 Å. These crystals formed in thermodynamic equilibrium have the character of extended chain-crystals.

The results described a) can be generalized for numerous ring opening polymerizations in which crystalline polymer is formed, and b) are important to the theory of copolymerization in such systems. [VB 326 IE]

Structural Chemistry of Mercury

By *Drago Grdenić*[*]

Until recently[1] the only known mercury compound with a purely ionic structure was mercury(II) fluoride which has the cubic CaF_2-type structure. At present, ternary fluorides with the perovskite-type structure, and fluorometalates with the VF_3-type or $LiSbF_6$-type structure are known[2] in which mercury has octahedral coordination. In all other structures, even those involving oxygen, *e.g.*, the oxide, oxide halides, hydroxide halides, and salts of oxoacids, mercury is covalently bonded within an irregular coordination polyhedron. This is also true for the structure of mercury(II) hydroxide fluoride[3] containing chain-like cations

—(OH)—Hg—(OH)—Hg—

with an Hg—O bond length of 2.06 Å.

The free molecules or complexes of the mercury compounds contain either two collinear, three coplanar, or four tetrahedral bonds involving mercury. These bonds, defining the characteristic[4] coordination about mercury, are approximately equal to the sum of the covalent radii if 1.30, 1.37, or 1.48 Å is taken for the respective covalent radius of mercury. No structure containing an individual complex with the mercury atom in octahedral coordination has been reported up to now. The characteristic linear or trigonal coordination about mercury is completed in the crystal structure to the effective[4] coordination with the coordination number four, five, or six accomplished in a "distorted" tetrahedron, trigonal bipyramid, or octahedron. The effective coordination about mercury includes all atoms whose distance from the mercury atom is less than the sum of the van der Waals radii, 1.50 Å being taken for the van der Waals radius of mercury.

The lengths of the characteristic bonds are affected less than the angles between them, particularly in the "tetrahedral" effective coordination. The collinear characteristic bonds persist in many crystal structures as the two shortest bonds, the additional bonds in the effective "octahedral" coordination being either equal or, usually, equal in pairs. The equatorial angles at mercury deviate from 90° but the centrosymmetrically distorted octahedron is quite common. The collinearity of the Hg—C bonds also persists in the crystal structure of the symmetric organomercury compounds and is only slightly influenced by the ligands introduced. The substituted atoms or groups in the organic part of the molecule may affect the collinearity of the Hg—C bonds as well as the coplanarity in the molecule of the aromatic derivative.

According to recent results[5] there is no correlation between the electronegativity of the ligands and the Hg—Hg bond length in the mercury(I) compounds. Hg—Hg distances from 2.495 to 2.540 Å were found in thirteen crystal structures with an average of 2.508 Å. This is less than the sum of the covalent radius of 1.30 Å for collinear bonds in mercury(II) compounds, probably because of the d_π-p_π contribution to the Hg—Hg bond. The coordination

[*] Prof. Dr. D. Grdenić
Institute of Inorganic and Analytical Chemistry,
University of Zagreb
YU-41000 Zagreb, Ul. soc. revolucije 8 (Yugoslavia)

about mercury in mercury(I) compounds does not show any regularity. All known structures of the mercury(I) salt hydrates contain the oxonium group

$H_2O—Hg—Hg—OH_2$

with an Hg—O bond length between 2.14 and 2.20 Å. Chelate ligands or the anions of oxoacids are not symmetrically coordinated to the Hg—Hg ion. In mercury(I) arsenate[6] the smallest Hg—O distances lie between 2.16 and 2.23 Å, while in mercury(I) trifluoroacetate[7] this distance is 2.14 Å. It is interesting that no organomercury compound with Hg—Hg—C bonding has yet been described.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Ionic solvation in nonaqueous and mixed solvents is the title of a review by *J. I. Padova*. The author deals with: Thermodynamics of solvation and the determination of corresponding parameters (heat of reaction, free energy, and entropy); theory of solvation; solvation numbers; solvation in mixed aqueous-organic solvents; and transport processes (viscosity, electrical conduction, Stokes' law Walden's rule, association processes). [Ionic Solvation in Nonaqueous and Mixed Solvents. Mod. Aspects Electrochem. *7*, 1—82 (1972); 431 references]

[Rd 562 IE—G]

Recent developments in the catalysis of hydroformylation feature in a review authored by *F. E. Paulik*. After carbonylcobalt had long been considered the catalyst of choice and progress been restricted essentially to variations in process parameters, the chemistry of organic transition metal complexes afforded new scope for catalyst modifications which have led to reduced reaction temperatures and pressures and greater selectivity and stability of catalysis. Metal complexes with organophosphanes as ligands have proved to be particularly suitable and the publication therefore concentrates mainly on these catalysts. [Recent Developments in Hydroformylation Catalysis. Catal Rev. *6*, 49—84 (1972); 62 references]

[Rd 565 IE—G]

Catalyst studies with the aid of a temperature-programmed desorption technique are summarized by *R. J. Cvetanovi* and *Y. Amenomiya*. In this technique, which was first described by the authors in 1963, gas adsorbed on a catalyst is desorbed in a stream of inert carrier gas by programmed heating of the catalyst. The method has the advantage that no ultra-high vacuum is required and the conditions more closely resemble those encountered in practice. The literature is covered up to 1971 and a detailed account is given of Al_2O_3, SiO_2/Al_2O_3, carbon, metal oxides, and metals as catalyst materials. [A Temperature Programmed Desorption Technique for Investigation of Practical Catalysis. Catal. Rev. *6*, 21—48 (1972); 47 references]

[Rd 567 IE—G]

NMR in ferromagnets and antiferromagnets is the subject of a survey by *M. P. Petrov* and *E. A. Turov*. NMR is one of the most informative methods available for the study of the spatial distribution of local magnetic fields and spin density, of interactions between electrons and nuclei, and of the temperature dependence of magnetic moments. The pronounced changes in the NMR frequency and relaxation time with the temperature, *e.g.* in MnF_2, permits precise measurement of temperature between 10 and 40 K with an accuracy of 10^{-4} K. [Nuclear Magnetic Resonance in Ferromagnets and Antiferromagnets. Appl. Spectrosc. Rev. *5*, 265—330 (1972); 119 references]

[Rd 572 IE—G]

Concepts of reaction dynamics are discussed in a review by *J. C. Polanyi*. Starting from the concept of (attracting and repelling) energy surfaces the author discusses the individual collision processes in exothermic, endothermic, and thermoneutral reactions as well as reactions involving high collision energies. Energy distribution in reaction products is also dealt with. [Some Concepts in Reaction Dynamics. Accounts Chem. Res. *5*, 161—168 (1972); 43 references]

[Rd 596 IE—L]

The determination of the conformation of cyclic polypeptides in solution is discussed by *F. A. Bovey*, *A. I. Brewster*, *D. J. Patel*, *A. E. Tonelli*, and *D. A. Torchia*. It is shown that not only NMR but also IR, CD, and ORD data can be used in conjunction with energy calculations to give a self-consistent structure (or structures). Especially conclusive are the coupling constants of the α-CH- and NH-protons of the peptide skeleton.—Synthetic cyclohexapeptides as well as the decapeptide antamanide, the nonapeptide cyclolinopeptide A, and phalloidine, whose confor-

mations are illustrated as space filling models, are used as examples. [Determination of the Solution Conformation of Cyclic Polypeptides. Accounts Chem. Res. 5, 193—200 (1972); 69 references]

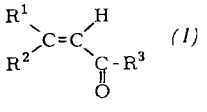
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Resin compositions or objects made from them that are decomposed and degraded by the action of light and whose destruction does not present the usual problems of environmental pollution consist of 1) 50—100 wt.% of a copolymer of a) 95—99.9 wt.% of styrene and/or methyl methacrylate, b) 5.0—0.1 wt.% of a diene monomer such as butadiene or isoprene, and c) up to 4.9 wt.% of an unsaturated ketone having the general formula *(1)*, such as methyl vinyl

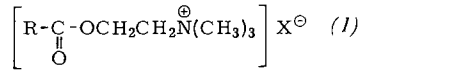


(1)

ketone, phenyl vinyl ketone, phenyl propenyl ketone, and/or benzylideneacetophenone, and 2) up to 50 wt.% of a thermoplastic resin that is different from *(1)*, *e.g.* polystyrene, PVC, polyethylene, *etc.* [DOS 2165157; Sekisui Kagaku Kogyo K. K., Osaka]

[PR 60 IE—O]

Antistatic agents for the treatment of high polymers that retain their antistatic activity irrespective of the mode of application and exhibit good compatibility with the high polymer are choline ester salts having the general formula *(1)*, *e.g. N*-(hexanoyloxyethyl)- or *N*-(octanoyloxyethyl)-trimethylammonium chloride. The compounds *(1)* are



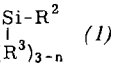
(1)

R = straight-chain alkyl group C_5-C_{17}
$X^{\ominus}$ = singly charged anion, preferably $Cl^{\ominus}$ or $NO_3^{\ominus}$

advantageously added together with 3—20% (based on the total quantity of antistatic) of choline chloride to the polymers, particularly polyolefins, PVC, polystyrene, or their copolymer mixtures. [DOS 2157290; Unilever N. V., Rotterdam]

[PR 61 IE—O]

Antithrombogenic plastic components consisting of *e.g.* polyethylene, polypropylene, or polystyrene, PVC, polyvinyl acetate, or polyacrylonitrile are obtained by bonding a heparin layer to an aminosilane coupler having the general formula *(1)*. R^1 denotes halogen or alkoxy, R^2 is amino-



(1)

alkyl, R^3 is alkyl, and $n = 1$—3. The surface of the resin is first impregnated with the aminosilane *(1)* and a swelling agent until it is swollen and the aminosilane is bonded to the resin. The aminosilane *(1)* is protonated by sufficiently long immersion of the resin in an aqueous acidic salt solution. The plastic component is then immersed in an aqueous acidic solution of a heparin salt, whereupon the heparin is bonded to the aminosilane coupler *(1)*. The plastics treated in this way are used in medicine as materials for artificial organs, since clotting or hemolysis on contact with blood or serum is suppressed. [DOS 2154542; Corning Glass Works, Corning]

[PR 84 IE—E]

A hydrogen transfer reaction for the preparation of unsaturated compounds, preferably having a diene structure, starts with unsaturated compounds A, which serve as hydrogen donors, and organic hydrogen acceptors B; catalysts based on complexes of Group VIII metals in which the metals are present in a low valence state are used. The reactants A and B may be the same or different, and must contain at least one ethylenically unsaturated bond. The process can be applied both to aliphatic and to cycloaliphatic unsaturated compounds, as well as to unsaturated compounds having functional groups, such as nitrile, ester, or ether groups. Conjugated dienes with a well-defined steric configuration are obtained. — In one example, hexene, which serves both as A and B, is allowed to react in the presence of $IrH_3[P(C_6H_5)_3]_2$ to form hexane and *trans,trans*-2,4-hexadiene. The reaction is carried out in an inert solvent, preferably in an inert atmosphere and with the addition of small quantities of hydrogen, above normal temperature and at or above normal pressure. [DOS 2149934; Snam Progetti S.p.A., Milan]

Oxonium Ions in Organic Chemistry. By *H. Perst*. Verlag Chemie GmbH, Weinheim/Bergstr. and Academic Press, New York—London 1971. 1st ed., ix, 202 pp., 6 figs., 12 tables, cloth DM 55.—.

The importance of oxonium compounds in organic chemistry is due partly to their great preparative value, particularly in alkylations, and partly to the fact that they are reactive intermediates in many organic reactions.

In seven chapters, this book summarizes the present knowledge of oxonium ions in organic chemistry, which has not yet reached unmanageable proportions. After a brief introduction to historical development (4 pp.), classification and nomenclature of oxonium ions are discussed (6 pp.), followed by a section on their stability (11 pp.). The fourth chapter deals with formation and methods of preparation (35 pp.), Chapter 5 with the reaction behavior of oxonium salts (42 pp.). Reactions which proceed *via* oxonium ions, or where oxonium ions are supposed to be reactive intermediates, are summarized in Chapter 6 (27 pp.). In the last section, the application of oxonium salts in synthetic work is described (39 pp.). An appendix concerning the structure of oxonium ions refers mainly to protonation products of carbonyl compounds investigated in recent years by NMR spectroscopy.

In the discussion of unsaturated oxonium ions, differentiation from carbonium ions presents a fundamental difficulty since, due to electronegativity differences, the positive charge will be localized predominantly at carbon atoms. It would, therefore, have been better to omit the rather lengthy discussion of the carbo-cation problem (see *e.g.* pp. 13 *et seq.*, 63 *et seq.*, or 78 *et seq.*) in favor of "true" oxonium ions. In the reviewer's opinion, this objection also applies to the much too detailed presentation of pyrylium salts which have been given much more space than trialkyloxonium salts, both in the chapter on methods of preparation and that on synthetic application.

The presentation of a number of tables must be criticized. To recognize all details in Table 9, for example, one needs good light and above-average vision or the aid of a magnifying glass. The continuous numbering of formulas does not offer much of an advantage since most structural formulas are reproduced several times in any case, and the literature references are numbered chapter by chapter.

Apart from these minor shortcomings, however, the book provides a very good synopsis of an important class of compounds, and thus is a welcome addition to the review literature.

Franz Effenberger [NB 151 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Bindung, Struktur und Reaktionsmechanismen in der organischen Chemie (Bonding, Structure, and Reaction Mechanisms in Organic Chemistry). By *I. Ernest*, Springer Verlag, Wien New York, 1972, x, 389 pp., bound DM 98.—.

Contents: Structure of organic compounds; general characteristics and classification of organic reactions; polar reaction; free radical reactions; multicenter reactions involving cyclic electron shifts.

Light Guide Systems for the Ultraviolet Region of the Spectrum

By Helmut Dislich and Alfred Jacobsen[*]

Whereas diverse and highly refined fiber optics have long been in technical use for the conduction of visible light, traditional but expensive silica glass lenses and prisms have had to be utilized until quite recently for the transmission of ultraviolet light. The reason for this was the lack of suitable materials. UV light cannot be transported to any technically useful extent either with pure glass-glass (core and sheath materials) light guides or with plastic-plastic light guides. UV light guides for wavelengths down to 200 nm can be produced by combination of a silica glass as the core material with a tetrafluoroethylene-hexafluoropropylene copolymer or methylpolysiloxane as the sheath material. Fiber optics of this type constitute a new aid for medical technology, medicine, and many technical and scientific fields, whose range of applications cannot yet be fully envisaged.

1. The Principle of Light Conduction

If a rod or a fiber made of transparent material having a high refractive index n_1 is coated with a transparent sheath of a material having a lower refractive index n_2, light falling on the end surface is conducted through the rod or fiber as a result of total reflection. The light is reflected without loss at the interface between these media (whereas loss occurs on reflection at a mirror surface), and is transmitted through the system in a zigzag path until it emerges at the other end. Important characteristics of such systems are:

1. the light transmittance
2. the aperture angle.

Both should be as large as possible. To achieve this, the core material in particular should have excellent transmittance, and the sheath layer, which should also be transparent, should have an excellent optical contact with the core. This means that the sheath must be in smooth and uniform contact at all points to allow loss-free total reflection. The difference between the refractive indices $n_1 - n_2$ should be as large as possible, since this determines the aperture angle $2\alpha_0$ at which light can be conducted (see Fig. 1) in accordance with

$$n_0 \sin \alpha_0 = \sqrt{n_1^2 - n_2^2}$$

(n_0 is the refractive index of the surrounding medium).

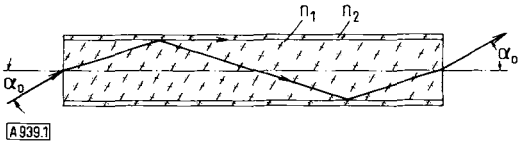

Fig. 1. Principle of light conduction.

1.1. Known Systems

The simplest case of light conduction is when light is transmitted along a straight or only slightly curved (radius

[*] Dr. H. Dislich and Dipl.-Phys. A. Jacobsen
Laboratorien des Jenaer Glaswerk Schott & Gen.
65 Mainz, Postfach 2480 (Germany)

of curvature >20 diameters) path through an unsheathed rod of glass or plastic. The surrounding air then acts as the low-refractivity sheath. Systems of this type have serious disadvantages since the optically effective sheath surface is exposed, and scratches and dust deposits lead to light scattering and hence to losses. The light guides used in practice are therefore predominantly of the sheathed variety.

The sheathed systems correspond to Figure 1, and those consisting of massive rigid rods require no further description. However, flexible light guides consisting of bundles of fibers have become much better known, if only because of the fact that they can be used to "guide light round corners", and in the case of "coherent bundles of fibers" one can actually see round corners, a possibility that fascinates even the optical layman. The light in this case is led through optically isolated flexible fibers as illustrated in Figure 1. A large number of these fibers are combined into a bundle, the fibers being cemented together at the ends and polished. The bundles are enclosed in a protective metal or PVC tube, and can be widely used in medicine (endoscopy) and in industry. If the arrangement of the fibers in relation to one another at the point where the light enters corresponds to that at the point where the light emerges, transmission of images is possible. If the fibers are unordered, they can be used only for the transmission of light.

Finally, mention should be made of fiber rods; these also consist of a large number of optically isolated fibers, which are fused together over their entire length and are therefore rigid. These are coherent, *i.e.* capable of transmitting images, and can be subsequently bent round relatively sharp corners.

Arising from these basic types there are a large number of interesting variations, which greatly extend the existing possibilities in optics. However, it is not the aim of this report to present a comprehensive description of the current position in this respect. Such an account has appeared elsewhere[1].

2. Materials

To lead up to the subject proper, let us first consider the question of the materials that can be used. As was mentioned above, the decisive factor is the light transmittance. The traditional material of optics is glass. The entire development of fiber optics in the Jenaer Glaswerk Schott & Gen. was carried out with high-quality optical glasses, so that both the cores and the sheaths of the commercially available products[2] consist of glass.

The possibility of using pure plastics systems has been under discussion for a long time. *Kapany*[3] showed that the fiber-forming polymers in the drawn state have disadvantages in comparison with glass fibers because of the anisotropy resulting from their partial crystallinity. He also noted disadvantages with regard to surface quality. However, the flexible systems developed by Du Pont[4,5] are produced from plastics. These consist of a polymethyl methacrylate core and a low-refractivity sheath of partly fluorinated plastics.

We were interested in plastics only as sheath materials, as we wished to take advantage of the outstanding properties of glass as a core material, in particular its good optical transmittance, surface accuracy, and polishing qualities of the end faces where the light enters and emerges.

2.1. The Core Material of the UV Guides

All the possibilities discussed so far are concerned with the conduction of visible light, in some cases extending into the near infrared region. Ultraviolet light with shorter wavelengths could not be conducted, since the transmittance of the core materials was insufficient. For light with wavelengths of down to 200 nm, there is no choice as far as core materials are concerned; practically the only possibility is high-purity silica glass, which must be of outstanding optical quality (in particular free from bubbles), and which can be drawn to fibers. We used Suprasil® (manufacturer: Heraeus-Schott, Quarzschmelze GmbH). For light having a wavelength of 365 nm, it is occasionally possible, within limits, to use special UV-transparent glasses if the optical path length is not excessive. However, this possibility is mentioned only in passing, as it is of no fundamental importance.

2.2. The Sheath Material of UV Fiber Optics

Flint glass has the following refractive indices at various wavelengths: $n_{546}=1.460$; $n_{365}=1.475$; $n_{155}=1.506$.

An optically isolating material for silica glass must therefore consist of a material that has a sufficiently low refractive index at all wavelengths and that is transparent to light of the wavelength in question.

One's first thought is naturally of the wide range of optical glasses, which is shown in Figure 2 in the form of the usual $n_d-\nu_d$ diagram. n_d is the refractive index for the d line (587.6 nm), and ν_d is the Abbé number, a measure of the dispersion.

Though the optical catalog of the Jenaer Glaswerk Schott & Gen. lists several hundred types of optical glasses, it is immediately clear that these do not include one with a sufficiently low refractive index to make it suitable for use as a sheath material. Here we reach a limit to the current optical possibilities of glasses. The present limit of the glass range in the direction of low refractive indices is shown by a broken line in Figure 2. The continuous lines are the limits of the individual glass types. The dot-dash line surrounds the region of the transparent plastics. In the direction of higher refractive indices, the glass region extends far beyond the top of the diagram.

Since glasses offer no further help with regard to a suitable sheath material, the next step is to consider other inorganic, UV-transparent materials with extremely low refractive indices. One such material is magnesium fluoride, which is commonly used as a transparent coating deposited from the vapor phase, *e.g.* as an antireflective coating on optical lenses.

While the properties of the material are promising, the technical difficulties of the vapor deposition of coatings

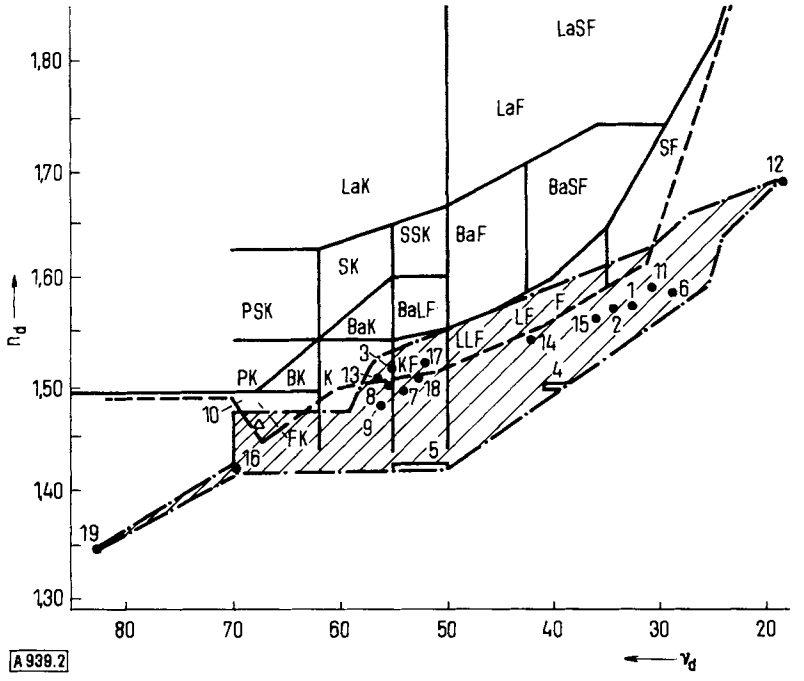

Fig. 2. Glass region and plastic region in the $n_d - \nu_d$ diagram. $\nu_d = (n_d - 1)/(n_F - n_C)$ (Abbé number). n_F, n_C: refractive indices for the F and C lines. ---: present limit of the glass region, -·-·-: present limit of the region of transparent plastics having known $n_d - \nu_d$ values. Δ: silica glass; •: plastics 1—19. 1, styrene-acrylonitrile copolymer; 2, poly-*o*-diallyl phthalate; 3, polymethyl α-chloroacrylate; 4, methylphenylpolysiloxane; 5, methylpolysiloxane; 6, poly-α,α-dimethyl *p*-(*p*-hydroxyphenylmethyl)phenyl hydrogen carbonate; 7, polymethyl methacrylate; 8, polydiethylene glycol diallyl carbonate; 9, cellulose acetate; 10, cellulose propionate; 11, polystyrene; 12, poly-*N*-vinylcarbazole; 13, polycyclohexyl methacrylate; 14, polyvinyl chloride; 15, epoxy resin (Araldite CY 206); 16, poly-2,2,2-trifluoroisopropyl methacrylate; 17, methyl methacrylate-α-methylstyrene copolymer; 18, methyl methacrylate-acrylonitrile copolymer; 19, tetrafluoroethylene-hexafluoropropylene copolymer (Teflon FEP).

several μm thick on fibers impose such severe limits that technically useful products are unobtainable[6].

2.3. Optical Properties of Plastics

Another alternative to the classical materials of optical glasses is offered by the transparent plastics, whose region is indicated by the shaded area in the $n_d - \nu_d$ diagram (Fig. 2). It is interesting to note that the region of the transparent plastics extends considerably beyond that of the glasses, and coincides only in part with the latter[7].

A general comparison of the positions in the $n_d - \nu_d$ diagram (optical positions) with the chemical structures of the polymers reveals simple principles, which have been fundamentally known for a long time[8], and which are simply confirmed or expanded by newly developed plastics.

Highly aromatic plastics such as polystyrene, polyaryl carbonates, or even poly-*N*-vinylcarbazole have high refractive indices and low Abbé numbers; fluorinated and particularly perfluorinated polymers are characterized by low refractive indices and high Abbé numbers.

With the aid of the Lorentz-Lorenz equation

$$R_M = \frac{n^2 - 1}{n^2 + 2} \frac{M}{d}$$

R_M = molar refraction, M = molecular weight, d = density, n = refractive index

it is possible to estimate (and even to calculate fairly satisfactorily with the aid of atomic, group, and bond refractions if the density is known) the hypothetical limits for the optical position of the plastics[8]. If hypothetical polymers are speculatively included in this calculation, one arrives at the result that as far as one can see at present, there will presumably be no polymers with refractive indices appreciably above $n_d = 1.73$ or below $n_d = 1.33$, and that the center of the glass region cannot be reached with plastics.

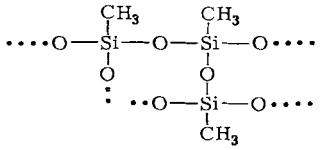
It may be noted in passing that this places limits on the competition that is sometimes referred to between optical glasses and plastics. The competition arises in the region of overlap between glasses and plastics. In general, however, a more interesting area in optics is that of glass-plastic combinations, particularly here in the case of UV light guides.

Plastics have recently become available whose chemical structure, according to the relations discussed here, suggests that they should have optical properties such as are required of a sheath material for UV light guides. These materials are methylpolysiloxane and tetrafluoroethylene-hexafluoropropylene copolymer (points 5 and 19 respectively in Fig. 2).

2.4. Methylpolysiloxane

Where can we find a material for coating rods or fibers of silica glass which has a refractive index lower than that of silica glass and a good UV transparency? Such properties are embodied in a methylpolysiloxane that became known in an optical quality in the middle 1960's[9],

in which the Si—O skeleton of silica glass carries one methyl group per silicon atom, the lowest possible degree of substitution.



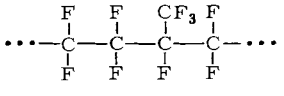
It is obtainable in principle by hydrolysis and polycondensation of a methyltrialkoxysilane $CH_3—Si(OR)_3$[9], and is trifunctionally crosslinked in the cured state. The optically perfectly clear material, while very transparent to UV light, has sufficiently low refractive indices as a result of the incorporation of CH_3 groups. The refractive index has fallen from 1.460 to 1.418 at 546 nm and from 1.475 to 1.453 at 365 nm.

A silica glass rod is immersed in a 50% solution of partly condensed methyltriethoxysilane in alcohol, withdrawn at a constant rate (in addition to other parameters, this mainly determines the coating thickness), and heated to a maximum of 135 °C. The silica glass rod is thus provided with a sheath of very good optical quality, and exhibits an aperture angle of $2\alpha_0 = 29°$ at 365 nm.

While some of the problems in the transport of UV light were solved with these rigid light guides[10, 11], flexible UV fiber optics still remained as the principal aim. A silica glass fiber can in principle be coated continuously, as required here. However, the curing times for the above polycondensation are too long for production, particularly when good optical quality is essential. Further investigations were therefore carried out with the object of finding a plastic with a still lower refractive index and a shorter setting time.

2.5. Tetrafluoroethylene-Hexafluoropropylene Copolymer

Point 19 in Figure 2 shows the extreme optical position of the material known by the trade name Teflon FEP®. With $n_{546} = 1.347$, $n_{365} = 1.356$, and $n_{255} = 1.376$, it has a lower refractive index than any other plastic known at present. Because of its branched structure as a copolymer



of tetrafluoroethylene and hexafluoropropylene, it does not exhibit the strong crystallization tendency of polytetrafluoroethylene, and so remains sufficiently transparent. Coatings of very fine particles can be applied from aqueous dispersions, and after removal of the water and the dispersing aids by heating, these particles can be fused to form a continuous, optically satisfactory film. This is again a property of the copolymer that it does not share with polytetrafluoroethylene.

We shall not go into details of the technically interesting as well as troublesome development of the continuous coating of a silica glass fiber 100 µm in diameter[12]. The first requirement was to draw a bubble-free, stria-free, and scratch-free fiber of uniform thickness continuously from silica glass. This fiber was passed through the aqueous dispersion of Teflon FEP and then through a long furnace. The processes of drying, evaporation of the dispersing aids, and fusion of the remaining Teflon FEP particles to form a continuous film required accurate adjustment of temperature gradient and of time, mainly because of the need to avoid thermal decomposition of the copolymer. Special care was necessary to lead the relatively fragile fiber over many guiding rollers without damaging its surface[*].

The essential point seems to be that the problem of the conduction of UV light by any desired route to any desired place has been solved[12] by combination of the outstanding UV transmittance of silica glass and its ability to be drawn into fibers with the good UV transmittance and the extremely low refractive index of a polyperfluoroalkane[13], and that this is the only solution found so far.

Figure 3 shows the spectral transmittance of flexible UV light guides in the form of a bundle of fibers.

3. Construction and Uses of UV Light Guides

The coated silica glass fibers have recently been used, mainly during the past year, for the development of many UV-conducting components, which have been included by the Industrial Research Council in the USA (Chicago) among the hundred most significant new technical developments of 1972. The product should be regarded primarily as a new tool for medical technology, medicine, physics, materials testing, photochemistry, and many other fields extending as far as genetics.

3.1. Properties

The system is optically transparent between 200 and 2200 nm; this range is interrupted only by an absorption band at 1400 nm and some weak harmonics of the OH absorptions. The optical transparency was measured with light entering the light guide at an aperture angle of 5°. The significant feature is the relatively high, uniform transmittance in the visible and near UV regions (Fig. 3). Light guides 1800 mm long reach values of more than 40% in the region between 280 and 1300 nm.

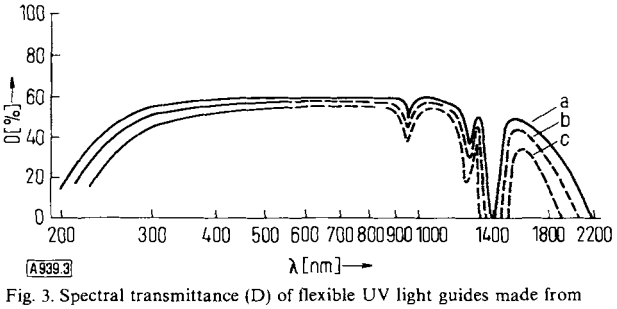


Fig. 3. Spectral transmittance (D) of flexible UV light guides made from silica glass coated with Teflon FEP. Length of light guide: a, 500 mm; b, 1000 mm; c, 1800 mm.

[*] Thanks are due in particular to Dr. *Buyken* for development to the production stage.

The second important property of the UV light guides is their aperture angle. The better the optical contact between the fiber core and the sheath, the smaller are the losses in the numerous total reflections.

Light rays substantially parallel to the optical axis accordingly suffer little loss. Light rays entering the fiber at angles close to the critical angle of incidence α_0 suffer losses that increase with the length of the fiber. Since the angle relationship between the incident light rays and the optical axis remains substantially unchanged, it is found in practice that the aperture angle varies with the length of the light guide. The results of measurements are shown in Figure 4.

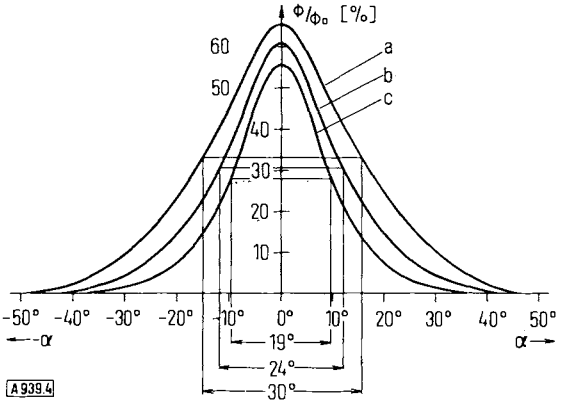

Fig. 4. Angular distribution of the emerging radiation characteristic at 546 nm for silica glass coated with Teflon FEP. Length of light guide: a, 500 mm; b, 1000 mm; c, 1800 mm. The values in the center between the arrows are 2α (50%).

Flexible UV light guides were illuminated uniformly from all directions at the entry end. The intensity distribution of the light emerging from the light guide as a function of the angle with respect to the optical axis shows different opening angles for different lengths if one considers the half widths of the bell-shaped curve. For glass-glass light guides, this value corresponds to the theoretically calculated aperture angle $2\alpha_0$, and is independent of the length of the light guide. This is an indication of the excellent optical contact between fused glasses. The junction between silica glass and the plastic used here is not so perfect, hence the dependence of the aperture angle on the length. One can theoretically expect $2\alpha_0 \approx 68°$; however, the measured aperture given in Fig. 4 is adequate for practical purposes.

Flexible UV light guides possess good stability to UV radiation. The optical transmittance was unchanged by continuous irradiation for a period of several thousand hours with light of wavelength 254 nm at a light density of 1 mW per 4 mm^2 cross section of bundle.

Much greater light intensities can be transmitted at long wavelengths, *e. g.* 320 nm, since solarization effects decrease exponentially with increasing wavelength. X-Radiation in a dose of about 10^5 r causes a decrease in transmittance only in the short-wave region, whereas no adverse effects are detectable in the visible region of the spectrum.

The heat stability of flexible UV light guides depends essentially on their protective tube and on the cement used to bond the fibers at the ends of the bundle. Whereas the light-guide fibers themselves can withstand continuous exposure to temperatures of 250 °C without loss of transmittance, the maximum temperatures to which the ends of the bundles may be exposed are 150—180 °C. On the other hand, no change in transmittance was observed on cooling to −200 °C.

Flexible UV light guides are resistant to water even at temperatures of up to 90 °C. A slight decrease in the optical transmittance occurs only in boiling water.

3.2. Applications of UV Fiber Optics

The uses of UV fiber optics are numerous, and their full extent cannot yet be seen. They considerably facilitate working with UV light. Commercially available UV light sources and the necessary mains equipment are relatively bulky at present. UV light guides enable UV light to be transported to places that are inaccessible to such bulky equipment, and UV light can therefore be used even inside complicated instruments (Fig. 5). Flexible light guides can

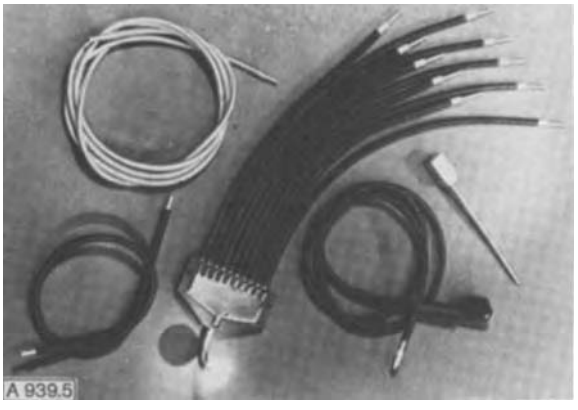

Fig. 5. Different types of light guide.

be led around many corners, like electrical wires, without loss of light. Where relative movement occurs between the UV light source and the receiver, UV light guides form a flexible connection. They serve as secondary light sources in explosion-proof areas or Faraday cages, leading the radiation into these structures easily and with low losses from UV light sources situated outside.

Flexible UV light guides help in many ways in the development of rational automatic analytical equipment for medicine, chemistry, and biochemistry. The transport path of the liquids to be investigated can be considerably shortened, since the light is brought to the point of investigation and the geometry of the UV light sources is of no importance, whereas it was formerly necessary to bring the liquid to the light source.

Wide fields of application arise in medicine, biochemistry, microscopy, and physiology through defined illumination or irradiation of objects with UV light. Certain drugs that accumulate in animal organs and tissues fluoresce on excitation with UV light (Fig. 6). The fluorescence

in the visible region of the spectrum can then be observed with other light guides or endoscopes or under the microscope.

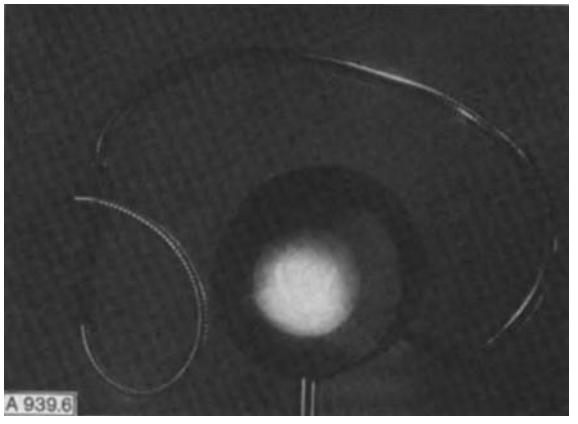

Fig. 6. A flexible light guide transmits UV light and excites fluorescence.

It should be noted that as early as 1964—1966[14] a specific absorption of certain antibiotics (tetracyclines) on carcinomas was observed, and (a decisive point here) the adsorbed antibiotics fluoresced on excitation with UV light. The fiber optics with limited UV transmittance that were available at that time were adequate for these experiments. Following this work, the recognition of cancer with the aid of UV fiber optics has at least become conceivable.

Possibilities for the use of UV light guides also occur in the field of plastics that polymerize and cure under the influence of UV light. Paints and adhesives can be treated very easily with flexible fiber optics. In dentistry, plastics have been developed for application to teeth as varnishes to provide protection lasting several years against caries. With UV light guides, the varnish can be irradiated and cured on the teeth in any dental practice.

Flexible UV light guides combined with light guides for the visible region of the spectrum as two-arm systems form ideal fluorescence light barriers. UV light is led to the point of investigation through one arm. The visible fluorescence light reaches a light-sensitive receiver through the other arm, which cannot transmit reflected UV stray light because of its spectral transmittance. Use is made of this possibility in labeling machines, the designation being printed in code with fluorescent ink and being read automatically. Two-arm UV light guides also give excellent results in automatic letter-sorting machines and stamp-cancelling machines. The actual UV light source is situated far from the reading point, and is accommodated where sufficient space is available in the machine. Numerous UV-conducting components are used in spectrographs, in which the light entering through a slit is led by a cross-section converter to a detector. The cross sections of the light guide can be matched to the geometry of the other optical and electro-optical components (cf. Fig. 6).

The possibilities of UV fiber optics have not yet been exhausted. The applications of UV light can still be greatly extended by means of this new tool for industry and science. Numerous light-guide systems with special dimensions and shapes are available for this purpose.

Elemental Sulfur—A Challenge to Theory and Practice[**]

By Max Schmidt[*]

Surprisingly little is still known about many aspects of the system "elemental sulfur", in spite of its being one of the longest known and common "chemical substances" and today available cheaply and in great purity. This paper summarizes some of the newer investigations that have increased our understanding of this system.

1. Introduction

Four years ago the answers to a world-wide questionnaire that had been circulated to academic research Institutes were published[1]. Though certainly incomplete, these showed that at least 2250 scientists were then engaged in sulfur chemistry in no fewer than 275 laboratories.

Problems concerning sulfur chemistry arise in all branches of chemistry—from inorganic chemistry through biochemistry, organic chemistry, physical chemistry and industrial chemistry to purely theoretical chemistry and finally also in environmental pollution.

From the many known and still unknown sulfur compounds our School is at present interested particularly in those molecules in which at least two sulfur atoms are directly linked to one another, because we consider the nature of the sulfur-sulfur bond to constitute an important, still unsolved problem[2].

The apparently simplest chemical compound containing such sulfur-sulfur bonds in the molecule is, of course, elemental sulfur itself, to which indeed this progress report must be largely restricted.

We can follow the history of sulfur back to the days of Sodom and Gomorrah[3]. Nowadays, sulfur is a very cheap material which is available industrially with unusual simplicity, in a purity that is exceptionally high for an element, and in enormous quantities. The present annual world consumption of sulfur amounts to *ca.* 40 million tons. That, so far, only a negligibly small proportion of this production is used directly as the element is mainly because we still know and understand far too little about the properties of sulfur to be able to change them to meet selected practical ends. One typical example of this is that scientists are still in dispute about the "melting point" of sulfur (see Section 2).

2. Elemental Sulfur

2.1. General

What actually is sulfur? Is that a real question? Certainly not if we are content with the answer, trivial today, that it has the simplest stoichiometric composition conceivable, merely a series of atoms of mass number 16. This answer, however, clarifies only the centuries-long arguments about the "composition" of sulfur, whether this was a combination of one "fiery" principle with one "acid" principle, a matter that was very intimately connected with the development of chemistry from ancient times through alchemy to the present day[4]. Nevertheless, this answer is of no further help if we want to know more about sulfur than that it is an element. Actually, this element presents an extremely complicated chemical system which is still far from fully understood. According to the external conditions, that system comprises sulfur molecules each containing from at least two atoms to several hundred thousand, mixed together in great variety:

$$S_x (x = 2 \text{ to } \approx 10^6!)$$

We are dealing here with true dynamic equilibrium mixtures that change their molecular composition on dissolution and by formation of new chemical bonds.

In this connection let us note yet again a fundamental misunderstanding that is often injected at the beginning of chemistry teaching, namely that there is a difference in principle between chemical elements on the one hand and chemical compounds on the other. There is in fact no essential difference between compounds composed of atoms all of the same kind and those composed of atoms of different kinds. Except for the noble gases, all the elements are chemical compounds whose properties at any one time depend greatly on the nature of the bonding and/or on the molecular size in the "modification" under consideration. Consider, for instance, the pairs graphite—diamond, white phosphorus—black phosphorus, or ozone—molecular oxygen. In these cases chemical reactions change the properties—reactions whose study, with the resultant understanding and ability to influence the properties, have been neglected for a surprisingly long time. The interaction between atoms—whether they are the same or different plays no decisive role—is the main problem in chemistry, the questions namely: how do atoms react with one another by means of their electron shells? why do they do this? and how?

If we consider the system "elemental sulfur" from this viewpoint it immediately becomes clear that the apparently simple question asked at the beginning of this Section still cannot be answered at all completely. The main reason for this is the surprisingly well developed tendency and

ability of sulfur to combine with itself to form chains or rings; only carbon is superior in this respect. Sulfur atoms have six outer electrons, of which the two unpaired 3p electrons are used for covalent bonding to neighboring atoms (Fig. 1). It follows that the chains cannot be collinear but must be zig-zag.

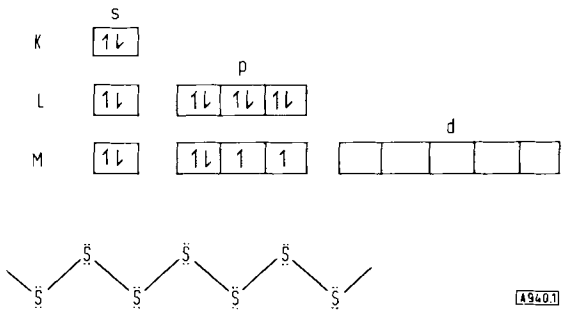

Fig. 1. Electronic configuration of a sulfur atom in the ground state; two-dimensional representation of a three-dimensional sulfur helix.

Such zig-zag chains are not planar because each sulfur atom has two further electron pairs which prevent free rotation around the sulfur-sulfur bond and thus produce a dihedral angle of $\approx 100°$. By dihedral angle is meant the angle formed by the planes each containing any two neighboring three out of four atoms in a section of the chain (cf. Fig. 2). According to whether we proceed upwards or downwards when passing from the third to the fourth atom in the first plane, we have the beginning of a right-handed or a left-handed helix:

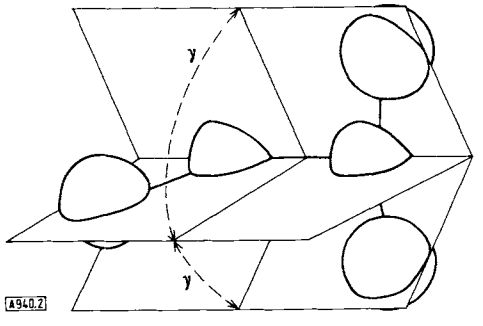

Fig. 2. Dihedral angle (γ) between any three neighboring of four sulfur atoms, which begin a right- or a left-handed helix.

Sulfur chains (and, of course, also sulfanes, *i.e.* compounds containing chains of sulfur atoms) thus have helical configurations. A helix with zero translation leads to a non-planar ring.

2.2. Well Known Sulfur Modifications

We shall now recapitulate briefly what textbooks usually teach about the system "elemental sulfur", this being often coupled with a general exposition of the concept of allotropy—an exposition that is only too frequently an example of how to kill any interest in the subject. To make matters worse, nowhere else in chemistry does one find such an incurably confused nomenclature as for sulfur: as if it were not enough that literally almost the whole Greek alphabet plus very honorable generic names have been misused to denote mixtures of largely unknown composition, hardly a single name has been used consistently for one material, and the same name has not seldom been used for different allotropic forms and for mixtures[5]. Most of this is better forgotten. Let us stick to the relatively few facts that are really firmly based. The most important fact is that, under normal conditions, only one compound of sulfur atoms is thermodynamically stable, namely the eight-membered cyclooctasulfur, S_8 (Fig. 3); for reasons mentioned above, this is not planar but has a crown form; it crystallizes in rhombs, which at 95.4 °C pass into monoclinic crystals.

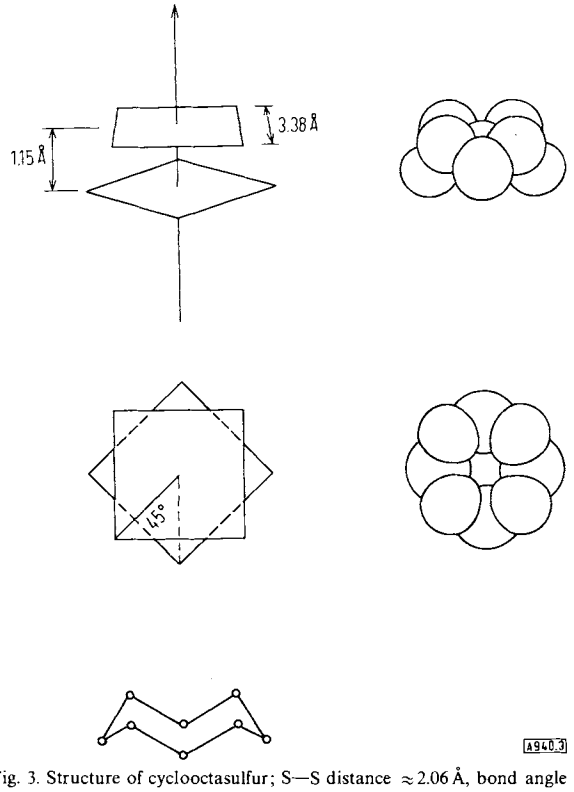

Fig. 3. Structure of cyclooctasulfur; S—S distance ≈ 2.06 Å, bond angle $\beta \approx 108°$, dihedral angle $\gamma = 98°$.

It is this cyclooctasulfur that we normally mean when we speak of sulfur. It is yellow—'sulfur-yellow'—but only at room temperature; at low temperatures it becomes snow-white. The color, or colors, of sulfur will be discussed below.

At ≈ 119 °C solid cyclooctasulfur passes into a pale-yellow mobile melt which, remarkably, solidifies again only at a temperature 4—5 °C lower than the melting point. This phenomenon, investigated so frequently and yet of old so unsuccessfully, has been ascribed to the difference between the "ideal" and the "natural" melting point of sulfur. Yet, precisely expressed, this means only that S_8 has not got a reversible melting point, but that at or below the melting point it decomposes partly to form other molecules which depress the solidification temperature.

Further heating of the sulfur melt leads at ≈ 160 °C to a peculiar phenomenon which we remember as a lecture experiment in our first term: the melt suddenly becomes very viscous and plastic; within a very narrow temperature range the viscosity increases by a factor of 2000! Further

heating slowly decreases the viscosity again, until at the boiling point of 444 °C the melt is again mobile, during which processes the color changes from pale yellow to deep red; sulfur can thus be not only white or yellow but also deep red! Finally, sulfur vapor is said to contain various molecules each containing an even number of atoms, namely S_8, S_6, S_4 and S_2.

If the temperature change is then slowly reversed, sulfur passes from the gas phase by way of the melt with its remarkable anomaly (now naturally in the reverse order) until at room temperature one has again cyclooctasulfur. If the melt is suddenly chilled from above 160 °C, the famous plastic sulfur is obtained—a still imprecisely understood mixture of components some soluble and some insoluble in carbon disulfide.

Somewhat "outside" this sulfur system lies cyclohexasulfur, S_6 (Fig. 4), known for 80 years as a barely considered laboratory curiosity:

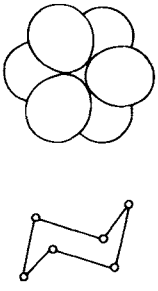

Fig. 4. Structure of cyclohexasulfur; S—S distance ≈ 2.06 Å, bond angle $\beta \approx 102°$, dihedral angle $\gamma \approx 75°$.

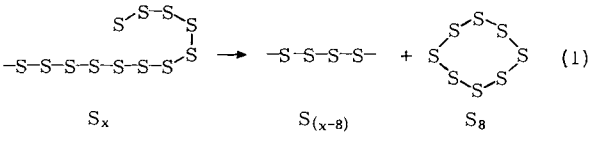
Its chair-shaped molecules form shiny orange-red crystals. This S_6, together with S_8, were until recently the only properly defined compounds containing only sulfur atoms. S_6 shows considerable ring strain in that it polymerizes already at ≈ 50—60 °C. Chemically it reacts with both nucleophiles and electrophiles in redox reactions that are up to 10000 times faster than those of S_8![6] Further, it is extremely sensitive to light. This is perhaps the place to mention the peculiar but generally disregarded fact that all sulfur-sulfur bonds are in principle sensitive to light, although this is quantitatively much dependent on the "strain" in the bonding. Even the most stable form of sulfur, S_8, polymerizes, for instance in benzene solution merely under the action of strong sunlight. The polymeric and chemically very reactive "photosulfur" thus formed depolymerizes rapidly in the dark, re-forming the eight-membered ring[7]. The mechanism proposed for this production of stable eight-membered rings from the longer chain molecules is that thermal movements and the preferred geometry of S_8 cause the terminal atom of a chain to attack always the eighth atom, with simultaneous formation of one sulfur-sulfur bond and cleavage of another.

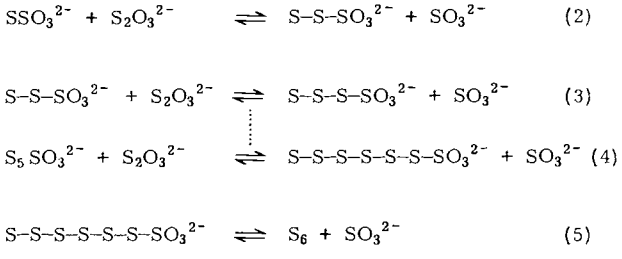


S_x $S_{(x-8)}$ S_8 (1)

Indeed, this "rolling up" of sulfur chains to rings is the reason why all compounds composed of sulfur atoms are converted finally into S_8[8].

Even quite feeble illumination converts S_6, either in solution or in the solid state, into S_8. For this change a direct reaction $4\,S_6 \not\rightarrow 3\,S_8$ is logically excluded; the six-membered rings that are breaking up must first form longer helical molecules, which then unwind so as to yield eight-membered rings in the manner illustrated above.

Current opinion is that exactly the opposite takes place, namely stepwise formation of sulfur chains during formation of S_6 (admittedly in rather poor yield) when thiosulfates are decomposed by mineral acids at low temperature, a reaction which was discovered already in the preceding century:



$SSO_3^{2-} + S_2O_3^{2-} \rightleftharpoons S\text{–}S\text{–}SO_3^{2-} + SO_3^{2-}$ (2)

$S\text{–}S\text{–}SO_3^{2-} + S_2O_3^{2-} \rightleftharpoons S\text{–}S\text{–}S\text{–}SO_3^{2-} + SO_3^{2-}$ (3)

$S_5SO_3^{2-} + S_2O_3^{2-} \rightleftharpoons S\text{–}S\text{–}S\text{–}S\text{–}S\text{–}S\text{–}SO_3^{2-} + SO_3^{2-}$ (4)

$S\text{–}S\text{–}S\text{–}S\text{–}S\text{–}S\text{–}SO_3^{2-} \rightleftharpoons S_6 + SO_3^{2-}$ (5)

In this reaction, polysulfanemonosulfonic acids (discovered earlier by us[9]) are formed starting from monosulfanemonosulfonic acid (thiosulfuric acid), the chain length increasing until it is long enough for the terminal sulfur atom to attack the other end of the chain, which it does by ring closure and extrusion of a sulfite ion[8]. This equilibrium reaction can be reversed by a sufficient excess of sulfite: there then occurs the familiar stepwise nucleophilic "sulfite degradation" of sulfur that leads to thiosulfate[9]. That in this special case the cyclohexasulfur can be separated from the main product S_8 is due to the very different solubility relations of the two modifications[10].

2.3. New Sulfur Modifications from Sulfanes and Chlorosulfanes

Since the nature of this modification, known previously as "Engel's sulfur" or "Aten's sulfur", was recognized, there has been no dearth of attempts to prepare sulfur rings other than S_8 and S_6; prior to our work, they were all unsuccessful. Also, there has been no lack of theoretical attempts to calculate and predict the stability or instability of hypothetical sulfur rings[11].

In view of this rather unsatisfactory situation we asked ourselves whether it might be possible to build new thermodynamically unstable compounds containing only atoms of one kind, *i.e.* new modifications of an element, by scientifically planned, kinetically controlled syntheses. This object would be the more easily achieved the fewer reaction steps were needed to combine precisely defined molecular units into the desired ring. Our first successes with this principle were when we used a two-stage redox reaction between sulfanes and chlorosulfanes:

$$H_2S_x + Cl_2S_y \longrightarrow 2\,HCl + S_{x+y} \quad (6)$$

$$\overset{-2}{H\text{–}S_x\text{–}H} + \overset{+2}{Cl\text{–}S_y\text{–}Cl} \longrightarrow \overset{0}{H\text{–}S_x\text{–}S_y\text{–}Cl} + HCl \quad (7)$$

$$H\text{–}S_x\text{–}S_y\text{–}Cl \longrightarrow HCl + \overset{S_x\ S_y}{\frown} \quad (8)$$

$$H_2S_4 + Cl_2S_2 \longrightarrow 2\,HCl + S_6 \quad (9)$$

In an open-chain sulfane the sulfur chain as a whole has the oxidation state -2, and in a chlorosulfane correspondingly $+2$. The overall reaction (6) is formally very simple, but for various reasons it is experimentally extremely difficult to realize it in such a way that pure sulfur is formed and not long-chain sulfanes or chlorosulfanes. It is essential to use the dilution principle, so that the unsymmetrically substituted intermediate product with a mean oxidation state ± 0 has the opportunity to split off hydrogen chloride when it assumes a suitable geometric orientation [reaction (8)].

We studied this procedure for the case of cyclohexasulfur [reaction (9)], whose properties were known. After an unstable modification of sulfur had thus for the first time become preparatively available in a pure form, we tackled the synthesis of new rings. From suitable components ($x+y$ in the general overall equation $= 12$) we then obtained the new sulfur modification cyclododecasulfur, S_{12}[12]. Contrary to *Pauling*'s prediction[13], this compound which crystallizes in pale yellow needles is disconcertingly stable; it "melts" appreciably higher than any other known form of sulfur, namely at 148 °C, although admittedly not reversibly but with decomposition. X-ray structure analysis showed the highly symmetrical form of the twelve-membered ring (Fig. 5), in which the atoms are arranged in three planes—six in the middle plane and three each symmetrically above and below it[14].

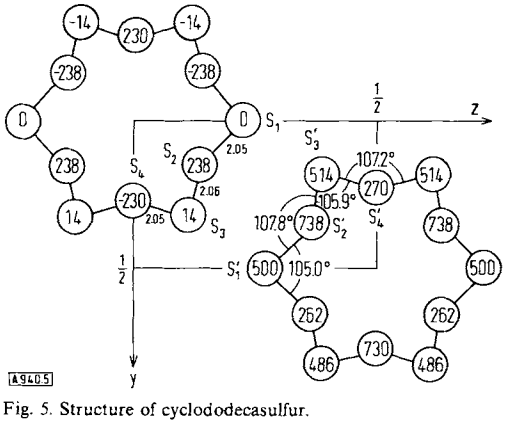


Fig. 5. Structure of cyclododecasulfur.

Like S_8, cyclododecasulfur S_{12} forms "regular" solutions in carbon disulfide, but its solubility therein is more than 150 times lower than that of S_8[10]. This unexpected solubility relation made it possible to separate the very stable new form from the large excess of S_8 and thus also to look for it in "normal" sulfur. And in fact cyclododecasulfur could be isolated from cooled sulfur melts, pre-heating to ≈ 120 °C being sufficient[15]. This finding throws a new light on the composition of sulfur melts, and their earlier interpretation thus requires reinvestigation, as will be briefly mentioned again below. As a small curiosity it may be mentioned here that small amounts of S_{12} crystallize out if saturated benzene solutions of S_6 are left for a short time in the light[6].

A rather stable cyclooctadecasulfur, S_{18}, which decomposes at 126 °C, and a cycloicosasulfur, S_{20}, with a decomposition temperature of 121 °C could also be obtained from sulfanes and chlorosulfanes[16]. Their interesting structures (Figs. 6 and 7) have been elucidated quite recently[16a, 16b]. Bond distances, bond angles and dihedral angles are similar to those in S_8 and S_{12}.

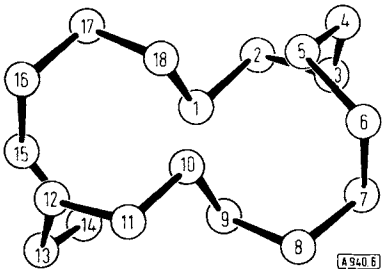

Fig. 6. Structure of cyclooctadecasulfur; S—S distance ≈ 2.06 Å, bond angle $\beta \approx 106°$, dihedral angle $\gamma \approx 85°$.

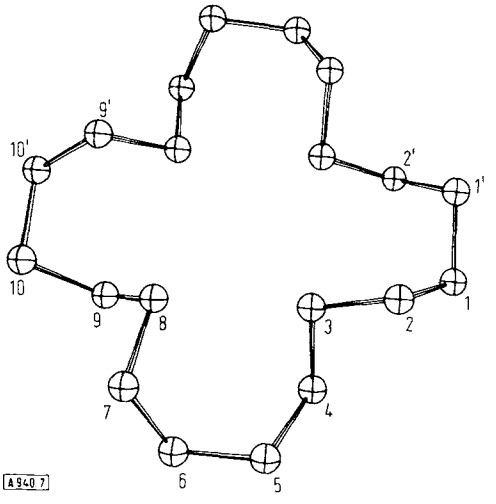

Fig. 7. Structure of cycloicosasulfur; S—S distance ≈ 2.04 Å, bond angle $\beta \approx 106°$, dihedral angle $\gamma \approx 85°$.

Our optimism about obtaining further relatively small sulfur rings by the procedure described was sadly damped by unexpected experimental difficulties. For example, it is almost impossible to carry out reactions with 100%-pure, homogeneous sulfanes, for the extremely unstable compounds of this class readily form equilibrium mixtures of various chain lengths, and these necessarily lead to various cyclic molecules, some of which are liquid at room temperature. Sulfur that is liquid at room temperature! an interesting phenomenon indeed, but once again only an indefinite mixture like the long-known melts. Because of the marked sensitivity of the strained rings to heat, light, or indeed even rough surfaces, all attempts at separation, *e.g.* chromatographically, have so far failed except when particularly favorable solubility relations prevailed, as between S_6, S_8, S_{12}, S_{18}, and S_{20}.

3. Sulfur Rings Containing Hetero Atoms

3.1. Rings Containing Metal Atoms

Out of this rather unhopeful position we found a way that brought us a few steps forward, namely by substituting for the sulfane a much more stable sulfur compound, of exactly defined composition, as starting material for the redox reaction that affords the sulfur rings.

A few years ago, when studying organometallic sulfur compounds, we synthesized a chair-form six-membered ring comprising five sulfur atoms and one titanium atom, where the metal atom carried also two π-bonded cyclopentadienyl ligands[17]. This bis(π-cyclopentadienyl)titanium pentasulfide (Fig. 8) is the prototype of a class of compound containing sulfur rings with a transition-metal atom as hetero atom; such compounds are under intensive study at the present time.

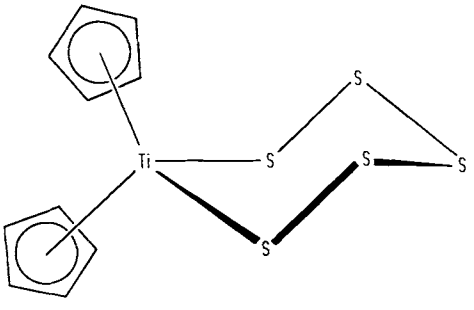

Fig. 8. Structure of bis(π-cyclopentadienyl)titanium(IV) pentasulfide.

It is interesting that at about the same time *Katz* and *Jones*[18] showed by X-ray structure analysis that this group includes a compound with the somewhat unusual stoichiometric composition $(NH_4)_2PtS_{15}$, known for almost 70 years but subjected to hardly any notice. In the PtS_{15}^{2-} ion the octahedrally coordinated Pt atom is the hetero atom in three chair-form six-membered rings, each of which contains five sulfur atoms whilst the Pt atom is common to all three rings—a structure that is hardly a daily occurrence in sulfur chemistry (see Fig. 9).

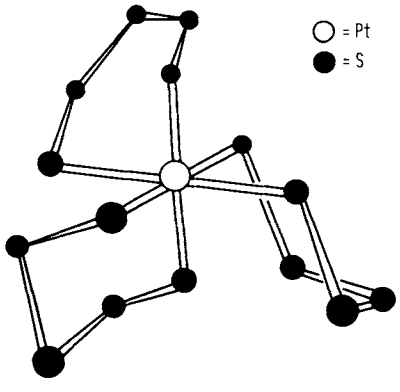

Fig. 9. Structure of the ion PtS_{15}^{2-}.

These remarkable metal-containing sulfur rings will not be discussed in detail here. However, one important question about their chemistry must be asked although it is not yet possible to give a convincing answer; it is this: Why, in these compounds, are ring sizes favored and stable that in wholly sulfur rings are very unstable or incapable of existence, as for example the six-membered sulfur rings mentioned above and—for molybdenum[19]—a five-membered ring containing four sulfur atoms and one metal atom? Consider our titanium compound (above): even conditions that we should expect to favor formation of other ring sizes always lead to formation of only the six-membered ring, which is apparently extremely favored; the permanganate-colored crystals melt only at 201 °C, indicating a thermal stability of sulfur chains that would have been inconceivable to a sulfur chemist a short time ago.

3.2. Rings Containing Methylene Groups

The question about ring size and stability applies not only to wholly sulfur rings but also to sulfur heterocycles other than those with transition-metal atoms. Two examples will suffice: As a model substance for cyclooctasulfur minus the sulfur-sulfur bonds we have built up a tetrameric thioformaldehyde[20] in which each second sulfur atom of the S_8 ring is replaced by an isoelectronic $-CH_2-$ group. In this series, the resulting 1,3,5,7-tetrathiacyclooctane, melting at 48 °C, is appreciably less stable than the well-known 1,3,5-trithiane which contains a six-membered ring; the former is readily converted irreversibly into a crystalline high polymer that melts undecomposed at 245 °C and corresponds to the unstable polymeric sulfur.

The powerful influence of the methylene group as "hetero atom" on the size of the more stable cyclic sulfur compounds has also been clearly shown in recent work by *Fehér et al.*[21]

3.3. Rings Containing Selenium Atoms

What do we observe if we insert sulfur's closest relative, namely a selenium atom, as hetero atom between sulfur atoms? Unlike sulfur, cyclooctaselenium is very unstable, changing spontaneously into the thermodynamically stable, high-polymeric selenium with a helical conformation. Why? We are not yet sure. What is the position with compounds containing both sulfur and selenium? At what stoichiometric composition do the stability relations between the eight-membered ring and the chain polymer "tip over"? Isolated attempts at an answer by melting the elements together in various stoichiometric proportions and mass-spectroscopic study of the gas phase above such mixtures do not lead us further here. We should bear in mind that, even for the (still hypothetical) eight-membered ring system comprising S_7Se to SSe_7, the conceivable different structural arrangements of these so closely related atoms can lead to more than 40 different isomers; we can then see clearly that only carefully planned syntheses, if any, will provide any possibility of isolating definite compounds as products. We have not made too remarkable progress in such investigations. Nevertheless, we now know three of the seven possible "stoichiomers"

containing an eight-membered ring, namely S_7Se, S_6Se_2 and S_5Se_3. As to the question about the influence of the hetero atoms on molecular size, it is significant that we can now say the following with certainty: In the sulfur-selenium system the sulfur is dominant up to a stoichiometry of at least 62:38 atom-% of sulfur to selenium. For, as in the wholly sulfur system, the (not yet realized) six-membered ring is certainly considerably less stable than the polymeric helix, which in turn changes again, spontaneously, into the thermodynamically most stable eight-membered ring.

Monoselenacyclooctasulfur, S_7Se, which presents no structural problem, was prepared by *Cooper* and *Culka*[22] from dichloroheptasulfane and hydrogen selenide by our synthetic method for chalcogen rings:

$$Cl_2S_7 + H_2Se \rightarrow 2HCl + S_7Se \quad (10)$$

We ourselves wanted to assess the possibility of existence of a six-membered ring of four sulfur and two selenium atoms by the reaction:

$$2Cl_2S_2 + 2H_2Se \not\rightarrow 4HCl + S_4Se_2 \quad (11)$$

but we had no success. Under the mild conditions sufficing for synthesis of cyclohexasulfur we always obtained as intermediate only a polymer of the same stoichiometry, thus:

$$2nCl_2S_2 + 2nH_2Se \rightarrow 4nHCl + (S_4Se_2)_n \quad (12)$$

This helix contained throughout its length a series of two sulfur atoms and one selenium atom. It very rapidly undergoes the reaction

$$(S_4Se_2)_n \rightarrow {}^2/_3 m S_5Se_3 + {}^1/_3 m Se_6Se_2 \quad (13)$$

yielding the new eight-membered rings S_5Se_3 and S_6Se_2 in the expected proportion 2:1 by the "rolling up" mechanism described in Section 2.2 for pure polymeric sulfur. Diselenacyclooctasulfur, S_6Se_2, forms lemon-yellow crystals melting at 124 °C; and triselenacyclooctasulfur, S_5Se_3, forms magnificent orange-red crystals melting at 120 °C; the difference in their solubilities is sufficient for them to be separable on a preparative scale and they are notably stable[23].

4. New Modifications of Sulfur from Metal-containing Sulfur Rings

After this excursion into the field of sulfur molecules containing hetero atoms we return to the desired rings containing atoms all of the same type. There we have got a little further by substituting the very stable titanium-sulfur six-membered ring for the very labile sulfanes in the redox reaction with chlorosulfanes described above. Bis(π-cyclopentadienyl)titanium(IV) pentasulfide reacts quantitatively with dichloromonosulfane, thus:

$$(C_5H_5)_2TiS_5 + SCl_2 \rightarrow (C_5H_5)_2TiCl_2 + 1/n(S_{6n}) \quad (14)$$

it affords di(π-cyclopentadienyl)titanium dichloride and sulfur, the latter being separable into 87% of cyclohexasulfur ($n=1$) and 11% of cyclododecasulfur ($n=2$)[24]. This gave us our first chance of synthesizing a ring with an odd number of members, by treating the titanium compound with dichlorodisulfane, S_2Cl_2, thus:

$$(C_5H_5)_2TiS_5 + S_2Cl_2 \rightarrow (C_5H_5)_2TiCl_2 + S_7 \quad (15)$$

Theoretical predictions made relatively small, odd-membered sulfur rings such as S_7 appear unlikely; if we exclude a planar ring with a uniform dihedral angle of 180°, which is impossible on bond-theoretical ground, we find that a seven-membered ring with equal bond lengths, bond angles and dihedral angles cannot be constructed. In spite of this, reaction according to eq. (15) occurs even under quite mild conditions[24]. Cycloheptasulfur crystallizes in yellow needles. It melts reversibly at 39 °C. X-ray structure analysis[25] has disclosed definite differences between the various dihedral angles. In the chair form of the seven-membered ring (Fig. 10) four atoms lie almost exactly in one plane. This therefore presents an element modification

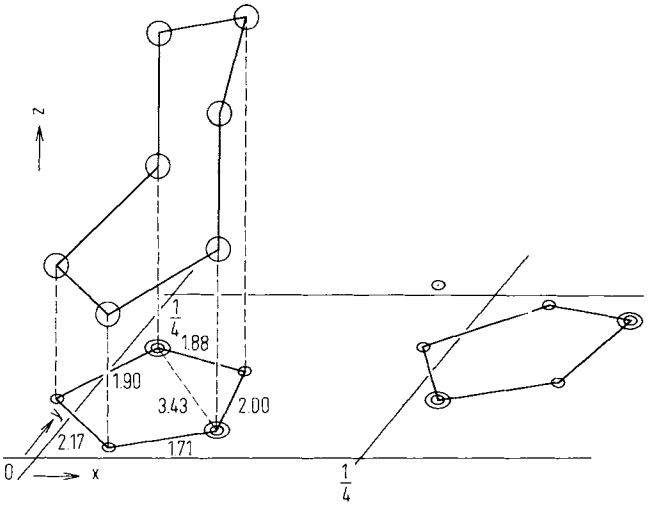

Fig. 10. Perspective view of a cycloheptasulfur molecule and its xy projection (bond lengths in Å).

in which identical atoms exist in differing electronic environments and thus have different energy contents. The ring strain is apparent in, *inter alia*, a notable sensitivity to light and heat: S_7 polymerizes even at *ca.* 45 °C; wherefore cycloheptasulfur can be kept for a long period only in the dark and the cold; even then it is converted slowly—to about 50% in a year—into a new insoluble but crystalline form of sulfur, the crystal structure of which has not yet been studied.

We have succeeded in preparing also a second ring containing an odd number of sulfur atoms, namely cyclononasulfur, from the titanium-sulfur ring and dichlorotetrasulfane[26]:

$$(C_5H_5)_2TiS_5 \xrightarrow{+HCl} (C_5H_5)_2Ti(Cl)S_5H \xrightarrow[-HCl]{+S_4Cl_2}$$
$$(C_5H_5)_2Ti(Cl)S_9Cl \rightarrow (C_5H_5)_2TiCl_2 + S_9 \quad (16)$$

Since the reactivity of chlorosulfanes decreases markedly with increasing chain length, S_4Cl_2 can no longer cleave the titanium-sulfur bond. We therefore made use of a trick: adding a small amount of hydrogen chloride cleaves the original ring, giving the sulfane derivative with five sulfur atoms, which, on reaction with S_4Cl_2, regenerates HCl and builds up a chain of nine sulfur atoms; and this cyclizes to the expanded nine-membered ring on elimination of the titanium dichloride complex. Its stability is about the same as that of S_6.

Very recently we have been successful in an analogous reaction with S_6Cl_2, thus:

$$(C_5H_5)_2TiS_5 + S_6Cl_2 \xrightarrow{HCl} (C_5H_5)_2TiCl_2 + S_{11} \quad (17)$$

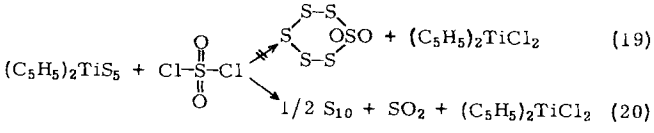
In this way we obtained cycloundecasulfur as the third compound with an odd-membered sulfur ring[27]. This new modification of sulfur can also be kept only in the dark and under cooling.

Are there also rings smaller than S_6? We do not yet know. From our experiments it appears anyway that if a pure cyclopentasulfur can be prepared at all it will be very unstable. Bis(π-cyclopentadienyl)molybdenum tetrasulfide which, as mentioned above, contains a five-membered ring of four sulfur and one molybdenum atom, reacts with SCl_2 thus:

$$(C_5H_5)_2MoS_4 + SCl_2 \rightarrow (C_5H_5)_2MoCl_2 + S_5\ (??) \quad (18)$$

The dichloro complex is formed together with elemental sulfur that is liquid at room temperature. The pronounced tendency of this sulfur to polymerize has so far prevented its characterization. The mass spectrum of a fresh sample did show a strong S_5^+ line, but along with mass lines of larger sulfur ions. We do not yet know, however, whether the latter were formed directly during the synthesis or as a result of polymerization[27]. The question of the existence of a five-membered sulfur ring is thus still open.

Next we may ask a question that has much interest from a bond-theoretical aspect: Are there well-defined sulfur rings with an oxidized sulfur atom of oxidation state +6 in the ring, *i.e.* with a sulfonyl group? According to our experiments to date we must answer this question in the negative. We may cite one example: if our compound with the titanium-sulfur ring is treated, not with SCl_2, but with sulfonyl chloride, the formation of a six-membered cyclic sulfone is conceivable:



however, apparently owing to the instability of a —S—SO_2—S— group, sulfur dioxide is split off, as in (20).

In this connection the result of recent experiments by *Steudel* is of particular interest. He succeeded in isolating cyclooctasulfur monooxide from the product of reaction of "crude sulfane" with thionyl chloride[28], thus:

$$H_2S_x (x \approx 4\text{—}6) + SOCl_2 \rightarrow 2HCl + S_8O + ? \quad (21)$$

This is the first sulfur-ring compound containing an oxygen atom bonded to it.

It is important also that reaction (20) does not give an isolable five-membered sulfur ring, but instead a further new sulfur modification, cyclodecasulfur[24], whose crystals resemble those of all the other new cyclic sulfurs, except S_{12}, S_{18} and S_{20}, in having little stability towards light or heat. Thus we now have the compounds S_6, S_7, S_8, S_9, S_{10}, S_{11}, S_{12}, S_{18} and S_{20} available for comparative study—a task that is still far from complete. The definite proof of their mere existence, however, throws up several questions about interpretation of the whole sulfur system to which I shall return briefly below. But first I shall insert a few remarks about charged sulfur molecules, some of which have aroused great interest in the last few years.

5. Charged Sulfur Molecules

The neutral sulfur molecules described in the preceding Sections change their nature in characteristic manners when either reduced to oxidation state −2 or oxidized to oxidation state +2.

It has been known for a very long time that cyclooctasulfur is reduced by sulfide or hydrogen sulfide ions to polysulfide ions S_x^{2-}, these naturally being partly protonated in water. The nucleophilic attack of S^{2-} ions on the electrophilically acting S_8 ring is the rate-determining step in that reaction:

$$S_8 + S^{2-} \rightarrow S_9^{2-} \quad (22)$$

The ring is broken to give the open-chain nonasulfide ion. Such open-chain polysulfide ions are rapidly degraded further (=further reduced) to shorter chains[29], for example thus:

$$S_9^{2-} + S^{2-} \rightarrow S_8^{2-} + S_2^{2-} \text{ or} \quad (23)$$
$$S_4^{2-} + S_2^{2-} \rightarrow 2S_3^{2-}, \textit{ etc.} \quad (24)$$

Such negatively charged sulfur ions can also be easily obtained free from water, for example by reduction of elemental sulfur by non-noble metals. They are all open-chain, doubly negatively charged fragments of a sulfur helix[30].

For an account of very recent interesting studies on the colored radical anions S_x^- see Ref.[30a].

In the reverse process, however, namely oxidation, the S_8 ring may under certain circumstances remain intact, though with a change of conformation.

As early as 1804[31] it was known that sulfur dissolves in oleum with formation of colored compounds—according to the conditions red, yellow or blue. The best known of these "compounds", the blue "S_2O_3", has been in the literature for nearly 100 years[32] and is mentioned in many textbooks even nowadays. S_2[33] and recently the radical ions $(X_2S{-}SX_2)^+$[34] or S_x^+[35] have also been made responsible for the colors. It is now regarded as proved that the various colors should be considered as due to the cations S_{16}^{2+}, S_8^{2+} and S_4^{2+}, and I must describe these briefly.

A solution of sulfur in oleum must contain other species in addition to these diamagnetic ions, for such solutions are paramagnetic, as has been known for 16 years[36]. The nature of these paramagnetic ions has not yet been finally decided. S_4^+, S_5^+, S_7^+ and S_8^+ have been discussed[37,38], the favorite in the most recent investigations being S_5^+.

The diamagnetic ions have been studied mainly by *Gillespie et al.*[39] who succeeded in oxidizing elemental sulfur to the red cations S_{16}^{2+} in various reactions[40–42]:

$$2S_8 + 3AsF_5 \rightarrow S_{16}(AsF_6)_2 + AsF_3 \quad (25)$$

$$2S_8 + 3SbF_5 \rightarrow S_{16}(SbF_6)_2 + SbF_3 \quad (26)$$

$$2S_8 + S_2O_6F_2 \rightarrow S_{16}^{2+} + 2SO_3F^- \quad (27)$$

The deep blue S_8^{2+} ion was obtained by further oxidation, thus:

$$S_8 + 3AsF_5 \rightarrow S_8(AsF_6)_2 + AsF_3 \quad (28)$$

$$S_8 + 5SbF_5 \rightarrow S_8(Sb_2F_{11})_2 + SbF_3 \quad (29)$$

X-ray crystal structure determination[43] showed that in this case the eight-membered ring remained intact, but that its conformation was changed from *exo-exo* (crown form of cyclooctasulfur) to *exo-endo* (Fig. 11).

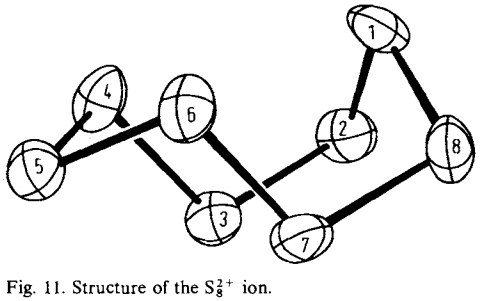


Fig. 11. Structure of the S_8^{2+} ion.

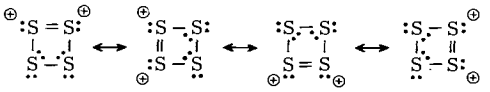
The average S—S separation (2.04 Å) in the doubly positively charged ring is identical with that in the neutral ring.

The pale yellow S_4^{2+} ion is obtained from S_8 and $S_2O_6F_2$ in liquid sulfur dioxide or from S_8 and SbF_5 at 150 °C. The compounds $S_4(SbF_6)_2$ and $S_4(SO_3F)_2$ are diamagnetic. Spectroscopic findings[44] provide compelling reasons for believing that, like Se_4^{2+} which has been defined by X-ray structure investigations[45], the cation S_4^{2+} exists as a planar "Hückel aromatic compound":



These charged sulfur molecules will keep research workers busy for some time yet and may be expected to provide many further interesting results. They will also exert an influence on our ideas about elemental sulfur itself, a subject to which I must now return.

6. Sulfur Vapor

First a few words about the gas phase above sulfur melts: This contains all possible fragments from S_8, and in addition traces of S_9 and S_{10}[30], as proved by mass spectrometry and contrary to statements in the textbooks mentioned above.

Blue S_2, *i.e.* blue sulfur, whose paramagnetism corresponds to that of the oxygen molecule, was obtained in a pure state by *Meyer* out of the gas phase under certain conditions, or better by photolysis of S_2Cl_2, and after being frozen in a matrix was very exactly characterized[46]. Recent results from *Ginsberg et al.*[47,48] should be noted here as of especial interest: these workers stabilized S_2—analogously to O_2—by π-bonding it to rhodium or iridium in phosphane complexes at room temperature (Fig. 12).

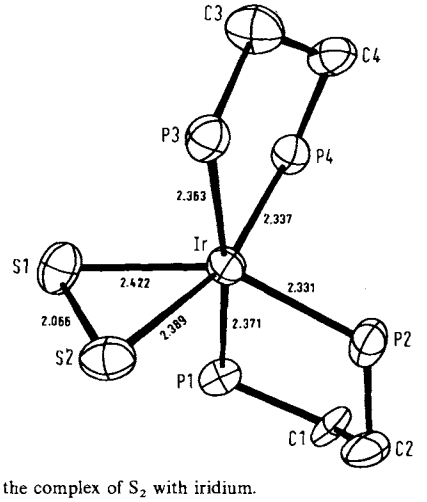


Fig. 12. Structure of the complex of S_2 with iridium.

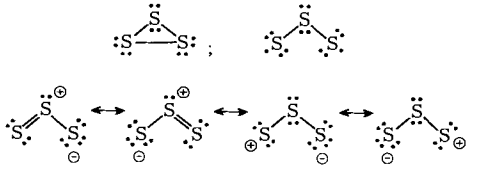
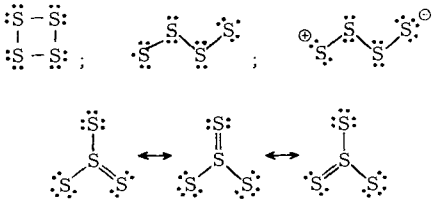
But what do we know about the nature of the other components of the gas phase? The mass, *i.e.* the number of atoms, of the higher aggregates of S_3 tells us nothing at all. It seems an impermissibly crude simplification to regard the problem as solved by determining the masses of the aggregates of sulfur atoms that occur as positive ions in a mass spectrometer. Many problems merely begin at that stage! For example, is S_3 a ring, a diradical chain, a trithioozone or sulfur dithiooxide?



In this connection there is the interesting new observation that S_3 and S_4, obtained by photolysis of S_3Cl_2 and S_4Cl_2, respectively, in an organic glass correspond exactly in their absorption and thus in their colors—intense green and dark red, respectively—to the colors of hot sulfur melts and hot sulfur vapor. They do indeed cause the color of the melt and vapor[46].

To go a step further, what is the structure of S_4, which we know in the gas phase? Is it a ring, a diradical, a bipolar compound or a chain with double bonds? Recent HMO calculations[46] ascribed a completely unexpected, especial stability to a branched structure, namely sulfur trithiotrioxide.



This mathematical result certainly sets a challenge to the preparative chemist.

And we know absolutely nothing about the aggregates S_5, S_6, S_7, S_8, S_9, S_{10}, S_{11}, and S_{12} beyond that they have been shown to exist in the gas phase.

7. Sulfur Melts

We return now to the melts, which are surely the most complicated part of sulfur chemistry and about which we are still largely in the dark[49]. After many unsuccessful attempts to interpret their singular phenomena, the hypothesis of *Tobolsky* and *Eisenberg*, which has a most polished mathematical foundation[50], is nowadays generally adopted.

On this hypothesis a sulfur melt represents a reversible monomer-polymer equilibrium with cyclooctasulfur as the "monomer" which is *via* catenaoctasulfur in thermal equilibrium with high-polymeric *polycatena*sulfur, thus:

$$n\,S_{8\,(ring)} \rightleftharpoons n\text{—}S_8\text{—}_{(chain)} \rightleftharpoons (S_8)_{n\,(chain)} \qquad (30)$$

This interpretation can, however, no longer be maintained unchanged. The existence, in the melt, of sulfur compounds other than multiples of S_8 is proved unambiguously. The problem is thus open again and is the subject of renewed intensive theoretical study. According to *Semylen*'s more recent calculations[51], even at 120 °C, *i.e.* barely above the melting point, the mobile, pale yellow S_8 melt contains 8.2 wt.-% of larger rings containing an average of 13.8 atoms per ring. The "melting point" of sulfur is thus clearly a decomposition point and, by the theory of "regular solutions", we have estimated a true melting point of ≈ 133 °C for S_8[10]. At 120 °C the still mobile melt already contains almost 20% of rings with an average of 17.6 atoms per ring, and at 160 °C there should be 30% of larger rings.

What happens at the critical temperature where at a single stroke the melt suddenly becomes so viscous that the flask can be turned upside down without anything spilling out? We must admit that we do not yet know. Presumably we are then dealing with giant macromolecules. But why are they formed so suddenly and what is their structure? Are they rings or chains, and, if chains, are they diradicals or polar chains or do they contain fluxional double bonds? The problem of their conformation seems beyond hope when we remember that each time a chain is lengthened by one atom there are two equally justifiable alternatives for the new dihedral angle; thus simple calculation shows that there are $2^{(n-3)}$ (!) possibilities for each chain (n = the number of chain members), which gives about 130 possibilities for even 10 atoms and 9000 for 20 atoms; the theoretically possible conformations for molecules containing several hundred thousand atoms, such as may well exist in sulfur melts at ≈ 200 °C, run into astronomical figures.

Why do we nevertheless wish to clarify the situation? Well, because a knowledge of what happens in sulfur melts would enable us to influence their behavior and thus to multiply the practical applications of this substance that is so cheap and available in such huge quantities.

On continued heating, sulfur melts slowly become more mobile again and an increasingly deeper red until finally almost black-red. Because of thermal cracking of the macromolecules into smaller fragments the viscosity decreases up to the boiling point of 444 °C. The composition of the melt at this temperature is quite unknown. According to investigations by *Meyer*, the color becomes continuously more intense because, from the temperature of liquid air at which sulfur is snow-white, up to about 200 °C, there is a steady red shift of the absorption edge and thus of the absorption in the visible region, and this is caused by increasing thermal population of excited states of S_8 and later also by absorption due to higher polymers. The much stronger red shift of the absorption edge and thus the faster increase in color that finally occur at the higher temperatures—new absorption maxima appear at 4100 and 5300 Å—are to be ascribed to formation of S_3 and S_4 molecules which are present in a concentration of $\approx 2\%$ in hot polymeric sulfur and also cause the very intense color of the vapor[46]. The longer radical chains, analogous to the isoelectronic alkanediyl radicals, should be almost black. I cannot quite reconcile myself to the view that chilled, insoluble sulfur is again pale because the chain ends are saturated by impurities, for example hydrogen atoms, although that cannot be excluded—polymeric alkanes are, after all, colorless. However, cycloalkanes are also colorless! It seems thus more probable that "insoluble" sulfur consists of cyclic molecules which, as we know from the solubility relations of cyclododecasulfur, need not be all too large.

The proof that there are very reactive molecules such as S_3 and S_4 in sulfur melts throws a new light also on the very interesting reactions of hot sulfur with hydrocarbons, but I cannot go into that subject here.

A few words more about the much discussed "critical temperature" of sulfur. Our view is that, in principle, it cannot be determined. The prolonged dispute about the exact polymerization temperature, often treated as a matter

of the purity of the sulfur, is irrelevant today, as a few simple experimental results will show. First, however, an interesting interpretation of the conditions in sulfur melts should be mentioned, which was suggested several years ago but has been largely neglected[52]. *Wiewiorowski et al.* interpreted the conditions in sulfur melts on the basis that diradical sulfur chains form charge-transfer complexes with still unbroken S_8 rings as chain endings. Can we then imagine that, at the "critical temperature", the concentration of the eight-membered rings still present in the equilibrium mixture no longer suffices to stabilize the relatively short chains, so that these unite to give the macromolecules observed and thus cause the sudden increase in viscosity?

We are now familiar with highly viscous and therefore polymeric sulfur at temperatures as low as $\approx 45\,^{\circ}C$—this is the pale yellow polymerizate of cycloheptasulfur. Between 60 and 80 °C, S_6, S_9, S_{10}, and S_{11} form a similar polymerizate which on further heating to above $\approx 120\,^{\circ}C$ becomes mobile again and then once more plastic before, at 444 °C, it is once more less viscous and boils. However, we are also able to alter the "critical temperature" of "ordinary" sulfur by design: adding a mere $\approx 2\%$ of S_6 to sulfur melts at $\approx 150\,^{\circ}C$ lowers the polymerization temperature by $\approx 10\,^{\circ}C$—a phenomenon that lasts for *ca.* 20 minutes. And the opposite is also possible: we can prevent the polymerization of sulfur to highly viscous compounds up to at least 200 °C—*i.e.* retain sulfur melts in a mobile state—by adding as little as 1—2% of thermally stable, cyclic sulfur compounds such as trithiane or trimeric thioacetaldehyde. Do these rings take over the stabilizing role of the unstable S_8 rings in formation of complexes by sulfur chains? Anyway, they can be recovered from the sulfur unchanged and quantitatively[53]. At this point, however, I must break off speculation and thus also the discussion of liquid sulfur.

8. General Concluding Remarks

It is to be expected that the sulfur problem will continue to excite interest for a long time yet, even if no further groups of atoms are unrolled. Alone the future necessity, for prevention of environmental pollution, to remove sulfur dioxide from the combustion products of fossil fuels and, preferably, for practical reasons, to convert it into elemental sulfur[54], will have its effect on the price of sulfur: the world price of sulfur, which has varied for so long, will then settle down into a "valley" which will perhaps be deeper than has previously been assumed. This foreseeable development should encourage us to make a virtue of necessity! If by solving the environmental SO_2 problem we make sulfur into a new cheap material, what large quantities will be available! The following few, arbitrarily selected, potential uses, which we can only sketch here, are based on serious experiments in different laboratories: sulfur as a filler to modify organic polymers, as a covering for slow-acting fertilizers, as a material for marking streets, as an additive to improve the quality of bituminous material in road construction; and, finally, in the building industry—potentially a particularly important application—as a surprisingly stable mortar for conventional building stone, but also as a construction unit on its own if filled with sand or made into a foam; *etc.* The idea of a "front parlor" made of sulfur is certainly unusual, but that is not intended; we should think rather of the need that so often arises for urgent manufacture of prefabricated buildings units for disaster areas: heated sand, mixed with sulfur, would be ready for immediate use.

In this connection a final word on flammability. Several recent investigations have shown that adding a few percent of certain materials, such as styrene and maleic acid, reduces the flammability of sulfur drastically—sufficiently for practical use—and that conversely, even though it sounds like a paradox, adding sulfur to polystyrene or polyurethane foams considerably increases their fire-resistance[55]. The more we learn how to modify the mechanical and chemical properties of the system "elemental sulfur", the more varied will be its future applications as a raw material; and these modifications will be the more successful the more knowledge and understanding we have of sulfur.

Insofar as this report treats the results of our own School, thanks are due to the dedicated and skilled work of the following collaborators: Frau B. Jutzi, Dr. H. D. Block, Frau Dr. B. Block, Dr. G. Knippschild, Dr. H. Kopf, and Dr. E. Wilhelm, who has been engaged for the longest time and most intensively with elemental sulfur. Grateful thanks are offered for financial support from Bayer AG, the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft and the Sulphur Institute Washington/London.

Hydrazidinyl Radicals: 1,2,4,5-Tetraazapentenyls, Verdazyls, and Tetrazolinyls

By Franz A. Neugebauer[*]

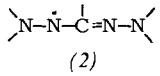
Dedicated to Professor Theodor Wieland on the occasion of his 60th birthday

This report reviews the preparation of hydrazidinyls and their chemical and physical properties.

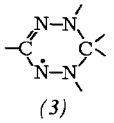
1. Introduction

π radicals with allylic structure are often notable for their great stability, especially when the allylic system leads to an extensive, symmetrical delocalization of the unpaired electron. An historically interesting[**] example for such a stable allyl radical is (2,2'-biphenyldiyl)phenylallyl[1]. *Kuhn* and *Trischmann*[2] discovered a remarkably stable class of allylic radicals in the verdazyls *(3)*. These radicals are much more stable than the corresponding hydrazyls *(1)*[3], and in many cases even exceed the stability of the radical standard diphenylpicrylhydrazyl[4].

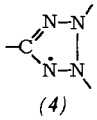
(1)



(2)



(3)



(4)

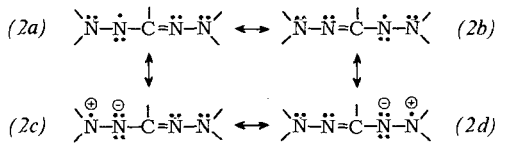
The discovery of the verdazyls has prompted the examination of other radicals having the same basic structure (*(2)* and *(4)*). We shall refer to this basic structural element as the *hydrazidinyl* system, in analogy to the nomenclature of the amidines and hydrazidines. The various representatives of this class are then *hydrazidinyls*.

[*] Doz. Dr. F. A. Neugebauer
Max-Planck-Institut für Medizinische Forschung
Abteilung Molekulare Physik
69 Heidelberg, Jahnstrasse 29 (Germany)

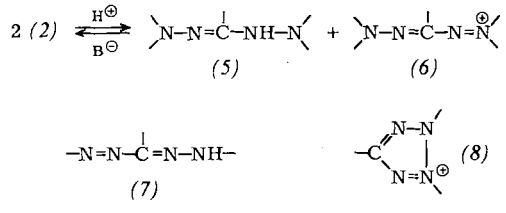
[**] The paper in ref. [1] was first submitted to J. Amer. Chem. Soc. for publication on June 9, 1932, but not accepted until April 10, 1957. The paper was rejected in 1932 because the general opinion was that the properties of the compound were incompatible with the structure of a carbon radical. The unequivocal proof of the structure with the ESR method was not possible until 25 years later.

2. The Hydrazidinyl System

The hydrazidinyl system may be described as a neutral azamethine system with an uneven number of methine groups and π electrons[5]: $7+2n$ π electrons and $5+2n$ atoms, with $n=0$. Because of the hydrazyl resonance *(2a)*↔*(2c)*, the free electron pairs of the outer nitrogen atoms are included in the π electron system. The relative weights of the resonance structures, and thus the spin density distribution, depend on the geometry of the hydrazidinyl system and on the nature of the substituents.



The linear hydrazidinyl system is realized in the 1,2,4,5-tetraazapentenyl radicals *(2)*[6]. In the verdazyls *(3)*[2], the hydrazidinyl system is forced into a *cis,cis* configuration, while the extreme case of directly bonded outer nitrogen atoms is found in the tetrazolinyls *(4)*[7-12]. 1,2,4,5-Tetraazapentenyls and verdazyls undergo a reversible disproportionation in the presence of acid[2,6], forming hydrazidines *(5)* and azacyanine cations (*(6)*; $4+2n$ π electrons and $3+2n$ atoms, $n=1$[5]). The basic structure is retained in this case. This is not so in the corresponding reaction of tetrazolinyls. The product formazan *(7)* has a different basic structure from *(4)* or the product tetrazolium ion *(8)*.

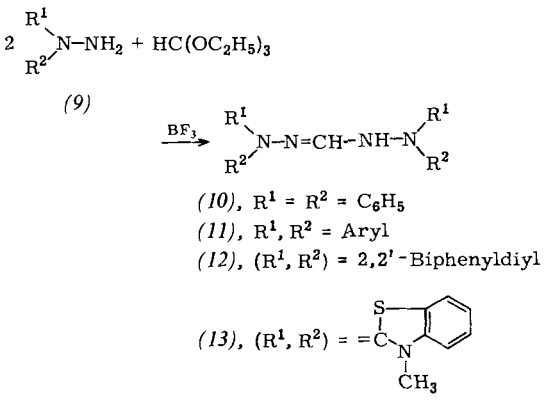


3. 1,2,4,5-Tetraazapentenyls

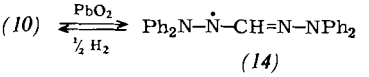
All known[6] open-chain hydrazidinyls are monomeric and have aromatic or other highly conjugated substituents on the outer nitrogen atoms. The parent compound, 1,1,5,5-tetraphenyl-1,2,4,5-tetraazapentenyl *(14)*, has been isolated as a pure crystalline substance.

3.1. Preparation and Chemical Properties

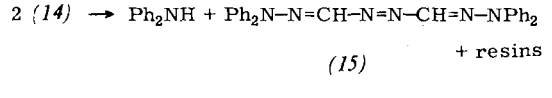
The synthesis of tetraazapentenyls starts with the colorless hydrazidines *(10)*—*(13)*, which can be prepared by the condensation of asymmetrically substituted hydrazines *(9)* with triethyl orthoformate in the presence of BF_3[6,13]. Solutions of *(10)*—*(13)* take on a intense blue-green color in the presence of air or, more effectively, upon addition of Ag_2O or PbO_2. Careful dehydrogenation of *(10)* with PbO_2 yields the hydrazidinyl *(14)*, which crystallizes as



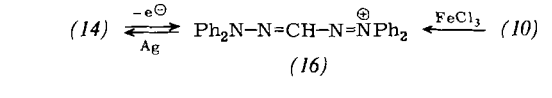
almost black prisms. The hydrogenation of *(14)* leads back to *(10)* with the absorption of 0.5 moles of H_2.



Pure crystals of *(14)* have a shelf life of several weeks. In solution, however, *(14)* decomposes within two days, as do the corresponding radicals from *(11)*—*(13)*. Cleavage of an N—N bond and recombination of the products leads to the orange-red azo compound *(15)*, diphenylamine (*via* the disproportionation of diphenylaminyl), and polymeric substances. *(15)* is also the main product of the thermal decomposition of *(10)* in boiling dimethylformamide (DMF). Radical *(14)* is an intermediate of the latter reaction.



The disproportionation of the tetraazapentenyls in the presence of acids is fully reversible if carried out with the exclusion of oxygen. Oxidizing agents such as halogens, $FeCl_3$, or $C(NO_2)_4$ remove the unpaired electron immediately from the radicals, forming the corresponding deeply colored tetraazapentadienium ions. These cations can be reduced to the radicals again with finely powdered silver. The azacyanine salts can be prepared by oxidation of the hydrazidines to the cations with $FeCl_3$ or $C(NO_2)_4$, followed by precipitation of the perchlorates with perchloric acid or of the double salts with $FeCl_3$ or $AuCl_3$.



3.2. Physical Properties

The symmetry of the π electron systems of tetraazapentenyls and azacyanine cations is demonstrated clearly by the absorption spectra. In the IR spectra, the νNH (3400 cm^{-1}) and νC=N (1650 cm^{-1}) bands of the hydrazidine *(10)* are replaced in the radical *(14)* by bands at 2100 and 2130 cm^{-1}. The latter are in the region of the allene and carbodiimide stretching frequencies and stem from the allylic system

$-\dot{N}-CH=N- \leftrightarrow -N=CH-\dot{N}-$

The radicals (640 nm) and the azacyanine cations (550 nm) both have strong bands in the visible spectral region, the exact positions being dependent on the nature of the outer substituents. Solutions of tetraazapentenyls obey Beer's law. According to susceptibility measurements, *(14)* is also monomeric in the solid phase (298—90 °K)[6].

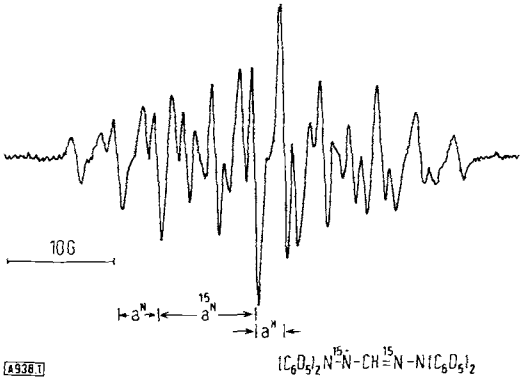


Fig. 1. ESR spectrum of 1,1,5,5-tetrakis(pentadeuteriophenyl)-[2,4-^{15}N]-1,2,4,5-tetraazapentenyl in benzene: $a^{N1,5}=3.73$, $a^{15N2,4}=9.06$, and $a^{HC-3}=2.63$ G.

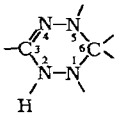
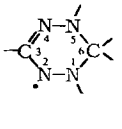
The analysis of the ESR spectra of selected substituted tetraazapentenyl radicals (cf. Fig. 1) yielded the following coupling constants for the backbone chain of *(14)*[14]: $a^{N1,5}=3.75$, $a^{N2,4}=6.5$, and $a^{HC-3}=2.76$ G. The large splitting of the nitrogens in positions 2 and 4 demonstrates clearly the allylic character of the tetraazapentenyl system, with high spin density at these positions. The g values of the tetraazapentenyls are all around 2.0036[14].

4. Verdazyls

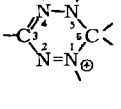
Because of the delocalized nature of the radical *(3)* and the cation *(18)*, the systematic nomenclature (*s*-tetrazine nomenclature[*]) of these systems, which requires a localized unpaired electron, becomes unprecise. Furthermore, the *s*-tetrazine nomenclature leads to long, unwieldly names and requires a renumbering of the atoms when going from the radical to the cation. On the other hand, the shorter and simpler verdazyl nomenclature proposed by *Kuhn* gives a better characterization of the paramagnetic resonance system, and will be adopted for this discussion.



(17): Leucoverdazyl (1,2,3,4-tetrahydro-*s*-tetrazine[*])



(3): Verdazyl (3,4-dihydro-*s*-tetrazin-1-(2 *H*)-yl[*])



(18): Verdazylium (5,6-dihydro-*s*-tetrazinium[*])

[*] Only this terminology is used in Chemical Abstracts.

The term leucoverdazyl will only be used in direct connection with verdazyls.

The geometry of the verdazyl backbone has been determined by X-ray diffraction analysis of 1,3,5-triphenylverdazyl[15]. The verdazyl ring takes on an unsymmetrical boat conformation (Fig. 2), in which the atoms in the conjugated system—including the phenyl substituents—are nearly coplanar. The phenyl groups on N-1 and N-5 lie only 9° and 12°, respectively, out of the plane of the nitrogen atoms, and are slightly twisted in anti-propeller fashion by 13° and 23°. In agreement with this picture of the verdazyl structure, NMR experiments on dissolved verdazyls indicate a hindered ring inversion[16].

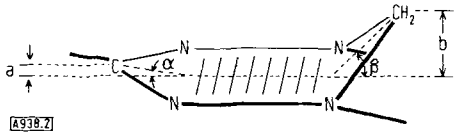


Fig. 2. The deviation of the verdazyl ring from planarity in 1,3,5-triphenylverdazyl: $a=0.099$ Å, $b=0.590$ Å; $\alpha=9.5°$, $\beta=42.9°$ [15].

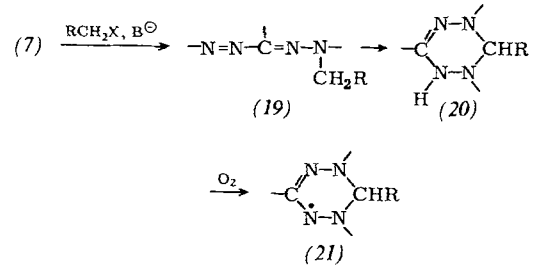
The high stability of these radicals has made possible the synthesis of many mono-, bis-, tris-, and polyverdazyls, all of which are substituted on N-1 and N-5 with aromatic or equivalent conjugated groups. On the other hand, great variation of the substituents is possible in positions 3 and 6[2,16,17]. No case of dimerization of a verdazyl has been observed to date.

4.1. Preparation

Verdazyls were discovered during attempts to alkylate formazans[2]. It has been verified by experiment that formazans *(7)* are first alkylated to *N*-alkylformazans *(19)*. These compounds often cyclize at room temperature to yield leucoverdazyls *(20)*, which are then dehydrogenated by atmospheric oxygen to the verdazyls *(21)*. The procedure is simple: Formazan, alkylating agent, and base (BaO, $Ba(OH)_2 \cdot 8H_2O$) are stirred in an aprotic solvent (DMF) in the presence of air. Almost all formazans are alkylated under these conditions, but the choice of alkylating agents seems to be restricted to primary alkyl halides or dialkyl sulfates.



This reaction stops at the alkylformazan stage *(19)* if the formazan is only substituted at the 1,5 positions or if the substituents at these positions are of electron withdrawing nature (4-nitrophenyl, diphenylcarbamoyl)[2,18-20]. Two isomeric *N*-alkyl derivatives may be formed if the substrate has different substituents at posi-

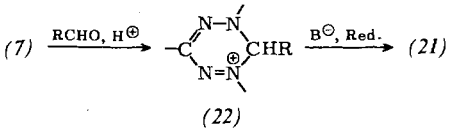
tions 1 and 5[20]. Stable *N*-alkylformazans rearrange to leucoverdazyls at higher temperatures (100 °C), and these can be dehydrogenated to the verdazyls with an equivalent amount of an oxidizing agent ($K_3Fe(CN)_6$[2], $FeCl_3$[16]).

The aminoalkylation of formazans also appears to be possible. The reaction of 1,3,5-triphenylformazan with formaldehyde and secondary amines yields verdazyls with dialkylamino groups at position 6[17], presumably *via* the intermediates *(19)* and *(20)* (R = 1-piperidyl, *etc.*).

Diazomethane has also been used as the alkylating agent in some special cases (*e.g.* 1,3-diphenyl-5-(2-benzothiazolyl)verdazyl[21]).

The alkylation procedure has also been used successfully for the preparation of bis-, tris-, and polyverdazyls[22], either *via* alkylation of bis-[23-25], tris-[23,26], and polyformazans[27,28], or by reaction of monoformazans with bifunctional alkyl halides[23,25] or with *p*-chloromethylpolystyrene[29].

Verdazyls can also be prepared easily by reacting formazans with formaldehyde[2]. In the presence of acid ($KHSO_4$, BF_3, HCl), formazans *(7)* condense with formaldehyde to yield verdazylium ions *(22)*, which are reduced to the verdazyls by an excess of aldehyde upon addition of base. Many mono- and bisverdazyls have been prepared in this manner[2,18,23,30-32]. Other aliphatic aldehydes (acetaldehyde, *etc.*) can be used in place of formaldehyde, but the method fails when aromatic aldehydes (benzaldehyde) are used.



(22)

Verdazyls are also formed in the reaction of formazans with formaldehyde in the presence of base and oxygen[2]. In this reaction the verdazyls are not formed directly, but are the products of an unknown reaction sequence[24].

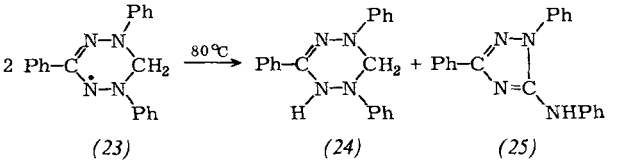
Reactions of verdazyls which leave the unpaired electron unchanged have found some use in special synthetic problems. For instance, aminoverdazyls can be acylated with acyl chlorides or converted into bisverdazyls with bifunctional acyl chlorides[33]. The reaction with aldehydes yields aldimines[24]. Polyverdazyls can be synthesized *via* polycondensation or polyaddition of a diaminoverdazyl with terephthalaldehyde, terephthaloyl chloride, or 1,4-phenylene diisocyanate[34]. Polyverdazyls (homo- and copolymers) can also be prepared by *anionic* polymerization of vinyl substituted verdazyls[35].

4.2. Chemical Properties

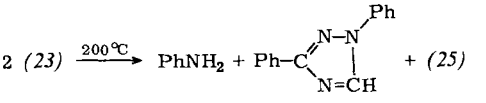
Crystals of the parent compound 1,5-diphenylverdazyl have a shelf life of a few weeks. The stability of derivatives increases with the nature of the substituent at C-3 in the following order: H[2] < CH_3[16] < $COOR$[18] < $C(CH_3)_3$[36], C_6H_5[2]. Verdazyls with *tert*-butyl or aryl substituents at C-3 remain unchanged over a period of years. The stability is evidently affected by the chemical reactivity of the group at C-3 (α- and β hydrogens) and by its ability to sterically shield the verdazyl ring. Replacing a hydrogen at C-6 by alkyl[16] or phenyl[2] groups also stabilizes the verdazyls[37].

With few exceptions, verdazyls are also stable for a period of weeks in dilute solutions. In saturated solutions, however, the radical concentration decreases considerably in a matter of days.

As with other stable radicals, disproportionation reactions become a key factor in such solutions. Keeping a saturated solution of 1,3,5-triphenylverdazyl *(23)* in benzene at reflux temperatures for a day yields 1,3,5-triphenylleucoverdazyl *(24)* and 5-anilino-1,3-diphenyl-1,2,4-triazole *(25)* in a 1:1 ratio[38]. Similarly, thermolysis of *(23)* at 200 °C produces aniline, 1,3-diphenyl-1,2,4-triazole *(26)*, and *(25)*[2,38]. Aniline and *(26)* are evidently the thermolysis products of *(24)*.

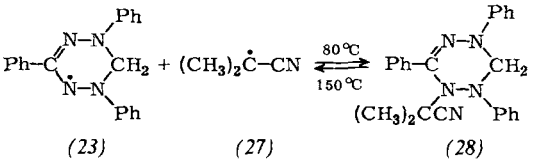


(23) (24) (25)



(26)

The autoxidation of benzaldehyde and the radical polymerization of vinyl monomers is inhibited by verdazyls, which are transformed to N-2 substituted leucoverdazyls *(29)*[2,39-42] in the process. The cyanopropyl radical *(27)* reacts with 1,3,5-triphenylverdazyl *(23)* in good yield (>60%) at temperatures below 100 °C[43]. The product of the combination reaction *(28)* dissociates again at temperatures above 100 °C, whereby *(29)* is consumed in side reactions, and the verdazyl *(23)* can be reisolated in high yield (77%). Thus, *(27)* can be used as an effective protecting group in the synthesis of verdazyls[33].

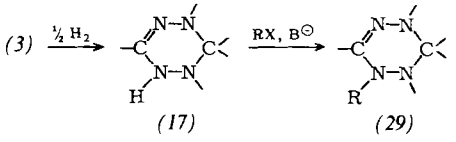


(23) (27) (28)

The green verdazyls *(3)* can be reduced to the colorless leucoverdazyls *(17)* by reducing agents such as $Na_2S_2O_3$, H_2S, dihydropyridines, ascorbic acid, *etc.* The mechanism of the hydrogen transfer from dihydropyridines to verdazyls has been thoroughly studied[44-47]. "Microhydrogenation"[48] is a convenient method of checking the purity of verdazyls[2,23], because the hydrogenation over a Lindlar catalyst or 5% $Pd/BaSO_4$ stops at the leuco compound after consumption of 0.5 moles of H_2[*]. The N—H group of leucoverdazyls *(17)* can be easily alkylated, *(17)* → *(29)*.

[*] Mononitroverdazyls take up 3.5 moles of H_2 to yield aminoleucoverdazyls.

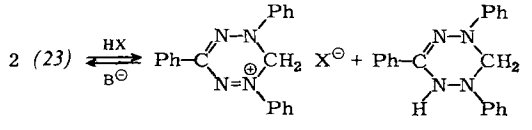
The *N*-alkyl derivatives *(29)* are sometimes formed in side reactions during the alkylation of formazans[2,36,49]. NMR studies indicate that a slow nitrogen inversion occurs in *(29)*[49].



(17) *(29)*

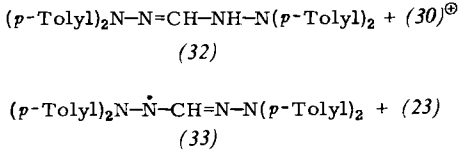
Verdazyls are oxidized immediately by halogens, $FeCl_3$, or $C(NO_2)_4$ to the corresponding verdazylium ions *(18)*, which can be isolated as the perchlorates or as the double salts ($FeCl_4^-$, $AuCl_4^-$, $PdCl_4^{2-}$, $PtCl_6^{2-}$)[2,31,50]. These cations are azacyanine dyes with *cis,cis* configuration of the methine chain. Substituents in the *para* position of the *N*-phenyl rings lead to a bathochromic shift of the first absorption band of the verdazylium ion *(30)* at 548 nm, regardless of the nature of the substituent (electron donor or acceptor)[31,50]. As might be expected, the bathochromic effect of electron donors is more prominent. The "mean value rule" for polymethine dyes[51] applies also to the verdazylium ions. Electron donating substituents in the *para* position of the *meso*-*C*-phenyl ring also effect a bathochromic shift of the first transition, while electron acceptors cause a small hypsochromic shift[50].

Verdazyls disproportionate in the presence of acids to form verdazylium ions *(30)* and leucoverdazyls *(31)*[2,30,52]. This reaction has been utilized in the form of a potentiometric titration for the quantitative determination of the radical concentration[28,29]. Leucoverdazyls are easily oxidized: atmospheric oxygen dehydrogenates *(31)* to *(30)* in weakly acidic solutions[2,30].



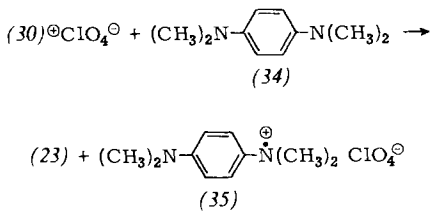
green *(30)* violet *(31)* colorless

Combined electron and proton transfer reactions may be observed if the redox potentials allow: 1,2,4,5-Tetraazapentene *(32)* and 1,3,5-triphenylverdazylium ion *(30)* react to form 1,2,4,5-tetraazapentenyl *(33)* and 1,3,5-triphenylverdazyl *(23)*[50].



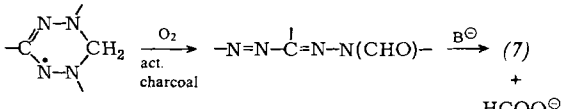
(32) *(33)*

Electron exchange reactions of two diamagnetic compounds to form two radicals are also possible in the absence of base, if the electron donating component reacts to form a radical cation. For example, the addition of verdazylium perchlorate *(30)* to a solution of tetramethyl-*p*-phenylenediamine *(34)* in benzene is followed by the precipitation of pure Wurster's blue *(35)* as the perchlorate[50].



(34) *(35)*

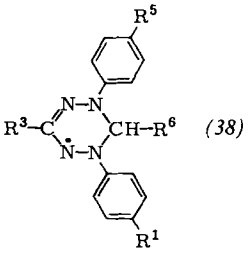
In the presence of activated charcoal, verdazyls with a methylene bridge in position 6 *(36)* are oxidized slowly to 5-formylformazans *(37)* by atmospheric oxygen. These formazan derivatives can be hydrolyzed with base to form formazans *(7)* and formate[37]. This oxidative ring opening, as well as the photochemical degradation of verdazylium salts[2], serves as a chemical proof of the fact that the backbone structure of the formazan chain is retained in the verdazyls.



(36) *(37)*

4.3. Physical Properties of the Monoverdazyls

In concurrence with the polymethine structure of verdazyls, the first electronic transition, which is almost independent of solvent, is found at about 700 nm. Extension of the conjugated system *(38)*, either by substitution in the *para* position of the *N*-phenyl rings (R^1, R^5) or in the *meso* position at C-3 (R^3), leads to a bathochromic shift of the longwave band—irrespective of the electron donating or withdrawing nature of the substituent. The bathochromic shift increases with various substituents in the following order: $R^1=R^5$ ($R^3=C(CH_3)_3$):H < $COOCH_3$, CN, OCH_3 < NO_2; R^3 ($R^1=R^5=H$):H < $C(CH_3)_3$ < CH_3 < C_6H_5 < 4-$C_6H_4OCH_3$ < 4-$C_6H_4NO_2$[24,31,50]. The "mean value rule"[51] for polymethine dyes is valid for verdazyls. The substituent R^6 does not take part in the conjugation system, but it can lead to a hypsochromic shift *via* steric interaction with this system. 1,3,5-Triphenylverdazyls with $R^6=C_6H_5$[2], NC_5H_{10}[17] exhibit a hypsochromic shift of about 20 nm in comparison with the parent compound. The electronic spectra of the verdazyls have yet to be satisfactorily interpreted within HMO theory[53].



(38)

The IR spectra of the leucoverdazyls have several bands in common which are characteristic of the structure: a sharp νNH band (3400 cm^{-1}), and a very strong ω phenyl band around 1600 cm^{-1}, which overlaps the much weaker νC=N band (the latter two bands are separated in the

2,4-^{15}N compound)[2, 14]. Many bands in the IR spectrum of 1,3,5-triphenylverdazyl are shifted by ^{15}N labeling (see Table 1). The small wave numbers of these bands in comparison with that of a pure νC=N absorption (1600 cm^{-1}) demonstrates that, as was to be expected, the *cis,cis* hydrazidinyl system is a strongly coupled system. An analysis of the vibrational system has not yet been reported[54, 55].

Table 1. Bands [cm^{-1}] in the IR spectrum of 1,3,5-triphenylverdazyl which are shifted by 2,4-^{15}N substitution [24].

[a] Extinctions relative to the strongest band of the spectrum ($E_{rel}=1$).

Verdazyl solutions obey Beer's law. The monomeric nature of dissolved verdazyls has also been confirmed by NMR susceptibility measurements[56]. The paramagnetic susceptibilities of crystalline verdazyls obey the Curie-Weiss law over a wide range of temperatures[23]. Spin compensation due to exchange interactions is observed only at temperatures under 30°K[57]. The measurement of the *ortho-para* hydrogen conversion rate in the presence of verdazyls demonstrated experimentally that the specific rate constant is not only dependent on the magnetic moment of the added radical, but also on its molecular structure[58].

The typical ESR spectrum of verdazyls has nine lines or line groups in the intensity ratio 1:4:10:16:19:16:10:4:1. The coupling constants a^N of the four nitrogen atoms of the verdazyl ring are all about 5—6 G[2].

The proton coupling constants in the parent compound 1,5-diphenylverdazyl can be determined by comparison with the more highly resolved spectra of selectively substituted derivatives[18]. The splitting $a^{N1,5}$ is influenced by the nature of the substituent in the *para* position of the *N*-phenyl ring. The effect can be correlated with the Hammett relationship[31]. The *g* values of the verdazyls are around 2.0034.

The magnitudes and signs of the HFS coupling constants can also be determined from the paramagnetic shifts in the NMR spectra of free radicals[59]. This method has been applied to the stable monomeric verdazyls with great success (*cf.* Fig. 3). Both ^{1}H and ^{2}H HFS coupling constants of many verdazyls could be determined and unequivocally assigned using this method[16, 60-62]. In addition, the temperature dependence of the C-6 methylene proton resonance demonstrated the presence of an inversional equilibrium in the verdazyl ring in solution[16]. The dynamic nuclear polarization in verdazyl solutions has also been studied[63].

The spin densities of the verdazyls—from NMR and ESR data—are comparable with the calculated *(McLachlan)*

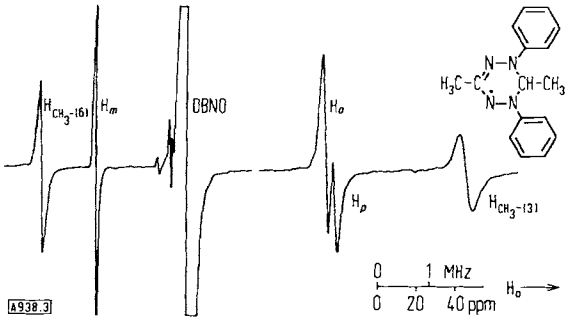

Fig. 3. The ^{1}H-NMR spectrum of 3,6-dimethyl-1,5-diphenylverdazyl in di-*tert*-butyl nitroxide (DBNO) [16].

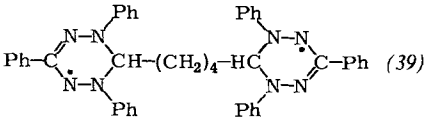
spin density distributions of 1,5-diphenyl- and 1,3,5-triphenylverdazyl[53, 61]. The greater part of the free spin (≈80%) is distributed almost equally among the four nitrogen atoms of the verdazyl ring. Thus, the resonance structures *(2a)* and *(2c)* of the hydrazidinyl system have about equal weight in the verdazyls.

4.4. Physical Properties of Bis- and Trisverdazyls

Verdazyl moieties can be linked together at the ring positions N-1, C-3, N-5, and C-6. Nearly all known bis- and trisverdazyls fall into three groups, namely those linked symmetrically at N-1,N-1'-, at C-3,C-3'- and at C-6,C-6'.

A typical example for C-6,C-6' coupling is the bisverdazyl *(39)*[23]. The absorption spectrum of *(39)* is identical to that of the component verdazyl moieties. Susceptibility measurements over a wide temperature range yielded a value of 2.45 μ_B. The ESR spectrum at ambient temperature shows only one broad signal, but at reduced temperatures a dipolar zero-field splitting of $D=25$ G can be observed[62]. Thus *(39)* is a diradical with an almost degenerate singlet-triplet ground state. As is to be expected, the HFS coupling constants—determined in the ^{1}H-NMR spectrum—are half as large as those in the monoverdazyls[62].

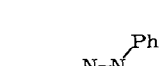


(39)

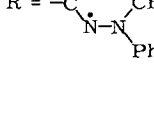
C-3,C-3' coupling of the verdazyl moieties through a conjugated bridge yields diffuse π electron systems with more than one unpaired electron. Prominent examples are the bisverdazyl *(40)* and the trisverdazyl *(41)*[23]. The ESR spectrum of *(40)* at ambient temperature shows signs of hyperfine structure ($a^N=2.8$ G). Two independent measurements of the zero-field splitting at 77°K have been reported: $D=43.1$ G[64] and $D=45$ G, $E=2$ G[62]. The ^{1}H-NMR spectrum yielded the coupling constant $a^H=0.12$ G for the protons of the bridging phenyl ring, while the splittings of the *N*-phenyl protons are about half as large as in the corresponding monoverdazyl[62]. These results and also susceptibility measurements (298–77°K) lead to the conclusion that the ground state of *(40)* is a nearly degenerate singlet-triplet state. Susceptibility measurements

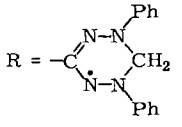
on the trisverdazyl *(41)*, which were carried out over a wide temperature range in solution and in the solid state, gave a value of $3\,\mu_B$. The ESR spectrum of *(41)* at ambient temperature shows hyperfine structure ($a^N = 2$ G). The analysis of the low temperature ESR spectrum yielded the zero-field parameter $D' = 28.5$ G. Thus, the trisverdazyl *(41)* has a nearly degenerate doublet-quartet ground state[65].

(40)



(41)





N-1,N-1′ coupling of verdazyl systems through conjugated bridges also leads to diffuse π electron systems, for example *(42a)*—*(44a)*[23,66]. The ESR spectra of these bisverdazyls at ambient temperature show hyperfine structure ranging in strength from very weak (*(42a)*) to strong (*(43a)*, *(44a)*), $a^N = 2.8$ G. The susceptibility values (298–90 °K) of *(43)* and *(44)* in the solid state correspond to degenerate singlet-triplet states. On the other hand, *(42)* has a lower molecular susceptibility, which decreases as the temperature is reduced. The absorption spectrum of *(42)* at ambient temperature (Fig. 4) shows in addition to the usual verdazyl bands a new band at 550 nm. This additional band becomes stronger at reduced temperatures, while the band at 440 nm becomes weaker. The process is reversible. This reduction in the concentration of bisverdazyl and in the paramagnetic susceptibility at low temperatures must be due to an intramolecular process, because the absorption spectra are independent of concentration. The unpaired spins of *(42a)* form a new double bond to the bridge, resulting in a diamagnetic, double zwitterion with a quinonoid bridge *(42b)* similar to the central structural element of Chichibabin's hydrocarbon. Increasing the length of the bridge tends to stabilize the bisverdazyl relative to the diamagnetic form. Thus in the low temperature spectrum of *(44)*, the band due to the diamagnetic zwitterion *(44b)* can only just be identified as a shoulder (Fig. 5). According to the susceptibility measurements and the ESR data, the bisverdazyls *(42a)*—*(44a)* are characterized by closely lying singlet and triplet states.

5. Tetrazolinyls

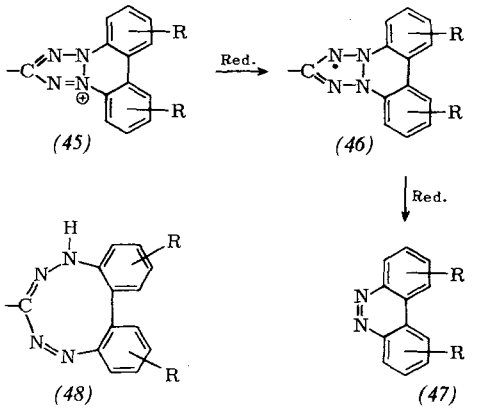
In tetrazolinyls *(4)*, the outer nitrogen atoms of the hydrazidinyl system are directly coupled to each other. Many "phototetrazolinyls"[*] *(46)* are isolable[67–70], but only one example *(50)* of a simple tetrazolinyl has been isolated to date[70,71]. All known tetrazolinyls are monomeric and are substituted on N-2 and N-3 by aromatic or other highly conjugated groups.

5.1. Preparation and Chemical Properties

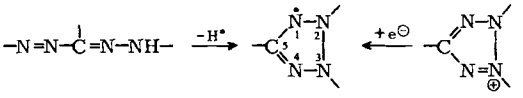
The reduction of phototetrazolium salts *(45)* with sodium amalgam, sodium dithionite, or sodium stannite led to the discovery and isolation of the first radicals of tetrazolinyl type[7,67–69]. The preparation is still restricted to this approach, because the lower oxidation state of the radicals,

[*] Derived from phototetrazolium ions; 2,3-(2,2′-biphenyldiyl)tetrazolinyls or 1*H*-benzo[c]tetrazolo[2,3-*a*]cinnolin-1-yls.

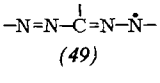
the cycloformazans *(48)*, have not yet been prepared[72]. The reduction of the phototetrazolinyls leads only to degradation products, *i.e.* benzo[*c*]cinnolines *(47)*.



As demonstrated by the strong ESR signals of the solutions, tetrazolinyls *(4)* are formed by reduction of tetrazolium ions *(8)* with potassium stannite[8], propiophenone anion[10], or silver amalgam[11], by dehydrogenation of formazans *(7)* with atmospheric oxygen[9,10] or lead dioxide[73], or by comproportionation of formazans and tetrazolium salts in basic medium[10]. The dehydrogenation of formazans to tetrazolinyls with di-*p*-tolylaminyl proceeds under very mild conditions[12]. Using this reaction, 5-*tert*-butyl-[70] and 5-phenyl-2,3-bis(4-nitrophenyl)tetrazolinyl[14] can be prepared and isolated. The dehydrogenation of bisformazans leads to mono- and bistetrazolinyls, as was demonstrated by ESR spectroscopy[73].

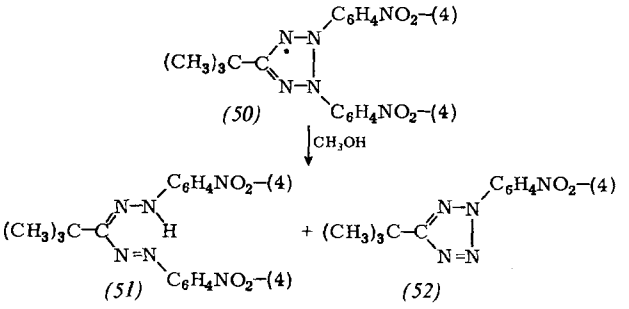


The oxidation state intermediate between formazans and tetrazolium ions might be formulated as the 1,2,4,5-tetraazapentadienyl radical *(49)*. However, ESR measurements have unequivocally identified the radicals as being tetrazolinyls and not the open-chain valence isomers[12,74,75]. Presumably, tetraazapentadienyls are the first products of the dehydrogenation of formazans. These intermediates, however, are not identifiable and evidently rearrange immediately to the more stable tetrazolinyls.



(49)

The stability of the tetrazolinyl radicals, which are inert towards oxygen under normal conditions, increases with increasing electron acceptor character of the *p*-substituents of the *N*-phenyl rings. Nitro-substituted tetrazolinyls *(50)* and cyano-substituted phototetrazolinyls are the most stable examples[70]. If care is taken to exclude light, CO_2, and water vapor, the crystalline radicals can be kept for months without decomposing. In weakly acidic medium (methanol), tetrazolinyl *(50)* decomposes immediately, forming formazan *(51)* and tetrazole *(52)*[70]. Under the same conditions, phototetrazolinyls yield benzo[*c*]cinnolines *(47)*. The reduction of phototetrazolinyls also leads to *(47)*. Conversely, tetrazolinyl *(50)* can be reduced to the formazan *(51)* with sodium dithionite. The oxidation of the tetrazolinyls and phototetrazolinyls with bromine or iodine proceeds with quantitative yield to the corresponding tetrazolium ions[67,70].

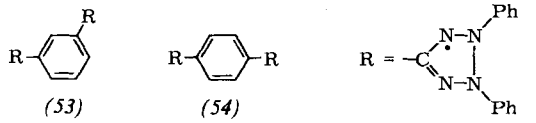


5.2. Physical Properties

In keeping with the tetracyclic conjugation system, the absorption spectra of the phototetrazolinyls have many bands in the UV range and a characteristic long-wave band at 600—700 nm. This band undergoes a bathochromic shift when the *N*-phenyl rings are substituted in the *para* position: H (608 nm), CH_3 (625 nm), CN (695 nm)[70]. Tetrazolinyl *(50)* has a long-wave band at 590 nm.

The experimental susceptibility values of tetrazolinyl *(50)* and several phototetrazolinyls are almost equal to the theoretical values for monoradicals. The Curie-Weiss law is valid over a wide temperature range (298 – 80 °K)[70,76]. These radicals are also monomeric in solution down to 70 °K (low temperature absorption spectra).

The ESR spectra of the tetrazolinyls have a nine-line hyperfine structure[8-12]. The coupling constant $a^{N2,3}$ (6.1—8.65 G) is distinctly larger than $a^{N1,4}$ (5.4—5.8 G), and is highly dependent on the nature of the *p*-substituents of the *N*-phenyl rings. The changes in $a^{N2,3}$ obey the Hammett equation[12,70,74]. In addition to the nitrogen coupling constants, high resolution ESR spectra of selectively substituted tetrazolinyls also yield the proton coupling constants of the parent compound 2,3-diphenyltetrazolinyl[74]. Similarly, the analysis of the highly resolved ESR spectra of selectively substituted phototetrazolinyls yielded $a^{N2,3}$ (6.3—7.8 G), $a^{N1,4}$ (3.75—3.9 G), and all hydrogen splittings of the parent compound 2,3-(2,2'-biphenyldiyl)-tetrazolinyl[75]. The *g* values of the tetrazolinyls are around 2.0037, and those of the phototetrazolinyls about 2.0036.



(53) *(54)*

Low temperature ESR spectra of the bistetrazolinyls *(53)* and *(54)* yielded the zero-field parameters $D = 51.6$ G and 37.9 G, respectively[73].

The spin densities—obtained from the ESR data of the radicals—are in satisfactory agreement with the calculated *(McLachlan)* spin density distribution for the tetrazolinyl structure. The ratio of the nitrogen coupling constants $a^{N_2}:a^{N_1}$ in the hydrazidinyl system goes from 1.7 in the tetraazapentenyls through 1.0 in the verdazyls to 0.75 in the tetrazolinyls and 0.5 in the phototetrazolinyls. In contrast to the allylic tetraazapentenyls, the major spin density in the tetrazolinyls is found on the outer nitrogen atoms of the hydrazidinyl system. This spin is partly delocalized into the *N*-phenyl rings by electron withdrawing substituents. The most stable tetrazolinyl *(50)* has almost equal coupling constants for all nitrogen atoms. This example demonstrates clearly the importance of optimal delocalization of the unpaired electron for the stability of free radicals.

Bredt Compounds and the Bredt Rule

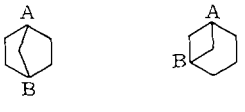
By Gert Köbrich[*]

Dedicated to Professor Theodor Wieland on the occasion of his 60th birthday

The Bredt rule, which proved useful in earlier decades mainly as an exclusion criterion in the assignment of structures, has in recent years become the stimulus for efforts to synthesize strained bicyclic systems with a bridgehead double bond. On the basis of the ring-strain forces operating in such systems, an extended Bredt rule is discussed. The "Bredt compounds" to which this rule applies, which include bicyclic systems not previously considered from this point of view (*e.g.* bridged methylenecyclopropanes), form a clearly circumscribed, interesting field within the chemistry of highly-strained hydrocarbons with ring unsaturation.

1. Introduction

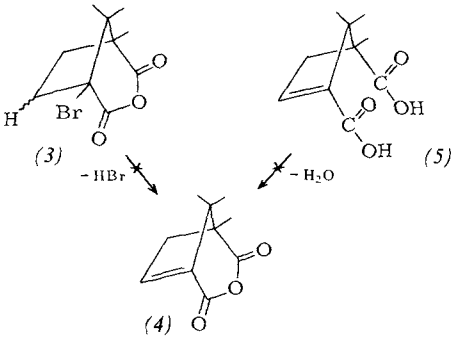
According to the rule formulated by *Bredt* and called after him, "in systems of the camphane and pinane series and related compounds *(1)* and *(2)*, the branching points A and B of the carbon bridges (the bridgeheads) cannot be involved in a carbon double bond"[1].



(1)

(2)

An experimental observation that led *Bredt* to this realization shortly after the turn of the century will be outlined here[2]. Firstly, the attempted dehydrobromination of the anhydride *(3)* was unsuccessful, whereas the corresponding dicarboxylic ester could be smoothly dehydrobrominated; secondly, the unsaturated dicarboxylic acid *(5)* was found to be incapable of forming its internal anhydride *(4)*, whereas saturated analogs underwent this cyclization very readily. The resistance to the formation of *(4)* and related bicyclic structures was correctly attributed by *Bredt* to the ring strain that would necessarily result from the distorted geometry of the carbon double bond at the bridgehead in comparison with normal olefins.



The correctness of *Bredt*'s hypothesis was soon shown very impressively by the fact that it was found necessary to revise all earlier structural assignments contrary to his postulate[3]. The Bredt rule therefore initially served, and still serves, as an exclusion criterion in the determination of constitutions of unsaturated bicyclic compounds. This aspect, which is now mainly of historical interest, will not be considered further here, particularly since it has been presented in great detail by *Fawcett*[4] in a survey of the literature published up to 1950.

Another aspect has proved to be interesting and important for the future[5, 6]. If the ring strain prevents the formation of a double bond at the bridgehead in the bicyclic structures *(1)* and *(2)*, it will certainly also do so in compounds with smaller rings, *e.g.* in the bicyclo[2.1.1]hexane system; however, this rule will not be absolutely valid for the higher homologs of *(1)* and *(2)*, since with a sufficiently large number of atoms in the ring it is possible to construct completely strain-free molecular models of bridgehead olefins. This raises the question how far the Bredt rule is valid for the higher homologs of *(1)* and *(2)*, or in other

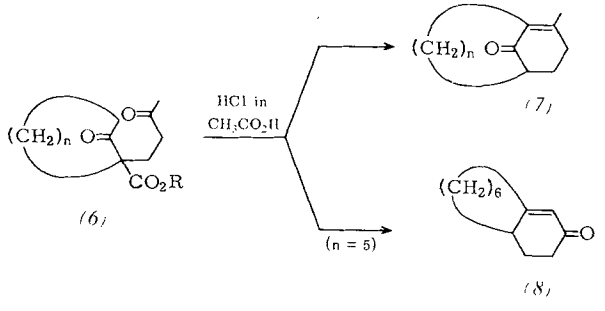
[*] Prof. Dr. G. Köbrich
Institut für Organische Chemie der Technischen Universität
3 Hannover, Schneiderberg 1 B (Germany)
Based on a lecture given in Regensburg on July 3, 1972.

words, the ring size beyond which it is no longer valid. When considered in this way, the rule changes from a fact to a problem, and from an aid in the investigation of structures to a subject for investigation, whose current interest is shown by a number of very recent studies. It would admittedly be inappropriate to consider this problem in isolation. It forms part of the broader chemistry of strained ring systems, with which it is closely interwoven. The aim of the following discussion is to fit the Bredt rule into its place in this wider context.

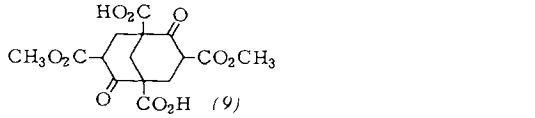
2. Isolable Bridgehead Olefins

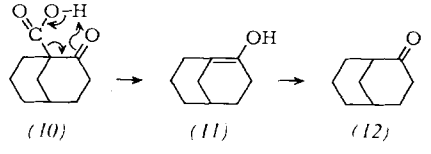
The range of validity of the Bredt rule, in the sense of our problem, can be defined only by negative evidence. The successful preparation of a bicyclo[*x.y.z*]alk-1-ene shows that the rule is not valid for this compound, though failure to prepare this compound does not necessarily indicate the validity of the rule. The information derivable from an experiment is thus crucially dependent on the appropriate choice of experimental conditions, particularly the "correct" synthetic pathway. A highly strained compound will be formed only if a sufficiently energy-rich precursor that reacts irreversibly and in only one direction is available, and its isolation will be successful only if no subsequent reactions occur.

The first attempts to establish a boundary were made in 1948/49 by *Prelog et al.*[7] in the intramolecular aldol condensation of the compounds *(6)*. The compounds *(7)* with a bridgehead double bond were formed smoothly from the homologs with $n \geq 5$; with $n=5$, *(8)* was formed in addition to *(7)* in an alternative reaction, and with $n<5$ *(7)* was no longer obtained.

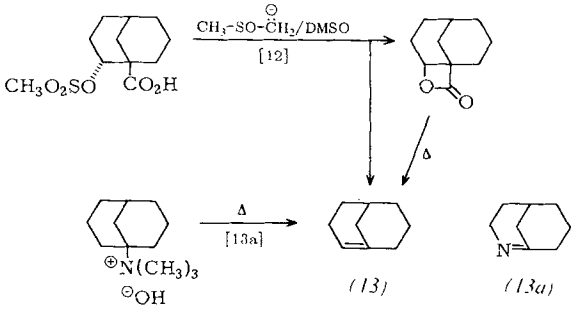


For purposes of comparison, it is useful to denote the sum $x+y+z$ of the numbers of bridge atoms in a bicyclo[*x.y.z*]alk-1-ene by *S*, as was done by *Fawcett*[4]. In the following discussion, moreover, the number for the bridge containing the bridgehead double bond will be indicated by a bar. The compound *(7)*, $n=5$, for which the Bredt rule is no longer valid according to *Prelog et al.*, is thus a [5.3̄.1] system with $S=9$. The ability of even smaller bicyclic structures with a bridgehead double bond, such as the [3̄.3.1] compound *(13)*, with $S=7$, to exist at least for a short time was suggested by the smooth decarboxylation of bicyclic β-keto acids such as *(9)*[8] and *(10)*[9].

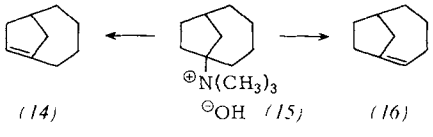




According to the current view on the decarboxylation mechanism of β-keto acids[10], this reaction should proceed *via* enols having the ring skeleton *(11)*. A similar conclusion can be drawn from the *triple* H/D exchange in the ketone *(12)* in basic media[11]. In 1967, the research groups of *Marshall*[12] and *Wiseman*[13a] succeeded in preparing the stable bicyclo[3.3.1]non-1-ene *(13)* by the three paths outlined below. The aza analog *(13a)* is now also known[14].



The isomeric [4.2̄.1] and [4̄.2.1] systems *(14)* and *(16)* were also synthesized shortly afterwards. Hofmann elimination in *(15)*, with kinetic product control, gave the (presumably) thermodynamically less stable *(14)* in higher yield than *(16)*[13b].



3. Relations between Structure and Ring Strain

The hydrocarbons *(13)*, *(14)*, and *(16)* at present mark the lower limit for stable bridgehead olefins. This admittedly does not mean that compounds having $S=7$ in general lie outside the range of validity of the Bredt rule, since the number of bridge atoms *S* gives only an incomplete picture of the ring strain. It can be used for predictions regarding strain and stability only when one is considering similar (homologous) bicyclic structures. Bridgehead olefins might even possibly be more stable than bicyclic systems with different structures and with a higher *S*. Another determining factor for a given *S* is the size of the individual bridges. The stability also depends on whether, for a fixed

ring skeleton, the bridgehead double bond is situated in a larger or in a smaller bridge. The following rules, which admittedly do not yet allow comparison in every case, can be deduced for bicyclic structures with the aid of models:

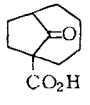
Rule A. For homologs with different S values, the ring strain varies inversely with S[4].

Rule B. For a given S, the ring strain varies inversely with the size of the larger of the two rings with respect to which the bridgehead double bond is *endocyclic*[13] (for explanations and reasons see Section 7).

Rule C. For a given bicyclic ring skeleton, the ring strain varies inversely with the size of the bridge containing the bridgehead double bond.

Rule C explains, for example, the greater stability of *(16)* in comparison with *(14)*. It follows from rules B and C, for example, that *(15)* does not give the least stable [4.2.1̄] system *(17)*, whose lower formation tendency is also reflected in the failure[15] to decarboxylate the β-keto acid *(18)*.

(17)



(18)

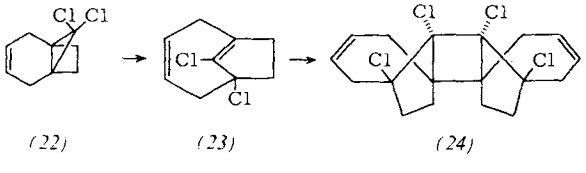
According to rule C, among the as yet unknown bicyclic structures *(19)* to *(21)*, *(19)* should be less stable than *(13)*, and *(21)* should be less stable than *(20)*. The investigation of these systems with $S=7$ should be interesting and important, since they presumably lie on the borderline between stable and unstable compounds as defined in Section 6.

(19)

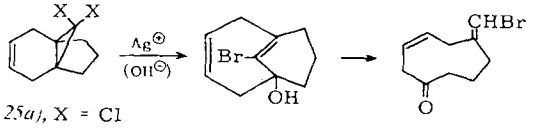
(20)

(21)

Initial reports of such investigations have appeared in very recent publications. Thus the [4.2.1̄] compound *(23)* is formed as a short-lived intermediate by cyclopropyl-allyl rearrangement of dichlorocyclopropane *(22)* at about 25 °C, as shown by the isolation of the head-to-head dimer *(24)* whose structure has been elucidated by X-ray methods (mirror symmetry)[46a]. The ring strain in *(23)* is estimated as 20—22 kcal/mol. The dichloride *(25a)*, a higher homolog of *(22)*, is thermally stable. However, the corresponding dibromide *(25b)* (and likewise also the dihydro derivative)



(22) *(23)* *(24)*

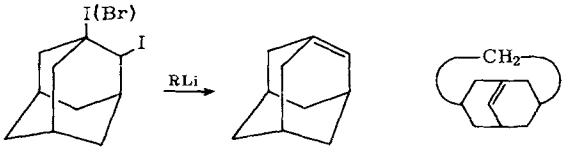


(25a), X = Cl
(25b), X = Br

(26) *(27)*

undergoes silver-salt catalyzed skeletal rearrangement to the cyclononene compound *(27)*, the [4.3.1̄] system *(26)* being a suspected intermediate[46b].

We encounter a particularly interesting bridgehead olefin in adamantene *(29)* which turns out to be a derivative of the [3.3.1̄] system *(19)* when drawn in the distorted fashion chosen for formula *(30)*, but with an even higher ring strain owing to the additional methylene group. Its intermediacy in the dehalogenation of 1,2-diiodo (and 1-bromo-2-iodo-)adamantane *(28)* by organolithium compounds is apparent from the almost quantitative formation of a hydrocarbon $C_{20}H_{28}$[47], which is presumably a head-to-tail dimer of *(29)*[47a]. *(29)* is assumed to have a "double bond" with completely decoupled π electrons[47b].



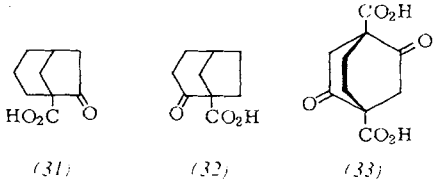
(28) *(29)* *(30)*

Thus no isolable [$x.y.1̄$] compounds have so far been obtained with $S=7$; the bridgehead olefins of this structure under current investigation belong to the unstable intermediates to be discussed below.

4. Unstable Compounds with $S<7$

According to the current view, bridgehead olefins with $S<7$ are capable of existing, but are unstable. Our as yet very incomplete knowledge is based on the circumstantial evidence that is usual for short-lived intermediates, and is subject to the uncertainties associated with this method.

This is true *e.g.* for the above-mentioned decarboxylation of β-keto acids with carboxyl groups attached to the bridgehead carbon atom. The fact that decarboxylations occur with difficulty if at all in systems with $S \leqslant 6$[16-19] can be safely interpreted as resistance to the formation of the corresponding ring-strained enols. On the other hand, it is very doubtful whether the normal decarboxylation mechanism *via* enols [see formulas *(10)* and *(11)*] is followed under forcing conditions, as in the thermolyses of the β-keto acids *(31)*, *(32)*[18] and *(33)*[19] between 260 and 320 °C.

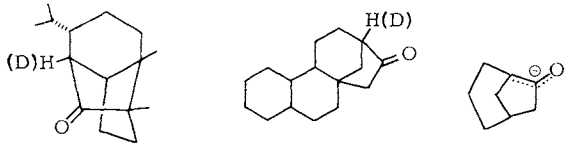


(31) *(32)* *(33)*

A variant has been proposed[18] (and criticized[13a, 20]), in which the bridgehead atom retains its sp^3 hybridization in the course of the elimination of CO_2. According to *Buchanan et al.*[20], the decarboxylation of optically active *(33)*, contrary to expectation, proceeds with complete race-

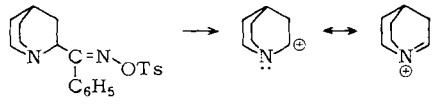
mization. It could therefore involve an initial ring cleavage, followed by the normal decarboxylation and a recyclization. It is significant that the monocarboxylic acid formed from *(33)* is not decarboxylated further[20].

The decarboxylation of small bicyclic β-keto acids obviously does not allow reliable deductions concerning the existence or non-existence of ring-strained bridgehead olefins, owing to its unconfirmed mechanistic premises. Nevertheless, the recently accomplished base-catalyzed H/D exchange at the bridgeheads of the ketones *(34)*[48a] and *(35)*[48b] that are adjacent to the carbonyl groups provides some indication of the existence of enolates of type *(36)*, however short-lived they may be.



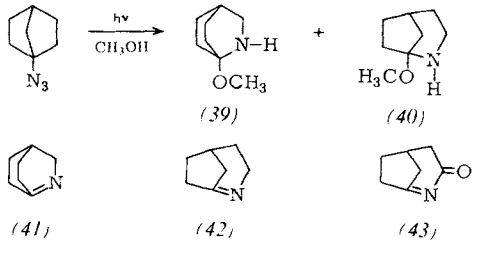
(34) *(35)* *(36)*

Azabicycloolefins with $S=6$ have been variously postulated as intermediates. Thus the thermolysis of *O*-tosyl-2-quinuclidinyl phenyl ketoxime proceeds partly as a fragmentation *via* the carbenium ion *(38a)* and is faster than that of the homomorphous alicyclic compound, which decomposes exclusively by Beckmann rearrangement. The greater formation tendency of *(38a)* can be explained by resonance stabilization involving the bridgehead-immonium mesomeric structure *(38b)*[21].



(37) *(38a)* *(38b)*

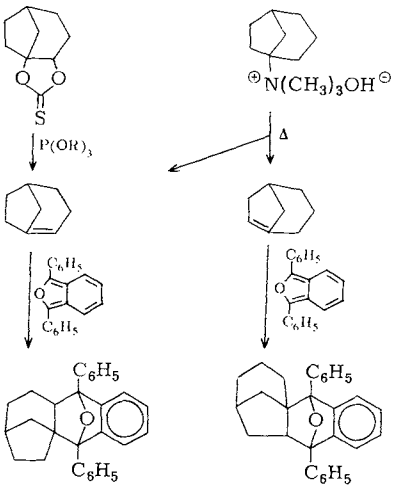
The azabicyclic compounds *(39)* and *(40)* formed in roughly equal amounts on photolysis of 1-azidonorbornane in methanol could be derived from the primary ring-expansion products *(41)* and *(42)* by addition of methanol. However, the authors[22a] favor a synchronous process that avoids these energy-rich intermediates. The *N*-protonated *(42)* is nevertheless postulated as an intermediate in the reduction of *(40)* with $LiAlH_4$ [to *(40)* with H instead of OCH_3][22a]. The unsaturated lactam *(43)* is a plausible intermediate in the oxidation of the corresponding saturated lactam with lead tetraacetate[22b].



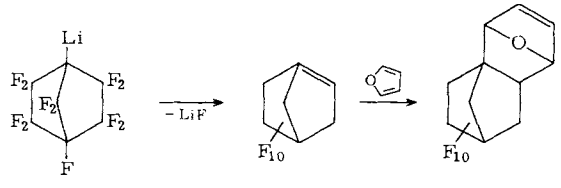
(39) *(40)*

(41) *(42)* *(43)*

Evidence has recently also been obtained for the intermediacy of bicyclo[3.2.1]oct-1-ene[13c]: thermolysis of the thiocarbonate 2,4-dioxatricyclo[6.2.1.0^{1,5}]undecane-3-thione with trialkyl phosphite in the presence of 1,3-diphenylisobenzofuran yields 62% of a mixture whose spectral data are compatible with the structure of the expected Diels-Alder adduct (mixture of stereoisomers). Hofmann elimination with the structurally analogous quaternary ammonium hydroxide gives 0.3% of a product which could also contain the adduct of the [3.2̄.1]bicycloolefin.

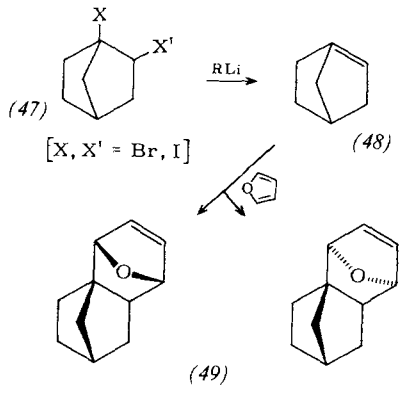


For these reasons and on the basis of the following observations, therefore, it may be assumed that bicyclic systems with $S=6$ and a double bond at the bridgehead can exist, though there is as yet no satisfactory experimental proof. It should be stressed that conclusive proof of this would not be contrary to the Bredt rule in its original version, which was formulated for systems with $S=5$. It is interesting to note, however, that two "forbidden" 1-norbornenes ($S=5$) have recently been detected as short-lived intermediates. In 1965, *Tatlow et al.* observed the elimination of LiF from 1-lithioperfluoronorbornane *(44)* to give perfluorinated 1-norbornene *(45)*, which was characterized mainly by its diene reaction with furan to form the two possible stereoisomers of the cycloadduct *(46)*[23a]. If the halogen at the bridgehead of *(44)* is replaced by H, however, the β elimination does not take place[23b]. Because of this surprising substituent effect, one cannot deduce the existence of the unsubstituted compound *(48)* from that of *(45)*. The existence of *(48)* was demonstrated in 1971 by *Keese* and *E.-P. Krebs*[24]: Dehalogenation of the vicinal dihalides *(47)* with butyllithium in the presence of furan results in the formation of the cycloadduct *(49)*. The 1-norbornene intermediate *(48)* is confirmed by the discovery that the two stereoisomers of *(49)* are always formed in a ratio of 1:4, regardless of the nature of the halogen and of the organometallic agent.

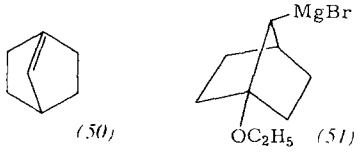


(44) *(45)* *(46)*

There is so far no evidence of the existence of the isomeric norbornene *(50)*. Its relatively (according to rules B and C) and absolutely low formation tendency is indicated on the one hand by the apparently exclusive formation

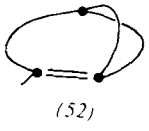


of *(45)* from *(44)* and on the other by the unusual thermal stability of the Grignard compound *(51)* (no β elimination at 80 °C)[25].



5. Causes of the Ring Strain

The instability of the bicyclic systems to which the Bredt rule is applicable is a result of the increased ring strain in relation to saturated compounds having the same structure, as mentioned earlier. The additional strain is due partly to the widening of tetrahedral angles to 120°, and mainly to the fact that a double bond does not exhibit the free rotation of σ bonds. The dihedral angles formed by the single bonds from the bridgehead atom with the valences from the other atom of the double bond are therefore no longer unimportant. The dihedral angles of 0° and 180° in the planar olefins cannot be achieved at bridgeheads of small bicyclic systems, since three of the four bonds from the ends of the double bond, as parts of the bicyclic system, curve away in the same direction, *i.e.* toward the other bridgehead [see formula *(52)*]. The two olefinic carbon atoms cannot therefore achieve the usual coplanar arrangement with the four atoms bonded to them, nor can they form the normal bond angles of 120°. The reasons for the ring strain are therefore as follows:

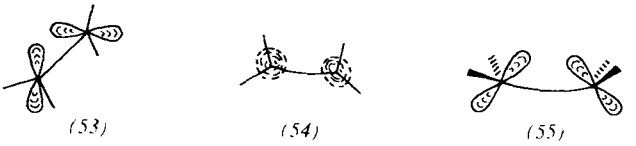


(52)

1. The most important and most characteristic reason is the twisting of the π bond about the axis joining the two olefinic carbon atoms[7].

This is a consequence of the fact that the four bonding partners of the olefinic carbon atoms cannot lie in the same plane, and optimum overlap of the two p orbitals is therefore prevented. The extreme case, with a twisting angle of 90°, would be a biradical or *C*-ylide [formula *(53)*].

2. Planar [formula *(54)*] and nonplanar [formula *(55)*] deformations of the σ bonds emerging from the unsaturated



(53) (54) (55)

centers. These deformations combine to give a resultant that also influences the degree of overlap of the two p orbitals.

Little is known at present about the effects of these deformation forces on the nature of the "double bond". The distortion of the π bond is presumably accompanied by a change in hybridization, with admixture of s components into the p orbitals and an increase in the p character of the σ bonds. For *trans*-cyclooctene, whose relation to bridgehead alkenes will be discussed in Section 7, the configuration shown in formula *(56)*, with the bonds bent downwards and the orbital lobes on both carbon atoms extended in the opposite direction, has been proposed[26]. In bridgehead alkenes with non-equivalent olefinic carbon atoms, this change of hybridization should be greater for the bridgehead atom, which is more exposed to the shearing forces.

(56) (57)

According to preliminary model calculations by *Keese* and *Krebs*, the configuration shown in *(57)*, with a roughly sp^3-hybridized bridgehead atom and a p orbital on the neighboring atom, is in fact energetically more favorable than *(56)* for 1-norbornene *(48)*. Its π-bond order is only about half of that of ethylene, and it carries an excess charge on the bridgehead atom[24b].

The question arises whether the extreme case is not more adequately represented by a dipolar (*C*-ylide) structure

than by a diradical. No confirmatory experimental evidence has yet been obtained for this assumption. In polar additions to bicyclo[3.3.1]non-1-ene *(13)*, the nucleophile, contrary to the above model and in agreement with the Markownikoff rule, always adds to the bridgehead atom[12,13a]; however, this compound is much less strained, and is therefore possibly atypical. The spontaneous cyclodimerizations of unstable bridgehead olefins could provide more reliable information: assuming comparable steric conditions, head-to-tail cycloaddition should take precedence over the head-to-head process. However, the few results obtained so far indicate occurrence of both types.

6. Bredt Compounds

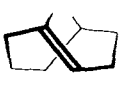
There are no empirical parameters available at present for the quantitative correlation of structural effects and ring strain. The Bredt rule is thus a qualitative statement with fluid boundaries. It would be unreasonable (and it

is not usual in the literature) to regard it in its original version (Section 1) as a strict prohibition of existence for certain compounds. Exceptions were mentioned in Section 5, and future investigations will undoubtedly show that other "forbidden" bicyclic systems can exist, so that the Bredt rule would ultimately become meaningless, despite its inherent value. The objection that the "forbidden" compounds do not possess a "true" double bond, but are biradicals or betaines, would be too sophistic an apology. It seems much better to interpret the Bredt rule as characterizing an unstable rather than a non-existent class of bicyclic compounds. It is then possible and meaningful to refer to the bicyclic systems to which it is applicable as "Bredt compounds" (see also Scheme 1 in Section 10) and to define them as follows: "Bredt compounds are bicyclic (and polycyclic) systems (alicycles and heterocycles) that, in addition to a strained σ-bond skeleton, have a twisted π bond at a bridgehead, and *purely* because of this ring strain, in contrast with compounds having the same structure but without this π bond, are unstable at room temperature."

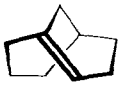
7. Comparison with Strained *trans*-Cycloalkenes

The above definition of Bredt compounds is based primarily on ring-strain rather than structural criteria. It is thus more comprehensive than the original Bredt rule, even in its extended form given in the introduction. To illustrate the consequences, let us consider some classes of ring-unsaturated compounds whose unstable members, in part, are not Bredt compounds by definition, and in part have until now been traditionally regarded as not being subject to the Bredt rule.

The relationship of the Bredt bicyclic systems with the *trans*-cycloalkenes, which was recognized as early as 1933 by *Ebel*[6], is particularly striking. According to *Allinger*[28a], the ring strain in *trans*-cyclooctene *(58)*, the smallest stable member[27], is due to the same deformation forces that occur in Bredt compounds according to Section 5, as can be seen from molecular models. In fact, bicyclo[3.3.1]non-1-ene *(13)* (Section 2), the smallest stable bridgehead olefin, may be regarded as a bridged *trans*-cyclooctene, and can be constructed from the latter in models without much additional strain [formulas *(58)* and *(59)*][13a]. According to thermochemical data, *(13)* has a ring strain of 12 kcal/mol, as compared with 9.2 kcal/mol in *trans*-cyclooctene[29]. The calculated heat of hydrogenation of *(13)* is 12.85 kcal/mol less, *i.e.* its ring strain is greater by this amount, than that of the Δ^2 isomer[28b]. The instability of bicycloolefins smaller than *(13)* is paralleled by the instability of *trans*-cycloheptene[30], whose calculated ring strain is about 10 kcal/mol higher than that of *trans*-cyclooctene[28b].



(58)

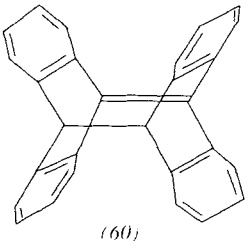


(59) [≡ *(13)*]

A double bond at the bridgehead of a bicyclic system is always exocyclic with respect to one of the three rings and endocyclic with respect to the other two. According to *Wiseman*[13], the number of atoms in the larger of the two rings with the endocyclic double bond provides information about the relative stability of the bicycloalkene (rule B, Section 3). This explains *e.g.* the greater stability of the [$\bar{3}$.3.1] and [$\bar{4}$.2.1] systems *(13)* and *(16)* in comparison with the [3.3.$\bar{1}$] and [4.2.$\bar{1}$] isomers *(19)* and *(17)*, since the largest ring with an endocyclic double bond is cyclooctene in the first two compounds as opposed to cyclohexene and cycloheptene, respectively, in the other two. The applicability of this rule is admittedly limited, since it does not allow comparison of isomers such as *(14)* and *(16)* or *(20)* and *(21)* ([$\bar{x}$.*y*.*z*] and [*x*.$\bar{y}$.*z*] systems in general) that differ only in the position of the double bond in the largest unsaturated ring. In this case rule C provides supplementary information.

8. Systems Containing a Zero Bridge

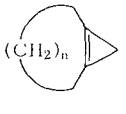
[$\bar{x}$.*y*.0] systems, *i.e.* bicyclic systems with a zero bridge, were always tacitly or expressly[4] excluded from the problem of the Bredt rule in the past. This restriction does not exist in our definition of Bredt compounds. If an unstable [$\bar{x}$.*y*.0] system exhibits the strain characteristics mentioned, it can be classified as a Bredt compound; otherwise it cannot. To establish a limit, let us consider some strained bicyclic systems; in order to determine the causes of their ring strain, we shall again use their imaginary derivation from unsaturated monocycles.



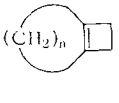
(60)

A revealing limiting case from the standpoint of the last section is the strained hydrocarbon *(60)*, which was prepared by *Weinshenker* and *Greene* in 1968[31] (its 5-chloro derivative was known even earlier as an intermediate[32]). It may be regarded as a doubly bridged *trans*-cyclooctene, but on symmetry grounds, only non-planar deformation forces act on its double bond (see Section 5); it thus lacks the twisting of the double bond that is typical of Bredt compounds. A significant feature is the direct linkage of two bridgeheads by a double bond.

(61)



(62)

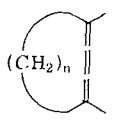


(63)

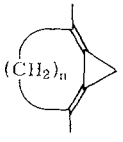
The same is true of 1,2-bridged cyclopropenes *(62)* and cyclobutenes *(63)*, which can be derived from the corresponding cycloalkynes *(61)* by expansion of the π bond, which lies *in* the plane of the ring, to a three-membered or four-membered ring. The smallest stable cycloalkyne

is the sterically shielded 3,3,7,7-tetramethylcycloheptyne [skeleton: *(61)*, $n=5$][33]; the cyclopropenes *(62)* become unstable on transition from $n=5$ to $n=4$[34], and the cyclobutenes *(63)* on transition from $n=3$[35] to $n=2$[36].

In the cyclobutatrienes *(64)*, with 1,2,3-cyclodecatriene [*(64)*, $n=6$] as the smallest stable compound[37], expansion of the π bond, which is situated *in* the plane of the ring, leads to the bridged bismethylenecyclopropanes *(65)*, which should be isolable with $n=5$ or even 4 because of the associated bending of the central σ bond.



(64)

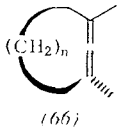


(65)

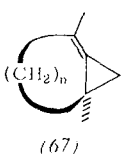
In small-ring cycloalkynes and cyclobutatrienes, the π bonds, whose orbitals lie in the plane of the ring, are subject to planar deformation forces, but not to twisting strains. The same is true of the bicyclic systems *(62)*, *(63)*, and *(65)*, as is confirmed by molecular models. Unstable bicyclic systems with a zero bridge are thus not Bredt compounds if the double bond is also the zero bridge or if the same bridge contains another double bond at the other bridgehead.

The situation is different in bicyclic systems that can be thought of as derived from cycloallenes *(66)*. The smallest compound of this type that is stable at room temperature is 1,2-cyclononadiene [*(66)*, $n=6$][38]; lower homologs with $n=3$ to 5 are unstable[39], but the homolog with $n=5$ has been detected directly by spectroscopy at low temperatures[40].

Cycloallenes present another, formerly overlooked analogy between the ring strain of unstable monocyclic systems and that of Bredt compounds. Short methylene bridges cause not only planar and non-planar deformations of the two double bonds, but also twisting of the π bonds, since they distort the end valences of the allene from the natural dihedral angle of 90° toward a coplanar arrangement. If one π bond of the allene is expanded to a three-membered ring, we obtain a bridged methylenecyclopropane *(67)*. The same forces typical of Bredt compounds that act in the cycloallene *(66)* also act in the methylenecyclopropane, but the ring strain for a given ring size is less, since the three linearly arranged carbon atoms in *(66)* now form an angle of about 150°, and their end valences form a dihedral angle of less than 90°.

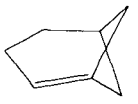


(66)

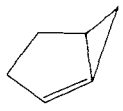


(67)

This relationship with "classical" Bredt compounds can also be demonstrated as follows. If a carbon atom bonded to two bridgeheads is cut out of bicyclo[3.1.1]hept-1-ene *(68)*, which certainly is a Bredt compound, we obtain the compound *(69)*, which is identical with *(67)*, for $n=2$. This should have a ring strain roughly comparable with that of *(68)*, but the twisting strain is slightly reduced in favor of the deformation forces (see Section 5). Thus



(68)

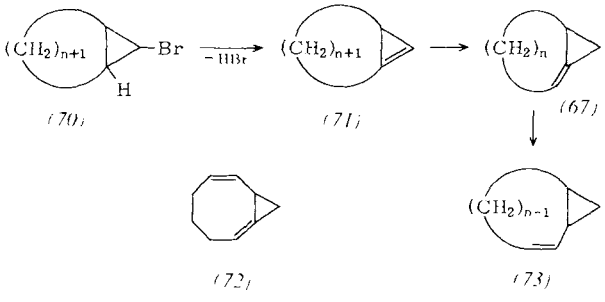


(69)

if an $[\bar{x}.1.1]$ or $[x.\bar{1}.1]$ system is a Bredt compound, the $[\bar{x}.1.0]$ or $[x.\bar{1}.0]$ system with one carbon atom less may be assumed to be a Bredt compound too. We note as a selection rule, however, that a one-carbon bridge containing a double bond cannot be removed, since this would give a bicyclic system with a double bond between the two bridgeheads.

9. Bridged Methylenecyclopropanes as a Test Case for the Bredt Rule

According to the above argument, bridged methylenecyclopropanes *(67)* can be used as a basis for statements regarding the range of validity of the Bredt rule. Compounds *(67)* with $n\geq 6$ are obtainable by carbene additions to cycloallenes *(66)*, and are stable[37]. According to *Gardner et al.*[41a], lower homologs are formed on dehydrobromination of bridged bromocyclopropanes *(70)* with strong bases.

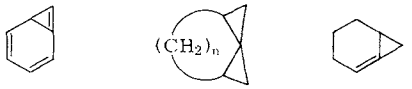


(70) *(71)* *(67)* *(72)* *(73)*

However, only bicyclo[6.1.0]non-1-ene [*(67)*, $n=5$] can actually be isolated; the didehydro derivative *(72)* can be prepared analogously by double dehydrochlorination of 9,9-dichlorobicyclo[6.1.0]nonane[41b]. As was mentioned earlier, these two compounds may be compared with bicyclo[6.1.1]dec-1-ene, $S=8$, and are therefore stable as expected. The bicycles *(67)* with $n\leq 5$ that are of interest to our discussion, on the other hand, cannot be isolated in basic media, because of their rearrangement to the less strained Δ^2 isomers *(73)*[41a]; more highly unsaturated derivatives undergo further additions and skeletal rearrangements[41b,42]. Since the formation conditions favor isomerizations, no conclusions can be drawn from these results concerning the thermal stability of the bridged methylenecyclopropanes *(67)* with $n\leq 5$. The same is true for the bridged cyclopropenes *(71)*, whose unsaturated member *(74)* was postulated as an intermediate in the phenylcarbene rearrangement[43].

Literature data allow the following assessment. The bridged methylenecyclopropanes *(67)* are formally links between

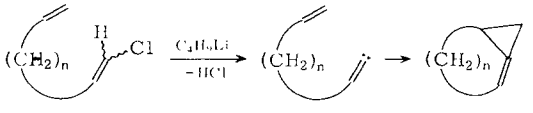
the cycloallenes *(66)* and the tricyclo[x.1.0.0^{1,3}]alkenes *(75)*. The former are stable from the nine-membered ring on (see above), and the latter from the five-membered ring on [*(75)*, $n=2$][43]. It should therefore also be possible



(74) *(75)* *(76)*

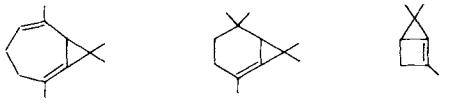
to isolate the compound *(67)* with a seven-membered ring ($n=4$). *(69)*, which contains two bridge atoms less than *(67)*, $n=4$, is clearly unstable according to the above arguments, and the link *(76)* is thus an interesting test case.

Starting with suitably substituted chloroolefins of the type *(77)*, we checked these predictions for the intramolecular cyclopropanation of unsaturated carbenes *(78)* as represented by the following scheme, which, having a high driving force, proceeds under mild conditions and without subsequent isomerization[44].



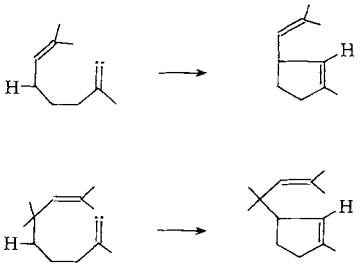
(77) *(78)* *(67)*

In this way a (substituted[*]) chloroolefin *(77)* with $n=4$ gave a stable hydrocarbon, to which the constitution *(79)* was assigned[44a]. From a lower homolog with $n=3$, it was possible to obtain the compound *(80)*, whose double bond at the bridgehead has been confirmed[44b]. The compound *(80)* decomposes at room temperature with a half-life of about 70 hours, and can thus be classified as a Bredt compound. The next lower homolog *(82)*, as expected, could not be isolated. Its transient existence has been deduced from the formation of dimeric hydrocarbons $C_{18}H_{28}$: The pentacyclic system *(83)*, whose structure has been established by X-ray analysis[44f], is the main product $\leq -50\,^{\circ}C$ and obviously results from a head-to-head *exo* addition of two molecules of *(82)*. The major

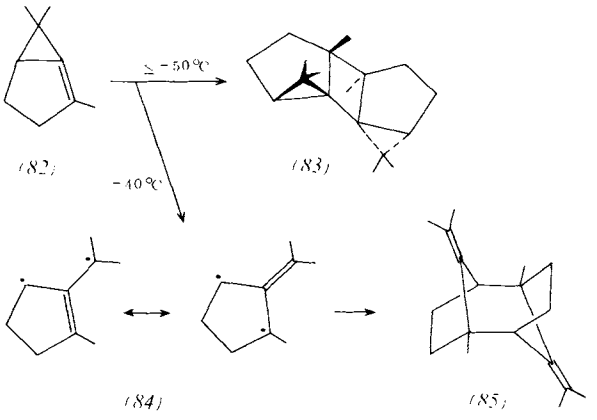


(79) *(80)* *(81)*

[*] The methyl groups prevent elimination to form an acetylene and facilitate the cyclopropanation. The additional double bond in *(67)* prevents intramolecular CH insertion of the intermediate carbenoid, which always occurs readily if the formation of a cyclopentene is possible [44a, 44e]:



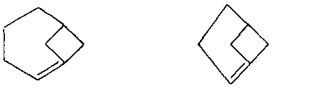
product at $-40\,^{\circ}C$ is the tricyclic compound *(85)* (the spectroscopic data are also in accord with a structure having two methyl groups at *neighboring* bridgehead atoms), which is probably formed *via* the trimethylenemethane intermediate *(84)*[44c].



(82) *(83)* *(84)* *(85)*

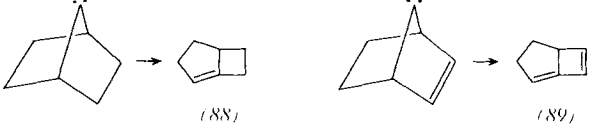
The limits of the cyclization *(78)*→*(67)* are reached with the trimethyl derivative of *(78)* with $n=1$, which reacts *inter*molecularly instead of undergoing the intramolecular reaction to form the enormously strained bicyclo[2.1.0]-pent-1-ene *(81)* ("housene")[44d].

On the basis of the above results and arguments, it can be predicted for the homologous series of bicyclo[x.1.1]alk-1-enes that *(86)* ($S=6$) and *(87)* ($S=5$) are compounds that can exist with moderate and short lifetimes respectively; the higher homolog *(20)* ($S=7$) might be stable at room temperature.



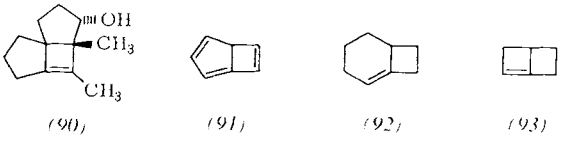
(86) *(87)*[≡*(68)*]

[$\bar{n}$.2.0] and [n.$\bar{2}$.0] systems with sufficiently small n are also Bredt compounds. However, they are more flexible than bridged methylenecyclopropanes *(67)* and cyclopropenes *(71)* having the same number of bridge atoms. The recent literature contains reports on the isolation of *(88)* and *(89)* from carbene isomerizations[45a], the



(88) *(89)*

synthesis of *(90)* as a derivative of a photoisomerization product[45b], and the intermediate occurrence of the compound *(91)*[45c]; the higher homolog *(92)* is also

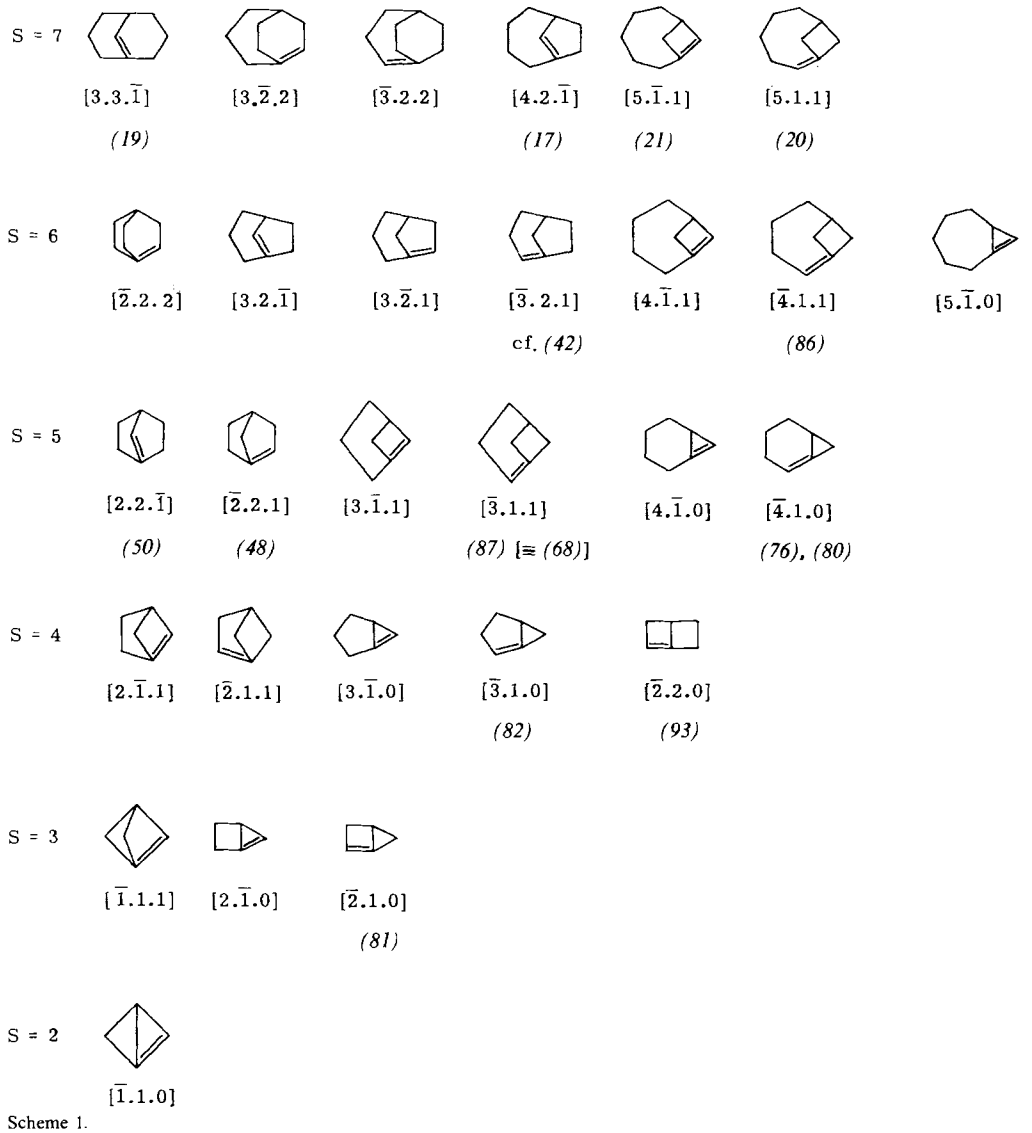


(90) *(91)* *(92)* *(93)*

known[45d]. The boundary between stable and unstable compounds is evidently crossed only with [2̄.2.0] systems *(93)*.

10. Outlook

Scheme 1, to which one could add a long series of heterocyclic and polycyclic analogs, shows 28 bicycles containing a bridgehead double bond and with $S \leqslant 7$, which may nowadays be assumed to be Bredt compounds, or for which at least the reverse has not yet been proved. Insofar as any conclusion can be drawn from rules A to C, these compounds are arranged from top to bottom and from right to left in order of increasing ring strain; the majority have not yet been investigated. One could naturally argue about whether the hypothetical bicyclo[1.1.0]but-1-ene, which stands at the end of the series, should really be classified as a Bredt compound, since its immense ring strain must be due much more to deformation of the σ skeleton than to twisting strains on the unsaturated centers. One can see here the entanglement of our problem with other aspects of the chemistry of ring-strained hydrocarbons. However, one cannot deny the heuristic value of the Bredt rule as a guideline and stimulus for synthetic and mechanistic studies.



Scheme 1.

Anomalies in the Structural Chemistry of Silicon

By Hans Bürger[*]

In contrast to carbon, silicon fails to form multiple bonds that are stable at room temperature. Consequently molecules in which silicon exhibits coordination numbers (CN) of 1, 2, and 3 may only be obtained at very high or low temperatures. Under these conditions their structural features, including multiple bonds, resemble those of carbon. On the other hand, silicon is capable of forming various hexacoordinated compounds making use of its d orbitals. Nitrogen and oxygen bonded to silicon develop an unusual stereochemistry: planar nitrogen, nearly or completely linear oxygen, and considerable shortening of SiN, SiO, and SiF bonds are specific examples. $N(SiR_3)_2$ and CH_2SiR_3 ligands permit stabilization of unusually low CNs of many metals and give rise to amino and alkyl derivatives of unexpectedly high stability due to the particular electronic, steric, and kinetic effects of the R_3Si group.

1. Introduction

The rapid increase in the number of new silicon compounds was for a long period not adequately accompanied by structural investigations. The limited structural data available 10 to 20 years ago suggested in some cases close analogies with carbon but in other cases significant specific behavior of silicon was indicated, for which a bonding theory different from that for carbon was adopted.

Research in the fields of reaction mechanisms (*L. H. Sommer*), of physical chemistry (*e.g.* photoelectron spectroscopy) and of molecular structure determinations has increasingly extended our knowledge of the bonding and structural characteristics of silicon. In particular the renaissance of electron diffraction during the last few years has enabled an almost comprehen ive series of structural determinations of suitably volatile silicon compounds; many of these investigations were performed by *G. M. Sheldrick* and *A. G. Robiette*.

The present widened physico-chemical basis of silicon chemistry[1] and the extent of available structural information nowadays permit and justify selection of those features specific to silicon which distinguish it from carbon. These are presented in the following review which, however, is not intended to be exhaustive, attention being focused primarily on silicon's "exotic" CNs 1, 2, 3, 5, and 6 which have not previously been given such consideration[1-3].

Apart from the structural anomalies to be discussed silicon exhibits of course a vast range of normal structures more closely resembling those of carbon, but, as with the chemical properties, predictable differences occur due to the greater atomic radius and the lower electronegativity. They are reflected, *e.g.*, in the steric requirements of the R_3Si group, its mobility with respect to 1,2; 1,4; O,N; and CN,NC migrations, and other fluxional behavior.

2. Silicon with CN 1

Di- and triatomic molecules and ions containing a Si atom involved in only one bond of variable bond order are remarkably well known from microwave, matrix IR, and electronic absorption and emission spectra at different resolutions. The methods of investigation applied must take into account the short lifetime and the narrow range of stability at unusual temperatures. Astrochemistry has shown that these conditions frequently prevail in extraterrestrial space, the radiation of many stars arising from emission of the electronic spectra of silicon derivatives such as SiF or SiCC. The studies leading to the following results have been considerably stimulated by astrochemistry.

It is of course true that no molecule such as CO, which is stable at room temperature, is known in silicon chemistry. The analogous SiO polymerizes at a few °K forming $(SiO)_2$, $(SiO)_3$[4], and species of higher degrees of polymerization, fragmentation into monomeric SiO occurring upon heating to 1500 °K.

In view of this difference between CO and SiO and the opposite sign of the dipole moment in chalcogenides of carbon and silicon (due to the lower electronegativity of Si; Table 1) the electronic structures and (relative) molecular parameters of species with CN 1 differ less than one might have expected[5].

The approximate ionization potentials listed in Table 2 suggest a separation of p from s electrons for both C and Si of 7—10 eV. Consequently considerable interaction

Table 2. Ionization potentials [eV] of valence electrons.

	C $^3Ps^2p^2$ [a]	C sp^3 [b]	Si $^3Ps^2p^2$	Si sp^3 [b]	Si s^2pd [c]

is expected to occur between molecular orbitals of appropriate symmetry to which ns and np of Si (and C) have contributed. This favors the following order of molecular orbitals

$$\ldots(n\sigma_g)(n\sigma_u)(n\pi_u)\ n\sigma_g)(n\pi_g)(n\sigma_u)$$

(Scheme 1) for C_2, Si_2, CO, and SiO, the energies of $(n\pi_u)$ and $(n\sigma_g)$ however being quite similar. Of these orbitals $(n\pi_u)$ is strongly bonding while both $(n\sigma_u)$ and $(n\sigma_g)$ may vary between weakly bonding and antibonding in character. In consequence such differences cause ground and excited state electronic structures which differ for C and Si.

C_2 and Si_2

While C_2 has a singlet $X^1\Sigma_g^+$ ground state[*], both this state and the triplet state $^3\Pi_u$ of approximately the same energy are excited states for Si_2 which has a $^3\Sigma_g^-$ ground state[8,9]. Comparison of the $^3\Pi_u$ and $^3\Pi_g$ molecular parameters (*a* and *d* for C_2, *D*, and *L* for Si_2; Scheme 1) reveals an increase in bond order for C_2, but a decrease for Si_2. This is qualitatively suggested assuming a stronger antibonding character of the $(n\sigma_g)$ MO for Si_2 than for C_2. A similar difference is observed for C=C=C/Si=C=C[10] and likewise for CN and SiN.

	$^3\Sigma_g^-$	$^3\Pi_u$	$^1\Sigma_g^+$	$^3\Sigma_u^-$	$^3\Pi_g$

r_e [Å]	2.246	2.155	—	2.663	2.255

Scheme 1. Electronic structures of C_2 and Si_2.

A $X^2\Sigma^+$ ground state (Scheme 2) is common to both CN and SiN[5,11]. On going to the second excited state $B^2\Sigma^+$ ($A^2\Pi_i$ has not yet been observed for SiN), which requires 3.1 ± 0.1 eV in both cases, shortening of the CN bond, but lengthening and weakening of the SiN bond occur. An approximate bond order of 2.5 may be assigned to both ground states.

The aim of this arbitrary selection is to demonstrate that the molecular parameters are fairly similar in corresponding derivatives of monovalent carbon and silicon. Except for CO and its derivatives such as isonitriles, instability

at room temperature is common to all molecules of this group, in which the anomalous behavior of silicon is least pronounced.

[*] Regarding the use of the symbols employed here and in the following see IUPAC: Manual of Symbols and Terminology for Physicochemical Quantities and Units. Butterworths, London 1970, p. 29.

Atomic spectroscopy

The letter-symbols indicating quantum states are:

$L,l = 0$: S, s	$L,l = 4$: G, g	$L,l = 8$: L, l
$= 1$: P, p	$= 5$: H, h	$= 9$: M, m
$= 2$: D, d	$= 6$: I, i	$= 10$: N, n
$= 3$: F, f	$= 7$: K, k	$= 11$: O, o

A right-hand subscript indicates the total angular momentum quantum number *J* or *j*. A left-hand superscript indicates the spin multiplicity $2S+1$.

Examples:

$^2P_{3/2}$—state ($J = 3/2$, multiplicity 2)
$P_{3/2}$—electron ($j = 3/2$)

An atomic electron configuration is indicated symbolically by:

$$(nl)^\kappa(n'l')^{\kappa'}\ldots$$

Instead of $l=0, 1, 2, 3, \ldots$ one uses the quantum state symbols s, p, d, f, ...
Example: the atomic configuration: $(1s)^2(2s)^2(2p)^3$

Molecular spectroscopy

The letter symbols indicating molecular electronic quantum states are in the case of *linear molecules:*

$\Lambda,\lambda = 0$: Σ, σ
$= 1$: Π, π
$= 2$: Δ, δ

and for *non-linear molecules:*

A, a; B, b; E, e; *etc.*

3. Silicon with CN 2

Structural differences are more developed in compounds of C and Si with CN 2. While SiO_2 resembles SiO and HNSi in failing to form a monomer stable at room temperature, singlet-SiF_2 is in contrast thermally more stable than singlet-CF_2. The former polymerizes in the gas phase at room temperature and low pressure with a half-life of minutes, whereas the latter has a half-life of approximately 1 s at 1 torr and room temperature, which is nevertheless remarkable for a carbene. The ease of formation and stability of silylenes has promoted extensive development of their chemistry which shows many similarities to carbene chemistry[12].

CH_2 and SiH_2

Apart from quite obvious structural differences between divalent carbon and divalent silicon there are some minor ones which may be detected only upon thorough investigation. Compounds of C and Si with H and O exhibit more obvious mutual deviations. For instance, the radicals CH_2 and SiH_2 generated by flash photolysis of CH_2N_2[13] and $C_6H_5SiH_3$[14] or by low temperature photolysis of SiH_4[15] differ considerably in geometry and electronic structure.

Table 3. Ground and excited states of CH_2 and SiH_2 [14, 15].

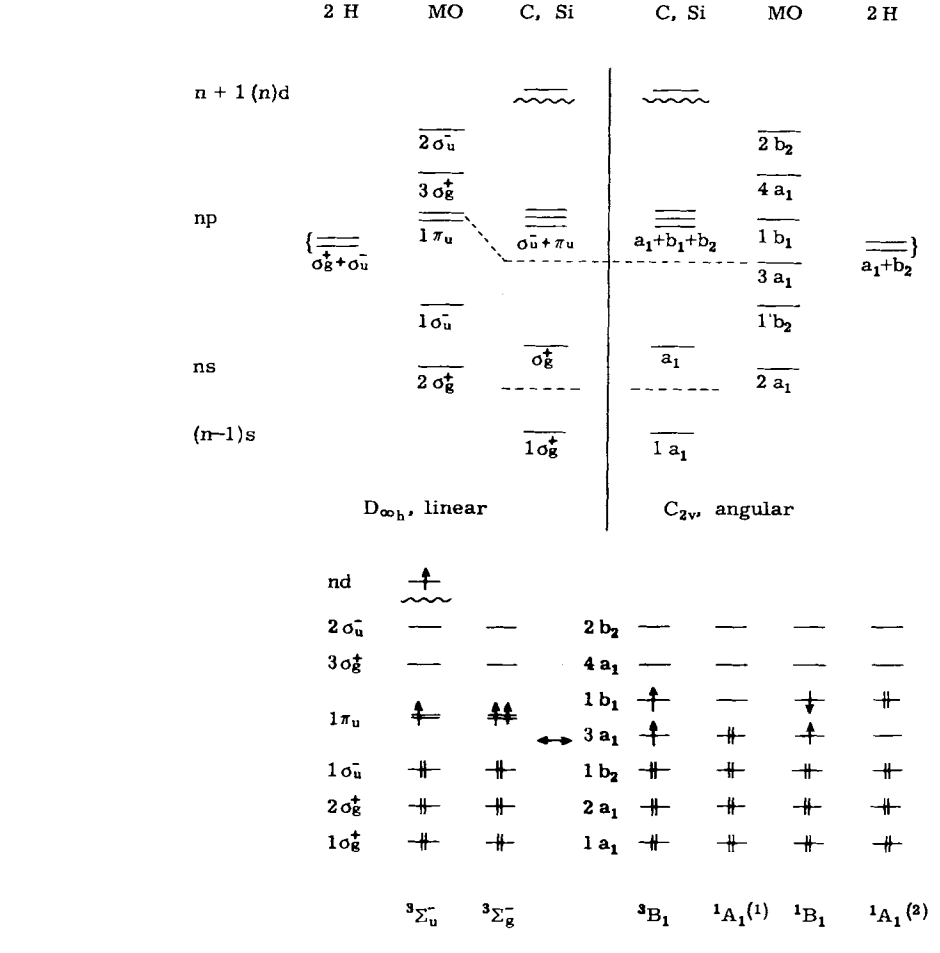
[a] For CD_2.
[b] Only valence electrons considered.



Scheme 3. Electronic states of CH_2 and SiH_2.

Table 3 demonstrates that CH_2 has a nearly linear triplet ground state (X^3B_1), the HCH angle being $\approx 140°$; it was long assumed to be linear. In contrast, no triplet spectrum of SiH_2 has been observed so far, and in accord with matrix investigations[15] the singlet $^1A_1$ state ($\sphericalangle$HSiH 92.1°) is assumed to be the ground state. This bent state has been detected for CH_2 too; it lies $\leq 8000\,cm^{-1}$ above the X^3B_1 ground state and has an HCH angle of 102.4°. According to calculations by *Jordan*[16] this triplet state $^3B_1$ of SiH_2 is $16180\,cm^{-1}$ above the ground state. As SiH_2 is usually formed in an excited singlet state from which an allowed transition leads to the singlet ground state, detection of a triplet state is expected to be difficult. Scheme 3 depicts qualitatively the electronic structures of the different states.

Monomeric SiO_2 has not yet been studied extensively. A linear OSiO structure was deduced from the failure of a molecular beam of SiO_2 generated at 2500 °K to undergo deflection in an electrostatic quadrupole field[17]. Furthermore, divalent silicon is present in Si_2O_2 and Si_3O_3 formed from SiO at a few °K in N_2 and Ar matrices[14]. Infrared spectra including isotope shifts suggest a planar four-membered ring structure with D_{2h} symmetry for the dimer, the OSiO angle being 87°, and a planar six-membered ring with D_{3h} symmetry and an OSiO angle of 100° for the trimer. The SiO stretching force constants (≈ 3.6 mdyn/Å) correspond to a SiO single bond; cf. SiO ($^1\Sigma$) 9.0 mdyn/Å!

Investigations of the dihalides CF_2/CCl_2 and $SiF_2/SiCl_2$ are consistent with a common $^1A_1$ ground state characterized by an angle of approximately 100°, which is considerably widened in a singlet upper state. The widening in the excited $^1B_1$ state is obvious from the progression of the $^1A_1 \rightarrow {}^1B_1$ electronic transition with ν_2' ($250\,cm^{-1}$ in SiF_2, $201\,cm^{-1}$ in $SiCl_2$), the bending frequency of the $^1B_1$ state. However, the geometry of the excited states has not yet been accurately determined[18].

A similar widening upon electronic excitation $A' \rightarrow A''$ occurs for HSiX species (X = Cl, Br, I)[19]. This widening is smaller than that observed upon excitation of HCF and HCCl[20]. In both cases the excitation causes a strengthening of the CX and SiX bonds (Table 4). Again the widening of the bond angle is apparent in the electronic spectrum from the extended progression with ν_2', the bending frequency of the excited state. The linearization barrier is small and increases in the order HCCl, HCF, HSiBr, HSiCl, not exceeding a height of $2250\,cm^{-1}$ above the lowest vibrational level for HCCl.

Table 4. Electronic states of HCF, HCCl, HSiCl, and HSiBr.

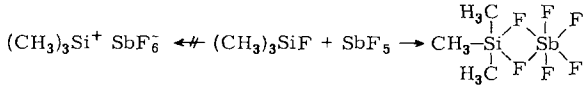
[a] For DCCl.

In conclusion, comparable compounds of C and Si exhibit both structural similarities and specific differences. One should, however, keep in mind that the chemistry of sp hybridized carbon has no silicon counterpart.

4. Silicon with CN 3

Similarly, differences are apparent between species of trivalent carbon and silicon. So far no chemistry of sp^2 hybridized silicon has been established: in contrast to C, Si prefers to adopt a CN of 5 with sp^3d structure arising from d orbital participation. A "sp^3d" complex is formed instead of $(CH_3)_3Si^+$ if $(CH_3)_3SiF$ in SO_2FCl is treated with an excess of SbF_5[21].



Carbonium ions may easily be prepared and analyzed under similar conditions.

4.1. Silyl Radicals

Compared with silicenium ions (not obtained so far), radicals like $R_3Si^{\cdot}$ are of greater importance. They too differ considerably from their carbon analogs, as do also the conditions under which they are formed. As discussed in detail by *Davidson*[22], radical formation by hydrogen abstraction or by pyrolysis, yielding olefin-like $p\pi p\pi$ bond systems, is less favored for silicon than for carbon which, in contrast to silicon, tends to form $p\pi p\pi$ double bonds.

A structural difference is observed between the simplest radicals CH_3 and SiH_3. The planarity of $^{\cdot}CH_3$, which is hardly in doubt[23], confirms predictions[24] which in turn suggest a pyramidal geometry for $^{\cdot}SiH_3$. This suggestion has been experimentally proved for $^{\cdot}SiH_3$ radicals prepared by different reactions. A pyramidal structure has been deduced both from nuclear coupling constants $A(^{29}Si)$ (dependent on hybridization) of $^{\cdot}SiH_3$ obtained on γ irradiation by ^{60}Co of SiH_4 in Xe and Ar matrices[25] and an infrared investigation of $^{\cdot}SiH_3$ obtained on vacuum UV photolysis of SiH_4 in a matrix[15]. A p:s ratio of 5.2 to 5.7 for the free electron corresponding to a pyramidal angle of 15 to 16° or a bond angle of 113—114° has been derived from ESR spectra of the series of $(CH_4)_nSiH_{3-n}$ radicals[26]. A slight flattening of the radicals may however be discerned as n increases, the flattening being more pronounced for radicals like $(CH_3)_3SiSi(CH_3)H$ and $(CH_3)_3SiSi(CH_3)_2$.

4.2. Halosilyl Radicals

While the structures of CH_3 and SiH_3 differ considerably, no similar differences have so far been observed for

CF_3/SiF_3 and $CCl_3/SiCl_3$. All these radicals are pyramidal with bond angles near to 109° 28′, but further interpretation of the data reported for CF_3 (ESR, matrix IR, rapid scan IR following flash photolysis[27]), SiF_3 (matrix IR of vacuum UV photolyzed products[28]), CCl_3 (matrix IR[29], bond angles not very certain), and $SiCl_3$ (matrix IR[30]) is not yet justified.

Besides the X_3Si radicals, the X_3Si^- anions are of interest. While the structure of the known $SiCl_3^-$ anion has not been reported, the silyl derivatives of the alkali metals $KSiH_3$, $RbSiH_3$, and $CsSiH_3$ have been studied by X-ray diffraction and broad line NMR[31]. A HSiH bond angle of $94\pm4°$ was deduced assuming a SiH distance of 1.48 Å. Comparison with the HCH angle of $LiCH_3$ and KCH_3 is of limited significance: the CH_3 groups are likely to be pyramidal in both compounds[32] and, in view of the well-known difficulties in determining hydrogen positions by X-ray diffraction, the value of $111\pm8°$ for the HCH angle of $LiCH_3$ appears rather uncertain.

4.3. Silicon and Silicides

Silicon's inability to form an sp^2 hybrid is also observed for the element itself, which has the diamond structure and fails to form a graphite analog. Lepidoid, layer-like silicon obtained from $CaSi_2$ is not considered to be an analog of graphite because it consists, like $CaSi_2$, of puckered Si_6 rings.

Nevertheless CN 3 is by no means rare in silicides. On the one hand, planar, graphite-like $(Si)_\infty$ units have been observed, *e.g.* for β-USi_2 *(4A)*, and on the other, the puckered $(Si)_\infty$ structure corresponding to $CaSi_2$ *(4B)*, three-dimensional crosslinking as in $ThSi_2$, and finally 2- and 4-atomic $(Si)_m^{x-}$ units *(4C, 4D)*, including their derivatives of "molecular" size, have also been reported. In contrast, ionic carbides prefer C^{4-} or C_2^{2-} structures[34].

(4D)

Generally a close relationship to the isoelectronic neighboring elements is evident; thus CaSi, SrSi, and BaSi exhibit a $(Si^{2-})_\infty$ zigzag chain structure corresponding to $(Se)_\infty$[35].

The structural relationship between Si_4^{4-} (Ba_2Si_4, K_4Si_4) and P_4 is also apparent from the vibrational spectra[36]. The tetrahedral anions $(4K^+)Si_4^{4-}$ and $(4K^+)Ge_4^{4-}$ resemble P_4 and As_4 in giving infrared absorptions corresponding to F_2 vibrations. Table 5 lists the observed frequencies and the derived force constants. The close relationship of C_2^{2-} to N_2 and of Si_4^{4-} and Ge_4^{4-} to P_4 and As_4 is clearly demonstrated by their vibrational spectra.

Table 5. Parameters of molecules and ions.

	r MM [Å]	ν MM [cm^{-1}]	f MM [mdyn/Å]
N_2	1.10	2330	22.4
C_2^{2-}	1.20	2240	17.7
P_4	2.21	461 (F_2)	2.04
As_4	2.435	250	1.49
Si_4^{4-}	2.46	334/359	1.05
Ge_4^{4-}	2.56	188/202	0.87

5. Silicon with CN 5

Carbon involved in five or more individual bonds is assumed to occur only in transition states of short lifetime. In contrast carbon with CN >4 may be stabilized by polyelectronic polynuclear systems with particular bond properties, *e.g.* carbides, $CRu_6(CO)_{17}$ (C in the center of a Ru_6 cluster), and carboranes (*e.g.* $C_2B_{10}H_{12}$ in which carbon occupies two vertices of an icosahedron).

Consequently the specific chemistry and structure of compounds in which silicon forms 5 or 6 individual bonds is not analogous to that of carbon derivatives, but related to the behavior of heavier group IV homologs and some transition metals.

The ready formation of penta- and hexa-coordinate Si is usually ascribed to the accessibility of low-lying d orbitals. These extra orbitals should enable the number of σ bonds to exceed 4, lower the energy of transition states, thus accelerating reactions, participate in intramolecular dπpπ bonding, and finally diminish the energies of electronic transitions and facilitate formation of radicals by taking up an electron[1].

The following representative topics have been selected from the chemistry of pentacovalent silicon. The anion SiF_5^- which is isoelectronic with PF_5 has been reported. It may be isolated as $[Ph_4As][SiF_5]$[37] which is isostructural with $[Ph_4As]I$. All fluorine atoms appear to be equivalent in the ^{19}F-NMR spectrum due to exchange processes. In aqueous solution rapid hydrolysis is observed, forming species with a CN of 6[38]. Similar behavior has been reported for alkyltetrafluoro- and dialkyltrifluorosilicates $RSiF_4^-$ and $R_2SiF_3^-$.

The structure of SiF_5^- is assumed to be trigonal-bipyramidal, resembling PF_5, and this geometry has been observed throughout for Si with CN 5: in pentameric $[(CH_3)_2NSiH_3]_5$ *(5A)* with an essentially planar ten-mem-

bered $(SiN)_5$ ring[39], in the 1:1 adduct of $N(CH_3)_3$ and $SiCl_4$ *(5B)*[40], and in the silatranes.

An interesting group of chelate compounds deriving from triethanolamine are called silatranes *(5C)*[41]. In these compounds three oxygen atoms or one carbon and two oxygen atoms occupy equatorial positions, and the forth ligand Z and the nitrogen atom occupy axial sites of a trigonal bipyramid. The order of the coordinative SiN bond (which is less than unity throughout) and the angle α (which amounts to 90° for an undistorted trigonal bipyramid) are governed by the nature of the ligand Z. Some structural data of silatranes are reproduced in Table 6.

Table 6. Structural data of silatranes.

Z	N(CHRCHRX-)$_3$	*r* SiN [Å]	α [°]	Ref.
m-$O_2NC_6H_4$	$N(CH_2CH_2O-)_3$	2.116	95.8	[42]
C_6H_5	$N(CH_2CH_2O-)_3$	2.193	97.1	[43]
C_6H_5	$N(o\text{-}C_6H_4O-)_3$	2.334	100	[44]
CH_3	$N(CH_2CH_2O)_2(CH_2CH_2CH_2)$	2.336	100	[45]

Distortion of the trigonal bipyramid arises by simultaneous lengthening of the SiN bond and widening of α. The trigonal bipyramidal arrangement is also preferred by bis(*o*-phenylenedioxo)phenylsilicate *(5D)*, the axial SiO bonds (1.794 Å) being considerably longer than the equatorial ones (1.700 Å)[46]. An intramolecular coordination of a Lewis base atom affording pentacoordinate silicon similar to the situation in silatranes has been established for cyclobis(benzamidodimethylsilane) *(5E)*. The exocyclic SiO contact of 2.613 Å is however comparatively long and the bond is weaker than that between Si and N in the silatranes[47].

The silicon atom may participate in two-electron three-center bonds of boranes[48], bridge two transition metal atoms, or form M···H···Si bonds. Recent structure determinations by X-ray diffraction of *(5F)* and *(5G)* established the position of all atoms, but were not able to clarify whether additional direct SiM bonds appear along with the hydrogen bridges[49]. Obviously the valence bond approach fails to provide an adequate description of the bonding in these compounds.

6. Silicon with CN 6

Substitution reactions at a tetracovalent carbon or silicon atom frequently proceed *via* a pentacovalent intermediate; further expansion of the coordination sphere is not likely to occur.

However, *Corriu* and *Leard*[50] were able to demonstrate that an optically active triorganochlorosilane $R^1R^2R^3SiCl$ in inert solvents is racemized by Lewis bases such as Me_2NCHO, $(Me_2N)_3PO$, or Me_2SO, the process following second order kinetics. This suggests involvement of a hexacovalent intermediate, probably with octahedral structure.

CN 6 is favored if a silicon atom is linked to several halogen atoms such as F and Cl. This CN is achieved *e.g.* by addition of halide ions ($\rightarrow SiF_6^{2-}$) or suitable Lewis bases with O, N, or P atoms.

The octahedral SiF_6^{2-} ion is readily formed; it decomposes to SiF_4 and 2 HF when heated in acidic aqueous solution. A comparison of SiF bond lengths and force constants for different coordination numbers of Si merits attention (Table 7). The strongest ground state SiF bond is observed in SiF_4.

Table 7. Properties of SiF bonds.

Molecule/ion	*r* SiF [Å]	*f* SiF [mdyn/Å]	Ref.
SiF ($X^2\Pi_r$)	1.600	4.9	[5]
SiF_2	1.591	5.0	[51]
SiF_3	1.56	5.5	[28]
SiF_4	1.55	6.3	[3]
SiF_6^{2-}	1.66...1.71	3.5	[3, 52]

Tetrahalides may direct two added Lewis base atoms into *cis* and *trans* positions; both types of coordination have been established in silicon chemistry. Geometric requirements of the ligand force SiF_4·bipyridyl (bipy) into a *cis* configuration[53], while SiF_4·2 pyridine (py)[54] adopts a *trans* arrangement of the ligands. Table 8 presents some data on $Si(Hal)_4L_2$ complexes.

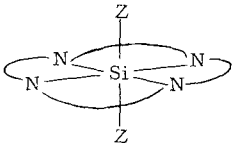
The *cis*-SiF_4L_2 adducts exhibit two different types of SiF bonds; those which are *trans* to L are the shorter ones

Table 8. $Si(Hal)_4L_2$-type complexes.

Compound	Geometry	r SiHal [Å]	r SiL [Å]	Ref.
$SiF_4 \cdot 2py$	*trans*	1.64	1.93	[54]
$SiF_4 \cdot bipy$	*cis*	1.66 (2×)	1.98	[53]
		1.63 (2×)		
$SiF_4 \cdot 2NH_2R$	*cis*	?	?	[55]
(R = H, CH_3, NH_2)				
$SiCl_4 \cdot 2py$	*trans*	?	?	[56]
$SiCl_4 \cdot 2P(CH_3)_3$	*trans*	2.20	2.26	[57]
		2.30		
$SiBr_4 \cdot 2P(CH_3)_3$	*trans*	?	?	[40]

in $SiF_4 \cdot bipy$. Two pairs of F atoms which show different reactivities on reaction with silylamines may be recognized in $SiF_4 \cdot 2NH_3$, contrasting in this respect with *trans*-$SiF_4 \cdot 2py$[58].

In complexes formed by tetradentate ligands, as in Si porphyrins or Si phthalocyanines[59,60], the geometry is governed by the planar macrocycle; the free coordination positions are axial *trans* and may be occupied by —F, $-OSiR_3$ *(6A)*, or (—O—)/2 *(6B)*. In the latter case, the Si phthalocyanine fragments are arranged in layers, the SiO distance of 1.659 Å being half the distance between two layers.



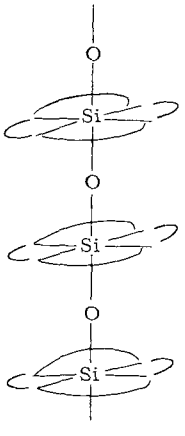
(6A)

macrocycle: porphin

Z = F, $OSiR_3$[59]

macrocycle: phthalocyanine

Z = $OSiR_3$[60]



(6B)

$(PcSiO)_x$[61]

The silicon atom usually prefers CN 4 if linked to oxygen atoms, but exceptions such as thaumasit and high pressure modifications of SiO_2 are known. Tetrahedral SiO_4 units are common to the great majority of silicates, which form different types by different crosslinking.

In this context, it is significant that silicon diphosphate SiP_2O_7 has a structure in which each Si atom is coordinated by six O_3POPO_3 groups. On the other hand, all six terminal O atoms of the O_3POPO_3 groups are joined to different Si atoms. This structure may be interpreted in terms of SiO_6 octahedra sharing corners with PO_4 tetrahedra[62]; the POP angle is approximately 139°.

The octahedral (Table 9) is longer than the tetrahedral SiO distance. In general, long and relatively weak bonds are characteristic for Si with CN 6; in this respect the element differs somewhat from its neighbors P and S.

Table 9. SiO distances [Å] for CN 4 and CN 6.

SiO_4^{4-}	1.60	[63]

7. Unusual Structural Parameters of Tetracovalent Silicon

Silicon contrasts with carbon not only in its coordination chemistry but also because it can induce specific structural and chemical properties in groups to which it is linked. This ability is particularly pronounced when it is bonded to N and O; however, derivatives of heavier elements behave quite normally in this respect.

7.1. Bonding Properties

The electronegativity of silicon would suggest that it attracts bonding electrons in bonds to C, N, O, and F less than carbon; consequently SiOH and SiNH compounds should be weaker acids than corresponding COH and CNH compounds, while O and N, when linked to Si, should exhibit stronger Lewis base properties.

The reverse is observed. An interpretation assuming back bonding $\ddot{X}—Si \leftrightarrow \overset{\curvearrowright}{\ddot{X}}—Si \leftrightarrow \overset{\oplus}{\ddot{X}}=\overset{\ominus}{Si}$ of (p→d)π type has proved useful. According to this, the lone pair of the X atom, preferably of p character, interacts with Si d orbitals of suitable symmetry, thus reducing the electron density at X and strengthening the XSi bond.

While some of the consequences for chemical properties at the X atom will be discussed in Chapter 8, some structural aspects caused by the specific action of the Si atom are dealt with here.

In a discussion of bonding between X and Si one should distinguish between two effects. Firstly, there is rehybridization to produce high p character in lone pairs on X induced by the Si atom. Secondly, there is the amount of π bonding reflected by SiX bond shortening or equivalent parameters. Both phenomena, though independent, are usually observed to occur simultaneously. Thus (p→d)π strengthening is possible for pyramidal $N(SiH_3)_3$ without rehybridization, though it is less effective than for a planar molecule.

7.2. Bond Angles

Structural data so far available indicate that unusual bond angles occur only for SiN and SiO compounds. A precise structural determination of disilylmethane, however, revealed that even carbon uses s-rich orbitals for its bonds to silicon[64], and the same arguments hold for the planarity of the $(Me_3Si)_3C^{\cdot}$ radical, deduced from ESR spectroscopy[65].

Table 10 presents some typical bond angles for simple silyl compounds and compares them, as far as possible, with analogous C and Ge derivatives.

Table 10. SiXSi bond angles: comparison with C and Ge compounds.

Compound	∢ [°]	Ref.	Compound	∢ [°]	Ref.
$H_3Si-CH_2-SiH_3$	114.4	[64]	$H_3C-CH_2-CH_3$	112.4	[64]
$H_3Si-O-SiH_3$	144.1	[68]	$H_3C-O-CH_3$	111.5	[67]
$H_3Si-O-CH_3$	120.6	[66]	$H_3Ge-O-GeH_3$	126.5	[69]
$H_3Si-NH-SiH_3$	127.7	[70]	$H_3C-NH-CH_3$	111±3	[67]
$(H_3Si)_3N$	119.7	[71]	$(H_3C)_3N$	110.6	[64]
			$(H_3Ge)_3N$	120	[72]
$H_3Si-S-SiH_3$	97.4	[73]	$H_3C-S-CH_3$	98.9	[69]
			$H_3Ge-S-GeH_3$	98.9	[69]
$(H_3Si)_3P$	96.45	[74]	$(H_3C)_3P$	99.1	[67]
			$(H_3Ge)_3P$	95.39	[75]

The exceptional behavior of O and N is obvious, while analogous sulfur and phosphorus compounds behave normally, like alkyl derivatives, with respect to the angles at S and P and to the Lewis basicity of the lone pair(s). This view is supported by the fact that the inversion barrier of trivalent phosphorus, though small, corresponds exactly to the value predicted for phosphanes from the group electronegativity of the substituents[76].

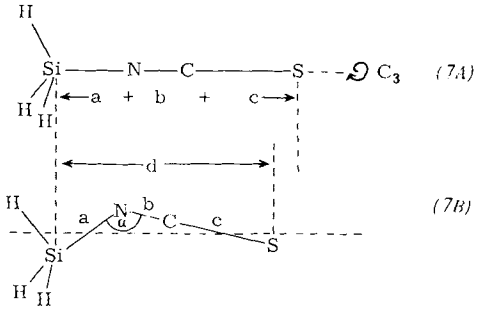
Nitrogen is invariably planar when linked to two or three Si atoms, as in $(H_3Si)_2NH$[70], $(H_3Si)_2NCH_3$, $(H_3Si)_2NBF_2$, $(H_3Si)_2NN(SiH_3)_2$[77], and corresponding trimethylsilyl compounds; see also Section 8. However, a single silyl group will not always flatten nitrogen, as has been demonstrated by $(CH_3)_2NSiH_3$: the SiN bond is tilted out of the CNC plane by 27.8°[78]. In contrast, planar nitrogen has been observed for $(CH_3)_2NSiF_3$ and $(CH_3)_2NSiCl_3$[79], and also for silylpyrrole[80] where the planarity favors participation in the delocalized π system (which is less pronounced, however, than for pyrrole itself[81]).

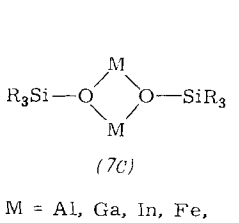
The bond angles at the X atoms are only slightly altered upon changing the substituents at the Si atom: $(H_3Si)_2NH$ (127.7°) and $(Me_3Si)_2NH$ (125.5°)[82] differ in their SiNSi angles by only 2.2° (only slightly greater than the experimental error), while the SiOSi angle increases from 144.1° in $(H_3Si)_2O$ and 146° in $(Cl_3Si)_2O$[83] to 155.7° in $(F_3Si)_2O$[84], the increase corresponding to an enhancement in the s character of the bonding electrons of oxygen from 44.7 to 47.6%.

The SiNSi bond angle in $(H_3Si)_3N$ was found by electron diffraction to be slightly smaller than 120°. This is, however, not equivalent to deviation from planarity because the angle is averaged over molecules in different phases and occupying different levels of the Si_3N out-of-plane bending vibration. Only an infinitely small number is passing through the equilibrium (planar) structure at any given moment.

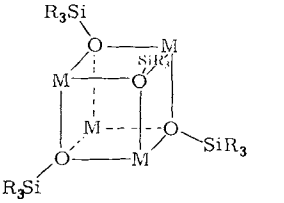
7.3. Pseudohalides

Structural parameters obtained by averaging over molecules in different vibrational states are particularly interesting for pseudohalides because high excited levels of low-lying bending vibrations are occupied in these molecules. Consequently the average molecule of, *e.g.*, H_3SiNCS, will not have the equilibrium structure *(7A)*, but at the moment of electron diffraction exhibits shrinkage *(7B)*; *d* will be smaller than $a+b+c$.





M = Al, Ga, In, Fe, Au[99,100]



M = alkali metal, CH_3Be, RHg, RZn, RCd[100,101]

Table 11 presents the bond angles α for some silyl and methyl pseudohalides and quotes the method by which they were determined. The figures clearly indicate that the angles sometimes differ less between analogous silicon and carbon compounds than for the same compounds when different methods of investigation are used. Nevertheless, comparison of microwave data obtained for H_3SiNCS and H_3CNCS indicates the special behavior of silicon. In this context it should be pointed out that the differences mentioned so far do not reflect experimental uncertainties of the structural investigations but are due to the specific relation between the speed of the method used and that of the intramolecular motions.

The SiOSi bond angle is always smaller than 180°, but greater than 120° in the molecules mentioned so far; however, it was found to be actually 180° in $Ba_3Si_4Nb_6O_{26}$ and $Ba_3Si_4Ta_6O_{26}$[92].

Table 11. SiNC and CNC angles α in pseudohalides.

H_3CNCS	147.46	MW	[89]

[a] MW = microwave spectroscopy, ED = electron diffraction, X = X-ray structural analysis, IR/Ra = IR/Raman spectroscopy.

If a siloxy group is linked to electropositive, coordinatively unsaturated atoms, the oxygen atom usually becomes three-coordinated, while remaining bonded to one single Si atom. Four-membered ring *(7C)* or cubane structures *(7D)* are most favored.

Quite a number of monomeric silanolates are also known, among which $Me_3SiOReO_3$ ($\measuredangle$SiORe 164°) and $(Ph_3SiO)_2CrO_2$ ($\measuredangle$SiOCr 133.1 and 162.7°) have been characterized by structural analyses[93].

7.4. Distances

Judging by distances, an increase in bond orders by (p→d)π overlap occurs for SiN, SiO, SiF, and presumably SiCl bonds. However, a qualitative estimation of the extent of π bonding from the bond shortening is difficult for several reasons. Firstly the single bond reference length can only be estimated, and secondly it is well known that, as in carbon compounds, electronegative substituents and increased s character operate in the sense of bond strengthening. Table 12 lists some typical SiX distances and compares them with the expected values.

Table 12. Typical SiX distances [Å].

SiC 1.88 [a]

$SiCl_4$ 2.01 [3]	H_3SiCl 2.049 [96]

[a] Sum of covalent radii, corrected according to *Schomaker-Stevenson*.

SiN, SiO, and SiF bonds reveal their exceptional properties in two respects: on the one hand the distances are shorter by 0.1 to 0.15 Å than expected for single bonds, and on the other hand they are systematically sensitive to substituent effects, contrasting with the angles in this respect. Normal behavior is demonstrated by various silylphosphanes.

8. Unusual Aspects of Coordination and Stability

Experiments have shown that the Lewis base strength of oxygen and nitrogen drops considerably upon silyl substitution. Addition of Lewis acids to SiO and SiN compounds or quaternation of nitrogen in silylamines are only achieved in exceptional cases; siloxonium compounds, however, which possess the $R_3SiO<$ fragment have been met with in Section 7. Due to their reduced Lewis base strength $SiNR_2$ and SiOR derivatives are extremely useful for the transfer of NR_2 and OR groups in cases where HNR_2 or HOR would undergo addition rather than substitution. In particular, transition metal halides easily enter into the following reactions:

$$TiCl_4 + Me_3SiNR_2 \rightarrow Me_3SiCl + R_2NTiCl_3$$
$$WF_6 + n\,Me_3SiOR \rightarrow n\,Me_3SiF + (RO)_nWF_{6-n}$$

In this context the detection of the bis(trimethylsilyl)oxonium ion $(Me_3Si)_2OH^+$ in mixtures of $(Me_3Si)_2O$ and "magic acid" ($HSO_3F/SbF_5/SO_2$) is particularly noteworthy[103]. Also contrary to expectation, silylammonium salts could be isolated from the following reactions[104]:

$$Me_3SiCo(CO)_4 + Me_3N \rightarrow [Me_3SiNMe_3]^+[Co(CO)_4]^-$$
$$Me_3SiNMe_2 + HCo(CO)_4 \rightarrow [Me_3SiNHMe_2]^+[Co(CO)_4]^-$$

Though silyl derivatives of most metals have been obtained during the last few years, they do not display any unexpected structural features apart from strong substituent effects. They resemble the alkyl compounds in many respects, quite often exhibiting steric effects similar to those of the *tert*-butyl group. Among the compounds not stabilized by extra ligands $Hg(SiMe_3)_2$, $In(SiMe_3)_3$, and $Tl(SiMe_3)_3$ should be noted. They are reported to be monomeric, volatile, and thermally rather unstable[105].

Unusual bonding and coordination numbers occur however when a metal and silicon are connected by nitrogen or carbon bridges; metal silanolates may also exhibit this particular behavior.

8.1. Metal Bis(silyl)amides

In many cases metals M exhibit their lowest CNs ever observed (2, 3) in metal bis(silyl)amides $[(R_3Si)_2N]_xM$. These compounds may be obtained without difficulty from metal halides and alkali metal bis(silyl)amides[106]; due to their molecular size as monomers (except for alkali metal and Cu derivatives) they also number among the most volatile metal compounds.

Sterically, a metal atom M is perfectly shielded by two or more $(R_3Si)_2N$ groups. At the same time it may, at least in part, increase its effective electron number by participating in the NSi_2 (pπdπ) system. Available structural and spectroscopic investigations establish the planarity of the overall $MNSi_2$ bond system in which M has a geometry corresponding to its CN: MN_2 linear, MN_3, LMN_2, and L_2MN trigonal planar. Alkali metal bis(silyl)amides possessing a formally monovalent metal atom are associated, becoming increasingly ionic from Li to Cs; a CN 1 has not yet been established for these compounds. They add Lewis bases such as ether or dioxane. $LiN(SiMe_3)_2$ (115 °C/1 torr) and $NaN(SiMe_3)_2$ (202 °C/2 torr) may be distilled without decomposition[106]. $LiN(SiMe_3)_2$ easily changes its degree of association, being obviously dimeric in solution, but forming a trimer in

the solid state which consists of a planar $(LiN)_3$ six-membered ring with a SiNSi angle of 118°[102]. According to spectroscopic investigations the SiNSi angle widens to ≈140° as the ionic character increases. It was found to be 136° in $KN(SiMe_3)_2 \cdot 2$dioxane, in which the K atoms are pentacoordinated by N and four O atoms of different dioxane molecules[107].

8.2. Metal Bis(disilylamides)

A CN of 2 is rather unusual for metals, being known only for Zn, Cd, Hg, Cu, and Ag. However, the bis(trimethylsilyl)amido group stabilizes this coordination number not only for Zn, Cd, and Hg, but also for many other metals. Table 13 lists some monomeric metal bis(disilylamides).

$[(Me_3Si)_2N]_2Co$	73	101/0.6	green	4.83	[112, 113]
$[(Me_3Si)_2N]_2CoPPh_3$	dec. >90			4.84	[113]
$[(Me_3Si)_2N]_2Ni$	<20	80/0.2	red		[111]

Linear NMN fragments have been established for M = Be *(8A)*[114], Zn, Cd, Hg[109], Cr *(8B)*[110], and Co[112]; furthermore they will probably be present if M is Mn or Ni. *(8B)* may be expected to have a tetrahedral or distorted octahedral structure; the observed square planar *trans* arrangement in which chromium can use dsp^2 hybrid orbitals is consistent with the reported value of four unpaired electrons. $[(Me_3Si)_2N]_2CoPPh_3$ and $(Me_3Si)_2NNi(PPh_3)_2$ (μ_{eff} 1.91 μ_B) possessing planar N_2CoP and $NNiP_2$ units respectively are examples of CN 3, which is very uncommon for Co and Ni[113].

8.3. Metal Tris(disilylamides)

Similarly CN 3 is far from common in the coordination chemistry of metals. Nevertheless such a coordination number appears in many metal tris(disilylamides), which at the same time will not add any further ligand [except in *(8D)*]. All $M[N(SiMe_3)_2]_3$ compounds obtained so far are isostructural, and planarity of the MN_3 and $MNSi_2$ fragments has been established by X-ray diffraction for M = Al, Cr, and Fe *(8C)*. Table 14 compares the tris(disilylamides) of various metals. Noteworthy is the high thermal stability which allows these compounds to be sublimed *in vacuo* (except for the Ti^{III} compound) despite their high molecular weights of about 530.

As in *(8B)* chromium has a formal oxidation state of +2 in $[(Me_3Si)_2N]_3CrNO$ *(8D)*[110], but a (nearly tetrahedral) trigonal pyramidal environment. Comparison of distances shows the CrN bonds to be considerably shorter in *(8D)* than in *(8B)*, strongly suggesting the presence of N→Cr pπdπ bonds enabling Cr^{II} to approach the [Kr] noble gas configuration.

Furthermore, comparison of *(8B)* and *(8D)* demonstrates that the formation of N→Mπ bonds cannot be the only reason for low coordination numbers of metal atoms and the high thermal stability observed. Probably both steric requirements of the ligands and a Lewis base strength of nitrogen, which is reduced by silicon and thus supresses nitrogen bridging, favor the formation and stability of monomeric bis- and tris(disilylamides).

8.4. Trimethylsilylmethyl Compounds

The last Section of the review is devoted to trimethylsilylmethyl compounds which have only recently attracted attention and appear to have initiated a most promising rapid development in silicon chemistry.

The lithium compound $(Me_3Si)_3CLi$, which decomposes at room temperature only after some weeks, belongs to this class of compounds[120]. When formulated as an ion the carbanion $(Me_3Si)_3C^-$ is isoelectronic with the nearly

Table 14. Metal tris(disilylamides).

Compound	Subl. temp. [°C/torr]	M.p. [°C]	Color	μ_{eff} [μ_B] [298 °K]	Ref.
$[(Me_3Si)_2N]_3Al$	< 120/0.5	188	colorless	diam.	[116]
$[(Me_3Si)_2N]_3Ga$	< 120/0.5	187	colorless	diam.	[116]
$[(Me_3Si)_2N]_3In$	< 120/0.5	168	colorless	diam.	[116]
$[(Me_3Si)_2N]_3Sc$	sublimable	172–174	colorless	diam.	[117]
$[(Me_3Si)_2N]_3Ti$	nonsublimable		blue	1.62	[117]
$[(Me_3Si)_2N]_3V$	$95/5 \times 10^{-3}$		brown	2.38	[117]
$[(Me_3Si)_2N]_3Cr$	$80/5 \times 10^{-3}$	120	green	3.74	[111, 117]
$[(Me_3Si)_2N]_3Fe$	$80/5 \times 10^{-3}$	135	green-black	5.94	[112, 115, 117, 118]
$[(Me_3Si)_2N]_3La$		145–149	colorless	diam.	[119]
$[(Me_3Si)_2N]_3Pr$		155–158	yellow-green	param.	[119]
$[(Me_3Si)_2N]_3Sm$	$75–100/10^{-4}$	155–158	yellow	param.	[119]
$[(Me_3Si)_2N]_3Eu$		159–162	orange	param.	[119]
$[(Me_3Si)_2N]_3Gd$		160–163	colorless	param.	[119]
$[(Me_3Si)_2N]_3Lu$		167–170	colorless	diam.	[119]

or entirely planar $(Me_3Si)_3N$ and may similarly be stabilized by resonance. The unusual properties of the $(Me_3Si)_3C^{\cdot}$ radical have been mentioned before in Section 4.1.

Stabilization of transition metal alkyls may in general be accomplished by ligands which undergo π bonding or by particular kinetic effects. Apart from having favorable steric properties, the CH_2SiMe_3 group prevents metal alkyls from decomposing by olefin elimination:

$$M{-}CH_2CH_2R \rightarrow MH + CH_2{=}CHR$$

The trimethylsilylmethyl derivatives of transition metals described recently are remarkable in several respects: they are thermally more stable than corresponding alkyls (if the latter are accessible at all) and make low CNs available for transition metals, thus partly resembling benzyl compounds. A selection of the monomeric, relatively volatile compounds is presented in Table 15. Some of them are very effective catalysts for the polymerization of α-olefins.

The $CSiR_3$ group may also be involved in bridging and in multiple bonding because of three free positions on the α-carbon atom. This makes possible the formation of a quasiaromatic MCMC four-membered ring system *(8E)*[122], in which MC distances in the ring are considerably smaller than the exocyclic bond lengths. On the other hand, compounds with MoMo and WW triple bonds may be obtained *(8F)*[123]; it is very likely that the last men-

Thermodynamics of Addition Polymerization Processes[**]

By K. J. Ivin[*]

The polymerizability of compounds such as 1,1-disubstituted ethylenes, aldehydes, ketones, isocyanates, and five- and six-membered ring compounds is determined largely by thermodynamic considerations. The transition from non-polymerizability to polymerizability, corresponding to a change in the sign of ΔG, is often quite sharp. Factors which generally make the free energy of polymerization more negative, and which therefore favor polymerization, are low temperature, high pressure, and high monomer concentration. Additional driving force is sometimes available if the monomer is in the supercooled (glassy) state rather than the crystalline state, or if the polymer crystallizes on formation. Alkyl substituents have an unfavorable effect on polymerizability; halogen substituents have a favorable effect. Many monomers which do not homopolymerize for thermodynamic reasons will copolymerize with a second monomer to the extent of forming copolymers containing 50 or even 66 mol per cent of the first monomer.

1. Introduction

α-Methylstyrene polymerizes at 0 °C yet does not polymerize at 100 °C[1], except at high pressure[2, 3]. α-Methoxystyrene copolymerizes readily with styrene but does not homopolymerize at any temperature[4]. Acetaldehyde can be made to polymerize either by lowering the temperature to below −40 °C or by raising the pressure at room temperature[5]. These are but three of the many observations in polymer chemistry that have a thermodynamic explanation. An understanding of the thermodynamics of polymerization processes is therefore of some importance to the preparative chemist in search of new polymers.

Three types of interwoven equilibria may be distinguished in addition polymerization systems:

1. equilibria between polymeric species;
2. equilibria between species which may be described as monomeric;
3. equilibria between monomeric and polymeric species.

Most polymers contain a multitude of chain lengths and a polymer in which all these species are present in their equilibrium proportions is said to possess the most probable, or thermodynamic distribution of molecular weights[6]. For long chain polymer the enthalpy per monomer unit is constant, so that equilibria of type 1 are governed solely by entropy considerations. The distribution in most polymers is determined by the kinetics of the process and generally (but not always) differs from the thermodynamic distribution[6]. The latter may be attained in time if there is available a reasonably fast mechanism, such as ester interchange[7], or reversible propagation in a "living" anionic system[8].

The best documented case of type 2 is provided by the siloxanes where oligomeric ring species can open to give the same high polymer. When the rings are above a certain size the heat of polymerization is effectively zero and the equilibria are again governed by entropy considerations. For type 3 equilibria, in contrast to types 1 and 2, the heat of reaction plays an important, often dominant, role in determining the position of equilibrium. We shall discuss a number of examples of this type of equilibrium and will later return to type 2 equilibria. We will finally consider the effect of reversible propagation steps on copolymer composition.

2. Addition Polymerization Considered as an Aggregation Process

The criterion for equilibrium for any chemical reaction at constant temperature and pressure is that the free energy change for the reaction, ΔG, shall be zero. Addition polymerization reactions differ, however, from all other types of reaction in that a large number of monomer molecules come together to form a single macromolecule. This gives to such reactions some of the features more usually associated with physical aggregation processes such as freezing. In particular there exists a sharp temperature, known as the "ceiling temperature", above which the formation of long-chain polymer does not occur, analogous to a melting point, above which the formation of macroscopic crystals does not occur. The essential feature common to both types of aggregation is that at a sharp temperature the free energy for the aggregation process is zero. In both cases the transition temperature is depressed by the addition of diluent, and is independent of the size of the aggregate except when this is very small.

The observation of a ceiling temperature[9] and the use of this term dates from 1938 although its thermodynamic explanation was not fully recognized until ten years later[10]. The reverse effect, that of a floor temperature, has long been known in the case of sulfur[11]: the formation of long chains only occurs above 159 °C. The complete generality of the ceiling temperature effect is illustrated in Table 1; a more complete list may be found in the Polymer Handbook[23].

[**] A detailed account of this topic will shortly appear in *A. D. Jenkins* and *A. Ledwith*: Reactivity, Mechanism and Structure in Polymer Chemistry, published by John Wiley & Sons Ltd. Some of the illustrations and other material are reproduced by permission of the publishers.

Table 1. Some observed ceiling temperatures T_c.

Monomer	Concn. (mol/l)	Solvent [a]	Polymer structure	T_c (°C)	Ref.
styrene	1.2×10^{-4}	benzene	—CH_2—CHPh—	110	[12]
α-methylstyrene	pure	—	—CH_2—CMePh—	61	[2]
	0.76	THF		0	[1, 13, 14]
methyl atropate	pure	—	—CH_2—C(COOMe)Ph—	− 8	[15]
	1.0	toluene		−40	[15]
formaldehyde	0.06	CH_2Cl_2	—O—CH_2—	30	[16]
acetaldehyde	pure	—	—O—CHMe—	−31	[17]
tetrahydrofuran	pure	—	—O—$(CH_2)_4$—	80	[18]
1,3-dioxolane	1.0	CH_2Cl_2	—O—CH_2—O—$(CH_2)_2$—	1	[19]
phthalaldehyde	1.0	CH_2Cl_2		−43	[20]
thioacetone	pure	—	—S—CMe_2—	95	[21]
n-hexyl isocyanate	2.0	DMF	—NHex^n—CO—	−22	[22]

[a] THF = tetrahydrofuran, DMF = dimethylformamide.

For a given medium and monomer concentration there is a particular ceiling temperature. Taking the reverse viewpoint one may say that for a particular temperature and medium there is a certain equilibrium monomer concentration. Thermodynamically there is no distinction; the only difference lies in the choice of independent variable. Experimentally both approaches may be used; in some cases it is feasible to allow the system to come to equilibrium at a particular temperature and then to measure the monomer concentration; in others, particularly where the equilibrium is less mobile, it is more convenient to plot the rate, yield, or degree of polymerization as a function of temperature, and to obtain the ceiling temperature by extrapolating the dependent variable to zero[24].

3. The Physical State of the System; Some Possible Situations

Since $\Delta G = 0$ at T_c it follows that

$$T_c = \Delta H / \Delta S \qquad (1)$$

where ΔH and ΔS are the appropriate heat and entropy changes for the polymerization process (per mol of monomer) under the prevailing conditions. Any factor which affects ΔG will also affect T_c, either through ΔH or ΔS or both. The main factors affecting ΔG for a given monomer are the concentration of monomer and the hydrostatic pressure. Minor factors are the nature of the solvent and the presence of dissolved solutes, particularly the polymer; or in the case where the polymer is insoluble, its degree of crystallinity. Any given situation may be analyzed in terms of a thermodynamic cycle containing the step:

$$M\,(liq) \rightarrow \frac{1}{n} M_n\,(amorphous) \qquad \Delta H_{lc}, \Delta S_{lc}, \Delta G_{lc}$$

This is illustrated for various particular cases below.

3.1. Polymer and Monomer Immiscible

This type of equilibrium polymerization is rather rare. It is characterized by a ceiling temperature below which there is *complete* conversion of monomer to polymer, just as a pure liquid freezes completely when the temperature is below its freezing point. *n*-Butyraldehyde may be an example of this[25].

If the polymer is formed in the crystalline state (at a temperature below its melting point) there is an additional driving force favoring polymerization; this is probably an important factor in the polymerization of 2-piperidone[26]. Conversely it is thermodynamically advantageous to start from monomer in the supercooled (glassy) state rather than the crystalline state and this could be of assistance when attempting to polymerize "difficult" monomers such as acetone[27].

Formaldehyde[28], chloral[29], fluoral[29], tetrahydrofuran[30], and 1,3-dioxolane[30] provide examples of direct equilibrium between monomer vapor and condensed polymer and in these systems the depolymerization process is akin to sublimation.

3.2. Polymer Soluble in Monomer

There are many examples of this type. In contrast to immiscible condensed systems (Section 3.1) polymerization below T_c stops short at a point which, to a good approximation, is independent of the molecular weight of the polymer. This is illustrated in Figure 1 for the cationic polymerization of tetrahydrofuran[18].

Thermodynamic analysis of such systems takes account of the effect of polymer on the chemical potential of the monomer and also of the variation of the chemical potential of the polymer with composition. Eq. (2) is the resulting expression under conditions of moderately large degree of polymerization and not too small volume fraction Φ_2 of the polymer. Φ_1 is the volume fraction of the monomer and χ the polymer-monomer interaction parameter, which commonly has a value of 0.3—0.5.

$$\Delta G_{lc}/RT = 1 + \ln\Phi_1 + \chi(\Phi_2 - \Phi_1) \qquad (2)$$

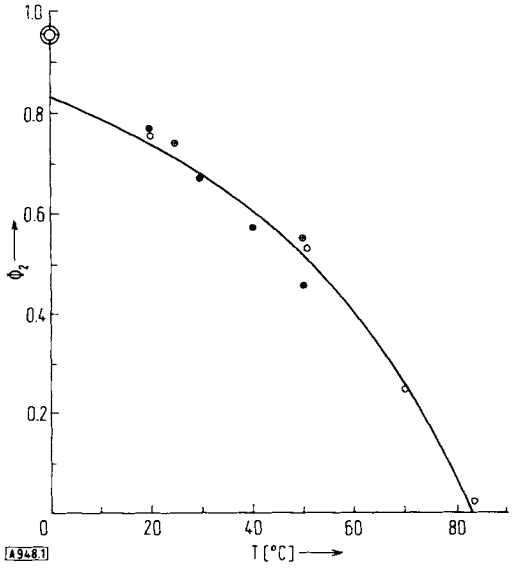

Fig. 1. Equilibrium volume fraction of polymer Φ_2 in the bulk polymerization of tetrahydrofuran [18]. The three sets of points (●, ○, ⊕) come from three different groups of workers. The line is drawn from eq. (2) taking $\chi = 0.3$, $\Delta H_{lc} = -12.4$ kJ mol^{-1}, $\Delta S_{lc} = -40.8$ J K^{-1} mol^{-1}.

This equation provides a satisfactory representation of the data for tetrahydrofuran (Fig. 1).

3.3. Polymer and Monomer in a Solvent

Numerous equilibrium systems of this type have been studied, some of which are shown in Table 1. Ceiling temperatures in such systems are usually quite sharp but the equilibrium monomer concentration $[M_e]$ varies with solvent and with polymer concentration. Thus for trioxane[31] at 30 °C, $[M_e]$ is 0.05 mol/l in benzene, 0.13 mol/l in 1,2-dichloroethane, and 0.19 mol/l in nitrobenzene. For α-methylstyrene[32] at 0 °C, $[M_e]$ is 0.78 mol/l if only a trace of polymer is present, but 0.34 mol/l in the presence of 4 mol/l of polymer (expressed in terms of mol monomer units).

The thermodynamic analysis of such systems involves the interaction between monomer and polymer (χ_{12}), solvent and polymer (χ_{32}), and monomer and solvent (χ_{13}). Eq. (3) is the resulting expression when the degree of polymerization is large, V_1 and V_3 being the molar volumes of monomer and solvent respectively[32].

$$\Delta G_{lc}/RT = 1 + \ln\Phi_1 + \chi_{12}(\Phi_2 - \Phi_1) + (\chi_{13} - \chi_{32}V_1/V_3)\Phi_3 \qquad (3)$$

Eq. (3) differs from eq. (2) by the inclusion of the last term. Generally χ_{13} shows a greater dependence on solvent than χ_{32} and is mainly responsible for the variation of $[M_e]$ or Φ_1 with solvent. When the variation of Φ_1 with Φ_2 is not too large it can be shown from eq. (3) that Φ_1 will be a linear function of Φ_2, as found for the polymerization of α-methylstyrene in tetrahydrofuran[32] and dioxane[33].

Any treatment in terms of eq. (3) is bound to be approximate since the interaction parameters are liable to vary with composition and temperature. Recourse has therefore frequently been made to a less exact treatment in terms of eq. (4),

$$T_c = \Delta H_{ss}/\Delta S_{ss} = \Delta H^0_{ss}/(\Delta S^0_{ss} + R\ln[M]) \qquad (4)$$

where ΔH_{ss} and ΔS_{ss} are the heat and entropy changes for the polymerization of monomer in solution to polymer in solution at the ceiling temperature for a monomer concentration [M]. Variations of the activity coefficients of the monomer and polymer with temperature or with composition are thus absorbed into the values of ΔH^0_{ss} and ΔS^0_{ss} (standard state 1 mol/l) instead of being expressed through the interaction terms in eq. (3). These usually show a sufficiently small and steady variation that eq. (4) provides a good representation of the experimental data, as shown for isobutyraldehyde[34] in Figure 2. The slope of the plot of log $[M_e]$ against T^{-1} gives an average value of ΔH^0_{ss} which may be combined with appropriate heats of solution of monomer and polymer to obtain ΔH_{lc}. Values of ΔH_{lc} or ΔH^0_{ss} obtained by the application of eqs. (2), (3), and (4) are generally in good agreement with calorimetric data. Details may be found in the Polymer Handbook[23].

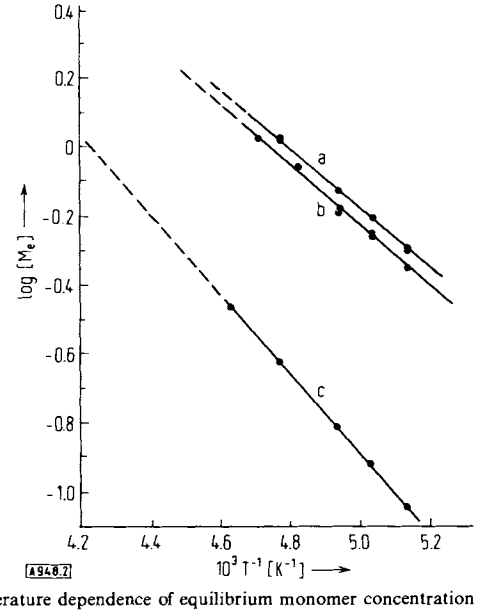

Fig. 2. Temperature dependence of equilibrium monomer concentration of isobutyraldehyde in: a, tetrahydrofuran; b, diethyl ether; and c, *n*-pentane [34].

Eq. (4) may also be derived from kinetic considerations, assuming that long chain polymer is formed[24]. The variation of $[M_e]$ with solvent and polymer concentration must reflect the variation of the propagation and depropagation rate constants with the nature of the reaction medium. For a given medium the ceiling temperature must of course be independent of the mechanism of the reaction, provided the polymer has the same structure.

3.4. Soluble Monomer and Insoluble Polymer

When a solution of monomer gives an insoluble polymer, it is possible for the crystallinity and hence the free energy of the polymer to vary with the solvent. An example is the formation of poly(3-methyl-1-butene sulfone) from mix-

tures of 3-methyl-1-butene and sulfur dioxide[35]. In sulfur-dioxide-rich mixtures the polymer has a free energy up to 3kJ mol^{-1} lower than that formed from a 3-methyl-1-butene-rich mixture at the same temperature and evidence has been obtained that the former polymer is more crystalline than the latter[36].

4. Effect of Pressure

The variation of T_c with pressure P may be expressed in the form of the Clapeyron-Clausius equation

$$d\ln T_c/dP = \Delta V/\Delta H \quad (5)$$

where ΔV and ΔH are the volume and enthalpy changes for the polymerization under the prevailing conditions. For pure α-methylstyrene[2,3] and for tetrahydrofuran[37] $\log T_c$ has been shown to be a linear function of pressure, the slope being consistent with the known values of ΔV and ΔH. Since practically all addition polymerizations are accompanied by a decrease in both volume and enthalpy the most favorable thermodynamic conditions for polymerization are high pressure and low temperature, a point worth bearing in mind when attempting to polymerize "difficult" monomers such as acetone. Generally one or other of these variables has been applied to encourage such monomers to polymerize, but seldom both together. The effect of pressure can be quite substantial, of the order of 100 K rise for a pressure of several thousand atmospheres.

5. Effect of Monomer Structure on Polymerizability

5.1. Compounds Containing Double Bonds (C=C, C=O, N=C)

Ethylene and most mono-substituted ethylenes can be readily polymerized and the back reaction is unimportant except for exceptionally low concentration and high temperature, for example at 10^{-3} mol/l and 120 °C for styrene. Reversibility is more in evidence for 1,1-disubstituted ethylenes and the ability of the monomer to polymerize is then critically dependent on the nature of the substituents, especially their bulkiness. This may be seen, for example, in the series CH_2=CRCOOMe. For R = Me (methyl methacrylate) the monomer polymerizes at 60 °C, but for R = Et, *n*-Pr, and Ph, the temperature must be lowered, say to −78 °C to bring about polymerization. For R = *iso*-Pr, *n*-Bu, *iso*-Bu, *sec*-Bu, *tert*-Bu, cyclohexyl, and benzyl high polymer cannot be made at any temperature[38,39]. Again, for the series CH_2=CMeX, the equilibrium concentration of monomer in tetrahydrofuran at 0 °C increases in the order β-naphthyl < *p*-biphenylyl < phenyl and polymerization does not occur for *o*-substituted aromatic substituents, including α-naphthyl[14,39,40]. In this series both ΔH^0_{ss} and ΔS^0_{ss} show variations with structure, but taking ethylenic monomers as a whole[24] ΔH is more sensitive to structure than ΔS.

Two effects on ΔH may be distinguished. First, resonance or hyperconjugation in the monomer tends to lower $-\Delta H$, some of the stabilization energy being lost on polymerization; second, steric hindrance in the polymer tends to lower $-\Delta H$. The first effect operates for styrene and the second for most 1,1-disubstituted ethylenes such as isobutene, methyl methacrylate, and α-methylstyrene.

Before leaving ethylenic monomers we may note that a methoxy group in place of a methyl group has a decidedly adverse effect on polymerizability. Thus α-methoxystyrene cannot be polymerized[4]. Conversely a nitrile group in place of an ester group has a beneficial effect: atroponitrile, CH_2=CPhCN, has a ceiling temperature much above that of methyl atropate[15,41].

Similar effects of substituents may be seen in the case of aldehydes. Thus formaldehyde is readily polymerized in solution if the concentration exceeds the equilibrium value[16] (0.06 mol/l in methylene chloride at 30 °C) but acetaldehyde and propionaldehyde must be cooled below −31 °C to induce them to polymerize in the pure state[17]. Further substitution in the α position to give isobutyraldehyde, Me_2CH—CHO, lowers T_c to −63 ° for a 1 M solution in tetrahydrofuran[34]. Pivalic aldehyde, Me_3C—CHO, is unpolymerizable at −78 °C[42]. Substitution by halogen, however, has a beneficial effect. Thus pure liquid 1,2-dichloropropionaldehyde, CH_2Cl—CHCl—CHO, has a ceiling temperature in the region of 0 °C[43]. The substituents have a considerable effect on both ΔH and ΔS in the polymerization of aldehydes.

Certain isocyanates polymerize through the N=C bond to give 1-nylons and a ceiling temperature effect is shown very clearly in the case of *n*-hexyl isocyanate[22] (Table 1). The non-polymerizability of many other isocyanates, particularly those substituted close to the nitrogen atom, is attributable to a lowering of the ceiling temperature. For example isopropyl[22] and 1-phenylethyl[44] isocyanates will not polymerize but phenyl[45] and 2-phenylpropyl[44] isocyanates will polymerize.

Many alkenes copolymerize with sulfur dioxide to give 1:1 copolymers (polysulfones) regardless of the composition of the feed and thermodynamically such systems may be treated like homopolymerizations. These reactions exhibit well-defined ceiling temperatures and were in fact the first in which the effect was recognized[9]. Increasing substitution by alkyl groups near the double bond causes a progressive lowering of ceiling temperature until with alkenes such as 2-ethyl-1-butene, 2,4,4-trimethyl-1-pentene, and 4-methyl-2-pentene no copolymer is formed at any temperature[46].

5.2. Ring Compounds

The compounds discussed in Section 5.1 may be regarded as two-membered rings. If the rings are enlarged by the incorporation of successive methylene groups we may expect the free energy of polymerization at first to become more negative, to be close to zero for five- and six-membered rings, then to become negative again and finally to approach a value close to zero. This statement is based on data for the cycloalkanes[24]. Alkyl substituents invariably make ΔG_{lc} less negative (more positive) and so reduce

Table 2. Polymerizability (+ or −) of some unsubstituted rings.

Group	Type of ring		Name of 5-ring	No. of ring members 5	6	7
1	1,3-C_nNO		2-oxazolidinone	−	+	
2	1,3-C_nN_2		2-imidazolidinone	+	−	+
3	1,2-C_nOS		1,2-oxathiolane 2,2-dioxide	+	−	
4	1,3-C_nO_2		1,3-dioxolane	+	−	+
5			ethylene carbonate	−	+	
6	1,2-C_nS_2		1,2-dithiolane	+	+	+
7	C_nN		pyrrolidine	−	−	+
8			2-pyrrolidinone	+	+	+
9			succinimide	−	−	
10			2-pyrrolidinethione	−		+
11	C_nO		tetrahydrofuran (oxolane)	+	−	+
12			2-oxolanone (γ-butyrolactone)	+	+	+
13			2,5-oxolanedione (succinic anhydride)	−	−	+
14	C_nS		2-thiolanone (γ-thiobutyrolactone)	−	+	+

the thermodynamic polymerizability, as for ethylene derivatives. But whereas the cycloalkanes are not generally polymerizable for kinetic reasons, heterocyclic compounds nearly always polymerize by ring-opening when it is thermodynamically possible; in other words non-polymerizability may nearly always be taken as synonymous with a positive free energy of polymerization.

The polymerizability of fourteen different types of unsubstituted five-, six-, and seven-membered ring compounds is summarized in Table 2. It will be observed that seven-membered rings generally polymerize (there are some exceptions to this rule, not shown in Table 2), but that with five- and six-membered rings sometimes both polymerize (groups 6, 8, 12), sometimes neither polymerize (groups 7, 9, 13), sometimes only the five-membered rings polymerize (groups 2, 3, 4, 11) and sometimes only the six-membered rings polymerize (groups 1, 5, 14). This reflects the sensitivity of the sign of ΔG to small changes in the nature of the five- and six-membered rings.

As an example of the effect of substituents we show the behavior of five-membered rings in Table 3. A reaction of particular interest is the formation of polysaccharides from the bicyclic dioxolane derivatives[47, 48]. Details, and similar tables for six- and seven-membered rings, may be found elsewhere[16, 49].

6. Ring-Chain Equilibria Involving Rings of Different Sizes

When tetraoxocane, the cyclic tetramer of formaldehyde, is polymerized in 1,2-dichloroethane at 50 °C, its concentration falls to an equilibrium value of less than 0.008 mol/l, but at the same time an equilibrium concentration of 0.2 mol/l trioxane is built up[50]. Such behavior is typical of a whole range of cyclic compounds[23, 49]. The establishment of equilibrium between cyclic compounds containing different numbers of repeat units usually occurs *via* linear polymer or oligomer but sometimes a direct ring expansion mechanism is available as in the polymerization of cycloalkenes on the catalyst $WCl_4/ROH/RAlCl_2$ to give a macrocyclic polyene. For cyclooctene there is evidence for the

Table 3. Polymerizability of five-membered rings (hydrogen atoms not shown).

formation of a range of cyclic compounds containing up to 15 or more monomer units[51,52]. Likewise in the polymerization of tetrameric dimethylsiloxane, $(Me_2SiO)_4$, it has been established that the equilibrium mixture contains cyclic structures with up to 400 monomer units, the total macrocyclic population representing up to 10% of the whole polymer[53].

The data on the dimethylsiloxane system provided the first and still the most extensive test of the Jacobson-Stockmayer[54] theory of ring-chain equilibria. The theory assumes that the rings are strainless, that the end-to-end distances of linear chains are governed by Gaussian statistics (random-flight model, no excluded volume effect), that the probability of ring formation is governed by the frequency with which the ends of linear chains coincide, and that the probability of bond formation is independent of whether the two ends form part of the same or separate chains. The theory has recently been modified[55] to take account of valence angles and excluded volume effects (rotational isomeric states model) and in this modified form not only predicts that K_x for the equilibrium

$$\underset{\text{(linear)}}{M_y} \rightleftharpoons \underset{\text{(linear)}}{M_{y-x}} + \underset{\text{(cyclic)}}{c\text{-}M_x} \qquad K_x$$

is a linear function of $x^{-2.5}$, as found experimentally for $x > 15$, but also gives the correct value of the proportionality constant (Fig. 3). Deviations for $x < 15$ may be attributed to the failure of the assumption that the rings are strainless, *i.e.* for small rings the enthalpy of polymerization must also be taken into account.

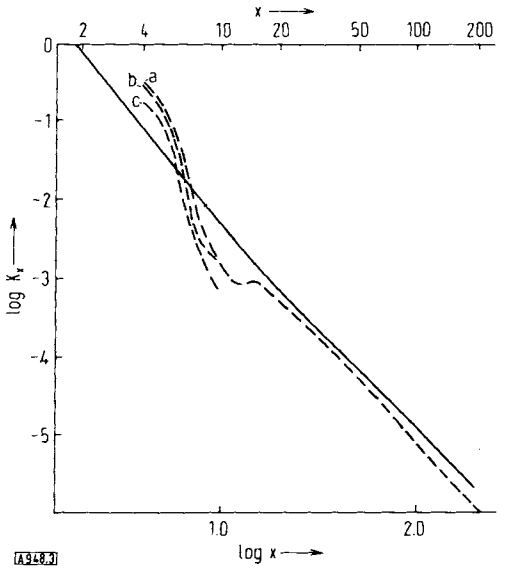

Fig. 3. Macrocyclic equilibrium constants for $(Me_2SiO)_x$.
$M_y \rightleftharpoons M_{y-x} + c\text{-}M_x$, K_x.
a, b, c are experimental curves of three groups of workers. Full line calculated by *Flory* and *Semlyen* [55].

7. Copolymerizations Involving Reversible Propagation

The copolymerization of two monomers M_1 and M_2 is generally considered in terms of four propagation steps:

$$M_1^* + M_1 \rightarrow M_1^* \quad k_{11} \qquad r_1 = \frac{k_{11}}{k_{12}}$$

$$M_1^* + M_2 \rightarrow M_2^* \quad k_{12}$$

$$M_2^* + M_2 \rightarrow M_2^* \quad k_{22} \qquad r^2 = \frac{k_{22}}{k_{21}}$$

$$M_2^* + M_1 \rightarrow M_1^* \quad k_{21}$$

where M_1^*, M_2^* represent growing polymer chains possessing M_1 and M_2 end-units respectively. The copolymer composition, expressed as the relative rates of removal of the two monomers, $d[M_1]/d[M_2]$, is then given by the Lewis-Mayo equation:

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]}{[M_2]} \frac{\{r_1[M_1]+[M_2]\}}{\{r_2[M_2]+[M_1]\}} \tag{6}$$

This equation has been found satisfactory for a wide variety of monomers, but it is clear that it may fail if one of the reverse reactions becomes important compared with its forward reaction, as may happen when the temperature is close to the ceiling temperature for the homopolymerization of one of the monomers. If M_2 is far above its ceiling temperature then it may so happen that although $M_2^* + M_2 \rightarrow M_2^*$ is strongly reversed, $M_1^* + M_2 \rightarrow M_2^*$ is not. Under these circumstances the *effective* values (not the actual values) of k_{22} and r_2 are zero and eq. (6) reduces to eq. (7):

$$\frac{d[M_1]}{d[M_2]} = 1 + r_1 \frac{[M_1]}{[M_2]} \tag{7}$$

Figure 4 shows an example of this type of behavior for M_2 = α-methoxystyrene, a monomer which itself is unpolymerizable[4]. At low values of $[M_1]/[M_2]$ the copolymer tends to the alternating 1:1 composition. If r_1 is less than 0.01 for this type of system the composition of the copolymer will be close to 1:1 over a wide range of feed composition, as for example in the radical copolymerization of styrene with *trans*-1,2-dibenzoylethylene[56]. Other unpolymerizable monomers which can be copolymerized with a second monomer to give compositions close to 1:1 include oxygen, carbon monoxide and dioxide, carbon oxide sulfide and disulfide, sulfur dioxide, phenyl isothiocyanate, tetrahydropyran, 2-methyltetrahydrofuran, benzaldehyde, hexafluoroacetone, 1,1-diphenylethylene, *trans*-stilbene, *trans*-1,2-di(2-pyridyl)ethylene, *trans*-1,2-diacetylethylene, and α-stilbazole. Details are given elsewhere[49].

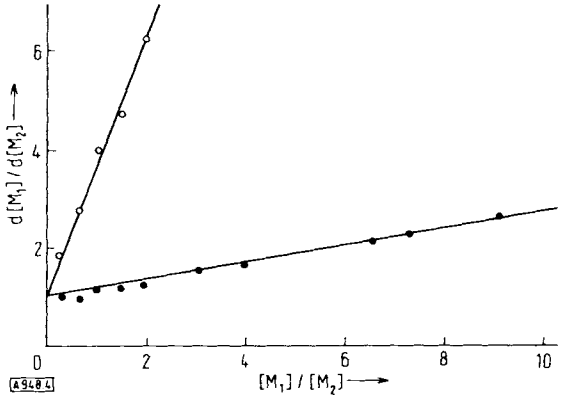

Fig. 4. Radical copolymerization of α-methoxystyrene (M_2) with methyl acrylate (—•—•—) and methyl methacrylate (—o—o—) at 60 °C [4]. $r_1 = 0.17$ for methyl acrylate; $r_1 = 2.5$ for methyl methacrylate.

The limiting composition at high temperature and low $[M_1]/[M_2]$ for copolymerization systems containing reversible propagation steps involving M_2 is not always 1:1. Sometimes only homopolymer of M_1 is produced, indicating that both $M_2 + M_2^* \rightarrow M_2^*$ and $M_1^* + M_2 \rightarrow M_2^*$ are strongly reversed; this behavior is found with the copolymerization of two alkenes with sulfur dioxide[57]. In other cases the limiting composition is 1:2 ($M_1 : M_2$) indicating that M_2 can add to $M_1M_2^*$ but not to $M_1M_2M_2^*$; this applies for example to the radical copolymerization of styrene[58,59], methyl acrylate[58], and acrylonitrile[58] (M_1) with methyl atropate (M_2) at 60 °C.

The reason for these different types of behavior must be sought in the reasons for the reversibility or non-occurrence of the polymerization of M_2. If the heat of polymerization of M_2, and hence ceiling temperature, is low because of

steric strain in the polymer it is likely that this strain will be entirely removed if every other M_2 unit is replaced by an M_1 unit. Sometimes this will be so if every third M_2 unit is replaced by M_1. These two cases correspond to the limiting compositions of 1:1 and 1:2 ($M_1:M_2$), examples of which have been given above. If, however, the heat of polymerization of M_2 is low for other reasons, there may be no significant difference in the heats, and hence reversibilities, of the reactions $M_1^* + M_2 \rightarrow M_1M_2^*$ and $M_2^* + M_2 \rightarrow M_2M_2^*$. In this case only homopolymer of M_1 will be produced under conditions of high temperature and low $[M_1]/[M_2]$.

A number of papers have been published[57, 60, 61] concerning the theoretical description of the transition from "normal" behavior as described by eq. (6) to "limiting" behavior, for example as described by eq. (7), but so far there have been comparatively few experimental studies[57, 62–65].

Isolation and Identification of v-Tetrazine Derivatives on Decomposition of Nitrosamine Anions[**]

By *Dieter Seebach, Dieter Enders, Bernd Renger,* and *Werner Brügel*[*]

Dedicated to Professor F. Kröhnke on the occasion of his 70th birthday

Hitherto there has been no compound with an established *v*-tetrazine structure[1] in which four contiguous nitrogen atoms are incorporated into an aromatic *(1)*, partially [*e.g. (2)*] or fully hydrogenated six-membered ring; tetrahydro derivatives *(2)* would be particularly interesting for comparison with the well known, open-chain 2-tetrazenes *(3)* of *trans* configuration, as possible inverse dienophiles, and as precursors for preparation of diazetidines *(4)*.

We have now found that the *N*-oxides *(5a)*, *(5b)*, and *(5c)*, respectively, can be isolated as decomposition products of metalated nitrosamines[2] (dimethylnitrosamine, methylcyclohexylnitrosamine, and 1-nitrosopiperidine) in 30%—45% yields and can be reduced quantitatively by trimethyl phosphite to the oxygen-free compounds *(6a)*, *(6b)*, and *(6c)*, respectively. Proof of the structures of the new compounds (C, H, and N contents within 0.3%, osmometric molecular weights within 5% of the theoretical values) rests on spectroscopic studies: The mass spectra of *(5a)*—*(5c)* show an $(M-O)$, and *(6c)* an $(M-N_2)$ line. In the NMR spectrum ($CDCl_3$) the presence, for example, of C_s symmetry only in *(5a)* is evident from the appearance of two CH_3 singlets ($\delta=2.92$ and 3.08 ppm) and an AA'BB' multiplet (3.3 ppm) for the CH_2 groups, whilst *(6a)* shows a 6H (3.05 ppm) and a 4H singlet (3.12 ppm). In the UV region (CH_3OH) *(5a)*—*(5c)* have $\lambda_{max}=288$—294 nm ($\log\varepsilon\approx 4.08$), and the tetrahydro-*v*-tetrazines *(6a)*—*(6c)*, like 2-tetrazenes *(3)*, have two maxima [270—280 ($\log\varepsilon\approx 3.7$) and 220—225 nm ($\log\varepsilon\approx 3.4$)]. The IR spectra contain intense bands in the region characteristic for azoxy (1480 and 1300 cm^{-1}) and azo compounds (1450 cm^{-1}). In the N1s-ESCA spectrum of *(5c)* the ionization typical[3] of azoxy-N atoms is present at 403 eV, whereas the reduced *(6c)* shows only a relatively sharp band at 399 eV. Finally, *Nelsen* and *Fibinger*[4] obtained *(6a)* independently in 4% yield by oxidation of the bishydrazine *(7)*, and the two samples were identical.

(6a), b. p. 85 °C/10 torr
(6b), dec. 92—94 °C
(6c), m. p. 67 °C

The route by which the oxides *(5)* are formed from the nitrosamines is at present under study; above −80 °C the solutions of the lithium derivatives[2] give intense ESR signals. Hence we are certain that decomposition occurs by way of radicals.

8-Quinolinecarboxylic Acid from 3,1-Benzoxazin-4-ones and Enamines

By *Wolfgang Steglich* and *Oswald Hollitzer*[*]

3,1-Benzoxazin-4-ones and ynamines afford 4-(dialkylamino)quinolines and 3,3-disubstituted 4(3*H*)-quinolones[1]. With enamines the reaction takes a different course: the CO_2 group is retained and 8-quinolinecarboxylic acids such as *(3)* and *(4)* are formed.

If the 2-(trifluoromethyl)-3,1-benzoxazin-4-ones *(1a)* to *(1c)*[1] are treated in ether or acetonitrile with *N,N*-diethyl-1-butenamine, the diethylammonium salts *(2)* of the 8-quinolinecarboxylic acids are precipitated after a short time; these salts are filtered off and partitioned between 1 N NaOH and ether, the free acids *(3)* being obtained by acidifying the aqueous phase. The mother liquor remaining after isolation of *(2)* contains varying amounts of the diethylamides *(5)* of *N*-(trifluoroacetyl)anthranilic

(6), R^1 = H, R^2 = Piperidino

ingly soluble acid can be obtained pure by crystallization from $CHCl_3$.

The structures of compounds *(3)* and *(4)* follow unambiguously from the analytical and spectroscopic data and, in the case of *(3a)*, was confirmed by degradation to the known 2-(trifluoromethyl)quinoline[3].

As in the ynamine reaction[1], the formation of the quinolinecarboxylic acids *(3)* and *(4)* is initiated by attack of the nucleophile on the C=N double bond, but in the present case the resulting betaine *(7)* can, after ring-opening, be converted by a proton shift into a phenylazabutadiene *(9)* which affords the products on disrotatory 6π-ring closure and ejection of amine[4].

This differs from other reactions of similar type[5,6] in that the quinoline system is rapidly produced, even on ice-cooling, probably due to conjunction of several factors. It is conceivable that in the transformation *(7)*→*(8)* the resulting carboxylate group favors formation of the (*E*)-configuration that is necessary for the electrocyclic ring closure and that the ring closure is assisted by hydrogen bonding and the influence of the CF_3 group[7].

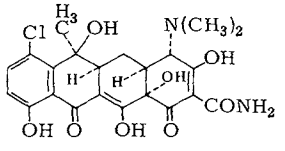
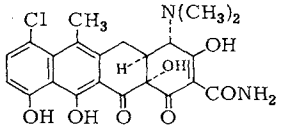
Total Synthesis of Anhydroaureomycin[**]

By *Hans Muxfeldt*, *Heinrike Döpp*, *John E. Kaufman*, *Joachim Schneider*, *Philip E. Hansen*, *Andrew Sasaki*, and *Timothy Geiser*[*]

Anhydroaureomycin *(2)*, which is readily accessible from aureomycin *(1)*[1] by treatment with mineral acids[2], can



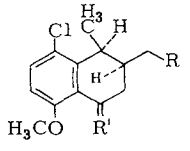
(1)

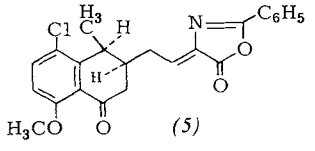


(2)

be reconverted into aureomycin *(1)* by a remarkable photooxidation and subsequent reduction[3]. Thus, a total synthesis of *(1)* can be limited to a total synthesis of *(2)*.

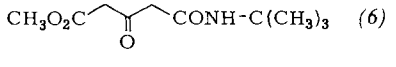
Reduction of the racemic nitrile *(3)*[4] by hydridodiisopropylaluminum and subsequent acid work-up affords the aldehyde *(4)* (m. p. 120—124 °C) which undergoes condensation with hippuric acid and lead acetate in acetic anhydride to yield the oxazolone *(5)* [m. p. 157—159 °C; UV (acetonitrile): $\lambda_{max}(\varepsilon)=222$ (33300), 242 (16600), 255 (10300), and 299 nm (26100)].





(5)

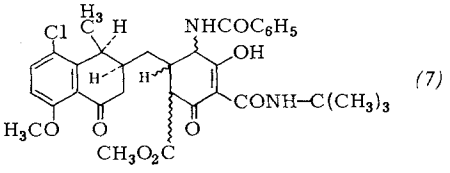
(3), R = CN, R' = $-O-CH_2-CH_2-O-$
(4), R = CHO, R' = O



(6)

A further structural unit used was the methyl *N-tert*-butyl-3-oxoglutaramate *(6)*; this compound was obtained (m. p. 65—66 °C) from dimethyl 3-oxoglutarate with *tert*-butylamine and *p*-toluenesulfonic acid in boiling dioxane.

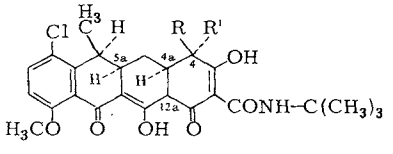
Addition of *(5)* and *(6)* to a boiling mixture of tetrahydrofuran and ether containing one equivalent of sodium hydride yields, analogously to reactions described previously[5], a mixture of stereoisomers and tautomers *(7)*. The structure of this mixture follows from analytical data, the IR spectrum ($\lambda_{max}=3.30$, 5.71, 5.95, and 6.30 µm in $CHCl_3$) and the UV spectrum [$\lambda_{max}(\varepsilon)=227$ (31400), 278 (16000), and 326 nm (3700) in 0.01 N methanolic NaOH].



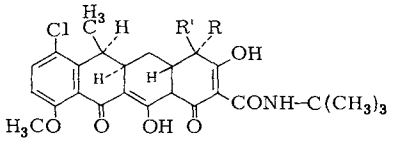
(7)

When an excess of sodium hydride is used for a reaction time of 48 h, further condensation of the intermediate compounds *(7)* affords a 76% yield of a stereoisomeric and tautomeric mixture of the tetracyclic compounds *(8)*, *(9)*, *(10)*, and *(11)*. That these are tetracyclic products follows from the analytical data of the mixture and its characteristic absorption [λ_{max} in methanolic sodium borate solution at 462 nm ($\varepsilon=50000$), absorption of fully conjugated borate complexes]. All four isomers could be isolated pure by crystallization and chromatography and then characterized. An appreciably easier isolation of *(9)* and *(11)* was achieved on finding that *(8)* epimerized to *(9)*, and *(10)* to *(11)*, on dissolution in pyridine under nitrogen. The mixture of *(9)* and *(11)* was readily separated by crystallization and subsequent chromatography of the mother liquors on silica gel.

A good indication of the configuration at C-4a in *(8)* and *(9)*, and also in *(10)* and *(11)*, was provided by the electronic spectra of these compounds in 0.01 N methanolic sodium hydroxide. In alkaline solution, *(8)* and *(9)* can pass into a coplanar, torsion-free, fully conjugated



(8), R = $NHCOC_6H_5$, R' = H
(9), R = H, R' = $NHCOC_6H_5$



(10), R = $NHCOC_6H_5$, R' = H
(11), R = H, R' = $NHCOC_6H_5$

anion by enolization, but in *(10)* and *(11)* C-12a remains tetrahedral because complete conjugation involves torsional strain (Fig. 1).

Further, an optically active compound (+)-*(12)* that is analogous to *(11)* in the configuration of its ring system

[**] Tetracyclines, Part 8. — Part 7: *H. Muxfeldt, G. Hardtmann, E. Vedejs, F. Kathwala*, and *J. B. Mooberry*, J. Amer. Chem. Soc. *90*, 6534 (1968). This work was carried out at the University of Wisconsin, Madison, Wis., at Cornell University, Ithaca, N.Y., and at Universität Stuttgart. Financial support from the National Institutes of Health, the National Science Foundation, the Hoffman La Roche Anniversary Foundation, Chas. Pfizer & Co., Inc., and the Deutscher Akademischer Austauschdienst is gratefully acknowledged.

gives a CD spectrum differing unambiguously from that of (−)-6-demethyl-6-deoxytetracycline *(13)*[6].

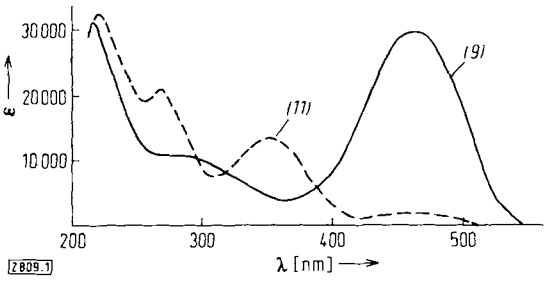

Fig. 1. Electronic spectra of *(9)* and *(11)* in 0.01 N methanolic NaOH.

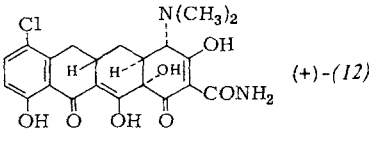
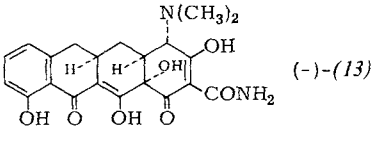
Information about the configuration at C-4 in *(8)* and *(11)* is provided by the ^{1}H-NMR spectra. *(10)*, 4-H in $CDCl_3$: $\tau = 4.5$ (q), $J = 4$ Hz and in CF_3COOD: $\tau = 4.6$ (d), $J = 4$ Hz; *(11)*, 4-H in CF_3COOD: $\tau = 5.2$ (d), $J = 12$ Hz. These results show that in *(10)* 4-H and 4a-H must be equatorial and in *(11)* *trans*-diaxial. *(8)* and *(9)* behave analogously to *(10)* and *(11)*, respectively. Thus both *(9)* and *(11)* can be converted into anhydroaureomycin, but here we shall describe only the reactions leading from *(11)* to *(2)*.

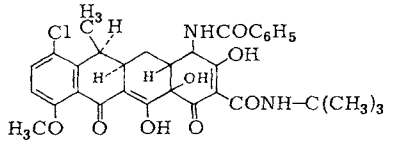


(+)-*(12)*

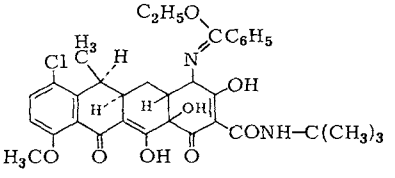


(−)-*(13)*

For *cis*-hydroxylation[7] on C-12a, oxygen was passed through a glass frit into a vigorously stirred solution of *(11)* in dimethylformamide and triethyl phosphite at −9 °C. After a few minutes 1.2 equivalents of potassium *tert*-butoxide was added and the whole was treated with oxygen for a further 20 min. On acidic work-up, a 76% yield of *(14)* was isolated and characterized by its ^{1}H-NMR spectrum and the UV spectra at various pH's that were typical of 12a-*cis*-hydroxylated compounds. ^{1}H-NMR spectrum: 4-H in $CDCl_3$, pyridine and D_2O: $\tau = 4.95$ (d), $J = 11.5$ Hz. UV spectrum in 0.1 M methanolic sodium borate solution: $\lambda_{max}(\varepsilon) = 218$ (30500), 269 (17200), and 338 nm (12750); in 0.01 N methanolic HCl: 220 (29700), 268 (23750), and 356 nm (15100); in 0.01 N methanolic NaOH: 218 (29000), 268 (19150), and 367 nm (9140).



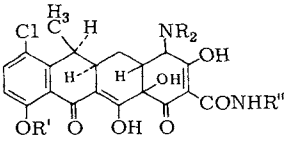
(14)



(15)

Fission of the amide group on C-4 of *(14)* by alkylation with *Meerwein*'s reagent[8] and subsequent hydrolysis of the benzimidate *(15)* by dilute HCl under the usual conditions proved very unsatisfactory; on the one hand, the tetrafluoroboric acid present prevented complete alkylation of *(14)* and on the other there occurred a partial acid-catalyzed epimerization of *(15)*; and finally the hydrolysis of *(15)* was not homogeneous. Only poor yields of the amine *(16)* and its C-4 epimer resulted, while fission back to the amides predominated.

The following method gave approximately quantitative yields of *(16)*:*(14)* was alkylated with *ca.* 5 equivalents of *Meerwein*'s reagent at room temperature in methylene chloride containing an excess of tetra-*N*-methyl-1,8-naphthalenediamine[9], the base then being precipitated as sparingly soluble tetrafluoroborate. After the alkylation the reaction mixture was treated with anhydrous methanol and worked up after a few hours. Naturally, none of the amide *(14)* is formed under these conditions and, further, epimerization of *(15)* is hindered in the acid-free medium[10]. *(16)* can be isolated easily as its crystalline tetrafluoroborate salt, from which it is liberated by sodium



(16), R = H, R' = CH_3, R'' = $C(CH_3)_3$
(17), R = R' = CH_3, R'' = $C(CH_3)_3$
(18), R = CH_3, R' = R'' = H

acetate. The configuration on C-4 of *(16)* follows from that of the reaction products. Mass spectrum of *(16)*: $m/e = 504$ (M).

Methylation of the 4-amino group by the usual alkylation agents such as methyl iodide affords only mixtures of *N*-mono-, *N*,*N*-di-, and *N*,*N*,*N*-tri-methyl derivatives which are difficult to separate, but *(17)* is obtained in good yield when *(16)* is treated with sodium trihydridocyanoborate[11] in the presence of an excess of *Hünig*'s base and formaldehyde. Acidic work-up affords the crystalline hydrochloride of *(17)*. Mass spectrum of *(17)*: $m/e = 532$ (M).

The protecting groups R' and R'' in *(17)* were removed by merely heating the compound in 48% HBr at 100 °C; during evaporation the hydrobromide of *(18)* crystallized from the reaction mixture. Mass spectrum of *(18)*: $m/e = 462$ (M). Electronic spectra in 0.1 M methanolic sodium borate solution: $\lambda_{max}(\varepsilon) = 220$ (13900), 244 (15800), 268 (12500), and 384 nm (16240); in 0.01 N methanolic NaOH: 228 (13800), 244 (15600), 264 (13600), and 386 nm (14900); in 0.01 N methanolic HCl: 231 (14300), 268 (17000), 347 (11800), and 368 nm (11800). The absorption at $\tau = 5.98$ in the ^{1}H-NMR spectrum is characteristic of *trans*-4-H/4a-H in tetracyclines[12].

(18) is spontaneously dehydrated by dichlorodicyanobenzoquinone in dioxane[13]. The dehydration product is identical with anhydroaureomycin *(2)* in its chromatographic behavior on polyamide and distinctly different from the 4-*epi*-isomer. IR, electronic, mass, and ^{1}H-NMR spectra are also identical. Electronic spectrum in 0.01 N HCl:

$\lambda_{max}(\varepsilon)=228$ (28600), 274 (50000), 337 (4300), and 435 nm (8300). ^{1}H-NMR spectrum (100 MHz) in CF_3COOD: $\tau=7.32$ (s) C-6-methyl, 6.72 (s) *N*-methyl, 6.65 (s) *N*-methyl, 5.83 (d) 4-H ($J=2$ Hz)[12]. Mass spectrum: $m/e=460$ (M).

The low coupling constant of 4-H in the ^{1}H-NMR spectrum of *(2)* (whether obtained from natural or synthetic material) leads to the conclusion that *(2)* exists in a conformation in which the dihedral angle between 4-H and 4a-H lies between 65 and 105°, possibly owing to H-bonding between the nitrogen on C-4 and the OH group on C-12a.

This procedure may be regarded as a total synthesis of aureomycin *(1)* if the synthetic racemate of *(2)* can be resolved, which may be difficult because of ready epimerization at C-4.

Structural Investigations of Tellurium Subhalides: Modified Tellurium Structures

By *Rüdiger Kniep, Dietrich Mootz,* and *Albrecht Rabenau*[*]

Dedicated to Professor Georg Brauer on the occasion of his 65th birthday

Only recently has the existence of tellurium subhalides Te_yX (X = Cl, Br, or I; $y \geq 1$) been unambiguously proved[1]. We report the first investigations of the structures of these compounds. They are intended to provide information as to how the "unsaturation" with respect to tellurium is reflected in the crystal structures.

We have further prepared the compounds Te_2Cl and Te_2I[2] as additions to those reported in [1]. Single crystals of all the compounds, suitable for structure analysis, were prepared. Their lattice constants were determined by angle measurements on a diffractometer or refined from previous data[1]; the values for Te_2Cl were determined photographically. The space groups were deduced from Weissenberg photographs. The unit cell of Te_3Cl_2 was transformed in order to achieve a monoclinic angle closer to 90°.

Table 1. Tellurium subhalides: crystallographic data.

	a / α	*b* / β	*c* [Å] / γ	Space group	*Z*
Te_3Cl_2	10.137	8.651	7.075	$P2_1/n$	4
	—	100.86°	—		
Te_2Cl	14.82	12.81	4.00	Pnam	8
Te_2Br	14.922	12.842	4.004	Pnam	8
Te_2I	15.294	13.694	4.123	Pnam	8
TeI	9.957	7.991	8.214	P1, P$\bar{1}$	8
	104.38°	90.13	102.91°		
Te_xI	15.384	4.179	12.001	C2, Cm	16
	—	128.09°	—	C2/m	atoms

As shown in Table 1, the subhalides of general composition Te_2X form an isotypic series. An orthorhombic structure had been reported for a 1:1 compound in the system tellurium-iodine[3]; however, the sample in question was probably triclinic TeI (see Table 1), as suggested by its orthorhombic pseudosymmetry, reinforced by frequent twinning, and a great similarity in lattice dimensions.

For the crystal structure analysis of Te_3Cl_2 we determined the intensities of 2610 independent reflections with $Mo_{K\alpha}$ radiation ($\theta_{max}=35°$) on an automatic single-crystal diffractometer; the *R* factor is at present 9.2% with corrections for absorption and extinction not being applied.

Figure 1 shows the building unit of this structure, an infinite tellurium screw, such as is present with a simpler conformation and higher symmetry in elemental tellurium. Each third Te atom binds two Cl atoms axially, thereby giving the composition Te_3Cl_2. The coordination of this

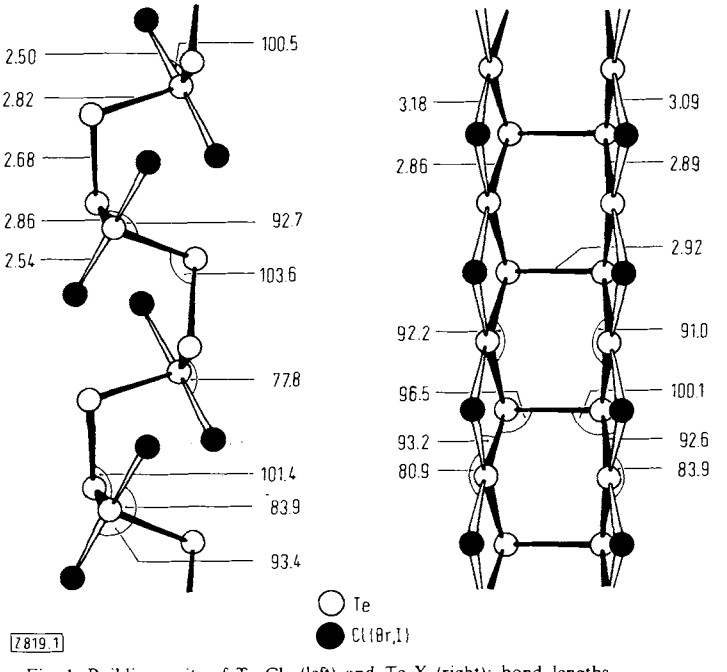

Fig. 1. Building units of Te_3Cl_2 (left) and Te_2X (right); bond lengths [Å] and bond angles [ ]. The data for Te_2X are those for Te_2I.

Te atom is trigonal-bipyramidal when the remaining lone pair is taken into account; analogous coordination of tellurium has been reported for, *e.g.*, the eight-membered rings of Cl_2TeS_7 and Br_2TeS_7[4]. The bond lengths and

[*] Dipl.-Chem. R. Kniep, Prof. Dr. D. Mootz, and Prof. Dr. A. Rabenau
Max-Planck-Institut für Festkörperforschung
7 Stuttgart 1, Postfach 1099 (Germany)

angles between Te atoms are similar to those in elemental tellurium. The shortest atom separations between neighboring building units are 3.4 Å.

Structure analyses for the isotypic halides Te_2X were carried out with Te_2Br and Te_2I. 748 reflections for the bromide ($\theta_{max}=25°$) and 1255 reflections for the iodide ($\theta_{max}=30°$) were measured with $Mo_{K\alpha}$ radiation on a diffractometer; the R factors were 7.5% and 8.1%, respectively, after anisotropic refinement. The data for the iodide were corrected for absorption.

Figure 1 also shows the macromolecular structural unit of this structure type. Here too a skeleton of Te atoms lies parallel to the crystallographic c-axis, this time with bridging halogen atoms on the edges[5]. All the atoms are in mirror planes perpendicular to the c-axis. The two Te atoms with bonds to halogen atoms show planar, approximately square coordination; this, and bivalent halogen atoms, were also found for the $(TeBr)_2$ four-membered ring of an N,N'-ethylenethiourea-$TeBr_2$ complex[7]. The two remaining independent Te atoms of the building unit are bonded only to tellurium in a trigonal-pyramidal arrangement.

Their relation to the structure of the semiconducting element makes the tellurium halides[8] a compound class that also has physical interest.

Reactions of Hexachlorodisilane with Methylene and Dichlorocarbene[**]

By *Manfred Weidenbruch* and *Claude Pierrard*[*]

During investigation of the chemical and thermal behavior of systems containing silicon-silicon bonds we have found that hexachlorodisilane *(1)* reacts smoothly with the dichlorocarbene generator phenyl(trichloromethyl)mercury[1] in the presence of sodium iodide[2] to yield pentachloro(trichloromethyl)disilane *(2)*:

$$\underset{(1)}{Cl_3Si{-}SiCl_3} + C_6H_5{-}Hg{-}CCl_3 \longrightarrow \underset{(2)}{Cl_3C{-}\overset{Cl}{\underset{Cl}{Si}}{-}SiCl_3} + C_6H_5HgCl$$

The molecular ion does not appear in the mass spectrum of *(2)* determined with 70 eV excitation energy, an effect observed also for other polyhalodisilanes, being replaced by a fragment poorer by one Cl atom, namely $Si_2CCl_7^+$ (m/e for $^{35}Cl=313$), along with the ions $Si_2Cl_5^+$, $SiCCl_5^+$, $SiCCl_4^+$, $SiCCl_3^+$, $SiCl_3^+$, CCl_3^+, $SiCl_2^+$, and CCl_2^+.

The reaction is remarkable insofar as no insertion of halocarbenes into Si—Cl bonds had been achieved previously[3]. The CCl_2-transfer is proved by the reaction of *(1)* with (bromodichloromethyl)phenylmercury[1-4] carried out under the same conditions since here too we were able to isolate only *(2)* and not the possible transmetalation product (bromodichloromethyl)pentachlorodisilane.

$$(1) + C_6H_5{-}Hg{-}CCl_2Br \longrightarrow (2) + C_6H_5HgBr$$

Reaction of *(1)* with sodium trichloroacetate, which has also been proposed as a source of dichlorocarbene[5], in tetrachloroethane to aid dissolution affords only a mixture of chloro(trichloroacetoxy)disilanes. Carrying out this reaction without a solvent, in a boiling excess of *(1)*, leads to pyrolysis and rearrangement that provide linear perchloropolysiloxanes *(3)* of which the members with $n=1$ [b.p. ≈ 50 °C/0.8 torr, mass spectrum: $m/e=361$ ($Si_3{}^{35}Cl_7O_2^+$) along with $Si_2Cl_5O^+$, $Si_2Cl_4O^+$, $Si_2Cl_3O^+$, $SiCl_3^+$] and $n=3$ [b.p. ≈ 100 °C/0.5 torr, mass spectrum: $m/e=589$ ($Si_5{}^{35}Cl_{11}O_4^+$) along with $Si_4Cl_9O_3^+$, $Si_3Cl_7O_2^+$, $Si_2Cl_5O^+$], predominate.

$$(1) + n\ NaO_2C{-}CCl_3 \xrightarrow{C_2H_2Cl_4} \begin{cases} Si_2(O_2C{-}CCl_3)_nCl_{6-n} + n\ NaCl \\ Cl_3Si(OSiCl_2)_nOSiCl_3 \quad (3) \end{cases}$$

Methylene, formed under Cu-catalysis from diazomethane *(4)*, reacts with *(1)* in ether between −40 and −30 °C to afford pentachloro(chloromethyl)disilane *(5)*, b.p. 20 to 25 °C/0.5 torr, which can be separated from unchanged *(1)* only with difficulty because of their similar volatilities; mass spectrum: $m/e=245$ ($Si_2CH_2{}^{35}Cl_5^+$).

On reaction with more *(4)*, insertion of CH_2 into a second Si—Cl bond gives 1,1,2,2-tetrachloro-1,2-bis(chloromethyl)disilane *(6)* [b.p. 65—68 °C/0.3 torr, ^{1}H-NMR[6]: $\delta=3.35$ ppm (s), mass spectrum: $m/e=259$ ($Si_2C_2H_4{}^{35}Cl_5^+$)]; its constitution is proved by its reaction with methylmagnesium iodide to give 1,2-bis(chloromethyl)-1,1,2,2-tetramethyldisilane *(7)* [b.p. 65 °C/2 torr; ^{1}H-NMR: $\delta=0.2$ (12 H/s) and 2.9 ppm (4 H/s)], which had already been prepared by a different route[7].

$$(1) + CH_2N_2 \xrightarrow[-N_2]{Cu} \underset{(4)}{} (ClCH_2)Cl_2Si{-}SiCl_3 \xrightarrow[-N_2]{+(4)} (ClCH_2)Cl_2Si{-}SiCl_2(CH \quad (6)$$

$$(5)$$

$$Cl(CH_3)_2Si{-}Si(CH_3)_2Cl \xrightarrow{+(4)} ClCH_2(CH_3)_2Si{-}Si(CH_3)_2CH_2Cl$$

$$(8) \qquad (7)$$

Attempts to convert 1,2-dichloro-1,1,2,2-tetramethyldisilane *(8)* into *(7)* by reaction with *(4)* were unsuccessful. Analogous behavior was observed with the series of chloro(methyl)silanes, the reactivity towards *(4)* decreasing with increasing number of methyl groups and finally disappearing[3].

Institut für Anorganische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Retention of the silicon-silicon bonds in all the carbene reactions described above was demonstrated, not only by analytical and spectral data of the isolated products, but also by spontaneous evolution of hydrogen on alkaline hydrolysis and reduction of Ag^{I} ions to metallic silver.

Pentachloro(trichloromethyl)disilane (2):

Phenyl(trichloromethyl)mercury (15 g, 38 mmol) was heated with hexachlorodisilane *(1)* (21 g, 77 mmol) and NaI (0.5 g) under argon for 6 h at 120 °C (bath temperature). The solid that separated was filtered off after addition of light petroleum. Fractional distillation of the filtrate gave pure *(2)*, b. p. 68 °C/0.6 torr (32% yield, 4.2 g), along with *(1)*, b. p. 25 °C/3 torr. The product *(2)* (4.0 g) was also obtained analogously from (bromodichloromethyl)-phenylmercury (15 g) and *(1)* (21 g).

IR (capillary; cm^{-1}): 860 s, 790 m, 732 vs, 702 s, 610 vs, 590 vs, 580 vs, 525 s, 498 s, 458 s, 448 m, 420 s, 360 s, and 342 m.

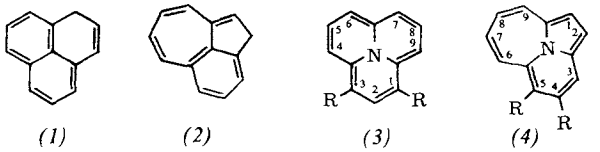
Diethyl Cycl[4.3.2]azine-4,5-dicarboxylate[**]

By *Wilhelm Flitsch* and *Bernhard Müter*[*]

The potential formation of a 12π electron periphery in the tricyclic arenes *(1)* and *(2)* and in the corresponding cyclazines *(3)* and *(4)*, respectively, confers a certain degree of similarity to antiaromatic systems on these compounds.

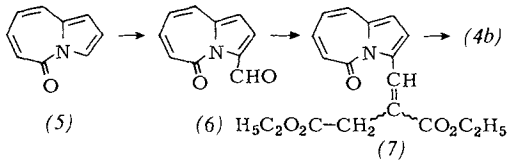
Both phenalene *(1)* and the isoelectronic compound 2*H*-benz[*cd*]azulene *(2)* possess a nonbonding molecular orbital[1,2b] so that, in spite of differing symmetries[3], the two compounds can form cations, anions, and radicals[2]. Symmetry-based differences between the two resonance systems appear mainly in the chemical properties of the compounds[2].



(1) *(2)* *(3)* *(4)*

(a), R = H; *(b)*, R = $CO_2C_2H_5$

Leaver et al.[4] described the cycl[3.3.3]azine *(3a)*, corresponding to the anion of *(1)*, and found it to be paratropic, in contrast to earlier expectations. A comparison of tricyclic arenes and hetarenes having a 12π periphery requires cycl-[4.3.2]azine *(4a)*, corresponding to the anion of *(2)*, the first derivative of which will now be described.



(5) *(6)* $H_5C_2O_2C-CH_2$ $CO_2C_2H_5$ *(7)* *(4b)*

The synthesis of the ester was accomplished starting from 3a-azaazulen-4-one *(5)* which we obtained by Wittig olefination of 2-pyrrolecarbaldehyde with 3-methoxycarbonyl-2-propenylidenetriphenylphosphorane and subsequent base-catalyzed cyclization[5]. A Vilsmeier reaction of *(5)* afforded *(6)* [yellow needles, m. p. 112 °C from benzene, 70% yield, IR: $\nu_{CO} = 1665, 1650\,cm^{-1}$] from which we obtained *(7)* [yellow oil, 50% yield, IR: $\nu_{CO} = 1735, 1710, 1670\,cm^{-1}$] by heating for 24 h with 1,2-bis(ethoxycarbonyl)ethylidenetriphenylphosphorane[7] in benzene. Two hours' heating in pyridine/piperidine (10:1) resulted in ring closure to give diethyl cycl[4.3.2]azine-4,5-dicarboxylate (diethyl 9b-azabenz[*cd*]azulene-4,5-dicarboxylate) *(4b)* [violet needles, m. p. 87 °C from light petroleum, 50% yield, IR: $\nu_{CO} = 1726, 1709\,cm^{-1}$][6].

The ring proton signals appear at very high field in the NMR spectrum of *(4b)*, in spite of the two ester groups. The influence of the ester groups on the chemical shifts becomes apparent on comparison of the compounds *(3a)* and *(3b)* (Table 1).

Table 1. ^{1}H-NMR spectra (τ values) of compounds *(3a)* [4] in $[(CH_3)_3Si]_2O$, *(3b)* [4] in $CDCl_3$, and *(4b)* in CS_2.

Cpd.	1-H	2-H	3-H	4-H	5-H	6-H	7-H	8-H	9-H
(3a)	7.93	6.35	7.93	7.93	6.35	7.93	7.93	6.35	7.93
(3b)	—	2.84	—	3.23	3.86	4.77	4.77	3.86	3.23
(4b)	4.82	4.94	4.00	—	—	from 5.52 to			6.52

Like the isomeric cycl[3.3.3]azines, the cycl[4.3.2]azines are strongly paratropic. Symmetry-based differences between the two systems will only be clearly apparent when the NMR spectrum of *(4a)* becomes available. Nevertheless the nonuniform peripheral charge distribution expected for the nonalternant system *(4)* can already be seen from the properties of the two ester groups: two ν_{CO} bands are observed in the IR spectrum, and only one ester group undergoes transesterification on treatment with 5% methanolic sodium methoxide solution at the boiling temperature.

We were able to prepare a further cycl[4.3.2]azine derivative *(9)* in 10% yield by reaction of 4-cyanomethylen-3a-azaazulene *(8)*, obtainable from *(5)* and cyanomethylenetriphenylphosphorane[5], with oxalyl chloride in benzene (12 h, 25 °C). Compound *(9)* decomposes without melting

above 300 °C. NMR signals at $\tau = 1.7$—2.5 correspond to the ring protons. The position of the ν_{CO} bands (1645, 1610 cm^{-1}) accordingly indicates strong interaction between the CO groups and the π electrons of the ring system.

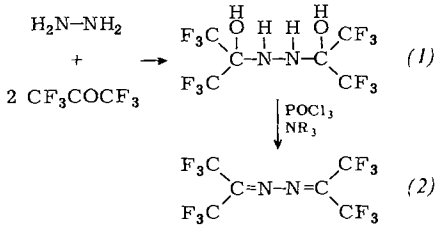
A Simple Synthesis of Hexafluoroacetone Azine[**]

By *Klaus Burger, Josef Fehn*, and *Willy Thenn*[*]

The syntheses previously reported for perfluorinated azines[1,2], in particular for hexafluoroacetone azine *(2)*[3-5], are complicated and proceed in several steps.

On direct treatment of hydrazine or hydrazine hydrate with an excess of hexafluoroacetone we obtained the diadduct *(1)*, which afforded hexafluoroacetone azine *(2)* by loss of water on treatment with phosphorus oxide trichloride and a tertiary amine (*e.g.* quinoline) at 0—15 °C. All the properties of the product agree with those previously recorded[3].



Hexafluoroacetone azine (2)

Hydrazine (3.2 g, 100 mmol) or its hydrate (5.0 g, 100 mmol) in methylene dichloride (100 ml) is treated with an excess of hexafluoroacetone with vigorous stirring in a closed apparatus and under a CO_2-cooled reflux condenser. The reaction is exothermic; cooling is necessary if the hexafluoroacetone is introduced very rapidly. Then the volatile products are removed at water-pump vacuum. The residue is added to ice-cooled quinoline (131 g, 1 mol) and thereafter treated with $POCl_3$ (38.1 g, 250 mmol) with vigorous stirring. The mixture is finally left at room temperature for 4—6 h and the product *(2)* is removed by condensation in a high vacuum. Purification is accomplished by fractional condensation or distillation through a short column. Yield 21.4 g (65%) of *(2)*.

Synthesis of 1,2λ^5-Azaphosphoridines[1][**]

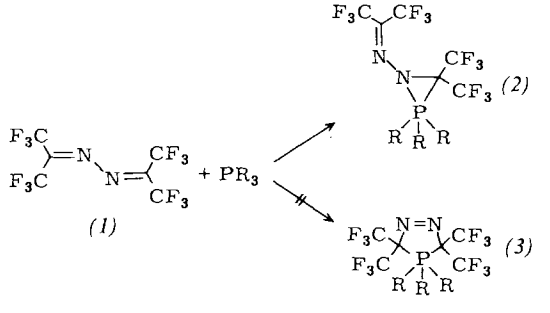
By *Klaus Burger, Josef Fehn*, and *Willy Thenn*[*]

Addition of criss-cross type is characteristic of azines[2] derived from aromatic aldehydes, cyclohexanone, cyclopentanone[3,4], or hexafluoroacetone[5], but examples of 1,2-[6] and 1,4-addition[7] are also known. A five-membered ring structure has been ascribed to an adduct of an azine and phosphorochloridic ester[8].

In anhydrous hexane at 0 °C hexafluoroacetone azine *(1)*[9] reacts with phosphorous esters or tris(dimethylamino)-phosphane to yield 1:1 adducts *(2)* (Table 1). These compounds have considerable thermal stability.

The ^{1}H-NMR spectra of *(2a)* and *(2b)* show signals for three equivalent *P*-alkoxy groups [(CCl_4, internal TMS) *(2a)*: $\delta = 3.75$ ppm (d), $J_{PH} = 11.7$ Hz]. The ^{19}F-NMR spectra [(CF_3COOH external) *(2a)*: $\delta = -0.32$ (m), -12.45 ppm (broad); *(2b)*: -0.78 (m), -12.65 ppm (broad)] also lie in the expected region[10]. These data contraindicate formation of the products by 1,4-addition *(3)* and suggest 1,2-addition to afford *(2)*.

The formation of the hitherto unrecorded 1,2λ^5-azaphosphoridine system[11] is further indicated by the ^{13}C-NMR spectra[12]. An unambiguous molecular peak, absence of the fragment $m/e = [M - N_2]^+$, and occurrence of the fragment $m/e = [M - (CF_3)_2CN]^+$ of intensity 100%, for *(2b)*, $m^* = 220.4$ (494→330), are further arguments in favor of structure *(2)*.



1-(Hexafluoroisopropylimino)-2,2,2-trimethoxy-3,3-bis(trifluoromethyl)-1,2λ^5-azaphosphoridine (2a)

Trimethyl phosphite (2.48 g, 20 mmol) is slowly added dropwise to a stirred solution of hexafluoroacetone azine *(1)*

Diradicals as Intermediates in Chemical Reactions; 2,3-Dimethylene-1,4-cyclohexadiyl[1]

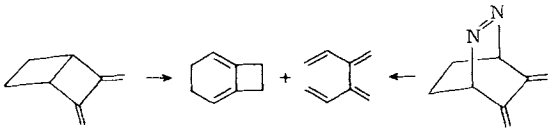
By *Wolfgang R. Roth* and *Gerhard Erker*[*]

Tetramethyleneethane *(1)* has been repeatedly postulated as an intermediate in thermal rearrangements[3], and both a planar and an orthogonal arrangement have been discussed for its structure[4]. We have been interested in a derivative of *(1)*, namely 2,3-dimethylene-1,4-cyclohexadiyl *(2)*, in which the ethano bridge makes a planar or nearly planar geometry compulsory.

(1) 
 *(2)*

The anhydride of bicyclo[2.2.0]hex-5-ene-2,3-dicarboxylic acid[5] was converted into 2,3-dimethylenebicyclo[2.2.0]-hexane *(3)* by successive catalytic hydrogenation, reduction to the diol, conversion into the ditosylate, and elimination by potassium *tert*-butoxide/DMSO[6]. In the gas phase at 110 °C *(3)* rearranges to a mixture (67:33) of bicyclo[4.2.0]octa-1,5-diene *(4)*[7] and 3,4-dimethylene-1,5-hexadiene *(5)*[8].

A mixture of products of precisely the same composition was obtained on gas-phase thermolysis (110 °C) of 5,6-dimethylene-2,3-diazabicyclo[2.2.2]oct-2-ene *(6)*, which was obtained (m.p. 40 °C) in *ca.* 8% yield from dimethyl 1,2-dihydrophthalate through intermediacy of the diol, ditosylate, and *N*-phenyltriazolinedione adduct, the last-mentioned intermediate being subjected successively to catalytic hydrogenation, alkaline hydrolysis, elimination, and oxidation by $CuCl_2$.



(3) *(4)* *(5)* *(6)*

An intermediate formation of *(3)* during decomposition of *(6)* can be excluded because, although *(3)* and *(6)* have comparable thermal stability, *(3)* is not formed on thermolysis of *(6)* in either a stationary or a flow system (detection by VPC).

The formation from either *(3)* or *(6)* of exactly the same product mixture, whose composition is independent of the reaction temperature and the pressure, indicates a common intermediate to which we ascribe the structure of the diradical 2,3-dimethylene-1,4-cyclohexadiyl *(2)*.

Unlike the gas-phase reaction, heating *(3)* or *(6)* at 110 °C in dilute cyclohexane solution affords mainly (*ca.* 65%) the dimers of *(2)*, accompanied by *ca.* 5% of the product

(3) →  ← *(6)*

(7) *(8)*

mixture *(4)* + *(5)* (67:33) and *ca.* 30% of polymer. The two main products of the dimer fraction, amounting together to about 80%, were isolated by gas chromatography; on the basis of their spectroscopic properties they are regarded as tricyclo[10.4.0.$0^{4,9}$]hexadeca-4,8,12,16-tetraene *(7)* and 15-methylenetricyclo[9.3.1.$0^{3,8}$]pentadeca-3,7,11-triene *(8)*[9].

The same dimers, free from the rearrangement products *(4)* and *(5)*, were formed on photolysis (Philips HPK 125, Pyrex filter) of *(6)* (0.1% solution in pentane), together with polymers.

On irradiation of a 1 M solution of *(6)* in hexafluorobenzene at −180 °C in an EPR spectrometer a progressively broadening singlet is overlaid by a triplet spectrum that can be ascribed to *(2)*: A six-line spectrum (D=0.0204 cm^{-1}; E=0.00159 cm^{-1}) appears centered at 3300 gauss and the (Δm=2) transition with lower intensity at 1650 gauss[10].

This triplet species observed in the EPR spectrum seems to be responsible for dimer formation. Thus, if either *(3)* or *(6)*, dissolved in hexachlorobutadiene, is thermolyzed in the preheated probe of an NMR instrument, intense emission signals corresponding to the absorption signals of the dimers are observed. The same nuclear polarized spectra are recorded on photolysis of *(6)*, in solution in hexachlorobutadiene, if this is carried out in the NMR apparatus[11].

[*] Prof. Dr. W. R. Roth and Dipl.-Chem. G. Erker
Lehrstuhl für Organische Chemie I der Universität
4630 Bochum, Universitätsstrasse 150 (Germany)

A necessary condition for the occurrence of the CIDNP signals is that at least one reactant in the dimer formation shall be in a triplet state[12]. In view of the EPR experiments the intermediate *(2)* can fill this role. The second reactant can be either a similar triplet molecule or a molecule of starting material. Indications that the dimerization occurs preferentially between two triplet molecules are provided by the facts that the CIDNP signals appear only in emission[11] and further that on thermolysis or photolysis of *(3)* or *(6)*, respectively, the triplet diradical cannot be trapped by 1,3-cyclohexadiene or 1,2-dimethylenecyclohexane.

That *(2)* reacts differently according to whether it is produced in the gas phase or in solution may be an expression of a difference in spin multiplicities. In the gas phase the conversion into the triplet state occurs only slowly and cannot compete with the rate of formation of *(4)* and *(5)*; but in solution the intersystem crossing probability is very much greater and we observe the reactions of the triplet.

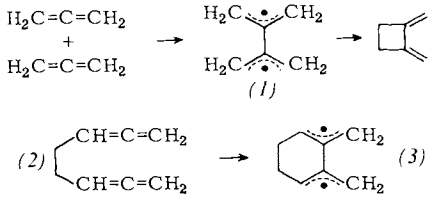
Mechanism of Allenic Dimerization

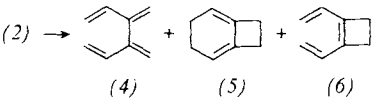
By *Wolfgang R. Roth*, *Margerita Heiber*, and *Gerhard Erker*[*]

Tetramethyleneethane *(1)* has been repeatedly postulated as an intermediate in allenic dimerization[1]. We have sought proof of this hypothesis in the case of 1,2,6,7-octatetraene *(2)*, which if it reacts analogously should give rise to the diradical 2,3-dimethylene-1,4-cyclohexadiyl *(3)*. The behavior of *(3)* in the gas phase and in solution has already been described[2].



[*] Prof. Dr. W. R. Roth, Dipl.-Chem. M. Heiber, and Dipl.-Chem. G. Erker
Lehrstuhl für Organische Chemie der Universität
4630 Bochum, Universitätsstrasse 150 (Germany)

According to *Skattebøl* and *Solomon*[3], *(2)* rearranges at 310 °C to 2,3-dimethylene-1,5-hexadiene *(4)*. We have now observed that thermolysis of *(2)* in the gas phase at 120 °C leads, not only to *(4)*, but also to bicyclo[4.2.0]octa-1,5-diene *(5)* and 1,2-divinyl-1-cyclobutene *(6)*[4]. The rearrangement is strictly first order and is characterized by the activation parameters $E_a = 24.8 \pm 0.2$ kcal mol^{-1} and $A = 0.9 \times 10^{10}\,s^{-1}$.



The relative concentrations of the rearrangement products are independent of the reaction temperature (80—150 °C) but not of the pressure. Whereas *(4)* is formed almost exclusively below 10^{-2} torr, yet at *ca.* 1 torr product ratios of *ca.* 60:25:15 are observed for the isomers *(4)*, *(5)*, and *(6)* and are shifted in favor of *(5)* by increasing pressures, so that in solution (infinitely high pressure) the ratios 40:60:0 are attained.

This pressure-dependence can be understood if the rearrangement of *(2)* is formulated as proceeding *via* a vibrationally excited intermediate to which we assign the structure *(3)*[5]. If the intermediate is able to get rid of its excess energy sufficiently rapidly by collision (high pressure), then we find that the ratio for *(4)*:*(5)* is very close to that expected from *(3)* which is 33:67[2]. As the pressure is lowered, *(3)* transfers increasing amounts of its excess energy to its rearrangement products *(4)* and *(5)*, which, insofar as they are not deactivated by collision, can either regenerate *(3)* or afford divinylcyclobutene *(6)*.

As shown in independent experiments, *(6)* rearranges at 170 °C to a mixture of *(4)* and *(5)*, and at 250 °C *(5)* passes irreversibly into *(4)*. The formation of *(6)* from *(4)* and/or *(5)* thus appears to contradict thermodynamics, but it becomes intelligible if one remembers that equilibrium conditions do not exist in this middle pressure range. At very low pressures, which provide a sufficient lifetime for the excited molecule to equilibrate, we observe the expected, almost exclusive formation of the thermodynamically most stable product *(4)*.

Thermolysis of *(2)* in solution (cyclohexane, 120 °C) affords, along with *(4)* and *(5)*, a *ca.* 30% yield of the dimerization products of the triplet diradical *(3)*[2]. If this reaction is carried out in the NMR spectrometer, CIDNP signals of the dimers appearing in emission can be recorded. That the ratio of triplet to singlet reaction[2] is distinctly less than for 2,3-dimethylenebicyclo[2.2.0]hexane or 5,6-dimethylene-2,3-diazabicyclo[2.2.2]oct-2-ene can be due to the vibrationally excited state of *(3)*, through which the lifetime of the diradical is shortened and the chance of transition to the triplet is lessened.

[4] The spectroscopic properties of all new compounds are in accord with the assigned structure.

[5] The postulated excess energy of *(3)* can be estimated at *ca.* 25 kcal mol^{-1} by consideration of the changes in bond energy (replacement of two π- by one σ-bond: 50 kcal mol^{-1}), the gain in resonance

energy (2×12 kcal mol^{-1}), the removal of allene strain (2×13 kcal mol^{-1} [6]), and the observed activation energy.

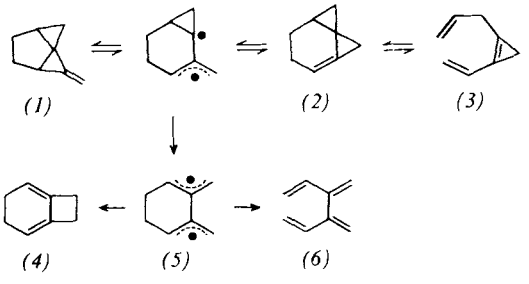
Thermal Rearrangement of 2-Methylenetricyclo[4.1.0.0^{1,3}]heptane

By *Wolfgang R. Roth* and *Gerhard Erker*[*]

Seeking methods for preparation of the diradical 2,3-dimethylene-1,4-cyclohexadiyl *(5)*[1] we became interested in the thermolysis of 2-methylenetricyclo[4.1.0.0^{1,3}]heptane *(1)*[2].

If *(1)* is heated in the gas phase (1 torr) at 120 °C, the compound is converted by a methylenecyclopropane rearrangement[3] into an isomeric compound which we regard as tricyclo[5.1.0.0^{1,3}]oct-3-ene on the basis of its spectroscopic properties. At 150 °C a third member of the equilibrium mixture appears, and this was identified as 1-allyl-2-vinyl-1-cyclopropene *(3)* which is connected with *(2)* by an intramolecular Diels-Alder reaction.



(1) *(2)* *(3)* *(4)* *(5)* *(6)*

At 180 °C the equilibrium mixture of *(1)*, *(2)*, and *(3)* rearranges irreversibly into a mixture of bicyclo[4.2.0]octa-1,5-diene *(4)* and 3,4-dimethylene-1,5-hexadiene *(6)*. Although the ratio of *(4)* and *(6)* produced is independent of reaction temperature and it is thus unlikely that *(4)* and *(6)* are formed by competing parallel reactions, yet a pronounced dependence on pressure is observed: below 10^{-2} torr the tetraene *(6)* is formed almost exclusively; as the pressure is increased the concentration of *(6)* decreases continuously in favor of *(4)*, until at 100 torr the ratio is *ca.* 1:1.

The formation of *(4)* and *(6)* can be understood if it proceeds through the intermediacy of the diradical 2,3-dimethylene-1,4-cyclohexadiyl *(5)* which, in view of the pressure-dependence of the product ratio, must apparently be formed in a vibrationally excited state. Owing to this excess energy the rearrangement products *(4)* and *(6)* can be converted one into the other, insofar as they are not deactivated by collision, so that reaction leads to preferential formation of the thermodynamically most stable product *(6)*. In the middle pressure range also 1,2-divinyl-1-cyclobutene should be formed by secondary rearrangement of the excited products; this compound is, however, unstable at 180 °C and can then no longer be detected owing to its rearrangement to *(4)* and *(6)*[4].

Further support for the intermediate occurrence of the diradical *(5)* is found in the thermolysis of *(1)* in cyclohexane: besides polymers one obtains the dimerization products of the triplet diradical; and if this reaction is carried out in the NMR spectrometer CIDNP signals of the dimers appearing in emission can be observed here also[1].

The Diradical 2,3-Dimethylene-1,4-cyclohexadiyl as Intermediate in Thermal Gas Phase Rearrangements[**]

By *Wolfram Grimme* and *Heinz-Joachim Rother*[*]

The mechanism of the dimerization of allene to 1,2-dimethylenecyclobutane appears dualistic. The stereospecificity of the reaction demonstrated for one case[1] is best accounted for by a concerted process controlled by the orbital phases[2], whereas an isotope effect[3] applying to the product distribution but not to the reaction rate indicates the intermediacy of the 2,3-dimethylenetetramethylene diradical. In the latter case stereospecificity would result only if formation and cyclization of the diradical obeyed the selection rules[2]. This condition appears to be fulfilled for the second reaction step since, in the degenerate dimethylenecyclobutane rearrangement, the 2,3-dimethylenetetramethylene diradical (also described as "tetramethyleneethane") is formed and cyclizes again conrotatorily[4]. We have studied allenic dimerization for an intramolecular case since there the 2,3-dimethylenetetramethylene diradical formed as intermediate is limited as to its geometry and the rotatory sense of cyclization.

Skattebøl and *Solomon*[5] have described the thermal rearrangement of 1,2,6,7-octatetraene *(5)* to 3,4-dimethylene-1,5-hexadiene *(8)*. They do not record any direct "dimerization product" containing the dimethylenecyclobutane partial structure but discuss the diradical 2,3-dimethylene-1,4-cyclohexadiyl *(6)* as intermediate.

We repeated the thermolysis of *(5)* in the inlet port of a gas chromatograph and found that, between 250 and 300 °C with 5 to 50% conversion, the product *(8)* is accompanied by bicyclo[4.2.0]octa-1,5-diene *(9)* [NMR (CCl_4, TMS internal): $\tau = 4.84$ (2H), 7.30 (4H), 7.88 ppm (4H); UV (in cyclohexane): $\lambda = 271$ nm ($\varepsilon = 5100$); dehydrogenated to benzocyclobutene by tetrachloro-*o*-benzoquinone]. The kinetically controlled product ratio *(8)*:*(9)* between 250 and 300 °C amounts to $(1.05 \pm 0.05):1$; it increases at higher temperatures since above 330 °C *(9)* passes into *(8)*. The diradical 2,3-dimethylene-1,4-cyclohexadiyl *(6)* can reasonably be regarded as the precursor of both products if the two extreme conformations are taken into consideration: The chair conformation with two twisted allyl groups *(6a)*, which is the primary product of union of the allene units, possesses in the two 2p-orbitals

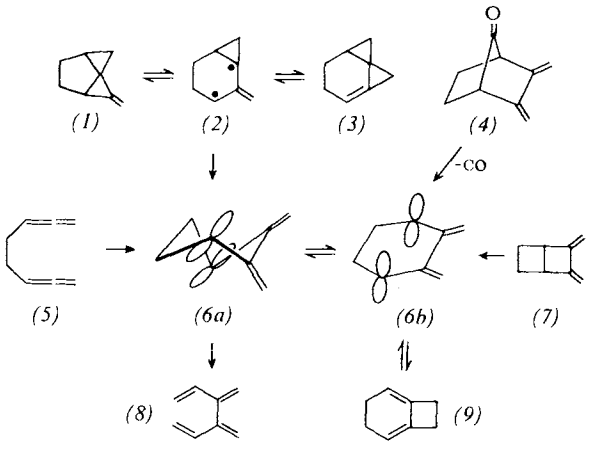
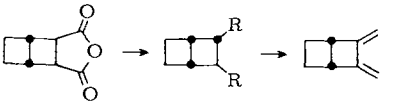
[**] We thank Prof. *W. R. Roth*, Bochum, for information about his independent work on this problem; cf. *W. R. Roth* and *G. Erker*, Angew. Chem. 85, 510 (1973); Angew. Chem. internat. Edit. *12*, 503 (1973).

of the ring that are both parallel to the 5,6-bond the prerequisite for ring opening to form *(8)*. In the planar 2,2'-bisallyl diradical *(6b)*, however, the way to conversion into *(9)* is open and should, according to theory, occur by disrotation.



To confirm the occurrence of *(6)* in thermolysis of the "bisallene" *(5)*, we attempted to produce *(6)* by a different route. We found that, on stationary thermolysis in the gas phase above 105 °C, 2-methylenetricyclo[4.1.0.0^{1,3}]-heptane *(1)*[7] is in equilibrium with tricyclo[5.1.0.0^{1,3}]oct-3-ene *(3)* [NMR (CCl_4, TMS internal): $\tau = 4.35$ (1H), 7.49 (1H, A part of an AB system), 7.7—8.3 (4H), 8.46, 8.73 (2H, AB system), 8.5—8.9 (1H), 9.10 ppm (1H, t)]. The rate constants for the initial stages of the forward and reverse reaction at 105 °C afford the equilibrium constant $K = [(1)]:[(3)] = 0.9 \pm 0.2$. The equilibration is a methylenecyclopropane rearrangement[8] whose intermediate *(2)*, being of methylenetrimethylene diradical type, would be expected to be readily convertible into the diradical *(6)* by opening of the three-membered ring. Experimentally both *(1)* and *(3)*, under the above-mentioned conditions for flow-thermolysis, gave, in addition to their equilibrium partner and a product of subsequent reaction of *(3)* (which we regard as 1-allyl-2-vinyl-1-cyclopropene), the compounds *(8)* and *(9)* in the ratio 1.05:1 as obtained previously. These results indicate that *(6)* is formed as intermediate in both reactions. It is further necessary to require that the diradical is formed in the chair conformation *(6a)* also from the equilibrium mixture of methylenespiropentanes *(1)* and *(3)*; this geometry is achieved if both cyclopropane rings of *(1)* open with one orbital remaining orthogonal to the π-system, as is the case in the methylenecyclopropane rearrangement[8].

A further precursor of the diradical *(6)* could be 2,3-dimethylenebicyclo[2.2.0]hexane *(7)*, from which the planar conformation *(6b)* could arise on disrotatory opening[6] of the central bond. We prepared this compound by analogy with the synthesis of 5,6-dimethylenebicyclo[2.2.0]hex-2-ene[9], starting from the anhydride *(10)*[10] of bicyclo[2.2.0]hexane-*exo*-2,3-dicarboxylic acid. After esterification of *(10)* with HCl in methanol, isomerization by sodium methoxide in the same solvent afforded the dimethyl *trans*-dicarboxylate *(11)*[11] (m.p. 49 °C, 90%). Reduction with $LiAlH_4$ then gave the diol *(12)* as a viscous oil (b.p. 88—90 °C/10^{-4} torr, 94%), which provided the ditosylate *(13)* (m.p. 79 °C, 80%) on esterification by *p*-toluenesulfonyl chloride in pyridine. When *(13)* was treated with potassium *tert*-buto ide in dimethyl sulfoxide and the mixture was distilled at room temperature and 0.1 torr, 2,3-dimethylenebicyclo[2.2.0]hexane *(7)*[12] collected in 78% yield in a trap cooled to −78 °C [NMR (CCl_4, TMS internal): $\tau = 4.85$ (2H, s), 5.30 (2H, s), 6.7 (2H, m), 7.2—8.2 ppm (4H, m); UV (in cyclohexane): $\lambda = 243$ ($\varepsilon = 9500$, sh), 252 (11000), 260 nm (8000, sh)].



In the inlet port of the gas chromatograph at 150 °C *(7)* rearranges to *(8)* and *(9)*. The mass balance of 80% shows that rearrangement of the compound in the gas phase is largely intramolecular, whereas dimers are formed on thermolysis in solution[13]. Between 170 and 300 °C the product ratio *(8)*:*(9)* amounts to (0.45 ± 0.02):1, *i.e.* twice as much *(9)* is formed as when starting from *(5)*. This difference accords with our assumption that *(7)* forms primarily the planar diradical *(6b)*, from which *(9)* then arises.

The diradical 2,3-dimethylene-1,4-cyclohexadiyl is thus proved to be a very reactive intermediate, which in the gas phase reacts further before reaching its conformational equilibrium, yielding the dimethylenehexadiene *(8)* from the chair conformation with twisted allyl units, and the bicyclo[4.2.0]octadiene *(9)* from the planar conformation.

Finally it should be mentioned that no conclusion can be drawn about the conformation of the diradical *(6)* when this is formed by thermal fragmentation of 2,3-dimethylene-7-norbornanone *(4)*[14] since at the required temperature (≥ 430 °C in the inlet port of the gas chromatograph) the product *(9)* is largely converted into its isomer *(8)*.

Cope Rearrangement of *cis*-Bicyclo[6.1.0]-nona-2,6-diene and Its 9-Hetero Analogs[**]

By *Wolfram Grimme* and *Klaus Seel*[*]

cis-Divinyl-substituted three-membered rings undergo the Cope rearrangement very readily, but the rate of their reaction varies characteristically with the nature of the ring atoms. For example, all attempts to synthesize *cis*-divinylcyclopropane[1] at reaction temperatures down to −40 °C gave only its rearrangement product 1,4-cycloheptadiene, and analogously an attempt to isolate 1-ethyl-*cis*-divinylaziridine[2] at 50 °C was unsuccessful. *cis*-Divinyloxirane[3], however, is known and undergoes Cope rearrangement to 4,5-dihydrooxepin only above 75 °C. A similar stabilizing effect is shown by benzene oxide[4], which opens to the seven-membered ring with a higher activation energy than is needed for dimethyl 7,7-norcaradienedicarboxylate[5]. To date there have been no quantitative results published for the differential reactivity of a series of heteroanalogous *cis*-divinyl-substituted three-membered ring compounds.

We have recently prepared *cis*-bicyclo[6.1.0]nona-2,6-diene *(2a)* by selective catalytic hydrogenation of *cis*-bicyclo[6.1.0]nona-2,4,6-triene *(1a)* protected by the 1,1,1-trifluoro-2,4-pentanedionatorhodium(I) group[6]. In spite

tfacac = 
of its *cis*-divinylcyclopropane structural unit this compound is stable at 0 °C and transforms only slowly at room temperature into *cis*-bicyclo[5.2.0]nona-2,5-diene *(3a)*[7]. This deceleration of the Cope rearrangement is caused by steric compression as well as by a lower reaction energy; it was shown by stereoselective deuteration that the transition state connects the coiled conformations of *(2a)* and *(3a)* with one another[6].

This process of selective hydrogenation, when applied to 9-oxabicyclo[6.1.0]nona-2,4,6-triene *(1b)*[8] and ethyl 9-azabicyclo[6.1.0]nona-2,4,6-triene-9-carboxylate *(1c)*[9], yielded 9-oxabicyclo[6.1.0]nona-2,6-diene *(2b)* and ethyl 9-azabicyclo[6.1.0]nona-2,6-diene-9-carboxylate *(2c)*, respectively. The melting points of the olefins protected by the organorhodium group, and the yields on introduction and removal of this group, are collected in Table 1.

The compound *(2b)*, which is stable at room temperature, rearranges at 90 °C to 4-oxabicyclo[5.2.0]nona-2,5-diene *(3b)*. However, *(2c)* is stable only up to −10 °C and

Table 1. Selective reduction of 9-heterobicyclo[6.1.0]nonatrienes *(1b)* and *(1c)*.

Starting cpd.	*(1)-Rh* Yield [%]	M. p. [°C]	*(2)-Rh* Yield [%]	M. p. [°C]	*(2)* Yield [%]
(1b)	85	160	80	174	92
(1c)	41	133	88	111	76

passes into ethyl 4-azabicyclo[5.2.0]nona-2,5-diene-4-carboxylate *(3c)* already at 0 °C. The structures of the new heterocycles follow from comparison of the NMR spectra (Table 2) with those of the alicyclic analogs *(2a)* and *(3a)*[6].

Table 2. NMR signals of the heterobicyclononadienes, measured in CCl_4 at 60 MHz with TMS as internal standard. Chemical shifts are in ppm (τ), coupling constants in Hz.

Cpd.	Vinyl-H	Methine-H	Methylene-H	
	AB system (*J*)	Singlet	Multiplet	
(2b)	4.30, 4.62 (12)	6.60	7.3—8.1	
(2c)	4.29, 4.58 (10)	6.92	7.1—8.3	
	AX system (*J*)	Multiplet	Multiplet	Multiplet
(3b)	3.85, 5.39 (8.5)	6.9	7.6—8.1;	8.1—8.7
(3c)	3.20, 5.16 (10)	6.9	7.6—8.2;	8.2—8.7

The Cope rearrangement of all three bicyclo[6.1.0]nonadienes *(2)* occurs in one direction only, giving the bicyclo[5.2.0]nonadiene systems *(3)*. It is stereospecific between the coiled conformations of the starting and terminal compounds: as for the carbocycle[6], so also for the labeled compounds *(2b)-D* and *(2c)-D* the deuterium atoms that are *syn* on the eight-membered ring remain *syn* on the four-membered ring of the rearrangement products.

We have applied kinetic analysis to the Cope rearrangements of *(2a)—(2c)*, these being comparable in mechanism and geometry. For this purpose samples of each compound, dissolved in CCl_4, were rearranged in a thermostat at four temperatures and the compositions were investigated ten times in each run by NMR spectroscopy at −20 °C. Applying the method of least squares to the experimental data gave three sets of first-order rate constants with a correlation of ≥0.98; the constants of the Arrhenius equations are given in Table 3.

Table 3. Arrhenius constants for the Cope rearrangement of bicyclo[6.1.0]nona-2,6-dienes. Limits of error are standard deviations.

Cpd.	*T* [°C]	log *A*	E_a [kcal mol^{-1}]
(2a)	35—48	13.25	25.0±0.50
(2b)	91—105	12.89	28.6±0.85
(2c)	0—17	12.35	21.3±0.60

The results show that the decreases in the rates of the Cope rearrangements *(2c)>(2a)>(2b)* are due mainly to a difference of *ca.* 3.6 kcal mol^{-1} in each pair of activation energies. The sequence in this series does not correspond to the enthalpies of reaction since $\Delta\Delta H_f^0$ is found to be lowest for the carbocycle by summation of bond increments[10]; this result is supported by the reversible rearrangement of the 9-methylbicyclo[6.1.0]nonadienes[6]. There is as yet no satisfactory explanation for the differential (here displayed quantitatively for one example) beha-

vior of the C—C bonds in cyclopropane and its hetero analogs in pericyclic reactions.

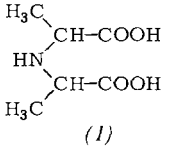
Determination of the Structure of the Vanadium Compound, Amavadine, from Fly Agaric

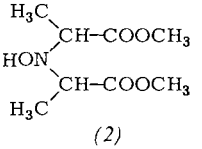
By *Helmut Kneifel* and *Ernst Bayer*[*]

We have isolated from fly agaric, *Amanita muscaria,* a pale blue compound containing vanadium[1] which we call amavadine. Elemental analysis gave the composition $C_{12}H_{20}N_2VO_{11}\cdot H_2O$. The molecular weight was determined as 415[1]. According to the ESR and IR spectra the vanadium is quadrivalent in the form of a $>VO$ group[1]. It has not proved possible to remove and isolate the chelating organic ligands of amavadine. Determination of the structure is made still harder by the low volatility of the compound which prevented us obtaining a mass spectrum and by the paramagnetism which precluded the use of NMR spectra.

Hydrolysis of amavadine by 6 N hydrochloric acid affords mainly L-alanine. In 1 N sodium hydroxide solution sodium pyruvate and acetaldehyde are formed as well as alanine. Reduction of amavadine by zinc and acetic acid yielded α,α'-iminodipropionic acid *(1)*. The identities



(1)

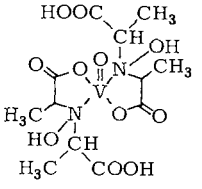


(2)

of all the degradation products were proved by mass spectrometry, nuclear resonance, preparation of derivatives and comparison of these with authentic specimens. Assuming an iminodipropionic acid derivative to form a 2:1 complex with the vanadyl group shown to be present, and the sixth coordination position to be occupied by water, it remains only to assign one additional oxygen atom per iminodipropionic acid residue. Iminodipropionic acid itself is not the complexing agent, as was shown by comparison of amavadine with the vanadyl complex of *(1)* which we synthesized.

The first indication about the additional oxygen atoms came from ESR spectroscopic detection of a nitroxyl radical on oxidation of amavadine in an alkaline medium. Finally a dimethyl ester $C_8H_{15}NO_5$ was isolated after methanolysis of amavadine in methanol/H_2SO_4; this was identified as dimethyl *N*-hydroxy-α,α'-iminodipropionate *(2)* by means of its mass spectra and degradation reactions.

N-Hydroxy-α,α'-iminodipropionic acid was prepared by treating hydroxyammonium chloride with α-bromopropionic acid at pH = 10 and purification by ion-exchange chromatography on a weakly basic resin AG 3 X 4 (Biorad). Reaction of this compound with vanadyl sulfate in water gave a complex *(3)* that was identical with amavadine in chromatographic behavior, electron spin resonance, electronic spectrum, and positions of the IR absorptions. The synthetic complex differs only in its chirality from the natural complex whose two optically active carbon atoms exist in the L-configuration (see above).



(3)

It cannot be excluded that in the fungal mycellium of *Amanita muscaria* the amavadine may be fixed as a metal proteide to a macromolecular component, this loose fixation being destroyed during the isolation[2].

Amavadine is the first naturally occurring vanadium compound whose structure has been elucidated. It shows no apparent similarity to the, admittedly not yet fully clarified, blood pigment of the tunicates, hemovanadin[3].

The structure of the complexing agent is remarkable as being a new ligand in both natural and synthetic chelates.

Transmetalation and Double Metal Exchange: A Convenient Route to Organolithium Compounds of the Benzyl and Allyl Type[**]

By *Manfred Schlosser* and *Jürgen Hartmann*[*]

In the presence of potassium *tert*-butoxide, *n*-butyllithium metalates even such weakly acidic hydrocarbons as benzene[1], arylalkanes[1,2], and alkenes[1–3]. In those cases where this metal/hydrogen exchange leads to a resonance-stabilized organometallic species, it is an organo*potassium* compound that precipitates[2,4]. The initially accompanying lithium *tert*-butoxide can be completely removed by wash-

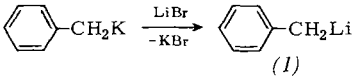
[**] This work was supported by the Schweizerischer Nationalfonds (Project No. 2.539.71).

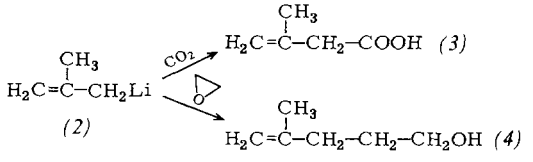
ing with benzene or toluene, in which it is sufficiently soluble.

On treatment with an equivalent amount of lithium bromide[5] the pure organopotassium residue is converted into a soluble organolithium compound and insoluble potassium bromide[6]. Thus it is possible to prepare benzyllithium *(1)* (89%) from toluene and to eliminate all by-products by filtration. This material can be stored longer than when prepared conventionally[7].



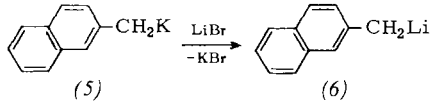
(1)

Starting from isobutene the procedure afforded pure 2-methylallyllithium *(2)* which was converted into the acid *(3)* (60%) and the alkenol *(4)* (72%).



(2)

However, organometallic compounds with a bulky organic moiety, such as 2-naphthylmethylpotassium *(5)*, are themselves too soluble to permit selective removal of the alkoxide by washing. In such cases one has to employ the organopotassium compound or, after metal exchange, the organolithium compound *(6)* in the presence of lithium *tert*-butoxide[8].



(5) *(6)*

Activation with potassium *tert*-butoxide has a definite advantage over the principally equivalent activation with tetramethylethylenediamine (TMEDA)[9,10]. Numerous reactions, such as addition to enolizable ketones and nitriles as well as stereoselective diene polymerizations[11], are only possible in the absence of highly electropositive metals and powerful solvating agents. Once present, TMEDA remains strongly associated with the organolithium compound[9,12]. In contrast, the metal introduced by potassium *tert*-butoxide can be completely removed by subsequent exchange with lithium, the activation thus being "switched off" again.

Benzyllithium (1)

Twice sublimed potassium *tert*-butoxide (100 mmol) was suspended in dry toluene (100 ml) under an inert gas in a three-necked flask fitted with a sintered glass exit[13]. Dropwise addition of an equivalent of *n*-butyllithium (15% solution in hexane) produced a bright red precipitate. After 30 minutes' stirring the solution was pressed through the glass frit, the residue treated with fresh toluene (100 ml), and the solution again allowed to pass through the glass frit. The washing process was repeated twice. The residual red solid was dried for 1 hour at 0.3 torr; diethyl ether (200 ml) was then added at −78 °C and while the mixture was warmed to room temperature dry LiBr (100 mmol) was also added. The insoluble KBr was removed by filtering the orange-yellow solution through the frit into a Schlenk burette. Back titration[14] with 1,2-dibromoethane indicated a yield of 85%; derivatization with trimethylchlorosilane afforded 89% of benzyltrimethylsilane[15] (gas-chromatographic comparison with authentic material[16]: 2.5 m 20% Apiezon L, 100—230 °C; decane as "internal" standard, weight-based calibration factor: 2.1). According to flame spectrometry the Li/K ratio was 44 : 1; the proportion of potassium can be further reduced by retreatment with LiBr.

Isobutenyllithium (2)

Modifying the procedure given above, the metalation was carried out at −20 °C. The excess of isobutene was allowed to evaporate, and the residue was washed with benzene instead of toluene. Since it is practically insoluble in diethyl ether, the yellow isobutenylpotassium was taken up in tetrahydrofuran and treated with LiBr. Double titration indicated a yield of 80%; no potassium could be detected in the hydrolyzed product, either by flame spectrometry or by Kalignost precipitation. Carboxylation yields 3-methyl-3-butenoic acid *(3)*[15] (60%; b.p. 67—68 °C/17 torr) and treatment with ethylene oxide at 0 °C gives 4-methyl-4-penten-1-ol *(4)*[15] (72%; b.p. 144—146 °C/760 torr).

2-Naphthylmethylpotassium (5)

2-Methylnaphthalene was metalated as described for benzyl lithium, except that only a stoichiometric amount of the hydrocarbon was employed. Carboxylation converts the resulting blackish red solution into 2-naphthylacetic acid[15] (75%; m.p. 139—141 °C; ref. [17]: 137—139 °C).

The Primary Processes of Photosynthesis

By *Gernot Renger*[*]

The overall process of photosynthesis is divided, spatially and functionally, into two large sections:

A) The system of the primary processes of photosynthesis characterized by a high structural organization within membranes. In this system, induced by light-activated photogenerators, $NADP^+$ is reduced with water as donor, leading to the evolution of O_2. The process is coupled with an ATP synthesis.

B) The Calvin cycle, which leads *via* enzyme reactions in a liquid plasma phase to the reduction of CO_2 with NADPH and ATP. Light is not required for these reactions.

Introduction of flash-photometric and flash-polarographic methods made it possible to analyze the elementary reactions taking place within the system of the primary processes[1]. These investigations led to the following picture of the functions of the above mentioned system[2]:

1. There exists an adaptation system (consisting of *ca.* 500 chlorophyll molecules together with additional accessory pigment molecules in each electron-transport chain) which allows the optimal adaptation to the flow of light quanta *via* energy-transfer mechanisms. At low light intensities the quanta are trapped over a large cross sectional area and are transferred to the reactive centers; and at high light intensities the excess quanta are exhausted out of the system, thereby avoiding an irreversible photodestruction[3].

2. Electron transport is driven by two photogenerators operating in series. In the photogenerators I (excitable by $\lambda < 730$ nm) and II (excitable by $\lambda < 700$ nm) an excited electronic state leads to a geometrically defined charge separation forming electrons and holes. The primary electrons and holes induce secondary electron-transfer reactions. The holes produced by photogenerator II oxidize H_2O to O_2 by a water-splitting enzyme system; the electrons from photogenerator I reduce $NADP^+$ to NADPH *via* a series of enzyme reactions. The electrons produced by photogenerator II discharge in a series of dark reactions the holes formed at photogenerator I. In this reaction chain there is an electron pool (capacity 14 electrons per chain) in which at least 10 electron transport chains are interconnected.

3. Because of the anisotropic arrangement of the photogenerator poles perpendicular to the plane of the thylakoid membrane, the charge separation induced by light leads to the build-up of an electric field across the membrane. Utilization of the electrochromism effect enables the pigment molecules embedded into the thylakoid membrane to be used as molecular voltmeters and as molecular ammeters. In this way, after appropriate calibration, both the size of the fields and the kinetics of the induced ion flows can be measured[4].

4. Proton flow plays a role owing to participation of protonizable groups in electron transport systems. The kinetics of this flow were analyzed by means of indicators. In light a gradient of 3 to 4 pH units ($pH_{interior} < pH_{exterior}$) is built up over the thylakoid membrane[5].

5. The water-splitting enzyme system has the ability to store holes. H_2O is oxidized to O_2 only when four holes have been accumulated. The lifetime of the trapped holes depends on the state of accumulation and can be influenced by chemical reagents[6].

6. For the mechanism of energy conservation leading to the formation of ATP, it could be shown that the energy is stored primarily as an electrochemical potential across the thylakoid membrane. It is assumed that this potential induces an ion transfer (probably an H^+-flow) through a special enzyme system, the ATPase. In this way chemical reactions are started in the ATPase that lead to binding of phosphate to ADP[2]. Details of this mechanism are unknown.

Structure and Function of Natural Proteinase Inhibitors

By *Harald Tschesche*[*]

Inhibition of proteolytic activities by proteinase inhibitors is one of the natural control mechanisms of enzymatic activity in the organism and is comparable with repression of enzyme synthesis at the DNA-RNA transcription level and with allosteric inhibition of completed enzymes. Proteolytic activities such as that of trypsin can be limited as to location and time either by permanent inhibitors such as the trypsin-kallicrein inhibitor from bovine organs[1] or temporarily[2] by, *e.g.*, the secretory trypsin inhibitors of mammalian pancreas. The enzymatic inactivation is due to a competitive inhibition with stoichiometric formation of a 1:1 molar complex C of enzyme T and inhibitor I or I*, which according to *Laskowski, Jr.*[3], occurs *via* a loose addition complex L or L*:

$$T + I \rightleftharpoons L \rightleftharpoons C \rightleftharpoons L^* \rightleftharpoons T + I^*$$

Figure 1 shows the complete covalent structure of the secretory trypsin inhibitor I from porcine pancreas[4]. It is characterized by a compact arrangement in which the active site (Lys^{18}-Ile^{19}) forms a "cyclic substrate" within a ring that is closed by a disulfide bridge, in accord with the hypothesis of *Ozawa* and *Laskowski, Jr.*[3]. The C-terminus is attached to the remainder of the molecule in a chain that runs parallel to the active site and contains the "potential breaking point" (Arg^{44}-Gln^{45}) for inactivation of the molecule during temporary inhibition. The

[*] Doz. Dr. H. Tschesche
Organisch-Chemisches Laboratorium der
Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

inactivation is initiated by a partial proteolysis reaction at the reactive center with cleavage of the Lys^{18}-Ile^{19} bond to form a modified but still active inhibitor I*. Subsequent cleavage of the Arg^{44}-Gln^{45} bond inactivates the molecule. Therefore blocking of Arg^{44} against tryptic cleavage by butanedione holds up the inactivation by a factor of 25.

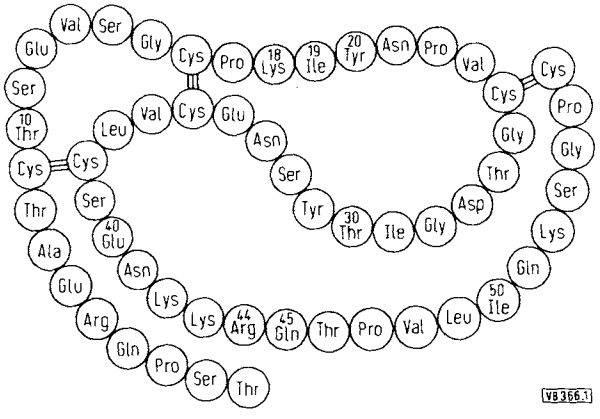

Fig. 1. Complete covalent structure of the porcine pancreatic secretory inhibitor I.

From the covalent structure we can conclude that the inactivation is made easier by the parallel courses of the polypeptide chains that contain, respectively, the active site and potential breaking point, since only a slight reorientation of the enzyme molecule in the loose addition complex L* from the active site to the potential breaking point is required. Comparison of the primary structures of the inhibitors from pig and sheep (also from ox[5]) shows that the C-terminal partial sequences (residues 44—56) rarely undergo mutation, thus underlining the importance of this portion of the molecule for the biological function of the whole.

The physiological role of the secretory pancreatic inhibitors is probably to be sought in prevention of premature zymogen-activation of the enzymatic digestive potential in the acinar cells or the duct of the gland. The mechanism of temporary inhibition later permits biological recovery of the inhibited enzyme.

This phenomenon of temporary inhibition is shown also by two isoinhibitors from mammalian sperm, in the inactivation of trypsin (from bovine and porcine pancreas)[6], which were first isolated in pure form from seminal plasma of the boar. The seminal inhibitor I contains 67 amino acids, galactosamine and glucosamine; in inhibitor II there are one lysine and one arginine residue less. The amino acid compositions and N-terminal sequences show that there is no homology between these two inhibitors secreted by the vesicular gland and the inhibitor secreted by the pancreas (Fig. 1). Besides a temporary inhibition of trypsin the two seminal inhibitors exhibit permanent inhibition of the egg-penetrating acrosin of boar sperm in a 1:1 stoichiometric reaction. This last-mentioned finding could be of special importance for the fertilizing capacity of sperm, *i.e.* for its attainment of fertilizing ability in the female genital tract and thus for its ability to penetrate the egg cell membrane (zona pellucida) which *in vivo* occurs with participation of acrosin[7, 8].

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The use of spectroscopic methods in the structural analysis of coal and petroleum is dealt with by *J. G. Speight.* The author considers UV, IR, NMR, mass, and ESR spectroscopy, as well as X-ray diffraction and electron microscopy. All these techniques furnish information on structural details of the two natural products, but so far it has not proved possible to combine these details into a comprehensive overall picture, not least owing to the chemical and physical (solubility problems) complexity of the mixtures designated coal and petroleum. The literature is covered up to August 1970. [The Application of Spectroscopic Techniques to the Structural Analysis of Coal and Petroleum. Appl. Spectrosc. Rev. *5,* 211—263 (1972); 306 references]

[Rd 571 IE—G]

Photochemistry in macromolecular systems is considered by *J. E. Guillet.* The photochemical reactions typical of

chromophoric groups in small organic molecules also occur in macromolecules. The most important ones are: photodimerization; photoisomerization; generation of free radicals; photocyclization; photorearrangement. Polymeric ketones are particularly suitable for obtaining an insight into such processes. Apart from the influence of viscosity, molecular weight, concentration, and chain mobility, particular importance attaches to intramolecular energy transfer. [Photochemistry in Macromolecular Systems. Naturwissenschaften *59*, 503—509 (1972); 23 references]

[Rd 605 IE—M]

Toxic proteins capable of inhibiting protein synthesis are considered by *S. Olsnes*. Thus Colicin E3 kills susceptible bacteria by inhibiting ribosome function. Diphtheria toxin blocks protein synthesis in eukaryotes by inactivating peptidyl transferase II. The plant toxins abrin and ricin probably also interfere with some of the processes necessary for elongation of the peptide chain. [Toxic Proteins Inhibiting Protein Synthesis. Naturwissenschaften *59*, 497—502 (1972); 82 references]

[Rd 607 IE—M]

Reductions of functional groups by sulfurated hydridoborates such as $NaBH_2S_3$ and their particular application to steroidal ketones are discussed by *J. M. Lalancette, A. Frêche, J. R. Brindle*, and *M. Laliberté*. Reagents of this type are readily accessible from hydridoborates and S, Se, or Te in *e. g.* THF, diglyme, or dioxane. Aldehydes and ketones are reduced to the alcohols at low temperatures and also to the disulfides at higher temperatures. Aromatic nitro groups can be reduced in a highly selective manner to amino groups. Reduction of the 3-oxo groups of steroidal ketones proceeds without attack of oxo groups at C-11, C-12, C-17, and C-20. [Reduction of Functional Groups with Sulfurated Borohydrides. Application to Steroidal Ketones. Synthesis *1972*, 526—532; 20 references]

[Rd 612 IE—M]

Spectroscopic studies on electron donor-acceptor systems are the topic of a review by *C. N. R. Rao, S. N. Bhat*, and *P. C. Dwivedi*. An introduction to the theory of such systems is followed by an account of their investigation by electronic, IR, Raman, NMR, and ESR spectroscopy. The article provides an exhaustive survey of the available literature (latest references from 1970) but the authors emphasize the need for a critical approach to many of the data considered. [Spectroscopy of Electron Donor-Acceptor Systems. Appl. Spectrosc. Rev. *5*, 1—170 (1972); 564 references]

[Rd 569 IE—G]

Hydrogenations and isomerizations over zinc oxide are the subject matter of an article authored by *R. J. Kokes* and *A. L. Dent*. The review deals with the active sites of the catalyst, the mechanism of ethylene hydrogenation, and reactions with propylene, butene, and acetylenes. It is seen that all the reactions listed can be considered in common terms if the active site is regarded as a metal-oxygen pair (*i.e.* a cation-anion pair) that can effect heterolytic cleavage of an acidic C—H bond. [Hydrogenation and Isomerization over Zinc Oxide. Advan. Catal. *22*, 1—50 (1972); 75 references]

[Rd 578 IE—G]

The nuclear magnetic resonance of molecules oriented in electric fields is considered in a survey penned by *C. W. Hilbers* and *C. MacLean*. They cite relevant literature up to 1971 and also report unpublished experimental results. The following topics are discussed: theory of NMR spectroscopy of oriented molecules; comparison of experimental results with theoretical predictions; dependence of the NMR spectrum on the angle between the molecules in a liquid; and relationships between the Kerr effect and the nuclear magnetic resonance in an electric field. [NMR of Molecules Oriented in Electric Fields. NMR *7*, 1—52 (1972); 50 references]

[Rd 573 IE—G]

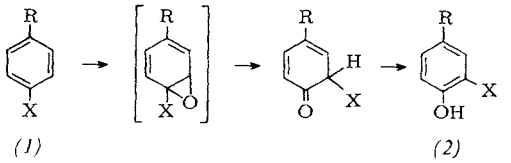
"Carboxypeptidase A: a mechanistic analysis" is the subject of review by *E. T. Kaiser* and *B. L. Kaiser*. Carboxypeptidase catalyzes the hydrolysis of peptides or esters of *N*-acyl α-amino acids and *O*-acyl α-hydroxy acids adjacent to the terminal COOH groups. One Zn^{2+} ion is required per molecule of enzyme. The mode of action of the enzyme is deduced by the authors from the results of kinetic findings, studies of structure-reactivity relationships, and pH dependence in reactions with synthetic substrates, as well as from the experimental results. Arg^+-145, Glu-270, and a molecule of water bound to zinc participate directly in the process. [Carboxypeptidase A: a Mechanistic Analysis. Accounts Chem. Res. *5*, 219—224 (1972); 43 references]

[Rd 601 IE—L]

The application of phenolic oxidation to the total synthesis of isoquinoline- and related alkaloids in the subject of a report by *T. Kametani* and *K. Fukumoto*. The term phenolic oxidation denotes the oxidative radical coupling between the phenolic O atom or a C atom (*ortho* or *para* to the OH group) and a corresponding atom of another phenol to give C—O and C—C bonds. This mode of reaction is of considerable significance for the biosynthesis of numerous natural products; it can frequently be imitated in the laboratory with the aid of oxidizing agents such as $FeCl_3$ and $K_3[Fe(CN)_6]$. [Application of Phenolic Oxidation to the Total Syntheses of the Isoquinoline and Related Alkaloids; Biogenetic Type Synthesis. Synthesis *1972*, 657—674; 106 references]

[Rd 603 IE—M]

The significance of arene oxides and the NIH shift in metabolism, toxicity, and carcogenicity of aromatic compounds is discussed by *J. W. Daly, D. M. Jerina*, and *B. Witkop*. The primary products of aromatic substrates are arene oxides which undergo conversion into, *e. g.*, dihydro diols (by spontaneous isomerization into phenols). Introduction of the OH group by monooxygenases is accompanied by a migration [*(1)→(2)*] of the original substituent



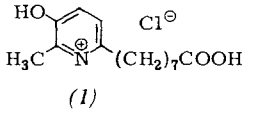
(1) *(2)*

(usually H, less frequently CH_3 or halogen), *i.e.* the NIH shift. The toxicity of aromatic pharmaceuticals and the

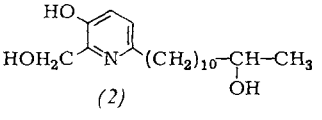
carcinogenic action of polycyclic aromatic hydrocarbons have been shown in model experiments to be interpretable in terms of arene oxide opening by nucleophilic groups present in tissues and covalent binding to biopolymers. [Arene Oxides and the NIH Shift: The Metabolism, Toxicity and Carcinogenicity of Aromatic Compounds. Experientia *28*, 1129—1264 (1972); 189 references]

[Rd 604 IE—M]

Syntheses of carpyrinic acid *(1)* and related pyridines having long aliphatic chains are discussed by *G. Fodor, J.-P. Fumeaux*, and *V. Sankaran*. Compound *(1)* is a key intermediate in the synthesis of alkaloids bearing piperidine groups and such long chains. The authors give four synthetic



(1)



(2)

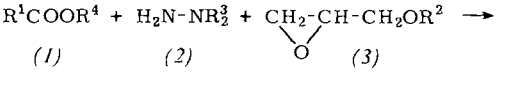
routes to *(1)*. The synthesis of dehydroprosopine *(2)*, an important intermediate in the total synthesis of prosopine and prosopinine, is reported. The article also gives an account of the synthesis of fire ant venoms (2-methyl-6-alkyl- and alkenylpyridines). [Syntheses of Carpyrinic Acid and of Related Pyridines with Long Aliphatic Chains. Synthesis *1972*, 464—472; 34 references]

[Rd 613 IE—M]

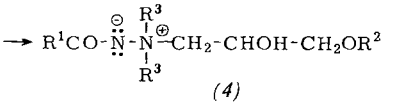
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

New surface active ammonioamidates *(4)* with long-chain ether residues on the quaternary nitrogen atom can be prepared by heating equimolar quantities of carboxylic esters *(1)*, dialkylhydrazines *(2)*, and glycidyl ethers *(3)* at 60—80°C. For example, from 15 g of *N,N*-dimethylhydrazine, 60.5 g of dodecyl glycidyl ether, and 18.5 g of



(1) *(2)* *(3)*



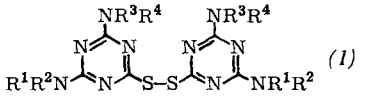
(4)

R^1 = H, CH_3, C_2H_5; R^2 = aliphatic residue (C_8—C_{18}), preferably linear with an even number of C atoms, which may be saturated or unsaturated; R^3 = CH_3, C_2H_5; R^4 = alkyl (C_1—C_4)

methyl acetate in 100 ml of butanol at 60°C, one obtains *N,N*-dimethyl-*N*-(2-hydroxy-3-dodecyloxypropyl)ammonioacetamidate. The ammonioamidates have an excellent washing and cleaning action, particularly below 60°C, and are therefore suitable for use as components in cold washing products for wool or fully synthetic textiles. The ability to disperse calcium soaps is good. Some of the compounds, *e.g. (4)* with $R^1 = C_2H_5$, $R^2 = C_{12}H_{25}$, and $R^3 = CH_3$, are characterized by low foaming power, and can therefore be used in particular for machine-wash detergents. [DOS 2059289; Henkel & Cie GmbH, Düsseldorf]

[PR 80 IE—V]

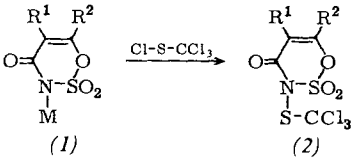
A mixed accelerator for the vulcanization of natural and synthetic rubbers based on halogen-free dienes consists of a) bis(1,3,5-triazinyl) disulfides *(1)* in which one of the residues R^1—R^4 is hydrogen and the others are identical or different, linear or branched alkyl groups (C_1—C_4), b) a mercapto accelerator, and possibly c) a thiuram accelerator. The use of the mixture avoids the disadvantage of the long heating time required when compounds *(1)* are used alone; the high stress values of the vulcanized products are not impaired. [DOS 2109244; Degussa, Frankfurt; Bayer, Leverkusen]



(1)

[PR 98 IE—E]

New *N*-trichloromethylthiooxathiazinones *(2)* are obtained by reaction of metal salts of oxathiazinones *(1)* with trichloromethylsulfenyl chloride between 0°C and the boiling

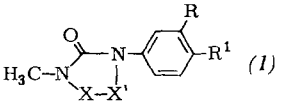


(1) *(2)*

point of the solvent (apolar or polar). The oxathiazinones *(2)* can be used against fungus diseases of cultivated plants. [DOS 2059249; Farbwerke Hoechst AG; Frankfurt/Main-Höchst]

[PR 100 IE—N]

Aminoimidazolidinediones and iminoimidazolidinediones *(1)* exhibit a primarily herbicidal but also fungicidal and



(1)

R = H, Cl, CH_3; R^1 = H, Cl, Br, SCH_3; X or X': >CO; X' or X: >C=N—R^2, >CH—NH—R^2; R^2 = H, substituted phenyl, other (substituted) substituents

bactericidal action. They can be obtained by several known methods. [DOS 2107146; C. H. Boehringer Sohn, Ingelheim]

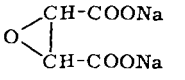
[PR 106 IE—N]

High molecular weight, fully aromatic copolyamide-phosphonamides, which can be made into filaments, fibers, and sheets and used for the production *e.g.* of high-temperature electrical insulators, flame-resistant protective clothing, parachutes, and fuel containers, can be prepared by addition of a phosphonic dihalide, *e.g.* phenylphosphonic

dichloride, to a melt of at least one excess aromatic diamine, *e.g. m*-phenylenediamine, at a high temperature. After the reaction, the product is dissolved in a conventional solvent for aromatic polyamides, such as dimethylacetamide or *N*-methyl-2-pyrrolidone, at least one aromatic dicarboxylic acid halide, *e.g.* isophthaloyl chloride, is added to this solution between 0 and −20 °C, and the mixture is polycondensed to completion at this temperature to obtain a high molecular weight product. [DOS 2062774; Farbwerke Hoechst AG, Frankfurt/Main-Höchst]

[PR 58 IE—O]

The *cis* isomer of disodium epoxysuccinate *(1)* can take the place of sodium tripolyphosphate, which has until now been extensively used as a builder in detergents and cleaning mixtures, but which should no longer be used because of its adverse effect on bodies of water. Since *(1)* contains no



(1)

plant nutrients such as phosphorus or nitrogen, unlike polyphosphate, it has no eutrophic effect on fresh-water flora, and in particular it does not lead to excessive growth of algae. The natural development of the fauna and flora of the water bodies is not disturbed by *(1)*, so that the detergents present in washing agents can be biologically degraded. 20—45 wt.% of the detergent mixture consists of alkaline sodium salts, of which 40—85 wt.% preferably consists of *(1)*. The full action of *(1)* is achieved in washing baths at pH 9. *(1)* has sufficient thermal stability for use at normal washing temperatures. Its prime cost is very little above the cost of tripolyphosphate. *(1)* is prepared by epoxidation of maleic acid with 30% H_2O_2 at 60 °C in aqueous solution in the presence of sodium tungstate. [DOS 2160908; Produits Chimiques Pechiney-Saint-Gobain, Paris]

[PR 81 IE—V]

To prepare *N*-disubstituted glycines, amino alcohols such as triethanolamine are oxidized with O_2 in the presence of Pt, possibly on a catalyst support and possibly in the presence of a solvent at 25—110 °C. The glycines obtained in this way are used for organic syntheses, as textile auxiliaries, and particularly as builders for detergents. [DOS 2103724; Chemische Werke Hüls, Marl]

[PR 110 IE—B]

BOOK REVIEWS

Elektronenanlagerungs-Massenspektrographie organischer Substanzen (Electron Addition Mass Spectrography of Organic Substances). By *M. von Ardenne, K. Steinfelder,* and *R. Tümmler*. Springer-Verlag, Berlin-Heidelberg-New York 1971. 1st ed., viii, 403 pp., 109 figs., stitched DM 68.—.

The present book sums up several years' work by the authors in the development and application of electron addition (EA) mass spectrography in the Manfred von Ardenne Research Institute, Dresden.

The fundamentals of the method are presented in the first part of the book, and are followed by a description of the equipment and general questions of sample preparation, measuring technique, and evaluation of the spectra. After a discussion of the ionization mechanisms, there is a short comparison of the EA mass spectra of negative and positive ions.

In the second part of the book, after dealing with a number of possible applications, mainly in the chemistry of natural products, the authors present a clear description of the classes of substances that have been investigated so far and of the decomposition rules that have been explained. The book ends with extensive tables containing the EA mass-spectroscopic data known at present.

The book should be equally valuable to the advanced chemist and to the specialist in the field of mass spectrometry. As an additional method, EA mass spectrography will undoubtedly find much more frequent use in analytical chemistry in the future for the solution of special problems, despite the need for larger samples than in electron bombardment mass spectrometry.

Gerd Remberg [NB 136 IE]

Real-Lexikon der Medizin (Encyclopedia of Medicine). 6 volumes in a loose-leaf system. Edited by *G. Thiele* and *H. Walter*. Urban & Schwarzenberg, München. Vol. 3 (F-Hyperl) 1969/70, ii, 804 pp., 140.— DM. Vol. 4 (Hyperm—Melusinidae) 1971/72, viii, 802 pp., numerous figures and tables, 160.— DM.

Two thirds of the encyclopedia[*] have now been completed. They show that the work is not only important for doctors, but will be of use also (and perhaps especially) to those who have a sort of scientific point of contact with medicine on the chemical side. Its content is lexical in the best sense, *i.e.* for each concept one not only finds a definition, but also learns something about the factors that make the object in question or the associated phenomenon important in medicine. In some cases, however, the necessary conciseness of expression leads to impenetrable brevity, which makes the explanation understandable only to those who are already fundamentally in possession of the information, but which may nevertheless serve as an indication to the novice that he still has something to learn here (as under the keyword "gamma globulins"). A literature reference to open the door to further studies would have been useful in this connection, but perhaps this is too

[*] Cf. Angew. Chem. internat. Edit. *8*, 222 (1969).

much to ask. There are interesting things to be learnt in this book, *e.g.* that "ammonium carbonicum" (why not ammonium carbonate?) is also known as "Geistersalz", or that 2,6-lupetidine is not described in medical (or rather pharmaceutical) circles as 2,6-dimethylpiperidine, but is known by the grander-sounding name "nanofinum". This is not necessarily the editors' fault, but at the same time it does not contribute much to a mutual understanding between different scientific disciplines. However, the chemist will welcome the clear and detailed schemes of important metabolic processes. On the whole, we have here a work that is outstanding for the care with which it has been edited, and that will be of great value to its owner (not least because of the inclusion of English and French equivalents of numerous keywords).

Helmut Grünewald [NB 130 IE]

Handbuch des kathodischen Korrosionsschutzes [Handbook of Cathodic Corrosion Protection]. By *W. v. Baeckmann* and *W. Schwenk*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971, 1st ed., xxii, 422 pp., 204 figs., 53 tables, cloth DM 140.—.

Mainly in connection with the growing use of underground pipelines for petroleum and petroleum products, water, and natural gas and the steadily expanding use of underground cable systems, cathodic corrosion prevention has developed into a branch on a par with protection by surface coatings *etc.* More than in any other branch of corrosion prevention, precise knowledge of the electrochemical principles is essential to success here, since currents and potentials are used to intervene in the corrosion process; the effects can be determined much more accurately than *e.g.* those of a process that takes place over a long period, such as the diffusion of electrolytes.

The present book presents, for the first time in German, a comprehensive treatment of the entire field of cathodic and anodic corrosion protection, and the mathematical formulas collected in the Appendix show the importance of the calculations. Since no calculation is possible without the results of measurements, a chapter on general measuring techniques is included; the problems of measurement must be considered at the planning stage, and repeated check measurements are also necessary later.

The range of problems that can be solved with the aid of cathodic protection will be appreciated even from the following incomplete list of objects that can be successfully protected: pipelines, storage tanks, telephone cables, power cables, ships, steel constructions in sea water, and underground plants, and also the protection of specific objects such as hot-water systems and cold-water systems. The possibility of calculation also allows a fairly accurate estimate of costs (installation costs, operating current costs, maintenance costs, anode consumption, *etc.*).

The book, which represents the sum total of existing knowledge, should remain the standard work for a long time. Finally, a survey of correct terminology is presented; a side effect may be that this will be used by other authors in the future. Despite its high price, it is to be hoped that this book will reach the widest possible circle of readers.

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH, Weinheim/Bergstr. 8th fully revised Edition.

System No. 49: Niobium, Part B 3. Oxoniobates (excluding alkali metal niobates). Editor: *Herbert Lehl.* Compiled by *Hartmut Bergmann.* 1971. vi, xxii, 330 pp., 205 figures, Balacron DM 411.—.

The third volume of Part B, which was started in 1970[1], deals with oxoniobates, from those of the alkaline earth metals to those of vanadium. The importance of this class of compounds can be seen from the mere size of the volume, which covers the literature up to 1970. This is due to the special electrical and optical properties of the oxoniobates which are playing an increasingly important role both in industry and in science. Polycrystalline preparations are often prepared by heat treatment of oxide mixtures or of simultaneously precipitated oxide hydrates and of mixtures of the carbonates or oxalates, as well as by heating niobium with metal oxides or by oxidation of niobium alloys. The equilibrium diagrams of the systems have been very thoroughly investigated in many cases with the aid of X-ray and thermoanalytical methods. Many products of the systems discussed have found practical use, examples being the "PZT piezoceramics". These consist of $Pb(Zr,Ti)O_3$ modified with Nb_2O_5 and other oxides, and have advantages in respect of temperature resistance and aging resistance over the $BaTiO_3$ piezoceramics in electromechanical transducers. The volume contains very many figures showing equilibrium diagrams, lattice structures, and temperature dependence of dielectric constants, elastic coefficients, piezoelectric constants, and other parameters of ceramic preparations. The last section of the volume, "Definition and General Literature", would have been better placed at the beginning, though it is referred to there, together with the remark that the alkali metal niobates are discussed in "Niobium" volume B4, which is to be published in 1972, and will complete System No. 49.

System No. 47: Lead, Part B1. The element (excluding electrochemical behavior). Principal editor: *Anna Bohne-Neuber.* 1972. vi, xx, 497 pp., 87 figures, Balacron DM 596.—.

Whereas Part C of System No. 47 (Lead), which was published in 1969—1971[2], dealt with the metallurgy, alloys, and compounds of lead, the present first volume of Part B is concerned with the element. The second volume will be devoted to the electrochemistry of lead.

The present volume first describes the abundance, preparation, enrichment, separation, and properties of the numerous lead isotopes. As a result of accurate atomic weight determinations, it has recently become necessary, as for many other elements, to limit the accuracy formerly aimed at and claimed for the atomic weight, since the fluctuations of the isotope abundances, which are considerable even for ordinary lead, are much greater still for the naturally occurring radiogenic leads. The most recent value for the atomic weight of lead on the ^{12}C scale is 207.2. After a short chapter on the properties of the nuclides (nuclide masses, nuclear moments, excitation, decay), the properties of the atom and of the atom-ions (both the free atom-ions and the Pb^{2+} ions in crystals and solutions) are described. Pb^{3+} ions exist in crystals. Considerable space is devoted to the description of the crystallographic properties of lead, which also deals with

its deformation and softening. The description of the mechanical, thermal, magnetic, electrical, and optical properties is also very extensive (almost 100 pages), in agreement with its industrial importance.

The second part of the volume is devoted to the chemical behavior of the metal and of lead ions in solution. The divers uses of lead in the chemical industry are mainly based on its chemical resistance to sulfuric acid and the ease with which it is shaped. The chapter "Detection and Determination" is very detailed. Though the data on the determination and separation methods are confined to the more recent secondary literature and the principal monographs since 1950 [apart from this the reader is referred to the Handbuch der analytischen Chemie (Handbook of Analytical Chemistry) edited by *W. Fresenius* and *G. Jander*], the list of the most important recent literature since 1950 on general detection methods and detection and determination in special cases occupies about 100 pages.

A chapter entitled "Toxicity", which deals with lead poisoning by foodstuffs, lead in the air, and water containing lead, the manner in which lead acts in the body, and diagnosis and therapy, completes the volume, which will certainly be of interest to others besides chemists. Physicists, metallographers, metallurgists, the lead-processing industry, and toxicologists will also find it a rich source of information. The literature is covered up to and in some cases beyond the end of 1969.

System No. 47: Lead B 2. The element (electrochemical behavior). Editor: *Gerhart Hantke.* 1972. vi, xiv, 416 pp., 173 figures, Balacron DM 505.—.

With a lapse of only a few months since the appearance of Part B 1 of System No. 47, Lead, Part B 2 has now also been published. This volume deals with the electrochemical behavior, which was excluded from the first volume.

The great interest and the consequent intensive studies that have been devoted to the electrochemical properties of lead have their origin in its fields of use. A thorough knowledge of the electrochemical behavior is demanded on the one hand by the large-scale use of lead in the lead accumulator for the storage of electricity, and on the other by lead coating for the production of accumulator plates or for the protection of other metals against corrosion, or by electrolytic deposition for the refining of lead.

The data on the lead accumulator are confined in the present volume to a bibliography, which contains only the monographs and reviews on this subject. The discussion of electrolytic deposition, on the other hand, occupies almost half of the volume (188 pages). The chapter deals in detail with the deposition of lead from aqueous and non-aqueous solutions, from suspensions, and from melts. Lead can even be deposited electrolytically from solid lead compounds. The remainder of the volume is divided into the chapters: Standard potential; Electrolytic solution pressure; Ionic mobility; Potentials; Electrokinetics; Cathodic hydrogen overpotential; Oxygen overpotential; Behavior as an electrode; Behavior as a cathode; Behavior as an anode.

The material is arranged well. Though the literature is fully evaluated only up to the end of 1968, numerous important later reports are also covered. Chemists will be disturbed by a series of faults in terminology, only a few of which will be mentioned here. On p. 25, phosphoric acid and its primary, secondary, and tertiary sodium salts are referred to as "PO_4 compounds". It would also have been more accurate, in Section 11.3.37 (pp. 370—380), to use either the name diphosphate or the correct formula $P_2O_7^{4-}$ instead of P_2O_7. The authors are equally free with ionic charges in Section 11.3.33 (pp. 360—370), in which the correct formula $PbSiF_6$ and the incorrect formula $Pb(SiF_6)_2$ appear to be randomly distributed both in the marginal headings and in the text. The description "natronalkalisch" (roughly equivalent to "soda-alkaline") *e.g.* on pp. 384 and 386, is unfortunate, since its meaning is unclear, particularly to foreign users of the volume. It would also have been better, in view of the world-wide readership, to use the internationally accepted abbreviation EDTA (which is also used by *G. Schwarzenbach*) instead of ädt (p. 348) for ethylenediaminetetraacetic acid and its anions. The inclusion of lead thiocyanate among the lead cyanide compounds (p. 23) is wrong.

Despite many minor faults of the type mentioned, the volume is an important source of information, which offers an encyclopedic description of the electrochemical behavior of lead, *i.e.* properties of this metal that are in daily use by nearly every one of us, and that form the basis of an entire industry.

Extrachromosomal DNA in Bacteria

By Werner Goebel[*]

In addition to chromosomal DNA carrying the genetic information of the cell, many bacterial cells contain smaller circular DNA factors known as plasmids or episomes. These genetic elements endow the cell with additional biochemical capabilities. The fertility factors (F and F'), the antibiotic resistance factors (R), the colicinogenic factors (Col), the hemolytic factors (Hly), and other extrachromosomal DNA systems are described. These small DNA molecules can be isolated, and are therefore particularly suitable for the investigation of DNA replication and the stable establishment of genetic material in the bacterial cell.

1. Introduction

Deoxyribonucleic acid (DNA) contains the genetic information of every cell that is capable of division, and so determines the biochemical capabilities of the cell. Whereas the DNA of higher organisms (eukaryotic cells) is contained in the cell nucleus in the complicated structure of the chromosome[1], that of the bacterial cell exists in a "free" form (prokaryotic cells), presumably bound to the cell membrane[2]. Though bacteria have no chromosomes, bacterial DNA is frequently also referred to as chromosomal DNA. The information contained in the base sequence of the DNA (genetic code)[3] is transcribed into messenger ribonucleic acid (m-RNA) by RNA polymerase[4]. The information of the m-RNA is translated into proteins on the ribosomes[5] in a complicated but now largely understood process[6]. These proteins catalyze the chemical processes in the cell if they are enzymes, and contribute to the construction of the cell if they are structural proteins.

Unless the chromosomal DNA of the cell is modified by spontaneous mutations or by mutations induced by chemicals, UV radiation, *etc.*, the genetic information and hence the biochemical capabilities of the cell remain constant. All the cells of one type of bacterium should therefore exhibit exactly the same behavior. It is found, however, that individuals possessing additional biochemical capabilities occasionally appear: some *E. coli* cells can grow in the presence of one or more antibiotics, others release proteins that have a bactericidal action on other *E. coli* bacteria, and so on. These additional properties differ from chromosomal characteristics in the following respects: They can, albeit very rarely, spontaneously segregate on cell division. They can be eliminated by treatment with agents such as acridine orange[7], ethidium bromide[8], and sodium dodecyl sulfate[9]. Conversely, they can be transferred in many cases by cell contact to other bacteria that previously did not possess these characteristics.

It is now known that these properties are not determined by the chromosomal DNA but by additional DNA elements that are physically separate from the chromosomal DNA in the bacterial cell and are therefore known as "extrachromosomal DNA elements" or as "episomes" or "plasmids"[10]. These additional genetic elements can give the cell decisive selectional advantages under special growth conditions. However, a bacterial cell is not dependent on these plasmids, which are therefore described as "non-essential".

The purpose of the present article is to provide a general picture of the variety of these extrachromosomal DNA

[*] Priv.-Doz. Dr. W. Goebel
Institut für Mikrobiologie und Molekularbiologie der Universität Hohenheim
7 Stuttgart 70, Otto-Sander-Strasse 5 (Germany)

systems in bacteria. Special emphasis is placed on the physiological importance of these additional genetic elements to the bacterial cell and on their biochemical properties. Since the literature in this field has become very extensive, only a selection can be offered here (for reviews see[10-13]).

2. The Fertility or Sex Factor (F) of *Escherichia coli*

The first observation to suggest that bacterial DNA can be transferred from one bacterial cell to another was made by *Lederberg* for the intestinal bacterium *Escherichia coli*[14]. In this process, known as "conjugation", two bacterial cells come together, one of these being described as the male or donor cell and the other as the female or recipient cell. The process is determined by an extrachromosomal DNA element, the F (fertility) or sex factor. Through this F DNA, characteristics that are essential for conjugation become pronounced. The F^+ cell (male cell) forms specific cell wall appendages, which are known as sex pili or F pili (Fig. 1). Through these, contact is made with the female F^- bacterium. It is not yet certain whether the F pili are also involved in the transfer of the DNA.

The F pili have two properties: They confer a new antigen property upon the male bacterial cell[15] and they are specific receptors for certain bacteriophages[16].

During the conjugation, the extrachromosomal F DNA is transferred at a high rate ($\approx 100\%$) from the male to the female cell; chromosomal genes may occasionally also be transferred. The transfer of the F DNA presumably takes place by the "rolling-circle mechanism" illustrated in Figure 2. In this mechanism, one of the two strands of the plasmid DNA is forced out of the donor cell into the recipient cell. The complementary DNA strand is formed inside the recipient cell. The complementary strand to the DNA strand retained in the donor cell is also replicated[17,18].

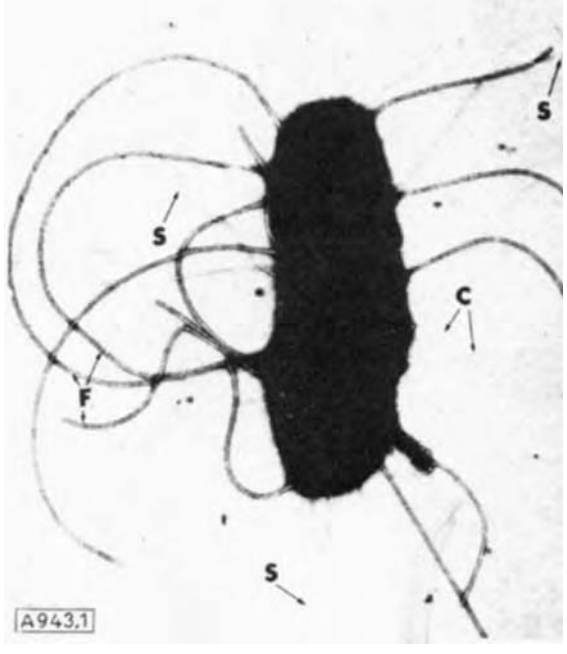

Fig. 1. Male F^- cell of *Escherichia coli* (after [7]). S = sex or F pili, C = normal pili, F = flagella. Magnification approx. 2500×.

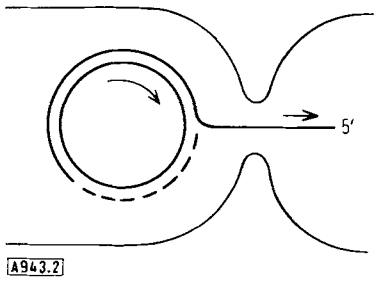

Fig. 2. Rolling circle model for the transfer of plasmid DNA during conjugation. The heavy DNA strand of the extrachromosomal factor unrolls on the covalently closed complementary light strand and is pushed through a plasma bridge (F pilus?) into the recipient cell. The synthesis of the complementary DNA strand takes place in the recipient cell (after [17,18]).

The F DNA may occasionally be integrated into the chromosomal DNA of the bacterium[19], and is then a covalently bonded component (Fig. 3). In this Hfr state

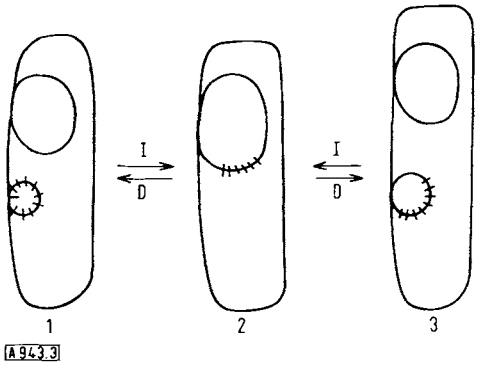

Fig. 3. Integration (I) and dissociation (D) of the F factor. 1) Male (F^+) cell, autonomous F state; top: chromosome, bottom: F factor. 2) The integration of the F DNA into the chromosomal DNA leads to the Hfr state. Dissociation can lead either back to the original state (1) or to the formation of an F' factor. 3) Male (F') cell, autonomous F' state. The F' factor carries a section of the chromosomal DNA in addition to the F DNA.

(Hfr = high frequency of recombinants), the male cell has the ability to transfer also the chromosomal DNA, in part or in whole, to a recipient cell during conjugation.

By dissociation, the F DNA can return from the integrated Hfr state to the autonomous extrachromosomal F^+ state. During this process, the F factor may occasionally take with it sections of the chromosomal DNA[20]. This results in the formation of F' factors (Fig. 3), which, in addition to the F properties (*e.g.* pilus formation, phage-specificity, transfer properties), also possess chromosomal characteristics. Thus the F' lac factor possesses all the genes required for the construction and regulation of the enzymes for the degradation of lactose. F' gal, in addition to the F properties, also encodes all enzymes for the degradation of galactose.

The F factor and some F' factors have now been isolated by methods discussed in Section 9. They are large circular DNA molecules.

On the basis of the rate of conversion of "supercoiled" F DNA into open-circular F DNA (see Section 9) by X-rays, *Freifelder* obtained a molecular weight of 45×10^6 daltons (D) for F DNA and 51×10^6 to 81×10^6 D for

F′ DNAs[21]. Other workers, who used mainly electron microscopy and sedimentation analysis for the determination of the molecular weight of F DNA, found a value of 62×10^6 D[22]. F′ factors, as one might expect, are larger. Careful measurements have given a molecular weight of 107×10^6 D for the F′ factor F′-Col V-Col B-trp-cys[23], which, in addition to the F DNA, carries the colicinogenic factors Col V and Col B (see Section 5) and the genes for the enzymes of the tryptophan and cysteine biosyntheses. F′ lac DNA has a molecular weight of 130×10^6 D according to sedimentation analysis. The number of F and F′ factors in the *E. coli* cell is small, and cannot be more than one or two copies per bacterial cell[24].

3. Antibiotic Resistance Factors (R) of Enterobacteria

Extrachromosomal DNA factors that have attracted special attention because of their potential danger to man are the antibiotic resistance factors or R factors. The phenomenon of transferable multiple antibiotic resistance in enterobacteria was first described by *Watanabe*[25,26], and is connected with the occurrence of R factors. Like the F and F′ factors these possess fertility and transfer properties, and can thus transfer the characteristic of multiple antibiotic resistance to suitable recipients by conjugation. The recipient cells for the transfer of R factors are mainly the bacteria belonging to the class of Enterobacteriaceae. The best-known of these is the generally harmless intestinal bacterium *Escherichia coli*. However, they also include bacteria that must be regarded as decidedly pathogenic, such as *Salmonella typhimurium*, which causes gastroenteritis, *S. typhi*, the agent responsible for typhoid, and *S. paratyphi*, the agent that causes paratyphoid, as well as the strains of *Shigella* that must also be considered as pathogenic enterobacteria (*e.g. Shigella dysenteriae*, which causes dysentery and severe diarrhea). These diseases, which are generally referred to as salmonelloses and shigelloses, may be endemic. It has already been seen in some cases how dangerous the course of these diseases can be if the pathogens carry R factors (Table 1).

In addition to the enterobacteria, *Pseudomonas* species, *Pasteurella* strains (*e.g. Pasteurella pestis*, the plague pathogen), and *Vibrio* strains (*e.g. Vibrio cholerae*, the cholera pathogen) can also act as recipients for R factors *in vitro*[28,29]. However, recent investigations on *Vibrio cholerae* strains carrying R factors have shown that with one exception (R ts 1 factor), all transferred R factors are unstable in this host and segregate after a few generations[30].

In addition to enterobacteria, naturally occurring *Pseudomonas* strains with R factors have also been isolated[31,32]. As a result of the intensive use of antibiotics in medicine and in animal feeding, antibiotic-resistant enterobacteria are now very widespread[10]. Under laboratory conditions, the R factors can be transferred with different probabilities to all known recipients; relatively little is known about the frequency of the transfer of R factors from one bacterial cell to another in the human or animal organism[33]. It cannot be ruled out in principle, however, that *Escherichia coli* having R factors could transfer multiple antibiotic resistance to salmonellae or shigellae *e.g.* in the human intestinal tract. Even a low transfer frequency in this direction can have a serious effect if antibiotics are in use at the same time, since under this selection pressure, only the antibiotic-resistant salmonellae or shigellae survive.

R factors are nowadays divided into two groups according to their effect on the F factor; these groups are designated as Rfi$^+$-factors and Rfi$^-$-factors.

If Rfi$^+$-factors are transferred to an F$^+$ strain, the F properties such as pilus formation and the ability to conjugate and to transfer are inhibited (fi$^+$ = "fertility inhibition" positive)[34,35]. The DNA of such R factors is assumed to code for a cytoplasmic repressor, which can also act on F DNA. Rfi$^-$-factors, on the other hand, do not inhibit the F properties on transfer to an F$^+$ strain. However, they can inhibit the pilus formation and the transferability of the fertility factor Col I (see Section 5).

It has been possible to show in some cases that the complete R factor consists of two DNA sections, which are known as the resistance (R) determinant and the resistance transfer factor (RTF). Thus in the transfer of R factors from R$^+$-*E. coli* bacteria to the enterobacterium *Proteus mirabilis*, the initially uniform R DNA dissociates into two distinguishable circular DNA molecules[36,37] (Figs. 4 and 5). The smaller DNA molecule ($MW = 10 \times 10^6 - 12 \times 10^6$ D) has the properties of the R determinant. It confers multiple

Table 1. Detection of salmonellae carrying R factors in four epidemics (modified after [27]). A = ampicillin, S = streptomycin, K = kanamycin, C = chloramphenicol, T = tetracycline, Su = sulfonamides.

antibiotic resistance, but has no transfer properties. Bacterial cells that contain this plasmid are resistant to antibiotics, but they cannot transfer this resistance further. The larger DNA molecule (MW 55×10^6 D) is presumably the RTF portion. It possesses transfer properties, but does not confer any resistance to antibiotics. Bacterial cells that contain only this plasmid are no longer resistant to antibiotics, but can transfer this plasmid to recipient cells in the same way as F^+ bacteria.

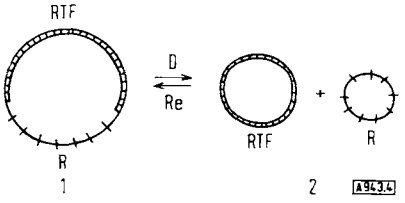

Fig. 4. Dissociation (D) of a complete R factor (1) into an RTF part and an R determinant (2), and recombination (Re).

The DNA of the R determinant contains genes that code for the production of specific antibiotic-inactivating enzymes. Chloramphenicol is inactivated by an R-specific acetylase[38,39], which can acetylate the antibiotic on the hydroxyl group of the side chain (Fig. 6). R-specific enzymes have also been detected for the inactivation of ampicillin (β-lactamase), streptomycin (phosphorylase), neomycin, and kanamycin (acetylases)[40-42]. Resistance to tetracyclines and sulfonamides results from the inhibition of their uptake caused by R factors[43,44]. The molecular nature of this permeability barrier is not yet known. The extent of this multiple antibiotic resistance produced by R factors depends on the number of resistance genes and hence on the number of inactivating enzymes. An R factor can thus give a cell transferable resistance to a single antibiotic (*e.g.* tetracycline) or to six or more antibiotics at the same time *e.g.* chloramphenicol, streptomycin, ampicillin, sulfonamides, neomycin, kanamycin, *etc.*).

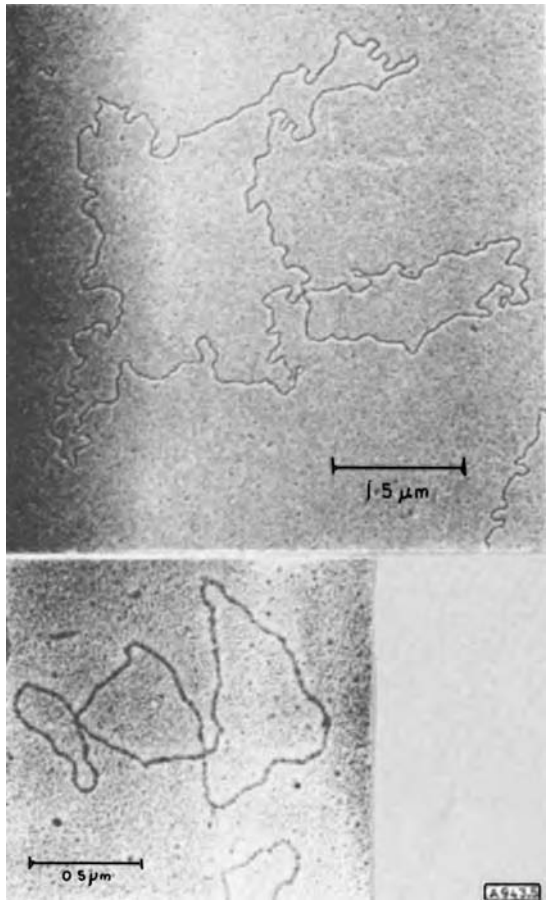

Fig. 5. Electron micrograph of DNA molecules after dissociation of an R factor into the RTF part (upper photograph) and the R determinant (lower photograph) on transfer in *Proteus mirabilis* (after [37]).

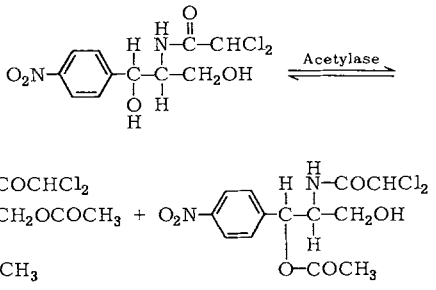

Fig. 6. Inactivation of chloramphenicol by the acetylase determined by an R factor.

4. Penicillinase Plasmids of Staphylococci

Penicillin-resistant strains of staphylococci are widespread. This resistance is due to the occurrence of the "penicillinase plasmids", whose molecular properties have been investigated in particular by *Novick* and by *M. H. Richmond* in *S. aureus*[45,46]. These penicillinase plasmids are a class of extrachromosomal DNA elements that resemble the portion of the R factors known as the resistance (R) determinant in enterobacteria (see Section 3). The molecular weight of these plasmids is between 15×10^6 and 18×10^6 D[47]. In addition to the resistance to penicillin, they frequently also confer resistance to erythromycin and to heavy metal ions such as Cd^{2+}, As^{3+}, and Hg^{2+}[48].

The resistance to penicillin is due to the formation of penicillinases, *i.e.* enzymes that are inducible by penicillin[49]. Penicillinase plasmids can be divided into two groups on the basis of their mutual compatibility in a bacterial cell (see Section 8). These plasmids can not only exist in the extrachromosomal, autonomous state but can occasionally also be integrated into the host chromosome or into another plasmid that is present in the host cell[50]. These plasmids are not themselves transferable like the R factors of enterobacteria, but are presumably transferred by bacteriophages from one bacterial cell to another. A transfer process of this type is known as transduction.

5. Colicinogenic Factors (Col) of *Escherichia coli*

A large number of naturally occurring strains of *E. coli* have extrachromosomal DNA elements, known as Col factors, that among other unknown gene products code for the formation of colicins. The colicins are antibiotically active proteins that occur extracellularly[51] and have interesting modes of action. Their action is confined to colicin-sensitive strains of *E. coli* and closely related Enterobacteri-

aceae, in which they are able to inhibit protein biosynthesis, RNA or DNA synthesis, or oxidative phosphorylation. A model has been proposed for the mode of action of the colicins that involves an indirect effect of the colicin on the biochemical target[52-54]. This model is based on the following experimental observations.

Colicin molecules are adsorbed on specific receptors on the cell surface. The curve for the destruction of sensitive bacteria by colicins follows one-hit kinetics, *i.e.* an adsorbed colicin molecule can bring about the lethal action with a certain probability. The action of the bound colicin molecules can be eliminated if the cells are treated with trypsin shortly after their adsorption.

It has been deduced from these experimental findings that all colicins remain on the outside of the cytoplasmic membrane and influence the biochemical targets indirectly. All the biochemical changes observed in sensitive cells after the adsorption of colicins are concerned with the biosynthesis of macromolecules such as DNA, RNA, and proteins or the oxidative phosphorylation. All these processes are associated with the cell membrane in some way. It has therefore been deduced that the adsorption of a colicin molecule on the membrane initially causes a change in the receptor site, which in turn initiates the transmission of a signal to the target (protein biosynthesis, nucleic acid synthesis, oxidative phosphorylation). The mechanism of this indirect transmission is unknown. According to this view, the colicin does not pass inside the cell.

However, recent investigations on the mode of action of colicin E_3, which blocks protein biosynthesis, also points to a direct action of the colicin on the biochemical target. Thus colicin E_3 can fragment 16S r-RNA *in vitro*[55,56].

Some of the colicinogenic DNA factors, like the F factor and the R factors, possess transfer properties[57,58]. A few of these factors lead to pili similar to those produced by the F factor. The colcinogenic factor I (Col I), on the other hand, is an entirely different transfer factor. Though it causes the production of pili (I pili), these differ from F pili morphologically, in their antigenic properties, and in their adsorption capacity for specific bacteriophages[59,60]

6. Other Extrachromosomal DNA Factors with Transfer Properties

In addition to the three large classes of extensively studied extrachromosomal DNA elements [F (F'), R, and Col factors] there are a number of other extrachromosomal factors with transfer properties.

6.1. Hemolytic Factors (Hly) of *E. coli*

A number of pathogenic strains of *E. coli* are characterized by their ability to produce hemolysins. (Hemolysins are proteins that can lyse erythrocytes, see Fig. 7.) There appears to be a direct relation between the ability of these strains to form hemolysins and their pathogenicity[61]. *H. W. Smith* was the first to observe that the ability to form hemolysins is transferable at least in some hemolytic strains of *E. coli*, and is therefore presumably also determined by extrachromosomal DNA[62]. We were recently able to isolate two extrachromosomal DNA elements (Hly factors), which can occur either separately or together, from hemolytic *E. coli* bacteria[63,64]. Their molecular weights are different ($40—45 \times 10^6$ nd $60—65 \times 10^6$ D); they both carry the determinant for hemolysin production. The larger hemolytic DNA has derepressed transfer properties, whereas the transfer of the smaller hemolytic DNA is mostly repressed.

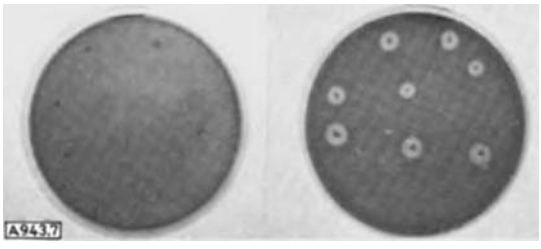

Fig. 7. Blood agar plate with hemolytic and non-hemolytic colonies of *Escherichia coli*. Left: non-hemolytic wild strain, right: hemolytic wild strain.

In the presence of the smaller DNA, the transfer properties of the larger are also inhibited. The smaller DNA presumably codes for a cytoplasmic transfer repressor that can also act on the larger DNA. The two hemolytic DNA factors exhibit extensive homologies in their nucleotide sequence, as has been shown by hybridization experiments. It may therefore be assumed that the smaller DNA was formed by removal of a number of DNA sections from the larger DNA, or that the larger DNA originated from the smaller factor by integration of additional DNA.

6.2. Other Factors

Other genotypic characteristics that are presumably transmitted by transferable plasmids are the ability to form enterotoxins[65] and to produce K-88 antigen[66] in *E. coli*. The production of H_2S in *E. coli*[67] and the degradation of D-camphor and octane by species of *Pseudomonas*[68] also appear to be determined by extrachromosomal transferable DNA elements. It is interesting to note that in the bacterium *Rhizobium trifolii*, which produces plant tumors, the genetic elements that determine the effectiveness (Eff^+) and the infectivity (Inf^+) also appear to be extrachromosomal in nature[69].

7. Plasmids with Unknown Properties

From the many plasmids to which it has not yet been possible to assign biochemical properties, let us consider here only one interesting group, *i.e.* the minicircular plasmids. These DNA molecules are characterized by the fact that they are unusually small. Their molecular weights range from about 1×10^6 to 3×10^6D. Any genetic information contained in these DNA molecules would thus be limited to one to six genes. The first plasmid of this group was isolated by *Cozzarelli et al.* from *E. coli* 15[70]. Other plasmids of similar sizes were isolated from wild strains of *E. coli* and characterized[71] (Fig. 8). It is interesting

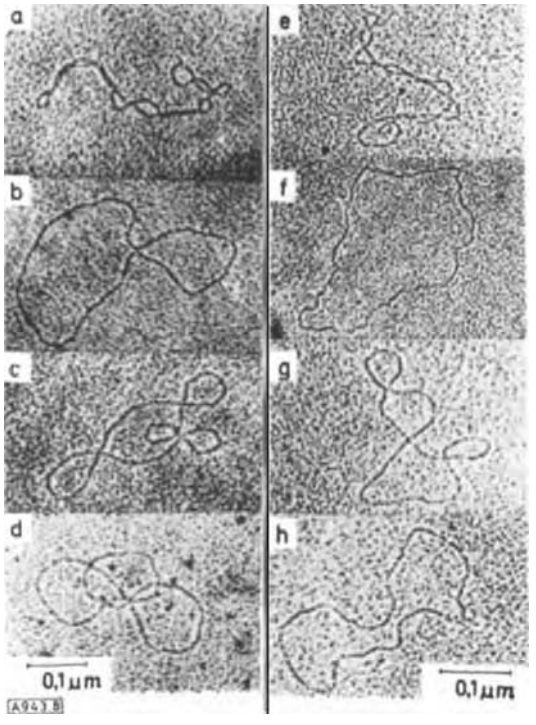

Fig. 8. Minicircular DNA, isolated from two wild strains of *E. coli*. a—d: Supercoiled (a) and open-ring (b—d) DNA from *E. coli* SC 78 (contour length 1.2±0.05 µm). e—h: Supercoiled (e) and open-circular (f—h) DNA from *E. coli* SC 79 (contour length 0.95±0.05 µm) (after [71]).

to note that these minicircular plasmids from *E. coli* exhibit extensive sequence homologies with one another and with the small colicinogenic factor E_1 (Col E_1) discussed earlier[71].

8. Compatibility between Bacterial Plasmids

A bacterial cell can simultaneously act as the host for several different extrachromosomal DNA factors if these plasmids are compatible with one another. It has been shown, however, that two very closely related DNA elements cannot exist stably together. Thus two related F factors, R factors, Col factors, or penicillinase plasmids cannot be stabilized at the same time in an *E. coli* cell, nor can an F factor in an Hfr cell.

On the basis of this phenomenon, the plasmids are divided into incompatibility groups. Members of such groups are incompatible with one another, whereas two plasmids from different groups can be present in the same host[72,73,45]. The incompatibility is thought to arise from the presence of specific plasmid attachment sites or replication sites, presumably on the membrane[74], which are essential for the stable incorporation of plasmids (see Section 11).

Temperature-sensitive mutants of *S. aureus* have been isolated that were no longer able to incorporate plasmids of one compatibility group stably at elevated temperature, though they could stabilize plasmids of another group, and *vice versa*[75]. It is thought that these mutants have no functioning membrane sites for the plasmids of the compatibility group in question at the restrictive temperature. It appears that only a limited number of such attachment or replication sites are available in the bacterial cell for a given group of plasmids. A plasmid entering a cell in which this site (or these sites) is (are) already occupied by another plasmid of the same compatibility group therefore cannot be replicated in this host and transmitted on cell division.

9. Physical Properties and Isolation Methods

The amount of extrachromosomal DNA in bacterial cells containing plasmids is generally approximately 0.5—3% of the chromosomal DNA. Most methods for the separation of extrachromosomal DNA from chromosomal DNA make use of the fact that all the bacterial plasmid DNA molecules found so far occur in a covalently closed, twisted (supercoiled) conformation. This compact conformation is converted into the more bulky open-circular conformation as a result of a break ("nick") in one of the two DNA strands, which may be brought about either mechanically (*e.g.* by shearing forces) or enzymatically by "nicking" endonucleases[76,77] (Fig. 9). In the supercoiled conformation the circular DNA molecule has physical properties that distinguish it from open-circular and linear DNA molecules:

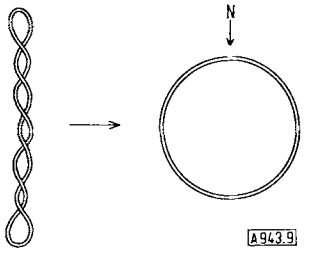

Fig. 9. Transition of a DNA from the supercoiled conformation to the open-circular conformation. The single-strand break or "nick" (N) is caused by endonucleases or by mechanical action.

It is less sensitive to shearing forces; the sedimentation rate in a neutral density gradient is higher[78]. The two strands of a supercoiled DNA molecule cannot be separated under denaturing conditions (pH = 11.5—12.5 or heating above the melting point), since they are joined topologically. Fast renaturation therefore occurs on neutralization to pH 7.0 to 8.0 or on cooling[79,80]. At pH 12.5 the denatured molecule, with its strands still joined topologically, assumes a very complex structure[80] whose sedimentation rate is approximately twice that in the supercoiled conformation in neutral solution[81]. Moreover, the buoyant density of the DNA in this compact conformation at pH 12.5 is 0.08 g/cm^3 higher than the buoyant density of the supercoiled conformation in neutral solution, whereas the buoyant density of the denatured strands of the open-circular form is only 0.06 g/cm^3 higher than that of the native form[82-84].

Supercoiled DNA binds intercalating dyes (*e.g.* ethidium bromide) more weakly than open-circular and linear DNA[85,86]. Since the binding of ethidium bromide to DNA is associated with a decrease in the buoyant density of the DNA, the relative decrease in the density of supercoiled DNA is smaller than that of a corresponding open-circular or linear form[85].

Most methods for the isolation of extrachromosomal DNA make use of the properties described. Only a brief description of the principles of the most important methods can be given below.

The first step in all isolation methods is lysis of the bacterial cells under mild conditions; shearing forces must be avoided and nucleolytic activities inhibited. The bacterial cells *(e.g. E. coli)* are therefore suspended in hypertonic buffer solutions and treated with lysozyme. This enzyme causes hydrolysis of the murein, an essential component of the cell wall of the bacteria. The resulting spheroplasts (bacterial cells that have lost an essential part of their cell walls) are lysed in the presence of sodium ethylenediaminetetraacetate (which inhibits the activity of deoxyribonucleases by complexing Mg^{2+}, Ca^{2+}, and Mn^{2+} ions) usually by detergents, but occasionally by osmotic shock or by treatment with alkali. The detergents that have proved most effective are sodium dodecyl sulfate, sarcosyl NL-30, sodium deoxycholate, and the nonionic detergents Brij 58 and Triton X 100. These last two are able to lyse spheroplasts of *E. coli* without destroying the complex of the cell membrane and the chromosomal DNA. This complex can therefore be removed by relatively low speed centrifugation (6000 × g), while the much smaller extrachromosomal DNA largely remains in the supernatant. The cell lysates obtained are subjected to the further purification steps either directly[87] or after removing the bulk of the chromosomal DNA as described[88].

The most important method for the purification of supercoiled DNA is probably equilibrium centrifugation in a cesium chloride gradient in the presence of an excess of ethidium bromide, which was first described by *Radloff et al.*[85]. In this process, the DNA is separated into a band of higher density, which contains the supercoiled DNA, and a band of lower density, which contains linear and/or open-circular DNA.

Another method makes use of the ease of renaturation of supercoiled DNA. Alkaline denaturation followed by neutralization, converts linear and open-circular DNA molecules into single-strand DNA, while the covalently closed DNA rings return to the supercoiled conformation. The supercoiled DNA can be separated by filtration through nitrocellulose, on which the denatured single-strand DNA is retained[89]. A corresponding separation can be achieved by chromatography on benzoylated or naphthoylated DEAE columns[90].

Because of its greater sensitivity to shearing forces (see above), linear chromosomal DNA can be fragmented more easily than the supercoiled extrachromosomal DNA by mechanical stirring. Subsequent sedimentation in an alkaline sucrose gradient (see below) results in the separation mainly of larger supercoiled DNA molecules such as F and F′ factors and R factors from the chromosomal DNA[91,92].

A method that was frequently used at first is based on the transfer of plasmids into host cells whose DNA has a different buoyant density *(e.g. Proteus mirabilis)*. The two DNA species can then be separated either by repeated equilibrium centrifugation in a CsCl gradient or by chromatography on columns packed with kieselgur coated with methylated albumin (MAK column)[93].

10. Special Plasmid DNA Molecules

The DNA purification methods described allowed the discovery of a series of interesting forms of plasmid DNA. Examples are the oligomeric and catenated DNA forms and the DNA replication intermediates[94–100].

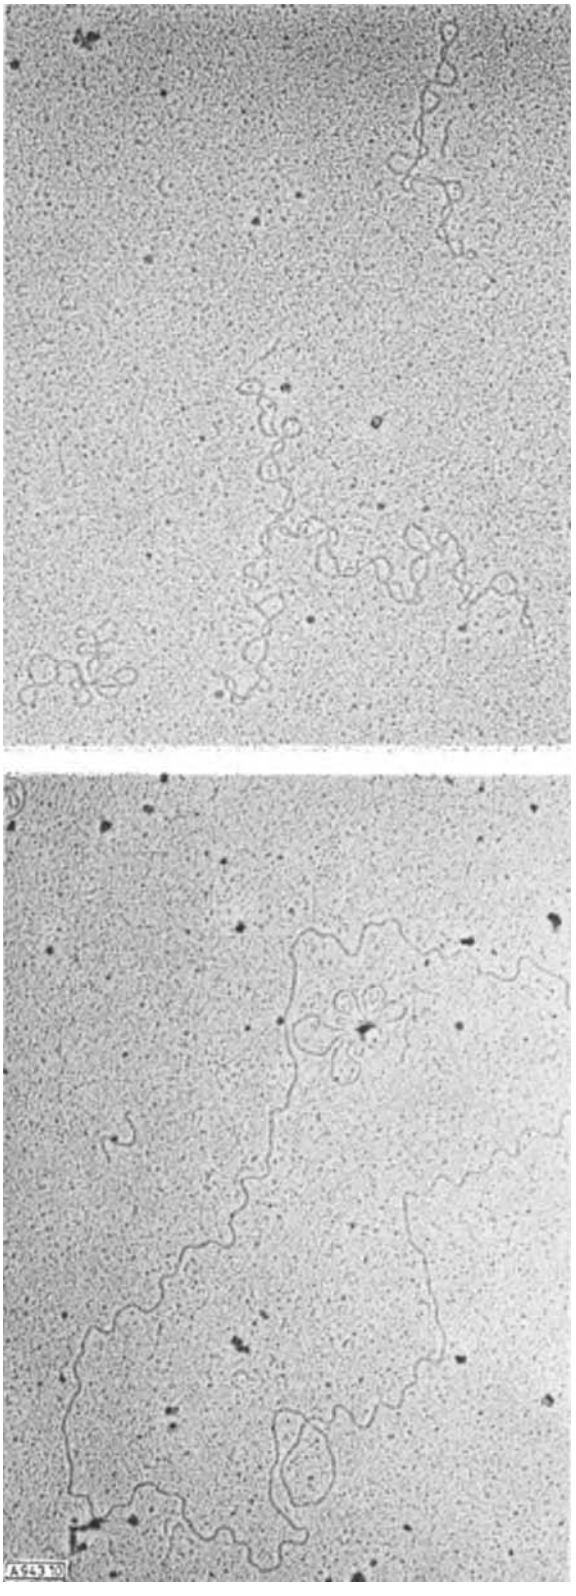

Fig. 10. Oligomeric DNA of the colicinogenic factor E_1 from *E. coli*. Top: two supercoiled monomeric Col E_1 DNA molecules and a supercoiled trimeric form. Bottom: open-circular trimeric Col E_1 DNA molecule (after [99]).

The term "oligomeric DNA" is applied to cyclic DNA molecules consisting of two or more covalently bonded identical genomes (Fig. 10), while in catenated DNA molecules two or more genomes are held together by topological bonding (as in catena compounds[101]) (Fig. 11). Oligomeric DNA molecules, like monomeric DNA, can occur in the supercoiled conformation and in the open-circular conformation. Their physical properties (apart from their size) and hence the isolation methods are the same as for the monomeric form.

Catenated DNA molecules, on the other hand, can assume different conformations and hence different properties, which affect their isolation. Catenated molecules consisting of only two components already offer three possibilities.

1. Both molecules are in the supercoiled conformation (Fig. 11a). Such a DNA molecule has the same properties (sedimentation, denaturation, dye adsorption) as a supercoiled oligomeric DNA of the same size, and can be distinguished from the latter by electron microscopy.

2. Both molecules are in the open-circular form (Fig. 11b). Such molecules cannot be distinguished from corresponding open-circular oligomers by their physical properties. Once again, differentiation is readily possible only by electron microscopy.

3. One molecule is in the supercoiled conformation and the other in the open-circular conformation (Fig. 11c and 11d). These catenated DNA molecules differ characteristically in their physical properties from supercoiled and from open-circular DNA of the same size. Their capacity to bind certain dye molecules (ethidium bromide) is logically intermediate between that of open-circular DNA and that of supercoiled DNA. In a CsCl-ethidium bromide gradient (see Section 9), therefore, these DNA molecules are found in a middle band between the heavy band of the supercoiled DNA and the light band of the linear and open-circular DNA[94]. The sedimentation behavior of these catenated DNA molecules in neutral and in alkaline gradients also differs characteristically from that of supercoiled and of open-circular DNA[94]. Catenated DNA molecules having three or more topologically linked components, which may in turn be monomeric or oligomeric forms, have also been isolated. Only very low concentrations of oligomeric and catenated DNA molecules occur in most plasmids under normal bacterial growth conditions. Formation of these DNA forms can however be enhanced at least for some plasmids[95,98,99,102–104].

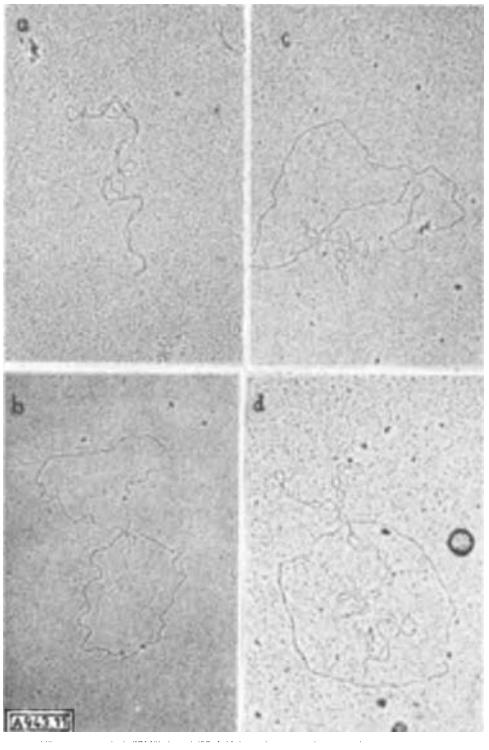

Fig. 11. Catenated DNA of the colicinogenic factor E_1 from *E. coli*. a) Catenate of two topologically linked supercoiled Col E_1 DNA molecules. b) Catenate of two open-circular monomeric Col E_1 DNA molecules. c) Catenate of a supercoiled monomeric and an open-circular dimeric Col E_1 DNA molecule. d) Catenate of a supercoiled trimeric and an open-circular dimeric Col E_1 DNA molecule (after [99]).

Two processes have been proposed for the formation of oligomeric and catenated DNA forms, *i.e.* 1) recombination[94], in which two plasmid DNA molecules are linked by breakage and reciprocal reunion (Fig. 12), and 2) erroneous replication[95] (Fig. 13) (see Section 11). The

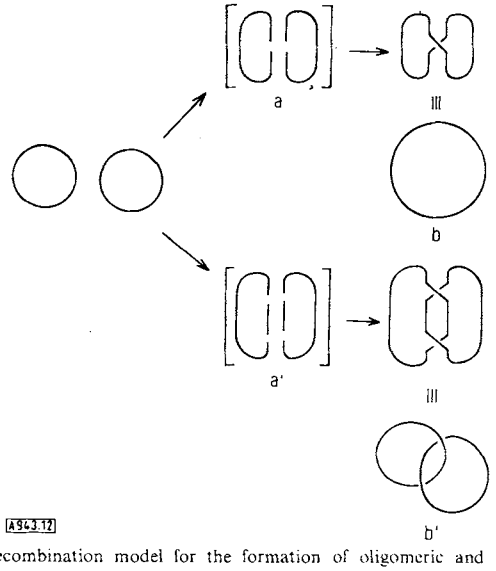

Fig. 12. Recombination model for the formation of oligomeric and catenated DNA molecules (modified model after [94]). The circular DNA molecules are broken either once (a) or twice (a'). With a single break, a reciprocal linkage gives a dimeric DNA molecule (b), whereas with a double break and reciprocal linkage, a catenated DNA molecule (b') is formed.

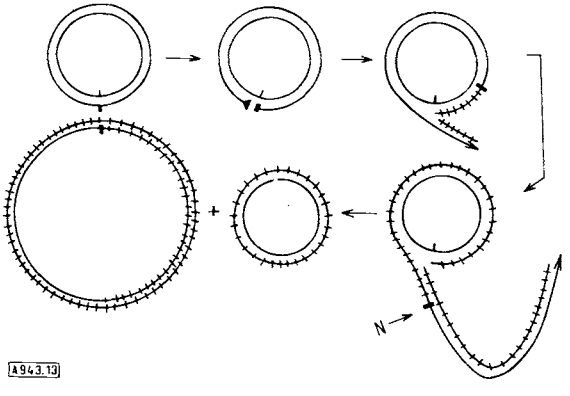

Fig. 13. Replication model for the formation of oligomeric DNA forms (modified model after [95], see also Fig. 16). The "error" in the replication here is that the endonuclease (N) cuts the linear strand, not after the first replication cycle, but only after the second (or third, *etc.*) cycle. Ring closure of the linear strand then leads to multiple (oligomeric) DNA molecules in addition to a monomeric DNA molecule. ——— parent (old) DNA, -HHHH- newly replicated DNA.

question which process is correct cannot yet be answered with certainty; a series of findings appear to support erroneous replication[95,105].

11. Replication of Extrachromosomal DNA Factors

There are a number of recent reviews[106–109] on the mechanism of DNA replication in bacteria, the details of which are still largely unknown. Only the broad features will be presented here, and known peculiarities of the replication of plasmid DNA will be pointed out. The replication of any autonomous genetic unit (replicon)[74] can be divided into three stages:

1. Attachment of the DNA to a specific replication site, which is presumably situated on the cell membrane of the bacterium[2].

2. Initiation of DNA synthesis[108], for which both a positive[74] and a negative[110] regulation mechanism have been postulated.

3. Elongation of the growing DNA chain by enzymatic polymerization of deoxyribonucleoside triphosphates, the two parent strands of the DNA acting as templates (Fig. 14)[111].

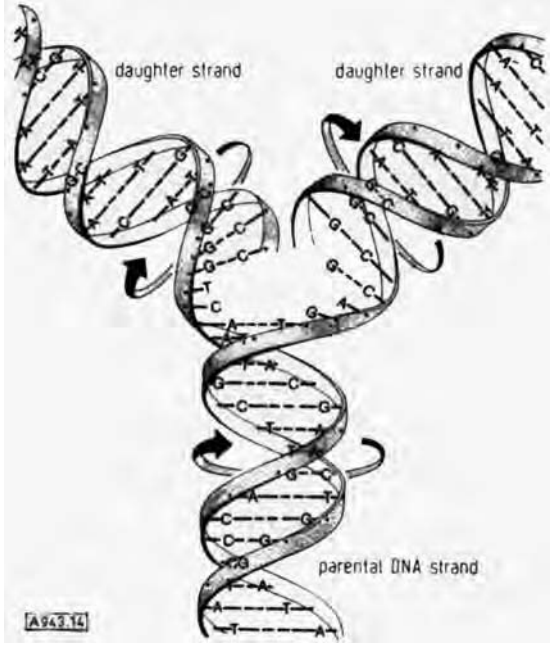

Fig. 14. Semiconservative replication of a linear DNA molecule.

Both for bacterial chromosomal DNA and for plasmid DNA, there is a body of evidence pointing to the existence of specific membrane attachment sites (see Section 8).

For the initiation of DNA synthesis of a covalently closed circular plasmid DNA molecule, a specific break in one of the two DNA strands, which allows the separation of the strands, has been postulated. It is not known whether this important step is regulated by a substance having a positive action (initiator) or by one with a negative action (repressor). The continuous synthesis of two proteins, which is influenced in different ways by chloramphenicol[106], is evidently a pre-requisite for the initiation of the synthesis of chromosomal DNA in *E. coli*. Chloramphenicol also inhibits the initiation of the DNA synthesis of many transfer factors. Interesting exceptions are the nontransmissible plasmids, the colicinogenic factor E_1 and the minicircular DNA of *E. coli* 15, both of which continue replication in the presence of chloramphenicol[71,113]. Other observations also indicate that more than one mechanism is involved in the initiation of plasmid DNA[98,114].

As has been shown by the isolation and the genetic characterization of temperature-sensitive DNA replication mutants, the elongation of chromosomal DNA in *E. coli* involves at least four proteins, though their biochemical nature is largely unknown[112]. These mutants exhibit normal synthesis of the chromosomal DNA at 30 °C, whereas the replication of this DNA stops at 40—43 °C. Biochemical studies on the replication of plasmids in replication mutants of this type in which the elongation is defective have shown that as in the initiation, there are also characteristic differences between the various plasmids in the elongation[98,122–124,127]. The difference in the dependence of the plasmid replication on the various DNA polymerases of *E. coli* is particularly interesting.

Since the isolation of a mutant (Pol A) that has practically no DNA polymerase I (Kornberg polymerase) activity, but nevertheless exhibits normal growth and normal synthesis of the chromosomal DNA[117], it has been assumed that the polymerase I plays no part in the semiconservative replication of the chromosomal DNA in *E. coli*, but is a repair enzyme for the DNA[118]. Two further DNA polymerases (II and III) have now been detected[119–121]. Recently *Gefter et al.* were able to show that a class of temperature-sensitive DNA replication mutants (dna-E mutants) have a temperature-sensitive DNA polymerase III activity[112]. This discovery shows that the polymerase III has an important function in the semiconservative DNA synthesis. This enzyme also appears to be responsible for the semiconservative replication of transfer factors. However, a number of experimental findings suggest that the polymerase I is involved in the replication of the colicinogenic factor E_1 and of the minicircular DNA of *E. coli* 15[122–124], whereas polymerase III does not appear to be necessary. DNA polymerase II does not take part in the replication of plasmid DNA in any of the systems investigated so far[121a].

Two models have been proposed for the semiconservative replication of circular plasmid DNA, *i.e.* the classical "Cairns model" (Fig. 15)[115] and the "rolling circle model" (Fig. 16)[116].

By electron-microscopy, both "Cairns structures" and "rolling circle" structures (circular DNA molecules with a double-stranded linear tail) have been found for Col E_1 DNA

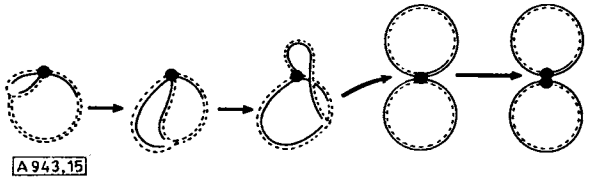

Fig. 15. Replication of a circular DNA molecule after *Cairns*. The model is based on the assumption that the replication always begins at the same origin and proceeds in the same direction (modified after [115]).

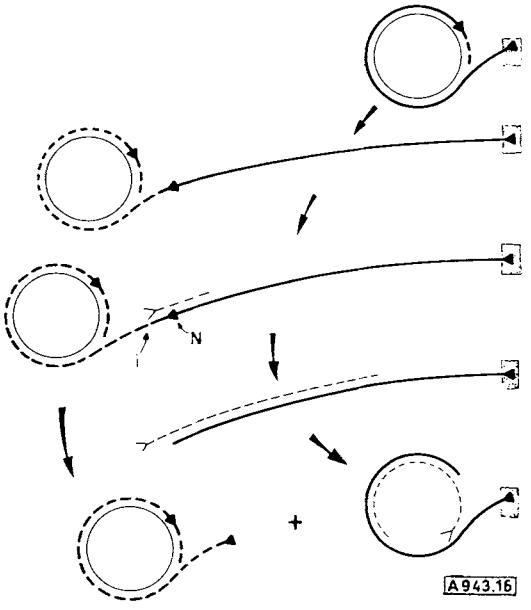

Fig. 16. Replication of a circular DNA molecule according to the "rolling circle model" of *Gilbert* and *Dressler*. One strand of the circular double-stranded DNA is opened and the free end is fixed to a membrane site. The broken strand is continuously withdrawn from the unrolling intact circular strand and replicated in steps (broken line). The initiation of the synthesis of the complementary strand begins on the withdrawn strand at i. An endonuclease (N="nickase") separates the replicating structure in such a way that two circular DNA molecules are formed after ring closure of the linear part (after [116]).

and for minicircular DNA from *E. coli* 15[97, 103, 104]. No definite conclusion can therefore be drawn as to which of the two models is correct for the replication of plasmid DNA. It is possible that both occur simultaneously.

Clear differences are found in the mode of replication of the various plasmids if one follows the behavior of the individual copies of plasmid DNA during a cell division cycle. If there is one copy of plasmid DNA per chromosome, the plasmid DNA is replicated synchronously with the chromosomal DNA, *i.e.* exactly one replication cycle of the plasmid DNA occurs during one replication of the chromosomal DNA. In the case of plasmids of which there are many copies per chromosome (*e.g.* Col E_1, minicircular DNA of *E. coli* 15, R factor NR 1 in *P. mirabilis*), though a constant number of DNA copies are replicated, the individual copies are randomly selected, *i.e.* during one replication cycle of the chromosome, some copies are replicated once, others twice or more frequently, and a corresponding number of copies not at all[125–127]. This random selection of the copies to be replicated suggests that either there are fewer specific replication sites on the cell membrane than there are DNA copies, or there are no specific sites at all in the cell for these plasmids (see Section 8).

The results described here indicate that the DNA replication of plasmids does not proceed by a single mechanism in which all the components are the same. This could also be evidence that more than one DNA replication mechanism is possible in the bacterial cell.

12. Closing Remarks

The bacteria, particularly the most extensively studied enterobacterium *Escherichia coli*, have an abundant supply of extrachromosomal DNA, which provides them with extra biochemical capabilities in addition to those determined by the chromosomal DNA. Though these additional genetic elements are described as "non-essential", they can offer the cell a decisive advantage in selection. It should also be recalled here that some plasmids, particularly the R factors, present a potential danger to man that should not be underestimated. Through their ability to inactivate antibiotics and to transfer this property to other suitable bacteria, and favored by the sometimes indiscriminate use of antibiotics, they lead to the development of increasing numbers of antibiotic-resistant strains among bacteria that are pathogenic to human beings, and these are then extremely unresponsive to therapeutic treatment with antibiotics. The specific properties of these plasmids, such as the ease of transfer from cell to cell and the ability to increase the information capacity by recombination make them variable genetic systems that are suitable for the rapid spread of genetic information.

Because of their small size, the plasmids are generally suitable subjects for investigations on fundamental questions connected with the establishment and self-duplication of genetic material in bacteria. The origin of these genetic elements is still completely unknown. In this connection, the reader can only be referred to speculations[12, 128]. The nature of most of the gene products that are determined by plasmids is also unknown.

The investigation of these DNA systems will undoubtedly enrich our understanding of the genetic and biochemical relationships in bacteria in the years to come.

Our own work cited here was carried out in collaboration with Fräulein H. Schrempf, Frau B. Royer-Pokora, Frau W. Schroen, W. Schiess, J. Kreft, and K. Kapassakalis, and was generously supported by the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie. I am particularly grateful to Professor F. Lingens for financial support and for his interest in this work.

Structural Information from the Habit of Crystals

By Heinz Follner[*]

The question whether information about the internal structure of crystals can be deduced from their external form, *i.e.* from their habit, has often been discussed. A rule formulated by *Donnay* and *Harker* attempts to establish the relationship on the basis of structural geometry. Deviations from this rule make it clear that purely geometric correspondence criteria are only of limited application. Physical factors are also taken into account in the PBC vector method. A combination of the two methods can be of practical use in some cases for the determination of the crystal structures of organic compounds.

1. Introduction

The development of the determination of crystal structures has now reached such an advanced stage both theoretically and experimentally that it is possible to give details of the crystal structure and of bonds between the atoms. This should not lead us to forget that the processes responsible for the crystal structure are still largely unknown. Only in rare cases is it possible to explain satisfactorily why nature favors a certain crystal structure for a substance.

Since crystals first became the subject of scientific investigations, numerous studies have been concerned with the question of the relation between the external form of the crystal and its internal structure. A first step toward an understanding of crystalline substances was the discovery, in the 17th century, of the law of constant angles between corresponding faces of a given type of crystal. Identification of types of crystals was made possible by the mere discovery that every chemically uniform substance forms a characteristic group of crystal shapes. With the possibility of elucidating crystal structures by X-ray methods, the conditions were provided for the derivation of regular relationships between structure and morphological appearance.

1.1. Correspondence Between Structure and Crystal Form

The structure and the form of the crystal that grows are related by the equilibrium polyhedron. According to *Gibbs*[1], the specific free surface energy is of decisive importance to the habit of the crystals. The Gibbs-Curie law defines the surface polyhedron that exists when the free energy has reached a minimum. *Wulff*[2] was able to show that the converse of this law is also valid[3,4]. If the free surface energies of all the faces of a crystal are known, the equilibrium polyhedron can be constructed. Since the free surface energy (except in a few simple cases) cannot yet be given in a general form[5,6], this law cannot be applied to practical problems of crystal morphology. A further complication results from the fact that the equilibrium polyhedron and the actual growth form are rarely the same.

Another approach to finding a correlation between crystal structure and growth form is based on the strictly geometric structure of the crystal. As will be shown later, this approach falls short of requirements in many cases. The relationships indicated are shown in Figure 1.

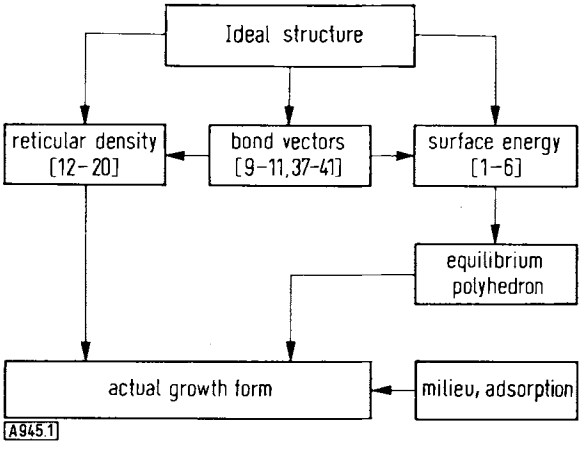

Fig. 1. Correspondence between crystal structure and morphological appearance [7].

2. The Donnay-Harker Rule

2.1. The Bravais Law

Extensive morphological studies, particularly on the naturally occurring minerals, have shown that the number of different types of faces in a given type of crystal is small. The Miller indices (*hkl*) are generally simple whole numbers. This is easy to understand if one considers that the rate of growth of a crystal face is particularly dependent on irregularities such as steps or angles, which distinguish faces with higher indices. The great ease with which further structural components are deposited in these places is very impressively shown by the illustrations of decorated crystal faces containing structural faults such as screw or step dislocations (Fig. 2).

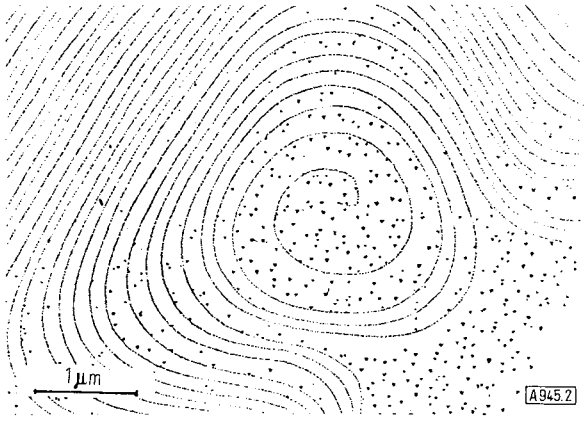

Fig. 2. Growth stages of a screw dislocation on a (111) face of a silver crystal [8].

Bravais[12] and *Friedel*[13–16] were able to correlate structure and external crystal form under the assumption that the crystal faces and the lattice planes are parallel. The morphological importance of a face increases with the density of its population of structural components. The reticular density of a lattice plane, which is defined as the number of atoms per (simple primitive) unit of area, is a measure of the morphological importance of a crystal face. The reticular density is thus proportional to the distance between lattice planes $d(hkl)$, whose calculation requires only the knowledge of the lattice constants. This simple criterion has proved effective for arranging faces in order of importance for a series of substances.

2.2. The Influence of Structural Symmetry on the Crystal Form

The 230 crystallographic space groups result from the combination of symmetry operations such as rotation, reflection, and translation. The combination of translation with rotation or with reflection leads to screw axes and glide planes respectively. These composite symmetry elements are contained in some of the 14 Bravais lattices, which, as basis, have the space groups as translation lattices. *Donnay* and *Harker*[17, 18] recognized that screw axes and glide planes change the population densities of lattice planes in certain zones, a fact that had already been pointed out by *Niggli*[19].

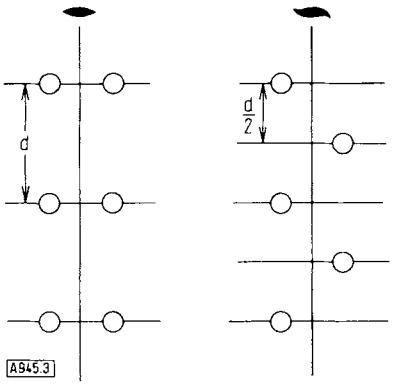

Fig. 3. Change in reticular density of lattice planes due to screw axes.

It is clear from the diagram of a twofold screw axis (Fig. 3) that, in contrast to a twofold rotation axis, intermediate layers with only half the reticular density arise normal to the axis. This fact reduces the morphological importance of this crystal face. A well-known example is quartz[18], which crystallizes in the trigonal space group $P\,3_1 2 (P\,3_2 2)$. Because of the threefold screw axis, the basal face (0001) is only eighth in the hierarchy of possible faces. Quartz crystals with developed (0001) faces are in fact rarely found (Fig. 4).

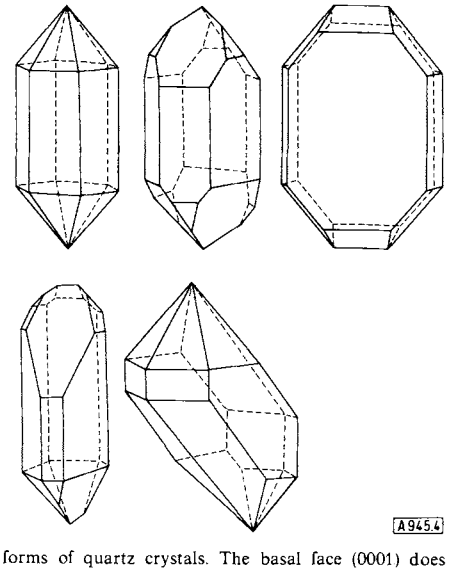

Fig. 4. Various forms of quartz crystals. The basal face (0001) does not occur here.

Glide planes have a similar effect on the reticular density of certain planes. Figure 5 shows a glide plane parallel to the plane of the drawing with a translation component along the *b* axis. The correct face hierarchy is obtained here by doubling the (0 *kl*) indices with *k* odd. It is significant that multiply primitive translation lattices (face-centered and body-centered lattices) also increase the reticular densi-

ties of certain lattice planes and so change the morphological hierarchy.

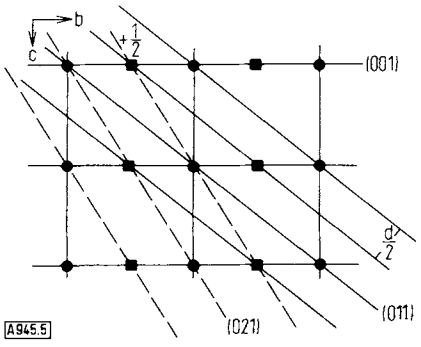

Fig. 5. Change in reticular density of lattice planes due to glide planes.

According to *Donnay* and *Harker* it is possible to set up a characteristic hierarchy of the face forms for each space group. This means that conclusions regarding the symmetry of the arrangement of atoms can be drawn from the crystal morphology. When this is carried out systematically for all 230 space groups one obtains 97 "morphological aspects", whose selection rules are closely related to the extinction rules of X-ray crystallography.

This method can be illustrated by two examples. The mineral garnet, $Al_2Ca_3(SiO_4)_3$, crystallizes in the cubic space group I a3d[18]. The dominant face forms are {011}, {112}, and {123}. Cubic and octahedral forms are rare. The occurrence of the first group of faces points to a body-centered unit cell. In a body-centered translation lattice, planes for which $h+k+l$ is even are favored.

X-ray structure determination has given the space group P mcn for aragonite[20, 21]. The face forms occurring in the three zones [100], [010], and [001] lead to the morphological aspect P *cn, which corresponds to the space groups P 2_1cn or P mcn. *Donnay* and *Harker*[17, 18] have successfully carried out investigations of this type on pyrite, sulfur, spinel, analcime, muscovite, goethite, lepidocrocite, columbite, baryte, and stephanite, among others. Further the method could be applied to phosphophyllite, hopeite, descloizite, strengite, variscite, and scorodite[22].

A method described by *Niggli*[23], in which crystal zones are emphasized as important structural directions, has a similar basis. Such directions are characterized by the shortest distance between identical structural components. The form system of a space group can be developed from specific zones.

2.3. Deviations from the Donnay-Harker Rule

The Donnay-Harker rule has given agreement of crystal and structural symmetries for many substances. As the volume of investigation results increased, however, cases of discrepancies between morphological and structural types became known. Deviations from a rule present grounds for a critical examination. The limits of applicability of the Donnay-Harker method will be discussed below.

1. The reticular density of the lattice planes by definition includes only coplanar structural components. The surface atoms are generally not on planes in the mathematical sense. The concept of the reticular density is therefore meaningful only if the thickness of the surface layer is negligible.

2. The general validity of the Donnay-Harker rule is also limited by the fact that the reticular population of the lattice planes, as a purely geometric factor, does not take the physical properties into account. A simple example of this is sodium chloride[18]. The dominant face form is the cube and not the octahedron. According to the Donnay-Harker rule, however, the (111) face should be favored in the space group F m3m. Cadmium oxide crystallizes in the same space group and in the same type of structure as sodium chloride. In this case, however, the preferred face form is {111}. The best agreement between the natural face hierarchy of sodium chloride and the hierarchy given by the Donnay-Harker rule is found if the structure is based on a simple primitive translation lattice. This is the case if no distinction is made between sodium and chlorine. The difference in behavior between NaCl and CdO is undoubtedly due to the difference in the type of bonding.

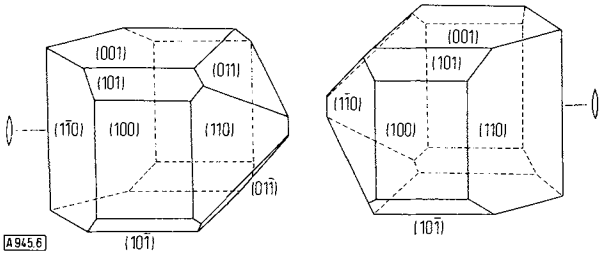

Fig. 6. Enantiomorphic crystal forms of tartaric acid.

3. The Donnay-Harker correspondence principle does not distinguish between parallel crystal faces of acentric space groups. The problem of the absolute configuration of a crystalline compound cannot be solved in this way. The attempt to determine the absolute configuration of tartaric acid from the morphological appearance[24] is therefore of interest in this connection. It can be seen from Figure 6, which shows two enantiomorphic crystals, that there are no parallel counterfaces to the sphenoid faces (011) and (01$\bar{1}$). *Waser*[24] thought that he could show in the structure found by *Beevers* and *Stern*[25, 26] (Fig. 7) that a difference exists according to whether a molecule is deposited on such a face from the left or from the right. *Waser* correlated this behavior with the absolute configuration of tartaric acid.

An X-ray study on a rubidium derivative[27] led to a different result, and showed that qualitative criteria are not generally sufficient to answer this question. It can also be quite problematic to decide whether such cases involve a structure-induced hemihedrism or whether environmental factors have influenced the crystal habit. The observation by *Turner* and *Lonsdale*[28] that the reason for the occurrence of the faces (011) and (01$\bar{1}$) without parallel counterfaces in the case of tartaric acid could be connected with

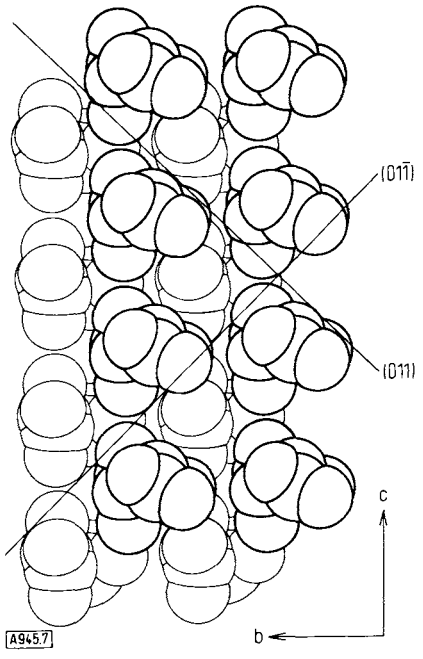

Fig. 7. Crystal structure of tartaric acid [24].

time-dependent hindrance by the solvent would only confirm the assumption that there are in fact differences in crystal growth along the polar axis.

4. The limit of applicability of the Donnay-Harker rule is also reached if the morphological symmetry of a crystal does not agree with the structural symmetry[29-31]. It is necessary to differentiate here between an increase (hypermorphism) and a decrease (hypomorphism) in the macrosymmetry in relation to the symmetry of the arrangement of the atoms. One case of hypomorphism is cuprite, Cu_2O, which was discussed in detail by *Kleber*[32], and which was long regarded as an example of the crystal class 432. According to its structure cuprite belongs to the crystal class m3m. Statistical studies give the face hierarchy {111}, {110}, {100}, {211}, {221}. According to the Donnay-Harker rule, however, {110} is the dominant face form. The preference for the octahedron is undoubtedly connected with the fact that the copper atoms in the structure form a face-centered lattice and the oxygen atoms form a body-centered lattice. Other examples of hypomorphism are α-sulfur (Fddd→222), phosgenite (P4/mbm→422), and sal ammoniac (Pm3m →422), while examples of hypermorphism are barytocalcite ($P2_1 \rightarrow 2/m$) and citric acid monohydrate ($P2_12_12_1 \rightarrow mmm$).

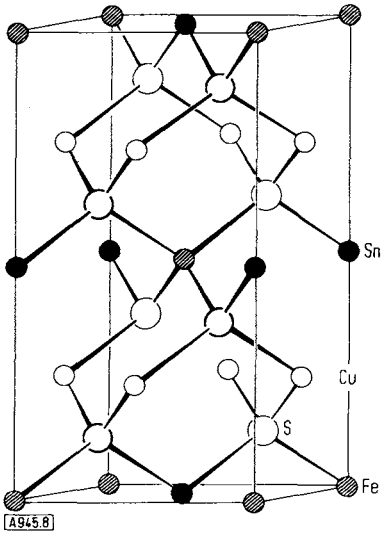

Fig. 8. Crystal structure of stannite, Cu_2FeSnS_4 [34].

An article by *Garrido*[33] on stannite, chalcopyrite, wulfenite, and manganite shows that in certain circumstances a differentiation between the structural symmetry and pseudosymmetry is possible on the basis of the statistical face frequency. For example stannite, Cu_2FeSnS_4, crystallizes in the space group $I\bar{4}2m$[34]. If no distinction is made between copper, iron, and tin atoms, the structure is based on a translation lattice face-centered on all sides (Fig. 8). The lattice constant in the c direction is thus halved. This pseudosymmetry is also shown by optical crystallometry. When the pseudomorphological aspect is taken into account, however, the face hierarchy is not characteristic of an F-lattice (Fig. 9).

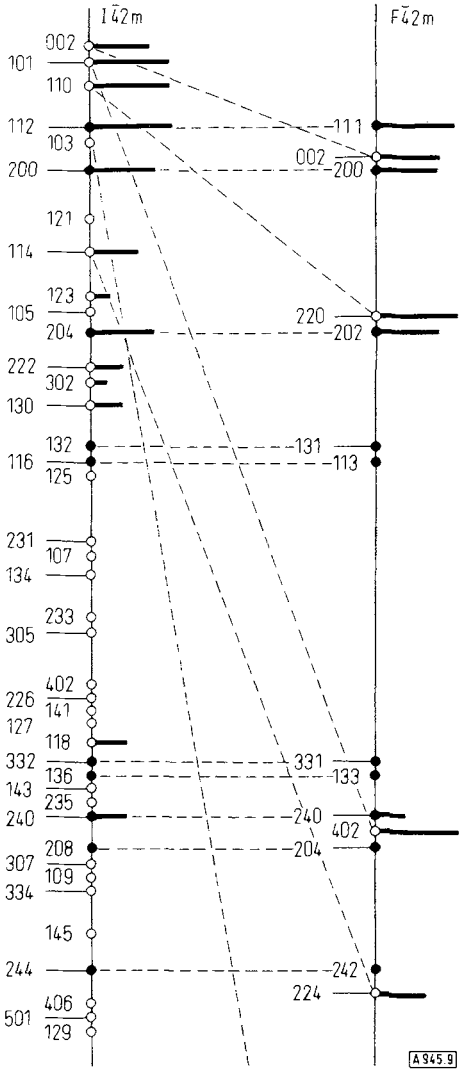

Fig. 9. Face hierarchy of stannite [33]. True symmetry: $I\bar{4}2m$; pseudosymmetry: $F\bar{4}2m$. The lengths of the horizontal full lines correspond to the statistical face frequency. Because of pseudomorphology the faces indicated by open circles change their position on the D-value scale.

In most types of crystals with discrepancies between structural symmetry and macrosymmetry, the structure determination has shown special arrangements of the atoms. The determination of the true structural symmetry can be made extremely difficult in these cases by the apparent presence of glide planes and screw axes. *Kleber*[35] has considered the structure of wulfenite ($PbMoO_4$) from this standpoint. Systematic absences of X-ray reflections lead here to the space group $I\,4_1/a$, which does not agree with the macrosymmetry (crystal class 4). *Kleber* found that certain displacements of the oxygen atoms do not cancel the extinction rule "$(hk0)$ only with $h(k)=2n$". The a glide plane is no longer a space-group-dependent symmetry element in this case. Accurate detection will not be easy if the shifts are only slight. *Leciejewicz*[36] unfortunately did not follow up *Kleber*'s suggestion in his redetermination of the structure of wulfenite.

3. The PBC Vector Method

The connection between structural and morphological elements certainly cannot be provided by criteria of the Donnay-Harker rule alone. It is clear from the departures from the rule that the external form of a crystal cannot always be explained by its structure. The concept of the reticular density of a lattice plane is a purely geometric quantity. It does not take into account physical factors such as bond character and electron density distribution.

An important advance in this respect was represented by the work of *Hartman* and *Perdok*[37-41], which provided the conditions required for the chemical bonding to be taken into account. The authors started from the assumption that the external form of the crystal is determined by bonds running through it like a chain. A strong bond vector has a decisive influence only if this bond continues uninterrupted through the entire structure. In complicated structures a chain of bonds may consist of several bond units. The effective direction is given by the vector sum of all the bond units. Since crystals have a three-dimensional periodic structure, one need only investigate the situation in the unit cell. The vector sum is known as the periodic bond chain vector (PBC vector). The rate of growth along such a direction is determined not by the strongest but by the weakest bond vector in the chain. *Hartman* and *Perdok* concluded that the position of a face in the hierarchy is determined by the number of PBC vectors running parallel to it. On this basis it was possible to group the crystal faces into three types:

1. F faces. These contain at least two PBC vectors.
2. S faces. Only one PBC vector runs parallel to these faces.
3. K faces. These contain no PBC vectors.

The three types of faces can be easily illustrated for the sodium chloride structure (Fig. 10). (010), (110), and (111) have the character of F, S, and K faces respectively. The situation is more complicated in the case of the barium sulfate structure. Investigation of the bonding showed that the principal crystal faces are F faces (Table 1). The occurrence of the single K face is attributed to the adsorption

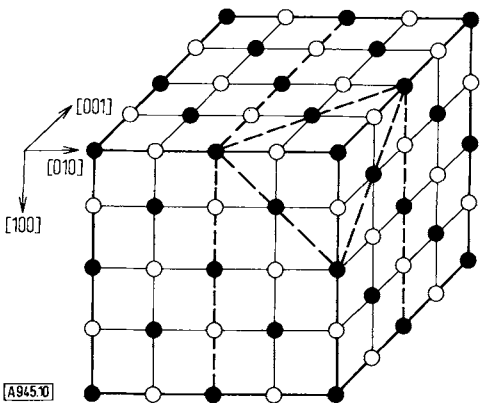

Fig. 10. PBC vectors in the structure of NaCl. The faces (010), (110), and (111) are indicated by broken lines.

of impurities. It is now known that the adsorption of foreign particles can alter the growth type of a crystal face.

Table 1. Face forms of barium sulfate [40].

Face symbol	Combination-persistence [%]	Face character (PBC)	(Donnay-Harker)
(001)	97.8	F	6
(210)	91.9	F	7
(101)	86.4	F	1
(011)	85.9	K	3
(010)	70.8	F	12
(211)	69.2	F	9
(100)	61.1	F	2
(410)	38.9	S	26
(102)	37.3	S	8
(111)	26.5	S	4
(213)	25.9	S	28
(230)	25.9	S	>29
(201)	24.4	S	5
(214)	16.7	S	>29
(212)	15.7	S	13
(310)	14.6	S	>29
(110)	11.4	S	16

This approach also explains why *Niggli*'s principle[23] of correspondence between lattice lines and zone axes cannot lead to agreement of a high order between morphological and structural elements. Lattice directions with the highest populations need not always correspond to the most stable zone axes.

4. Possible Applications

Concrete conclusions regarding structure can be drawn in certain cases by combination of the PBC vector method and the Donnay-Harker rule. *Hartman*[42] was able to determine the approximate positions of the centers of gravity of the molecules in the unit cell for a number of organic compounds (Table 2), knowing only the crystal form (cleavability) and the symmetry of the structure (space group, unit cell, cell content). The method is based on the following considerations. If a morphological face hierarchy $\{h_1k_1l_1\}$, $\{h_2k_2l_2\}^*$... *etc.* arranged according

Table 2. Coordinates of the centers of gravity of organic molecules calculated from morphological data. The comparison values in parentheses were taken from the known crystal structures [41].

Compound	x	y	z	Ref.
p-Chloroaniline	3/4 (0.7499)	1/4 (0.25)	0 (0.9932)	[43]

Ribonuclease (orthorhombic)	0 (0)	0 (0)	1/4 (0.25)	[47]
Ribonuclease (monoclinic)	− (0.17)	0 (0)	3/4 (0.74)	[47]
α-Bromoisotutin	0 (0.0899)	2/3 (0.6715)	1/12 (0.0761)	[48]

to $d(hkl)$ values contains sets of indices whose faces do not appear on the crystal and that precede observed face forms in the hierarchy, the correct order can be found by multiplication of these indices by a whole number n: $\{h_2k_2l_2\}$*, $\{nh_1nk_1nl_1\}$, *etc.* The factor n will not generally be greater than two.

The knowledge of such additional "extinction rules" is necessary for the calculation of the coordinates of the centers of gravity. If $A(x_1y_1z_1)$ and $B(x_2y_2z_2)$ are the centers of gravity of two crystallographically identical molecules situated on parallel $(h_1k_1l_1)$ planes with an interplanar distance of $d(h_1k_1l_1)/n$, one obtains the simple relation

$$1/n = h_1(x_1 - x_2) + k_1(y_1 - y_2) + l_1(z_1 - z_2).$$

A number of compounds for which it has been possible to carry out these calculations are listed in Table 2. *p*-Chloroaniline[43] crystallizes in the space group P nma with four molecules in the unit cell. It follows immediately that the center of gravity of the molecule must lie on the reflection plane (at $y = 1/4$). The only face form found in the crystal is {111}. Arrangement according to $d(hkl)$ values gives the order {101}, {011}, {111}*, {002}, {200}, {102}, from which it follows that the indices of {101} and {011} must be doubled to obtain an order corresponding to the experimental findings. This fact can be used for the calculation of the center-of-gravity parameters with the aid of the above relation.

The coordinates of the centers of gravity can also be determined for papain[44] on the basis of similar considerations. Some interesting structural conclusions can be drawn even from Figure 11.

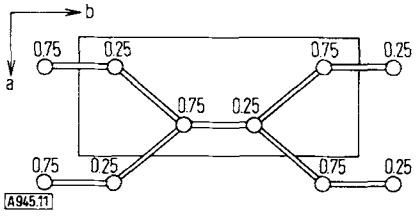

Fig. 11. Centers of gravity of molecules in the papain structure, projected on (001) [41].

Hazell[45] developed an "X-ray variant" as a supplement to this method. This author started with a structure consisting only of the centers of gravity of the molecules. The structure factor must give a maximum or a minimum for a face form that occurs on the crystal. If an unknown crystal face appears in the hierarchy before the face forms that occur, the structure factor in this case should be $F = 0$. As can be seen from Figure 12, the results of the calculations for α-$(NSOCl)_3$ agree with the values in Table 2.

5. Closing Remarks

The clarification of the correspondence between crystal form and internal structure is of great importance to crystal chemistry, and is undoubtedly helping toward a physical understanding of crystal structures. Though a large number of observations in this field have been reported in numerous publications, the Donnay-Harker rule is still the most effective method for the investigation of correspondence problems. However, this topic has been overshadowed somewhat in the past few years by the pure determination of structures. There is as yet no general basis for the clarification of the complicated processes that lead to the development of crystal faces. The discussion of the problems will certainly be more successful if more attention is given to the physicochemical processes instead of the purely geometric correspondence criteria.

Very Low-Pressure Pyrolysis (VLPP); A Versatile Kinetic Tool

By D. M. Golden, G. N. Spokes, and S. W. Benson[*]

The theory and applications of the very low-pressure pyrolysis technique to the study of the rates and mechanisms of unimolecular reactions, radical-radical, and radical-molecule bimolecular reactions, surface recombination of atoms, heterogeneous reactions, and vibrational energy transfer are reviewed.

1. Introduction

It is the dream of every kineticist to have an apparatus which will give him a direct, unique, and quantitative view of all the products and reactants involved in an elementary chemical reaction. Various types of apparatus have been constructed to achieve this goal; some have come tantalizingly close to reaching the objective in special cases. But all too often, chemical complexity, secondary reactions, impurities, or surface reactions have turned the dream into a painful nightmare of incongruous or inconsistent results.

Perhaps the most ubiquitous difficulty dogging the experimental study of kinetic systems is that of secondary reactions. Frequently, the results of an initial chemical event in a simple system are completely concealed by a complex network of very rapid secondary processes. In the simple pyrolysis reactions of hydrocarbons, the olefin products generally start to change the course of the reaction after only 0.01 mol-% have been formed. It is equally difficult in oxidation studies to deduce initial steps from the multitude of complex products that are found in the very earliest stages of the reaction.

About eight years ago we constructed the "dream" system which appeared capable of giving direct, quantitative information on the rate of elementary, gas-phase chemical reactions. The principle behind the scheme was to flow a reactive gas at very low pressures into a heated Knudsen cell where it might decompose unimolecularly. Reactants and products would then flow molecularly (at large mean-free paths) through a relatively large exit hole into the ionization chamber of a mass spectrometer where they would be analyzed directly. At sufficiently low pressures, there would be no collisions between the products of the initial pyrolytic step and other species, and thus no secondary reactions. Because of this, we labeled the system "Very Low-Pressure Pyrolysis" or VLPP for short.

From its earliest days, VLPP has lived up to its expectations and proven itself capable of yielding information on the nature of the primary products of unimolecular, pyrolytic reactions. With the use of transition state treatments[1]

[*] Dr. D. M. Golden, Dr. G. N. Spokes, and Prof. S. W. Benson
Department of Thermochemistry and Chemical Kinetics
Stanford Research Institute
Menlo Park, California 94025 (USA)

of unimolecular reactions (both RRK and RRKM[*]), it has yielded Arrhenius parameters for unimolecular rate constants. In addition, it has been adapted quite generally to quantitative studies of fast bimolecular gas-phase reactions, as well as heterogeneous reactions. It also lends itself quite well to studies of energy transfer. Because of this general versatility of VLPP as a kinetic tool, we have felt it worthwhile to summarize our experiences with it and review some of its potential, as well as its demonstrated applications.

2. Some General Conditions for Operation of VLPP

If one wishes to eliminate secondary reactions in a chemical system, one thought suggests itself very quickly. Secondary reactions are generally bimolecular. Primary kinetic events are most often unimolecular. One can mitigate, drastically reduce, and even eliminate secondary, bimolecular reactions by working at sufficiently low pressures and for sufficiently short times.

Let R• be a radical or atom produced in a primary unimolecular event, such as bond fission, and t_r be the residence time of R• in the reaction system before it is observed or escapes. Let [M] be the concentration of any reactive species in this system (including, possibly, R•), and k_M be the bimolecular rate constant for attack of R• on M. Then the condition that very little secondary reaction occurs can be expressed:

$$f_r = t_r k_M[M] \ll 1 \qquad (2.1)$$

where f_r is the fraction of R• undergoing secondary reaction in time t_r.

If we arbitrarily select t_r as 10^{-3} seconds, and f_r as 0.01, then since $k_M \leq 10^8$ $lmol^{-1}s^{-1}$, for even very rapid radical-molecule reactions, the condition can be satisfied by choosing $[M] \leq 10^{-7}$ mol/l $\approx 4 \times 10^{-3}$ torr. Lower pressures permit us to increase t_r or k_M proportionately.

Such conditions require a flow system with very short residence times and very rapid quenching or sampling. The only analytical instrument that can accommodate itself to such small samples, and a wide variety of reactions is a mass spectrometer. One also requires relatively high temperatures to make initial rates fast enough. This, then, is the simple system illustrated schematically in Figure 1 for a VLPP experiment.

There is an immediate objection to such an experiment familiar to every kineticist. If the pressure is so low that there are no secondary reactions, then almost all collisions of both reactive molecules and products will be with the walls. Doesn't this experiment virtually assure that observed reactions will all be heterogeneous?

At first glance, such an objection seems very serious. However, heterogeneous reactions are usually slow reactions. They require a molecule or radical to reside on a surface or active site and then undergo chemical rearrangement.

[*] RRK and RRKM are abbreviations for the Rice-Ramsperger-Kassel and Rice-Ramsperger-Kassel-Marcus theories.

But the fastest competing reaction for such an adsorbed molecule is not chemical rearrangement with its relatively low A-factor and moderate activation energy, but rather reevaporation, which has a very high A-factor and usually a lower activation energy. Furthermore, as the temperature

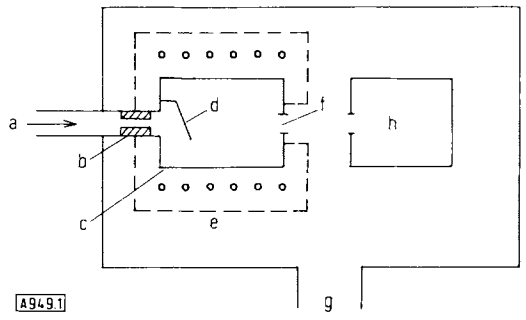

Fig. 1. Simple sketch of a VLPP apparatus. a = Gas inlet, b = capillary (i. d. 1—2 mm), c = Knudsen cell reactor, d = baffle to prevent molecular streaming, e = electric furnace, f = exit hole (2—10 mm), g = exit to very fast pumps, h = mass spectrometer detector.

increases, the residence time of a molecule or radical on the surface decreases. In fact, as we shall see in more detail later on, it is difficult to observe heterogeneous reactions in VLPP experiments. They need to have a collision efficiency with the surface usually in excess of 10^{-4} in order to be observed; thus, only very fast heterogeneous reactions can be measured with VLPP.

3. Scope of VLPP

In the eight years that have elapsed since our initial efforts at VLPP, the technique has become a refined and sophisticated tool for the quantitative study of very rapid reactions, both homogeneous and heterogeneous. We have operated VLPP from room temperature to 1400 °K with a quartz reactor and to 1900 °K with an alumina reactor. A brief summary of the range of problems to which VLPP has been applied is as follows:

a) To observe quantitatively the nature of the primary products of a unimolecular, thermal reaction, including both molecular or radical products.

b) Measurement of the rates of "fast" unimolecular reactions, *i.e.*, $10^{-1}\ s^{-1} \leq k \leq 10^4 s^{-1}$.

c) Measurements of the rates of "very fast" bimolecular reactions, *i.e.*, 10^{11} $lmol^{-1}\ s^{-1} \geq k \geq 10^{5.5}$ $lmol^{-1}\ s^{-1}$. These include atom-molecule, radical-molecule, and radical-radical reactions.

d) Measurements of the rates of "very fast" heterogeneous reactions, *i.e.*, collision yields $\geq 10^{-5}$. These studies have been done with atoms, molecules, and/or radicals.

e) Rates of energy transfer between highly excited molecules and surfaces or other molecules.

From a historical point of view, it is of interest to note that VLPP is the first technique to be generally applicable to the measurement of absolute rate constants for radical-

molecule reactions and radical-radical termination reactions.

4. Nature of the Experiment

In a simple VLPP experiment, molecules of reactant gas are allowed to flow under steady state conditions into a Knudsen cell reactor (Figure 1) made of fused silica (or other appropriate material) which is electrically heated in a controlled and uniform way. The flow rate is confined to a range such that the mean free path of molecules within the cell exceeds the exit aperture diameter by a factor of *ca.* ten. This guarantees molecular effusion in the exit beam. Usually the mean free path is kept longer than the vessel diameter so that most collisions of reactant molecules are with the walls. Under these conditions, "stirring" is very rapid and the reactor fulfills the kinetic requirements for behaving like a well-stirred reactor. That is, mixing of the entering gas with residual gas takes a time which is very small compared to t_r, the total residence time in the system[2]. Each Knudsen cell reactor of the type depicted in Figure 1 is characterized by a collision number,

$$Z_w = A_v/A_h \tag{4.1}$$

where A_v is the area of the walls of the reactor, and A_h is the area of the escape aperature. Z_w is the average number of collisions with the walls made by a molecule during its residence in the cell. The residence time, t_r, of the average molecule of mass M in the reactor is given by the Knudsen equation[3] as:

$$t_r = \frac{4V}{\bar{c}A_h}\ s^{-1} \tag{4.2}$$

where V is the volume of the reactor in cm^3, and $\bar{c}$ is the mean unimolecular speed given by kinetic theory as:

$$\bar{c} = \left(\frac{8RT}{\pi M}\right)^{1/2} = 1.46 \times 10^4 \left(\frac{T}{M}\right)^{1/2}\ cm/s \tag{4.3}$$

It is useful to define a first-order rate constant, k_{em}, which characterizes the rate of escape of a species of mass M from the reactor:

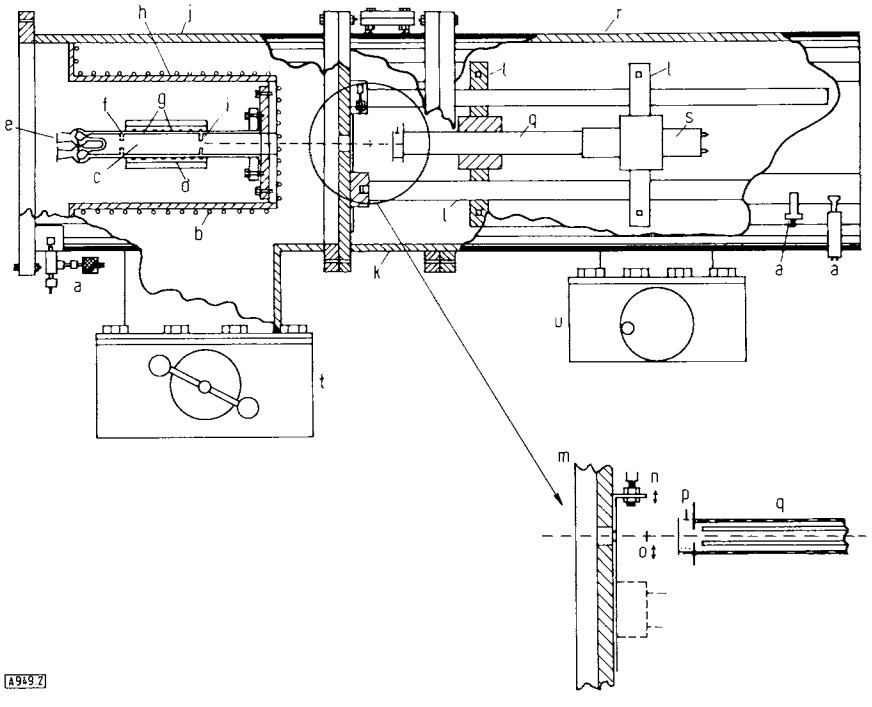
$$k_{em} \equiv \frac{1}{t_r} = 3.65 \times 10^3 \frac{A_h}{V}\left(\frac{T}{M}\right)^{1/2} \tag{4.4}$$

The frequency of collision of the average molecule with the reactor walls, ω, is given by:

$$\omega \equiv \frac{Z_w}{t_r} = Z_w k_{em} = \frac{\bar{c}A_v}{4V} \tag{4.5}$$

which depends *only* on the reactor geometry and not on its aperture size.

Reactor geometries and aperture sizes which we have employed have led to collision numbers ranging from *ca.* 100 to 20000 with collision frequencies of *ca.* $10^{4.5}\ s^{-1}$, implying average residence times from *ca.* $10^{-2.5}$ to 1 s.



A 9292

Fig. 2. VLPP-II for studies of bimolecular reactions. Overall length of apparatus *ca.* 110 cm. a = Auxiliary inlet, b = water cooling, c = reactor, d = heater, e = gas inlet for reactants, f = baffles, g = thermocouple locations, h = reactor chamber, i = exit aperture, j = differential pumping chamber, k = central support section with electrical and mechanical access to system, l = spectrometer support, m = gas beam from reactor, n = adjustable collimater slit, o = vibrator (89 Hz), p = ionization chamber, q = quadrupole mass filter, r = mass spectrometer, s = multiplier (FW 141), t = six inch gate valve, u = four inch gate valve.

Gases which exit through the aperture are sampled with a quadrupole mass spectrometer, and the mass spectrum recorded.

Figure 2 shows a more complex arrangement which employs a differential pumping technique and allows higher flow rates to be attained in the reactor without unduly high pressures obtaining in the mass spectrometer (VLPP-II).

Figure 3 depicts a reactor which has been designed to allow the changing of aperture sizes *in situ*. This reactor, which we have called the "triple-aperture reactor" has been described in detail elsewhere[4].

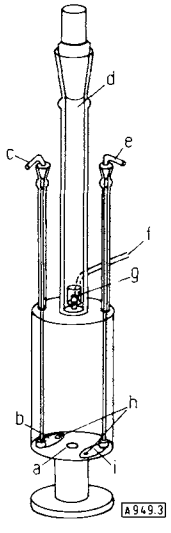


Fig. 3. Triple aperture quartz reactor system. a = Hole (1 cm dia.), b = aperture plate (3.3 mm dia.), c = 3.3 mm aperture plate manipulator, d = removable section with ground joint, e = 1 mm aperture plate manipulator, f = gas inlet tube, g = device for heating of solids and pyrolysis of emerging gases, h = aperture plates may be independently moved to cover 1 cm hole, i = aperture plate (1 mm dia).

If F_M is the flux of molecules M into the reactor cell, then under steady state conditions, with no reaction going on, the steady state concentration of M in the reactor is given by:

$$[M]_{ss} = \frac{F_M}{V k_{em}} = \frac{R_M}{k_{em}} \qquad (4.6)$$

V is the volume of the reactor and $R_M = F_M/V$ is the specific flux of M into the reactor. Typical fluxes have ranged from 10^{14} to 10^{17} molecules/s; typical reactor volumes are *ca.* 30—140 cm^3.

5. History of a Reacting Molecule

A molecule entering the Knudsen reactor through the entrance capillary (Fig. 1) is close to room temperature. It will make a few wall collisions in the entrance leads, and then it begins a sequence of collisions with the hot reactor walls. It probably reaches the translational and rotational temperature of the reactor walls within 3 to 5 wall collisions and then will probably take another 10 to 20 collisions to achieve something very close to the vibrational temperature of the reactor walls. Such a molecule is not, however, ready to react.

In order for a molecule to undergo unimolecular reaction, its internal (*i.e.*, vibrational) energy must exceed the activation energy of the particular reaction. Such highly excited molecules form an extremely small and exceptional population in the "tail" of the Maxwell-Boltzmann energy distribution. The unimolecular chemical reaction can be looked upon as an "indicator" which signals the appearance of such hot molecules in the energy spectrum.

There is consequently a natural "induction" period τ_i in VLPP experiments during which no chemical reaction takes place and which measures the time required for a population of cold molecules to achieve internal energies in excess of the activation energy for reaction.

If we select a temperature T at which the unimolecular reaction rate constant for a reactive molecule M exceeds 10^4 s^{-1}, and introduce M into a reactor cell of variable collision number Z_w, we may anticipate the behavior shown in Figure 4. At higher collision numbers the fraction of reacting molecules, x_r, slowly rises until it becomes proportional to Z_w, and then finally, with still greater Z_w, the fraction asymptotically approaches unity.

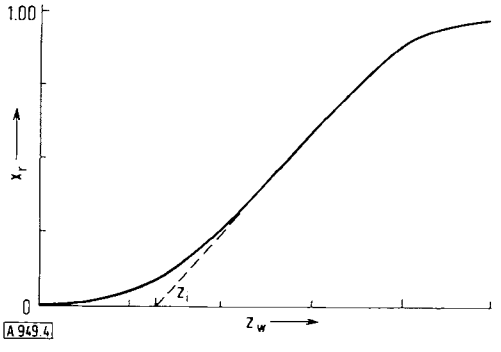

Fig 4. Fraction x_r of reacting molecules as function of the collision number Z_w.

If we extrapolate the linear portion of this curve to the axis, it will intersect at a value of $Z_w = Z_i$, which we can label the induction collision number. Z_i is essentially the number of collisions required for a molecule to reach an internal energy in excess of activation energy. It will turn out to be a measure of the rate of internal energy transfer ("chemical" accommodation) between a molecule and the walls of the vessel.

With most of the molecules we have studied, Z_i is less than 40 collisions, and we have so far been able to spend little time in this interesting area.

6. Unimolecular Decompositions

Let A be a molecule which can undergo an *irreversible* unimolecular decomposition whose stoichiometry is:

$$A \rightarrow pP + qQ \qquad (6.1)$$

If k_1 is the first-order rate constant for this process, and k_{ea} the first-order rate constant for A to escape from the vessel, then the steady state concentration of A is (eq. 4.6):

$$[A]_{ss} = \frac{R_A}{k_1 + k_{ea}} \tag{6.2}$$

and for a typical stable product, P, the steady state concentration is:

$$[P]_{ss} = \frac{p k_1 [A]_{ss}}{k_{eP}} \tag{6.3}$$

$$\text{Defining: } [A]_0 \equiv \frac{R_A}{k_{ea}} = [A]_{ss} \text{ when } k_1 = 0 \tag{6.4}$$

$$f \equiv \frac{[A]_0 - [A]_{ss}}{[A]_0} = \text{fraction of A decomposed} \tag{6.5}$$

$$F \equiv \frac{f}{1-f} = \frac{[A]_0 - [A]_{ss}}{[A]_{ss}} = \frac{k_1}{k_{ea}} \tag{6.6}$$

The essence of the technique can be ascertained from the understanding that equation (6.2) describes $[A]_{ss}$ as resulting from the competition between chemical reaction (k_1) and escape from the reactor (k_{ea}). VLPP is thus a relative rate measurement technique, wherein one of the processes is not a chemical reaction, but rather a physical process whose rate constant can be computed from easily known parameters of the experiment thus yielding *absolute* values of chemical rate constants.

The signal measured at the mass spectrometer detector can be calibrated as a function of the flow rate R_M for each reactant and product species M, and at constant temperature should just be proportional to the flux of M reaching the detector. If this signal is I_M, then:

$$I_M = \alpha_M k_{em} [M]_{ss} \tag{6.7}$$

where α_M is the calibration factor for species M.

For the unimolecular reaction (6.1) we can measure a signal I_A due to A or I_P due to any of the products P. Most of the time we have performed both reactant and product measurements. Mass balances are usually good to within about 5%. If we choose to follow reactant A, then:

$$I_A = \alpha_A k_{ea} [A]_{ss} \tag{6.8}$$

and

$$I_A^0 = \alpha_A k_{ea} [A]_0 = \alpha_A R_A \tag{6.9}$$

and from eq. (6.6):

$$F = \frac{[A]_0 - [A]_{ss}}{[A]_{ss}} = \frac{I_A^0 - I_A}{I_A} = \frac{k_1}{k_{ea}} \tag{6.10}$$

F is an experimentally measured quantity, as is k_{ea}. The constant k_1 is then calculated from eq. 6.10. The precision of measurement is greatest for $F = 1$ and least (unless measuring product) near $F = 0$ or very large. We usually confine our measurements to $1/9 \leqslant F \leqslant 9$ (*i.e.*, $0.1 \leqslant f \leqslant 0.9$).

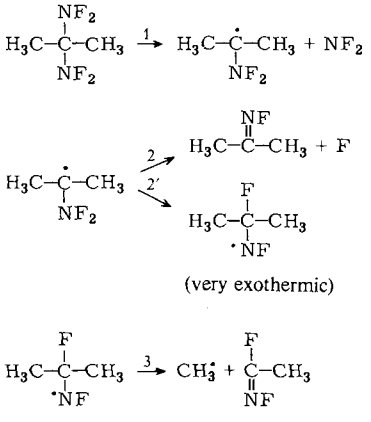
7. Some Unimolecular Product Studies

Our first studies of unimolecular reactions yielded very unexpected but interesting results. In the hope of detecting free radicals directly, as others had done with similar apparatus[5], we chose to look at the pyrolysis of 2-nitropropane. We anticipated finding NO_2 and isopropyl radicals. We did find[6], as we raised the reactor temperature, the expected disappearance of parent peaks, but no peaks corresponding to NO_2 or isopropyl radicals. Instead, we could identify what seemed to be a C_3H_6 mass spectrum and an unexpected spectrum of what could only be HNO_2. All search for radical fragments proved negative! Looking into the literature on NO_2 pyrolysis, we found that we had resolved an old controversy over its mechanism. Instead of radicals, the initial thermal step gives molecules in a direct, concerted process:

$$i\text{-}C_3H_7NO_2 \rightarrow HNO_2 + CH_2{=}CH{-}CH_3 \tag{7.1}$$

The mass spectrum of HNO_2 was confirmed by introducing an authentic sample into the mass spectrometer.

In a subsequent study of a class of related compounds, the substituted difluoramines, we verified that for both 1,1- and 1,2-bis(difluoroamino)propane, the initial thermal act was the fission of the relatively weak C—N bond to give free radicals and NF_2[7]. However, rapid secondary reactions occurred which were of great interest and which could be deduced from the residual spectra. One of these was an unexpected isomerization in competition with a secondary bond fission:



(7.2)

The fluoroimino products were identified from unique mass peaks which could not be accounted for in any other way and were subsequently confirmed by long-duration experiments in which the reaction products were trapped directly in a liquid nitrogen trap, isolated[8], and identified.

It was of particular interest to show, and we did, that there was no molecular elimination of HF from the 1,2-isomer or of HNF_2 from either species.

It was also of interest to observe that in the pyrolysis of 2-nitropropane, an unstable intermediate, HNO_2, was produced which did not decompose, while with the NF_2 compounds, radical intermediates were formed which did decompose. As we shall see, this is a typical feature of high-temperature, VLPP experiments, and one readily deduced from the theory of unimolecular reactions. HNO_2 has only a weak HO—NO bond (48 kcal/mol). It, nevertheless, doesn't decompose in our experiment with $t_r = 10^{-2}$ seconds, even at 1000 °K where its high-pressure unimolecular half-life would be about 10^{-5} second. The reason is that it is too small a molecule with too few internal degrees of freedom. In VLPP its rate has become second order and fallen off by a factor of more than 10^3. In contrast, the larger NF_2-containing radicals have many internal degrees of freedom and their rates are much faster in VLPP. In addition, they also have lower activation energies for fission or isomerization than HNO_2.

Similar studies[9] have revealed 1,2-elimination of H_2 from a saturated hydrocarbon. At about 1100 °K isobutane cleaves into H_2 + isobutene. The 1,2-elimination of H_2 from ethyl benzene has also been observed[10] as a much faster process than that for isobutane. These are theoretically interesting reactions, since they are "forbidden" by orbital symmetry rules, and we hope to be able to study them further.

Perhaps one of the most surprising of our primary product studies came in the observation of the pyrolysis of monomethyl hydrazine[11]. Instead of the expected split into amino and methylamino radicals, we were able to demonstrate that primary decomposition was wholly into stable molecules, $NH_3 + CH_2{=}NH$ and $H_2 + CH_3{-}N{=}NH$.

8. Relationship of k_1 to $k_{1\infty}$

The rate constants k_1 (and, of course, those for the reverse reactions) will be a function of ω, the frequency of collision of the average molecule with the walls of the reactor. This is a result of the fact that the frequency of wall collisions is not sufficient to maintain an equilibrium distribution of energy in the reacting molecules and thus the rate constant measured is lower than $k_{1\infty}$, the constant for $\omega \rightarrow \infty$. This is commonly referred to as "fall-off" since a plot of k_1 vs. ω shows the fall-off of k_1 from the value $k_{1\infty}$.

The relationship between k_1 and $k_{1\infty}$ is given by RRK(M) theory, and it is possible to predict k_1 if the Arrhenius parameters of $k_{1\infty}$ are known. Accordingly, if the value of the Arrhenius A-factor is known, the value of the activation energy may be determined from a fit of k_1 vs. T to a computed curve. Details of such determinations of activation energies are given in several publications[4].

In general, A-factors for unimolecular processes can be estimated with considerable accuracy if the process is unambiguous. If, on the other hand, doubt exists as to whether a given process is occurring *via* bond homolysis or molecular elimination, estimated A-factors may differ by *ca.* $10^{3\pm1}$ s^{-1}, and both would still give good fits to a k vs. T curve, albeit, of course, for different values of the activation energy. Often VLPP can answer questions of this type *via* the mass spectral product analysis, since few, if any, secondary reactions will have occurred.

9. Arrhenius Parameters for Unimolecular Rate Constants

One of the simplest examples of a reaction of this type is the dehydroiodination of isopropyl iodide. The high-pressure Arrhenius parameters are well known[12] and the determination of k_1 by VLPP can be thought of as a test of the method granting the correctness of the RRK(M) treatment. The results of pyrolyzing isopropyl iodide in the triple-aperture reactor (Fig. 3) using VLPP-I apparatus are compared with the RRKM *predicted* values in Figure 5(a)[4].

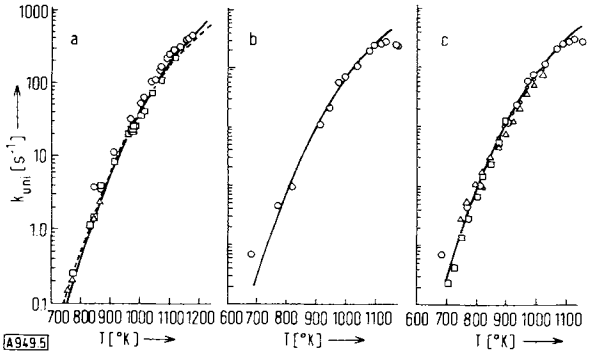


Fig. 5. Elimination of HI from isopropyl iodide; plot of k_{uni} as function of T. a) Measurements in apparatus VLPP-I. ——: RRK plot, – – –: RRKM plot. –○–○–: $Z = 285$, –□–□–: $Z = 1920$, –△–△–: $Z = 22400$. b) Measurements in apparatus VLPP-II. –○–○–: $Z = 2000$. c) Measurements in apparatus VLPP-III. –○–○–: $Z = 29000$, –□–□–: $Z = 1930$, –△–△–: $Z = 176$. All three cases gave the values $E_0 = 44.4$ kcal/mol, $\log A_\infty = 13.69\ s^{-1}$, $E_\infty = 45.5$ kcal/mol.

Isopropyl iodide has also been pyrolyzed using a VLPP-II apparatus (Fig. 2) in a *ca.* 2000-collision reactor with ω higher by 1.88 than in the triple-aperture reactor; the results are shown in Figure 5(b). A third VLPP apparatus (VLPP-III) modeled directly on VLPP-I, has been constructed at Stanford Reasearch Institute by Drs. *D. S. Ross* and *L. Piszkiewicz*. The results of isopropyl iodide pyrolysis in their "triple-collision" reactor are shown in Figure 5(c).

The agreement among the results from the three different VLPP systems is taken to indicate, with a great deal of certainty, the efficacy of the technique.

n-Propyl iodide pyrolysis has also been investigated[4]. We wanted to obtain a value for the activation energy of the dehydroiodination of *n*-propyl iodide as a quantitative measure of the difference between the value for this anti-Markownikoff process and the Markownikoff elimination in isopropyl iodide. VLPP seemed well adapted to this study as static systems are complicated by the presence of the I atom catalyzed HI elimination.

The VLPP of *n*-propyl iodide did indeed produce propylene and HI, but in competition with the production of *n*-propyl radicals and I atoms. The radicals quickly split to give ethylene and CH_3, so that by monitoring total iodide

disappearance, and both ethylene and propylene appearance, both rate constants could be measured.

RRK theory was properly modified to take into account the competition between the processes and the results are shown in Figures 6 and 7.

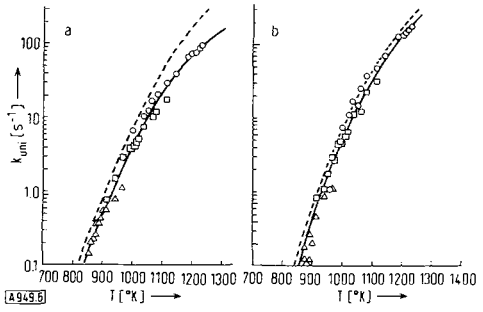

Fig. 6. a) Elimination of HI from *n*-propyl iodide; plot of k_{uni} as a function of *T*. ——·——: RRK/2 plot; – – –: RRK plot; - o - o -: $Z = 285$, – □ – □ –: $Z = 1920$, – △ – △ –: $Z = 22400$; $E_0 = 47.5$ kcal/mol, log $A_\infty = 12.9$ s^{-1}, $E_\infty = 48.4$ kcal/mol. b) Cleavage of C—I bond in *n*-propyl iodide; k_{uni} as a function of *T*. Key to curves as in Fig. 6a. $E_0 = 52.0$ kcal/mol, log $A_\infty = 15.5$ s^{-1}, $E_\infty = 54.9$ kcal/mol.

A number of other reactions have been investigated purely as a demonstration of the efficacy of the method. These include the pyrolyses of ethyl acetate[13], cyclobutane[14], and di-*tert*-butyl peroxide[15]. Only cyclobutane yielded other than a simple verification that VLPP results agreed with the high-pressure parameters. The agreement between the VLPP results and the previously determined values of the Arrhenius parameters in all but the cyclobutane pyrolysis, lend credence to the suggested changes in the cyclobutane values[14].

2,3-Dimethylbutane and 2,2,3,3-tetramethylbutane[16] have been pyrolyzed and found to fit the rate parameters measured by *Tsang*[17, 18].

In the course of using them as thermal sources of methyl, ethyl, isopropyl, and *tert*-butyl radicals, we have pyrolyzed di-*tert*-butyl peroxide, di-*tert*-amyl peroxide[15], azoethane, dipropionyl peroxide, azoisopropane, and 2,2'-azoisobutane[19].

In the case of di-*tert*-amyl peroxide, if the *A*-factor is assigned in a manner analogous to di-*tert*-butyl peroxide, where the high-pressure parameters are already known, the value of the activation energy which matches the observed data best is within 1 kcal/mol of the value for di-*tert*-butyl peroxide. *Tsang*[20] observed the same sort of lowering for *tert*-amyl vs. *tert*-butyl bond dissociation energies.

The results for 2,2'-azoisobutane can be compared with previous high-pressure results in both static[21] and flow[22] systems. (The value preferred in Ref. [12] is not correct.)

In earlier work[23] *Benson* and *Spokes* showed that the elimination of HCl from 1,1,1-trichlorethane was compatible with the parameters already established[24] in high-pressure work.

In an unpublished qualitative preliminary study[25] *Spokes* and *Golden* have pyrolyzed C_2F_4 and found their results compatible with C—C bond scission at a rate compatible with the known thermochemistry of CF_2 radical production.

Other examples of reactions of this category that have been studied by VLPP include the pyrolyses of the three benzylamines, $PhCH_2NH_2$, $PhCH_2NH(CH_3)$, and $PhCH_2N(CH_3)_2$[26]. Here the reactions were benzyl-N bond homolyses, and a reasonable choice of *A*-factors led directly to values of the heats of formation of the aminyl radicals. (There are secondary reactions in these systems—namely, radical decompositions and, perhaps, disproportionations—but as long as there is no recombination to reform the reactant or reactions which destroy it, other than the unimolecular decomposition, equation 6.10 holds.)

Table 1 shows the results of investigations on several other nitroalkanes (using VLPP-III).

Table 1. Kinetic data for some nitroalkanes (VLPP-III)[a]

Cpd.	log *A* [s^{-1}]	E_a [kcal/mol]
$(CH_3)_2CHNO_2$	11.3	39 ± 1
$CH_3CH(NO_2)CH_2NO_2$	11.5	41 ± 1
$CH_3CH_2CH(NO_2)_2$	17.5	47 ± 1
$CH_3C(NO_2)_2CH_3$	17.5	46 ± 1
$CH_3CH_2CF(NO_2)_2$	17.5	47 ± 1

[a] These investigations were sponsored by the U.S. Office of Naval Research. The results are preliminary data presented prior to publication and were kindly supplied by Dr. *D. S. Ross* and Dr. *L. Piszkiewicz* of the Physical Organic Chemistry Department of the Stanford Research Institute.

All alkanes with geminal nitro groups undergo C—N scission at about the same rate. The C—N bond strength in each of the three molecules is 46 to 47 kcal/mol, *i.e.* the effects of H-, CH_3-, and F-substitution at C-1 on the C—N bond strength are apparently the same. The nongeminal 1,2-dinitropropane, on the other hand, has a C—N bond strength of *ca.* 60 kcal/mol, and undergoes faster cyclic elimination of HONO. Comparing 2-nitropropane with 1,2-dinitropropane shows that the second NO_2 in the dinitro compound seems to have little effect on the rate of elimination.

10. Radical-Molecule Reactions

Since it is possible to work up to pressures of 4×10^{-2} torr in vessels with 1 mm exit diameter holes, VLPP can be used to study fast bimolecular reactions. These include reactions which go at virtually every collision ($k_B \approx 10^{11}$ lmol^{-1} s^{-1}) to those which have a collision yield of one in 10^5 ($k_B \approx 10^6$ lmol^{-1} s^{-1}).

Between temperatures of 300 and 1500 °K, very few, if any, bimolecular reactions between stable molecules have rate constants of this order of magnitude. Only radical-molecule and radical-radical reactions are so fast. We have studied both in VLPP.

To study radical-molecule reactions in VLPP, we need a source of radicals and a method for introducing molecules at known concentrations. Conventional pyrolysis techniques can be used to provide radicals and we have, for example, produced CH_3 radicals by the pyrolysis of di-*tert*-butyl peroxide. At temperatures in excess of about 500 °K,

this molecule decomposes rapidly into 2-*tert*-butoxyl radicals, which in turn rapidly decompose into two CH_3 radicals + two acetone molecules. Above 700 °K in a 1000-collision reactor, one finds essentially quantitative decomposition into $2CH_3^{\cdot} + 2CH_3COCH_3$.

As radical sources we have also used: acyl peroxides $[(n\text{-}C_3H_7\text{—}CO_2)_2 \rightarrow 2C_3H_7^{\cdot} + 2CO_2]$, azo compounds $(R_2N_2 \rightarrow 2R^{\cdot} + N_2)$, oxalate esters $(ROCOCO_2R \rightarrow 2R^{\cdot} + 2CO_2)$, and peroxyesters $[(RCO_2OR') \rightarrow R^{\cdot} + R'O^{\cdot} + CO_2]$.

Chemical reactions can thus be used to produce free radicals and the second reactant can be introduced by premixing in known amounts with the reactive radical source or else through a second inlet. Each inlet system supplies reagent with or without added carrier gas[*] *via* a controllable flow system which can be quantitatively calibrated over a flow range of 10^{13} to 10^{17} molecules/s.

One of the first reactions studied was[27] that between CH_3 radicals and O_2. For over 40 years now, this reaction has been proposed as one of the key, fast steps in hydrocarbon oxidation with a stoichiometry:

$$CH_3^{\cdot} + O_2 \rightarrow CH_2O + {}^{\cdot}OH \qquad (10.1)$$

However, we were able to show that over the temperature range 500—1400 °K, there was no measurable CH_2O produced in over 10^4 collisions of CH_3 with O_2. Assuming an Arrhenius A-factor for such a reaction of 10^8 $l\,mol^{-1}\,s^{-1}$, this implies an activation energy E_1 in excess of 14 kcal. If the A-factor is $10^{9.5}$, as it is for the addition reaction, then $E_1 \geq 24$ kcal. These results essentially rule out reaction (10.1) as a significant contributor to hydrocarbon oxidation.

Similar studies[28] with allyl radical and O_2 show that it too does not react with O_2 in over 10^4 collisions; consequently, the proposed reaction

$$\dot{C}H_2\text{—}\dot{C}H\text{—}\dot{C}H_2 + O_2 \rightarrow CH_2{=}CH\text{—}CHO + HO^{\cdot} \qquad (10.2)$$

also has a high activation energy and is not an important reaction in the oxidation of C_3H_8 or of C_3H_6.

In contrast, the reaction $CH_3^{\cdot} + NO_2$ gave copious yields of CH_2O *via:*

$$CH_3^{\cdot} + NO_2 \rightarrow (CH_3ONO)^* \rightarrow CH_3O^* + NO \qquad (10.3)$$
$$\downarrow$$
$$CH_2O + H$$

While we made no effort to obtain quantitative data on the overall reaction, the rate constant must be in excess of $10^{9.5}$ $l\,mol^{-1}\,s^{-1}$ with $E_{act}=0$. Allyl radicals also react rapidly with NO_2.

Our first extensive measurements of radical-molecule reactions were made with the reaction of CH_3 radicals with DBr[29] using a dual entry reactor. If we use the reaction of $CH_3^{\cdot}$ (from pyrolysis of di-*tert*-butyl peroxide with HI, as an example of the method, we can titrate $CH_3^{\cdot}$ with HI by progressively increasing the concentration of HI (*i.e.*, flow of HI) in the reactor at fixed flow of peroxide. The CH_3 radicals formed in the pyrolysis have the possibilities of either escaping from the reaction vessel or of reacting with HI. The steady state concentration of $CH_3^{\cdot}$ in the reactor is then given by:

$$[CH_3]_{ss} = \frac{R_{CH_3}}{k_{eCH_3} + k_B(HI)_{ss}} \qquad (10.4)$$

where R_{CH_3} is the rate of production of CH_3 radicals in the reactor and k_B is the bimolecular rate constant for reaction with HI:

$$CH_3^{\cdot} + HI \xrightarrow{k_B} CH_4 + I \qquad (10.5)$$

The product CH_4 gives a mass spectrometer signal I_{CH_4}, given by:

$$I_{CH_4} = \alpha_{CH_4} k_{eCH_4} [CH_4]_{ss} = \alpha_{CH_4} R_{CH_4} \qquad (10.6)$$

but since $R_{CH_4} = k_B[CH_3]_{ss}[HI]_{ss}$:

$$I_{CH_4} = \alpha_{CH_4} k_B [HI]_{ss} [CH_3]_{ss} \qquad (10.7)$$

and from equation (8.4):

$$I_{CH_4} = \frac{\alpha_{CH_4} k_B [HI]_{ss} R_{CH_3}}{k_{eCH_3} + k_B [HI]_{ss}} \qquad (10.8)$$

The other stable product, acetone (Ac), can be used as a marker for the decomposition and $R_{Ac} = R_{CH_3}$. The signal of acetone is given by:

$$I_{Ac} = \alpha_{Ac} k_{eAc} [Ac]_{ss} = \alpha_{Ac} R_{Ac} = \alpha_{Ac} R_{CH} \qquad (10.9)$$

Hence, dividing equation (8.9) by equation (8.8):

$$\frac{I_{Ac}}{I_{CH_4}} = \frac{\alpha_{Ac}}{\alpha_{CH_4}} \left[1 + \frac{(k_{eCH_3}/k_B)}{[HI]_{ss}} \right] \qquad (10.10)$$

But $I_{HI} = k_{eHI}\alpha_{HI}[HI]_{ss}$, hence:

$$\frac{I_{Ac}}{I_{CH_4}} = \frac{\alpha_{Ac}}{\alpha_{CH_4}} \left[1 + \frac{(k_{eCH_3}/k_B) k_{eHI} \alpha_{HI}}{I_{HI}} \right] \qquad (10.11)$$

Equation (10.11) is a perfectly general equation which states that a plot of the ratio of the observed signals I_{Ac}/I_{CH_4} should, at a fixed temperature and for a given reactor, be a linear function of $(1/I_{HI})$, the reciprocal signal observed for HI. It doesn't matter what other reactions occur in the reactor, what fraction of the peroxide is decomposed, or how many of the *tert*-butoxyl radicals are themselves trapped by the HI.

Figure 7 shows a typical plot obtained for the reaction of $CH_3^{\cdot}$ with DBr following equation (10.11). The intercept in such a plot is simply the known ratio of calibration

[*] Inert carrier gas is frequently added to act as an internal standard for analytical calibration purposes. It is also useful (in 10- to 100-fold excess) for obtaining accurate flow measurements when working at very low flow rates.

factors $\alpha_{Ac}/\alpha_{CH_4}$, while the ratio of the intercept to slope will yield the desired rate constant k_B[*].

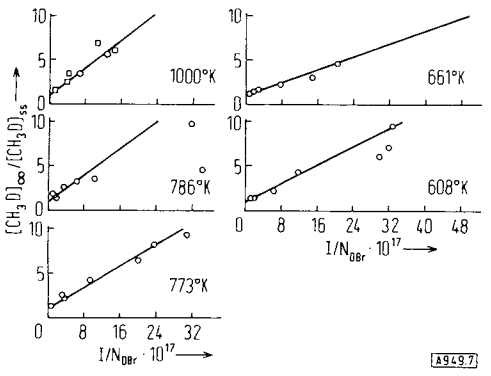

Fig. 7. "Titration" of $CH_3^\cdot$ with DBr.

The technique of the experiment is to establish a steady flow of peroxide and measure I_{CH_4} (should be zero), and I_{Ac}. HI is then introduced, and its flow progressively increased until (if possible) we have scavenged all CH_3 radicals, and we have obtained one CH_4 molecule for every acetone molecule. The same experiment is then repeated for enough different rates of flow of peroxide to make sure that the data are not flow dependent.

By such a method we could measure k_B for $CH_3^\cdot + DBr$ between 700 and 1100 °K and show that it was consistent with the known rate constant for the reverse reaction and the known thermochemical data for the species involved, including the CH_3 radical:

$$CH_3^\cdot + DBr \underset{-1}{\overset{1}{\rightleftarrows}} CH_3D + Br^\cdot \qquad (10.12)$$

$$K_1 = k_1/k_{-1} = \exp\{-\Delta G_1^0/RT\} \qquad (10.13)$$

We have also obtained data[**] by similar methods for the reactions of $CH_3^\cdot$ with HI, with NO_2, with I_2, for *tert*-BuO$^\cdot$ with HI, and with DBr, for *tert*-Bu$^\cdot$ with HI, and with DI.

Because of its great flexibility, VLPP has opened up an entirely new area for the hitherto almost inaccessible field of fast, radical-molecule reactions. Currently, we are investigating methods of atom production which will permit the direct study of fast atom-molecule reactions up to 1500 °K.

When radicals are being "titrated", as in the above experiment, those which do not react, escape. The escaping radicals can often be directly detected mass spectrometrically by lowering the ionizing voltage from the normal ≈ 70 eV to ≈ 10—13 eV. If we call the mass spectral intensity due to radicals at that voltage, I_R, then

$$I_R = \alpha_R k_{eR}[R] \qquad (10.14)$$

and the same sort of analysis as above indicates that for $CH_3^\cdot + HI$:

$$\frac{I_{Ac}}{I_{CH_3}} = \frac{\alpha_{Ac}}{\alpha_{CH_3}}\left[1 + \frac{I_{HI}k_B}{\alpha_{HI}k_{eHI}k_{eCH_3}}\right] \qquad (10.15)$$

Thus k_B can be measured from the slope and intercept of a plot of I_{Ac}/I_{CH_3} vs. I_{HI}.

11. Radical-Radical Reactions

Radical-radical reactions have been among the most difficult to study on an absolute basis. Until quite recently, the photochemical sector[30] method had been the only technique available for this study, and the results from it have been erratic—often in error by factors of from 10 to 10^3. In part, the difficulty lies in the problem of not knowing precisely the termination products of a chain reaction. Only for $CH_3^\cdot$ recombination has it given reliable results.

In VLPP only those gas-phase bimolecular processes which are rapid enough to compete with escape from the reactor occur. Given the lifetimes quoted earlier and the flow rates attainable, the rate constants for such processes have to be $\gtrsim 10^{6.5}$ lmol^{-1} s^{-1} ($Z = 2\times10^4$); $\gtrsim 10^{7.5}$ lmol^{-1}s^{-1} ($Z = 2\times10^3$); and $\gtrsim 10^{8.5}$ lmol^{-1} s^{-1} ($Z = 2\times10^2$).

These numbers generally limit the nature of these bimolecular processes to radical-radical and fast radical-molecule interactions, unencumbered with the complexities, such as chain reactions, which usually accompany them in the more conventional techniques.

In the event that the reaction studied is reversible, for example[31]

1,5-hexadiene (biallyl) (BA) $\underset{k_r}{\overset{k_1}{\rightleftarrows}}$ 2 allyl

equation (6.10) is modified and becomes

$$\frac{k_1}{k_{eba}} = \frac{F}{1 - 2K[BA]F} \qquad (11.1)$$

where $K = k_r/k_1$, and rearrangement gives

$$\frac{1}{F} = \frac{k_{eba}}{k_1} + 2K[BA]F \qquad (11.2)$$

thus a plot of $1/F$ vs. $[BA]F$ should be linear and k_1 is then obtainable from the intercept and K from the slope.

Even though both k_1 and k_r may not be the true high-pressure limiting rate constants, or even completely or in part heterogeneous, the principle of detailed balancing guarantees that the data will still give the true equilibrium constant K.

The pyrolysis of diallyl oxalate

Allyl—OCO—CO_2—allyl (DA) → 2 Allyl + 2CO_2

also generates allyl radicals, and the usual steady state treatment yields:

[*] α_{HI}, k_{eCH_3}, and k_{eHI} are known instrumental constants.

[**] Due to lack of time, much of this work has not been checked and so remains unpublished.

$$\frac{k_1}{k_1 + k_{eba}} = \frac{2k_{eba}^2[DA]}{2k_{eCO_2}[CO_2] - k_{eba}[DA]} \equiv Yk_{eba} \qquad (11.3)$$

Thus, as Y is an observable and k_{eba} is known, the left-hand side of (11.3) can be measured. Under conditions where $k_1 \gg k_{eba}$, this is equal to K.

The data which we obtained covered the temperature range 913 to 1063 K. By using both diallyl oxalate and biallyl as sources of allyl radicals, we were able to apply both equations (11.2) and (11.3). We obtained values for K, and also for ΔH and ΔS, in excellent agreement with previously measured values of ΔH and theoretically estimated values of ΔS.

Similar behavior has also been observed[10] in the high-temperature pyrolysis of ethyl benzene. Above 850 K this splits into $PhCH_2^{\cdot} + CH_3^{\cdot}$. At higher flow rates, one observes an apparent decrease in the first-order rate constant due to the recombination of $CH_3^{\cdot} + PhCH_2^{\cdot}$. Under these conditions, $2CH_3^{\cdot}$ will not recombine nor will $2PhCH_2^{\cdot}$. It is thus an ideal system for observing cross-combination.

The free radical R generated by the reaction:

$$RXR \xrightarrow{k_1} 2R + X$$

may react bimolecularly to combine (k_r) and/or disproportionate, (k_d), or it may "react" unimolecularly to escape. If R is the flow rate into the reactor of RXR, f is the fraction decomposed, and $k_{ea}[RXR]$ is the rate of escape of RXR through the reactor aperture, then we may write:

$$k_1[RXR] = R - k_{ea}[RXR] = fR \equiv T \qquad (11.4)$$

and from the above scheme, using $k_{er}[R]$ to denote the rate of escape of radicals R out of the reactor,

$$2T = 2(k_r + k_d)[R]^2 + k_{er}[R] \qquad (11.5)$$

Since $k_{er_2}[R_2] = k_r[R]^2 \equiv D$, where $k_{er_2}[R_2]$ is the rate of escape of R_2 from the reactor,

$$[R] = (D/k_r)^{1/2} \qquad (11.6)$$

Finally, combining equations (11.5) and (11.6) yields

$$\frac{T}{D} = \frac{k_r + k_d}{k_r} + \frac{k_{er}}{2k_r^{1/2}D^{1/2}} \qquad (11.7)$$

The quantities T and D are easily measured from intensities of the appropriately calibrated mass peaks as determined by the quadrupole mass spectrometer. Thus a plot T/D as a function of $(k_{er}D^{-1/2})$ should yield a straight line, the slope of which will be a measure of the rate constant for radical combination k_r and the intercept of which will thus yield k_d[*]. This procedure can be carried out at various temperatures, and the temperature dependence of k_r and k_d can be determined.

We have applied equation (11.7) to measurement of k_r for ethyl, isopropyl, and *tert*-butyl radicals obtained from various sources[32]. (The best source of radicals seems to be the azo compounds, the decomposition of which cleanly yields radicals with no measurable side reactions.) For any given aperture size, the Brauman plots are indeed linear, and their intercepts yield reasonable values for the ratio k_r/k_d. However, as illustrated in Figure 8 for *tert*-butyl radicals, a different straight line is obtained in reactors of different aperture size. The reason for this can be shown to be a wall catalyzed first-order loss of radicals, and at the time of this writing, reactors whose interior surfaces are coated with KCl are being used to eliminate the surface reaction.

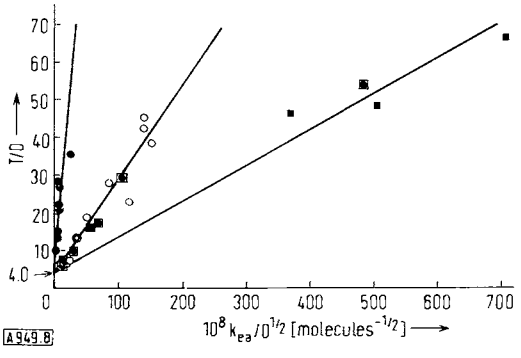

Fig. 8. Recombination of *tert*-butyl radicals, measurements in apparatus VLPP-I. $(k_r \cdot k_{r\infty})_{RRKM} = 0.96$; $k_d/k_{r\infty} = 3.1$; intercept from RRKM = 4.2; ·-●-●-·: $Z = 22400$, ·-○-○-·: $Z = 1920$, -■-■-: $Z = 280$; -⊡-⊡-: results with VLPP-II (volume corrected), $Z = 2000$.

It should also be noted that from three straight lines, such as depicted in Fig. 8, we can solve for a value of the first-order wall catalyzed rate constant k_w, since the effect on equation (11.7) is to change the numerator of the second term on the right-hand side to $(k_{er} + k_w)$.

Measurements at the time of writing, which must still be considered preliminary, yield the following values:

$k_{r\infty}$ (*tert*-butyl) $\approx 6 \times 10^8$ l mol^{-1} s^{-1} at 650 °K
$k_{r\infty}$ (isopropyl) $\approx 5 \times 10^9$ l mol^{-1} s^{-1} between 700 and 800 °K
$k_{r\infty}$ (ethyl) $\approx 10^{10}$ l mol^{-1} s^{-1} between 800 and 900 °K

There are some serious problems with these numbers, some of which may be resolved when they are measured at other temperatures. The values are too high compared to the accepted values[12] for the reverse processes and the overall values[12] of ΔH and ΔS.

12. Collisional Effectiveness in Vibrational Energy Transfer

The successful use of RRK(M) theory to relate k_1 to $k_{1\infty}$ for unimolecular reactions under VLPP conditions implies the correctness of the assumption used, namely that collisions of critically energized molecules with the reactor walls are 100 percent efficient in deenergizing same.

[*] Since the basic form for this equation was suggested by Professor *J. I. Brauman* of Stanford University during his sabbatical residence at Stanford Research Institute, we have come to call these plots "Brauman Plots".

If the flow rates used are increased to the point where the number of gas-gas collisions are comparable to the gas-wall collisions, always maintaining the condition that the mean-free path is large compared to the escape aperture, the increase in k_1 can be used as a measure of the effectiveness of gas-gas collisions compared to gas-wall collisions.

In the study of the pyrolysis of cyclobutane[14] the pressure dependence of the rate constant was measured at 969 °K. Individual RRKM curves were calculated according to the relation

$$k = \int_{E^*}^{\infty} \frac{P[E]k[E]}{1+k[E]/\omega_T} dE$$

where ω_T is the total collision efficiency. This can be written

$$\omega_T = \beta_s\omega_s + \bar{\beta}_g\omega_g$$

where β_s and $\bar{\beta}_g$ are relative collision efficiencies for gas-wall and gas-gas collisions, respectively. β_s was assumed to be unity and $\bar{\beta}_g$ is the average value for the different species under study. The experimental data are best fitted by the value $\bar{\beta}_g = 0.1$—0.2, and are the same for cyclobutane and SF_6. At the pressures used in this experiment k/k_∞ was about 0.08, and the effects of changing pressure should easily have been measured.

13. Surface Recombination of Atoms

The mechanism for surface catalyzed recombination of atoms is expected to be (S = surface site, assumed constant and surface diffusion neglected):

$$X + S \underset{-1}{\overset{1}{\rightleftarrows}} S{-}X \qquad (13.1)$$

$$X + S{-}X \xrightarrow{2} X_2 + S \qquad (13.2)$$

If $k_{-1} \gg k_2(X)$, the rate will be second order w.r.t. X. If, however, the reverse is true, it will be first order with a rate given by:

$$R_{X_2} = \frac{k_1k_2[X][S^0]}{k_1 + k_2} \equiv \gamma\omega[X] \qquad (13.3)$$

where ω is the collision frequency of atoms with the surface and the efficiency factor γ is called the recombination coefficient. No matter what the mechanism, the rate is always proportional to the total active surface.

If atoms are introduced into a multiple aperture VLPP reactor, the value of γ for the material of which the reactor is constructed can be ascertained from the change in mass spectral intensities of the atoms with change in aperture. When the rate of recombination is first order [eq. (13.3)], we find:

$$\gamma = \frac{(I'_X/I_X - 1)}{2Z_w[1 - I'_XZ'_w/I_XZ_w]} \qquad (13.4)$$

where I'_X and I_X are the intensities due to the atom in experiments using two different apertures, and Z'_w and Z_w are the collision numbers corresponding to these two apertures. Equation (13.4) results from comparison of the steady state concentrations of atoms as the aperture is changed (R_X being kept constant). Note that the measurements of γ together with R_{X_2} can be used to obtain absolute ionization efficiencies α_X of the species X.

We are currently measuring the values of γ for oxygen-atoms as a function of temperature for treated and untreated quartz surfaces.

14. Heterogeneous Reactions

The following studies have been carried out in our laboratories:

1. Reaction of oxygen with a carbonaceous char[33].
2. Pyrolysis of *tert*-BuO_2H in quartz and stainless steel reactors[34].
3. Pyrolysis of $CHCl_3$ in quartz reactors[23].
4. Pyrolysis of carbonylmetal compounds in a quartz reactor[35].
5. Pyrolysis of hydrocarbons in a special reactor capable of operating up to 1600 °C.

There are two basic categories of heterogeneous reactions. In the first, the gaseous reactant reacts directly with the substrate; in the second, the reactant is catalytically transformed into products. Of the studies that we have carried out so far, the pyrolysis of *tert*-BuO_2H[34] is probably the only example of true catalysis, although some details remain to be clarified in the case of the high-temperature reaction of ethane.

tert-Butyl hydroperoxide has been pyrolyzed in both quartz and stainless steel reactors[34]. The product pattern is dramatically different in the two cases. In the quartz reactor, the mechanism could be accounted for by the homogeneous reactions:

$$\textit{tert}\text{-}BuO_2H \rightarrow \textit{tert}\text{-}BuO^{\cdot} + OH^{\cdot}$$
$$\textit{tert}\text{-}BuO^{\cdot} \rightarrow CH_3^{\cdot} + (CH_3)_2CO$$

At higher pressures, isobutylene oxide is formed:

$$OH^{\cdot} + t{-}BuO_2H \rightarrow H_2O + \text{>}\!\!\!\diagup\!\!\!\diagdown\text{-}OOH \quad \text{(fast)}$$

$$CH_3^{\cdot} + t{-}BuO_2H \rightarrow \text{>}\!\!\!\diagup\!\!\!\diagdown\text{-}OOH + CH_4 \quad \text{(very slow)}$$

$$\text{>}\!\!\!\diagup\!\!\!\diagdown\text{-}OOH \rightarrow \text{<}\!\!\!\diagup\!\!\!\diagdown\text{O} + OH^{\cdot}$$

Isobutylene oxide, acetone, and lower mass number species were detected. The predicted Arrhenius parameters for the pyrolysis of the parent compound to yield acetone were in agreement with the observed reaction rate constant.

In the stainless steel reactor, the reaction rate was much faster and the mass spectrum of the product quite different.

The major product was *tert*-BuOH, although acetone and isobutene were also prominent. Isobutylene oxide is not produced. We infer that the reaction in the metal system is catalyzed by surface oxides of iron, chromium or nickel. The proposed mechanism was:

$$tert\text{-}BuO_2H(g) \underset{-1}{\overset{1}{\rightleftarrows}} tert\text{-}BuO_2H(s)$$

$$tert\text{-}BuO_2H(s) + O^{2-}(s) \xrightarrow{2} tert\text{-}BuO_2^-(s) + OH^-(s)$$

or

$$tert\text{-}BuO_2H(s) + O^{2-}(s) \xrightarrow{3} tert\text{-}BuO^-(s) + HO_2^-(s)$$

Products arise from decomposition and further reaction of the surface species. Details remain speculative. The temperature at which reaction occurs suggests that the surface reactions have a slightly higher activation energy than reevaporation, $k_2+k_3<k_{-1}$. A value of about 21 kcal was suggested for the above surface reactions.

The internal surfaces of the reactor showed no changes in color as a consequence of reactions of *tert*-BuO_2H. We conclude that the reaction was one of almost pure catalysis.

It is specially noteworthy that the "much" slower (because of its endothermicity of ≈ 14 kcal/mol) surface-catalyzed dehydration of *tert*-BuOH to *i*-$C_4H_8 + H_2O$ did not occur.

The reaction of oxygen gas with carbonaceous chars has also been studied in our VLPP systems[33,35]. We have prepared charry carbonaceous surfaces in the form of thin films by pyrolysis of an epoxy resin film. The samples in the form of coatings on the inside surface of a quartz cylinder were inserted into a VLPP reactor and reacted with oxygen gas at temperatures up to 1300°K.

The reactivity of these films is a complex function of the chemical history of the sample. At first, reactivity is relatively low; then, as the surface of the sample burns away, it becomes more active. In addition to this, a greater amount of surface area is available for reaction. As reaction proceeds, the film becomes exhausted and the rate of reaction declines to zero. The rate "constant" varies with temperature in approximate agreement with the Arrhenius equation. The major reaction product at all temperatures is CO with about 10% CO_2. The reaction is lower than first order in oxygen. This deviation from first-order behavior is less pronounced at gas flows of 10^{14} per second than at 5×10^{16} per second for a char of superficial area 36 cm^2. Exposure to the atmosphere can deactivate the char.

In our initial studies with this system[33] we reported first-order rate constants about 10^5 faster than those observed in similar studies with graphites + O_2. Later, incomplete[35] studies showed that these fast rates were the result of an astonishingly rapid catalytic oxidation produced by the presence of a stainless steel endplate in the system. An all-quartz vessel gave much slower rates with lower O_2 dependence. This is an interesting result with much potential importance for the study of catalytic oxidation.

The pyrolysis of $Mo(CO)_6$ indicates[35] that a surface chain reaction takes place. Apparent first-order rate constants for the disappearance of $Mo(CO)_6$ change from *ca.* 2 s^{-1} at 473°K to *ca.* 500 s^{-1} at 526°K, leading to an activation energy of *ca.* 50 kcal/mol and an *A*-factor of *ca.* 10^{24} s^{-1}. The high *A*-factor is indicative of a chain reaction.

Hydrocarbon gases have been pyrolyzed[36]. Gases such as ethane, ethylene, and benzene have been found to react with high probability (>0.005 per collision) at temperatures above 1600°K. Reactor walls participate in the chemical reaction. For example, carbon monoxide is copiously evolved when benzene or toluene react in an alumina reactor; carbon monoxide is also a significant product when pyrolysis is carried out in a quartz reactor.

Ethane is significantly less reactive than the unsaturated compounds in quartz, alumina, and carbon reactors.

15. Summary

The technique of VLPP is well established as a method for measuring unimolecular rate constants. These data, in conjunction with RRK(M) theory, can yield high-pressure activation energies if reasonable estimates of activation entropy can be made. This is a useful method for obtaining the heats of formation of free radicals formed in a unimolecular bond homolysis, as well as activation energies for some important concerted processes.

The general applicability of VLPP as a tool for the measurement of rapid bimolecular reactions is currently being assessed. In this type of application, VLPP yields important rate parameters for radical-molecular and radical-radical reactions. The extension to reactions of atoms is also being investigated.

Experiments carried out at pressures such that gas-gas collisions begin to compete with gas-wall collisions can be used to measure the relative effectiveness of walls and gases in the transfer of vibrational energy in the study of unimolecular reactions in the "fall-off" region of pressures.

The system lends itself very well to the study of fast heterogeneous reactions; that is, both on "inert" surfaces and on chemically active surfaces. In such systems it gives unique information not otherwise available. The system lends itself very well to the direct observation of the chemistry and kinetics of chemically active species such as atoms and radicals.

The bulk of the work mentioned here was supported by the National Aeronautics and Space Administration under contract NAS 7—472. Support has also come from the Air Force Office of Scientific Research, contract F—44620—71—C—0103, the Environmental Protection Agency, Grant AP—00353, and NASA contra NAS 2—6776.

Postdoctoral Fellows who carried out a large number of the experimental studies were N. A. Gac, K. D. King, R. K. Solly, P. C. Beadle, and M. J. Perona.

The Physical Mechanism of the Chemical Bond[1]

By Werner Kutzelnigg[*]

First the interplay of kinetic and potential energy *via* the uncertainty relation is described with the aid of a variational function for the ground state of the H atom. The H_2^+ ion is used to illustrate the physical mechanism of the occurrence of the chemical bond. The formation of the chemical bond can be divided into three steps: 1. the quasi-classical (electrostatic) interaction of the unchanged electronic charges of the separate atoms; 2. the interference of the atomic orbitals, which (in the case of positive interference) leads to a displacement of charge into the bonding region and to a decrease in the kinetic energy; 3. deformation of the molecular orbitals to restore the correct balance of kinetic and potential energy. In simple models, it is often sufficient to consider just the second step. A two-electron bond is not fundamentally different from a one-electron bond. In larger molecules it is possible to distinguish between long-range and short-range interatomic contributions to the chemical bond. If the former are small, *i.e.* in molecules with non-polar bonds, a one-electron molecular orbital theory can be justified. Finally, the possibility of describing molecules by localized bonds is discussed.

1. Introduction

The first publication to deal with the theory of the chemical bond on a quantum-mechanical basis appeared in 1927[2], *i.e.* 46 years ago. One cannot deny nowadays that quantum chemistry has had a lasting influence on chemistry as a whole, though it was accepted only reluctantly during its first few decades.

There is nevertheless still an extremely wide gap between descriptive theoretical chemistry used in chemistry textbooks and computational quantum chemistry of present-day research. Many concepts from the early days of quantum chemistry that have found their way into the descriptive theory have become insignificant or useless in current

Present address: Lehrstuhl für Theoretische Chemie, Ruhr-Universität Bochum (Germany)

quantum-chemical research. It often seems that even the chemical bond itself is one such concept. Ideas about binding patterns are not necessary input for the calculation of the properties of a molecule from approximate solutions of the Schrödinger equation. Such ideas become relevant only when one attempts to gain a physical understanding of the results of the calculation, or even to make significant statements about the molecule without calculation.

In the early phase of quantum chemistry, calculation and interpretation went hand in hand, and the theory was fed more with material from chemical experience than with information from the Schrödinger equation; the results of quantum-chemical research during the past 20 to 30 years, on the other hand, have had little effect on theoretical chemistry as taught in chemistry textbooks. Many obsolete ideas were thus obstinately adhered to in the textbooks. Attempts have in fact been directed toward a deductive theory of the chemical bond whose predictions should not depend either on the nature of the approximation chosen or on the current state of chemical experience[3, 4], but access to these is probably too difficult for the uninitiated. In the present article we shall try to explain some aspects of a modern theory of the chemical bond.

In particular, an effort will be made to clarify the physical mechanism of the occurrence of chemical binding. If more reference is made to H_2^+ than to molecules that are more familiar to the chemist, the reason is that the decisive mechanism can in fact be understood from this molecule-ion.

The reader will appreciate that the fact that a question is asked does not mean that its answer is known. The question of the nature of the chemical bond has by no means been fully clarified.

2. Kinetic and Potential Energy in the H Atom

Atoms and molecules are systems of masses (nuclei and electrons) between which there is Coulomb attraction or repulsion, and which move according to the laws of quantum mechanics. As in macroscopic systems, for example a planetary system, the concepts *kinetic energy T*, *potential energy V*, and *total energy* $E = T + V$ are found to be useful for the description of the system.

Let us consider the motion of an electron (of charge $-e$ and mass m) about a proton, which we shall assume to be at rest. Let r be the distance between the electron and the nucleus. Let v be the velocity and $p = mv$ the momentum. The kinetic energy T and the potential energy V (Coulomb's law) are then given by

$$T = \frac{m}{2} v^2 = \frac{1}{2m} p^2; V = -\frac{e^2}{r} \tag{2.1}$$

In a system of Cartesian coordinates with the proton at the origin, according to Pythagoras

$$r = +\sqrt{x^2 + y^2 + z^2} \tag{2.2}$$

where x, y, and z are the coordinates of the electron.

The concepts used above retain their meaning in quantum mechanics, with the limitation (which we shall discuss later) that neither the position nor the momentum is accurately known, since these two parameters are subject to *Heisenberg*'s uncertainty principle. For example, if Δx is the uncertainty of the x coordinate and Δp_x the uncertainty of the component p_x of the momentum in the x direction, the product of these uncertainties cannot be reduced indefinitely, but is governed by

$$\Delta x \cdot \Delta p_x \approx \hbar \tag{2.3}$$

($h = 2\pi\hbar$ is Planck's action quantum).

Because of the uncertainty regarding the location of the electron, we do not know where the electron is situated, but can only give a probability distribution $\rho(x,y,z)$ for its position. $\rho(x,y,z)$ is also known as the electron density, and

$$\rho(x,y,z)\, dx dy dz = \rho(x,y,z)\, d\tau \tag{2.4}$$

is the probability of finding the electron in a volume element $d\tau$ in the position x,y,z. Since there should be a total of one electron present, the total probability must be equal to 1, *i.e.*

$$\int \rho(x,y,z) d\tau = \int_{-\infty}^{+\infty} \iint \rho(x,y,z)\, dx dy dz = 1 \tag{2.5}$$

For a one-electron system the electron density is equal to the square of the magnitude of the wave function

$$\rho(x,y,z) = |\psi(x,y,z)|^2 \tag{2.6}$$

The wave function of the ground state of the H atom is given by

$$\psi = N \cdot e^{-r} \tag{2.7}$$

where r is measured in atomic units of length a_0 ($1\, a_0 = \hbar^2/me^2 = 0.523$ Å) and N is a normalizing factor[5], which ensures that (2.5) is satisfied.

Let us now suppose we do not know that the wave function of the ground state of the H atom is equal to $N \cdot e^{-r}$ and assume simply that it is an exponential function; we therefore introduce an undetermined factor η into the exponent, *i.e.* we let

$$\psi = N \cdot e^{-\eta r} \tag{2.8}$$

(The normalizing constant N then also depends on η[5], but we are not interested in the explicit dependence at the moment.) Figure 1 shows $|\psi|^2$ as a function of r for various η (since the ordinate is logarithmic, $|\psi|^2$ is a straight line in every case). We interpret $|\psi(r)|^2$ as $|\psi(|x|)|^2$ for $y = 0$ and $z = 0$, *i.e.* as the electron density along the x axis. We should then also consider the mirror image of Figure 1 reflected in the ordinate, since $|\psi(|x|)|^2$ has the same value for $+x$ as for $-x$.

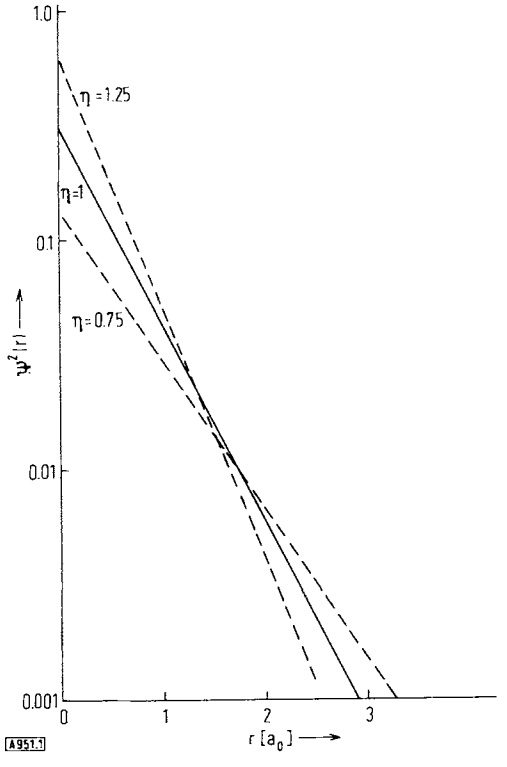

Fig. 1. Electron density $\psi^2(r)=N^2\cdot e^{-2\eta r}$ of the atom for various orbital exponents η.

Since positive and negative values of x are equally probable, the mean $\langle x\rangle$ of x is equal to zero[6] (the symbol $\langle f\rangle$ is used for the mean of a quantity f over the distribution given by ρ).

The extent to which the electron is located close to the nucleus, on average, is determined by the uncertainty[7] of its distribution. The greater η, the steeper is $|\psi^2|$ (Fig. 1), the smaller therefore is the uncertainty regarding its location, and the greater is the probability of finding the electron in the vicinity of the nucleus. An explicit calculation gives the following expression for the uncertainty of the x coordinate (for $y=z=0$; similar expressions are found for the uncertainty of the y and of the z coordinates)

$$\Delta x = \frac{1}{\eta}\cdot a_0 \tag{2.9}$$

The positional uncertainty is thus inversely proportional to η[7].

What influence has η on the potential energy V? The greater the value of η, the greater is the probability, on average, of finding the electron in the vicinity of the nucleus. Since $V=-e^2/r$, the greater η and the smaller therefore the mean distance $\langle r\rangle$ of the electron from the nucleus, the greater is $|\langle V\rangle|$, *i.e.* the lower (more negative) is $\langle V\rangle$, the mean of the potential energy.

An accurate calculation gives

$$\langle V\rangle = -\eta \text{ a.u.} \tag{2.10}$$

if the atomic unit (1 a.u.=1 Hartree$=m\cdot e^4/\hbar^2=627.2$ kcal/mol) is taken as the unit of energy.

How does the kinetic energy T vary with η? For the answer to this, let us consider the uncertainty principle. The greater the value of η, the greater is the average probability of finding the electron in the vicinity of the nucleus, *i.e.* the more it is localized and the smaller is its positional uncertainty. With increasing η, therefore, the uncertainty of momentum must increase, and higher momenta become more probable, *i.e.* the kinetic energy increases. Figure 2 shows the probability distribution of the momentum for various values of η, which demonstrates more precisely the results of our qualitative considerations[8].

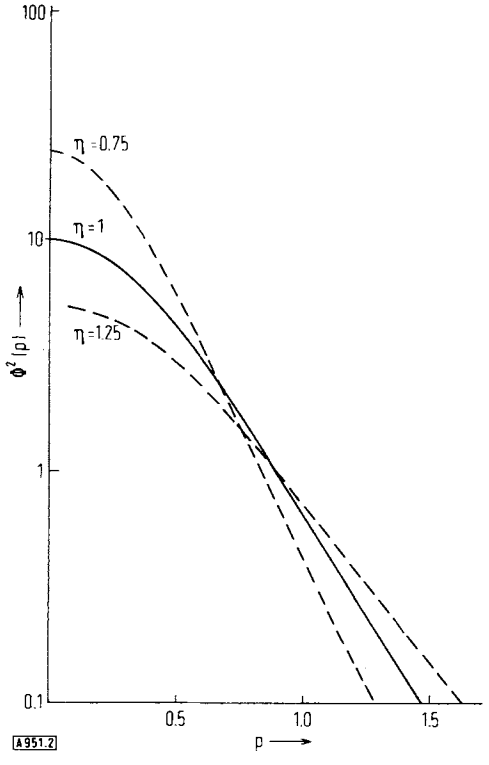

Fig. 2. Momentum distribution $\phi^2(p)$ corresponding to $\psi(r)=N\cdot e^{-\eta r}$ for various values of η.

The mean $\langle p_x\rangle$ of the x component of the momentum vanishes for the same reason as $\langle x\rangle$. For the uncertainty Δp_x, calculation gives

$$\Delta p_x = \frac{1}{\sqrt{3}}\cdot\eta\cdot\frac{\hbar}{a_0} \tag{2.11}$$

which, together with (2.1) and (2.9) shows in fact that the product $\Delta p\Delta p_x$ is independent of η and is of the order of magnitude $\hbar$. The mean of the kinetic energy is proportional to the square of the uncertainty in the momentum

$$\langle T\rangle = \frac{1}{2}\eta^2 \text{ a.u.} \tag{2.12}$$

$\langle T\rangle$, $\langle V\rangle$, and $E=\langle T\rangle+\langle V\rangle$ are shown in Figure 3 as functions of η. We see that E has a minimum for $\eta=1$ and that the following relation is accurately satisfied at the position of the minimum:

$$E=\langle V\rangle+\langle T\rangle=-1+\frac{1}{2}=-\frac{1}{2}\text{ a.u.} \tag{2.13}$$

In the ground state, an atom or molecule assumes the *lowest* possible energy as a compromise between the lowest possible potential energy (large in magnitude, since $\langle V \rangle$ is negative) and the lowest possible kinetic energy (small in magnitude, since $\langle T \rangle$ is positive). A large η (steep function) is more favorable from the standpoint of the potential energy and a small η from the standpoint of the kinetic energy, the best compromise being $\eta = 1$.

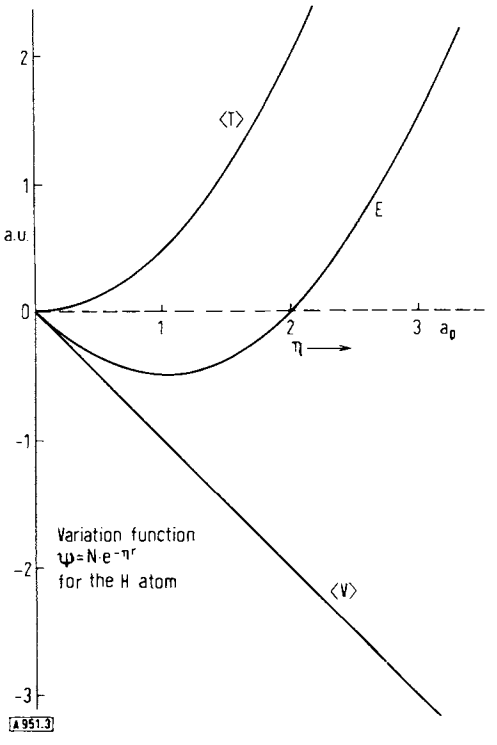

Fig. 3. Kinetic energy $\langle T \rangle$, potential energy $\langle V \rangle$, and total energy E as a function of η.

It can be shown (though we shall not pursue this here) that the energy value for the H atom cannot be reduced below -0.5 a.u. even by variations of the wave function other than variation of η (*e.g.* by modification of the functional form of ψ), *i.e.* that -0.5 a.u. is the *absolute* minimum of the energy of an H atom. According to the variation principle, a wave function that makes the energy an absolute minimum is automatically a solution of the Schrödinger equation for the ground state of the system in question.

The fact that an atom or molecule has a ground state, *i.e.* that there is a limit to the degree to which the energy can become negative, is a direct consequence of the relationship of $\langle T \rangle$ and $\langle V \rangle$ *via* the uncertainty principle. In classical physics, there is no lowest possible energy and there is no limit to how close the orbital curve lies to the nucleus, whereas in quantum mechanics the kinetic energy ensures that this is not possible[9].

$$\langle T \rangle = -E = \frac{1}{2} \text{a.u.} \tag{2.14}$$

This relation between $\langle T \rangle$ and E is generally valid for systems with Coulomb interactions, and is known as the *virial theorem*. We shall make use of this again later.

3. The H_2^+ Ion. Quasi-Classical Interaction and Interference

Let us now proceed from the simplest atom, H, to the simplest molecule, H_2^+. This molecule consists of two protons and one electron (Fig. 4). In order to understand the chemical bond in this molecule-ion, we shall build up H_2^+ in steps, starting with an isolated H atom and a proton.

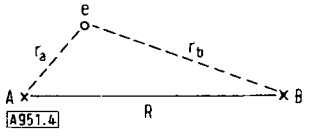

Fig. 4. Distances in the H_2^+ ion.

Let a be the wave function (atomic orbital) of an H atom centered on the first proton, and b that of an H atom centered on the second proton.

$$\begin{aligned} a &= N \cdot e^{-r_a} \\ b &= N \cdot e^{-r_b} \end{aligned} \tag{3.1}$$

The electron density of an electron that forms an H atom with the nucleus A would thus be a^2, and that of an electron about the nucleus B would be b^2. If we assume that the electron has equal probabilities of belonging to the nucleus A and to the nucleus B, we can deduce that the electron density in H_2^+ should be given by[10].

$$\rho_{QK} = \frac{1}{2}[a^2 + b^2] \tag{3.2}$$

The subscript QK of ρ denotes "quasi-classical"; the above argument will be described as quasi-classical, by which we mean that we simply add the electron densities of the atoms participating in a bond, without taking into account any change in the electron density as a result of bonding[11].

This quasi-classical description of the H_2^+ ion (or of another molecule) is only a first step on the way from the separate atoms to the molecule.

We shall first examine the magnitude of the energy of an H_2^+ if its electron density is given by ρ_{QK}.

The energy of this quasi-classical H_2^+ is found to be identical with that of an H atom plus that of a proton at a distance R[12].

$$E_{QK} = E(\text{H}) + \frac{e^2}{R} - E_{Ke} \tag{3.3}$$

$$E_{Ke} = \int e^2 \frac{|a(r_a)|^2}{r_b} \, d\tau \tag{3.4}$$

The first term in (3.3) is simply the energy of an H atom ($= -0.5$ a.u.), while the other two terms depend on R. For large values of R, E_{Ke} is almost equal to e^2/R, so that the last two terms in (3.3) cancel out for large R. For shorter distances E_{Ke} is equal to the Coulomb interaction of the nucleus B with that part of the charge of

the electron that is situated inside a sphere around the nucleus A whose surface passes through the nucleus B[13]. For $R \rightarrow 0$, E_{Ke} tends toward a finite value, while the internuclear repulsion e^2/R becomes infinite. The internuclear repulsion predominates at short distances.

As a consequence of the *penetration* of the nucleus into the electron cloud, the overall result is a repulsion that is purely electrostatic. Detailed evaluation of the quasi-classical H_2^+ gives (in atomic energy units)

$$E_{QK} = -\frac{1}{2} + \left(1 + \frac{1}{R}\right) e^{-2R} \tag{3.5}$$

From a comparison of E_{QK} with the true energy of H_2^+ (Fig. 5), it is clear that we have failed to reproduce the energy minimum that is decisive for the occurrence of bonding.

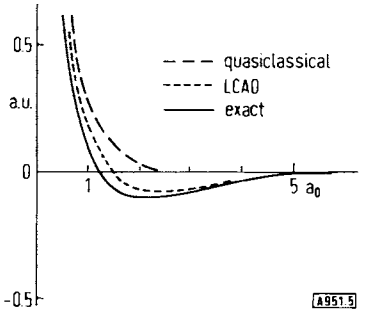

Fig. 5. H_2^+ potential energy curve.

What have we done wrong? Our quasi-classical argument would be analogous to superimposing two light beams by simply taking the sum of the individual intensities as the total intensity. The intensity of a light beam is equal to the square of its amplitude, just as the electron density is the square of the wave function. We know that we must in fact add the *amplitudes* of the light waves, and that the effects associated with the fact that addition of the amplitudes does not give the same result as addition of the intensities are known as *interference*.

If we take the wave nature of the electron seriously, we should add wave functions in this case instead of densities, *i.e.* in addition to the quasi-classical effects, we shall also have to consider interferences. Let us now examine these more closely.

The atomic orbitals (AOs) a and b are known except for the sign. Addition of these orbitals can give both $(a+b)$ and $(a-b)$, so that we have the possibility of positive and negative interference. $(a+b)$ or $(a-b)$ should be a wave function for an electron, *i.e.* we require these wave functions to be normalized to 1; for example

$$\begin{aligned} \int \psi_+^2 \, d\tau &= N^2 \int (a+b)^2 d\tau = N^2 \int [a^2 + 2ab + b^2] d\tau \\ &= N^2 \{\int a^2 d\tau + \int b^2 d\tau + 2\int ab \, d\tau\} \\ &= N^2 \{1 + 1 + 2S\} = 1 \end{aligned} \tag{3.6}$$

We have taken into account here the fact that a and b are each normalized to 1, and we call the integral

$$\int ab \, d\tau = S \tag{3.7}$$

the "*overlap integral*" between a and b.

It follows directly from (3.6) that

$$N = \frac{1}{\sqrt{2(1+S)}} \tag{3.8}$$

i.e. that in the case of positive interference, the wave function of H_2^+ is

$$\psi_+ = \frac{1}{\sqrt{2(1+S)}} [a + b] \tag{3.9}$$

The corresponding electron density is then

$$\rho_+ = \psi_+^2 = \frac{1}{2(1+S)} [a+b]^2 = \frac{1}{2(1+S)} [a^2 + b^2 + 2ab] \tag{3.10}$$

Let us compare this electron density with that derived from our quasi-classical considerations.

$$\rho_{QK} = \frac{1}{2} [a^2 + b^2] = \frac{1}{2(1+S)} [a^2 + b^2 + Sa^2 + Sb^2] \tag{3.11}$$

$$\Delta\rho = \rho_+ - \rho_{QK} = \frac{1}{2(1+S)} [2ab - Sa^2 - Sb^2] \tag{3.12}$$

This change $\Delta\rho$ in the electron density distribution as a result of the interference is of the following nature. Where a and b are both large, the electron density is increased because of the contribution $2ab$; where only a or only b is large, the electron density decreases. Electronic charge is transferred from the vicinity of the nuclei into the bonding region. This change in the electron density along the line joining the nuclei is illustrated in Figure 6.

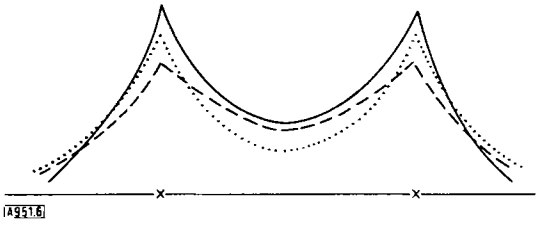

Fig. 6. Schematic representation of the quasi-classical electron density (...) and the quantum-mechanical electron density without promotion (---) and with promotion of the AOs (—) in the H_2^+ ion.

The inclusion of this interference effect in the argument does in fact lead to a decrease in energy, to a minimum in the potential curve, and hence to chemical bonding (cf. Fig. 5).

Now comes the critical question. What physical mechanism is responsible for the fact that the (positive) interference of the atomic orbitals leads to a decrease in energy and hence to bond formation? Nearly all textbooks give an incorrect answer to this question.

It is claimed that the accumulation of charge in the bonding region causes a decrease in the potential energy, since the electron is then situated preferentially in a region in which it is attracted simultaneously by both nuclei. This

corresponds to saying that the interference produces *additional* electron density, *i.e.* it is completely forgotten that this electron density must be taken from somewhere else, since the total number of electrons is not affected by the interference. However, if one considers that the phenomenon is really only a displacement of charge, one finds that electron density is removed from places that are much more favorable to the potential energy, particularly in the immediate vicinity of a nucleus. The interference actually leads to a slight increase in the potential energy, and not to a decrease.

Thus if a change in the potential energy is not responsible for bonding, the decisive factor can clearly only be the kinetic energy.

This is in fact considerably reduced by the interference. *Hellmann*[14], in 1933, was probably the first to recognize this fact, for which he also gave an intuitive explanation (possibly oversimplified, but essentially correct). The transition from the separate atoms to the molecule increases the space available to the electrons (the electron in this case), *i.e.* the positional uncertainty increases. However, an increase in the positional uncertainty implies a decrease in the uncertainty of the momentum. Since the average momentum is zero, smaller momenta become more probable overall, *i.e.* the kinetic energy becomes smaller.

How was the evidently incorrect explanation of the chemical bond (it was said to be based on a decrease in the potential energy, and thus to be electrostatic in nature) able to persist for so long? One reason is undoubtedly a widespread carelessness in dealing with overlap integrals. Thus it is common to proceed as if S could be neglected. It then appears indeed as if

$$\rho_+ = a^2 + b^2 + 2ab = \rho_{QK} + 2ab \tag{3.13}$$

i.e. as if there were a "spontaneous generation" of charge in the bonding region. There is much that could be said on the topic of "neglect of overlap"[15]. We shall content ourselves here with expressing our sympathy for those who feel duped when (as often occurs) they are first taught that overlap is the decisive reason for the occurrence of chemical bonding, and are then told two lectures later that the overlap integral can be disregarded.

A second reason why the incorrect explanation of chemical bonding was able to persist is the widespread partiality in chemistry for electrostatic models, which is apparently justified (but only apparently) by the Hellmann-Feynman theorem[16]. The idea that the kinetic energy of the electrons in the molecule plays a decisive part evidently meets with certain difficulties of visualization.

There is also a third reason. This is connected with the virial theorem and an impermissible amalgamation of the approximate solution and the exact solution of the Schrödinger equation. It will be necessary to consider this more fully.

What we have just seen is that the interference of the atomic orbitals has practically no influence on the potential energy, but that it reduces the kinetic energy and so leads to bonding.

We must remember, however, that the wave function (3.9) formed by linear combination of the atomic orbitals (abbreviated to LCAO) is an approximate wave function of H_2^+ and not the exact wave function, and that it undoubtedly differs in some way from the exact wave function.

Actually the virial theorem is applicable for the exact wave function of a diatomic molecule at the equilibrium distance in the same form as for atoms (cf. Section 2, (2.14))

$$\langle T \rangle = -E \tag{3.14}$$

If the virial theorem is valid, however, the following argument is straightforward. The occurrence of bonding means that the energy of the molecule is greater in magnitude than the sum of the energies of the separate atoms.

$$|E_{\text{mol.}}| \geq |E_{\text{sep. at.}}| \tag{3.15}$$

Since the virial theorem (3.14) is valid both for the molecule and for the separate atoms and since $\langle T \rangle$ is always positive, one obtains

$$\langle T \rangle_{\text{mol.}} \geq \langle T \rangle_{\text{sep. at.}} \tag{3.16}$$

In other words, the kinetic energy of the molecule is greater than that of the separate atoms.

On the basis of the virial theorem, therefore, some authors[17] have tried to extend the Hellmann picture of chemical bonding *ad absurdum*. However, they were defeated by a fallacy. The elucidation of this fallacy was due in particular to *Ruedenberg*[4, 18].

Since the interference of the AOs leads to a decrease in the kinetic energy, whereas in the exact wave function of the H_2^+ ion the kinetic energy is greater than in the H atom, something else must happen on the way from our approximate solution to the exact solution. In other words, in addition to the two contributions discussed so far, *i.e.* quasi-classical interaction and interference, a third contribution to the chemical bond must also be present. However, this contribution is less important than the first two, since these have already led to a fairly good potential curve.

To understand what such a third step signifies, let us make use of an apparently far-fetched analogy. Let each of two business concerns have receipts ($-V$), expenditures (T), and profit ($-E$). Suppose that a concern operates most rationally when the ratio of expenditures T to profit E has a certain value, and assume for simplicity that the optimum ratio is such that

$$\text{expenditures } (\langle T \rangle) = \text{profit } (-E) \tag{3.17}$$

(virial theorem). Now suppose that the two concerns merge. Certain expenditures that each concern previously had to bear separately are now necessary only once. The total expenditure $\langle T \rangle$ decreases, with the result that the profit E automatically increases. ("Bonding" occurs.) However the ratio $\langle T \rangle : (-E)$ is no longer 1:1, *i.e.* no longer corresponds to optimum profitability, since T had become smaller and E larger. A *further* increase in profit is therefore possible

if the joint concern undertakes additional expenditures that did not pay in the case of a single concern. A superficial observer would now say that expenditures and receipts increased after the amalgamation, the receipts to a greater extent, so that the increased profit is due to an increase in receipts. This commentator completely overlooks the fact that the decisive step toward the increase in profits was the saving of certain expenditures.

How does this argument apply to the theory of chemical bonding?

Once interference of the AOs and the associated decrease in kinetic energy has led to bonding, the ratio of kinetic to potential energy for the molecule is no longer optimum; the positional uncertainty has become too great and the uncertainty of momentum too small. We cannot therefore have reached the energy minimum for the molecule in this way.

We can see how we can at least come closer to this aim if we apply what we learned for the H atom. We introduced a variable factor η into the exponent in the LCAO function.

$$\psi_+ = \frac{N}{\sqrt{2(1+S)}}\left[e^{-\eta r_a} + e^{-\eta r_b}\right] \tag{3.18}$$

Let us again consider the influence of variation of η on the potential and kinetic energy. The most favorable "compromise η" is now found to be $\eta = 1.25$ (different from the value of $\eta = 1$ for the H atom). The electron density (cf. Fig. 5) becomes steeper in the vicinity of the nucleus, the positional uncertainty decreases, and the uncertainty of momentum and the kinetic energy increase; the positional uncertainty is decreased mainly *perpendicular* to the bond direction, and is actually increased along the bond direction as a result of bonding. The kinetic energy of the motion normal to the bond direction increases accordingly; along the bond direction, however, the decrease in kinetic energy due to interference predominates. An important point in any case is that the increase in the kinetic energy and the decrease in the potential energy as a result of the variation of the exponential factor η is purely *intra-atomic* and has nothing to do with what happens in the bonding region, where the decrease in the kinetic energy is still the decisive effect. One can also say that the molecule is slightly compressed normal to the bond direction, and the resulting increase in the kinetic energy ensures that the virial theorem is satisfied.

We have just broken down the occurrence of bonding into three steps, *i.e.* a first "quasi-classical" step, a second step in which the atomic orbitals of the free H atoms are caused to interfere, and a third step in which we restored the balance of the positional uncertainty and the uncertainty of momentum in the molecule. The same result is obtained if the order of the last two steps is reversed:

1. We change the atomic orbitals of an H atom into atomic orbitals with $\eta = 1.25$, *i.e.* we prepare them, so to speak, for bonding. We thus increase the kinetic energy and decrease the potential energy without essentially changing the total energy of the H atom. The quasi-classical interaction of the promoted AOs is not qualitatively different from that of the unprepared orbitals.

2. The two atomic orbitals "prepared" ("promoted") for bonding in this way are allowed to interfere. Charge is thus displaced into the bonding region, and the kinetic energy changes in the bonding region.

This order of the steps, though just as arbitrary as that described earlier, is possibly somewhat clearer and more suggestive, particularly since the idea of preparation (promotion) of the atoms for bonding is also useful in another connection.

To summarize, therefore, we find three contributions to the bond energy in H_2^+:

1. The *quasi-classical interaction* of the nuclei and of the electron density distributions of the "unbound" atoms. This interaction is only repulsive, but the repulsion (as a result of the penetration into the electron shell) begins only at very short distances.

2. The *interference*. This may be additive (constructive) or subtractive (destructive). We have considered only the case of additive interference. This leads to a displacement of charge from the vicinity of the nucleus into the region between the nuclei (in the opposite direction in the case of negative interference). The charge displacement is accompanied by a decrease in kinetic energy, which causes bonding (or in the case of negative interference an increase in kinetic energy and hence repulsion).

3. *Deformation* of the atomic orbitals. This is essentially a contraction here[19]; the AOs adapted to the molecule are more localized in the vicinity of the nuclei. A change in the AOs on molecular formation is generally referred to as "promotion" or conversion into the valence state. In the case of H_2^+, the promotion leads only to a change in the balance of the intra-atomic potential and kinetic energies; it has substantially no influence on the binding energy. However, it is important to the correct behavior of the wave function at small internuclear distances (this will not be discussed here).

As was stressed this third contribution is less important than the first two. It is therefore often disregarded, with some justification. Considerations based on the virial theorem naturally have no place in models of the chemical bond in which the third step is disregarded.

4. Models of the One-Electron Bond

So far we have encountered three contributions to the chemical bonding in H_2^+. However, to describe the bonding as simply as possible while still at least qualitatively retaining the essential points, one may consider only the contribution due to interference. The quasi-classical repulsion in the neighborhood of the minimum is in fact extremely small (cf. Fig. 5), so that while disregarding the quasi-classical term seriously affects the potential curve at short distances, it has little influence in the vicinity of the minimum. Disregarding the promotion changes the potential curve only quantitatively but not qualitatively.

Let us therefore confine ourselves entirely to the interference contribution. The charge displacement due to interference

$$\Delta\rho_+ = \frac{1}{2(1+S)}\{2ab - Sa^2 - Sb^2\} \tag{4.1}$$

is associated with an energy change consisting of a change in the kinetic and in the potential energy.

$$\Delta E_+ = \Delta\langle T\rangle + \Delta\langle V\rangle \tag{4.2}$$

Both $\Delta\langle T\rangle$ and $\Delta\langle V\rangle$ consist of contributions corresponding to the breakdown of $\Delta\rho$ in accordance with (4.1)

$$\begin{aligned}\langle T\rangle &= \frac{1}{2(1+S)}\{2T_{ab} - ST_{aa} - ST_{bb}\}\\ \Delta\langle V\rangle &= \frac{1}{2(1+S)}\{2V_{ab} - SV_{aa} - SV_{bb}\}\end{aligned} \tag{4.3}$$

where V_{ab} is the mean of the potential energy $-e^2/r$ calculated with the charge density a b, and V_{aa}, V_{bb}, T_{ab}, T_{aa}, and T_{bb} are defined analogously. Since, because of the equivalence of a and b, we apparently have

$$\begin{aligned}T_{aa} &= T_{bb}\\ V_{aa} &= V_{bb}\end{aligned} \tag{4.4}$$

with

$$\begin{aligned}H_{ab} &= T_{ab} + V_{ab}\\ H_{aa} &= V_{aa} + T_{aa} = E(\mathrm{H})\end{aligned} \tag{4.5}$$

we can also write

$$\Delta E_+ = \frac{1}{1+S}\{H_{ab} - S\cdot E(\mathrm{H})\} = \frac{1}{1+S}\beta \tag{4.6}$$

if the quantity

$$\beta = H_{ab} - S\cdot E(\mathrm{H}) \tag{4.7}$$

is regarded in *Mulliken*'s sense[3] as the *reduced* resonance integral, while H_{ab} is often referred to simply as the resonance integral[20].

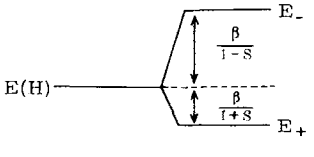
An analogous argument for the antibonding state of H_2^+

$$\psi_- = \frac{1}{\sqrt{2(1-S)}}[a-b] \tag{4.8}$$

gives the following expression for its change in energy due to interference

$$\Delta E_- = -\frac{1}{1-S}\beta \tag{4.9}$$

The fact that both positive and negative interference are possible thus leads to splitting of the energy in accordance with the well-known scheme:



Because of the denominators $(1+S)$ and $(1-S)$, the splitting is not symmetrical in this approximation. The splitting would be symmetrical about $E(\mathrm{H})$ if, as is often done in the textbooks, the overlap integral S were disregarded in relation to 1. If one considers that S has a value of ≈ 0.6 at the equilibrium distance of H_2^+ ($R = 2\ a_0$), one is inclined to think that it is not permissible to neglect S here, since in this case

$$\frac{1}{1+S} \approx 4\cdot\frac{1}{1-S} \tag{4.10}$$

It would be even more objectionable to neglect S in eq. (4.7)[15], since (again for $R = 2\ a_0$)

$$\begin{aligned}&H_{ab} \approx -0.38;\ S\cdot E(\mathrm{H}) \approx -0.3\\ &\beta \approx -0.08\end{aligned} \tag{4.11}$$

If one considers the exact energies of the bonding and of the antibonding states of H_2^+ for $R = 2\ a_0$, one obtains

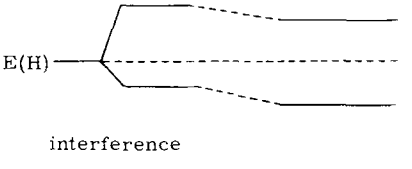
$$\begin{aligned}\Delta E_- &= +0.332\\ \Delta E_+ &= -0.102\end{aligned} \tag{4.12}$$

which is actually a non-symmetrical splitting. The quotient

$$|\Delta E_+|/|\Delta E_-|$$

however, is smaller than that obtained if only the interference is taken into account.

This is understandable, since the variation of η, which gives a different optimum for ψ_+ and ψ_-, decreases both energies. In many cases (but not for H_2^+) this decrease is such that the overall result is an almost symmetrical splitting, and that it seems as if S could be simply omitted in (4.6) and (4.9), as indicated in the following scheme.



When this is so, the energies of the bonding and of the antibonding states for a two-center one-electron bond can be approximately expressed in terms of the reduced resonance integral β by the simple relation

$$E_\pm = E(\mathrm{H}) \pm \beta \tag{4.13}$$

One can also go a step further and consider that to a first approximation only the change in the kinetic energy as a result of the interference contributes to β, the potential energy being completely disregarded. If the change in the kinetic energy is described, as in *Hellmann*'s model, by a change in the space available to the electrons, one obtains the simplest possible (and naturally also the crudest) model

of the chemical bond, the "free electron" model. If we describe the space available to the electrons of an atom by a cubic box of edge length l, the ground state of this particle in the box is given by[21]

$$E_1 = \frac{3h^2}{8ml^2} \tag{4.14}$$

The formation of a molecule is now pictured as the fitting together of two cubic boxes with one face in common and removal of the separating wall. The ground state in this brick-shaped box has the energy

$$E_2 = \frac{2h^2}{8ml^2} + \frac{h^2}{32ml^2} \tag{4.15}$$

The binding energy (decrease in energy) would thus be

$$\Delta E = E_2 - E_1 = -\frac{3h^2}{32ml^2} \tag{4.16}$$

It is somewhat more realistic, instead of allowing twice as much space for the molecule as for the atom, to assume some interpenetration of the two cubes. Let us consider the following as an explanation of the model.

To describe the H_2^+ ion, we choose l such that E_1 according to (4.14) is equal to the kinetic energy $\frac{1}{2}$ a.u. of the H atom. A simple argument then shows, since 1 a.u. $= me^4/\hbar^2$, $h = 2\pi\hbar$, and 1 $a_0 = \hbar^2/me^2$, that

$$l = \pi\sqrt{3}a_0 \approx 5a_0 \tag{4.17}$$

In H_2^+, the equilibrium distance between the nuclei is 2 a_0, so that one should expect a box length of 7 $a_0 \approx \frac{7}{5}l$ (2.5 a_0 to the right and to the left of the nuclei and 2 a_0 between the nuclei) in the direction of the axis of the molecule. The change in energy due to the increase in the size of the box is then

$$\Delta E \approx \frac{h^2}{8ml^2}\left[\left(\frac{5}{7}\right)^2 - 1\right] \approx -\frac{h^2}{16ml^2} \approx -\frac{1}{6}E_1 \approx -0.08 \text{ a.u.} \tag{4.18}$$

The binding energy estimated in this way is evidently of the correct order of magnitude. However, far-reaching conclusions should not be drawn from oversimplified models. The true electron distribution is naturally very different from that of our model. Moreover, the model can be valid only for energy *differences* (as a result of the interference), but not for the energy of the atom or molecule itself. The potential energy is completely disregarded in this model; though it has little effect on molecule formation, it is very important to the stability *e.g.* of the H atom. In the model, $\langle T \rangle$ for the H atom is $+0.5$ a.u., and $\langle V \rangle = 0$, so that $E = +0.5$ instead of the true value of -0.5 a.u.

Note that the model just discussed is semiempirical. By this we mean that it involves a quantity (in this case l) whose value is found not from the model itself but by comparison with accurate values (known from experiment or from accurate calculations; comparison in this case with the kinetic energy of the H atom in the ground state). The equilibrium distance of H_2^+[22] also was not calculated but assumed.

5. One-Electron and Many-Electron Contributions to the Chemical Bond

Let us forget for the moment the excessively simplified models and try to apply what we have learnt from H_2^+ to the bond in an arbitrarily chosen molecule. At least one point remains to be clarified before we can do this. H_2^+ contains only one electron, whereas all other molecules have more than one; in addition to the energy contributions discussed so far, therefore, there will also be contributions due to the interaction of the electrons, *i.e.*

a) contributions due to the Coulomb repulsion of the charge clouds assigned to the various electrons;

b) the so-called exchange interaction of the electrons, which is connected with the fact that the wave function of a many-electron system must be antisymmetric with respect to the interchange of two electrons (as required by the Pauli principle);

c) the so-called electron correlation, which denotes those corrections that arise from the fact that electrons are not simply charge clouds interacting as such in a static manner but that thay "try to avoid each other".

The questions we must ask ourselves are:

1. Does the presence of the electron interaction contributions fundamentally change the picture of the chemical bond that we have built up?

2. Which of the three electron interaction contributions a) to c) are important and which are not?

In this connection, one may also ask the more particular but by no means unimportant question whether an electron-pair bond (as in H_2) is fundamentally different from a one-electron bond (as in H_2^+).

Those familiar with the history of quantum chemistry will know that the first work on the theory of the chemical bond, *i.e.* that of *Heitler* and *London* on the H_2 molecule[1], was deliberately accepted as a two-electron theory. The chemical bond was correlated by *Heitler* and *London* with a so-called *exchange integral*, which has since then played a central part in the "valence bond" approximation (which is an extension of the Heitler-London model to larger molecules). However, we have known at least since the fundamental publication of *Mulliken*[3] on the MO theory that the Heitler-London exchange integral is not an exchange integral in the true sense[23], and that in fact the electron exchange between atomic orbitals is of practically no importance to chemical bonding.

The Heitler-London exchange integral is a sum of several contributions, the most important of these being essentially equal to the energy contribution due to interference in the case of H_2^+, *i.e.* it is a one-electron integral. The fact that chemical bonding was regarded for a long time as a two-electron effect (as an exchange interaction) goes back on the one hand to the tradition of assigning electron *pairs* to valence lines, and is due on the other hand to the success of the Slater theory of the atom, in which it was in fact possible to attribute the energy differences between different terms having the same configuration to exchange integrals.

The fact that *true* exchange integrals between atomic orbitals do not play a decisive part in chemical bonding is

connected with an observation made by *Mulliken*, according to which these exchange integrals can, to a close approximation, be expressed in terms of Coulomb integrals[24] and overlap integrals. As a result of the validity of this Mulliken approximation, the interference of the AOs has very little influence on the interaction of the electrons, in other words the interaction of the electrons can be calculated on a quasi-classical basis. The effect of the interference is essentially confined to the kinetic energy and to a small extent to the potential energy of the electrons in the field of the nuclei and the core electrons. These are both one-electron contributions.

In any molecule, therefore, the effects responsible for the chemical bond are the same as in H_2^+, *i.e.*:

1. Quasi-classical Coulomb interaction between nuclei and electrons of the separate (different) atoms.

2. Interference of the AOs and the associated decrease in the kinetic energy.

3. Promotion of the AOs.

Unlike the situation in H_2^+, however, it should be noted that in addition to the charge displacement from the atoms into the bonding region as a result of the interference, there is also a charge transfer from one atom to the other in the general case as a result of the difference in the electronegativities of the atoms. This charge transfer is particularly pronounced in polar (ionic) molecules. That it does contribute to bonding and the extent to which it contributes are sufficiently evident, and we shall not pursue this question further[25]. A charge transfer of this type naturally alters the quasi-classical interaction. As a fourth effect that contributes to bonding, we now merely mention:

4. Charge transfer.

When we say that the exchange interaction of the electrons is not important, we must point out that in addition to this and the Coulomb interaction of the electrons, the electron correlation mentioned earlier occurs as a third interaction. This cannot be disregarded for the occurrence of a chemical bond, and is indeed essential for a quantitative theory of the chemical bond. It is sufficient to say here that in the case of a two-electron bond it is most favorable from the standpoint of interference if the two electrons occupy the same bonding molecular orbital, but this double occupation means that the electrons come very close together, even with large distances between the nuclei. From the standpoint of electron correlation, on the other hand, it is energetically more favorable if the electrons can avoid each other. Interference and correlation therefore compete with each other in such a way that the interference predominates at short internuclear distances and the correlation at large distances. However, this competition has the overall result that the bond energy of an electron-pair bond is less than twice the bond energy of a corresponding one-electron bond (where the interference can become fully effective). The bond energy in H_2^+, for example, is 0.102 a.u.; twice this value is 0.204 a.u., whereas the bond energy in H_2 is 0.174 a.u. To complete the picture, we can now add the fifth contribution to the bond:

5. Competition between interference and correlation in electron-pair bonds.

6. Long-Range and Short-Range Forces

Whereas in the last section we distinguished between one-*electron* and many-*electron* contributions to chemical binding, we shall now classify the binding energy according to one-*center* and many-*center* contributions, "center" being identified with atom. If the Mulliken approximation is valid and if part of the electron correlation is approximately taken into account for the many-electron integrals, the energy can be expressed as follows[26]:

$$E = \sum_{\mu} E_{\mu} + \sum_{\mu<\nu} E_{\mu\nu} \tag{6.1}$$

i.e. with only one-center and two-center contributions to the bond.

The sum of the energies of the separate atoms is naturally given by

$$E^0 = \sum_{\mu} E_{\mu}^0 \tag{6.2}$$

where E_{μ}^0 is the energy of the μth atom, so that the following expression is found for the bond energy ΔE:

$$\Delta E = E - E^0 = \sum_{\mu} (E_{\mu} - E_{\mu}^0) + \sum_{\mu<\nu} E_{\mu\nu} \tag{6.3}$$

A one-center contribution $E_{\mu} - E_{\mu}^0$ to the binding energy can obviously be interpreted as the "promotion energy" of the μth atom (where we also regard conversion into an ion as promotion). A two-center contribution $E_{\mu\nu}$, on the other hand, denotes the interaction between the μth and the νth atom. Every two-center contribution of this type consists of two components, one due to the quasi-classical Coulomb interaction between the two atoms and one due to the interference of the AOs of the atoms.

$$E_{\mu\nu} = E_{\mu\nu}^{QK} + E_{\mu\nu}^{interf.} \tag{6.4}$$

There are characteristic differences between the two contributions, particularly in their range. For large distances between the μth and νth atoms, $E_{\mu\nu}^{QK}$, as is always the case for Coulomb interactions, behaves as follows:

$$\lim_{R_{\mu\nu}\to\infty} E_{\mu\nu}^{QK} = \frac{e^2 Q_{\mu} Q_{\nu}}{R_{\mu\nu}} \tag{6.5}$$

where Q_{μ} and Q_{ν} are the "effective charges" of the μth and νth atoms. This interaction has a long range, provided that Q_{μ} and Q_{ν} do not vanish. The interference contribution $E_{\mu\nu}^{interf.}$, on the other hand, is directly related to the overlap of the AOs of the two atoms. On the whole this overlap depends *exponentially* on the distance $R_{\mu\nu}$ between the atoms ab, *i.e.* it has a short range and is important only between atoms that are *nearest neighbors* in the molecule. $E_{\mu\nu}^{QK}$, on the other hand, also acts between atoms that are further apart in the molecule, provided that these carry effective charges.

It is also interesting to note that the interference contributions contain essentially only one-electron contributions of the type discussed for H_2^+.

Let us consider in particular a molecule with nonpolar (or only weakly polar) bonds in which all the effective charges Q_μ of the atoms are negligible. The only contributions to the chemical bond are then short-range contributions, *i. e.* contributions that act only between nearest neighbors. The bond energy then depends only on the nearest neighbors of any given atom and not on the actual geometry of the molecule. The proximity conditions are referred to collectively as the *topology* of the molecule (one could also speak of local geometry as opposed to overall geometry). As an example, let us consider *cis*- and *trans*-1,3-butadiene, both of which have the same topology but different geometry.

Since Q_μ is in fact approximately 0 for all μ, long-range forces are of no decisive importance and the energy difference between the two "isomers" is extremely small.

The description of the bonding in molecules without polar bonds is greatly facilitated by the fact that to a first approximation, this description involves only the topology and not the geometry of the molecule. It should be remembered, however, that a description that is permissible for nonpolar molecules may be completely wrong for polar molecules. A number of inconsistencies in the use of greatly simplified quantum-chemical methods are due to the fact that these methods were applied to polar molecules though they are justified only for nonpolar ones.

7. MO Theory

The term MO theory is unfortunately used with two meanings, which, though connected, mean fundamentally different things. We are referring to the distinction between the "complete MO theory" and the "one-electron MO theory".

In the complete MO theory, one begins with a wave function that is an antisymmetrized product of molecular orbitals (MOs), and the best MOs are then determined such that the total energy becomes a minimum. The electron correlation is ignored here, and errors also arise because of the necessarily finite basis of the AOs (from which the MOs are constructed as linear combinations). Otherwise, however, none of the integrals or other terms in the energy expression are disregarded or approximated.

The one-electron MO theory, on the other hand, which we shall now describe briefly, is the result of a series of simplifications of the quantum-chemical energy expression and omissions of contributions that are regarded as small.

In a molecule in which the effective charges Q_μ of all the atoms vanish (this is a more rigorous requirement than that the molecule should be nonpolar, but we shall use the simple description "nonpolar"), there are no long-range forces, *i. e.* no direct interactions between non-adjacent atoms. Thus only contributions for nearest neighbors, *i. e.* for atoms connected directly by chemical bonds, need be taken into account in the sum $\sum_{\mu<\nu} E_{\mu\nu}$. These contributions are closely connected with the interference of the AOs[27], and the following expression is approximately valid

$$E_{\mu\nu} = \sum_i n_i c_\mu^i c_\nu^i H_{\mu\nu} \tag{7.1}$$

the sum being taken over the MOs. In this expression, n_i is the occupation number of the i-th MO (n_i may have the values 0, 1, or 2), and c_μ^i is the coefficient of the μth AO in the i-th MO. Thus if ψ_i is the i-th MO and λ_μ is the μth AO, ψ_i can be written as

$$\psi_i = \sum_\mu c_\mu^i \chi_\mu \tag{7.2}$$

Finally, $H_{\mu\nu}$ in (7.1) for $\mu \neq \nu$ is the resonance integral[20] between the μth and the νth AOs, and is directly connected with the interference of this MO, whereas $H_{\mu\mu}$ can be interpreted under certain conditions as the ionization potential of the μth AO in its valence state.

We assumed in eq. (7.1) that each atom has only one AO available; it would otherwise have been necessary to give the AOs two subscripts, one denoting the atom and the other the AO of an atom, and it would also be necessary in (7.1) to carry out summation over the AOs of the μth and of the νth atoms. For clarity, we limit ourselves to a single subscript (corresponding to the case of one AO per atom).

If (7.1) is a sufficiently good approximation, the MO coefficients c_μ^i can be calculated from a system of linear equations of the following type[28]

$$\sum_\nu H_{\mu\nu} c_\nu^i = \varepsilon_i \sum_\nu S_{\mu\nu} c_\nu^i \tag{7.3}$$

where

$$S_{\mu\nu} = \int \chi_\mu \chi_\nu \, d\tau \tag{7.4}$$

is the overlap integral of the AOs χ_μ and χ_ν.

The system of equations (7.3) can be solved only if the (for the time being unknown) ε_i assume certain numerical values, *i. e.* values such that the determinant

$$|H_{\mu\nu} - \varepsilon_i S_{\mu\nu}| \tag{7.5}$$

vanishes. The ε_i can be interpreted as the energies of the MOs, and the binding energy is approximately given by

$$\Delta E = \sum_i n_i \varepsilon_i - \sum_\mu n_\mu H_{\mu\mu} \tag{7.6}$$

In this equation, n_μ of course denotes the occupation number of the AO in the isolated atom.

Under certain conditions, it is justifiable to equate the overlap integral $S_{\mu\nu}$ for $\mu \neq \nu$ to zero and *at the same*

time to replace the resonance integrals $H_{\mu\nu}$ by the reduced resonance integrals $\beta_{\mu\nu}$[15].

If the diagonal elements $H_{\mu\mu}$ are then denoted by α_μ and if the Hückel matrix is defined by the elements $\tilde{H}_{\mu\nu}$

$$\tilde{H}_{\mu\nu} = \begin{cases} \alpha_\mu \text{ for } \mu = \nu \\ \beta_{\mu\nu} \text{ for } \mu \neq \nu \end{cases} \tag{7.7}$$

then from (7.3) and (7.5)

$$\sum \tilde{H}_{\mu\nu} c_\nu^i = \varepsilon_i c_\mu^i \tag{7.8}$$

$$|\tilde{H}_{\mu\nu} - \varepsilon_i \delta_{\mu\nu}| = 0 \tag{7.9}$$

whereas (7.6) remains formally the same. The energy ε_i assigned to the i-th molecular orbital is then simply equal to the i-th eigenvalue of the Hückel matrix. The lowest value of ΔE according to (7.6), *i.e.* the binding energy of the molecule, is obtained if the lowest MOs are filled in sequence. According to the Pauli principle, the maximum occupation number is $n_i = 2$. An MO φ_i, which is a linear combination of the AOs in this approximation, gives binding between two atomic orbitals χ_μ and χ_ν only if the interference between these atoms is positive, *i.e.* if the coefficients c_μ^i and c_ν^i (cf. (7.2)) have the same sign (provided $S_{\mu\nu} > 0$), in other words if

$$c_\mu^i \cdot c_\nu^i > 0 \tag{7.10}$$

Otherwise, *i.e.* if $c_\mu^i c_\nu^i$ is negative, negative interference exists between χ_μ and χ_ν, and we have the opposite of binding. The sum over the contributions of all MOs[29]

$$p_{\mu\nu} = \sum_i n_i c_\mu^i c_\nu^i \tag{7.11}$$

is consequently a measure of the strength of the bond between these atoms, and is therefore known as the bond order[29]. It must be emphasized, however, that bond orders can be defined only within certain approximations, and are not quantities that have anything to do with the bond itself.

Negative interference means a nodal surface[30] of the MOs between the AOs in question. The (energetically) lowest MOs have no nodes between the atoms, and the number of nodes generally increases with increasing ε_i. The same result is also found when one attempts to describe the bonding by means of the electron gas model instead of by the Hückel MO approximation, as indeed a close analogy exists between the HMO approximation and the free electron model[31].

Let us consider a number of examples to illustrate the arguments of this section.

1. *H_2^+ and H_2.* Both have the Hückel matrix

$$\tilde{H} = \begin{pmatrix} \alpha & \beta \\ \beta & \alpha \end{pmatrix}$$

with the eigenvalues

$$\varepsilon_1 = \alpha + \beta$$

$$\varepsilon_2 = \alpha - \beta$$

Since $\beta < 0$, ε_1 is the lower of the two MO energies. The occupation numbers are $n_1 = 1$ for H_2^+ and $n_1 = 2$ for H_2, and the bond energies are therefore

$$\Delta E = (\alpha + \beta) - \alpha = \beta \text{ for } H_2^+$$

$$\Delta E = 2(\alpha + \beta) - 2\alpha = 2\beta \text{ for } H_2$$

We have already derived this approximate expression for H_2^+ in Section 4 and we also explained the approximations that lead to this result. The one-electron MO approximation gives exactly twice the bond energy of a one-electron bond for a two-electron bond. It was shown in Section 4 that this is not quite correct, the exact values being

$$\Delta E = -0.102 \text{ a.u. for } H_2^+$$

$$\Delta E = -0.174 \text{ a.u. for } H_2$$

2. *He_2.* The Hückel matrix and the eigenvalues are the same as for H_2. However, it is now necessary to accommodate four electrons; this is possible only if both ψ_1 (which is bonding) and ψ_2 (which is antibonding) are doubly occupied. With $n_1 = n_2 = 2$ one obtains

$$\Delta E = 2(\alpha + \beta) + 2(\alpha - \beta) - 4\alpha = 0$$

Thus no bonding occurs between two He atoms[32], and similarly the electrons of the K shells in the molecules Li_2 to F_2 take practically no part in bonding. The fact that there is no chemically bound Ne_2 molecule can be explained in a similar manner.

3. *H_3^+.* At equilibrium, this molecule has the structure of an equilateral triangle. Each of the three atoms is directly bound to each of the others, so that the Hückel matrix is

$$\tilde{H} = \begin{pmatrix} \alpha & \beta & \beta \\ \beta & \alpha & \beta \\ \beta & \beta & \alpha \end{pmatrix}$$

The eigenvalues ε_i of this matrix are

$$\varepsilon_1 = \alpha + 2\beta$$

$$\varepsilon_2 = \alpha - \beta$$

$$\varepsilon_3 = \alpha - \beta$$

There is room for two electrons in the lowest MO, $n_1 = 2$.

$$\Delta E = 2(\alpha + 2\beta) - 2\alpha = 4\beta$$

The binding energy of H_3^+, with respect to $2H + H^+$, should therefore be twice that of H_2, with respect to 2 H, *i.e.* the proton affinity of H_2 should be roughly equal to the binding energy of H_2. This agrees surprisingly well with experimental values and with values from good quantum-chemical calculations.

H_3^+ embodies the simplest case of a three-center bond. This good functioning of the Hückel approximation for H_3^+ should not be overprized since the Hückel approxima-

tion completely fails for the neutral H_3. With $n_1=2$ and $n_2=1$, we should have

$$\Delta E = 2(\alpha+2) + \alpha - \beta - 3\alpha = 3\beta$$

i.e. H_3 should have a binding energy of β with respect to H_2+H, whereas in reality H_3 is not a stable molecule[33].

4. *BeH_2 (linear).* The Hückel matrix here is

$$\tilde{H} = \begin{pmatrix} \alpha_K & 0 & 0 & 0 & 0 \\ 0 & \alpha_s & 0 & \beta_{sh} & \beta_{sh} \\ 0 & 0 & \alpha_p & \beta_{ph} & -\beta_{ph} \\ 0 & \beta_{sh} & \beta_{ph} & \alpha_h & 0 \\ 0 & \beta_{sh} & -\beta_{ph} & 0 & \alpha_h \end{pmatrix}$$

The first line (column) relates to the 1s AO (K) of Be, the second line (column) to the 2s AO of Be, the third to the 2p AO of Be, and the fourth and fifth to the two H atoms. The reduced resonance integral β_{sh} takes into account the interference between 2s of the Be atom and 1s of an H atom.

Since the 1s AO of Be is so strongly localized in the neighborhood of the nucleus that it does not interfere with the 1s AOs of the H atom, we find that it is an MO by itself.

$$\Psi_1 = K$$

Since the molecule is symmetrical with respect to inversion at the Be atom, the MOs must be either symmetrical or antisymmetrical with respect to this center. For each type there is one bonding and one antibonding MO. Since we have to accommodate six electrons, we need the two bonding MOs

$$\psi_2 = c_{22}s + c_{24}(h_1 + h_2)$$
$$\psi_3 = c_{33}p + c_{34}(h_1 - h_2)$$

in addition to ψ_1. In ψ_2 the 2s AO of the Be atom binds the H atoms, and in ψ_3 the 2pσ AO; both are three-center MOs.

The molecular orbitals of the MO theory are found to be delocalized over the entire molecule, even though such delocalization contradicts chemical intuition. One might have preferred to see BeH_2 described by two-center Be—H bonds.

8. Localized and Delocalized Bonds

A fully equivalent localized description is in fact possible for molecules like BeH_2. To understand this, one must bear in mind that the MOs are not uniquely defined, and that a different choice of MOs can give the same results with respect to all the observable properties of a molecule.

The wave function of the MO theory (but we must base our argument here on the "complete MO theory" and not on the "one-electron MO theory") is a Slater determinant.

To illustrate this let us consider a very simple example, *i.e.* the first excited triplet state of the H_2 molecule, in which both the bonding and the antibonding MO are singly occupied with equal spin[34].

The wave function (spin-free) in the determinant form is

$$\phi = \frac{1}{\sqrt{2}} \begin{vmatrix} \psi_+(1) & \psi_+(2) \\ \psi_-(1) & \psi_-(2) \end{vmatrix} \tag{8.1}$$

or multiplied out

$$\phi = \frac{1}{\sqrt{2}} \{\psi_+(1)\psi_-(2) - \psi_-(1)\psi_+(2)\} \tag{8.2}$$

We shall now assume further that the interatomic distance is so great that the overlap between the AOs a and b becomes vanishingly small, so that

$$\psi_\pm = \frac{1}{\sqrt{2}}[a \pm b] \tag{8.3}$$

Insertion of (8.3) in (8.2) leads, after simple multiplication, to

$$\phi = \frac{1}{\sqrt{2}} \{a(1)\,b(2) - b(1)\,a(2)\} = \frac{1}{\sqrt{2}} \begin{vmatrix} a(1) & a(2) \\ b(1) & b(2) \end{vmatrix} \tag{8.4}$$

The wave function ϕ thus does not change when the delocalized MOs ψ_+ and ψ_- are replaced by the localized MOs a and b. This is possibly not too surprising in the example chosen. If both the bonding (ψ_+) and the antibonding (ψ_-) linear combinations of the AOs a and b are occupied, no bonding occurs and the electrons can also be packed, intuitively speaking, into the original AOs. It is clear that in the ground state of H_2 with the one-determinant wave function in which ψ_+ is doubly occupied (with α and β spin), a different choice of the MOs is not possible, since only one MO occurs in the wave function.

In the ground state of He_2, on the other hand, we have substantially the same situation as in the H_2 triplet. Instead of double occupation of each of the two MOs ψ_+ and ψ_-, the AOs a and b may each be doubly occupied. There is no molecule He_2, but only two He atoms.

Let us return to the example of the H_2 triplet. The AOs a and b are obtained from the MOs ψ_+ and ψ_- in accordance with (the converse of (8.3))

$$a = \frac{1}{\sqrt{2}}[\psi_+ + \psi_-]$$
$$b = \frac{1}{\sqrt{2}}[\psi_+ - \psi_-] \tag{8.5}$$

One can also satisfy oneself that any choice of orbitals φ_1 and φ_2 in accordance with

$$\varphi_1 = u_{11}\psi_+ + u_{12}\psi_-$$
$$\varphi_2 = u_{21}\psi_+ + u_{22}\psi_- \tag{8.6}$$

leads to the exactly identical wave functions

$$\phi = \frac{1}{\sqrt{2}} \begin{vmatrix} \psi_+(1) & \psi_+(2) \\ \psi_-(1) & \psi_-(2) \end{vmatrix} = \frac{1}{\sqrt{2}} \begin{vmatrix} \varphi_1(1) & \varphi_1(2) \\ \varphi_2(2) & \varphi_2(2) \end{vmatrix} \tag{8.7}$$

provided that the matrix of the coefficient is unitary, *i.e.* provided that (for real u_{ik})

$$\begin{aligned} (u_{11})^2 + (u_{12}{}^2 = (u_{21})^2 + (u_{22})^2 = 1 \\ u_{11}\,u_{21} + u_{12}\,u_{22} = 0 \end{aligned} \tag{8.8}$$

Among the infinite range of possible choices for the two MOs, there are two outstanding sets (and this is generally valid, not only for our example), *i.e.*:

1. The canonical MOs, in this case ψ_+ and ψ_-; these are adapted to the symmetry of the problem, ψ_+ being symmetric with respect to inversion at the symmetry center of the molecule, and ψ_- antisymmetric.

2. The equivalent MOs[35], in this case *a* and *b*; these are interchanged on application of symmetry operators (in this case inversion at the center).

In the example considered, the equivalent MOs happen to be identical with atomic orbitals (AOs).

This is not the case *e.g.* in BeH_2, were the equivalent MOs

$$\varphi_1 = \frac{1}{\sqrt{2}}(\psi_2 + \psi_3) = \frac{c_{22}}{\sqrt{2}}s + \frac{c_{33}}{\sqrt{2}}p + \frac{(c_{24} + c_{34})}{\sqrt{2}}h_1 + \frac{(c_{24} - c_{34})}{\sqrt{2}}h_2$$

$$\varphi_2 = \frac{1}{\sqrt{2}}(\psi_2 - \psi_3) = \frac{c_{22}}{\sqrt{2}}s - \frac{c_{33}}{\sqrt{2}}p + \frac{(c_{24} - c_{34})}{\sqrt{2}}h_1 + \frac{(c_{24} + c_{34})}{\sqrt{2}}h_2 \tag{8.9}$$

can be constructed from the MOs φ_2 and φ_3 (cf. Section 7).

Since, as it turns out,

$$c_{22} \approx c_{33}; \quad c_{24} \approx c_{34} \tag{8.10}$$

we have approximately

$$\begin{aligned} \varphi_1 &\approx c_{22}\frac{s+p}{\sqrt{2}} + \sqrt{2}\cdot c_{24}\cdot h_1 \\ \varphi_2 &\approx c_{22}\frac{s-p}{\sqrt{2}} + \sqrt{2}\cdot c_{24}\cdot h_2 \end{aligned} \tag{8.11}$$

i.e. the equivalent MOs are approximately localized in one Be—H bond each, and can be approximately interpreted as two-center MOs, each formed from the AO of a hydrogen atom and a "hybrid AO" of the central atom

$$\begin{aligned} d_1 &= \frac{1}{\sqrt{2}}(s+p) \\ d_2 &= \frac{1}{\sqrt{2}}(s-p) \end{aligned} \tag{8.12}$$

Localized bonds in the chemical sense are in fact always present if it is possible to construct equivalent MOs that, to a good approximation, are each localized in one bond. However, such a transformation is not always possible and *Hund*[36] was able in 1931 to state the necessary condition for the possibility of the localization of bonds. This condition, for each atom in the molecule, is:

number of valence electrons = number of AOs participating in the bond = number of neighbors

The condition is satisfied in BeH_2. Be has 2 valence electrons (the 1s electrons, which do not take part in bonding, are not counted), 2 neighbors, and 2 AOs (2s and 2p) that participate in bonding. The corresponding number for each of the two H atoms is 1.

In BeH_2^+, however, localization is no longer possible, since there is only one valence electron of Be available, whereas the number of AOs and the number of neighbors remain the same. This is an indication that the use of localized MOs is unsuitable for the description of the ionization of molecules (which is now so important in connection with photoelectron spectroscopy), since such MOs are meaningful for neutral molecules, but not for ionized molecules.

As can be generally shown, the orbitals whose energies represent the best one-electron approximation for ionization potentials are in fact the canonical MOs. The orbitals that the photoelectron spectroscopist must think about are necessarily the canonical orbitals. It would be quite wrong, however, to conclude from the delocalization of the ionization that the description of neutral molecules in the ground state by localized bonds is invalid. This error is unfortunately often made[37].

H_3^+, for example, cannot be described by localized two-center bonds. In this case each H has $\frac{2}{3}$ electron, 2 neighbors, and 1 valence AO.

The π bond in benzene is not localized either, *i.e.* not localizable. In this case (now only with reference to the π bond) the number of neighbors is 2, whereas the number of electrons and of AOs is only 1. A similar situation is found for diborane B_2H_6, in which each B atom has 4 H atoms as neighbors but only 3 valence electrons. However, B_2H_6 can be described by four 2-center BH and two 3-center BHB bonds. The bonds are thus largely localized even in B_2H_6, but in localized 2-center and 3-center bonds. This localizability of the bonds completely collapses in other boron hydrides, *e.g.* in $[B_{12}H_{12}]^{2-}$, where only the canonical (symmetry-adapted) MOs are adequate (as in benzene).

Systems with delocalized bonds (many-center bonds) are often characterized by unusual stability, particularly when the number of valence electrons is smaller than the number that would correspond to localized electron-pair bonds (electron-deficient compounds). This is not surprising, since it can be seen even from the example of H_2/H_3^+ that two electrons form a two-center bond with a binding energy of $\Delta E \approx -100$ kcal/mol, whereas the same two electrons form a three-center bond with $\Delta E \approx -200$ kcal/mol.

9. Electron Correlation and the Chemical Bond

In the use of a one-electron MO theory (such as the Hückel approximation), the quasi-classical electrostatic interaction of the effective charges in the molecule is disregarded, among other things. A complete MO theory takes these long-range forces into account, but even this is still far from an exact solution of the quantum-mechanical problem. As was mentioned, the errors of the one-determinant approximation are referred to as electron correlation.

Electron correlation has an impact on the chemical bond in several respects. Two effects in particular are important. The first is concerned with the false asymptotic behavior of the MO wave function for large internuclear distances. It has already been mentioned that in the MO theory two electrons occupy the same orbital. This means that they come very close together, even at large internuclear distances.

By taking electron correlation into account, one gives the electrons the opportunity to avoid each other, so to speak. One can readily understand that this contribution of electron correlation increases with the internuclear distance. In the H_2 molecule, for example, it is to be expected for large R that there will be one electron in the neighborhood of each nucleus, whereas the wave function of the MO approximation forces the electrons to be situated in the neighborhood of the same nucleus with the same probability as in the neighborhood of different nuclei. It is often said (though this formulation is somewhat misleading) that the MO function gives too much weight to "ionic structures" at large distances. The correlation under discussion here, which ensures the correct behavior for $R \rightarrow \infty$, is known as left-right correlation. It allows the electrons to avoid each other by ensuring that when one electron is on the left (at nucleus A) the other is preferentially on the right (at nucleus B). There are also in-out and angular correlations, which must be taken into account if binding energies are to be calculated accurately.

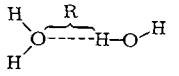
All the correlation effects just mentioned refer to a single bond electron pair, and one can therefore speak of intra-bond correlation. Its contribution is important whenever unpaired electrons participate in a bond, as can be seen from the following list[38,39].

	ΔE (MO) [eV]	$\Delta E_{corr.}$ [eV]
H_2	−3.64	−1.11
Li_2	−0.17	−0.88
N_2	−5.27	−4.63
F_2	+1.37	−3.05

As is generally believed, the correlation energy does not change much if no electron pairs are separated on dissociation of the molecule, the number of electron pairs remaining the same, *e.g.* in semipolar bonds such as

$$NH_4^+ \rightarrow NH_3 + H^+$$

or in hydrogen bonds



However, constancy of the number of electron pairs is not enough to ensure approximate constancy of the correlation energy on dissociation. In addition to the *intra*-bond correlation, the correlation between different bonds, which may be regarded as a sort of van der Waals attraction between these bonds, is also found to be important. Undoubtedly a rather spectacular case in which the change in the *inter*-bond correlation energy makes a decisive contribution to the binding energy is the system $2\,BH_3 \rightarrow B_2H_6$. The MO theory gives a value of approximately 10 kcal/mol for the dimerization energy of BH_3, while the change in the inter-bond correlation energy is approximately 25 kcal/mol, corresponding to a total dimerization energy of about 35 kcal/mol[40]. In BH_3, there are only three possible pairs of bonds with a common B atom whereas in B_2H_6 there are eleven such pairs, *i.e.* five more than in two separate BH_3 units. The change in the correlation energy that accompanies the change in the number of adjacent bonds is responsible for the bulk of the "electron-deficient bonding" in B_2H_6[40]. This should be born in mind particularly since chemistry textbooks are never at a loss to explain this type of bonding with the aid of a qualitative MO theory without even considering electron correlation.

I am grateful to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for their support of my investigations, and to Dr. R. Ahlrichs and Dr. V. Staemmler for examining the manuscript and for many discussions on this topic.

[4] *K. Ruedenberg*, Rev. Mod. Phys. 34, 326 (1962).

[5] The integration, which is conveniently carried out in spherical polar coordinates, leads for ψ according to (2.8), of which that according to (2.7) is a special case (with $\eta = 1$), to $\int \psi^2 d\tau = N^2 \cdot \pi \cdot \eta^{-3} = 1$, whence it follows directly:

$$N = \sqrt{\frac{\eta^3}{\pi}}.$$

[6] The mean $\langle f(x) \rangle$ of any function $f(x)$ averaged over the distribution $\rho(x)$ is defined as

$$\langle f(x) \rangle = \int_{-\infty}^{\infty} \rho(x) f(x) d\tau$$

This integral vanishes for $f(x) = x$, since replacement of x by $-x$ leaves $\rho(x)$ unchanged but reverses the sign of $f(x)$. To each contribution in the integral for positive x, there is an exactly opposite contribution for negative x, so that the integral as a whole vanishes.

[7] The uncertainty of the mean of a function $f(x)$ is defined as

$$\Delta f(x) = + \{\langle f^2(x) \rangle - \langle f(x) \rangle^2\}^{\frac{1}{2}} = + \{\int \rho f^2 d\tau - (\int \rho f d\tau)^2\}^{\frac{1}{2}}$$

Since $\langle f(x)\rangle$ vanishes in the given case $[f(x)=x]$, we have simply

$$\Delta x = + \{\rho x^2 d\tau\}^{\frac{1}{2}} = + \left\{\frac{1}{\eta^2}\right\}^{\frac{1}{2}} = \frac{1}{\eta}$$

in atomic units of length (a_0).

Whereas the mean of x, y, or z vanishes, that of r is different from zero. One obtains

$$\langle r\rangle = \frac{3}{2\eta}$$

The mean distance of the electron from the nucleus, apart from a factor of 1.5, is thus equal to the uncertainty of the x coordinate (for $y=z=0$).

[8] If the wave function $\psi(x)$ of a quantum-mechanical state is given, the probability amplitude $\phi(p_x)$ for the distribution of the corresponding momentum component p_x is generally given by

$$\phi(p_x) = (2\pi)^{-\frac{1}{2}} \int_{-\infty}^{+\infty} \exp\left(\frac{i p_x x}{\hbar}\right) \cdot \psi(x) dx$$

i.e. by a Fourier transformation. The probability that a particle has a momentum between p_x and $p_x + dp_x$ is then simply $|\phi(p_x)|^2\, dp_x$. For the function (2.8) one obtains (in a three-dimensional generalization of the above argument)

$$\phi(p) = \sqrt{\frac{32}{\pi}} \cdot \frac{\eta^{\frac{5}{2}}}{(p^2+\eta^2)^2}$$

where $p = \sqrt{p_x^2+p_y^2+p^2}$ is the magnitude of the momentum, and p is measured in units of $\hbar/a_0$.

The mean momentum corresponding to our wave function (2.8) is

$$\langle p\rangle = \frac{8}{3\pi} \cdot \eta \cdot \frac{\hbar}{a_0}$$

Compare this with Δp_x according to eq. (2.1). The relation between positional distribution and momentum distribution used here is a rigorous formulation of the uncertainty relation.

[9] The reader may be surprised that we were able to derive the wave function and the energy of the ground state of the H atom without explicitly referring to the Schrödinger equation. In fact, however, the Schrödinger equation is equivalent to the variation principle

$$\delta E = \delta\{\langle T\rangle + \langle V\rangle\} = 0$$

The wave function ψ, which makes the energy stationary with respect to *arbitrary* variations of ψ, is automatically a solution of the Schrödinger equation. We have not allowed all variations of ψ here, but have varied only η; this limitation is not serious because the exact wave function is contained in the family of "variation functions" (*i.e.* for $\eta=1$). If we had chosen *e.g.* the expression $\psi = N \cdot e^{-\alpha r^2}$ instead of (2.8) and tried to find the minimum of E as a function of α, we would have obtained only an approximate solution of the Schrödinger equation. However, we could have been confident that the energy calculated in this way would be *higher* than the true energy; the more closely our ψ approaches the correct ψ, the nearer is the calculated energy to the true energy. To understand that our procedure is really equivalent to a solution of the Schrödinger equation, one must appreciate that we have correctly calculated the expected value $\langle T\rangle$ of the kinetic energy; this can be done either in the usual manner by using the operator of the kinetic energy and the wave function in the "configurational representation" or, as we have done here, by using both in the "momentum representation", in which the momentum operator is simply multiplicative.

[10] In analogy with (3.2) we also think of the momentum distribution as being formed quasi-classically from those of the separate atoms.

[11] We use the term "quasi-classical" here in the sense introduced by *Ruedenberg* [4]. This has nothing to do with the WKB approximation, which was occasionally also described as "quasi-classical", though the description "semi-classical" is more usual.

[12] The kinetic energy of half an electron in each of the atomic orbitals a and b and the potential energy in the field of its own nucleus together give exactly the energy $E(H)$ of a H atom in the field of its nucleus. In addition to this there are the potential energy e^2/R of the internuclear repulsion and twice the attraction $-E_{Ke}$ of half an electron in an AO by the other nucleus. There is no repulsion between electrons, since there is only one electron present at all, and there is no "self-interaction" of an electron.

[13] The potential energy of the interaction of a point particle of charge q and a spherically symmetrical charge distribution ρ of total charge Q is simply $V=qQ/R$, where R is the distance of the particle from the center of gravity of the charge distribution, if the particle is outside the charge distribution. It is $V=0$ if the charge distribution ρ is situated in a spherical shell and the particle is situated in the (charge-free) interior of the spherical shell. If the particle is situated anywhere within the charge distribution, ρ can always be divided into two components such that the particle is outside with respect to one and inside with respect to the other. Only the first of these two components contributes to the potential energy.

If the nucleus B penetrates into the charge cloud of the electron in the AO, the attraction between the two is smaller in magnitude than the internuclear repulsion.

[14] *H. Hellmann*, Z. Phys. *35*, 180 (1933).

[15] The success of the calculations in which overlap is neglected is due to a misconception that was pointed out in particular by *Mulliken* [3]. The energy expression of the LCAO approximation for H_2^+ is

$$E_\pm = \frac{E(H) + E_{QK} \pm H_{ab}}{1 \pm S}$$

where H_{ab}, the so-called resonance integral, denotes the energy (kinetic + potential) belonging to the charge distribution *a.b.* If one neglects S (though in reality $S=0.6$), one obtains

$$E_\pm = E(H) + E_{QK} \pm H_{ab}$$

On the other hand, the correct $E_\pm$ can be transformed to

$$E_\pm = E(H) + E_{QK} \pm \frac{H_{ab} - S[E(H) + E_{QK}]}{1 \pm S} = E(H) + E_{QK} \pm \frac{\beta}{1 \pm S}$$

The correct expression and the incorrect expression are now formally very similar. When, as was usually the case, H_{ab} and β were not really calculated but regarded as semi-empirically adjustable parameters, it was practically impossible to differentiate between the two possibilities, and it appeared that overlap could be neglected. Neglect of overlap actually means that the bond energy is expressed by the reduced resonance integral β instead of by the resonance integral H_{ab} [3].

[16] The Hellmann-Feynman theorem says that the forces acting on a nucleus in a molecule are exactly equal to those calculated electrostatically from the given charge distribution of the electrons and the other nuclei. However, the critical point is that the Hellmann-Feynman theorem is valid only for the charge density calculated from the *exact* wave function, and not for those calculated from approximate wave functions. The Hellmann-Feynman theorem is therefore unsuitable for the theory of the chemical bond, since we are always concerned here with approximate wave functions. The charge density that is actually built up in a molecule is determined not only by the electrostatic factors but also by the kinetic energy; a purely electrostatic model of the chemical bond is therefore impossible.

[17] *E.g. P. O. Löwdin*, J. Mol. Spectrosc. *3*, 46 (1959). The reproach that *Hellmann* had not taken the virial theorem into account is the more grotesque in that in the same article in which he proposed the picture of the chemical bond that is named after him, *Hellmann* derived the virial theorem for molecules (simultaneously with and independently of *Slater*) and discussed in detail its role in connection with models of the chemical bond.

[18] *M. J. Feinberg, K. Ruedenberg*, and *E. L. Mehler*, Advan. Quantum Chem. *5*, 28 (1970); *M. J. Feinberg* and *K. Ruedenberg*, J. Chem. Phys. *54*, 1495 (1971).

[19] In reality, the deformation is rather more complicated, but the major part of this deformation is taken into account for H_2^+ by a variation of η.

[20] *Ruedenberg* [4] uses the symbol β for the original resonance integral H_{ab} (cf. [15]) and γ for the reduced resonance integral (4.7). *Mulliken* [3] uses the symbols γ and β in exactly the opposite senses.

[21] The derivation of this expression can be found in any introductory textbook of quantum mechanics. The energy of the ground state for a one-dimensional motion is $h^2/8ml^2$, and for an electron in a box having the edge lengths a, b, and c is given as $\frac{h^2}{8m}\left(\frac{1}{a^2}+\frac{1}{b^2}+\frac{1}{c^2}\right)$.

[22] This argument suggests that in a description of the chemical bond by the free electron model, the box should be so chosen that about one bond length is left over to the right and to the left of the outer atoms. The contributions of the kinetic energy normal to the bond direction can be completely eliminated in this approach, since they do not change during the development of the bond; the so-called one-dimensional free electron model thus becomes plausible.

[23] By "true" we mean the definition of the exchange integrals in the atomic theory.
The "exchange integral" of the Heitler-London theory is defined as

$$K = \int a(1)b(2)H(1,2)b(1)a(2)\mathrm{d}\tau_1\mathrm{d}\tau_2$$

where $H(1,2)$ is the complete Hamiltonian operator of the H_2 molecule. If we break down $H(1,2)$ into one-electron and two-electron contributions and introduce the abbreviations that are more familiar to us from H_2^+, we obtain for K:

$$K = 2S \cdot H_{ab} - 2S \cdot E_{K\epsilon} + S^2 \cdot \frac{e^2}{R} + (ab|ba)$$

where $(ab|ba)$ is an exchange integral in the "true" sense

$$(ab|ba) = \int a(1)\, b(2) \frac{1}{r_{12}} b(1)\, a(2)\, \mathrm{d}\tau_1\, \mathrm{d}\tau_2$$

This is positive, whereas K as a whole is negative. The dominant contribution to K is $2S \cdot H_{ab}$, and this is directly connected with the interference of the AOs (exactly as for H_2^+). H_{ab} and S are *one-electron contributions*, *i.e.* each is obtained by integration over the coordinates of one electron.

[24] The term "Coulomb integrals" denotes integrals of the form

$$\int [a(1)]^2 \frac{1}{r_{12}} [b(2)]^2\, \mathrm{d}\tau_1\, \mathrm{d}\tau_2$$

that describe the Coulomb repulsion of two electrons in the AOs a and b, which are therefore quasi-classical in nature.

[25] In the limiting case of purely ionic bonding, the binding energy consists, to a good approximation, of two contributions: one component $I_A - A_B$, the difference between the ionization energy of one atom and the electron affinity of the other, which represents the energy change due to charge transfer and is the only contribution present for $R \rightarrow \infty$, and the contribution of the Coulomb attraction of the opposite charges formed on the atoms. These two contributions naturally also play a certain part in polar but not purely ionic compounds.

[26] It is not entirely self-evident that an approximate breakdown of the energy into one-center and two-center contributions is possible, and the derivation of eq. 6.1 with explicit expressions for E_μ and $E_{\mu\nu}$ is not trivial. For details, see the book to be published by Verlag Chemie, Weinheim, *W. Kutzelnigg:* Einführung in die Theoretische Chemie, Bd. 2: Die chemische Bindung [Introduction to Theoretical Chemistry, Vol. 2: The Chemical Bond].

[27] The results for H_2^+ suggest that in nonpolar molecules the quasi-classical repulsion of the atoms becomes effective only at distances shorter than the bond length, so that its contribution is small when the geometry is close to the equilibrium geometry.

[28] The system of equations (7.3) is obtained as the condition that the optimum c_μ^i must satisfy if one tries to find the minimum of the energy expression (7.1) as a function of the coefficients c_μ^i with the subsidiary condition that the MOs (7.2) are normalized to 1 and are mutually orthogonal.

[29] *C. A. Coulson* and *H. C. Longuet-Higgins*, Proc. Roy. Soc. London *A 191*, 39 (1947).

[30] Nodal surfaces are surfaces on which the wave function vanishes in such a way that it has opposite signs on either side of the nodal surface.

[31] *K. Ruedenberg*, J. Chem. Phys. *22*, 1878 (1954); *N. S. Ham* and *K. Ruedenberg*, *ibid. 29*, 1199, 1215 (1958).

[32] The potential curve for He_2 has in fact a minimum in the ground state, this minimum occurring at a distance of 5.6 a_0 and a "binding energy" of about 20 cal/mol. The mechanism of the occurrence of this "van der Waals minimum" is fundamentally different from that of a true chemical bond, and we cannot discuss it here.

[33] The explanation for the failure of the one-electron MO theory in this fairly simple example is rather complicated (cf. the textbook announced in [26]). We shall merely mention that it is accompanied by a pronounced promotion of the AOs in the bonding MO and substantial shielding of the nuclear charge for the formally weakly antibonding MO, with the result that the latter becomes strongly antibonding. In the light of these arguments, it is merely fortuitous that the one-electron MO theory works so well for H_2^+, H_2, and H_3^+.

[34] In the ground state of H_2, the MO ψ_+ (usually called $1\sigma_g$) is doubly occupied, and in the first excited state ψ_+ and ψ_- (also called $1\sigma_u$) are both singly occupied. Whereas in the ground state $1\sigma_g^2$ one electron necessarily has α spin and the other β spin, a triplet state with parallel spins and a singlet state with antiparallel spins are possible for the configuration $1\sigma_g 1\sigma_u$. The wave function of the triplet state ($^3\sum_\mu^-$) in the one-determinant approximation is

$$\frac{1}{\sqrt{2}} \begin{vmatrix} \psi_+(1)\,\alpha(1) & \psi_+(2)\,\alpha(2) \\ \psi_-(1)\,\alpha(1) & \psi_-(2)\,\alpha(2) \end{vmatrix} = \alpha(1)\,\alpha(2) \frac{1}{\sqrt{2}} \begin{vmatrix} \psi_+(1)\,\psi_+(2) \\ \psi_-(1)\,\psi_-(2) \end{vmatrix}$$

The wave function is thus the product of a spin function and a space function. We can confine the following discussion to the pure space function (8.1).

[35] The name "equivalent orbital" is due to *Lennard-Jones et al.* [*J. E. Lennard-Jones*, Proc. Roy. Soc. London *A 198*, 1, 14 (1949); *J. E. Lennard-Jones et al.*, *ibid. A 202*, 155, 166 (1950)], though the concept underlying the name is older [36]. Generalizations of the "equivalent orbitals" to situations where they are not definitely determined by the symmetry were given on the one hand by *S. F. Boys* [Rev. Mod. Phys. *32*, 296 (1960)], and on the other by *C. Edmiston* and *K. Ruedenberg* [Rev. Mod. Phys. *35*, 457 (1963)].

[36] *F. Hund*, Z. Phys. *74*, 1, 565 (1931). These are the fundamental articles on the subject of "localized bonds".

[37] *E.g.*: *E. Haselbach*, *E. Heilbronner*, *A. Mannschreck*, and *W. Seitz*, Angew. Chem. *82*, 879 (1970); Angew. Chem. internat. Edit. 9, 902 (1970). This article ends with the words "... that, in keeping with modern social trends, electrons also prefer to live in a commune, rather than in pairwise isolation". Attractive as this anthropomorphism appears, it is nevertheless false, since "pairing" or "living in a commune" are not really alternatives for electrons, and since PE spectroscopy does not yield information about the commune in the "ground state", but only shows how it reacts to the removal of one of its members.

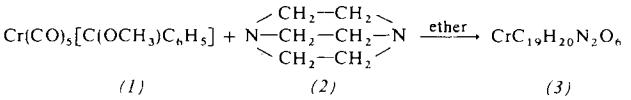
1,4-Diazabicyclo[2.2.2]octane(phenylmethoxy)-methylenepentacarbonylchromium(0), a Novel Nitrogen Ylide-Transition Metal Complex[1]

By *Fritz R. Kreissl, Ernst Otto Fischer, Cornelius G. Kreiter,* and *Karin Weiss*[*]

Primary and secondary amines replace the alkoxy group in alkoxycarbene complexes to form aminocarbene complexes. Kinetic studies have revealed that this reaction obeys a fourth order rate law[2]. A nitrogen ylide complex was assumed as an intermediate of the aminolysis.

The reaction of secondary and tertiary alkylphosphanes with alkoxy-, thio-, and selenocarbene complexes of chromium and tungsten at low temperature to give phosphorus ylide complexes[3–5] suggested that suitable tertiary amines should be able to form isolable nitrogen ylide complexes under similar conditions. Unlike primary and secondary amines, these would be incapable of further aminolytic reaction with the alkoxy group after having undergone nucleophilic addition to the carbene carbon. The postulated ylide intermediates should thus be isolable.

The reaction of red phenylmethoxycarbenepentacarbonylchromium(0) *(1)* with 1,4-diazabicyclo[2.2.2]octane *(2)* in diethyl ether led to a yellow diamagnetic crystalline powder which was characterized as a 1:1 addition product of *(1)* and *(2)* of the empirical formula $CrC_{19}H_{20}N_2O_6$ *(3)* by total analysis.



(1) *(2)* *(3)*

In aqueous $KHSO_4$ solution, *(3)* releases *(2)*; however, *(1)* is not regenerated but instead phenylhydroxycarbenepentacarbonylchromium(0) is found[6]. This result indicates that the original metal-carbene carbon bond of *(1)* is retained in the 1:1 complex and underlines the enhanced reactivity of the *O*-methyl group in the ylide complex.

The structure of *(3)* was determined from its IR, ^{1}H-NMR, and ^{13}C-NMR spectra.

The IR spectrum of a CH_2Cl_2 solution of *(3)* contains two absorptions at 2032 w and 1894 vs cm^{-1} in the νCO region which indicate the presence of a $Cr(CO)_5$ group.

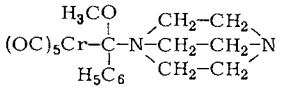
The ^{1}H-NMR spectrum of a [D_6]acetone solution of *(3)* exhibits four signals at $\tau = 2.62$ (m,5), 6.49 (m,6), 6.61 (m,6), and 6.74 (s,3). The first signal is ascribable to the phenyl protons, and the last one to the *O*-methyl protons. The signals at $\tau = 6.49$ and 6.61 form a characteristic AA'BB' spectrum, which is in full accord with addition of *(2)* to the carbene C atom of *(1)* *via* an N atom. The relative broadness of the lines precluded accurate determination of the coupling constants. The asymmetric C atom in *(3)* does not effect a visible signal splitting of the diastereotopic methylene protons which would lead to an ABCD system. The OCH_3 signal displays a considerable upfield shift compared to that of *(1)* (*trans*: $\tau = 4.88$, *cis*: $\tau = 5.78$). The resultant decrease of the electron deficiency at the coordinated carbene carbon atom on addition of *(2)* is also clear from a comparison of the ^{13}C-NMR spectra of *(1)* and *(3)* (Table 1).

Table 1. ^{13}C-NMR shifts (in ppm) of $Cr(CO)_5[C(OCH_3)C_6H_5]$ *(1)* in [D_6]benzene and $Cr(CO)_5C[(OCH_3)(C_6H_5)NC_6H_{12}N]$ *(3)* in [D_6]acetone; TMS as internal standard.

	CO_{cis}	CO_{trans}	Cr—C	C_6H_5	OCH_3	$N_2C_6H_{12}$
(1)	216.67	224.57	351.42	153.82 130.26 128.38 122.89	66.62	
(3)	223.75	228.50		155.80 128.06 124.39	51.78	54.39 45.63

In addition to the appearance of two new ^{13}C signals, corresponding to the added diamine, the 15-ppm upfield shift of the *O*-methyl carbon signal is particularly characteristic. No signal is observed for the former carbene carbon, presumably because of a prolonged relaxation time or interactions with the N atom.

In view of all the available data, compound *(3)* can be regarded as having the structure of a nitrogen ylide complex.



The reaction of *(1)* with trimethylamine under the same conditions as for *(2)* also leads to a yellow product that is under investigation at the present time.

Procedure:

$N(C_2H_4)_3N$ (0.56 g, 5 mmol) is added to a solution of $Cr(CO)_5[C(OCH_3)C_6H_5]$ (1 g, 3.2 mmol) in ether (20 ml) under nitrogen at room temperature. During 2 to 3 hours' stirring the solution becomes lighter and a yellow precipitate is formed. Addition of pentane (30 ml) completes the precipitation. The product is purified by dissolution in a little CH_2Cl_2 and reprecipitation with pentane. It is then taken up in a minimal volume of CH_2Cl_2 at room temperature and allowed to slowly recrystallize at −100 °C. Isolation at −60 °C on a cooled fritted glass funnel and subsequent drying (20 h) in a high vacuum at −30 °C affords a yellow powder, m.p. 101 °C; yield 0.88 g (65% based on *(1)*).

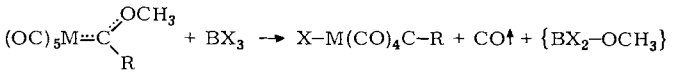
trans-Halogeno[alkyl(aryl)carbyne]tetracarbonyl Complexes of Chromium, Molybdenum, and Tungsten —A New Class of Compounds Having a Transition Metal-Carbon Triple Bond[1]

By *Ernst Otto Fischer, Gerhard Kreis, Cornelius G. Kreiter, Jörn Müller, Gottfried Huttner*, and *Hans Lorenz*[*]

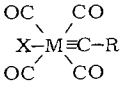
Methyl- or phenylmethoxycarbenepentacarbonyl complexes of chromium, molybdenum, and tungsten[2] react with boron trihalides (X=Cl, Br, I) in alkanes to give readily crystallizing, yellow to colorless thermolabile diamagnetic compounds of composition $XM(CO)_4CR$. It appears that the reaction involves simultaneous removal of the CH_3O group and a CO ligand and introduction of halogen into the complex according to:



$$(OC)_5M{=}C(OCH_3)R + BX_3 \rightarrow X{-}M(CO)_4C{-}R + CO\uparrow + \{BX_2{-}OCH_3\}$$

M = Cr, Mo, W; R = CH_3, C_6H_5; X = Cl, Br, I

The new complexes closely resemble one another in their mass spectroscopic behavior. The molecular ion $XM(CO)_4CR^+$ is invariably accompanied by a fragmentation pattern $XM(CO)_nCR^+$ with $n=3,2,1,0$. Only the phenyl derivatives with chromium as central metal atom give an intense peak at *m/e* 178 which we assign to tolan. This was the first indication that the new compounds might contain a *carbyne* ligand, *i.e.* a coordinated carbon atom bearing only an alkyl or aryl group. Dimerization of liberated phenylcarbyne ligands would explain the appearance of tolan in the mass spectrum. A second fragmentation series is observed for $Cl{-}W(CO)_4C{-}CH_3$ in which the molecule first loses the chlorine atom; not till then does successive loss of the four CO ligands take place. We consider the following arguments to substantiate



the proposed novel type of complex structure containing the sp hybridized C atom having two σ bonds to the organic alkyl or aryl group and to the metal at an angle of about 180°C and simultaneously participating in two additional $p_\pi-d_\pi$ bonds and thus maintaining the noble gas configuration at the metal atom manifested in the diamagnetism found experimentally for the complexes.

1. Total analyses established the composition $XM(CO)_4CR$ (X=Cl, Br, I; M=Cr, Mo, W; R=CH_3, C_6H_5).

2. All the mass spectra and two cryoscopic molecular weight determinations afforded relative molecular masses corresponding to monomeric structures.

3. The dipole moments (benzene, 20°C) lie between 4 and 6 D.

4. The IR spectra of the novel carbyne complexes all exhibit a very intense band (E) in the νCO region at about 2037–2051 cm^{-1} accompanied by a further weak to medium band (A_1) at about 2120 cm^{-1}. The number of bands and their intensity ratios provide unequivocal evidence for a *trans*-disubstituted tetracarbonyl complex $M(CO)_4L^1L^2$ with $L^1 \neq L^2$. The higher wave number shift of the maximum intensity band (E) relative to a comparable *trans*-substituted carbene complex such as $(C_6H_5)_3PCr(CO)_4[C(CH_3)(OCH_3)]$[3] amounts to about 150 cm^{-1}. The strong withdrawal of electrons from the metal atom by the carbyne ligand is compensated by the considerable charge transfer from the CO ligands to the metal, leading to an increase in the CO bond order and a marked short wave shift of the νCO frequencies. The νCO absorption of some carbyne complexes are listed in Table 1.

Table 1. IR spectra in the ν_{CO} region (*n*-hexane, cm^{-1}).

	A_1	E
$Br{-}W(CO)_4C{-}CH_3$	2125 s	2038 vs
$I{-}W(CO)_4C{-}C_6H_5$	2119 m	2037 vs
$Br{-}Cr(CO)_4C{-}C_6H_5$	2113 m	2051 vs
$I{-}Cr(CO)_4C{-}C_6H_5$	2106 m	2046 vs

5. The tungsten halogen frequencies in the far IR could be assigned for the somewhat more stable complexes $Br{-}W(CO)_4C{-}C_6H_5$, $I{-}W(CO)_4C{-}C_6H_5$, and $I{-}W(CO)_4C{-}CH_3$ (Table 2).

Table 2. FIR spectra in the ν MX region (cm^{-1}).

$Br{-}W(CO)_4C{-}C_6H_5$	ν_{W-Br}	180
$I{-}W(CO)_4C{-}C_6H_5$	ν_{W-I}	144
$I{-}W(CO)_4C{-}CH_3$	ν_{W-I}	144

6. ^{13}C-NMR studies also confirm our structural concept (Table 3). The almost constant position of the carbyne carbon resonance when the halogen is changed rules out bonding of the latter to the original carbene carbon, which has now become a carbyne carbon, and indicates direct metal-halogen coordination.

Table 3. ^{13}C-NMR shifts (CD_2Cl_2, ppm relative to TMS, internal).

	$C_{Carbyne}$	C_{CH_3}	C_{CO}
$Cl{-}W(CO)_4C{-}CH_3$	288.8	38.8	194.0
$Br{-}W(CO)_4C{-}CH_3$	288.1	38.6	192.7
$I{-}W(CO)_4C{-}CH_3$	286.3	38.0	191.7

In contrast, the following ^{13}C-NMR shifts are found for the $H_2C{=}CH{-}X$ system: X=Cl 126.0; X=Br 115.5; X=I 85.3 ppm[4].

The position of the ^{13}C resonance of the carbyne carbon at somewhat higher field strengths compared to that of the carbene carbon in the starting material is remarkable. The corresponding signals differ by about 45 ppm in the tungsten complexes and by about 20 ppm in the chromium complexes. The lower shielding in the chromium complexes compared with the tungsten complexes, suggests a drop in electronic stabilization; this probably accounts for their enhanced thermolability. Measurement of the carbon-carbon coupling constant in the complex $BrCr(CO)_4C{-}C_6H_5$ should reveal the carbyne carbon to be directly bonded to phenyl.

The carbon resonances of the CO ligands coincide in a single peak in all the compounds studied so far. Thus all the

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. G. Kreis, Priv.-Doz. Dr. C. G. Kreiter, Doz. Dr. J. Müller, Doz. Dr. G. Huttner, and Dipl.-Chem. H. Lorenz
Anorganisch-chemisches Laboratorium der Technischen Universität 8 München 2, Arcisstrasse 21 (Germany)

CO ligands are equivalent and the *trans* arrangement of the halogen and carbyne ligands already suggested by the IR spectrum is confirmed.

7. The ^{1}H-NMR spectra of the carbyne complexes measured in CD_2Cl_2 contain the expected signals. Some of them show considerable upfield shifts compared to the resonances of the corresponding carbene complexes[2] again evidencing the relatively high spin density at the carbyne carbon which is stabilized largely at the expense of the $M(CO)_4X$ group but hardly at all at the expense of the alkyl or aryl group. As particular feature of the $XW(CO)_4C{-}CH_3$ complexes, the methyl singlets are accompanied by satellites, which can be explained by coupling of the methyl protons with the tungsten isotope ^{183}W having a nuclear spin of 1/2.

Table 4. ^{1}H-NMR spectra, measured in CD_2Cl_2.

	$\tau_{C_6H_5}$	T[°C]		τ_{CH_3}	T[°C]
$Cl{-}W(CO)_4C{-}C_6H_5$	2.54 (s)	−15	$Cl{-}W(CO)_4C{-}CH_3$	7.77 (s)	−15
$Br{-}W(CO)_4C{-}C_6H_5$	2.45 (s)	−15	$Br{-}W(CO)_4C{-}CH_3$	7.88 (s)	−15
$I{-}W(CO)_4C{-}C_6H_5$	2.47 (m)	−15	$I{-}W(CO)_4C{-}CH_3$	8.12 (s)	−15
$Br{-}Mo(CO)_4C{-}C_6H_5$	2.43 (m)	−30	$Br{-}Cr(CO)_4C{-}CH_3$	7.42 (s)	−20
$Br{-}Cr(CO)_4C{-}C_6H_5$	2.45 (m)	−30	$I{-}Cr(CO)_4C{-}CH_3$	7.56 (s)	−15
$I{-}Cr(CO)_4C{-}C_6H_5$	2.28 (m)	−15			

8. The X-Ray structure analysis of $[(C_6H_5C)W(CO)_4I]$ backs up the other findings. (Space group Pbca; $a = 2010.3$, $b = 1211.8$, $c = 1126.4$ pm; $Z = 8$; $d_{exp.} = 2.46$, $d_{calc.} = 2.48$ g cm^{-3}; R factor presently: $R_1 = 0.11$ for 704 independent non-zero reflections.) The pseudooctahedral structure is reproduced in Figure 1.

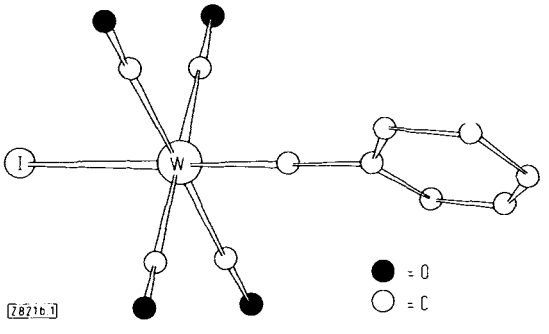


Fig. 1. Schematic representation of the molecular structure of $[(C_6H_5C)W(CO)_4I]$.

The distance of the carbyne carbon from tungsten of 188 ± 10 pm is shorter than the $W{-}C_{CO}$ distances (214 ± 10 pm), which in turn are somewhat larger than the corresponding distances in $W(CO)_6$ (205.8 ± 0.3 pm)[5]. The maximum deviation of the individual metal-ligand groups from the ideal linear arrangement is 20°. The d_{W-I} distance amounts to 284 ± 2 pm.

Procedure:

All operations should be carried out under nitrogen and with dried (Na, P_4O_{10}) and N_2-saturated solvents. A solution of methoxycarbene complex (2–3 g) in pentane (50 ml) is treated portion by portion with the boron trihalide (BBr_3 at *ca.* −15 °C, BCl_3 and BI_3 at *ca.* +10 °C). Rapidly ensuing decomposition necessitates further treatment of the reaction mixture at −20° to −40 °C.

The crude product obtained by drying in a high vacuum is purified by chromatography with pentane/methylene chloride on silica gel. If the reaction does not go to completion (possibly with BI_3), the starting complexes are eluted first whereas the new complexes migrate only slowly. After removal of the uppermost layer of silica gel elution is conducted at −30 °C and the eluate concentrated to about 1.5 ml at −20 °C *in vacuo*. Addition of pentane (10–15 ml) and cooling to −100 °C precipitates a finely crystalline deposit of the carbyne complexes. They are washed with pentane (*ca.* 4 ml, −100 °C) and dried (high vacuum, −20 °C, 1–2 d). The yields vary between 20 and 70%.

Tris(ethylene)nickel(0)

By *Karl Fischer, Klaus Jonas*, and *Günther Wilke*[*]

In 1872, *Zeise* discovered the first transition metal compound containing complexed ethylene $KPtCl_3 \cdot C_2H_4 \cdot H_2O$[1]. Most of the transition metal-olefin complexes to have been prepared since contain stabilizing ligands, *e. g.* phosphanes, in addition to the olefin. Binary complexes are known only with special kinds of olefins, such as cyclic polyolefins or those having a strained double bond. The first complexes of this type to be described were all-*trans*-1,5,9-cyclododecatrienenickel(0)[2] *(1)*, bis(1,5-cyclooctadiene)nickel(0)[2], and tris(bicycloheptene)nickel(0)[3].

We now wish to report the first binary metal-ethylene complex, tris(ethylene)nickel(0) *(2)*, which, like tetracarbonylnickel in the series of carbonyl-nickel complexes, can be regarded as the parent of all olefin-nickel(0) complexes.

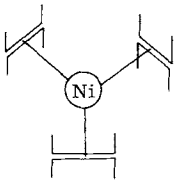
Reaction of a deep red solution of *(1)* in diethyl ether with ethylene at 0 °C leads to a pale yellow solution whose ^{1}H-NMR spectrum shows that the cyclododecatriene (CDT) has been largely displaced from the nickel by ethy-

[*] Dipl.-Chem. K. Fischer, Dr. K. Jonas, and Prof. Dr. G. Wilke
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

lene and that three ethylene molecules have become bonded to the nickel.

$$\underset{(1)}{\text{ttt-CDT—Ni(0)}} + 3C_2H_4 \rightarrow \underset{(2)}{(C_2H_4)_3Ni(0)} + \text{ttt-CDT}$$

On cooling of the solution to −78 °C, compound *(2)* crystallizes in the form of long colorless needles. The ^{1}H-NMR spectrum of the isolated complex *(2)* in deuteriotoluene at −30 °C exhibits a singlet for the ethylene protons at $\tau = 6.89$. If the solution contains additional free ethylene the signal experiences a downfield shift with simultaneous line broadening, which we attribute to exchange between free and complexed ethylene. The IR spectrum of *(2)* contains characteristic bands at 3065, 1511, and 1242 cm^{-1}. We assume that the three ligands adopt an approximately trigonal-planar arrangement around the central atom in tris(ethylene)nickel(0).



A similar arrangement of coordinated bonds is also assumed for all-*cis*-1,5,9-cyclododecatrienenickel(0)[4], and has been established by X-ray structure analysis[5] for tris(bicycloheptene)nickel(0).

The ethylene in *(2)* can again be displaced stepwise from the nickel. Equimolar amounts of $(C_6H_{11})_3P$ or $(C_6H_5)_3P$ yield the known complexes $(C_6H_{11})_3PNi(C_2H_4)_2$ and $(C_6H_5)_3PNi(C_2H_4)_2$[6] respectively. An excess of $(C_6H_5)_3P$ or $(C_6H_5O)_3P$ affords the corresponding $L_4Ni(0)$ complexes.

The new binary ethylene complex *(2)* reacts quantitatively with tri-*n*-butylaluminum at 0 °C yielding triethylaluminum and butene:

$$\underset{(2)}{Ni(C_2H_4)_3} + Al(C_4H_9)_3 \rightarrow Al(C_2H_5)_3 + 3C_4H_8 + Ni$$

The reaction occurs catalytically with an excess of ethylene and tri-*n*-butylaluminum. Apparently this reaction is the key step of the "nickel effect" discovered by *Ziegler* and *Holzkamp*[7].

Procedure:

The deep red solution of all-*trans*-CDT—Ni(0) *(1)* in ether (*ca.* 5 mmol/10 ml) is saturated with ethylene at −30 °C and then stirred at 0 °C for *ca.* 1 h until decolorized. On cooling to −78 °C *(2)* crystallizes but is usually contaminated with CDT and a little *(1)*. The crystalline mixture is dissolved in a small volume of cold ether and allowed to react further under ethylene at 0 °C for ½ h. On recooling to −78 °C, *(2)* precipitates as long colorless needles. The product is washed twice with liquid ethylene at −130 °C. Evaporation of the residual ethylene at −78 °C leaves analytically pure *(2)* in *ca.* 20% yield. The complex is stable up to 0 °C.

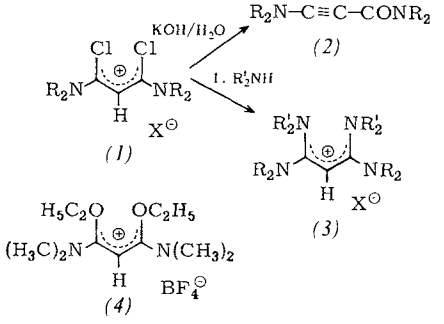
Allenetetramine and Dialkoxydiaminoallene

By *Heinz Günter Viehe* and *Zdenek Janousek*, together with *Rudolf Gompper* and *Dietrich Lach*[*]

The salts of 1,3-diamino-1,3-dichloroallyl cations such as *(1)* have become readily available by reaction of *N,N*-disubstituted acetamides and *N*-dichloromethylene-*N,N*-dialkylammonium chloride (phosgeneimmonium chloride)[1]. The action of alkalis on *(1)* affords ynamines, *e.g. (2)*, in 70% yield[2].



Treatment of *(1)* with secondary amines yields hydrolysis-resistant salts of 1,1,3,3-tetrakis(dialkylamino)allyl cations that can be isolated as perchlorates or chlorides, *e.g. (3a)*, $R = R' = CH_3$, $X = ClO_4$; *(3b)*, $R = R' = C_2H_5$, $X = Cl$.

Of comparable stability to the salts *(3a)* and *(3b)* is the salt *(4)*[3] obtained in crystalline form by alkylation of *N,N*-dimethyl-β-ethoxy-β-dimethylaminoacrylamide[4] with triethyloxonium tetrafluoroborate.

The cations of *(3)* and *(4)* may be regarded as protonation products of allenetetramine *(5)* and dialkoxydiaminoallene *(6)* respectively, which appear particularly interesting as electron-rich allenes whose reactivity should even exceed that of tetramercaptoallene[3,5] and tetramethoxyallene[6] (cf. [3,7,8]).

(3) and *(4)* can be converted into the allenes *(5)* and *(6)* either with *n*-butyllithium or, in the case of salts that are only soluble in polar solvents, with an excess of sodium amide in anhydrous liquid ammonia.

(5) and *(6)* are distillable, water-clear liquids that can be stored for days without decomposition in the absence of air and moisture. They react spontaneously with air, generating fumes. The hydrolysis of *(5b)*, leading to the amide *(7)*, and the reaction of *(6)*, affording the salt *(8)*, provide proof of the structures shown, as do the available spectral data.

(5a) undergoes an exothermic reaction with phenyl cyanate to give a salt that can be isolated as the perchlorate

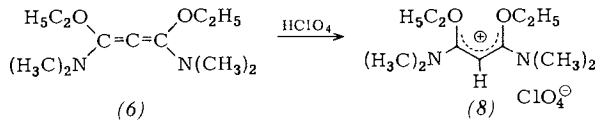
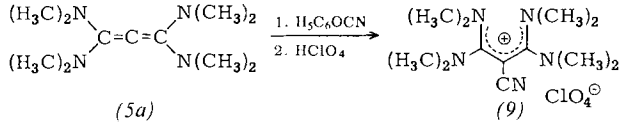
(5b) (7)



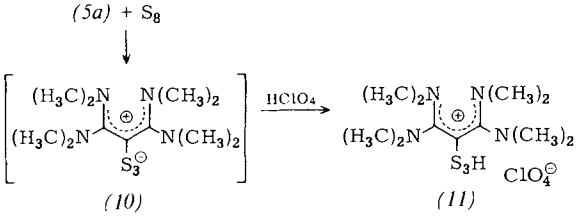
(6) (8)

(9). The low wave number of the split nitrile band at 2190 cm^{-1} is a striking feature of the IR spectrum of (9).



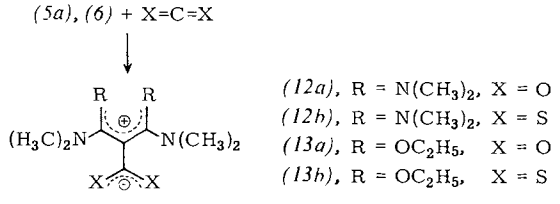
(5a) (9)

Reaction of (5a) with a suspension of sulfur in methylene chloride/ether occurs within an hour to give (10) which was isolated as (11) after protonation with perchloric acid.



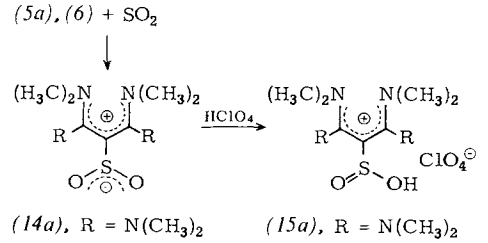
(10) (11)

Compounds (5a) and (6) react extremely readily and in good yields with carbon dioxide to give the dipolar adducts (12a) and (13a) respectively. Carbon disulfide affords (12b) and (13b). The four dipoles are stable for days in an inert gas atmosphere.



(12a), R = $N(CH_3)_2$, X = O
(12b), R = $N(CH_3)_2$, X = S
(13a), R = OC_2H_5, X = O
(13b), R = OC_2H_5, X = S

Reaction of (5a) and (6) with sulfur dioxide yields the products (14a) and (14b), respectively, which are only moderately stable or unstable at room temperature; they can be converted into the sulfinic acids (15a) and (15b) respectively on treatment with perchloric acid.



(14a), R = $N(CH_3)_2$ (15a), R = $N(CH_3)_2$
(14b), R = OC_2H_5 (15b), R = OC_2H_5

The above experiments show that the allenetetramines and the dialkoxydiaminoallenes are comparable in their reactivity with the ynamines[9] and the ethylenetetramines[10]

Tetrakis(diethylamino)allene (5b)

Butyllithium (6 ml, 1.7 M solution in light petroleum) was added dropwise to a stirred solution of 3,3-bis(diethylamino)-*N,N,N',N'*-tetraethylacrylamidinium chloride (3b)[11] (1.83 g, 5.65 mmol) in dry tetrahydrofuran (10 ml). The temperature of the mixture increased to the boiling point. After the addition was complete (*ca.* 5 min) the solvent was evaporated off without prior removal of precipitated LiCl. The residue was vacuum distilled (0.05 torr) as rapidly as possible. The procedure afforded 1.16 g (70%) of (5b) as a colorless oil having a strong characteristic odor; b.p. 110—120 °C/0.05 torr.

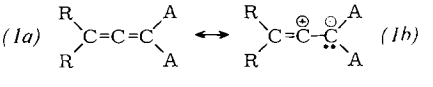
Cycloadditions of Electron-Deficient Allenes[**]

By *Rudolf Gompper* and *Dietrich Lach*[*]

Cycloadditions to electron-rich allenes are two-step reactions involving dipolar intermediates[1]; in a number of cases the reaction stops at the primary dipolar adducts[1,2]. Electron-deficient allenes (1) [A = electron-withdrawing group (−M effect)], for which a similar behavior is expected, exhibit a polarity related to that of ketenes[3], whose cycloadditions to olefins[4] can be described as concerted reactions[3,5] or as two-step reactions proceeding *via* dipolar intermediates[6,7]. By studying the cycloadditions of electron-deficient allenes to electron-rich multiple-bond systems, we hoped to obtain *inter alia* further insight into the mechanistic details of the cycloadditions of heterocumulenes.



(1a) (1b)

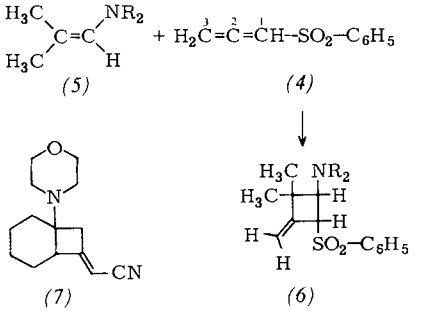
[*] Prof. Dr. R. Gompper and Dr. D. Lach
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] Support of this work by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Whereas 1,1-bis(alkoxycarbonyl)allenes *(3)*[9], which are accessible from bis(alkoxycarbonyl)methylenetriphenylphosphoranes *(2)*[8] and diphenylketenes, display a disappointingly low reactivity, 1-benzenesulfonylallene *(4)*[10] reacts with aminoisobutenes *(5)* to give methylenecyclobutanes *(6)* [structural proof from NMR spectra; *(6a)*: R_2N—C—H $\tau = 7.31$ (1 H, d), SO_2—C—H $\tau = 5.63$ (1 H, m), $=CH_2$ $\tau = 4.90$ (2 H, m)].

$$(C_6H_5)_3P{=}C(CO_2R)_2 + (C_6H_5)_2C{=}C{=}O \rightarrow$$
(2)
$$(C_6H_5)_2C{=}C{=}C(CO_2R)_2 + (C_6H_5)_3PO$$
(3)
$R = CH_3, C_2H_5$

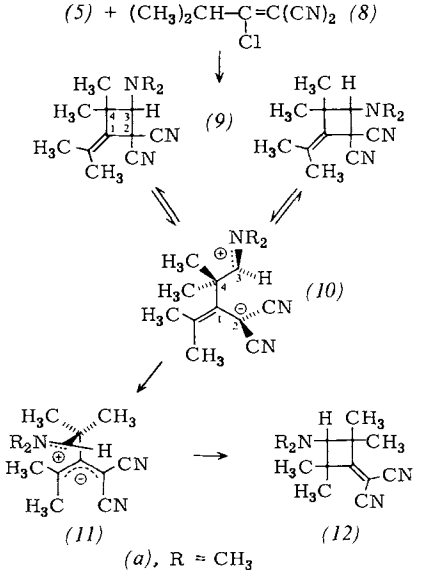
The cyclobutanes *(6)* are formed by cycloaddition to the C^1C^2 double bond of *(4)*. In contrast, the cyclobutane *(7)* arises by cycloaddition of morpholinocyclohexene[11] to the C^2C^3 bond of 1-cyanoallene[12].



(5) *(4)* *(7)* *(6)*

(a), R = CH_3
(b), R+R = $(CH_2)_4$

Attempted elimination of hydrogen chloride from 1-chloroisobutylidenemalodinitrile *(8)* with tertiary amines afforded only polymeric products. However, if *(8)* is treated with 2 equivalents of *(5)* then the isopropylidenecyclobutanes *(9)* can be isolated. In acetone, acetonitrile, and at elevated temperatures also in chloroform, but not in benzene, carbon tetrachloride, and cyclohexane, the compounds *(9)* give just one NMR signal for the two methyl groups at C^4.



(11) *(12)*

(a), R = CH_3
(b), R+R = $(CH_2)_4$

This phenomenon can be explained in terms of rapid equilibration between *(9)* and the zwitterion *(10)* (rapid rotation around the C^3C^4 bond). The coalescence temperature in $CDCl_3$ is 76 ± 1 °C for *(9a)* and 37 ± 1 °C for *(9b)*.

If a solution of *(9)* is allowed to stand, the appearance of the new cyclobutane *(12)* can soon be detected in the NMR spectrum. Conversion into *(12)* is complete after several hours' heating. The rearrangement of *(9)* into *(12)* most probably also proceeds *via* the dipole *(10)* (rotation around the C^1C^4 bond); the intermediacy of *(11)* also seems likely. The reaction is of first order; the activation energy determined between 55 and 75 °C amounts to $E_A = 11.1 \pm 1.0$ kcal/mol for *(9b)*.

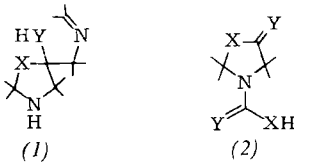
1,3-Anionic Cycloadditions of *trans,trans*-1,3-Diphenyl-2-azaallyllithium to Heterocumulenes[1][**]

By *Thomas Kauffmann* and *Rudolf Eidenschink*[*]

The accessibility of *trans,trans*-1,3-diphenyl-2-azaallyllithium *(5)* in amine- and lithium-amide-free solution by thermal ring cleavage of *N*-lithio-2,3-diphenylaziridine[3] has now made feasible studies on the behavior of *(5)* toward compounds undergoing ready irreversible addition of amines and lithium amides. We have reacted *(5)* with the heterocumulenes shown in the reaction scheme below. Since *(5)* adds normally to CO double bonds but undergoes cycloaddition to CN double bonds, and owing to the predictably high nucleophilicity of the anionic cycloadducts, we expected to obtain open-chain, cyclic, and bicyclic adducts, as well as the mixed types *(1)* and *(2)*.



(1) *(2)*

[*] Prof. Dr. Th. Kauffmann and Dipl.-Chem. R. Eidenschink
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

All expected structures except *(1)* were formed on adding an equimolar amount of the heterocumulene, as a THF solution either dropwise or in the solid state (CO_2) at −40 °C within 2 min, to an amine- and lithium-amide-free solution of *(5)* in THF/*n*-hexane (*ca.* 9:1) under nitrogen and allowing the components to react (see Table 1) in

Table 1. Products prepared.

	Product	Reaction temp. [°C]	time [a] [min]	Yield [%]	M.p. [°C]
(3)	2-(*N*-benzylideneamino)-phenylacetic acid	−60	60	*ca.* 50	— [5]
(4)	2,4,7,9-tetraphenyl-1,6-dithia-3,8-diaza-spiro[4.4]nonane	−40	3 (!)	31	154—155

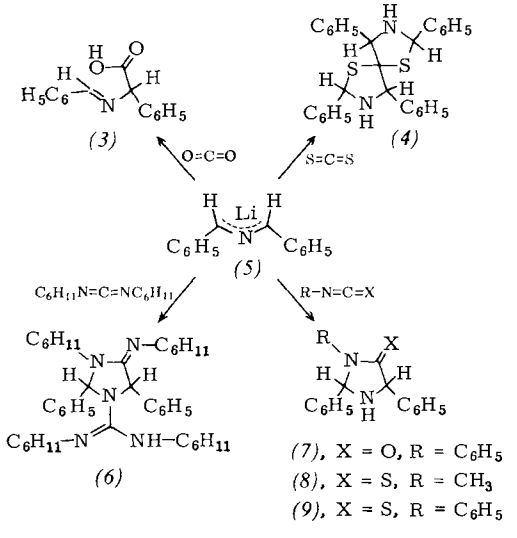
(8)	3-methyl-2,5-diphenyl-imidazolidine-4-thione	−40	30	46	[c]
(9)	2,3,5-triphenyl-imidazolidine-4-thione	−40	30	59	124

[a] The time required for the dropwise addition is not included.
[b] No reaction at −40 °C.
[c] B.p. 90 −95 °C/0.1 torr; m.p. (picrolonate) 171 °C.

the stirred mixture. After addition of water (at the temperature given) the products *(4)* and *(6)*—*(9)*, which have apparently not yet been described elsewhere, could be isolated, while the compound *(3)*, which has hitherto defied attempted isolation could be detected by degradation to α-aminophenylacetic acid. The compositions of the isolated compounds follow from elemental analysis and spectra (MS, NMR, IR). The configuration of the substituents at the chiral centers of *(4)* and *(6)*—*(9)* has not yet been established.



The reaction *(5)*→*(4)* represents the first example of 1,3-anionic cycloaddition to a CS double bond. Attempts to prepare the monocycloadduct of carbon disulfide were unsuccessful. Apparently the first step is slower than the second, as in the 1,3-dipolar cycloaddition of diphenylnitrile imine to carbon disulfide[6].

The cycloaddition to the asymmetric heterocumulenes proceeds predominantly or exclusively at the CN double bond, for no other products were detectable apart from the imidazolidine derivatives *(7)*—*(9)*[7].—Since only one diastereomeric form could be isolated in each case, in spite of careful column chromatographic work-up of the products, all the cycloadditions described are probably stereospecific.

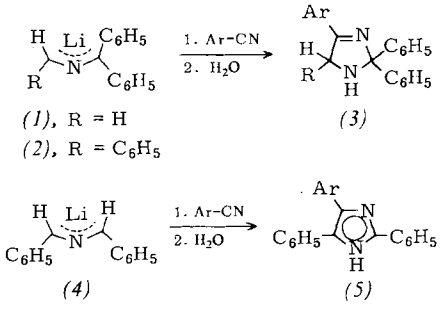
[7] A corresponding regiospecificity has also been observed in 1,3-dipolar cycloadditions to isocyanates and isothiocyanates. The 1,3-dipole diphenylnitrile imine, on the other hand, undergoes cycloaddition to equal extents to the CN and CS double bonds of phenyl thiocyanate: cf. *R. Huisgen*, Angew. Chem. *75*, 604 (1963); Angew. Chem. internat. Edit. *2*, 565 (1963).

1,3-Anionic Cycloaddition of 2-Azaallyllithium Compounds to Nitriles[1][**]

By *Thomas Kauffmann, Alfred Busch, Kai Habersaat*, and *Edgar Köppelmann*[*]

We have found that 2-azaallyllithium compounds undergo cycloaddition to aromatic nitriles to give either 3-imidazolines *(3)* or, as a result of a secondary reaction that is presumably initiated by elimination of lithium hydride[3], imidazoles *(5)*. "Enolizable" nitriles such as propio- or butyronitrile were found to be unsuitable as 1,3-anionophiles (0 or 1% cycloadduct formation respectively). Such nitriles are probably deactivated by α-lithiation with concomitant consumption of the azaallyllithium compound.



In two cases aromatic nitriles gave rise to open chain products. These 4-amino-2-azabutadienes, whose enamine structure *(6)* has been established by spectroscopy, are labile yellowish red substances which polymerize within a few days on exposure to air. As far as we know, enamines

[*] Prof. Dr. Th. Kauffmann, Dipl.-Chem. A. Busch, Dipl.-Chem. K. Habersaat, and Dr. E. Köppelmann

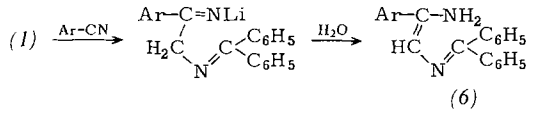
44 Münster, Orléans-Ring 23 (Germany)

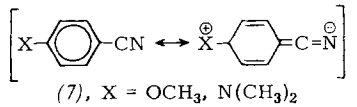
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of this kind—unsubstituted amino group and CC double bond conjugated with a CN double bond—are new[4].

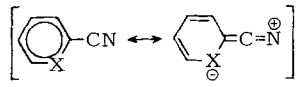


(6)

Since 1,1-diphenyl-2-azaallyllithium (1) undergoes cycloaddition to nitriles containing a group displaying a +M effect, whereas only normal addition takes place with the nitriles (8), the cycloaddition would appear to require a relatively high electron density at the nitrile nitrogen.



(7), X = OCH_3, $N(CH_3)_2$



(8), X = N, CH

The 2-azaallyllithium compounds (1), (2), and (4) were prepared from azomethines and lithium diisopropylamide in solution (THF/*n*-hexane, *ca.* 5:1)[5]. To these stirred solutions were added equimolar amounts of the nitriles in THF at −60 °C. Further details regarding execution of the reaction may be seen in Table 1. The composition

Table 1. Products prepared.

	Reactants	Product	Yield [%]	M.p. [°C]
(1) +	*m*-tolunitrile [a]	(3a) 2,2-diphenyl-4-(3-tolyl)-3-imidazoline	31	307—308
(1) +	*p*-methoxybenzonitrile [a]	(3b) 2,2-diphenyl-4-(4-methoxyphenyl)-3-imidazoline	47	124
(1) +	*p*-dimethylaminobenzonitrile [b]	(3c) 2,2-diphenyl-4-(4-dimethylaminophenyl)-3-imidazoline	42	152—153
(2) +	benzonitrile [a]	(3d) 2,2,4,5-tetraphenyl-3-imidazoline	10	203—204
(4) +	benzonitrile [b]	(5a) 2,4,5-triphenylimidazole	52	273
(4) +	*m*-tolunitrile [a]	(5b) 2,4(5)-diphenyl-5(4)-(3-tolyl)imidazole	50	278—279
(4) +	*p*-tolunitrile [a]	(5c) 2,4(5)-diphenyl-5(4)-(4-tolyl)imidazole	52	229—230
(4) +	nicotinonitrile [a]	(5d) 2,4(5)-diphenyl-5(4)-(3-pyridyl)imidazole	47	215—216

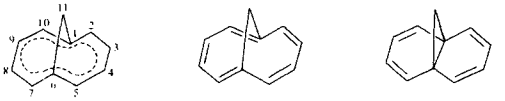
An Aromatic-Olefin Equilibrium: 1,6-Methano-[10]annulene-Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-Tetraene Valence Tautomerism[**]

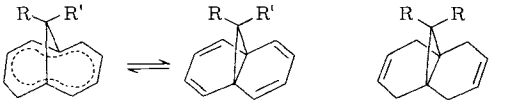
By *Harald Günther*, *Hans Schmickler*, *Wolfgang Bremser*, *Franz A. Straube*, and *Emanuel Vogel*[*]

Numerous physical studies concur in indicating 1,6-methano[10]annulene (1) to possess a delocalized π-electron decet[1,2]. Alternative olefinic structures such as (2) or (3) can however become important in derivatives of (1). Thus our knowledge of the norcaradiene-cycloheptatriene system[3] suggests that (3), as "double norcaradiene", is an attractive valence tautomeric structure for 1,6-methano[10]annulenes bearing suitable substituents at C-11.



(1) (2) (3)

Such systems may also be expected to undergo rapid reversible valence tautomerization of type (4)⇌(5)[4].



(4) (5)

(4a) ⇌ (5a), R = R' = CH_3 (6), R = H
(4b) ⇌ (5b), R = CH_3, R' = CN (7), R = CH_3
(4c) ⇌ (5c), R = $CH_2C_6H_5$, R' = CN

Evidence favoring the last alternative has been provided in particular by the behavior of 11,11-disubstituted 1,6-methano[10]annulenes[5] and the spectroscopic data of the dimethyl compound (4a)[4]: in the ^{1}H-NMR spectrum of (4a) the peripheral protons (δ = 6.22, 6.11) are shielded by *ca.* 1 ppm compared to those of (1)[2c], and the ^3J values [J(2,3) = 9.78, J(3,4) = 6.85 Hz] resemble the corresponding constants in the 1,3-cyclohexadiene system[6].

[**] Applications of ^{13}C-Resonance Spectroscopy, Part 6.—Part 5: ref. [11]. Generous support of this work by the Deutsche Forschungsgemeinschaft and the Fonds der chemischen Industrie is gratefully acknowledged.

In the UV spectrum[4] the extinction of the long-wave band at 350–400 nm[2a,f] characteristic of *(1)* has decreased significantly [*(1)*: ε(385)=135[2a]; *(4a)*: ε(385)=39, both in cyclohexane][7].

We have now been able to establish the existence of fluxional systems of type *(4)*⇄*(5)* by variable-temperature ^{13}C-NMR measurements (Table 1, Fig. 1)[8]. Mere consideration of the high position of the C-1,6 resonance of *(4a)* at 35 °C [δ=81.7 ppm; Δσ=+32.9 ppm compared to *(1)*[9]] suggests time averaging[10]. C-11 in *(4a)* (δ=16.9 ppm) is considerably more shielded than in *(1)* (Δσ=+17.9 ppm), although the methyl groups should have a deshielding effect as indicated in particular by the data pertinent to the systems *(6)* and *(7)*. Lowering the temperature leads to a downfield shift both for the absorption of C-1,6 and for that of C-11. This confirms that the aromatic structure *(4a)* is the more stable one. Predictably, the resonances of the other C atoms that are sp^2 hybridized in both isomers are affected only slightly.

C-1,6 and C-11 are subject to even more pronounced shielding in 11-cyano-11-methyl-1,6-methano[10]annulene *(4b)*⇄*(5b)*[12], in which the resonance of C-1,6 is found beyond the region typical for sp^2 hybridized C atoms. This observation accords with the expected substituent effect of the cyano group, as π-acceptor and stabilizer of three-membered rings[3], on the valence tautomerism. It is interesting that the temperature effect is opposed to that for the system *(4a)*⇄*(5a)*. Accordingly, the tetraene *(5b)* is more stable than the [10]annulene *(4b)*. The highest C-1,6 resonance to be observed so far was found for 11-benzyl-11-cyano-1,6-methano[10]annulene *(4c)*⇄*(5c)*[13].

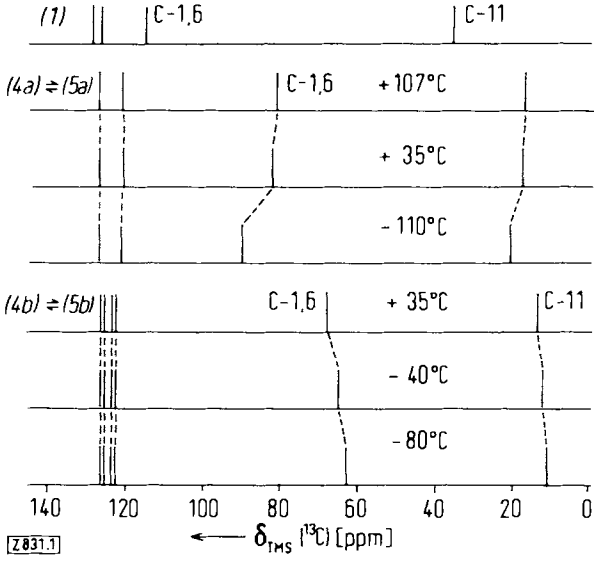

Fig. 1. Schematic representation of the ^{13}C-NMR spectra of *(1)* and the fluxional systems *(4a)*⇄*(5a)* and *(4b)*⇄*(5b)*; tetramethylsilane as internal standard.

The ^{13}C-NMR frequencies of the parent system *(1)* change only insignificantly with temperature. However, as for the norcaradiene-cycloheptatriene system, the findings for the substituted compounds indicate that a certain equilibrium concentration of the valence-tautomeric "norcaradiene", *i.e.* tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene *(5)*, where R=R′=H, will be present, even though its contribution may be minimal[14].

It has not yet been possible to slow down the rate of the valence tautomerization *(4)*⇄*(5)* sufficiently to permit observation of the individual ^{13}C-NMR spectra of the two isomers. It may therefore be assumed that the energy barrier of the rearrangement is extremely low[16]. This appears understandable in view of the relatively small distance between C-1 and C-6 in *(1)* (2.26 Å) which favors formation of the cyclopropane bond[17].

[a] All spectra were recorded using the Fourier transform technique with broad band ^{1}H decoupling; measuring frequency 22.6 MHz, Bruker HX-90 spectrometer.

[b] Cf. also ref.[9]; the assignments of all ^{13}C resonances have meanwhile been confirmed experimentally by the observation of typical fingerprints in the non-decoupled spectrum according to ref.[11].

[6] *H. Günther* and *H.-H. Hinrichs*, Liebigs Ann. Chem. *706*, 1 (1967).

[7] There is still some uncertainty as to the correct interpretation of the C-1—C-6 distance in solid *(4a)* (1.80 Å) found by X-ray structural analysis (*R. Bianchi, A. Mugnoli*, and *M. Simonetta*, Chem. Commun. *1972*, 1073).

[8] ^{13}C-NMR spectroscopy [10] proves superior to ^{1}H-NMR spectroscopy in this case because the C-1,6 and C-11 resonances are more sensitive probes for the valence tautomerism *(4)*⇌*(5)*. The changes in the resonance frequencies due to chemical exchange amount to *ca.* 2000 Hz (C-1,6) but less than 100 Hz in ^{1}H-NMR spectroscopy (peripheral protons). Moreover, the ^{13}C-NMR spectra are not complicated by spin-spin coupling. Previous ^{1}H-NMR spectra accordingly did not lead to clear-cut results.

[14] In 11,11-dimethylene-1,6-methano[10]annulene [13] C-1 and C-6 are deshielded in comparison with *(1)* (δ = 123.2 ppm). Here the introduction of the three-membered ring could effect opening of the angle C-1—C-11—C-6 and thereby increase the distance between C-1 and C-6. It has not yet been established whether the deshielding is the result of an equilibrium shift or a manifestation [15] of the separation-dependent overlapping of the $2p_z$ orbitals on C-1 and C-6 in the aromatic system which has been detected experimentally[2a,e,f]. A "normal" substituent effect (replacement of the H atoms at C-11 by —CH_2—CH_2—) could also be responsible for the deshielding, although the findings for *(6)* and *(7)* make this possibility appear rather unlikely.

[15] Cf. *A. V. Kemp-Jones, A. J. Jones, M. Sakai, C. P. Beeman*, and *S. Masamune*, Can. J. Chem. *51*, 767 (1973).

[16] In one case we found a barrier ΔG^{*} of 8—9 kcal/mol for the comparable norcaradiene-cycloheptatriene system[3a]. Here the splitting of the ^{13}C resonances was observed already at *ca.* −90 °C. (*H. Günther, W. Peters*, and *R. Wehner*, unpublished). Since no line broadening could be detected for *(4a)*⇌*(5a)*, even at −110 °C, the known relationship between coalescence temperature and free energy of activation affords $\Delta G^{*} < 6.6$ kcal/mol for a δν value of 2000 Hz[8,10] for this system.

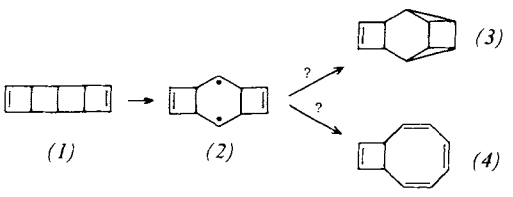
[17] Since this is to our knowledge the first case of valence tautomerism between an aromatic compound and an olefin the energetics of the system *(4)*⇌*(5)* are of particular interest. A ΔH° value of the order of 0.2 kcal/mol in favor of *(4a)* can be estimated from the ^{13}C data of *(4a)*⇌*(5a)*. The question whether the dynamic process can also be ascribed to a valence tautomerism of the type *(2)*⇌*(3)* cannot be answered by ^{13}C-NMR spectroscopy. However, this possibility can be ruled out on the basis of the UV spectra, which exhibit bands characteristic of the delocalized 10π system[2a,f] in all case . (We are grateful to Dr. *W. A. Böll* for a discussion on this point.)

Thermolysis of the Tetracyclo[4.4.0.0^{2,5}.0^{7,10}]-deca-3,8-diene System. π-Homoconjugation or σ-Hyperconjugation?[**]

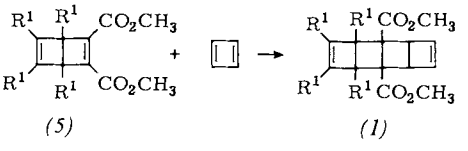
By *Hans-Dieter Martin* and *Mirko Hekman*[*]

In the present communication we report the differing thermolytic behavior of two representatives of the $(CH)_{10}$ system *(1)*[1], namely *(1a)* and *(1b)*. It was of particular interest to establish whether an intermediate 1,4-diradical *(2)*[2] undergoes stabilization by intramolecular cycloaddition to a double bond to give *(3)*, in the same way as a number of 1,3-diradicals[3], or fragmentation with cleavage of a σ bond to give *(4)*.

(1a) is not accessible from *(6)* by photochemical butadiene-cyclobutene isomerization[4]. We synthesized



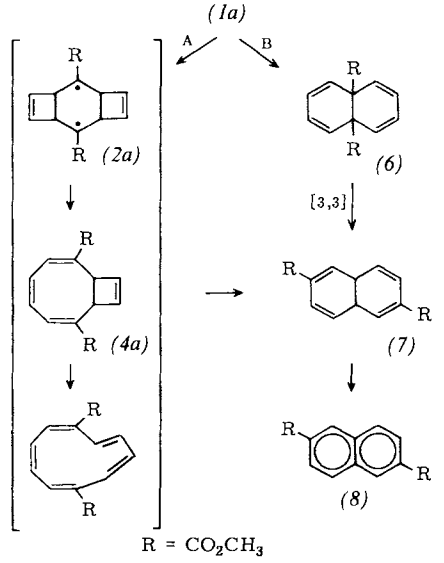
(1a) from the Dewar benzene *(5a)* and cyclobutadiene, and obtained the product as colorless crystals of m.p. 61—63 °C (from pentane) [NMR (60 MHz, CCl_4): 3.72 (4H, m), 6.40 (6H, s), 6.72 τ (4H, m); mass spectrum: $m/e = 246$ (M^+)].



(a), R^1 = H; *(b)*, R^1 = CH_3

The final product of thermolysis (50—80 °C in CCl_4) of *(1a)* is 9,10-dihydronaphthalene *(7)* [NMR ($CDCl_3$): τ = 2.90 (2H, m), 3.45 (2H, d, J_{AB} = 9.5 Hz), 3.85 (2H, d, J_{AB} = 9.5 Hz), 6.20 (6H, s), 6.93 (2H, m); UV in CH_3CN: $\lambda_{max}(\varepsilon)$ = 285 nm (≈ 2600[5])]. According to the UV spectrum the two six-membered rings in *(7)* must be *trans*-fused [the unsubstituted 9,10-dihydronaphthalenes differ drastically in their electronic spectra; $\lambda_{max}(\varepsilon)$: *cis* 248 nm (4072)[6], *trans* 276 nm (3850)[7]].

Compound *(7)*, the only defined thermolysis product, readily aromatizes to 2,6-bis(methoxycarbonyl)naphthalene *(8)*, which was found to be identical with an authentic sample. Formation of *(7)* could follow route A or B. It appears improbable that route B is operative [particularly as *cis*-fused *(7)* would then be expected] since thermolysis of *(6)*[8] gives a mixture of several dihydronaphthalenes. Moreover, the radical-stabilizing methoxycarbonyl groups favor cleavage according to A.

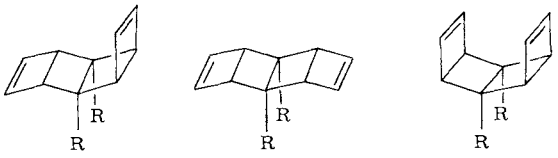


The geometry of *(1a)* is unknown. Alternatives *(1a)*-I and *(1a)*-III can be ruled out with some degree of certainty on the basis of the NMR spectrum. Double resonance experiments show that irradiation at τ = 6.72 causes the

[*] Dr. H.-D. Martin and Dipl.-Ing. M. Hekman
Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)

[**] We are grateful to the Deutsche Forschungsgemeinschaft for financial support.—Part 5 of "Small Rings".—Part 4: *H.-D. Martin* and *M. Hekman*, Angew. Chem. *84*, 995 (1972); Angew. Chem. internat. Edit. *11*, 926 (1972). Part 3: [3].

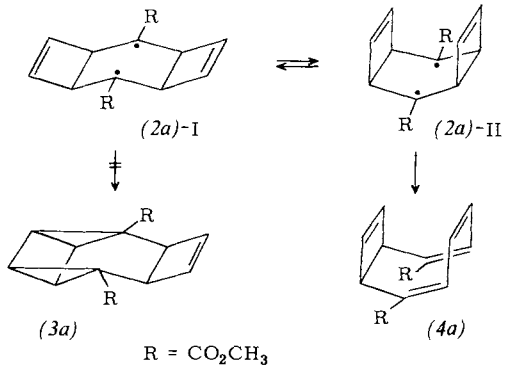
multiplet at $\tau = 3.72$ to collapse to a singlet at $\tau = 3.72$ ($W_H = 0.7$ Hz). This can be regarded as an argument against *(1a)*-I. The olefinic protons of *(1a)*-III would be expected at considerably higher field ($\tau \approx 4.5$—4.8[9]).



(1a)-I *(1a)*-II *(1a)*-III

R = CO_2CH_3

No intramolecular cycloaddition of *(2a)* to give *(3a)* is observed. Instead the findings can be interpreted in the following way: the diradical *(2a)* exists as two conformers *(2a)*-I and *(2a)*-II.



(2a)-I *(2a)*-II *(3a)* *(4a)*

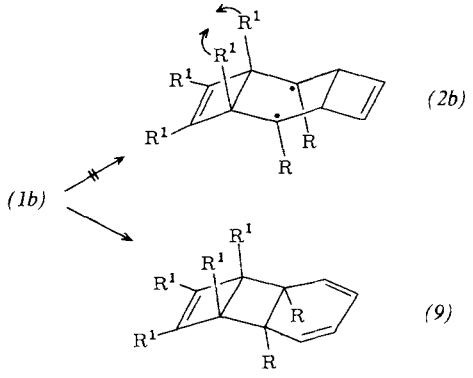
R = CO_2CH_3

Through-space interaction[10] between the radical centers and the double bonds in *(2a)*-I would be permitted by the prevailing geometry (π-homoconjugation) and could be responsible for the formation of *(3a)*; however, no such interaction is actually observed. On the other hand, through-bond interaction[10,11] of the radical centers *via* the intermediate σ bond (hyperconjugation) cannot be neglected in either conformation. If this kind of conjugation dominates then fragmentation to give *(4a)* will be promoted. This is the case in the situation under study. The fact that thermolysis of bicyclo[2.2.0]hexanes[12] predominantly yields *cis,trans*-dienes can be explained in terms of the chair conformation of the intermediate diradical. However, *(2a)*-II is unable to exist in such a conformation.

Further support for route A comes from the thermolysis of the tetracycle *(1b)* obtained from *(5b)* and cyclobutadiene. [*(1b)*, NMR ($CDCl_3$): $\tau = 3.70$ (2H, m), 6.36 (6H, s), 6.59 (2H, m), 8.50 (6H, s), 8.89 (6H, s); mass spectrum: $m/e = 302$ (M^+); m.p. 91—92 °C (from pentane)].

Compound *(1b)* exhibits a considerably greater thermal stability than *(1a)*. Fragmentation does not occur below 150 °C, the major product being dimethyl phthalate which presumably arises by opening of the unsubstituted cyclobutene ring in *(1b)* to give *(9)* followed by Alder-Rickert cleavage. Under the drastic reaction conditions necessary it was impossible to detect *(9)*. The mutual steric hindrance of the two methyl groups in *(2b)* increases the activation energy for the formation of this radical compared to the reaction *(1a)* → *(2a)*; ring cleavage to give *(9)* dominates.

The kinetics of thermolysis of *(1a)* in perchlorobutadiene were measured between 50 and 80 °C. The parameters



(2b) *(1b)* *(9)*

R = CO_2CH_3, $R^1 = CH_3$

obtained by the method of least squares ($E_a = 24.5$ kcal/mol, $\log A = 12.0$, $\Delta S^{\neq} = -5.8$ cal deg^{-1} mol^{-1}, $\Delta H^{\neq} = 23.8$ kcal/mol, $\Delta G^{\neq} = 25.7$ kcal/mol at $T_m = 338$ °K) also evidence a unimolecular decomposition by route A and not by route B since $E_a \geq 27$ kcal/mol and $\log A \approx 14$[13] would be expected for cleavage of a cyclobutene ring in *(1a)*. This would be inconsistent with the negative activation entropy observed, which can however be satisfactorily interpreted by formation of a resonance stabilized diradical *(2a)*. The lowering of the activation energy compared with bicyclo[2.2.0]hexane ($E_a = 36$ kcal/mol) is readily explained by the effect of the methoxycarbonyl groups.

Owing to the occurrence of side reactions the kinetics of thermolysis of *(1b)* are more complicated. The consumption of *(1b)* (Σk_i) affords an apparent activation energy ($\Sigma k_i E_i / \Sigma k_i$) $E_a = 34$ kcal/mol and $\log A = 14.4$. Since formation of dimethyl phthalate is the main reaction one can write $k_{(1b)\rightarrow(9)} = k_1 > k_2, k_3 \ldots$ The parameters measured for the consumption of *(1b)* are thus an approximation for the values corresponding to the reaction *(1b)* → *(9)*; the decomposition of *(9)* is certainly not rate-determining. The difference between the *A* factors $10^{12.0}$ and $\approx 10^{14}$ for *(1a)* and *(1b)* respectively also clearly underlines the difference in thermolysis mechanisms. The route proposed for *(1b)* is in full accord with $\log A \approx 14$[13]. The cleavage of the basic system of *(9)* with aromatization is not unexpected[14].

The behavior of the 1,4-diradical *(2a)* is therefore consistent with theory[11], unlike that of 1,3-diradicals whose intramolecular cycloaddition[3] (controlled by π-homoconjugation) can become the sole reaction path.

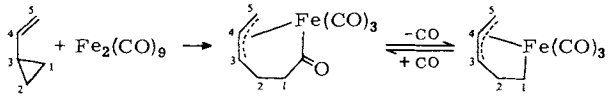
Metal-Catalyzed [4+2]-Cycloaddition of a Vinylcyclopropane Group to a C—C Bond of a Cyclopropane Ring: Synthesis and Degenerate Valence Isomerization of a Bishomobenzene-Fe(CO)$_3$ Derivative[1]

By *Rudolf Aumann*[*]

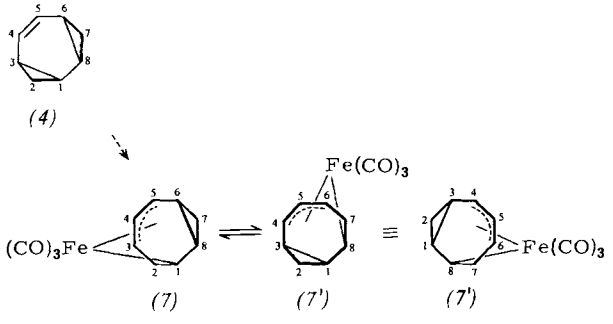
Cycloaddition of vinylcyclopropane groups *(1)* to carbonyliron-carbon bonds affords Fe-heterocycles *(2)* that decompose reversibly into 1,3,4,5-η-pentenediyl-Fe(CO)$_3$ compounds *(3)* and carbon monoxide[2,3].



(1) *(2)* *(3)*

Systems of type *(3)* are potential intermediates in hitherto unknown metal-catalyzed [4+2]-cycloadditions of vinylcyclopropane systems to unsaturated C—C bonds.

I have synthesized a model compound *(7)* in which an intramolecular addition of the C^6—C^8 bond of the cyclopropane ring to the 1,3,4,5-η-Fe(CO)$_3$ unit can be recognized by a degenerate valence isomerization *(7)*⇌*(7')*.

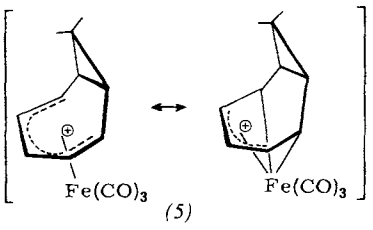


(4)

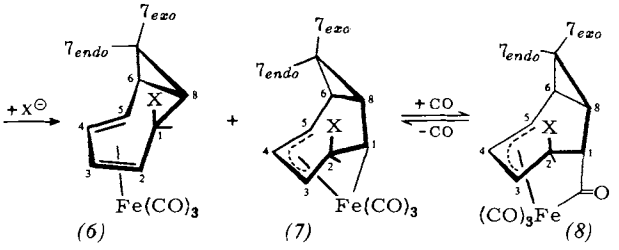
(7) *(7')* *(7')*

Since *cis,cis*-bishomobenzene *(4)* is unsuitable for synthesis of *(7)* owing to its thermal instability, this compound *(7)* was prepared by a novel route[5], namely kinetically controlled addition of H$^-$ to compound *(5)* which is easily accessible from the cyclooctatetraene-Fe(CO)$_3$ complex[4a].

(7a) is thus formed in 18% yield alongside already known *(6a)*[4a] and a little *(6c)*[4b] (total yield 90%) on treatment of *(5)* with a 3% solution of $NaBH_4$ in ice-water. With carbon monoxide, *(7a)* gives an adduct *(8a)* (m.p. 86 to 87 °C, dec.), which can be separated by fractional crystallization from pentane at −60 °C and which decomposes to regenerate *(7a)* in a vacuum (5 torr; 40 °C)[2].



(5)



(6) *(7)* *(8)*

(a), X = H; *(b)*, X = D; *(c)*, X = OH

A degenerate valence isomerization *(7)*⇌*(7')* can indeed be detected. Formally it involves migration of the cyclopropane ring from positions 6, 7, 8 to 1, 2, 3 and simultaneous shift of the π-allyl-iron bond from 3, 4, 5 to 4, 5, 6 and of the σ-carbon-iron bond from 1 to 8. The rearrangement is recognizable by deuterium-labeling of C^2[6]. Since, however, a 1:1 equilibrium *(7b)*⇌*(7b')* is rapidly established in a solution of *(7b)* at room temperature, this investigation was carried out starting with compound *(8b)* which can be isolated in pure form, since it is more stable kinetically than *(7b)*, and which is connected with *(7b)* by the equilibrium[2] *(7b)* + CO⇌*(8b)*.

In the ^{1}H-NMR spectrum of *(8b)* (Fig. 1) a slow decrease in the intensity of the resonance signal of $H^{2\,endo}$ can be observed at 40 °C simultaneously with an increase to equal extent of the remaining proton signal (*ca.* 95% deuterium) due to $H^{2\,pseudoaxial}$, while the intensity of the other signals remains unchanged. Equilibrium requires *ca.* 25 min in benzene at 40 °C.

Failure attended an attempt to demonstrate the exchange of magnetic environments of the protons 4↜5, 3↜6, 2↜7, 1↜8 by the double resonance-relaxation technique[7] because *(7a)* isomerizes to 1,3,5-cyclooctatriene-Fe(CO)$_3$[8,9] at temperatures required for this experiment.

Product analysis indicates that the addition of the C^6—C^8 bond to the 1,3,4,5-η-Fe(CO)$_3$ unit of *(7)* occurs with retention at all the carbon atoms involved. We propose the systematic symbolism $3\eta\pi_s + 1\eta\pi_s + 2\sigma_s$ for this new type of cycloaddition by analogy with the nomenclature used by *Woodward* and *Hoffmann* for pericyclic reactions[10] and by *Cotton* for organometallic compounds[11].

In this connection the degenerate valence isomerization *(6)*⇌*(6')* is also of interest. If *(6b)* (m.p. 39 °C) is heated in benzene for 15 h at 90 °C, redistribution of the deuterium between the ring positions 1 *pseudoaxial* and 7 *endo* is observed[13]. This can be interpreted in terms of a valence isomerization *(6)*⇌*(6')* which, unlike the rearrangement observed with uncomplexed bicyclo[5.1.0]-2,4-octadiene[12], proceeds with retention at C^6 and C^8.

All compounds were characterized by elemental analyses, mass, IR, and ^{1}H-NMR spectra (cf. Fig. 1; assignment by double resonance experiments). The influence of substituents X on the position of the equilibria *(6)*⇌*(6')* and *(7)*⇌*(7')* is still under investigation.

[13] Small amounts of deuterium are incorporated at ring positions 3 and 5 due to 1,5-hydrogen shifts on the metal side of the ring ligand. This could be demonstrated convincingly also by "inverse labeling", using a compound *(6)*, in which all hydrogen atoms except $H^{1\ pseudoaxial}$ are substituted by deuterium as starting material for rearrangement studies (*R. Aumann*, unpublished results).

1,3,5-Tri-*tert*-Butylpentalene. A Stabilized Planar 8π-Electron System[**]

By *Klaus Hafner* and *Hans Ulrich Süss*[*]

Dedicated to Professor Fritz Kröhnke on the occasion of his 70th birthday

The question of the nature of bonding in pentalene *(1)* has motivated numerous experimental and theoretical studies during the past 50 years[1] and frequently led to a great deal of controversy[2]. Whereas "aromatic" properties were initially postulated for *(1)*, recent quantum mechanical calculations predict for a delocalized pentalene according to a D_{2h} structure *(1a)* resonance destabilization by

(1a) *(1b)*

about 6 kcal/mol relative to a polyolefin structure of C_{2h} symmetry *(1b)*[3,4]. The hydrocarbon *(1)* should accordingly be characterized by high reactivity and low thermal stability. This is confirmed by the latest experimental results: attempts to prepare *(1)* and its 2-methyl, 1,3-dimethyl, and 1,3-di-*tert*-butyl derivatives exclusively yielded the dimerization products[5]. On photolysis at −196 °C[5] some of these yield the highly thermolabile monomers (detected by UV spectroscopy). Similar observations were made by *de Mayo et al.*[6] on attempted preparation of 1-methylpentalene, whose existence could likewise only be deduced from UV and IR spectra owing to its unusually pronounced tendency to undergo dimerization even at temperatures below −100 °C.

NMR spectroscopic studies of a simple pentalene were expected to provide information about the bonding character of this cyclooctatetraene perturbed by a central σ bond and thus to afford a solution of the "pentalene problem". This required a derivative of *(1)* whose dimerization is hindered by steric affects only. This requirement is fulfilled by 1,3,5-tri-*tert*-butylpentalene *(7)*.

The synthesis of *(7)* was readily accomplished by reaction of lithium *tert*-butylcyclopentadienide *(2)* with the ketimonium salt *(3)*[7] in ether/methylene chloride (2:1) at 0 °C (15 h). The reaction mixture is then rapidly worked up at 0 °C and the product mixture chromatographed on Al_2O_3 (activity 3, basic) at −75 °C with *n*-pentane. Com-

pound *(7)* is isolated in about 10% yield[9] as deep-blue crystals (scales) of m.p. 59 °C (low temperature MS (at −100 °C): $M^+ = 270$[10]). The crystals are stable for several hours at room temperature in the absence of air, while a low concentration *n*-hexane solution of the compound is stable for several days under N_2. Dimer formation has not yet been observed.

By analogy with the preparation of 2-methyl- and 1,3-dimethylpentalene[5], *(2)* and *(3)* probably first yield the fulvene *(4)* which undergoes electrocyclic reaction to give *(5)*. Subsequent double 1,5 H shifts lead to the 1,5-dihydropentalene *(6)* which suffers 1,4-elimination of dimethylamine to furnish *(7)*.

The UV spectrum of *(7)* [(in *n*-hexane at 20 °C): $\lambda_{max} = 211$ ($\log\varepsilon = 4.27$), 280 (3.34), 333 (3.50), and 598 nm (1.81)] is in good agreement with calculated[4] values for the electronic spectrum of *(1)* and resembles those of mono- and dimethylpentalenes[5,6] as well as those of hexaphenylpentalene[11], 1,3-bis(dimethylamino)pentalene[12], and 1,4-diamino-2,5-dicyano-3,6-dimethylpentalene[13].

The pentalene structure *(7)* is proved by the NMR spectra, which provide additional information about the bonding

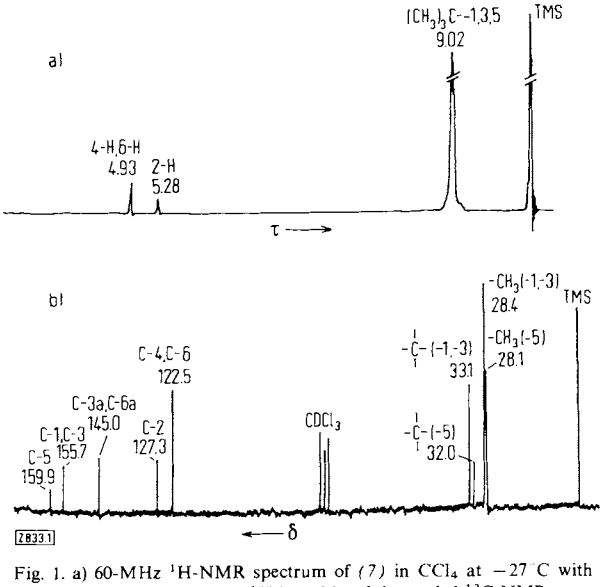

Fig. 1. a) 60-MHz ^{1}H-NMR spectrum of *(7)* in CCl_4 at −27 °C with TMS as internal standard. b) ^{1}H-broad band decoupled ^{13}C-NMR spectrum of *(7)* in $CDCl_3$ at −50 °C with TMS as internal standard.

character of the 8 π-electron system. The 60-MHz ^{1}H-NMR spectrum of *(7)* (Fig. 1a) shows two singlets of intensity 2:1 for the three ring protons, while the absorptions of the *tert*-butyl protons coincide to give just one signal. The ^{13}C-NMR spectrum of *(7)* (Fig. 1b)[14] contains five signals in the sp^2 C range for the ring system. This assignment was deduced from the off-resonance spectrum, the known influence of *tert*-butyl groups on neighboring sp^2 C atoms, as well as the relative intensities of the signals of C-1/C-3, C-5, C-3a/C-6a on the one hand and of C-2, C-4/C-6 on the other. In contrast to the 60-MHz ^{1}H-NMR spectrum, the ^{13}C-NMR spectrum permits recognition of the different *tert*-butyl groups.

The ring proton signals of *(7)* are shifted upfield compared to those of heptalene (τ = 4.2 and 4.9)[15], cyclooctatetraene (τ = 4.31)[16], and particularly those of fulvene (τ = 3.9)[17] and 1,2-dihydropentalene (τ = 3.29—4.18)[18]. The same observation is made on comparison with the signals of the outer protons of [16]annulene (τ = 4.67)[19] and of 1,7-methano[12]annulene (τ = 4.2—4.6)[20], both of which exhibit a paramagnetic ring current.

Accordingly, a paramagnetic ring current is probably operative in *(7)* too, the compound thus possessing "antiaromatic" character. The presence of only five signals in the ^{13}C-NMR spectrum for the eight ring C atoms of *(7)* rules out the existence of a localized bond system depicted by one of the Kekulé structures *(7a)* and *(7b)*. However, our present experimental results do not permit a decision whether the π-electron system of *(7)* is delocalized in the same way as *(1a)* or is undergoing rapid oscillation between the Kekulé structures *(7a)* and *(7b)*.

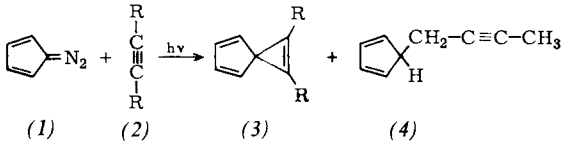
Definite Proof of Spiroconjugation in [1.2]Spirenes[**]

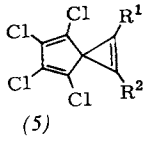
By *Heinz Dürr, Bernd Ruge*, and *Heribert Schmitz*[*]

Linkage of conjugated segments of polyenes (ribbons[1]) *via* a formally sp^3-hybridized C atom should lead to a spirene exhibiting an interaction designated as spiroconjugation[2]. HMO[2] and CNDO/2 calculations[3] on [1.2]spirene[**] predict stabilization of the HOMO by interaction between the π ribbons while the energy of the LUMO remains largely unaffected[2,3]. This should result in a hypsochromic shift of the longest wavelength UV band compared with that of the partially hydrogenated system *(7)*.

However, both electronic and steric substituent effects can perturb the system and mask the spiroconjugation. Thus the spirene *(5c)* provides no unequivocal evidence for spiroconjugation[2], whereas *(5d)* and *(5e)* exhibit a marked hypsochromic shift in the UV spectrum[4]. These differing results prompted us to synthesize the alkyl-substituted [1.2]spirenes *(3a)* and *(3b)* in order to substantially eliminate substituent effects.



(1) *(2)* *(3)* *(4)*



(5)

(a), R = CH_3 *(d)*, R^1 = H, R^2 = CO_2CH_3

(b), R = C_2H_5

(c), R^1 = R^2 = C_2H_5 *(e)*, R^1 = R^2 = CO_2CH_3

Compounds *(3a)* and *(3b)* were prepared by irradiating diazocyclopentadiene *(1)* in 2-butyne *(2a)* or 3-hexyne *(2b)* with long wave UV light (λ > 360 nm) until evolution of nitrogen had ceased (cf. ref. [5]). *(3a)* and *(3b)* are pale yellow oils (yield 47 and 35% respectively) which decompose on attempted gas chromatography but could be purified by chromatography and vacuum microdistillation at room temperature.

The structure follows from the spectra. IR: *(3a)*: 1938; *(3b)*: 1925 cm^{-1} (cyclopropene stretching mode); NMR: *(3a)*: τ = 3.8—4.0 (m) and 3.3—3.5 (m) (cyclopentadiene H), 7.86 ppm (s) (CH_3) (2:2:6); *(3b)*: τ = 3.3—3.5 (m) and 3.7—3.9 (m) (cyclopentadiene H), 7.53 (q) (^3J = 7.5 Hz) (CH_2) and 8.95 ppm (t) (CH_3) (2:2:4:6); mass spectrum: *(3b)*: *m/e* = 146 (M^+); UV, see Table 1. Further structural proof comes from the Diels-Alder adducts of *(3a)* and *(3b)* to tetracyanoethylene and to 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (cyclopropene band at 1860 to 1880 cm^{-1}).

(6) *(7)* *(8)*

Table 1. UV data for [1.2]spirenes *(3a)* and *(3b)* and the 5,5-disubstituted cyclopentadienes *(6)*—*(8)*.

Cpd.	Solvent	λ_{max} [nm]	ε
(3a)	methanol	239	1300
(3b)	methanol	241	2450
	isooctane	242	2900
(6)	ethanol	250	2880
(7)	ethanol	257	2690
(8)	ethanol	254	2750

The possibility of spiroconjugation was examined by comparison of the UV spectra of *(3a)* and *(3b)* with those of *(6)*—*(8)* which cannot show spiroconjugation. The theoretically predicted hypsochromic shift[2,3] of the longest wavelength absorption band is indeed observed on comparison of *(3a)* and *(3b)* with *(8)*. It amounts to 12—15 nm, *i.e.* 5—6 kcal/mol.

While the UV spectra of spirotetraenes may be compared with those of the corresponding saturated hydrocarbons[6,7], the method runs into difficulties with *(3a)*, *(3b)*, and *(7)*. The p orbitals (Walsh model) of the cyclopropene single bonds can enter into pseudoconjugation *via* the sp^2-hybridized spiro-C atom with the π electrons of the five-membered ring[8]. In *(3a)* and *(3b)* a hypsochromic shift becomes operative due to spiroconjugation and a bathochromic shift due to pseudoconjugation. Comparison of *(7)* and *(8)* shows that the latter effect should result in a bathochromic shift of the order of 3 nm. In reality the stabilization of *(3a)* and *(3b)* will therefore be greater than 5—6 kcal/mol. Spiroconjugation can thus be regarded as established in [1.2]spirenes. Photoelectron spectroscopic studies are currently in progress.

1,2-Diethylspiro[2.4]hepta-1,4,6-triene (3b):

A solution of *(1)* (4.0 g, 43.5 mmol) in *(2b)* (150 ml) was irradiated, after 15 minutes' purging with N_2, with a Philips HPK 125 W lamp (GW_v filter) for 4 h at 0 °C. (60—70% of the calculated amount of N_2 was liberated.) Unreacted *(2b)* was then removed *in vacuo* and the blackish brown residue rapidly chromatographed over silica gel (150 g) with CH_2Cl_2. Chromatography with CCl_4 under the same conditions afforded *(3b)* as a pale yellowish oil. Prior to spectroscopy *(3b)* was distilled in a microapparatus at room temperature.

Mesomolecules. Polyaza-Polyoxa Macropolycyclic Systems[**]

By *Jean-Marie Lehn, Jacques Simon*, and *Joseph Wagner*[*]

The chemistry of molecular systems presents quite a clear dichotomic separation into the micromolecules of organic chemistry (M.W. < 500) and the macromolecules of polymer chemistry and biochemistry (M.W. > 5000). Although these definitions of size are arbitrary, it nevertheless appears that comparatively very few organic chemical studies have been directed towards the design, the synthesis, and the properties of molecules of intermediate size, *i.e.* mesomolecules (not considering systems akin to natural products like porphyrins, corrins, peptides, *etc.*).

Such systems may present a multitude of new properties compared to "small" molecules, by the mere token of their size and the resulting palette of possible structural variations, while also being challenging synthetic targets. A number of macrocyclic[1], macrobicyclic[2-4], and macrotricyclic[5,6] molecules have been synthesized recently. Many of them may act as ligands for the formation of selective inclusion complexes[1,3,4,6-8] ("cryptates")[7] with various metal cations; natural macrocyclic peptides and depsipeptides also form cation complexes[9]; macrocyclic polysugars, the cyclodextrins, are able to form molecular inclusion complexes[10]. The common feature of these systems, which are still of relatively small size, is the presence of a molecular cavity which confers upon them their specific properties.

We present here the synthesis of several macrotricyclic and macrotetracyclic molecules. The intramolecular cavity of these systems is appreciably larger than in the previously reported cation ligands[1,3,4,6]; thus, in addition to new conformational and cation complexation properties, they might be able to complex molecules, *i.e.* to function as specific molecular receptors[14].

Monoprotection of the macrocyclic diamine *(1)*[3a] using benzyl chloroformate in benzene (diamine: chloroformate = 1:1) gives compound *(2)* (viscous oil) in 50% yield[12]. Condensation of *(2)* with the diacyl dichlorides *(3a)*, *(3b)*[11], and *(3c)* (m.p. 92 °C) affords respectively the diamides *(4a)*, *(4b)*, and *(4c)*, which are then converted into *(5a)*, *(5b)*, and *(5c)* with hydrogen bromide in acetic acid (48%). Products *(4)* and *(5)* have not yet been obtained in a crystalline form; the yields are about 90% for the two steps.

The next step is performed under high dilution conditions following a procedure very similar to the one used for the synthesis of the previously described macrobicyclic systems[3]. Condensation of *(5a)*, *(5b)*, and *(5c)* with the dichlorides *(3a)*, *(3b)*, and *(3c)* respectively (in benzene and in the presence of three equivalents of triethylamine) affords the macrotricyclic tetracarboxamides *(6a)* (m.p. 185—186 °C; yield 75%), *(6b)* (m.p. 185 °C; yield 70%), and *6c)* (m.p. 223 °C; yield 55%). These tetraamides *(6)* are reduced by diborane in tetrahydrofuran[13] (reflux for about 10 hours). Hydrolysis of the resulting products with 6N HCl (reflux for about 10 h) followed by passage

of the aqueous solutions over a quaternary ammonium resin column in its hydroxide form affords the macrotricyclic tetraamines *(7a)* (m.p. 45—46 °C; yield 90%), *(7b)* (m.p. 64 °C; yield 90%), and *(7c)* (m.p. 152 °C; yield 90%).

Removal of the tosyl groups of *(7c)* by treatment with sodium in liquid ammonia/ethylamine (1:1) gives *(8)* (m.p. 92—94 °C; yield 70%). The hexaamine *(8)* is then condensed under high dilution conditions with dodecanedioyl dichloride to give the macrotetracyclic diamide *(9)* (viscous oil; 40%). Reduction with diborane followed by acid hydrolysis and passage over a basic resin column, following the procedure used above for the *(6)*→*(7)* conversion, leads to the macrotetracyclic diamine *(10)* (viscous oil; yield 95 %).

The analytical and spectral (^{1}H-NMR, mass) data for all compounds were in agreement with the proposed structures *(1)*—*(10)*. The ^{13}C-NMR spectra of *(6b)* and *(6c)* are also in agreement with these structures. The tri- and tetracyclic substances *(6)*—*(10)* are all soluble in water except *(6c)* and *(7a)* (slightly soluble), as well as in most organic solvents.

Molecular and Cation Complexes of Macrotricyclic and Macrotetracyclic Ligands[**]

By *Jean-Marie Lehn*, *Jacques Simon*, and *Joseph Wagner*[*]

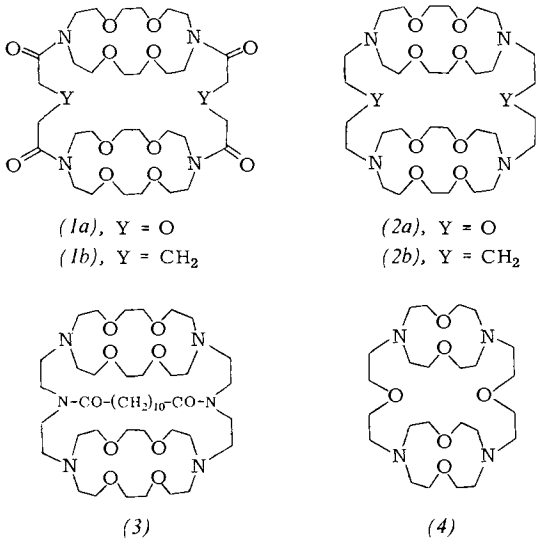
The molecular recognition process involved in the association of two or more chemical species to form a complex is controlled by the chemical information stored in the ligand[1]. The control of spherical recognition of alkali cations[1] by synthetic macrocyclic[2], macrobicyclic[3], and macrotricyclic[4] ligands forming inclusion complexes has been the subject of a number of recent studies.

Beyond the spherical substrate (alkali cations), the next step resides in the design of synthetic ligands for organic molecules, *i.e.* of synthetic molecular receptors. In addition to being selective, such complexes might also in principle display highly specific functions. For instance, they may act as protoenzymes or induce the transport of molecules through various "membrane" type barriers.

Substances capable of functioning as receptors for molecules should contain a molecular cavity so as to be able to form inclusion complexes. Up to now one kind of compound, the macrocyclic polysugars, cyclodextrins[5], has been shown to form well defined inclusion complexes with various molecular substrates[5-7]. Occlusion of solvent molecules by macrocyclic molecules has also been reported[8].

We present here a report on the complexation properties displayed by the macrotricyclic and macrotetracyclic molecules[9]. Three types of complexes have been observed and we now describe the nature and the qualitative properties of these species.

First, the formation of *metal cation complexes* has been observed as in the case of the previously described substance *(4)*[4]. A chloroform solution of *(2a)* turns yellow when solid sodium, potassium, or cesium picrate is added,



owing to the dissolution of the salt by complexation of the cation. It is probable that complexes of both 1:1 and 2:1 cation/ligand stoichiometries may be obtained. A complex [*(2a)*, 2NaI] has been isolated and characterized. The formation of 1:1 and 2:1 complexes with several alkali cations has been detected for compounds *(2a)* and *(2b)* using cation selective electrodes. In analogy with the results obtained for compound *(4)*, these cation complexes may be formulated as 1:1 and 2:1 inclusion complexes of the [3]-cryptate type[4].

Second, *lipophilic cation/lipophilic anion association* occurs when salts containing a complexable cation and a lipophilic anion are used. The fluorescence of the fluorescent probe 6-*p*-toluidinonaphthalene-2-sulfonate (TNS) is known to increase markedly when the anion complexes with a lipophilic substrate[10, 11]. In the present case, complexation of an alkali cation in aqueous solution by the ligand *(2a)* gives a lipophilic cation. The TNS anion may then associate with the cation complex, forming a lipophilic cation/lipophilic anion pair. Such an association should lead to a strong increase in TNS fluorescence. This is indeed observed for ligand *(2a)* with the TNS potassium salt, but no special effect is found for the other alkali cations (Fig. 1). Thus, K^+ probably forms a quite stable complex with *(2a)* and the resulting [*(2a)*, K^+] species associates with the anion forming a neutral pair {[*(2a)*, K^+], TNS^-}.

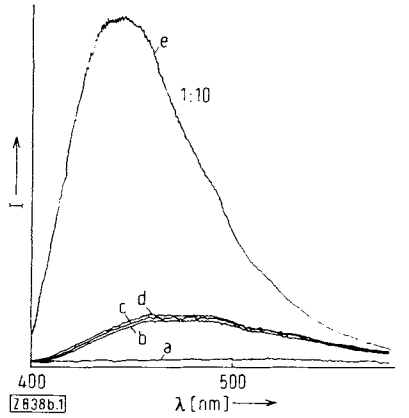


Fig. 1. Fluorescence spectra of the TNS^- anion a) $N(C_2H_5)_4^+$ TNS^-; b) $N(C_2H_5)_4^+$ TNS^- + *(2a)*; $N(C_2H_5)_4^+$ TNS^- + *(2a)* + LiI: $N(C_2H_5)_4^+$ TNS^- + *(2a)* + CsI; c) $N(C_2H_5)_4^+$ TNS^- + *(2a)* + NaI; d) $N(C_2H_5)_4^+$ + *(2a)* + RbI; e) $N(C_2H_5)_4^+$ + *(2a)* + KI (scale reduced by a factor of 10 for e). Solvent: water; concentrations: $N(C_2H_5)_4^+$ TNS^-: 10^{-3} mol/l; *(2a)*: 10^{-2} mol/l; salt: 10^{-2} mol/l.

[**] Molecular Receptors, Part 2.—Part 1: ref. [9].

These results have been checked with a previously described macrobicyclic ligand for which TNS fluorescence enhancement occurs in the presence of a cation forming a complex stable in water[3]. The phenomenon has also been observed recently with natural ligands (*e.g.* valinomycin) in water[12] or in membranes[13].

Finally, *molecular complexes* have also been detected. Indeed, in the absence of any complexable cation, notable TNS fluorescence enhancements are still observed in the presence of ligands *(1)*—*(3)* (Fig. 2). This may be attributed to the formation of molecular complexes between the lipophilic TNS substrate and the ligand. Figure 2 shows that the fluorescence intensity increases with the ligand lipophilicity and is higher for a given amide *(1)* than for the corresponding amine *(2)*. Furthermore, by far the most intense fluorescence is found in the case of the macrotetracyclic ligand *(3)*, for which molecular models clearly display a hollow shape with a well defined intramolecular cavity. Fluorescence enhancements have been described in the case of cyclodextrin inclusion complexes[6, 14].

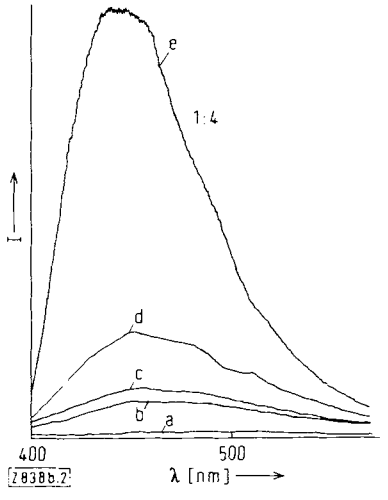

Fig. 2. Fluorescence spectra of the TNS^- anion (cation $N(C_2H_5)_4^+$, 10^{-3} mol/l) in the presence of the following ligands (10^{-2} mol/l) a) none; b) *(2a)*; c) *(1a)*; d) *(1b)*; e) *(3)* (scale reduced by a factor of 4 for e). Solvent: water.

It is tempting to propose that the molecular complexes formed by the present synthetic ligands are also of the inclusion type. However, the present results do not yet permit distinction between an external addition complex and an inclusion complex. Nevertheless, the ligands *(1)*—*(3)* do indeed function as molecular receptors.

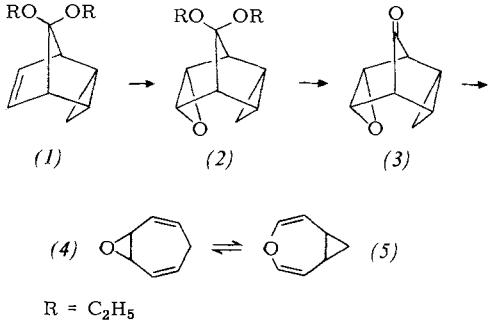
Rapid Reversible Cope Rearrangement between the *sym*-Oxabicyclo[5.1.0]octa-2,5-dienes

By *Helmut Klein, Wilhelm Kursawa*, and *Wolfram Grimme*[*]

The rapid reversible Cope rearrangement of bicyclo[5.1.0]-octa-2,5-diene (also known as 3,4-homotropilidene)[1] was spectacularly extended to bullvalene[2] and semibullvalene[3], but so far has been limited to carbocycles[4]. In the present communication we describe the *sym*-oxabicyclo-[5.1.0]octa-2,5-dienes *(4)* and *(5)*, a pair of heterocycles in mutual equilibrium *via* a rapid Cope rearrangement.



The Diels-Alder adduct *(1)*[5] of 5,5-diethoxycyclopentadiene and cyclopropene can be converted by *m*-chloroperbenzoic acid in methylene chloride into the liquid epoxide *(2)* which is hydrolyzed by 70% aqueous acetic acid to the epoxy ketone *(3)* [81%; m. p. 129 °C; NMR ($CDCl_3$, TMS internal): $\tau = 6.82$ (t) (epoxide H), 7.20 (sex) (bridgehead H), 8.82 ppm (m) (cyclopropane H); IR (KBr): $\nu_{C=O} = 1768\ cm^{-1}$]. We deduce the epoxy ring to be *endo* from the deshielding of one of the secondary cyclopropane protons in *(2)* and *(3)* relative to those in hydrogenated *(1)* and the corresponding ketone, as well as from the coupling constant of 1.5 Hz between the epoxide and bridgehead protons[6].

Sublimation of the ketone *(3)* through a capillary heated to 380 °C (45 cm, 0.3 cm diam.) in a stream of N_2 induced fragmentation to CO and 8-oxabicyclo[5.1.0]octa-2,5-diene *(4)* (92%) obtained crystalline at −70 °C. The structure of the new heterocycle, which is liquid at room temperature, follows from the spectral data. The UV spectrum [(cyclohexane): $\lambda_{max} = 280$ ($\varepsilon = 600$), $\lambda_{min} = 258$ nm (450)] exhibits extensive end absorption and its shape resembles that recorded for 2,6-dimethyloxepin[7]. As in the case of 3,4-homotropilidene, the IR spectrum displays an intense band at 1664 cm^{-1}, accompanied by a characteristic band at 1138 cm^{-1} due to the epoxide ring.

However, the most convincing structural evidence comes from variable temperature NMR spectra (Fig. 1). The

[*] Dipl.-Chem. H. Klein, W. Kursawa, and Dr. W. Grimme
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

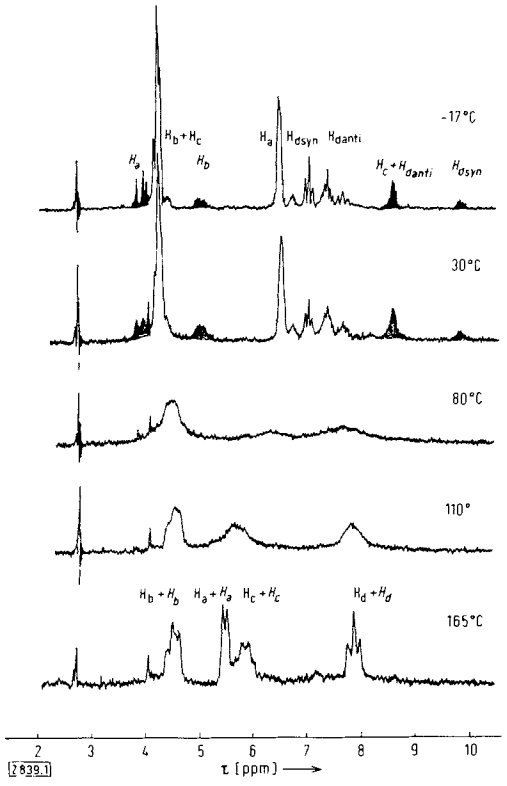


Fig. 1. ^{1}H-NMR spectrum of the equilibrium of *sym*-oxabicyclo[5.1.0]-octa-2,5-dienes at various temperatures [60 MHz, *sym*-tetrachlorodideuterioethane, $CHCl_3$ ($\tau = 2.75$) as internal standard]. The residual ^{1}H of the solvent absorbs at $\tau = 4.06$. The signals of the epoxytropilidene *(4)* are listed in regular type, those of the homooxepin *(5)* in italics, they are also shaded.

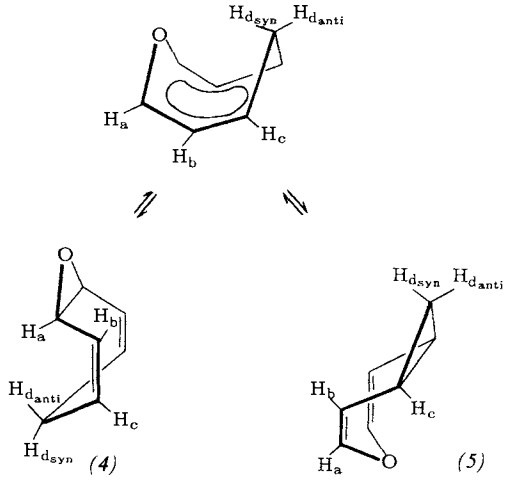
spectrum at -17 °C is dominated by two narrow multiplets at $\tau = 4.30$ and 6.50 and by a split AB system at 6.90 and 7.55 ppm ($J_{A,B} = 17$ Hz) ascribable to the protons indicated in the 3,4-epoxytropilidene *(4)*. In addition, there appear a low intensity AB system with a split B part at $\tau = 3.95$ and 5.10 ($J_{A,B} = 7.5$ Hz) and two multiplets at 8.60 and 9.85 ppm. These signals arise from the protons of the valence isomer 4,5-homooxepin *(5)* present in small amount. At about 30 °C the signals become diffuse, indicating an equilibrium between *(4)* and *(5)* that is just becoming dynamic on the NMR time scale. Further increase in temperature leads *via* coalescence to the appearance of four new signals exhibiting fine structure at 165 °C. This reversible temperature dependence of the spectrum results from the increasing rate of equilibration $(4) \rightleftarrows (5)$ causing the absorption of the interconverting protons to be recorded at an average value. The methylene protons H_d, showing separate absorptions in each of the two equilibrating species corresponding to their *syn* and *anti* configuration, can only be equivalent in the high temperature spectrum when their two average values coincide. This is the case when the more strongly shielded methylene proton ($\tau = 9.85$) of the cyclopropane ring exchanges with the less shielded one ($\tau = 6.90$) of the seven-membered ring and the other two methylene protons interconvert correspondingly.

The coupling constants ^3J and ^4J[8] of the bridgehead and methylene protons reveal that both equilibrium components are in the transoid conformation and that the exchange pattern mentioned above, which has been confirmed by double resonance, interrelates the *syn* and the *anti* methylene protons of *(4)* and *(5)* respectively. This would indicate the cisoid conformation for the transition state in analogy to the 3,4-homotropilidene rearrangement[9].



The equilibrium constant $K = [(4)]:[(5)]$ is found to be 6.45 and 4.12 for -17 and 30 °C, respectively, by integration of the NMR spectra; the position of the averaged signals at 165 °C affords a value of 1.67. The transition $(5) \rightarrow (4)$ is thus characterized by $\Delta\Delta H_f^0 = -1.67 \pm 0.33$ kcal/mol and $\Delta S^0 = -4.4 \pm 1.0$ cal mol^{-1}deg^{-1}. The free energy of activation for the rearrangement can be roughly estimated as $\Delta F^{\neq} = 17$ kcal/mol from the coalescence spectrum[10].

The dynamic equilibrium at room temperature between epoxytropilidene and homooxepin corresponds to the "fluxional structure" of 3,4-homotropilidene[1] and impressively confirms for an intramolecular case our previous finding[11] that the activation energies for the Cope rearrangements of *cis*-divinyl-substituted three-membered rings lie closer together than formerly assumed.

Polynuclear π-Cyclopentadienyl-Sulfur-Molybdenum Complexes from Propylene Sulfide and π-Cyclopentadienylcarbonylmolybdenum Hydrides[1]

By *Wolfgang Beck*, *Wolfgang Danzer*, and *Gerhard Thiel*[*]

The reaction of hydridopentacarbonylmanganese with propylene sulfide proceeds *via* insertion of sulfur into the Mn—H bond to give the dimeric SH-bridged complex $[Mn(CO)_4SH]_2$[2]. In other reactions with metal hydrides too, 2-methylthiirane proves to be a simple reagent for introduction of sulfur atoms into metal complexes under mild conditions[3].

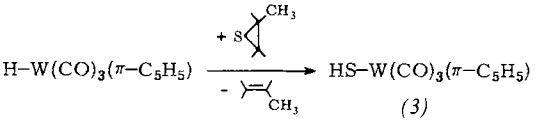
Thus $HMo(CO)_2[P(OC_6H_5)_3]$ (π-C_5H_5) and propylene sulfide (molar ratio 1:1) in tetrahydrofuran at 20 °C yield lustrous black, oxygen-sensitive crystals of (π-$C_5H_5)_3Mo_3S_4$ *(1)*. The mass spectrum of *(1)* contains the series of ions $(C_5H_5)_{3-n}Mo_3S_4^+$ and $(C_5H_5)_{3-n}Mo_3S_3^+$ ($n=0$—3), as well as $(C_5H_5)_{3-n}Mo_3S_4^{2+}$ and $(C_5H_5)_{3-n}Mo_3S_3^{2+}$ ($n=0,1$); the stability of the Mo_3S_3 unit warrants attention. The structure of the diamagnetic cation $(\pi\text{-}C_5H_5)_3Mo_3S_4^+$ is known[4]; a three-membered Mo_3 ring is also assumed for the neutral molecule *(1)*, the compound *(1)* being predicted to have a smaller Mo—Mo distance than in the cation by the MO model of *Dahl*[4].

If $HMo(CO)_2[P(OC_6H_5)_3]$ (π-C_5H_5) is allowed to react under similar conditions with an excess of propylene sulfide, black crystals of the dinuclear complex $(\pi\text{-}C_5H_5)_2Mo_2S_4$ *(2a)* are formed. A red isomer $(\pi\text{-}C_5H_5)_2Mo_2S_4$ *(2b)* which is more readily soluble in methylene chloride is formed from $HMo(CO)_3(\pi\text{-}C_5H_5)$ and propylene sulfide. The mass spectra of *(2a)* and *(2b)* contain the ions $(C_5H_5)_2Mo_2S_n^+$ ($n=4$—0), $C_5H_5Mo_2S_n^+$ ($n=3,1$), $Mo_2S_n^+$ ($n=4,3$), and $(C_5H_5)_2Mo_2S_n^{2+}$ ($n=4$—2). *(2a)* differs from *(2b)* in the additional appearance of a metastable peak arising from the fragmentation

$$(C_5H_5)_2Mo_2S_4^+ \rightarrow (C_5H_5)_2Mo_2S_2^+ + S_2$$

and above all in an additional intense IR band at 482 cm^{-1} (νS—S?). These findings indicate a structure with two disulfide bridges for *(2a)*. The structure of an isoelectronic complex $(\pi\text{-}C_5H_5)Mo(SCH_3)_4Mo(\pi\text{-}C_5H_5)$ has already been established by *Dahl*[5]. A structure analogous to the oxo compound $(\pi\text{-}C_5H_5)(O)MoS_2Mo(O)(\pi\text{-}C_5H_5)$[6] seems plausible for *(2b)*.

The reaction of $HW(CO)_3(\pi\text{-}C_5H_5)$ with propylene sulfide proceeds without displacement of carbon monoxide:



(3)

The IR spectrum of the product *(3)* exhibits two νCO bands at 2028 and 1937 cm^{-1} (in CS_2); the SH proton appears at τ 12.79 in the ^{1}H-NMR spectrum (solution in CS_2)[7].

mixtures of $CsCuCl_3$ and CsCl (1:1, p.a. grade chemicals *ex* Merck; 15h, 370 °C, F_2 stream).

Guinier diagrams according to *Simon*[3] contain no Cs_3CuF_6 reflections and confirm the splitting of the $K_2[PCl_6]$-type reflection pattern ("*a*" ≈ 8.7 Å) which is probably due to the Jahn-Teller effect expected for the low spin d^7 configuration.

Preliminary measurements show $Cs_2[CuF_6]$ (F: exp. 25.5, 25.8%; calc. for Cs_2CuF_6: 25.71, for Cs_2CuF_5: 22.39%) to be *paramagnetic* and practically ($\Theta = -3$ K) to obey the Curie law (3.2—294 K). As for $Cs_2K[AgF_6]$[4] the observed magnetic moment $\mu = 1.5_5$ μ_B lies well below the expected value (1.73 μ_B, spin only). The presence of Cu^{III} is thus ruled out. The reason for the low moment is not yet known for either compound.

Proof of the Chirality of Rapidly Interconverting Enantiomers[**]

By *Albrecht Mannschreck*, *Violet Jonas*, and *Bernd Kolb*[*]

A few years ago *Pirkle*[1] described a new method for the determination of enantiomeric purity. This method is based on the possibility of observing different NMR spectra for enantiomers when they undergo a sufficiently strong enough interaction in solution with an optically active auxiliary compound[2]. To explain this effect, it is assumed that two diastereomeric association complexes are formed which are in equilibrium with the unassociated components.

Most of the previous observations of diastereomeric association complexes are related to enantiomers which cannot interconvert thermally, namely chiral molecules with tetravalent C, P, or N atoms. In some cases enantiomers were investigated whose rates of interconversion are very low at room temperature, for example, a number of sulfoxides[2-4] and sulfinic acid derivatives[2], allenes[5], as well as *trans*-diaziridines. Recently we were able to prove the chirality of the latter class of compounds[6] using this method[7]. Here we report our results for diastereomeric association complexes of enantiomers which interconvert *rapidly* at room temperature[8].

The barriers to N^1 inversion are known for 1,2-diazetidinones[9], *e.g.*, $\Delta G_c^{\ddagger} = 17.0 \pm 0.2$ kcal/mol at 48 °C for *(1)*[10] (Fig. 1) in $CDBr_3$. At lower temperatures *(1)* shows separate signals for the diastereotopic methyl groups Me^1 and Me^2 and for the N^2-methylene protons H_A and H_B ($J = 15.5$ Hz). The existence of the enantiomers, *(R)-(1)* and *(S)-(1)*, is demonstrated by the observation that some of the ^{1}H-NMR signals split when optically active O^2, O^3-dibenzoyltartaric acid, *e.g.* (+)-*(2)*, is added. This occurs for Me^1 ($\delta = 1.15$ and 1.23), Me^2 (1.40 and 1.43), and H_B (3.60, $J = 15.5$ Hz, and 3.71, $J = 15.5$ Hz) at −55 °C (Fig. 1a). These splittings do not appear in the presence of the racemic auxiliary compound (±)-*(2)* (Fig. 1b), as is to be expected because of rapid exchange[2] of the components of a diastereomeric association complex.

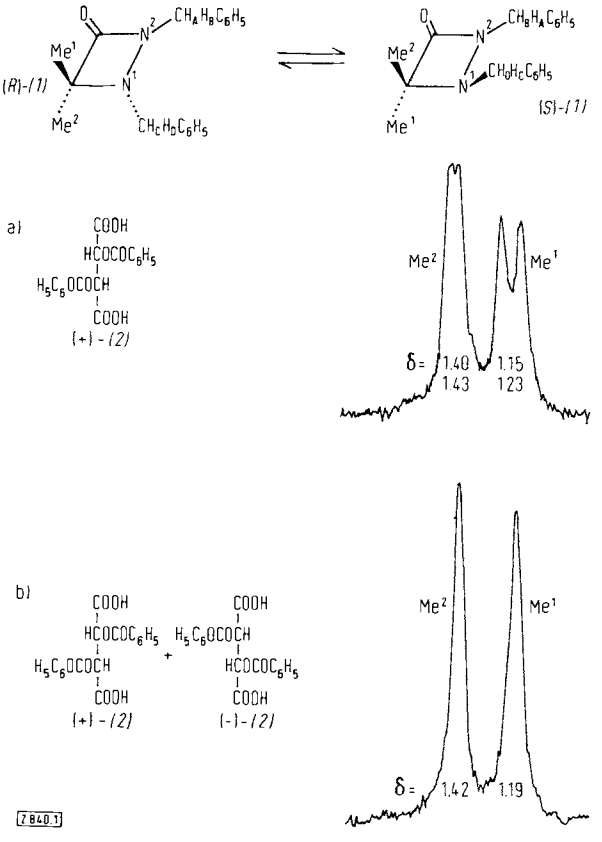

Fig. 1. ^{1}H-NMR signals of the methyl groups of (*RS*)-4,4-dimethyl-N^1,N^2-dibenzyl-1,2-diazetidinone, (*RS*)-*(1)*, in $CDCl_3$ at −55 °C and 100 MHz in the presence of an equimolar amount a) of (2*R*, 3*R*)-O^2, O^3-dibenzoyltartaric acid, (+)-*(2)*, or b) of the corresponding (2*RS*, 3*RS*)-acid, (±)-*(2)*, as auxiliary compound.

Details about the barriers to *N*-aryl rotation have been given for appropriately 2,6-disubstituted aniline derivatives[11], *e.g.*, $\Delta G_c^{\ddagger} = 16.5 \pm 0.3$ kcal/mol at 70 °C for *(3)* and >20 kcal/mol at >127 °C for *(4)* (Fig. 2) in C_4Cl_6. The rather high barrier to rotation about the partial N—N double bond leads to the (*E*)/(*Z*) isomeric nitrosamines *(3)* and *(4)*. They can be separated[12, 14] and equilibrate at a measurable rate at 29 °C in CCl_4, with formation of an equilibrium mixture of 58% *(3)* and 42% *(4)*[11, 13] which was used for the measurements described below. Due to hindered *N*-aryl rotation in *(3)* and *(4)*, separate NMR signals are observed at 10 °C for the diastereotopic methylene protons H_A and H_B ($J = 14.0$ Hz) and H_C and H_D ($J = 14.1$ Hz). The enantiomers *(R)-(3)*, *(S)-(3)*, *(R)-(4)*, and *(S)-(4)* (Fig. 2) can be detected by adding optically active 2,2,2-trifluoro-1-phenylethanol, *e.g.*, (+)-*(5)*, which causes most of the signals to split (Fig. 2a). As expected, these splittings do not appear in the presence of racemic auxiliary compound (±)-*(5)* (Fig. 2b).

The chirality of enantiomers in unresolved racemic mixtures cannot be proved with chiroptical methods. However, in favorable cases this can be achieved indirectly by the observation of diastereotopic atoms within a molecule by NMR spectroscopy, as was originally done in the cases of *(1)*[9], *(3)*[11], and *(4)*[11]. The procedure described

[**] Application of NMR Spectroscopy of Chiral Associates, Part 1. This work was supported by the Fonds der Chemischen Industrie. Prof. Dr. *G. Snatzke*, Bochum, gave us some helpful information.

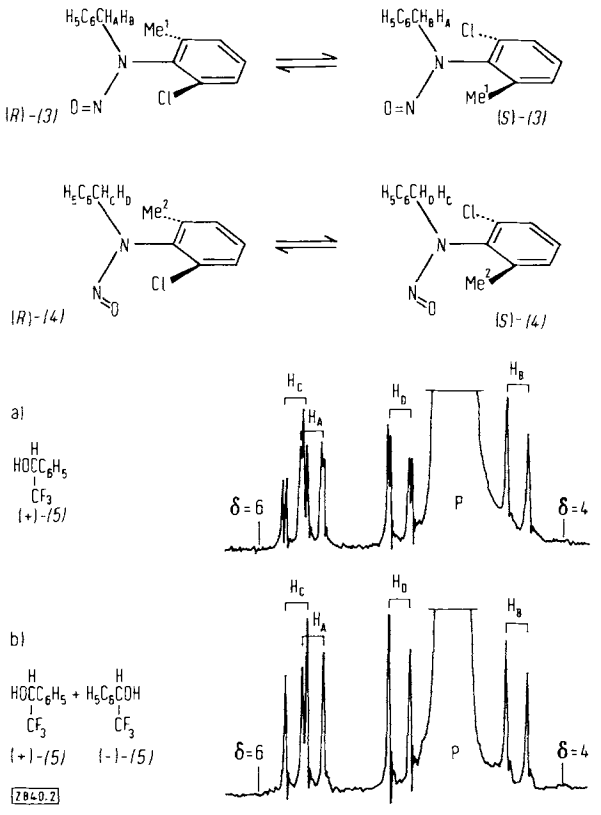

Fig. 2. ^{1}H-NMR signals of the methylene groups of (*E*)-(*RS*)-(2-chloro-6-methylphenyl)benzylnitrosamine, (*RS*)-*(3)*, and of the (*Z*) isomer, (*RS*)-*(4)*, in CCl_4 at 10°C and 100 MHz in the presence of a six-fold molar amount a) of (*S*)-2,2,2-trifluoro-1-phenylethanol, (+)-*(5)*, or b) of the corresponding (*RS*)-alcohol, (±)-*(5)*, as auxiliary compound. P: OCH and OH absorptions of *(5)*. δ and *J* values see Table 1.

The chemical shift differences Δδ (Table 1) for the matching protons appearing in the presence of the optically active auxiliary compounds decrease with increasing temperature[2] since this causes the association equilibria to shift towards the free components. The presently investigated enantiomers interconvert rapidly, so that, in addition, there is the possibility of a coalescence of the signals of the matching protons which is brought about kinetically. The successful detection[16] of such coalescences offers a new method of determining the interconversion rates of enantiomers.

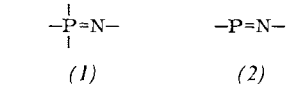
[Bis(trimethylsilyl)amino][(trimethylsilyl)imino]phosphane, a Phosphazene with Tervalent Phosphorus[1]

By *Edgar Niecke* and *Wilhelm Flick*[*]

Compounds of four-coordinated phosphorus of type *(1)* are known in the form of phosphazenes, phosphane imides, and phosphorus nitrides or phosphoranylidenes[2]. However, the existence of a derivative of tervalent phosphorus with a phosphazene structural component *(2)* has not previously been proved[3].



(1) *(2)*

By preparing [bis(trimethylsilyl)amino][(trimethylsilyl)-imino]phosphane *(3)* from [bis(trimethylsilyl)amino]difluorophosphane[4] and lithium bis(trimethylsilyl)amide we have achieved the first synthesis of a phosphazene of coordination number 2.

(3) is a pale yellowish-green liquid, extremely sensitive to hydrolysis, which can be preserved for considerable times below 0 °C with protection from light; however, even traces of impurities cause rapid decomposition to very dark brown products.

The composition and structure of the compound were proved by elemental analysis, mass-, vibrational-, ^{1}H-, ^{29}Si-, and ^{31}P-NMR-spectra and by several characteristic reactions.

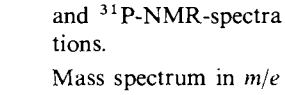
Mass spectrum in *m/e* (relative intensity): 278 (74%) *M*, 263 (100%) $M-CH_3$, 248 (1%) $M-2CH_3$, 218 (4%) $M-4CH_3$, 205 (8%) $M-Si(CH_3)_3$, 203 (22%) $M-5CH_3$, and further fragments.

Vibrational spectrum (IR, Raman, liquid) in the range $1500 > \tilde{\nu} > 400$ cm^{-1}: ≈1430 m, br, 1435 0.2 (dp); –, 1407 1.4 (dp); 1397 m, – all $\delta_{as}(CH_3)$; ≈1280 sh, 1282 (?); 1265 sh, 1264 (p); 1253 vs, 1253 (p); 1244 s, 1242 (?), all $\delta_s(CH_3)$ and ν(P=N) (rel. total intensity 9.5); 939 vs, 937 0.7 (dp) ν_{as}(SiN); 897 vs, 896 0.6 (p) ν(PN); 865 sh, 865 0.4 (dp); 846 vs, br, 850 0.1 (?); 835 sh, 836 0.7 (dp) all $\rho_{as}(CH_3)$; 768 m, 770 0.1 (dp); 753 m, 753 1.2 (dp) both $\rho_s(CH_3)$; 681 s and 675 s, ≈680 5.0 (dp); 645 m, 648, 8.0 (p); 621 m, 623 1.5 (p) all ν(SiC); 588 s, 590 9.5 (p); 449 s, 450 8.5 (p) ν(SiN) and ν_s(SiN). ^{1}H-NMR spectrum (20% solution in C_6H_{12}; TMS internal) at 25 °C: silylimino-H: δ = –0.10 ppm); $J_{H^{13}C}$ = 122.5, $J_{H^{29}Si}$ = 6.6 Hz); silylamino-H: δ = –0.31 ppm (d), J_{HP} = 1.52 Hz ($J_{H^{13}C}$ = 121, $J_{H^{29}Si}$ = 6.9 Hz). Coalescence of the silyl peaks at 77 °C[5]. With Δν = 12.6 Hz (60 MHz), $\Delta G_c^{\neq}$ amounts to 18.3 kcal/mol.

The ^{1}H- decoupled ^{29}Si-NMR spectrum (pure substance, TMS external) shows two doublets in the intensity ratio 2:1 with a highly shielded ^{29}Si nucleus in the silylimino group and a larger ^{29}Si—^{31}P interaction in the Si—N=P grouping: silylimino-^{29}Si: δ = 2.2 ppm, J_{SiP} = 26.8 Hz; silylamino-^{29}Si: δ = –8.2 ppm, J_{SiP} = 9.1 Hz.

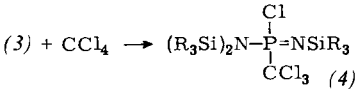
N-Silylated N=P—N compounds containing quadrivalent phosphorus also show a corresponding behavior in $\delta_{^{29}Si}$ and J_{SiP}[5a].

In the ^{31}P-NMR spectrum (50% solution in C_6H_{12}; H_3PO_4 external reference) the resonance signal (δ = –325 ppm) is found at extremely low field, in a region not reached by any phosphorus compound previously known[6]. Comparison with the chemical shifts of the three-coordinated aminophosphanes (δ = –78.4 to –133.6 ppm for compounds of the type $P(NR_2)_3$[6]) shows a frequency shift of *ca.* 200 ppm to lower field for the aminoiminophosphane—a result that is observed also on passing from alkyl- or aryl-phosphanes to the resonance-stabilized compounds of tervalent phosphorus with coordination number 2, namely the phosphabenzenes[7]. A lower shielding of the ^{31}P nucleus is also exhibited by the recently described dialkylaminophosphane cation,



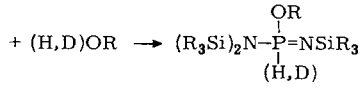
(δ^{31}_P = –274 ppm[8]), in which the phosphorus is likewise coordinated with two nitrogen atoms.

High reactivity of the considerably electrophilic phosphazene *(3)* is observable in a series of exothermic 1,1-additions[4] to phosphorus, such as:



(3) + CCl_4 → $(R_3Si)_2N-P(Cl)(CCl_3)=NSiR_3$ *(4)*

(4): Yield 95%; b.p. 118—119 °C/0.02 torr; ν(P=N) = 1365 cm^{-1}; ^{31}P-NMR (30% solution in C_6H_{12}; H_3PO_4 external standard): δ = –3.8 ppm.



(3) + (H,D)OR → $(R_3Si)_2N-P(OR)(H,D)=NSiR_3$

(5a, b)

(5): Yield 70—75%; b.p. 72—74 °C/0.2 torr; ν(P=N) = 1310 to 1315, ν(PH) = 2380, ν(PD) = 1715 cm^{-1};

^{31}P-NMR (30% solution in C_6H_{12}, H_3PO_4 external standard): $\delta = -4.1$ *(5a)*, -3.8 *(5b)* ppm, $^1J_{PH} = 587.7$, $^1J_{PD} = 90.0$, $^3J_{HP} = 13.5$ *(5a,b)* Hz.

Experimental:

$PF_2N(SiR_3)_2$ (85 g, 0.37 mol) was added dropwise to a stirred suspension of $Li(NSiR_3)_2$ (100 g, 0.6 mol) in light petroleum (b. p. 40—60 °C) at room temperature in a 500-ml three-necked flask fitted with a reflux condenser and dropping funnel. After 3 hours' stirring, most of the solvent was removed and the residue was fractionally distilled under reduced pressure. The fraction passing over at 50 to 60 °C/0.01 torr was freed from residual $PF_2N(SiR_3)_2$ by being kept for 20 h at room temperature and 0.01 torr. Redistillation gave pure *(3)* at 62—63 °C/0.01 torr (yield 55 g, 53%).

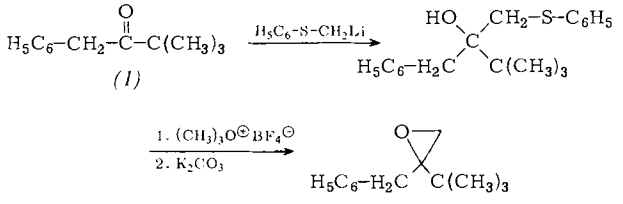
CONFERENCE REPORTS

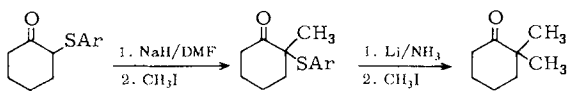
New Methods for the Alkylation of Carbonyl Compounds

By *R. M. Coates*[*]

Carbonyl compounds play a key role in organic synthesis, particularly in the formation of new carbon-carbon bonds. One such transformation, within the general class of nucleophilic alkylation reactions, is methylene (alkylidene) transfer, a conversion usually effected by sulfonium ylides. As in the case of the analogous methylenation reaction[1], we have found[2] that the structural limitations on methylene transfer by ylides (steric hindrance and proton abstraction) may be substantially reduced by use of a three reaction sequence originating with addition of phenylthiomethyllithium[3]. A pertinent example is the efficient methylene transfer to the sterically hindered and enolizable substrate, benzyl *tert*-butyl ketone *(1)*.



Electrophilic alkylation α to carbonyl functions constitutes an important method for creation of quaternary carbon centers in synthesis. We have recently developed some new procedures for regiospecific α-quaternization. By means of the sequential operations of alkylation-reduction-alkylation upon β-thioaryl ketones of type *(2)*, overall regiospecific geminal dialkylation of ketones may be achieved.



(2)

[*] Prof. Dr. R. M. Coates
Department of Chemistry

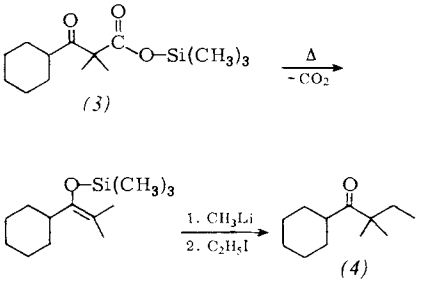
University of Illinois at
Urbana, Ill. 61801 (USA)

The regiospecific transformation of a quaternary-type β-keto ester to a quaternary alkyl ketone of type *(4)* may be carried out through pyrolytic decarboxylation of trimethylsilyl β-keto esters *(3)*[4] to trimethylsilyl enol ethers and subsequent enolate generation and alkylation.



These methods enhance the flexibility and scope of the relatively few known methods[5] for the regiospecific synthesis of α-quaternary ketones.

Studies on Methyleneimmonium Salts

By *Heinrich Volz*[*]

Methyleneimmonium salts are of interest from both a preparative and a mechanistic viewpoint. They have been discussed as reactive intermediates in the following reactions: Mannich reaction; Leuckart-Wallach reaction; Polonovski reaction; fragmentation of γ-halo amines.

The methyleneimmonium salts *(1)* used in our studies (perchlorates, tetrafluoroborates, and hexachloroanti-

[*] Prof. Dr. H. Volz
Institut für Organische Chemie der Universität
75 Karlsruhe, Richard-Willstätter-Allee (Germany)

monates) were prepared by hydride abstraction with corresponding triphenylcarbenium salts from tertiary amines containing at least one methyl group[1]. The hydride abstraction occurred specifically at the methyl group (primary H > secondary H > tertiary H—kinetic product control).

$$H_3C{-}NR_2 + (C_6H_5)_3C^{\oplus}X^{\ominus} \rightarrow H_2C{=}\overset{\oplus}{N}R_2X^{\ominus} + (C_6H_5)_3CH$$

(1). IR: $\gamma_{C=N} = 1668$—1675; $\gamma_{CH_2} = 3140$—3155 cm^{-1}; NMR (δ, TMS): $CH_2 = 8.1$—8.3 ppm; J_{CH_2} (gem) = 7.2—7.6 Hz; $J_{^{13}C-H} = 186.2$ Hz.

Hydride abstraction from the methyl group of the tertiary amine can be regarded as a functionalization of this methyl group. Methyleneimmonium salts can be utilized preparatively for degradation and synthetic reactions: degradation takes place with water to give the secondary amine (demethylation), with acetate in acetic anhydride to give the acetylated secondary amine; reaction with Grignard reagents converts the methyl group into a larger ligand and Mannich bases are formed with C—H acidic compounds.

Investigations in connection with the Polonovski reaction confirmed the mechanism discussed by *Huisgen, Bayerlein,* and *Heydkamp*[2, 3].

Reduction of methyleneimmonium salts with formic acid (Leuckart-Wallach reaction) affords the tertiary amine in a yield exceeding 90%. Kinetic studies show that the reaction in formic acid (reagent and solvent) is of pseudo-first order. The kinetic isotope effect of this reaction is $k_H/k_D = 2.12$ for *N*-mesityl-*N*-methylmethyleneimmonium perchlorate *(1a)*. The activation parameters are $\Delta H^{\neq} = 21.8$ kcal/mol and $\Delta S^{\neq} = -23$ cal mol^{-1} deg^{-1}. The reaction is accelerated by addition of base. *N*-Mesityl-*N*-methylaminomethyl acetate reacts with formic acid some 5×10^4 times faster than *(1a)* under the same reaction conditions (substrate base catalysis).

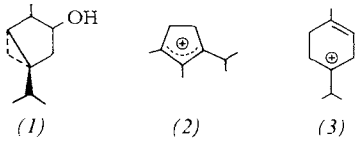
Evolution and biosynthesis of terpenoid pheromones and hormones are reviewed by *H. Z. Levinson*. The biosynthesis of terpenoid compounds was possible at a very early stage, according to inclusion material found in samples of Sudanese shale estimated as 2.5×10^9 years old. It is conceivable that isoprenoids assumed functions as pheromones and hormones after the transition from the abiogenic to the biochemical era. Terpenes and steroids act, *e.g.*, as pheromones in fungi, as hormones in higher plants, and as both in arthropods. The biosynthesis of terpenoid compounds that fulfil functions in communication, coordination, growth, and reproduction proceeds in a highly economic fashion. The same enzymatic steps frequently reoccur in numerous species at different levels of phylogenetic development. [Zur Evolution und Biosynthese der terpenoiden Phermone und Hormone. Naturwissenschaften 59, 477—484 (1972); 126 references]

[Rd 609 1E—M]

The mechanism of the oxo reaction is the subject of a report by *M. Orchin* and *W. Rupilius*. Although more that 2.5 million tons of alcohols are produced annually by the oxo process (also called hydroformylation), many details of the reaction mechanism are still unclear. The authors have therefore described the state of knowledge, and of speculation, as witnessed by the literature published up to 1971. [On the Mechanism of the Oxo Reaction. Catal. Rev. 6, 85—131 (1972); 79 references]

[Rd 566 1E—G]

A review of the chemistry of thujane derivatives from 1947 to 1972 is authored by *D. Whittaker* and *D. V. Banthorpe*. The absolute configurations and the conformations were determined by spectroscopy. Most of the thujane derivatives [four epimers of *(1)*] are obtained from the naturally



(1) *(2)* *(3)*

occurring thujanones by hydroboration and reduction. On oxidation the thujane ring is opened or modified, *e.g.* aromatized, or O functions are introduced. In concentrated

H_2SO_4 the four epimeric thujyl tosylates give solutions exhibiting the same NMR and UV spectra, which are assigned to the ion *(2)*. The biogenesis of thujanes could proceed *via* the ion *(3)*. [The Chemistry of Thujane Derivatives. Chem. Rev. *72*, 305—313 (1972); 115 references]

[Rd 615 IE—M]

Adsorption and catalysis on evaporated alloy films is the title of a comprehensive review by *R. L. Moss* and *L. Whalley*. The copper/nickel system has been most frequently studied, while a much lower number of publications is concerned with the palladium/gold, -/silver, and -/rhodium systems. The original authors' views are given for each reaction and alloy and described together with the reviewers' comments. [Adsorption and Catalysis on Evaporated Alloy Films. Advan. Catal. *22*, 115—189 (1972); 165 references]

[Rd 576 IE—G]

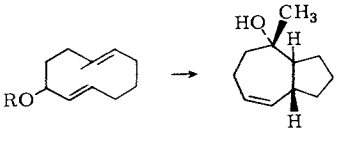
Synthetic applications of cyclopropene cycloadditions are discussed by *M. L. Deem*. Such cycloadditions permit the incorporation of allyl, cyclopropyl, oxopropenyl, and oxocyclopropanyl groups, or their elimination or hydrogenation fragments, into five- and six-membered carbo- and heterocyclic systems. Suitable reagents include cyclopropene, cyclopropenone, cyclopropenethione, and substituted cyclopropeneimides, as well as substituted calicenes and other triafulvenes. [Cyclopropenes as Reagents for Synthesis. Cycloaddition Reaction with Cyclopropenes. Synthesis *1972*, 675—619; 128 references]

[Rd 606 IE—M]

The relationships between the chemical structure of phospholipids and biomembranes is the topic of an article by *L. L. M. van Deenen*. The combination of lipophilic and hydrophilic regions in the one molecule renders phospholipids ideal building blocks for biological interfaces and, in keeping with present-day concepts, crucial for the formation of all biomembranes. The study of phospholipids in artificial membrane systems shows that simple diffusion of nonelectrolytes and the effectiveness of carrier-induced transport processes depend on the lipid parameters. These observations have been confirmed with natural membranes. [Phospholipide. Beziehungen zwischen ihrer chemischen Struktur und Biomembranen. Naturwissenschaften *59*, 485—491 (1972); 39 references]

[Rd 608 IE—M]

Progress in the synthesis of hydroazulenes (completely or partially hydrogenated azulenes) that are of interest, *inter alia*, as perfumes and potential pharmaceuticals, is reported by *J. A. Marshall*. Stereoselective syntheses are possible 1) by rearrangement of bicyclic compounds having cyclohexane rings, 2) by cleavage of tricyclic compounds, and



(1), R = p-O_2N-C_6H_4-CO

3) by cyclization of olefins such as *(1)*. [Progress in Hydroazulene Synthesis. Synthesis *1972*, 517—525; 38 references]

[Rd 611 IE—M]

The theory of electronic transitions between states of different total spin is outlined by *L. L. Lohr jr.* There are essentially two mechanisms by which these forbidden transitions can gain intensity: in isolated species (in gases, dilute solutions, and with low concentrations of the transition metal ion in a nonabsorbing solid) by spin-orbit coupling; in bi- or polynuclear complexes or with higher concentrations of absorbing ions in solids by exchange interaction between neighboring ions. This interaction manifests itself by a breakdown of Beer's law and sometimes by the occurrence of electronic overtone and combination bands caused by simultaneous electronic transitions in two like or different ions. [Spin-Forbidden Electronic Excitations in Transition Metal Complexes. Coord. Chem. Rev. *8*, 241—259 (1972); 74 references]

[Rd 630 IE—H]

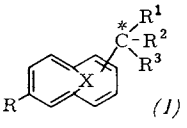
A survey of the coordination chemistry of trivalent iron is given by *S. A. Cotton*. It begins with an account of the physical methods relevant for the elucidation of iron(III) complex structures. The complexes that can be isolated in the solid state are then described in the order of the donor atoms. A table with the known X-ray structures of iron(III) complexes (about 30) completes the review. [Some Aspects of the Coordination Chemistry of Iron(III). Coord. Chem. Rev. *8*, 185—223 (1972); 263 references]

[Rd 631 IE—H]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

2- or 3-Substituted 1,6-bridged cyclodecapentaenes *(1)* are chemotherapeutically active compounds. Depending on the nature of the substituents, the compounds *(1)* exhibit



(1)

R = H, alkyl, cycloalkyl, alkoxy, carbocyclic acyloxy; R^1, R^2 = H, alkyl; $R^1 + R^2 = >CH_2$; $R^1 + R^2 + C^* =$ cycloalkyl; R^3 = CHO, CH_2OH, or hydrolyzable esters or ethers as precursors thereof, COOH, COOalkyl, COOalkali metal, $CONH_2$, $CON(alkyl)_2$; X = CH_2, CCl_2, CF_2

anti-inflammatory, analgesic, and antipyretic activity, or serum cholesterol-depressing and fibrinolytic activity. The cyclodecapentaenes *(1)* can be prepared by several methods, which are discussed in detail. The organic groups mentioned all contain only a few C atoms. [DOS 2051012; Syntex Corp., Panama]

[PR 89 IE—N]

Degradable manufactured articles, particularly films, whose decomposition rate depends on exposure to sunshine and on the temperature, consist of polymers having at least 50 wt.% of 1-butene units and contain 0.001 to 30 wt.% of stabilizers, the quantity of the latter being such that the

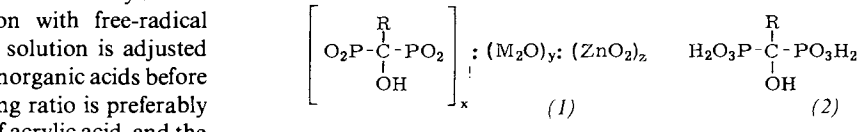
stability is 5000 to 70000 temperature-corrected Langley units. The polymer may in particular be poly-(1-butene) having a molecular weight of 10000 to 3000000, preferably 40000 to 1500000, which should have an isotacticity of more than 70%. Conventional stabilizers are used. The stability of the products is adjusted to suit the prevailing climatic conditions and the particular application intended. For example, it is possible to produce agricultural covering films that decompose at the conclusion of the growth period of the plants in question, with the result that their mechanical removal before the ground is used again is no longer necessary. [DOS 2158379; Princeton Chemical Research Inc., Princeton, N.J.]

[PR 68 IE—S]

Thermally reversible coacervates, *i.e.* polymer solutions that reversibly undergo phase separation with formation of polymer-rich aqueous phases at certain temperatures, are obtained when mixtures of acrylamide and acrylic acid are polymerized in aqueous solution with free-radical catalysts and the pH of the polymer solution is adjusted to values below 3.3 by the addition of inorganic acids before or after the polymerization. The mixing ratio is preferably 50 mol-% of acrylamide to 50 mol-% of acrylic acid, and the total concentration should be between 5 and 15 wt.%. Examples of inorganic acids mentioned are sulfuric acid and hydrochloric acid. The more acidic the solution, the higher is the temperature at which the coacervate is formed, *e.g.* 30 °C at pH 3.0 and 40 °C at pH 1.5. There is also a dependence on the molecular weight of the polymer. The synthetic coacervates can be used in the same way as gelatin-gum arabic coacervates *e.g.* for the production of coatings, microcapsules, *etc.* If cooled objects are immersed in a coacervate solution above the transition temperature, the coacervate is deposited on these objects in the form of a coating. [DOS 2060571; Farbenfabriken Bayer AG, Leverkusen]

[PR 66 IE—S]

New vitreous compositions having the general formula *(1)* are excellent corrosion inhibitors in aqueous systems, particularly for iron and steel, and can also be used to combat boiler scale and as dispersing agents. The water-soluble materials *(1)* contain about 5 to 21 wt.% of zinc, and unlike the phosphates used in the past, they do not form undesirable deposits. The alkali metal- and/or ammonium-zinc "mixed glasses" have been prepared by evaporation of aqueous solutions obtained from zinc salts,



(1) *(2)*

R = alkyl ($C_1 - C_5$), phenyl, benzyl; M = alkali metal and/or NH_4; $x = 1$; $y = 1$ to 1.75; $z = 0.25$ to 1

α-hydroxy-1,1-diphosphonic acids *(2)*, and alkali metal and/or ammonium hydroxide with adjustment of the pH to specific values. [DOS 2151552; Calgon Corp., Pittsburgh, Pa.]

BOOK REVIEWS

Organic Reactions and Orbital Symmetry. By *T. L. Gilchrist* and *R. C. Storr*. Cambridge University Press, London 1972. 1st ed., viii, 271 pp., numerous figures bound £ 1.80.

This is an outstanding description of one-step reactions (also known as concerted, synchronous, or pericyclic reactions), which can be wholeheartedly recommended to the chemistry student. The theory and classification of such reactions developed by *Woodward* and *Hoffmann* was a revolutionary innovation in organic chemistry. The significance of this theory and the equivalence of all qualitative theoretical derivation concepts (orbital symmetry, HOMO/LUMO and aromatic transition state) are presented objectively and with many practical examples in typical Anglo-Saxon manner: clearly, concisely, and presupposing neither theoretical knowledge nor familiarity with the numerous reactions discussed. It is repeatedly stressed that while the Woodward-Hoffmann "rule" gives the steric course for "allowed" synchronous reactions, a reacting system naturally chooses the path having the lowest energy, which is often a multi-step process.

The fact that the terms "stereospecific" and "stereoselective" (*e.g.* pp. 13 and 154) are not used in accordance with the generally accepted definition (textbooks by *Eliel* and *Mislow*) and the selection of an awkward representation for the systems with odd numbers of p orbitals (allyl and pentadienyl, pp. 26, 113, and 208) are only minor faults.

After the classification of the reaction mechanisms and an introduction to the general theory of one-step reactions, the book contains chapters on electrocyclic transformations, cycloadditions and their reversal (thermal, photochemical, and metal-catalyzed) including pericyclic reactions, sigmatropic shifts, and substitution, addition, and elimination mechanisms. The authors cite relevant articles and reviews, extending up to 1971, for further reading in special fields.

Dieter Seebach [NB 135 IE]

Charge Transfer Interactions of Biomolecules. By *M. A. Slifkin*. Academic Press, London—New York 1971. 1st ed., xx, 271 pp., numerous figures and tables bound $ 16.50.

Even the scientific book market from time to time comes up with a curiosity, a case in point being the present volume, which opens after the model of Genesis 1 with

the lapidary sentence: "All molecules are built up from atoms". (Oh, quite so!). It is not surprising, therefore, that the hydrogen bond is referred to in the Foreword as a special case of "charge transfer complexing", and that by the time he reaches the end the reader must be convinced that Man, God, the world, the cancer problem, and Sigmund Freud are nothing but charge transfer complexes.

Since *Szent-György*'s "Introduction to Submolecular Biology", charge transfer complexes have indeed developed into a problem of bio-traumatology. Father *Mulliken* was wide of the mark with his sober but (like much that is sober) dull definition, and the spectrum of phenomena covered by it extends to "charge transfer complex without charge transfer". The author appeals to predecessors in the field (*R. Foster:* "Organic Charge Transfer Complexes", London 1969), who evidently regard all weak chemical interactions as charge transfers, since this has become accepted in the literature (p. 10).

Once his wide field has been marked off in this way, the author ploughs on heroically. On p. 47 we learn that water is "the obvious solvent" for biochemicals, since it is both very transparent and very cheap. On p. 55 the last veil drops: there are now also charge transfer complexes that are formed only very slowly, *e.g.* from α-amino acids and chloranil. The author makes generous references to his own research data here, and has apparently taken no great pains to rule out the possibility of a slow chloranil-catalyzed autoxidation.

The charge-transfer idea then becomes a total farce *e.g.* in connection with complexes of the same amino acids and riboflavin. The author is fair enough to admit that doubt was cast on his interpretation as early as 1965 by *Kosower*, who very reasonably interprets the association of amino acids and flavin "as due to hydrophobic bonding of the amino acids to the flavin, the spectral changes being simply perturbation effects."

Whether true charge transfer effects as defined by *Mulliken* are biologically relevant remains to be established, probable as it may be in certain cases of biological signal transmission. Further knowledge on this point will be obtainable only through extremely sharp physicochemical differentiation. The present book merely thickens the mist over this landscape.

Structure and Function of Nucleosides and Nucleotides[1]

By Wolfram Saenger[*]

The nucleosides participating in biological processes consist of a sugar and a heterocyclic nucleobase; the nucleotides, which occur as monomers and as building units of polymeric nucleic acids, contain an additional phosphoester group. The complexity of the molecules leads to a complex stereochemistry with which the present progress report is concerned. Particular attention will be devoted to conformational considerations at the sugar groups, the *syn-anti* conformation, the position of the C(5′)—O(5′) bond relative to the sugar group, and the conformation of the phosphoester bonds. The article touches upon base pairing and base stacking, as well as forces stabilizing the *syn* conformation, and also deals with the reaction mechanism of the enzyme pancreatic ribonuclease as established from the stereochemistry of nucleotides and the mechanisms of action of the antileukemia drug 6-azauridine and the antibiotic actinomycin D. Views on the effects of the unusual structures of the "rare" nucleosides 4-thiouridine, isopentenyladenosine, and dihydrouridine on the structure of transfer ribonucleic acid are also presented.

1. Introduction

Biological processes are determined at a molecular level by amino acids and nucleosides. The nucleosides are made up of a sugar group to which a heterocyclic nucleobase is bound by a β-*N*-glycosidic linkage (Fig. 1). The sugar group in the ribonucleosides is a D-ribose, and that in the deoxyribonucleosides is a D-*erythro*-D-pentose (2′-deoxy-D-ribose). The nucleobases, the actual active groups of the nucleosides, are amino- and hydroxyl-substituted purine and pyrimidine derivatives: adenine (A); guanine (G); cytosine (C); uracil (U); thymine (T). The corresponding ribonucleosides are designated adenosine (rA), guanosine (rG), cytidine (rC), uridine (rU), and deoxyribonucleosides by the prefix deoxy- and the abbreviations dA, dG, dC, dT[2]. The nucleotides (adenylic, guanylic, cytidylic, uridylic, thymidylic acids) contain an additional phosphoester group at the 3′- or 5′-hydroxyl function of the sugar group. Moreover, cyclic intramolecular 3′,5′- or 2′,3′-phosphodiesters also exist (Fig. 1).

In the biopolymers deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) the nucleotides are linked *via* internucleotide 3′,5′-phosphodiester bonds; their sequence contains the biological information. Depending on their particular biological function, both kinds of nucleic acids can exist as a single strand (coil) or as double-stranded complexes with a right-handed helical structure. In these complexes two nucleic acid chains are invariably arranged in an antiparallel fashion such that strictly complementary bonding occurs between opposite nucleobases A and U(T), and G and C, *via* specific hydrogen bonds[3]. This base pairing assists in stabilizing the structure of the double-stranded nucleic acids and is essential for biological information transfer from nucleic acid to nucleic acid and from

[*] Priv.-Doz. Dr.-Ing. W. Saenger
Max-Planck-Institut für experimentelle Medizin,
Abteilung Chemie
34 Göttingen, Hermann-Rein-Strasse 3 (Germany)

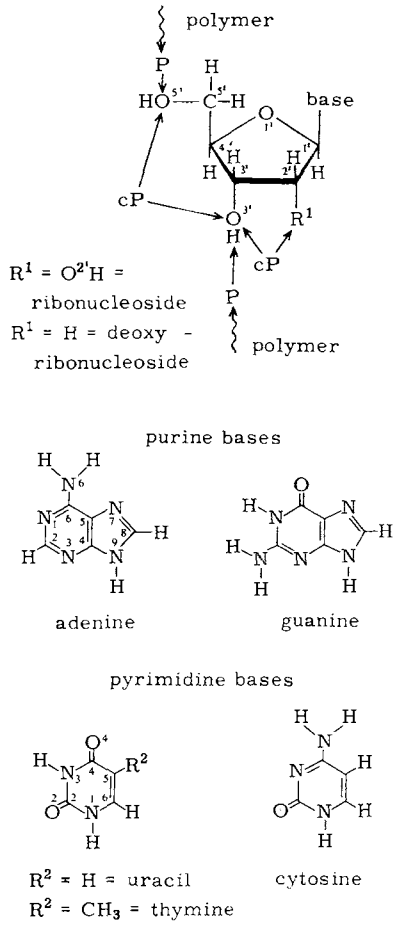

Fig. 1. Chemical structure and nomenclature of nucleosides and nucleotides. "cP" and "polymer" refer to the hydroxyl groups of the sugar group involved in the formation of cyclic phosphodiesters and 3',5'-internucleotide bonds (in the polymeric nucleic acids). Relevant examples may be found in Figs. 11–13. Uridine is present in ribonucleosides, and thymidine in deoxyribonucleosides.

nucleic acid to protein (protein biosynthesis) in which an information-carrying nucleic acid is read off as a template[4–6].

However, nucleotides participate in biological processes not only as components of nucleic acids but also as monomers in the form of "high-energy" nucleoside 5'-triphosphates as energy donors, as substrates of various enzymes, and as components of numerous coenzymes[4–6]. Naturally occurring modified nucleosides and nucleoside phosphates also play an important role as antibiotics[7], and synthetic nucleosides and their 3'- or 5'-phosphoesters are employed as drugs and for the study of molecular biological reactions. This clearly illustrates the intimate connection between the molecular structure and the biological function of a nucleotide.

The structure of a nucleotide or nucleoside is described by:

1. the conformation of the sugar group and the phosphoester bond;

2. the conformation at the glycosidic linkage, *i.e.* the position of the base relative to the sugar group;

3. atomic bonding distances and angles within a molecule;

4. intermolecular interactions, especially hydrogen bonding (base pairing) and base stacking.

These parameters can be determined by various methods providing data of greater or lesser general validity. Results of X-ray structural analyses constitute the main substance of this paper since they provide the most comprehensive and unequivocal information.

2. General Features of X-Ray Structural Analysis and the Structural Parameters of Molecules; Dihedral Angles

In structural analysis by X-ray diffraction a crystal of the substance under study is irradiated with monochromatic X-rays and the radiation diffracted by the crystal lattice is registered on photographic film, or even better by scintillation counters[8,9]. The symmetry of the reflection pattern and the distances between the reflections afford the crystallographic space groups ("symmetries") and the dimensions of the unit cell, while the intensities and relevant phase angles yield the positional coordinates of the individual atoms in the asymmetric system of the unit cell. Owing to the favorable experimental data/parameter ratio of between six and ten for each three coordinates and six atomic vibrational parameters of the atoms the coordinates of all the atoms except the protons can be determined to within an accuracy of about 0.003 Å[*]. Thus atomic bonding distances and angles, which generally lie in the range of 1.2 to 2.0 Å and 90 to 130°, respectively, can be given with standard deviations of *ca.* 0.005 Å and 0.4°[10].

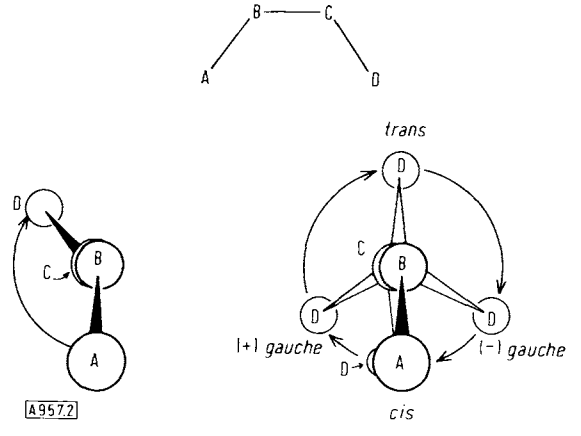

Fig. 2. Definition of the dihedral angles and the *cis*, *trans*, *gauche* regions.

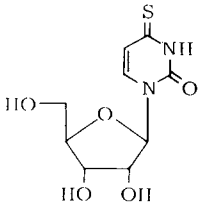
Dihedral (torsional) angles are employed in describing the conformation of a molecule[11]. In the atomic group A—B—C—D (Fig. 2) these angles denote the angle between the bonds A—B and C—D looking along the B—C bond (*i.e* with C behind B). The dihedral angle A—B—C—D is zero when A—B and C—D are *cis*-planar to each other, and is regarded as positive when C—D is twisted clockwise relative to A—B.

A dihedral angle is designated *cis* or *trans* when the angle is approximately 0 or 180° and as (+) *gauche* or (−) *gauche* when the angle is about +60 or −60°.

[*] For technical reasons the positions of the protons of an organic molecule can only be given with a tenfold lower accuracy than those of the other atoms.

On crystallization of a substance, intermolecular forces such as van der Waals forces, dipole forces, ionic and hydrogen bonding forces become operative[4, 12] which are almost completely absent in solution or in the gaseous state at suitable dilutions. X-Ray structure analyses revealed that these intermolecular forces affect the bonding distances hardly at all, and the bonding angles but slightly; however, they have a considerable effect on the dihedral angles. It thus follows that molecules often crystallize in a form other than that of minimum energy and that conformational studies by X-ray structural analysis only give unequivocal results when a series of similar compounds is analyzed.

This is precisely the case for nucleosides and nucleoside phosphates; perusal of the available data provides an insight into energy minima, rotational barriers, and rare conformations, and into the formation of hydrogen bonds and the packing of the molecules in the crystal lattice. Figure 3 illustrates the crystal structure of 4-thiouridine as the result of a typical X-ray structure analysis[13]. The



4-thiouridine

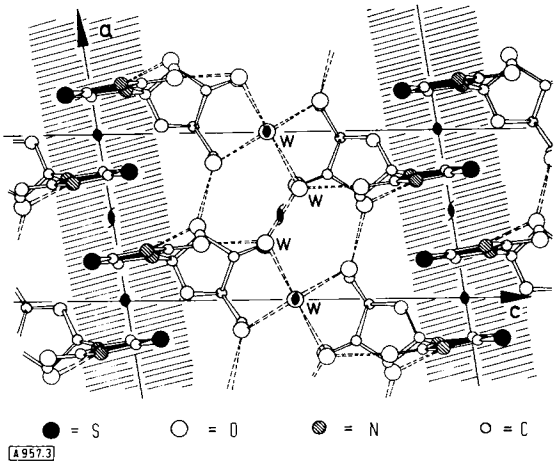


Fig. 3. Crystal structure of 4-thiouridine (projection along the *b* axis, space group monoclinic, C 2). Hydrogen bonds are shown as dashed lines and regions of hydrophobic character are emphasized by hatching. The 4-thiouracil rings are almost perpendicular to the plane of the paper and the molecules of water of hydration are labeled W.

structure is viewed along the crystallographic *b* axis. The planes of the 4-thiouracil groups are almost perpendicular to the plane of the paper and are arranged parallel to one another in a ribbon of hydrophobic character. An arrangement parallel to the plane of the paper is assumed by the ribose groups, together with included water of hydration; these groups form a band of predominantly hydrophilic nature which is stabilized and characterized by numerous hydrogen bonds.

3. Structure of Nucleosides and Nucleotides

3.1. Geometry of the Bases

Figure 4 shows the bond lengths and bond angles in the most important planar nucleobases[14]. The preponderance of double and single bond character respectively is apparent from the interatomic distances in the carbonyl and amino groups[12]; no tautomeric forms other than those shown in Figure 4 have been found in the crystal structure of the nucleosides although other forms have been predicted theoretically[15] and detected experimentally[16].

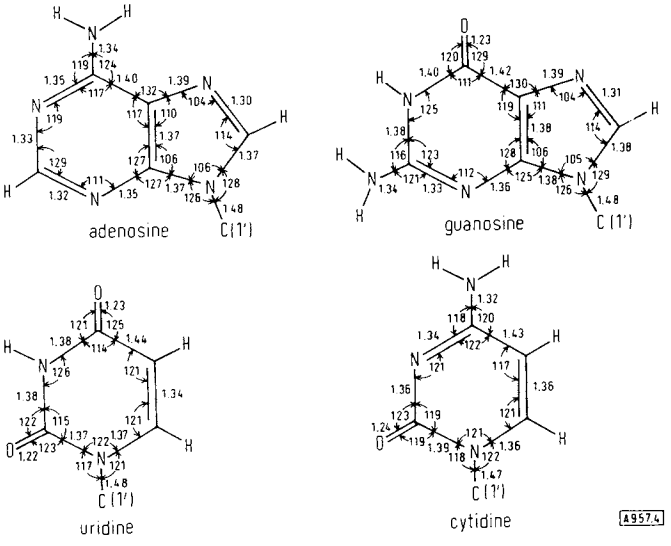

Fig. 4. Atomic bonding distances [Å] and angles [ ] in nucleosides (rounded off values from ref. [14]). Standard deviations 0.01 Å and 1°. Only C(1') of the ribosyl group is shown.

X-Ray structure analyses indicate that adenosine is protonated at N(1), guanosine at N(7), cytidine at N(3), and uridine at O(4)[14]. Protonation slightly modifies the geometry of the bases: the bond lengths change in accord with the new resonance structures and the bond angles at the protonated nitrogens are widened by about 5°[17–19].

3.2. Geometry of the Sugar Group

Figure 5 shows the average geometric data established for the sugar group. The atomic bonding distances and angles differ slightly but significantly depending on the nature and conformation of the sugar rings; however, we shall not go into these differences here.

Generally speaking, the C(4')—O(1') bond is longer than the O(1')—C(1') bond, an observation explainable in terms of the differing substitution at C(4') and C(1'). All the other bond lengths and angles lie in the "normal" range[10], although individual differences do occur.

Like the atoms of other five-membered rings, the five atoms of the ribose or deoxyribose rings are arranged in an envelope or half-chair conformation. Substituent effects lead to preference of those conformations in which the

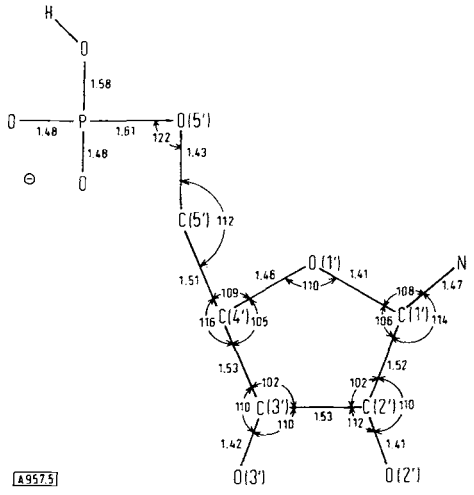

Fig. 5. Atomic bonding distances [Å] and angles [°] in nucleotides (averages values). Only the nitrogen atom on C(1') of the bases is shown.

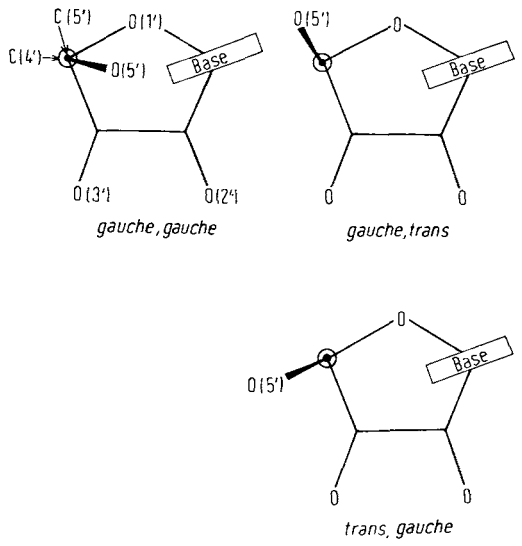

atoms C(2') and C(3') are displaced by about 0.5 Å from the plane through the other atoms C(4')—O(1')—C(1'). Atoms lying on the same side of this plane as C(5') are designated *endo* and those on the other side *exo*[20]. The envelope and half-chair conformations observed in riboses and deoxyriboses are illustrated in Figure 6.

The envelope conformations C(2')-*endo* and C(3')-*endo* are encountered equally commonly; C(3')-*exo* has only been observed in three deoxyribonucleosides, and C(2')-*exo* not at all[21,22]. The transition between corresponding half-chair and envelope conformations occurs readily in the horizontal direction of Figure 6 but is subject to energy barriers in the vertical direction. The most unambiguous conformational description is provided by the endocyclic dihedral angles which lie in the range given in Figure 8.

The C(5')—O(5') bond can rotate relative to the sugar ring, assuming three possible conformations, designated *gauche, gauche*, *gauche, trans*, or *trans, gauche* depending upon whether the angles φ_{OO}, O(5')—C(5')—C(4')—O(1'), and φ_{OC}, O(5')—C(5')—C(4')—C(3'), lie close to $-60°$, $+60°$, to $+60°$, 180°, or to 180°, $-60°$[23] (Fig. 7).

Energy calculations predict approximately equal contributions from the three conformations[24]. However, crystallographic and spectroscopic data indicate an overwhelming preference for the *gauche, gauche* conformation

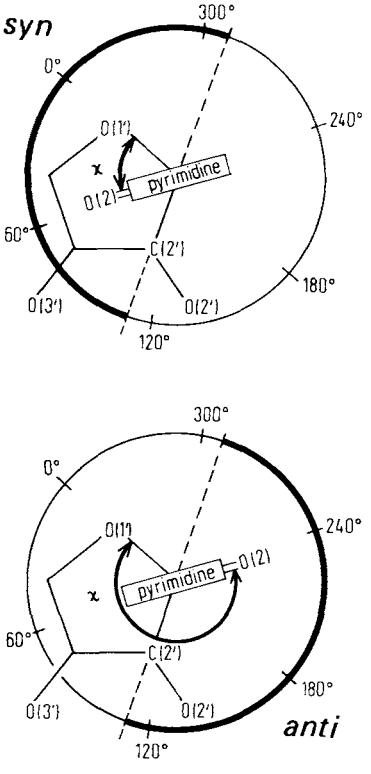

Fig. 7. Conformations at the C(4')—C(5') and C(1')—N bonds. See text for definition of the angle χ.

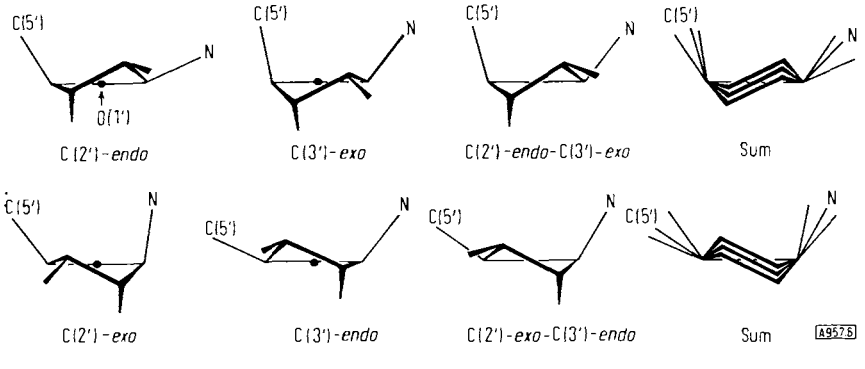

Fig. 6. Representation of the various sugar conformations. Depending on the conformation of the sugar the relative positions of the atoms C(5') and N(1) of the nucleobase can vary by up to about 0.5 Å.

over the other two[25]; an interpretation could lie in the exclusive ability of this conformation to engage in intramolecular C(6)—H ··· O(5') and C(8)—H ··· O(5') hydrogen bonding between the O(5') atom and the pyrimidine and purine base respectively[26].

3.3. Conformation about the Glycosidic C(1')—N Bond

Rotation of the base around the glycosidic bond relative to the sugar group is not free but subject to steric hindrance, primarily by the *endo* proton at C(2')[25]. Thus the nucleosides and nucleoside phosphates can exist in two conformations, designated *syn* and *anti*, depending upon whether O(2) in pyrimidine nucleosides or N(3) in purine nucleosides lies above the plane of the sugar group or points away from it[27,13] (Fig. 7). The position of the base is given by the dihedral angle χ_{CN}, *i.e.* O(1')—C(1')—N(1)—C(2) in pyrimidine nucleosides and O(1')—C(1')—N(9)—C(4) in purine nucleosides[28]. The *syn* and *anti* conformations are defined by values of χ_{CN} between about 290 to 110° and 110 to 290° respectively.

3.4. Conformation of the Phosphoester Bonds

The conformation observed in monomeric phosphodiesters and mononucleotides and in double-stranded helical nucleic acids are summarized in Figure 8.

Apart from adopting the conformations of the helical nucleic acid structures in which the dihedral angles are determined by geometrical conditions (formation of the right-handed helix), monomeric nucleotides can also assume a whole variety of conformations[21,22]. The angles ϕ(O(5')—C(5')), $180\pm40°$, and ψ(C(5')—C(4')), $60\pm25°$, are exceptional in that they are limited to the values given in both nucleotides and polymeric nucleic acids, probably due to the (base) C—H ··· O(5') hydrogen bonding mentioned above which stabilizes these conformations[29]. Moreover, the angle ψ'(C(4')—C(3')) assumes two values, $80\pm10°$ and $150\pm20°$, arising from the C(3')-*endo* and C(2')-*endo* or C(3')-*exo* sugar conformations.

Generalizing, it may be said that the various conformations of the sugar phosphate skeleton in double-stranded nucleic acids of helical structure are due primarily to the mobility of the sugar group. In monomeric nucleotides and in single-stranded nucleic acids, however, the high degree of flexibility arises from the numerous possible conformational angles of the sugar moiety and the phosphoester bond.

4. Correlation between Structure and Function of Nucleosides and Nucleotides

The above structural parameters of nucleosides and their phosphates will now be interpreted with the aid of examples. Since we cannot possibly consider all the studies published hitherto[30], just a few results of a characteristic nature will be given which permit a correlation between structure and function.

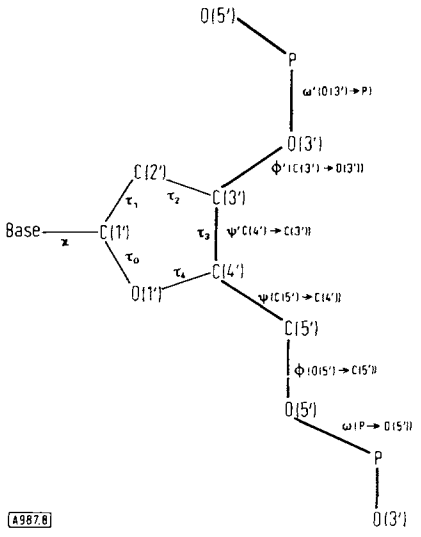

Fig. 8. Dihedral angles in nucleotides. The endocyclic angles describe the sugar conformation, and the angles ψ, ϕ, ω, ψ', ϕ', ω' the conformation of the sugar phosphate chain; *e.g.* ψ(C(5')—C(4')) denotes the angle O(5')—C(5')—C(4')—C(3'). M and M + P indicate whether the values of the angles apply only to the monomers (M) or also to polymeric helical nucleic acids (M + P).

angles in sugar group:

C(2')-*endo* and C(3')-*exo*	$\tau_1, \tau_3 = 30\pm10°$ $\tau_0, \tau_2 = 330\pm10°$ $\tau_4 = 0\pm10°$	
C(3')-*endo*	$\tau_1, \tau_3 = 330\pm10°$ $\tau_2, \tau_4 = 30\pm10°$ $\tau_0 = 0\pm10°$	

angles in sugar phosphate chain:

ω(P—O(5'))	$290\pm20°$ $70\pm10°$	P + M M

4.1. Base Pairing

The regular structure of double stranded helical DNA and RNA is a consequence of coplanar coupling between the nucleobases A and U(T) and of G and C *via* specific N—H ··· O and N—H ··· N hydrogen bonds of the Watson-Crick type[3] (Figs. 9a and 9b). Stacked one above another these base pairs form the (hydrophobic) nucleus of the helix around which the (hydrophilic) sugar phosphate chain is wound in a right-handed fashion. The most striking feature of the Watson-Crick base pairs is that they are mutually isomorphous and that the glycosidic linkages,

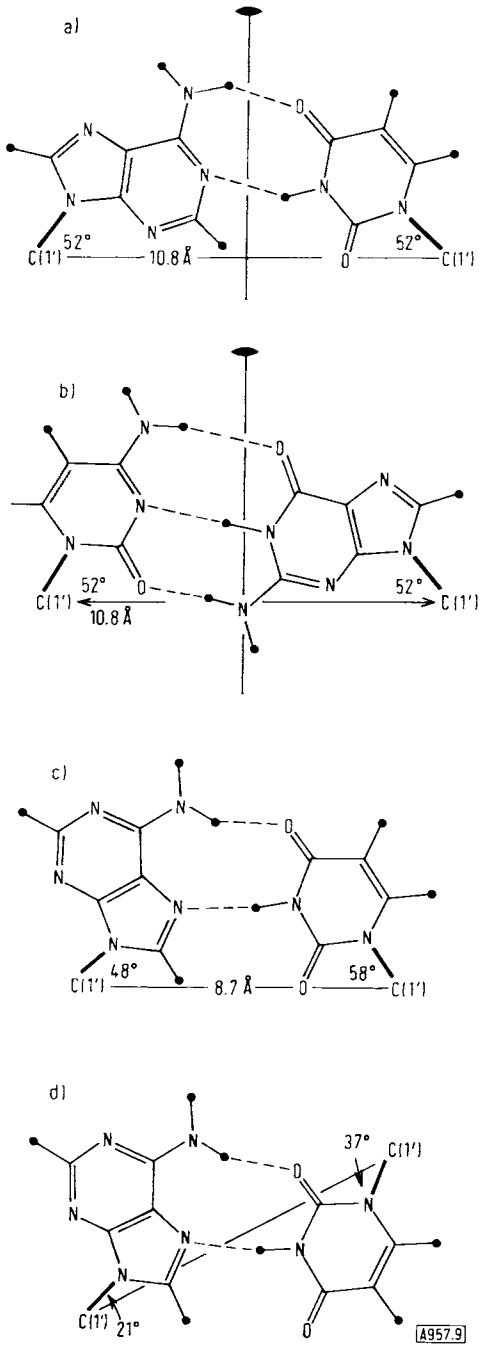

Fig. 9. Structure of the isomorphous a) A:U(T) and b) G:C base pairs according to *Watson* and *Crick*, and c) of the A:U(T) base pair according to *Hoogsteen* and d) the "inverse" Hoogsteen pair. The twofold axes relating the glycosidic bonds are shown in 9a and 9b. The N—H ··· N or N—H ··· O hydrogen bonds are about 2.9 Å long.

and thus the attached sugar phosphate chain, can be superimposed on rotation around twofold axes.

No less than 24 other pairing schemes between monomeric nucleosides are also conceivable in addition to the base pairs of the kinds illustrated in Figure 9[39], but only few have so far been found experimentally. Spectroscopic measurements[40,41] on nucleoside analogs in aprotic solvents indicated that not only heterologous base pairs (between different bases) but also homologous base pairs (between identical bases) can be formed. However, the heterologous A:U(T) and G:C complexes are more stable than all other conceivable hetero- or homologous base combinations by a factor of at least ten.

Co-crystallization of equimolar amounts of guanosine and cytidine derivatives always gives complexes with Watson-Crick base pairing, whereas complexes of adenosine and uridine (thymidine) derivatives have so far only been found to exhibit Hoogsteen base pairing (Figs. 9c and 9d)[42,14]. This finding would suggest that the Watson-Crick type A:U(T) base pairs, unlike the G:C base pairs, are not preferred energetically in helical RNA and DNA but result from steric contraints of the sugar phosphate chain.

4.2. Base Stacking

The nucleobases are of predominately aromatic hydrophobic character and tend to adopt a stacking arrangement in a hydrophilic environment and on crystallization. Parallel aromatic planes are separated by the expected van der Waals distance of 3.4 Å.

Base stacking is stabilized mainly by interaction between the dipoles of the amino or carbonyl groups and the neighboring π-electron systems[43] and by van der Waals forces[44].

The stacking properties of thio- and halo-substituted nucleobases are particularly pronounced[43]. As shown in the series of analogs 4-thiouridine[13], 2,4-dithiouridine[45], *arabino*-4-thiouridine[37], 3'-acetyl-4-thiothymidine[46], and co-crystalline 9-methyladenine:1-methyl-4-thiouracil[47], hydrogen bonding in nucleoside derivatives is determined by packing forces whereas a heterologous "inverse" Hoogsteen base pairing is present in the co-crystalline system (Fig. 9d). Since base pairs of the types shown in Figure 9 are generally found in co-crystalline samples whereas pure crystalline nucleosides do not exhibit any kind of uniform hydrogen bonds it can be assumed that the formation of heterologous base pairs dominates over packing forces but that the formation of homologous base pairs competes unsuccessfully[48].

The principal effect of base stacking on the stability of the structure of a helical nucleic acid complex becomes apparent on comparison of the properties of the homologous polymers polyuridylic acid [poly(uridine 5'-phosphate)], poly-U, and the 2-thio analog, poly-s^2U, in which uracil is replaced by 2-thiouracil. At low temperature, poly-U exhibits a double helical structure which "melts" to a single-stranded, coiled structure above 8°C; it can therefore form a complex with polyadenylic acid and function as a template in protein biosynthesis. In contrast, poly-s^2U forms a double-stranded helical complex with itself which is stable up to 68.5°C; this complex formation is favored to such a degree that poly-s^2U does not complex with poly-A and cannot be used in protein biosynthesis[49]. X-Ray diffraction studies on fiber samples of this material[50] have shown that its structure closely resembles that of A-DNA[51]. The nucleic acid strands adopt an antiparallel arrangement, thus leading to the base pair structure illustrated in Figure 10 with NH ··· S and NH ··· O hydrogen bonds.

The stability of the poly-s^2U helix cannot be due to the relatively weak N—H ··· S hydrogen bonding but must

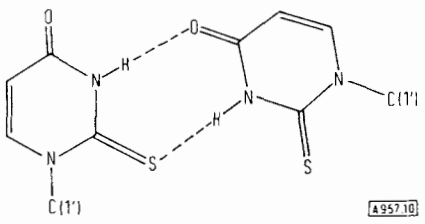

Fig. 10. Base pair in homopolymeric double-stranded helical poly-2-thiouridylic acid, poly-s^2U.

arise from stacking of the 2-thiouracil rings above one another with characteristic S(2)···N(1) interaction operating between neighboring nucleobases, similar to that found in the crystal structures of monomeric thiopyrimidine nucleoside derivatives[48]. Two effects tend to stabilize the helix: the readily polarizable thiocarbonyl groups can interact with the π-electron systems of adjacent 2-thiouracil groups, and in addition the relatively hydrophobic 2-thiouracil groups associate on helix formation in a hydrophobic linear region which is separated from the exterior medium, water, by the ribose phosphate chain[48].

4.3. Factors Determining the Conformation at the Glycosidic C(1′)—N Bond

NMR studies have shown that in solution nucleosides exist in a *syn-anti* equilibrium which lies almost exclusively on the side of the *anti* conformation in pyrimidine nucleosides but only predominately so in purine nucleosides[52,53]. The *syn* conformation can be forced by two kinds of effects: *inter*- and *intra*molecular forces.

4.3.1. *Inter*molecular Forces

On attachment of a nucleoside to a surface, whether to the active site of an enzyme, on incorporation into a double-stranded helical structure, or on crystallization, it has to adopt either the *syn* or the *anti* conformation. Which it actually adopts under these conditions cannot be predicted since intermolecular interactions such as hydrogen bonding forces, stacking effects, and general packing can play a crucial role.

As examples we can cite the purine nucleosides 3′-*O*-acetyladenosine[54], 6-thioinosine[55], 5′-deoxy-5′-methylammoniumadenosine[56], 2′-deoxyguanosine[57], formycin-HBr[58], adenosine 3′,5′-cyclophosphate[34], guanosine[59], inosine[59], and the pyrimidine derivatives 4-thiouridine[13], 2′-deoxy-2′-fluorouridine 3′,5′-diacetate[60], cytidine 2′,3′-cyclophosphate[35] obtained as crystals in the *syn* conformation. These purine nucleosides were all found to contain an *intra*molecular O(5′)—H···N(3) hydrogen bond providing additional stabilization for the *syn* conformation; 4-thiouridine however did not exhibit a potential *intra*molecular O(5′)—H···O(2) bond. On dissolution of this nucleoside, *syn-anti* equilibration occurs; as with all the other pyrimidine nucleosides, the equilibrium lies mainly on the *anti* side[61].

4.3.2. *Intra*molecular Forces

*Intra*molecular interactions can even stabilize the *syn* conformation in solution, as demonstrated by the nucleosides 8-bromoadenosine and 8-bromoguanosine[62] bearing a substituent adjacent to the glycosidic bond on the base component, and by N^1-β-D-ribosyl-6,7-dimethyllumazine[63], 6-methyluridine[64], and orotidine[53]. These molecules exist solely in the *syn* conformation since there is no room for the bulky substituents "above" the sugar ring.

However, these nucleosides thereby acquire an interesting property: their 5′-triphosphates cannot act as substrates for nucleotide polymerases[65,66]. This also means that the substrates for polymerases must be present in the *anti* conformation to be recognized by the active site so that reaction can ensue.

4.4. Mechanism of Action of the Enzyme Pancreatic Ribonuclease A

Pancreatic ribonuclease A specifically cleaves ribonucleic acids in such a manner that an intermediate pyrimidine 2′,3′-cyclophosphate is formed by transesterification. This cyclophosphate is further hydrolyzed to the 3′-phosphate. Both processes are reversible (Fig. 11).

Essentially two mechanisms have hitherto been discussed for the reaction of the pyrimidine 2′,3′-cyclophosphate with a nucleophile[67]: On the one hand the nucleophile can

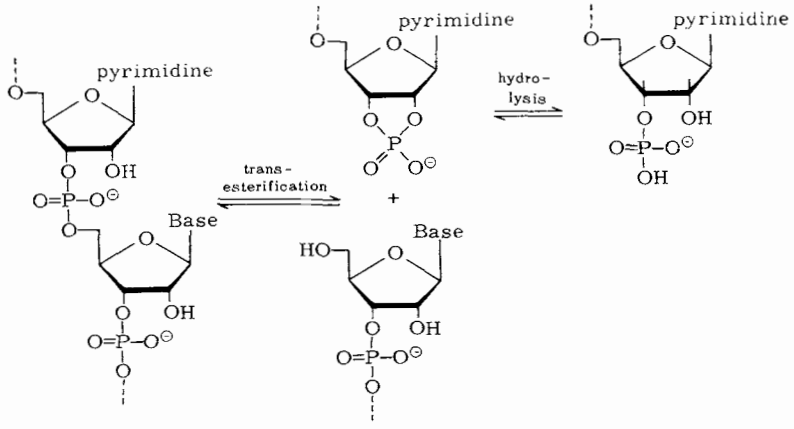

Fig. 11. Action mechanism of the enzyme pancreatic ribonuclease A.

attack the phosphorus atom on the side opposite the O(2') ester atom (in-line attack S_N2 mechanism), and on the other hand it can enter the vicinity of the O(2') atom (adjacent mechanism, the pyrimidine nucleoside 3'-phosphate arising *via* formation of an intermediate containing a pentacovalent phosphorus atom followed by pseudorotation of the five ligands).

4.5. Mechanism of Action of the Antileukemia Drug 6-Azauridine

6-Azauridine is an effective agent for the treatment of leukemia[7, 69]. Uridine kinase converts it *in vivo* into 6-azauridylic acid which inhibits the decarboxylation of orotidylic to uridylic acid by the enzyme orotidylic acid decarboxylase. The *de novo* synthesis of uridylic acid, and furthermore the synthesis of fresh RNA, is thus blocked (Fig. 13). X-Ray structure analysis of 6-azauridine-5'-phosphoric acid trihydrate (6-azauridylic acid) showed that this molecule, unlike all the nucleoside 5'-phosphates studied so far[21, 22], adopts the *gauche, trans*[70], and not the *gauche, gauche* conformation, about C(4')—C(5'). This unusual conformation is stabilized by electrostatic repulsion between the negatively charged nitrogen N(6) (0.42 unit charge) and the ester oxygen O(5')[71]. Just a small chemical, isoelectric modification thus has considerable stereochemical consequences. The positions of the phosphate groups in

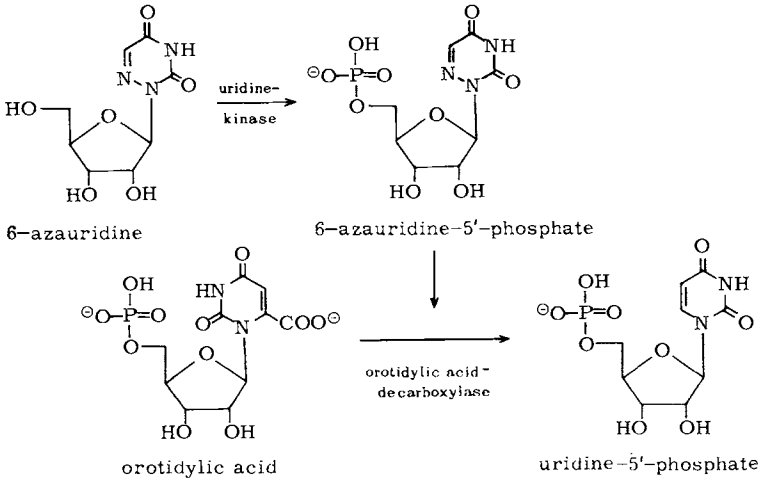

Fig. 13. Action mechanism of the antileukemia drug 6-azauridine.

In order to decide between the two mechanisms, the *endo* isomer of uridine 2',3'-cyclothiophosphate[18] was treated with pancreatic ribonuclease A in the presence of methanol as a nucleophile and the resulting methyl ester having an asymmetric phosphorus atom was isolated[68]. Thio-substituted uridine 2',3'-cyclophosphate had to be used in this experiment because the natural substrate cannot yield an asymmetric stereochemically defined reaction product.

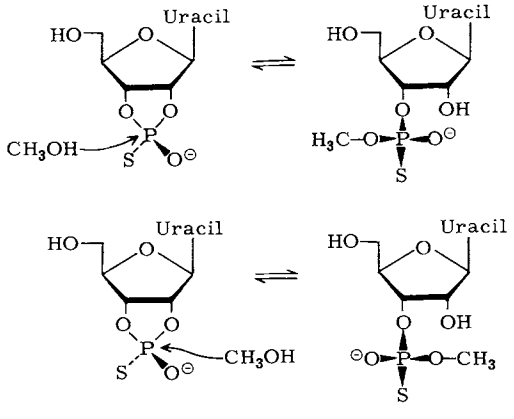

Fig. 12. Reaction of uridine 2',3'-cyclothiophosphate in methanol in the presence of ribonuclease A. The crystallographically determined structures of uridine 2',3'-cyclothiophosphate and the reaction product indicate occurrence of the in-line mechanism (S_N2). The adjacent mechanism would have yielded the isomeric product shown below.

The molecular structure of reactant and product, which were determined unequivocally by X-ray structural analysis, revealed that reaction had occurred by the in-line mechanism (S_N2)[68]. RNA is probably cleaved by pancreatic ribonuclease A in the same fashion.

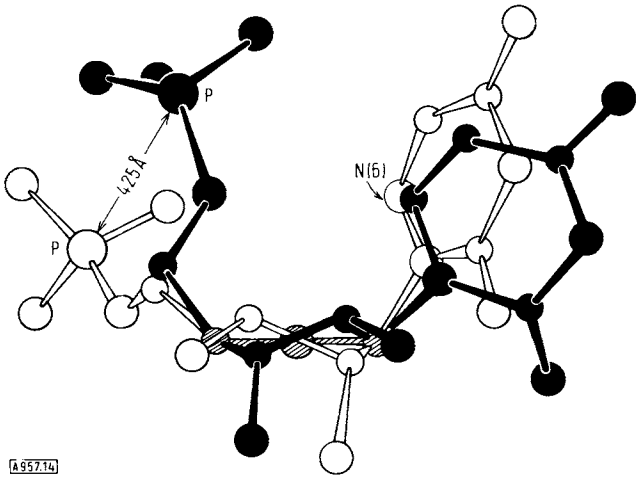

Fig. 14. Comparison of the structures of *gauche, gauche*-uridine 5'-phosphate (bold lines) and *gauche, trans*-6-azauridine 5'-phosphate. Interestingly, in addition to the phosphate group the atoms C(5') and N(1) also adopt differing positions as a result of the C(2')-*endo* and C(2')-*exo*—C(3')-*endo* sugar conformations (cf. also Fig. 6). The two molecules were drawn from crystallographic coordinates in such a way that the hatched atoms C(4')—O(1')—C(1') are common to both.

6-azauridylic acid and "normal" uridylic acid differ by 4.25 Å if the molecules are arranged such that the atoms C(4')—O(1')—C(1') are common to the two molecules (Fig. 14).

NMR studies[72] and X-ray structural analyses of analogous structures suggest that orotidylic acid will also have a *gauche, trans* conformation. Thus, the inhibition of the enzyme orotidylic acid decarboxylase can apparently be rationalized by binding of 6-azauridylic acid to the active site instead of the structurally similar orotidylic acid, thereby blocking the enzyme for metabolism of the true substrate.

Since the nucleoside 6-azauridine, which occurs in a *gauche, trans* conformation[71,72], also acts as substrate for the enzyme uridine kinase it appears that either this enzyme is not very specific, phosphorylating both *gauche, trans*-6-azauridine[71,72] and the "normal" *gauche, gauche*-uridine[72] at the 5'-hydroxyl group, or both substrates are fixed in a particular conformation on the surface of the active site and then undergo reaction.

4.6. Binding of Actinomycin D to DNA

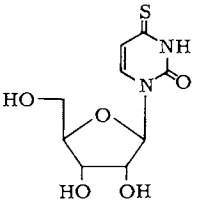
The antibiotic actinomycin D consists essentially of an aromatic phenoxazone chromophore linked to two peptide rings containing five amino acids each. The action of actinomycin D can be explained by its specific binding to DNA *via* G:C base pairs which interferes with readout of the information stored in the DNA[2]. As shown by X-ray structural analysis on a co-crystalline sample of actinomycin D and deoxyguanosine[73], one guanine is stacked above the phenoxazone ring and one below; the guanines can undergo hydrogen bonding with the peptide rings. Studies on models have demonstrated that actinomycin must be bound analogously to DNA: The phenoxazone chromophore inserts between consecutive G:C and C:G base pairs and hydrogen bonding takes place between guanine groups and the peptide rings of actinomycin D. Such a sequence-specific insertion does not distort the twofold symmetry of DNA mentioned above since actinomycin D itself has an approximately twofold axis[80].

4.7. Structures of the "Rare" Nucleosides 4-Thiouridine, Isopentenyladenine, Dihydrouridine

As adaptor molecules in protein biosynthesis, transfer ribonucleic acids (tRNA) mediate between messenger RNA, growing polypeptide chain, and amino acids yet to be incorporated[2,4–6,74,75]. Depending on their specificity they contain 70–85 nucleotides and are made up of double-stranded helical and single-stranded non-helical structural units. They contain about 10% of "rare" nucleosides such as 4-thiouridine, isopentenyladenosine, dihydrouridine, some of which are located at particular sites in the molecule and thus probably exert a structure- and specificity-determining effect.

4.7.1. 4-Thiouridine

Although it exists as the *anti* conformer in solution[61], 4-thiouridine crystallizes from water as the monohydrate in the unusual *syn* conformation[13] which is stabilized by crystal packing forces.

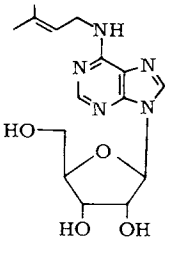


Co-crystalline samples of the 4-thiouridine analog 1-methyl-4-thiouracil and 9-methyladenine[41] prove to have "inverse" Hoogsteen-type base pairing with N(3)-U—H···N(7)A and N(6)A—H···O(2)U hydrogen bonds in which the sulfur atom does not participate. Moreover, this is the only base found so far in which purine and pyrimidine bases are stacked alternately in the crystal structure of the monomer.

Since the 4-thiouridine in *Escherichia coli* tRNA always occupies the same position, at a connection between two double-stranded helical regions[74], we may assume that it is incorporated to stabilize a particular tRNA structure by virtue of its conformational, base pairing, and base stacking properties, which differ from those of uridine.

4.7.2. Isopentenyladenine

The purine derivative N^6-(2-isopentenyl)adenosine is a component of the anticodon loop in a variety of tRNAs[74]. As was found in the crystal structures of N^6-(2-isopentenyl)-

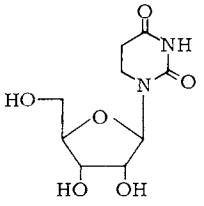


adenine[76] and N^6-(2-isopentenyl)-2-methylthioadenine[77], the isopentenyl groups project from the adenine ring in such a manner that the N(1) position is shielded and therefore inaccessible for Watson-Crick base pairing. This result supports the model concept that the anticodon loop should be single-stranded and devoid of base pairing so that messenger RNA can be read out by base pairing with the tRNA anticodon loop[78].

4.7.3. Dihydrouridine

Dihydrouridine crystallizes as the hemihydrate with two molecules in the asymmetric unit cell[79,80]. The molecules are in the *anti* conformation and the dihydrouracil group is not planar but in a half-chair conformation in both molecules. The conformation about the C(4')—C(5') bond is preferentially *gauche, trans* in both molecules. Having a non-

planar, nonaromatic base, dihydrouridine shows less tendency to participate in stacking than uridine. This factor, together with the preferred *gauche*, *trans* instead of



gauche, *gauche* conformation about the C(4')—C(5') bond, suggest the suitability of dihydrouridine for breaking a double-helix structure.

5. Conclusion

The first X-ray structural analyses of nucleotides were carried out with the aim of determining the structures of polymeric nucleic acids[81]. Although structural analyses on nucleic acids, which rely mainly on X-ray fiber diagrams of relatively low resolution, received considerable stimulus from the structural parameters determined for numerous nucleosides, nucleotides, and co-crystalline samples of base pairs, structural analysis of nucleic acid components has largely shaken off its model character. The reason is that nucleosides and nucleotides are *per se* biologically active units which can interact with enzymes. Thus a knowledge of the stereochemistry of the nucleosides and nucleotides permits conclusions to be drawn about the processes occurring at the active sites of enzymes.

The past four years have seen the preparation of single crystals of tRNA in several laboratories[75], and the first X-ray structure analysis of a tRNA was recently reported[82]. These structural studies will provide more details about the functional mechanism of tRNA and permit an insight into the conformation and the packing of the nucleotides in the polymer. Apart from the actinomycin-DNA complex[73] very little is known about the nature of nucleic acid-protein adduct formation. A research aim of the near future will be to prepare relevant co-crystalline samples to study these interactions which are of such paramount importance in biochemistry.

My own studies mentioned in this report are largely the fruits of the excellent cooperation that has taken place with Dr. P. C. Manor, Dr. S. K. Mazumdar, Dr. C. H. Schwalbe, Dr. D. Suck, and Miss U. Wittenberg, and of discussions with biochemists on the staff of this institute, to whom I am extremely grateful. I also wish to express my indebtedness to Prof. Dr. F. Cramer for his unfailing interest in structural problems and his support.

Chemical Analysis of Synthetic Fibers[**]

By Dietmar Nissen, Volker Rossbach, and Helmut Zahn[*]

Dedicated to Professor Paul Schlack on the occasion of his 75th birthday

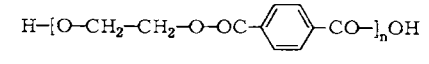
The analytical characterization of synthetic fibers has not kept pace with their development and production. Whereas the "second-generation" fibers have already conquered the market, the chemical investigation methods used until now for the three classical fiber polymers of the polyester, polyamide, and polyacrylonitrile types are still frequently unsatisfactory. Though they satisfy the requirements of production supervision and quality control, they do not supply enough information to enable us to understand and to explain the degradation of and damage to the polymers under hydrolytic, thermal, or thermooxidative influences. This report presents methods of chemical analysis that open up new possibilities for investigations of this nature on synthetic fibers. The results reported for commercial products must not be taken as an assessment of quality. They are simply intended to show the diversity to be expected in the chemical properties and to emphasize the practical basis of the chemical analysis of synthetic fibers.

1. Introduction

"One of the most frustrating problems in the early production of synthetic fibers was the inability to define polymer quality other than in terms of drawability and spinnability." This sentence from *Schlack*[1] shows how far it was necessary to come in order to reach the present position in the analytical characterization of synthetic fiber polymers[2, 3]. However, though a number of physical methods are now available, particularly for routine investigations, it is essential for synthetic fiber research to possess substantially complete and absolute numerical values for the chemical properties of the fibers, *i. e.* not simply comparison values such as are obtained in many test methods.

It appears from the literature[4] that fundamental new developments of fiber polymers are probably to be expected in the immediate future only to a limited extent and for special applications. In any case, the chemical modification of the three classical fiber polymers (Fig. 1) polyester, polyamide, and polyacrylonitrile is becoming increasingly important, and considerable problems are at the same time being raised for analytical chemistry. Methods from the analysis of natural macromolecules can help to solve these problems, as will be shown in the following discussion. Thus end group determination methods for polyesters and polyamides can be based on the well-known methods for the sequencing of proteins, such as the hydrazinolysis method of *Akabori*[6] and the dinitrophenylation technique of *Sanger*[7]. A method for the determination of acidic groups in cellulose by staining with methylene blue[8] can also be applied to the investigation of polyacrylonitrile, polyamide[9], and polyester[9, 9a, 14].

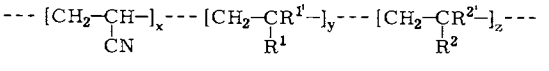
The polymers spun into filaments are not molecularly uniform substances, but contain a certain percentage of oligomers (polymer analogs having low molecular weights), which have proved valuable as model substances for the polymers, but have an adverse effect in the technical processing of the fibers. Analysis of the oligomers is therefore of great practical importance.



Polyester, PES (polyethylene terephthalate, PET [Terylene type])

Polyamide 6, PA 6 (polycaprolactam [Perlon])

Polyamide 6,6 (polyhexamethylene adipamide [Nylon type])



Polyacrylonitrile (modified), PAC

R^1, R^2 = various neutral, acidic, or basic groups; R^1, R^2 = alkyl or hydrogen

Fig. 1. Structural formulas of synthetic fiber polymers of the polyester, nylon, and polyacrylonitrile types [5].

The chemical characterization of commercial synthetic fibers also includes the investigation of any extraneous substances present, since these help to determine the processability of the fibers and their properties in use. However, the heterogeneity of these classes of substances, such as spinning oils, delustering agents, optical brighteners, light stabilizers, heat stabilizers, antistatics, and catalyst residues, makes both qualitative and quantitative determinations difficult, so that practically no generally valid, standardized analytical methods have been developed so far.

2. Determination of the Structural Units of Synthetic Fiber Polymers

Since the discovery of paper chromatography and later of thin layer chromatography, these methods have become

[*] Dr. D. Nissen, Dr. V. Rossbach, and Prof. Dr.-Ing. H. Zahn

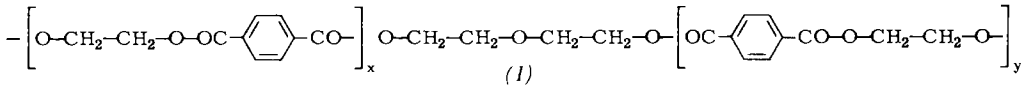
[**] Expanded version of a lecture to the 4th Textile Technical Forum, Schloss Elmau, 1972; 7th report in the series: Synthetic Fibers in the Wool Industry. 6th report: *W. L. Lindner*, Polymer *14*, 9 (1973).

essential aids in the analysis of synthetic fibers because of their ease of use. Once the polymer has been broken down into its monomeric units or their derivatives, these methods rapidly yield qualitative information on the composition of the macromolecules. Gas chromatography is also suitable for such routine determinations[10], and is also used for determination of the undesirable diethylene glycol structure [middle part of *(1)*] in polyethylene terephthalate[11].



(1)

Besides paper chromatography and thin layer chromatography, which have been in use for some time for the determination of the structural units of commercial nylon[12], polyurethane[12], and polyester[13], paper electrophoresis, which has been recommended for the analysis of hydrolysis products of nylons[13], has also proved useful in the qualitative determination of the monomer units of copolyesters[14] (Fig. 2).

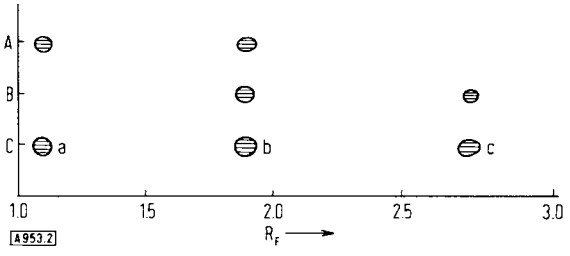


Fig. 2. Electropherogram of HCl hydrolysis products of modified polyester fibers (reference substance for the R_f values: Neucoccin [C. I. 16255]). A) Unitika copolyether ester, B) DuPont Dacron 65, C) reference substances (a: *p*-(β-hydroxyethoxy)benzoic acid, b: terephthalic acid, c: 5-sulfoisophthalic acid).

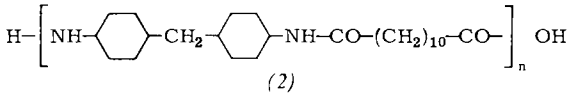
By thin layer chromatography of hydrolysis products of the silk-like Qiana fibers, it is possible to show with the aid of reference substances that this product is the polyamide of bis(4-aminocyclohexyl)methane and *n*-decanedicarboxylic acid *(2)*[15].



(2)

On the other hand, the structural units of copolymers of acrylonitrile cannot be determined by this simple method, since the paraffinic polymer chain (Fig. 1) cannot be hydrolyzed.

3. Importance of the Oligomers to the Analysis of Synthetic Fibers

As early as 1925, *Staudinger* and *Lüthy*[16] described the isolation of methyloligooxymethylene methyl ethers (CH_3—[OCH_2—]$_n$$OCH_3$; $n = 1$ to 14) and acetyloligooxymethylene acetates (CH_3CO—[OCH_2—]$_n$$OCOCH_3$; $n = 1$ to 20), though the molecular homogeneity of these substances was difficult to check by the means available at that time. This opened up a field of research whose importance was underlined by *Carothers*[17] in 1930 in his suggestion that low molecular weight homologs be isolated from synthetic polymers for chemical and physical structural investigations aimed at obtaining an understanding of the high polymers. Nine years later, *Schlack* and *Kunz*[18] extracted the cyclic dimer *(3)* and trimer *(4)* as well as monomeric lactam from caprolactam polymers.

(3), n = 2
(4), n = 3

Attempts made between then and 1967 to synthesize polymers with definite chain lengths or ring sizes from the monomers to allow the study of changes in the physical and chemical properties with increasing degree of polymerization have been reviewed by *Heidemann*[19].

To avoid the difficulties associated with the direct synthesis of oligomers, repeated efforts were made to obtain the pure oligomers by fractionation of the extract from the polymers[20], since the formation of oligomers is a phenomenon that accompanies melt condensation in particular, and oligomers can therefore be easily isolated from such polymers[19] as "natural", though usually undesirable, components. The most important of the fiber-forming polymers produced by melt condensation are the nylons and polyesters.

The specific synthesis of oligomers with degrees of polymerization greater than 8 is difficult if not impossible by conventional methods, not only because of solubility factors. As a result of incomplete reaction, costly purification of the resulting mixture is necessary in every case[21,22]. This is also the case when the Merrifield technique[23] is used for the preparation of higher linear polyamide and ethylene terephthalate oligomers, *i.e.* the purity of the products is usually unsatisfactory[24-26], which agrees with experience in peptide chemistry. In the preparation of acrylic acid oligomers, the use of molecularly uniform phenol-formaldehyde condensates as a template should help to provide definite products[27].

Following the remarkable successes of *Rothe et al.*[24], *Kusch*[25], *Repin*[28], and *Pénisson*[29] in the synthesis of higher linear and cyclic oligomers of the nylon 6, nylon 6,6, and ethylene terephthalate series, it can nowadays be said that for most purposes, oligomers with degrees of polymerization of less than 10 are quite satisfactory as model substances for the polymers. Thus from the heptamer upward, the dimethyl esters of polyethylene terephthalate do not differ from the polymer in their solubility, melting point, X-ray powder pattern, or IR spectrum[29]. In the nylon 6,6 series, X-ray studies show the same super-

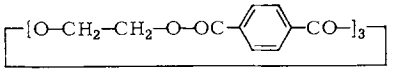
structure for the tetramer and pentamer as for the polymer[30].

An important objective of oligomer research has thus been achieved, namely the provision of substances for model reactions in which the molecular uniformity of the compounds ensures a simpler situation than in the case of an unfractionated polymer. Oligomers with degrees of polymerization of less than 10 are adequate for this purpose, and have already been used in many cases (Table 1).

Table 1. Scalar properties of polymers, investigated with oligomers as model substances [19, 31].

Melting point
Viscosity
UV and IR absorption
Crystallinity and conformation (X-ray studies, IR and NMR spectroscopy, density measurements)
Influence of chain length and structure on a covalently bonded chromophore (2,4-dinitrophenyl, 4-nitro-1-naphthyl residue) [32, 33]
Dyeing mechanism (crystalline ponceau 6R [C.I. 44], 2,4-dinitro-1-fluorobenzene, disperse dyes)
Absorption of moisture
Rate of hydrolysis
Photostability [34]
Thermostability [34, 35]

Interest is now being focused mainly on the manner in which the oligomers are formed and on their behavior in the production and processing of fiber-forming polymers. Thus the difficulties encountered in the processing (spinning, texturing, dyeing) of polyethylene terephthalate, which are caused by the escape mainly of the cyclic trimer *(5)* from the fiber, have led even recently to investigations



(5)

having practical aspects[36, 37]. These investigations are greatly facilitated by the model substances. Attempts have recently been made to decrease the content of oligomer by extraction of the granulated polymer before spinning in order to obtain polyester filaments with better properties for HT (high-temperature) dyeing[38].

Table 2. Analytical characterization of Qiana oligomers [15].

[b] Eluent: tetrahydrofuran/cyclohexane/water [39].

With the continuous development of new homopolymer and copolymer synthetic fibers, the need to prepare suitable oligomers for their analytical investigation will continue in the future. Table 2 shows the results of attempts to isolate oligomers from Qiana poly[(4,4'-methylenedicyclohexyl)dodecanamide] *(2)*[15].

4. Determination of the Functional Groups of Polyesters, Nylons, and Polyacrylonitrile

The functional groups (—OH, —COOH, —SO_3H, —OSO_3H, —NH_2, —CN) of the three fiber polymers polyester, nylon, and polyacrylonitrile and of the modified types derived from them are of great importance to their processability and to their properties in use, and play a crucial part in cases of damage. The specific determination of these groups is therefore important for the evaluation of a polymer and the detection of changes due to external influences such as hydrolysis, thermolysis, thermal oxidation, and irradiation.

4.1. Determination of Acidic Groups

4.1.1. Carboxyl End Groups of Polyesters

The reason why every polyethylene terephthalate (PET, polyesters of the Terylene type) contains carboxyl end groups as well as the hydroxyl groups resulting from the synthesis method is the thermal cleavage of the polymer chains due to the relatively high polycondensation temperatures and the residence times required to obtain high molecular weights[40–42]. The resulting ratio of hydroxyl to carboxyl groups provides a measure for the assessment of the chemical quality of the polyester[43]. Thus hydroxyl groups are particularly important to the thermal stability of polyesters[44, 45], since, as long as there are free hydroxyl end groups present in the molten polymer, the vinyl ester groups that are formed together with carboxyl groups on chain scission are transesterified with formation of a new polyester linkage[44]. A carboxyl group is thus formed at the expense of a hydroxyl group, but the average degree of polymerization has not decreased. On heat treatment of fibers below the melting point between 180 and 220 C, on the other hand, an increase in molecular weight occurs with consumption of both types of end groups[33, 46, 47].

The content of carboxyl groups is an important factor in connection with the susceptibility to hydrolysis[48], since these end groups have a catalytic effect in this process[46]. Their number can be increased by hydrolytic[49] or photolytic[50, 51] damage and by thermal oxidation[52, 53].

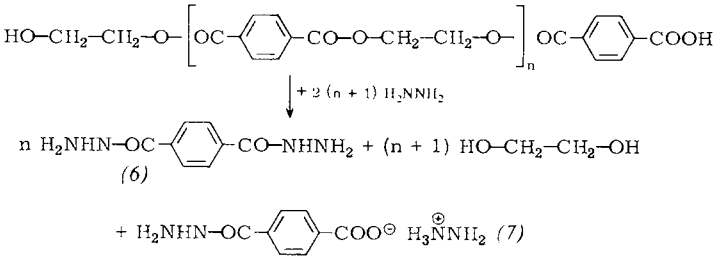
The determination of carboxyl end groups in PET is thus not only important for the determination of the number average molecular weight, but also serves for the elucidation of damage to the polymer by hydrolysis, heat, and light. In view of this fact, it seems peculiar that acidimetric titration is still the most commonly used method for the determination of carboxyl groups in PET, with addition of an indicator for visual end point determination[54] or with photometric[55], potentiometric[56], or conductomet-

ric[57] end point determination, since titration methods are not specific for end groups and can give reasonably reliable results only up to an average molecular weight of 20000. Above this limit, the ratio of the end groups (which are present in very small concentrations) to frequently unidentifiable impurities that interfere with the titration becomes increasingly unfavorable. This disadvantage cannot be overcome by the use of larger polymer samples and dilution of the titrant[58].

Chemical methods have also been described for the determination of carboxyl end groups in aliphatic polyesters, but these have not been used for PET. The conversion of the carboxyl groups into methyl ester groups by reaction with diazomethane should allow the determination of carboxyl groups by a methoxyl group analysis[59]. Alternatively, these groups may be allowed to react with phenyl isocyanate in the presence of pyridine. The resulting anilide end groups are determined by hydrolysis and photometric determination of the aniline formed[60].

4.1.1.1. Principles of the Determination of Carboxyl End Groups by Hydrazinolysis

A new possibility for the chemical determination of carboxyl groups in PET is offered by the application of the principle developed by *Akabori et al.*[6], according to which C-terminal amino acids in proteins are determined by hydrazinolysis[33]. The hydrazinolytic degradation of PET, which proceeds readily, has already been used for a wide range of purposes, *e.g.* for the separation of PET from mixtures with wool[61], for the investigation of the harmful action of organic bases on PET fibers[62], for the determination of the degree of crosslinking of cured polyester resins[63], and for the determination of methyl ester groups and diethylene glycol groupings in PET[11,43,64]. However, no analytical use has so far been made of the fact that the reaction of hydrazine with PET leads to quantitative cleavage of ester linkages in the polymer, with liberation of terephthalomonohydrazide *(7)* as the hydrazinium salt from C-terminal[*] terephthalic acid units, together with large quantities of terephthalodihydrazide *(6)* as the main product. The monohydrazide can be separated from the reaction mixture by ion exchange (Fig. 3) and determined photometrically.



The polyester material is allowed to react for five hours at 70 °C with 250 times as much of a hydrazine/dioxane/*n*-butanol mixture (15:70:15). The hydrazinolysis mixture is evaporated and then extracted with water. The extraction solution is discontinuously adsorbed on QAE Sephadex A-25 ion exchanger, which is then washed with water. The adsorbed terephthalomonohydrazide is desorbed with a measured elution volume of 0.1 N hydrochloric acid and determined photometrically at the absorption maximum of 240 nm. The content of carboxyl end groups is found from a calibration curve plotted for synthesized terephthalomonohydrazide.

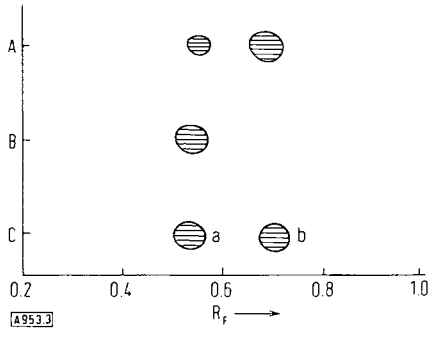


Fig. 3. Thin layer chromatogram of the hydrazinolysis products of a polyethylene terephthalate. A = before ion exchange; B = after ion exchange; C = reference substances (a: terephthalomonohydrazide *(7)*, b: terephthalodihydrazide *(6)*). Silica gel HF 254 (Merck, Darmstadt, Germany); dioxane/ammonia (25%)/water (65:8:27).

Under these analytical conditions, the reaction of PET with hydrazine proceeds uniformly and does not lead to the formation of secondary hydrazides, which could be formed at higher temperatures if the excess of reagent is too small[65].

4.1.1.2. Application of Hydrazinolysis

The contents of carboxyl end groups found for polyethylene terephthalate fibers are between 20 and 59 meq/kg of fiber, depending on the manufacturer and the type of fiber (Table 3); these values agree with recent literature data[45,66].

Table 3. Content of carboxyl end groups in commercial polyethylene terephthalate fibers.

The results are compared with values obtained by a colorimetric indicator method. The principle of this method was used by *Hensley*[67] for the determination of traces

[*] In this connection the term "C-terminal" means carboxyl terminal.

of acid in dimethyl terephthalate. In analogy with this method, the color reaction between the indicator bromophenol blue in its anionic form and the carboxyl groups is used for the quantitative photometric determination of the latter in PET. The decrease in the blue color is proportional to the number of equivalents of acid present in the solution.

The inadequacy of this non-specific method can be seen on comparison of the results (Table 3) with those obtained by hydrazinolysis. The differences which are sometimes pronounced are due to the fact that ionic fiber additives do not interfere with the end-group-specific formation of terephthalomonohydrazide *(7)* and its detection, whereas they can influence the color change of the indicator. Similar differences are also found in the determination of amino end groups in nylon fibers by titration on the one hand and by dinitrophenylation on the other (Table 7).

4.1.2. Carboxyl End Groups of Nylons

The carboxyl groups of nylons are partly responsible for the net charge of these polymers, and hence, according to *Zollinger*[68], influence their dyeability by acidic dyes. They are mainly determined by titration in benzyl alcohol according to *Waltz* and *Taylor*[69] in many variants[70]. The end point is determined conductometrically, potentiometrically, or visually with color indicators. Because of the high dissolution temperature of nylons in benzyl alcohol (approx. 160 °C), considerable quantities of benzoic acid are formed during the analysis. Attempts have been made to eliminate this methodical error by very precise standardization of the analytical conditions. Other solvents described for the determination of carboxyl groups, such as 2,2,2-trifluoroethanol[71, 72] and β-phenylethanol[73], have only occasionally been used.

In *Pätzold*'s method[72], the nylons dissolved in trifluoroethanol are titrated conductometrically with aqueous sodium hydroxide solution. As in the acidimetric titration in benzyl alcohol[69], the graphical determination of the equivalence point in this method leads to unsatisfactory results. On the other hand, definite reproducible values are obtained by mathematical evaluation, in which the regression lines for both branches of the titration curve are determined, the transition section being disregarded, and the intersection is determined mathematically.

In this way, carboxyl group contents of 50 to 68 meq/kg, depending on the manufacturer and the intended use, are found for a number of commercial nylon fibers (Table 7).

The titrimetric determination of the carboxyl end groups is more problematic than that of the amino end groups, owing to the lack of suitable solvents for nylons. Nevertheless, only one method for the specific chemical determination of carboxyl end groups has been reported in the literature. *Staudinger* and *Schnell*[74] esterified the carboxyl groups in the heterogeneous phase with a solution of diazomethane in ether and determined the methoxyl content by the Zeisel method. This method has also been used more recently[75]. As was shown by *Smith*[76], however, 25% of the carboxyl groups remain unesterified even after reaction for seven days.

The reaction in the homogeneous phase in the system calcium chloride/methanol/acetic anhydride, based on a method given by *Blackburn* and *Phillips*[77] for the methyl esterification of wool, also leads to only 58% reaction of the carboxyl groups[32].

4.1.3. Acidic Groups of Polyacrylonitrile

The acidic groups in polyacrylonitrile fibers may be strongly acidic sulfo or sulfate groups and weakly acidic carboxyl groups. The sulfo groups constitute about 80% of the total content of strongly acidic groups[78]. They are introduced into the polymer either by the catalyst as end groups[79] (reactions (a)—(d)) or with comonomers (Fig. 4) that are polymerized into the polyacrylonitrile[80] or grafted onto the preformed polymer[81]. Carboxyl groups can also be formed by hydrolysis of nitrile and other groups during polymerization[83, 84] or processing[85].

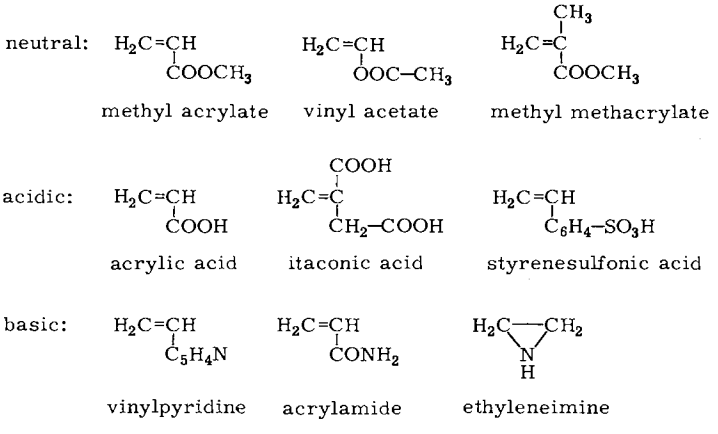

Fig. 4. Typical comonomers for the preparation of polyacrylonitrile fibers [80, 82].

Beckmann and *Glenz*[86] were the first to carry out quantitative determinations of acidic groups in acrylonitrile polymers by titration. *Kirby* and *Baldwin*[83] later showed that the values obtained are too low. These authors developed a method in which the strongly acidic groups and the weakly acidic groups can be determined separately by potentiometric titration. However, since many of the acidic groups are present in the polymer as salts, an ion exchange must be carried out before the titration.

The sulfonate and sulfate groups can also be determined by IR spectroscopy[87]; however, this method requires a difficult calibration with radioactive sodium.

Hilden[88–90] describes a simple determination of the acidic groups of polyacrylonitrile, in which the polymer is dyed

with methylene blue [C.I. 52015], a basic dye that was used earlier for the investigation of fiber damage in polyacrylonitrile[91]. The fibers are dyed in the heterogeneous phase at various pH values to achieve selective bonding of the dye to the strongly acidic groups in the acidic range and to the strongly acidic and weakly acidic groups in the neutral range: the content of weakly acidic groups can then be calculated by difference. Table 4 shows the results obtained in this way for a series of commercial polyacrylonitrile fibers.

Table 4. Determination of acidic groups in commercial polyacrylonitrile fibers by dyeing with methylene blue [88].

DuPont Orlon 75 B	67	75
Phrix Redon F	58	62

[a] Dyeing at pH 1.6.
[b] Dyeing at pH 6.5.

Apart from the fact that the heterogeneous reaction makes quantitative dye saturation of the functional groups problematic[92], since the accessibility of these groups depends on the temperature, the fine structure of the fiber[86,93], and the ion distribution[92], the determination of the weakly acidic groups is also difficult for other reasons. Whereas the bonding of the dye to the strongly acidic groups is partly covalent in character[94], the dye molecules bonded by the weakly acidic groups partly dissociate again during the extraction for the removal of unbound dye. The values for the strongly acidic groups thus agree with other literature data[83], whereas those for the weakly acidic groups are considerably lower.

4.2. Determination of the Basic End Groups of Nylons

In the analysis of nylons, the determination of the basic groups, which are generally referred to simply as amino groups, is more important than that of the carboxyl groups, since the content of basic groups determines the ability of the fibers to be dyed with reactive, acidic, and 2:1 metal complex dyes[93,95,96], and is also important for the recognition of fiber damage due to acids[97], heat[98], or light[99]. The basic end groups are mainly determined in practice by photometric or conductometric titration or by titration with the addition of color indicators[100]. What was said about the titrimetric determination of carboxyl groups in polyesters is also applicable to these analytical methods: they are non-specific, and so do not allow a differentiation between basic end groups and other basic groups (total basicity).

Despite the growing importance of the analysis of basic end groups, particularly for newly developed special end-group modified or copolymerized nylons (Fig. 5)[101–103], only a few chemical determination methods are to be found in the literature.

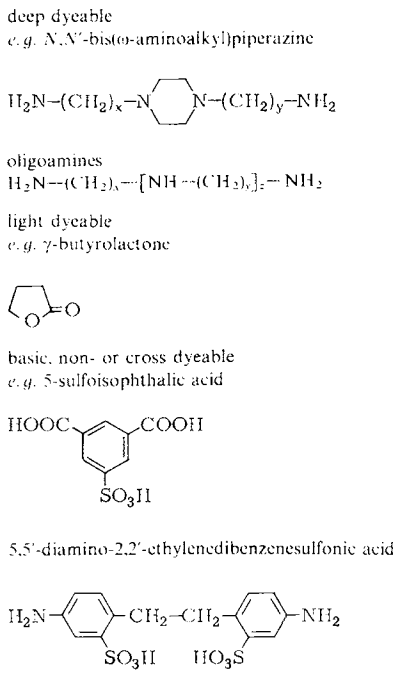

Fig. 5. Modifying components for the production of nylon fibers with modified dyeability [101–103].

A qualitative method is based on the ninhydrin reaction[104]. *Richter et al.*[105] developed a quantitative method, which should be particularly suitable for the determination of low contents of primary amino end groups, and which involves reaction with succindialdehyde to form pyrrolyl end groups, which are then determined colorimetrically by the Ehrlich reaction. 2,4-Dinitro-1-fluorobenzene (DNFB) is the reagent most commonly used for the chemical determination of amino end groups.

4.2.1. Principles of the Dinitrophenylation of Nylons

As early as 1953, one of us and *Rathgeber*[98] dinitrophenylated nylon 6 (Fig. 6) and nylon 6,6 by a procedure taken from wool analysis[106].

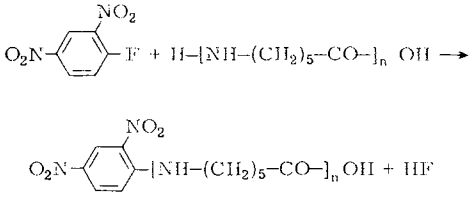

Fig. 6. Reaction of nylon 6 with 2,4-dinitro-1-fluorobenzene (DNFB).

However, structure-dependent errors have been detected in this method[107,108]. Thus since the diffusion of the reagent is rate-determining in the heterogeneous phase, fine-structure parameters such as the degree of orientation of the fibers influence the accessibility and reaction of the amino groups (Fig. 7).

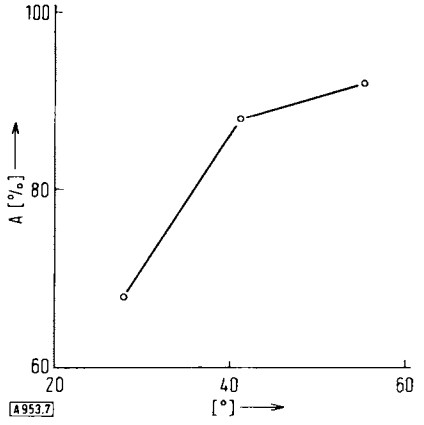

Fig. 7. Proportion A of amino groups that can be dinitrophenylated with 2,4-dinitro-1-fluorobenzene in nylon 6 fibers with different degrees of orientation. Abscissa: azimuthal half widths of the 020 reflection as a measure of the degree of orientation of the fibers.

Garmon and *Gibson*[109] therefore carried out the dinitrophenylation in the homogeneous phase with a very large excess of reagent, with the result that the photometric determination of the dinitrophenylated end groups becomes inaccurate. These authors also failed to consider that the total basicity and the content of amino groups may be different in commercial nylon fibers. Basic fiber additives may react with DNFB, a fact that must be disregarded in this method, which also allows no differentiation between different dinitrophenylatable groups such as primary and secondary amino groups and amidine groups.

Dinitrophenylation in the homogeneous phase in the system 2,2,2-trifluoroethanol/sodium hydrogen carbonate/water[32,110] eliminates these difficulties and also allows a differentiation between the basic end groups mentioned.

The nylon is dissolved in a 1.7% solution of DNFB in 2,2,2-trifluoroethanol (nylon concentration: 1%), and 5% aqueous sodium hydrogen carbonate solution is added (6%). After 14 hours the DNP-nylon (DNP=2,4-dinitrophenyl) is precipitated with 10 times as much water at pH 3, freed from adhering reagent by extraction with ethyl acetate, and dried. The DNP-nylon is then dissolved in trifluoroethanol and determined photometrically at the 350 nm absorption maximum. The content of amino end groups is determined from a calibration curve plotted for DNP-oligomers from the nylon 6 and nylon 6,6 series, for which the chromophore has been found to be independent of the structure.

A DNFB-catalyzed condensation of the amino and carboxyl groups such as was observed by *Heikens et al.*[111] for ε-aminocaproic acid in an ethanol-water mixture containing hydrogen carbonate takes place only to a very small extent in this model substance under the above analytical conditions (content of DNP-ε-aminocaproyl-ε-aminocaproic acid $\leqslant 5$ mol-%). This is probably due to the large excess of reagent.

Since the activation parameters of the dinitrophenylation for ε-aminocaproic acid and for the polymer have been found to agree (Table 5), so that the "principle of equal reactivity"[112,113] is satisfied, a condensation can also be ruled out for the polymer. Thus in the dinitrophenylation of nylon, no amino groups are lost by side reactions.

Table 5. Activation parameters, determined according to the Eyring theory of the activated complex, for the dinitrophenylation of ε-aminocaproic acid and nylon 6 at 30 °C.

	ΔH^* [kcal/mol]	ΔG^* [kcal/mol]	ΔS^* [cal deg^{-1} mol^{-1}]
ε-Aminocaproic acid	15.0	22.6	−23.9
Nylon 6	16.7	23.1	−20.2

No molecular weight fractionation occurs in the isolation of the DNP-nylon, as is shown by the correlation of the values obtained with those found potentiometrically[69] in the molecular weight range between 6000 and 18000 (Table 6). If the analytical conditions are adhered to, the dinitrophenylation proceeds quantitatively, as difference analyses by the method of *Richter et al.*[105] have shown.

Table 6. Determination of the basic groups of nylon 6 (without added regulators) [a] by potentiometry [69] and by dinitrophenylation.

$\bar{M}_n$	Basic groups [meq/kg]	
	Potentiometry	DNP method
17500	58	54
14000	72	67
12200	82	77
9000	110	101
6300	160	147

[a] These products were kindly made and characterized for us by BASF, Ludwigshafen.

4.2.2. Use of Dinitrophenylation

4.2.2.1. Determination of Primary Amino Groups

Amino group contents of between 26 and 65 meq/kg of fiber have been found for commercial fibers of the nylon 6 and nylon 6,6 types, depending on the manufacturer and the intended use (Table 7).

End group equivalence of the free and acylated amino groups to the carboxyl groups has been found for unbranched polycaprolactam[115]. This is confirmed by the complete end group analysis of nylon 6 fibers (Table 7), but only if the total amino group content is calculated from the dinitrophenylation values and compared with the content of carboxyl groups found conductometrically. Alkalimetric titration usually gives excessively high contents of amino groups because of its non-specificity. This also explains why the number average molecular weights calculated from the dinitrophenylation values are higher than the values given in the literature[116] or at the upper limit of the range[117], since the latter were all determined by titrimetric methods.

For a complete end group analysis, the acylated amino groups must also be determined. The acyl residues are derived from monofunctional carboxylic acids (acetic acid, propionic acid, benzoic acid) added to the nylon 6 and nylon 6,6 polymerization mixtures as molecular weight stabilizers. Because of these regulators, equivalence of the free end groups cannot be expected in technical nylon.

A method is described in the literature for the determination of the acetyl residues[118,119], in which the acetic

[a] R = CH_3, C_2H_5, C_6H_5.

acid liberated by phosphoric acid is distilled azeotropically with xylene and then titrated. The following procedure[32] is simpler. The nylon is digested with 50% sulfuric acid, and the organic acids are steam distilled and then titrated potentiometrically. The pK value gives an indication of the acid present.

Though this method has a fairly high coefficient of variation (Table 7), the statement by *Dinse* and *Praeger*[118] that microanalytical or semimicroanalytical acetyl determinations on nylons are impossible does not appear to be justified.

4.2.2.2. Determination of Secondary Amino Groups and Detection of Amidine Groups

McIntire et al.[120], in 1953, described the possibility of differentiating between primary and secondary amines by dinitrophenylation, since the absorption maximum of the primary DNP-amine at 350 nm is displaced to 390 nm for secondary DNP-amine (Fig. 8).

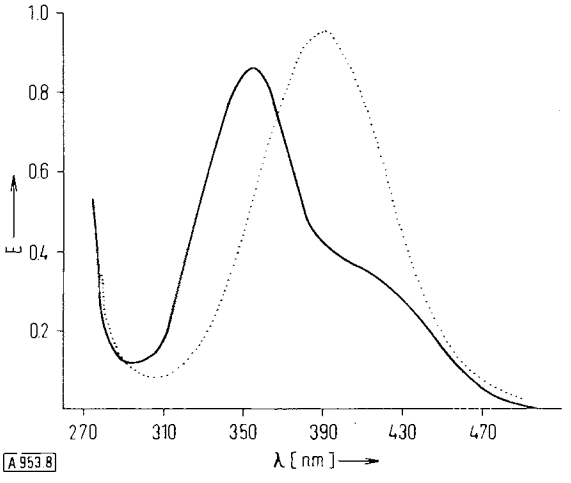

Fig. 8. Spectra of dinitrophenyl-*n*-propylamine (—) and dinitrophenyl-di-*n*-propylamine (····) in 2,2,2-trifluoroethanol ($c = 5.1 \times 10^{-5}$ mol/l).

The spectra of a large number of dinitrophenylated primary and secondary amines show that when the alkyl residue H—$[CH_2—]_n$ has a chain length of $n > 1$, the chromophore absorbs independently of the structure of the rest of the molecule.

The presence of secondary amino groups can therefore be deduced from the extinction ratio E^{350}/E^{390} of a dinitrophenylated polyamide. The spectral behavior is evaluated for the quantitative determination of primary and secondary amino groups in polymers by a two-component analysis developed on the basis of measurements on DNP-monoalkylamines and DNP-dialkylamines.

$c_1 = (7.49 \times E^{350} - 3.62 \times E^{390}) \times 10^{-5}$ mol/l

$c_2 = (7.21 \times E^{390} - 3.41 \times E^{350}) \times 10^{-5}$ mol/l

c_1, c_2 = concentration of primary and secondary amino groups

E^{350}, E^{390} = extinctions at 350 and 390 nm

In addition to many other products that are formed by the action of heat on aliphatic polyamides, particularly in the presence of oxygen, a number of primary and secondary amines, amino acids, and other compounds containing nitrogen, which should react with DNFB because of their structure, have been described[121–123]. However, since it has been necessary until now to liberate and isolate these substances by hydrolysis in order to detect them, there are only a few known groupings that are formed in the polymer during thermal degradation and can be dinitrophenylated there. *Kamerbeek et al.*[124] showed that in nylon 6 and nylon 6,6 at high temperatures, two amino end groups react with elimination of ammonia, so that a secondary amino group is formed with chain doubling.

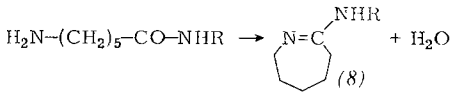
$2\ R—NH_2 \rightarrow R—NH—R + NH_3$

R = HO—$[CO—(CH_2)_5—NH—]_n$CO—$(CH_2)_5$ or

HO—$[CO—(CH_2)_4—CO—NH—(CH_2)_6—NH—]_n$CO—$(CH_2)_4$—CO—NH—$(CH_2)_6$

In NMR studies on the gelation of nylon 6 and nylon 6,6, secondary and tertiary amino groups were recently detected in the polymer itself[125].

There is also a possibility that nylon 6 contains the semicyclic amidines of the type *(8)* postulated by *Schlack*[126], though these have not yet been directly detected.

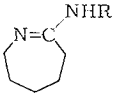


(8)

R = HO–[CO–$(CH_2)_5$–NH–]$_n$ CO–$(CH_2)_5$

For nylon 6,6, a reaction between the cyclopentanone Schiff bases mentioned by *Wiloth*[127] and DNFB must be considered, and dinitrophenylation of the pyridines detected by *Goodman*[128] is also possible. All these basic groups are included in the results of titrimetric determinations, and are generally referred to simply as amino groups, despite their different p*K* values.

2-Benzylamino-1-aza-1-cycloheptene *(9)* and 2-butylamino-1-aza-1-cycloheptene *(10)* can be used as model substances for the investigation of semicyclic amidine groups in thermally damaged nylon 6[129].



(9), R = CH_2-C_6H_5
(10), R = n-C_4H_9

Dinitrophenylation experiments on these compounds[*] show that both the exocyclic and the endocyclic amidine nitrogen react with DNFB, but that the reaction does not proceed uniformly[129a].

A comparison of the spectrum of peramidinated and dinitrophenylated nylon 6 with that of a thermolyzed product (30 h at 185—195 °C in the absence of oxygen) that had subsequently been deaminated[130] and then dinitrophenylated shows good agreement (Fig. 9, curves b and c respectively). As when dinitrophenylated secondary amino groups are present, a change in the extinction ratio E^{350}/E^{390} is found in relation to untreated nylon 6 containing only primary amino groups (Fig. 9, curve a).

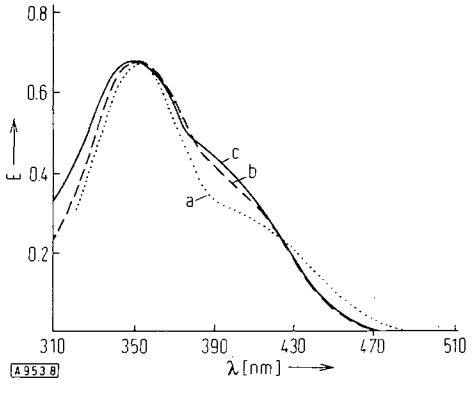


Fig. 9. Spectra of a) dinitrophenylated nylon 6 (c = 0.065 %), b) peramidinated and dinitrophenylated nylon 6 (c = 0.60 %) and c) thermolyzed, deaminated, and dinitrophenylated nylon 6 (c = 1.1 %) in 2,2,2-trifluoroethanol.

[*] Reference substances were kindly supplied by Prof. Dr. *H. Herlinger*, Stuttgart.

This may be taken as the first direct evidence that the non-deaminatable basic groups formed in nylon 6 by the action of heat are amidine groupings. The spectra of nylon 6,6 samples treated in the same way indicate that amidines are also formed here by thermolysis. Attempts by *Schlack* and *Rieker*[131] to prove the existence of these groups in peramidinated polycaprolactam by removal and isolation of the amidine heterocycle were successful only for low molecular weight model substances. On the other hand, they have been detected by thin layer chromatography[132] and determined indirectly by titration[133] in cationically polymerized nylon 6.

4.3. Determination of the Hydroxyl End Groups of Polyesters

For a chemical determination of the hydroxyl end groups, these groups must first be allowed to react with a reactive compound. Because of the low content of these groups in fiber-forming polyesters[145], calculation by measurement of the excess reagent after the manner of a back-titration, as suggested by a number of authors[134–140], seems problematic[141]. Direct methods are based on the determination of the groups introduced into the polymer in polymer-analogous reactions (carboxyl[142], haloacyl[143–148], *N*-phenylcarbamoyl[136, 149, 150], benzoyl[151], sulfosalicyl groups[152]). However, analyses of this nature require an additional determination of the original carboxyl group content (this also applies to the repeatedly described determinations by exchange of active hydrogen atoms with isotopes[153]) or a multiple quantitative reaction of the polymer.

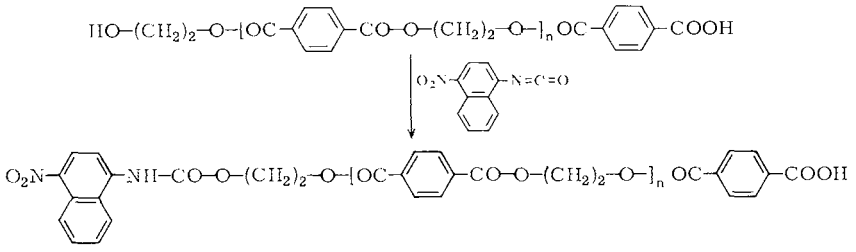
The reaction with phenyl isocyanate was first used by *Griehl* and *Neue* for the determination of hydroxyl groups in PET[143]. These authors, and also *Batzer* and *Mangold*[154] and *Gaylord* and *Rosenbaum*[155], who allowed PET to react with hexamethylene diisocyanate, determined the hydroxyl group content from a nitrogen analysis of the polyester urethane obtained; because of the very low nitrogen contents, however, this cannot yield satisfactory results. The accuracy of the phenyl isocyanate method was improved by the work of *Kern*[149] and of *Hendrix*[56], but the analytical procedure required is complicated. The polyester urethane formed is hydrolyzed to remove aniline, which is diazotized, coupled with 1-naphthylethylenediamine or 2-naphthol, and determined colorimetrically.

The use of a colored isocyanate, on the other hand, decisively simplifies the determination of the hydroxyl end groups[133].

4.3.1. Principles of the Determination of Hydroxyl End Groups with 4-Nitro-1-naphthyl Isocyanate

The reaction of PET with 4-nitro-1-naphthyl isocyanate (NNI) yields a yellow *N*-(4-nitro-1-naphthyl) urethane of the polymer, whose chromophore absorbs independently of the structure of the rest of the molecule, as has been

shown for *N*-(4-nitro-1-naphthyl) urethanes of ethylene terephthalate oligomers (Fig. 10).



The polyester material is dissolved in nitrobenzene, and sufficient NNI in nitrobenzene is added to make the solution 1% with respect to polyester and 1.8% with respect to NNI. After five hours at 130 °C, the *N*-(4-nitro-1-naphthyl) urethane of the polyester is precipitated in ten times as much ether, reprecipitated twice from nitrobenzene with ether, and finally extracted with ether. The polyester urethane is dissolved in phenol/*o*-dichlorobenzene (3:2) and determined photometrically at 375 nm. The content of hydroxyl groups is calculated with the aid of a calibration curve plotted for *N*-(4-nitro-1-naphthyl) urethanes of the

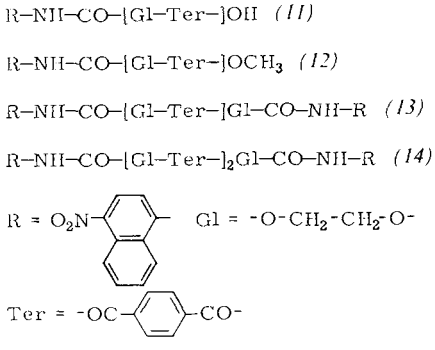


Fig. 10. Calibration line for the determination of the hydroxyl end group concentration from the molar extinction (at 375 nm) of PET treated with 4-nitro-1-naphthyl isocyanate (NNI). The calibration line was plotted for the *N*-(4-nitro-1-naphthyl) urethanes *(11)*–*(14)* of ethylene terephthalate oligomers.

ethylene terephthalate series. The hydroxyl end groups are thus determined by a single chemical reaction of the polymer. This leads to only small quantities of by-products of the reagent, which can be removed without difficulty by reprecipitation. As investigations on oligomers have shown, reaction of carboxyl groups of the polyester with the isocyanate takes place to a negligible extent, if at all, under the conditions used[156].

Table 8 shows a comparison of the results of the NNI method with those of the method described by *Conix*[142], which requires a double determination of the carboxyl group content before and after the reaction of the hydroxyl groups with succinic anhydride and has a large confidence belt[139].

[c] Coefficient of variation = 2.4%; confidence belt = ±2.2 meq/kg (for 95% statistical certainty).

4.3.2. Application of the Hydroxyl End Group Determination with 4-Nitro-1-naphthyl Isocyanate

The hydroxyl group contents found by the NNI method for PET homopolyesters are between 35 and 79 meq/kg, depending on the manufacturer and the intended use (Table 9).

These values together with the results obtained by the hydrazinolysis method give remarkable differences in the ratios of hydroxyl to carboxyl groups in the fibers investigated; this ratio can play an important part in the thermal behavior of the polyester[44,45]. The molecular weights $\overline{M}_n$ (number average) were calculated from the results given by the determination methods developed for both end groups, the methyl ester end groups that may be present in very small concentrations in PET[157] being disregarded. As was shown by *Zimmermann* and *Becker*[43], however, a complete end group analysis should include testing for methyl ester groups, since these can interfere with the polycondensation, and their content in the PET should yield information on the course of the production process.

The molecular weights obtained for the PET homopolyester fibers of the normal type are between 23000 and 28000, and correspond to data in recent publications[40,45,66,158]. Low molecular weights (approx. 17000) were found for the two pilling-resistant PET fiber types; the low molecular weights are probably responsible for this property of the fibers[40,66,159].

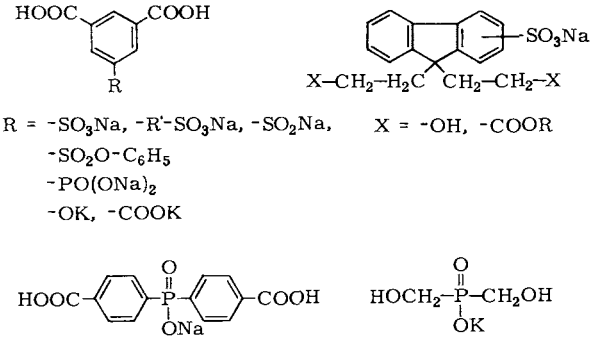
5. Determination of Comonomers in Polyesters and Polyacrylonitrile

5.1. Investigation of Chemically Modified Polyesters

The difficulty of dyeing of polyester fibers and their susceptibility to pilling can be problematic in practice. In efforts to overcome these difficulties, the homopolyester of terephthalic acid and ethylene glycol has been subjected to numerous chemical modifications by copolymerization of a third component[40,66]. In this way, the dyeability with dispersed dyes can be improved (Table 10) or dyeing with basic dyes can become possible (Fig. 11). On the other hand, no technically and economically satisfactory solution has so far been found to the problem of the modification of PET for dyeing with anionic dyes, owing to the thermal sensitivity of the required modifying components containing basic nitrogen.

There have been only a few publications dealing with the quantitative determination of comonomers in chemically modified polyesters. These are concerned with the examination of the total hydrolysis product of the polymer and the use of spectroscopic detection methods (IR, NMR)[160].

1) incorporation of co-components during polymer production



2) incorporation of anionically active substances prior to or during the spinning process

3) after-treatment of filaments and fibers with SO_3, SO_2Cl_2, and $ClSO_3H$

Fig. 11. Modification of PET to allow dyeing with cationic dyes [66].

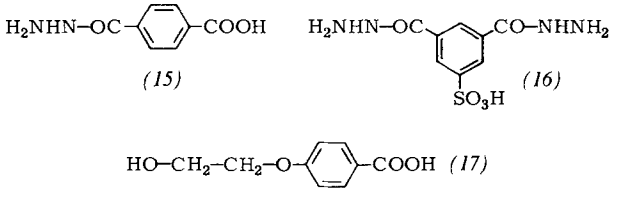
[a] Substitution products are also suitable.

5.1.1. Determination of Aromatic Comonomers with Acidic Substituents

The hydrazinolysis method is also suitable for the investigation of chemically modified polyesters, and in addition to the determination of carboxyl end groups it also allows the quantitative determination of aromatic comonomers with acidic substituents[133]. Thus on ion exchange of the hydrazinolysis products of basically dyeable polyester fibers copolymerized with sodium 5-sulfoisophthalate, the hydrazides of the comonomer are isolated because of their unchanged sulfo group, as well as terephthalomonohydrazide.

The ion-exchange eluate may be regarded as a two-component system if no differentiation is made between the sulfoisophthalic acid derivatives (dihydrazide and monohydrazide) that are isolated together with terephthalomonohydrazide. A quantitative simultaneous determination of the comonomer content and of the carboxyl end groups, which are equivalent to the C-terminal terephthalic acid, thus becomes possible. Terephthalomonohydrazide *(15)* and 5-sulfoisophthalodihydrazide *(16)* are used as calibration substances for the development of a two-component analysis based on the difference in the spectral behavior of the compounds (Fig. 12).



$c_1 = (6.21 \times E^{240} - 1.04 \times E^{212}) \times 10^{-5}$ mol/l

$c_2 = (2.62 \times E^{212} - 0.51 \times E^{240}) \times 10^{-5}$ mol/l

c_1, c_2 = concentration of terephthalomonohydrazide and 5-sulfoisophthalodihydrazide respectively

E^{240}, E^{212} = extinctions at 240 and 212 nm

For three basically dyeable PET copolyester fibers, comonomer contents of 1.6 to 1.8 mol % of sodium 5-sulfoisophthalate were found, based on the monomer unit [$OCH_2CH_2OOC—C_6H_4—CO$] (Table 11). These results are lower than the values given in the literature[160, 161].

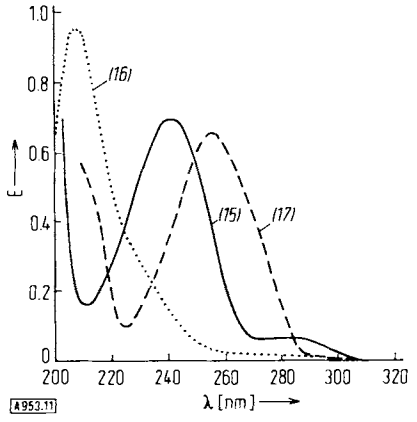


Fig. 12. UV spectra (in 0.1 N HCl) of terephthalomonohydrazide *(15)*, *p*-(β-hydroxyethoxy)benzoic acid *(17)* ($c = 4 \times 10^{-5}$ mol/l), and 5-sulfoisophthalodihydrazide *(16)* ($c = 2 \times 10^{-5}$ mol/l).

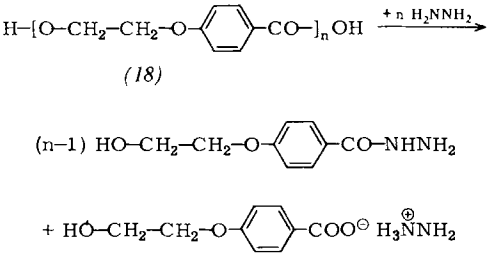
5.1.2. Determination of Aromatic Hydroxy Carboxylic Acids

The ester linkages in homo- and copolyether ester fibers with *p*-(β-hydroxyethoxy)benzoic acid *(17)* as the monomer unit or comonomer unit are also quantitatively broken by hydrazine, though only after a longer reaction time.



In the case of poly-[*p*-(2-ethylenoxy)]benzoate (A-Tell) *(18)*, the hydrazinolysis method results in the isolation of *p*-(β-hydroxyethoxy)benzoic acid *(17)*, which is equivalent to the C-terminal carboxyl groups of the polymer, and which is quantitatively determined with the corresponding pure compound as the calibration substance (Table 11).

The hydrazinolysis products of the copolyether ester, on the other hand, yield terephthalomonohydrazide *(15)* and *p*-(β-hydroxyethoxy)benzoic acid *(17)*, which correspond to different C-terminal monomer units. The ratio of the numbers of monomer units carrying carboxyl groups

Table 11. Contents of carboxyl end groups and of comonomers in copolyester and homopolyether ester fibers.

can be determined by a photometric two-component analysis developed with the pure compounds. This may be regarded as the first step toward a chemical sequence analysis of this polymer, which has so far been attempted only with the aid of high-resolution NMR spectroscopy[160].

$c_1 = (7.65 \times E^{240} - 3.27 \times E^{258}) \times 10^{-5}$ mol/l

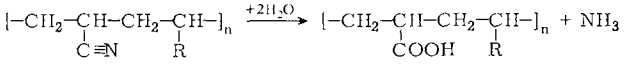
$c_2 = (7.91 \times E^{258} - 3.49 \times E^{240}) \times 10^{-5}$ mol/l

c_1, c_2 = concentration of terephthalomonohydrazide and *p*-(β-hydroxyethoxy)benzoic acid

E^{240}, E^{258} = extinctions at 240 and 258 nm

5.2. Investigation of Copolymerized Polyacrylonitrile

The comonomers present in commercial polyacrylonitrile fibers (Fig. 4) can be determined directly, according to *Hilden*, by hydrolysis of the nitrile groups[88], with quantitative formation of carboxyl groups and ammonia; the ammonia can be easily determined by titration, and the content of nitrile groups can be calculated from the result.



However, no differentiation is possible in this method between hydrolyzable nitrile groups and amide groups. The content of incorporated comonomer is deduced from the difference between the nitrile content expected for pure acrylonitrile and that found for the polymer in question. The comonomer contents obtained in this way vary widely from one fiber to another (6 to 14%, Table 12).

6. Determination of Extraneous Substances

Dyeability and strength, as the most important textile properties, are determined by the chemical structure and fine structure of the polymers. The extraneous substances, however, must also be taken into account in the analysis of synthetic fibers. These include preparing agents, delustering agents, optical brighteners, light stabilizers, heat stabilizers, antistatics, *etc.*, which are added to the fiber polymers to modify their application properties.

Since the substances mentioned belong to very different classes, which may be present *e.g.* even in a single spinning oil, it seems impossible to find any generally applicable methods. Since the treatment of synthetic fibers with these additives is undergoing constant development and modification, it is extremely difficult to analyze them qualitatively and quantitatively[162-165].

However, the importance of these investigations is shown *e.g.* by the influence of surface-active compounds, *e.g.* in spinning oils, on the viscosity behavior[166], on titrimetric end group determinations[32,33], and on the dyefastness of the fibers[167]. Methods for the analysis of wool[168] appear to be of only limited value for the determination of extractable ionic substances[32,33].

A spectrophotometric determination of phosphorus, which is important in connection with stabilizers containing phosphorus[52], has been described by *Telep* and *Ehrlich*[169]. *Dinse* and *Ewert*[170] have developed a polarographic method for the determination of titanium dioxide in PET and nylon 6 materials. Polarography[171], atomic absorption spectroscopy[172], X-ray fluorescence spectroscopy, and neutron activation analysis[32,33,158] are suitable for the determination of titanium and for the analysis of traces of heavy metals, which may come from impurities, catalyst residues, or labeling additives. The determination of the heavy metal content shows very clearly the importance of the analysis of extraneous substances, since heavy metals can influence the stability of the fibers to light, heat, and thermal oxidation.

Table 12. Contents of acrylonitrile and of comonomers in commercial polyacrylonitrile fibers [88].

Producer, trade name	Experimental acrylonitrile content [%]	Calculated comonomer content [%] from nitrile group content	from nitrogen content
Bayer Dralon	90.5	9.5	9.6
Bayer Dralon bifilar	89.9	10.1	9.9
DuPont Orlon 42	90.4	9.6	9.5
DuPont Orlon 74	86.0	14.0	9.6
DuPont Orlon 75	91.2	8.8	8.9
DuPont Orlon 75B	94.1	5.9	9.8
Phrix Redon F	91.0	9.0	8.9
Hoechst Dolan 50	91.5	8.5	7.2

As a comparison, the comonomer content was also determined from the content of nitrile groups, which can be calculated from the result of a Kjeldahl nitrogen determination. In the case of Orlon 74, a considerably higher comonomer content is found by hydrolysis than by elemental analysis; this means that part of the nitrogen contained in this fiber is present in an unhydrolyzable form. This fact, the characteristic IR spectrum, and the dyeability with acid dyes[88] support the assumption that this fiber contains a heterocyclic amine (*e.g.* vinylpyridine), a conclusion that cannot be drawn from the nitrogen analysis alone.

7. Conclusion

In the foregoing discussions, we have described new specific chemical methods for the determination of functional

groups in polymers, which allow more far-reaching conclusions to be drawn regarding the chemical structure and the behavior of synthetic fibers than *e.g.* from most of the titration methods used. Methods were shown for the recognition of fiber damage and the quantitative chemical determination of comonomers. It is clear that the chemistry of natural macromolecular products, which has already provided the stimulus for the synthesis of fiber-forming polymers, is also a fruitful basis for their analysis.

We thank Dipl.-Chem. I. Kramer, Dipl.-Chem. R. Altdorf, and Dipl.-Chem. D. Müller-Schulte for permission to use some of their research results. We are also grateful to the companies that supplied the fiber material. We thank the Landesamt für Forschung beim Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Verband der chemischen Industrie for their support of this work.

Chemistry and Applications of Liquid Crystals

By Ralf Steinsträsser and Ludwig Pohl[*]

Approximately 5% of all organic compounds are transformed at their melting point into liquid crystals—thermodynamically stable, anisotropic liquids which in contrast to isotropic melts appear turbid and are also known as mesophases. Such melts are classed as smectic, nematic, and cholesteric liquid crystalline phases, depending upon the arrangement of the constituent molecules. The discovery of numerous potential applications during the past ten years has awakened the study of liquid crystals from its former slumber as a physical curiosity and placed it in the limelight of the scientific stage. Uses in display systems for measured values and for computer and process data, as well as for remote controlled timetables, for windows of variable light-transmission, *etc.*, appear particularly promising. Not only black-and-white contrasts are now possible but also color production.

1. Introduction

Directionally dependent (anisotropic) properties are observed independently of the state of aggregation only for substances having a regular arrangement of constituent molecules. If the order is three-dimensional in nature then the substance is a crystalline solid, while two- or one-dimensional order is characteristic of crystalline liquids or liquid crystals[1-5].

The main emphasis of the present progress report will be placed on recent applications of liquid crystals and on the connection between chemical structure and the principal physical effects.

2. Structure and Properties of Liquid-Crystalline Phases

Smectic, nematic, and cholesteric liquid-crystalline phases can readily be distinguished on the basis of their optical, rheological, and thermodynamic properties. The structures characteristic of smectic phases were first observed with soaps (Greek σμῆγμα) under the polarizing microscope. The nematic phases owe their name to their threadlike (Greek νέματος) appearance under the polarizing microscope. And finally the designation cholesteric derives from cholesterol whose derivatives were the first compounds seen to exhibit such phases.

2.1. Smectic Liquid-Crystalline Phases

Smectic phases have a two-dimensional structure. As seen in Figure 1 their molecules are arranged in layers. Since hardly any interaction occurs between the ends of the molecules the layers can readily slip over one another. The high viscosity and surface tension of smectic phases are a consequence of the high degree of order.

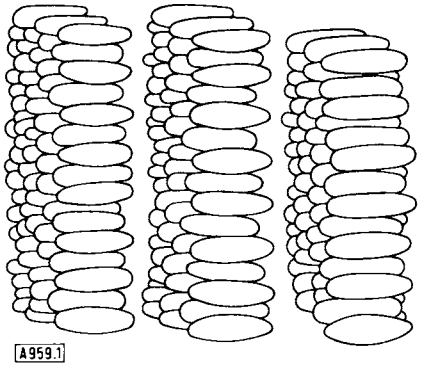

Fig. 1. Structural model of a smectic phase.

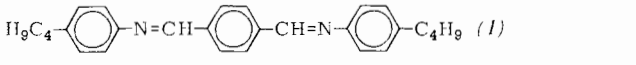
Depending on the molecular arrangement it is possible to distinguish at least five different smectic states which are classified by the symbols A to E according to *H. Sackmann* and *Demus*[2]. Three additional smectic phases designated F, G[6], and H[7] have also been proposed. Pure compounds too, on warming or cooling, can pass through several smectic phases bounded by first-order

transition points. The transition points of such polymorphous systems can be determined by differential thermal analysis (DTA). Figure 2 shows the DTA curves of *p*-bis(*p*-*n*-butylphenyliminomethyl)benzene *(1)*, a compound for which *Taylor et al.*[8] observed one nematic and three smectic phases (S_A, S_C, S_B). The upper curve a) was recorded on warming of the crystalline solid and the lower one b) on cooling of the isotropic melt. Phase transitions between several liquid crystalline phases and the isotropic phase cannot be supercooled.



(1)

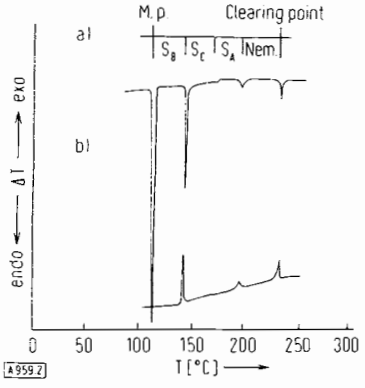


Fig. 2. Differential thermal analysis of *p*-bis(*p*-*n*-butylphenyliminomethyl)-benzene *(1)*; a) heating curve, b) cooling curve.

The identification and assignment of smectic phases has been pursued in recent years above all by *H. Sackmann et al.*[2,9–12]. Apart from thermal analysis, three main methods of study are preferred.

2.1.1. Microscopic Studies

In most cases characteristic patterns can be recognized under the microscope when liquid crystalline preparations are viewed between crossed Nicols. These textures arise from the differing orientation of the optical axes of adjacent regions that are in themselves optically homogeneous. The boundary lines between these regions, the lines of discontinuity, are typical of the textures which permit a first, albeit not always unequivocal, distinction of the various smectic phases. The three smectic phases characterized thermoanalytically in Figure 2 were found to give a focal conic (S_A), a smectic schlieren (S_C), and a mosaic texture (S_B)[8].

2.1.2. Miscibility Relationships in Binary Systems[2,10–12]

Evaluation of phase diagrams of two compounds having liquid-crystalline properties assumes that perfect miscibility of two anisotropic phases is only possible if both have the same kind of structure. Perfect miscibility of an unknown smectic phase with a component known to be, *e.g.* S_B, would indicate the presence of a smectic B phase. This method has been employed to establish the identity of numerous phases formerly known merely as "smectic".

2.1.3. X-Ray Analysis[7,13–16]

The layer arrangement of the molecules could be confirmed for the A, B, and C phases by X-ray diffraction diagrams[15]. Such an arrangement, although of higher order, is highly probable also for the smectic E phase, while a cubic structure is under discussion for the smectic D phase.

(2)

The smectic H modification was found by *de Vries et al.*[7] for *p*-ethyl-*N*-(*p*-*n*-butoxybenzylidene)aniline *(2)* between 40.4 and 51 °C and classified on the basis of X-ray diffraction and microscopic investigations. A three-dimensional layer structure has been proposed in which the long molecular axes are inclined to the plane of the layer and the molecular planes adopt a herringbone arrangement.

This example clearly demonstrates that it is often difficult to distinguish between a solid and a liquid crystalline state. While the high order suggests a second solid crystalline modification, the fact that the phase transition at 51 °C cannot be supercooled indicates the existence of a true liquid crystalline phase which shows the known smectic textures under the polarizing microscope. The lines of discontinuity merge and reorder themselves when a shearing force is exerted on the objects by application of light pressure with a needle or by lateral displacement of the cover glass[7].

The only significant application of smectic phases discovered so far is their use as solvents in ESR and Mössbauer spectroscopy (cf. Sections 5.3 and 5.4)[*].

2.2. Nematic Liquid-Crystalline Phases

The uniform order within a molecular plane of smectic systems is absent from nematic phases (Fig. 3). The latter merely exhibit a time- and spatially averaged parallel orientation of the long molecular axes within relatively small regions and are consequently much less viscous than smectic phases[17].

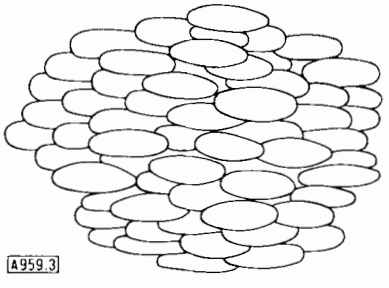

Fig. 3. Structural model of a nematic phase.

The ideal case—*i.e.* parallel orientation of all molecules over large regions—can only be achieved by expenditure

[*] *Note added in proof* (July 23, 1973): It has meanwhile been found that smectic C phases are suited for the production of electrooptical memory devices [188].

of additional energy, *e.g.* by electric or magnetic fields. In real nematic liquids, however, the preferred orientation is subject to continuous change, the angle by which the preferred direction changes from place to place not being defined as it is in cholesteric liquid crystals (Section 2.3).

The quality of the parallel orientation can be characterized by the degree of order S which is unity for the ideal nematic phase and zero for the isotropic phase. It has a value between 0.3 and 0.8 for normal nematic liquid crystals and decreases steadily with rising temperatures, suddenly falling to 0 at the transition point to the isotropic melt[13, 18].

Nematic "single crystals" ($S=1$) are optically and dielectrically uniaxial, the symmetry axis running parallel to the molecular axis. The values of the dielectric constant ε, the susceptibility χ, the refractive index n, or of other anisotropic properties measured in this direction are given the subscript 1, and the values measured in a perpendicular direction the subscript 2. In nematic liquid crystals the molecular long axis is also the direction of maximum polarizability of the molecule; thus a positive birefringence ($n_1 > n_2$) is always observed[19–22].

The diamagnetic anisotropy of nematic phases ($\Delta\chi = \chi_1 - \chi_2$) is also always positive since the susceptibility is always greater along the molecular long axis than in the perpendicular direction.

In contrast, the dielectric anisotropy ($\Delta\varepsilon = \varepsilon_1 - \varepsilon_2$) can be positive or negative and depends upon the varying contributions of shift and orientation polarization in the different axial directions which are determined by the molecular structure[23, 24].

Uniformly oriented nematic preparations also exhibit anisotropic electric conductivity[25–29], thermal conductivity[30, 31], ultrasonic velocity[32], diffusion[33], and viscosity[34]. Values of anisotropic measurements must always be accompanied by the measuring temperature since they are all strongly temperature-dependent. The manifold applications of nematic phases will be described in Section 4.

2.3. Cholesteric Liquid-Crystalline Phases[1, 3]

The cholesteric mesophase represents a special case of the nematic structure in that it is also characterized by a parallel orientation of the long axes of the molecules which however varies regularly from place to place. As shown in Figure 4 there is a uniform preferred direction within a given layer which is rotated in a uniform direction through a constant angle relative to that in the adjacent layer. Seen over several layers this leads to a skewed arrangement of the molecular layers[35]. The twisted structure and the sense of the rotation are induced by the chiral form of the participating molecules. Cholesteric phases were first observed in cholesterol derivatives.

Mixing of cholesteryl esters having right-handed and left-handed helical arrangements in a particular ratio and at a definite temperature, the nematic temperature T_n, at which the rotatory powers of the components cancel each other, leads to a nematic liquid crystal which is termed a compensated cholesteric liquid crystal[36]. Such cholesteric-nematic phase transitions can be induced not only thermally but also by application of electric[37, 38] and

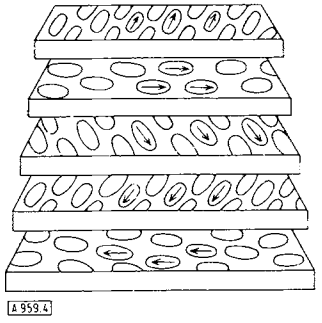

Fig. 4. Structural model of a cholesteric phase. The preferred orientation of the long molecular axes within a layer is rotated through a constant angle relative to that within the adjacent layer (helical structure).

magnetic fields[39, 40]. Moreover, the cholesteric structure can also be produced by addition of a chiral, not necessarily liquid-crystalline, compound to a nematic liquid[41] or by resolution of nematic racemates[42], thus clearly illustrating the close relationship between cholesteric and nematic structure.

Most of the optical properties result from the twisted structure, *e.g.* the extremely high optical rotation, the circular dichroism, and the technically important selective reflection of the spectral region whose wavelength corresponds to the pitch of the helix[43]. A change in pitch caused by thermal[43, 44], magnetic[45], or electrical energy[46–48] manifests itself in a change in optical properties.

Of particular importance in practice is the temperature dependence of selective reflection in the visible spectrum because it enables cholesteric liquid crystals to be used as temperature indicators in medical diagnoses[49, 50], in nondestructive testing of materials[51, 52], or for infrared image converters[53]. Experiments have also be performed to exploit this effect for the production of color TV tubes[54, 55] but have so far been thwarted by the difficulties inherent in converting an electrical impulse into a local warming effect in a manner satisfying practical requirements. Other electrooptical applications of cholesteric liquid crystals are based either on the above mentioned cholesteric-nematic phase transition by electric fields[46] or on the conversion of the transparent planar cholesteric texture into the strongly dispersive focal conic texture, which opens up the possibility of producing optical storage systems[56–58] (cf. Section 4.4).

3. Relationship between Chemical Structure and the Occurrence of Liquid-Crystalline Phases

Recent studies on the relationship between molecular structure and the appearance of anisotropic mesophases have been performed mainly by *Brown*[59], *Dave*[60], *Gray*[1, 61], *de Jeu*[62], *Kast*[63], and *Wiegand*[64]. *Kast* also compiled a list of all compounds known up to 1959 that possess liquid-crystalline properties[65].

3.1. Molecular Structure of Nematic and Smectic Compounds

The thermodynamic stability of liquid crystalline phases can be characterized in terms of the clearing point, *i.e.* the temperature at which the energy content of the anisotropic and the isotropic liquid is equal and both modifications are present.

Comparison of the clearing points of compounds of analogous structure differing only in one particular feature permits assignment of the contribution of such partial structures to liquid-crystalline character. The most important knowledge gained in this way will now be summarized and illustrated with the aid of a characteristic example:

The greater the anisotropy of the polarizability of a molecule, the higher the clearing point and the stability of mesophases. Accordingly, the compounds forming liquid crystals generally are composed of long, planar rigid molecules usually consisting of a conjugated aromatic system.

Table 1. Compounds of types *(3)*—*(9)*.

(3)–*(9)*

Type	X	Name	Ref.
(3)	—CH=CH—	*trans*-stilbenes	[66]
(4)	—C≡C—	tolanes	[67]
(5)	—N=N—	azobenzenes	[68, 69]
(6)	—N=N— (O)	azoxybenzenes	[70, 71]
(7)	—CH=N(O)—	nitrones	[72]
(8)	—CH=N—	Schiff bases	[73, 74]
(9)	—O—CO—	phenyl benzoates	[75]

Compounds of types *(3)* to *(9)* (Table 1) have been intensively studied[76–78] in connection with the applications considered in Section 4. Of the stilbenes *(3)*, only the *trans* isomers are able to form liquid-crystalline phases. Although the correspondingly substituted *cis*-stilbenes are also planar they do not have a linear molecular structure. Owing to their low degree of conjugation the esters *(9)* have the lowest clearing points. Methyl substituents *ortho* to the bridge or on the bridge itself in the case of stilbene effect mutual twisting of the phenyl rings for steric reasons, thus reducing the polarizability along the long molecular axis and thereby the stability of the mesophase[66, 79]. Replacement of aromatic rings by bi- or mono-cyclic aliphatic systems has a similar effect[80, 81]. Additional permanent dipoles shift the clearing points to higher temperatures. Whereas the central bridge of the molecule induces anisotropic melting properties, the nature and chain length of the wing groups determine which of the mesophases occurs.

If the wing groups are ether or ester groups linked to the molecular skeleton *via* oxygen, the lone pairs also contribute to the π-electron system, thus enhancing the thermal stability of the mesophases:

(6a), R = R′ = *n*-C_4H_9 [69], clearing pt. 28 °C (m. p. 14 °C)
(6b), R = *n*-C_4H_9, R′ = OC_4H_9 [70], clearing pt. 91 °C (m. p. 37 °C)
(6c), R = R′ = OC_4H_9 [82], clearing pt. 137 °C (m. p. 102 °C)

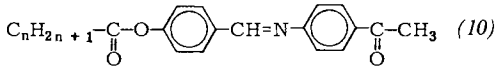
Table 2 illustrates the effect of varying the wing groups on the liquid-crystalline properties of a homologous series[83].

The acetic ester *(10)*, $n=1$, goes directly from the solid to the isotropic liquid state at 114.5 °C; only on careful supercooling to 105 °C does the latter phase yield a metastable nematic phase. Such systems are termed monotropic. An enantiotropic, *i.e.* thermodynamically stable, nematic phase is observed for the propionic ester *(10)*, $n=2$. The compounds with $n=3$ and 4 also give monotropic smectic phases in addition to enantiotropic nematic phases, while both the nematic and the smectic phases of the higher homologs ($n=5$—7) are enantiotropic.

As the chain length increases, the tendency to form smectic phases increases at the expense of the nematic phase until eventually only smectic phases are observed at a chain length of, in the present case, more than seven carbon atoms.

This behavior has been observed in all homologous series of ethers, esters, ketones, or directly linked alkyl chains in various classes of compounds and can therefore be generalized.

Table 2. Transition points [°C] of a homologous series of type *(10)* [83]. Monotropic transitions are indicated in parentheses.



(10)

n	solid/ isotropic	smectic [a]		nematic	anisotropic/ isotropic (clearing pt.)
1	114.5	—			(105.0)
2		—		106.0	113.0
3		S_A:	(73.5)	87.5	115.0
4		S_A:	(84.0)	101.0	105.5
5		S_C:	86.5	92.0	110.5
6		S_C:	94.5	100.0	107.0
7		S_C:	89.0	107.0	111.5
8		S_C:	83.0	—	111.5
9		S_C:	79.0	—	116.0

[a] S_A and S_C signify smectic A and C phases. Further transitions to monotropic smectic phases were observed.

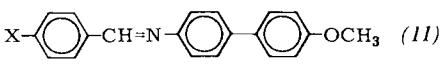
Table 2 also reveals another generally valid principle: the clearing points alternate within a homologous series, usually diverging towards lower values but sometimes also to higher values[62].

Chain branching in the substituent reduces the tendency to form anisotropic melts because steric hindrance precludes an optimum parallel arrangement of the molecular skeletons. The intramolecular steric hindrance increases the nearer the branching point approaches the rigid central part of the molecule[84].

Young et al.[85] found that incorporation of a particularly readily polarizable atom can compensate the unfavorable steric effect of chain branching. While the *tert*-butyl com-

pound *(11a)* is not liquid crystalline, the trimethylsilyl *(11b)*, trimethylgermyl *(11c)*, and trimethyltin *(11d)* analogs form smectic mesophases (Table 3).

Table 3. Melting and clearing points [°C] of compounds *(11a)*—*(11d)*.



(11)

Cpd.	X	m.p.	clearing point
(11a)	$(CH_3)_3C$	190	—
(11b)	$(CH_3)_3Si$	180	183
(11c)	$(CH_3)_3Ge$	176	175 (monotropic)
(11d)	$(CH_3)_3Sn$	165	173

The central part of the molecule can be modified in a variety of ways. Thus when bearing suitable substituents, compounds having the structural features *(12)*—*(18)* exhibit liquid crystalline behavior[1,165] [X and Y in *(15)* have the same significance as in compound *(1)* and the compounds of types *(3)*—*(9)*]. Free carboxylic acids, such as *para*-substituted benzoic or cinnamic acids, occur as double molecules in the melt and thus form a planar system of sufficient length.

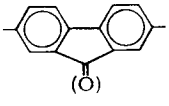
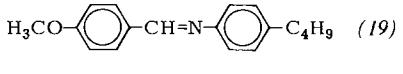
(17) [88]



(18)

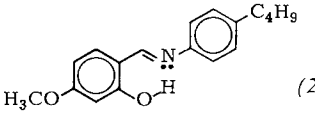
3.2. Nematic Liquid Crystals Having Special Properties

Subsequent to the discovery of their possible electrooptical applications (Section 4) an intense search was instituted for suitable nematic substances having low melting points and high clearing points, favorable anisotropic properties, and adequate stability towards chemical and physical effects.



(19)

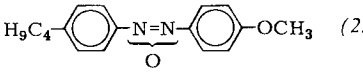
The first nematic compound found to be a liquid at room temperature, *p-n*-butyl-*N*-(*p*-methoxybenzylidene)aniline (MBBA) *(19)*, m.p. 20 °C, clearing point 47 °C, was described in 1969 by *Kelker et al.*[73]. Moreover, binary eutectic mixtures of Schiff bases have been prepared, some of which melt far below 0 °C[73,74]. However, since the sensitivity of Schiff bases to hydrolysis severely impairs their technical utilization, attempts are made to stabilize them by introduction of an intramolecular hydrogen bond as in compound *(20)*, m.p. 44.7 °C, clearing point 64.5 °C[89]. A significant but insufficient stabilization is noted. The increase in the clearing point is accompanied by an increase in melting point compared to compound *(19)*.



(20)

Studies on more stable structural types showed that the substituent combination *p-n*-butyl/*p*-methoxy also leads to the lowest melting representatives *(21)* and *(22)*, respectively, of the azo- and azoxybenzenes[68,70] [*(21)*, m.p. 32 °C, clearing point 47 °C; *(22)*, m.p. 16 °C, clearing point 76 °C]. The azoxy product *(22)* consists of a mixture of the two N—O isomers. Admixture of 35% of the isomeric pair *p*-ethyl-*p*-methoxyazoxybenzene gave a eutectic (clearing point 75 °C) melting at −5 °C[70].

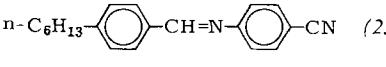
(21)



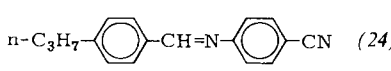
(22)

The azomethines and azoxybenzene derivatives mentioned so far exhibit a negative dielectric anisotropy. If there is no permanent electric dipole perpendicular to the long molecular axis (ε_2) or the *para* position carries a strongly polar group, then the dielectric constant ε_1 in the direction of the long axis will predominate, and the dielectric anisotropy ($\Delta\varepsilon = \varepsilon_1 - \varepsilon_2$) will be positive. The dielectric anisotropy of the azoxybenzene derivative *(22)* amounts to −0.2, and that of the azobenzene analog *(21)* +0.2. That the ether oxygen in *(22)* also makes a crucial contribution to the permanent transverse dipole moment is apparent from a comparison of the dielectric anisotropy of *(22)* with that of *p,p'*-di-*n*-butylazoxybenzene (+0.19)[69,90].

Nitrile groups in one of the *para* positions increase the dielectric anisotropy. Thus a dielectric anisotropy of +14 was recently reported[91] for the eutectic system comprising 2/3 *(23)* and 1/3 *(24)*, m.p. −30 °C, clearing point 62 °C.



(23)



(24)

The phase diagrams of binary nematic systems display the known depression of freezing point which leads in

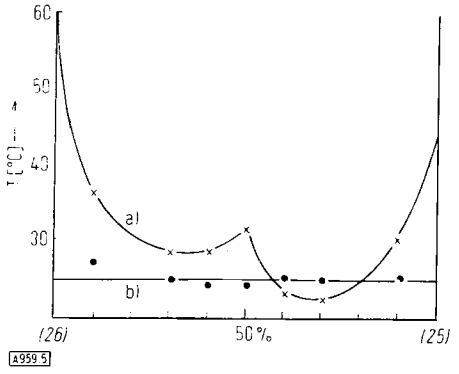


Fig. 5. Phase diagram of a binary mixture of the phenyl benzoates (25) and (26): a) melting points, b) clearing points.

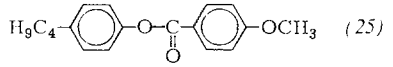
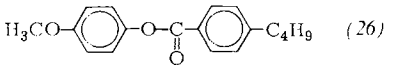
some cases to very low-melting eutectics. Since the melting temperature of such mixtures can be calculated by the classical van't Hoff-Schröder-Van Laar formula under certain conditions, it is also possible to calculate the eutectic composition of binary systems[92].



(25)

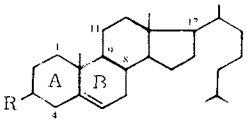


(26)

The clearing points lie practically on a straight line between the clearing points of the two pure components. Figure 5 depicts a phase diagram of the monotropic nematic compounds (25) and (26) which form an enantiotropic nematic eutectic. The 2:1 composition of the eutectic, also found in the (23)/(24) mixture, is typical of numerous binary nematic systems[93].

3.3. Molecular Structure of Cholesteric Compounds

Cholesteric mesophases occur primarily in cholesterol derivatives of type (27) in which the hydroxyl group in position 3 is esterified with aliphatic[65] or aromatic[94,95] carboxylic acids, hydrogen carbonates[96], or inorganic acids[65]. Here, too, long-chain substituents enhance the tendency to form enantiotropic smectic phases which undergo transition to cholesteric mesophases at elevated temperatures.



(27)

The only hydrogenation product of cholesterol able to form esters having cholesteric properties is 5α-cholestan-3β-ol. In the 5β compound, rings A and B are *cis* to each other, thus ruling out the planar conformation which is also an important structural feature of the cholesteric mesophase[97,98]. Studies by *Pohlmann et al.*[99] and *Atallah et al.*[100] on the influence of the position of a double bond in steroids and triterpenes on the formation and type of mesophases revealed that mesophase formation is not supported by a C-1, C-4, or C-8 double bond in the steroid molecule, whereas a double bond between C-9 and C-11 permits a cholesteric phase. The nature and length of the 17β side chain also exert a considerable influence on the mesomorphic behavior of the molecule[101]. Accordingly, extensive variations of the cholesterol molecule are possible without loss of liquid-crystalline properties. It is therefore hardly surprising that cholesteric mesophases have also been found for derivatives of other naturally occurring steroids such as sitosterol[65] or 9,13-cyclopropane triterpenes[102]. However, nonsteroidal compounds of nematogenic structure can also form cholesteric mesophases provided that they contain optically active substituents[65,103]. It appears that an asymmetric center suffices to impart to the nematogenic molecules the helical arrangement necessary for formation of a cholesteric mesophase.

4. Use of Nematic Liquid Crystals in Electrooptic Display Devices

Application of electric fields of a few hundred to several ten-thousand V/cm can induce changes in the state of order of thin nematic liquid-crystalline films. These changes in order are observable as changes in optical properties such as transparency, light scattering, birefringence, or color. Such electrooptical effects can be observed and utilized in a set-up consisting of two conducting glass plates coated on the inside with a transparent SnO_2 or In_2O_3 layer and between which there is a 5–50 μm uniformly

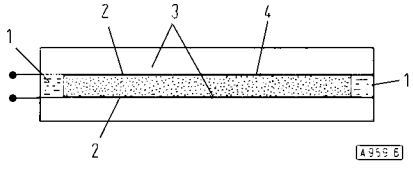


Fig. 6. Section through a liquid crystal display device. 1, separating foil; 2, electrode layer of SnO_2, In_2O_3, or a similar substance; 3, glass plate; 4, nematic phase (5–25 μm).

oriented nematic film (Fig. 6). Thinner layers are difficult to produce and thicker ones exhibit strong light scattering.

4.1. Orientation of Nematic Liquid Crystals at Interfaces

In cells of the above type the liquid crystal molecules can adopt orientations with their long axis either perpendicular or parallel to the walls (Figs. 7a and 7b). The former case is described as a homeotropic phase or orientation, and the latter as a homogeneous one. The orientation of the molecules at the interface is transmitted to the internal molecules by dispersive interaction. The methods used for production of uniformly oriented layers are still largely empirical.

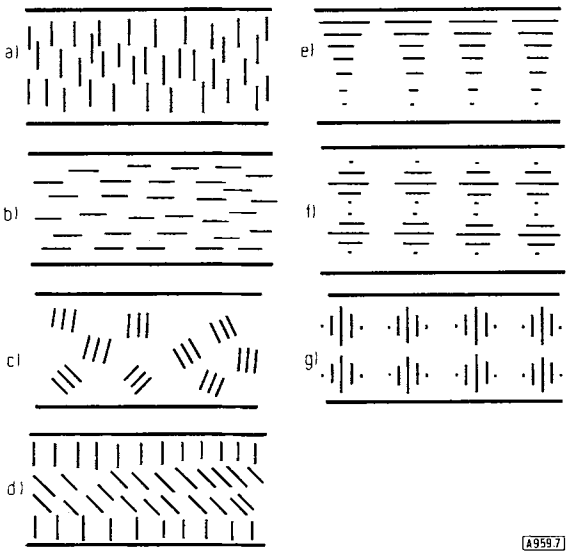

Fig. 7. Possible orientations of thin liquid crystalline layers; a, homeotropic; b, homogeneous; c, disordered, dynamic scattering; d, deformed homeotropic; e, twisted homogeneous; f, cholesteric planar; g, cholesteric focal conic structure.

The homeotropic orientation (Fig. 7a) can be achieved by treatment of the glass plates with an ethanolic lecithin solution[104] or by addition of polyamide resins[105] or quaternary ammonium salts[106] to a nematic liquid crystal. Some commercially available nematic phases are already doped so as to automatically adopt a homeotropic orientation[107].

The homogeneous orientation (Fig. 7b) can be brought about by unidirectional rubbing of the electrode surfaces with polishing cloths[108] or pastes containing diamond dust[109]. Such treatment produces submicroscopic grooves parallel to which the molecules adjacent to the interface become aligned. As demonstrated by *Berreman*[110], any other orientation of these molecules would incur expenditure of additional elastic energy. Homeotropic or homogeneous orientations are reported to be inducible according to choice by dipping the electrodes into solutions of *N*-hexadecyl-*N*,*N*,*N*-trimethylammonium bromide depending on the concentration and rate of immersion[111]. More reproducible homogeneous phases are obtained at electrode surfaces whose conducting surface has been condensed on at an angle of about 85° [112].

4.2. Interactions between Electric Fields and Nematic Liquid Crystals[90, 113]

Three kinds of electrooptical effect are known to occur in liquid crystals, *viz.* dielectric, piezoelectric, and electrohydrodynamic effects. The first two arise solely from the influence of electric fields without simultaneous participation of charge transport and are known collectively as field effects. They result from static, so-called dielectric deformation of the existing orientation of the liquid crystals and become operative above a certain threshold voltage that, for dielectric effects, is independent of the layer thickness but dependent upon the dielectric anisotropy and the splaying, bending, or twisting of the liquid crystalline layer[114, 115].

Nematic crystals exhibiting positive dielectric anisotropy (cf. Section 3.2)—this applies to molecules having a strong electric dipole in the direction of the long molecular axis—align their long axes parallel to the direction of the field under the influence of a DC or AC potential. This homeotropic orientation is further promoted by a flow of charge carriers between the electrodes.

Field effects are more complicated in the case of nematic substances having negative dielectric anisotropy[29, 90]. For small AC potentials (5—10 V depending on conductivity and thickness of sample) a static deformation of the layer takes place, irrespective of whether it was originally homogeneous or homeotropic. A system of largely parallel striations is observed under a polarizing microscope. The line textures are called Williams domains after their discoverer[116–118]. The long axes of the molecules are arranged substantially parallel to the surface of the electrodes.

The same phenomenon is observed at higher potentials as long as their frequency is in excess of the cut-off frequency. This term denotes the frequency at which the preferred orientation of the liquid crystalline molecules due to the field is no longer subject to interference by migration of charge carriers[90, 119]. It is dependent upon the conductivity of the material and lies below 30 Hz for liquid crystals having $R > 10^{12}$ ohm cm and above 30 Hz for those with $R < 10^{12}$ ohm cm.

With potentials having frequencies lying below the cut-off frequency, fields in excess of about 10 kV cm^{-1} lead to perturbation of the molecules oriented parallel by the field owing to the flow of charge carriers between the electrodes, thus displacing the molecules from their stable equilibrium positions and destroying the overall optical homogeneity except for very small residual regions which act as scattering centers for light (Fig. 7c). Viewed under a polarizing microscope these small regions are seen to undergo vigorous turbulent motion. Macroscopically, this turbulence manifests itself in a sharp increase in scattering, conveying the impression that a transparent glass is transformed into a frosted glass on application of the DC or AC potential. This phenomenon is known as "dynamic scattering"[120].

4.3. Electrooptical Display Devices Employing Nematic Liquid Crystals

Most of the commercially available displays utilizing liquid crystals are currently based on the dynamic scattering effect. In addition, increasing use is being made of pure field effects for electrooptical applications.

4.3.1. Displays Based on Dynamic Scattering[121, 122]

Dynamic scattering cells can be constructed in a transmission or a reflection mode. In the former case both electrodes are transparent, and in the second the rear electrode is a mirror. All systems of this kind are characterized by their flat construction (2—3 mm thick), high contrast ratios in excess of 100:1 (the best contrast being obtained with homeotropic or homogeneous phases), low driving voltages

between about 20 and 30 V, and minimum power consumption of at most 500 $\mu W/cm^2$ of active display area.

Fig. 8. Example of a liquid crystal display based on dynamic scattering.

The lifetime of such display systems depends upon whether they work with AC or DC. For AC operation values in excess of 10000 operating hours are reported. DC operation often leads to gradual deposition of the ions required for dynamic scattering so that the conductivity often drops below the threshold potential for dynamic scattering. This effect can be suppressed by addition of less than 1% of a charge-transfer acceptor, *e.g.* chloranil, which lowers the threshold potential by a factor of 2[123].

The switching times depend on the layer thickness of the nematic phases, the driving voltage, the conductivity, the dielectric anisotropy, and the viscosity. The following values are typical for the standardized commercial nematic material[107] used for dynamic scattering applications (conductivity: 4×10^{-10} to 10×10^{-10} ohm^{-1} cm^{-1}):

T_r (raise time):	18 to 28 ms
T_d (decay time):	25 to 50 ms

(measuring conditions: $d = 10\,\mu m$, $U = 25$ V/50 Hz, SnO_2 electrodes)

Apart from digital and analog display of measured values, time of day, and computer and process data (Fig. 8), display systems with nematic liquid crystals are suitable for use in, *e.g.* remotely controlled flight timetables, windows of variable transmission, or advertising displays. Unlike conventional luminous display they become more and more legible as the brightness of the environment increases.

4.3.2. Display Devices Based on Electroelastic Deformation of Vertically Aligned Nematic Layers (DAP Effect)

Homeotropically oriented layers of negative dielectric anisotropy readily undergo elastic deformation on application of an electric field parallel to the principal optical axis of the molecules, leading to a displacement from their perpendicular orientation (Fig. 7d). This effect is designated as deformation of vertically aligned phases or in abbreviated form as the DAP effect[124, 125]. The degree of deformation depends on the applied voltage. In the extreme case the molecules flip out of their homeotropic into a homogeneous orientation. The potential required for displacement of the molecules lies in the range 5—10 V and is thus much lower than the corresponding driving voltage of 20—30 V for dynamic scattering. The occurrence of dynamic scattering during deformation is avoided by the use of high resistance liquid crystals and AC potentials having frequencies above the cut-off frequency.

Homeotropic liquid crystalline layers behave like optically positive, uniaxial crystals. Light entering the crystals in the direction of the optical axis emerges unchanged. If such a liquid crystalline layer is situated between crossed polarizers the overall system cannot transmit light and thus appears black.

If the liquid crystalline layer is deformed by application of an electric field, the angle between the optical axis of the liquid crystal and that of the incident light, *i.e.* the angle of incidence, differs from zero and birefringence occurs. Under these conditions, and using parallel light the intensity (I) of the emerging light depends on the phase difference δ between the ordinary and the extraordinary ray as shown in eq. (1).

$$I = I_0 \sin^2(\delta/2) \tag{1}$$

The phase difference itself varies with the difference between the refractive index of the extraordinary ray (n_e) and the ordinary ray (n_o) according to eq. (2).

$$\delta = \frac{2 \times \pi \times d}{\lambda} \Delta n, \quad \Delta n = n_e - n_o \tag{2}$$

For a given layer thickness d and wavelength λ (monochromatic light) the angle of incidence can be varied at will between 0 and 90° *via* the deformation of the homeotropic phase by the applied voltage. It is thus possible to switch the system from opacity to transparency, *i.e.* from dark to light. Contrast ratios in excess of 500:1 are perfectly feasible[126].

4.3.3. Display Devices Based on an Electroelastic Deformation of Homogeneous Nematic Layers (Fréedericksz Effect)

Homogeneously oriented nematic liquid crystals of positive dielectric anisotropy can be reoriented homeotropically by application of a DC or AC field perpendicular to the long molecular axis. This effect, the counterpart of the deformation of vertically aligned phases, produces the same observable effect as the latter and was described by *Fréedericksz* as long ago as 1933[127]. Such a layer between crossed polarizers can be switched from transparency to opacity, *i.e.* from light to dark.

4.3.4. Display Devices Based on Electroelastic Deformation of Twisted Nematic Layers (Schadt-Helfrich Effect)

Homogeneous phases can also be obtained in which the liquid crystals exhibit a preferred orientation differing by 90° between the opposite electrode surfaces[114] (Fig. 7e). Polarized light passing through such a twisted layer

is accordingly rotated through 90°, and between crossed polarizers the system is transparent. An electric field can induce homeotropic reorientation of the phase if the molecules possess a positive dielectric anisotropy (Fig. 7b). Polarized light is then unaffected and the system is opaque, appearing black. This effect, discovered by *Schadt* and *Helfrich*[114], yields high contrasts, and exhibits threshold potentials of less than 1 V[91], driving voltages of 2—5 V[128], and power consumptions of 1—50 $\mu W/cm^2$.

4.4. Electrooptical Effects Based on Textural Changes in Liquid Crystals

Addition of a chiral compound to a nematic liquid leads to two further effects, depending upon the anisotropy, designated as memory and transparency effects. Both arise from light scattering by disordered phases. However, since they represent stable textures and are not due to turbulence within small liquid crystalline regions, they differ fundamentally from dynamic scattering.

4.4.1. Memory Effect in Liquid Crystals[48, 56, 129]

Mixtures of a nematic liquid crystal of negative dielectric anisotropy and a cholesteric[130] or non-liquid crystalline chiral substance such as L-menthol[131] can be used to prepare thin films whose order corresponds to the planar cholesteric texture (Fig. 7f). Application of a DC potential transforms this phase into a strongly deformed, light-scattering phase exhibiting a focal conic texture (Fig. 7g) and having randomly oriented helical axes in the individual subregions. After removal of the applied potential the disordered phase reverts to the original ordered state within minutes or days, depending on the concentration of the chiral component (1—10%)[132]. An AC potential of 50 to 100 V whose frequency must exceed the cut-off frequency and is generally above 700 Hz, can reconvert the disordered into the ordered phase within milliseconds[133]. This reversible change of texture permits the construction of an optical memory device in which information can be recorded with an DC potential and erased with an AC potential.

4.4.2. Transparency Effect in Liquid Crystals[134]

For mixtures comprising 30—90% of a nematic liquid crystal of *positive* dielectric anisotropy and 70—100% of a cholesteric liquid crystal, a disordered molecular arrangement, or focal conic texture, is the most stable possibility. Such a liquid crystalline film therefore exhibits pronounced light scattering. An AC potential can transform the disordered phase into an unstable homeotropically oriented, transparent layer which reverts to the disordered state when the potential is removed. The switching times depend, *inter alia*, on the thickness of the layer, the dielectric anisotropy, and the mixing ratio of nematic to cholesteric liquid crystals, and lie below 10 ms; the AC potentials required are between 30 and 100 V.

4.5. Production of Colors with Nematic Liquid Crystals

Apart from black-and-white contrasts, nematic liquid crystals can also be used for generating colors by virtue of interference phenomena in homogeneous or homeotropic layers or of reorientation of dichroic dyes embedded in a liquid crystalline matrix.

4.5.1. Colors from Tunable Domains

Homogeneously or homeotropically oriented layers (3 to 6 μm thickness) of high resistance ($> 10^{12}$ ohm cm) nematic liquid crystals with negative dielectric anisotropy exhibit Williams domains (Section 4.2) when an applied potential alternates at a frequency in excess of the cut-off frequency. The width of the domains can be reduced by a factor of 10 from *e.g.* 10 to 1 μm if the applied potential is raised by the same factor, *e.g.* from 10 to 100 V. Such liquid crystalline layers therefore behave as a tunable optical diffraction gratings which, being phase gratings, are highly efficient. If a directional filter which only transmits light of a particular diffraction angle is placed behind one of these gratings and white light shone onto the set-up, any desired spectral color can be obtained by changing the applied potential[135–137].

4.5.2. Colors Produced by Reorientation of Aligned Phases (DAP and Fréedericksz Effect)

If white light is used instead of monochromatic light with the set-up described in Sections 4.3.2 and 4.3.3, then according to eq. (2) the phase difference between the ordinary and the extraordinary ray occurring on deformation of the homeotropic or homogeneous phase depends not only upon the angle of incidence but also upon the wavelength. Interference between these two rays thus leads to the appearance of Newtonian colors. For a given direction of observation any desired spectral color can be obtained by variation of the applied potential.

4.5.3. Colors Produced by Dichroic Liquid-Crystalline Color Switches

Dyes exhibiting differential absorption of polarized light in the directions of the individual axes are called dichroic. Representatives of this group include indophenol blue, alizarin, and oil yellow. Since the guest molecules dissolved in a nematic liquid crystal frequently adopt the same orientation as the liquid-crystalline host molecules and are reoriented with the latter by electric fields, dichroic dyes can be utilized in the production of color switches[138–140] that can be tripped from colored to colorless or *vice versa* (Fig. 9).

A *homogeneously* oriented film (Fig. 9a) of a nematic liquid crystal of *positive* anisotropy doped with 1—2% of a dichroic dye absorbs only light polarized in the direction of the transition moment. Such a system is therefore colored. If a doped liquid crystalline layer is aligned homeotropically by a DC or AC potential (Fig. 9b) interaction no longer occurs between the chromophore and the incident light and the system is colorless.

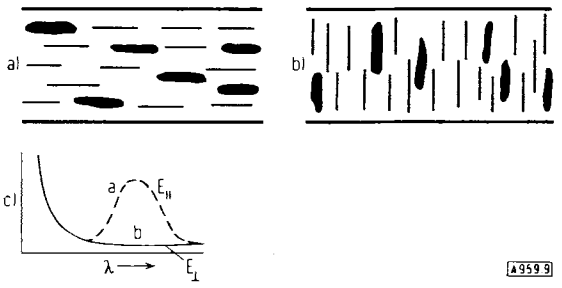

Fig. 9. Inclusion of dichroic dye molecules in a nematic layer: a, absorbing; b, nonabsorbing; c, absorption curves.

Conversely, a corresponding *homeotropic* layer of a nematic liquid crystal of *negative* anisotropy is colorless in its quiescent state and becomes colored when it undergoes homogeneous reorientation. A color switch of this kind also functions with unpolarized light. Since the driving voltages required are of the same order as those required for dynamic scattering the latter type of color switch, in contrast to the former, requires AC potentials having frequencies in excess of the cut-off frequency for dynamic scattering.

4.6. Piezoelectric Effect in Nematic Liquid Crystals

The phenomenon of piezoelectricity as known for natural electrets such as quartz or tourmaline and which nowadays finds wide technical application in quartz crystal oscillators was first detected in liquid crystals in 1972[141].

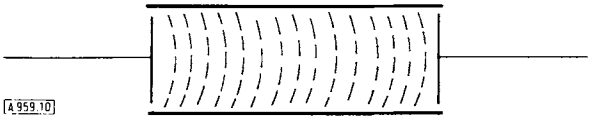

Fig. 10. Distorted homeotropic layer exhibiting piezoelectric properties.

If an electric potential is applied perpendicular to the molecular orientation of a homeotropic layer of nematic liquid crystals of negative dielectric anisotropy, the orientation of the liquid crystals becomes distorted in the direction of the field (Fig. 10). The liquid crystalline layer which was originally isotropic to the incident light striking it parallel to the preferred orientation becomes anisotropic due to the distorted molecular arrangement and thus birefringent. This bending or piezoelectric effect leads, *e.g.* for layer thicknesses of *ca.* 100 µm and field strengths of 100 V/cm, to an optical phase difference between the ordinary and extraordinary refractive rays of 300 Å.

5. Liquid Crystals as Anisotropic Solvents for Molecular Spectroscopy

Anisotropic spectroscopic molecular properties, *e.g.* polarization of an electronic or vibrational transition in the UV or IR or the magnitude of a direct intramolecular dipole-dipole interaction in NMR and ESR, can only be observed with oriented molecules. Corresponding studies can be performed both in the solid state and in liquid crystalline solvents[3, 142–145].

Since the molecules dissolved in a liquid crystal are frequently aligned parallel to the preferred orientation of the principal axis of the liquid crystal it becomes possible to study not only the anisotropic molecular constants of the liquid crystal itself but also those of the molecules dissolved therein.

Planar or elongated molecules can be dissolved in nematic liquid crystals in concentrations up to 30 mol-% without destroying the liquid crystalline state. This limiting value is frequently much lower for spherical molecules. The dissolved molecules usually exhibit a lower degree of order than the solvent molecules. Since the clearing point is invariably lowered more than the melting point the nematic range is significantly narrower than that of the pure solvent. Spectroscopic studies therefore require liquid crystals with wide mesophase ranges, which should be liquid crystalline at room temperature to facilitate experimental work.

5.1. Liquid Crystalline Solvents in Optical Molecular Spectroscopy

Determination of the polarization of absorption or fluorescence bands is usually performed with single crystal sections. High intensity bands require single crystal sections less than 1 µm thick whose preparation and handling is not easy and sometimes even impossible. The alternative procedure of working with non-absorbing single host crystals or with stretched plastic films[146–148] into which the sample under study has been previously incorporated is complicated and again sometimes impossible. In contrast, nematic liquid crystalline solvents permit the recording of polarization spectra in the same simple manner in which spectra are measured in isotropic solvents.

Investigation of the polarization of a transition with the aid of homogeneously oriented liquid crystalline layers requires use of linearly polarized light. Measurements in homeotropic phases, however, also permit the direction of the transition moment to be determined without polarized light, the spectrum of the nematic solution being recorded first and then that of the isotropic solution above the clearing point. The difference in intensity between the individual bands allows unambiguous assignment of their polarization[149].

5.1.1. Use of Liquid Crystals in Absorption and Fluorescence Spectroscopy

The intrinsic absorption of nematic liquid crystals of the Schiff base, azoxybenzene, or phenyl benzoate type preclude their use as solvents for recording polarized absorption of fluorescence spectra except for molecules whose spectra lie above 350 nm[150, 151]. Compensated cholesteric liquid crystals (see Section 2.3), on the other hand, represent nematic solvents which transmit light above 250 nm and which can readily be supercooled to give vitreous solutions by quenching[36, 152–154].

While the degree of order S of dissolved molecules, and its temperature dependence, can also be ascertained from

polarized absorption spectra[155-157], these quantities cannot generally be obtained from the corresponding fluorescence spectra since the polarized fluorescence of the dissolved molecules is anisotropic in the various axial directions, *i.e.* may be quenched to varying extents. Hence the fluorescence intensity measured is no longer solely dependent on the molecular orientation[158].

5.1.2. ORD and CD in Nematic Solvents

On dissolution of chiral compounds in a nematic solvent the solute molecules induce a helical ordering of the liquid crystalline molecules and thus transform the nematic liquid into a cholesteric phase which exhibits optical rotatory dispersion (ORD) and circular dichroism (CD)[41]; 1—2 mol-% of the chiral compound suffice to effect this transition. The effect is caused both by asymmetric molecules such as L-menthol[159] and by dissymmetric structures such as diazacycloctatetraene derivatives[41], the sense of rotation of the helix depending upon the chirality of the solute molecules. Since the induced specific rotation of the cholesteric liquid crystalline solution can far exceed 1000° and is hence three orders of magnitude larger than that of the molecular compounds or molecules dissolved in isotropic solution, these effects, which were first described by *Stegemeyer et al.*, are suitable for detecting small amounts of optically active or chiral molecules having very low optical activities.

5.1.3. Induction of Optical Activity by Cholesteric Solvents

The complementary phenomenon, *i.e.* induction of a Cotton effect within the absorption bands of achiral molecules with the aid of a cholesteric liquid crystalline solvent, has meanwhile also been established[160-164]. Here the helical structure of the cholesteric solvent is impressed upon the spatial arrangement of the dissolved molecules, leading to molar amplitudes of the induced rotatory dispersion of the order of 10^7 deg cm^2. These values thus exceed *e.g.* those of the pronouncedly chiral compound hexahelicene (8.62×10^5 deg cm^2) by several orders of magnitude. *E. Sackmann*[165] and *Saeva*[166] have developed a method of establishing the polarization of the pertinent electronic transition of the dissolved achiral molecule from the sign of the induced Cotton effect. The method clearly supplements the techniques hitherto available for determining the direction of electronic transition moments in molecules.

5.1.4. IR Spectroscopy in Nematic Solvents

Owing to their numerous absorption bands nematic liquid crystals find only limited use as anisotropic solvents for recording polarized IR spectra, which differ from the non-polarized IR spectra only in the intensities of analogous bands. This intensity difference which is known as infrared dichroism permits determination of either the degree of order[156,157,167] or the vibrational class of the individual bands of the dissolved molecule[151,168]. The method has been used primarily for investigation and assignment of —C≡N, —C=O, —C≡C—, and =C=O stretching vibrations.

5.1.5. IR-ORD in Nematic Solution

The theory of rotatory dispersion predicts that Cotton effects should also occur in the infrared. However, the amplitudes of these anomalies are four orders of magnitude smaller for vibrational than for electronic transitions. Nevertheless, as *Schrader* and *Korte*[169] were able to show for the first time, Cotton effects also occur in the IR with amplitudinal values of several thousand deg per mm when chiral molecules are dissolved in nematic solvents. The frequencies at which these IR Cotton effects are observed agree, as in the UV, with the absorption bands of the liquid crystal but not with those of the dissolved molecule.

5.2. NMR Spectroscopy in Nematic Solvents[3,142,143]

Proton and fluorine nuclear magnetic resonance spectroscopy in nematic solvents is already a routine method for determining bond angles and relative bonding distances in proton deficient molecules and has been treated in detailed reviews[170-172]. Advances in the field of Fourier transform NMR spectroscopy have meanwhile facilitated measurements on nuclei of low sensitivity and low natural abundance, *e.g.* ^{13}C-NMR spectra, without preliminary isotopic enrichment[173]. If the degree of order of the solute molecules is known, the direct ^{13}C-^{1}H nuclear spin coupling constants $D_{^{13}C-^1H}$ obtained from these spectra, which at 1 500 Hz are larger than the indirect ^{13}C-^{1}H coupling constants $j_{^{13}C-^1H}$ by a factor of 10, can be utilized for calculating not only the H—C—H bond angles but also C—H bond lengths. In contrast, the analogous anisotropic proton spectra yield only relative internuclear distances *via* the direct ^{1}H-^{1}H coupling constants. Because of the numerous possible dipole couplings in molecules containing many protons the resonances exhibit such extensive splitting, as in anisotropic proton spectra, that analysis is no longer possible. The application of this method is therefore limited to small molecules.

5.3. ESR Spectroscopy in Liquid Crystals

ESR spectra in liquid crystalline solvents provide extremely valuable information, also for the preparative chemist[174-176]. Both liquid crystalline[175,177] and glassi[177,178] nematic, supercooled compensated cholesteric[153] and also smectic liquid crystals[179,180] are used in these studies. The direct dipole-dipole interaction between the unpaired electrons of a multiple radical which is averaged to zero by Brownian motion in isotropic solution is retained in liquid crystalline solution and appears—*e.g.* as a triplet for a biradical—alongside the hyperfine splitting. Thus an ESR spectrum in liquid crystalline solution, in contrast to the results obtained in isotropic solution, provides a clear-cut answer to the question of how many unpaired electrons a radical contains[174,184]. It also permits calculation of the concentration, and its temperature dependence, of multiple radicals[181].

Highly complex ESR spectra can be considerably simplified by electron-nucleus double resonance experiments

(ENDOR). Low-melting azoxybenzene derivatives have proved particularly suitable for such studies[182].

5.4. Mössbauer Spectroscopy in Smectic Phases

One of the few applications of smectic phases has recently been found in Mössbauer spectroscopy[183–187]. The possibility of translational molecular motion in all three spatial directions in nematic phases rules out their use as matrices for Mössbauer measurements. Recoilless γ-resonance is feasible, however, in smectic solvents where translational motion is permitted within a molecular layer in the direction of the long molecular axis but not in a perpendicular direction. Measurement of Mössbauer spectra in a smectic rather than a solid matrix has the advantage of simplified sample preparation, provided the substance under study is sufficiently soluble. The intensity of the spectra is albeit lower than in crystalline matrices.

6. Outlook

Although it is only in the last 10 years or so that the potential technical applications of nematic liquid crystals have been studied in depth, these substances now occupy a strong position in the field of electrooptics in such applications as digital indicators for electronic clocks, table-top calculators, and measuring instruments; in the near future we shall see their application in remote controlled traffic signs and information boards, vehicle instrument panels, special window panes, in which the degree of light penetration may be controlled, and camera shutters. Looking further into the future, we can also anticipate optical memory devices and flat large area color television screens.

Reactive Monomeric Carbonic Acid Derivatives

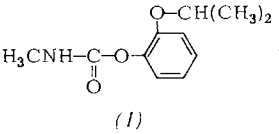
By Engelbert Kühle[*]

Monomeric carbonic acid derivatives that can react by addition or substitution are systematically discussed according to the three tabular surveys A, B, and C, from which a principle for the classification of carbonic acid derivatives can be readily deduced. For each type of compound, a brief description is given first of the principal syntheses and then of the reactions, and the heterocycles obtainable by addition, disubstitution, or coupled addition-substitution are also considered. The carbonic acid derivatives discussed can be synthesized from very simple and in most cases cheap base chemicals.

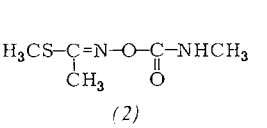
Introduction

The derivatives of carbonic acid are usually discussed only briefly in textbooks of organic chemistry, though carbonic acid chemistry actually offers the synthetic worker a multitude of possibilities for the synthesis of new compounds, and carbonic acid derivatives have a very wide range of uses in industrial chemistry.

The industrial importance of carbonic acid chemistry is clear from the following brief enumeration of its uses. Urea-formaldehyde and melamine resins have been in use for a long time; polycarbonates and polyurethanes are modern plastics used *e.g.* as foams, paint components, and products with rubbery properties. Cyanuryl chloride is used as a reactive component for dyes and as a starting material for herbicides. Arylalkylureas and *N*-arylcarbamic esters also have herbicidal properties, while aryl *N*-methylcarbamates, *e.g. (1)*, and *N*-methylcarbamidoximes, *e.g. (2)*, are used as cholinesterase inhibitors for the control of insects.



(1)



(2)

The fungicides used in agriculture include the dithiocarbamic acids; *N*-trihalomethylthio compounds, which can also be regarded as carbonic acid derivatives, are used for the same purpose. Very many carbonic acid derivatives are found in drugs. The range extends here from the old-established barbiturates to the modern antidiabetics based on sulfonylureas. A number of sulfonamides used in pharmaceutical applications are also based on carbonic acid derivatives. Finally, carbonic acid structures are found in complicated natural products, *e.g.* in antibiotics (streptomycin) and vitamins (folic acid), and as essential components of the nucleic acids (guanine, cytosine, thymine).

The purpose of the present article is to make the reader more familiar with low molecular weight carbonic acid chemistry through the system used here. To keep matters simple, the article deals only with carbonic acid compounds that can react by addition or chlorine substitution. Other halogens are considered only in special cases.

The tabular surveys at the beginning of each section are arranged in such a way that the elements or groupings of the 7th to the 5th main groups of the periodic system appear from top to bottom in the vertical direction and from left to right in the horizontal direction.

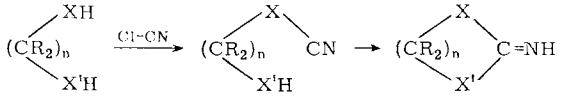
A. Compounds Containing a CN Triple Bond

		I— CN
1	Cl—	Cl—CN
2	RO—	RO—CN
3	RS—	RS—CN
4	ClS—	ClS—CN
5	R_2N—	R_2N—CN

A 11. Cyanogen Chloride

Cyanogen chloride is generally available as a 7% aqueous solution or as the anhydrous product in gas cylinders. It is synthesized by chlorination of hydrocyanic acid or alkali metal cyanides in water[1] or in inert organic solvents[2].

Cyanogen chloride can add to CC multiple bonds in the same way as the halogens, but only in the presence of $AlCl_3$ as a catalyst[3]. Conversely, it can add a wide range of electrophilic agents across its CN triple bond, in some cases with rearrangement, examples being the addition of chlorine[4, 5], phosgene[6], and acyl chlorides[7, 8] to form isocyanide dichlorides (B I4) and of SO_3 to form chlorosulfonyl isocyanate[9] (B II4). Nucleophilic substitution of the chlorine in cyanogen chloride leads with phenols to esters of cyanic acid (A I2), with thiols to esters of thiocyanic acid (A I3), and with amines to cyanamides (A I5). Numerous five-membered and six-membered heterocycles can be synthesized by substitution followed by addition to suitable 1,2- and 1,3-disubstituted nucleophiles[10].



n = 2, 3

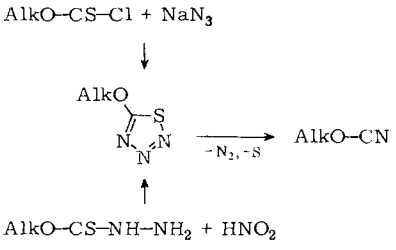
X, X' = O, S, NR'

A 12. Esters of Cyanic Acid

The synthesis of the cyanates, which are isomeric with the isocyanates (B II4), has been achieved only during the last few years. Aromatic cyanates can be obtained by reaction of phenols with cyanogen chloride in the presence of a base[11]. The yields are very good.

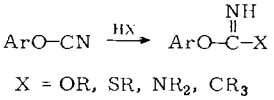
The only aliphatic cyanates that can be obtained by this method are the esters with strongly acidic alcohols, such as trichloroethyl cyanate[12].

Aliphatic cyanates are generally obtained by thermolysis of 5-alkoxy-1,2,3,4-thiatriazoles[13–15].



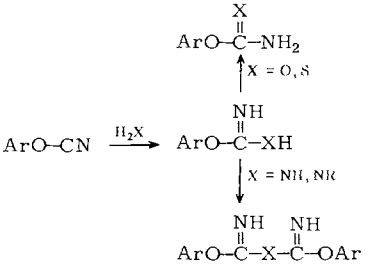
The alkyl cyanates are relatively unstable, since they readily isomerize to isocyanates or trimerize[15]. Nucleophilic substitutions have been achieved only on the alkyl cyanates, using nucleophilic anions (I^-, SCN^-, OCN^-)[16].

The addition of nucleophilic compounds, which has occasionally also been carried out with alkyl cyanates[16], has been extensively studied for aryl cyanates[11]. This reaction, which proceeds under mild conditions and in many cases with catalysis by acids or bases, often leads to further reaction products, depending on the other reactant (cyclizations, transfer of cyano groups). The addition of nucleophiles with a proton on the O, S, or N atom and of CH acids follows the indicated general scheme in the first step. A C—C linkage thus occurs with CH acids.

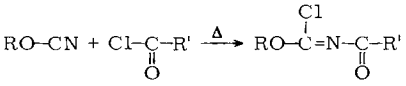


X = OR, SR, NR_2, CR_3

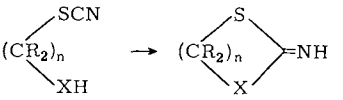
When water or hydrogen sulfide is used, the adducts isomerize to form esters of carbamic or thiocarbamic acid, while ammonia and primary amines lead to 2:1 adducts.



The addition of acyl chlorides to cyanic esters, which proceeds only at high temperatures, leads to *N*-acyliminocarbonic ester chlorides[17]. This reaction also takes place with sulfenyl chlorides.



Numerous heterocycles can be synthesized by further reactions, particularly with bifunctional systems or directly by 1,3-dipolar additions (with hydrazoic acid, diazomethane, nitrile oxides, nitrile imines)[11].



n = 2, 3
X = O, S, NR

A 13. Esters of Thiocyanic Acid

The thiocyanates are isomers of the thermodynamically more stable isothiocyanates (B III4), and can be rearranged into the latter in many cases by heating. Numerous methods are known for the synthesis of thiocyanates, but their application is limited in most cases to certain types.

Aliphatic thiocyanates are obtainable by the action of alkylating agents on alkali metal thiocyanates, but depending on the nature of the aliphatic residue, isothiocyanates may also be formed as by-products or as the principal products[18,19]. The addition of dithiocyanogen and of thiocyanogen chloride to CC multiple bonds leads to 1,2-bis(thiocyanates)[20] and to 2-chloro-1-thiocyanates respectively (cf. A I4).

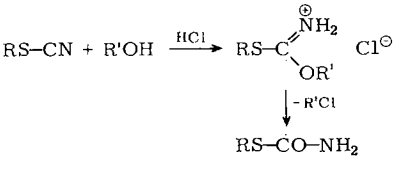
X = -SCN, Cl

With both reagents, aromatic compounds (phenols, amines) undergo electrophilic ring substitutions with formation of aryl thiocyanates[20,21] (cf. A I4). Another specific synthesis for aryl thiocyanates is the reaction of alkali metal thiocyanates with diazonium salts in the presence of copper salts (Gattermann-Sandmeyer synthesis)[22].

Two methods with a wider range of applications start with sulfenyl chlorides or thiols. The synthesis from sulfenyl chlorides and alkali metal cyanides[23] can be modified by reaction of sulfenyl chlorides with formamide in thionyl chloride[24].

Finally, in analogy with the synthesis of the cyanates (A I2), thiolates or thiols[25,26] react with cyanogen chloride to form thiocyanates.

The thiocyanates are also related to the cyanates in their reaction behavior. Thus alcohols can be added to the CN triple bond in the presence of hydrogen chloride, though the number of examples known in this case is smaller[27].

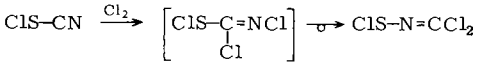


Cyclizations by intramolecular addition of suitable nucleophilic groups in position 2 or 3 lead to five-membered or six-membered heterocycles[28].

A 14. Thiocyanogen Chloride

Like dithiocyanogen, thiocyanogen chloride may be regarded as a pseudohalogen, which is polarized into Cl^- and SCN^+. The compound, which is reasonably stable only in cold solution, can be obtained by chlorinolysis of dithiocyanogen in a chlorine-resistant solvent such as chloroform[29]. Instead of starting with dithiocyanogen, one can obtain thiocyanogen chloride by direct chlorination of alkali metal thiocyanates[30].

Excess chlorine adds to the CN triple bond with rearrangement to form chlorosulfenyl isocyanide dichloride ("thiocyanogen trichloride")[31,32].

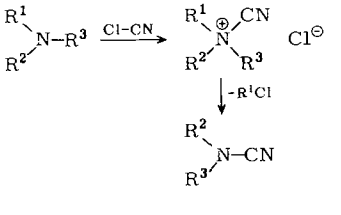


As a pseudohalogen, thiocyanogen chloride adds to olefins under mild conditions to form 2-chloro 1-thiocyanates[29].

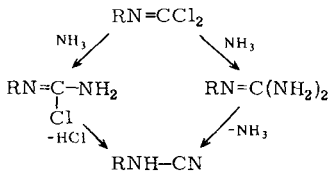
As was mentioned in Section A I3, thiocyanogen chloride can also convert aromatic compounds (amines, phenols, phenol ethers, higher aromatic hydrocarbons) into aryl thiocyanates, and does so more effectively than dithiocyanogen[30,33].

A 15. Cyanamides

Unsubstituted cyanamide[34], which is obtainable from calcium cyanamide, can be converted into alkylcyanamides by alkylation, as can the alkali metal cyanamides[35]. A general method for the synthesis of substituted cyanamides is based on the reaction of cyanogen chloride with primary or secondary amines and with hydrazines and hydrazides at low temperatures[36]. Even tertiary amines, which undergo a von Braun degradation with cyanogen chloride, with elimination of alkyl chloride, are suitable for this purpose[37].



Monosubstituted cyanamides can also be obtained from isocyanide dichlorides (B I4) and ammonia *via* the chloroformamidines or guanidines[38].



Finally, thioureas and isothioureas can be converted into cyanamides by elimination of hydrogen sulfide or thiols[39]. Monosubstituted cyanamides, as weakly basic compounds, are acylated by carbonyl chlorides, sulfonyl chlorides, esters of chlorocarbonic acid, acid anhydrides, isocyanates, *etc.*[36].

Like cyanates and thiocyanates, the cyanamides readily undergo nucleophilic addition to the CN triple bond[36]. Reaction in this way with Grignard reagents leads to amidines[36]. The addition of acyl chlorides yields *N*-acylchloroformamidines[17,40].

X = O, S, NR^2

B. Compounds Having Two Formally Similar Ligands on the Carbon Atom

	I $=CCl_2$	II. $=C=O$	III $=C=S$	IV $=C=NR$

2	O=	$O=CCl_2$	$O=C=O$	
3	S=	$S=CCl_2$	$S=C=O$	$S=C=S$
4	RN=	$RN=CCl_2$	$RN=C=O$	$RN=C=S$	$RN=C=NR$

B 11. Tetrachloromethane (Carbon Tetrachloride)

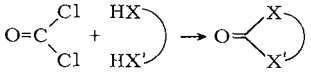
Though tetrachloromethane can be obtained by perchlorination of carbon disulfide (B III3), it can be included only formally in carbonic acid chemistry as the "tetrachloride of orthocarbonic acid". Substitution of the chlorine atoms in this compound generally calls for extreme conditions. However, tetrachloromethane can be converted into phosgene in the laboratory in oleum at about 80 °C[41].

Alcoholysis with sodium alkoxides yields orthoformates and orthocarbonates[42], whereas sulfidizing leads back to carbon disulfide. With nitrogen trichloride or *N*-chloroisocyanide dichloride in the presence of Lewis acids, carbon tetrachloride can form dichloromethane bis(isocyanide dichloride) and chloromethane tris(isocyanide dichloride)[43,64].

B 12. Carbonic Acid Dichloride (Phosgene)[140]

The industrial synthesis of phosgene is based on the addition of chlorine to carbon monoxide in the presence of active charcoal[44].

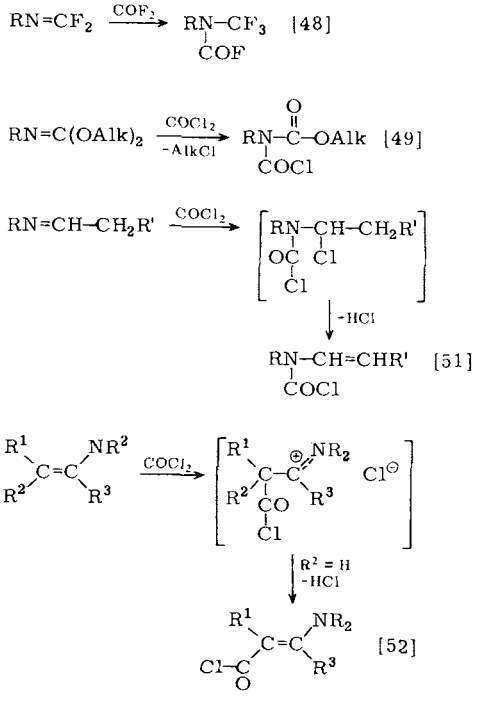
The reactions of phosgene extend mainly to nucleophilic substitutions of the two chlorine atoms, the reactivity being stepped in such a way that monosubstitution products such as carbonic ester chlorides (C II1), thiocarbonic *S*-ester chlorides (C II2), or carbamoyl chlorides (C II4) can be easily prepared. Corresponding reactions with substitution of both chlorine atoms lead *e.g.* to diesters of carbonic acid, thioesters of carbonic acid, ureas, and urethanes. Isocyanates (B II4) can be obtained with primary amines. With suitable bifunctional nucleophiles, phosgene gives a wide range of five-membered and six-membered heterocycles[45].



X, X' = O, S, NR

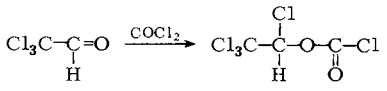
Under Friedel-Crafts conditions, phosgene reacts with aromatic hydrocarbons, dialkylaminobenzenes, *etc.*, to form ketones or carbonyl chlorides, depending on the proportions of the reactants[46].

Phosgene can add to CN multiple bond systems and enamines to form a wide range of compounds, which may be stabilized by formation of secondary products. Mention should also be made of an addition of carbonic acid difluoride.



Phosgene also behaves as an acid chloride toward the carbonic acid derivatives with CN multiple bonds that are described in this article, such as cyanates, cyanogen chloride, isocyanates, and carbodiimides[17,6,47,50,62].

Phosgene can also add to activated carbonyl compounds, such as chloral, in the presence of a tertiary amine[53].



The importance of phosgene as a chlorinating agent will be mentioned here only in passing. Thus phosgene reacts *e.g.* with *N,N*-disubstituted carboxamides to form α,α-dichloroamines ("amide chlorides"), and with ureas to form dichloromethylenediamines ("carbamide chlorides")[53a].

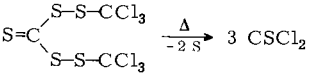
B I3. Thiocarbonic Acid Dichloride (Thiophosgene)

Thiophosgene is obtained by reductive dechlorination of trichloromethanesulfenyl chloride (C I3) or its derivatives.

Trichloromethanesulfenyl chloride itself can be converted into thiophosgene with tin(II) chloride in hydrochloric acid solution[54], with tetralin in organic solution[55], with SO_2[56], or with H_2S[57].

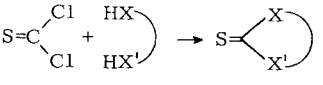
The *S*-trichloromethyl arenethiosulfonates, which are obtainable from aromatic sulfinic acids and trichloromethanesulfenyl chloride, are thermally decomposed into thiophosgene and aromatic sulfonyl chlorides[58].

The product formed from sodium trithiocarbonate and trichloromethanesulfenyl chloride decomposes similarly when heated, with elimination of sulfur[59].



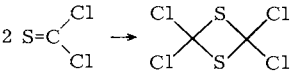
The two chlorine atoms can also be selectively substituted in thiophosgene. If only the first chlorine is replaced by a nucleophilic group, one obtains *e.g.* thiocarbonic *O*-ester chlorides (C III1), dithiocarbonic ester chlorides (C III2), or thiocarbamoyl chlorides (C III4). Replacement of both chlorine atoms then gives symmetrical or unsymmetrical mono-, di-, and trithiocarbonic esters, thioureas, thiourethanes, dithiourethanes, and isothioureas. Isothiocyanates (B III4) are also formed with primary amines, depending on the procedure.

Finally, reaction with suitable bifunctional partners again leads to five-membered or six-membered heterocycles.



X, X' = O, S, NR

Additions to the CS double bond in thiophosgene are possible, whereas the CO double bond of phosgene cannot undergo such additions. Under the action of sunlight, thiophosgene slowly dimerizes to tetrachloro-1,3-dithietane[60].



Perhalogenated methanesulfenyl chlorides add smoothly to the thiocarbonyl group of thiocarbonic difluoride in the presence of UV radiation to form disulfides[61].

Like phosgene, thiophosgene also adds to the CN double bond of carbodiimides[62].

B I4. Iminocarbonic Dichlorides (Isocyanide Dichlorides)

Isocyanide dichlorides can be synthesized by numerous routes[32]. One that is widely applicable is the chlorination of isothiocyanates, which has the desired result in the aliphatic, cycloaliphatic and acylated series, and partly also in the aromatic series, and involves iminochloromethanesulfenyl chlorides (C IV3) as intermediates[32].

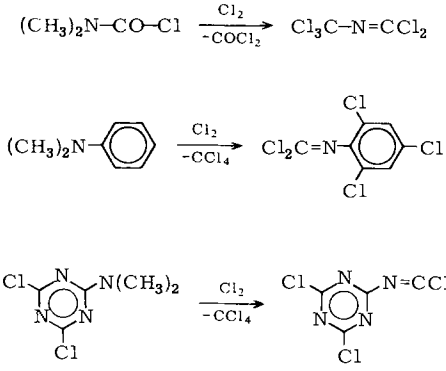
The addition of chlorine to isocyanides proceeds smoothly in many cases[63], whereas the chlorination of isocyanates with phosphorus pentachloride leads to the desired products only in the aliphatic and cycloaliphatic series[32].

The addition of cyanogen chloride to compounds containing reactive chlorine has been extensively studied. It extends from addition to elementary chlorine[4] *via* phosgene[6]

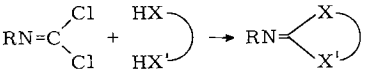
and tetrachloromethane (in the form of *N*-chloroisocyanide dichloride)[64] to acyl and sulfenyl chlorides[7, 8]. A variant of this method is based on the combined action of chlorine and cyanogen chloride on olefins, and leads to 2-chloroalkyl 1-isocyanide dichlorides[5].

Highly chlorinated aliphatic, aromatic, or heterocyclic isocyanide dichlorides are obtained from *N,N*-dimethylamines in high temperature chlorinations with elimination of acyl chloride or of polychloromethane. Some examples are given below[65].

The number of products that can be formed from isocyanide dichlorides by replacement of one or both of the chlorine atoms is immense (see C IV1, C IV2, C IV4, B II4, B III4, B IV4)[66]. Finally, with strong reducing agents such as trialkylphosphanes, isocyanide dichlorides lose both chlorine atoms to from isocyanides[66].

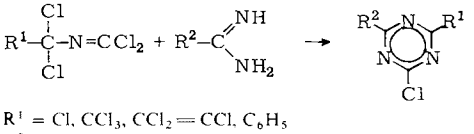


A wide variety of five-membered, six-membered, and higher heterocycles can be obtained by replacement of both chlorine atoms with bifunctional nucleophiles[66].



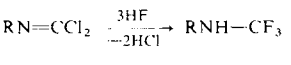
R = alkyl, cycloalkyl, aryl, acyl, RS, RSO_2, $(RO)_2P(O)$;
X,X' = O, S, NR

α-Chlorinated isocyanide dichlorides (*e.g.* trichloromethyl, α,α-dichlorobenzyl, or chlorocarbonyl isocyanide dichloride) exhibit preferential replacement of the α-chlorine atom and one of the chlorine atoms on the carbonic acid C atom with bifunctional compounds to form heterocycles containing chlorine[67].

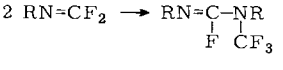


R^1 = Cl, CCl_3, $CCl_2=CCl$, C_6H_5
R^2 = H, alkyl, aryl, CH_3S

The addition reaction of isocyanide dichlorides that has been most extensively studied so far is the reaction with hydrogen fluoride, which leads by chlorine-fluorine exchange to *N*-trifluoromethylamines[66].



The *N*-trifluoromethylcarbamoyl fluorides, which can be obtained from isocyanide difluorides and carbonyl difluoride, were mentioned in Section B I2. In this connection, mention should be made of the dimerization of isocyanide difluorides to form *N*-trifluoromethylfluoroformamidines[66].



Additions have also been carried out with diazomethane, epoxides, and sodium azide, as well as other compounds[66].

B II2. Carbon Dioxide

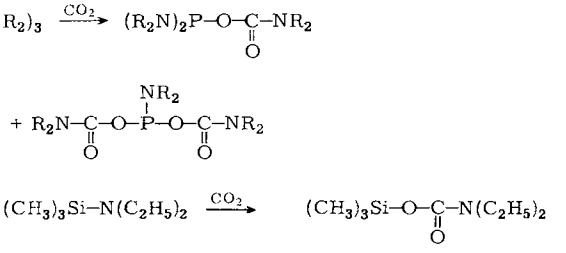
As an "inorganic representative" of carbonic acid chemistry, carbon dioxide is distinguished in its reactive behavior only by addition reactions. Thus carbon dioxide is added by alkoxide solutions to form half esters of carbonic acid[68], by ammonia and amines to form salts of carbamic acid[69], and by organometallic compounds to form carboxylic acids[70].

X = O, NR, CR_2; M = metal, H (amine)

A special variant of the formation of carboxylic acids is the Kolbe-Schmidt synthesis of salicylic acid, in which sodium phenoxide is converted into 2- and 4-hydroxybenzoic acids by reaction with carbon dioxide at high temperatures, probably *via* sodium phenyl carbonate[71].

Aromatic hydrocarbons react with carbon dioxide under Friedel-Crafts conditions to give aromatic carboxylic acids[71].

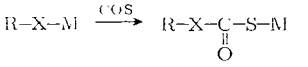
Insertions have been reported for the action of carbon dioxide on amides of trivalent phosphorus or arsenic and on silylamines[72].



B II3. Carbon Oxide Sulfide[73]

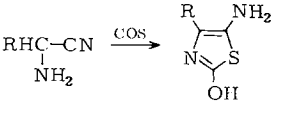
Carbon oxide sulfide, which can be prepared from ammonium thiocyanate and acids[74], is obtained on the industrial scale on decomposition of cellulose xanthate.

Carbon oxide sulfide, like carbon dioxide, can add to alkoxides[75], amines[76], and Grignard compounds[77], with formation of potassium *O*-alkyl thiocarbonate (Bender's salt) and amine salts of thiocarbamic acids or thiocarbonic acids.



X = O, NR, CR_2; M = metal, H (amine)

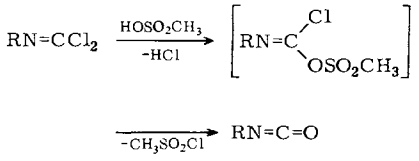
Aliphatic α-amino nitriles undergo addition and cyclization with carbon oxide sulfide to form 5-amino-2-hydroxythiazoles[78].



B II4. Isocyanates[139]

The most important industrial process for the synthesis of monoisocyanates and diisocyanates is based on the phosgenation of primary amines, which can be used both as the free bases and in the form of the hydrochlorides[79]. The lower aliphatic isocyanates, whose boiling points are so close to the decomposition points of the corresponding carbamoyl chlorides that they cannot be separated by distillation, can be obtained in the pure state by thermal cleavage of urethanes[80] or of trisubstituted ureas[81].

Other processes for the production of isocyanates are the Lossen degradation of carboxylic acid azides[82], alkylation of alkali metal or silver cyanate[83], chlorination of monosubstituted aliphatic formamides[84], and the selective reaction of isocyanide dichlorides with methanesulfonic acid, which leads to elimination of methanesulfonyl chloride and formation of isocyanates[85].



Acyl isocyanates are obtained from carbonyl chlorides and silver cyanate, while sulfonyl isocyanates are obtainable by phosgenation of sulfonamides[86].

Isocyanates are practically unique among chemical compounds in their excellent addition capacity, of which industrial use is made in many instances. They can add on all compounds containing mobile protons, possibly in the presence of catalysts, to give stable products in most cases (*e.g.* HF, HCN, hydrogen sulfite, hydroxylamine, hydroxy compounds, thiols, amines, hydrazines, oximes, carboxylic acids, carboxamides, sulfonamides, CH acids)[87].

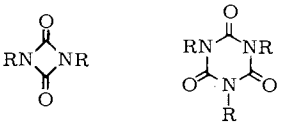
Electrophiles can also add to isocyanates. Bis(chlorocarbonyl)amines are formed on addition of phosgene (cf. B I2). Sulfur dichloride[88], carboxylic acid chlorides[89], and carbamic acid chlorides[90] also add to aliphatic isocyanates in a similar manner.

Isocyanates react with double bond systems, often with 1,2 cycloaddition. However, the resulting four-membered heterocycles decompose readily in most cases with decarboxylation. Thus isocyanates react with carbonyl compounds to form Schiff bases, with *N*-substituted amides to form amidines, with anhydrides of dicarboxylic acids to form imides, with nitroso compounds to form azo compounds, and with sulfoxides to form sulfimides. Addition to semipolar bonds of organophosphorus compounds proceeds particularly readily, and leads in the case of phosphorimides to carbodiimides. This is the basis of the synthesis of carbodiimides from isocyanates with catalysis by phospholene oxides (B IV 4). Olefins give stable β-lactams only with the very reactive chlorosulfonyl isocyanate, and vinyl ethers only with sulfonyl isocyanates, whereas enamines, which have no hydrogen in the β position, can also react with aliphatic and aromatic isocyanates to give four-membered heterocycles. Finally, 1,2-cycloadducts of isocyanates and carbodiimides have also been reported[91].

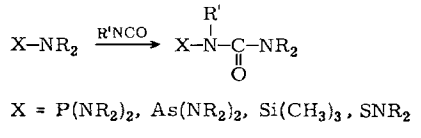
Isocyanates react in 1,3-dipolar additions with their CN double bond as the dipolarophile, *e.g.* with nitrones, azomethine imines, nitrile imines, alkylene oxides, and alkylene carbonates.

Acyl isocyanates with a carbonyl, thiocarbonyl, or imidoyl grouping can also be used to a limited extent as dienes or dienophiles for 1,4 cycloadditions. Other isocyanates can also undergo this reaction in some cases[91].

An important characteristic of isocyanates is the readiness with which they oligomerize. Depending on the reaction conditions, one obtains the dimeric uretdiones, which can be converted back into the monomer by thermal cleavage, or the stable isocyanurates[91].



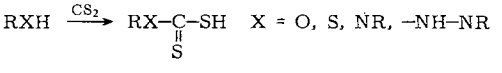
Isocyanates also undergo insertion with amides of trivalent phosphorus or arsenic and with trimethylsilylamines and sulfenamides[72] (cf. B II2).



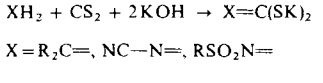
B III3. Carbon Disulfide

Carbon disulfide, a common solvent, is already being used industrially for addition reactions.

In analogy with the reactions of carbon dioxide and carbon oxide sulfide, carbon disulfide adds to alkoxides to form xanthates[92], to thiolates to form esters of trithiocarbonic acid[93], to ammonia and amines to form dithiocarbamic acids[94], and to hydrazines to form dithiocarbazic acids[95].



Carbon disulfide reacts with CH acids[96], cyanamide[97], and primary sulfonamides[98] in alkaline media to give the dialkali metal salts of dithio acids.



Carbon disulfide can also undergo insertions into compounds of trivalent phosphorus[72].

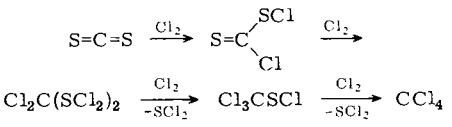
Stable 1,2 cycloadducts are obtained from carbon disulfide only in the presence of sulfur, whereas trithiones are formed with enamines, ketimines, and malodinitrile[99].

Carbon disulfide reacts with hydrazoic acid, nitrile imines, azomethine imines, and alkylene oxides or sulfides to form 1,3 cycloadducts[99].

Unlike the carbonic acid derivatives containing a CN multiple bond, which enter into diene reactions only in excep-

tional cases, carbon disulfide adds to enamines or dienamines in the manner of a Diels-Alder reaction to form α-dithiopyrones[99].

The reaction of carbon disulfide with chlorine leads by addition and subsequent chlorination *via* dichloromethanedi(sulfenyl chloride)[100] and trichloromethanesulfenyl chloride (C I3) to tetrachloromethane (B I1).



B III4. Isothiocyanates

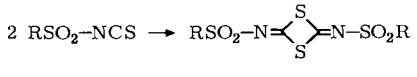
The isothiocyanates, which are isomeric with the thiocyanates (A I3), are characterized as S analogs of the isocyanates (B II4) by the readiness with which they add to nucleophilic and electrophilic systems. They also resemble the isocyanates in their synthesis, as is shown by the thiophosgenation of primary amines or their hydrochlorides[101]. The alkylation of salts of thiocyanic acid and the rearrangement of esters of thiocyanic acid are also analogous to reactions that are commonly used for the synthesis of isocyanates[101]. Other methods for the preparation of isothiocyanates are the oxidation of *N*-monosubstituted dithiocarbamic acids (*e.g.* with heavy metal salts, iodine, phosgene, NaOCl)[101], the cleavage of diarylthioureas with acids[101], and the reaction of isocyanide dichlorides with Na_2S or P_2S_5[38]. Acyl isothiocyanates can be prepared from the acyl chlorides with alkali metal thiocyanates, and in the homogeneous phase with trimethylsilyl isothiocyanate[102]. Finally, sulfonyl isothiocyanates can be synthesized by phosgenation of salts of *N*-sulfonyliminodithiocarbonic acid[103].

The readiness of the aliphatic and aromatic isothiocyanates to undergo addition is less than that of the isocyanates. Thus isothiocyanates are not hydrolyzed in cold water. However, they add other nucleophiles, including CH acids.

$$RN{=}C{=}S + HXR' \rightarrow RNH{-}CS{-}XR'$$
$$X = O, S, NR, CR_2$$

The addition of chlorine to form iminochloromethanesulfenyl chlorides (C IV3) will not be discussed here.

The tendency to oligomerize is also much weaker than in the case of the isocyanates. However, trimers of the isothiocyanates have been reported[104]. The sulfonyl isothiocyanates, like thiophosgene, very readily form dimers, but these can be converted back into the monomers by thermal cleavage[103].



Stable 1,2 cycloadducts can be formed with carbodiimides.

In 1,3-dipolar additions, isothiocyanates can react both with their CN double bond (in reactions with nitrones and azomethine imines) and with their CS double bond (in reactions with diazo compounds and alkylene oxides)[105].

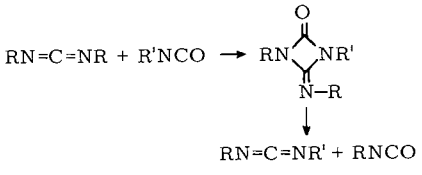
Unlike the sulfonyl isothiocyanates, 2-pyridyl isothiocyanate and imidoyl isothiocyanates dimerize to form six-membered 1,4 cycloadducts[105].

B IV 4. Carbodiimides[106]

Carbodiimides are the tautomers of the cyanamides (A I5) and, like these, they can be prepared by elimination of hydrogen sulfide or of thiol from suitably substituted thioureas or isothioureas[106]. Carbodiimides are also obtainable directly from cyanamides by special alkylation[107], silylation[108], or sulfenylation[109]. A very important method for the synthesis of symmetrical carbodiimides is the catalytically initiated decarboxylation of two molecules of an isocyanate, the catalysts used being oxides or sulfides of phospholenes or phospholanes[110].

$$2RN{=}C{=}O \xrightarrow{-CO_2} RN{=}C{=}NR$$

In the case of sterically hindered aromatic isocyanates, a tertiary amine is sufficient to bring about the decarboxylation[111]. Unsymmetrical carbodiimides can be formed from the resulting symmetrical carbodiimides by the action of other isocyanates *via* thermally unstable uretone imines[111].



Carbodiimides and *N*-sulfonylcarbodiimides can be obtained by "iminophosgenation" of hydrochlorides of primary amines with isocyanide dichlorides[66].

$$RN{=}CCl_2 + R'{-}NH_3^{\oplus}Cl^{\ominus} \rightarrow RN{=}C{=}NR' + 3HCl$$

Other methods for the synthesis of carbodiimides are based *e.g.* on the dehydration of ureas[106], the deamination of guanidines[66], and the pyrolysis of tetrazoles[106].

The reaction of the carbodiimides are dominated by the additions of compounds containing protons (water, hydrogen sulfide, hydrogen cyanide, alcohols, thiols, phenols, amines, carboxylic acids, CH acids *etc.*). The adducts with bifunctional compounds often react with cyclization[106].

$$RN{=}C{=}NR \xrightarrow{HXR'} RN{=}C(XR'){-}NHR$$

Electrophiles such as dicarboxylic acid anhydrides or acyl chlorides also add to carbodiimides[62]. Carbodiimides

X = Cl, RCOO

form heterocyclic products with bifunctional compounds such as oxalyl chloride[112] or diketenes[113].

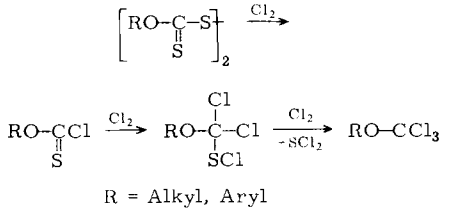
As well as for the above-mentioned synthesis of unsymmetrical carbodiimides, which proceeds *via* a 1,2 cycloadduct, carbodiimides can also be used as dipolarophiles for 1,3 cycloadditions with hydrazoic acid, nitrile imines, diazomethane, and alkylene oxides[114].

C. Compounds with a Chlorine Atom and a Doubly Bonded Ligand or Two Additional Chlorine Atoms

	I	II	III	IV
1	RO—	RO—	RO—	RO—
2	RS—	RS—	RS—	RS—
3	ClS—	ClS—	ClS—	ClS—
4	R_2N—	R_2N—	R_2N—	R_2N—

C I1. Trichloromethyl Ethers

The trichloromethyl ethers and the trichloromethyl thioethers (C I2), like tetrachloromethane, occupy a special place in this discussion, since they cannot be regarded as carbonic acid derivatives in the usual sense. Trichloromethyl ethers can be obtained from *O*-ester chlorides of thiocarbonic acid or from xanthogen disulfides by chlorination at low temperatures. The alkoxy- or aryloxydichloromethanesulfenyl chlorides that occur as intermediates can be isolated[115,116].



R = Alkyl, Aryl

Trichloromethyl ethers react with water, sodium phenoxide, alcohols, and carboxylic acids to form true derivatives of carbonic acid; for example, the reaction with water leads to ester chlorides of carbonic acid, and the reactions with alcohols lead to carbonates[115].

The very stable trifluoromethyl ethers can be obtained from ester fluorides of carbonic acid and sulfur tetrafluoride[117].

C I2. Trichloromethyl Thioethers

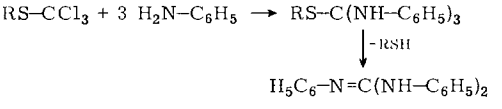
Trichloromethyl thioethers RS—CCl_3 can be obtained by the same synthesis principle as was used for trichloromethyl ethers (C I1), *i.e.* by chlorination of ester chlorides of dithiocarbonic acid in the cold[118].

Aromatic trichloromethyl thioethers can also be synthesized by electrophilic substitution of trichloromethanesulfenyl chlorides (C I3) with aromatic hydrocarbons, phenols, and aromatic amines[119].

R = H, OH, NR'_2

2-Chlorinated trichloromethyl thioethers can be prepared by addition of trichloromethanesulfenyl chloride to olefins[120].

Trichloromethyl thioethers are broken down by aniline to form triphenylguanidine and the thiol[121].

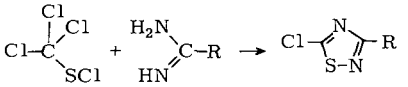


C I3. Trichloromethanesulfenyl Chloride

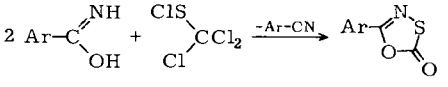
The only synthesis of trichloromethanesulfenyl chloride, which can also be carried out industrially, is based on the iodine-catalyzed chlorination of carbon disulfide (B III3)[120,122]. The relationship of trichloromethanesulfenyl chloride with thiophosgene was reported in Section B I3.

Because of its sulfenyl chloride function, trichloromethanesulfenyl chloride can add to CC and CN multiple bonds[123]. Very extensive studies have been carried out on the substitutions with nucleophiles, in which the chlorosulfenyl grouping reacts preferentially[119,120], though under the action of strong nucleophiles in excess, several or even all of the chlorine atoms can also be substituted, *e.g.* with alcohols to form orthocarbonates or with strongly basic amines to form guanidines[119].

With suitable bifunctional compounds, a smooth ring closure occurs with formation of five-membered heterocycles. Thus amidines and *S*-alkylisothioureas yield 5-chloro-1,2,4-thiadiazoles[119].

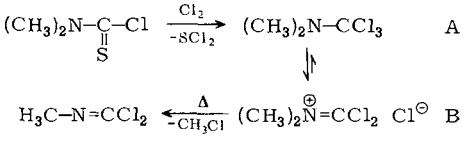


The reaction with aromatic carboxamides leads, with formation of the aromatic nitrile, to 2-oxo-5-aryl-1,3,4-oxathiazoles[119].

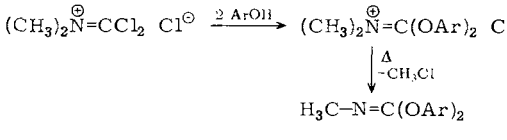


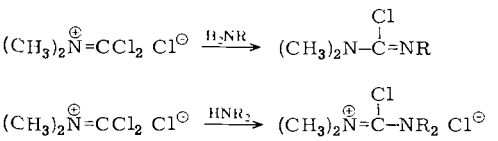
C 14. Dichloromethylenedimethylammonium Chloride (Trichloromethyldimethylamine)

The product, which can be obtained by chlorination of *N*,*N*-dimethylthiocarbamoyl chloride (C III4), is not in the form A with three covalently bonded chlorine atoms, but occurs as the salt-like dichloromethylenedimethylammonium chloride (B)[118,124]. This very reactive compound can be converted by pyrolysis into methyl isocyanide dichloride with elimination of methyl chloride[124].

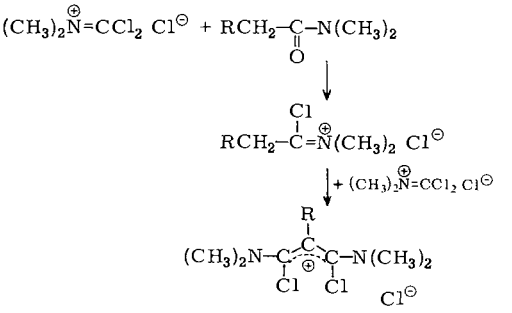


Dichloromethylenedimethylammonium chloride reacts in various ways with nucleophiles. Phenols give novel immonium salts, which form iminocarbonates when heated or are converted into diphenyl carbonates by hydrolysis[124]. With ammonia, all the chlorine atoms are substituted simultaneously with formation of dimethylcyanamide, whereas chloroformamidines (C IV4) or their hydrochlorides ("urea dichlorides") are formed with primary or secondary amines, depending on their basicity[124].





Dichloromethylenedimethylammonium chloride also reacts with active methylene compounds under mild conditions[125]. Thus reaction with *N*,*N*-dimethylcarboxamides in a molar ratio of 2:1 yield novel 1,3-dichloromalonylamines, which can be used for cyclizations[126].



C III. Carbonic Ester Chlorides (Chlorocarbonates)[127]

Carbonic ester chlorides are synthesized from phosgene and alcohols or phenols. Primary and secondary alcohols react even without the addition of an HCl acceptor, whereas addition of a base is necessary in the case of tertiary alcohols and phenols.

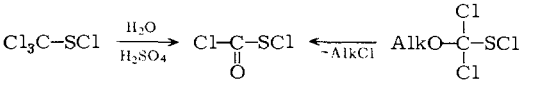
Carbonic ester chlorides are comparable to the chlorides of carboxylic acids, and react with all nucleophiles including CH acids.

C II2. Thiocarbonic *S*-Ester Chlorides[128]

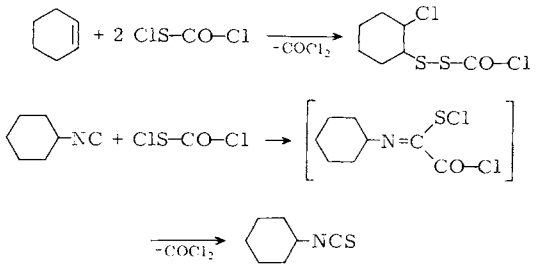
The thiocarbonic *S*-ester chlorides are obtainable in the same way as the sulfur-free analogs (C III) from phosgene and thiolates. The chlorine in these compounds can again be easily substituted by nucleophilic residues.

C II3. Chlorocarbonylsulfenyl Chloride[131]

Chlorocarbonylsulfenyl chloride can be prepared by partial hydrolysis of trichloromethanesulfenyl chloride (C I3) in sulfuric acid solution[129] or by thermolysis of alkoxydichloromethanesulfenyl chloride with elimination of alkyl chloride[130].



Like the other compounds of the C II series, chlorocarbonylsulfenyl chloride can generally take part only in substitution reactions, and in this case use can be made of the difference in the reactivities of the two chlorine atoms. The sulfenyl chloride function also allows additions, but these frequently proceed anomalously with elimination of phosgene, as shown by the two examples[131].

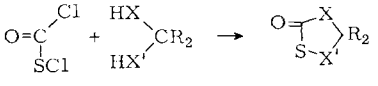


Chlorocarbonylsulfenyl chloride reacts with alcohols in a molar ratio of 1:1 to form alkoxycarbonylsulfenyl chlorides[131], whereas thiols give the thermodynamically

favored disulfide grouping, with formation of alkylchlorocarbonyl disulfides[131].

As expected, chlorocarbonylsulfenyl chloride and the alkoxycarbonylsulfenyl chlorides and alkyl chlorocarbonyl disulfides obtainable from it can also react with other nucleophiles.

Chlorocarbonylsulfenyl chloride is also very useful for the synthesis of heterocyclic systems. Thus five-membered rings are obtained, usually in a smooth reaction, with 1,3-bifunctional nucleophiles[131].



C II4. Carbamoyl Chlorides[132]

Whereas unsubstituted carbamoyl chloride ("urea chloride") and the monosubstituted carbamoyl chlorides that occur as intermediates in the isocyanate synthesis are relatively unstable, the disubstituted carbamoyl chlorides obtainable from secondary amines and phosgene are stable compounds that can be purified by distillation or crystallization.

These compounds are synthesized either in the cold in the presence of a tertiary amine as an acid acceptor or with heating to drive off the hydrogen chloride formed in the reaction.

Tertiary amines with lower alkyl groups can also be converted into carbamoyl chlorides in a sort of Braun degradation with elimination of alkyl chloride

Carbamoyl chlorides are also obtainable by chlorination of dialkylformamides with sulfuryl chloride[124] or sulfur dichloride/pyridine[133].

The carbamoyl chlorides behave toward nucleophiles as acyl chlorides, but with reduced activity. Within this class of compounds, the reactivity decreases still further on transition from the aliphatic to the aromatic members.

Carbamoyl chlorides are also suitable for the synthesis of carboxamides under Friedel-Crafts conditions. In the presence of catalysts such as tin tetrachloride, carbamoyl chlorides add to aliphatic isocyanates to give persubstituted allophanoyl chlorides[90].

C III1. Thiocarbonic *O*-Ester Chlorides[134]

In analogy with the preparation of carbonic ester chlorides (C III), thiocarbonic *O*-ester chlorides can be obtained from thiophosgene if alkoxides or phenoxides are used.

Besides the nucleophilic substitutions, additions of chlorine to the CS double bond have been reported; as was mentioned in Section C II, these reactions lead to alkoxy- or aryloxydichloromethanesulfenyl chlorides and then to trichloromethyl ethers.

C III2. Dithiocarbonic Ester Chlorides[128]

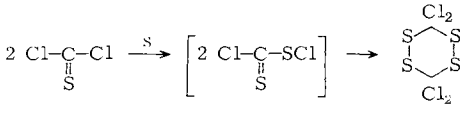
The dithiocarbonic ester chlorides are obtainable from thiols or thiolates and thiophosgene; trithiocarbonic diesters or dithiocarbamic esters, for example, can be obtained from these in normal substitution reactions.

The addition of chlorine to the CS double bond leads here *via* the alkylthiodichloromethanesulfenyl chloride to the trichloromethyl thioether (cf. Section C I2).

C III3. Chlorothiocarbonylsulfenyl Chloride

Chlorothiocarbonylsulfenyl chloride is the only one of the carbonic acid derivatives discussed here that has not yet been synthesized.

The sulfurization of thiophosgene, which was described in 1887[135], leads not to this product but to a dimer, as our experiments have shown. The formation of a 1,2,4,5-tetrathiane may be assumed on the basis of mass-spectroscopic studies.



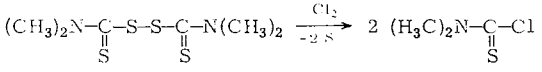
The structure is confirmed by the mass-spectroscopically detected fragmentation to tetrachloroethylene. The formation of the heterocycle becomes understandable if one considers that sulfenyl chlorides add to CS double bonds[123].

C III4. Thiocarbamoyl Chlorides[136]

As in the case of the carbamoyl chlorides, only the disubstituted compounds are stable among the thio analogs. They can be synthesized by thiophosgenation of secondary amines, which may be used in the form of their hydrochlorides, as in the phosgenation.

$$R_2NH + Cl{-}CS{-}Cl \rightarrow R_2N{-}CS{-}Cl$$

The chlorinative cleavage of tetrasubstituted thiuram disulfides with simultaneous removal of sulfur also leads directly to thiocarbamoyl chlorides.



Finally, thiocarbamoyl chlorides are also obtained on chlorination of disubstituted thioformamides with sulfur dichloride/pyridine or chlorine[133, 137].

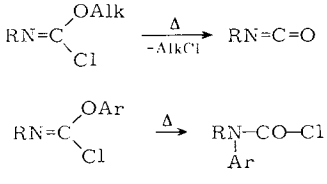
The thiocarbamoyl chlorides are comparable to the carbamoyl chlorides in their reactivity in nucleophilic substitutions. The dichloromethylenammonium chlorides (C I4) are formed on chlorination.

C IV1. Iminocarbonic Ester Chlorides[38]

The iminocarbonic ester chlorides, which are readily obtainable from isocyanide dichlorides (B I4) and alkoxides or phenoxides, contain a mobile chlorine atom, which can be used for further substitutions.

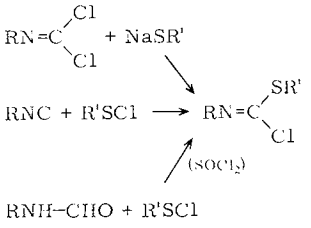
$$RN{=}CCl_2 + NaOR \rightarrow RN{=}C(Cl){-}OR$$

The *O*-alkyl esters of this class of compounds readily lose alkyl chloride when heated, with formation of isocyanate, whereas the *O*-aryl esters isomerize to carbamoyl chlorides in the manner of a Chapman rearrangement.



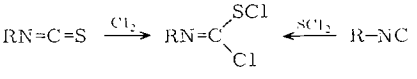
C IV2. Iminothiocarbonic Ester Chlorides[38]

There are three fundamental routes for the synthesis of this class of compounds: the reaction of isocyanide dichlorides with thiolates in a molar ratio of 1:1, the addition of sulfenyl chlorides to isocyanides, and the addition of sulfenyl chlorides to monosubstituted formamides in the presence of thionyl chloride. The chlorine atom in these compounds can again be substituted by nucleophilic residues.

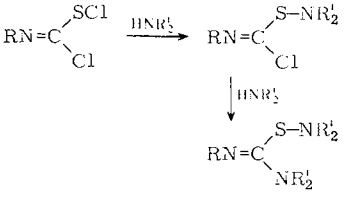


C IV3. Iminochloromethanesulfenyl Chlorides[131]

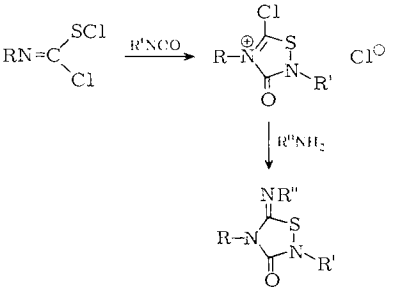
Iminochloromethanesulfenyl chlorides are readily obtainable by addition of chlorine to isothiocyanates or by addition of sulfur dichloride to isocyanides.



According to the investigations carried out so far, iminochloromethanesulfenyl chlorides give the expected substitution products only with amines.

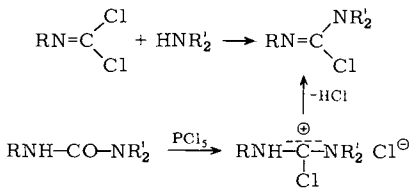


On the other hand, iminochloromethanesulfenyl chlorides are very suitable for cyclizations, in which use is made of the readiness with which the sulfenyl chloride group adds to CC and CN multiple bonds. In the resulting salts containing a five-membered heterocyclic cation, the chlorine atoms may be substituted by nucleophiles in a secondary reaction. This is illustrated by the addition of isocyanates. In addition to isocyanates, other classes of compounds that react particularly readily are isothiocyanates and cyanates, as well as vinyl ethers and enolizable aldehydes and ketones.



C IV4. Chloroformamidines[38]

Chloroformamidines are obtainable by reaction of isocyanide dichlorides (B I4) with primary or secondary amines in a molar ratio of 1:1 or by chlorination of substituted ureas[138], *e.g.* with phosphorus pentachloride.



The alkyl-substituted chloroformamidines are sufficiently basic to add hydrogen chloride with formation of chloroformamidinium chlorides ("urea dichlorides").

In nucleophilic substitutions, an increase in reactivity is observed from purely aliphatic *via* aromatic-aliphatic compounds to *N*-acylated chloroformamidines.

6. Conclusion

It is remarkable that since the first experiments on the synthesis of carbonic acid derivatives by *F. Wöhler* about 150 years ago (1828: synthesis of urea from ammonium thiocyanate) this field of chemistry has only just been revived and enlarged by some new classes of compounds.

It is hoped that the present review on carbonic acid derivatives, which command great interest for both pure and applied organic chemistry, may help to ensure that this class of compounds will in future continue to enrich our theoretical and practical knowledge.

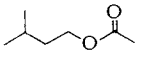
Recent Results in Insect Pheromone Chemistry

By John G. MacConnell and Robert M. Silverstein[*]

Pheromones are substances which are secreted to the outside by an animal, especially an insect, and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavior or developmental process. The name is derived from the Greek *pherein* (to bear, transmit) and *hormon* (impel, excite). Pheromones include, *inter alia*, sex attractants, warning substances, and "aggregation pheromones". Many of these substances are effective at very low concentration. The insect pheromones are predominantly derivatives of long-chain, slightly branched hydrocarbons.

1. Introduction

Perhaps the first written account of a pheromonal interaction in insects was that of *Charles Butler*, who in 1609 described how honeybees are attracted and provoked to mass attack by a substance released as a result of a single initial sting[1]. *Huber*, in 1792, found that this attack behavior could be attributed to the sting odor[2]. In 1962, more than 350 years after *Butler*'s description, a compound at least partially responsible for the mass attack (the so-called sting pheromone) was identified as *iso*-pentyl acetate *(1)*[3].



(1)

To date, literally hundreds of pheromonal interactions have been demonstrated or implicated in organisms as diverse as rodents[4], coelenterates[5], crabs[6], tadpoles[7], rhesus monkeys[8], fungi[9], algae[10], and earthworms[11]; as might be expected, there has been much speculation about human pheromones[12].

It is our goal in this article to review selectively recent work in the area of insect pheromones, paying particular attention to those of known chemical constitution. To avoid the problems of classification of pheromones of uncertain biological function or significance, or those whose elicited response depends on context, we have organized our review on a taxonomic basis rather than on a chemical class or presumed pheromonal function basis.

Although we are nominally reviewing insect pheromones, we also include recent work on some other arthropods. We exclude from this discussion the already vast literature on insect hormones, except where these substances have been shown to have some role in intraspecific communication. We also exclude what appear to be purely defensive secretions.

2. Definitions

Karlson and *Butenandt*[13] and *Karlson* and *Lüscher*[14,15], in 1959, proposed the term "pheromone" for "substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behaviour or a developmental process"[14]. Two general classes of pheromones were distinguished[13]: the olfactorily active, and the orally active. These two groups correspond closely to the "releaser-primer" terminology of *Wilson* and *Bossert*[16]. The *releasers* involve a more or less immediate behavioral response usually lasting only a few seconds or minutes once the chemical signal is discontinued; the *primers* involve long-term, physiological changes[16].

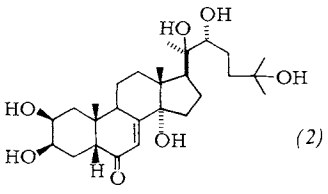
3. Arthropoda Excluding Insecta

The huge phylum Arthropoda is divided into several classes which range from the extinct Trilobita and the obscure Tardigrada and Pentastomida, to the familiar Crustacea (lobsters, barnacles, pill bugs, *etc.*), Arachnida (spiders, scorpions, ticks and their allies), Diplopoda (millipedes), Chilopoda (centipedes), and, of course, Insecta. In the next two Sections, we discuss some of the pheromonal interactions known from arthropods other than insects.

3.1. Crustacea

Sexual attraction in crustaceans of the order Decapoda, which includes lobsters, crabs, shrimps, *etc.*, has been known for some time[17]. Recently it was shown by *Ryan*[6] that water in which premolt females of the crab *Portunus sanguinolentus* have been kept elicits in males of this species the same characteristic response as does the female itself. Noting that in many decapods mating occurs immediately after the female molts, *Kittredge*, *Terry*, and *Takahashi*[18] were led to suspect that the crustacean molting hormone, crustecdysone *(2)*[19], might also be the sex pheromone released by the female. They found that premating behavior was exhibited by males of the crab *Pachygrapsus crassipes* exposed to very dilute solutions of crustecdysone. Indeed, males of *P. crassipes* respond to solutions as dilute as

10^{-13} M. Two crab species in the genus *Cancer* also respond to somewhat higher concentrations of crustecdysone. Although it was not rigorously identified, it appears that the sex pheromone of these crabs is either their own molting hormone, crustecdysone, or some compound very similar to it. Based largely on this finding, *Kittredge* and *Takahashi* recently advanced a proposal on the evolution of sex pheromone communication in the Arthropoda[20].



(2)

The female of the crab *Callinectes sapidus* uses another molting hormone, callinecdysone A, as its only molting hormone during the early premolt stage[21]. Later, as mating approaches, small amounts of crustecdysone accompany the callinecdysone A[21]. It is possible that in this species, unlike *Cancer* and *Pachygrapsus*, two distinct compounds are used for the two activities, the callinecdysone A functioning mainly as the molting hormone and the crustecdysone as the sex pheromone.

Sex pheromonal communication has recently been demonstrated in the amphipod crustacean, *Gammarus duebeni*[22].

3.2. Arachnida

Among the spiders (order Araneae), evidence has recently been obtained for sex pheromones in four species in the family Lycosidae[23].

Among the mites and ticks (order Acari), there is evidence for sex pheromones in at least four species[24, 25, 26]. In *Tetranychus urticae*[25] and *Amblyomma americanum*[26], the males are attracted to the females; in *A. maculatum*, however, the females are attracted to the males[24]. In very recent work, *Berger*[27], working with *A. americanum*, has identified a female-derived sex pheromone as 2,6-dichlorophenol. The phenol is present in mature females in amounts approximating 5 nanograms per animal. Several careful experiments failed to support the hypothesis that the phenol was an artifact. *Berger* has found 2,6-dichlorophenol in similar amounts in Gulf Coast ticks, *A. maculatum*[28]. Experiments are underway to determine whether females can synthesize the phenol from appropriately labeled precursors[28].

4. The Insects

According to *Borror* and *DeLong*[29], the class Insecta contains 27 orders; we consider only those orders in which pheromonal communication is of known primary importance. The various orders are discussed in the sequence and with the limits given by *Borror* and *DeLong*.

4.1. Orthoptera

Both releaser and primer effects have been found in the Orthoptera (roaches, grasshoppers, locusts, *etc.*), but no orthopteran pheromones have been chemically identified.

Probably the best known problem among orthopteran pheromones is that related to the structure of the sex attractant produced by the female American cockroach, *Periplaneta americana* (family Blattidae). This pheromone not only attracts the male, but is also important in sex recognition and in the release of courtship behavior in the male[30]. *Jacobson, Beroza*, and *Yamamoto*[31] proposed the structure 2,2-dimethyl-3-isopropylidenecyclopropyl propionate, for this pheromone, but this proved to be incorrect[32].

Recently, *Bowers* and *Bodenstein*[33] found several plant-derived compounds to be sex pheromone mimics. In addition, on the basis of some chemistry carried out on crude pheromone preparations, they concluded that the natural pheromone may be an unsaturated ketone with additional functionality sensitive to base. The structure remains unknown. For reviews on cockroach mating behavior, see the papers by *Roth* and *Willis*[34] and *Barth*[35].

Several orthopteran species exhibit aggregation behavior at certain times in their lives; aggregation mediated by pheromones has been observed in the cockroach *Blattella germanica*[36], in the cricket *Acheta domestica*[37], and in the locust *Schistocerca gregaria*[38]. In addition to the pheromone responsible for aggregation, *B. germanica* also produces a primer pheromone: young nymphs reared in isolation are delayed in growth and development[39]. Females of *S. gregaria* have a strong tendency to oviposit in groups[38]; in addition, both sexes produce primer pheromones which act to synchronize the production of adults in a very localized population[40]. *Blight et al.*[41] have identified several volatile compounds from laboratory colonies of this locust, but the significance of these substances is unknown.

4.2. Isoptera

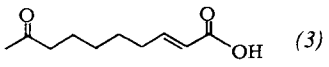
Termites constitute the order Isoptera. Pheromonal communication is well developed among these relatively primitive insects[42].

The most primitive of the termite families, the Mastotermitidae, contains but one species, *Mastotermes darwiniensis*. *Moore* (cited in Ref. [42b], p. 428) has found that extracts of the sternal gland of *M. darwiniensis* will induce trail following in this species.

Lüscher[43] found that workers of *Kalotermes flavicollis* (Kalotermitidae) perceive the presence of the primary reproductives (the "king" and "queen") *via* nonvolatile substances occurring on the reproductives' antennae. If antennal contact is prevented, the workers behave as if the colony had lost its royal pair and will raise a supplementary reproductive pair. *Hrdý et al.*[44] found that extracts of honeybee "queen substance" when fed to queenless workers of *K. flavicollis* largely inhibit the development of supplementary reproductives; extracts of queens of

Odontotermes (family Termitidae) inhibit queen rearing by worker honeybees[45]. The implication is that worker termites may perceive the presence of their queen *via* a pheromone not unlike that used by the honeybee queen, (*E*)-9-oxo-2-decenoic acid *(3)*. A compound which may be identical to queen substance was recently identified in extracts of queen heads of *Odontotermes assmuthi*[46].

An attractant, (*Z*)-3-hexen-1-ol *(4)*, appears to be important in the attraction of *K. flavicollis* to nestmates, particularly to larvae and nymphs[47].



(3)

(4)

Hummel and *Karlson*[48,49] have isolated from *Zootermopsis nevadensis* (family Hodotermitidae) several fractions which are active in the trail pheromone bioassay. An active hydrocarbon, $C_{11}H_{20}$, of unknown structure, was isolated as was hexanoic acid, from an extract of termites. Hexanoic acid is reported[50] to have the same biological activity as the natural pheromone. Farnesol (which does not occur in the trail pheromone secretion) is equally active[50], and ethyl dodecanoate is some 200 times as potent as hexanoic acid in eliciting trail following (10^7 Spureinheiten per mg)[51]. *Pasteels*[52] has shown that the sternal glands of adults of both sexes of *Z. nevadensis* produce attractants for the opposite sex. During nymphal stages, this gland produces the trail pheromone[53]; later, in the adult, it secretes a sex-specific attractant.

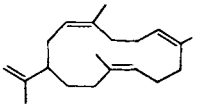
Esenther et al.[54] reported that cultures of the wood-rotting fungus *Lenzites trabea* produce a material which is attractive to *Reticulitermes flavipes* and *R. virginicus* (Rhinotermitidae). *Smythe et al.*[55] found that one of the attractants elicits trail following in the termites and associated the natural trail pheromone with this substance from the fungus-infected wood. Termite extracts were shown to contain the same compound[55]. This substance was isolated[56] and identified[57] as (*Z*,*Z*,*E*)-3,6,8-dodecatrien-1-ol *(5)*.

(5)

Stuart (Ref. [42d], particularly pp. 96—97 and 100—101) has questioned this identification of the *Reticulitermes* trail pheromone; the following discussion more or less summarizes *Stuart*'s arguments. In spite of the extreme activity of synthetic *(5)* in the bioassay[57b], the experiments described so far have not demonstrated unequivocally that this compound is actually secreted by the termites and deposited as the trail-marking pheromone. Since only whole body extracts have been made, there is no proof that the trienol is produced or stored in the sternal gland, the organ presumed to store and deposit the trail pheromone[42c]. In addition, in view of the relatively large amount of the trienol occurring in the surrounding wood[55], it is quite possible that the trienol isolated from the termite extracts does not represent sternal gland contents, but contents of the gut (or any other tissue not associated with trail laying). That the termites are able to follow an artificial trail of an extremely attractive substance may not be unexpected.

Moore[58] has identified several monoterpenes in the defensive secretions of termites from four genera (*Nasutitermes*, *Tumulitermes*, *Amitermes*, and *Drepanotermes*) in the largest termite family, Termitidae. He has also suggested that they may serve as alarm pheromones. This suggestion, however, has been questioned by *Maschwitz*[59] and *Stuart* (Ref. [42d], pp. 91—93).

Stuart[53,60] showed that *Nasutitermes* termites mark a trail with a substance deposited from the sternal gland. *Moore* subsequently isolated from extracts of whole *N. exitiosus* termites a trail-active fraction[61]. The molecule was characterized as a diterpene hydrocarbon, $C_{20}H_{32}$, with four double bonds and one ring[61]. On the basis of UV and NMR spectra and of microozonolysis experiments, this substance (nasutene) has been tentatively assigned structure *(6)*[62]. The cembrane skeleton was confirmed by comparison of perhydrocembrene with perhydronasutene, which proved identical. The precise location and stereochemistry of the double bonds are not certain. This substance also elicits trail-following in *N. walkeri* and *N. graveolus*[61]. It remains to be seen if this substance originates in the sternal gland.

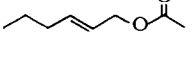


(6)

4.3. Hemiptera

The Hemiptera (true bugs) are arranged into about 50 families; evidence for pheromonal communication has been reported in the hemipteran families Cimicidae[63], Lygaeidae[64], Miridae[65], Pyrrhocoridae[66], and Reduviidae[67].

The liquid in the abdominal glands of males of the giant water bug, *Lethocerus indicus* (family Belostomatidae) is used in Thailand as a seasoning for certain foods. *Butenandt* and *Tâm*[68] identified the major volatile constituent as (*E*)-2-hexenyl acetate *(7)*. They postulated that it may serve as a sex attractant or aphrodisiac. *Pattenden* and *Staddon*[69], however, have presented evidence that the ester is neither sex- nor species-specific.



(7)

There is evidence that the bronze-orange bug, *Musgraveia* (=*Rhoecocoris*) *sulciventris*, and the southern green stink (or green vegetable) bug, *Nezara viridula* (Pentatomidae), produce pheromones. *Park* and *Sutherland*[70] have proposed that the (*E*)-2-octenyl acetate that they isolated from a steam distillate of both sexes of *M. sulciventris* may act as an attractant or aphrodisiac. The same function

may also be served by the (*E*)-2-decenyl acetate found in the related bug, *Biprorulus bibax*[70]. *Gilby* and *Waterhouse*[71] identified eighteen compounds in the scent secretion of *Nezara viridula*. Although most of these compounds may be used for defensive purposes, a sex pheromone may be among them, for *Mitchell* and *Mau*[72] have shown that males of *N. viridula* produce a substance that is highly attractive to females.

4.4. Homoptera

The order Homoptera includes the cicadas, aphids, scale insects and allies; over 30000 species are known. Chemical communication has been demonstrated in the families Aphididae[73], Coccidae[74], Diaspididae[75], and Pseudococcidae[76].

Kislow and *Edwards*[77] found that the green peach aphid, *Myzus persicae*, (Aphididae) is repelled by its own defensive secretion and by squashed aphids. The substance responsible for this behavior has been designated an alarm pheromone and identified by *Bowers et al.*[78] as (*E*)-β-farnesene *(8)*. It has also been identified in the aphids *Macrosiphum*

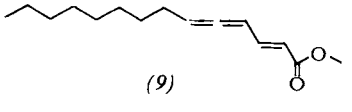
(8)

rosae, *Acyrthosiphon pisum*, *Schizaphis graminum*, and *Aphis gossypii*, where it also presumably acts as an alarm pheromone[78].

4.5. Coleoptera

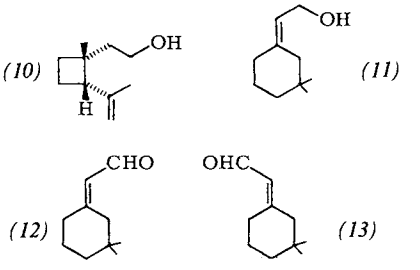
Coleoptera (beetles and weevils) is the largest order of insects and has an appropriately large literature on pheromonal communication. In addition to the families discussed below, pheromones have been suggested or demonstrated in the following families: Anobiidae[79], Buprestidae[80], Carabidae[81], Chrysomelidae[82], Coccinellidae[83], Lampyridae[84], Lycidae[85], Malachiidae[86], Meloidae[87], Platypodidae[88], Staphylinidae[89], and Tenebrionidae[90].

Hope et al.[91] observed that males of the dried bean beetle, *Acanthoscelides obtectus* (Bruchidae) produce a sweet, fruity odor and suggested this might be a pheromone. In 1970, *Horler*[92] identified this substance as (−)-methyl (*E*)-2,4,5-tetradecatrienoate *(9)*, which is the first known allenic sex pheromone. The racemic ester has recently been synthesized[93].



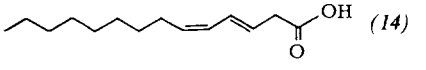
(9)

Males of the boll weevil, *Anthonomus grandis* (Curculionidae), produce a pheromone that attracts the females[94]. A suitable bioassay was developed[95], and *Tumlinson et al.*[96] identified the four synergistic components of the pheromone as (+)-2-(*cis*-isopropenyl-1-methylcyclobutyl)-ethanol *(10)*, (*Z*)-2-(3,3-dimethylcyclohexylidene)ethanol *(11)*, (*Z*)-2-(3,3-dimethylcyclohexylidene)acetaldehyde *(12)*, and (*E*)-2-(3,3-dimethylcyclohexylidene)acetaldehyde *(13)*. Syntheses of the cyclohexane[97] compounds and of the cyclobutane[98] compound have recently been reported. The mixture of the four synthetic compounds is attractive to females in the field[99].



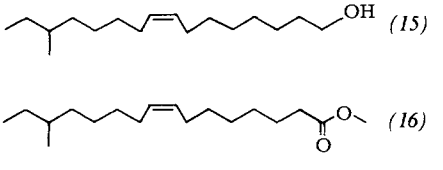
(10) *(11)* *(12)* *(13)*

The sex attractant of the black carpet beetle, *Attagenus megatoma* (Dermestidae), has been identified[100] as (*E,Z*)-3,5-tetradecadienoic acid *(14)*; a synthesis of this acid and its geometric isomers has been reported[101].



(14)

Species in the dermestid genus *Trogoderma* are very important pests of stored grains and consequently have received considerable attention regarding control and eradication. Sex pheromones are present in females of several species[102], and *Yinon* and *Shulov*[103] have presented evidence for an aggregation pheromone in *T. granarium*. The "assembling scent" components of *T. granarium* have been identified[104] as common free fatty acids (oleic, palmitic, and linoleic) and their ethyl esters. Two of the four attractive components of the female *T. inclusum* pheromone were identified by *Rodin et al.*[105] as (*Z*)-(−)-14-methyl-8-hexadecen-1-ol *(15)* and (−)-methyl (*Z*)-14-methyl-8-hexadecenoate *(16)*. *DeGraw* and *Rodin*[106] have published syntheses of these two compounds. Cross attraction studies have been reported for *T. inclusum*, *T. simplex*, *T. variabile*, *T. glabrum*, and *T. sternale*[107a].



(15) *(16)*

The sex attractant pheromone of *T. glabrum* consists of six components, each of which is active individually. Three of these have been identified as hexanoic (caproic) acid, γ-caprolactone, and the (*E*) isomer of compound *(15)*; the others are the next lower and higher homologs of compound *(16)*, and a long chain unsaturated alcohol[107b]. *Lilly* demonstrated[108] that females of the sugar beet wireworm, *Limonius californicus* (Elateridae) produce a sex attractant. It was identified in 1968 by *Jacobson*, *Lilly*,

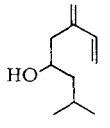
and *Harding*[109] as pentanoic (valeric) acid. A carboxylic acid has also been implicated as the sex pheromone of the Pacific Coast wireworm, *L. canus*[110]. Sex pheromones have also been reported in the elaterid genera *Agriotes*[111], *Ctenicera*[111], and *Hemicrepidius*[112].

The grass grub beetle, *Costelytra zealandica* (family Scarabaeidae), is attracted to certain synthetic resins[113], particularly a phenol-formaldehyde resin. The natural pheromone from females was subsequently isolated and identified as phenol[114]. Apparently the phenol is not produced by the *C. zealandica* females themselves but by bacteria that live in the colleterial glands in their abdomens[115]. It would be interesting to see if virgin females raised under sterile conditions (or treated with appropriate antibiotics) are attractive to males.

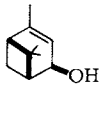
The bark beetles in the family Scolytidae have been the subject of extensive pheromone studies because of their economic importance; an estimated annual loss of about 5×10^9 board feet of timber in the USA is attributed to them.

Typically, individuals of one sex select the individual host tree in which mating and oviposition occur. In the process of excavating a "nuptial" chamber, frass (a mixture of wood fragments and fecal pellets) is extruded, whereupon a mass attack by both sexes ensues in response to the pheromones in the frass.

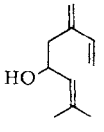
Isolation and identification of the attractant pheromone in the frass of male *Ips paraconfusus* Lanier (= *Ips confusus* LeConte) represents the first identification of an attractant in the order Coleoptera[116]. The attractant pheromone consists of three monoterpene alcohols: (−)-2-methyl-6-methylene-7-octen-4-ol *(17)*, (+)-*cis*-verbenol *(18)*, and (+)-2-methyl-6-methylene-2,7-octadien-4-ol *(19)*. These three compounds have been synthesized[117].



(17)



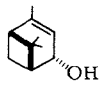
(18)

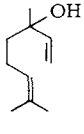


(19)

The first and third compounds were later assigned the trivial names ipsenol and ipsdienol, respectively, since they are widely distributed through the genus *Ips*. None of these compounds is active individually, but the combination of all three attracts beetles in the field. Ipsenol has recently been reported to be the aggregating pheromone for *Ips grandicollis*[118], and ipsdienol plus *cis*-verbenol for *Ips calligraphus*[119]. *trans*-Verbenol *(20)* has been reported in hindguts of male and female *Ips calligraphus*[119], and linalool *(21)* has been identified in frass

(20)

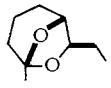




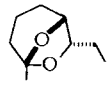
(21)

of female *Ips paraconfusus* and male *Ips pini*[120a]. No biological significance has been attached to either compound, but linalool is of interest in that it is isomeric with ipsenol and can readily be mistaken for it because of very similar gas chromatographic behavior. Cross attraction studies have been carried out on several *Ips* species[120b].

The attractant pheromone of the female Western pine beetle, *Dendroctonus brevicomis*, consists of *exo*- *(22)* and *endo*-7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane *(23)*, named *exo*-brevicomin and *endo*-brevicomin, respectively[121].



(22)



(23)

(24)

The response of both sexes is strongly synergized by myrcene (from the tree resin) and by 1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane *(24)* (called frontalin[122]) from the male[123]. The three bicyclic ketals have been synthesized[122, 124].

Three large-scale field tests have been conducted in two areas that have been chronically infested with *D. brevicomis*.

A mixture of *exo*-brevicomin, frontalin, and myrcene was used to bait large sticky traps. No definitive statements can be made until much more information has been assimilated, but qualitative, intuitive evaluations look very promising.

The pheromone chemistry and biology of three other bark beetles, *D. frontalis*, *D. ponderosae*, and *D. pseudotsugae*, have also been reported in several papers[*] and some attempts have been made to summarize the arguments involving methodology and interpretation of pheromone studies of bark beetles in general[123a, 125].

4.6. Lepidoptera

In 1965, *Jacobson*[126] listed 140 species of Lepidoptera suspected of producing pheromones; in 1970, he added another 31 species[127]. Most of the identified female sex pheromones are unsaturated normal aliphatic alcohols or acetates (for reviews, see Refs. [127—136]). We shall now focus our attention on some structurally unusual lepidopterous pheromones, on pheromones produced by males, and on some recent structural proposals.

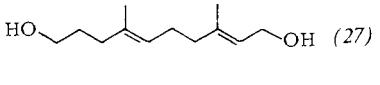
Some species of tiger moths (Arctiidae) in the genera *Holomelina* and *Pyrrharctia* utilize the saturated hydrocarbon 2-methylheptadecane *(25)* as a female sex pheromone[137].

(25)

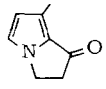
Males of some butterflies in the family Danaidae seduce their respective females with aphrodisiac scents disse-

[*] The reader is referred to the following works: *J. A. A. Renwick* and *J. P. Vité*, Contrib. Boyce Thompson Inst. Plant Res. *24*, 283 (1970); *J. A. Rudinsky*, *ibid. 24*, 311 (1970); *J. P. Vité* and *J. A. A. Renwick*, *ibid. 24*, 323 (1970); *J. A. A. Renwick*, *ibid. 24*, 337 (1970); *J. P. Vité*, *ibid. 24*, 343 (1970).

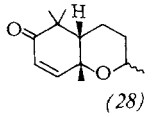
minated by brushlike struktures ("hair-pencils") on the abdomen[138]. In the genera examined, *Danaus*[139], *Lycorea*[140], and *Euploea*[139c], several unusual compounds have been identified: 2,3-dihydro-7-methylpyrrolizin-1-one *(26)*[139a,c,d,140], (*E*,*E*)-3,7-dimethyl-2,6-decadiene-1,10-diol *(27)*[139a], and the diacid corresponding to *(27)*[139b].



(27)



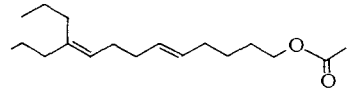
(26)



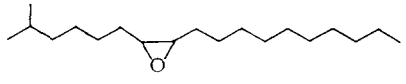
(28)

A second component of the hair-pencil secretion of the monarch butterfly, *Danaus plexippus*, has been isolated and has tentatively been assigned the structure: *cis*-1,3,7,7-tetramethyl-2-oxabicyclo[4.4.0]dec-9-en-8-one *(28)*[140b].

The pink bollworm moth, *Pectinophora gossypiella* (Gelechiidae) uses (*E*)-10-propyl-5,9-tridecadienyl acetate *(29)* as its female sex pheromone[141]; the propyl side chain makes this an unusual natural product. This compound has also been synthesized[142].



(29)



(30)

After many years of research, the sex attractant of the female gypsy moth, *Porthetria dispar* (Lymantriidae), has been identified. *Bierl*, *Beroza*, and *Collier*[143] identified the pheromone ("disparlure") as (*Z*)-7,8-epoxy-2-methyloctadecane *(30)*. On the basis of a series of microchemical tests[144], the pheromone was postulated to be an alkyl epoxide. Treatment of the original extract with *m*-chloroperbenzoic acid increased activity tenfold, supporting the epoxide hypothesis and suggesting a search for the precursor olefin[145]. An olefin was isolated that was highly active in the bioassay after epoxidation; it was identified as (*Z*)-2-methyl-7-octadecene. The synthetic pheromone, properly formulated, is at least as attractive to males as are live females[146]; it promises to be useful in the control of the gypsy moth[147]. A synthesis has recently been reported by *Eiter*[148].

Male moths in the family Noctuidae have "hair-pencils" as do the danaids discussed above; their secretions are believed to serve the same purpose[149]. Benzaldehyde has been identified in several species[149a,150], as have several other simple compounds[150a]. In the southern armyworm, *Pseudaletia separata*, it has been suggested[150b] that benzaldehyde serves to inhibit the female's initial escape reaction from the male, although in *P. unipuncta* it would appear that benzaldehyde may not be of communicative significance[150c].

Röller et al.[151] identified *n*-undecanal as the sex attractant of the greater wax moth, *Galleria mellonella* (family Pyralidae). This aldehyde and (*Z*)-11-octadecenal, both produced by males of *Achroia grisella*, have been reported by *Dahm et al.*[152] to be components of the sex pheromone of this pyralid species.

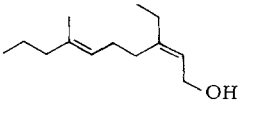
Henderson et al.[153] identified the sex pheromone of the female pine emperor moth, *Nudaurelia cytherea* (Saturniidae), as (*Z*)-5-decenyl 3-methylbutanoate *(31)*.

(31)

Sex pheromones have been demonstrated in many species in the family Tortricidae[154]; here we consider those of only four species. *Weatherston et al.*[155] identified the sex pheromone in females of the eastern spruce budworm, *Choristoneura fumiferana*, as (*E*)-11-tetradecenal. The identification included the use of electroantennograms (EAG's) to monitor the isolation of the pheromone. This technique, based on the pioneering work of *D. Schneider* and his colleagues at Seewiesen, depends on the fact that electrical signals, generated by an isolated insect antenna as a result of receptor site activity, can be amplified and visualized by an oscilloscope or other suitable device. *Roelofs et al.* have used the EAG method to advantage in studying many lepidopterous attractants[136]. The pheromones of the tortricids *Paralobesia viteana*[156] and *Zeiraphera diniana*[157] have been characterized using the EAG technique in conjunction with classical structural analysis. *Birch* found the EAG approach unreliable for studying pheromones from male noctuid moths[158].

Roelofs et al.[159] characterized a female-derived sex attractant of the codling moth, *Laspeyresia* (=*Carpocapsa*) *pomonella*, as (*E*,*E*)-8,10-dodecadien-1-ol *(32)*. The identification was based primarily on EAG response and gas chromatographic comparison with certain standards. The synthetic compound is attractive to males both in the laboratory and in the field[159]. However, *McDonough et al.*[160] proposed structure *(33)*, (*Z*,*E*)-7-methyl-3-propyl-2,6-decadien-1-ol, for one of the attractants. They did not detect any (*E*,*E*)-8,10-dodecadien-1-ol *(32)* in the codling

(32)



(33)

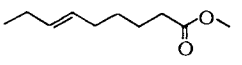
moths. The discrepancy between these results awaits resolution. *George* and *McDonough*[161] have reported that seven bioactive fractions, including *(33)*, can be obtained from female *L. pomonella*.

4.7. Diptera

There is evidence for pheromonal communication in numerous dipteran species, but only two pheromones have

been identified. *Carlson et al.*[162] characterized the sex attractant of the common housefly, *Musca domestica* (Muscidae), as (*Z*)-9-tricosene. Very recently, *Jacobson et al.*[163] identified two components of the male-derived sex pheromone of the Mediterranean fruit fly, *Ceratitis capitata* (Tephritidae), as (*E*)-6-nonen-1-ol *(34)* and methyl (*E*)-6-nonenoate *(35)*.

(34)

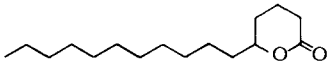


(35)

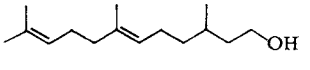
4.8. Hymenoptera

Although the order Hymenoptera is only about the third largest order of insects in terms of identified species, the volume of literature on pheromonal communication is larger than that of any other invertebrate group. Here pheromonal communication has attained its greatest development: for example, *Wilson* (see Ref. [42a], p. 218) states that most of the social organization of the fire ant *Solenopsis invicta* (= *Solenopsis saevissima richteri*, red form) may be mediated by as few as ten pheromones. Our discussion is limited to recent work on some hymenopteran pheromones of known chemical constitution (for detailed reviews see Refs. [42a, 59, 130, 164—171]).

Both isomers of citral have been identified[172] in the mandibular gland secretion of the bee *Hylaeus cressoni* (family Colletidae); dihydroambrettolide is responsible for the musk-like scent of the bees *Halictus albipes* and *H. calceatus* (family Halictidae)[173]. These compounds probably act as pheromones, but their precise functions are uncertain. The "queen substance" for the oriental hornet, *Vespa orientalis* (Vespidae) has been identified[174] as δ-hexadecalactone *(36)*. Some territorial marking pheromones of male bumblebees (*Bombus* species, family Bombidae) have been characterized as rather complex mixtures of terpenes, ethyl esters, acetates, and other compounds[175]. The main component of the marking scent of *B. terrestris* is 2,3-dihydrofarnesol ((*E*)-3,7,11-trimethyl-6,10-dodecadien-1-ol) *(37)*[176].



(36)



(37)

The queen substance for the honeybee, *Apis mellifera* (Apidae), (*E*)-9-oxo-2-decenoic acid, has recently been isolated from the three other species in this genus, *A. cerana*, *A. indica*, and *A. florea*[177], where it presumably serves the same functions as in *A. mellifera*. The sting pheromone, isopentyl acetate, is also shared by the four *Apis* species[178].

2-Heptanone, another bee alarm pheromone[179], occurs only in the mandibular glands of *A. mellifera*[178]. The Nassanoff gland, peculiar to the genus *Apis*, produces a secretion which contains several monoterpenoid compounds, the most attractive of which are reported to be the two isomers of citral[180]. Several functions for this secretion have been demonstrated (queen finding[181], marking of food sources[182]), but the full biological significance of the exudate probably remains to be established[167].

Nineteen analogs of (*E*)-9-oxo-2-decenoic acid have been evaluated as sex attractants for *A. mellifera*[183]. The specificity of the drone's receptor site is so extreme, that *any* modification of the molecule results in complete loss of activity. Similar experiments have been reported with analogs of the alarm pheromones, isopentyl acetate and 2-heptanone[184].

Citral has been identified[185] in the mandibular gland secretion of workers of the stingless bee *Trigona subterranea* (Apidae). Depending on concentration and context, the workers react in various ways when confronted with synthetic citral.

The literature on ant (Formicidae) pheromones is large and diverse. We shall concern ourselves here with only those pheromones whose structures have been elucidated in the past four to five years.

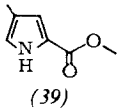
Pheromones have been implicated recently in the aggressive behavior of the Australian bull ant, *Myrmecia gulosa*, a member of the most primitive living subfamily of ants, Myrmeciinae[186]. *Cavill* and *Williams*[187] had identified several hydrocarbons in this species' Dufour's gland, but they do not appear to be involved in alarm or attack behavior[186].

(38)

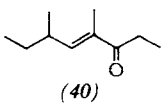
6-Methyl-5-hepten-2-one *(38)* has been known for some time to be an alarm pheromone for several Australian *Iridomyrmex* species (subfamily Dolichoderinae)[188]. It has recently been identified as an alarm pheromone component in an *Iridomyrmex* species from Florida, which raises some interesting chemotaxonomic questions since this group of ants has been identified with 2-heptanone[189].

The only identified pheromones in the subfamily Ponerinae are dimethyl sulfide and dimethyl trisulfide, identified in 1967[190] in the mandibular gland secretion of *Paltothyreus tarsatus*. These sulfides appear important in defense and in the communication of alarm.

Trail following is one of the most conspicuous activities of ants; in spite of much research, only one ant trail pheromone has been identified. The major component of the trail pheromone of the Texas leaf-cutting ant, *Atta texana* (Myrmicinae) was recently characterized as methyl 4-methylpyrrole-2-carboxylate *(39)*[191]. Several analogs of *(39)* have been synthesized and possess considerable trail pheromone activity[192]. In addition, the pyrrole may well be a component of the trail pheromone of other ants in this tribe (Attini)[193].



(39)



(40)

Many alarm pheromones are known from myrmicine ants. Among these are 3-octanone in the genera *Crematogaster*[194], *Myrmica*[195], *Acromyrmex*[196], and *Trachymyrmex*[196]; 6-methyl-3-octanone in *Crematogaster*[194d] and *Myrmica*[197]; (*E*)-2-hexenal in *Crematogaster*[194b]; and 4,6-dimethyl-4-octen-3-one *(40)* in *Manica*[198]. Sex pheromones have recently been demonstrated in some myrmicine ants[199].

Although formic acid has been known from ants for 300 years, only recently has it been shown to communicate alarm in the genera *Formica*[169] and *Camponotus*[200] (subfamily Formicinae).

The alarm pheromone of *Lasius spathepus* (Formicinae) has recently been characterized as *citronellal*[201]. This monoterpene aldehyde has also been detected in *L. flavus*[202], *L. carniolicus*[202], and *L. alienus*[203]. However, *n*-undecane appears to be the principal alarm pheromone for *L. alienus*[203]. Many other hydrocarbons and mono- and sesquiterpenes have also been reported in this genus[202–204]. The Dufour's gland secretion of *Anoplolepis custodiens* consists almost entirely of saturated and unsaturated normal hydrocarbons from C_{10} to C_{21}[205]; they do not, however, appear to be alarm pheromones. *Regnier* and *Wilson*[206] report that *n*-undecane serves as an alarm pheromone and as a spreading agent for formic acid in the formicine *Acanthomyops claviger*. The pheromones of the slave-making ants *Formica sanguinea*[207] and *Polyergus rufescens*[207b] have also been investigated. In these species, mixtures of simple aliphatic acetates serve as alarm pheromones. Finally, *Bergström* and *Löfqvist*[208] have identified 40 volatile compounds in the Dufour's gland secretion of *Camponotus ligniperda*. Included are *n*-alkanes, alkenes, alkadienes, alkanols, alkenols, several acetates, 2-pentadecanone, farnesene and farnesyl acetate. Formic acid and the *n*-alkanes from nonane to dodecane elicit alarm; *n*-tridecane, the most abundant component, elicits little if any alarm, but may function as a spreading agent.

5. The Future of Pheromones

Pheromones and attractants can be expected to play increasing roles in the integrated control of various insect pests. Although there have been some disappointing results, there have also been notable successes; further study of insect pheromones is surely justified from an economic and environmental standpoint. Nor should the continuing intellectual challenge be overlooked.

Chemically identified pheromones are known from only seven of the twenty-seven insect orders; but it would seem that intraspecific chemical communication may eventually be detected in every order. The study of insect pheromones will continue to occupy an exciting and relevant part of the chemical literature for many years to come.

We thank Dr. Murray S. Blum, and Dr. John M. Brand of the University of Georgia for valuable comments and criticisms; we also thank Dr. R. S. Berger, Dr. G. Bergström, Dr. M. Beroza, Dr. W. S. Bowers, Dr. D. H. Calam, Dr. R. C. Gueldner, Mr. M. Jacobson, Dr. P. Karlson, Dr. L. M. McDonough, Dr. J. Meinwald, Dr. J. A. A. Renwick, Dr. W. L. Roelofs, Dr. J. P. Vité, and Dr. J. Weatherston for allowing us to quote unpublished work and for helpful comments.

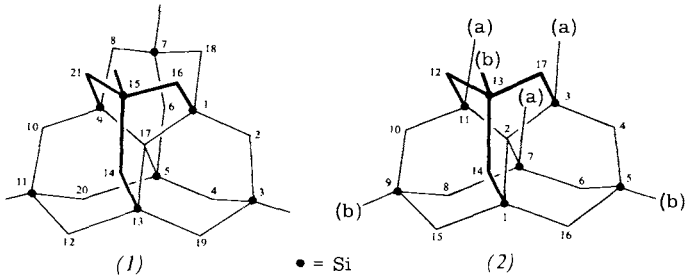
Carbosilanes Having a New Silicon-Carbon Skeleton ("Silascaphanes"[**])

By *Gerhard Fritz, Gerwig Marquardt,* and *Heinz Scheer*[*]

Extensive separation of the pyrolysis products of tetramethylsilane (TMS)[1] (pyrolysis conditions: *ca.* 700 °C, gas phase) led to the discovery of a new type of carbosilane whose six-membered rings composed of alternating carbon and silicon atoms exist only in the boat form and which thus differ from the "carborundanes"[2] (sections of the ideal carborundum lattice as molecular skeleton with the SiC six-membered rings exclusively in the chair form).



(1) • = Si —• = Si–CH_3 *(2)*

We have isolated the compounds $Si_8C_{17}H_{36}$ *(1)* and $Si_7C_{16}H_{36}$ *(2)* as the first derivatives of this class.

The molecule of compound *(1)* has the symmetry of the space group $P\bar{4}3m\text{-}T_d^1$, possesses four threefold axes, and contains twelve six-membered rings made up of alternating Si and C atoms in the boat form (octasiladodecascaphane).

Compound *(1)* is obtained as white crystals of m. p. 265 °C. Precise determination of the relative molecular mass gave *m/e* 464.09613 (calc. for $Si_8C_{17}H_{36}^+$ 464.0971); the most intense peaks were for *m/e* 464 ($M=Si_8C_{17}H_{36}^+$) and 449 ($M-CH_3=Si_8C_{16}H_{33}^+$), as well as *m/2e* 217 ($[M-2CH_3]/2=Si_8C_{15}H_{30}^+/2$). The molecule contains four equivalent $SiCH_3$ groups and twelve equivalent Si_2CH_2 groups. Accordingly, the ^{1}H-NMR spectrum (solvent CCl_4) exhibits only two singlets at $\tau=9.91$ (Si—CH_3) and 10.24 (Si—CH_2—Si) in the intensity ratio 1:2. X-ray structure analysis[3] confirmed the structure of *(1)*.

Compound *(2)* contains one SiC unit less than the carbosilane *(1)* and thus lacks the possibility of optimum linkage to six-membered ring systems characteristic of the latter; *(2)* contains nine SiC six-membered rings in the boat form (heptasilanonascaphane). The molecule has one threefold axis.

Compound *(2)* is obtained as white crystals of m.p. 225–226 °C. Precise molecular mass determination: *m/e* 424.11999 (calc. for $Si_7C_{16}H_{36}^+$ 424.12018). ^{1}H-NMR (solvent CCl_4): two signals each in the $SiCH_3$ region ($\tau=9.80$ and 9.89) and in the Si_2CH_2 region ($\tau=10.20$ and 10.27). Mutual shielding leads to an upfield shift of the signal due to $SiCH_3$ groups (a) relative to $SiCH_3$ groups (b). Molecular models show that the three methylene groups of C atoms 14, 15, 16 and the six methylene groups of C atoms 4, 6, 8, 10, 12, 17 are mutually equivalent. Accordingly, the relative intensity ratio of the $SiCH_3$ proton signals amounts to 1:1 (9.0:8.7), and that of the Si_2CH_2 protons 1:2 (5.8:11.8).

The carbosilane *(2)* is an isomer of the carborundane *(3)*, which has already been obtained from the pyrolysis products of TMS[2], and of the compound *(4)* which we have now prepared for the first time.

The upper half of the molecule *(4)* has a Si-adamantane structure with SiC six-membered rings in the chair form while the lower half contains the three "side" SiC six-membered rings in the boat form. *(4)* thus represents a combination of the two structural types.

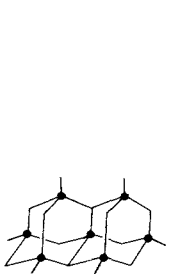
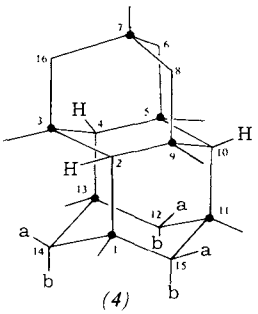
Institut für Anorganische Chemie der Universität (TH)
75 Karlsruhe, Englerstrasse 11 (Germany)

[**] Owing to the complexity of the IUPAC nomenclature we propose that such compounds with alternating fixed SiC six-membered rings in the boat form (Latin *scapha*) be known as "silascaphanes", *e.g.* 3,7,11,15-tetramethyl-1,3,5,7,9,11,13,15-octasiladodecascaphane, the numbering of the atoms agreeing with the official nomenclature.



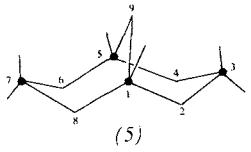
(3)



(4)

Compound *(4)* is obtained as white crystals of m. p. 240–242 °C. Precise mass determination for $M-CH_3$ ($M=Si_7C_{16}H_{36}^+$): *m/e* 409.09816 (calc. for $Si_7C_{15}H_{33}^+$ 409.0967). ^{1}H-NMR: three sharp signals in the $SiCH_3$ region ($\tau=9.71$, 9.74, and 9.77; in benzene). The protons of the CH_3 groups attached to Si atoms 1, 11, 13 are mutually equivalent and differ from those on Si atoms 3, 5, 9 which are also mutually equivalent. They all differ from the CH_3 group on Si atom 7 leading to a relative intensity ratio of 3:3:1. The signal of the Si_2CH_2 protons with C atoms 6, 8, 16 appears at $\tau=10.30$, and that of the Si_3CH protons on C atoms 2, 4, 10 at $\tau=10.84$ (both singlets); relative intensity ratio 2:1. The protons a and b on the C atoms 12, 14, 15 have different chemical environments so that an AM spectrum results ($\tau_A=10.55$, $\tau_M=9.87$; $J_{AM}=12.6$ Hz). The coupling is established by double resonance experiments. The 220-Hz spectrum clearly shows the AM pattern.

The simplest carbosilane having fixed SiC six-membered rings in the boat form is compound *(5)* (tetrasiladiscaphane which we have now also isolated from the pyrolysis products of TMS; SiCl-containing derivatives are known[4]. The compound has already been synthesized by another route[5].



(5)

The carborundanes predominate over the silascaphanes in the pyrolysis products of tetramethylsilane. On the basis of the C—C (1.54 Å) and Si—C (1.85 Å) distances in six-membered rings the boat form should be more stable for carbosilanes than for hydrocarbons.

Compounds *(1)* to *(5)* were isolated alongside other products by gas chromatography from the previously described[2] viscous pyrolysis products of $Si(CH_3)_4$ after preliminary work-up by column and gel chromatography.

Nomenclature[**]:

(1): 3,7,11,15-Tetramethyl-1,3,5,7,9,11,13,15-octasilaoctacyclo[7.7.1.1^{1,7}.1^{3,13}.1^{5,11}.1^{9,15}.0^{5,17}.0^{13,17}]heneicosane; *(2)*: 3,5,7,9,11,13-Hexamethyl-1,3,5,7,9,11,13-heptasilahexacyclo[7.5.1.1^{1,5}.1^{3,13}.0^{2,7}.0^{2,11}]heptadecane; *(4)*: 1,3,5,7,9,11,13-Heptamethyl-1,3,5,7,9,11,13-heptasilahexacyclo[9.3.1.1^{3,7}.0^{2,9}.0^{4,13}.0^{5,10}]hexadecane; *(5)*: 1,3,3,5,7,7-Hexamethyl-1,3,5,7-tetrasilabicyclo[3.3.1]nonane.

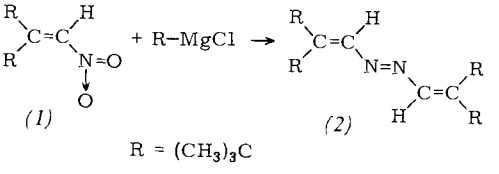
The First Divinylazo Compound and Its RadicalAnion[1]

By *Wilhelm Ahrens* and *Armin Berndt*[*]

Reaction of the nitroalkene *(1)*[2] with *tert*-butylmagnesium chloride afforded, in addition to several colorless products of undetermined constitution, orange crystals of a substance *(2)* which is very soluble in nonpolar solvents (light petroleum, benzene, CCl_4) but only sparingly soluble in polar solvents (acetonitrile, DMSO, ethanol). Mass spectroscopic elemental analysis revealed the composition $C_{20}H_{38}N_2$[3]. Since the NMR spectrum of *(2)* (in CCl_4, relative to TMS) only contains three singlets at $\delta=7.0$ (2H), 1.3 (18H), and 1.5 ppm (18H), two $C_{10}H_{19}N$ units must be linked together symmetrically. This observation and the similarity of the electronic excitation spectrum to that of azobenzene[4] indicate the constitution of a 3,8-di-*tert*-butyl-2,2,9,9-tetramethyl-5,6-diazadeca-3,5,7-triene (2,2′-di-*tert*-butyl-3,3,3′,3′-tetramethylazo-1-butene) for *(2)*. Compound *(2)* is the first divinylazo compound to be described. Unlike the thermolabile 1-phenylazo-1-alkenes[5], compound *(2)* can be sublimed at 180 °C under normal pressure without decomposition.



(1) + R–MgCl → *(2)*

R = $(CH_3)_3C$

The relatively low extinction coefficient of the n→π* excitation ($\varepsilon=232$ for $\lambda=440$ nm) and the high ε values of the π→π* excitation ($\varepsilon=18100$, 28400, and 28100 for $\lambda=337$, 322, and 313 nm respectively) suggest that the vinyl substituents on the azo group are *trans* configurated. *cis*-Configurated azoarenes[6] and alkylazoarenes[7] are characterized by relatively high ε values for the n→π* transition and relatively low ε values for the π→π* transition. The absence of any absorption at 230—240 nm apparent on comparison with the spectrum of azobenzene confirms the assignment of these bands to transitions of the phenyl groups[8].

In the Raman spectrum (in CCl_4) *(2)* gives a strong band at 1415 cm^{-1} and a broad band of medium intensity at 1567 cm^{-1} in the regions characteristic of N=N vibrations (1408—1447 and 1558—1579 cm^{-1})[9]. In acetonitrile *(2)* can be reduced electrolytically (tetra-*n*-propylammonium perchlorate as conducting salt) to the radical anion. Its ESR spectrum (Fig 1a) can be reconstructed with $a^N=5.1$ G (2N) and $a^H=2.0$ G (2H) (Fig. 1b). Under the same measuring conditions we found $a^N=5.0$ G (2N) (literature data: 4.84, 5.1, and 5.2 in various solvents[10])

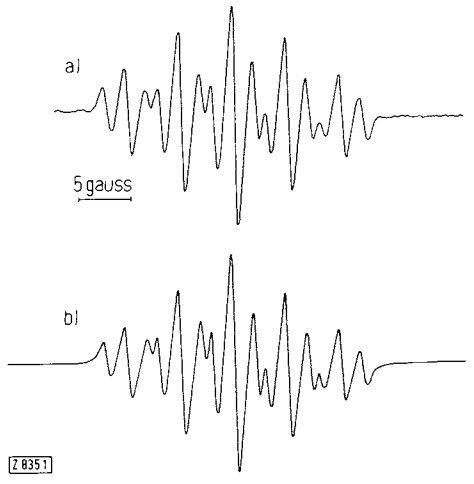

Fig. 1. a) ESR spectrum of the radical anion of *(2)* in acetonitrile at 25 °C; b) computer simulated spectrum with $a^N = 5.1$ G (2 N) and $a^H = 2.0$ G (2 H), line width 0.75 G.

for the radical anion of azobenzene. Assuming a direct proportionality between a^N and the spin density at the nitrogen ρ^N, which is justifiable in numerous cases, a proportionality constant Q^N of 16.5 G is obtained from $a^N = 8.25$ G for the radical anion of 2,2'-azoisobutane[11] and $\rho^N = 0.5$. Hence a value of $\rho^N = 0.31$ follows for the radical anion of *(2)*. The spin density at C_α is calculated as $|\rho_\alpha^C| = 0.085$ with the aid of the McConnell equation and the value of $Q_{C-H}^H = -23.7$ G generally valid for radical anions. The normalization condition $\sum_i \rho_i = 1$ thus yields a spin density of 0.28 at c_β, ρ_α^C being given a theoretically justified negative sign. HMO spin density calculations by the McLachlan method[12] with the parameters used for the azobenzene radical anion give $\rho^N = 0.30$, $\rho_\alpha^C = -0.10$, and $\rho_\beta^C = 0.30$ if the effect of the *tert*-butyl substituents is neglected.

In the mass spectrum of *(2)* which contains relatively few fragment ions the signal at $m/q = 153$ is particularly striking since it represents the base peak at electron impact above 20 eV and still has 80% of the intensity of the molecular ion at 16 eV whereas only the fragments M − 56 and M − 57 then have intensities above 5% (loss of *tert*-butyl radicals and of isobutylene respectively). The absence of a half integral signal at $m/q = 153.5$ proves that the peak at 153 (exact mass 153.1515) is not due to a doubly charged molecular ion but to an ion of composition $C_{10}H_{19}N^+$. In contrast to azobenzene, which preferentially fragments with cleavage of the C—N bond[13], *(2)* very readily cleaves at the N=N bond.

Attempts to convert nitroalkenes subject to less steric hindrance into the corresponding divinylazo compounds have so far been unsuccessful.

3,8-Di-tert-butyl-2,2,9,9-tetramethyl-5,6-diazadeca-3,5,7-triene (2):

A Grignard solution obtained from magnesium (1.46 g, 60 mmol) and *tert*-butyl chloride (5.56 g, 60 mmol) is slowly added dropwise to a solution of *(1)* (1.85 g, 10 mmol) in dry ether (4 ml) at −15 °C (ice/salt) under an inert gas. After 10 minutes' stirring of the cooled mixture it is hydrolyzed with aqueous ammonium chloride solution. The aqueous phase is extracted into ether; the combined ether extracts are twice washed neutral with water. After drying of the ethereal solution over magnesium sulfate and evaporation of the ether, part of the product *(2)* crystallizes. The filtrate is taken up in ethanol and a further crop of crystalline *(2)* is obtained in the cold. Recrystallizing twice from ethanol affords 56.1 mg (3.7%) of analytically pure *(2)* of m.p. 182—183 °C.

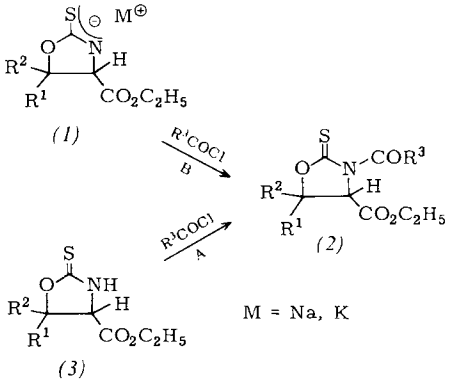
Ethyl 3-Acyl-2-thioxo-1,3-oxazolidine-4-carboxylates and Their Conversion into Ethyl α-(*N*-Acylamino)acrylates[**]

By *Dieter Hoppe*[*]

Ethyl 2-thioxo-1,3-oxazolidine-4-carboxylates *(3)* are formed in good yields by basic condensation of ethyl α-isothiocyanatoacetates with carbonyl compounds[1]. Their acylation with acyl halides in benzene/triethylamine at room temperature leads to ethyl 3-acyl-2-thioxo-1,3-oxazolidine-4-carboxylates *(2)*[2] (procedure A, see Table 1). The acyl compounds *(2)* are more conveniently obtained



directly from alkali metal salts *(1)* formed as primary products in the synthesis of *(3)*[1] by addition of acyl halides to the reaction mixture (procedure B).

Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

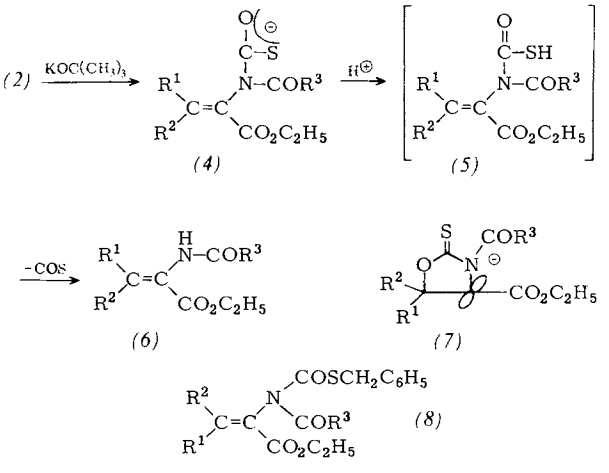
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The structural assignment of *(2)* as *N*-acylation product follows from the IR spectrum: an intense absorption at 1770 cm^{-1} shows the compounds *(2a)*—*(2g)* to be urethanes; a C=N frequency at about 1600 cm^{-1} characteristic of the alternative oxazoline structure is not observed.

The acyl compounds *(2)* are converted into the ethyl α-(*N*-acylamino)acrylates *(6)* by treatment with potassium *tert*-butoxide (50% excess) in tetrahydrofuran at −60 °C and subsequent neutralization with glacial acetic acid (Table 1). *(6b)* and *(6f)* were obtained by heating *(2b)* and *(2f)* to 160—180 °C for 2 h with 5 mol-% of triethylammonium chloride.

All compounds *(6)* gave satisfactory CH analyses and were characterized by their IR and NMR spectra. Stereochemical assignments were based on the NMR spectra. Isomeric oxazolidinethiones *(2)* and aminoacrylates *(6)* can be separated by chromatography on silica gel with ether/light petroleum.

α-Acylaminoacrylic esters *(6)* are of significance for the preparation of unsubstituted[6] and β-functional α-amino-acids[7]; since not only R^1 and R^2 but also R^3 can be varied within wide limits, the amino protecting group can be adapted to subsequent synthetic steps from the very beginning of a reaction sequence.



The first detectable intermediate formed is *N*-acyl-*N*-vinylthiocarbamate *(4)* which is converted into the free thiocarbamic acid *(5)* on acidification and thence into the aminoacrylates *(6)* by loss of carbon oxide sulfide. *(4)* can be trapped, *e.g.* with benzyl bromide, as *N*-acyl-*N*-vinylthiourethane *(8)*.

Available evidence indicates a concerted ring cleavage[3]. Thus *trans-(2g)* gives exclusively *Z-(6g)*, while *cis-(2g)* affords predominantly *E-(6g)* (*E*/*Z* ≈ 3 : 1). A two-step process *via* the anion *(7)*—analogous to base-induced ring cleavage of oxazoline-[4] and 2-alkylthiooxazoline-4-carboxylic esters[5]—would give roughly equal product ratios starting from both isomers. Moreover, base-catalyzed H/D exchange could not be detected in oxazolidinethione. Isomerization of the thiocarbamic anion *E-(4g)*, as has been detected for *E-(4a)*, probably accounts for the incomplete stereospecificity of the reaction of *cis-(2g)*.

Diethyl 5,5-dimethyl-2-thioxo-1,3-oxazolidine-3,4-dicarboxylate (2b):

Route A: Ethyl chloroformate (2.17 g, 20 mmol) was added without cooling to a solution of ethyl 5,5-dimethyl-2-thioxo-oxazolidine-4-carboxylate[11] *(3b)* (4.06 g, 20 mmol) and triethylamine (2.15 g, 21 mmol) in benzene (50 ml) initially cooled to 0 °C. The mixture was then stirred for 30 min at room temperature and allowed to stand for 1 h at 0—5 °C before the triethylammonium chloride was filtered off and the solvent evaporated off in a water pump vacuum. The residue was recrystallized from tetrachloromethane and afforded 4.5 g of *(2b)*. IR (KBr): 1740, 1770 cm^{-1} (CO).—^{1}H-NMR ($CDCl_3$): τ = 5.35 (s, 4-H), 8.37 and 8.53 (both s, CH_3).

Ethyl cis- and trans-3-benzyloxycarbonyl-5-phenyl-2-thioxo-1,3-oxazolidine-4-carboxylate (2g):

Route B: A mixture of ethyl isothiocyanatoacetate (5.8 g, 40 mmol) and benzaldehyde (4.3 g) in tetrahydrofuran (10 ml) was added dropwise to a vigorously stirred solution of potassium *tert*-butoxide (4.5 g, 40 mmol) in dry tetrahydrofuran (50 ml) under nitrogen at −60 °C. Stirring was continued for 30 min at −60 °C and the mixture was then allowed to warm up to −20 °C whereupon benzyl chloroformate (6.9 g, 40 mmol) in a little tetrahydrofuran was run in. After 30 min the solvent was removed under water-pump vacuum in a rotary evaporator and the residue taken up in dichloromethane (100 ml) and ice-water (30 ml). Washing twice with water (2 × 30 ml), drying the solution over sodium sulfate, and evaporation of the solvent in a vacuum furnished 14.8 g of crude *(2g)* as a bright yellow

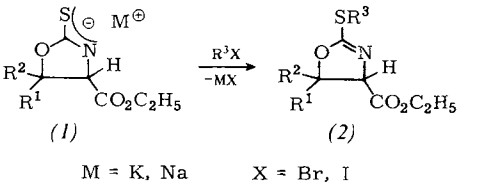
2-Alkylthio-2-oxazoline-4-carboxylic Esters and Their Conversion into α-(*N*-Alkylthiocarbonylamino)acrylic Esters[**]

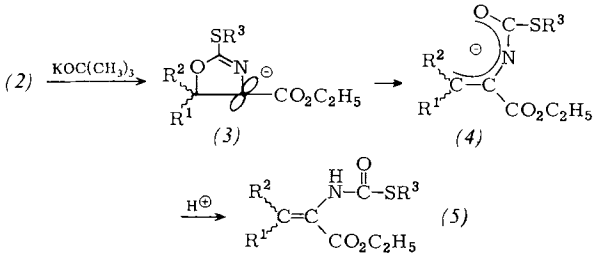
By *Dieter Hoppe*[*]

Whereas acylation of ethyl 2-thioxo-1,3-oxazolidine-4-carboxylates[1] or their ambidentate anions *(1)* leads to 3-acyl-1,3-oxazolidine-2-thiones[2], alkyl halides attack the sulfur atom to yield ethyl 2-alkylthio-2-oxazoline-4-carboxylates *(2)*.

The oxazolines *(2)* are obtained without intermediate isolation when ethyl isothiocyanatoacetate and carbonyl compounds are treated with potassium *tert*-butoxide or sodium hydride in tetrahydrofuran[1] and the resulting salts *(1)* are allowed to react with alkyl halides. The oxazoline structure follows from the strong IR band at 1600 cm^{-1} (C=N).



The 2-alkylthiooxazolines *(2)* are anionized α to the carbonyl group by strong bases such as potassium *tert*-butoxide in tetrahydrofuran at −60 °C. The anions *(3)* undergo ring cleavage[3] yielding the *S*-alkyl-*N*-vinylthiourethane anion *(4)*. After acidification with acetic anhydride the ethyl α-(*N*-alkylthiocarbonylamino)acrylates *(5)* can be isolated by chromatography or crystallization (Table 1).



Diastereomeric oxazolines [$R^1 \neq R^2$ in *(2)*] yield *E/Z* mixtures of aminoacrylates *(5)* that are readily separated by chromatography on silica gel with ether/light petroleum. Expectedly, ring cleavage is not stereospecific: thus *trans-(2e)* gives the acrylic ester *(5e)* in an *E/Z* ratio of 1 : 3.3. Compounds *(5)* are of potential interest as reactants for amino acid synthesis, particularly since the alkylthio group can be removed selectively[4].

The aminoacrylic esters gave satisfactory CH analyses. They were characterized by their NMR and IR spectra [3300 (NH), 1710—1720 (CO_2R), 1640 and 1500 (NCOSR) and 1600—1650 cm^{-1} (C=C)].

Ethyl 2-benzylthio-5,5-dimethyl-2-oxazoline-4-carboxylates (2b):

A mixture of ethyl isothiocyanatoacetate (5.8 g, 40 mmol) and acetone (2.4 g, 40 mmol) in tetrahydrofuran (20 ml)[1] was added dropwise over 30 min to a stirred suspension of finely divided sodium hydride (0.98 g, 40 mmol) in anhydrous tetrahydrofuran at 20—30 °C under nitrogen. Stirring was continued at this temperature until evolution of hydrogen had ceased (1 h), the mixture cooled to −20 °C, and after removal of the cooling bath benzyl bromide was added (6.8 g, 40 mmol). After 30 minutes' stirring at room temperature the solvent was evaporated off in a water pump vacuum and the residue taken up in chloroform (100 ml) and ice-water (30 ml). Washing was repeated twice with water (2 × 30 ml), the chloroform solution dried over sodium sulfate and concentrated in a rotary evaporator. Distillation afforded 9.0 g of *(2b)*.—IR (film): 1735 (C=O), 1590 cm^{-1} (C=N).—^{1}H-NMR (CCl_4): $\tau = 5.82$ (s, 4-H), 8.54 (s), and 8.74 (s) (gem. CH_3).

ESCA Investigations of Bis(arene)chromium Complexes

By *Herbert Binder* and *Ch. Elschenbroich*[*]

He(I) photoelectron spectra have been reported for symmetrical and unsymmetrical bis(arene)chromium complexes[1], but there have been no previous measurements of the corresponding X-ray photoelectron (ESCA) spectra[2] which could provide valuable information about the intramolecular charge distribution. We now report ESCA investigations [measurements were performed on an A.E.I. ES-100 photoelectron spectrometer, Al-K$\alpha_{1,2}$ radiation (1486.6 eV)] for the π-complexes *(1)*—*(5)*.

Chemical shifts δE_B can be determined from the measured electron-binding energies E_B and from the former it is possible in principle to describe the electronic environments of atoms in the molecules. We were especially interested in the charge distribution between the central metal and aromatic ligands as a function of ring size. The complexes *(1)*—*(5)*, however, yield only one, unstructured line (line width 1.7 eV) for the C1s level. Clearly the π-bonded ligands C_nH_n ($n = 5$, 6, or 7) differ in δE_B by an amount less than 0.5 eV, from which the limit for the difference in charges on the ligands C_5H_5 and C_7H_7 can be estimated: since a whole positive charge localized on a C atom leads to a shift δE_B of *ca.* 5 eV for the C1s level[4], complete charge separation $(C_5H_5)^{\delta-}Cr(C_7H_7)^{\delta+}$ ($\delta = 1$) would, it is to be expected, lead to a difference of about 1.7 eV between the C1s binding energies for the ligands cyclopentadienyl (δE_B(C1s) = −5/5 = −1.0 eV) and cycloheptatrienyl (δE_B = +5/7 = +0.7 eV). The fact that for *(5)* these C1s binding energies differ by <0.5 eV indicates that $\delta < 1/3$. Thus the charge distribution between the ligands in unsymmetrical sandwich complexes of chromium is largely equalized, which accords with the low dipole moment of 0.8 D[5] and with ^{1}H-NMR results[6].

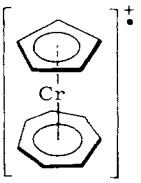
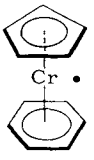
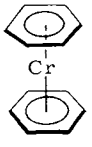
(1b), counter ion $[PF_6]^-$



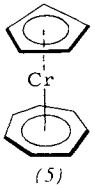
(2a), counter ion $[B(C_6H_5)_4]^-$
(2b), counter ion $[PF_6]^-$



(3)



(4)



(5)

Table 1 contains the E_B values for the Cr2p$_{1,2}$,Cr2p$_{3,2}$ (spin orbit doublet) and for the Cr3p and Cr3s levels as well as the line widths for Cr2p$_{3/2}$ and the observed Cr3s multiplet splittings[7,8]. Since the C1s binding energies for the complexes *(1)*—*(5)* are equal within experimental error, the total charges on the complexes show the Cr binding energies to be divisible into two groups *(1)*—*(2)* and *(3)*—*(5)*. This confirms previous ESR findings[9] according to which one electron is removed from an MO

Cr metal	—	—	—	—	—	44.8 [10]

[a] Referred to $E_B(C1s) = 286.6$ eV [3].
[b] Decomposition during measurement (binding energies and multiplet splitting identical with those for CrF_3 [8]).

If the Cr binding energies shown in Table 1 are compared with the corresponding value for Cr metal (reduced)[10] and with the results of *Carlson et al.*[8] for a series of Cr compounds, it is evident that the Cr atom carries a partial positive charge in the π-complexes *(1)*—*(5)*. Thus the central atom is the positive end of the bonding dipole metal-aromatic ligand also in the neutral complexes *(3)*—*(5)*. The acceptor character ($Cr3d \rightarrow C_nH_n$, π*) of the ligands is greater than their donor character (Cr3d, $4s \leftarrow C_nH_n$, π). The same result is derived from recent semiempirical[11] and *ab-initio*[12] MO calculations. For the two isoelectronic complexes *(4)* and *(5)* the larger E_B(Cr) value of *(5)* indicates more pronounced π*-acceptor properties for the unsymmetrical ligand combination π-C_5H_5|π-C_7H_7 than for the symmetrical combination π-C_6H_6|π-C_6H_6.

It can further be recognized from the Cr binding energies ($2p_{1/2}$, $2p_{3/2}$, 3s, 3p) that *(3)* belongs unambiguously to the group of Cr^0 complexes in respect to the intramolecular charge distribution although it can be formally described as a $Cr^I(d^5)$ complex.

Removing a 3s electron from a paramagnetic molecule leads to conditions of various spin multiplicities which differ in energy (multiplet splitting) according to the different values of the exchange integral.

Table 2. Comparison of ESR and ESCA data for the complexes *(1)*—*(3)*.

	(2)	*(1)*	*(3)*
$a(^{53}Cr)$ [G]	19.0	18.1	14.7
ΔE(Cr3s-3d) [eV]	2.3	2.2	<1
$E_B(Cr2p_{1/2})$[eV]	586.8	586.7	585.5

In Table 2 the ESR hyperfine coupling constants[13] $a(^{53}Cr)$ and the binding energies $E_B(Cr2p_{1/2})$ are compared with the ESCA multiplet splittings ΔE(Cr3s-3d). Both the ESR coupling constants and the ESCA multiplet splittings decrease with decreasing charge on the central atom, which corresponds to increasing delocalization of the unpaired $Cr3d_{z^2}$ electron. A correlation of this type between ΔE(Cr3s-3d) and $a(^{53}Cr)$ appears reasonable, if one considers that the isotropic hyperfine interaction of the unpaired electrons of *(1)*—*(3)* (which have predominant $Cr3d_{z^2}$ character[9]) depends on the size of the exchange integral between $3d_{z^2}$ and 3s, since the spin density of a d orbital can be transferred to the Cr nuclear position only by polarization of the inner s shells.

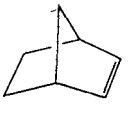
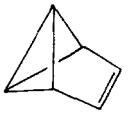
Cycloadditions of Benzvalene

By *Manfred Christl*[*]

Olefins having a strained double bond display a pronounced reactivity in numerous cycloadditions. The Diels-Alder additions[1,2] and 1,3-dipolar cycloadditions[3] of norbornene *(1)* may be cited as examples. Steric conditions similar to those in *(1)* prevail in benzvalene[4], presumably with even greater strain. *(2)* should therefore exhibit comparable dipolarophilic and dienophilic activity. The question then arises: How does the bicyclobutane system behave?



(1)



(2)

Dissolution of the stable 2,4,6-trimethylbenzonitrile oxide[5] in an ethereal solution of *(2)* afforded 98% of colorless *(3a)*, m.p. 101—103 °C[6], after 15 h at room temperature. Structural information was provided by the ^{1}H-NMR spectrum (Table 1) in which the absorptions of the mesityl group are accompanied by the characteristic signals of the protons in positions 1 and 6 of the 2-isoxazoline system[7] and a four-proton multiplet. The absence of signals due to olefinic protons suggests that the bicyclobutane system remains intact.

Reaction of benzonitrile oxide with *(2)* by the *in-situ* method[8] gave 88% of *(3b)* (m.p. 106—108 °C; NMR, see Table 1).

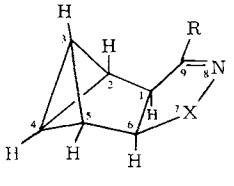
(9) [d] C_6C_6	1.86 m			2.02 m			2.52 m	2.27 m	8.0	

[a] $J_{2,3} \approx J_{2,4} \approx J_{3,5} \approx J_{4,5} \approx 1.8$ Hz. All other coupling constants are < 1.5 Hz.
[b] $J_{2,3} \approx J_{2,4} \approx J_{3,5} \approx J_{4,5} \approx 1.9$ Hz.
[c] 1-H to 5-H give rise to a multiplet between 1.5 and 2.3 (4H) and a multiplet at 2.66 (1H).
[d] $J_{2,3} = J_{3,5} = 1.05$ Hz; $J_{2,4} = J_{4,5} = 2.4$ Hz.

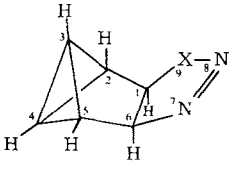
Diphenylnitrilimine[9] reacted with *(2)* to give a quantitative crude yield of the yellowish product *(4)*, m.p. 171—173 °C. In the NMR spectrum (Table 1) the signals of 1-H and 6-H appear in a region typical of 2-pyrazoline protons[7]. The coupling constants of the protons on the bicyclobutane skeleton are in good qualitative agreement with those of bicyclobutane itself[10]. Phenyl azide and *(2)* afforded a good yield of the colorless triazoline *(5)* (m.p. 116 °C, NMR, see Table 1).

Diazomethane and *(2)* gave 32% of the colorless liquid 1-pyrazoline *(6)* [b.p. 55—60 °C (bath)/0.1 torr; UV(cyclohexane): $\lambda_{max} = 330$ nm ($\varepsilon = 280$); NMR, see Table 1].

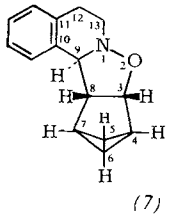
Reaction of 3,4-dihydroisoquinoline *N*-oxide and *(2)* furnished a crude yield of 95% of *(7)* [m.p. 143—145 °C (dec.). NMR ($CDCl_3$): δ = 7.15—7.60 (m, 4 aromatic H), 5.05 (br. d, 3-H); $J_{3,8} = 7.6$ Hz; 4.35 (br. d, 9-H), $J_{8,9} = 6.3$ Hz; 2.75—3.60 (m, 5H), 2.00—2.75 (m, 4H)].



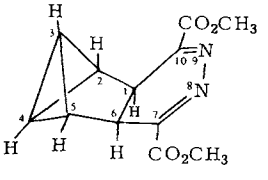
(3a), X = O, R = Mesityl
(3b), X = O, R = C_6H_5
(4), X = N-C_6H_5, R = C_6H_5



(5), X = N-C_6H_5
(6), X = CH_2

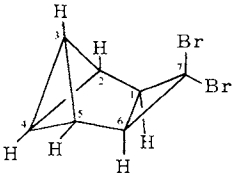


(7)



(8)

The reaction of 3,6-bis(methoxycarbonyl)tetrazine with *(2)* was accompanied by vigorous evolution of nitrogen and gave 65% of the orange compound *(8)*, m.p. 104—108 °C. The NMR spectrum (see Table 1) indicates the predicted c_s symmetry.



(9)

Dibromocarbene[11] added to *(2)* to give a 19% yield of the liquid quadricyclic compound *(9)*, b.p. 55—60 °C (bath)/0.1 torr. The c_s symmetry can be deduced from the NMR spectrum (see Table 1). The assignment is based on a 0.4 Hz long-range coupling of 4-H with 1-H and 6-H (M mechanism[12]) which is not found for 3-H owing to the less favorable steric arrangement of the bonds.

The simplicity of the above reactions opens up a route to a wide range of quadricyclic compounds. The highly strained bicyclobutane system should confer interesting properties upon them. This aspect is currently under study.

CIDNP Evidence for Divergent Behavior of Singlet and Triplet Radical Pair Encounters in the Photo-Claisen Rearrangement

By *Waldemar Adam, Hanns Fischer, Hans-Jürgen Hansen, Heinz Heimgartner, Hans Schmid*, and *Hans-Rudolf Waespe*[*]

The detection of *meta* product[1] besides the usual *ortho* and *para* products[2] in the photo-Claisen rearrangement offers a unique opportunity to explore the possibility of divergent behavior of triplet *versus* singlet radical pair combinations as a result of the phases of the spin density distributions[3] of the radical pairs involved. Consequently, at least in principle the necessity of an escape reaction in the radical pair theory of Chemically Induced Dynamic Nuclear Polarization (CIDNP)[4] could be obviated.

In this communication we demonstrate that the photo-Claisen rearrangement of *p*-cresyl β-methallyl ether *(1)*, analogous to the related photo-Fries process[5], indeed involves radical pair intermediates and suggest that our findings of triplet encounters affording *meta* and singlet encounters affording *ortho* and *para* coupling products reflect divergent singlet-triplet radical pair behavior.

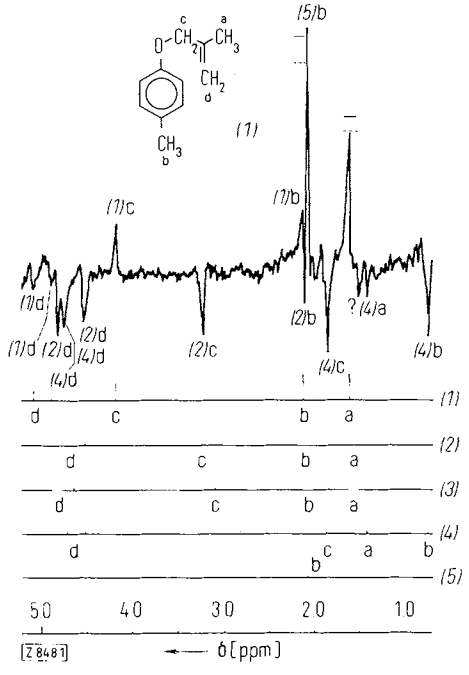

Fig. 1. CIDNP effects in the photo-Claisen rearrangement of *p*-cresyl β-methallyl ether *(1)* in benzene. Horizontal bars above the polarized spectrum of *(1)* indicate intensity of resonances before (——) and after (– – –) irradiation. Vertical lines below polarized spectrum indicate the position of the resonances of the authentic products *(1)*—*(5)* (TMS standard). *(1)* d, *(2)* c, *etc.* denote H^d of *(1)*, H^c of *(2)*, *etc.*

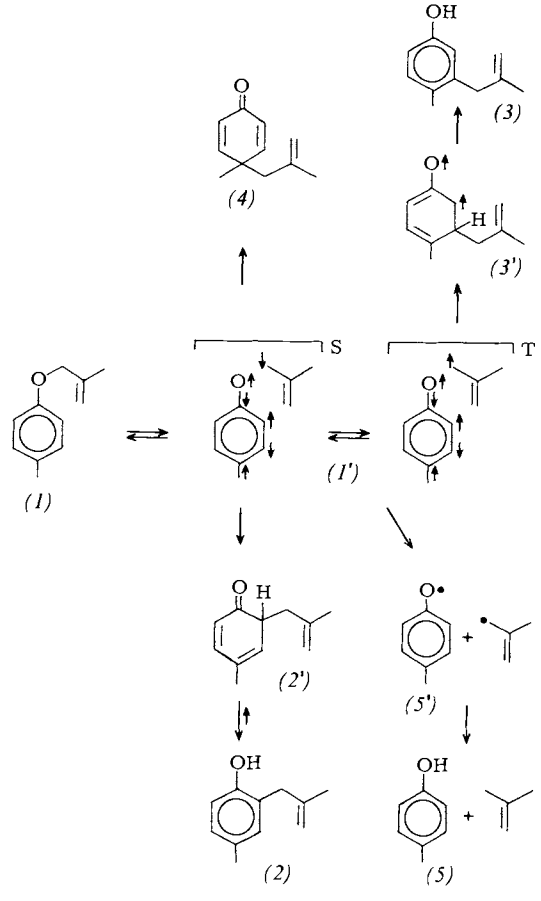
When a solution of *p*-cresyl β-methallyl ether *(1)* in benzene was irradiated in a quartz tube directly in the Varian HA-100 D NMR spectrometer with an unfiltered 1000 W mercury arc, the polarized spectrum in Figure 1 was observed. In terms of stick diagrams the resonances for each of the authentic photo-products are specified in δ(ppm) relative to TMS for the reformed ether *(1)*, the *ortho*, *meta*, and *para* products *(2)*, *(3)*, and *(4)*, respectively, and the cleavage phenol *(5)*. Control experiments revealed that irradiation of each of the authentic photoproducts *(2)* through *(5)* in C_6H_6 did not lead to the CIDNP effects displayed in Figure 1, demonstrating that the photo-Claisen rearrangement, analogous to the related photo-Fries process[5], proceeds *via* a radical pair mechanism (Scheme 1).



Scheme 1. Radical cage mechanism for the polarized products of the photo-Claisen rearrangement of *p*-cresyl β-methallyl ether *(1)*.

In view of the limitations of benzene for the detection of the *meta* product *(3)* due to severe overlapping of resonances, we examined the photolysis of *(1)* in a variety of polar and nonpolar solvents. The CIDNP results in these solvents paralleled those in benzene, but those in methanol and methyl formate were particularly informative since the resonances of the *p*-methyl protons (H^b, see Fig. 1) were now sufficiently resolved to observe the polarization of all products. The CIDNP effects in methanol (spectrum A) and methyl formate (spectrum C) are exhibited in Figure 2. Again the stick diagrams below each spectrum show the chemical shifts relative to TMS of the respective authentic products. Surprising is the fact that the polarization

of the *p*-methyl protons (H^b) of the *meta* product *(3)* is in the opposite sense of that for the *p*-methyl protons of the *ortho* and *para* products *(2)* and *(4)* respectively (see spectra A and C in Fig. 2).

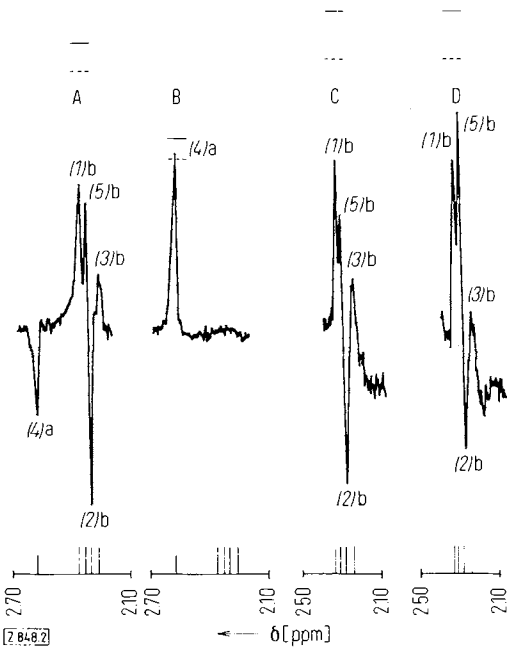


Fig. 2. CIDNP effects in the photo-Claisen rearrangement of *p*-cresyl β-methallyl ether *(1)* in methanol (spectrum A), of 4-(β-methallyl)-4-methyl-2,5-cyclohexadienone *(4)* in methanol (spectrum B), of *(1)* in methyl formate without (spectrum C) and with tri-*n*-butyltin hydride (spectrum D). The horizontal and vertical lines have the same meaning as in Fig. 1.

To exclude the possibility that the polarization of the *meta* product *(3)* arises from secondary reactions of the photo-labile *para* product *(4)*, we performed a control experiment by irradiating a 0.10 M methanolic solution of authentic cyclohexadienone *(4)* under the conditions of the photolysis of the Claisen ether *(1)* in methanol. Although *(4)* was considerably more rapidly photo-consumed than *(1)*, under comparable conditions of *ca.* 10% conversion no polarized products *(1)* to *(5)* could be detected in the photolysis of *(4)* by NMR monitoring of the methyl protons of the *para* product *(4)* and the *p*-methyl protons (H^b) of *(1)*, as shown in spectrum B of Figure 2. Finally, to eliminate the possibility that the *meta* product *(3)* is formed *via* free radicals, we irradiated a 0.025 M solution of *(1)* in methyl formate in the presence of 0.05 mol/l of tri-*n*-butyltin hydride (TBTH) radical scavenger[6] under identical conditions as for the first experiment. As spectrum D in Figure 2 demonstrates, the polarization of the *p*-methyl protons (H^b) of the *meta* product *(3)* could not be scavenged (even up to 0.10 mol/l TBTH) although the same degree of polarization for the *p*-methyl protons of *(1)* and *(2)* was achieved. It has been established that allyl radicals can be scavenged by TBTH[7]. Yet the *p*-methyl protons (H^b) of the *p*-cresol *(5)* exhibited a substantially larger polarization in the presence of TBTH. Thus, the TBTH scavenging experiment signifies that the *meta* product *(3)* must be principally formed from the primary pair like the Claisen ether *(1)* and the *ortho* and *para* products *(2)* and *(4)*, respectively; but the *p*-cresol *(5)* must be predominantly a radical scavenged product.

With the help of *Kaptein*'s formula for net polarization[8] and the ESR parameters for the related phenoxyl and allyl radicals[9], we find perfect agreement between experiment and theory if we assume that $\mu<0$ (singlet radical pair), $\varepsilon>0$ (pair products) for the Claisen ether *(1)*, *ortho* and *para* products *(2)* and *(4)*, respectively, and $\varepsilon<0$ (escape product) for *p*-cresol *(5)*, as in the case of the photo-Fries rearrangement[5]. However, the polarization of the *meta* product *(3)*, which does not arise *via* secondary processes of the *para* product *(4)* and cannot be scavenged by TBTH, must also be that of a primary pair process, though it is opposite (A) to the normal E polarization of the other pair products *(1)*, *(2)*, and *(4)*.

To account for this novel result, we combine the explanation for the divergent behavior of singlet and triplet states of β,γ-unsaturated ketones[3] with the current radical pair theory of CIDNP[4], and suggest the mechanism shown in Scheme 1. Phenoxyl-allyl radical pairs *(1')* are formed from the excited singlet state of *(1)*. Nuclear spin dependent interactions and *g*-factor differences cause the singlet *(1'S)* and triplet *(1'T)* character of the pairs to become nuclear spin and time dependent. From the spin distributions in the phenoxyl and allyl radicals[9] (Scheme 1) it is evident that radical pairs which are in state *(1'S)* at the instant of reencounter are likely to give the pair products *(1)*, *(4)*, and *(2)*, the latter *via* its tautomer *(2')* in a time interval short enough to preserve its nuclear polarization. Yet, radical pairs which are in state *(1'T)* during the reencounter cannot give products *(1)*, *(2)*, and *(4)* directly in view of unfavorable spin pairing but have the opportunity to combine at the *meta* position forming the triplet diradical *(3')* or to separate and eventually give escape products *(5)*. The triplet diradical *(3')* rearranges to the *meta* product *(3)* under spin inversion on a time scale preserving its nuclear polarization as in the *(2')*→*(2)* conversion.

It should be stressed that our mechanism (Scheme 1), suggested here to account for the opposite polarizations of *(1)*, *(2)*, and *(4) versus (3)* and *(5)* in terms of the divergent singlet-triplet radical pair coupling, permits the observation of CIDNP effects in systems *without escape reactions*[4]. Of course, our CIDNP results do not rule out minor concurrent paths leading to non-polarized products.

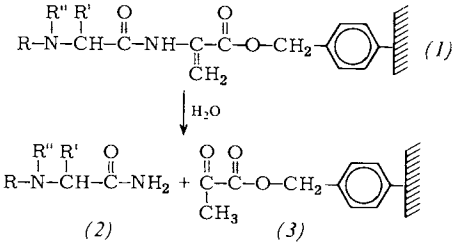
Solid Phase Synthesis of Peptides with Carboxyl-Terminal Amides—Thyrotropin-Releasing Factor (TRF)[**]

By *Erhard Gross*, *Kosaku Noda*, and *Bruce Nisula*[*]

Dedicated to Professor Theodor Wieland on the occasion of his 60th birthday

The α,β-unsaturated amino acid dehydroalanine[1] $H_2C{=}CNHR{-}COOH$, R = acyl or aminoacyl, may be employed in various ways in the solid phase synthesis of peptides[4]. It may, for instance, act as vehicle for the attachment of peptides to insoluble supports [see *(1)*] and/or donate its nitrogen to amide groups [see *(2)*][5]. The latter occurs under acidic conditions in the presence of equimolar ratios of water and may be invoked once the desired number of amino acid residues has been added to the growing peptide chain.



(1)

(2) *(3)*

(1a), R = Boc; R′ = R″ = H
(1b), R = Boc-leucylalanyl, R′ = R″ = H
(1c), R = Boc; R′—R″ = —CH_2—CH_2—CH_2—
(1d), R = Boc-pyroglutamylhistidyl, R′—R″ = —CH_2—CH_2—CH_2—
(2a), R = leucylalanyl, R′ = R″ = H
(2b), R = pyroglutamylhistidyl, R′—R″ = —CH_2—CH_2—CH_2—

The model peptide leucylalanylglycine amide and the thyrotropin-releasing factor (TRF), pyro-L-glutamyl-L-histidyl-L-proline amide (L-5-oxo-2-pyrrolidinylcarbonyl-L-histidyl-L-prolinamide)[8,9] were synthesized, in order to test the utility of this novel route to peptide amides.

Boc-glycyldehydroalanine (Boc = *tert*-butyloxycarbonyl) [m. p. 157–159 °C, decomp., $\lambda_{max}(CH_3OH) = 241$ nm ($\varepsilon = 5560$); Gly 1.00; NH_3 1.03], prepared in 84 % yield from Boc-glycyl-*O*-tosylserine methyl ester by β-elimination[10], was coupled to the chloromethylated (1.25 mmol Cl/g) styrene-2 % divinylbenzene copolymer[4] in dimethylformamide in the presence of triethylamine (40 °C; 48 h) to give the peptide resin *(1a)* (0.41 mmol Boc-dipeptide/g).

Boc-leucylalanylglycyldehydroalanine resin *(1b)* was obtained after two successive cycles of solid phase synthesis[4,11] with Boc-amino acids under the reaction conditions given in Table 1. Treatment of *(1b)* in the presence of 1 equivalent of water with 1 N hydrogen chloride in glacial acetic acid for 30 min at 50 °C resulted in a) the cleavage of the dehydroalanine residue with formation of the amide *(2a)* and the pyruvyl resin *(3)*; b) the simultaneous removal of the Boc-protecting group from the H_2N-terminus.

Leucylalanylglycine amide *(2a)* was solidified by trituration in ethyl ether. Crystallization from methanol/ethyl ether gave a product (91 % yield) which showed single spots and the given R_f values upon thin layer chromatography on silica gel in the following solvent systems[12]: A 0.14, B 0.62, C 0.35; Gly 1.00, Ala 0.98, Leu 1.00, NH_3 0.98. Elemental analysis gave the expected values.

Table 1. Solid phase synthesis of peptides attached to the support *via* dehydroalanine. Boc-amino acids and DCC were used in fivefold excess. Abbreviations: TFA = trifluoroacetic acid; NEt_3 = triethyl amine; Boc = *tert*-butyloxycarbonyl; DCC = dicyclohexylcarbodiimide; AA = amino acid.

10. CH_2Cl_2 wash (3 ×)	1.5
11. EtOH wash (3 ×)	1.5

Boc-prolyldehydroalanine [m. p. 154–156 °C; $\lambda_{max}(CH_3OH) = 240$ nm ($\varepsilon = 5300$); Pro 1.00, NH_3 1.01], obtained in 59 % yield from Boc-prolyl-*O*-tosylserine methyl ester under the conditions of β-elimination[10], was coupled (25 °C; 48 h) to the chloromethylated (2.3 mmol Cl/g) styrene-2 % divinylbenzene copolymer as described for *(1a)* to give the Boc-prolyldehydroalanine resin *(1c)* (0.51 mmol of Boc-dipeptide/g).

Boc-pyroglutamylhistidylprolyldehydroalanine resin *(1d)* was synthesized according to the procedure given for *(1b)* using Boc-amino acids in the coupling steps.

Pyroglutamylhistidylproline amide (TRF) *(2b)* was isolated after treatment of *(1d)* with 1 equivalent of water in 1 N hydrogen chloride in glacial acetic acid as specified for *(2a)*. A minor contamination was removed by partition chromatography on silica gel in the solvent system chloroform/methanol = 1:1. The purified tripeptide amide (TRF) gave single spots and the given R_f values upon thin layer chromatography in the following solvent systems[12]: A 0.03, B 0.46, D 0.27, E 0.27; Glu 1.00, Pro 1.02, His 0.99, NH_3 1.00; $[\alpha]_D^{20} = -45.1$ (*c* 0.25 glacial acetic acid); yield 63 %.

The biological activities of *(2b)* and another sample of synthetic[13] TRF (Abbott Laboratories, North Chicago, Illinois) were compared in the mouse bioassay[14,15]. Potency estimates and 95 % confidence limits (C. L.) were calculated by the methods of *Brownlee*[16] and *Finney*[17], respectively. One nanogram of TRF synthesized on the dehydroalanine resin was equivalent to 1.2 nanograms (95 % C. L. 0.67–2.20 ng) of the reference preparation.

Statistical Synthesis and Intraannular Reaction of a Rotaxane[**][1]

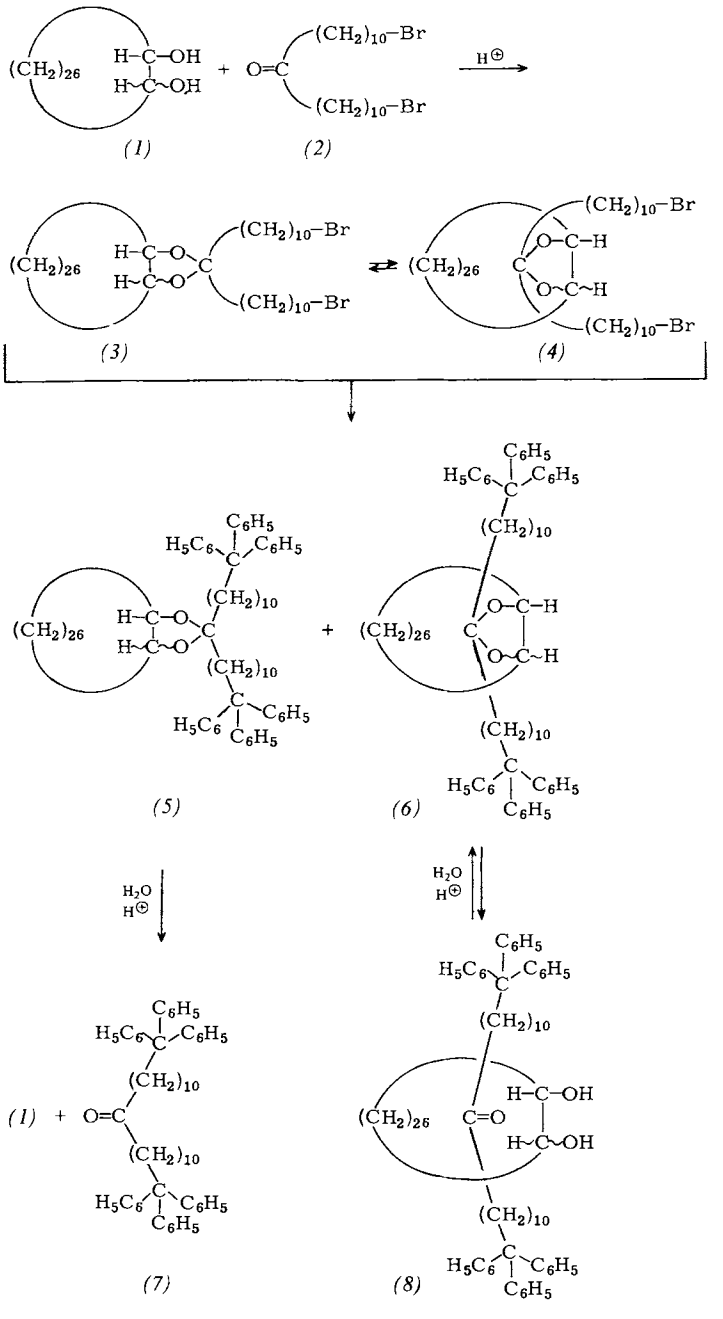
By *Gottfried Schill, Wolfgang Beckmann*, and *Walter Vetter*[*]

So far, only two variants of the statistical syntheses of rotaxanes[2] have been realized[3]. Described here is the statistical synthesis of the rotaxane *(8)* starting from the 28-membered macrocyclic diol *(1)* and the long-chain α,ω-bifunctional ketone *(2)*.

The ketalization of *(1)* (mixture of meso- and racemic forms) with *(2)* in the presence of *p*-toluenesulfonic acid[4] gave the ketal *(3)*, which might exist in extra-intraannular conformational equilibrium with *(4)*. The mixture obtained was converted into *(5)* and the prerotaxane *(6)* by reaction with triphenylmethyllithium[5] at −15 to −20 °C. Acid-catalyzed hydrolysis of the mixture gave the starting diol *(1)*, the axis *(7)*, and the rotaxane *(8)*. Separation by column and thin-layer chromatography afforded the rotaxane *(8)* as a colorless oil [yield: 0.12% based on *(5)* + *(6)*]. In a second experiment the yield amounted to 0.13%. In all solvents used so far it appears as a single spot in the thin-layer chromatogram.

The rotaxane *(8)* was characterized by its mass, NMR, and IR spectra.

In the mass spectrum the peak for the trityl ion is so intense, *m/e* 243 (100%) (no other peak, apart from those of its isotopic and fragmentation ions *m/e* 165 (5%) and 167 (5%) reach a height of 4% of the base peak), that only a few peaks of relatively slight intensity can be ascribed to the rotaxane structure of the molecule.



The molecular ion M^+ (*m/e* 1218) is scarcely detectable. The upper end of the spectrum terminates with a series of peaks at *m/e* 1214 to 1218 (0.005% of the base peak) due to M and (M − H) peaks of dehydrogenation products, as are often observed for large molecules with extensive fragmentation. Characteristic mass peaks occur at *m/e* 1200 (0.05%) and 1182 (0.10%). These correspond to the loss of one and two molecules of water, respectively, from the rotaxane molecular ion[6]. The mass range below these signals is devoid of peaks down to *m/e* 795. The ion *m/e* 795 (0.48%) corresponds to the protonated axial moiety and constitutes a fragment typical of all mechanically linked molecules[2]. It is formed by transfer of a hydrogen atom from the ring to the axis within the same molecule. The radical center on the ring thus formed can lead to fragmentation of the ring and thus to release of the axis. The protonated axis exhibits a characteristic cationic fragmentation: it eliminates two molecules of benzene in two steps, thus giving rise to two mass peaks at *m/e* 717 (2.2%) and 639 (0.45%).

[**] *G. S.* and *W. B.* thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support of this work. Thanks are also due to Badische Anilin- & Soda-Fabrik AG, Bayer AG, Farbwerke Hoechst AG, and Chemische Werke Hüls AG for supplies of chemicals.

These are accompanied by two extraordinarily intense signals of the corresponding metastable ions.

The diol *(1)* is characterized by mass peaks at *m/e* 423 (M−H, 0.15%) and 407 (M+H−H_2O, 0.34%). The appearance of these ions is typical for the fragmentation of protonated alcohols, as observed after chemical ionization[7], and is indicative of an H-transfer from the axis to the ring.

^{1}H-NMR spectrum in CCl_4 (100 MHz, TMS internal): δ = 7.16 (m, 30 Aryl-H), 4.30 (t, 2 H—C—O), 2.48 (t, 4 CH_2-trityl), 2.30 (t, 4 CH_2—CO), 1.47 (s, 2 OH), 1.26 ppm (m, 84 CH_2).

IR spectrum (film): 3400 (OH), 1710 cm^{-1} (C=O).

The prerotaxane *(6)* was obtained in pure form as a colorless oil (yield 55%) by reketalization of *(8)* with *p*-toluenesulfonic acid in the presence of a 5 Å[8] molecular sieve. It was characterized by its mass spectrum [*m/e* 1200, 0.17% (M^+), 817,52% (M−trityldecyl), 243, 100% (trityl)].

The synthesis of *(6)* from *(8)* is the first example of an intraannular[9] reaction.

$Te_3Cl_{13}^-$: A Novel Ionic Degradation Product of the Cubane-Type Compound $(TeCl_4)_4$[**]

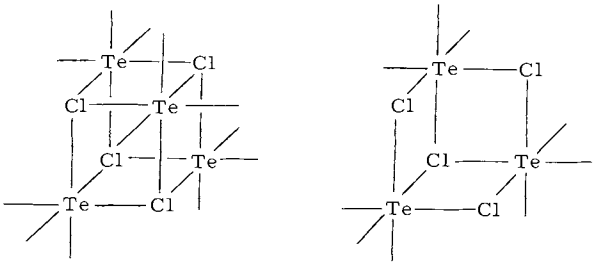
By *Bernt Krebs* and *Volker Paulat*[*]

Depending on the electronic environment, the stereochemical activity of the inert electron pair on the Te atom in tellurium(IV) halides leads to various and, in some cases, unusual types of structures: Thus, the adduct $TeCl_4 \cdot AlCl_3$[1,2] contains $TeCl_3^+$ and $AlCl_4^-$ ions and in $TeCl_4 \cdot PCl_5$[3,4] polymeric $(TeCl_5^-)_n$ and PCl_4^+ ions are present, while tellurium tetrachloride itself has a tetrameric, cubane-type molecular structure in the solid state[5].

Molecular weight determinations on benzene solutions of $TeCl_4$[6,7] indicated the probability of equilibria between $(TeCl_4)_4$ and lower molecular species. We therefore attempted to isolate possible degradation products of $(TeCl_4)_4$ from such solutions: When a solution of equimolar amounts of tellurium(IV) chloride (Te_4Cl_{16}) and triphenylmethyl chloride (or chlorides of other large organic cations such as, *e.g.* $(C_2H_5)_4N^+$, cf. Ref. [8]) in benzene is warmed gently, a dark brown solution is formed from which yellow-brown needle-shaped crystals having the composition $(C_6H_5)_3CTe_3Cl_{13}$ can be isolated:

$$Te_4Cl_{16} + (C_6H_5)_3CCl \rightarrow (C_6H_5)_3CTe_3Cl_{13} + 1/4\ Te_4Cl_{16}$$

The compound is stable at room temperature in absence of moisture and melts at 196—198 °C. As shown by complete X-ray structural analysis, the novel $Te_3Cl_{13}^-$ ion is in fact structurally a fragment of $(TeCl_4)_4$, from which a $TeCl_3^+$ group has been cleaved by a Cl^- ion functioning as Lewis base:



Te_4Cl_{16} $Te_3Cl_{13}^-$

The $Te_3Cl_{13}^-$ ion consists of three distorted $TeCl_6$ octahedra, joined *via* edges to give a trigonal unit with idealized C_{3v} symmetry. This general type of $x_3\ y_{13}$ structure has been predicted from structural systematics, but it has not been observed previously.

The bond lengths and mean bond angles are given in Figure 1. Similarly as in $(TeCl_4)_4$, in $TeCl_3^+AlCl_4^-$ and $PCl_4^+TeCl_5^-$ the difference between terminal bond lengths (mean value 2.342 Å) and bridge bond lengths (mean value 2.841 Å) is considerable because of presence of the inert electron pair and as a result of the weaker bridging bonds; as expected the bonds to the triply bound bridge atom Cl-1 are the longest.

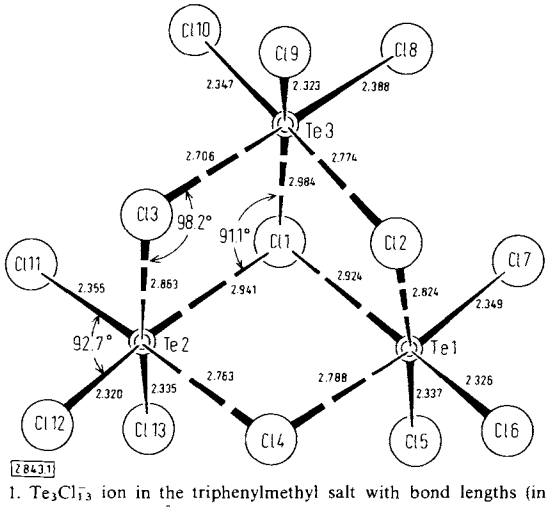


Fig. 1. $Te_3Cl_{13}^-$ ion in the triphenylmethyl salt with bond lengths (in Å, standard error 0.005 Å) and bond angles (averaged over chemically equivalent angles).

$(C_6H_5)_3CTe_3Cl_{13}$ crystallizes monoclinically ($P2_1/c$) with $a = 11.095$, $b = 16.444$, $c = 20.439$ Å; $\beta = 114.50°$; $Z = 4$; $d_{x\text{-ray}} = 2.13$, $d_{exp} = 2.12$ g cm^{-3}.

The IR spectrum (Nujol/polyethylene) shows bands in the 400—33 cm^{-1} range at 341, 332, 317, 305, 208, 170, 156, 72 cm^{-1}, the first four being mainly due to the vibrations of the terminal $TeCl_3$ groupings.

If the above degradation of tetrameric tellurium(IV) chloride is carried out a stage further (cf. also Ref. [8, 9]), using 2 mol

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of chloride donor per mol Te_4Cl_{16}, a further $TeCl_3^+$ group is split off to give compounds of the type $M^I_2Te_2Cl_{10}$ (M^I voluminous cation). When using tetraphenylarsonium chloride the compound $[(C_6H_5)_4As]_2Te_2Cl_{10}$ could be isolated as yellow crystalline platelets in analytically pure form.

The new $Te_2Cl_{10}^{2-}$ ion, whose dimeric structure has been confirmed by cryoscopic measurements, very probably consists of two edge-to-edge coupled octahedra. A structural analysis is under way. $[(C_6H_5)_4As]_2Te_2Cl_{10}$ crystallizes triclinically ($P\bar{1}$) with $a=12.114$, $b=20.663$, $c=10.654$ Å; $\alpha=94.44$, $\beta=94.07$, $\gamma=89.73°$; $Z=2$; $d_{x\text{-ray}}=1.72$, $d_{exp}=1.70\,g\,cm^{-3}$.

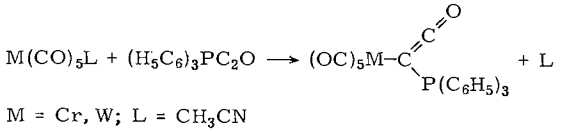
Phosphorus Ylide Complexes of Group VI as Sources of Carbonylmethylene[**]

By *Heinz Berke* and *Ekkehard Lindner*[*]

Because of their lability phosphorus ylide complexes[1-5] can undergo interesting rearrangements. We have observed that, apparently because of the reduced basicity of the resonance-stabilized ylide, Wittig-like reactions do not occur when (carbonylmethylene)triphenylphosphorane[6] reacts with hexacarbonyl complexes of group VI metals[2,4]; instead, ylide complexes are formed by replacement of CO. For chromium and tungsten it is preparatively best to use the photochemically produced complexes $M(CO)_5CH_3CN$[7]:



$M(CO)_5L + (H_5C_6)_3PC_2O \longrightarrow (OC)_5M{-}C(=C{=}O)P(C_6H_5)_3 + L$

M = Cr, W; L = CH_3CN
M = Mo; L = CO

M	Cr	Mo	W
	(1)	*(2)*	*(3)*
m.p. (dec.) [°C]	146	105	145

Elemental analyses, molecular weight determinations and IR and mass spectra proved the composition and structure of the new ylide complexes *(1)*—*(3)*; these are yellow and in some cases soluble even in nonpolar solvents.

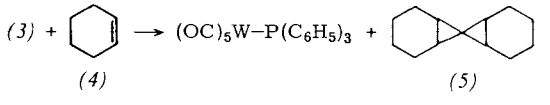
Table 1. Characteristic IR frequencies (in cm^{-1}) of the ylide complexes *(1)*—*(3)*.

Compound	ν(CO)	$\nu_{as}(C_2O)$	$\nu_s(C_2O)$	Phase
$(H_5C_6)_3PC_2O$		2104 vs	1312 m	Solid/KBr
		2104 vs		Soln./CCl_4
(1)	2051 s (A_1)	2083 s		
	1977 vw (B_1)			
	1932 vs (E)			
	1904 s (A_1)			
			1310 m	Solid/KBr
(2)	2061 m-s (A_1)	2084 m-s		Soln./CCl_4
	1985 w (B_1)			
	1938 vs (E)			
	1906 s (A_1)			
			1314 m	Solid/KBr
(3)	2058 m-s (A_1)	2084 m-s		Soln./CCl_4
	1953 w (B_1)			
	1928 vs (E)			
	1903 s (A_1)			
			1311 w	Solid/KBr

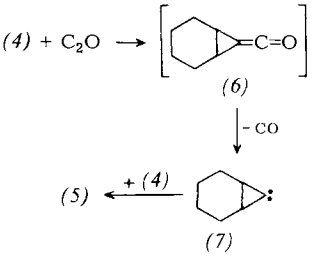
The C_2O group of (carbonylmethylene)triphenylphosphorane is characterized especially by the asymmetric and symmetric C_2O stretching vibrations (see Table 1). On coordination of the ligand to chromium, molybdenum or tungsten $\nu_{as}(C_2O)$ is shifted by *ca.* 20 cm^{-1} towards lower frequencies. The long-wave position of the CO stretching vibrations of the $M(CO)_5$ groups of *(1)*—*(3)* indicates that, as expected, the ylide ligand has only slight π-acceptor character. Its easy replacement by tetrahydrofuran or dimethylformamide is to be ascribed to the same cause, as shown by time-dependent IR studies. In only slightly polar solvents such as CCl_4 the compounds *(1)* and *(2)* yield $Cr(CO)_6$ and $Mo(CO)_6$, respectively, along with unidentified products; with the more stable tungsten complex *(3)* an analogous result is observed only above 50 °C. Further, the mass spectra, which are characterized by thermolysis reactions, display rearrangements of this type.

It should be particularly noted that $M(CO)_5P(C_6H_5)_3$ (M = Cr, Mo or W) and C_2O occur as products of thermolysis. If the tungsten complex *(3)* is heated with a carbene trapping substance, *e.g.* cyclohexene *(4)*, for some hours at 110 °C, analytically pure $W(CO)_5P(C_6H_5)_3$ can be isolated [ν(CO): 2073 m, 1985 w, 1945 vs cm^{-1}; solution in CCl_4]; 7,7'-spirobinorcarane *(5)*[8] can also be obtained on thin-layer chromatography.



(3) + *(4)* → $(OC)_5W{-}P(C_6H_5)_3$ + *(5)*

Formation of *(5)* is indicated particularly by the mass spectrum: molecular ion at $m/e=176$; olefinic ν(C—H) and ν(C=C) absorptions do not appear in the IR spectrum, but only more aliphatic C—H and C—C stretching vibrations. *(5)* is probably formed from the carbene C_2O and



(4)[9] by way of an unstable cyclohexyleneketene *(6)* which is converted by spontaneous loss of CO into the carbene *(7)* which reacts further with an excess of *(4)*.

Experimental:

$M(CO)_5CH_3CN$ (M = Cr or W) (3 mmol) is heated with $(C_6H_5)_3PC_2O$ (906 mg, 3 mmol) in boiling diethyl ether (50 ml) for 3—4 h under N_2. The mixture is filtered and the residue is extracted with ether. After removal of the ether from the solution, chromatography in benzene on an Al_2O_3 column (activity III) under N_2 gives an eluate which is concentrated under reduced pressure. Treatment with light petroleum in excess at −30 °C yields needles of the ylide complex *(1)* or *(3)*, which after isolation are dried in vacuum (yield 20—30%). For preparation of the molybdenum compound *(2)*, $Mo(CO)_6$ (2.64 g, 10 mmol) and $(C_6H_5)_3PC_2O$ (3.02 g, 10 mmol) are heated in benzene (50 ml) under N_2 for 4 h at 80 °C; after removal of the solvent the excess of $Mo(CO)_6$ is sublimed off in high vacuum and the product is purified as for *(1)* and *(3)*.

^{13}C-NMR Spectrum of Ketene[**]

By *Joachim Firl* and *Wolfgang Runge*[*]

^{13}C-NMR spectroscopy can provide insights into the bonding situation and electron distribution of the ground state of organic molecules through the chemical shifts and spin-spin coupling constants[1,2] if sufficiently similar molecules are compared.

In connection with a systematic investigation of the molecular structure of allenes[3], and ketenes[4] we have measured the ^{13}C spectra of a series of ketene derivatives[4]. Ketene itself shows unusual resonance positions, not only in comparison with those of the isoconjugated allene but also with the chemical shifts of organic compounds in general. The proton noise decoupled PFT ^{13}C-NMR spectrum was measured at 22.63 MHz in $CDCl_3$, with TMS as internal standard, at −60 ± 5 °C on a Bruker-HX-90 spectrometer. The chemical shifts δ_C and the ^{13}C—H spin-spin coupling constant we have found are given in Figure 1.

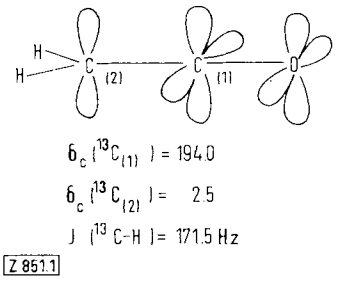

Fig. 1. ^{13}C-NMR data of ketene. Chemical shifts [ppm] referred to TMS.

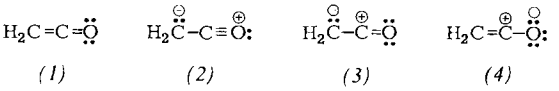
The most remarkable characteristic of the ketene spectrum is the extreme high-field position of the terminal carbon atom resonance—far outside the region usually assumed to be typical for formally sp^2-hybridized carbon atoms: the terminal carbon atom is shielded by about 120 ppm relative to ethylene (δ_C = 122.8 ppm)[2]. Even with respect to the terminal carbon atom resonance of allene (δ_C = 74 ppm)[2], where this carbon is also bonded to a formally sp-hybridized carbon atom, a high-field shift of 72 ppm is found. The terminal C atom of ketene is even one of the most shielded carbon atoms so far observed in ^{13}C-NMR spectra of organic compounds[2]; its chemical shift is less than that of ethane (δ_C = 5.9 ppm)[2].

Calculations of the shielding constants with CNDO orbitals[4] indicate that the stronger shielding of the terminal carbon atom of ketene in comparison to that in allene has to be attributed to both a larger diamagnetic and a less negative paramagnetic shielding constant resulting from higher electron density at that atom. On the other hand, the ^{13}C—H spin-spin coupling constants of ketene (Fig. 1) and allene [$J(^{13}C—H)$ = 168 Hz][2] are of comparable magnitude. The value of the ^{13}C—H coupling constant is mainly determined by the Fermi contact term, which depends upon the size of the valence s-orbitals thus reflecting the hybridization. The almost identical values of $J(^{13}C—H)$ for these two molecules therefore indicate that their σ-bonding situation is very similar and that the stronger shielding in ketene has to be attributed mainly to a higher π-electron density.

The central C atom in ketene is strongly deshielded, as is that in allene (δ_C = 213 ppm)[2]. Compared with the resonance position of carbon monoxide $:\overset{\ominus}{C}\equiv\overset{\oplus}{O}:$ (δ_C = 181.3 ppm)[2], the central C atom resonance in ketene is shifted somewhat to lower field and is found in the region of carbonylmetal complexes, *e.g.* $Ni(CO)_4$ (δ_C = 191.6 ppm)[2]. This result shows the considerable triple-bond character of the C=O bond of ketene and is in agreement with a MO description of ketene with localized CNDO orbitals[5]. According to this picture, ketene has two sets of π-orbitals, one being delocalized over two centers, and the other over three centers, from O to C-2 (Fig. 1). The latter is therefore isoconjugated with the π-system of an allyl anion.



(1) *(2)* *(3)* *(4)*

As the result, ^{13}C-NMR spectroscopic data show that of the mesomeric structures of ketene *(1)*—*(4)*, the structure *(2)* contributes significantly to the ground state. This is in agreement with the molecular *g* value and the para-

Asymmetric Induction by a Chiral Bisphosphane-Rhodium Complex in the Hydroformylation of Aliphatic Olefins[1]

By *Giambattista Consiglio, Carlo Botteghi, Christian Salomon*, and *Piero Pino*[*]

We have already reported on the asymmetric hydroformylation of aromatic olefins with chiral cobalt- and rhodium-complexes as catalysts[1]. In the present communication we now describe the hydroformylation of aliphatic olefins in presence of catalysts prepared *in situ* from (−)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)-butane["(−)-diop"] and $RhH(CO)(PPh_3)_3$. Hydroformylations carried out by the usual methods[2] gave the results shown in Table 1, which we interpret as follows:

1. Asymmetric induction is greater at room temperature and normal pressure than under "typical oxo conditions"[3]. The reaction conditions, however, do not appear to have any influence on the prevailing configuration of the products. The highest optical yield (27%) was achieved in the case of *cis*-butene.

2. The (*R*) enantiomer predominates in all the aldehydes formed from vinyl olefins.

3. The optical purity of the aldehydes generated from *cis*-olefins is greater than that of the aldehydes arising from the corresponding *trans*-olefins; their prevailing configurations, however, are identical.

4. The prevailing configuration of the 2-methylbutanal obtained from 1-butene is different from that of the same aldehyde obtained from *cis*- and *trans*-butene.

5. The two aldehydes obtained from *cis*- and *trans*-2-hexene, 2-methylhexanal and 2-ethylpentanal, have different prevailing configurations.

Formally, the predominating enantiomer of the aldehyde, in the case of prochiral[4] olefin formylation, is always formed by addition of carbon monoxide and hydrogen to the same "prochiral side" of the olefin, *i.e.* that side of the olefin which, when bound to the metal atom, generates the (*S*) configuration at the carbon atom undergoing the attack by carbon monoxide (scheme (1))[5].

Since the 2-methylbutanal obtained from *trans*-butene has a different prevailing configuration from that obtained from 1-butene, the two diastereomeric alkylrhodium complexes [scheme (2): *(3a)* and *(3b)*], which can be considered as intermediate products[2], must be formed in different concentrations. As a consequence the in asymmetric induction takes place during the formation of the alkylrhodium complex, *i.e.* during the formation of the π complexes *(2a)* and *(2b)* and/or their transformation into *(3a)* and *(3b)*. As yet, it is not possible to decide whether this asymmetric induction determines which aldehyde antipode will predominate in the reaction products, as a possible asymmetric induction during subsequent reaction steps[2], namely during the reversible CO insertion and the aldehyde splitting, could reverse the prevailing arrangement of the alkyl groups around the asymmetric carbon atom.

It is remarkable that olefins having symmetry C_{2v} (with a plane of symmetry perpendicular to the double bond)

Table 1. Hydroformylation of aliphatic olefins with $RhH(CO)(PPh_3)_3$ and (−)-diop (molar ratio 1:4) in aromatic solvents [olefin/rhodium = 3.0×10^2 – 1.6×10^3; $p_{H_2}/p_{CO} = 1$].

such as *e.g. cis*-butene are asymmetrically hydroformylated. Since both sides of the olefin are equivalent in this case, the alkylrhodium diastereomers should be formed in equal concentration and the asymmetric induction should take place in later reaction steps. However, the possibility that the asymmetric induction for this olefin takes place partly or exclusively during formation of the alkylrhodium complex should not be overlooked. In fact, due to the presence of the asymmetric ligand in the catalytic complex, the olefin could have a preferred conformation, and thus the reactivities of the two olefinic asymmetric carbon atoms bound to the metal atom could be different.

Tetraiodosilanebis[tricarbonyliron(0)] [**]

By *Günter Schmid*[*] and *Hans-Peter Kempny*

The halogen atoms of neutral inorganic halides form potential complex ligands. We describe here the first example of coordination of such "Lewis bases" to metal atoms of carbonyl-metal compounds.

The synthesis of tetraiodosilanebis[tricarbonyliron(0)] *(1)* confirms that such complexes are capable of existence. After UV irradiation of a solution containing a mixture of $Fe(CO)_5$ and SiI_4 in molar ratio 5:1 in pentane, a complex $SiI_4[Fe(CO)_3]_2$ is formed which can be isolated, although in very small yield, as volatile, dark red crystals. This new complex is readily soluble in apolar solvents such as cyclohexane, pentane, benzene, *etc.* It decomposes rapidly above 35 °C, even under an inert gas; light and air also cause decomposition; however, the compound can be sublimed at 20 °C/0.1 torr and is stable for a considerable time below −15 °C. Osmometric molecular weight determination shows the compound to exist as the monomer (exp. 798; calc. 815.5).

That $SiI_4[Fe(CO)_3]_2$ is considerably more volatile than SiI_4 is presumably due to shielding of the coordination sphere of the tetrahedral SiI_4 molecule by the $Fe(CO)_5$ units since this hinders intermolecular interaction between the I and the Si atoms in the crystal lattice.

The IR spectrum of *(1)* shows four CO stretching vibrations, at 2076, 2045, 2010 and 2002 cm^{-1}, of which two result from splitting of the longest-wave band. Only the decoupled $Fe(CO)_3$ groups should be subject to the selection rules for the symmetry of these vibrations, since coupling of the ν(CO) vibrations *via* SiI_4 can be ruled out[11].

Assuming a trigonal-bipyramidal environment for both iron atoms a pair of three CO stretching vibrations should be observed in the *cis*-configuration (Fig. 1) for both C_{2v} and C_s symmetry[2]. D_{3h} symmetry with *trans*-I ligands can be excluded for steric reasons; it permits only one IR-active CO stretching vibration. Splitting of the longest-wave ν(CO) vibration is presumably due to a small decrease in the symmetry of the $Fe(CO)_3$ group[3].

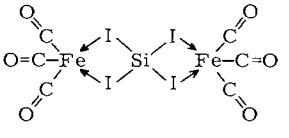

Fig. 1. Proposed structure of $SiI_4[Fe(CO)_3]_2$ *(1)*.

The occurrence of unchanged tetraiodosilane in the complex can be proved by reaction of *(1)* with tributylphosphane or pyridine, which affords $SiI_4 \cdot P(C_4H_9)_3$ or $SiI_4 \cdot 4C_5H_5N$[4], respectively.

Experimental:

A solution of SiI_4 (5.36 g, 10.0 mmol) and $Fe(CO)_5$ (9.80 g, 50.0 mmol) in pentane (400 ml) is irradiated with rigorous exclusion of air in a water-cooled recycling apparatus by a 150 W UV lamp for 4—5 h. The solution rapidly turns brown and CO is evolved. After filtration, the reaction

mixture is freed from solvent and the excess of $Fe(CO)_5$ under reduced pressure at 0—10 °C. A carmine-red oil can be separated from the residue in a high vacuum and this eventually crystallizes. Further purification by sublimation in a high vacuum at room temperature affords 10—20 mg of dark red crystals of composition $SiI_4[Fe(CO)_3]_2$.

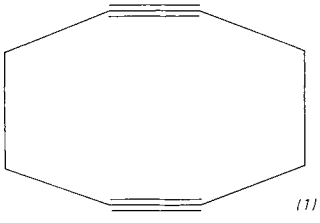
1,5-Cyclooctadiyne[***]

By *Else Kloster-Jensen* and *Jakob Wirz*[*]

In the course of our investigations on butatriene we have isolated small quantities of the highly strained, hitherto unknown compound, 1,5-cyclooctadiyne *(1)*. It crystallizes in colorless prisms, dec. 105 °C, which are stable at 0 °C under exclusion of air.



(1)

Z 854.1

The monocyclic hydrocarbon *(1)* is characterized by the following spectroscopic data: ^{1}H-NMR: one singlet at $\delta = 2.62$ ($CDCl_3$/TMS), 2.53 (CCl_4/TMS), 2.21 ppm (C_6D_6/TMS). ^{13}C-NMR (C_6D_6): δ (referred to TMS) = 20.2 (t, $J_{CH} \approx 140$ Hz), 95.8 ppm (s). MS: $m/e = 104.0611 \pm 0.002$ (calc. 104.0626), 103, 78, 52; $m^* = 58.5$ for $104 \rightarrow 78 + 26$. IR (CCl_4): 2910, 2865, 2832, 2237 (weak), 2175 (weak), 1436, 1423, 1115, 552, 434 cm^{-1}. UV (*n*-pentane): end-absorption $\lambda < 230$ nm. Photoelectron spectrum: three superimposed π-bands in the range of 9.0 to 10.0 eV, a fourth π-band at 10.1 eV.

Catalytic hydrogenation of *(1)* yields cyclooctane almost quantitatively after uptake of four equivalents of H_2. Ozonolysis of *(1)*, followed by alkaline hydrolysis, affords succinic acid in good yield as sole product. Conclusive evidence for the structure of *(1)* was provided by an X-ray structure analysis by *Römming*[1]. The molecule has a center of symmetry, and the carbon ring deviates only slightly from planarity (0.023 Å from the regression plane through the C-atoms). Interatomic distances: C1—C2 1.185, C2—C3 1.459, C3—C4 1.530, and C1—C6 2.569 Å. Bond angles: $\sphericalangle$ C1—C2—C3 159.1 and $\sphericalangle$ C2—C3—C4 110.8° (standard deviations ≤ 0.005 Å and 0.3°).

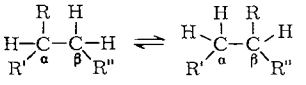
Stereochemistry of the Coenzyme-B_{12}-dependent Methylmalonyl-CoA-Mutase Reaction. Investigation with Ethylmalonyl-CoA[**]

By *János Rétey* and *Boleslaw Zagalak*[*]

All the coenzyme-B_{12}-dependent enzymatic rearrangements studied so far proceed according to eq. (1):



(1)

The replacement of R by H or of H by R occurring at C_α and C_β has been investigated stereochemically in a few cases, but in none of these cases could the steric course be elucidated at both migration centers. Inversion was observed in the glutamate-mutase reaction ($R = CHNH_2$—COOH, $R' = COOH$, $R'' = H$)[1] and in the propanedioldehydrase reaction ($R = R'' = OH$, $R' = CH_3$)[2], and retention in the methylmalonyl-CoA-mutase reaction ($R = COSCoA$, $R' = COOH$, $R'' = H$) at the center studied[3].

The difference in the steric course was remarkable because of the analogies previously observed between these reactions[4]. Is the mechanism of the methylmalonyl-CoA-mutase reaction really different from that of the other two rearrangements or is the steric course not an immediate consequence of the mechanism of the rearrangement step? To answer this question it was desirable to study the steric events if possible at both migration termini in the methylmalonyl-CoA-mutase reaction. Methylmalonyl-CoA itself is not suitable for such a study. On the other hand we found that ethylmalonyl-CoA is also a substrate for the mutase from *Propionibacterium shermanii*.

We have treated (2*RS*)-ethylmalonyl-CoA, prepared analogously to (2*RS*)-methylmalonyl-CoA[5], with purified me-

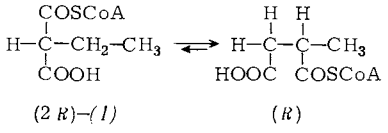
[**] This work was supported by the Schweizerischer Nationalfonds zur Förderung der Wissenschaftlichen Forschung (Project No. 3.635.70).—We thank Prof. *J. W. Cornforth* and Dr. *G. Ryback,* Milstead Laboratory of Chemical Enzymology, Sittingbourne (England), for determination of the ORD curves, Dr. *J. Völlmin,* Kinderspital Zürich, for the coupled gas-chromatographic-mass-spectroscopic analysis, Dr. *J. Seibl,* Laboratorium für organische Chemie der ETH Zürich, for the mass spectra, and Prof. *R. Ernst* and Mr. *A. Frei,* Laboratorium für physikalische Chemie der ETH Zürich, for determining the 220-MHz NMR spectra.

thylmalonyl-CoA-mutase from *Propionibacterium shermanii*[6]. The reaction was about 1000 times slower than that of the natural substrate, as was shown by gas-chromatography of the product mixture after its conversion into the dimethyl ester. Simultaneous mass-spectroscopic investigation proved that the product was indeed a mixture of dimethyl ethylmalonate and methylsuccinate. After hydrolysis, the main portion of the product mixture was separated by thin-layer chromatography and the methylsuccinic acid was assigned (*R*)-chirality on the basis of its ORD spectrum[7]. On the well-founded assumption that the ethylmalonyl-CoA *(1)* taking part in the mutase reaction has the same configuration [(2*R*)] as the natural substrate[3,8], the enzymatic reaction can be described by eq. (2):



(2)

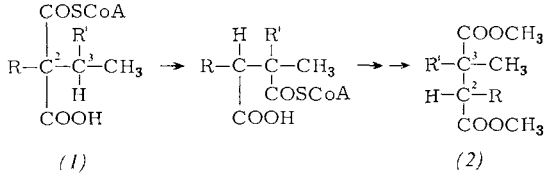
(2*R*)-*(1)* (*R*)

To obtain further information about the steric course of the reaction, specifically deuterated substrates were introduced. Dimethyl methylsuccinate seemed a suitable derivative for differentiation of the methine and methylene protons in the product: its corresponding protons appear in the 220 MHz NMR spectrum as three separate multiplets [($CDCl_3$), $\delta = 2.35$ (q), 2.70 (q), and 2.90 (sex)]. Assignment of the methylene protons to the two quadruplets at 2.35 and 2.70 ppm was achieved by means of the spectra of stereospecifically deuterated reference samples. Treating methylfumaric (mesaconic) or methylmaleic (citraconic) acid with diimide in deuterium oxide gave samples of racemic *threo*-[2,3-$^2H_2$]- and *erythro*-[2,3-$^2H_2$]-methylsuccinic acid, respectively, which were converted into the dimethyl esters. In the corresponding region of the 220-MHz NMR spectrum the *threo*-dimethyl ester gave only one signal, at 2.35 ppm, and the *erythro*-dimethyl ester gave a signal at 2.70 ppm.

This assignment of the NMR signals was the basis for interpretation of the following enzymatic experiments:

Deuterated ethylmalonyl-CoA *(1a)* was prepared in deuterium oxide and then treated in the same solvent with a methylmalonyl-CoA-mutase preparation (from *Propionibacterium shermanii*) containing epimerase; this procedure ensured the presence of deuterium at C-2. On hydrolysis of the products methylsuccinic and ethylmalonic acid were obtained in the ratio 11 : 4, which proves that the epimerase is active also with ethylmalonyl-CoA.

The dimethyl ester of the (*R*)-methylsuccinic acid *(2a)* (ORD) obtained in this way contained 95% of monodeuterated molecules (MS). The signal at 2.70 ppm was absent from the 220-MHz NMR spectrum, so that the sample must have been (2*R*,3*S*)-[3-^{2}H]-methylsuccinic acid.



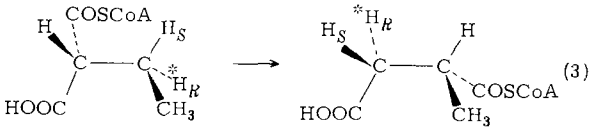
(1) *(2)*

(a), R = D, R' = H; *(b)*, R = H, R' = D

From this result it follows that the replacement at C-2 of the ethylmalonyl-CoA occurs with retention.

To round off the stereochemical picture we still needed a sample of ethylmalonyl-CoA stereospecifically deuterated in the methylene group. Starting from (*R*)-[1-^{2}H]-ethanol[9], prepared enzymatically[10], we synthesized (3*S*)-[3-^{2}H]-ethylmalonic acid by alkylating diethyl malonate with the derived ethyl *p*-toluenesulfonate. The configurational inversion expected to occur during the replacement was confirmed by decarboxylating the deuterated ethylmalonic acid to (3*S*)-[3-^{2}H]-butyric acid and measuring its ORD curve[11].

Mono-coenzyme A derivative *(1b)* of the (3*S*)-[3-^{2}H]-ethylmalonic acid thus prepared and characterized was converted by methylmalonyl-CoA-mutase into (2*R*)-2-methylsuccinyl-CoA, which, on hydrolysis and treatment of the acid component with diazomethane, gave the dimethyl ester *(2b)* and this was studied by mass and NMR spectroscopy. The mass spectrum confirmed complete retention of the hydrogen isotope during the enzymatic reaction. The location of this isotope in the methine position followed from the NMR spectrum.



(3)

Thence it follows that reaction with the methylmalonyl-CoA-mutase from *Propionibacterium shermanii* involves the 3-H_R atom of the ethylmalonyl-CoA and that the replacement at C-3 also occurs with retention (eq. 3).

The First Oxoferrate(III) Having a Discrete Anion: $K_6[Fe_2O_6]$[1]

By *Hilmar Rieck* and *Rudolf Hoppe*[*]

During our studies on the hitherto rather neglected K/Fe/O system we have found that heating of intimate mixtures of binary oxides ($KO_{0.56}$+"$FeO_{1.0}$" with K:Fe=2.2:1; Fe bomb tube, 600 °C, 7 d) leads to red monoclinic single crystals having lattice constants $a=7.13_4$, $b=11.12_3$, $c=6.51_5$ Å; $\beta=102.3°$, shown to have the composition K_3FeO_3 ($R=R'=5.5\%$) by three dimensional structural analysis employing direct methods (706 *hk*0–*hk*9, diffractometer data, Mo-Kα). The space group is C2/m-C_{2h}^3; Table 1 lists the atomic parameters.

Table 1. Atomic parameters for $K_6[Fe_2O_6]$ (standard deviations in units of last decimal place given in parentheses).

	position	*x*	*y*	*z*	B[Å^2]
K^1	4g	0.	0.2621(1)	0.	1.67(2)

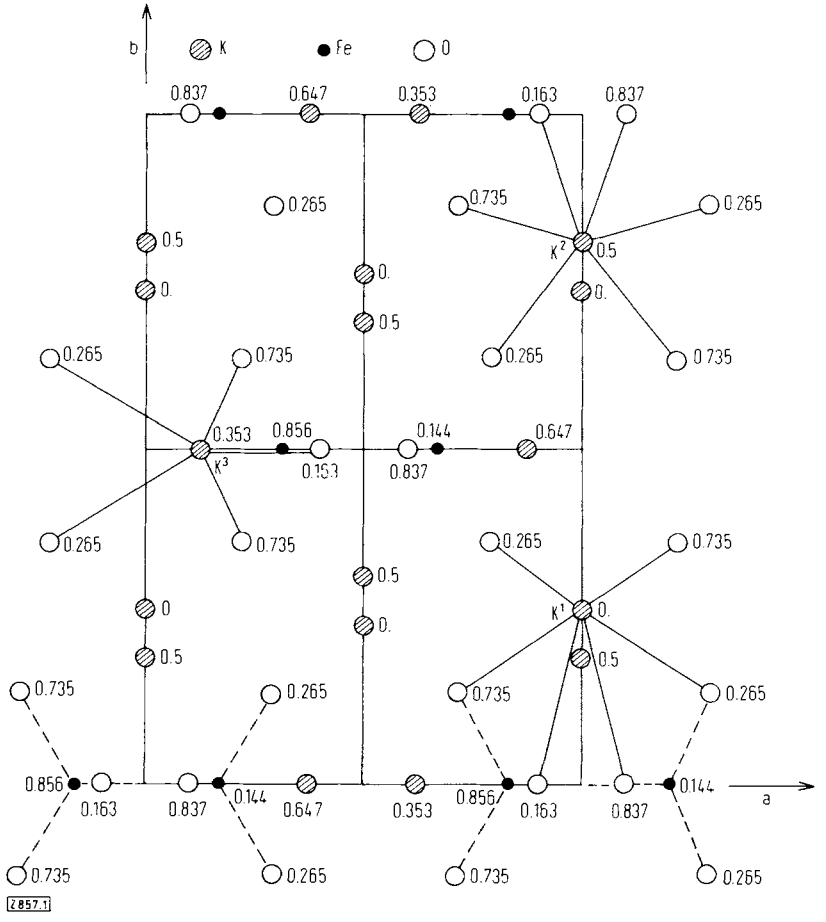

Fig. 1. Crystal structure of $K_6[Fe_2O_6]$; [001] projection. Height in fractions of *c*.

Surprisingly, the compound proves to be the first oxoferrate(III) with a discrete anion whose structure (two tetrahedra sharing a common edge, cf. Fig. 1 and Table 2) resembles that of the Fe_2Cl_6 molecule.

[*] Prof. Dr. R. Hoppe and Dipl.-Chem. H. Rieck
Institut für Anorganische und Analytische Chemie
der Universität
63 Giessen, Südanlage 6 (Germany)

Since the anion of $K_4[Ag_4O_4]$[2] is planar like the Ag_4Cl_4 molecule, that of $K_2[NiO_2]$[3] linear like the $NiCl_2$ molecule, and that of $Li_4[CoO_4]$[4] tetrahedral like the hypothetical $CoCl_4$ molecule, the structures of the discrete anions in other, as yet unknown transition metal oxides having high cation populations may reasonably be expected to resemble those of the corresponding chlorides.

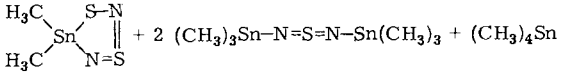
$(CH_3)_2SnS_2N_2$: A Compound Containing a Five-membered Tin-Sulfur-Nitrogen Ring[**]

By *Herbert Roesky* and *Hartmut Wiezer*[*]

Tetrasulfur tetranitride *(1)*[1] reacts almost quantitatively with tris(trimethylstannyl)amine *(2)* in the molar ratio 1:2, affording 5,5-dimethyl-1,3λ⁴,2,4,5-dithiadiazastannole *(3)*, sulfur *N,N'*-bis(trimethylstannyl)diimide *(4)*[2] and tetramethylstannane *(5)*.

$$S_4N_4 + 2\ [(CH_3)_3Sn]_3N \longrightarrow$$
(1) *(2)*



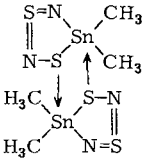
$+ 2\ (CH_3)_3Sn{-}N{=}S{=}N{-}Sn(CH_3)_3 + (CH_3)_4Sn$

(3) *(4)* *(5)*

However, according to IR investigations the first products from *(1)* and *(2)* are only *(4)* and sulfur. *(3)* and *(5)* are formed on vacuum-sublimation of the primary products at 45 °C/*ca.* 0.01 torr. Nucleophilic attack of the sulfur on one Sn atom of *(4)* then leads to ring closure with migration of a methyl group.

(3) is a yellow compound, solid at room temperature, decomposes at 198 °C, but can be recrystallized from CH_2Cl_2. It was characterized by elemental analysis and by its mass spectrum: $m/e = 242$ molecular ion (rel. intensity 58%), 227 $M-CH_3$ (100), 212 $M-2CH_3$ (5), 196 $(CH_3)_2SnSN$ (4), 181 CH_3SnSN (16), 166 SnSN (12), 135 CH_3Sn (33), 120 Sn (23), 46 SN (42); the tin-containing fragments are cited only for ^{120}Sn.

Cryoscopic determination of molecular weight in benzene (found 489) and osmometric determination in chloroform (found 479) afford, contrary to determination in the gas phase, double the relative molecular mass for *(3)* in solution, which we conclude indicates a dimeric structure.



According to the ^1H-NMR spectrum at room temperature (TMS externally) the methyl groups are equivalent: $\delta = -0.95$ ppm; $J_{H-^{117}Sn} = 66.3$, $J_{H-^{119}Sn} = 69.3$ Hz. The IR spectrum (KBr disc) shows absorptions at 2960 w, 2880 w, 1393 w, 1186 w, 1064 s, 1034 vs, 901 s, 778 s, 737 w, 701 s cm^{-1}.

Experimental:

$[(CH_3)_3Sn]_3N$ (11.5 g, 2.28 mmol), dissolved in CH_2Cl_2 (50 ml), is dropped with stirring into a suspension of S_4N_4 (2.1 g, 1.14 mmol) in CH_2Cl_2 (150 ml) at −20 °C. After warming slowly to room temperature (1 h), the solvent is removed in a vacuum. When the yellowish-red solid residue is heated, *(5)* (1.8 g, 86%) passes at 45 °C/*ca.* 0.01 torr into a condensation trap, and *(4)* separates on a sublimation finger; *(3)* (2.5 g, 91%) can be isolated from the residue by recrystallization from CH_2Cl_2.

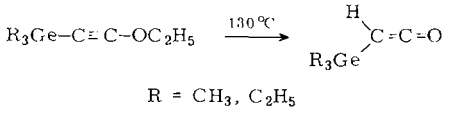
Silyl-, Germyl-, and Stannyl-substituted Ketenes

By *S. V. Ponomarev*[*]

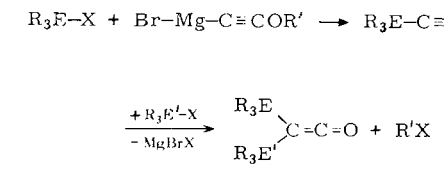
1965 saw the synthesis of (trimethylsilyl)ketene as the first ketene derivative in which a H atom was replaced by a homolog of carbon[1]. When studying the pyrolysis of germyl and stannyl derivatives of alkoxyacetylenes we found that the germyl and stannyl derivatives behaved differently: for instance, ethoxy(germyl)acetylenes gave monosubstituted germylketenes:



$R = CH_3, C_2H_5$

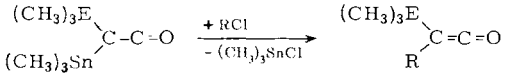
but bis(trimethylstannyl)ketene was formed on pyrolysis of ethoxy(trimethylstannyl)acetylene.

We have developed an adaptable method for preparation of such bis(organometallic) derivatives of ketene, in which an (alkoxyethynyl)magnesium bromide is treated with an excess of trialkylzinc or trialkylgermanium halide[2]:



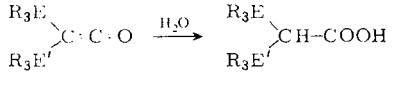
E = E' = Ge, Sn;
E = Si, E' = Ge, Sn; R = Me, Et, Pr; R' = Et, Bu

The stannylgermyl- or stannylsilyl-ketenes react readily with germyl or boryl halides, the stannyl groups being replaced by germyl or boryl groups[3]:



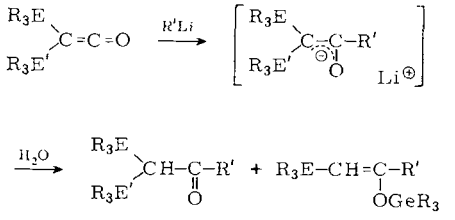
E = Si, Ge; R = Cl_3Ge, $(C_4H_9)_2B$

The bis(organometallic)ketenes are converted into the corresponding acetic acids by aqueous dioxane[4]:

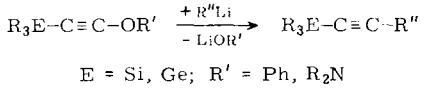


E = E' and E ≠ E' = Si, Ge

Treatment with organolithium compounds and subsequent hydrolysis afford the corresponding ketones and germyl-substituted enols[5]:

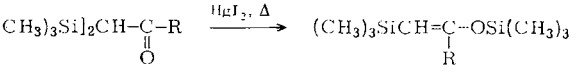


The metalated acetylene derivatives also react with alkyllithiums, but then the alkoxy group is removed by the nucleophile[6]:

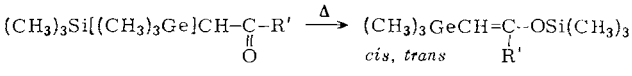


E = Si, Ge; R' = Ph, R_2N

Bissilylated ketones rearrange when heated or in the presence of HgI_2:



Only the trialkylsilyl group migrates in ketones containing different substituents:



This group can be removed as butyltrimethylsilane by butyllithium.

Reviews

Abstracts of selected progress reports and review articles

The reactions of hydrogen atoms in aqueous solutions are the subject matter of a review by *P. Neta*. The H atoms are generated, for instance, by radiolysis of water, reaction of hydrated electrons with acids, or photolysis of an organic compound (such as RSH) in solution. The reactions of the H atoms were studied by the observation of short-lived intermediates (*e.g.* by pulse radiolysis or ESR spectroscopy). The reactions of H atoms in aqueous solutions appear to be more selective than those of organic radicals. [Reactions of Hydrogen Atoms in Aqueous Solutions. Chem. Rev. *72*, 533—543 (1972); 65 references]

[Rd 610 IE—M]

The reduction of unsaturated organic compounds by the systems sodium/alcohol/ammonia (Birch reduction, A) and Li/lower amines (Benkeser reduction, B) is the subject of a comparative study by *E. M. Kaiser*. The article deals with the reduction of aromatic hydrocarbons, alkynes, alkenes, unsaturated ethers, acetals and ketals, unsaturated alcohols and amines, aromatic nitro compounds, carboxylic acids, ketones, epoxides, 5- and 6-membered heterocycles, and a number of S compounds. Saturated or partially saturated derivatives are generally obtained. The reaction is accompanied by reductive cleavage. B is usually more effective but less selective than A. However, the selectivity of B can be enhanced by suitable solvents. Reductive amination is also possible. [A Comparison of Methods Using Lithium/Amine and Birch Reduction Systems. Synthesis *1972*, 391—415; 133 references]

[Rd 614 IE—M]

Determination of the effective charges of anions by the positron method is reported by *G. M. Bartenev, A. Z. Varisov, V. I. Gol'danskii, E. P. Prokop'ev*, and *A. D. Tsyganov*. The annihilation of positrons by the electrons of a substance is usually accompanied by the emission of two γ quanta. This phenomenon offers two possibilities of determining the effective charges of anions: by measuring the angular distribution of the annihilation radiation or by measuring the lifetime of the positrons. Experimental data are given for about 100 oxides and salts. [Determination of the Effective Charges of Anions in Media of the Ionic Type by the Positron Method. Russ. Chem. Rev. *41*, 305—313 (1972); 67 references]

[Rd 622 IE—Q]

The insertion of isocyanides into metal-carbon bonds and reactions of coordinated isocyanides are reviewed by *Y. Yamamoto* and *H. Yamazaki*. Reactions of isocyanides with complexes having a metal-carbon σ-bond, with "carbene" complexes, and with metal azides are discussed, as well as reactions of isocyanide complexes with alkyllithium and Grignard reagents, with amines and alcohols, and oxidative additions of alkyl halides to isocyanide complexes. These reactions receive considerable attention because in some respects they resemble organic syntheses, especially polymerization reactions, catalyzed by transition metal ions. [Isocyanide Insertion and Related Reactions. Coord. Chem. Rev. *8*, 226—239 (1972); 47 references]

[Rd 629 IE—H]

Recent concepts relating to inorganic peroxo compounds are summarized by *I. I. Vol'nov*. A survey of existing data for the anions O_2^{2-}, O_2^-, and O_3^- is followed by descriptions of the structures of the simple and complicated peroxo compounds. In conclusion a scheme is presented for their classification. [Modern Views of the Nature of Inorganic Peroxy-Compounds. Russ. Chem. Rev. *41*, 314—322 (1972); 93 references]

[Rd 623 IE—Q]

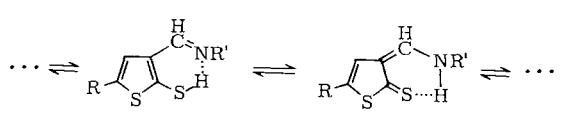
Advances in isocyanate chemistry from 1960 to 1971 are reported by *S. Ozaki*. The most significant of the numerous (more than 25) methods for the synthesis of isocyanates is the phosgenation of amines or their salts. The reaction of nitro compounds with carbon monoxide in the presence of noble metal compounds represents a new, one-step process. Apart from the frequently exploited nucleophilic additions of isocyanates, additions to double bonds, polymerizations, cyclizations, and insertions of the isocyanate group into Si—N, N—B, C—O, and other bonds have also been the subject of recent detailed studies. [Recent Advances in Isocyanate Chemistry. Chem. Rev. *72*, 457—496 (1972); 496 references]

[Rd 616 IE—M]

Coupling reagents for peptide synthesis are dealt with by *Y. S. Klausner* and *M. Bodansky*. Unsaturated ethers such as α-chlorovinyl ethyl ether convert N-protected amino acids initially into the chloride.—Addition of nucleophilic hydroxy compounds, *e.g.* pentachloro- and pentafluorophenol, reduces the racemization occurring during the activation of acyl peptides with dicyclohexylcarbodiimide. Of particular utility are the enol esters accessible from 1,2-oxazolium salts and carboxylic acids, which react with amino acid esters. Other coupling reagents include cyanamides, keteneimines, ketenes, ynamines, and acyloxyphosphonium ions. [Coupling Reagents in Peptide Synthesis. Synthesis *1972*, 453—463; 86 references]

[Rd 618 IE—M]

Syntheses and properties of new complex-forming thiophene derivatives—mercapto-, dimercapto-, and 3-alkyliminomethyl-2-mercaptothiophenes—are described by *Ya. L. Gol'dfarb* and *M. A. Kalik*. According to the NMR spectra, compounds *(1)* exist mainly in the form *(1a)*. The authors



(1) *(1a)*

also go into chelate formation by these thiophene derivatives and reactions of the metal chelates. [The Synthesis and Properties of New Complex-Forming Thiophen Derivatives. Russ. Chem. Rev. *41*, 360—370 (1972); 100 references]

[Rd 628 IE—Q]

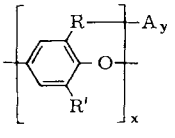
The chemistry of tetravalent niobium and tantalum and of trivalent zirconium and hafnium is reviewed by *D. A. Miller* and *R. D. Bereman*. All pertinent compounds have in common an extreme sensitivity toward oxygen and moisture; many conflicting data about these substances can therefore be found in the literature. These data are quoted non-critically. [The Chemistry of d^1 Complexes of Niobium, Tantalum, Zirconium, and Hafnium. Coord. Chem. Rev. 9, 107—143 (1972); 95 references]

[Rd 635 IE—H]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

A membrane of phenolic polyether *(1)*, which is itself known, is prepared by dissolution of the polymer in a mixture consisting of two solvents for the polymer with different



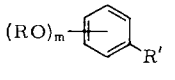
(1)

R = phenyl; R′ = phenyl, alkylphenyl, biphenylyl, terpenylyl, naphthyl; A = halogen; y = 0, 1, 2, 3, or 4; x is such that the specific viscosity of the polymer is between 0.3 and 1.5 (in cyclohexanone at 25 °C)

boiling points, casting on a support, and removal of at least part of the solvent having the lower boiling point. The resulting film is treated with a coagulant liquid and finally dried. It has a non-porous layer 0.1 to 10 μm thick and a porous layer 30 μm to 1 mm thick with open pores, the total volume of the pores constituting 20—80% of the total volume of the membrane. It can be advantageously used for the fractionation of gas mixtures containing oxygen, nitrogen, hydrogen, carbon dioxide, helium, or methane or for the separation of liquid mixtures by pervaporation. [DOS 2153646; Rhône-Poulenc S.A., Paris]

[PR 64 IE—Ö]

A new isomerization catalyst with which unconjugated alkenylalkoxybenzenes *(1)* can be almost quantitatively converted into the conjugated compounds is obtained by heating a mixture of alkali metal, alkali metal hydroxide, and aluminum oxide, possibly under an inert gas, to temperatures above the melting point of the alkali metal (200—500 °C). The alkali metal may be used as an alloy,



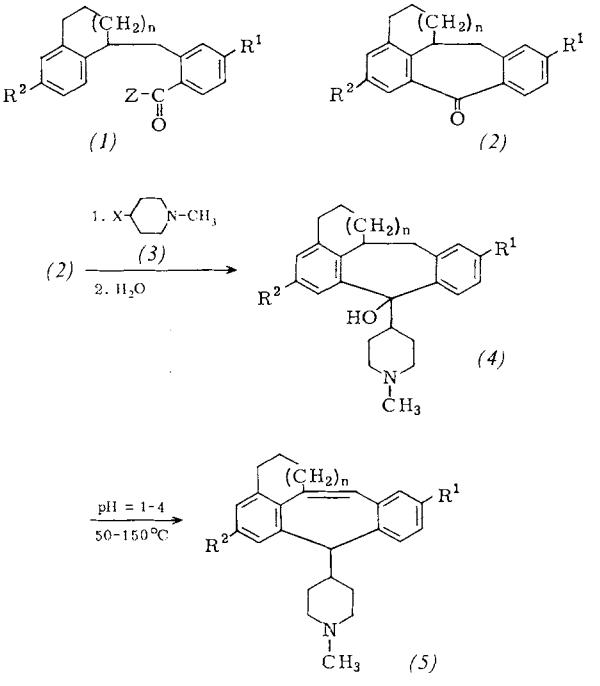
(1)

m = 1—5; R = alkyl (C_1—C_6), aralkyl, or, if $m \geq 2$ and at least 2 R are adjacent, together with the other residue a lower alkylene bridge; R′ = alkenyl residue, whose double bond is not conjugated with the benzene ring.

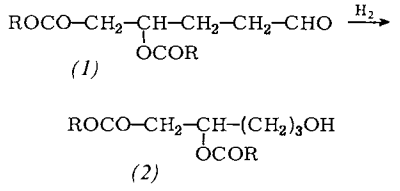
e.g. Na-K-alloy. One can also use several hydroxides, which need not correspond to the alkali metals used. The aluminum oxide support may be in any modification or may be in the form of a compound containing Al_2O_3, *e.g.* kaolin. One part by weight of alkali metal hydroxide is preferably used per 100—1 parts by weight of Al_2O_3, and 1 mol of alkali metal per 1—100 mol of alkali metal hydroxide. The catalyst can also be prepared by heating an alkali metal with aluminum oxide containing physically mixed water, water of crystallization, or OH groups that can be eliminated as water. The water content is usually 1.3—15 wt.%. The alkali metal is preferably used in a 1.01- to 2-fold amount. The catalyst, unlike dispersion catalysts, contains no free alkali metal. It is stable to air and water and remains catalytically active for a long time. Unlike with the acidic or basic isomerization catalysts used in the past, the compounds *(1)* can be rearranged even at room temperature with the new catalyst. The process may be carried out continuously or discontinuously, preferably under an inert gas. One part by weight of catalyst is used per 1000—1 parts by weight of *(1)*. For example, safrole can be quantitatively isomerized to isosafrole, or *o*-allylanisole to *o*-anethole. [DOS 2157534; Sumitomo Chemical Co. Ltd., Osaka]

[PR 79 IE—V]

Piperidylpleiadenes *(5)* **and piperidylpleiadenols** *(4)* are spasmolytic and can act as anticonvulsants. They are prepared by ring closure of the acids or acid derivatives *(1)* to form the ketones *(2)* (mineral acid or Friedel-Crafts



(1) *(2)* *(4)*



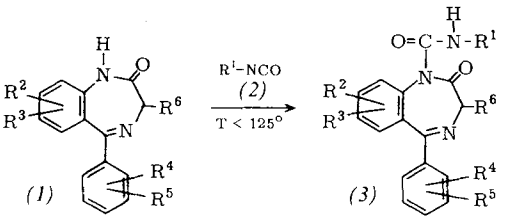
(1) is obtainable by the oxo synthesis from 1-vinylethylene diacylates. 1,2,5-Pentanetriol can be obtained from *(2)* by transesterification with methanol in the presence of an acidic catalyst. The OH group of *(2)* can be selectively etherified, esterified, ethoxylated, halogenated, and sulfonated. [DOS 2105968; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

[PR 102 IE—B]

High-impact thermoplastic graft copolymers of the ABS and MBS type (ABS = acrylonitrile/butadiene/styrene, MBS = methyl methacrylate/butadiene/styrene) can be prepared as follows by bulk or bulk-suspension polymerization. Preformed rubbery polymer A and preformed polymer B are dissolved in a mixture of graft monomers, and this mixture is polymerized with agitation to a conversion of 10 to 40% to form a dispersion in which the polymers A and B are dispersed in a solution of the polymer of the graft monomers in the remaining graft monomers; the latter are polymerized further in bulk or in aqueous suspension to a conversion of at least 50%. The polymer A is a polydiolefin with a high 1,4 content, and the polymer B is a 1,3-butadiene polymer. The latter is selected from homopolymers of 1,3-butadiene with at least 50% 1,2-linkage and copolymers of 1,3-butadiene with less than 50 wt.% of a copolymerizable monomer. The graft monomers comprise mixtures of styrene or a styrene homolog with acrylonitrile, its homologs, methyl methacrylate, or its homologs. The economical bulk and bulk-suspension process has until now been confined to the high-impact polystyrene resins, whereas ABS and MBS resins having good properties were obtainable only by the more expensive emulsion graft copolymerization. [DOS 2063291; Polymer Corp., Sarnia, Ontario]

[PR 69 IE—S]

Benzodiazepinecarboxamides *(3)* and their pharmacologically acceptable acid addition salts can be used as tranquillizers and sedatives for mammals and birds. They can be prepared by reaction of the benzodiazepines *(1)* with excess isocyanate *(2)* in inert organic solvents, preferably ethers. Some acid addition salts can also be used as mothproofing agents (*e.g.* the hexafluorosilicates) or herbicides (*e.g.* the trichloroacetates). [DOS 2149326; The Upjohn Co., Kalamazoo, Mich.]



R^1 = alkenyl (C_3—C_8), cycloalkyl (C_3—C_6), halogenoalkyl (C_2—C_6); R^2, R^3, R^4, R^5 = H, F, Cl, Br, CN, CF_3, alkyl (C_1—C_3); R^6 = H, alkyl (C_1—C_3)

[PR 92 IE—N]

New compounds of the type *(1)* **with hydrogen bonds** are obtained by reaction of at least 1% of a polyhydroxy compound having two or more OH groups, such as propylene glycol, glycerol, or polyoxyethylene glycol (MW 200—1000), with an iodophore (iodine adduct), such as polyvinylpyrrolidone-iodine or nonylphenoxypoly(ethylenoxy)ethanol-iodine complex. *(1)* is used in skin cleaners with

[R] · X *(1)* R = iodophore, X = polyhydroxy compound

a scouring action, which, in addition to the compound *(1)*, which has an antiseptic action, also contain a detergent, such as alkylsulfonic esters, Na *N*-cyclohexyl-*N*-palmitoyltaurate, Na *N*-fatty acid-*N*-methyltaurate, Na *N*-methyl-*N*-palmitoyltaurate, or Na lauryl sulfate, a substance with an abrasive action such as pumice, kaolin, or sand with a particle size of 100—1000 µm, and a pharmaceutically acceptable vehicle, *e.g.* polyoxyethylene glycol (MW 1500—6000). The cleaners can be used for the treatment of acne wounds contaminated with pathogens. [DOS 2105057; Mundipharma AG, Rheinfelden]

[PR 107 IE—Z]

To cleave thioacetals to form the carbonyl compound, the thioacetals are allowed to react with an alkylating agent such as methyl iodide in the presence of water and possibly a basic agent such as alkali metal carbonate or alkaline earth metal carbonate. Examples are the cleavage of 3-hydroxy-6,6-ethylenedithioandrostane, 3-hydroxy-20,20-ethylenedithio-5-pregnene, and 24,24-ethylenedithiocholane. [DOS 2204116; Roussel-Uclaf, Paris]

[PR 111 IE—B]

Determination of Organic Structures by Physical Methods. Vol. 3. Edited by *F. C. Nachod* and *J. J. Zuckerman*. Academic Press, New York—London 1971, 1st Edit., 472 pp., numerous figures and tables, bond $ 22.50.

Volume 3 contains articles on photoelectron spectroscopy, X-ray diffraction, optical rotatory dispersion and circular dichroism, thermochemistry, mass spectrometry, and electron spin resonance, as well as a section on "Configuration and Conformation by NMR".

C. R. Brundle and *M. B. Robin* describe the two classes of photoelectron spectroscopy, *i.e.* Turner molecular photoelectron spectroscopy (photoemission by short-wave UV radiation below 60 eV) and Siegbahn "Electron spectroscopy for chemical analysis" (abbreviated to ESCA photoemission by X-rays above 1000 eV). The effects of the molecular environment on the ionization potentials of the electrons of an atom in the molecule (chemical shifts) are described. Line splitting due to unpaired electrons, Jahn-Teller symmetry distortions, and spin-orbit coupling are discussed. A survey of the relations between certain structural characteristics and the chemical shifts of the ionization potentials underlines the importance of these data as structural parameters.

R. F. Stewart and *S. R. Hall* explain fundamental concepts and methods of X-ray diffraction. Their application to the identification of atoms and to the determination of bond lengths, bond angles, configurations, and steric structures of molecules is outlined. Possibilities of structural analysis as a result of the defects produced by incident X-rays and the determination of charge-density profiles of organic molecules with the aid of X-ray diffraction are illustrated by a number of examples.

P. Crabbe presents an introduction to ORD and CD spectroscopy, and outlines the effects of solvent, temperature, configuration, and conformation on the Cotton effects. The CD and ORD characteristics of numerous chromophores are described. The author explains Cotton effects of polypeptides and synthetic, optically active high polymers, as well as the application of CD and ORD spectroscopy to the determination of the α-helix content of such macromolecules. The knowledgeable reader will perhaps note the absence of any reference to magnetic circular dichroism and MORD spectroscopy.

The section "Thermochemistry", by *K. B. Wiberg*, deals with the measurement and evaluation of enthalpies of combustion, hydrogenation, isomerization, hydrolysis, ionization, and protonation, as well as the determination or estimation of rotation barriers and bond energies from thermodynamic and spectroscopic data. Classical and quantum-mechanical approximation methods for the calculation of thermodynamic molecular data are outlined.

D. Williams, in his article on "Mass Spectrometry", concentrates on energy and kinetic aspects of fragmentation reactions and on the structure of fragment ions. The use of mass spectrometry for the elucidation of structures of natural products is illustrated by examples such as the sequencing of peptides and the fragmentation of trimethylsilyl nucleosides and nucleotides in the field ion mass spectrometer.

G. A. Russel devotes his article on electron spin resonance to the incorporation of spin labels in organic molecules and the associated side reactions. Hyperfine splitting due to coupling with neighboring and remote unpaired electrons and magnetic nuclei (^{1}H, ^{13}C, ^{19}F) is discussed.

A criterion for distinguishing between the closely related concepts of configuration and conformation is the much shorter time scale of conformational changes. In this sense, *F. A. L. Anet* and *R. Anet* deal in the final section "Configuration and Conformation by NMR" with the use of NMR data such as coalescence temperatures, chemical shifts, coupling constants, and nuclear Overhauser effects for the determination of configurations and conformations.

All the articles are clearly written, and in accordance with the conception of the work, they concentrate on the application of the physical methods. Even those who are not very familiar with these fields are therefore provided with a survey of physical structural analysis. The lists of references, which consist almost exclusively of original sources in English published up to 1970, are fairly comprehensive, and together with numerous tables, they qualify Volume 3 for use as a reference work.

Eberhard Breitmaier [NB 121 a IE]

Determination of Organic Structures by Physical Methods. Vol. 4. Edited by *F. C. Nachod* and *J. J. Zuckerman*. Academic Press, New York—London 1971, 1st Edit., 381 pp., numerous figures and tables, bound $ 19.50.

Volume 4 is devoted to subsidiary fields of NMR spectroscopy that have gained importance through very recent developments and refinements of the NMR technique. The methods described have become more accessible to organic and inorganic structural chemists through the availability of mass-produced multichannel NMR spectrometers having high magnetic fields with facilities for frequency sweep and pulse operation as well as suitable computers.

W. Naegele, in Section 1, presents a brief introduction to the theory and instrumentation of high-field NMR spectroscopy. He then concentrates on applications to the determinations of structures of organic molecules. Considerable space is given to the 220 MHz ^{1}H-NMR spectroscopy of natural and synthetic polymers.

Section 2, by *N. Boden*, deals with pulse NMR spectroscopy and its use in the measurement of Fourier transform NMR spectra, in the measurement of spin-lattice relaxation times, and above all in spin echo experiments.

The methods of homonuclear and heteronuclear magnetic double resonance, which are necessarily also touched upon in other chapters of the volume, are the subject of Section 3 by *W. McFarlane*.

R. L. Lichter, *P. R. Wells*, *P. S. Pregosin*, *E. W. Randall*, and *J. R. van Wazer* describe, in Sections 4 to 7, methods and applications of hetero-NMR spectroscopy, mainly with the nuclei ^{15}N, ^{13}C, ^{31}P and with ^{7}Li, ^{29}Si, ^{77}Se, ^{117}Sn, ^{119}Sn, ^{195}Pt, ^{199}Hg, ^{205}Tl, and ^{207}Pb as the measuring probes.

The authors have managed to provide the reader with a great deal of information through illustrations, tables, and presentation. Large lists of references (which, however,

cite almost exclusively original sources in English) provide an opportunity for further reading on the topics discussed.

The description of recent developments and refinements and the treatment of numerous nuclei that were formerly not very common will provide stimulating material in particular for structural analysts and NMR spectroscopists. The presence of a number of gaps in the sections is unavoidable in view of the flood of literature and the rapid development of NMR spectroscopy.

Eberhard Breitmaier [NB 121 b IE]

New Techniques in Amino Acid, Peptide and Protein Analysis. Edited by *A. Niederwieser* and *G. Pataki*. Ann Arbor–Humphrey Science Publ., Inc., Ann Arbor Mich. 1971. 1st ed., 461 pp., numerous figures and tables. bound $ 22.50.

The rapid development of a field of science is almost inevitably linked with the development and introduction of new procedures. Thus the biological sciences brought with them considerable advances in chemical methods. The present book, or more precisely its first eight chapters, summarizes new experimental methods in the field of amino acids, peptides, and proteins: 1. ion-exchange chromatography of amino acids and peptides; 2. and 3. gas chromatography of amino acids and peptides (these two chapters overlap to some extent); 4. mass spectrometry of peptides; 5. molecular sieve chromatography; 6. thin layer gel filtration; 7. microelectrophoresis and synthesis of proteins in quantities of 10^{-7} to 10^{-9} g; 8. protein electrofocusing. The last two chapters (chemical accessibility and environment of amino acid residues in natural proteins and methods for the study of the quaternary structure of proteins), on the other hand, are surveys of methods with fairly superficial descriptions of techniques.

The editor has allowed the authors an individual approach to their own chapters. Overlapping occurs in places. However, the book as a whole will be successful in the editor's aim of presenting reliable surveys of the new experimental methods.

Karel Bláha [NB 138 IE]

Chemistry of Fungicidal Action, Molecular Biology, Biochemistry, and Biophysics. By *R. J. Lukens*. Springer-Verlag, Berlin–Heidelberg–New York 1972. 1st ed., xiii, 136 pp., 8 figs., bound DM 42.—

The present monograph presents a comprehensive survey of current knowledge on the chemistry of fungicides that are used for the protection of plants or industrial organic materials against destructive fungi. Its purpose is to explain general and common principles of fungitoxic phenomena within the framework of present-day views in cell biology.

The material is divided into the following sections: 1. chemical control of deterioration by fungi (3 pp.), 2. measurement of fungitoxicity (8 pp.), 3. fungitoxic barriers (18 pp.), 4. migration of fungicides to sites of action (8 pp.), 5. sites of action (17 pp.), 6. reaction of fungicides with cell constituents (11 pp.), 7. effects of fungicides on enzymes (9 pp.), 8. structure-activity relationships (15 pp.), 9. action of fungus on fungicide (8 pp.).

The formulas of the fungicides discussed are listed in a seven-page appendix.

The discussion is based on details from 460 references, whose main conclusions are presented succinctly and in a well coordinated manner. The monograph should be a very valuable aid to all biologists, chemists, and toxicologists concerned with phytopathology and microbiology, and should also provide a stimulus to close the gaps, some of them considerable, that still exist in our knowledge of the mode of action of fungicides.

Klaus Sasse [NB 141 IE]

The Raman Effect. Vol. 1. Principles. Edited by *A. Anderson*. Marcel Dekker, Inc., New York 1971. 1st ed., ix, 404 pp., numerous figures, bound $ 28.50.

A fundamental survey of the theoretical and experimental principles of the Raman effect and of its important applications in physics and chemistry is to be presented in two volumes. The book is intended for students and scientists seeking an introduction to the field of Raman spectroscopy. Volume 1 contains the following chapters: 1: Historical Introduction (*R. S. Krishnan*, 48 pp.), a rather long-winded account for the intended readership, with only a few tables, formulas, or critical comments. For example, a half page on "Born's Lattice Dynamics" is followed by a page on "Raman's Lattice Dynamics", with no indication for the beginner of the problem involved in this controversy and with no objective comparison. Chapter 2: Polarizability Theory of the Raman Effect (*G. W. Shantry*, 47 pp.) and Chapter 3: The Theory of the Raman Scattering of Crystals (*R. A. Cowley*, 87 pp.) are worth reading, particularly for physicists. Chapter 4: Raman Instrumentation and Technique (*C. E. Hathaway*, 104 pp.) gives a detailed account of the properties of gas discharge lamps, spectrographs, and photographic plates and of commercial instruments that have long since fallen out of use or been withdrawn from the market, together with detailed information on laser light sources and modern spectrometers. This is followed by Chapter 5: Stimulated Raman Effect (*P. Lallemand*, 56 pp.) and Chapter 6: Brillouin Scattering (*R. S. Krishnan*, 61 pp.), both of which are very good descriptions, which will be of interest in particular to the physicist.

The readers at which the book is aimed would find it more useful if Chapters 1 and 4 were dusted off somewhat and provided with critical comments. The present volume has little to offer the chemist. The applications in the fields of chemistry and physics are to be presented in Volume 2.

Bernhard Schrader [NB 144 IE]

Mechanism in Organic Chemistry. By *R. Alder*, *R. Baker*, and *J. M. Brown*. John Wiley & Sons, Inc., New York—London 1971, 1st Edit., x, 378 pp., numerous figures, bound £ 5.00.

The main purpose of the authors was to summarize in one volume the present situation in mechanistic organic chemistry for advanced students. They assume that the student is familiar with a textbook of organic chemistry (such as that by *Roberts* and *Caserio*) and that he has been introduced to the principles of physical chemistry. The aim of the book is to enable the reader to understand organic reaction mechanisms, to allow critical reading of original articles in this field, and ultimately to enable him to plan and execute his own experiments correctly.

The actual treatment of organic reactions is preceded by a general chapter, in which catalysis, the energies of ground and transition states, and isotope, ring-strain, solvent, steric, electronic, and stereoelectronic effects are discussed.

This is followed by "Dissociative Processes". This section deals with processes that follow the primary cleavage of a carbon bond, *i.e.* reactions of carbenium ions, carbanions, carbenes, and free radicals.

The third chapter surveys "Synchronous Reactions" in substitutions and eliminations.

Electrocyclic and sigmatropic reactions and cycloadditions are discussed in the fourth chapter, "Multicentre Reactions".

The fifth and final chapter is headed "Associative Reactions" and contains reactions in which intermediates having a new carbon bond are formed: electrophilic and free-radical aromatic substitutions, electrophilic and free-radical additions to unsaturated systems, nucleophilic addition-elimination reactions to the carbonyl group, and nucleophilic vinyl and nucleophilic aromatic substitutions.

There is no doubt that the authors have succeeded in making a representative and comprehensible selection from the many articles on organic reaction mechanisms published in recent years, so that the reader in particular who does not work in this field will obtain a general picture. Although it has not been entirely possible to avoid subjective evaluation, this must be attributed to the necessity of limiting the subject matter.

The rapid development of mechanistic organic chemistry and the new results that are continually being found in this field present a problem in the production of an up-to-date book of this nature. As an example, one might mention the S_N2 reaction, which perhaps would not nowadays be assigned without comment to the chapter on "Synchronous Reactions".

If one takes this into account, the book is an excellent supplement to advanced instruction, particularly since each chapter is provided with exercises, and the reader whose interests go beyond the scope of the book is referred to original articles and detailed reviews in 600 references, most of which are recent, and which extend up to 1970.

All in all, "Mechanism in Organic Chemistry" will be equally useful to students and to lecturers.

Gernot Boche [NB 123 IE]

Organophosphorus Chemistry. Vol. 2. Specialist Periodical Reports. Published by The Chemical Society, London 1971. 1st ed., xi, 292 pp., numerous figures, bound £ 7.—.

For the second time a group of Anglo-Saxon specialists under the expert direction of *S. Trippett* has undertaken to present a survey of phosphorus literature published between July 1969 and June 1970 to follow the first volume in this series, which was published in 1970 and covered the literature from the beginning of 1968 until June 1969. As in Volume 1, the arrangement of the material in the second volume is based mainly on the substance, though mechanistic aspects are also considered.

S. Trippett has once again acquired the services of eight expert co-authors, who present a "snapshot" of the present position of phosphorus chemistry based on the evaluation of more than 1200 references.

The material discussed in the second volume is divided into 11 chapters: Phosphines and Phosphonium Salts *(D. J. H. Smith)*; Pentacovalent Phosphorus Compounds *(S. Trippett)*; Halophosphines and Related Compounds *(J. A. Miller)*; Phosphine Oxides *(J. A. Miller)*; Acids of Trivalent Phosphorus and Derivatives *(B. J. Walker)*; Acids of Pentavalent Phosphorus *(N. K. Hamer)*; Phosphates and Phosphonates of Biochemical Importance *(D. W. Hutchinson)*; Ylides and Related Compounds *(S. Trippett)*; Phosphazenes *(R. Keat)*; Photochemistry, Free Radicals, and Deoxygenation Reactions *(R. S. Davidson)*; Physical Methods *(J. C. Tebby)*.

If one overlooks a few inaccuracies and printing errors, the second volume again gives a comprehensive survey of the rich and varied harvest collected in the course of only a year in the phosphorus field.

The importance of this periodical report to the national and international specialist world cannot be valued highly enough, since the standard work on phosphorus chemistry (*Kosolapoff*: Organophosphorus Compounds) is probably now in its last edition and there is already evidence of a literature gap, which can no doubt be closed with the aid of these "Periodical Reports". However, the German specialists, who tend to waste their time in endless meetings in these days of democratization of academic life and therefore frequently neglect the study of the specialist literature, are particularly grateful to their colleagues from a land where democracy has stood the test of time for this effective aid to coping with the literature.

Leopold Horner [NB 128 IE]

Terpenoids and Steroids. Vol. 1. Specialist Periodical Reports. Published by The Chemical Society, London 1971. 1st ed., xi, 557 pp., numerous figures, bound £ 11.—.

The present volume covers the literature between September 1969 and August 1970, but also extends further back for important topics to provide a broader basis for understanding. The material is divided up well: the terpenes into monoterpenes, sesquiterpenes, diterpenes and triterpenes, and carotenoids (with polyterpenes) and biosynthesis of terpenes and steroids, and the steroids into properties and reactions and syntheses.

The material in such a report must of necessity be presented very concisely, in view of its large volume (approx. 2400 references). The readability of the text is nevertheless still good. Formulas and sections of text are clearly arranged. Despite the understandable absence of a subject index, therefore, any desired special topic can be quickly found. The presentation by the various authors appears homogeneous and complete. The two steroid chapters overlap in a few points. The number of errors is within reasonable limits.

The report can be specially recommended to all those working in the terpene or steroid fields. It puts one's own field in its place in the range of topics, provides a check on one's own reading of the original literature, and extends one's vision to neighboring fields that one can no longer follow continuously. However, even chemists who do not specialize in terpenes or steroids will find the book useful, as it presents a collective survey of the publications of one year, and at the same time goes into a certain amount of detail.

It is to be hoped that the further annual issues of the report will be as compact, lucid, and reasonably priced as the first.

Wolfgang Sucrow [NB 139 IE]

Surface Self-Diffusion of Metals. By *G. Neumann* and *G. M. Neumann*. Diffusion Information Center, Solothurn/Switzerland, Bay Village, Ohio/USA 1972. 1st ed., 132 pp., 35 figs., numerous tables, paperback $ 15.—.

The present volume deals with the self-diffusion of metal atoms on the surface of metals under vacuum or in contact with an inert gas (or its own vapor). This limits the subject to some extent, so that important problems in which surface diffusion plays a part such as the electrochemical deposition and dissolution of metals at the metal/electrolyte phase boundary, or the diffusion of foreign substances in heterogeneous catalysis and in gas diffusion electrodes, are not discussed. If this limitation (which was no doubt necessary because of space considerations) is accepted, it must be acknowledged that the subject matter has been presented with commendable lucidity. This applies equally to the arrangement, the clear text, and the graphs and tables, which are also a credit to the printer. However, with the best will, the reviewer was unable to make out the white-black-gray marking mentioned in the text for the first, second, and third layers in the packed-sphere lattice models in Figures 20a—f. The omission of any detailed theoretical discussions, which would have necessitated reference to other literature in any case, makes for smooth reading. The review character of the work makes a subject index unnecessary. The material is clearly divided into four parts: experimental techniques, experimental results, theoretical considerations, and discussion. As a conclusion, one can see the superiority, with regard to information value, of the techniques that enable one to follow the individual motion of distinguishable particles. The present book is successful within the chosen limits.

B. Kastening [NB 150 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Die Chemische Industrie und ihre Helfer (The Chemical Industry and Ancillaries). Edited by *K. R. Selka*. 1972/73 Edition. Industrieschau Verlagsgesellschaft, Darmstadt. 612 pp., flexible covers. DM 30.—.

Contents: Advertisements and offers; economic situation; technical review and new products; keyword index for sources; index of advertisers.

Block Copolymers. Edited by *D. C. Allport* and *W. H. Janes*. Applied Science Publishers, London 1973. xxiii, 620 pp., bound £ 12.00.

Einführung in die Mathematik für Naturwissenschaftler (Introduction to Mathematics for Scientists). By *G. Kastner*, Bibliographisches Institut, Mannheim 1971. 210 pp., stitched DM 8.90.

Contents: Numbers; vector algebra; determinants and systems of linear equations; limits of series; functions of a real variable; differential calculus; integral calculus; Taylor series; functions of several variables; differential equations.

Einführung in die Massenspektrometrie (Introduction to Mass Spectrometry). By *H. C. Hill*. Translated into German and revised by *H.-F. Grützmacher*. Heyden, Rheine, London, New York 1973. 119 pp., stitched DM 16.—.

Contents: Instruments and sample introduction systems; principles of organic mass spectrometry; fragmentation of positive ions; interpretation of mass spectra.

Liquid Scintillation Counting, Vol. 2. Edited by *M. A. Crook, P. Johnson*, and *B. Scales*. Heyden, London, New York, Rheine 1972. ix, 327 pp., bound DM 72.—

Contents: Proceedings of a Symposium on Liquid Scintillation Counting, organized by the Society for Analytical Chemistry, Brighton, England, September 13—16, 1971.

Ramanspektren (Raman Spectra). By *K. W. F. Kohlrausch*. Reprint of the 1943 1st Edition. Heyden, London, New York, Rheine 1972. xiv, 469 pp., bound DM 135.—

Contents: Introduction; experimental methodology; vibrational modes and vibrational spectra of simple molecules or ions; Raman spectra of organic substances; Raman spectra of inorganic substances; action of intermolecular forces.

Lehrbuch der Textilchemie, einschließlich der textilchemischen Technologie (Textbook of Textile Chemistry, Including Textile-Chemical Technology). By *H. Rath*. 3rd Edit., Springer-Verlag, Berlin, Heidelberg, New York 1972. xii, 881 pp., bound DM 136.—.

Contents: Cellulose fibers; protein fibers, synthetic fibers; inorganic fibers; organic dyes; application of dyes; textile auxiliaries; water in textile factories; materials of construction for textile finishing machinery.

Surface Chemistry and Colloids. Edited by *M. Kerker*. Vol. 7 of the series "Physical Chemistry Series One". Edited by *A. D. Buckingham*. Butterworths, London—University Park Press, Baltimore 1972. 306 pp., bound £ 10.00.—A volume in the series "MTP International Review of Science".

International Edition in English

The Bacterial Flagella and the Flagellar Protein Flagellin[**]

By Wolfram Bode[*]

In comparison with the relatively complicated flagella of all nucleated organisms, most of the actively motile bacteria have very much simpler locomotion organelles. These flagella are long thin filaments with a helical superstructure, anchored at one end in the cell membrane. Helical waves pass along the flagella in the distal direction during locomotion. In the flagella, identical structural units of a single protein species, flagellin, are linked to one another by non-covalent bonds. The flagellin subunits can be separated from one another by mild methods, and their biochemistry as well as their structure and morphology can be investigated in the isolated state. Under certain conditions they can reaggregate *in vitro* to form polymorphous helical filaments, which are practically indistinguishable from intact flagella. In the flagellum, the elongated flagellin molecules have a layered arrangement in about ten parallel strands, which in turn form a hollow cylinder. Since this cylinder is deformed into a large helix, the individual chemically identical flagellin protomers and the protomer strands in the helical flagella are only quasi-equivalent. The conformation and bonding pattern of the individual longitudinal flagellin lines can presumably be controlled *in vivo* by the basal structures, so that movement within the flagellum could conceivably occur as follows. A cyclically induced change in the length of the individual strands could result in an apparent rotation of the helical flagellum. According to hydrodynamic calculations, the resulting forward thrust is sufficient to propel the bacteria at the observed speeds of up to 50 μm/s.

1. Introduction

All flagella of nucleated (eukaryotic) protozoa (*e.g.* Flagellata) and of the motile cellular forms of higher organisms (*e.g.* zoospores, spermatozoa of invertebrates and vertebrates), despite differences in external form and function, exhibit a surprising similarity of fine structure. Two central axial filaments cylindrically surrounded by nine peripheral double fibrils are always embedded in a matrix having little structure and joined to one another by fine secondary fibers[1–3]. It is assumed that the undulating or beating movements of the flagella are produced by contraction or by displacement of these protein fibrils in relation to one another.

The flagella of bacteria are very much smaller and have a simpler structure. In size and structure they resemble the individual peripheral and axial fibrils of the flagella of eukaryotes, and may therefore be regarded as a primitive fundamental type for the more complicated locomotion

[*] Dr. W. Bode

Abteilung Strukturforschung II
8033 Martinsried bei München
Am Klopferspitz (Germany)

[**] This article is based on a lecture delivered by the author to the Macromolecular Colloquium in Freiburg on March 2, 1972; cf. Angew. Chem. *84*, 357 (1972); Angew. Chem. internat. Edit. *11*, 334 (1972).

organelles. Because of their relatively simple structure, therefore, the flagella of bacteria are presumably the most useful subjects for studies aimed at obtaining fundamental information about the structure and function of contractile biological locomotion elements. In addition to a particularly detailed review[4], the general articles on the bacterial flagella include a number that deal with the locomotion mechanisms of bacteria[3, 5, 6] and with the genetics and structure of the flagella[7–11]. Existing knowledge on the form and fine structure of the flagella will be described below, as well as the presumed manner in which movement occurs within the flagella. The properties of flagellin, particularly its surprising ability to undergo aggregation *in vitro*, will be discussed in special detail.

2. Flagellation and the Form of Flagella

Many bacteria are capable of "swimming" in or on liquid media in the direction of a nutrient gradient. Most bacteria use highly specialized organelles, the flagella, for their active locomotion. Apart from these, there are only a few known motile bacteria without flagella, which move in other ways (*e. g.* spirochetes, myxobacteria[4, 6]).

The arrangement of the flagella on the bacterial cell is species-specific[12]. Bacteria are known with a single polar flagellum, with a flagellum at each cell pole, with a bundle of flagella at one pole or at both poles, or with numerous flagella over the entire cell surface (peritrichous flagellation, see Fig. 1). The flagella are mostly about 10 μm long and

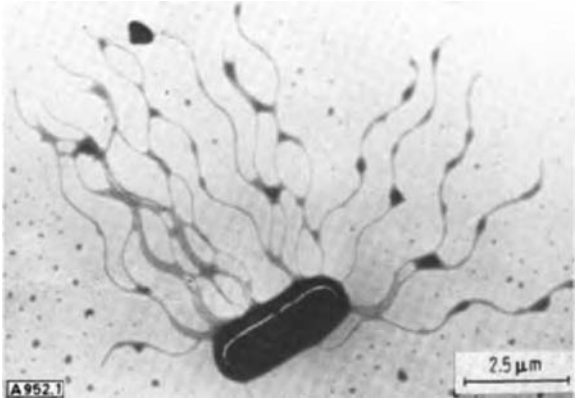

Fig. 1. Electron micrograph of a peritrichally flagellated bacterium (*Proteus mirabilis*) after negative staining with 2% potassium tungstophosphate solution at pH 7.

have a uniform but species-specific diameter of 120 to 200 Å. Both in the attached state and in the free state in solution, they have the shape of a helix[4]. When dried and contrasted on a flat support, the helical flagella collapse and appear under the electron-microscope as sinusoidal filaments, whose species-specific "wavelength" can be roughly equated to the pitch of the original helix and is normally just 2.5 μm for the peritrichous Eubacteriales, such as Proteus bacteria (Fig. 1), Salmonella, and Bacilli (normal type of flagella). Apart from a few paralyzed mutants[9], these normally flagellated bacteria can generally execute relatively rapid rotational and translational movements.

Mutants with low motility and having curly flagella have also been found, the wavelength of these flagella being roughly half of the wavelength of normal flagella, indicating that the pitch of the flagellar helix is roughly halved[4, 9, 10]. Practically immotile mutants with short circular flagella and completely immotile bacteria with perfectly straight flagella can also be observed[4, 10]. These changes in the shape of the flagella are mostly genetic in origin (cf. Section 4). In culture media with very low pH values, however, the short-wave form of flagella has also been observed for wild types of *Proteus mirabilis* that have normal flagella under normal growth conditions[4, 12].

Because they are so thin, single flagella can be observed under the optical microscope only after drying and special mordant staining[6]. In the case of the multiflagellated bacteria, however, the flagella associate during locomotion to form a thick helical bundle. The movement of this bundle of flagella as a whole can be observed under the optical microscope (Fig. 2). During active locomotion the

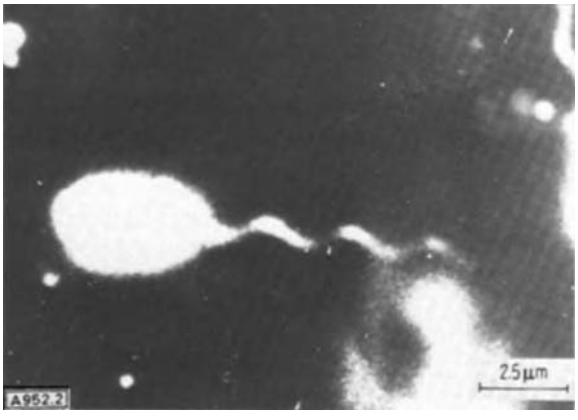

Fig. 2. Photomicrograph of a Salmonella bacterium with its bundle of normal flagella during locomotion (dark field illumination). The photograph was kindly supplied by *Dr. T. Iino* and *Dr. S. Asakura.*

bundle of flagella always points in the opposite direction to the motion. Helical waves continuously run along the bundle in the distal direction, with the result that the bundle assumes the appearance of a rotating helix. At the same time the body of the bacterium appears to move forward in the medium with a helical motion in the opposite direction. Some bacteria can reach speeds of 50 μm/s in this way, *i. e.* they can cover many times their own body length in one second.

When the bacteria are executing slow swimming movements it is sometimes possible to observe transitions of the bundle between two different helical shapes, corresponding respectively to a normal helix and to a helix with only half of the normal pitch (curly type)[10]. This ability of the bundle of flagella to occur successively or simultaneously in two definite, clearly distinguishable helical forms is known as biplicity. Since such transitions can be observed only relatively rarely during movement, however, they cannot be necessary to or responsible for the locomotion.

3. The Fine Structure of the Flagella

Whereas the flagella can be broken off at the cell wall by mechanical treatment, *e. g.* shaking, stirring, or centrifugation, whole flagella can be prepared (including anchoring) and investigated by mild enzymatic detachment of the cell wall and treatment with detergents[13, 14]. According to these investigations, all bacterial flagella, regardless of their source, consist of three morphologically distinguishable parts. The flagellum begins in a *basal body* connected to the cytoplasmic membrane, passes through the cell wall with the *flagellar hook*, and then continues in the long helical *main filament*.

It has only recently become possible to recognize fine structures in the isolated basal region[13]. It has been found that in gram-negative bacteria such as *E. coli*, there are four circular discs offset from one another on a relatively thin pin. In the inserted flagellum, three of the rings are probably each joined to one of the definite layers of the cell capsule of gram-negative bacteria, *i. e.* the cytoplasmic membrane (inside), the murein layer (center), and the lipopolysaccharide layer (outside)[13]. The connecting element between the basal body and the helical main filament is the flagellar hook, a slightly curved cylinder about 500 Å long (see Fig. 3). Its diameter is usually slightly greater than that of the filament, from which it also differs in its greater temperature resistance and its greater resistance to deaggregating agents[4, 13, 14]. It apparently consists of a protein different from that of the main filament[4, 14].

Fig. 3. Electron micrograph of a separated flagellum of *Proteus mirabilis* with hook and incised "tail end" (cf. text) after negative staining with 2% potassium tungstophosphate solution at pH 7.

Connected to the flagellar hook (often *via* a slightly narrower region) is the helical main filament; this part alone is often referred to as the flagellum. With a few exceptions, in which another protein envelops the filament in a flagellar sheath[4, 15], the flagella consist of chemically identical structural units of a single protein, flagellin. According to electron micrographs, egg-shaped morphological subunits, which according to their dimensions of about 50 Å[15, 16] must be identical with flagellin, form a cylinder (Fig. 4). In some cases the subunits appear to be roughly hexagonally packed, and a distinct oblique striation indicates a helical arrangement of the protomer strands (A

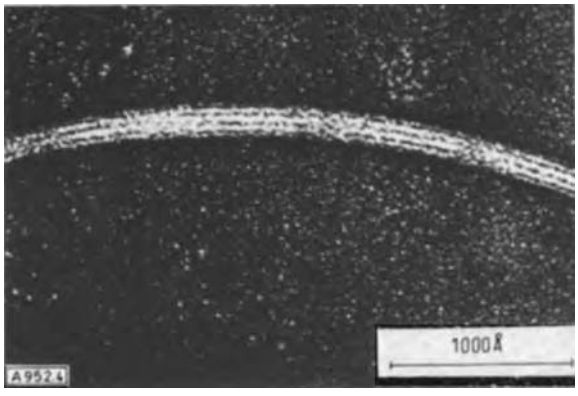

Fig. 4. Flagellum (B form) of *Pseudomonas fluorescens* with periodically disturbed longitudinal stripe pattern. The photograph (staining with uranyl acetate) was kindly supplied by Dr. *J. Lowy*.

form[15]). In other cases (Fig. 4) the cylinder wall appears to consist of eight[15], nine to ten[17, 18], or eleven[19, 20] longitudinal flagellin rows (B form[15]).

Very accurate determination of the distances between the subunits in the axial direction from electron micrographs and from X-ray fiber diagrams gave a value of 52 Å[21–23], while the lateral distances between the longitudinal rows or subunits were found to be 40 to 60 Å[4, 15, 16]. The distances in the axial direction, unlike those in the lateral direction, were found to be extremely resistant to variation with the degree of drying and the contrasting and preparation method[24].

Negative stain such as potassium tungstophosphate can deposit in the axial region of flagella that have been shaken off, particularly after shortening by ultrasound or by repeated freezing and thawing (Fig. 5). In this way contrast

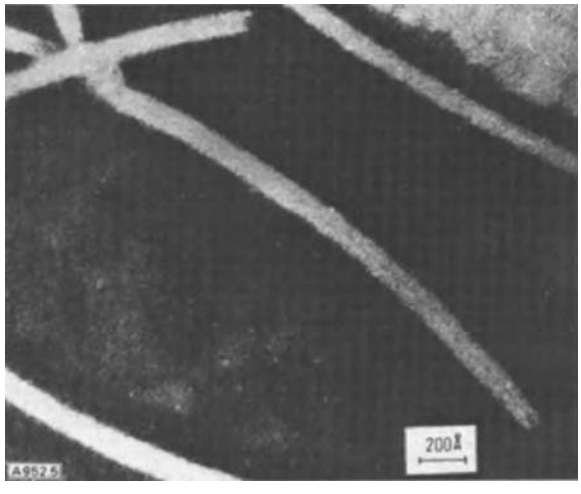

Fig. 5. Electron micrograph of flagella (*Proteus mirabilis*) treated with ultrasound, after negative staining with 2% potassium tungstophosphate solution at pH 7. A weak black central line is visible.

lines up to 30 Å thick can appear in the axis of short flagella[4, 16–18], but these are never so clearly visible as *e. g.* in the tobacco mosaic virus or in bacteriophage tails[15]. X-ray diffraction studies on oriented bundles of flagella[25] and small-angle X-ray measurements on flagella of various lengths in solution[17, 18] also indicate the presence of a hollow central channel. In the latter case the

flagella of *Proteus mirabilis* exhibit roughly the same scattering as a long hollow cylinder having an outside diameter of 150 Å and an inside diameter of 30 Å[18].

Differently formed ends can be observed in certain cases on short fragments of flagella[4, 10, 17, 18, 26, 27]. After negative staining one end is always round to pointed, while the other has an incised appearance (Fig. 6). After shadowing with heavy metal, on the other hand, only the tip is visible, while the "tail end" has disappeared[28]. As can be seen from Figure 3, this incision is situated at the distal end of the anchored flagellum, *i.e.* the end remote from the bacterial cell and the flagellar hook.

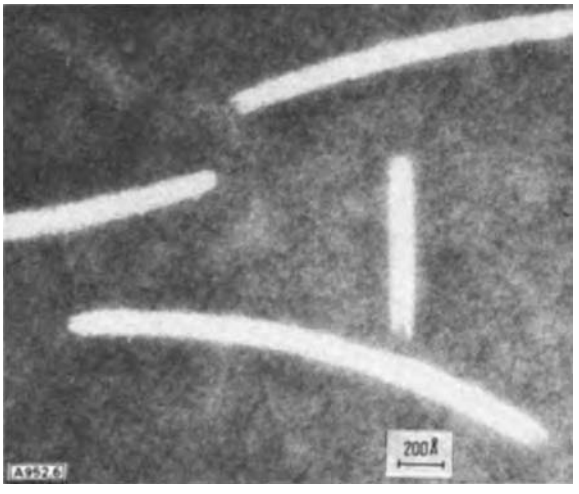

Fig. 6. Electron micrograph of flagella *(Proteus mirabilis)* treated with ultrasound, after negative staining with 2% potassium tungstophosphate solution at pH 7. A round to pointed end and an incised end are visible.

Enough observations have now been reported to enable us to build up a fairly detailed model of the fine structure of the flagellar filament. In the construction of this model we shall make use of yet another piece of information, which we cannot substantiate in full until Section 4. This is that the flagellin monomer is not spherical in shape, as was formerly assumed[15], but is a highly elongated molecule[17, 18]. Since cylindrical close packing of long protomers is possible only if each subunit is less voluminous close to the axis of the cylinder than at the periphery, a wedge should be a reasonable approximation to the actual shape of the protomer. Following *Lowy* and *Hanson*[15] it has been assumed in the fine structure model (Fig. 7) that (in the flagella of Eubacteriales) the flagellin protomers are lined up at regular intervals of 52 Å in eight roughly axially parallel strands, which in turn are combined to form a hollow cylinder. At the same time the protomers in neighboring lines are displaced and arranged hexagonally, and form helices with eight subunits per turn.

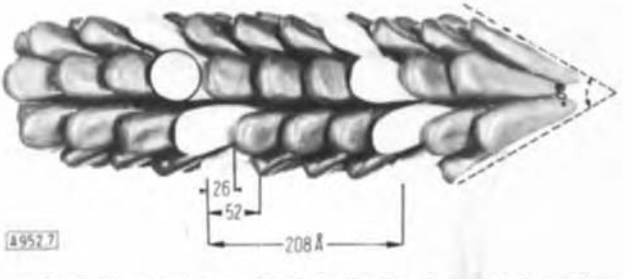

Fig. 7. Fine-structure model of the flagellar filament, built up from wedge-shaped subunits [18] (for explanation see text).

One of these four identical 8/4 helices is shown in Figure 7 with light coloring for better visibility. The helical surface lattice is defined by the crossing of the (four) 8/4 helices and the (eight) longitudinal lines (generally by two families of parallel helices). The exact arrangement of the protomers and the number of longitudinal lines (according to the latest measurements by optical diffraction[19, 20], nearer to eleven than to eight) are not definitely known at present. According to this model[18] the explanation of the morphological subunits, which appear in electron micrographs to be roughly round with a diameter of about 50 Å, is that only a small circular part of the elongated protomers can be seen on the surface.

With its conical end and its incised end, this model can also explain, on the molecular level, the different end structures of the polar flagella (Fig. 6). In contrast with the large axial channel with an effective diameter of about 60 Å in the Lowy-Hanson model, the protomers in this fine-structure model leave only a narrow free channel with a diameter of about 30 Å, as indicated by the X-ray measurements and the relatively weak stainability (Fig. 5).

4. Flagellin

On treatment with detergents, structure-disrupting salts[17], acids[29, 30], or alkalis, or on heating[31], the helical filament breaks down into identical flagellin subunits, which are therefore linked only by non-covalent bonds in the flagellum. Monomeric flagellin is usually prepared by thermal or acid-induced dissociation (cf. Ref. [4]). In the ultracentrifuge under physiological conditions (pH = 7, approx. 0.15 mol of NaCl/l), the molecular weight of flagellins from various organisms has been found to be about 40000[18, 29–33]. This value has been confirmed in denaturing reagents such as 6 M guanidinium hydrochloride, by sodium dodecyl sulfate disc-electrophoresis, or by analysis of the flagellin peptides after cleavage with trypsin or BrCN[18, 34–37].

It was thus also shown that in most cases flagellin is the only protomer, and the smallest protomer of the flagella and consists of a single peptide chain. However, two chemically very similar but distinguishable protein components have been found in the flagella of a few organisms[4]. It is not yet possible to decide whether this is due to a macroheterogeneity or to a microheterogeneity of the material examined[4]. In some Salmonella bacteria, however, two structural genes for the biosynthesis of flagellin have been found to occur together, one of these becoming active and the other inactive according to the phase (cf. Refs. [4, 9]).

The carbohydrate component that is sometimes detected in small quantities in flagellin preparations is probably due in most cases to contamination with cell-wall polysaccharides, which, in contradistinction to the H antigens of the flagella, are the bacterial O antigens[38]. All flagellins

have a characteristic amino acid composition. They never contain cysteine or tryptophan, they rarely contain proline or histidine, and they usually contain little methionine, tyrosine, and phenylalanine. Another striking feature is a relatively high content of nonpolar, hydrophobic amino acids. The rare amino acid ε-*N*-methyllysine has been found in some flagella[4, 34, 36]. A number of lysines localized in certain regions of the peptide chain are presumably methylated enzymatically in the completed flagellin molecule[36]. Immotile mutants with perfectly straight flagella have been produced from a wild type of *Bacillus subtilis* having normal helical flagella by treatment with mutagenic reagents[39, 40]. In every case the mutation resulted in the identical single amino acid substitution, *i.e.* in replacement of the original alanine by valine.

It is possible (cf. Section 5) to keep flagellin in solution in the monodisperse state for long times in neutral buffers[18, 29, 31]. This allows the measurement of shape and structure parameters of the flagellin. The radius of gyration and the Stokes radius of the isolated flagellin of *Proteus mirabilis* in neutral solution have been measured in this way (by X-ray small angle scattering and from its elution behavior on Sephadex gels), and were found to be about 40 and 37 Å respectively[17, 18]. For comparison, the radius of gyration and the radius of a compact sphere having the molecular weight and partial specific volume of flagellin would be only 17.5 and 23 Å respectively.

The sedimentation constant s is also very much smaller and the viscosity number $[\eta]$ larger than one would expect for a spherical solvated particle. Flagellin thus behaves hydrodynamically as an elongated rigid ellipsoid of revolution with an axial ratio of about 9:1[18]. Flagellin gives roughly the same scattering as a row of elongated geometric bodies having a somewhat smaller axial ratio and an average length of about 160 Å. On the assumption that the shape of the isolated flagellin is not very different from that of the polymerized flagellin, the fine-structure model was constructed from such equivalent scattering and wedge-shaped subunits (Fig. 7)[18].

It has been shown by optical rotatory dispersion (ORD) and circular dichroism (CD), two optical methods that yield information on the content of secondary structures in proteins, that at roughly physiological pH values and salt concentrations and at room temperature, the conformational and structural states of the isolated flagellin are independent of its previous treatment[18, 27, 41–44]. From its molar ellipticity of -8800 degrees·cm^2/decimol per mean amino acid residue at 220 nm, the content of α-helical structural regions in the flagellin of *Proteus mirabilis*[45] can be estimated by the usual methods to be about 25% (cf. other values in Refs. [4, 41–44]).

5. The *in vitro* Reaggregation

Flagellin can reaggregate *in vitro* to form long helical filaments that are practically indistinguishable from the original native flagella on examination in the electron microscope, from their X-ray diffraction pattern, or from their optical properties. This self-organization process is sometimes referred to as polymerization, though it does not involve the formation of covalent bonds. The flagellin from *Bacillus pumilus*, for example, polymerizes relatively rapidly in 0.02 M phosphate buffer between pH 5.4 and 5.6 (the isoelectric point of the flagellins is around 5) at 26 °C to form flagella-like filaments. Between pH 4 and 4.9, on the other hand, it forms linear structures, which are also converted irreversibly into helical filaments when the pH is raised[30]. Flagellin also polymerizes spontaneously in semiconcentrated neutral solutions of certain "salting-out" anions (*e.g.* CO_3^{2-}, F^-, SO_4^{2-}, HPO_4^{2-}) [10, 46, 47]. In this "salt polymerization", the formation rate and the number of fragments increase with the concentrations of flagellin and of salt in a molarity range between 0.4 and 1.2, while the length of the filaments ultimately formed decreases. From the concentration dependence of the length and formation rate of the filaments it has been estimated that about three monomers must come together for nucleation[10, 47].

Around pH 7 and in the presence of about 0.15 mol/l of sodium chloride, flagellin solutions remain monodisperse and stable for long periods, and detailed investigations can therefore be carried out on dissolved native flagellin (cf. Section 4). In the presence of flagella fragments (seeds) about 0.3 μm long, which can be prepared by ultrasonic treatment, on the other hand, the flagellin monomers polymerize relatively rapidly on these seeds under these conditions[31]. In this "seed polymerization" the fragments grow exclusively at the tail end (cf. Fig. 6)[27]. The polymerization rate is directly proportional to the number of seeds added. It increases with increasing monomer concentration up to a limiting or saturation value of about 15 mg of flagellin/ml, when the time between the incorporation of two monomers is about 0.3 s[10].

The stability of the flagella and the ability of flagellin to undergo seed polymerization show that the isolated flagellin in 0.15 M sodium chloride solution at about pH 7 and at room temperature is in a kinetically inhibited state; only the helical filaments are thermodynamically stable under these physiological conditions. Thus while seed formation is extremely slow and difficult, relatively fast chain growth occurs in the presence of seeds added as such or spontaneously formed in another solvent. Like *e.g.* the G-F actin system[48, 49], therefore, this flagella-flagellin system exhibits characteristic properties of a cooperative aggregation, such as are observed *e.g.* in crystallization or other phase transitions[50, 51].

In the theory of linear (or helical) cooperative aggregations[48, 50–52] it is assumed in the simplest case that above a certain nucleus size, all subsequent elementary equilibrium growth steps can be described by the same equilibrium constant K. Only the first nucleation steps should be thermodynamically less favorable, since the rate constants of the nucleation may be very much smaller than those of the elongation of the seed. This may be so *e.g.* because the monomers taking part must change their conformation together before or during the seed formation (see below) or because there are fewer bonding sites available per monomer in the seed than in the larger aggregates (cf. Ref. [48]). Though the smallest stable nucleus may

be a higher oligomer (see above), the more difficult nucleation step will be taken here as dimerization, with the dimerization constant $K_2 = \sigma \cdot K$ (after *Winklmair*[53]). The more the monomer needs the seed as a conformation or growth matrix, the smaller is the cooperativity parameter σ. The precise state of such a monomer-polymer equilibrium system then depends on σ and K (and hence on external parameters such as the pH, ionic strength, nature of the salts, temperature) and on the total protomer concentration c_t, since the reactions involved are bimolecular. In the case of very high cooperativity ($\sigma \ll 1$), the solution at $K \cdot c_t < 1$ contains almost exclusively monomer, whereas at $K \cdot c_t = 1$, *i. e.* at the critical micelle concentration $c_t = 1/K$, polymer suddenly also appears[48,53].

It has unfortunately not yet been possible to carry out true equilibrium measurements on flagellin (unlike in the case of actin[49]) to test the theory, since the association takes place extremely slowly close to equilibrium and the true equilibrium is therefore difficult to determine. In one case, however, there is a report of a "critical flagellin concentration" for Salmonella flagellin[10]. Thus it was observed viscometrically that at 40 °C, seeds depolymerized in solutions with flagellin concentrations of less than 0.6 mg/ml, whereas they were stable at a flagellin concentration of 0.6 mg/ml, and grew at the expense of the monomeric flagellin at higher concentrations. However, there is certainly no physically uniform flagellin species present at the experimental temperature of 40 °C. Thus with rising temperature the α-helical component of flagellin decreases rapidly above 27 °C[18] or 35 °C[41]. Dilatometric studies have also shown a change in the structure of unfolding of flagellin in this temperature range. During the polymerization of flagellin, the molar volume changes by +150 ml/mol of flagellin below 28 °C, and by twice this value above 35 °C[54]. The polymerization rate increases with rising temperature below 27 °C, but decreases again above this temperature[17,30,54]. In a semilogarithmic plot of the initial polymerization rate[17] or of the half life of the polymerization[54] against the reciprocal of the temperature, the Arrhenius activation energy of the growth step was found from the slope of the linear graph (between 4 and 20 °C) to be 8 to 10 kcal/mol. Apparently negative activation energies are found at higher temperatures because of the negative temperature coefficient of the polymerization rate (see above). Attempts have been made to explain this by a strongly temperature-dependent reversible pre-equilibrium between active and inactive forms of the monomer[17,54].

The CD and ORD spectra of flagella are similar to the spectra of flagellin, apart from a slight red shift[42,45]. However, the molar ellipticity per mean residue of the flagella at 220 nm, with a value of about −15000 degrees cm²/decimol[44,45], is 1.7 and 1.5 times the value for isolated flagellin in physiological buffers and in polymerization-promoting 0.9 M ammonium sulfate solution respectively[44,45]. This marked increase in the optical activity during polymerization is often interpreted as evidence of a conformational change that the monomer must undergo before, during, or after incorporation into the flagellum[4,10]. Without quantitative calculations or measurements in systems of similar complexity, however, it is difficult to estimate the extent to which the helical arrangement and close packing of the optically active protomers in the flagellum (see Fig. 7) can influence or increase the rotational strength of the electronic transitions (cf. cholesterol phases[55]). The particle scattering, which has been discussed and measured for very large optically active particles[56,57], does not appear to be the cause of these optical effects[10,44], particularly since this should in fact lead to smaller amplitudes (but cf. Ref. [4]).

The Salmonella and Proteus flagellins, with about 380 amino acid residues, have arginine at the carboxyl end[34,36,58]. After enzymatic cleavage with carboxypeptidase B the flagellin largely loses its ability to undergo spontaneous and rapid polymerization *in vitro*[45,58]. In the flagellum, on the other hand, this C-terminal arginine is resistant to enzymatic attack. The carboxyl terminus must therefore be localized in or near the contact surfaces between the flagellin protomers. Most of the tyrosine and methionine residues (5 to 10 and 2 to 10 respectively, depending on the flagellin species) are presumably also situated at the protomer bonding surfaces, since they are accessible to typical modification reagents or to hydroxide ions in the isolated flagellin, but not in the polymeric flagellum[4,17,36,43,59]. A particularly large number of apolar amino acids must also be involved in the intermolecular bonds, the content of such amino acids in flagellin being unusually high (see Section 4).

Typical indications of such hydrophobic bonds, in addition to weakly positive molar reaction enthalpies ΔH and strongly positive changes in molar volume ΔV, are strongly positive values for the molar reaction entropy ΔS. On association of peptide monomers, the number of contacts between hydrophobic groups and surrounding water molecules decreases, with the result that the latter gain increased freedom of movement. The resulting positive reaction entropy in particular favors the protein aggregation in accordance with the fundamental thermodynamic relation between ΔH and ΔS on the one hand and the molar free enthalpy of reaction ΔG on the other ($\Delta G = \Delta H - T\Delta S$)[60,61]. The considerable increase in the molar volume on polymerization of flagellin (see above) is also an indication of the participation of such hydrophobic intermolecular interactions in the flagellum. Calorimetric studies being carried out at present[62] will show how far this is supported by the enthalpy and entropy effects.

6. The Polymorphism

As was mentioned in Section 2, flagella with polymorphous helical forms have been found in bacteria, these forms being referred to as normal (n), short-wave or curly (c), and straight (s) (see Fig. 8). *Asakura et al.* have investigated the properties of flagellins that decide the flagella form or that are responsible for conformational adaptation by seed polymerization experiments with uniform or mixed solutions of n, c, and s flagellins[10,33,63]. On polymerization of a small quantity of n or c flagellin with many long c or n seeds, the newly grown piece of filament assumed the curly form in both cases. In solutions containing very

large quantities of n, c, or s flagellin together with a few short seeds (regardless of type), on the other hand, the form of the polymerizing filaments was largely determined by the nature of the monomer[33].

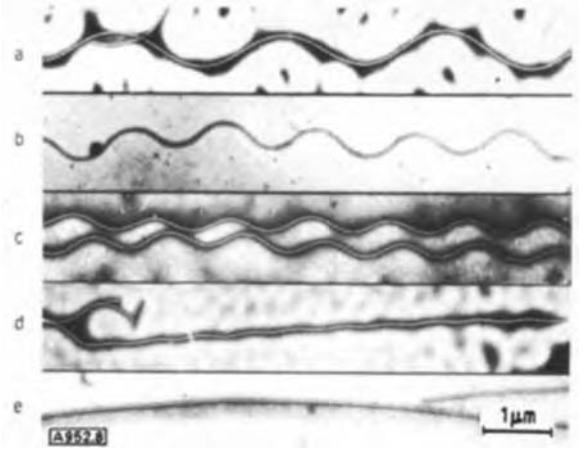

Fig. 8. Electron micrographs of the five stable types of filaments, obtained by copolymerization of n and s flagellins [10] in the ratios: a) 1:0 (normal (n), type I); b) 9:1 (type II); c) 1:1 (curly (c), type III); d) 1:9 (type IV); e) 0:1 (straight (s), type V). The photographs were kindly supplied by *Dr. S. Asakura*.

The filaments formed in this way were measured under the electron microscope and characterized by the contour length L per one wavelength λ and by their maximum wave height h. In the mixed polymerization of n and s flagellins, after the addition of a very small number of short seeds, five clearly distinguishable filament forms are observed, depending on the mixing ratio (cf. Fig. 8 and Table 1); whereas homogeneous solutions of n or

Table 1. Shape parameters of the filaments obtained by copolymerization of n and s flagellins (after [10], cf. text and Fig. 8).

	Type				
	I	II	III	IV	V
Contour length L [µm]	2.70	1.54	1.15	0.63	0
Wavelength λ [µm]	2.49	1.36	1.08	—	0
Wave height h [µm]	0.45	0.31	0.16	0.027	0

of s flagellin gave almost exclusively filaments of normal wavelength (Fig. 8a, type I) or straight filaments (Fig. 8e, type V), mixed solutions (n + s) gave three other undulating (helical) types of filaments II, III, and IV (Fig. 8b, 8c, and 8d). Since the wavelength and the contour length decrease with increasing content of s flagellin, the perfectly straight s flagella correspond to the limiting case of infinitely small L and λ values[10]. Similarly, the copolymerization of c and n flagellins gave, in addition to normal flagella, two shortwave types of filaments resembling types II and III (Fig. 8 and Table 1), depending on the mixing ratio[10,63].

It is interesting to note that the filaments formed by copolymerization were nearly always of the same form throughout, though because of their different polymerization rates the various types of flagellin were not quite uniformly distributed in the filaments. On rare occasions, under certain external conditions, reversible transformations between the n and the c forms were observed for filaments of pure n flagellin; in every case, the filaments as a whole assumed one of these forms[33] ("all-or none" case[61]). Apparently, therefore, it is energetically most favorable for the filaments to be of a uniform type over their entire length. Each flagellin species can be incorporated into several stable types of flagella. As their content in the mixture increases, however, the flagellins increasingly impose their preferred form on the filaments (see Fig. 8).

7. The *in vivo* Growth

Motile bacteria can develop complete flagella about 10 µm long within at most a few generations[4]. Under favorable growth conditions, for example, Salmonella bacteria can lengthen their flagella by about 0.15 µm/min at 37 °C[4,64]. It was mentioned in Section 5 that in seed polymerization *in vitro*, flagellin adds exclusively to the incised tail ends of the filaments (see Figs. 3 and 6). It has recently been shown by two elegant experiments that the *in vivo* growth of the flagella also takes place at the incised distal end, *i.e.* at the end remote from the bacterial cell. In the first experiment, use was made of the observation that certain normal strains in a complete medium containing *p*-fluorophenylalanine instead of phenylalanine produce only curly flagella instead of the normal flagella[65]. When the bacteria were transferred from a normal culture medium into one containing *p*-fluorophenylalanine, the growing flagella suddenly became curly in their distal regions. These regions must therefore have been synthesized last[66]. This surprising result has recently been confirmed by autoradiographic studies, in which the bacteria were incubated during their growth phase first in a cold medium and then in a tritium-labeled medium[66]. Evaluation in the electron microscope showed that film was blackened mainly by the parts of the filaments remote from the flagellar hook; these were therefore the labeled parts, and must have been formed last.

It is not yet known how the flagellin protomers are transported from the cell body to the often very distant growth zones of the flagella *in vivo*. In another experiment[67] the straight s flagella of immotile mutants were shortened by ultrasonic treatment, and relatively concentrated solutions of n flagellin were then added. After a time, actively motile bacteria were observed in the solution, some having heteromorphous flagella with a straight proximal part and a normal distal part, but most with completely normal flagella. The added n-flagellin must therefore have been polymerized from the solution onto the stumps of the flagella. It is almost certain, however, that the natural formation of flagella does not involve secretion by the cell of free dissolved flagellin into the open surrounding medium followed by growth after the fashion of seed polymerization, since free flagellin has never been detected in bacteria suspensions outside the cells. Moreover, the high *in vivo* growth rate observed at 37 °C was measurable *in vitro* only at room temperature and with relatively high

flagellin concentrations (approx. 5—10 mg/ml)[10,33] (cf. Section 5); the incorporation mechanisms *in vivo* and *in vitro* are therefore presumably different. It must be assumed that after its biosynthesis at the basal membrane[4] the flagellin is released into the flagellum channel detected by various workers (Section 3 and Fig. 5), where it "diffuses" actively or passively, according to the concentration gradient, to the distal end of the flagellum, and is incorporated directly there.

8. The Helix Form

In the fine structure model (Fig. 7), which should demonstrate among other things the probable short-range order within a short piece of filament, the flagellum filament is treated as a straight rod similar to the tobacco mosaic virus or the bacterial pili[1]. As described earlier (Section 2), however, most flagella are twisted into a helix both in the functional state and in the isolated state. Simple symmetry considerations show that because of the superhelical structure of the flagella the positions occupied by the individual, chemically identical flagellin subunits cannot be completely identical but since the proximity relations are only similar may occupy only quasi-equivalent positions in the flagellum[68]. This should also be taken into account in a refined flagella model that is nevertheless as simple as possible.

Klug[68] assumes two sets of protomer bonds with roughly equivalent energies, either of which alone leads to straight, easily distinguishable cylinders. Simultaneous (partial) saturation of both sets of bonds in a structure, on the other hand, is possible only in a cylinder whose axis is deformed into a helix. It will be shown below with the aid of another model how a tube consisting of many very similar structural units can assume several distinguishable superhelical forms according to the arrangement of these units. Following a suggestion by *Asakura*[10] it is assumed that the subunits can occur essentially in only two distinguishable forms (conformations) in the superhelix (flagella helix).

When the planar regular surface lattice[69] (Fig. 9a) is rolled up, one obtains the lateral surface of a straight cylinder (Fig. 9b), in which, by analogy with the fine-structure model (Fig. 7), subunits with schematized square cross sections are arranged in eight axially parallel lines (A to H). For simplicity, the subunits or protomers in neighboring lines are not shown displaced in relation to one another. They are completely identical or equivalent in their form and, apart from the two arbitrarily chosen ends, in their position and proximity relation.

Fig. 9. a) Surface lattice, and b) corresponding cylinder model.

Let us now consider the case in which all the protomers of one of the artibrarily chosen longitudinal lines (*e.g.* E) assume a somewhat longer and simultaneously angled form. The protomers of the other lines should try to preserve the original (shorter and square) form with retention of a closed tube surface; this is best achieved by the A line, which is furthest away from the E line. The corresponding planar surface lattice is shown in Figure 10a. The

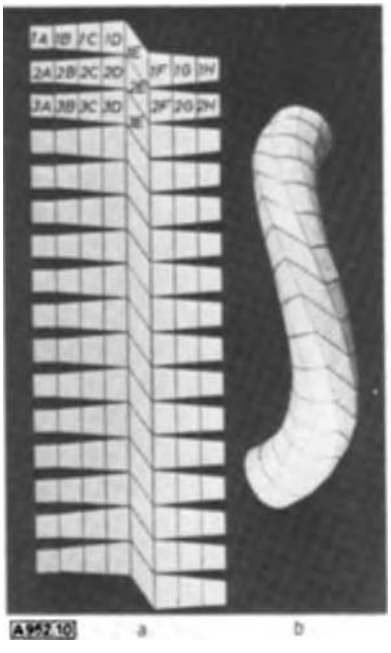

Fig. 10. a) Surface lattice, and b) corresponding superhelix model: for relations between Figures 9a and 10a see text.

introduction of the new type of protomer has the following consequences: its angled form leads to a displacement in the individual numbered transverse lines, so that these and also the longitudinal lines are no longer perpendicular to and parallel to the axis of the cylinder when the lattice is rolled up (Fig. 10a), but are oblique to the axis (Fig. 10b). At the same time, the cylinder will roll up because of the differences in length of the "longitudinal" lines. Since the longest (shortest) line of protomers always tries to lie along the outer, longer, (inner, shorter) line of curvature, the cylinder, because of their oblique course, does not become a torus, but is deformed into a large helix (Fig. 10b). The parameters of the helix are conclusively given by the displacement and the differences in size of the subunits. However, these now have only similar proximity relations, and their shapes and contact surfaces even in the central sections of the tube are no longer exactly identical, but are only quasi-equivalent.

If the protomers of another neighboring line (*e.g.* D in Figure 11a) now assume the longer angled form, an even tighter helix with a smaller pitch and a smaller diameter will be formed (Fig. 11b), and so on. Finally, if all the lines are transformed, because of the identity of the subunits, regardless of their (uniform) shape and size, one again obtains a straight cylinder (Fig. 12b), whose "longitudinal" lines A—H make a greater angle with the axis of the tube than those of any other cylinder or superhelix, and whose dimensions are different from those of the original straight cylinder (Fig. 9b).

For simplicity, the square arrangement of the protomers has been chosen in this model instead of the hexagonal arrangement found in the flagella (cf. Section 3 and Fig. 7). However, the latter could be introduced with no fundamental changes by mutual displacement of the "longitudinal" lines. This simple model now offers a plausible explanation for the polymorphism and the biplicity of the flagella. It shows how with a single protomer species, which can exist in only two forms (conformations), it is possible to build up several helical structures as well as cylindrical structures, depending on the occupation ratio, these helical structures differing from one another in contour length L, in pitch λ, and in the diameter of the helix (roughly equal to h).

In the superhelix models (Figs. 10 and 11), the "longitudinal" lines A to H include one or two longer than the others (D, E), one or two shorter than the others (A, B), and several lines of intermediate length, which run round the tube in large spirals (long-range helix). These spiral lines presumably correspond to the "longitudinal" flagellin lines (Fig. 7), which are probably not parallel to the axis of the filament, but inclined to it *e.g.* at an angle of 1 to 2° in the normal helical flagella[7]. The periodic disturbances in the longitudinal stripe pattern of negatively

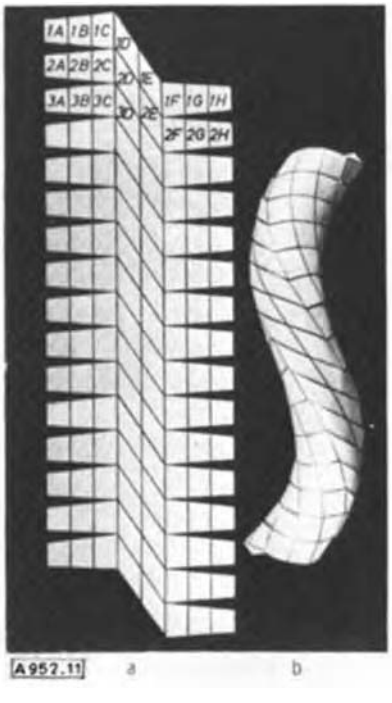

Fig. 11. a) Surface lattice, and b) corresponding superhelix model; for relations between Figures 11a and 10a see text.

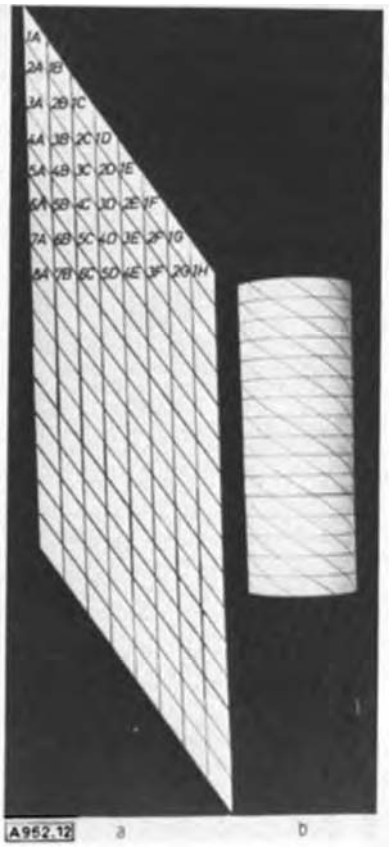

Fig. 12. a) Surface lattice, and b) corresponding cylinder model; for relations between Figures 12a and 11a see text.

stained flagella (see Fig. 4) have been satisfactorily explained as resulting from the superposition of the protomer strands on the upper and lower sides of the flagella, which form an acute angle with one another[7].

It has recently been shown by optical diffraction and optical filtering on electron micrographs of straight flagella that the (eleven[19]) protomer lines in straight flagella run at the fairly large angle of about 7° to the axis of the flagellum[19] (cf. Fig. 10d). For the sake of clarity the size relationships have been completely distorted in the models (Figs. 9 to 12). Thus the calculated number of protomers per turn of the helix is 4000 for normal flagella, whose helix diameter of 3400 Å[10,70] is many times their tube diameter of about 150 Å. Moreover, the protomers of the longest (outer) and of the shortest (inner) lines differ by only 1 to 2% in the n flagella. Because of this small, systematic variation in the regular bonding pattern (which is the definition of quasi-equivalence[68]) the c and n flagella acquire a helical structure that is evidently very much more stable than straight cylinders (with an equivalent arrangement of the protomers). Since the flagella are mostly in a uniform helical form, very strong cooperative proximity interactions must exist between the individual protomers[50].

9. The Movement of the Flagella

The model described above also provides a useful hypothesis for the manner in which motion occurs within the

flagellar filament. Since the filament evidently possesses no ATPase activity, it must be assumed to serve purely as a passive conductor of a helical wave motion induced by chemical energy in the basal region[68]. This requires a high cooperativity not only within the "longitudinal" lines, but also (*via* the hook portion) between these lines and the corresponding structures in the basal region. These structures could determine the conformations of the individual lines, so to speak, as allosteric effectors[71] (cf. end effects in linear biopolymers[50]). If *e.g.* the individual lines in the helical models (Figs. 10 and 11) were forced in cyclic succession into the longer angled structure, these lines would strive in turn to position themselves on the "outside" of the superhelix. The helical filament could thus pass through several microscopically indistinguishable and energetically fully equivalent (degenerate) microscopic states, which are presumably separated from one another only by low activation barriers (this is also indicated by the polymorphism). In this way undamped helical waves could travel along the flagellum to the tip[6, 7, 68], in agreement with observations on flagellar bundles (Section 2). This process would also lead to an apparent rotation of the helical filaments in relation to the base[5, 7, 72], the individual protomers retaining their orientation in space during the motion. Unlike a free rope with a plane wave traveling along it, however, a free helix could not produce a forward thrust by such a rotation; because of the conservation of angular momentum it would appear to be stationary[5]. Attachment to the large bacterial cell bodies prevents this free rotation and, on the contrary, allows by rotation, at different speeds, of the flagella on the one hand and of the cell body on the other, the production of a forward thrust[5, 6] that is sufficient, according to calculations, to propel the organisms at the observed speeds of up to 50 μm/s. This involves only viscous forces and not *e.g.* inertial forces[6].

In the author's opinion the flagellar hook (Section 3) plays an important part in connection with the structure and function of the filament. It is thought that the filament arises perpendicularly from the membrane and passes perpendicularly through the cell wall, and that only then does it assume the helical curvature. The curvature of the flagellar hook, which is assumed to be planar, could fulfill this function very satisfactorily. In the (apparently) rotating helix, the protomer line that is outermost in the helical part, *i.e.* that forms the longest helical line, should always be shortened in the hook; in other words, its structural and functional pattern should be exactly reversed. If the hook, which is situated outside the cell, is essential to the structure and function of the flagella, it must also be the first part to be formed if short flagella that are not yet complete are to be capable of functioning. This could be one reason for the unique fact that the flagella grow at their tips (Section 7).

10. Outlook

It must be pointed out that it was frequently necessary to use hypotheses in the foregoing discussion. Very many questions still remain unanswered, examples being those of the position and nature of the flagellin biosynthesis and the conversion of chemical energy into mechanical energy. The initiation, control, and coordination of the movement of the flagella is naturally still a complete mystery. One is inclined to localize this function in the basal region and the adjoining cell membrane. This must also be the seat of conduction mechanisms between the detect able chemoreceptors[73] and the motion centers, which are essential to the chemotactic and phototactic behavior of many bacteria, *i. e.* their ability to respond to nutrient gradients or light gradients by controlled reflexes[74]. The apparently simple bacterial locomotion organelles thus in reality form an extremely complicated structural and functional chain, about whose individual links little is known as yet. In the helical flagellar filament, nature may have presented us with a relatively simple structure that shows in exemplary fashion how information can be transmitted in the cell *via* linear or two-dimensional (membranous) protein aggregates by non-electrical means, *i. e.* by cooperative interactions in allosteric protein structures. At all events, structures similar to that of the flagellar tube have been found in mechanoreceptors, chemoreceptors, and photoreceptors[75–78].

I am grateful to Professor J. Engel and Dipl.-Chem. S. Knof for their criticisms and stimulating discussions.

Zintl Phases: Transitions between Metallic and Ionic Bonding

By Herbert Schäfer, Brigitte Eisenmann, and Wiking Müller[*]

Experimental studies on compounds of alkali and alkaline earth metals with semi- and metametals have considerably broadened the basis for a discussion of the transition from metallic to ionic bonding. Current interest is focused mainly upon the elucidation of the principles governing the structure of such compounds which are subject to a wide range of variation within this class of materials. A new definition of the term Zintl phase is proposed after consideration of available findings.

1. Introduction

Pauling and *Mulliken* have shown that the bonding in certain classes of inorganic compounds can be regarded as a transition from atomic to ionic bonding. Introduction of the electronegativity concept enabled chemists to describe the transition atomic bonding—ionic bonding and to correlate numerous individual observations.

No such considerations have been made for the transition from atomic bonding to metallic bonding. The first step in this direction is found in *Pauling*'s views on the metallic bond. Studies on complexes having direct metal-metal bonds by X-ray and magnetic methods have revealed interesting new facts. However, these have also failed to indicate new general guidelines so far.

The transition from metallic bonding to ionic bonding is only poorly characterized owing to a long period of comparative neglect. Although efforts were repeatedly made to incorporate ionic bonding contributions into descriptions of bonding even in early publications on metals and alloys, a systematic study of this transition was thwarted by experimental and methodological problems posed by the most suitable systems. In recent years its study has resulted in a broader knowledge of inorganic compounds and opened up new aspects in treatments of bonding in intermetallic phases, which is attracting increasing interest on the part of modern bond theory.

2. Choice of Material: Zintl Phases

According to *Pauling*, the polarity of a covalent bond can be estimated from the difference in electronegativity of the participating atoms. If this is accepted at least qualitatively in spite of many justified objections for the case of a metallic bond, then transitions between metallic bonding and ionic bonding may be expected in those intermetallic compounds whose components exhibit considerable differences in electronegativity. This applies in particular to compounds of the alkali and alkaline earth metals with the electronegative metals, metametals, and semimetals of Groups IIIB to VB and the transition metals having almost filled d shells. However, the latter type of compounds have so far been only poorly characterized with regard to their structure, thus precluding any generalizations. They will consequently not be discussed further

in this report. The phases known to be formed by alkali and alkaline earth metals with the other B-group elements are listed in Tables 1 to 9. High-pressure, high-temperature, and ternary phases have been omitted, as have compounds of the less electropositive element beryllium and the hitherto hardly studied compounds of radium.

The compounds of alkali and alkaline earth metals with elements of Groups VIIB and VIB are usually typical salts with regard to their physical and chemical properties and their structures. The compounds with elements of Group VB progressively discard the characteristics of ionic bonding with increasing atomic number of the electronegative component. They become increasingly metallic in appearance and occur in stoichiometries that are not readily reconciled with valence rules for salts. This tendency is even more pronounced in compounds with Group IVB and IIIB elements and transition elements.

The transition between ionic bonding and metallic bonding in this class of compounds was first studied systematically by *Eduard Zintl* who prepared numerous intermetallic compounds listed in Tables 1—9 for the first time and investigated their structures. In recognition of his contribution to their study, *Zintl*'s obituary by *Laves*[11] listed all intermetallic compounds of Tables 1—9 obeying rules of valence—according to the views of the day—under the heading "Zintl phases".

In so doing he particularly emphasized two criteria:

"a) Zintl phases crystallize in "non-metallic" typically salt-like structures (antifluorite, anti-Mn_2O_3, anti-La_2O_3, antitysonite, anti-BiF_3 lattices).

b) Zintl phases are always those phases of the alloy system concerned which contain the greatest amount of non-noble components."

The concept of Zintl phases was thus closely defined and coupled particularly *via* criterion b) with the condition that the upper limit of the alkali or alkaline earth metal in such compounds is determined by the maximum negative valence of the more electronegative element. However, this has proved to be inapplicable. Nor was any account taken of all those phases in which the anions are mutually linked by way of directional bonds as were frequently found in the ensuing period.

The difficulties arising from *Laves'* original definition of Zintl phases have led to repeated attempts at redefining the concept. It is usually approached crystallographically by metallurgists and crystallographers, who designate only cubic phases crystallizing in the NaTl lattice as Zintl phases. This covers only a very small group of compounds. In the language of the chemist, however, the term nowadays embraces intermetallic phases to which a pronounced ionic bonding component must be assigned. This limitation, while in accord with the aims of *Zintl's* work, has the disadvantage of being imprecise. Thus ionic bonding contributions were also discussed for Hume-Rothery[210] and for Laves

phases[211]. A new definition of the term "Zintl phases" therefore appears desirable and a relevant proposal will be presented at the close of this survey.

3. Preparation

The intermetallic compounds to be considered are generally obtained by fusing the elements together under an inert gas or in air under a protective salt melt. Subsequent purification is possible only in favorable cases (zone refining). When an unknown system is examined for new phases the method usually yields mixtures of compounds. The ratio of components must then be varied while a phase diagram is recorded until a homogeneous product is obtained. With metastable and peritectic compounds the conditions of preparation represent additional experimental parameters.

This time-consuming and tedious work is simplified by the particularly favorable circumstance that all metals and intermetallic compounds are deposited in crystalline form

from the melt. Carefully conducted cooling and annealing procedures often permit isolation of the phases formed from the melt as coarse crystals so that single crystals can be broken out of the reguli and their composition determined by modern microanalytical methods.

Methods of preparing intermetallic phases other than direct synthesis from the elements are usually limited in their application to particular systems and therefore of comparatively limited importance. Mention should be made of:

1. Direct reduction of generally oxidic compounds by carbon or hydrogen to the corresponding intermetallic compounds, *e.g.*:

$$2\,CaCO_3 + 4\,SiO_2 + 5\,C \rightarrow 2\,CaSi_2 + 7\,CO_2 \quad [144]$$

$$CaO + 2\,Pt + H_2 \rightarrow CaPt_2 + H_2O \quad [212]$$

2. Preparation in liquid ammonia. This technique is due mainly to *Zintl* who exploited the known solubility of alkali and alkaline earth metals in liquid NH_3 for the synthesis of compounds of these elements with other metals. For instance, a solution of Na in NH_3 is able to dissolve Pb metal, the reaction being considerably promoted by fine division of the reactant. For experimental purposes, therefore, a dissolved salt of the electronegative metal, *e.g.* PbI_2, ZnI_2, $Hg(CN)_2$, or even As_2S_3, in liquid NH_3 is reduced with a similar solution of Na. The resulting finely divided metal reacts in the same solvent to give the intermetallic compounds[43,114].

3. Amalgam metallurgy. This technique utilizes the solubility of numerous metals in mercury to prepare intermetallic compounds, the mercury being distilled off after reaction of the dissolved metals[213–215]. The method was developed only recently and has not yet been exploited to its limits of applicability. It is comparable with the method of preparing intermetallic compounds in a copper or aluminum matrix as already used by *Lebeau et al.*[216] and *Hönigschmid*[217].

Mainly physical methods are used in recording phase diagrams and testing for homogeneity: microscopic investigations, thermal analysis, determination of thermal conductivity, magnetic measurements, X-ray techniques, and recently in particular investigations with microprobes. In addition to classical analysis, X-ray structure determinations frequently prove of value in establishing the stoichiometry of an unknown phase. It is only with their help that exact stoichiometric studies could be performed for numerous compounds of highly complicated composition.

4. Characterization of the Bonding State

4.1. Physicochemical Criteria

The known characteristic properties of salts are employed in characterizing ionic bonding contributions. Such a property is the solubility in polar solvents. The phases discussed here cannot be dissolved without decomposition. However, in his studies in liquid NH_3 *Zintl* was able to show that in addition to halogens and chalcogens the elements of Groups VB and IVB are in principle able to form anions too. If *e.g.* Na is allowed to react with PbI_2 in liquid NH_3 as described in Section 3, and an excess of Pb salt is employed then deeply colored solutions are obtained. Measurement of transport numbers in these solutions indicate the presence of polyanions, *e.g.* Pb_9^{4-}, thus revealing the polar character of such compounds[43,114]. However, they are only stable as ammonia adducts; on evaporation of the solvent they decompose with destruction of the polyanions. Those elements shown by such experimental findings to be capable of occurring in a negatively charged state in solution are bounded by the so-called Zintl line in the Periodic Table. This line of demarcation runs between Groups IIIB and IVB. Recently, *Kummer et al.*[218] showed that analogous reactions also occur in aliphatic diamines. It proves particularly fortunate that crystalline compounds, *e.g.* $Na_4Sn_9 \cdot 6$ en, could be obtained in this way which will probably allow the structure of "Zintl polyanions" to be elucidated by X-ray methods in the near future.

The heat of formation of these compounds can also be employed in characterizing their bonding. Whereas alloy formation between metals of low electronegativity difference involves only a low heat tone, the heats of formation of Zintl phases are in some cases comparable with those of salt-like compounds. They can therefore be regarded as an indication of polar bonding contributions. Available experimental evidence is still too fragmentary for a systematic evaluation.

A similar lack of completeness attends the existing data on characteristic physical properties arising from the bonding in compounds of such systems. Their electrical conductivity and magnetism are known only in rare cases and provide no basis for systematization.

In contrast, the density has be measured for many of the compounds listed in Tables 1—9. *Biltz* had reported that the formation of heteropolar compounds from the elements is associated with a particularly pronounced volume contraction. Such effects are also noted with intermetallic compounds between components of widely differing electronegativity. In a systematic evaluation of the data then available *Biltz et al.* showed that in intermetallic compounds the alkali and alkaline earth metals undergo a volume contraction to a limited value of the volume ("increment") which is largely independent of the composition of the alloy[219]. These values were subsequently confirmed, in some cases several times, in other systems[72,212,236]. Table 10 lists the increments, the atomic volumes, and the percentage contractions. The values clearly demonstrate that the reduction in volume on formation of alkali and alkaline earth metal compounds with elements of Groups IB and IIB substantially involves the non-noble component while the noble metals undergo only relatively slight contraction if any. This accords with the observation of interatomic distances in compounds having alkali metal-alkali metal or alkaline earth metal-alkaline earth metal neighbors that are sometimes even considerably smaller than those in the elements. In terms of ionic bonding this preferential contraction of the alkali and alkaline earth metal could be attributed to loss of electrons and thus to the transition to the smaller cation. Another feature

Table 10. Comparison of atomic volumes with the increments in intermetallic phases of the alkali and alkaline earth metals with B-group elements (values taken from *Biltz* [212]).

Element	Atomic volume	Increment	% Contraction	Element	Atomic volume	Increment	% Contraction

				Bi	21.0	?	-

of Table 10 is that the elements of Groups IIIB and IVB also suffer contractions on compound formation which in some cases, *e.g.* Ge, Si, is hardly less pronounced than for the alkali or alkaline earth metals. On the other hand, crystal structure determinations which are readily available in particular for systems of the two elements given indicate that larger atomic distances than in the element are by far more common in compounds having Ge—Ge or Si—Si bonds. These two findings would appear contradictory at first glance. It should, however, be borne in mind that considerable covalent bonding is already present in the lattices of the semi- and meta-metals which results in atomic arrangements that are very bulky owing to directional bonding. On compound formation these voluminous lattices are broken open and considerably denser atomic packings become possible although the bond lengths are greater.

4.2. Spectroscopic Studies

Spectroscopic methods should, at least in principle, permit measurement of charge shifts between the components corresponding to ionic bonding contributions. The method of choice is X-ray spectroscopy, which has already provided valuable information for other classes of compounds[220].

When an atom enters into chemical bonding the energy of the inner shells is also modified. For instance, if the atom acquires a positive charge on compound formation the inner electrons become more firmly bound while acquisition of a negative charge leads to the opposite effect. The electrons occupying different levels all change their energy in the same sense but not by the same amount. If the characteristic X-ray spectrum of the atom is recorded on a high-resolution spectrograph the spectral lines are found to be shifted slightly relative to those recorded for the elemental state: they display a chemical shift. The shifts of the Kα line of Third Row elements are particularly readily measurable and have been the object of recent detailed studies. Accordingly, the Kα line of an element shows an increasingly pronounced short-wave shift with increasing oxidation number and increasing electronegativity of its bonding partner. However, it has also become apparent that additional factors, such as changes in coordination number, the shape of the coordination polyhedron (hybridization), and even the bond lengths *etc.*, are also operative in determining the chemical shift so that the position of the Kα line recorded for the element in question cannot be taken as the reference point for zero charge[221, 222]. Owing to these additional parameters an estimation of heteropolar bonding components by Kα spectroscopy will have to wait until completion of a broad-based study of the class of compounds under consideration supplemented by theoretical calculations. The material available is still rather meager. Measurements have been performed, *inter alia*, on Li_4Si, Mg_2Si, and Ca_2Si[223], and $CaSi_2$[224] (Si-Kα line in all cases), as well as $CaAl_2$[225] (Al-Kα). Without exception the shifts relative to the elemental state are very small or lie within the limits of accuracy of the method.

Similar difficulties are encountered in X-ray photoelectron spectroscopy (ESCA). On irradiation of an atom with sufficiently short wave X-ray quanta, electrons from the inner shells can depart from the atomic system with absorption of an X-ray quantum. Measuring the kinetic energy of the leaving photoelectrons yields information about the binding energy of these electrons prior to the absorption. Whereas X-ray spectroscopy always yields the difference in energy between two electronic levels, X-ray photoelectron spectroscopy provides a direct indication of the binding energy of the core electrons. Changes in binding energies relative to the elemental state, which are also designated chemical shifts, can thus be determined. According to *Siegbahn et al.*[234] these changes can be described by a simple ionic model, the chemical shift being proportional to the effective charge of the atom studied. A positive charge leads to a higher binding energy and a negative charge to a lower binding energy. Recent work on solids has shown, however, that additional parameters have to be considered as in the chemical shift of the Kα line.

Only few measurements on alkaline earth metal silicides have so far be carried out[226] from which, with all due reservations, a negative charge on the silicon is indicated by the simple ionic model.

4.3. Structural Studies

The results of X-ray crystal structure determinations have assumed great significance in discussions of the bonding in these phases. Relatively speaking, this is the field with the greatest amount of experimental material and will therefore now be considered in detail.

According to the structural findings, the class of compounds under study can be divided up into several large groups.

4.3.1. Phases Obeying the Zintl-Klemm-Busmann Concept

Zintl himself showed in numerous preparative and structural studies that alkali and alkaline earth metals could undergo combination *inter alia* with Group VB elements to give products having compositions stoichiometrically analogous to those expected for salts with element(V) anions (A^{3-} ions) having complete octets: M^{I}_3A or $M^{II}_3A_2$. A corresponding situation prevails with Group IVB elements only for some compounds with alkaline earth metals (Tables 11, 12, and 13). A common feature of all lattice types encountered here is that they lead to "isolated" element(V) or element(IV) atoms. The expression "isolated atoms" means that they have only other kinds of atoms as nearest neighbors, *i.e.* the distance to another atom of the same kind in the lattice is so great that no direct interaction can be assumed between them. The conditions for maximally uniform charge distribution throughout the lattice are thereby fulfilled and such lattice types are indeed found particularly frequently in the typical salts. *Zintl* consequently regarded this as an indication of a heteropolar bonding component in such phases.

In addition to the compounds exhibiting stoichiometries similar to those of the salts, systems of alkali and alkaline earth metals with Group VB, IVB, and IIIB elements contain many compounds not having this kind of composition. Structurally it is found that in these phases partial element(V), element(IV), or element(III) lattices are formed for which direct bonding between element(V), element(IV), or element(III) atoms has to be assumed from the observed interatomic distances. In order to explain these partial lattices a concept was developed that is based essentially on *Zintl*'s interpretation of the LiAl and NaTl lattices (Fig. 1). Concerning the structure of these compounds Zintl wrote: "There results... the concept of a skeleton made up of atoms B (B = element of Group IIIB) and supporting the crystal structure whose vacant sites are filled with Li or Na particles. The skeleton of B atoms is a diamond lattice such as exists *per se* only with C, Si, Ge, or Sn atoms, which are all characterized by having four valence electrons. The atoms of Al, Ga, In, Tl all have one electron too few to be able to form a diamond lattice. This deficit can, however, be compensated by incorporation of one atom of Li or Na (one valence electron per atom) per atom of Al, Ga, In, or Tl; there thus arises a diamond lattice of the last mentioned atoms whose vacancies contain the cores of the alkali atoms furnishing the electrons. That the spatial requirements of the alkali atoms under such conditions are considerably smaller than in the free metal likewise becomes understandable, for their

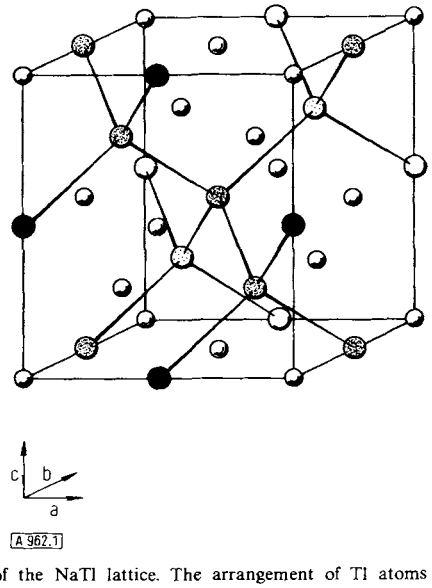

Fig. 1. Unit cell of the NaTl lattice. The arrangement of Tl atoms is emphasized (after ref. [227]).

internal function in the crystal structure lies in the direction of the transition to the much smaller alkali ion."

On the basis of available experimental evidence, which has meanwhile considerably increased, *Klemm* and *Busmann* have generalized this interpretation of the NaTl lattice[228]. Formulated in extreme terms, the non-noble metal transfers electrons to the more noble component of the alloy, the "anion former". With the resulting outer electronic configuration an "anion partial lattice" is constructed whose atomic arrangement corresponds to the element having the same number of valence electrons (Zintl-Klemm-Busmann concept).

The compounds obeying the Zintl-Klemm-Busmann concept are listed in Table 14 and compounds with particularly characteristic anionic partial lattices are represented in Figures 1 to 9. They impressively demonstrate the analogy to the corresponding elemental lattices.

However, Table 14 also contains compounds whose anion lattices are not isosteric with elemental lattices having the same number of valence electrons. Thus the alkaline earth metal compounds crystallizing in the CrB type form planar zig-zag chains of element(IV) atoms whereas the chains occurring in the Group VIB elemental structures are helical. The two-coordination of the atoms is however retained. $SrSi_2$[175] and LiGe[22] contain a three-dimensional Si or Ge structure (Figs. 6 and 7) which has not yet been observed in the elements of Group VB (Si^- and Ge^- being isoelectronic with the Group VB elements with regard to the number of valence electrons). In the anion partial lattices found, each atom has three other atoms of the same kind as nearest neighbors. The four atoms construct a flat distorted trigonal bipyramid whose base atoms each represent the apices of adjoining pyramids. The basal faces of these pyramids are mutually twisted, giving rise to a three-dimensional network. In contrast,

the Si pyramids in $CaSi_2$ are arranged in parallel planes (Fig. 5) resulting in a Si layer structure corresponding to metallic As.

These findings suggest that the limitation of the concept to the lattices of the elements may reasonably be dropped in favor of an extension of its validity to ensure the same number of bonds to neighbors of the same species, *i.e.* the $(8-N)$ rule should be fulfilled. The general valence rule of *Pearson*[227] also leads to the same result. According to this rule, phases made up of elements on opposite sides of the Zintl line comply to the condition:

$$\frac{n_e + b_a - b_c}{n_a} = 8$$

(n_e = total number of valence electrons; n_a = number of anions; b_a = number of electrons required for formation of anion-anion bonds; b_c = number of electrons required for formation of cation-cation bonds, including all valence electrons of the cations not participating in a bond.) There results, *e.g.* for $CaSi_2$ ($n_e = 10$; $n_a = 2$; $b_c = 0$), a value of $b_a = 6$ bonding electrons, *i.e.* a coordination number of 3 for the anion partial lattice.

Apart from compounds whose anionic atoms are assigned integral formal charges in an ionic formulation there are others which in a corresponding formulation have fractional charges but whose anion partial lattices nevertheless are closely related to those of the former compounds (Table 15).

Ionic formulation of Li_7Si_2 and Li_7Ge_2[12,17] leads to a formal charge of 3.5− on the element(IV) atoms. Figures 10 and 11 each show two sections through the unit cell that alternate in the cells. In both structures there are four isolated element(IV) atoms and two Si_2 or Ge_2 dumbbells per unit cell. According to these structural principles the formulas can be broken down in the following way:

$$2\,Li_7Si_2 \rightarrow \text{“}2\,Li_4Si\text{”} + \text{“}Li_6Si_2\text{”}$$
$$2\,Li_7Ge_2 \rightarrow \text{“}2\,Li_4Ge\text{”} + \text{“}Li_6Ge_2\text{”}$$

Formally, not only Si^{4-} ions but also Si_2^{6-} ions have to be considered, the latter being isoelectronic to Cl_2 dumbbells.

Ca_5Si_3[142], Sr_5Si_3[172], Ba_5Si_3[196], and Ba_5Pb_3[203] require a formal charge of 3.33− on the element(IV) atoms. While not being isotypic, these compounds have largely analogous structures. As an example, Fig. 12 shows a section of the structure of Ca_5Si_3. The unit cell contains four Si_2 dumbbells and four isolated Si atoms so that these formulas can also be broken down in line with the same principle, *e.g.*

$$Ca_5Si_3 \rightarrow \text{“}Ca_2Si\text{”} + \text{“}Ca_3Si_2\text{”}$$

For Ba_3Si_4[200], Sr_3G_4[229], and $Ca_{0.5}Sr_{2.5}Si_4$[142], ionic formulation leads to 1.5 negative charges on the element(IV)

Table 15. Compounds having a fractional formal charge on the element(IV) atom when formulated ionically.

Cpd.	Formal charge on X atom according to formula	Coordination	Structure of anion partial lattice	Bond lengths [Å] in anion partial lattice

atom. Figure 13 represents the isolated Si_4 unit occurring in the lattice of Ba_3Si_4. The Si atoms are arranged at the corners of two congruent isosceles triangles sharing the short base and oriented at an angle of 113° to each other. This Si unit can be derived from a Si_4 tetrahedron having one edge extended to such a degree that direct Si—Si interaction is no longer possible. However, differing coordinations of the Si atoms will occur: the Si atoms

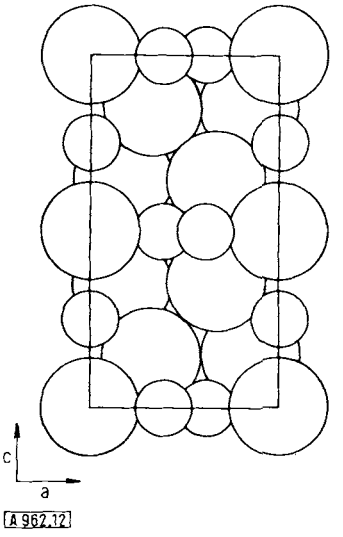

Fig. 12. Atomic arrangement in Ca_5Si_3. Projection of the unit cell onto the *a,c* plane.

on the common edge have three neighbors of the same species and those on the apices of the triangles two. To take account of this finding the three-coordinate Si atoms must be ascribed a negative charge because they correspond in their coordination to the elements of Group VB, while the two-coordinate ones are ascribed two charges because they resemble the dicoordinate Group VIB elements. Thus the overall Si_4 structural unit has six negative charges balanced by three Ba "ions".

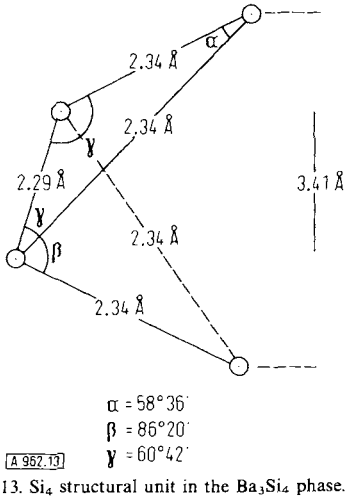

Fig. 13. Si_4 structural unit in the Ba_3Si_4 phase.

The atomic arrangement in the two isotypic phases Sr_3Ge_4 and $Ca_{0.5}Sr_{2.5}Si_4$ is depicted in Fig. 14. Planar Si or Ge hexagons are present which are coupled by way of opposite sides to form a one-dimensional infinite ribbon of hexagons. Although the structural principle is so very different from that of Ba_3Si_4, the same ratio of two- and three-coordinate Si atoms is observed in both cases, thus permitting assignment of a completely analogous charge distribution in accord with an ionic formulation.

These results show that for phases exhibiting fractional charges on the anionic components the charges may be resolved into the nearest integral values. The coordination

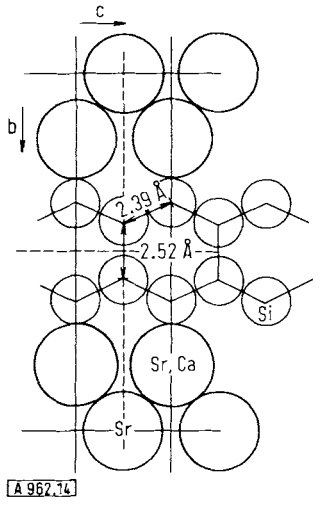

Fig. 14. Atomic arrangement in $Ca_{0.5}Sr_{2.5}Si_4$. Section at $x=0$.

in the anion partial lattice can accordingly be derived from the $(8-N)$ rule.

An analogous interpretation can also be given for the alkali metal and alkaline earth polyphosphides which have recently been elucidated by *von Schnering et al.* With the exception of Sr_3P_{14}, they all exhibit highly condensed, relatively complicated partial lattices of two- and three-coordinate phosphorus. It was found that in BaP_3[237] (with a mean formal charge of 0.666−) one three-coordinate (≙formal charge 0) and two two-coordinate phosphorus atoms (≙element of Group VIB ≙ formal charge 1−) per formula unit are balanced by one Ba^{2+} "ion". In completely analogous fashion, the P partial lattices of LiP_5 and LiP_7[238] each contain one two-coordinate P atom alongside four and six three-coordinate P atoms respectively. In KP_{15}[70] a two-coordinate P atom is accompanied by 14 three-coordinate P atoms which in this case

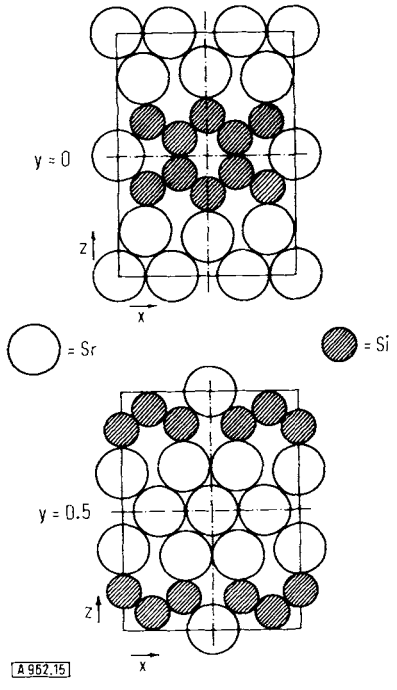

Fig. 15. Atomic arrangement of the second modification of SrSi.

are linked together to form structural units corresponding to those in Hittorf phosphorus[231]. A particularly clear example for the combination of two-coordinate and three-coordinate phosphorus atoms according to formal charge is also provided by the above-mentioned compound Sr_3P_{14}[239], in which isolated P_7^{3-} groups have been found. One P_7^{3-} unit contains four three-coordinate and three two-coordinate P atoms linked in complete analogy to the P_4S_3 molecule in which four three-coordinate P atoms and three two-coordinate S atoms are present.

This principle does become rather scholastic, however, in the hitherto unique case of a second modification of SrSi[208]. Figure 15 illustrates the isolated Si_{10} units occurring in the structure of this modification. Four three-coordinate, two two-coordinate, and four one-coordinate Si atoms are seen to be present. Calculation of the various formal charges from these coordination numbers indicates 20 negative charges for the overall Si_{20} unit which are compensated by 10 Sr "ions".

Assignment of the phase Sr_4Si_7[174] remains unclear. An ionic formulation indicates 1.14 negative charges on the Si atom. A structure of the α-$ThSi_2$ type is formed whose Si partial lattice is depicted in Figure 16. Stoichiometric

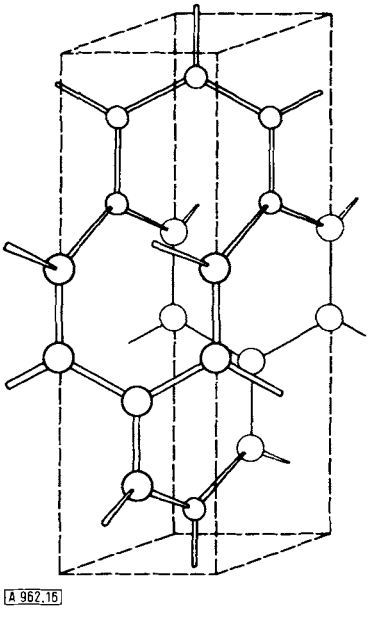

Fig. 16. Silicon partial lattice in α-$ThSi_2$ (after *A. F. Wells:* Structural Inorganic Chemistry. Clarendon Press, Oxford 1962).

deviation becomes possible because of disorder in the Si partial lattice. In this structure each Si atom has three nearest Si neighbors. The four atoms are located in a plane so that, as in $Ca_{0.5}Sr_{2.5}Si_4$ and in the second modification of SrSi, planar Si_4 groups appear as structural units. The spatial arrangement shown arises by linkage of such planar Si_4 groups mutually twisted through 90°. This spatial arrangement is built up by an eightfold equipoint which in the case of Sr_4Si_7 is statistically occupied by only seven Si atoms. This means that statistical divisions occur in the Si partial lattice which generate three two-coordinate Si atoms per isolated vacancy. The coexistence of two- and three-coordinate Si atoms is in harmony with

the calculated formal charge of between 1 and 2. However, there is no longer a clear-cut assignment in this case, particularly in view of a certain phase width, which is also a special feature of this compound.

4.3.2. Phases not Obeying the Zintl-Klemm-Busmann Concept

Apart from the phases corresponding to the extended Zintl-Klemm-Busmann concept there are others which do not fit into this scheme. They include phases in which the atomic ratio assumes values tending toward one extreme or the other.

a) Phases having a high content of electronegative element

Let us first consider phases particularly rich in electronegative elements. Of the phases with elements of Group IVB structures are available for the compounds Na_8Si_{46}[52], K_8Si_{46}[78,232], K_8Ge_{46}[78,232], K_8Sn_{46}[78], Na_xSi_{136}[52], and Li_2Sn_5[24].

The structure of the compounds Na_8Sn_{46} and K_8X_{46} (X = Si, Ge, Sn) can be described by analogy with the clathrates $8X{\cdot}46H_2O$ (Fig. 17) studied by *Claussen*[230] and by *Pauling* and *Marsh*. The Group IVB atoms occupy the positions of the water molecules. Twenty such atoms form a pentagonal dodecahedron. The unit cell contains two such dodecahedrons which are linked *via* six further Si, Ge, or Sn atoms in such a manner that six tetrakaidecahedrons per cell result, which are contained by twelve pentagonal faces in addition to two diametrically opposite hexagons. An alkali metal atom is located at the center of each of the tetrakaidecahedrons and the dodecahedrons leading to an atomic ratio of 8:46.

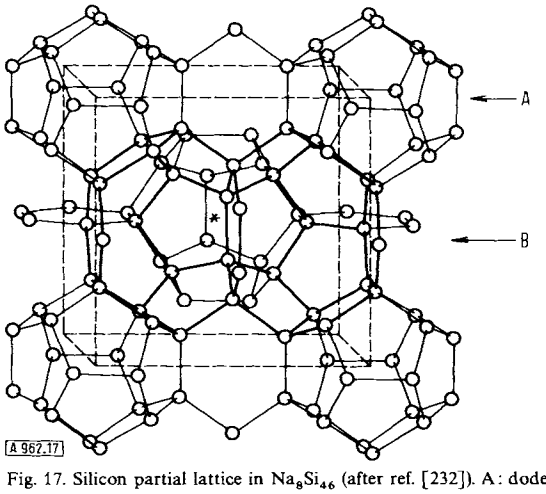

Fig. 17. Silicon partial lattice in Na_8Si_{46} (after ref. [232]). A: dodecahedron; B: tetrakaidecahedron.

Hagenmuller et al. have investigated a Na_xSi_{136} species[52]. Powder diagrams of this compound could be interpreted by assuming a clathrate-type structure corresponding to that of the gas hydrates $24X{\cdot}136H_2O$. The Si atoms again occupy the water-molecule sites and form a spatial network that likewise contains dodecahedrons and tetradecahedrons occupied to varying degrees by Na atoms. The element(IV) atoms in the two structures are surrounded approximately tetrahedrally by four close neighbors of the same species. The respective interatomic distances are only slightly greater than in the tetrahedral structure of the corresponding elemental lattices and the bonding angles approach the ideal tetrahedral angle to a greater or lesser extent.

In Li_2Sn_5[24] the partial Sn lattice consists of a spatial network which is however composed of six-coordinate Sn atoms (≙ coordination of the Sn atoms in white tin). Pentagonal parallel channels in which the Li atoms are fixed run through the structure (Fig. 18). The Sn—Sn distances are only slightly larger than in white tin (3.02 and 3.18 Å in white tin, 3.11 to 3.31 Å in Li_2Sn_5).

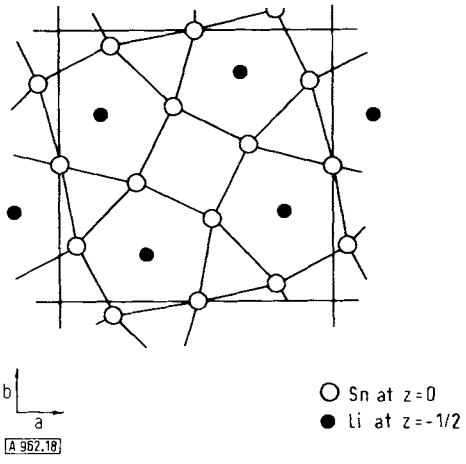

Fig. 18. Projection of the unit cell of Li_2Sn_5 onto the *a,b* plane (after ref. [24]).

b) Phases having a high content of electropositive element

Metallic structures with high coordination numbers were found by *Wölfel et al.* in $Ca_{33}Ge$ and Ca_7Ge[146]. The alkaline earth metal atoms are cubic close packed with superstructures imposed by the Ge atoms. The phases Ca_7Si, Sr_7Si, and Ba_7Si[147] are isotypic with Ca_7Ge.

Metallic structures are also found in the phases $Li_{22}Si_5$, $Li_{22}Ge_5$, $Li_{22}Sn_5$, $Li_{22}Pb_5$. They can be structurally related to the cubic space-centered cell of the lithium lattice itself. The lithium and element(IV) atoms are not however distributed randomly but an ordered atomic distribution is established which can be described to a first approximation as a cell with the sixfold axis of elemental lithium[9,26]. Studies on single crystals of $Li_{22}Si_5$ also revealed weak superstructure reflections which require a further fivefold increase in these cell constants[10]. Particularly striking is the valence electron concentration of these phases which is calculated as 21:13.5 and thus together with the structure found corresponds to the β-brass type of the Hume-Rothery phases. A similar observation is made for $Li_{10}Si_3$[13]. An atomic arrangement is also found here which has the unit cell of cubic space-centered lithium. Again the lattice constant of the lithium cell is multiplied to a first approximation by six so that the resulting cell contains 432 atomic positions. However, analysis and density and X-ray findings show only 416 sites to be occupied, *i.e.* there are 16 vacancies in the lattice. The valence electron concentration is found to be 21:12.4 and is thus close to the VEC of

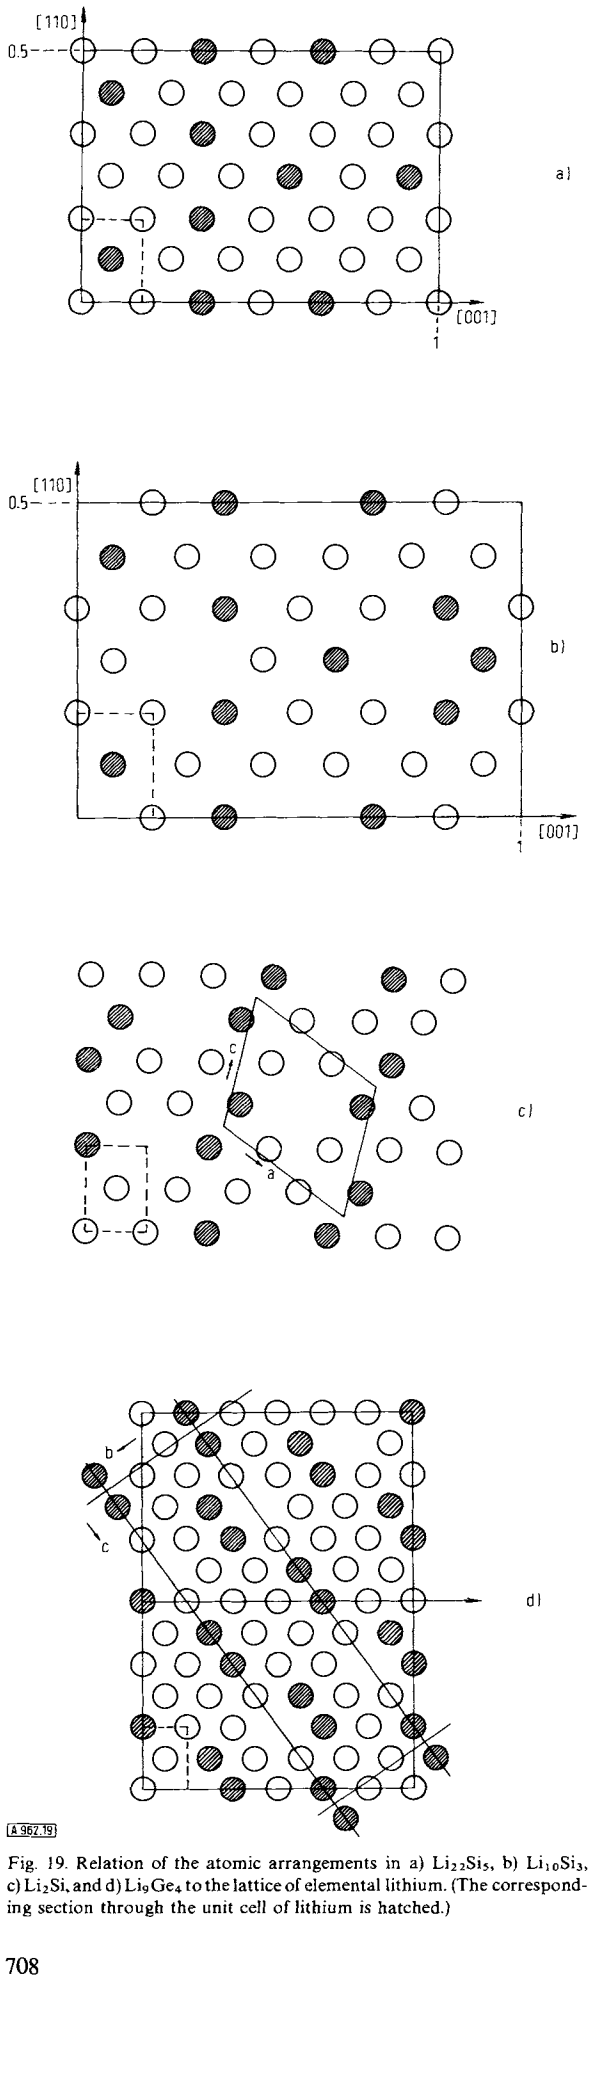

Fig. 19. Relation of the atomic arrangements in a) $Li_{22}Si_5$, b) $Li_{10}Si_3$, c) Li_2Si, and d) Li_9Ge_4 to the lattice of elemental lithium. (The corresponding section through the unit cell of lithium is hatched.)

the γ-brass phase which also has a corresponding number of lattice vacancies.

c) Other deviating phases

Metallic structures not obeying the Zintl-Klemm-Busmann concept are sometimes also found in compounds not having such extreme compositions. Thus *Ramsay* and *Zalkin*[27, 29] showed that all the stoichiometrically widely varying phases of the LiPb system can be structurally related to the cubic body-centered cell of elemental lithium. LiPb, Li_3Pb, and Li_7Pb_2, like $Li_{22}Pb_5$, contain isolated Pb atoms, *i.e.* only such as are surrounded by Li atoms, whereas Li_8Pb_3 contains an equal number of isolated Pb atoms and Pb_2 dumbbells. Dumbbells units of this kind are also present in Li_2Si[14] which can be described as monoclinic and, like the phases $Li_{22}Si_5$ and $Li_{10}Si_3$, can be related to the lattice of elemental lithium. Figures 19a—d provide a schematic illustration of the relationships between the structures of Li_2Si, $Li_{10}Si_3$, and $Li_{22}Si_5$, sections perpendicular to the face diagonals being shown for the structures of the last two compounds. Relative to the packing in elemental lithium 1/7 of all lattice sites in Li_2Si are vacant. In the real structure of course the atomic locations are distorted with regard to the positions in the ideal lithium lattice. This is even more the case in the structure of Li_9Ge_4[20], although the number of vacancies (1/10) is lower than in Li_2Si.

We also find a cubic closest packing with an ordered distribution of atoms in the Cu_3Au type in which the compounds Ca_3Pb[146], $CaPb_3$[153], $NaPb_3$[61], $CaSn_3$[151], Ca_3Sn[209], $CaTl_3$[153], $MgIn_{2.5}$[122], $SrBi_3$[171], Mg_3In (HT)[122], as well as $SrPb_3$[153] and $SrTl_3$[161], crystallize, both of the latter exhibiting tetragonal distortion.

The structures of the compounds $CaAl_2$[154], KBi_2[75], $RbBi_2$[69], $CsBi_2$[76], and KPb_2[85] show them to number among the Laves phases. Further variants of metallic lattices occur in particular with the compounds of alkali and alkaline earth metals with Group IIIB elements (Tables 1—9) which, however, will not be considered in detail within the framework of this report.

5. Discussion

A survey of the material available shows that most of the phases considered can be rationalized in terms of the extended concept due to *Zintl*, *Klemm*, and *Busmann*. It is, however, rather unsatisfactory that nothing can yet be said about the actual structures beyond the coordination of the atoms in the anion partial lattice. Thus the factors are still unknown which, for instance, determine which of the fundamentally feasible arrangements—layer structure, three-dimensional crosslinked structure, or isolated tetrahedrons—is formed *e.g.* in the series $CaSi_2$, $SrSi_2$, $BaSi_2$. Steric constants *e.g.* the size ratios of the atoms clearly play an essential role here, as has been underlined by attempts to incorporate barium into the $SrSi_2$ lattice in place of strontium[233]. It is also conceivable that the donor strength of the non-noble alloy component may

exert an effect. An influence of donor strength should also manifest itself in the bond lengths of the anionic partial lattice. Figure 20 represents a plot of the Si—Si distance in the silicides of formal charge 1−, for which the most experimental data has so far become available,

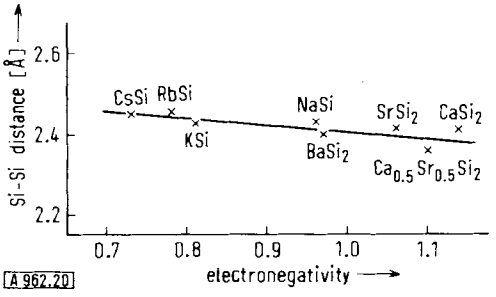

Fig. 20. Dependence of the Si—Si distance on the electronegativities of the alloy components (formal charge on silicon: 1 −).

versus the electronegativity of the electropositive alloy component. As the electronegativity increases a shortening of the bond lengths is seen to occur at the same coordination number (8—9). This is in full accord with the concept that the negative charge on the silicon partial lattice falls with decreasing donor strength of the alkali or alkaline earth metal and that the equally charged Si atoms are then subject to less mutual repulsion. Too few experimental data are available for more highly charged Si partial lattices to permit subscription to a similar view. In keeping with the higher formal charge, however, larger Si—Si distances are generally observed for a given coordination number.

Studies carried out in recent years, as shown above, have indicated that the validity of the extended Zintl-Klemm-Busmann concept is limited. It cannot be used in interpreting phases having atomic ratios tending to one extreme or the other. In both limiting cases the bonding state of the excess component dictates the crystal structure.

In addition, phases are also known which certainly fall within the province of the Zintl-Klemm-Busmann concept but whose anion lattices do not satisfy the $(8-N)$ rule.

A discussion of all these deviating phases reveals that the difference in electronegativity of the components is always particularly slight. This results either from the less pronounced electropositive character of the alkali or alkaline earth metal concerned—*e.g.* lithium or magnesium—or from the very low electronegativity of the anionic component—*e.g.* the heaviest elements of Group VB and IVB and all elements of Group IIIB. Both unfavorable features are frequently combined in the deviations. The extreme charge separation invoked by *Zintl*, *Klemm*, and *Busmann* loses all relevance and thereby its significance in determining the structure. The inadequacy of the extended concept is understandable in such cases.

Apart from the polar character of the classes of compounds discussed here, covalent binding contributions are also important in those phases having an associated anion partial lattice, as implicated by the validity of the $(8-N)$ rule. Within the anion partial lattice bond lengths are found experimentally which are comparable with those in the elemental lattices. The single-bond energies should therefore also play a determining role in the formation of these partial lattices. The single-bond energies of the Group IVB and VB elements are listed in Table 16. Most of

Table 16. Single bond energies for elements of Groups IVB and VB [235].

Bond	Bond energy [kcal/mol]	Bond	Bond energy [kcal/mol]
Si—Si	42.2	P—P	51.3
Ge—Ge	37.6	As—As	32.1
Sn—Sn	34.2	Sb—Sb	30.2
Pb—Pb	?	Bi—Bi	25

the phases deviating from the Zintl-Klemm-Busmann concept are indeed found with elements having a relatively low single-bond energy. The same conclusion can be drawn from the observation that the metallic bonding character increases on going from the top to the bottom of a group in the Periodic Table and in extreme cases, as for example those of white tin and lead, the element itself no longer conforms to the $(8-N)$ rule.

In spite of these limitations, it may be said that a fairly large group of compounds of the systems in question can be described by the extended Zintl-Klemm-Busmann concept. It appears an obvious step to utilize this description in a new definition of Zintl phases which embraces *Laves'* definition and, to a certain degree, the crystallographic definition: accordingly, the designation Zintl phases should apply to intermetallic compounds which display a pronounced heteropolar bonding contribution and in agreement with an ionic formulation in their anion partial lattices—if necessary after resolution of fractional charges into nearest integral values—obey the $(8-N)$ rule.

Our own work described in this progress report was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Bayerische Akademie der Wissenschaften, for which we are extremely grateful. We are indebted to Prof. Dr. Armin Weiss for his support and numerous stimulating discussions.

Nuclear Medicine and Radiochemistry

By Hans Götte and Gerhard Kloss[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Nuclear-medical diagnostic methods are widely used at present, examples being localization diagnosis *e.g.* of the thyroid, the kidney, and the spleen and function tests, *e.g.* on the thyroid and on the liver. For these tests it is essential to have organ-specific vehicle substances that can be labeled with suitable radionuclides. For *in-vivo* investigations, the exposure of the patient to radiation should be kept as small as possible, but the radiation must nevertheless be sufficient to allow the detection of the nuclide. Today, the therapeutic use of radionuclides is only small in comparison with their use in diagnosis.

1. Nuclear Medical Methods and Problems

1.1. *In-vivo* Methods

The possibility of using radioactive substances for the investigation of transport and distribution processes and of analytical questions has opened up previously inaccessible fields to the medical sciences. A new field of specialization, nuclear medicine, has arisen. This is a branch of science and clinical practice concerned with the diagnostic and therapeutic use of unsealed radioactive substances; at present, the number of uses in diagnosis is much greater than that in therapy.

Many of the diagnostic tests are *in-vivo* methods. They are based on the fact that some substances, when given *e.g.* by injection or orally, accumulate in certain organs. If compounds of this type can be labeled with γ-emitting radionuclides, they can be used as vehicles for the latter. It does not matter in principle whether the compound is labeled with a radioisotope of one of its component elements (isotope labeling) or with a non-isotopic radionuclide (foreign labeling or hetero-labeling). With the aid of special equipment, the scintigraph, it is then possible to record the distribution of the γ-quanta emitted by the radionuclides, *i.e.* to scan the distribution of the activity in the accumulating organ (Fig. 1).

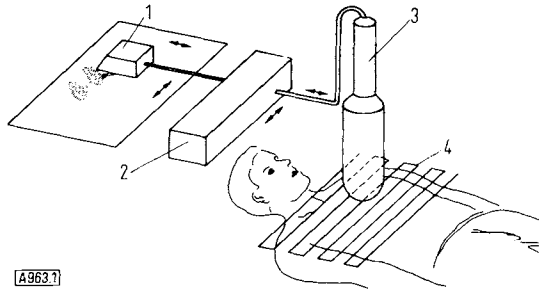

Fig. 1. Schematic diagram of the operation of a scintigraph: 1, point recorder; 2, amplifier; 3, scintillation counter; 4, collimator.

These activity diagrams are recorded by moving a mobile γ-radiation detector in a winding course over the organ in question. A point recorder moving at the same rate marks a point whenever the counter has recorded a certain pulse rate. If this pulse rate is not reached, the corresponding place on the recording paper is left blank. Instruments are also commercially available that print different colors according to the activity level, so that it is possible to distinguish stronger and weaker accumulation. Such scin-

Farbwerke Hoechst AG
623 Frankfurt (Main) 80 (Germany)

tigrams (or scans) can provide information on the existence of abnormalities in the storage properties of the organ in question. Morphological changes, *e. g.* some carcinomas, can be recognized in this way.

These localization tests are supplemented by function diagnosis, in which one measures the fraction of the labeled substance administered that is stored in the organ in question or excreted by it; the functioning of the organ can be deduced from the course of the curves. The radiation is detected by means of one or more fixed collimated detectors applied over the organ under investigation. The activity variation recorded by them is marked by a pen.

A gamma camera is used to follow rapid diffusion processes. This contains a large crystal with a collimator system between the crystal and the patient and a series of photomultipliers placed on the crystal. The activity distributions displayed on an oscillograph screen can be photographed at short intervals (function scintigraphy).

There are essentially three requirements that must be satisfied if a nuclear-medical preparation is to be suitable for such investigations, *i. e.* minimum exposure of the patient to radiation, harmlessness of the vehicle substance to the organism, and optimum diagnostic information.

For these reasons, a radiodiagnostic agent for *in-vivo* investigations should have the following properties:

1. To minimize exposure to radiation, as far as possible, the preparation should not contain particle emitters, since α- and β-rays give up all their energy in the tissue because of their short range; moreover, they make no contribution to the measurement. Preparations with radionuclides having short half-lives are preferred, but the half-life must be sufficiently long to guarantee that sufficient activity is still present for the measurement.

2. As far as possible, the radiodiagnostic preparation should be physiological, *i. e.* it should not cause any reactions in the organism nor should it be deposited as an exogenous substance. Unphysiological substances must be capable of being prepared with high specific activities so that after injection of very small quantities that are still tolerated by the organism without reaction, they are still sufficiently active for detection.

3. The radiodiagnostic preparation should be selectively accumulated by the organs or systems whose scintigrams are to be recorded or whose function is to be tested, since the radiation of radioactive material concentrated elsewhere interferes with the measurement.

4. To avoid chemical noxae, radiodiagnostic preparations whose residence time in the body is short, *i. e.* which are rapidly eliminated (unchanged or after metabolization), are preferred. However, the labeled vehicle substance must be stored as long as is necessary for the test.

5. The substance must also be isotopically and radiochemically pure. Thus it must contain only the desired radionuclide, and this must be present only in the desired chemical form.

6. The labeling must be stable both chemically and radiation-chemically *i. e.* toward its own radiation, so that no radioactive decomposition products occur. Moreover, the labeled molecule must not be changed by metabolic processes in the organism, unless the function test is based on such a biotransformation. If these stability conditions are not satisfied, labeled metabolites may appear in undesirable places and interfere with the measurement of the process or organ under investigation.

7. The radiation of the radionuclide used should be capable of being measured with high counting yields so that only a low activity need be administered, *i. e.* its γ-energy should be between 100 and 200 keV.

8. It must be possible to produce the preparations in a few steps, as far as possible by simple operations, at low cost, and in a pyrogen-free and sterile state.

These partly contradictory requirements are clearly often mutually exclusive. The ideal *in-vivo* radiodiagnostic preparation cannot exist. A compromise must be found in every case, and it is up to the nuclear physician to choose the most suitable of the available preparations.

The following examples are intended on the one hand to illustrate the type of problem that arises in nuclear medicine and to demonstrate the diversity of the methods used to deal with them. On the other hand, they are intended to show how much the required radioactive preparations can differ in their chemical composition and physical state, as well as to illustrate the degree to which it has so far been possible to satisfy the eight requirements by the use both of isotope-labeled and of hetero-labeled physiological and unphysiological substances.

1.1.1. Examples of Localization Diagnosis

Thyroid

Scintigrams of the thyroid are obtained after administration of radioactive iodide ions. Figure 2 shows the scintigram of a thyroid with a "hot" node such as appears for toxic adenomas, a palpable abnormality that was known earlier from pathological and anatomical investigations, but whose incidence and importance were recognized and its differentiation from other thyroid disturbances made possible only through nuclear medicine. It involves partly hyperfunctioning tissue that produces morbid states by over-production of thyroid hormones. It can be seen from Figure 3, on the other hand, that tissue that is incapable of storage, *i. e.* a "cold" node, is present here, and this points to a tumor.

Radioactively labeled iodine has partly ideal characteristics as a radiodiagnostic preparation for this diagnostic problem, since a physiological process, *i. e.* the absorption of iodide ions by thyroid tissue, is used to check this very process. Because of the long physical and biological half-life of I-131, which is the most commonly used isotope at present, radiation exposure must be taken into account.

Tc-99m has recently been used in the form of carrier-free pertechnetate for the investigation of the thyroid. This ion is absorbed by the thyroid in almost the same way as the iodide ion. The fact that investigations can also be carried out with pertechnetate shows that the diagnostic information can be obtained even under unphysiological conditions; the activity of the carrier-free technetium used, which is about 1 mCi (corresponding to 2×10^{-10} g), should not lead to any chemical damage, while the decrease in

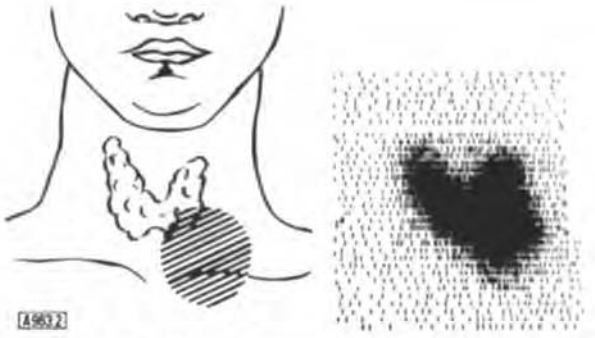

Fig. 2. Hot node; diagnosis: hyperfunction. Increased iodine storage in a node that enlarges the thyroid on the left. Schematic representation of the palpable node and scintigram.

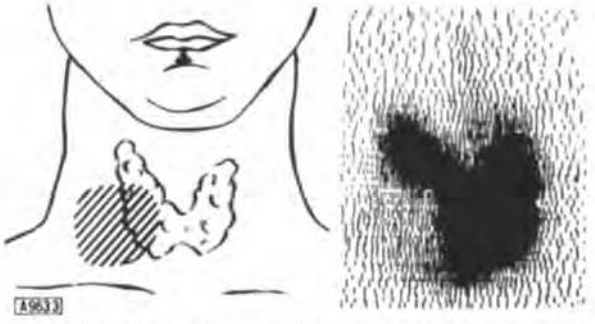

Fig. 3. Cold node; diagnosis: suspected carcinoma. Reduced iodine storage in a node that enlarges the thyroid on the right. Schematic representation of the palpable node and scintigram.

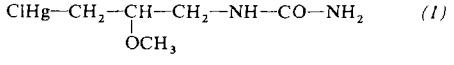
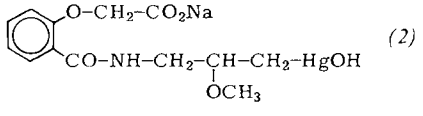
radiation exposure should be appreciable because of the short half-life of technetium.

Kidney

For the scintigraphic visualization of the kidneys, the nuclear physician has available three mercurial injection preparations with different physical and biological half-lifes: Hg-197- or Hg-203-labeled chlormerodrin *(1)* and Hg-203-labeled Salyrgan® *(2)*.



(1)



(2)

Use is made here of the well-known ability of the kidneys to accumulate selectively organomercury compounds and/or mercury liberated from them, *i.e.*, unlike in the preceding example, completely unphysiological compounds. An iron-ascorbic acid complex of unknown chemical structure that contains Tc-99m has recently also been placed on the market for this type of kidney investigation. This preparation is not only preferable because of reduced radiation exposure, but is probably also more physiological than the mercury compounds.

Lung

Scintigrams of the lung can be obtained with iodine-labeled protein particles. The aggregates measuring between 5 and 50 μm remain lodged in the capillaries only where the tissue is healthy. Regions with a disturbed blood supply are visible in the scintigram as light areas (Fig. 4); degenerate, *e.g.* carcinomatous, tissue can be detected in this way.

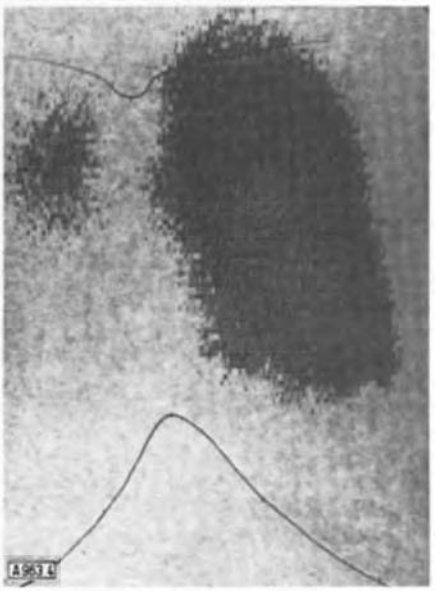


Fig. 4. Lung scintigram; extensive pathological findings. Only traces of functioning tissue remain on the right.

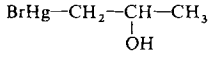
An unphysiological process is thus used here to scan an organ with a substance that can probably still be regarded as physiological. The protein particles have the advantage that they are broken down in the body with an average half-life of 4 to 6 hours, so that the capillaries again become permeable. From the medical point of view, this is an advantage over the use of an iron hydroxide sol labeled with In-113m, whose particles remain in the lung for a long time, even though the radiation exposure due to In-113m is less than that due to I-131.

Spleen

Erythrocytes labeled with Cr-51 and subjected to heat treatment or chemically damaged by labeling with BMHP-Hg-197 *(3)* can be used for the scintigraphy of the spleen.



(3)

The red blood cells, which are no longer capable of functioning, are filtered out of the blood stream and uniformly stored by the healthy spleen tissue, so that scanning becomes possible. Here again, therefore, use is made of a substantially physiological process: One uses the ability of the spleen to eliminate damaged erythrocytes, and the vehicle substance used is endogenous, but its physical behavior has been altered by hetero-labeling.

Brain

Scintigrams of brain tumors have recently been recorded mainly with Te-99m, again in the form of carrier-free pertechnetate. I-131-labeled albumin and the Hg-197-labeled

chlormerodrin mentioned in connection with kidney scintigraphy, as well as the EDTA complex of In-113m, have also been used for this purpose. The physiological properties thus evidently play a minor part if such different compounds have proved to be suitable vehicle substances. This is mainly because we are concerned here not with specific labeling of the tumor tissue but with portrayal of the damage caused by the tumor, *i.e.* the penetration of the blood-brain barrier, which can be recognized from the activity that diffuses into the pathological tissue.

1.1.2. Examples of Function Diagnosis

Thyroid

One of the earliest nuclear-medical tests, that of the thyroid, still occupies a dominant place among the function tests. The basis of the test is that the rate of absorption of carrier-free radioiodide ions by this organ is followed after oral administration, and deviations from normal values are recorded.

Liver

Function tests on the liver can be carried out with I-131-labeled Bengal rose. After intravenous injection of the preparation, the course of the activity is followed with shielded counters over the liver (uptake of activity) and over the head (escape of activity). Figure 5 shows how the absorption curves after administration of labeled Bengal rose differ according to the morbidity states of the liver (inflammations, blockage of the bile duct). The isotope-labeled compound is unphysiological, but is eliminated in a short time.

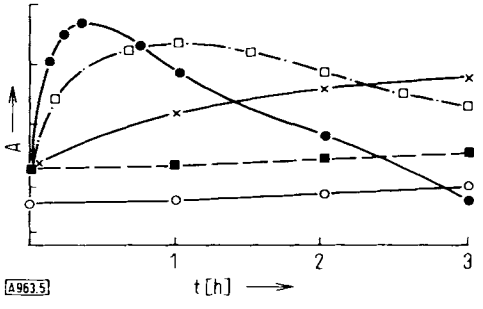


Fig. 5. Liver function test with I-131-labeled Bengal rose. ●···●, normal; □—□, partial blockage; ×—×, complete blockage; ■···■, acute hepatitis; ○—○, compensated cirrhosis.

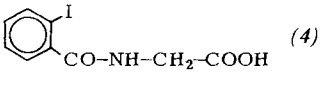
Investigations on the function of the reticuloendothelial system of the liver can be carried out with colloidal gold having a particle size of 300 Å; it must be remembered, however, that gold remains in the liver for a time after the activity has decayed.

Kidney

To measure the kidney clearance, which is a quantity indicating how many milliliters of plasma are freed from ballast materials per unit time, I-131-labeled *o*-iodohippuric acid *(4)* is injected intravenously and the course of the activity is followed with a counter applied over the heart (Fig. 6). This concentration is proportional to the concentration C in blood.



(4)

During and after mixing in the blood circulation, the labeled substance does not remain only in the blood stream but partly penetrates into extravascular spaces, and is also eliminated *via* the kidneys.

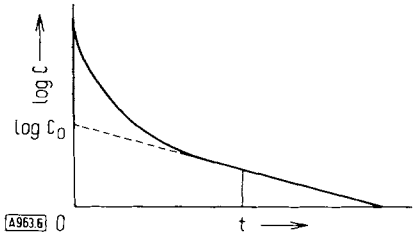


Fig. 6. Determination of the renal clearance with I-131-labeled *o*-iodohippuric acid *(4)*.

The part of the plot corresponding to this process is curved. Then, in a semilogarithmic plot, the concentration C decreases linearly, *i.e.* according to a uniform exponential function e^{-kt}. This means that an equilibrium prevails between the vascular and extravascular systems and the decrease in activity is then due to only one process, *i.e.* the renal clearance. Its value N_c can be calculated by determination of the half-life τ of the above process and the activity concentration C_t in a blood sample taken during the period of linear decrease (V = distribution volume in the body).

$$N_c = k \cdot V$$

$$-K = -\frac{\ln 2}{\tau};\ V = \frac{A_i}{C_0}$$

(A_i = activity injected)

Blood Volume

The function studies also include the determination of certain distribution volumes, particularly the blood volume. The methods are based on the dilution principle. To determine the blood volume, for example, a few ml containing a few μCi of I-131-labeled albumin or a suspension of erythrocytes labeled with Cr-51 and recently also transferrin labeled with In-113m, *i.e.* compounds that are unlabeled constituents of the blood and so do not leave the vascular system, are injected intravenously. The blood volume is calculated from their dilution after mixing in the body. Albumin hetero-labeled with I-131, like transferrin labeled with In-113m, behaves physiologically, since the labeling does not interfere with the properties of the protein in any case. Transferrin labeled with In-113m is the most favorable because of the short half-life of the nuclide, not only from the standpoint of radiation burden, but also because it allows the repetition of the determination at intervals of a few hours.

1.2. *In-vitro* Methods

In addition to the *in-vivo* methods, *in-vitro* methods that yield function-diagnostic information have recently also

been developed. Thus the binding capacity of a particular serum protein that binds thyroid hormones can be determined by addition of a known small quantity (about 0.01 ng) of radioiodine-labeled triiodothyronine to the serum and measurement of the fraction that is bound by the protein. The ratio of free to bound hormone allows conclusions to be drawn regarding hyperfunction, normal function, or hypofunction of the thyroid. The determination of these functional states, unlike the thyroid function test (with orally administered radioiodide ions), is achieved without any radiation exposure. This is a real advantage of the *in-vitro* method. Commercially available kits for such investigations contain the necessary reagents, the correct quantity of adsorbent, and 1 μCi of radioiodine-labeled hormone.

A more demanding method is that known as radioimmunoassay (Fig. 7)[1]. This is used for the determination of peptide hormones, *e.g.* insulin or growth hormone, as well as of other substances in human serum in the ng/ml range. The analytical method is based on the immunological reaction between antigen and antibody. The antibody is produced by injection of unlabeled polypeptide hormone, *e.g.* human insulin, into an animal, *e.g.* a rabbit or a guinea pig. An antibody is produced in the serum of the host organism within a few weeks. This antibody is capable of binding the antigen, *i.e.* the hormone, when the serum containing the antibody is mixed *in vitro* with another, *e.g.* human serum containing the antigen. This reaction proceeds slowly; the free antigen can be selectively separated from a solution that contains both the antigen-antibody reaction product and the free antigen by adsorption, *e.g.* on Amberlite.

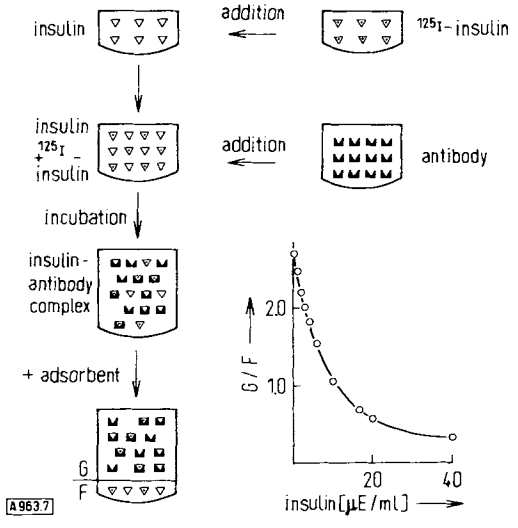

Fig. 7. Schematic representation of the principles of radioimmunoassay with the determination of insulin as an example. Bottom right: calibration curve. G = bound insulin, F = free insulin.

If the hormones to be determined can be labeled with radioiodine (polypeptides containing tyrosine or histidine can be iodinated and hence hetero-labeled with radioiodine), the quantities of antibody-bound hormone and of free hormone can be determined by simple measurement of the activity of the adsorbent and of the supernatant. The content of peptide hormones in the serum of a patient is determined with the aid of a calibration curve.

2. Functions of Radiochemistry in Nuclear Medicine

Nuclear medicine is closely linked with radiochemistry. The latter is responsible on the one hand for the routine production of the preparations required in nuclear medicine, *i.e.* the transformation of the radionuclides into the chemical and physical form suitable for use by the physician, while on the other hand, it is involved in the improvement of existing preparations and in the development and discovery of new labeled preparations. Its functions are thus primarily preparative. Starting from about 15 radionuclides that are important in nuclear medicine, more than 40 preparations (of very different types, as can be seen from Table 1) are prepared on a routine basis, about one third of these being isotope-labeled and two thirds hetero-labeled.

Table 1. Important nuclear-medical preparations in order of increasing half-life (τ).

Radionuclide	τ [d]	Vehicle substances
Indium-113m	0.07	transferrin, indium-EDTA complex
Technetium-99m	0.25	pertechnetate, iron-ascorbic acid complex, sulfur colloid
Copper-64	0.5	copper-EDTA complex
Mercury-197	2.7	chlormerodrin *(1)*, 1-bromomercuri-2-propanol *(3)* (BMHP)
Gold-198	2.7	colloidal gold, 5 or 30 nm
Molybdenum-99	2.8	^{99}Mo-^{99m}Tc generator
Xenon-133	5.6	dissolved in physiological saline
Iodine-131	8.05	albumin, *o*-iodohippuric acid *(4)*, insulin, iodoinsulin, triolein, thybon, L-thyroxine, iodoalbumin, Bengal rose, albumin particles 5—50 μm, sodium iodide
Phosphorus-32	14.3	sodium phosphate, tri-*n*-octyl phosphate (in lipiodol)
Chromium-51	28	chromium albumin, chromium-EDTA complex, ^{51}Cr-labeled erythrocytes
Ytterbium-169	30	ytterbium-EDTA complex
Mercury-203	47	Salyrgan *(2)*
Iodine-125	60	albumin, *o*-iodohippuric acid *(4)*, insulin, placenta hormone, growth hormone
Selenium-75	127	2-amino-4-(methylseleno)butyric acid (selenomethionine)
Cobalt-57 and Cobalt-58	270 and 71 resp.	vitamin B_{12}

2.1. Labeling Methods

The radioelement most commonly used in nuclear medicine is radioiodine, and this is followed by Tc-99m, Au-198, and the mercury isotopes 197 and 203. Depending on the half-life of the radionuclides, the nuclear-medical preparations containing them must be freshly prepared at regular intervals. The labeling with radionuclides may be

carried out by isotope exchange or by chemical synthesis. Isotope exchange can be used when the substance to be labeled is readily obtainable in the inactive form and conditions favorable for the exchange, *e.g.* temperature and exchange rate, can be found. This is so *e.g.* for Bengal rose and thyroxine, both of which are labeled with elemental I-131. The starting material must be free from iodinatable or already iodinated compounds whose exchange rates are roughly equal to or greater than the rate of the desired reaction. For preparative purposes, the isotope exchange method is largely confined to the elements bromine and iodine.

Important examples of isotope-labeled compounds obtained by chemical synthesis are I-131-labeled triiodothyronine, which is obtained by iodination, and the mercury-containing preparations BMHP *(3)*, chlormerodrin *(1)*, and Salyrgan *(2)*, which are obtained in one step by addition of radioactively labeled mercury acetate to CC double bonds.

Hetero-labeling is particularly interesting in nuclear medicine, since among other things it allows the radioactive labeling of existing endogenous substances or substances that behave physiologically but cannot be obtained synthetically in the isotope-labeled form. An important condition for the use of a hetero-labeled substance in many cases is that its properties are not affected by the incorporation of the non-isotopic radionuclide. This is frequently the case *e.g.* for hetero-labeled proteins, whose molecules should not differ in their physiological properties or in their immunological behavior from corresponding unlabeled molecules.

The larger the molecule to be hetero-labeled, the smaller is the probability that the introduction of atoms of an element that does not occur in the molecule will affect the properties of the compound. Proteins with molecular weights of between 1000 and a few million are therefore generally found to be favorable for hetero-labeling, whereas interfering changes are brought about in small molecules.

From these standpoints, the great importance of the two radioisotopes I-131 and I-125 in thyroid diagnosis and therapy and in connection with kidney clearance is not entirely due to their nuclear-physical qualities (half-life, radiation energy). Because of its chemical properties, radioiodine is used more often than other radioelements for the hetero-labeling of biological substances, particularly of proteins. There is frequently no detectable difference in chemical, biochemical, or immunological behavior between labeled and unlabeled molecules if less than 1 atom of iodine/protein molecule is introduced during the iodination and if mild reaction conditions can be maintained.

The substitution of hydrogen in these reactions takes place as follows:

$$RH + I_2^* \leftrightarrow RI^* + HI^*$$

Half of the activity used is liberated as hydrogen iodide; more than 90% of the radioiodine can thus be economically used only if the hydrogen iodide is converted back into iodine by oxidizing agents such as *N*-chlorotoluenesulfonamide, nitrous acid, or a peroxy compound. However, these hard reaction conditions are not tolerated by all proteins. In addition to the desired molecules that are unchanged by the labeling, damaged molecules are then also formed, and these must be separated by chromatography and electrophoresis. This also applies to the radiation-chemical decomposition products that are formed at high specific activities as a result of the natural radiation of the labeled substances.

The proteins radioiodinated in this way include I-131-labeled human albumin for the determination of blood volumes. This product is also used as the starting material for another diagnostic preparation, I-131-labeled albumin particles. To prepare these, I-131-labeled albumin is precipitated in the form of aggregates by heat and pH changes. The size of these particles can be varied by adjustment of the reaction conditions.

Some nuclear-medical preparations must be prepared by biosynthesis, since chemical synthesis would be too expensive. This is so *e.g.* of vitamin B_{12}, which is obtained from the metabolic products of microorganisms whose culture media contain Co-57 or Co-58.

2.2. Generators

The loss of activity during transport between the manufacturer of the nuclear-preparations and the user is important in the case of radionuclides with half-lives of less than 10 h unless the two establishments are situated close together. This difficulty can be overcome in some cases by the use of radionuclide generators. These instruments, which are also known as milking systems, allow the repeated separation of a short-lived daughter nuclide from a longer-lived parent nuclide with a high separation factor (10^6—10^8) by a simple chemical operation, so that the short-lived radionuclide obtained can be brought into the

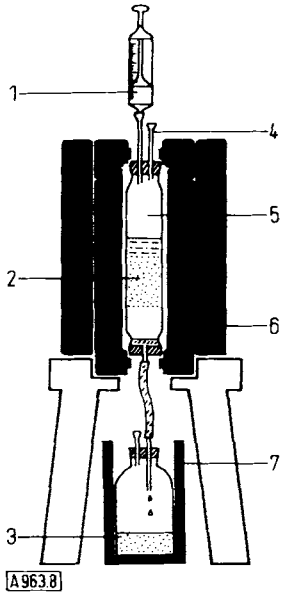

Fig. 8. Principle of a radionuclide generator: 1, syringe with sterile eluent solution; 2, sterilized adsorbent and parent nuclide; 3, sterile eluate with daughter nuclide; 4, deaeration cannula; 5, column replaceable after decay of the parent nuclide; 6, 7, lead shielding.

appropriate form for nuclear-medical use on the spot. The operation of such a generator is illustrated in Figure 8.

The longer-lived parent nuclide is supplied on an adsorbent in an elution column, which is closed at both ends with rubber caps. Elution is carried out by piercing these rubber caps with cannulas and injecting the elution liquid into the column. Before further treatment, the eluate is collected in a sterile receiver, also with a rubber cap.

Among these systems, the most important pairs for nuclear medicine are Mo-99/Tc-99m and Sn-113/In-113m. Technetium may be eluted in the form of carrier-free pertechnetate with isotonic salt solution and used in this form, or technetium-labeled sulfur colloid obtained from thiosulfate solution by acidification in the presence of the pertechnetate eluate may be used. The Tc-99m-iron-ascorbic acid complex can also be obtained by mixing the generator eluate with the dissolved complexing agent.

In-113m, which is obtained in the form of a hydrochloric acid eluate, is used *e.g.* for the labeling of transferrin, a protein of the globulin fraction that contains iron. The bonding of the indium to the protein is very strong; indium can evidently occupy the sites that are capable of accommodating iron. The eluate is adjusted to a certain pH value with sodium hydroxide solution and an amino acid and mixed with a transferrin solution such that one atom of radioindium is present per 50 protein molecules; there is no detectable difference in the behavior of labeled and unlabeled transferrin.

To make it easier for a nuclear physician to produce the radio-diagnostic preparations labeled with Tc-99m or In-113m kits containing all the reagents in the correct quantities and concentrations have been developed.

The extensive use of such short-lived radionuclides enables the need for minimal body burden on the patient to be largely satisfied. The importance of radionuclide generators in nuclear medicine is therefore steadily increasing. At a rough estimate, more than 10000 radionuclide generators are used annually in hospitals in the German Federal Republic.

The routine production and supply of radioactive preparations is always a race against time. It calls for precise cooperation between institutions of very different kinds. Because of the limited life of the nuclides, each step in the production cycle must be fitted to the next with very

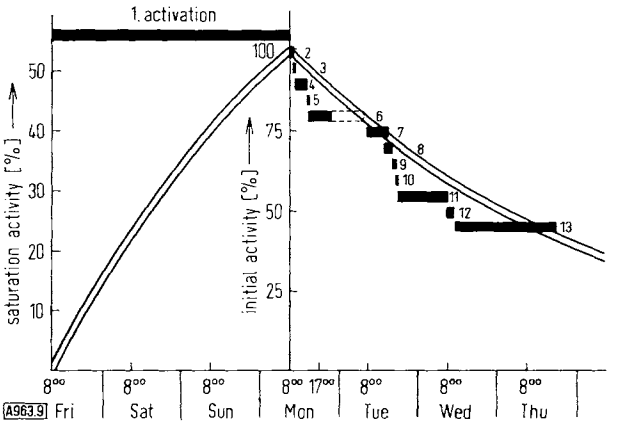

Fig. 9. Variation of activity during and after reactor irradiation of Hg-196 in the production and transport of Hg-197-labeled preparations.
The half-life of mercury-197 is 65 h. 1, activation; 2. discharge and transfer to containers; 3, transport from reactor to station (airport); 4, rail transport (air transport); 5, transport from station to radiochemical laboratory; 6, synthesis; 7, quality control; 8, dispensing; 9, packaging; 10, transport to carrier; 11, rail transport or air transport; 12, delivery; 13, use in the clinic.

little latitude and without loss of time. Figure 9 shows the time required for each step of the process in the synthesis of preparations containing Hg-197 (half-life 65 h) and the fraction of the activity produced that is present at the end of each step if no complications arise. No more than half of the activity produced in the reactor is available to the nuclear physician in this case.

In practice, it is necessary to allow for accidents and difficulties due both to technical factors and to the fact that up to six independent organizations are involved in the twelve steps; these include the reactor station, carriers, in some cases customs, production sites, and shipping agency. Ice and fog can also cause considerable interference.

Table 2 presents a survey of the starting activities and the corresponding, often invisible quantities that must be handled in syntheses in radiochemical laboratories. Fractions of these quantities could endanger both the personnel and the quality of the products if scattered around in an uncontrolled manner.

A condition that makes both synthesis and dispensing more difficult is the need to prepare many substances under aseptic conditions. A compromise is necessary in this case. Radiation protection calls for the use of pressures below atmospheric so that no radioactive material can

Table 2. Production processes for the most important radionuclides as well as activities and corresponding quantities handled in the preparation of radioactive drugs.

Radionuclide	Half-life	Production process	Activity per batch [Ci]	Quantity of radionuclide per batch [g]
Molybdenum-99	2.8 d	$[n\gamma]$	30	≈ 5
Technetium-99m	6.0 h	$^{98}Mo\ [n\gamma]\ ^{99}Mo \xrightarrow{\beta^-} {}^{99m}Tc$	30	$\approx 6.6 \times 10^{-6}$
Tin-113	115 d	$[n\gamma]$	1	$\approx 10^{-1}$
Indium-113m	1.7 h	$^{112}Sn[n\gamma]^{113}Sn \xrightarrow{\beta^-} {}^{113m}In$	0.1	$\approx 5.9 \times 10^{-9}$
Iodine-125	60 d	$^{124}Xe[n\gamma]^{125}Xe \xrightarrow{\beta^+} {}^{125}I$	0.1	$\approx 1 \times 10^{-5}$ (+0.001 g carrier)
Iodine-131	8.05 d	$^{130}Te[n\gamma]^{131}Te \xrightarrow{\beta^-} {}^{131}I$	2	$\approx 2 \times 10^{-4}$ (+0.001 g carrier)
Mercury-197	2.7 d	$[n\gamma]$	10	$\approx 5 \times 10^{-4}$ (+0.1 g carrier)
Gold-198	2.7 d	$[n\gamma]$	20	$\approx 1.5 \times 10^{-1}$
Mercury-203	47 d	$[n\gamma]$	2	≈ 1—2

escape, whereas sterile boxes should be under a pressure above atmospheric so that no non-sterile dust can enter them.

The synthesis is followed by quality control. It is first necessary to establish whether the preparation produced is contaminated with other radionuclides. It is then necessary to check whether the products are radiochemically pure. Moreover, the substances must be examined to see whether they contain pyrogens. This can usually be established during the few hours between the end of the synthesis and despatch. According to the pharmacopeias, sterility testing takes a very much longer time (ten days), and there is no time to wait for the results in the case of short-lived preparations. Here again we have two conflicting requirements, *i. e.* the desire for short-lived preparations to minimize the radiation exposure of the patient and the need to possess evidence of the sterility of the preparation at the time of delivery. In any case, the sterility of every batch must checked over the required period so that all those who have taken delivery of material from a given batch can be warned as soon as signs of non-sterility appear, and also to obtain an indication of the cause in the event of any accidents.

3. Research and Future Development

The second function of radiochemistry in nuclear medicine is in the field of development and research. Two lines of work can be distinguished here. One is concerned with the improvement of existing diagnostic possibilities, *i. e.* with the search for substances that are superior to those already in use with regard to organ-specific storage and also with regard to stability and physiological behavior as well as biological and physical half-lives. The other line is concerned with the fundamental investigation of new diagnostic problems.

3.1. New Radionuclides

It does not appear that the application of hitherto unused radionuclides for *in-vivo* methods could open up entirely new areas of diagnosis. On the other hand, it is conceivable that the use of some radionuclide that has not been employed in the past might lead to improvements. This category includes *e. g.* I-123, a 0.16 MeV γ-emitter with a half-life of 13 h. In thyroid diagnosis, this radioisotope would lead to a decrease in body burden by a factor of about 50 in comparison with I-131. However, its production requires the use of a cyclotron, and is therefore expensive. Moreover, owing to its short half-life, this isotope of iodine cannot be used for all thyroid investigations.

3.2. New Substances

Regarding the search for new substances with interesting physiological and chemical properties there is little evidence, as the examples listed in Table 1 have shown, that would allow the prediction of what type of compound might achieve importance in nuclear medicine. The known radiodiagnostic and radiotherapeutic preparations belong to such diverse classes of substances and exist in so many forms that this hardly offers a pointer for planned research. A brief glance at the history of the development of the principal radiodiagnostic preparations shows that while some of the nuclear-medical preparations were discovered as a result of deliberation, others were found by purely empirical research or even by accident. To take an extreme example: Who could have foretold in 1937, when *Segrè* discovered technetium—an element not existing on the earth, but which can be man-made—that its isotope 99m would be one of the most widely used radionuclides in nuclear medicine[2], or indeed that pertechnetate accumulates in the thyroid?

The use of radioiodine for thyroid diagnosis, on the other hand, was a follow-on from general medicine, so that *Hertz*, *Roberts*, and *Evans* were able to carry out the first nuclear-medical investigations in 1938[3]. Since *o*-iodohippuric acid has been in use for a long time as a contrast medium in X-ray diagnosis, *Tubis* labeled this substance with radioiodine for the first time and used it for the testing of kidney function[4]. Similar considerations led to the labeling of mercury-containing diuretics, *e. g.* Salyrgan, with radiomercury to allow the scintigraphic examination of the kidney. The use of particles of denatured protein in nuclear medicine is again the result of deliberation; however, chance also played a part in this case. *Taplin* first prepared these particles as a more physiological substance to replace radiogold colloid in liver diagnosis. His first experiments surprisingly gave good scintigrams of the lungs[5]; the particles were too large to pass through the lungs. A radiodiagnostic preparation for the lungs had thus been discovered. Smaller particles were suitable for the investigation of the liver.

Clues arising from general medicine will probably no longer be very helpful in the search for radiodiagnostic preparations. Recent preparations have been developed from biological considerations based on observation. One such preparation is transferrin labeled with In-113m. It was observed that carrier-free In-113m injected into the blood stream became bound to the plasma transferrin and so behaved as a chemically similar element to iron even *in vitro*.

However, an opportunity to find compounds that would be of interest in nuclear medicine has had to be ignored for years on economic grounds. Hundreds of thousands of chemical compounds are examined for possible activity in animal experiments in pharmacological laboratories throughout the world. If no such activity is found or if the test animal dies, the carcass is disposed of without examination to establish the organ in which the chemical compound administered or its metabolites have accumulated. It is conceivable that pointers for research with a definite purpose are lost forever here. There is a reasonable probability that compounds that behave organ-specifically would be found, and one would thus have a preliminary selection of substances that could be hetero-labeled and tested for use in nuclear medicine.

As evidence that there could be treasures in store here, one need only recall the circumstances involved in the

introduction of BMHP labeled with radiomercury as a radiodiagnostic preparation in 1963. The corresponding iodine compound had been prepared for the first time by *Sand* and *Hofmann* in 1900[6]. In 1957, it was examined by *Kessler et al.* for its diuretic action[7]. No such action was found, but the authors pointed out that the iodine compound accumulated to an unusual extent in the spleen. A few years later, on the basis of this result, *Wagner et al.* started to examine BMHP successfully for its properties as a radiodiagnostic preparation for the scintigraphy of the spleen[8].

3.3. Improvements to Known Diagnostic Methods

In attempts to improve radiodiagnostic preparations, the direction in which the search should be made is frequently indicated. The gold sol containing Au-198 that is used for liver diagnosis, which emits β- and hard γ-rays, leads to an appreciable radiation exposure of the liver. Moreover, the unphysiological colloidal gold remains in the organ under investigation after the activity has decayed, its elimination half-life being ≈ 30 days. I-131-Albumin particles, on the other hand, for roughly the same radiation exposure, are broken down with a half-life of 1—6 h. A sulfur colloid labeled with the shorter-lived (half-life 6 h) soft γ-emitter Tc-99m allows a considerable reduction of the radiation dose. It is necessary here to take into account the fact that colloidal sulfur is eliminated with a half-life of 25 days. Another aim will be to find a physiological substance that can be labeled with In-113m and is eliminated in a few hours. A preparation recently developed for lung investigations by several groups of workers consists of inactive particles that are labeled at the actual place of use with Tc-99m or In-113m from a milking system. The improvement in quality consists in the smaller radiation burden in comparison with particles labeled with radioiodine and in the fact that the previously prepared particles can be produced with greater uniformity.

3.4. Outlook

It still remains to be seen whether and to what extent the number of questions that can be answered by nuclear-medical means, as far as *in-vivo* methods with γ-emitters are concerned, will continue to increase in the future. The number of organs and hence the number of morbid states that can be examined is obviously limited. Since there are only a few organs that cannot be examined with the aid of the radiodiagnostic methods now available (these include the adrenal, the prostate, and the parathyroid), nuclear medicine will one day reach a limit in this direction. The same is true of efforts to improve existing diagnostic methods.

On the other hand, there still remains the fascinating problem, which overshadows all others, of finding substances with specific affinity for tumors, which, when radioactively labeled, would allow the localization of a wide variety of tumors and, if possible, that would also allow radiation therapy. If this could be achieved, α-emitters would also be of great importance in nuclear medicine, since their action could be confined to the region of the tumor because of their short range.

Thus if it appears that nuclear medicine is subject to certain limits insofar as γ-emitting radionuclides are used for *in-vivo* investigations, it will seem to the chemist that the use of the soft β-emitters H-3, C-14, and S-35 could open up new fields here. These pure β-emitters have only short ranges (less than 20 mg/cm^2); consequently, they cannot be detected outside the organism after incorporation, but can only be measured in excreta, body fluids, and tissue samples after suitable preparation. Investigations with H-3-, C-14-, and S-35-labeled compounds are therefore suitable for the study of metabolic processes, whose products can be detected and identified in the body fluids mentioned or in the respiratory air. Figure 10 shows the autoradiogram of a two-dimensional thin layer chromatogram of a urine extract from a test animal fed with a C-14-labeled chemically uniform pharmaceutical.

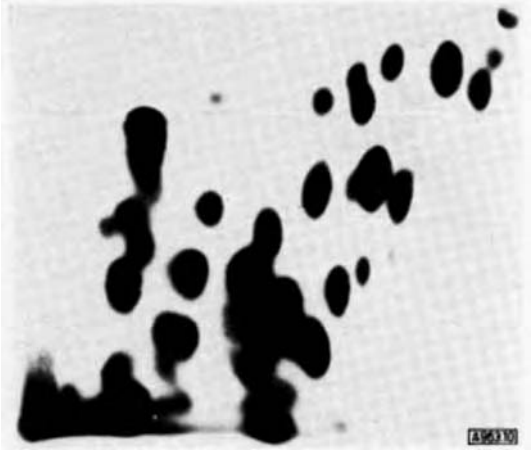

Fig. 10. Autoradiogram of a thin layer chromatogram of a urine extract from a test animal previously fed with a C-14-labeled pharmaceutical.

It is conceivable that this metabolite pattern will show characteristic changes as a result of a morbid process in the organism. If relationships could be demonstrated between abnormalities in the metabolism and morbid states, the three soft β-emitters should considerably extend the possibilities of nuclear-medical *in-vitro* investigations.

Interest in nuclear medicine has recently also been focused on the short-lived positron emitters produced by nuclear processes in the cyclotron. In particular, C-11 with a half-life of 20 minutes is becoming increasingly important. Fast methods for the synthesis of C-11-labeled carboxylic acids and suitable measuring equipment allow the deduction of information on the fate of these substances in the animal organism[9, 10].

The development of *in-vitro* methods must be considered apart from these aspects. The most important of these at present are the methods for the determination of peptide hormones on a radioimmunological basis. These will undoubtedly be applied to other substances, *e.g.* the prostaglandins and the steroids, and to the detection of drugs in the body. A special advantage of these methods is that, in principle, it is possible to automate them. The labeling

required for the *in-vitro* methods will not remain confined to radioiodine; radioimmunoassays based on tritium-labeled compounds are already well known. Whether it will be possible to use other radionuclides such as P-32 or S-35 without carriers (because of the high detection sensitivity required) is a question for preparative radiochemistry.

Chemistry and Significance of the Carbohydrate Moieties of Human Serum Glycoproteins

By Karl Heide and Hans-Gerhard Schwick[*]

Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

The glycoproteins exercise important biological functions as transport proteins, inhibitors, enzymes, hormones, complement factors, and immunoglobulins. Their chemistry is characterized by a number of rules. Thus only asparagine, threonine, or serine can carry the oligosaccharide groups; for the *N*-acylglycosylamine linkage involving asparagine, the grouping Asn-X-Thr or Asn-X-Ser is always present in the peptide chain. However, practically no agreement is found in the molecular weights of the glycoproteins, their carbohydrate contents, and the relative contents of the various sugars. The biological significance of the carbohydrate fraction has not yet been explained, but some idea of the part played by the easily removable neuraminic acid is being formed.

1. Introduction

Glycoproteins occur widely in nature. They consist of a protein component and sugars covalently bonded to it; by definition, these sugars should not be nucleic acids. We are interested here only in the glycoproteins of human blood plasma[1–7]. Numerically they constitute the major part of the plasma proteins, since out of the 60 or so proteins that have been well characterized and isolated in the pure form, only albumin, retinol-binding protein[8], and a few trace proteins are free from carbohydrates (Table 1). Quantitatively, on the other hand, because of the abundance of albumin, which constitutes more than 50% of the total protein, the carbohydrate-free proteins predominate.

Table 1. Carbohydrate-free human serum proteins. (The serum contains about 43% of glycoproteins and about 57% of carbohydrate-free proteins.)

Protein	Amount present in serum [mg/100 ml]
Albumin	4400
Retinol-binding protein	5
C-reactive protein	< 1
Lysozyme	1
α-Amylase (B) (saliva)	
Carboanhydrase

2. Chemical Composition and Structure of the Glycoproteins

2.1. Carbohydrate Content of the Glycoproteins

The sugar units found in the glycoproteins are *N*-acetylglucosamine, *N*-acetylgalactosamine, galactose, mannose, glucose, fucose, *N*-acetylneuraminic acid (sialic acid), and xylose. They were formerly determined by the modifications of known methods described by us[9]: galactose and

mannose by the orcinol method of *Sörensen* and *Haugaard*, hexosamine with *p*-dimethylaminobenzaldehyde in *Blix*'s modification of the method of *Elson* and *Morgan*, acetylneuraminic acid with *Bial*'s reagent by *Klenk*'s method, and fucose by the cysteine-sulfuric acid method of *Dische* and *Shettles*.

It has recently become possible to detect the sugars and to determine them quantitatively by improved chromatographic techniques[10–13]. Glucosamine and galactosamine are determined in the amino acid analyzer[14]. Neuraminic acid is usually determined by the thiobarbituric acid method[15]. *o*-Phenanthroline, which forms a colored complex with bound neuraminic acid without any pretreatment, has recently been recommended[16].

The carbohydrate contents of a series of human plasma proteins are shown in Table 2. Detailed data are also available for a number of plasma proteins (Table 3). The contributions of the various sugar units to the total carbohydrate content are shown in Table 4 (Ig = immunoglobulin).

Glycoproteins for which such detailed analyses have not yet been carried out are particularly the complement factors C5[47] and C9[48] and the lipoproteins. We were the first, in 1957, to detect carbohydrates in the lipoproteins[49],

which constitute about 10—15% of the total serum proteins. In β-lipoprotein, with a peptide content of 26.5%, we found 1.4% of hexoses, 0.2% of neuraminic acid, and 0.45% of acetylhexosamine. α_1-Lipoprotein has a peptide content of 41% with 1.3% of hexoses, 0.1% of neuraminic acid, and 0.25% of acetylhexosamine. These results were confirmed in 1966[50]. Of the six apolipoproteins, *i.e.* the peptide chains that form the skeleton of the lipoproteins, apo-Ser and apo-Ala contain carbohydrates[51].

It is now possible to compare the analytical values for very many more glycoproteins than was formerly the case. An important contributory factor here has been the work carried out in our laboratories on highly purified glycoproteins isolated from side fractions of the industrial plasma fractionation.

Examination of the tables shows that the carbohydrate contents of the plasma proteins cover a wide range. Prealbumin contains only 0.4% of hexoses, whereas the α_1-acid glycoprotein has a total carbohydrate content of about 38%. (Recent gas-chromatographic analyses indicate that prealbumin contains no carbohydrates at all[52]; moreover, the detection of such small quantities of hexoses by the orcinol method used by us is problematic.) The α_1-acid glycoprotein is taken as a standard type for structural investigations on serum glycoproteins.

The relations of the sugars to one another also vary. For example, Gc-globulin contains no neuraminic acid. There is no fucose in the histidine-rich α_2-glycoprotein, in fibrinogen, or in β_2-glycoprotein III. No galactosamine can be detected in the α_1-acid glycoprotein.

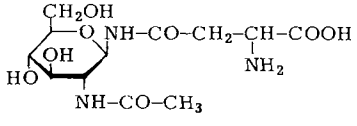
The galactose: mannose ratio (Table 3) is >1 in the carbohydrate-rich α_1-globulins, 1 in haptoglobin, and <1 in a number of other glycoproteins. The ratio total sugars: hexosamine is generally in the region of 2.9—3.4. The hexose: hexosamine ratio is 1 or slightly higher. The "secretory component" and C1q are exceptions here. C1q also has peculiarities in its amino acid composition[43].

The highest neuraminic acid values go together with a particularly high total carbohydrate content. This applies to the C1 inactivator and the α_1-acid glycoprotein. β_2-Glycoprotein III, with a total carbohydrate content of only 10%, has the highest relative content of neuraminic acid. Since the neuraminic acid residues carry a negative charge they give the glycoproteins a greater electrophoretic mobility. This is particularly noticeable in the case of the immunoglobulins (Tables 2 and 3).

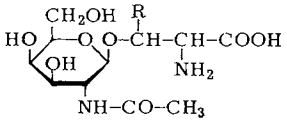
2.2. The Carbohydrate-Peptide Bond[11]

The carbohydrates are bonded to the peptide chains in the form of large oligosaccharide units. The molecular weights of these sugar complexes are 2370 in transferrin and 3170 in the α_1-acid glycoprotein. For investigations on the nature of the bond, the glycoproteins are treated either with pronase, a proteinase from *Streptomyces griseus*, or with a combination of pepsin, trypsin, chymotrypsin, or papain. The glycopeptides can be separated from the cleavage mixtures by fractionation. Excess amino acid residues are removed with pronase or carboxypeptidase.

The elucidation of the bonding is facilitated by the fact that the asparagine-carbohydrate bond is relatively stable to alkalis and acids. It is more stable to dilute acids than the glycoside linkages in the oligosaccharide complexes. It was therefore possible to isolate the compound *(1)* from a glycopeptide; in this compound the sugar complex



(1)

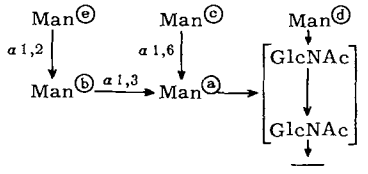


(2)

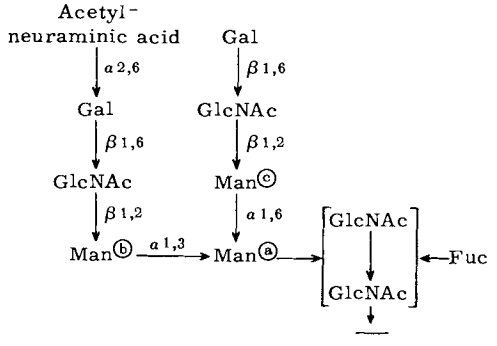
is bound *via* the reducing group of *N*-acetylglucosamine to the amide group of asparagine. This type of binding is characteristic of most plasma proteins. In addition to this *N*-acylglycosylamine linkage, the *O*-glycoside linkage as in *(2)* is also found[53]. In this case the sugars are bound *e.g. via* *N*-acetylgalactosamine to the hydroxyl group of threonine or serine. This linkage occurs together with the *N*-acylglycosylamine linkage in human IgA[54] and in rabbit IgG[55]. A Waldenström IgM was found to contain only the *N*-glycoside linkage[56].

2.3. Structure of the Oligosaccharide Units

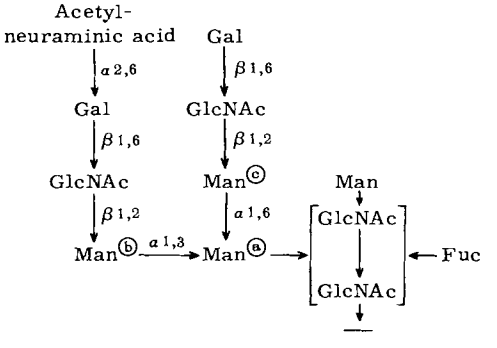
The sequence of the sugar units is determined by successive enzymatic degradation of the glycopeptides with glycosidases. Neuraminidase, β-galactosidase, α-mannosidase, and β-acetylglucosaminidase are used for this purpose[57].



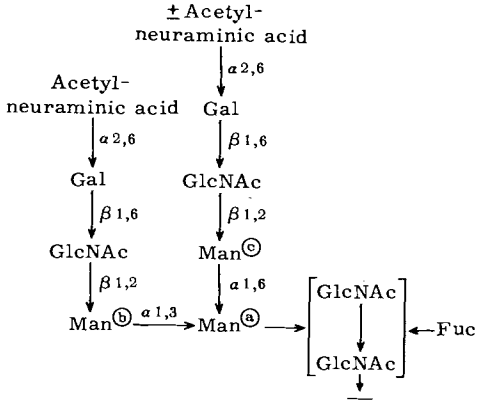
Glycopeptide I



Glycopeptide IV



Glycopeptide V



Glycopeptide VI

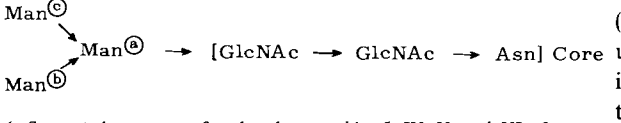


Fig. 1. Suggested structures for the glycopeptides I, IV, V, and VI of immunoglobulin M (IgM) after *Hickman et al.* [58]. The bonding asparagine residue counts as part of the core.

The enzymes also provide information on the type of linkage by which the sugar residues are joined. Further information on this point is obtained by periodate oxidation and by methylation of the glycopeptides with subsequent characterization of the alditol acetate derivatives of the methylated sugars by gas chromatography and mass spectrometry[58,59]. Alkaline hydrolysis followed by deamination with nitrous acid has recently also been recommended[60].

Investigations on the oligosaccharide units of IgM have shown that they are derived from two basic types: a simple type that consists only of *N*-acetylglucosamine and mannose and a complex type that also contains galactose, fucose, and neuraminic acid (Fig. 1). They evidently contain a common core. A fundamentally similar structure of the carbohydrate groups was also found earlier in the α_1-acid glycoprotein[1], fetuin, α_2-macroglobulin, transferrin[61], IgA[54], and IgG[62].

The sugar complexes are thus bonded to the peptide chain *via* *N*-acetylhexosamine in every case. In the α_1-acid glycoprotein, the carbohydrate group branches at the *N*-acetylglucosamine according to *Wagh*[63], while according to *Sato* it branches only at the mannose[1]. Mannose is also the branching point in transferrin[61] and in other immunoglobulins. The neuraminic acid (which is present as *N*-acetylneuraminic acid) and the fucose are terminal. Positional isomerism is therefore possible for these residues. The neuraminic acid is bonded to galactose. However, the α_1-acid glycoprotein also appears to contain one to three more difficultly removable neuraminic acid residues which are linked to *N*-acetylglucosamine[60].

Deviations from the normal structure of the sugar complexes have been observed for several proteins. A transferrin poor in neuraminic acid has been found in cerebrospinal fluid[7,64]. α_1-Acid glycoprotein poor in neuraminic acid has been found in the serum and urine of patients with Hodgkin's disease, psoriatic arthritis, and diabetes[65,66]. The explanation offered is that these patients with chronic diseases form glycoproteins in unusually large quantities over a long period, and that this causes their synthesis capacity to decrease. Variations of the carbohydrates has also been described in the case of fibrinogen[67,68]. Coagulation factor X from bovine plasma appears to occur in two forms; factor X-I has one to two neuraminic acid residues and one to two hexose residues less than factor X-II, though its coagulation activity is the same[69].

2.4. Localization of the Carbohydrates in the Peptide Chains

The exact localization of the carbohydrate complexes (denoted here by C1, C2, *etc.*) in the peptide chains is at present known only for IgM and IgG globulins and for the α_1-acid glycoprotein. In human IgM, each monomer (molecular weight 180000) contains ten oligosaccharide units[70], *i.e.* five for each μ chain (Fig. 2). C1 is situated in the Fd region, at about amino acid 170, and C2 in the hinge region near the disulfide bridge around position 230. C3, C4, and C5 are in the Fc region. C1, C2, and C3, which are situated in the interior of the molecule,

are of the complex type, whereas C4 and C5 consist only of hexosamine and mannose.

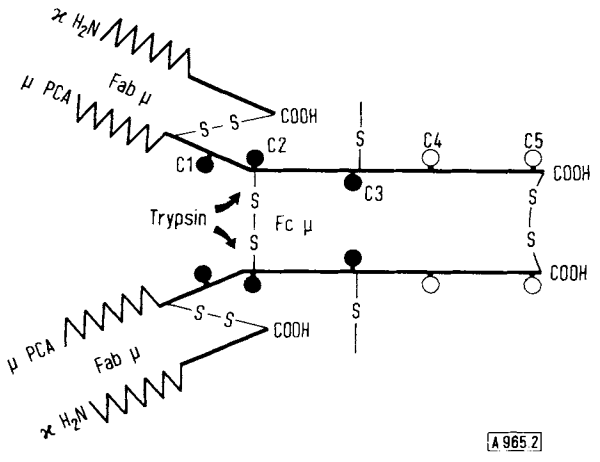

Fig. 2. Scheme of the polypeptide chain structure of a monomer unit of human IgM Ou with the positions of carbohydrate complexes C1—C5 (after [70]). PCA = 5-oxopyrrolidinecarbonyl.

These observations, which were made on the two Waldenström IgM globulins Ou and Di, have been confirmed for the IgM paraprotein Dau[71]. The carbohydrate compositions of the five oligosaccharide units of these three IgM globulins can be seen from Table 5. Apart from the mannose values in italics, the agreement is very good. It was particularly important in these investigations to ensure that the J chain was removed, since this also contains carbohydrates (see Table 3).

Table 5 also shows the microheterogeneity of the glycoproteins. Nearly all glycoproteins appear to contain the carbohydrate units in various stages of completion or with small modifications[2,58,72,73]. (It is not entirely correct to take the Waldenström globulins as an example for the demonstration of this microheterogeneity, since each paraprotein is unique; this is true of its amino acids, and possibly also of its carbohydrates.)

IgG contains only about one quarter of the carbohydrates (2.9%) present in IgM. In the case of rabbit IgG, these are present in three oligosaccharide units[55] (Fig. 3). C1 is situated in the Fd part of each of the two H chains and is detectable in about 15% of the molecules. C2 is situated unsymmetrically on only one H chain close to the disulfide bridge in about 80% of the molecules. C3 is again attached to both H chains in the Fc region (in position 67 reading from the carboxyl end) and appears to be present in all IgG molecules.

The fact that in addition to carbohydrate-poor IgG molecules there are also carbohydrate-richer molecules with several sugar units has also been reported in the case of human IgG[74]. Out of 76 IgG myeloma globulins, 29% had a higher carbohydrate content. In the carbohydrate-poor molecules, the carbohydrates are localized only in the Fc part. An example of this is the IgG1 globulin Eu, whose complete amino acid sequence is known and whose carbohydrate unit is attached to asparagine-297[75].

In molecules with a 2 to 2.5 fold increase in the carbohydrate content, the sugars also occur in the Fd part or in the L chains. In molecules with a 3 to 4-fold increase

Table 5. Carbohydrate composition of the glycopeptides of the IgM globulins Dau, Ou, and Di; values in residues per molecule (after [71]).

Dau	H chain [a]	C1	C2	C3	C4	C5	Total
Fucose	2	1	1				2

in the sugar content, they are found in the Fc and Fd parts and in the L chains. The carbohydrate-rich IgG molecules also contain more acetylneuraminic acid. Their acetylneuraminic acid : fucose ratio is 0.44—0.98, compared with 0.18—0.27 in the carbohydrate-poor IgGs.

Because of this higher content of acetylneuraminic acid, the carbohydrate-rich IgG molecules migrate more rapidly in electrophoresis. We had already been able to isolate faster-migrating IgG globulins of this type from highly purified normal serum gamma globulins by preparative zone electrophoresis. They contained 0.47% of acetylneuraminic acid, whereas the slowest IgG fraction contained only 0.18% of acetylneuraminic acid[76].

Abel et al.[74] estimate that 91% of IgG molecules are carbohydrate-poor and 9% carbohydrate-rich. The carbohydrate content of 2.9% is an average value. The IgM also contains molecules with L-chain carbohydrates. Bence-Jones globulins can therefore also contain carbohydrates, depending on the paraprotein from which they are derived[77].

The α_1-acid glycoprotein is a one-chain protein containing about 210 amino acids and five oligosaccharide units, all of which are situated in the N-terminal third of the molecule and attached to asparagine (Fig. 4)[78]. For a number of other proteins (Table 6) only the number of sugar units per molecule is known. Human fibrinogen, with a carbohydrate content of 2.8%, has sugar units in the Bβ and γ chains. The A_α chain is free from carbohydrate[79].

2.5. Influence of the Carbohydrates on the Physico-Chemical Behavior of the Glycoproteins

The high neuraminic acid content of the α_1-acid glycoprotein affects its physico-chemical behavior[82]. Comparative studies on the intrinsic viscosities, diffusion and frictional coefficients, and behavior in the ultracentrifuge of the native and the neuraminic acid-free glycoprotein indicate that the native molecule has a somewhat less regular shape. This shape could be explained by the assumption that all the neuraminic acid residues are localized in the N-terminal third of the peptide chain, and that this part of the molecule may therefore be more strongly hydrated than the other parts.

The high carbohydrate content also affects the determination of the molecular weight. In the gel filtration method with Sephadex G-75, for example, a molecular weight of 60000 is found for the α_1-acid glycoprotein (correct value: approx. 44000)[83]. When acrylamide gel electrophoresis in the presence of sodium dodecyl sulfate is used for the determination of the molecular weight, the values found depend on the degree of crosslinking of the gel[84]. This anomaly is attributed to weaker binding of the dodecyl sulfate by the oligosaccharide units than by the protein part.

Because of their strong hydration, the carbohydrate groups cause increased solubility of the glycoproteins. Thus the serum proteins that are richest in carbohydrate, *i.e.* C1 inactivator, α_1-acid glycoprotein, and hemopexin, belong to the seromucoid fraction. These proteins are not precipitated by perchloric acid and trichloroacetic acid, exhibit considerable heat resistance in solution, and require much greater quantities of precipitants for precipitation[85, 86].

A particularly interesting phenomenon is that of the freezing-point depressing glycoproteins of the Antarctic fish *Trematomus borchgrevinki*. These keep the blood from freezing even at −1.9 °C. There are essentially three glycoproteins involved, with molecular weights of 10500, 17000, and 21500. They are built up from Ala-Ala-Thr units. All the threonines are *O*-glycosidically linked to galactosyl-*N*-acetylgalactosamine. The activity is lost on oxidation of the hydroxyl groups of the sugar to carboxyl groups. At low concentrations (< 1%) these glycoproteins are as effective as sodium chloride. They thus cause a freezing point depression some 100 to 1000 times as great as that expected from their molecular weight[87, 88].

In ceruloplasmin, chemical changes influence the crystalline form. The native protein forms tetragonal prisms, while the neuraminic acid-free protein forms hexagonal prisms[89].

3. Significance of the Carbohydrate Component

The glycoproteins are responsible for important biological functions. They act as transport proteins, inhibitors,

enzymes, hormones, coagulation factors, complement factors, and antibodies. One might ask whether the carbohydrate component has anything to do with their function. This question is not easy to answer, as we still know too little. Some information is available only in connection with the significance of neuraminic acid. This terminal sugar can be relatively easily split off by neuraminidase[90]. A highly purified enzyme from *Vibrio cholera*, which is free from proteases, is available for investigations of this type.

3.1. Role of Neuraminic acid

The influence of treatment with neuraminidase on the biological activity of important glycoproteins is shown in Table 7. Some, including the hormones, are inactivated. The proteinase and complement inhibitors are not affected. The antibodies also suffer no loss of activity. The transport proteins can still bind their ligands and transport them. For example, neuraminic acid-free transferrin can still supply iron to the reticulocytes[91,92]. The bonding of cortisone to transcortin[93] or of progesterone to the α_1-acid glycoprotein[94] is also still possible.

Table 7. Influence of neuraminidase treatment on the biological activity of some glycoproteins.

Inactivation	No loss of activity	
Choriongonadotropin (HCG)	Cholinesterase	α_1-Antitrypsin
Follicle-stimulating hormone (FSH)	Thrombin	Antithrombin III
Erythropoetin	Hageman factor	Inter-α-inhibitor
MN substance	Transcortin	α_2-Macroglobulin
Migration inhibiting factor (MIF)	Thyroxine-binding globulin	C1-Inactivator
	Haptoglobin	
	Ceruloplasmin [a]	Antibodies
	Transferrin	
Fibrinogen		
Prothrombin		

[a] Binding of copper and oxidase activity.

Neuraminic acid-free ceruloplasmin injected into rabbits is eliminated from the circulation within a few minutes, and is then found in the liver parenchyma cells. These cells evidently have a special affinity for the galactose residues. On removal of the new terminal galactose with β-galactosidase, one again finds half-lives equivalent to those of native ceruloplasmin[95-97].

Removal of neuraminic acid from fibrinogen leads to a change in the structure of the fibrin clot[98,99], and neuraminic acid-free prothrombin, as we found earlier, is converted more rapidly into thrombin in concentrated citrate solution[100].

A phenomenon that is also closely related to the neuraminic acid content is the hemagglutination inhibition caused by influenza virus. Table 8 shows a number of serum glycoproteins arranged in order of their inhibitor activity towards the strain B/Maryland[101]. The inhibitor activity does not run parallel to the neuraminic acid content, since the α_1-acid glycoprotein, with 12% of neuraminic acid, is only a weak inhibitor in comparison with the uromucoid of *Tamm* and *Horsfall*, which contains only 7% of neuraminic acid. The inhibitor action increases after polymerization of the α_1-acid glycoprotein. A sufficiently high molecular weight is therefore essential. The fact that the glycoproteins exhibit different inhibitor effects against other strains of virus indicates that a special steric arrangement of the receptors is necessary. The terminal neuraminic acid residues of the glycoproteins occupy the neuraminidase receptors of the virus particles, so that these can no longer react with the erythrocytes[1,101].

3.2. Participation of Other Sugar Units

We have evidence for two other proteins that the carbohydrates are directly responsible for their activity. The complement component C9, which is responsible for the final phase of the complement reaction, forms a chelate with iron[102]. In its biological activity, it can be replaced by *o*-phenanthroline. In this case, the iron is bonded by the carbohydrates, since C9 is inactivated on oxidation with potassium metaperiodate. The ability of carbohydrate-rich glycoproteins to bind iron is demonstrated particularly impressively by gastroferrin[103]. This iron-binding glycoprotein of the gastric mucosa, with a molecular weight of about 260000, has a carbohydrate content of about

Table 8. Serum glycoproteins as inhibitors of hemagglutination due to influenza virus (strain B/Md) (after [101]).

	Inhibitor activity	Mol.-wt.	Neuraminic acid [%]	Neuraminic acid [mol/mol]
Blood group substance MM	100	12000000	11.5	4466

[a] Of *Tamm* and *Horsfall*.

85%. It is able to bind 6% of its own weight of iron. Neuraminic acid plays no part here.

A second example is the relatively obscure "colony stimulating factor" for granulocytes and macrophages, which is also inactivated on oxidation of the carbohydrates[104].

3.3. Carbohydrates as Inhibitors of Biological Reactions

The carbohydrates cover considerable parts of the surface of the glycoproteins and can thus inhibit the action of proteolytic enzymes. For example, native α_1-acid glycoprotein is split only with difficulty by trypsin and papain[105]. Ceruloplasmin is also known to have a certain resistance to papain[106]. Faster-migrating IgG globulins which have a higher carbohydrate content are similarly characterized by relatively high stability to hydrolysis[107]. The exocrine IgA, which exerts its protective function *e. g.* in the intestinal mucosa as a copro-antibody, should have a very high resistance to bacterial and digestive enzymes because of its carbohydrate content of 12%[108,109]. On the other hand IgD, with roughly the same carbohydrate content, is extremely readily attacked by proteolytic enzymes. Its carbohydrates appear to be situated in the Fd and Fc parts[110]. They must be so far apart that the hinge region is readily accessible for cleavage.

The α_1-acid glycoprotein can bind vitamin B_{12}, but has only a relatively low binding capacity in the native state. On removal of the neuraminic acid, the binding of vitamin B_{12} increases by a factor of 4[111]. The immunogenicity of the α_1-acid glycoprotein should also be increased by removal of the neuraminic acid. This procedure is recommended for the preparation of antiserums against this protein[112].

The removal of neuraminic acid has recently become interesting in tumor immunology. For example, tumor cells are treated with neuraminidase and reinjected into the patient with or without BCG[113,114]. The immune cells should now recognize the tumor antigens and destroy the tumor with the aid of antibodies, complement, and cellular immunity.

The fact that carbohydrates, and particularly neuraminic acid, hinder the development of humoral or cellular immunity is also of interest for transplantation immunology. In addition to immunosuppressive drugs, serum proteins are also able to suppress sensitization[115]. The best known and the most extensively discussed is *Mowbray*'s α-globulin[116]. This protein was able to inhibit antibody formation and the rejection of transplants. The experiments were difficult to reproduce, and it was finally concluded that the immunosuppressive action was due to ribonuclease activity. *Schmid et al.*[117] recently succeeded in isolating a peptide having a molecular weight of 4000—6000, which is practically free from carbohydrate, from *Cohn*'s fraction IV. This peptide can prevent the phytagglutinin-induced proliferation of lymphocytes and inhibit the formation of plaque-forming cells in mice immunized against sheep erythrocytes.

These substances do not appear to be identical with the chalones. These are substances that inhibit cell proliferation in certain tissues, *i. e.* inhibitors of mitosis. They are formed by the cells of this tissue, *e. g.* by lymphocytes, granulocytes, or fibroblasts, and are also important in transplantation and tumor immunology[118–120]. They can be isolated from diploid human fibroblasts, bovine spleen, or calf thymus. The molecular weights are between 30000 and 50000. The chalone from calf thymus is an acidic α-glycoprotein, and it seems reasonable to ask whether it is related to the α_1-acid glycoprotein.

3.4. Biological Properties in which Carbohydrates Play No Part

There are regions on the Fc part of the immunoglobulins that are important to placenta permeability, complement binding, phagocytosis, and species-specificity. Carbohydrates had been held responsible in particular for the first of these properties[121]. As has been shown by comparison of native mouse immunoglobulin with mouse immunoglobulins that had been treated with specific glycosidases, however, the sugars are not necessary for the placenta permeability[122].

The sugars also appear to be of no importance to the complement binding of the IgG globulins[123]. Isolated IgG glycopeptides did not affect complement binding, and twelve IgG myeloma globulins having different carbohydrate contents showed no dependence of the complement binding on the sugar content[124]. In phagocytosis experiments with numerous plasma proteins, we were unable to find any evidence of dependence on the sugars[125]. IgM, with a carbohydrate content of about 10%, stimulated phagocytosis effectively, but the carbohydrate-free C-reactive protein caused practically the same phagocytosis.

The species-specificity of the immunoglobulins also does not appear to involve the carbohydrates. The latter are not immunogenic[126]. A possible reason for this is that there are only a few basic types of glycoprotein-oligosaccharide units (Fig. 1) and that these have remained practically the same in the course of evolution. They are of widespread occurrence, and the body therefore does not react to them as to foreign substances.

This abundance of facts leads us to wonder about the true significance of the carbohydrates. Is there a single underlying principle common to all these phenomena, or are the sugars only there by accident, a relic of the dim past and of evolution?

3.5. Evolution of the Glycoproteins

Analyses of the amino acid sequences of a number of proteins have confirmed *Darwin*'s views. The major stages of evolution can be followed from the changes in the sequence of cytochrome c[127]. This protein, which plays a part in biological oxidation in the cells, has changed least in the course of evolution. The fine points of our family tree, particularly of the latest phases, can be seen from hemoglobin[128]. However, these two proteins contain no carbohydrate.

Because of their importance in prophylaxis and therapy, the immunoglobulins are the most extensively studied of the serum glycoproteins[129,130]. According to *Porter* and *Edelman*, who received the Nobel prize for this work in 1972[131], they consist of two light (L) and two heavy (H) peptide chains. The L and H chains are thought to be derived from an ur-gene, which codes only half of the L chain, and from which the present-day immunoglobulin genes have developed by gene duplication and hypermutation[132-135]. The chains of IgM, *i.e.* the μ chains, are probably biogenetically the oldest of the H chains.

In addition to the amino acid sequence, the carbohydrate composition also provides important information on the evolution of the immunoglobulins[136,137]. Thus the carbohydrate contents of the high molecular weight antibodies (IgM), whose H chain has a molecular weight of about 70000, have remained practically unchanged (Table 9). They also agree with the 7S-IgM antibodies that occur in some species, with which they are antigenically identical. The only exception is chicken IgM globulin, which has a lower carbohydrate content.

segment of this type containing carbohydrate is missing, as in the turtle, the carbohydrate content of the H chain is very low. On the other hand, if a chain segment that is poor in carbohydrate is missing because of divergent gene duplication, as could be the case in the African lungfish, the carbohydrate content of the H chains may be higher than for the H chains with three constant regions.

The molecular weight of the H chain of the LMW antibody in chickens is 66000. One might ask whether the increased carbohydrate content in comparison with that of human IgG could be due to an additional constant chain segment containing carbohydrate. There may be a relationship between this divergent structure and the changes in the conformation of chicken antibodies in salt solutions of various concentrations, which are thought to be responsible for the special precipitation behavior of chicken antibodies in agar gel[139]. It is well known that chicken antibodies require an NaCl content of 8% for the formation of immune precipitates.

Mannose, galactose, glucosamine, and acetylneuraminic acid have been found in the immunoglobulins of all species

Table 9. Carbohydrate composition of immunoglobulins of various species. AR = complete antigen relationship between HMW and LMW.

Class	Species [a]	Hexose [%]	Hexosamine [%]	Fucose [%]	Acetyl-neuraminic acid [%]	Total carbohydrate content [%]	AR

[a] The abbreviations HMW (high molecular weight) and LMW (low molecular weight) refer to molecular weights of IgM ~ 900000 and IgG ~ 150000 resp. for the native antibodies.

The H chains of IgG globulin, the γ chains, with molecular weights of about 50000, have nothing to do with the μ chain as far as common antigen determinants are concerned. As was shown in Table 2, they have a total carbohydrate content of less than 3% in man. The γ chains normally consist of a variable part (V) and three constant parts (C_1, C_2, and C_3), whose region covers about 110 amino acids with a molecular weight of about 12500[138]. If one of these constant regions is missing, as in the H chain of the turtle or of the African lungfish, the molecular weight of these shortened H chains is only about 38000.

In bovine IgG, the complex oligosaccharide unit C3 is localized in the C_3 region of the H chain. If a chain

of vertebrates investigated. The mannose:galactose ratio was greater than 1 in mammals and birds, and was of the order of 1 in animals below the birds. Fucose was absent in two of the species investigated[140]. The carbohydrate composition of the transferrins also differs considerably according to the species[141,142]. The differences are explained by the assumption that the proteins should contain different numbers of heteropolysaccharide units, *i.e.* one in monkey (macaque), chicken, and bovine transferrins, two in human, horse, and rabbit transferrins, and four in pig transferrin.

The relationship recently found by amino acid sequence analyses between the immunoglobulins and the α_1-acid

glycoprotein is particularly interesting in connection with the biogenetics of glycoproteins[143]. As can be seen from Fig. 5, the peptide chain of the α_1-acid glycoprotein contains two partial sequence duplications. Region B is homologous with the carboxyl end of segment A. Region D is homologous with region C. The amino-terminal segment

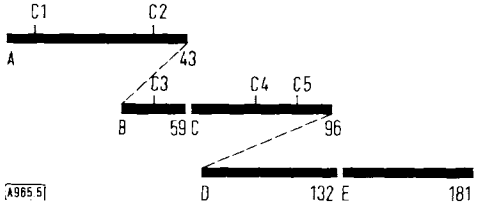

Fig. 5. Structure of the α_1-acid glycoprotein (cf. Fig. 4). To illustrate the homologous regions, the chain has been divided into regions A to E (after [143]).

A consisting of 43 amino acids is homologous with the amino-terminal end of the L chain (κ type) of IgG globulin. The 22 amino acids at the carboxyl end of region D exhibit a very high degree of homology with the α chain of haptoglobin[144]. Sequence E is homologous with a constant region of the H chain of rabbit IgG[*].

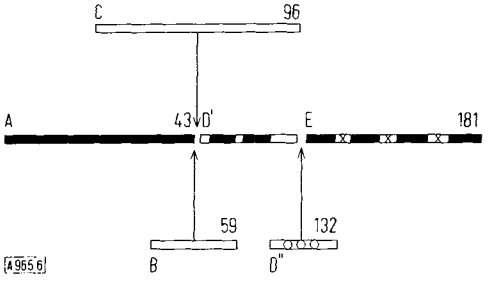

Fig. 6. Schematic representation of the "reduced" amino acid sequence of the α_1-acid glycoprotein. The regions B and C with sequence duplication and the haptoglobin sequence D are removed. The peptide chain then consists only of A, which corresponds to the variable region of the L chain of IgG, E, which resembles the constant region of the H chain of IgG, and a part of region D. It includes about 110 amino acids and is thus the hypothetic ur-immunoglobulin (after [143]).

If the segments with sequence duplication and the haptoglobin region are omitted, as shown in Fig. 6, one obtains a "reduced" peptide chain, which corresponds to the hypothetical ur-immunoglobulin. It is tempting to think that the α_1-acid glycoprotein arose from this.

In view of the genetic relationship between these two proteins, one may ask whether the α_1-acid glycoprotein still has any functional connection with immune defense, particularly since its content in the serum is greatly increased in all inflammatory processes, and how the sugars are incorporated into the peptide chain, *i. e.* how the glycoproteins are formed.

3.6. Synthesis of the Glycoproteins

There are essentially two sites for the synthesis of serum glycoproteins, *i. e.* the liver and the lymphoid tissue. Exceptions are the fibrin-stabilizing factor, which comes from the platelets, and a number of glycoprotein hormones, which come from the pituitary and the placenta. Most glycoproteins are synthesized exclusively in the liver[145–147] (Table 10). Transferrin appears to be formed in the liver and in lymphocytes. The immunoglobulins come from plasma cells, which are derived from B-lymphocytes. The plasma cells responsible for the formation of the secretory IgA can produce the protein in mammary glands, bronchi, intestinal mucosa, *etc.* It is possible that other glycoproteins are formed in the lymphocytes.

Table 10. Site of synthesis of glycoproteins of human plasma.

Glycoprotein	Synthesis site
α_1-Fetoprotein	Liver
α_1-Acid glycoprotein	Liver
Vitamin-B_{12}-binding protein TC I	Leukocytes
α_1-Antitrypsin	Liver
Prothrombin	Liver
Gc-Globulin	Liver
Haptoglobin	Liver
Antithrombin III	Liver
Ceruloplasmin	Liver
C I-Inactivator	Liver
Cholinesterase	Liver
α_2-Macroglobulin	Liver
Transferrin	Liver, lymphatic tissue spleen, mammary glands, lymphocytes, macrophages
C4	Liver
Hemopexin	Liver
β_2-Glycoprotein I	Liver
Fibrinogen	Liver
Factor XIII	Liver
Fibrin-stabilizing factor	Thrombocytes
Immunoglobulins	Lymphatic tissue: lymph nodes, spleen, mammary glands, plasma cells

The glycoprotein synthesis could proceed in three ways[53, 73]:

1. Protein and carbohydrate groups could be synthesized separately and combined at the site of formation of the peptide chain, *i. e.* the ribosomes.

2. The incorporation of the carbohydrate groups could occur after the peptide chain has left the ribosome and while it is in the endoplasmic reticulum.

3. A combination of the above two possibilities would also be conceivable, part of the carbohydrates being incorporated in the ribosome phase and the remainder attached later. Successive incorporation according to possibility 3 appears to be valid for the synthesis of the serum glycoproteins in the liver and lymphocytes. It has been shown with radioactively labeled leucine and ^{14}C-monosaccharides that the L chain of an IgG myeloma globulin is synthesized in about 30—40 seconds in mice[148–150]. The entire peptide component of the IgG molecule is formed in about 90 seconds. The antibodies found in the ribosome fraction are practically free from carbohydrate and only glucosamine can be detected. The antibodies now migrate to the periphery of the cell. On the way there through the channels of the endoplasmic reticulum, further monosaccharides are attached in steps by several glycosyl transferases, which are localized along the membranes of the

[*] The data in Fig. 4 do not entirely agree with those in Figs. 5 and 6. Fig. 4 is based on a peptide chain of about 210 residues and Figs. 5 and 6 on a chain of 181 residues. However, this has no effect, in principle, on the information deduced from Figs. 5 and 6.

rough and smooth endoplasmic reticulum and in the Golgi apparatus. The terminal fucose and acetylneuraminic acid residues are incorporated last. It takes a total of about 20 to 30 minutes for complete antibody molecules to appear outside the cell.

If the incorporation of monosaccharides is inhibited[151] by addition of 2-deoxy-D-glucose[152], the new antibody molecules no longer migrate to the periphery. They remain in the membranes containing ribosomes, and cannot pass into the rough endoplasmic reticulum or from there to the smooth membranes. The sugars do not appear to be important for the transport of the glycoproteins from the smooth endoplasmic reticulum or the Golgi apparatus out of the cell.

The synthesis of the oligosaccharide units is not controlled by a ribonucleic acid code as in the case of the peptide chain, but depends on the presence of the appropriate glycosyl transferases in the tissue in which the synthesis takes place. The presence or absence of these enzymes is naturally determined genetically. In the synthesis of ovotransferrin (conalbumin), which is identical immunologically and in its amino acid structure with chicken serum transferrin, but has a different carbohydrate composition (it contains only glucosamine and mannose), the enzymes required for the incorporation of further sugar residues were evidently absent[153]. Since the incorporation into the peptide chain is not coded by RNA, but must nevertheless be genetically controlled, it was assumed that the signal for the action of the glycosyl transferases is fixed in the amino acid sequence. Wherever Asn-X-Thr or Asn-X-Ser (where X can be any amino acid) occurs in the amino acid sequence hexosamine is to be attached to asparagine[2, 3, 154]. The amino acid X is thought to determine the type of oligosaccharide unit. One objection to this hypothesis is that the ribonucleases A and B have the same amino acid sequence, but one contains sugars and the other does not. As was mentioned in the case of chicken transferrins, however, the occurrence and nature of the glycosyl transferases also play a part, and there must be no inhibitors present for the incorporation of the sugars. This explains the occurrence of the sugars in the glycoproteins but the question of their true significance has not yet been answered.

3.7. Function of the Carbohydrates in Glycoproteins

According to *Eylar*'s hypothesis[155], the significance of the sugars is that they allow the proteins formed in the cells to pass out through the cell membrane into the extracellular space. They are thus a sort of chemical pass. *Eylar*'s view appeared to be confirmed by the findings of *Melchers* and *Knopf*[148, 150] (see Section 3.6). However, there are also arguments against this view. For example, serum albumin, which constitutes the major part of the plasma proteins, is synthesized in cells and can pass through their membrane, though it contains no carbohydrates. The anterior lobe of the pituitary gland secretes hormones; three of these, *i.e.* LH, FSH, and TSH, are glycoproteins, while the other three, *i.e.* growth hormone, ACTH, and prolactin, are not. The more recent work of *Esterly*[151] and of *Melchers*[152] also throw doubt on the hypothesis. The many phenomena described agree more closely with the view of *Winterburn* and *Phelps*[156, 157]. According to this view, the sugars are receptors in a recognition process. Examples of positive recognition would be:

1. hormones that find their target cell *via* neuraminic acid residues, such as chorionic gonadotropin and FSH, and which are inactivated when the neuraminic acid is removed;
2. the rapid catabolism of neuraminic acid-free ceruloplasmin. As long as the neuraminic acid was terminal, the liver parenchyma cells did not recognize the protein. The galactose residues exposed on removal of the neuraminic acid, on the other hand, were immediately recognized, possibly by sialyl transferases of the cell membrane, and the asialo-ceruloplasmin disappeared from the blood stream in a very short time;
3. the hemagglutination by influenza viruses.

Negative recognition would be *e.g.* the masking of antigen determinants or the covering of large areas of the molecular surface. These are the phenomena mentioned in Section 3.3 that are important at present in tumor and transplantation immunology. In view of the topicality of these modern lines of medical investigation, it should be worthwhile to try to discover the significance of the glycoproteins.
