
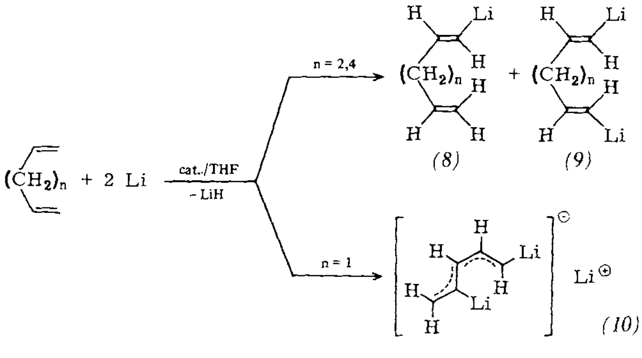
R = $(CH_2)_nCH_3$; n = 1,3,5

1,ω-Dienes (1,5-hexadiene and 1,7-octadiene) react with lithium and the same catalysts to give a mixture of (*E*)-1-lithio-1,ω-alkadienes *(8)* and (*E,E*)-1,ω-dilithio-1,ω-alkadienes *(9)*. The catalytic lithiation of 1,4-pentadiene, on the other hand, leads to a crystalline trilithium compound $C_5H_5Li_3$, which according to $^1$H- and $^{13}$C-NMR data and the results of silylation experiments has the constitution



*(10)*[8]; the compounds *(8)—(10)* are new. Isobutene and (*Z*)-2-butene cannot be lithiated under analogous conditions (0 °C, THF) and with the catalysts employed so far.

Organolithium compounds of the vinyl- and allyl-type are finding ever increasing use as reagents in organic syntheses[9]. The (*E*)-1-lithio-1-olefins *(2)* and *(7)* were previously synthesized[11] from (*E*)-1-halo-1-alkenes by reaction with lithium[10a–f], *n*-butyllithium[10g] or *tert*-butyllithium[10h–k]. (*E*)-1-Halo-1-alkenes, on their part, are obtainable by hydroalumination or hydroboration of 1-alkynes or of their 1-trimethylsilyl derivatives, followed by reaction with halogens[10e, 10k, 12], or by other methods[10h, k].

Catalytic lithiation opens up a first direct entry to (*E*)-1-lithio-1-olefins and hence also to (*E*)-1,2-disubstituted olefins and derivatives thereof[10k].

### *Procedure*[13]

All reactions must be carried out under argon.—

$C_2H_3Li$: A solution of *(1a)* (0.34 g, 1.1 mmol) and $ZnCl_2$ (anhydrous; 0.30 g, 2.2 mmol) in anhydrous THF (50 mL) is saturated with ethylene (1 bar) at 0 °C; lithium sand (1.45 g, 0.21 mol) is then added to the stirred solution under an atmosphere of ethylene. The uptake of ethylene, which commences after 10—15 min, is measured by means of a gas burette. Until completion of reaction at 0 °C a total of 2.28 L of ethylene (1 bar, 20 °C) is taken up within 6 h (Fig. 1). The suspension is filtered and the separated LiH washed with THF. Hydrolysis of an aliquot of the filtrate and mass spectroscopic analysis (MS) of the ethylene thus liberated reveals a $C_2H_3Li$-yield of 75% (referred to Li). The THF solution is evaporated down under reduced pressure, the residue taken up in ether/pentane (1 : 1), and the catalyst (violet precipitate) removed by filtration. The filtrate is evaporated down again and the residue recrystallized 2—3 times (each recrystallization at −78 °C) from THF/pentane (1 : 1). After drying (0.2 torr), $C_2H_3Li$ THF is obtained as colorless crystals[14].

$C_3H_5Li$: The lithiation of propene is carried out analogously to that of ethylene. The reaction mixture [*(1a)* (2.20 g, 7.0 mmol), $ZnCl_2$ (1.93 g, 14.2 mmol), $C_3H_6$ (1 bar) and lithium sand (4.89 g, 0.70 mol) in THF (150 mL)] takes up a total of 6.7 L of $C_3H_6$ (1 bar, 20 °C) within 14 h. The reaction mixture is filtered. The overall yield of $C_3H_5Li$ compounds (corresponding to their hydrolysis to propene) is 75% (referred to Li). Reaction of a part of the solution with trimethylchlorosilane and gas-chromatographic analysis of the silylation products formed[10c, 15] gives the following composition of $C_3H_5Li$ compounds (in %): 89.8 *(2)*, 0.5 *(3)*, 1.9 *(4)*, 7.8 *(5)*. $C_3H_5Li \cdot THF$ is isolated in crystalline form in the same way as described for $C_2H_3Li \cdot THF$. After two recrystallizations from THF/pentane (1 : 1) $C_3H_5Li \cdot THF$ is obtained with 98.5% content of *(2)* (rest: 0.1% *(3)*, 1.4% *(4)*)[16].

$C_8H_{15}Li$: Lithium sand (1.73 g, 249 mmol) is added with stirring to a solution of 1-octene (11.55 g, 103 mmol), *(1a)* (0.32 g, 1.0 mmol) and anhydrous $ZnCl_2$ (0.28 g, 2.0 mmol) in THF (100 mL) at 0 °C. The reaction mixture is stirred for 24 h at 0 °C. The dark-violet suspension is removed by filtration and the filtrate is evaporated to dryness at 0.2 torr; the distillate is found by gas chromatography to contain THF and 3.56 g of 1-octene (30.8% of that employed). The residue is dissolved in ether and the resulting solution, after treatment with trimethylchlorosilane (in excess) is stirred for 12 h. It is then extracted with water, washed neutral, dried with $CaCl_2$, and the ether is distilled off at normal pressure. Subsequent distillation under reduced pressure affords, *inter alia*, 13.97 g of a fraction (b.p. 35—43 °C/0.2 torr), which according to GC or GC-MS analysis consists of 74.8, 1.9, 0.8, 0.4 and 0.4% of the isomeric trimethylsilyloctenes (MW = 184.4) (rest hexamethyldisiloxane). The main component is (*E*)-1-trimethylsilyl-1-octene. The overall yield of $C_8H_{15}Li$ compounds is 83.2% (based on reacted 1-octene), with a selectivity of lithiation in the (*E*)-1-position of 95.5%.

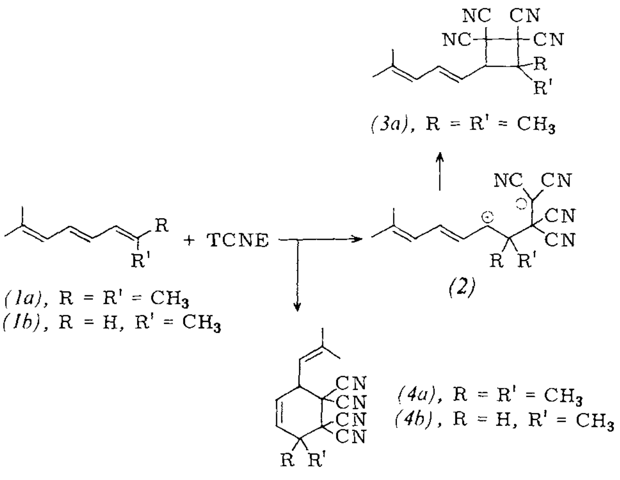
## Isomer Formation in the Cycloaddition Reaction of 2,7-Dimethyl-2,4,6-octatriene with Tetracyanoethylene

By *Alden D. Josey*[*]

Dimerization of isoprene in the presence of maleic anhydride bis(triphenylphosphane)palladium(0) occurs in a linear, tail-to-tail fashion to give 2,7-dimethyl-1,3,7-octatriene, which under conditions of base-catalysis rearranges to 2,7-dimethyl-2,*trans*-4,6-octatriene *(1a)*[1]. Isoprene is dimerized directly to *(1a)* by dad-modified chromium catalysts (dad = 1,4-diaza-1,3-diene)[2]. Reaction of *(1a)* with tetracyanoethylene (TCNE) resulted in formation of the "expected" Diels-Alder adduct 3,3-dimethyl-6-(2-methyl-1-propenyl)-4-cyclohexene-1,1,2,2-tetracarbonitrile *(4a)*[2]. The behavior of the triene in cycloaddition reactions proved, however, to be somewhat different: *(1a)* reacts with TCNE to form two cycloadducts in amounts dependent on the polarity of the solvent.

In anhydrous solvents, equimolar amounts of *(1a)* and TCNE produce an intense blue charge-transfer complex whose color is discharged slowly, increases in intensity as solvent is evaporated, and disappears completely on removal of the solvent *in vacuo*[3]. The crystalline residue could be separated by extraction with hot hexane into two isomeric compounds—the less-soluble *(3a)*, m.p. = 140—141.5 °C (from ethanol), and *(4a)*, m.p. = 90—92 °C. Conversion was quantitative.

The isomers were identified by NMR and UV spectroscopy[4]. As indicated by the relative intensities of the $^1$H-NMR signals at $\delta = 3.55$ (d, $J = 10$ Hz) and 4.15 (d, $J = 10$ Hz) of the non-olefinic ring H atoms of the [2+2]-cycloadduct *(3a)* or of the normal [2+4]-cycloadduct *(4a)* in the product mixture, formation of *(3a)* is favored by more polar solvents [*(3a)*:*(4a)* ≈ 33:67 in tetrahydrofuran (THF), 50:50 in acetonitrile], implicating *(2)* as a key intermediate.



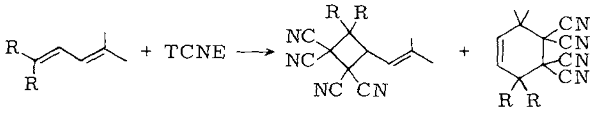
*(3a)*, R = R' = $CH_3$

*(2)*

*(1a)*, R = R' = $CH_3$
*(1b)*, R = H, R' = $CH_3$

*(4a)*, R = R' = $CH_3$
*(4b)*, R = H, R' = $CH_3$

That the cycloaddition of TCNE and substituted 1,3-butadienes leads to competing [2+2]-/[2+4]-cycloadditions is well known *e.g.* the reaction of *(5a)* to *(6a)*—in which the cyclobutane ring is closed at the less-hindered diene terminus—and to *(7a)* [0% in nitromethane, 30% in cyclohexane]. Our own work shows that full methyl-substitution of both diene termini in *(5b)* does not hinder the reaction but directs its course in $CH_3CN$ exclusively to the [2+2]-adduct *(6b)* in quantitative yield[6].



*(5a)*, R = H
*(5b)*, R = $CH_3$

*(6a)*, R = H
*(6b)*, R = $CH_3$

*(7a)*, R = H

In the formation of *(3a)* electronic factors (hexadienyl cation in *(2)*) alone cannot account for the regiospecificity of the [2+2]-cycloaddition toward the more hindered terminal double bond since the reaction of the less substituted triene *(1b)* with TCNE results in exclusive formation of the [2+4]-adduct *(4b)*[7].

It appears that the ability of the diene portion of the polyene to assume a planar, or very nearly planar, cisoid configuration in the transition state for cycloaddition (good in *(1b)*, poor in *(5b)*, intermediate in *(1a)*) must share with electronic stabilization of intermediate ions the role of determining how cycloaddition products are partitioned into the two observed modes. The unusual triene *(1a)* represents a case in which these effects are sufficiently balanced to permit both reaction modes.

## Synthesis of a Novel Amphoteric Polyelectrolyte by Polymerization of 6-Amino-2,4-hexadienoic Acid in Layer Perovskites[**]

By *Bernd Tieke* and *Gerhard Wegner*[*]

Alkylammonium compounds can be incorporated into inorganic matrices *via* hydrogen bridges. Well known examples of this phenomenon are intercalations in sheet silicates[1] and formation of complex crystals with transition metal halides $MX_2$, the so-called layer perovskites of formula $(C_nH_{2n+1}—NH_3)_2MX_4$[2]. Numerous investigations of the magnetic properties and phase changes in these layer perovskites have appeared[3]. However, their suitability as matrices for organic solid state reactions has not yet been studied.

The starting point for our investigations was the observation that ω-amino acids, as well as *n*-alkylamines, are able to crystallize in "layer perovskites". 6-Amino-2,4-hexadienoic acid *(1)* forms complex crystals with several transition metal halides $MX_2$ ($CdCl_2$, $CdBr_2$, $MnCl_2$, $FeCl_2$, and $CuCl_2$). Only the complexes with $CdCl_2$, $MnCl_2$ and $FeCl_2$ undergo a solid state reaction, upon UV- ($\lambda = 254$ nm) and $^{60}$Co-γ-irradiation, to form a 1,4-disubstituted *trans*-polybutadiene of structure *(2)*.

$$\underset{(1)}{n\,CHR^1{=}CH{-}CH{=}CHR^2} \rightarrow \underset{(2)}{\left(CHR^1{-}CH{=}CH{-}CHR^2\right)_n}$$

$$R^1 = CH_2NH_2,\ R^2 = COOH$$

The degree of conversion amounts to over 90% after a γ-dose of 30 Mrad. In the other complexes no polymerization reaction occurs. The possibility of a 1,4-addition polymerization of 1,4-disubstituted *trans,trans*-dienes has not previously been demonstrated, either for reactions occurring in the solid state or within canal complexes[4]. Apart from signals from the unreacted monomer, the 22.6 MHz $^{13}$C-NMR spectrum of a 1 N KOD solution of the dissolved crystals only showed signals from the 1,4-adduct after 30 Mrad irradiation: $COO^-$ ($\delta = 184.2$), isolated *trans*-C=C ($\delta = 135.4/134.2$) and three signals in the aliphatic C atom region ($\delta = 59.2/49.8/45.2$), which are assigned to the two asymmetric C atoms formed and the $CH_2NH_2$ group.

Assuming for present that the signals from the asymmetric C atoms can be assigned only to one chiral center and considering the mode of formation of the polymer in the crystalline state, an *erythro*-diisotactic arrangement of the substituents is proposed. The polymer occurs as a racemate.

X-ray structure investigations indicate that only slight structural changes occur during the reaction. In the $CdCl_2$ complex the distance between the two metal ion sheets only increases by 0.9 to 17.9 Å. The tacticity of the product, small structural changes, as well as the control of the reactivity by the ionic nature of the matrix, make a topochemical control of the reaction probable. From Figure 1 it is evident that the polymer chains, formed by 1,4-addition of the diene groups, lie extended in a plane parallel to the inorganic matrix.

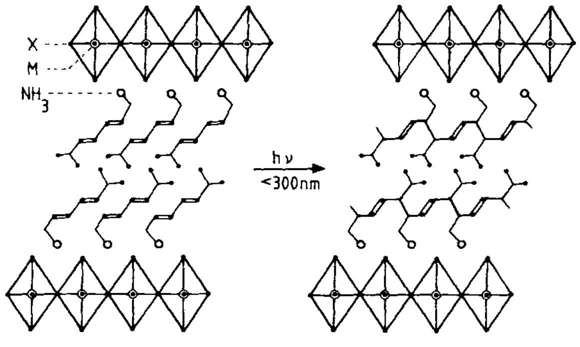

Fig. 1. Schematic representation of the reaction.

The polymerized amino acid can be separated from the matrix by solvation in strong bases and finally by reprecipitation as an amphoteric polyelectrolyte. It has an average molecular weight of *ca.* 35000 (determined by GPC in 2.5% aqueous $N(CH_3)_4OH$ solution), dissolves in strong acids ($pH \leq 2.0$) and bases ($pH \geq 10.2$) and is crystalline after reprecipitation. At present, we are investigating its suitability as a polymeric complexing agent.

### *Procedure*

2 mL of a 0.5 M aqueous solution of $MX_2$ is added to *(1)*[5] (2 mmol) dissolved in *ca.* 20 mL 0.1 N HCl. Crystallization follows by evaporation of the solvent over $P_2O_5$ in a desiccator. It is recommended that operations with $Mn^{2+}$ and $Fe^{2+}$ are carried out under a nitrogen atmosphere.

## A General Procedure for Intramolecular α-*tert*-Alkylation of Carbonyl Compounds[**]

By *Manfred T. Reetz*, *Ioannis Chatziiosifidis*, and *Konrad Schwellnus*[*]

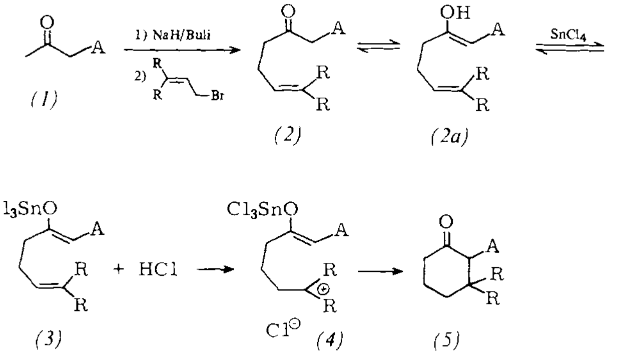
The problem of α-*tert*-alkylation of carbonyl compounds can be solved in a general way by reacting the cor-

---

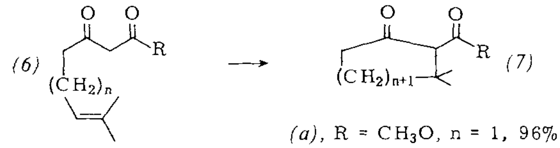
[*] Prof. Dr. M. T. Reetz, Dr. I. Chatziiosifidis and Dipl.-Chem. K. Schwellnus
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, 3550 Marburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

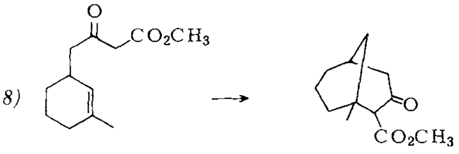
responding silyl enol ethers with *tert*-alkyl halides in the presence of Lewis acids[1]. We now report the results of systematic studies of *intramolecular* α-*tert*-alkylations[2]. Compounds having silyl enol ether and *tert*-alkyl halide functions are difficult to prepare[3]. In contrast, an alternative strategy involving Lewis acid-mediated cyclization of olefins of the type *(2)* derived from active methylene compounds *(1)*[4] to afford *(5)* is simple (A = activating group). In case of $SnCl_4$, the assumption of *O*-stannylation of the enolized form *(2a)* to generate *(3)* and HCl is plausible. Protonation of the olefin results in cyclization of the cation *(4)*[5].



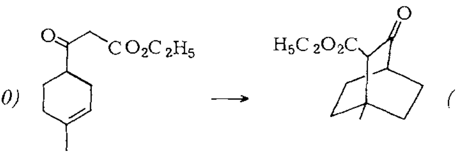
Besides catalytic amounts of $SnCl_4$, such Lewis acids as $TiCl_4$ or $(CH_3)_3SiCl$ in the presence of $ZnCl_2$ are also effective but the yields are lower by 20—30%. The intramolecular α-*tert*-alkylations leading to *(7)*, *(9)*, and *(11)* represent favored 6- and 7-*endo* trigonal cyclizations[6]. *(12)* does not undergo disfavored 5-*endo* trigonal CC bond formation, but rather *O*-alkylation yielding *(13)*.



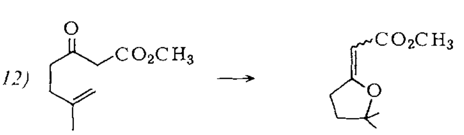
*(a)*, R = $CH_3O$, n = 1, 96%
*(b)*, R = $CH_3O$, n = 2, 62%
*(c)*, R = $CH_3$, n = 1, 80%



*(8)* → *(9)*, 61%

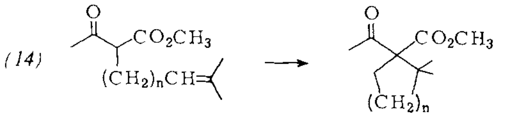


*(10)* → *(11)*, 63%



*(12)* → *(13)*, 65%

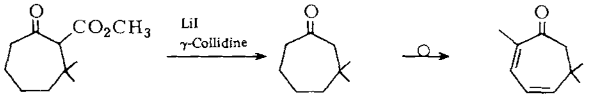
Rings with exocyclic carbonyl functions are also accessible. Whereas *(14a)* undergoes a favored 5-*exo* trigonal cyclization to yield *(15a)*, the ring forming reaction *(14b)*→*(15b)* is surprisingly slow. After a reaction time of 4 d, only *ca.* 20% of the product is present, in addition to some starting material *(14b)*. Although 6-*exo* and 6-*endo* trigonal cyclizations are both supposed to be favored[6], comparative kinetic data are seldom available: either the Baldwin-Rules do not apply to cationic systems, or other (perhaps thermodynamic) factors are involved.



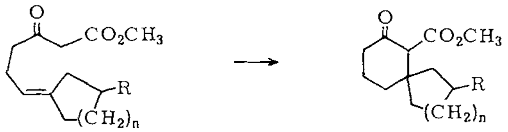
*(14)* → *(15)*

*(a)*, n = 2, 66%
*(b)*, n = 3, ≈ 20%

The method is likely to have application in terpene or steroid chemistry. For example, *(7b)* is easily decarboxylated to form the otherwise not readily accessible *(16)*, a compound which has been used previously as a precursor of eucarvone *(17)*[7]. The methodology described herein is also useful in the synthesis of spiro compounds of type *(19)*. Since the starting materials *(18)*[8] are rather easily prepared, the procedure is of synthetic interest.



*(7b)* → *(16)*, 97% → *(17)*



*(18)* → *(19)*

*(a)*, R = H, n = 1, 73%
*(b)*, R = H, n = 2, 72%
*(c)*, R = $CH_3$, n = 2, 71%

### Procedure

*(7a)*: $SnCl_4$ (0.73 g, 20 mol%) is slowly added to a stirred solution of methyl 7-methyl-3-oxo-6-octenoate *(6a)* (2.58 g, 14 mmol) in 40 mL dry methylene chloride at 0°C. The mixture is allowed to warm up to room temperature, stirred for about 14 h and poured into 50 mL ice-water. After washing twice with water and drying over $Na_2SO_4$, the solvent is stripped off and the residue distilled (kugelrohr, 80°C/0.4 torr): 2.48 g (96%) methyl-2,2-dimethyl-6-oxocyclohexanecarboxylate *(7a)*; $^1$H-NMR ($CDCl_3$): $\delta = 1.00$ (s, 3 H), 1.06 (s, 3 H), 1.33—2.33 (m, 6 H), 3.16 (s, 1 H), 3.66 (s, 3 H).

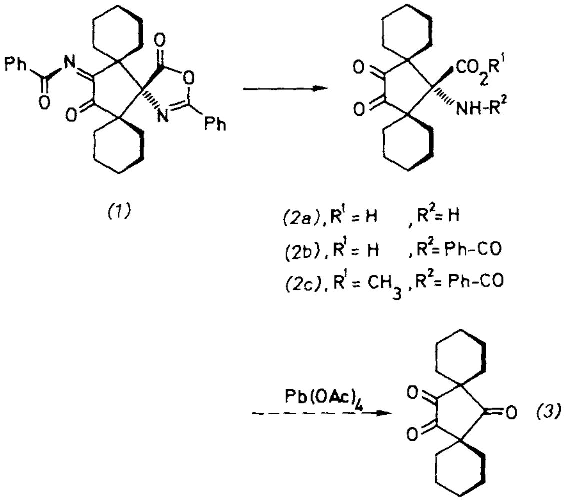
## Preparation of a Stable Diacyl Orthoester by O-Insertion on Reaction of a 1,2-Diketone with Lead Tetraacetate[**]

By *Siegfried Mohr*[*]

The readily accessible solid-state photodimer *(1)*[1a,b] should be suitable as an educt for the preparation of the previously unknown dispirotriketone *(3)*[1c]. The dioxoamino acids *(2a)* and *(2b)*, each of which are obtainable in high yield in one step from *(1)* by hydrolysis[1a,c], can be used as precursors for *(3)*. Lead tetraacetate has been used for the oxidative degradation of the amino acid function to the carbonyl group[2], but complications through the diketone group could not be ruled out, since non-enolizable 1,2-diketones can react with lead tetraacetate with O-insertion and formation of cyclic anhydrides or the corresponding esters[3].



*(1)*

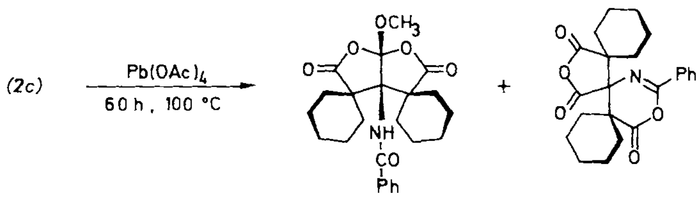
*(2a)*, $R^1 = H$, $R^2 = H$

*(2b)*, $R^1 = H$, $R^2 = Ph\text{-}CO$

*(2c)*, $R^1 = CH_3$, $R^2 = Ph\text{-}CO$

*(3)*

We first examined the reaction of the ester *(2c)*. It was found that the diketone group is seemingly stable towards an O-insertion on using lead tetraacetate; the yellow color of *(2c)* disappeared only on heating for 60 h at 100 °C in acetic acid, and the colorless oxidation products *(4)*[4] and *(5)*[5] were formed.



*(4)*, 71 %   *(5)*, 7 %

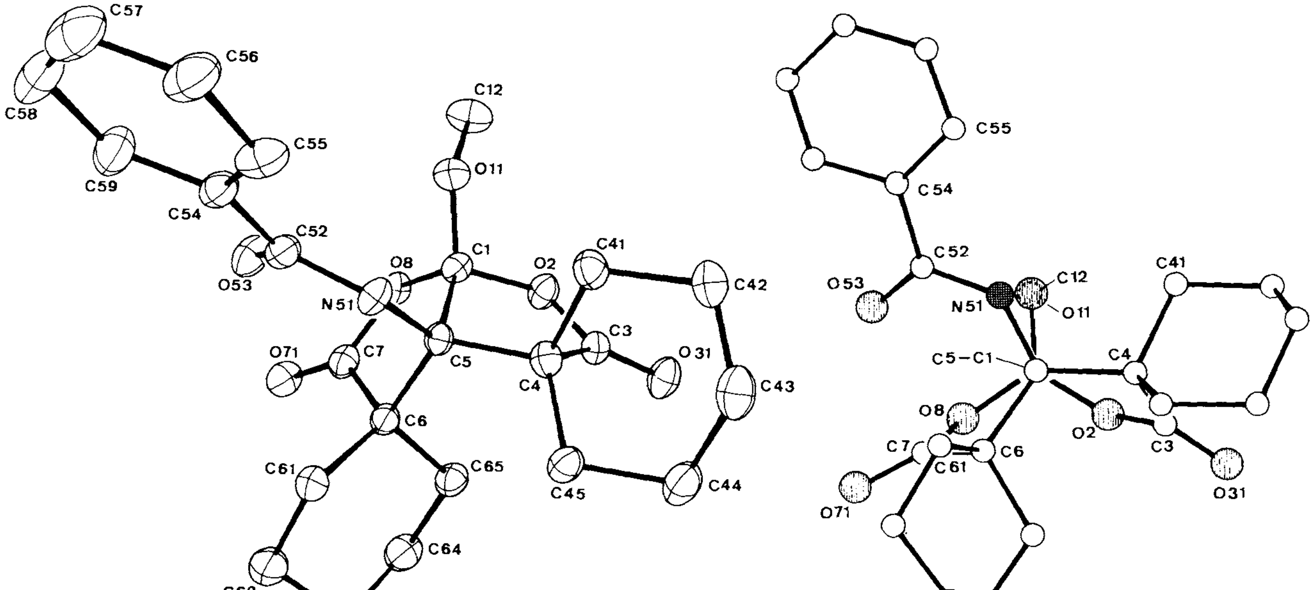


Fig. 1. a) ORTEP diagram (30%) of the diacyl orthoester *(4)*; b) parallel projection of *(4)* along the C5—C1 bond. Torsional angles: C4—C5—C1—O2 = 29.8, C6—C5—C1—O8 = 20.9, N51—C5—C1—O11 = 25.5°.—*(4)* forms colorless prisms; $a = 12.751(2)$, $b = 13.685(2)$, $c = 13.401(2)$ Å, $\beta = 108.46(1)°$, $P2_1/c$, $Z = 4$; 4541 independent reflections (4936 measured), of which 2419 with $I > 2\sigma(I)$, Enraf-Nonius CAD-4; direct methods, SHELX; $R = 0.054$.—The X-ray structure analysis was carried out in collaboration with Priv.-Doz. Dr. *C. Krüger* at the Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr.

The main product *(4)*[6] has a molecular weight of about 16 mass units higher than that of *(2c)* and the diketone group is no longer present (IR, UV)[4]. The spectroscopic data of *(4)*, however, are not completely reconcilable with

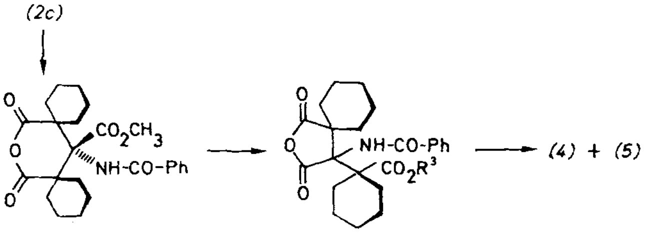
Olshausenstr. 40–60, D-2300 Kiel (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

the expected six-membered ring anhydride structure *(6)*; an unproblematical assignment of the IR and $^{13}$C-NMR spectra[4] was only possible after an X-ray structure analysis, which gave the very unusual structure of a tetracyclic dispirodiacyl orthoester (Fig. 1a) for this oxidation product. According to the $^{13}$C-NMR spectrum *(4)* has m-symmetry in solution. This is not so in the crystalline state; the central bicyclic dilactone system is twisted (Fig. 1b). The crystal structure analysis thus also confirms the similar conformation of the perhydrofuro[2,3-*b*]furans recently derived from LIS and force field calculations[7].

Acyl orthoesters are sensitive to hydrolysis; nevertheless, some monoacyl orthoesters have been isolated[8]. The diacyl orthoesters ought to be more sensitive. The unusual stability of *(4)* is possibly due to the bulkiness of the tetracyclic spiro structure.



*(6)*

*(7a)*, $R^3 = H$
*(7b)*, $R^3 = CH_3$

The colorless by-product *(5)* is formed from *(2c)* by formal O-insertion and subsequent cleavage of methanol. The given structure was confirmed by independent synthesis (cleavage of water with $Ac_2O$)[9a] from the five-membered cyclic anhydride-carboxylic acid *(7a)*[9b]. The last named reaction demonstrates that *(4)* and *(5)* could be formed *via* the anhydride esters *(6)* and *(7b)*, which have so far not been isolated.

# Trichloro(methyl)silane/Sodium Iodide, A New Regioselective Reagent for the Cleavage of Ethers[**]

By *George A. Olah, Altaf Husain, B. G. Balaram Gupta*, and *Subhash C. Narang*[*]

Since our first report in 1976[1a] and the independent studies of *Jung et al.*[1b] as well as *Voronkov et al.*[1c] numerous synthetic transformations have been carried out using iodotrimethylsilane. However, due to its hydrolytic susceptibity, its handling and storage pose difficulties. In view of this, several alternative *in situ* iodotrimethylsilane reagents or their equivalents have recently been reported. These methods include use of trimethyl(phenyl)silane/iodine[1a,2], hexamethyldisilane/iodine[3a,b,4], allyltrimethylsilane/iodine[5], 3,6-bis(trimethylsilyl)-1,4-cyclohexadiene[5] and chlorotrimethylsilane/sodium iodide[3b,c,6] reagents.

For the cleavage of ethers *(1)* in the presence of alcohols, however, all these reagents are unsuitable since the alcohols react to give the corresponding iodides. We now wish to report, however, the use of trichloromethylsilane/sodium iodide for the selective cleavage of ethers. The reagent reacts extremely readily with ethers at ambient temperatures resulting in highly regioselective cleavage (dealkylation) (Table 1). Trichloro(methyl)silane/sodium iodide was found to be more selective than chlorotrimethylsilane/sodium iodide.

Table 1. Dealkylation of ethers *(1)* by the methyltrichlorosilane/sodium iodide reagent:

$$\underset{(1)}{ROR'} + \underset{(2)}{MeSiCl_3} + \underset{(3)}{NaI} \xrightarrow[CH_3CN]{25\,^\circ C} \underset{(4)}{ROH} + \underset{(5)}{R'OH} + \underset{(6)}{RI} + \underset{(7)}{R'I}$$

| | Ether *(1)* | | *t*[h] | Products and Yields [%] [a] | | | |
|---|---|---|---|---|---|---|---|
| | R | R' | | *(4)* | *(5)* | *(6)* | *(7)* |

| *n* | $(CH_3)_2C$—$n$-$C_7H_{15}$ | $CH_3$ | 6 | 0 | — [b] | 100 | 0 |
| *o* | 3-stigmastanyl | $CH_3$ | 16 | 97 | 0 | 0 | — [b] |
| *p* | 3-stigmastanyl | $C_2H_5$ | 36 | 86 | 0 | 0 | — [b] |

[a] Isolated yield of the product. [b] Not isolated. [c] Isolated as a mixture of triphenylmethanol and triphenylmethane [8]. [d] THP = tetrahydropyranyl.

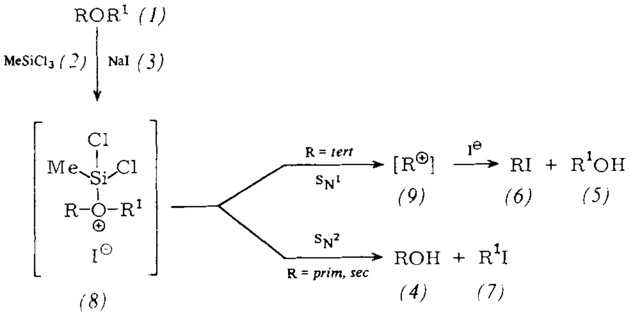
From Table 1, it is clear that for methyl ethers *(1a, f, h, o)* demethylation was the major reaction, affording alcohols as the sole products, provided the alkyl groups are either primary or secondary. In contrast, when as in *(1n)* alkyl group is tertiary the resulting cleavage product was

---

[*] Prof. Dr. G. A. Olah, A. Husain, Dr. B. G. B. Gupta, Dr. S. C. Narang
Hydrocarbon Research Institute
Department of Chemistry, University of Southern California
University Park, Los Angeles, California, 90007 (USA)

[**] Part 96 in the series: Synthetic Methods and Reactions. This work was supported by the National Institutes of Health and National Science Foundation.—Part 95, see *G. A. Olah, B. G. B. Gupta, A. P. Fung*, Synthesis, in press.

solely iodide. This can be rationalized on the basis of the increased Lewis acidity of trichloro(methyl)silane compared to that of chlorotrimethylsilane. Thus, in the case of *tert*-alkyl methyl ethers, the reaction predominantly takes place *via* an $S_N1$-pathway through a carbocation intermediate *(9)* producing iodides *(6)* as the major products. The *prim-* and *sec*-alkyl methyl ethers, however, prefer an $S_N2$-pathway resulting in alcohols *(4)* as the major products (Scheme 1).



Scheme 1. *(6)* or *(4)* are the major products.

Benzyl ethers *(1c, l)*, trityl ethers *(1d, k)* as well as tetrahydropyranyl ethers *(1e, m)* also undergo regioselective cleavage at ambient temperature to give quantitative yields of alcohols (Table 1). Ethyl ethers are, however, depending on the nature of the alkyl group cleaved with varying yields of alcohols *(4)* and iodides *(6)*. Thus, *sec*-alkyl ethyl ethers *(1b, g, p)* were cleaved regioselectively to the corresponding alcohols. But *prim*-alkyl ethyl ethers *(1i, j)* gave approximately 1 : 1-mixtures of alcohols and iodides (Table 1).

We have also found that the trichloro(methyl)silane/sodium iodide reagent can be used for the selective cleavage of ethers in the presence of alcohol or ester functions. Since this versatile highly regio- and stereoselective, mild and inexpensive reagent is easy to handle and is free of some of the difficulties connected with iodotrimethylsilane[7] reagents, it should find substantial synthetic use.

### *Experimental: General Procedure*

Trichloro(methyl)silane (1.8 g, 12 mmol) and *(1)* (10 mmol) are added, successively, with continuous stirring under a nitrogen atmosphere to a solution of NaI (1.8 g, 12 mmol) in dry acetonitrile (20 mL). The reaction mixture is monitored by thin layer chromatography (hexane) and $^1H$-NMR, and is then quenched with water, extracted with ether and the ethereal extract washed with aqueous solutions of $Na_2S_2O_3$ and NaCl. The ethereal extract is dried over anhydrous $Na_2SO_4$ and the solvent evaporated to yield the crude product, which is further purified by crystallization or distillation.

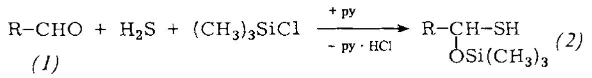
## Synthesis of α-Trimethylsiloxythiolene and α,α'-Bis(trimethylsiloxy) Disulfides[**]

By *T. Aida, T.-H. Chan*, and *David N. Harpp*[*]

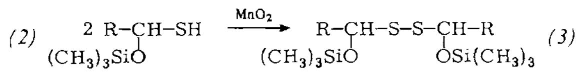
Recently, we reported that α-trimethylsiloxy sulfides provided high-yield access to α-iodosulfides and vinyl sulfides under mild conditions[1]. This success, and the possibility of developing novel α-functionalized sulfur compounds prompted us to examine the preparation and chemistry of α-trimethylsiloxythiols *(2)*. We wish to report that the title compounds can be prepared in good yield by an analogous method from the aldehyde (1), hydrogen sulfide and chlorotrimethylsilane in the presence of pyridine.



$$\underset{(1)}{R-CHO} + H_2S + (CH_3)_3SiCl \xrightarrow[-\,py\cdot HCl]{+\,py} R-\underset{OSi(CH_3)_3}{CH}-SH \quad (2)$$

A number of α-trimethylsiloxythiols *(2)* have been prepared by this method and are shown in Table 1. These compounds have a powerful stench, similar to that of an ordinary thiol and are reasonable stable. No decomposition is observed at periods up to 2—3 months storage under dry nitrogen in the refrigerator.

These siloxythiols *(2)* can be oxidized in high yield by $MnO_2$ at room temperature to the corresponding disulfides *(3)* (Table 1). These compounds are isolated as a 1 : 1 mixture of *meso-* and DL-forms and do not decompose after several months in the refrigerator. To our knowledge there are no examples of pure stable, α-functionalized disulfides in the literature.



$$(2) \quad 2\,R-\underset{(CH_3)_3SiO}{CH}-SH \xrightarrow{MnO_2} R-\underset{(CH_3)_3SiO}{CH}-S-S-\underset{OSi(CH_3)_3}{CH}-R \quad (3)$$

The compounds *(2)*, like other thiols, add photochemically to olefinic compounds affording the corresponding α-trimethylsiloxy sulfides thus providing an alternative route to vinyl sulfides[1,3]. *(4a)* and *(4b)* are typical examples.

It should be noted that *(4a)* is formed regiospecifically with an isolated yield of 88%.

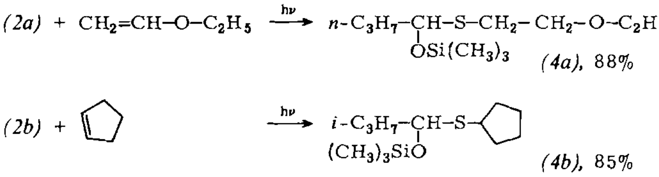
[a] Isolated yield. *(2)* decompose upon gas chromatography and show no molecular ion in the mass spectrum; the (CH$_3$)$_3$SiO group is cleaved first. [b] Isolated yield. *meso*- and DL-forms could not be separated by gas chromatography. *(3)* shows no molecular ion in the mass spectrum. [c] Determined by $^1$H-NMR spectroscopy. [d] The $^1$H-NMR indicates additional products. *(2f)* was fully polymerized after 13 h at room temperature.



$$(2a) + \mathrm{CH_2{=}CH{-}O{-}C_2H_5} \xrightarrow{h\nu} n\text{-}\mathrm{C_3H_7{-}\underset{OSi(CH_3)_3}{CH}{-}S{-}CH_2{-}CH_2{-}O{-}C_2H_5}$$

*(4a)*, 88%

*(2b)* +

$$\xrightarrow{h\nu} i\text{-}\mathrm{C_3H_7{-}\underset{(CH_3)_3SiO}{CH}{-}S{-}}$$

*(4b)*, 85%

*General Procedure*

H$_2$S is bubbled into a dry dichloromethane solution (150 mL) of *(1)* (0.07 mol), (CH$_3$)$_3$SiCl (0.10 mol) and pyridine (0.10 mol), and the solution vigorously stirred until no further gas is absorbed; the solution temperature is maintained below 15 °C. The solution is then stirred for 2 h at room temperature. After addition of dry pentane (150 mL), the mixture is cooled to −78 °C and the pyridinium chloride collected by filtration. The thiol *(2)* is distilled under reduced pressure.

## Hexameric Molybdenum Tetrachloride

By *Ulrich Müller*[*]

*Dedicated to Professor Josef Goubeau on the occasion of his 80th birthday*

Two modifications of molybdenum tetrachloride have so far been described in the literature: α-MoCl$_4$, which is probably made up of linear chains of octahedra sharing edges[1], and β-MoCl$_4$, which has been described as a layer lattice in which three Mo atoms are assumed to statistically occupy four positions with formation of cationic and anionic regions, [Mo$_2$Cl$_6$]$^{2+}$ and [MoCl$_6$]$^{2-}$, respectively[2]. However, recent theoretical studies on the possible structures of tetrahalides[3] led to a more detailed determination of the β-MoCl$_4$ structure.

Crystals of β-MoCl$_4$, which were prepared under exactly the same conditions as described earlier[2], exhibit an X-ray diffraction pattern of sharp reflections, strong diffuse lines, and weak diffuse lines which indicate the presence of a one-dimensional disorder. If the intensity maxima on the strong diffuse lines are treated as sharp reflections then these, together with the actual sharp reflections indicate the unit cell described earlier (trigonal, $a=605$, $c=1172$ pm)[2]. In disordered crystals the actual structure can only be determined if the intensities in the diffuse lines are fully investigated[4]; the maxima on them cannot be simply treated as sharp reflections. The sharp reflections alone are inadequate for a structure determination, they afford only a statistically averaged structural model[4]. In the case of β-MoCl$_4$ even the weak diffuse lines must also be taken into consideration; they require a doubling up of the lattice constants $a$ and $b$ to $a=b=1209$ pm.

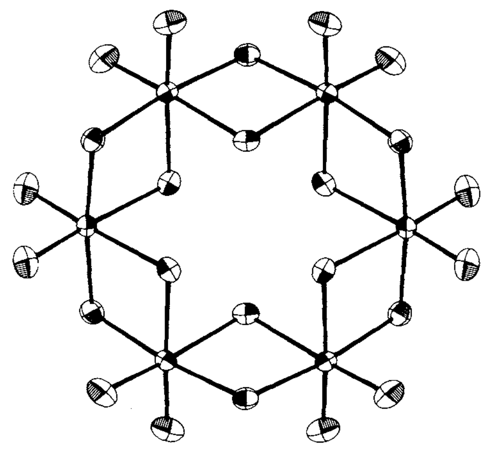

Fig. 1. (MoCl$_4$)$_6$ molecule in β-MoCl$_4$; ellipsoids of thermal vibration for 68% probability at 21 °C.

---

[*] Prof. Dr. U. Müller
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

A comparison of these lattice constants with the values expected for the theoretically predicted structural possibilities[3] suggests the likelihood of a structure type containing cyclic $(MoCl_4)_6$ molecules. An analysis of the intensities on the diffuse lines according to a recently described method[5] confirms this (refinement to $R=7.2\%$ for 226 measured points on diffuse lines and $R=2.8\%$ for 155 sharp reflections).

Our structural model shows that β-$MoCl_4$ is made up of hexameric cyclic molecules $(MoCl_4)_6$ (Fig. 1). The bond lengths are: Mo—$Cl_{terminal}$ 220, Mo—$Cl_{bridge}$ 243 and 251 pm. The molecules are arranged in layers (parallel to the plane of the picture in Figure 1. The stacking of the layers is disordered, but in such a way that the Cl atoms assume an hexagonal closest-packed arrangement. The pairwise closing up of metal atoms between adjacent octahedra, which is often observed in compounds of metals with electron configuration $d^1$ and $d^2$, is not apparent here, the Mo···Mo distances of 367 pm are too large for any notable interactions between the metal atoms; this is consistent with the known magnetic properties[2], which indicate a virtually undistorted $d^2$-configuration.

Although molybdenum tetrachloride has already been known for some time and has been the subject of repeated investigations, nothing has previously been mentioned about its ability to form hexameric molecules. There is as yet no other such example of a structure of this kind.

# Gas Chromatographic Separation of Carbohydrate Enantiomers on a New Chiral Stationary Phase

By *Wilfried A. König, Ingrid Benecke*, and *Hagen Bretting*[*]

Micromethods for the configurational analysis of low molecular weight chiral compounds are essential for the structural elucidation of natural products[1,2].

While the problem of the gas chromatographic determination of the configuration of the constituents of peptides and proteins seems to be solved[2], this is not the case with the constituents of polysaccharides. Since in nature sugars occur rather more frequently than amino acids in both configurations[3], a simple gas chromatographic procedure would be of interest for their analysis.

As early as 1968 *Pollock* and *Jermany* suggested a method involving oxidation of aldoses to aldonic acids, esterification with a chiral alcohol to diastereomeric aldonic acid esters and separation of the acetylated derivatives[4]. In a similar procedure the preparation of diastereomeric derivatives was achieved by glycosidation with (−)-2-butanol and separation of the trimethylsilylated derivatives on glass capillary columns[5]. In addition to the difficulties involved with the derivatization, the quantitative determination of enantiomers *via* formation of diastereomeric derivatives suffers from a systematic error arising from the incomplete purity of the chiral reagents.

We have now for the first time prepared a temperature-stable chiral stationary phase which allows the separation of volatile derivatives of carbohydrate enantiomers. This involves the saponification of methyl(cyanoethyl)silicone XE-60[6] with alkali and coupling the carboxylic groups formed to L-valine-(*S*)-α-phenylethylamide by conventional methods. Glass capillaries were coated with this modified polymer and trifluoroacetylated sugars[7] or their methyl glycosides separated. Columns prepared according to this procedure did not exhibit a reduction in their separation efficiency after continuous operation at temperatures up to 180 °C over several weeks.

Trifluoroacetylation of sugars (TFA = trifluoracetyl) resulted in an isomeric mixture of α- and β-furanosides and α- and β-pyranosides, which were identified by GC/MS-investigation[7]. The TFA-methyl glycosides (prepared by reaction of the sugars with methanolic 1.5 N HCl at 100 °C and subsequent trifluroacetylation) formed isomeric mixtures corresponding in composition to literature data[8] and were identified by measurement of their peak areas. The results are presented in Table 1 and in some examples in Figure 1. The TFA-groups appear to be essential for the separation, since trimethylsilyl derivatives of the sugars with comparable volatility are not separated.

Table 1. Gas chromatographic enantiomer separation of carbohydrates on a glass capillary column coated with XE-60-L-valine-(*S*)-α-phenylethylamide (TFA = trifluoroacetyl, P = pyranoside, F = furanoside). For conditions see Figure 1.

| Sugar | Separation Factor α/Column Temperature [°C] | | | |

| | [a] | 1.048/100 | β-P | 1.046/100 |
| | [a] | 1.026/100 | | |
| Fucose | | — | | — |
| | | — | | — |
| | [a] | 1.035/100 | [a] | 1.014/100 |
| | | | [a] | 1.046/100 |

[a] Designation uncertain.

The order of elution of enantiomers is not identical in all the examples investigated. In the case of TFA-derivatives of glucose and mannose and in that of the TFA-methyl glycosides, the L-enantiomers eluted before the D-enantiomers: the same order was observed for the first three isomeric pairs of TFA-arabinose, however, for the pair

---

Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)
Dr. H. Bretting
Zoologisches Institut und Zoologisches Museum der Universität
Martin-Luther-King-Platz 3, D-2000 Hamburg 13 (Germany)

with the longest retention time the order of elution is reversed (Fig. 1).

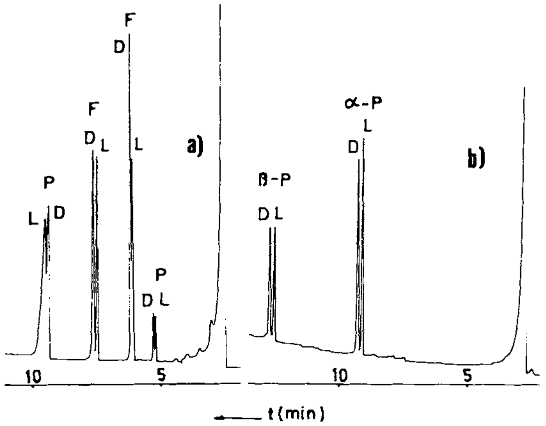

Fig. 1. Separation of carbohydrate enantiomers. a) TFA-derivatives of arabinose isomers, b) TFA-derivatives of α- and β-methylpyranosides of glucose. Glass capillary column (borosilicate glass, 40 m, 0.2 mm inner diameter) with XE-60-L-valine-(*S*)-α-phenylethylamide. $T = 100\,^\circ C$, temperature program 3 °C/min. (Carlo Erba 2101 A gas chromatograph, carrier gas: 0.7 bar $H_2$.) P = pyranoside, F = furanoside.

For galactose and fucose (6-deoxygalactose), in any case, the D-enantiomers are eluted prior to the L-enantiomers. The TFA-methyl glycosides of xylose (α- and β-pyranoses) are not separated. In the TFA-derivatives only one pair of enantiomers is separated (β-pyranoses). As in the case of glucose the L- is eluted before the D-form.

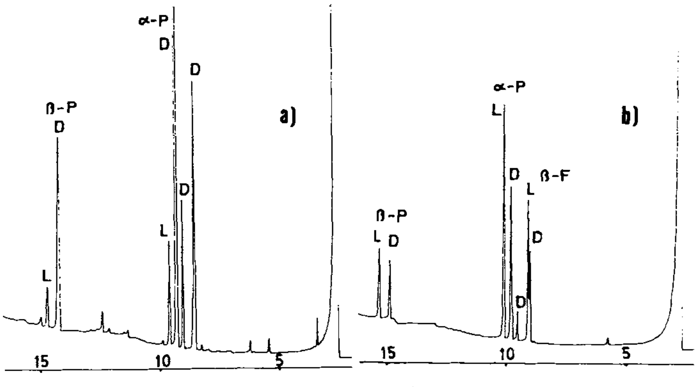

Fig. 2. Separation of TFA-methyl galactoside enantiomers: a) acid hydrolysate of *Helix pomatia* galactan, b) reference mixture of D- and L-galactose derivatives. For conditions, see Figure 1.

The utility of the new method may be demonstrated by the investigation of a hydrolysate of the galactan of the snail *Helix pomatia*. This high molecular, branched polysaccharide consists of D- and L-galactose. The chromatographic separation of the TFA-methyl glycosides and the electronic integration of peak areas of the α- and β-pyranosides, which are well separated (Fig. 2), showed that the galactan contains 14.4% L-galactose. This result is in agreement with measurements of the optical rotation by *Bell* and *Baldwin*[9].

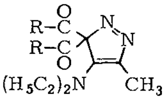
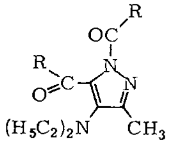
## Reaction of Dibenzoyldiazomethane with 1-Diethylaminopropyne

By *Rolf Huisgen, Maria Pilar Bosch Verderol, Alfred Gieren*, and *Viktor Lamm*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

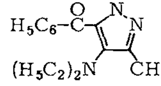
Dimethyl diazomalonate combines with 1-diethylaminopropyne at room temperature to give the 3*H*-pyrazole derivative *(1)*, which is converted into the pyrazole-1,5-dicarboxylic ester *(3)* by a 1,5-sigmatropic shift of an ester group ($t_{1/2} \sim 30$ days at 25 °C in $CDCl_3$)[1]; this aromatization of 3*H*-pyrazoles is known as the van-Alphen-Hüttel rearrangement[2].



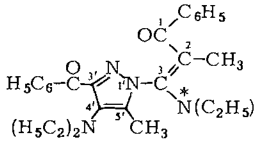


*(1)* R = $OCH_3$ *(3)*
*(2)* R = $C_6H_5$ *(4)*

As expected, the cycloaddition of dibenzoyldiazomethane to the same ynamine is slower, and the ensuing sigmatropic shift faster, than in the preceding example. The reaction of equimolar amounts in benzene (8 days, 20 °C, chromatography on silica gel) yielded 66% *(4)* (orange yellow needles, m.p. 74—75 °C) and 13% of a yellow 1:2 adduct (m.p. 84—85 °C); the primary adduct *(2)* was not detected. *Different* signals for ketone carbonyl ($\delta = 188.1$) and amide carbonyl C-atoms ($\delta = 165.2$) appear in the $^{13}C$-NMR spectrum ($CDCl_3$) of *(4)*, and the chemical shifts of the ring carbon atoms ($\delta = 152.1$, 137.4, 136.6) correspond to those of *(3)* ($\delta = 149.3$, 134.4, 130.9). The carbonyl frequencies of *(4)* absorb at 1670 and 1697 $cm^{-1}$. The aminolysis of *(4)* in refluxing diethylamine produced *(5)* and *N,N*-diethylbenzamide quantitatively.



*(5)*



*(6)*

---

[*] Prof. Dr. R. Huisgen, Dr. M. P. Bosch Verderol
Institut für Organische Chemie der Universität
Karlstr. 23, D-8000 München 2 (Germany)
Dr. habil. A. Gieren, Dipl.-Phys. V. Lamm
Max-Planck-Institut für Biochemie
Abteilung für Strukturforschung I
D-8033 Martinsried (Germany)

The pyrazole *(4)* reacted with 1-diethylaminopropyne to afford the above-mentioned 1 : 2 adduct (20 days, benzene, 20 °C, 70% yield), which was identified by an X-ray structure analysis (Fig. 1) as the vinylog *(6)* of a 1,3-dibenzoylpyrazole.

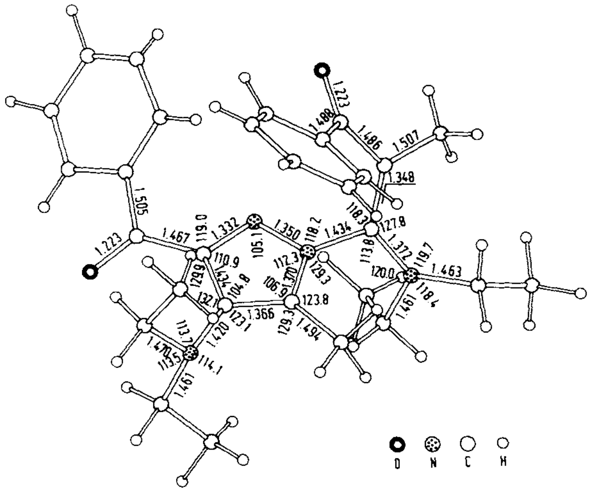


Fig. 1. Structure of 3-(3-benzoyl-4-diethylamino-5-methyl-1-pyrazolyl)-3-diethylamino-2-methyl-1-phenyl-2-propen-1-one *(6)* in the crystal. Bond lengths [Å] and angles [°] averaged between the two molecules of the asymmetric unit (σ of the non-averaged values: 0.002—0.006 Å and 0.2—0.3°) [3].

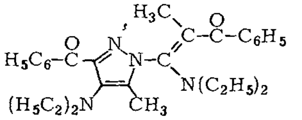
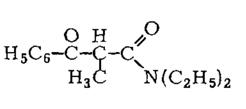
The $^1$H-NMR spectrum ($CDCl_3$) of this compound [$\delta = 2.09$ (s, $CH_3$), 2.16 (s, $CH_3$), 0.62, 2.78 (t and q, resp., ring-$N(C_2H_5)_2$), 1.18, 3.05 (t and q, resp., $^*N(C_2H_5)_2$] affords evidence of the stronger alkylideneammonium character of the amine function in the side chain due to β-ketoenamine resonance. When the solution of *(6)* in $CDCl_3$ was kept for several days at 20 °C, an equilibrium with 17% of a rotameric form was established in which the methyl singlets ($\delta = 1.72$ and 2.35) show a greater difference than in *(6)*. After slow evaporation, crystalline *(6)* was reisolated completely. A *cis,trans* isomerization, *(6)* $\rightleftharpoons$ *(7)*, is probable. Mild acid hydrolysis of the enamine *(6)* (two phases, ether/2 N HCl) furnished 95% *(5)* and 96% of *N,N*-diethyl α-benzoylpropionamide *(8)*.



*(7)*

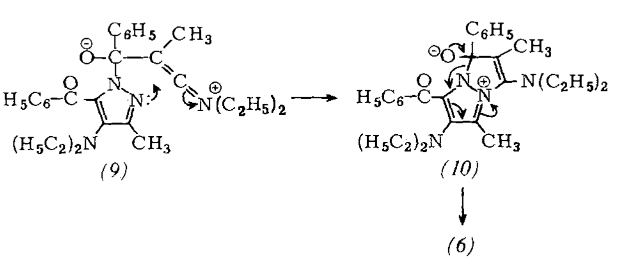


$$H_5C_6-\overset{O}{\overset{\|}{C}}-\underset{H_3C}{\overset{H}{C}}-C\genfrac{}{}{0pt}{}{\nearrow O}{\searrow N(C_2H_5)_2}$$

*(8)*

How does the insertion of the ynamine with concomitant rearrangement proceed in the reaction of *(4)*? Acylazoles are acylating reagents. The addition of the nucleophilic ynamine to give the zwitterion *(9)* is followed by a rearrangement to *(6)* *via* *(10)* as a conceivable further intermediate.

Insertions of ynamines into acylating reagents have been observed, *e.g.*, with phosgene[4] or diketene[5]. The migration of the side chain to the second pyrazole-N-atom in the conversion *(4)*→*(6)* presents a specialty. It was recently reported that the rearrangement of *(1)* into the corresponding 1,3-dicarboxylic ester is catalyzed by phenyl isothiocyanate or carbon disulfide[6]; a "conducted tour" mechanism presents a certain analogy to *(9)*→*(6)*.



The bond lengths of the planar pyrazole ring (Fig. 1) correspond to values between single and double bonds with a predominance of structure *(6)*. Neighboring substituents are twisted up to 6° against each other as a result of intramolecular van der Waals interactions. The conjugation of the π-substituents with the heterocycle is weakened by sterically enforced torsions. Whereas the bond plane of the 3′-carbonyl is only slightly twisted *versus* the pyrazole ring, the conjugation of the 4′-diethylamino group has vanished; the orbital of the lone pair is located in the ring plane and the nitrogen is pyramidal. The β-ketoenamine side chain is twisted by 52° at C3—N1′; its planarity is disturbed at C2—C3 only by 15°, but at C3—N* and C1—C2 by 43° and 45°, respectively. The shortening of the C3—N* bond to 1.372 Å is indicative of the conjugative coupling in the vinylogous carboxamide system, although the 5′-methyl enforces a substantial torsion of the mentioned bond.

Finally, structure *(6)* proves the orientation in the 1,3-dipolar cycloaddition which leads to *(2)* (the analogous structure *(1)* was established by chemical methods[1]); it is connected with the direction of addition, which is accompanied by a maximal energy gain in the HOMO-LUMO interactions (within the framework of the MO perturbation treatment of the concerted cycloaddition). The same orientation has been observed in the addition of α-diazocarbonyl compounds to enamines[7], whereas the addition to olefinic or acetylenic carboxylic esters takes place in the opposite direction[1].

lead to formation of difficultly separable mixtures. We have now developed a method for synthesizing the silanes $Ph_2Si(H)X$ *(5)*, in the first instance, in good yields and free of silicon-containing by-products.

Triorganosilanes $R_3SiH$ react photochemically with $CpMn(CO)_3$ ($Cp = \eta^5$-$C_5H_5$) and with ($\eta^5$-$CH_3C_5H_4$)$Mn(CO)_3$ *(1)* to give $Cp(CO)_2(H)Mn$—$SiR_3$ and the ($\eta^5$-$CH_3C_5H_4$)-complex, respectively[1]. We found in the case of diphenylsilane *(2)* (and other diorganosilanes) that only *one* Si—H bond is cleaved:

$$\underset{(1)}{(MeCp)Mn(CO)_3} + \underset{(2)}{Ph_2SiH_2} \xrightarrow[\text{hexane}]{h\nu,\ -CO} \underset{(3)}{(MeCp)(CO)_2(H)Mn\text{-}SiHPh_2}$$

$$(3) \xrightarrow[\text{reaction}]{\text{halogenation}} (MeCp)(CO)_2(H)Mn\text{-}SiXPh_2 \quad (4)$$

*(a)*, X = F; *(b)*, X = Cl; *(c)*, X = Br; *(d)*, X = I
(MeCp) = $\eta^5$-$CH_3C_5H_4$

In complex *(3)*[2], which is obtained in 75% yield, the remaining H-atom can be replaced by a halogen atom without the Mn—H or the Si—H bond being opened. Thus, *(4a)* can be prepared in 78% yield by reacting *(3)* for 30 min with a stoichiometric amount of $[Ph_3C]BF_4$ in $CH_2Cl_2$ at room temperature. When a solution of *(3)* in $CCl_4$ is treated with a small amount of $PCl_5$, *(3)* is chlorinated to *(4b)* in 72% yield within a few minutes. When dilute solutions of stoichiometric amounts of $Br_2$ or $I_2$ are slowly added dropwise at 0 °C to dilute solutions of *(3)* in pentane, *(4c)* and *(4d)* are obtained in 70 and 69% yield, respectively.

The new complexes *(3)* and *(4a)—(4d)* can be isolated as pale yellow solids by crystallization from pentane or by gel-chromatography[3]. They cannot be kept in the analytically pure state over a longer period, even with cooling. Their stability falls off on going from *(3)*≈*(4a)* to *(4d)* and rapidly decreases in polar solvents.

Reaction of *(4)* with CO under pressure leads to formation of the silanes *(5)* without by-products and with cleavage of the protecting group and regeneration of *(1)*. Beginning thermal decomposition of *(4)* is no problem, since the same silanes *(5)* are formed.

$$(4) \xrightarrow[\text{pentane, 100–120 °C, 3 h}]{\text{50–60 bar CO}} \underset{(1)}{(MeCp)Mn(CO)_3} + \underset{(5)}{Ph_2Si(H)X}$$

The silanes *(5)* can be smoothly separated on a gram scale from complex *(1)*, *i.e.* without major losses, by preparative high pressure liquid chromatography (PHPLC)[4] (overall yields of *(5)* 80—90% depending on the educt).

The reactions described here thus enable one only of the two silicon-bonded hydrogen atoms of diphenylsilane *(2)* to be replaced by halogen.

## Dispiro[2.0.2.4]deca-7,9-diene as a Ligand in Carbonyl-Transition Metal Complexes[**]

By *Dieter Wormsbächer, Frank Edelmann, Dieter Kaufmann, Ulrich Behrens*, and *Armin de Meijere*[*]

*Dedicated to Professor Edgar Heilbronner on the occasion of his 60th birthday*

The highest occupied molecular orbital (HOMO) of dispiro[2.0.2.4]deca-7,9-diene *(1)* [formula numbered by analogy to *(2)*] is exceptionally high[1a] owing to conjugation of the diene moiety with the two neighboring spirocyclopropyl groups[1a]. As is well known, cyclopropyl substituents are particularly effective electron donors towards electron-deficient centers, but poor electron acceptors[1b]. Since a diene(tricarbonyl)iron group as a rule also acts as an electron donor[2], we were interested to know whether or not there was a mutual electronic influence between diene(carbonyl)metal unit and spirobicyclopropyl group.

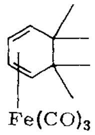
*(5a)*, M = Fe, L = CO
*(5b)*, M = Fe, L = $P(C_6H_5)_3$



*(6)*

The tricarbonyliron complex *(4a)* is obtained as an orange-yellow oil in 75% yield by reaction of *(1)* with (benzylideneacetone)tricarbonyliron ((bda)$Fe(CO)_3$)[3a] followed by chromatography on silica gel. In an analogous way reaction with (bda)[$P(C_6H_5)_3$]$Fe(CO)_2$[3b] and (bda)[$P(OC_6H_5)_3$]$Fe(CO)_2$[3b] afforded the corresponding complexes *(4b)* (40%, yellow crystals, m.p. 198—199 °C) and *(4c)* (35%, orange oil), respectively. Surprizingly, the reaction of *(1)* with $Fe_2(CO)_9$ led to formation of *(4a)* as the only product, although many vinylcyclopropane derivatives undergo ring opening under these conditions[4]. $Ru_3(CO)_{12}$ catalyzes the rearrangement of *(1)* to *o*-ethylstyrene[1a], whereas reaction with the more reactive tricarbonyl(1,5-cyclooctadiene)ruthenium[3c] leads, under mild conditions, to the complex *(4d)* (21%, lemon-yellow oil). In

contrast, *(1)* cannot be converted—even by treatment with tris(acetonitrile)tricarbonylchromium—into a tricarbonylchromium complex, in which the spirobicyclopropyl group also ought to function as a ligand[5].

Reaction of 5,5,6,6-tetramethyl-1,3-cyclohexadiene *(3)*[6], having the same type of substitution as *(1)*, with (bda)Fe(CO)$_3$ similarly afforded the tricarbonyliron complex [*(6)*]. The spectroscopic data of *(6)* and those of the complexes *(5a)*[7] and *(5b)*[8] of 1,3-cyclohexadiene *(2)* have been selected for comparison with those of the new carbonylmetal complexes *(4a)—(4d)* (Table 1).

Table 1. Spectroscopic data of the carbonylmetal complexes *(4)—(7)* and the free ligands *(1)—(3)* [numbering as shown in *(1)* and *(2)*].

[a] I cyclohexane, II KBr, III $C_6D_6$, IV $CCl_4$, V $CD_2Cl_2$. [b] Detailed analysis of the $^1$H- and $^{13}$C-NMR spectra of *(4a)* and *(6)*: *H. Günther*, unpublished results. [c] *F. M. Chaudhari, P. L. Pauson*, J. Organomet. Chem. *5*, 73 (1966). [d] *R. Burton, L. Pratt, G. Wilkinson*, J. Chem. Soc. *1961*, 594.

From the C≡O stretching vibration frequencies of *(4a)*, which were found to be insignificantly lower than those of *(5a)*, it can only be concluded that there must be very little difference between the π*-MOs of *(4a)* and *(5a)*[2]. The $^1$H- and $^{13}$C-NMR data would also lead to the same conclusion. Thus, the signals of the cyclopropyl protons of *(4a)—(4d)* are shifted only slightly (0.1—0.2 ppm) upfield compared to those of *(1)*, and the $^{13}$C-NMR signals of the cyclopropyl C-atoms C7—C10 in the complex *(4a)* are even shifted downfield. Consequently, the metal-complexed diene moiety cannot exercise its electron-donor action on the spirobicyclopropyl group.

According to an X-ray structure analysis the diene moiety in *(4b)* is completely planar (see Fig. 1), as is usual in such complexes[2]. The angle between this plane and the C$^4$—C$^5$—C$^6$—C$^1$ plane is *ca.* 39°; the bicyclopropyl group, with a dihedral angle of *ca.* 4°, has an almost synplanar conformation.

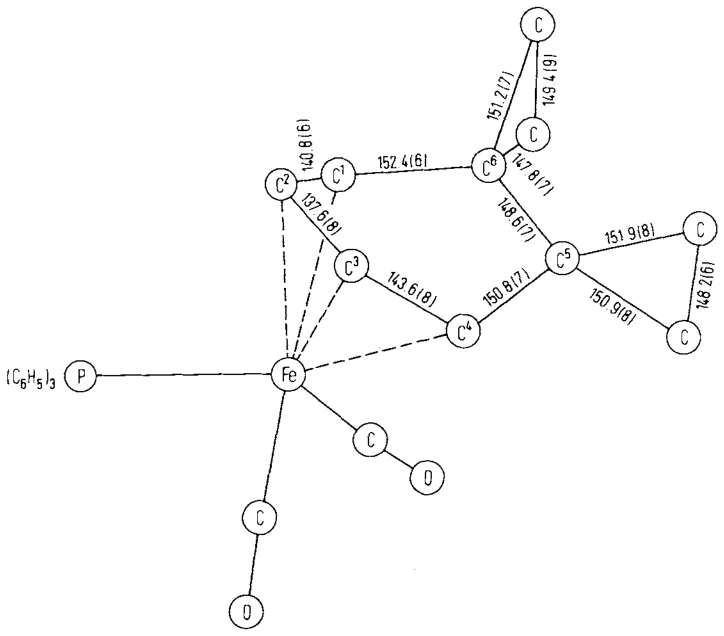

Fig. 1. Structure of *(4b)* in the crystal (monoclinic crystals, space group $P2_1/c$, $a = 871(1)$, $b = 1542(1)$, $c = 1867(2)$ pm, $\beta = 97.3(1)$; 2478 measured reflections, refined to $R = 0.041$).

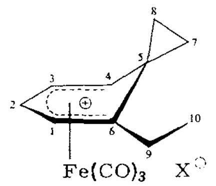

*(7a)*, X = $BF_4$
*(7b)*, X = $PF_6$

The most remarkable property of *(4a)* is its smooth reaction with ethereal tetrafluoroboric acid at room temperature to give the stable complex *(7a)*, while the free ligand *(1)* spontaneously polymerizes with superacids, even at −80 °C[9]. The orange-yellow crystalline compound *(7b)*, which precipitates from the aqueous solution of oily *(7a)* on addition of ammonium hexafluorophosphate, is to our knowledge the first complex of an ethylenebenzenium ion [formula numbered by analogy to *(2)*]. From its $^1$H- and $^{13}$C-NMR data (see Table 1) it is evident that the positive charge—other than in the case of the uncomplexed ion[10]—is not delocalized into the cyclopropyl group. Consequently, *(7)* should react with nucleophiles like a tricarbonylcyclohexadienyliron cation[11] and not like an ethylenebenzenium ion.

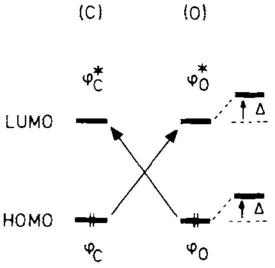
# Direct and Inverse Reactivity-Selectivity Relationship in the [1.2]-Addition of Singlet Carbenes to Olefins[**]

By *Wolfgang W. Schoeller*[*]

*Dedicated to Professor Josef Goubeau on the occasion of his 80th birthday*

Hitherto it has generally been assumed that the reactivities of carbenes towards olefins decrease with increasing selectivity in the order $CF_2 > CCl_2 > CBr_2$[1]. Contrary to this common understanding, we show that the selectivity of singlet carbenes $CL_2$ (L = halogen, $OCH_3$ *etc.*) can increase with increasing reactivity (inverse reactivity-selectivity relationship[2]).



Scheme 1.

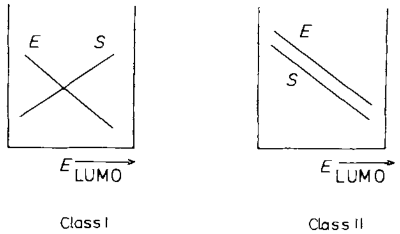
According to frontier orbital theory[3] the interaction between a carbene (C) and an olefin (O) (Scheme 1) is given by the following relation:

$$E = \frac{\beta^2 \varphi_0 \varphi_{C^*}}{E\varphi_C^* - (E\varphi_0 + \Delta)} + \frac{\beta^2 \varphi_C \varphi_{O^*}}{(E\varphi_O^* + \Delta) - E\varphi_C} \qquad \text{(a)}$$

where $E$ is determined in this picture by mutual transfer of electron density between the frontier orbitals HOMO and LUMO and is proportional to the logarithm of the rate constant of the reaction. A variation in O ($O_1, O_2, \ldots O_i$) causes a change in reactivity ($\lg k_1, \lg k_2, \ldots \lg k_i$) and hence corresponds to a change in the interaction energy $E$. If the trapping olefins $O_i$ differ only slightly in their electronic properties (*e.g.* by alkyl substitution at the π-system), the frontier orbitals of $O_i$ will be energetically raised or lowered[4] by the small amount $\Delta$[5]. Hence selectivity [eq. (b)] is related to reactivity [eq. (a)] as derived in the formalism of *differential* frontier orbital theory.

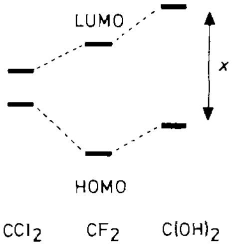
$$S \equiv \frac{\partial E}{\partial \Delta} = \frac{\beta^2 \varphi_O \varphi_{C^*}}{[E\varphi_C^* - (E\varphi_O + \Delta)]^2} - \frac{\beta^2 \varphi_C \varphi_{O^*}}{[(E\varphi_O^* + \Delta) - E\varphi_C]^2} \qquad \text{(b)}$$

For a reactivity-selectivity relationship the following limiting cases ($S > 0$) can be recognized:



Scheme 2.

*Class I:* Increase in selectivity and decrease in reactivity on raising the LUMO energy level of the carbene. This case corresponds to the classical reactivity selection principle (RSP)[2] (direct RSP). In the series of the halocarbenes (L = F, Cl, Br) the energy difference between the innermolecular frontier orbitals ($X = E_{LUMO(C)} - E_{HOMO(C)}$) decreases (less favorable $C_{2p} \cdot L_{np}$ overlap, $n = 2, 3, 4$) *e.g.*, with respect to $CF_2$ the species $CCl_2$ is more reactive, both electrophilically as well as nucleophilically[6].



Scheme 3.

Hence, the reactivity according to eq. (a) increases and simultaneously the selectivity according to eq. (b) decreases. Similar considerations hold for the selectivity region $S<0$ (nucleophilic carbenes).

For the series of halocarbenes we have plotted their selectivities against the corresponding LUMO energies[7] (Fig. 1).

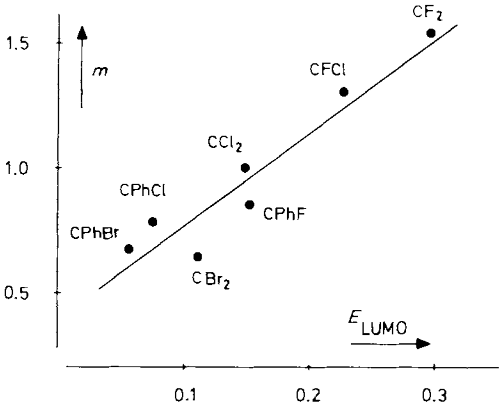


Fig. 1. Relative selectivities (with respect to $CCl_2$ under standard conditions [1]) *m* of the halocarbenes as a function of their LUMO energies (in β).

Accordingly, the selectivity of the carbene increases with increasing LUMO energy. Therefore, the halocarbenes are ruled by the direct RSP, which is in agreement with the view[1] that the selectivity of carbenes increases with increasing resonance stabilization ($CBr_2 < CCl_2 < CF_2$).

*Class II:* Decrease in reactivity and concomitant decrease in selectivity (inverse RSP) with increasing LUMO

energy of the carbene. If however the ligands at the carbene site (L = F, $OCH_3$, $NH_2$) stem from the second row of the long periodic system, the intermolecular HOMO-LUMO energy difference X remains constant to a first approximation (constant $C_{2p}-L_{2p}$ overlap). Lifting the LUMO of the carbene[3] therefore decreases its electrophilicity and diminishes its nucleophilicity. Contrary to $CF_2$, $C(OCH_3)_2$ reacts as a nucleophilic species[8a]. In addition, the selectivity of nucleophilic carbenes increases along the ligand sequence $L = OCH_3 < N(CH_3)_2$[8].

To summarize, our investigations reveal two different classes of carbenes on the basis of a differential formulation[9] of the frontier orbital model. These two classes obey a direct or inverse relationship between reactivity and selectivity.

The concept which we have demonstrated here for the series of carbenes is more general and can be equally applied to other frontier orbital controlled reactions, such as cycloadditions and radical reactions[9].

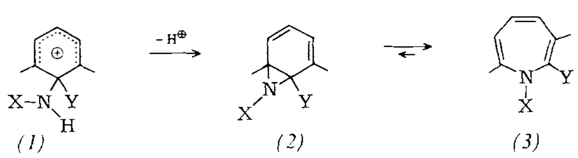
## 1*H*-Azepines from Anilides—A Novel Ring Expansion[**]

By *Heinz H. Eckhardt, Dorothea Hege, Werner Massa, Hartwig Perst,* and *Roland Schmidt*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

1-Substituted 1*H*-azepines[1] such as *(3)* have not yet been synthesized by ring-closure of an amino-substituted benzenium ion [*(1)*→*(2)*→*(3)*].



Although there are also other reaction routes open to a benzenium ion such as *(1)*[2] we have now been able to realize this mode of entry to 1*H*-azepine derivatives *(6)* in the triaryl series starting from the 2,4,6-triphenylanilides *(4)*. Formally, the requisite cation *(5)* is formed by electrophilic "*ipso*alkylation"[3] at the arene-C atom of *(4)* bearing nitrogen. Since *(5)* is not preparatively accessible in this way we have chosen the alternative route *via* the reactivity-umpolung of *(4)*[4]. Oxidation of the anilides *(4a)*—*(4f)*[5] with lead tetraacetate in the presence of methanol affords the *N*-(4-methoxy-2,5-cyclohexadien-1-ylidene)carboxamides *(7a)*—*(7f)* in 68—86% yield, which readily add nucleophiles at the C=N moiety[6]. Thus, the cyclohexadienylamides *(8a)*—*(8f)* are accessible in yields of up to 80—90% as potential precursors of *(5)* by reaction of *(4)* with methyllithium in diethyl ether[7].

Reaction of *p*-toluenesulfonic acid with *(8)* in toluene leads to elimination of methanol and formation of products which can be derived from a cation *(5)*. Whether the ring closure ensues *via* the nitrogen atom or *via* a center of the X moiety depends on the nucleophilicity of the substituents X in the *N*-position. Only the amide *(8f)* with the slightly nucleophilic tosyl moiety is directly converted (72% yield) into the 1*H*-azepine derivative *(6f)*.

Under the same conditions, in the case of *(8a)*—*(8e)* the *O*-alkylation typical for carboxamides[8] dominates over the desired *N*-alkylation, so that the bicyclic oxazoline derivatives *(9a)*—*(9e)* are obtained in yields of up to 85%. In addition, the anilides *(4a)*—*(4e)* are formed as demethylation products of *(5)* in *ca.* 10% yield. The compounds *(9)* are characterized $^1H$-NMR spectroscopically, *inter alia*, by an AB system for the vinyl protons (in $CDCl_3$; $\delta = 5.86$—

[++] X-ray structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie.

6.01 and 6.42—6.49, $J=1.3—1.5$ Hz); in the $^{13}C$-NMR spectrum they always show two signals typical for the quaternary bridgehead centers [in $CDCl_3$; $\delta=73.4—73.7$ (C—N) and 91.9—92.5 (C—O)]. The thermally unstable oxazolines *(9)* are suitable precursors for the azepines *(6)*: by heating to 180 °C, the derivatives *(9a)—(9e)* can be smoothly converted (84—93%) into the *N*-acyl-1*H*-azepines *(6a)—(6e)*[9] which, unlike the yellow tosylazepine *(6f)*, are almost colorless. The 1*H*-azepine structure *(6)* is confirmed by an X-ray analysis of a single crystal of *(6d)* (Fig. 1).

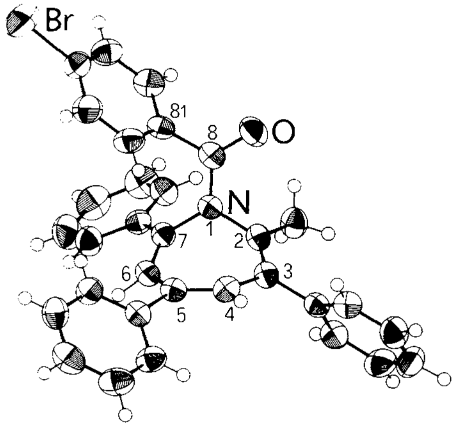

Fig. 1. ORTEP diagram of a molecule of *(6d)* in the crystal (thermal vibration ellipsoids with 50% probability). Space group $P\bar{1}$, $Z=2$, $a=1076.5(4)$, $b=1212.6(2)$, $c=1048.3(6)$ pm, $\alpha=93.62(3)$, $\beta=113.48(3)$, $\gamma=88.66(2)°$, $\rho_c=1.374$ g cm$^{-3}$. With 3089 independent reflections ($F_0>3\sigma$), measured on a four-circle diffractometer (CAD4, Enraf-Nonius, $Mo_{K\alpha}$-radiation) the structure could be refined to $R_w=0.046$ (weight $3/\sigma^2$). Bond lengths in the azepine ring: N—C2 = 144.8(4), C2—C3 = C6—C7 = 134.1(5), C3—C4 = 145.7(5), C4—C5 = 135.1(4), C5—C6 = 144.7(5), C7—N = 143.4(3) pm; amide moiety: N—C8 = 135.5(4), C8—O = 122.3(4) pm.

The azepine ring has, as expected, the boat-shaped conformation[10]; the atoms C2, C3, C6, and C7 lie in a plane which forms an angle of 120.7° with the NC2C7 plane and one of 151.2° with the C3C4C5C6 plane. The NC8OC81 plane is at an angle of only about 9.4° to the NC2C7 plane (in the direction of the equatorial position)[10]. The amide bond N—C8 in the crystal of *(6d)* is exclusively *E*-configurated; on the other hand, equilibrium mixtures are $^1H$- and $^{13}C$-NMR spectroscopically observable in solutions of *(6a)—(6e)*, in which the *E*-rotamer is slightly preferred[11].

Apart from the signals of the methyl-C atoms the $^{13}C$-NMR spectra of *(6)* contain only absorptions for $sp^2$-C atoms, among which C4 ($\delta=130.3—132.3$) and C6 (121.8—123.2) and the amide-carbonyl C-atoms (168.5—170.3) are always unambiguously assignable. In the IR spectrum (KBr) the C=O bands appear in the region typical for tertiary amides at 1638—1666 cm$^{-1}$.

Table 1. Characteristic data of the 1*H*-azepines *(6)* [a].

| *(6)* | Yield [%] | M.p. [°C] | $^1H$-NMR [b] H-4 [c] | C2—CH$_3$ [c] | others |
|---|---|---|---|---|---|
| *(a)* | 93 | 149—150 | (*E*): 7.00 | 2.33 | |
| | | | (*Z*): 6.90 | 1.76 | |
| *(b)* | 91 | 145—146 | (*E*): 7.02 | 2.31 | 2.21 (Aryl—CH$_3$) |
| | | | (*Z*): 6.93 | 1.78 | 2.38 (Aryl—CH$_3$) |
| *(c)* | 85 | 154—155 | (*E*): 6.95 | 2.30 | 3.68 (Aryl—OCH$_3$) |
| | | | (*Z*): 6.83 | 1.80 | 3.82 (Aryl—OCH$_3$) |
| *(d)* | 87 | 138—139 | (*E*): 7.03 | 2.31 | |
| | | | (*Z*): 6.93 | 1.79 | |
| *(e)* | 84 | 134—135 | (*E*): 6.90 | 2.15 | 1.91 (CO—CH$_3$) |
| | | | (*Z*): 6.82 | 2.08 | 2.18 (CO—CH$_3$) |
| *(f)* | 72 | 182—184 | 6.03 | 2.27 | 2.03 (Aryl—CH$_3$) |

[a] In $CDCl_3$ the (*E*):(*Z*) ratio for *(6a)—(6d)* is 4:3 and for *(6e)* 7:3. [b] 100-MHz spectra, $\delta$ values in $CDCl_3$ (int. TMS). [c] Homoallyl coupling between vinyl-H-4 and C2—CH$_3$ (*J ca.* 0.7 Hz) leads to weak signal broadening; the vinyl-H-6 signal is masked by the phenyl-H multiplet ($J_{H\text{-}4/H\text{-}6}<0.5$ Hz).

### *Procedure*

*(7a)*: Lead tetraacetate (8.0 g, 18 mmol) is added to a solution of *(4a)*[5] (6.08 g, 15 mmol) in toluene (50 mL) and methanol (100 mL) and the mixture stirred for 150 min at room temperature then treated with 30 mL of a saturated aqueous NaCl solution. The organic phase recovered after removal of the precipitate by filtration is washed, dried (over $Na_2SO_4$), and evaporated to dryness under reduced pressure. Yield 5.12 g (75%) *(7a)* as colorless crystals of m.p. 169—170 °C (from $CHCl_3$/methanol).

*(9a)*: A suspension of *(7a)* (1.37 g, 3 mmol) in anhydrous diethyl ether (1 mL) is treated at room temperature under $N_2$ with 10 mL of a 2 M ethereal solution of methyllithium. After one hours' stirring the mixture is hydrolyzed with 5 mL of water, then washed with 100 mL of a saturated aqueous $NH_4Cl$ solution and with water. The ethereal phase, after drying over $MgSO_4$ and evaporation to dryness under reduced pressure, yields 1.22 g (88%) of *(8a)* as an oil (mixture of *cis-trans*-isomers in the ratio 3:2). *(8a)* obtained from two such runs (2.30 g, 5 mmol) is dissolved without further purification in toluene (50 mL), treated with 50 mg of *p*-toluenesulfonic acid, and the resulting mixture stirred for 50 min at room temperature. After washing with 20 mL of a 0.2 M aqueous solution of $NaHCO_3$ and with water, the reaction solution is dried (over $Na_2SO_4$) and evaporated to dryness; the residue is taken up in $CHCl_3$ (5 mL) treated with *n*-hexane until cloudy and the anilide *(4a)* (0.19 g, 9.4%) allowed to crystallize out. The filtrate, after evaporation to dryness and recrystallization from $CHCl_3$/*n*-hexane furnishes 1.87 g (85%) of *(9a)* as colorless crystals of m.p. 173—174 °C.

*(6a)*: *(9a)* (0.31 g, 0.7 mmol) is heated under $N_2$ for 30 min at 180 °C in the absence of a solvent. After cooling it is taken up in 3 mL of $CHCl_3$ and *(6a)* is precipitated by addition of methanol; yield: 0.29 g (93%) as colorless crystals (Table 1).

*(6b)—(6e)* are prepared analogously; *(6f)* is formed directly on treatment of *(8f)* with *p*-toluenesulfonic acid.

# BOOK REVIEWS

**NMR of Chemically Exchanging Systems.** By *J. I. Kaplan* and *G. Fraenkel.* Academic Press, New York 1980. xi, 165 pp., $ 19.50.

The concept of a quantum-mechanical density matrix, introduced by *Johann (John) von Neumann* some 50 years ago, is widely regarded as an advanced subject. Apart from the classic works of *Abragam* and of *Slichter,* written by and for physicists, it has rarely made its way into textbooks on NMR spectroscopy; of those addressed to the chemist, many do not condescend to mention it at all. And that in spite of the fact that the density matrix formalism is not only indispensable for a genuine understanding of relaxation and exchange phenomena in NMR, but is also used routinely, by means of "canned" computer programs, in applications especially to exchange problems. A monograph which purports to fill this gap would thus appear to be a highly welcome addition to the NMR textbook literature.

Provided that it succeeds in its stated aim. The overwhelming impression on a first reading is that of an excessively formal treatment. About 70% of a typical page in the main body of the text, which is principally concerned with exchange, with one chapter on relaxation thrown in for good measure, is taken up by mathematical symbols; more precisely, there are no less than 1045 equations all told, squeezed into 162 pages of text. There probably exist readers who take delight in such a wallowing in formalism, but one wonders at their frequency. The typical needs of a nonspecialist would in this reviewer's opinion be better served by a concise presentation designed to exhibit the logical transparency of the theory. Such a compact and modern formulation does in fact exist, but the authors have chosen to follow their own predilections.

As an unavoidable consequence of this heavy emphasis on formalism, the physical content of the theory and its applications get short shrift. The opportunity of counterbalancing the overdose of mathematics by a copious use of well-designed figures has remained largely unexploited. There are preciously few in the first place, and the majority are moreover trivial or uninformative. Lineshapes are frequently displayed as freehand drawings, and drawn with a shaky hand to boot. Quite the worst example of its kind has been selected by the publisher to disgrace the cover of the book. One single page is devoted to experimental problems, which is of course totally inadequate. The authors acknowledge the necessity of using a computer for actual calculations, but no information is provided about where to obtain the relevant programs or how to use them. Readers wishing to learn about how to apply the formalism to the study of permutational mechanisms in the presence of molecular symmetry, which ranks among the chemically most exciting applications of the theory, are left out in the cold. The possibility of using group-theoretical techniques for simplifying the calculations is ignored. The citation policy is strangely selective; references to papers of marginal relevance are sometimes listed at great length, whereas there are gaping omissions otherwise. The carelessness in assembling the references is also reflected in the numerous misspellings and misquotations. As long as this fate only befalls some of the lesser luminaries, a kind of excuse may perhaps be concocted for the authors' sloppiness, but when it comes to names such as *Wangsness, McConnell, Hoffman,* even the patience of an indulgent reviewer begins to wear thin. It is particularly sad to notice that *Erwin Hahn,* one of the early pioneers, is not spared the indignity of seeing his name perverted to *Holm,* in the references as well as in the text.

Users of NMR spectroscopy wishing to educate themselves about density matrix methods are advised to turn to other sources, especially to articles in the modern review literature. Since they are not cited in the book, the authors of four of them, all excellent, are mentioned here: *P. D. Buckley, K. W. Jolly* and *D. N. Pinder* (1975); *R. L. Vold* and *R. R. Vold* (1978); *S. Szymanski, M. Witanowski* and *A. Gryff-Keller* (1978); *A. Steigel* (1978). The attention of specialists is drawn to the SNOB (selective neglect of bilinear terms) technique, which is based on the authors' original research. Although information about that topic can also be extracted from the journal literature, it is convenient to have it between the covers of a book. This is an interesting idea, whose potential for applications has hardly been tapped, but which holds great promise for the future. It is the part of the book which the present reviewer found worthwhile enough to read more than once.

## Corrigendum

The following corrections should be made to the short communication entitled "The Unusual Stereochemistry of the Cycloaddition of Vinyl Ethers with Sulfonyl Isothiocyanates" by *Ernst Schaumann, Hans-Günther Bäuch,* and Gunadi Adiwidjaja, Angew. Chem. Int. Ed. Engl. *20*, 613 (1981):

On p. 614, left-hand column, the table caption "Ylides" should read "Yields".

On p. 614, right-hand column, $^2J_{cis}$ and $^2J_{trans}$ in lines eight and nine should read $^3J_{cis}$ and $^3J_{trans}$, respectively.

On p. 614, right-hand column, in the last sentence "... between cumulated π-electron systems ..." should read "... between *non*-cumulated π-electron systems ...".

# Syntheses of Pyrethroid Acids

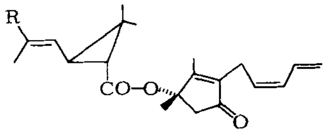
**By Dieter Arlt, Manfred Jautelat, and Reinhard Lantzsch**[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

In the course of the last decade the chemistry of insecticides was expanded with the discovery of new cyclopropanecarboxylic acid esters of specific structure, far superior in action to the hitherto known insecticides of other substance classes or the natural prototypes from the group of pyrethrum constituents. The discovery quickly precipitated a host of wide-ranging studies on the synthesis of these compounds. The development of selective methods of synthesizing complicated small rings called for a comprehensive repertoire: thus, synthesis of the compounds on an industrial scale makes use of sigmatropic rearrangement, radical addition, and nucleophilic ring closure with carbanions. These new industrial syntheses have acquired particular topicality because of their use of stereospecific and enantioselective methods.

## A) Introduction

The constituents of some chrysanthemum species (pyrethrum) have been used as insecticides since the early 19th century. In 1924 *Staudinger* and *Ruzicka*[1] discovered that the active constituents, *e.g.* pyrethrin I *(1)* and II *(2)*, are esters of 2,2-dimethyl-3-(2-methyl-1-propenyl)-1-cyclopropanecarboxylic acid [chrysanthemic or chrysanthemumic acid, cf. *(49)*] and of 3-(2-methoxycarbonyl-1-propenyl)-2,2-dimethyl-1-cyclopropanecarboxylic acid (pyrethric acid).



*(1)*, R = $CH_3$
*(2)*, R = $COOCH_3$

The first synthetic analogues of the natural chrysanthemic acid esters had already been prepared by *Staudinger*[2]. Some subsequently synthesized compounds of this group proved to be superior to the natural substances in their action, but due to their photolability their use remained restricted to the hygiene sector.

The situation changed at the beginning of the 'seventies, when a research team at the National Research and Development Corporation (NRDC)[3], led by *M. Elliott*, reported new analogues of the active constituents of pyrethrum, which stood out against the previously known chrysanthemates due to their quite extraordinary activity and photostability.

Thus began a worldwide development which ended in a new class of insecticides whose technical and economic significance is already comparable with that of the insecticidal esters of phosphorus acids and carbamates. The abnormally fast, almost spectacular development of these new pyrethroids—synthetic descendants of natural pyrethrum insecticides—has been due to their stability to atmospheric influences. In contrast to the natural prototypes,

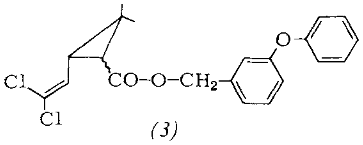
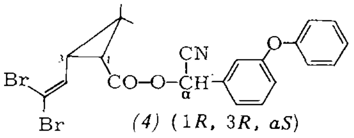
they can thus be used in agriculture. At the same time, this new class of substances includes the most effective insecticides known to date, the increase in activity making it possible to reduce the amount applied per unit area to a hundreth of that of conventional phosphorus acid esters.

*Farkas et al.* reported as early as 1958[4] that certain esters of 3-(2,2-dichlorovinyl)-2,2-dimethyl-1-cyclopropanecarboxylic acid [permethrinic acid, cf. *(147)*] act similarly to analogous chrysanthemic acid esters. Making use of this observation the above British group[3] combined this acid with *m*-phenoxybenzyl alcohol to obtain the ester permethrin *(3)*. A few years previously the chrysanthemic acid ester of this alcohol had already come to the attention of researchers at Sumitomo Chemical Co. Ltd. owing to its special insecticidal action. Minor structural alterations led to the enantiomerically pure active substance decamethrin *(4)*, characterized by still greater activity.



*(3)*
Permethrin



*(4)* (1*R*, 3*R*, α*S*)
Decamethrin

It is clear that the outstanding properties of the new pyrethroids have precipitated worldwide research activity in this sphere. The activity and imagination of industrial researchers have been particularly stimulated, leading to an abundance of new synthetic results in the pyrethroid sector. The development of rational and diverse routes for the preparation of the acid components of the new active constituents, termed the pyrethroid acids, was also of particular importance for their industrial preparation.

The hitherto most active insecticides are derived from cyclopropanecarboxylic acids in which the three-membered ring contains two geminal methyl groups and a β-substituted vinyl group. The advances in the synthesis of these important active substances are described synoptically in Section B of this review.

The cyclopropanecarboxylic acids on which the most important insecticides are based are listed in Scheme 1.

Analogous esters of 2,2,3,3-tetramethyl-1-cyclopropanecarboxylic acid *(222)* and of 2-(4-chlorophenyl)-3-methylbutyric acid, which in their action are comparable with the described cyclopropanecarboxylic acid derivatives, have also found practical application as insecticides. The synthesis of these compounds are more conveniently presented separately (see Section D).

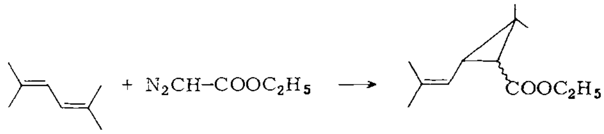
## B) Methods of Synthesizing Substituted 2,2-Dimethyl-3-vinyl-1-cyclopropanecarboxylic Acids

### 1. [2+1]-Addition

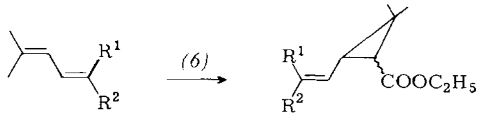
### 1.1. Diazoacetic Ester Synthesis

Following the structural elucidation[1] of the natural pyrethroids, *Staudinger* and *Ruzicka et al.* succeeded in synthesizing ethyl chrysanthemate *(7)*[5] by the reaction of 2,5-dimethyl-2,4-hexadiene *(5)* with the diazoacetic ester *(6)*, but the yield only amounted to 14% since only impure diene was available and no catalyst had been used.



*(5)* *(6)* *(7)*

*Campbell* and *Harper*[6] used very pure diene *(5)*[7] and worked at high temperatures with copper bronze as catalyst. They thus obtained a yield of 64% (*cis*:*trans* ratio = 1:3). When the synthesis is performed in a continuous fashion, the yield can be raised to 80%[8]. A further enhancement of the yield was achieved by catalyzing the reaction with rhodium(II) acetate[9].

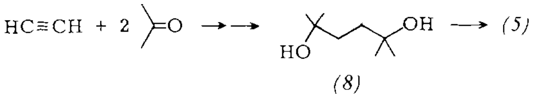


$R^1$, $R^2$ = $CH_3$, $CH_3$[5]; $CH_3$, $COOC_2H_5$[15];
Cl, Cl[4]; Cl, $CF_3$[37]; Cl, *p*-$ClC_6H_4$[31]

The diazoacetic ester synthesis is very generally applicable and relatively simple to perform in the laboratory; it has thus been used for practically all pyrethroid acid components. It is also carried out on the industrial scale. The main problem with these syntheses is preparation of the dienes.

1.1.1. 2,5-Dimethyl-2,4-hexadiene *(5)*

*Staudinger et al.*[5] only obtained *(5)* in an impure form by the dehydrochlorination of 2,5-dichloro-2,5-dimethylhexane. One very elegant synthetic method starts from acetylene and acetone[10] and proceeds *via* *(8)*.



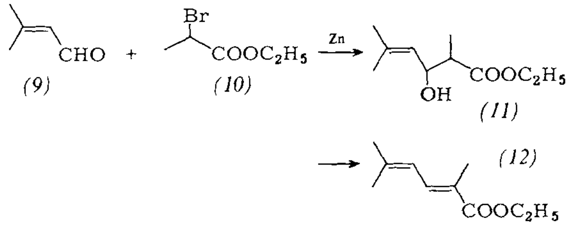
*(8)*

In other syntheses of *(5)*, methallyl chloride is dimerized with magnesium[7], sodium[11], or carbonylnickel compounds[12]. Above 500 °C addition of methallyl chloride to isobutene also takes place in low yield[13]. The primary product, 2,5-dimethyl-1,5-hexadiene, must then be isomerized to *(5)* at *ca.* 450 °C in the presence of an acid catalyst[7].

The diene *(5)* has also been obtained by Wittig reaction[14].

### 1.1.2. Ethyl 2,5-Dimethyl-2,4-hexadienoate *(12)*

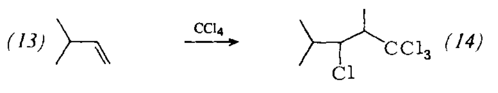
The diene *(12)* is obtained by a Reformatsky reaction of 3-methylcrotonaldehyde *(9)* with ethyl 2-bromopropionate *(10)* and subsequent dehydration with $POCl_3$[15].

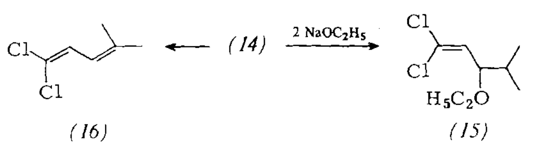


### 1.1.3. 1,1-Dichloro-4-methyl-1,3-pentadiene *(16)*

In the preparation of 3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylic acid (permethrinic acid)[4] the main difficulty was also the synthesis of the educt *(16)*.

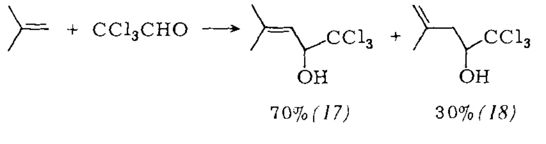
*(16) from 3-methyl-1-butene (13):* To arrive at *(16)*, *Farkas et al.*[4] added carbon tetrachloride to 3-methyl-1-butene *(13)*, but did not succeed in cleaving off two molecules of hydrogen chloride from the adduct *(14)* to give *(16)*; action of heat only resulted in formation of tar, while the allyl chloride produced by the action of sodium ethoxide immediately reacts further in a nucleophilic manner to give *(15)*.

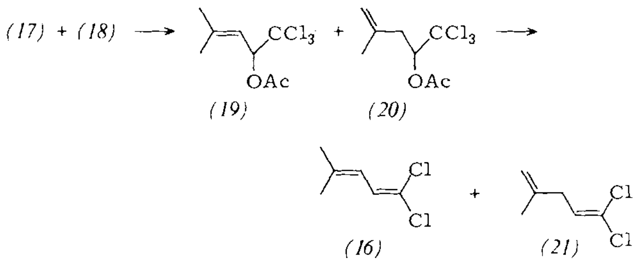




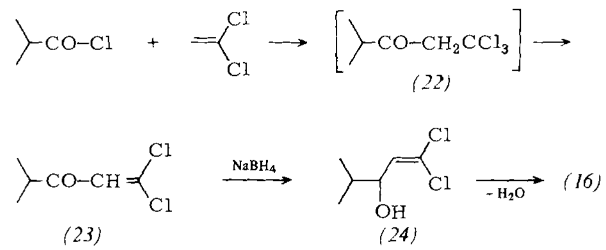
However, twofold dehydrochlorination by means of amines[16], with tin(IV) chloride[17], and with potassium hydroxide in anhydrous solvents[18] is described in the later patent literature.

*(16) from isobutene and chloral:* Because of the reactions described, *Farkas* did not introduce the chlorine atoms with carbon tetrachloride but with chloral. The addition of chloral to isobutene was already known[19]. The isomeric alcohols *(17)* and *(18)* were acetylated to *(19)* and *(20)* respectively and then converted into the isomeric dienes *(16)* and *(21)* with zinc in glacial acetic acid. Once the significance of permethrinic acid (cf. Scheme 1) as the basis for outdoor insecticides had been recognized, many industrial researchers[20] started examining ways of improving the diene synthesis of *Farkas et al.*[4]. Independently of this trend, the four completely new syntheses outlined below were also discovered.



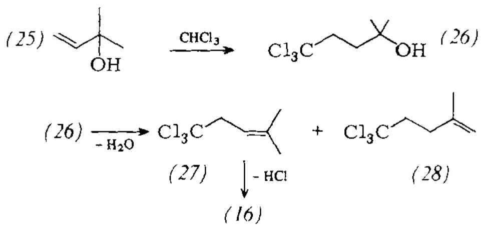


*(16) from isobutanoyl chloride:* The reaction of isobutanoyl chloride with 1,1-dichloroethene in the presence of aluminum chloride gives excellent yields of 1,1-dichloro-4-methyl-1-penten-3-one *(23)*[21]. The hydrogen chloride can be thermally cleaved from the initially obtained trichloroketone *(22)* by distillation[21], or better, especially in the preparation of larger quantities, with the aid of aqueous sodium hydroxide in the presence of phase-transfer catalysts[22]. After reduction with $NaBH_4$ and subsequent dehydration, the desired diene *(16)* is obtained in a high state of purity[23].



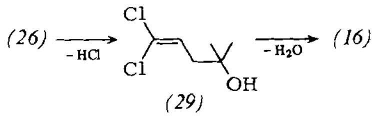
A patent application was later filed for the same synthetic route by other workers[24], the only difference being the reducing agent: Al(O*i*Pr)$_3$ was used instead of $NaBH_4$.

*(16) from isoprenol:* The second new synthetic route starts out from the known[25] addition product *(26)* of chloroform and 2-methyl-3-buten-2-ol *(25)*. The desired diene *(16)* is obtained by dehydration and dehydrochlorination.

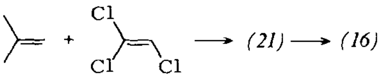


A mixture of 5,5,5-trichloro-2-methyl-2-pentene *(27)* and 5,5,5-trichloro-2-methyl-1-pentene *(28)* is obtained from *(26)*[25-27]. The latter must be isomerized or purified by distillation before the hydrogen chloride can be cleaved off[26].

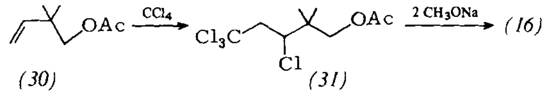
It is more advantageous—since it avoids the need for the non-quantitative isomerization of *(28)*—to cleave the hydrogen chloride from *(26)* first and then to dehydrate the product *(29)*[27]. In this case the newly formed double bond enters into conjugation with the one already present, and hence practically no *(21)* is produced.



*(16) from isobutene and trichloroethene:* At 500—540 °C 1,1-dichloro-4-methyl-1,4-pentadiene *(21)* is obtained in 65% yield by radical addition of isobutene and trichloroethene at 500—540 °C, with a conversion of about 20%. The compound must then be isomerized to the desired diene *(16)*[28].

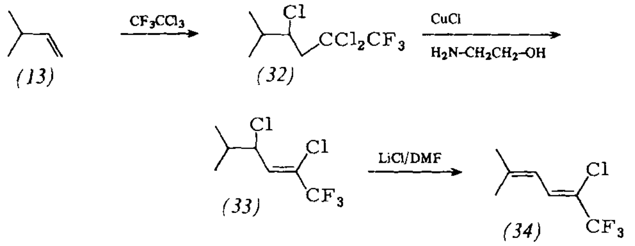


*(16) from dimethylbutenol derivatives:* A fourth synthetic method[29] starts from the acetate *(30)*. Addition of carbon tetrachloride to *(31)* gives 1,1-dichloro-4-methyl-1,3-pentadiene *(16)* *via* C—C bond cleavage under basic conditions.



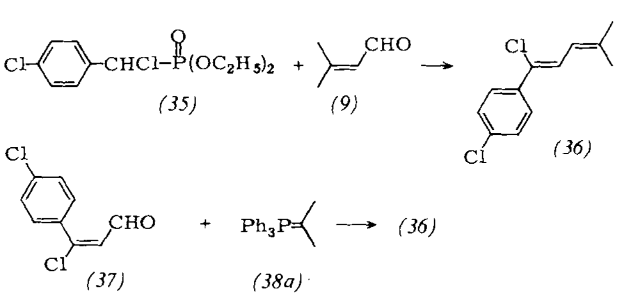
1.1.4. 2-Chloro-1,1,1-trifluoro-5-methyl-2,4-hexadiene *(34)*

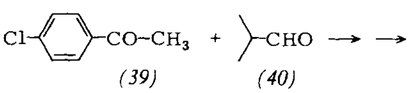
The diene *(34)* is, in principle, obtained by the same fundamental process as 1,1-dichloro-4-methyl-1,3-pentadiene *(16)* from 3-methyl-1-butene *(13)*, but special conditions had to be found for the dehydrochlorination of *(32)* and *(33)*[30] (DMF = dimethylformamide).

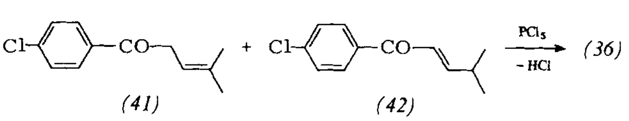


1.1.5. 1-Chloro-1-(4-chlorophenyl)-4-methyl-1,3-pentadiene *(36)*

The diene *(36)* can be obtained *e.g.* by a Wittig reaction[31], or by the reaction of *p*-chloroacetophenone *(39)* with isobutyraldehyde *(40)*[31]. A dimeric condensation product is obtained, which can be resolved into a mixture of the isomeric monomers *(41)* and *(42)*, which can in turn be converted into *(36)*.

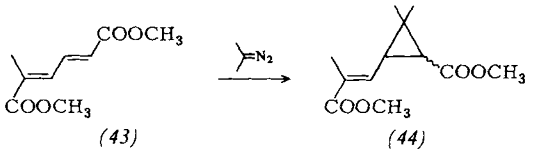






### 1.2. Diazopropane Synthesis

Whereas the introduction of C-1 by diazoacetic ester is one of the most important syntheses for pyrethroid acid components, there are only a few examples of the introduction of C-2. We shall, therefore, only mention the synthesis of the pyrethrate ester *(44)*[32,33] from diazopropane and (*E,E*)-α-methyl muconate *(43)*[34]. The pyrazoline intermediate can be isolated[33].



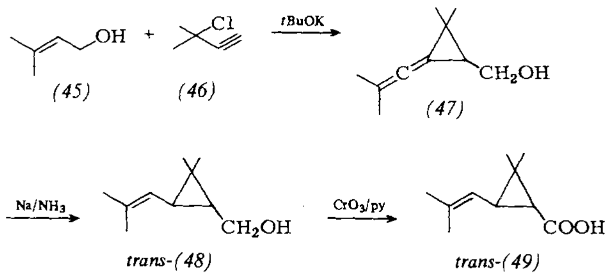
### 1.3. Intramolecular Diazo Syntheses

*cis*-Chrysanthemic acid and *cis*-permethrinic acid were obtained by an intramolecular cyclopropane ring closure of diazoketone[35] or of a diazoacetic ester[36] (see Section C).

### 1.4. Other Carbene and Carbenoid Additions

Further examples of carbene- and carbenoid-addition demonstrate the preparative range of this method, although this does not surpass or even reach the importance of the diazoacetic ester method.

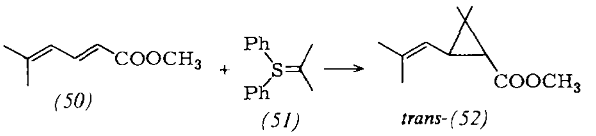
The *cis-trans* chrysanthemic acid ester *(7)* can be prepared from the diene *(5)* and diiodoacetic ester *via* a Simmons-Smith variant[38]. 1-Cyanopermethrinic acid ester was obtained by reacting the dichlorodiene *(16)* with activated acetonitriles such as cyanoacetic ester in the presence of copper(II) salts[39]. The reaction of α-halomalonic acid derivatives with copper or with copper salts and a base has also led to permethrinic acid derivatives[40]. Using dimethylallenecarbene it was possible to synthesize the alcohol *(48)*, a precursor of chrysanthemic acid *(49)*, from prenol *(45)*[41].



## 1.5. Ylide Additions

### 1.5.1. Sulfuranes

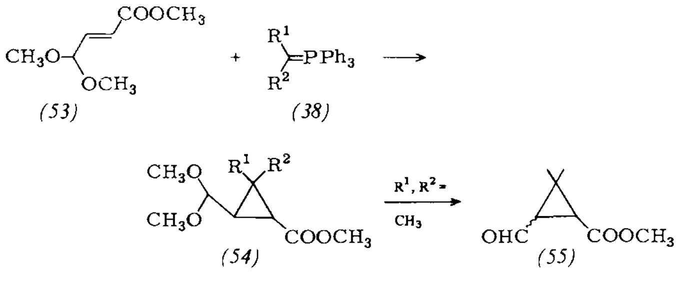
The possibility of using sulfuranes, such as *(51)*, for the synthesis of pyrethroids was demonstrated at an early stage using the chrysanthemic ester *(52)*[42]. Other pyrethroid acids[43] and intermediate products[44] have also been obtained with sulfuranes (see Section D).



*(50)* *(51)* *trans-(52)*

### 1.5.2. Phosphoranes

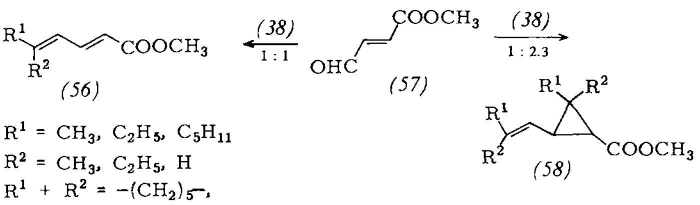
Three-membered ring formation in this series, using phosphoranes, was first reported by *Krief et al.*, who reacted methyl 4,4-dimethoxycrotonate *(53)*[45] with phosphoranes *(38)* to obtain the cyclopropanes *(54)*, which following hydrolysis to aldehydes constitute important intermediates for further pyrethroids (see Section B6).



*(53)* *(38)* *(54)* *(55)*

$R^1, R^2 = CH_3$; $R^1 + R^2 = -(CH_2)_4-$

Depending on the molecular ratio and the substituents, the dienecarboxylic ester *(56)* or the vinylcyclopropanecarboxylic ester *(58)* can be obtained from the aldehyde *(57)* and phosphoranes *(38)*[46]. However, the cyclopropanization to *(58)* was only possible with the isopropylidene and the cyclopentylidene phosphoranes *(38)*[45], the other phosphoranes *(38)* yielding the dienecarboxylic ester *(56)* exclusively. According to a mechanistic study, the chrysanthemic acid derivatives *(58)* are formed from the aldehyde *(57)* *via* a betaine[47]. On the basis of this finding, a single-vessel process for the production of the vinylcyclopropanecarboxylic ester *(58)* from two different phosphoranes has been developed[48].

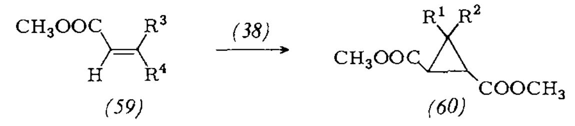


*(56)* *(57)* *(58)*

$R^1 = CH_3, C_2H_5, C_5H_{11}$
$R^2 = CH_3, C_2H_5, H$
$R^1 + R^2 = -(CH_2)_5-, -(CH_2)_4-$

$R^1, R^2 = CH_3$ [≡*(52)*]
$R^1 + R^2 = -(CH_2)_4-$

The cyclopropanization of fumaric or maleic esters *(59a)* and *(59b)*[49] with phosphoranes *(38)* opens up a stereospecific route to *trans*- and *cis*-caronaldehyde esters. In both cases the *trans*-1,2-cyclopropanedicarboxylic ester *(60)* is obtained, which is selectively converted into the *trans*- or *cis*-formylcyclopropanecarboxylic ester (see Section C).



*(59)* *(60)*

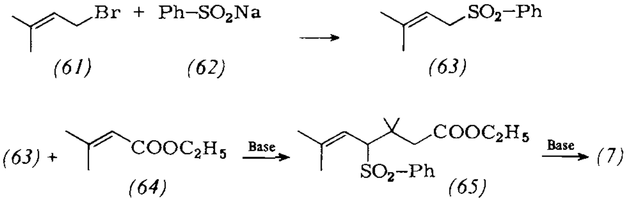
*(a)*, $R^3 = H$, $R^4 = COOCH_3$
*(b)*, $R^4 = COOCH_3$, $R^4 = H$

$R^1, R^2 = CH_3, C_2H_5$
$R^1 + R^2 = -(CH_2)_4-, -(CH_2)_5-$

## 1.6. Ring Closure by Addition-Elimination Reactions

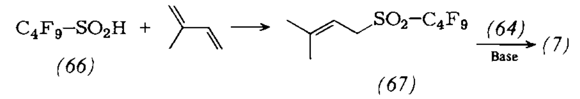
This section summarizes the methods in which the three-membered ring is produced by an addition-elimination reaction, although from the mechanistic point of view a strict separation of the ylide reactions is impossible.

*Martel et al.*[50] reacted the allyl sulfone *(63)*, obtained by alkylation of sodium benzenesulfinate *(62)*, with methyl crotonate derivatives such as *(64)* in the presence of bases. Depending on the quantity of base, *trans*-chrysanthemic acid ester *(7)* could be obtained in two separate steps or in a one-pot process. This process has subsequently been used for the preparation of numerous homologues[51,52] of chrysanthemic acid.



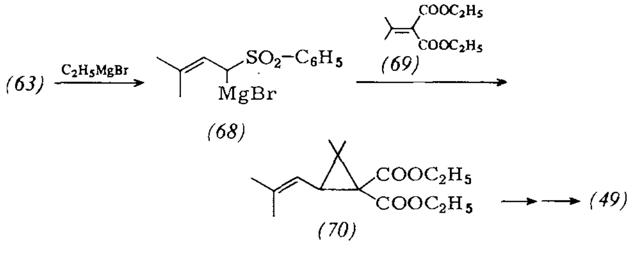
*(61)* *(62)* *(63)* *(64)* *(65)*

A more elegant access to allyl sulfones, the addition of perfluoroalkanesulfinic acids[53] to isoprene, simplifies the entire synthesis.



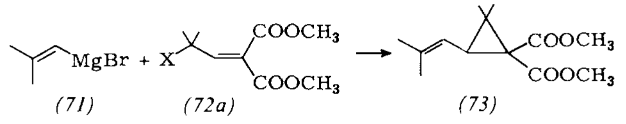
*(66)* *(67)*

A special variant of this process is the addition-elimination of the Grignard reagents *(68)*[54] to the isopropylidenemalonic ester derivatives *(69)* and subsequent conversion of the adduct *(70)* by hydrolysis and decarboxylation into chrysanthemic acid *(49)* (see Section B5.3). One variant is the reaction of the allyl sulfone *(63)* with 3-bromo-3-methylbutyric acid esters and potassium *tert*-butoxide to give *(7)*[55].



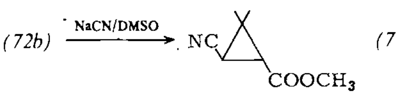
*(68)* *(70)*

The reaction of 2-methyl-1-propenylmagnesium bromide *(71)* with the (2-chloro-2-methylpropylidene)malonic ester *(72a)*[56], in which methyl 1-methoxycarbonylchrysanthemate *(73)* is formed as the main product, proceeds by a different course. The corresponding 2-bromide *(72b)* is largely reduced to the (2-methyl-1-propenyl)malonic ester.



*(a)*, X = Cl; *(b)*, X = Br

*Krief et al.*[57] similarly synthesized the *trans*-caronaldehyde ester. 3-Cyano-2,2-dimethylcyclopropanecarboxylic acid ester *(74)* was prepared from the bromo ester *(72b)* and sodium cyanide in a one-pot procedure, and this was then converted into the aldehyde *via* two routes (DMSO = dimethyl sulfoxide).



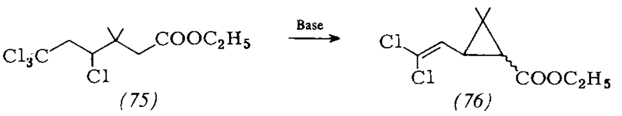
## 2. Nucleophilic Substitution

The most important processes for the preparation of vinylcyclopropanecarboxylic acids are based on ring closure by 1,3-elimination between C-1 as the nucleophilic center and C-2 or C-3 as the site of the substitution. For preparative reasons the connection between C-1 and C-3 is the more important.

### 2.1. Ring Closure between C-1 and C-3

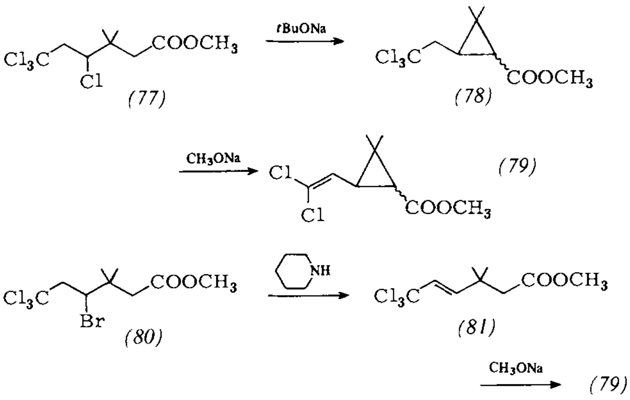
### 2.1.1. 1,3- and Vinylogous 1,5-Elimination

As a result of the activating influence of a carboxy group the action of bases on C-1 leads to formation of a carbanion, which upon ring formation substitutes a leaving group on C-3[58] or vinylogously on C-5[59]. Halogen atoms dominate the nucleofugal groups, in this case again chlorine. In many cases dehydrogenation often accompanies this cyclization, as shown by the final stage of the Sagami process[60].

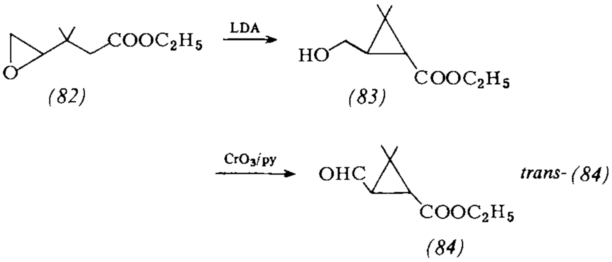


In many syntheses this reaction principle is applied with a modification of the carboxy group[61,62], the substituents on the vinyl group[37,63,64], the bases, and the solvent. Under special conditions the two steps can be carried out separately and consecutively[65,66].

The presence of another activating group facilitating the ring closure[67], such as carboxy, alkoxycarbonyl, cyano, or acyl on C-1, is determined by the accessibility of the initial products. The conversion into the monocarboxylic acid takes place in successive steps (see Section B 5).



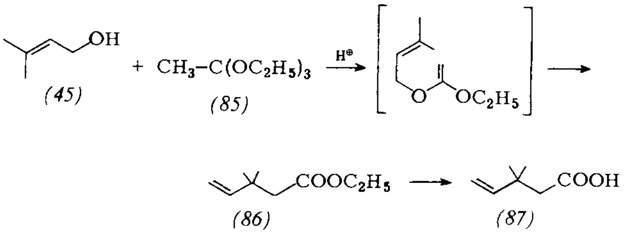
Cyclopropane ring closure with simultaneous opening of an epoxide *(82)* is used for the synthesis of the caronaldehyde ester *(84)*[68] (LDA = lithium diisopropylamide).



The intermediates capable of cyclization are essentially obtained by radical addition of polyhalogenated alkanes to 3,3-dimethyl-4-pentenoic acid derivatives, by Claisen rearrangement of corresponding halogenated allyl vinyl ethers, and by ring opening of lactones (see Sections B2.1.2—2.1.4).

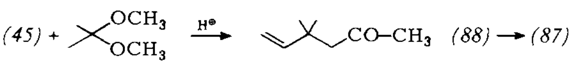
### 2.1.2. Addition of Polyhalogenated Alkanes to 3,3-Dimethyl-4-pentenoic Acid *(87)* and Derivatives

*Syntheses of (87):* 3,3-Dimethyl-4-pentenoic acid *(87)* and its derivatives are intermediates of central significance for a great number of pyrethroid syntheses. The acid was first prepared by a malonic ester synthesis[69]. Several new routes were opened up in the 'seventies. The synthetic route of the Sagami Chemical Research Center afforded direct access[60] from prenol *(45)* and orthoacetic ester *(85)* or ketene acetal *via* a Claisen rearrangement.



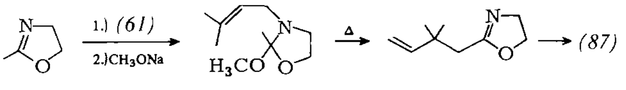
A Claisen rearrangement had already been used earlier to make other 3,3-dimethyl-4-pentene derivatives[70,71].

This reaction has become the starting point for many variants of the process[72]. The hexenone *(88)*[73], which is also an important intermediate for permethrinic acid, can be obtained in this way.



The synthesis of *N,N*,3,3-tetramethyl-4-pentenoic acid thioamide from prenyl chloride and *N,N*-dimethylthioacetamide is based on a thia-Claisen rearrangement[74].

Starting from 2-methyloxazoline *(89)* and prenyl bromide *(61)*, a 2-methoxyoxazolidine *(90)* can be prepared and which undergoes rearrangement into 2-(2,2-dimethyl-3-butenyl)oxazoline *(91)* upon pyrolysis[75].

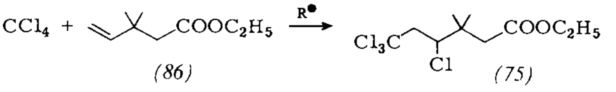


*(89)* *(90)* *(91)*

The radical addition of ethanol[76] and of acetaldehyde[77] to 3-methylcrotonic acid derivatives should similarly result in derivatives of *(87)*.

Further methods for the preparation of pentenoic acid *(87)* include the oxidation of 3,3-dimethyl-4-pentenal[78] with silver oxide, the addition of vinylmagnesium chloride to 3-methylcrotononitrile[79], and the combined substitution and elimination reactions of cyanide with 2,2-dimethyl-1,3-butanedisulfonates[80].

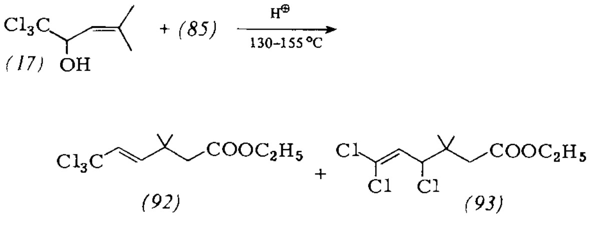
*Addition to (87) and derivatives:* The radical addition of polyhalogenated alkanes to derivatives of 3,3-dimethyl-4-pentenoic acid *(87)* is performed in a known fashion[81] *via* initiation by peroxides, metal salts, metal complexes, or light[60,72,82].



The most frequently used polyhalogenated alkanes are tetrahalogenomethanes such as carbon tetrachloride and chlorotribromomethane, although chlorinated and/or brominated higher alkanes[83] and fluorinated alkanes[37,64] have also been used. Instead of the dimethylpentenoic acid derivatives[84] their analogues, such as 4,4-dimethyl-5-hexen-2-one *(88)*[85], 3,3-dimethyl-4-pentenal[86], or isopentenyl malonic ester derivatives[87], can also be used, the conversion into monocarboxylic acid taking place at a later stage (see Section 5).

### 2.1.3. Claisen Rearrangement of Halogenated Allyl Vinyl Ethers

The reactions discussed in this section proceed *via* intermediate halogenated allyl vinyl ethers. Reference may also be made to a non-halogenated analogue arising in the formation of *(86)* from *(45)* and *(85)* (Section B 2.1.2).

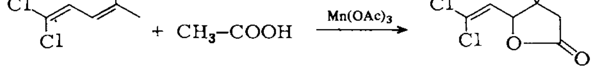


Whereas in the Sagami process the halogen is introduced after the Claisen rearrangement, this step is taken before the rearrangement in the synthetic procedure of the Kuraray company. The alcohol mixture, obtainable from chloral and isobutene (see Section B 1.1.1), is converted into the trichlorodimethylhexenoic esters *(92)* and *(93)*, after isomerization to *(17)*, by the action of orthoacetic ester *(85)* or ketene acetals[88]. This reaction is not restricted to chloral as educt, and gives rise to homologous permethrinic acids with other halogenated aldehydes[89].

### 2.1.4. Preparation and Ring Opening of Secondary Lactones

Since the ring opening of γ-lactones with halogenating reagents leads to γ-halogenated carboxylic acid derivatives[90], this constitutes a good method for the preparation of the precursors of the cyclopropane ring closure. Both secondary and tertiary lactones are suitable for this process, but intermediate products are obtained for coupling C-1 and C-2 from the tertiary lactones, as discussed in Section B 2.2. Only the secondary lactones, which can be prepared in many possible ways, can be used for ring closure between C-1 and C-3.

Lactones such as *(94)* are obtained from 1,1-dichloro-4-methyl-1,3-pentadiene *(16)* and carboxylic acids[91] by oxidation.



*(16)* *(94)*

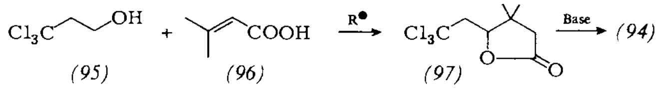
A novel route to *(94)* consists in the reaction of 1,1,1-trichloro-4-methyl-3-penten-2-ol *(17)* or its isomer *(18)* with 1,1-dichloroethene[92] in sulfuric acid.

$$(17) + CH_2{=}CCl_2 \xrightarrow{H_2SO_4} (94)$$

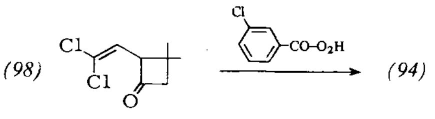
At high temperatures Claisen rearrangement of the alcohol *(17)* similarly gives the lactone *(94)*[93].

$$(17) + (85) \xrightarrow[100\text{-}190\ ^\circ C]{H^\oplus} (94)$$

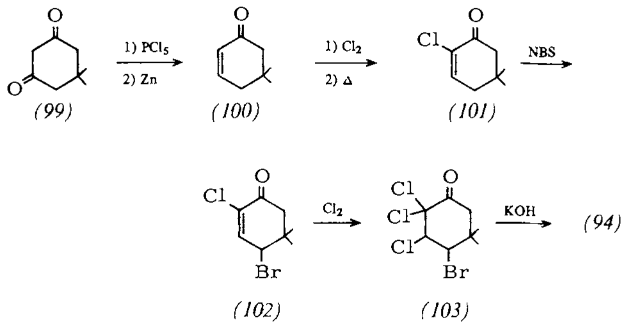
Radical addition of 3,3,3-trichloro-1-propanol *(95)* to 3-methylcrotonic acid *(96)* leads to the trichloroethyl lactone *(97)*, which can be dehydrohalogenated to *(94)*[94].



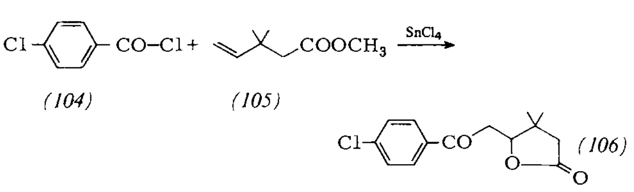
The cyclobutanone *(98)*, important as an intermediate for the Favorskii rearrangement (see Section 3), provides access to the lactone *(94)* by Baeyer-Villiger oxidation[95].



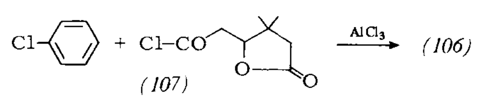
The diversity of the syntheses is demonstrated by another route that starts from 5,5-dimethyl-1,3-cyclohexanedione (dimedone) *(99)*, *via* the alkaline cleavage of tetrahalocyclohexanone *(103)*[96] (NBS = *N*-bromosuccinimide).



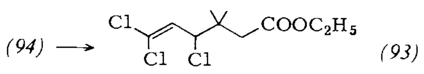
Acylation of the 3,3-dimethyl-4-pentenoic ester *(105)* with acid chlorides catalyzed by $SnCl_4$ yields secondary lactones *(106)*, whose ring cleavage permits the preparation of (styryl)cyclopropanecarboxylic acids[97].



The lactone *(106)* is similarly accessible by Friedel-Crafts acylation[97].

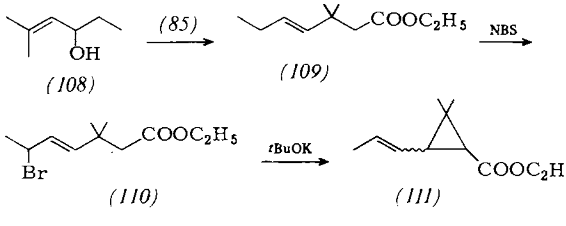


The cleavage of the lactone ring, *e.g.* in *(94)*, proceeds in conventional fashion with hydrogen chloride and alcohols or with inorganic acid halides and alcohols[91,98].

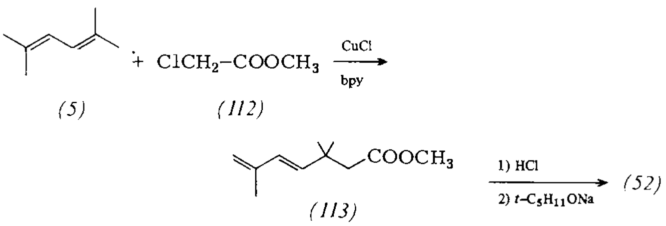


### 2.1.5. Other Halogenations

The allyl halogenations[63,99] of 4-alkenoic acid esters such as *(110)*, which also proceed *via* a Claisen rearrangement, must be regarded as exceptions. This halogenation makes it possible to prepare chrysanthemumic acid analogues such as *(111)*.

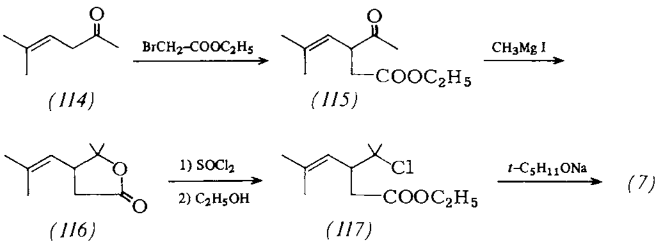


As a special method for the formation of methyl chrysanthemate *(52)*, *Julia et al.*[100] described the addition of methyl chloroacetate *(112)* to 2,5-dimethyl-2,4-hexadiene *(5)* with redox catalysis to give the diene ester *(113)*, which is then cyclized by alkoxide to *(52)* after hydrogen chloride addition. The yield of the process is low.



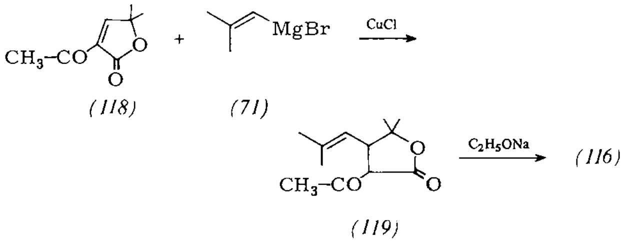
## 2.2. Ring Closure between C-1 and C-2

The bond between C-1 and C-2 in the pyrethroid ring can be formed in a similar manner by nucleophilic 1,3-elimination, the use of phase-transfer catalysts giving yields comparable to those in ring closures between C-1 and C-3. The γ-halogenated carboxylic acids required for this purpose are obtained from tertiary lactones such as *(116)*. Chrysanthemic acid syntheses, in particular, have been developed in this manner by ***Julia***, who prepared pyrocine *(116)* using isobutyraldehyde and acetone and after ring opening and cyclization obtained ethyl *trans*-chrysanthemate *(7)*[101].

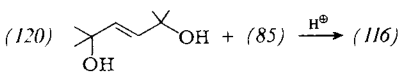


A similar synthesis, but based on a Claisen rearrangement, has been described[70].

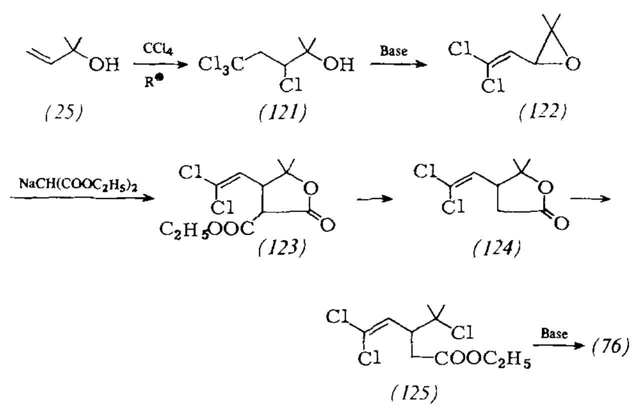
Japanese authors[102] have found a new route to the lactone *(116)*, preparing the acyl lactone *(119)* by a Michael addition from the butenolide *(118)* and cleavage of the ketone.



Claisen rearrangement of the butenediol *(120)* with orthoacetic ester *(85)* also gives rise to the pyrocine *(116)*[103].

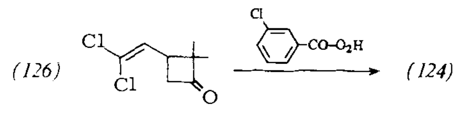


Processes for the preparation of (halovinyl)cyclopropanecarboxylic acids *via* tertiary lactones as intermediates were developed in parallel by ***Baeyer*** and ***Cheminova***[104]. To this end, 2-methyl-3-buten-2-ol *(25)* is used as the starting material and the tetrachloromethane adduct *(121)* converted with base into the epoxide *(122)*[105]. The reaction with malonic ester gives the lactone *(123)*, which after decarboxylation *via* the γ-chloro ester *(125)* yields the permethrinic acid ethyl esters *(76)*.



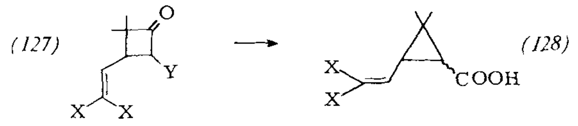
Chrysanthemic acid is synthesized in the same manner starting from 4,5-epoxy-2,5-dimethyl-2-hexene[106] and styrylcyclopropanoic acids[107] can be synthesized in an analogous manner.

The tertiary lactone *(124)* can also be obtained by Baeyer-Villiger oxidation from 3-(2,2-dichlorovinyl)-2,2-dimethylcyclobutanone *(126)*[108].



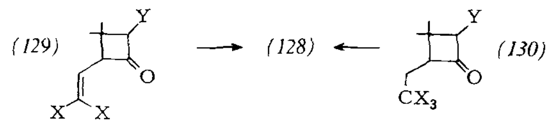
## 3. Favorskii Rearrangement

*Conia et al.*[109] found that α-halogenated cyclobutanones generally react to give cyclopropanecarboxylic acids in very good yields, and consequently this route has also been used for the preparation of pyrethroid acids of the general type *(128)*[110, 111].



X = $CH_3$, Cl, Br; Y = Cl, Br, O–Tosyl

The cyclobutanones *(129)* isomeric with *(127)* and their analogues *(130)* having a saturated side chain also react to give the cyclopropanecarboxylic acids *(128)*[112].

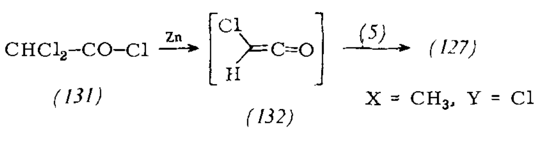


X = Cl, Br; Y = Cl, Br, O-Tosyl

In the case of *(130)* the Favorskii rearrangement and dehydrohalogenation are carried out in one step using aqueous sodium hydroxide.

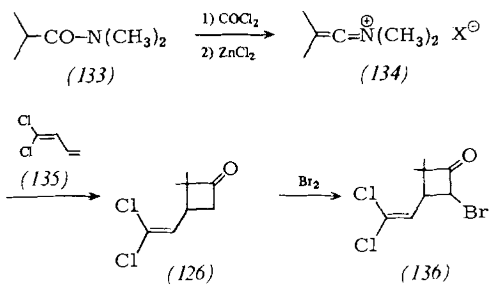
### 3.1. Preparation of Cyclobutanones of Type *(127)* and *(130)*

There are several possibilities for the preparation of the cyclobutanones but the process is fundamentally one of [2+2]-cycloaddition:

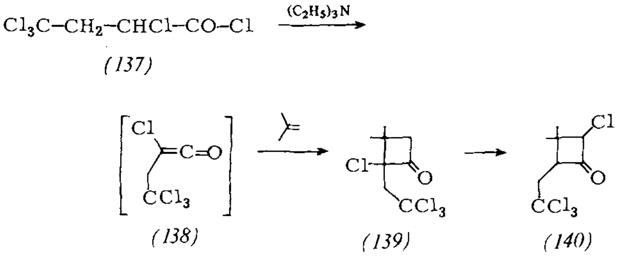


X = $CH_3$, Y = Cl

The relatively difficultly accessible monohaloketenes such as *(132)* are needed for the synthesis of *(127)*, Y = halogen. In the preparation of the derivative *(127)*, X = Cl, Y = Br [≡*(136)*] this is avoided by reacting 1,1-dichloro-1,3-butadiene *(135)*[113] with the alkenylideneammonium salt *(134)* to give *(126)*[111, 114]. The 4-bromine atom is introduced subsequently.



One route for the synthesis of the type *(130)* starts out from the addition product *(137)* of carbon tetrachloride and acrylic acid chloride[115].

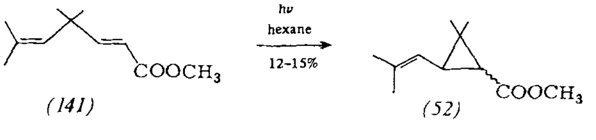


The rearrangement *(139)*→*(140)* [≡*(130)*, X = Y = Cl] proceeds with tertiary amines or quaternary ammonium salts[112].

## 4. Photochemical Formation of the Cyclopropane Ring

### 4.1. Di-π-methane Rearrangement

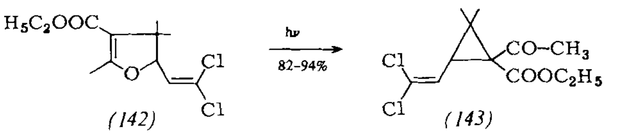
This relatively broadly applicable photochemical reaction leading to cyclopropane derivatives[116] has also been used for the synthesis of chrysanthemic acid methyl ester *(52)* from the dienoic ester *(141)*[117].



*cis* : *trans* = 1 : 2

### 4.2. Dihydrofuran Rearrangement

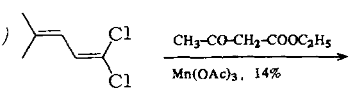
Irradiation of ethyl 5-(2,2-dichlorovinyl)-2,4,4-trimethyl-4,5-dihydrofuran-3-carboxylate *(142)*[118, 119] gives excellent yields of the ester *(143)*, a precursor of permethrinic acid.



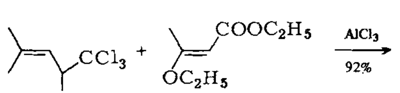
*(142)* *(143)*

Chrysanthemic acid has also been prepared in this way[118]. *(142)* is obtained by oxidative coupling of *(16)* with acetoacetic ester[120]. The reaction of *(17)* with the isocrotonic acid derivative *(144)* leads to better yields of *(142)*.

*(16)*



*(142)*



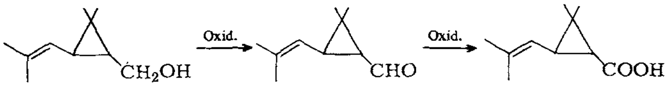
*(17)* *(144)* *(142)*

## 5. Reactions at C-1

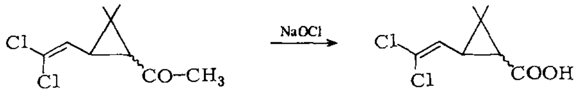
In some syntheses vinylcyclopropanes are formed after the ring closure and a further reaction at C-1 is required to obtain vinylcyclopropanemonocarboxylic acids. This is achieved by oxidation (Section B 5.1), hydrolysis (Section B 5.2), or decarboxylations and carboxylations (Section B 5.3).

### 5.1. Oxidation

Vinylcyclopropanemethanols and -carbaldehydes, which can be oxidized to the corresponding carboxylic acids, are accessible by the methods described in Sections B 1.4 and B 2.1 *via* addition of carbene and polyhalogenated methane or from natural products such as 3-carene[122]. Oxidation of the alcohol *(48)* with oxygen on a platinum catalyst[123] or with chromium trioxide[124] leads to the aldehyde *(145)*. With sodium periodate and ruthenium dioxide, mixtures of aldehyde and acid *(49)* are obtained[125]. Chromium trioxide/pyridine[41, 126], Jones' reagent[126], and silver oxide[123, 126] are suitable for selective oxidation of the aldehyde *(145)* to chrysanthemic acid *(49)*. Alkaline hydrogen peroxide has also been described as an oxidizing agent for the permethrinaldehyde[122]. The permethrinaldehyde can be converted into the carbonitrile *via* an intermediate oxime[127].



*(48)* *(145)* *(49)*



*(146)* *(147)*

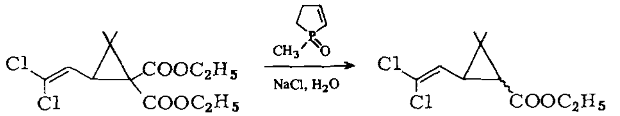
Methyl ketones such as *(146)* are converted into permethrinic acid *(147)* or its esters[128] by oxidative degradation (haloform reaction).

### 5.2. Hydrolysis

Nitriles often serve as precursors, and are formed by ring closure between C-1 and C-3 (Section B 2.1), by dehydration of oximes, or by decarboxylation of 1-cyanocyclopropanecarboxylic acids (Section B 5.3). Solvolysis of the nitriles yields both acids and esters[35, 129].

### 5.3. Decarboxylation and Carboxylation

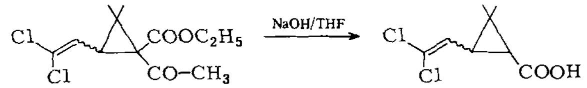
The 1,1-difunctional cyclopropanes, based on malonic acid derivatives and acetoacetic ester (Section B 2), must be degraded at the end of the synthesis of cyclopropanemonocarboxylic acid derivatives. Thermal decarboxylation of the dicarboxylic acids leads, *via* opening of the cyclopropane ring, to lactones of the type of *(124)*. The desired products can be obtained by heating in quinoline in the presence of copper[130]. Cleavage of diesters such as *(148)* can be carried out in $DMSO/H_2O$ using alkali metal salts[131] and with cyclic amidines and amines[132], and especially advantageously on heating with alkali metal salts in phospholine oxides[133].



*(148)* *(76)*

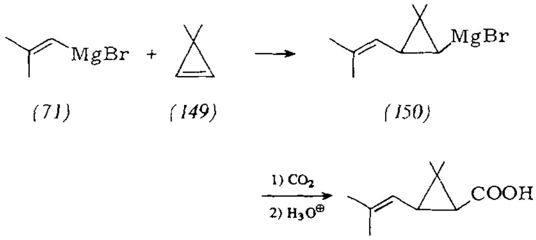
1-Cyanocyclopropanecarboxylic acids and esters are decarboxylated under analogous conditions to give mononitriles[67a, 134].

1-Acetylcyclopropanecarboxylic acid esters such as *(143)* are converted into permethrinic acid *(147)* by acid cleavage (THF = tetrahydrofuran)[67b, 118].



*(143)* *(147)*

Addition of the alkenyl Grignard compounds *(71)*[135] to 3,3-dimethylcyclopropene *(149)*, which is accessible *e.g.* from isobutene and chloroform, opens up a selective route to *cis*-chrysanthemic acid *(49)*. Carboxylation of the addition product leads to (*Z*)-chrysanthemic acid *(49)*.



*(71)* *(149)* *(150)*

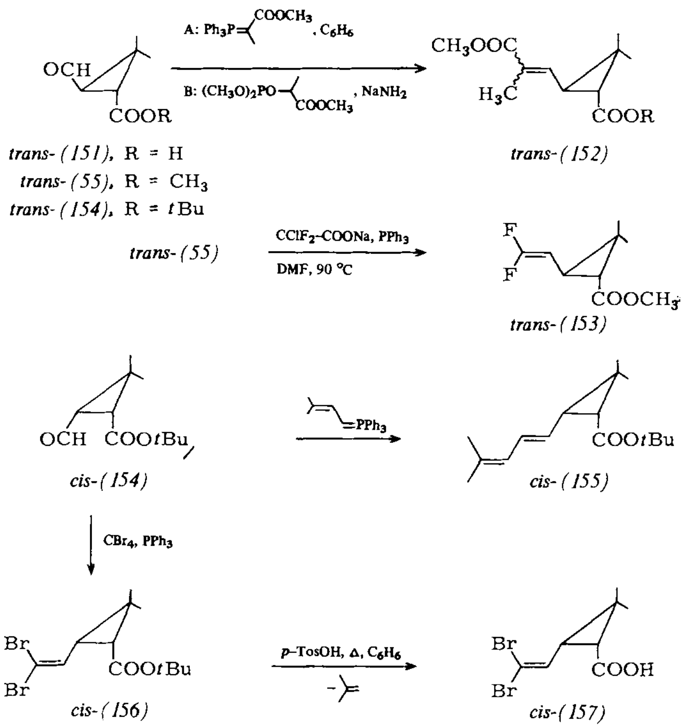
*cis-(49)*

## 6. Reactions at C-3

### 6.1. Syntheses Proceeding from Caronaldehydic Acid *(151)*

3-Formyl-2,2-dimethyl-1-cyclopropanecarboxylic acid *(151)* and its esters *(55)* and *(154)* are intermediates from which any pyrethroid acid with a (substituted) vinyl group in the 3-position can be made.

The Wittig reaction in its various forms[136a–f] and analogous olefinations[137] lead without any problems to the desired products (*E*:*Z* see [136g]). The production of the central building blocks of the synthesis, *e.g.* *(151)*, *(55)* and *(154)*, is time-consuming and elaborate. The addition of phosphoranes and sulfuranes to suitably substituted unsaturated compounds has already been mentioned as a synthetic route to these compounds (see Section B 1.5.2) and the extent that it is stereospecifically regulated is shown in Section C 4.5.

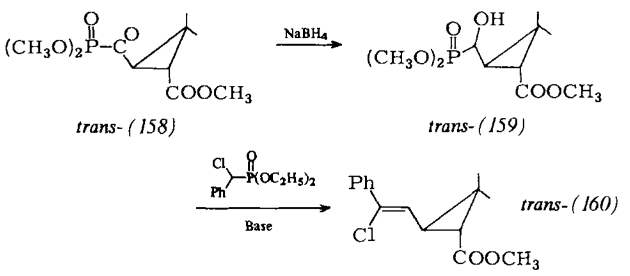


*trans-(151)*, R = H
*trans-(55)*, R = $CH_3$
*trans-(154)*, R = *t*Bu
*trans-(152)*
*trans-(55)*
*trans-(153)*
*cis-(154)*
*cis-(155)*
*cis-(156)*
*cis-(157)*

Ozonization of chrysanthemic esters had been used repeatedly for the preparation of caronaldehydic acid esters such as the particularly useful *tert*-butyl ester *(154)*. *Martel*[166] developed this process into a method for making enantiomerically pure *cis*- and *trans*-pyrethroid acids accessible from enantiomerically pure chrysanthemate (see Section C 4.5).

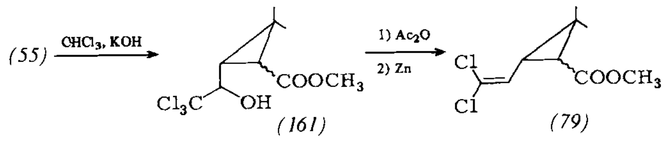
Other caronaldehydic acid syntheses (see *e.g.* Sections B 1.6 and C 4.5) also demand multistage and sometimes elaborate reaction sequences, so that equivalent synthesis elements have also recently been used for olefination reactions[138]. The ester *(158)* is obtained by reacting a caronic acid half-ester chloride and a phosphorous ester.

Aldol condensations of caronaldehydic acid esters such as *(154)* are also used with appropriate reaction partners, *e.g.* methyl propionate, for the preparation of pyrethroid acids[139].



*trans-(158)*
*trans-(159)*
*trans-(160)*

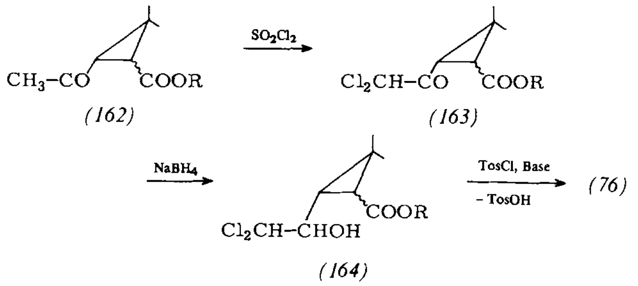
An alternative to the synthesis of 3-(2,2-dihalovinyl)-pyrethroid acids such as *(79)* by the Wittig reaction is the haloform addition to caronaldehydic acid (ester) in the presence of alkali metal hydroxides[140]. *(79)* is obtained in 65% yield [relative to *(151b)*].



*(161)*
*(79)*

### 6.2. Syntheses Proceeding from 3-Acetyl-2,2-dimethyl-1-cyclopropanecarboxylic Acid *(162)*

The ester *(162)* can be obtained by addition of alkoxycarbonylmethylenesulfuranes to mesityl oxide[141]. Selective halogenation to *(163)*, subsequent reduction to *(164)*, and elimination convert this precursor into important dihalovinylpyrethroid acids *e.g.* *(76)*[142].

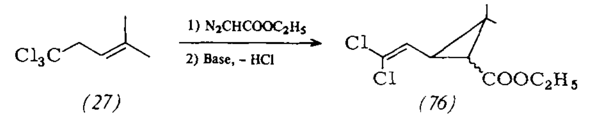


*(162)*
*(163)*
*(164)*

### 6.3. Pyrethroid Acids from Elimination Reactions on Alkyl Groups in the 3-Position

Eliminations leading to the production of the vinyl group in the 3-position are associated with many pyrethroid acid syntheses under basic conditions. Such secondary reactions are shown in the corresponding ring syntheses (see Sections B 2.1.1, B 2.1.4, B 2.2, B 3, C 4.2, and C 4.3).

It can sometimes prove advantageous to perform the elimination at the end of the synthesis if unsaturated precursors which are more expensive to make can thereby be avoided. Thus, the diazoacetic ester synthesis (see Section B 1.1) can also be carried out with *(27)* instead of the diene *(16)*, the cycloadduct being readily dehydrohalogenated at the end[142].

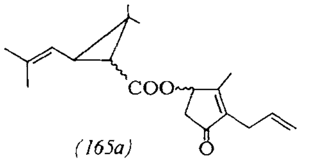


*(27)*
*(76)*

## C) Stereochemistry

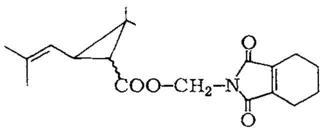
### 1. Superior Activity of Certain Enantiomers

The superior activity of *trans*-chrysanthemic esters, and especially of the enantiomers having the *trans*-(1*R*,3*R*) configuration, in combination with the natural pyrethroid alcohol components and in synthetic chrysanthemates such as allethrin *(165a)*[143] and tetramethrin *(165b)* has long been known. In contrast to this, it has been found that the 3-phenoxybenzyl esters of chrysanthemic acid have a superior activity when the *cis*-acid, and especially its (1*R*,3*S*)-enantiomer, is used as the acid component[144].



*(165a)*

Allethrin



*(165b)*

Tetramethrin

Analogous steric structure-activity relationships have been found for the insecticides derived from the dihalovinyl(dimethyl)cyclopropanecarboxylic acids. The first enantiomerically pure active principle introduced into practice [decamethrin, Decis®, *(4)*] contains as the acid component the *cis*-(1*R*,3*R*)-3-(2,2-dibromovinyl)-2,2-dimethyl-1-cyclopropanecarboxylic acid (decamethrinic acid). It was found that the esters of other (1*R*)-acids[145] are also several times more active than their enantiomers, and thus major efforts have been made to develop methods of preparation of sterically uniform pyrethroid acids.

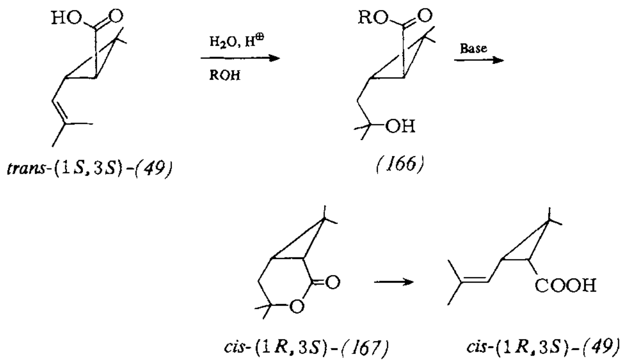
### 2. Methods of Separation

The resolution of *cis/trans*-mixtures and racemates by fractional crystallization of the *cis/trans*-acids or their diastereomeric salts with optically active bases has often been used for the preparation of the desired isomers[146]. Differences in the reactivity of the *cis*- and *trans*-acids permit separation techniques making use of a selective ester hydrolysis of *trans*-chrysanthemic acid[147] or a selective salt formation of *trans*-permethrinic acids[148]. The *cis*- and *trans*-acids can also be resolved by distillation[149].

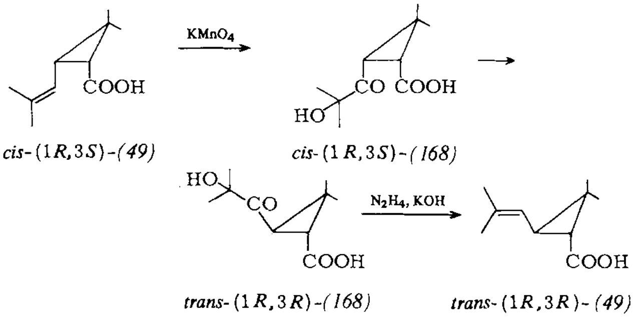
### 3. Isomerizations and Analogous Reactions

*cis*-Chrysanthemic acid *cis-(149)* can be isomerized to the *trans*-compound by basic catalysts[150] and by the action of Lewis acids on the acid chloride[151]. Similar isomerizations take place on heating permethrinic acid anhydrides in the presence of Lewis acids[152].

The *trans*-chrysanthemic acid *trans-(49)* can be converted into the *cis*-compound by hydration of the dimethylvinyl group and esterification to *(166)*[153], subsequent epimerization at C-1 with simultaneous lactone formation to give *(167)*, followed by elimination[154].



A method comprising oxidation of the dimethylvinyl group of the chrysanthemic acid to a ketol *(168)*, its epimerization and subsequent reduction with simultaneous elimination, has been used for the preparation of optically active *trans*-acid from optically active *cis*-acid *(49)*[155].



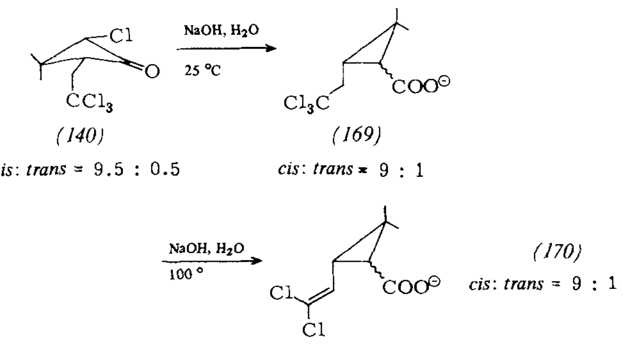
### 4. Stereoselective Syntheses

#### 4.1. Diazoacetic Ester Additions

Much effort has justifiably been expended on the stereoselective and enantioselective syntheses of pyrethroid acids by the application of special reaction conditions to known methods that do not proceed very selectively without suitable modification. Thus, in the reaction of *tert*-butyl diazoacetate with 2,5-dimethyl-2,4-hexadiene *(5)* the *trans*-chrysanthemic ester was obtained in high yield[156]. In the presence of copper(II) complexes with chiral ligands as catalysts the reaction of *(5)* proceeds enantioselectively both with diazoacetic esters[157] and with diazomalonic esters[158]. The synthesis of the *trans*-(1*R*)-acid was carried out by the addition of (−)-menthyl diazoacetate to *(5)*, using chiral catalysts, with an enantioselectivity of approximately 90%[159]. With rhodium(II) salts of carboxylic acids as catalysts, *e.g.* the pivalate, *cis*-enriched pyrethroid acid esters are obtained by diazoacetic ester addition to 1,1-dihalo-4-methyl-1,3-pentadienes[160].

#### 4.2. Favorskii Rearrangement

A Favorskii rearrangement of the *cis*-compound *(140)*[112] leads predominantly to the *cis*-carboxylate *(169)*, which on elimination without steric changes in the cyclopropane system, yields permethrinic acid *(147)* of predominantly *cis*-configuration[161] *via (170)*.



(140) cis: trans = 9.5 : 0.5

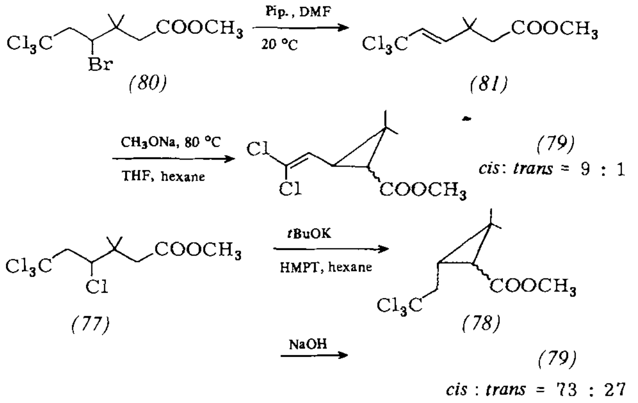
(169) cis: trans = 9 : 1

(170) cis: trans = 9 : 1

This route can also be used for the synthesis of enantiomerically pure acids when cyclobutanones, prepared by racemate resolution of the cyclobutanone hydrogen sulfite adducts, are used as educts[162].

### 4.3. 1,3-Ring Closure

The 1,3-ring closure of 4,6,6,6-tetrahalo-3,3-dimethylhexanoic acid esters such as (80) and (77) can be stereoselectively controlled using special reaction conditions[65, 163] (Pip. = piperidine, HMPT = hexamethylphosphoric triamide).



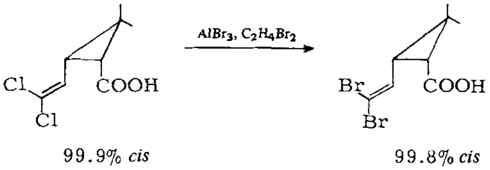
(80) (81)

(79) cis: trans = 9 : 1

(77) (78)

(79) cis : trans = 73 : 27

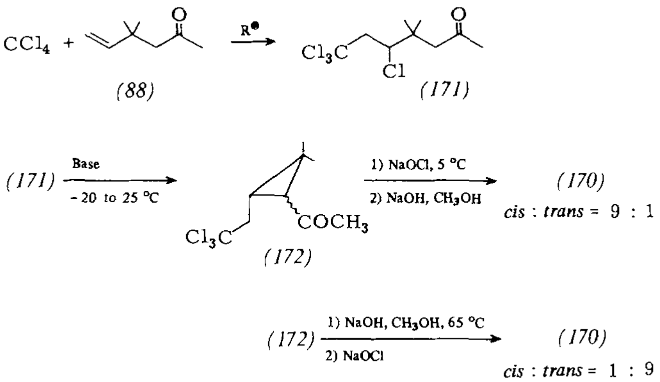
The chlorine atoms of the permethrinic acid (147) can be replaced by bromine atoms without a steric alteration of the cyclopropane system[163].



99.9% cis (147)

99.8% cis (157)

Stereoselective regulation of an analogous 1,3-ring closure proceeding from the ketone (171) leads to a cis-enriched isomeric mixture of the isomeric cyclopropyl methyl ketone (172). By varying the reaction conditions, this mixture can be further reacted to cis- or trans-rich permethrinic acid mixtures via the carboxylate (170)[164]. An alternative stereoselective synthesis is thus available, based on 4,4-dimethyl-5-hexen-2-one (88).



(88) (171)

(171) → (172) → (170) cis : trans = 9 : 1

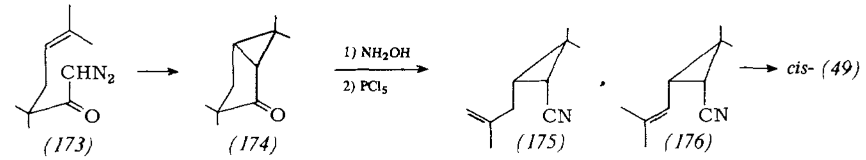
(172) → (170) cis : trans = 1 : 9

### 4.4. Intramolecular [2 + 1]-Addition

Intramolecular [2 + 1]-addition made possible the synthesis of cis-substituted cyclopropane precursors, which lead in one case (A) to the cis-chrysanthemic acid cis-(49)[150a] and in the other (B) to cis-3-(2,2-dihalovinyl)-2,2-dimethylcyclopropanecarboxylic acids cis-(147), X = Cl or cis-(157), X = Br[163].

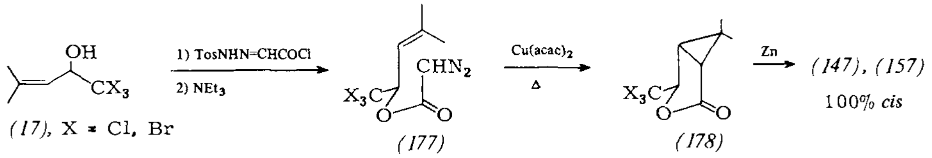
If synthesis B is carried out using (2R)-1,1,1-trichloro-4-methyl-3-penten-2-ol (17) as the educt, cis-(1R,3R)-permethrinic acid cis-(147) is obtained in 98% optical purity[163].

A



(173) (174) (175) (176)

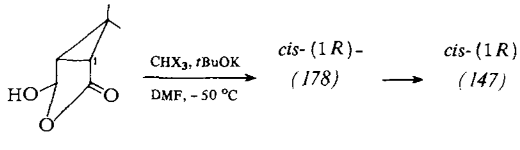
B



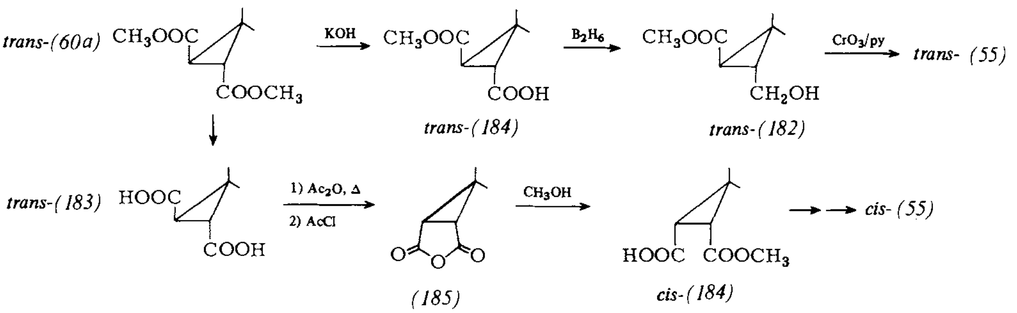
(17), X = Cl, Br (177) (178)

### 4.5. Isomerically Pure Precursors

The lactones (178) had already been used earlier by *Martel et al.*[165] as intermediates for the preparation of pyrethroid acids; in this case the haloform addition[140] to hemiacylals (179) of cis-caronaldehydic acid or pure enantiomers of this compound leading to the desired product.



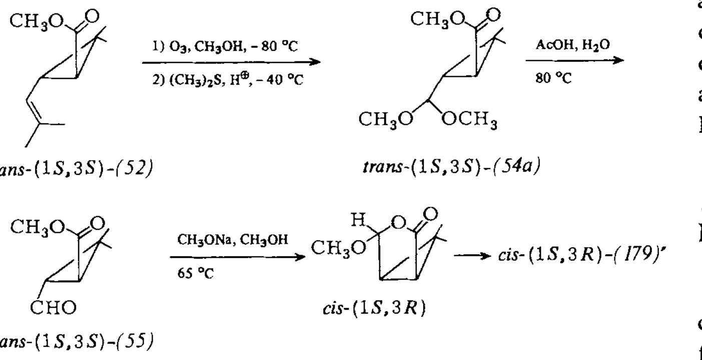
cis-(1R)-(179)



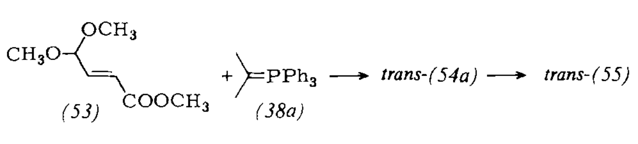
Derivatives of 3-formyl-2,2-dimethyl-1-cyclopropanecarboxylic acid (caronaldehydic acid) such as *(179)*, as pure stereoisomers or enantiomers, are probably the most valuable building blocks for the syntheses of sterically homogeneous pyrethoid acids. A Wittig reaction[136] and analogous olefinations[137, 138] lead directly to the target products with conservation of the configuration of the three-membered ring.

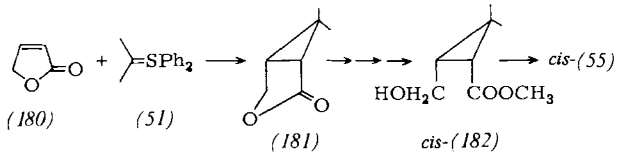
The educts probably used most commonly for sterically homogeneous caronaldehydes are the natural or synthetic sterically pure chrysanthemates, their ozonolysis leading directly to the desired intermediates.

*Martel* introduced this synthetic method for caronaldehydes and at the same time showed that by epimerization at C-3 4-hydroxy-6,6-dimethyl-3-oxabicyclo[3.1.0]hexan-2-one *(179)*, a synthetic equivalent of *cis*-caronaldehyde can be prepared from the *trans*-compound[166].



*Krief et al.* have devised several synthetic pathways to *trans*- and *cis*-caronaldehydes *(55)*: the starting material is the 4,4-dimethoxycrotonic ester *(53)*[45] or the butenolide *(180)*[167], whose reaction with isopropylidene(diphenyl)sulfurane *(51)* leads stereoselectively to the *trans*- or *cis*-substituted cyclopropane derivatives *(54a)* and *(181)*, which are converted into isomerically pure caronaldehydes by hydrolysis and if necessary by oxidation.





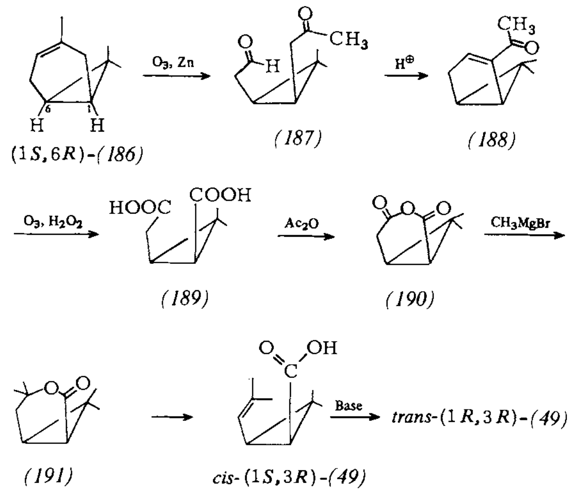
In another case, *trans*-caronic acid diester *(60a)* (see Section B 1.5.2) serves as an intermediate. This compound can be obtained both by an ylide addition to fumaric or maleic ester *(49)* or to 3-methylcrotonic ester[43], and by a 1,3-ring closure of α-bromoglutaric esters. A further synthesis proceeds *via* the caronic acid hemiester *(184)*, which is reduced selectively to the hydroxy acid *(182)* and finally oxidized to (*trans*-)caronaldehyde *(151b)*. The analogous synthesis of the *cis*-aldehyde is preceded by an isomerization of the *trans*-acid *(183)*[168].

These novel methods also indicate the difficult accessibility of the important building block of the synthesis, caronaldehyde, especially when the synthesis is aimed at sterically homogeneous isomers. This applies still more to the preparation of enantiomerically pure caronaldehyde, *e.g.* from terpenes (see Section C 5).

Mention must also be made at this point of recently published methods for the preparation of *cis*-chrysanthemic acid *cis-(49)* by selective hydrogenation of the analogous cyclopropenecarboxylic acids obtained by diazopropane addition to an ene-yne-carboxylic ester[169] or by Grignard addition[135] to 3,3-dimethylcyclopropene (see Section B 5.3).

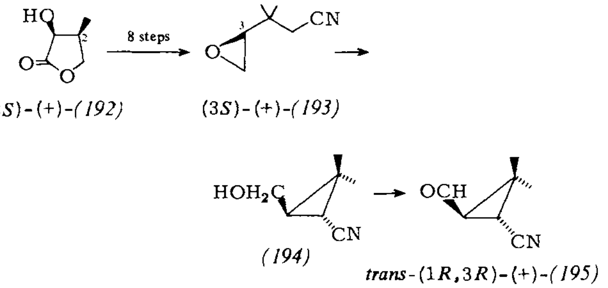
## 5. Pyrethroid Acids from Optically Active Natural Products

Enantiomerically pure pyrethroid acids—and especially chrysanthemic acid—have also been obtained starting from optically active natural products. (+)-3-carene, (1*R*, 5*R*)-(+)-α-pinene, and (2*R*)-(−)- and (2*S*)-(+)-pantolactone were used as starting materials.

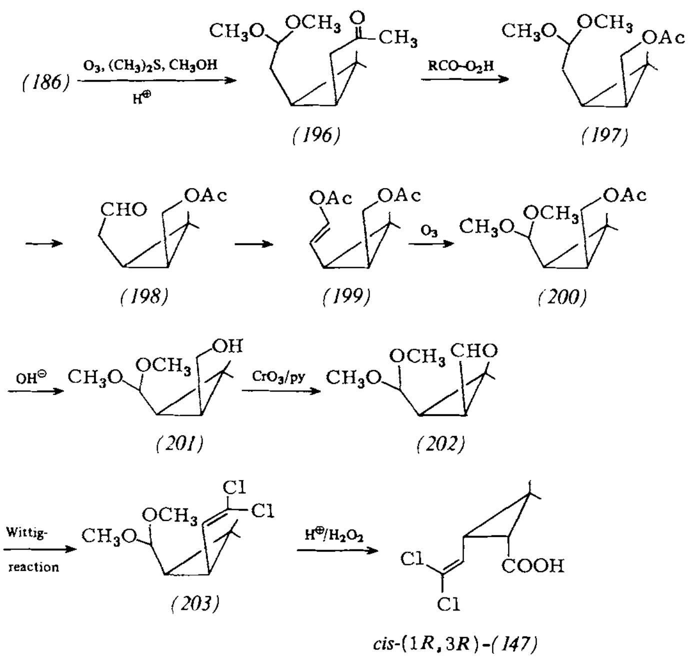


In this way *Matsui et al.*[170] obtained (1*R*,3*R*)-(+)-*trans*-chrysanthemic acid *(49)* from (+)-3-carene *(186)*. This synthetic route has since been improved by several working groups[171].

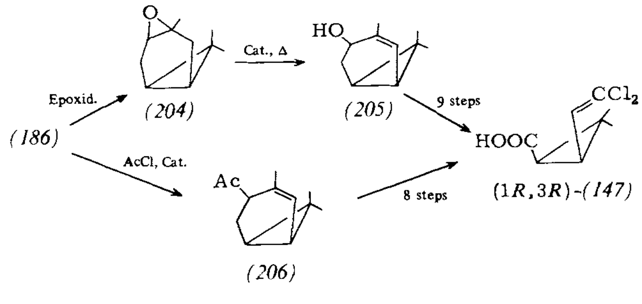
In the synthesis of (+)-*trans*-chrysanthemic acid from (1*R*,5*R*)-(+)-α-pinene[172] the decisive step is a Favorskii rearrangement. Synthesis from (2*S*)-(+)-pantolactone *(192)*[173] proceeds *via* the caronaldehydenitrile *(195)*.



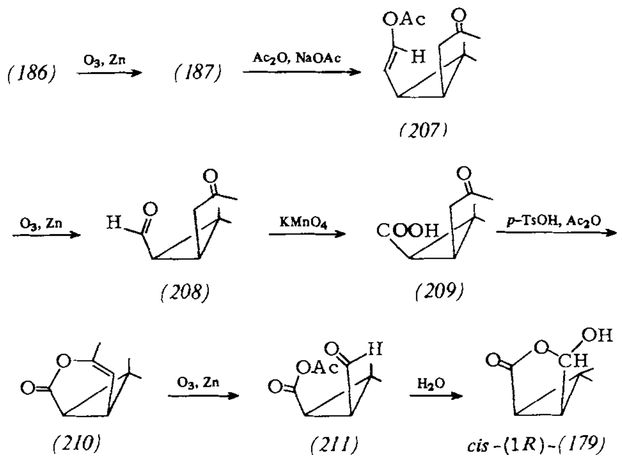
(+)-3-Carene *(186)* can also be used for the synthesis of (+)-*cis*-permethrinic acid *(147)*[122,174].



Two other synthetic routes start from the derivatives *(205)* and *(206)* of (+)-2-carene[175], which are obtained from (+)-3-carene *(186)*. These two multistage pathways[176,177] begin with an ozonization.



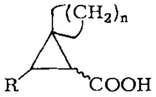
The cyclic hemiacetal *(179)* or *cis*-(1*R*)-caronaldehyde is also obtained from 3-carene as the starting substance.



## D) Synthetic Methods for other Pyrethroid Acids

### 1. Variation at C-2

The geminal dimethyl group is essential for the insecticidal action of the pyrethroid derivatives[179]. The substitution of even one methyl group by ethyl is enough to cause a sharp reduction in the action intensity[180]. Acid components with only one methyl group[181] and with spiroalkyl groups on C-2 *(212)* have been described[112b,182]. Such acids can be prepared by a Favorskii rearrangement or by diazoacetic ester synthesis.

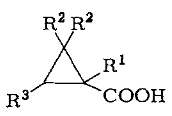


*(212)*, R = Alkyl, Dichlorovinyl
n = 0, 1, 2, 3

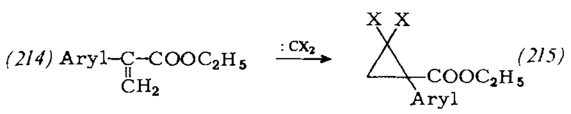
### 2. Variation at C-1

Additional substituents at C-1 have a stronger negative effect on the biological activity than a change at C-3[183].

However, esters of the acid type *(213)* with good insecticidal action are known. These include, above all, acids like *(215)* containing an aryl group at C-1 and hydrogen at C-3. The acids constitute a special case, since in place of the geminal methyl group at C-2 geminal halogen substituents also give rise to active esters[184]. The acids *(215)* can be prepared by Favorskii rearrangement or by carbene addition to atropic acid esters *(214)*.

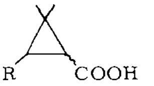


*(213)*, $R^1$ = Alkyl, Aryl, Phenoxy
$R^2$ = Methyl, Halogen
$R^3$ = Alkyl, Dihalovinyl



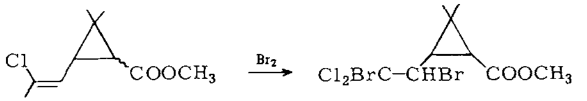
## 3. Variation at C-3

In the great majority of the acid components the substituents are varied at C-3. Compounds of the type *(216)* with a hydrogen atom at C-3 show the closest structural similarity to the vinylcyclopropanecarboxylic acids.



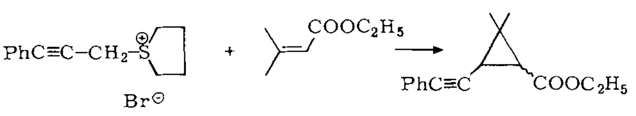
*(216)*, R = Alkyl, Aryl, Halogen, Alkoxy, Alkylthio

Acids *(216)* in which R = aryl are obtained by diazoacetic ester synthesis[185]. Aryl-substituted cyclopropanecarboxylic acids, which are claimed to have particularly good acaricidal action, are described in recent patent literature[186]. Acids with a heterocyclic residue R have also been patented[187]. Acids in which R is a saturated residue similarly give insecticidally active esters. R can be unsubstituted (methyl[188], isobutyl[189]) or it can be substituted by a halogen[190], alkoxy[191], or alkylthio[192] group. For example, haloethyl-substituted acids *(217)* are obtained by bromination of the permethrin ester *(79)*[193].



*(79)* *(217)*

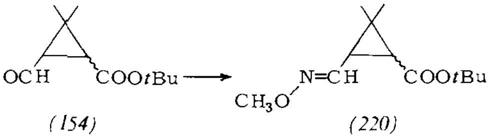
If R is an alkynyl group, as in *(219)*, the action is weaker than in the case of the corresponding vinyl-substituted esters. Acids with a triple bond are as a rule prepared by dehydrohalogenation[194]. The 2,2-dimethyl-3-(phenylethynyl)cyclopropanecarboxylic ester *(219)* was synthesized from the propargylsulfonium salt *(218)* and ethyl 3-methylcrotonate *(64)*[195]:



*(218)* *(64)* *(219)*

Finally, pyrethroid acid components in which R = halogen[196], alkoxy[183,197], and aryloxy[183,198] have been described.

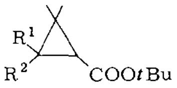
If the caronaldehyde-*tert*-butyl ester *(154)* [cf. *(151c)*] is reacted with hydroxylamine or an *O*-substituted hydroxylamine[199], the oxime ether *(220)* is obtained, from which esters with good "knock-down" activity can be made[179,199,200]: where the term "knock-down" activity means that the insects are rapidly paralyzed.

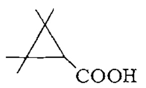


*(154)* *(220)*

Among the acids *(221)* in which there is no hydrogen atom at C-3, the 2,2,3,3-tetramethylcyclopropanecarboxylic acid *(222)*[201] has acquired particular significance. This acid is readily obtained by diazoacetic ester synthesis[202] or from 4-chloro-2,2,3,3-tetramethylcyclobutanone by a Favorskii rearrangement[110].

*(221)*

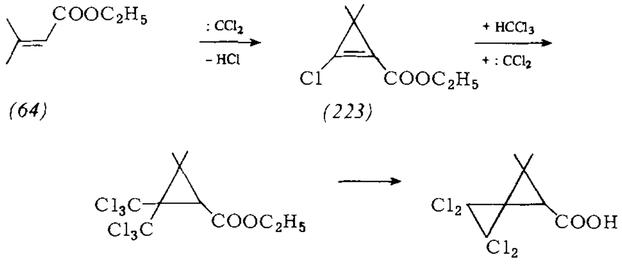




*(222)*

Wide variation of the structure *(221)* has only given rise to less effective compounds[183,203,204].

If $R^1$ and $R^2$ in *(221)* form a ring, spiro compounds are obtained, such as the 4,4,5,5-tetrachloro-2,2-dimethylspiropentane-1-carboxylic acid *(225)*[205], which is prepared from the ester *(64)* and dichlorocarbene with phase-transfer catalysis[206].

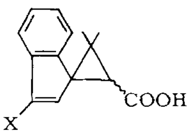


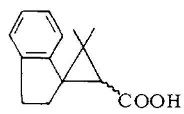
*(64)* *(223)*

*(224)* *(225)*

Greater importance attaches to spiro[2,4]heptanecarboxylic acids *(226)*–*(231)*[207], from which many esters have been synthesized.

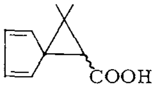
*(226)*, X = H
*(227)*, X = Cl

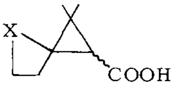




*(228)*

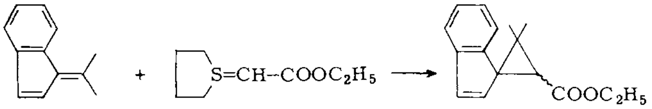
*(229)*





*(230)*, X = CH=CH
*(231)*, X = $CH_2$–$CH_2$

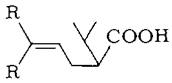
The ethyl ester *(234)* of the acid *(226)* is obtained from isopropylidenindene *(232)* and the sulfur ylide *(233)*[208].



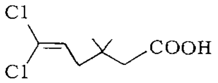
*(232)* *(233)* *(234)*

## 4. Pyrethroid Acid Components without a Cyclopropane Ring

Already in the 1920's *Staudinger* and *Ruzicka*[209] investigated whether the cyclopropane ring is absolutely necessary for the insecticidal action. Esters of "cut-up" chrysanthemic acid *(235)* proved to be inactive, though the esters *(236)* and *(237)* are said to have a certain insecticidal activity[210].



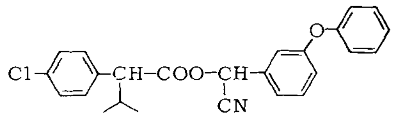
*(235)*, R = $CH_3$
*(236)*, R = Cl



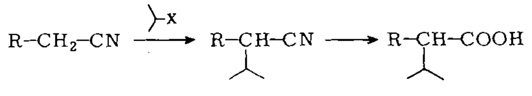
*(237)*

Fenvalerate *(238)* is a compound having an insecticidal activity of similar magnitude to that of permethrin *(3)*[211].

The 4-chlorophenyl-3-methylbutyric acid *(241)* is made by alkylation of 4-chlorophenylacetonitrile *(239)* and hydrolysis of the alkylated product[211,212]. The isopropyl group is essential for the insecticidal action: the methyl and isobutyl compounds are practically inactive, and the ethyl compound has only half the activity[211]. The analogous cyclopropyl compounds[212] also have a high activity.



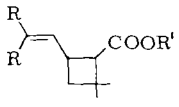
Fenvalerate *(238)*



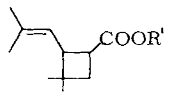
*(239)* *(240)* *(241)*

R = $p$-Cl–$C_6H_4$, X = Halogen

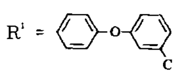
The substituents in the benzene ring can also be varied over a wide range, and the benzene ring itself can be replaced by a heterocycle, *e.g.* a furan[211], thiophene[211], or pyrrole ring[213].



*(242)*, R = $CH_3$; *(243)*, R = Cl



*(244)*



Cyclobutanecarboxylic acid esters such as *(242)* have only a weak activity[214], and the isomeric esters *(244)* have none[214]. The dichlorovinylcyclobutanecarboxylic acid esters *(243)* should also exhibit insecticidal activity[215].

## E) Future Prospects

The development of the new generation of insecticidal pyrethroids into a class of major economic significance is certainly not yet over. The essential task now is to find low-cost methods of production for the particularly active compounds.

The isomerically or enantiomerically pure active substances will only become an attractive proposition as agricultural chemicals when their manufacturing costs have been made comparable with those of their isomeric mixtures.

Evidently what is needed here is imagination and creativity. The future will undoubtedly demonstrate that stereoselective and enantioselective methods of synthesis can also be of great significance for industrial organic chemistry.

# Inorganic Pigments: Bases for Colored, Uncolored, and Transparent Products[**]

By Franz Hund[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Colored and uncolored inorganic pigments have been obtained since prehistoric times from natural minerals, at first empirically, then by specially developed methods. Since the beginning of the 18th century they have also gradually come to be studied scientifically, and today such research makes use of the latest techniques of solid-state physics and chemistry. On the basis of our knowledge of technically and aesthetically important properties, it has been possible in the last seventy years to make synthetic pigments superior to the natural ones, to increase production drastically while maintaining the pigment properties unchanged or improving them, and to broaden the range by the addition of new synthetic pigments. Nowadays it is in principle possible to write down a specification for many fields of application, taking into account aesthetic, technical, economic, and ecological aspects, and to make the corresponding inorganic pigment in adequate amounts. In what follows I shall discuss the dependence of the scattering and absorption constants of pigments on the refractive index, the wavelength of the light and the particle size, the properties of pigmented systems that depend on the particle geometry, and also some of the optical characteristics determined by the arrangement of the atoms in the crystal lattice.

## 1. Historical

Deliberate coloring by the use of natural or synthetic pigments is one of the oldest human activities, and because of the high stability of inorganic pigments the latter's preparation and use can be traced back over millenia. As has been shown by *Noll et al.*[1], pigments were already made synthetically in the city and river cultures of antiquity. More than 5 million tons of synthetic inorganic pigments *per annum* are nowadays produced industrially all over the world, and they have therefore become an important economic product[2].

## 2. Basic Concepts

An inorganic pigment[3a] is a colored or hueless colorant, practically insoluble in solvents and binders. The color produced by inorganic pigments[3b] is a sense-impression evoked by rays of light entering the eye. If the light source itself is standardized, the optical properties of a pigmented layer of lacquer or paint depend on the optical properties of the pigment particles, their size, their shape, and their volume concentration, and also on the optical properties of the (usually colorless) dispersion medium. Within certain limits, the pigment particle size and shape, and their distribution curves can be freely selected by the manufacturer so that the pigment properties that depend on these parameters can be varied, optimized, or developed in a desired direction. Aesthetic points of view apart, the most important properties for white pigments are the tinting strength and hiding power, and for black, gray, and colored pigments the tinctorial strength and hiding power. These properties[4] are determined by the scattering and absorption constants ($S_\lambda$ and $K_\lambda$) of the pigmented systems. In the case of white pigments the influence of the scattering constants predominates, and in the case of black pigments the influence of the absorption constant, with practically no wavelength dependence. Colored pigments are characterized by the ratio of the wavelength-dependent $S_\lambda$ and $K_\lambda$. Generally speaking, the tinting strength and hiding power of white pigments depend quite overwhelmingly on the scattering constant, and the tinctorial strength and hiding power of black and colored pigments are determined overwhelmingly by the absorption constant.

## 3. Dependence of the Scattering and Absorption Constants on the Refractive Index, Wavelength of the Light, and Particle Size

A relationship between the reflectivity $\beta_\lambda$ of a very thick pigmented coating and the absorption constant $K_\lambda$, together with the scattering constant $S_\lambda$ (both in the units of $\mu m^{-1}$), is given by the Kubelka-Munk equation[5a]:

$$\frac{(1-\beta_\lambda)^2}{2\beta_\lambda}=\frac{K_\lambda}{S_\lambda}$$

From *Mie*'s theory[5b], using simplified assumptions, we can calculate how the relative scattering cross section ($Q_S$) and the absorption cross section ($Q_A$), which are proportional to the scattering and absorption constants, depend on the (spherical) pigment particle size and the wavelength if we know the wavelength-dependent complex refractive

---

index ($m_\lambda = n_\lambda - i \cdot k_\lambda$) of the pigment and dispersion medium under parallel illumination. Table 1 gives the mean refractive indices of the most important inorganic pigments and some dispersion media. The real component $\bar{n}$ of the refractive index varies between 1.5000 and 3.0805.

Table 1. Refractive indices of the most important pigments and dispersion media (mean values for $Na_D$ radiation).

| Trivial name | Formula | $\bar{n}$ |
|---|---|---|
| Ultramarine | $Na_8(Al_6Si_6O_{24})S_2$ | 1.500 |
| Cobalt blue | $CoAl_2O_4$ | 1.76 |
| Titanite | $CaTiSiO_5$ | 1.947 |
| Zircon | $ZrSiO_4$ | 1.9548 |
| Lead white | $2\,PbCO_3 \cdot Pb(OH)_2$ | 2.015 |
| Zincite | $ZnO$ | 2.021 |
| Cassiterite | $SnO_2$ | 2.0489 |
| Goethite | α-FeOOH | 2.366 |
| Wurtzite | $ZnS$ | 2.367 |
| Zinc blende | $ZnS$ | 2.3676 |
| Pseudobrookite | $Fe_2TiO_5$ | 2.385 |
| Magnetite | $Fe_3O_4$ | 2.42 |
| Minium | $Pb_3O_4$ | 2.42 |
| Crocoite | $PbCrO_4$ | 2.45 |
| Chromium oxide | $Cr_2O_3$ | 2.50 |
| Greenockite | $CdS$ | 2.5175 |
| Anatase | $TiO_2$ | 2.5246 |
| Rutile | $TiO_2$ | 2.7462 |
| Hematite | α-$Fe_2O_3$ | 2.873 |
| Cinnabar | $HgS$ | 3.0805 |
| Linseed oil | | 1.5000 |
| Water | | 1.333 |
| Alkyd resins | | 1.500 |
| Enamel frit (glass) | | 1.500 |
| Flint glass | | 1.575 |

Figure 1 shows the spectral variation of the refractive index for two white pigments and one colored pigment. Figure 2 shows the relative scattering cross section $Q_S/\alpha$ as a function of the particle diameter, calculated by *Völz* from *van de Hulst*'s data[6] for $TiO_2$, $ZnS$, and $BaSO_4$ dispersed in linseed oil for a wavelength of 550 nm. The course of the curve shows that with increasing refractive index of the pigment the optimal particle diameter (maximum of the scattering cross section) is displaced in the direction of smaller values and the absolute contribution of the scattering maximum increases considerably. Of the inorganic white pigments, $TiO_2$ in the rutile form has the smallest optimal particle diameter (0.19 μm) and the largest relative scattering cross section.

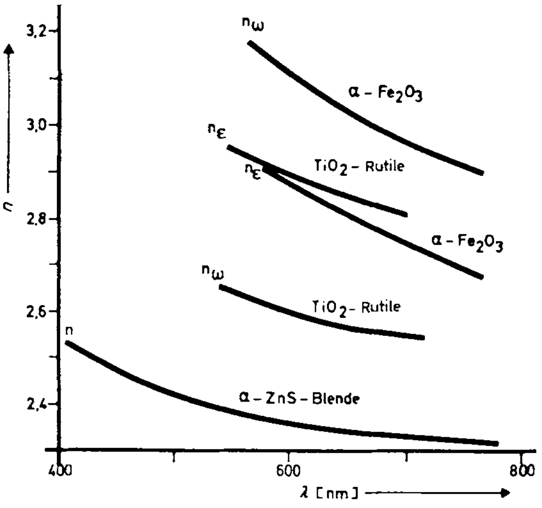

Fig. 1. Refractive index $n$ and wavelength $\lambda$.

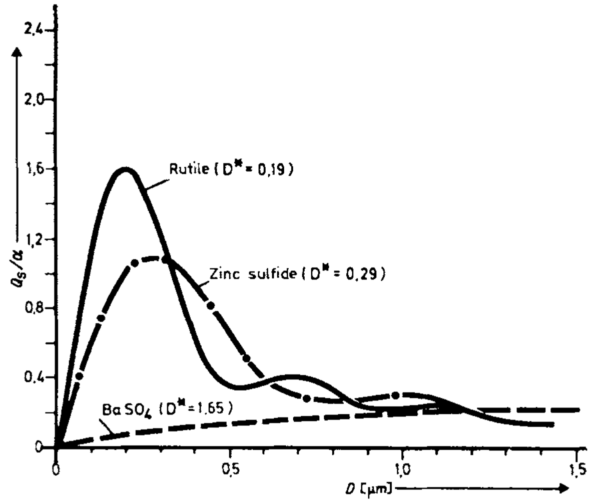

Fig. 2. Scattering curves of $Q_S/\alpha$ for $\lambda = 550$ nm, $D^*$ = optimal particle diameter [μm].

For α-$Fe_2O_3$, which crystallizes in the hematite lattice and is manufactured in very large amounts, Figure 3 shows, on the basis of *Brockes*'[7] data, the change in the relative effective cross sections for scattering ($Q_S/2\alpha$) and absorption ($Q_A/2\alpha$) as a function of the dimensionless particle size parameter $\alpha$[8]. With decreasing particle size the two cross sections at first increase up to a maximum. With a further reduction in the size of the pigment particles the relative scattering cross section falls very rapidly to zero, while the relative absorption cross section, after a shallow maximum, reaches finite high values at atomic dimensions. Thus, for colored inorganic pigments there are particle size regions in which scattering has disappeared and the wavelength-dependent absorption constant reaches finite values (transparent pigments!).

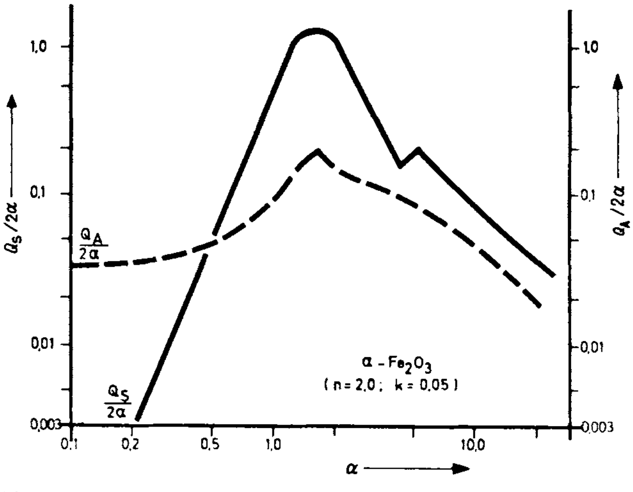

Fig. 3. Scattering, absorption, and particle size ($\alpha$ [8] ~ $D$ [μm]).

## 4. Properties of Inorganic Pigments that Depend on the Geometry of the Particles

For a given chemical composition, crystal structure, pigment volume concentration, and distribution in a dispersion medium, the optical and many other properties of *e. g.* an ideally pigmented lacquer coating are substantially determined by the size and shape of the particles and by their distributions about certain mean values. Important properties of pigmented systems, such as these, depend on the real geometry of the individual particles or their actual distribution in the dispersion medium and will be dealt with on the basis of individual examples.

### 4.1. Dependence of the Color of Red $\alpha$-$Fe_2O_3$ Pigments on Their Particle Size

The color of lacquer dispersions pigmented with isometric red $\alpha$-$Fe_2O_3$ particles can be determined numerically and unambiguously according to *Helmholtz*[9] from the dominant wavelength $\lambda_f$, the colorimetric purity $p_c$, and the radiance factor $A$.

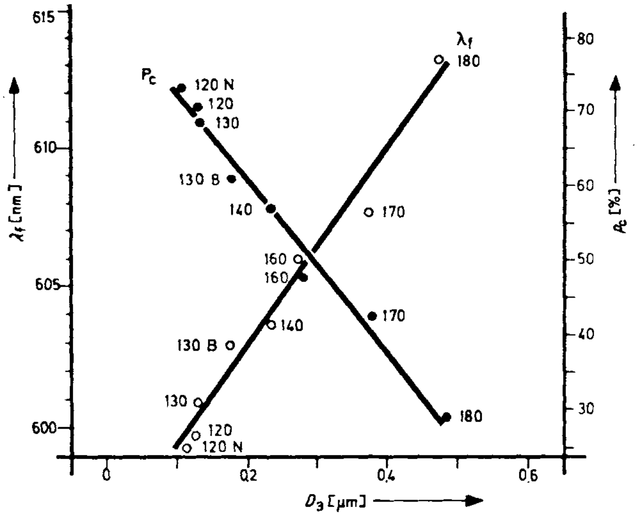

Fig. 4. Hue $\lambda_f$, color purity $p_c$, and particle diameter $D_3$ [10] of red iron oxides.

Figure 4 shows values of $\lambda_f$ (hue) and $p_c$ (color purity) of various colored iron oxide red pigments (commercial products) plotted against their diameter $D_3$[10]; with increasing diameter $\lambda_f$ rises and $p_c$ falls linearly, as previously described[11]. At the beginning, middle, and end of this series of pigments it can be seen in Figure 5a how the hue changes from a yellow-red to a blue-red with increasing particle diameter, and how the color purity decreases; the lower part shows, for a 1 : 5 mixture of iron oxide red and rutile, the extraordinarily strong coloring action (tinting strength) of these colored pigments. Figure 5b shows their spectral reflectance.

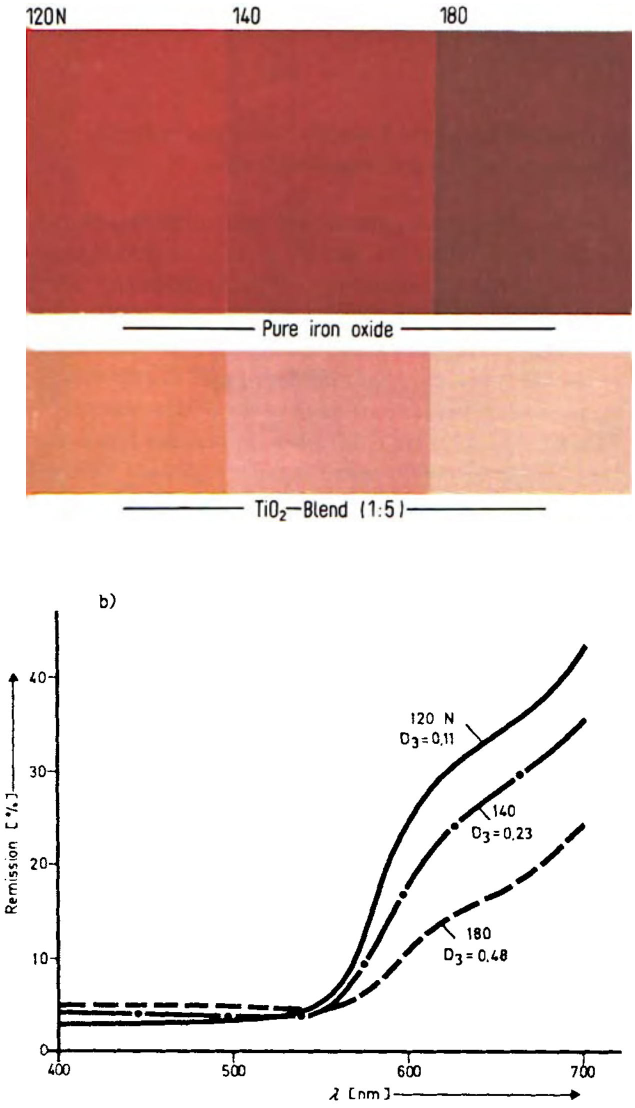

Fig. 5. a) Hue and tinting strength of red iron oxides (see Fig. 4 and text). b) Spectral reflectance and particle size.

### 4.2. Dependence of the Color of Red $\alpha$-$Fe_2O_3$ Pigments on the Particle Shape

Figure 6 presents the reflectance curves of two iron oxide pigments having the same crystal structure and same mean diameter $D_3$[10] but different particle shapes[12]. The acicular red iron(III) oxide 1130 shows a substantially higher reflectance in the long-wave region (600—700 nm), and therefore a higher scattering power, than pigment 730

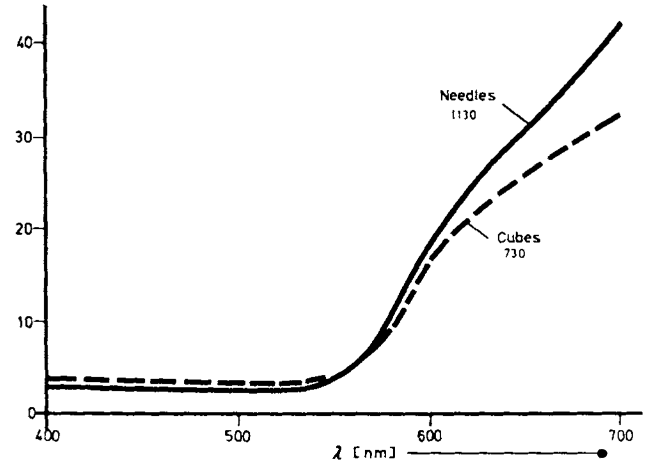

Fig. 6. Spectral reflectance and particle size of red iron oxides.

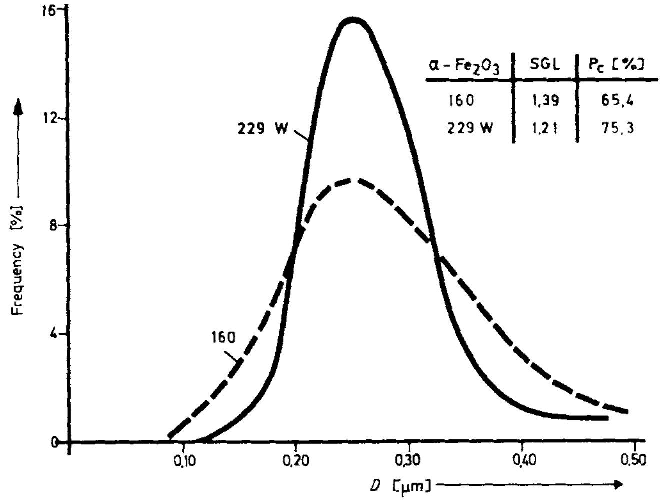
with its isometric particles; it therefore also has a yellower hue ($\lambda_f$), a higher color purity ($p_c$), and a higher radiance factor ($A$).

### 4.3. Dependence of the Color Purity of Red α-$Fe_2O_3$ Pigments on the Particle Size Distribution

For the same mean particle size, same isometric particle shape, and therefore the same hue ($\lambda_f$), an investigation was carried out to determine how the color purity ($p_c$) of red iron oxide pigments depends on the actual particle size distribution (SGL) about the mean value. The highest purity should occur only with monodisperse distributions[13] but because of the laws of nucleus formation, the growth of nuclei, and solid-state diffusion, in practice it is hardly ever possible to obtain monodisperse pigments. The particle size frequencies have Gaussian or log-normal distributions in which the deviation from monodispersity is described numerically by the standard deviations SG or SGL, respectively. Figure 7 shows particle size distribution curves with practically the same mean value but different widths of distribution. The calculated standard deviations SGL and color purities ($p_c$) derived from color measurements are plotted. With decreasing width of the distribution (decreasing SGL) and the same mean particle size, the color purity of the red iron oxide pigments increases considerably.



| α-$Fe_2O_3$ | SGL | $P_c$ [%] |
|---|---|---|
| 160 | 1,39 | 65,4 |
| 229 W | 1,21 | 75,3 |

Fig. 7. Particle size distribution and colorimetric purity.

### 4.4. Dependence of Tinting Strength on the Particle Size and the Particle Size Distribution

The relative tinting strength[14] or the tinctorial strength of colored or black pigments is a measure of the capacity of the inorganic pigment, on the basis of its absorption constant $K_\lambda$, to impart color to other light-scattering substances. The relationship of the tinting strength to $K_\lambda$, and therefore to the relative absorption cross section, also depends on the mean particle size and the widths of the particle size distribution. In Figure 8, the color intensity determined photometrically for a series of isometric α-$Fe_2O_3$ pigments[14] has been plotted against the volume-surface diameter $D_3$[10]. As a function of the particle size, the measured tinting strength follows a similar course to that of the relative absorption cross section ($Q_A/2\alpha$) in Figure 3 calculated by *Brockes*[7] after *Mie*[5b]. The luminosity of the pigment increases linearly with decreasing particle diameter $d_3$.

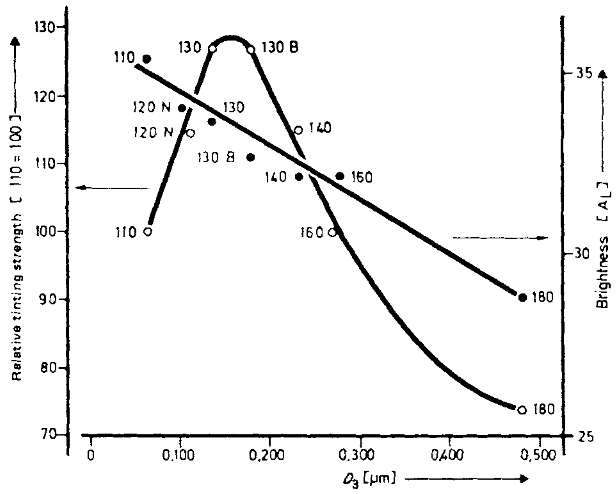


Fig. 8. Relative tinting strength, luminosity, and particle size of red iron oxides (see Fig. 4 and text).

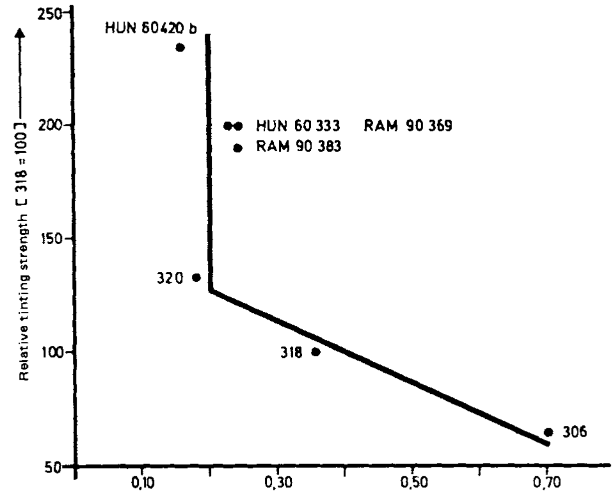

Fig. 9. Tinting strength and mean particle size of black iron oxides.

In Figure 9 the tinting strength of various isometric black iron oxide pigments ($Fe_3O_4$) has been plotted against the central value of the volume distribution curve (DZVL) from ultramicroscopic counts. In the upper range of particle sizes—as shown in Figure 8 for red α-$Fe_2O_3$ pigments—the tinting strength increases with decreasing particle size. At a certain small particle size it continues to rise markedly for some black pigments without a further reduction of the particle size. It can be seen from Figure 10, in which the real particle size distribution curves of these pigments are presented, that the further increase in the tinting strength with approximately constant particle diameter is due to the narrowing width of distribution of these pigments. From the degree of polydispersity of these pigments as a function of the logarithmic standard deviation SGL,

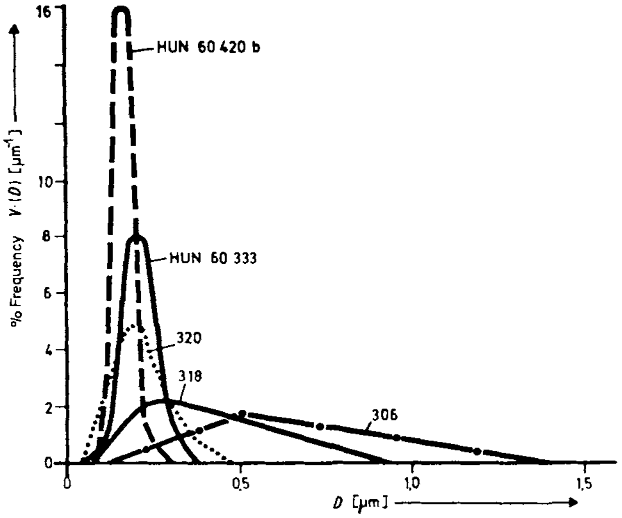

Fig. 10. Particle size distribution of various $Fe_3O_4$ pigments (see Fig. 9).

calculated from counts in Figure 11, it follows that the tinting strength increases approximately linearly with decreasing width of distribution (SGL) with the same mean particle size and the same particle shape.

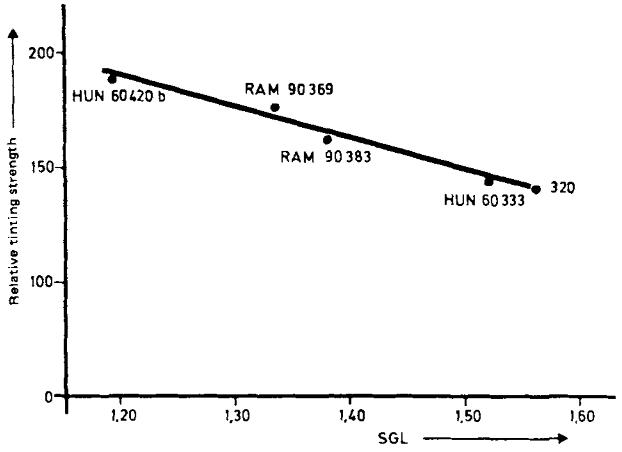

Fig. 11. Tinting strength (standardized $Fe^{3+}/Fe^{2+}$) and standard deviations of iron oxide black (see text).

### 4.5. Transparency of Red $\alpha$-$Fe_2O_3$ Pigments[15] and Particle Size

Figure 3 shows the dependence of the scattering and absorption of red iron oxides on the particle size. In the region to the left of the optimal particle diameter for the relative scattering cross section ($Q_S/2\alpha$), the scattering should decrease with further reduction of the particle diameter and finally disappear. Hence, the transparency of transparent dispersion media colored with such pigments should increase. Since $K_\lambda$ for $\alpha$-$Fe_2O_3$ disappears in the red wavelength region (600—700 nm), a transparent red coloration appears here as can be seen from Figure 12. It can also be seen how the transparency of the dispersion increases with decreasing particle diameter $D_3$ and how the original black and white checkered pattern becomes more recognizable with increasing transparency.

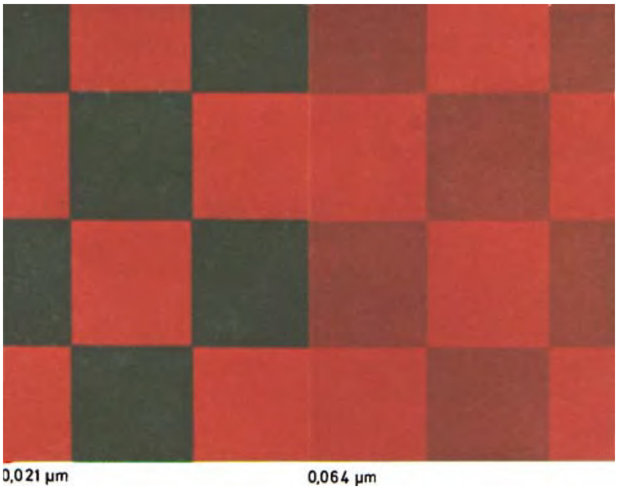

Fig. 12. Transparent iron oxide red ($D_3$=0.021 and 0.064 µm).

### 4.6. Tinting Strength of White Pigments: Dependence on the Refractive Index and Particle Size

The tinting strength of a white pigment[16] is its capacity to increase the reflectance of a dispersion medium that is intrinsically black or colored or one that has been made such through the inclusion of black or colored substances. The tinting strength of white pigments depends, through the scattering constant $S_\lambda$ and the relative scattering cross section ($Q_S/2\alpha$), on the refractive index and particle size.

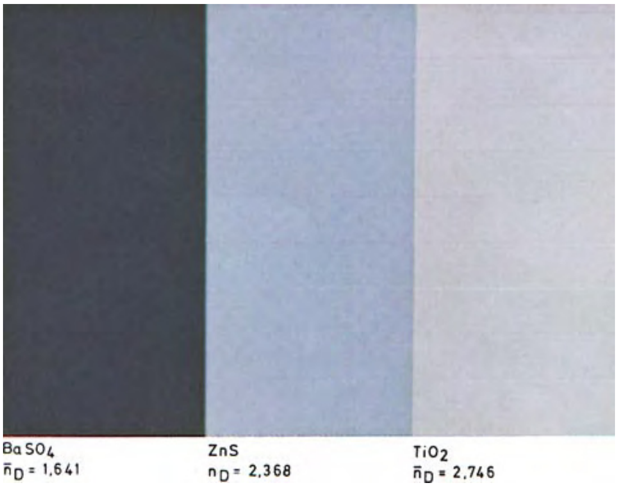

Fig. 13. Tinting strength (scattering constant) and refractive index of white pigments (5 : 1 with ultramarine).

Figure 13 shows the dependence of the tinting strength of various white pigments on their refractive indices. With equal weight proportions of white and blue pigments, the brightening action of the white pigments varies qualitatively with their refractive indices. The tinting strength of $TiO_2$ (rutile) with its optimal particle diameter of 0.19 µm is greater than that of ZnS (zinc blende) with its optimal diameter of 0.29 µm and much greater than that of $BaSO_4$ (barite) with its optimal diameter of 1.65 µm. The tinting strength of white pigments, like that of colored and black pigments, is a tinctorial property—the higher the numerical values, the smaller are the amounts necessary.

### 4.7. Hiding Power[17] of White Pigments: Dependence on Refractive Index and Particle Size

The hiding power of a pigmented lacquer film is its capacity to mask colors or color differences of the substrate. It follows from the Mie and Kubelka-Munk theory[5] that an increase of both the scattering constant $S_\lambda$ and the absorption constant $K_\lambda$ increases the hiding power. The white pigments $TiO_2$, ZnS, and $BaSO_4$ (see Section 4.6), having different refractive indices, were applied in a lacquer film, under the same conditions, to a black and white checkered pattern (Fig. 14). Since in the case of white pigments the absorption constant can be neglected, the hiding power of the three white pigments show a sequence similar to that of the tinting (Fig. 13). This is understandable, because both the hiding power and the tinting strength depend in the same way, through the scattering constant $S_\lambda$, on the refractive index of the white pigments.

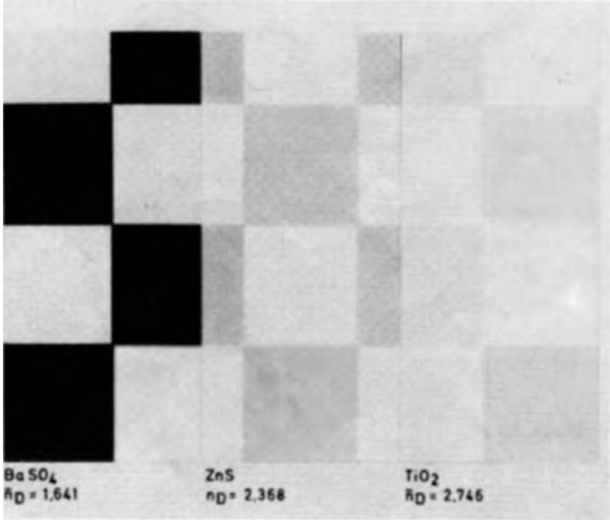

Fig. 14. Hiding power (scattering constant) and refractive index of white pigments.

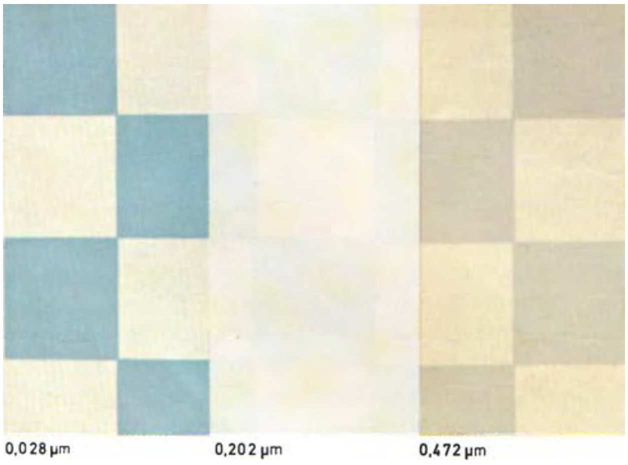

Fig. 15. Hiding power (scattering constant) and particle size $D_3$ of $TiO_2$.

In Figure 15, dispersions of $TiO_2$ pigments with different particle diameters $D_3$[10] were applied to a black and white checkered substrate under identical conditions. In agreement with *Völz*'s calculations (see Fig. 2), the hiding power determined by the relative cross section ($Q_S/\alpha$) of $TiO_2$ is very low for very small particles ($D_3 = 0.028$ µm) and very large at almost the optimal particle diameter (0.20 µm); it falls off again at still larger diameters (0.472 µm).

### 4.8. Dispersibility[18,19] (Dispersion Hardness) of Pigments

The "dispersion hardness" is a characteristic of the amount of pigment that must be dispersed in a dispersion medium; it is a quality characteristic that can be varied by the pigment manufacturer within certain limits by aftertreatment. A numerical value for the dispersion hardness is obtained from the rate of development of the tinting strength of pigments in a given binder. In the ideal final state of the dispersion all pigment agglomerates have been broken down into primary particles and aggregates, both of which are distributed statistically in each volume fraction of the medium. In Figure 16 the development of the tinting strength of a red iron oxide pigment has been plotted against the milling time.

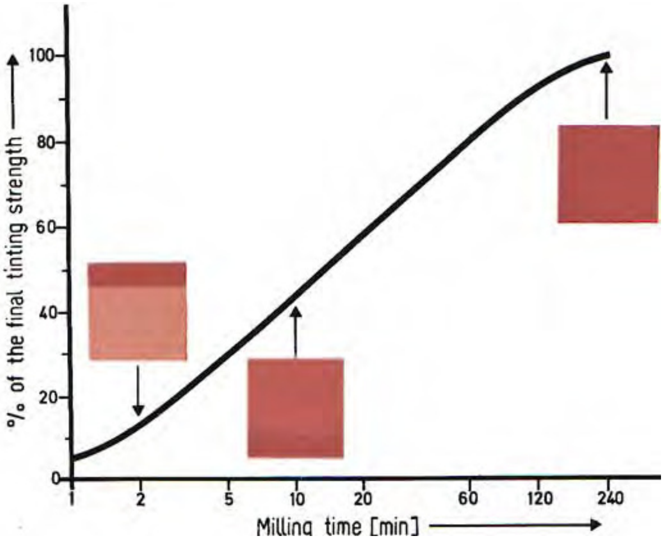

Fig. 16. Dispersibility of iron oxide red (110).

### 4.9. Dependence of the Oil Absorption[20] on the Particle Size and Particle Shape

The "oil absorption" of a pigment is the quantity of oil (in gram) needed to convert 100 g of the pigment into a putty-like mass under specified conditions. This characteristic, which is important for the practical application of pigments, depends on the particle size, particle size distribution, and most importantly on the particle shape; it increases with decreasing particle size and as their shape becomes more acicular.

## 5. Properties of Inorganic Pigments Depending on the Actual Atomic Arrangement

Until now the optical properties of inorganic pigments have been explained essentially on the basis of the real part $n_\lambda$ of the complex refractive index $m_\lambda = n_\lambda - i \cdot k_\lambda$, and its relationship to the size and shape of the particles have been considered. From a theoretical point of view, this exhausts the possibilities of modifying pigment properties by variations in the particle size and shape. Since the light absorption $K_\lambda$ retains finite high values down to atomic dimensions, the task arises of increasing the activity of colored pigments whose color is due to the presence of d- and f-elements in anions, with respect to hue, color purity, and tinting strength by changing the ligand field on an atomic scale. The motivation for this is the relatively high price and the limited natural occurrence of these elements.

### 5.1. Incorporation of d- and f-Elements in a Host of High Refractive Index

Using *Mie*'s theory[5b], *Brockes*[7] calculated how the relative absorption cross section ($Q_A/2\alpha$) changes when a substance with low $K_\lambda$ (small amount of a d-element in a colorless host) is incorporated into a pigment ($n_1$)/dispersion medium ($n_0$) system with $n_1/n_0 = 1.0$ and 2.0.

The relative absorption cross section has been plotted against the size of the pigment particles for the two cases in Figure 17. According to this, above a certain particle size the optical activity of the absorption constant ($Q_A/2\alpha$) of d- and f-elements in colorless hosts, with a large real part of the complex refractive index, is substantially larger than that in colorless hosts with a correspondingly low value. This situation has been observed in the incorporation of coloring $Ni^{2+}$ ions into spinel ($n \approx 1.0$) and rutile ($n \approx 1.83$) mixed phases; with the same amount of nickel and the optimal particle diameter, the tinting strength in the rutile phase is almost twice as high. All d- and f-elements can be incorporated into colorless hosts by application of the laws of heterotypic mixed-phase formation[21-24].

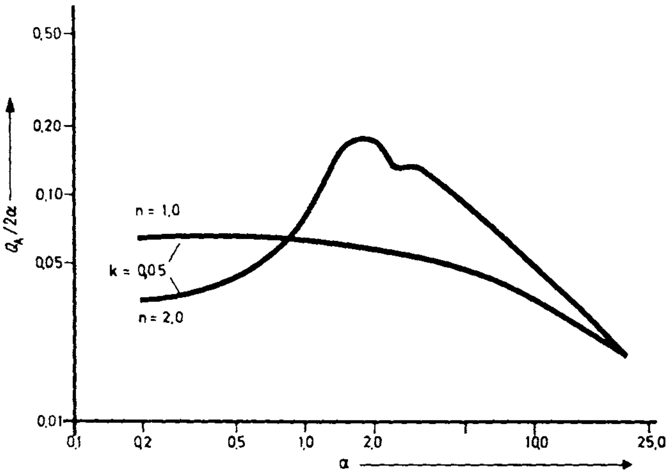

Fig. 17. Absorption, particle size ($\alpha$ [8]), and refractive index ratio ($n = 1.0$ or 2.0, $k = 0.05$).

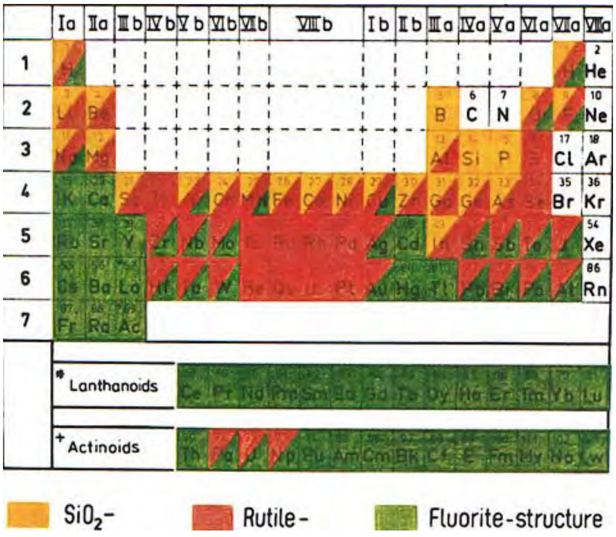

Fig. 18. Incorporation of elements in mixed phases.

Figure 18 shows the ability of the various elements of the periodic system to incorporate into $AO_2$ hosts with $SiO_2$-, rutile-, and fluorite-structures. Many new colored pigments[25] with $TiO_2$, $SnO_2$, and $ZrO_2$ as colorless host and coloring d- and f-elements have been developed on the basis of this principle in the last few years.

### 5.2. Lowering the Cation Coordination Number and Symmetry-Distortion of the Coordination Polyhedron

A further limited possibility of increasing the activity of d- and f-elements involves their incorporation into hosts by lowering the normal coordination number (in the case of oxides, this is determined essentially by the radius ratio of the cation and anion). Figure 19 shows that the molar extinction coefficient for cobalt increases by almost two orders of magnitude when the coordination number is lowered from 6 to 4. With the same coordination number of 6, for example for $Co^{2+}$, the absorption constant rises considerably when the polyhedron is distorted, as can be observed on going from (Mg,Co)O- to (Mg,Co)$TiO_3$-mixed phases[26].

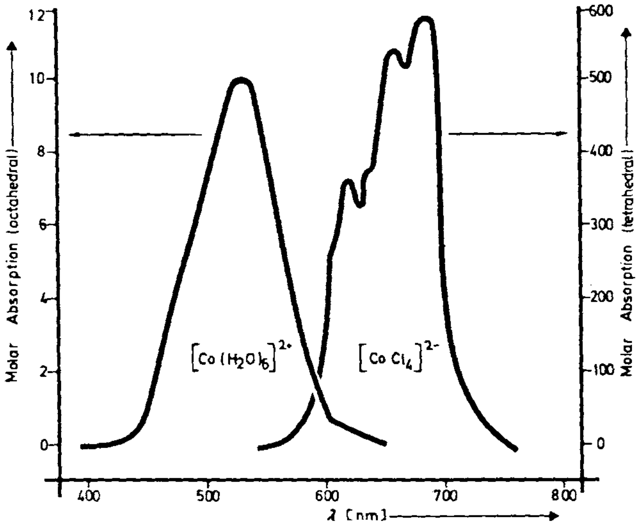

Fig. 19. Absorption and coordination of $Co^{2+}$ ions.

### 5.3. Change in the Ligand Field Strength

In the case of transition metal and lanthanoid ions the energy difference between the ground and excited states, the term difference $\Delta$, is so small that the absorption of light takes place in the visible part of the spectrum. This is responsible for the appearance of color. When d- and f-elements are coordinated with oxide, sulfide, or hydroxide ions, a ligand field forms round the coloring central cation, and the intensity of this field—inversely proportional to the distance—affects the term energy difference $\Delta$ of the cation[27]. Figure 20 shows the term-splitting for an octahedral oxygen ligand field around a $d^1$ cation as a function of the ligand field strength. The splitting increases with the strength of the ligand field, *i. e.* as the distance between the cation and the anion decreases. The effect of a change in the ligand field strength can be demonstrated for cadmium pigments crystallizing in the wurtzite lattice. A reduction of the distance by partial substitution of $Cd^{2+}$ (1.03 Å) by $Zn^{2+}$ (0.83 Å) increases the ligand field strength, displaces the absorption toward shorter wavelengths, and produces a green-yellow color. Increasing the distance by partial replacement of $S^{2-}$ (1.74 Å) by $Se^{2-}$ (1.91 Å) lowers the ligand field strength, displaces the absorption toward longer wavelengths, and changes the hue from yellow to a dark red. Figure 21 shows the spectral reflectance curves of pure CdS and of (Cd,Zn)S and Cd(S,Se) mixed phases, together with the color patterns.

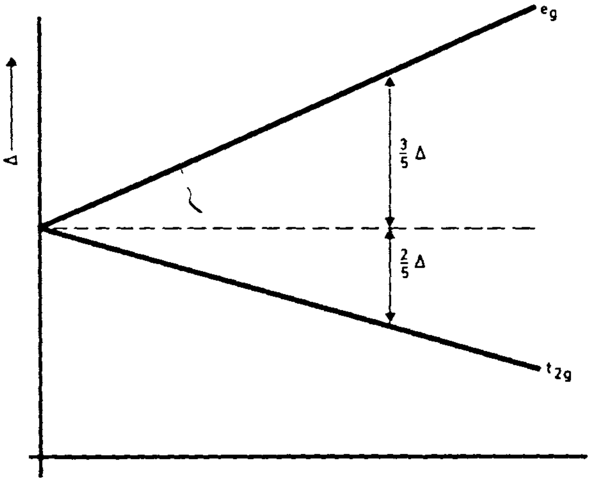

Fig. 20. Term splitting and ligand field (field strength $L$ proportional to the reciprocal distance between a $d^1$-cation and $O^{2-}$ligands, octahedral coordination).

# Phospha-alkenes and Phospha-alkynes, Genesis and Properties of the (p-p)π-Multiple Bond

By Rolf Appel, Fritz Knoll, and Ingo Ruppert[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Just as the octet rule had prevented the discovery of the inert-gas compounds, the systematic search for phosphorus-carbon- and phosphorus-nitrogen-compounds having (p-p)π-multiple bonds was hindered by the double bond rule. The first successful synthesis of mesomeric-stabilized phosphorus-carbon compounds with coordination number 2, seventeen years ago, was followed nine years later by the preparation of the imino-phosphanes whose intensive investigation has continued to the present day. A dramatic development has now begun in the phospha-alkene and -alkyne fields, and a large variety of preparative methods have been found. Several compounds of this type are amazingly stable, however they do not participate in typical ylide reactions such as the Wittig reaction. In contrast, the PC double bond is more comparable to that of olefins, which has been confirmed by the occurrence of *E,Z*-isomers and pericyclic reactions of phospha-1,5-hexadienes.

## 1. Introduction

Even today the double bond rule, according to which compounds with (p-p)π-bonds between elements of the first and those of higher periods should not exist, can be found in many text-books[1,2]. Compounds of carbon with silicon or phosphorus, containing this structural element

should exist at best as short-lived intermediates but never as stable species. Studies over the last two decades have revealed that this rule is no longer valid for phosphorus and silicon in its combination with carbon and nitrogen.

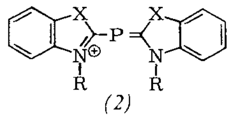
Numerous reports have appeared on the amino(imino)phosphanes, —N=P—N<[3], and mesomerically stabilized phosphorus-carbon compounds, in which the phosphorus has the coordination number 2[4,5]. In this article we have therefore only considered the most recent developments in the field of phospha-alkenes and -alkynes. We start with a brief historical review, sketching out the most important highlights on the way to PC-multiple bonds of lower coordinated, trivalent phosphorus.

The first experiment which led to the postulation of (p-p)π-interactions was carried out by *Gier*[6] in 1961 who obtained the phospha-acetylene *(1)* as a gas, stable only at low temperatures, by passing $PH_3$ through an electric arc between graphite electrodes. In 1964 *Dimroth* and *Hoffmann* described the first compound which is stable at room temperature because of the mesomeric structures of the phosphorus-carbon double bond of the two-coordinate phosphorus[7]. The actual existence of a delocalized (C2p—P3p)π-bond in the phosphamethine cyanine cations *(2)* could be determined by X-ray structure analysis[8]. In 1966 *Märkl* published the synthesis of the 2,4,6-triphenylphosphabenzene *(3a)*[9], and in 1971 *Ashe* succeeded in a very elegant synthesis of the unsubstituted phosphabenzene *(3b)*[10], in which the (p-p)π-bonds are also stabilized by resonance with the aromatic ring.

The breakthrough to isolable, acyclic compounds with localized (PC)-double-bond was initiated six years later by *Becker*[11]: Working on the synthesis of *P*-silylated acylphosphanes he observed a silyl migration from P to O and obtained the derivative *(4)*, the first example of a new structural type.

$P{\equiv}C{-}H$

*(1)*



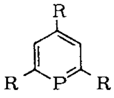
*(2)*

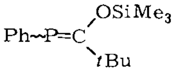
–X– = –CH=CH–, –S–, –NR–

R = $CH_3$, $C_2H_5$

*(3a)*, R = Aryl

*(3b)*, R = H





$$Ph{-}P{=}C\begin{matrix}OSiMe_3\\ tBu\end{matrix}$$

*(4)*

Since that time several important contributions to this dynamic field of research have also stemmed from the groups of *Issleib, Bickelhaupt,* and *Nixon*. Our group in Bonn first encountered this class of compounds in the chlorination of silyl-substituted methyldiphenylphosphanes with carbon tetrachloride[12,13]. Since then we have studied the mode of action of chlorocarbon compounds, especially $CCl_4$, $C_2Cl_6$, phosgene, and isocyanide dichlorides on tertiary phosphanes. The chronological presentation will now be left and a systematic survey of the available preparative methods for phospha-alkenes will be given: their properties and reactivity will also be discussed and compared with well known phenomena of the chemistry of hydrocarbons. Finally, the phospha-alkynes will be discussed.

## 2. Synthetic Routes to Phospha-alkenes

### 2.1. 1,2-Elimination

By analogy to the usual procedures in olefinic chemistry, a 1,2-elimination reaction at organophosphanes having

---

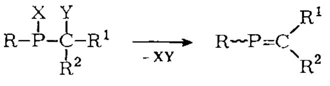
Anorganisch-chemisches Institut der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)

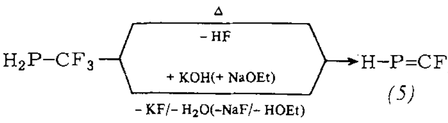
functional substituents X at phosphorus and Y at the α-C atom presents a good possibility of generating a PC-double bond. Substituents of opposite polarity which combine to a thermodynamically favored leaving molecule XY, are advantageous but not necessary.

The following possibilities have been verified to date: X = H, Y = F[14,15]; X = Cl, Y = H[14,16-19]; X = Br or I, Y = H[20]; X = Cl, Y = $SiMe_3$[12,13,21] and X = Y = Cl[20].



$$R{-}\overset{X}{P}{-}\overset{Y}{\underset{R^2}{C}}{-}R^1 \xrightarrow{-XY} R{\sim}P{=}C\begin{smallmatrix}R^1\\ R^2\end{smallmatrix}$$

A comparison of the distinct procedures demonstrates that as in the synthesis of *(5)* it is possible to choose either the thermal or base-induced elimination[14,15].



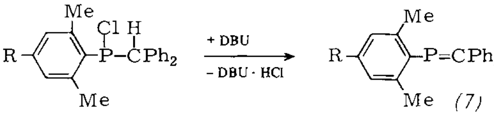
$$H_2P{-}CF_3 \xrightarrow[\text{+ KOH(+ NaOEt)}\ /\ \text{- KF/- }H_2O\text{(-NaF/- HOEt)}]{\Delta\ /\ \text{- HF}} H{-}P{=}CF_2$$

*(5)*

When the polarity of the substituents is reversed, *e.g.* X = Cl and Y = H, both pathways of synthesis can be used as shown in equations *(a)* to *(d)* (DBU = 1,5-diazabicyclo[5.4.0]undec-5-ene; DBO = 1,4-diazabicyclo[2.2.2]octane).

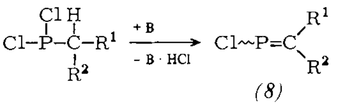
$$Cl_2P{-}CH_3 \xrightarrow[-HCl]{\Delta} Cl{-}P{=}CH_2 \qquad \text{(a)}$$

*(6)*



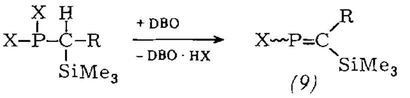
*(7)* (b)

*(7a)*, R = Me; *(7b)*, R = H



$$Cl{-}\overset{Cl}{P}{-}\overset{H}{\underset{R^2}{C}}{-}R^1 \xrightarrow[-B\cdot HCl]{+B} Cl{\sim}P{=}C\begin{smallmatrix}R^1\\ R^2\end{smallmatrix} \qquad \text{(c)}$$

*(8)*

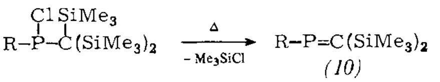


$$X{-}\overset{X}{P}{-}\overset{H}{\underset{SiMe_3}{C}}{-}R \xrightarrow[-DBO\cdot HX]{+DBO} X{\sim}P{=}C\begin{smallmatrix}R\\ SiMe_3\end{smallmatrix} \qquad \text{(d)}$$

*(9)*

| *(8)* | $R^1$ | $R^2$ | B | *(9)* | | R |
|---|---|---|---|---|---|---|
| *(a)* | H | Ph | DBO | *(a)* | Br | Ph |
| *(b)* | Ph | Ph | $NEt_3$ | *(b)* | Br | $SiMe_3$ |
| *(c)* | Ph | $SiMe_3$ | DBO or $NEt_3$ | *(c)* | I | Ph |
| *(d)* | $SiMe_3$ | $SiMe_3$ | DBO | | | |

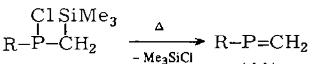
Looking at the different methods of preparation more closely it has to be pointed out that in contrast to the thermolytic HCl-elimination (eq. (a))[14], only the dehydrohalogenation in solution according to eqs. (b)—(d)[16-19] allows the isolation of marked amounts of pure phospha-alkenes. The use of suitable bases renders accessible not only the methylenephosphanes *(7a)* and *(7b)*[16], which are blocked at the phosphorus atom by bulky substituents, but even—extending the principle of synthesis to selected primary halogenophosphanes—*P*-halogen derivatives [eq. (c) and (d)][17-20]. The assumption[16] that PC-double bonds of the (p-p)π-type are stabilized above all by steric hindrance at the phosphorus atom is refuted by these results. Whereas the thermal HCl-elimination is inefficient, from a preparative point of view, the corresponding halosilane-elimination can be used synthetically. The action of heat on *P*-chloro(organo)phosphanes, with different silyl substituents at the methyl group, under conditions of reduced pressure, yields the *C*-silylated phospha-alkene *(10)*[21] and, surprisingly, also the carbon-unsubstituted phospha-alkene *(11)*[22] in pure form.



$$R{-}\overset{Cl}{P}{-}\overset{SiMe_3}{C}(SiMe_3)_2 \xrightarrow[-Me_3SiCl]{\Delta} R{-}P{=}C(SiMe_3)_2$$

*(10)*

*(10a)*, R = *t*Bu; *(10b)*, R = Ph



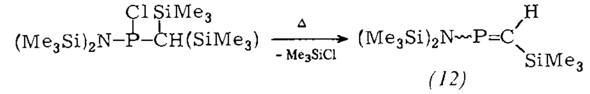
$$R{-}\overset{Cl}{P}{-}\overset{SiMe_3}{C}H_2 \xrightarrow[-Me_3SiCl]{\Delta} R{-}P{=}CH_2$$

*(11)*

R = 2, 4, 6-$tBu_3C_6H_2$

Methylenephosphanes which only possess small substituents also exhibit extraordinary stability. In the case of *(11)*, however, the shielding is due to the extremely bulky 2,4,6-tri-(*tert*-butyl)phenyl substituent on the phosphorus atom.

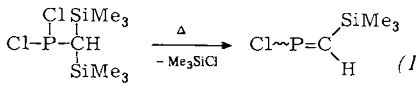
The amino-substituted chlorophosphanes also undergo a selective thermolysis, and this has been used in a one-pot synthesis of *(12)*[23].



$$(Me_3Si)_2N{-}\overset{Cl}{P}{-}\overset{SiMe_3}{C}H(SiMe_3) \xrightarrow[-Me_3SiCl]{\Delta} (Me_3Si)_2N{\sim}P{=}C\begin{smallmatrix}H\\ SiMe_3\end{smallmatrix}$$

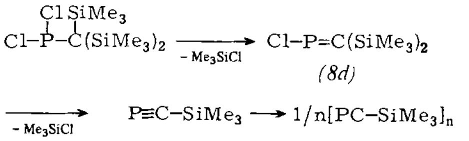
*(12)*

The extension to dichlorophosphanes, having several possibilities of elimination, leads to consecutive reactions. *(13)* can be formed by vapor phase pyrolysis and trapped at low temperatures[20]; the action of heat on the corresponding *C*-persilylated compound *(8d)* results in polymerization[21], due to the instability of the final product of the double elimination (see Section 5).



$$Cl{-}\overset{Cl}{P}{-}\overset{SiMe_3}{\underset{SiMe_3}{C}}H \xrightarrow[-Me_3SiCl]{\Delta} Cl{\sim}P{=}C\begin{smallmatrix}SiMe_3\\ H\end{smallmatrix}$$

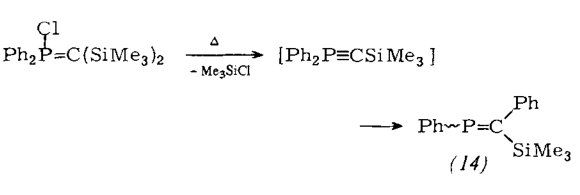
*(13)*



$$Cl{-}\overset{Cl}{P}{-}\overset{SiMe_3}{C}(SiMe_3)_2 \xrightarrow[-Me_3SiCl]{} Cl{-}P{=}C(SiMe_3)_2 \xrightarrow[-Me_3SiCl]{} P{\equiv}C{-}SiMe_3 \longrightarrow 1/n[PC{-}SiMe_3]_n$$

*(8d)*

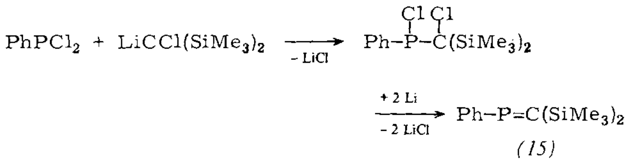
A surprising exception is the $Me_3SiCl$-elimination at the pentavalent phosphorus in the disilylated *P*-chloro(methylene)phosphorane in eq. (e). In this case the formation of *(14)* can be explained only by a subsequent reductive 1,2-(P,C)-shift of the phenyl group[12,13,20].



$$Ph_2\overset{Cl}{P}{=}C(SiMe_3)_2 \xrightarrow[-Me_3SiCl]{\Delta} [Ph_2P{\equiv}CSiMe_3] \longrightarrow Ph{\sim}P{=}C\begin{smallmatrix}Ph\\ SiMe_3\end{smallmatrix} \qquad \text{(e)}$$

*(14)*

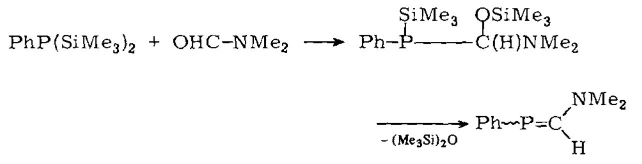
By analogy to the dehalogenation of vicinal dihaloalkanes with base or electropositive metals, the dechlorination of a *P*-chloro-α-chloroalkylphosphane with lithium offers another procedure for the introduction of the PC-double bond[20]. Certainly the general scope of application is restricted by the availability of the starting material.



*(15)*

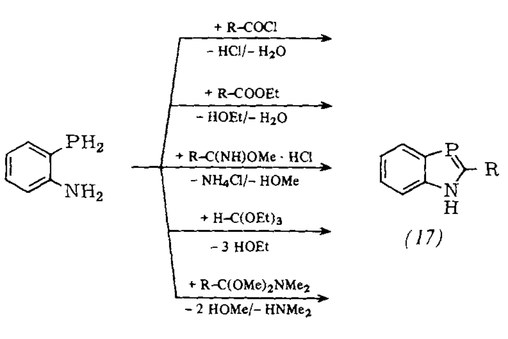
## 2.2. Condensation

The reactions in which the P—C-bond—involved in the 1,2-elimination step—must first be formed are to be distinguished from the procedures previously mentioned. The P—C-bond may be formed by addition of a silylphosphane or a phosphane having a P—H bond to a carbonyl group, followed by the elimination-step. In principal, this has to be considered as a condensation reaction, as demonstrated by the example of siloxane-elimination in the preparation of *(16a)*[24].



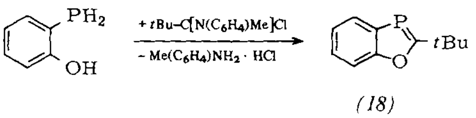
*(16a)*

The formation of a PC-double bond is particularly favored, if this is incorporated into a stabilizing ring skeleton. Accordingly, the condensation of *o*-phosphinoaniline with carboxylic acid derivatives, such as chlorides, esters, imidoesters, orthoformic acid esters or aminals, leads to the 1,3-benzazaphospholes *(17)*[22,25].



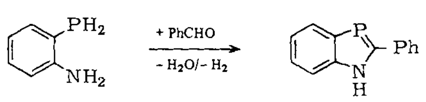
*(17)*

*o*-Phosphinophenol condenses with imidochlorides analogously to the 1,3-benzoxaphosphole *(18)*[22].

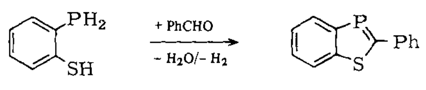


*(18)*

The addition compounds of *o*-phosphinoaniline and -thiophenol with benzaldehyde undergo hydrogen and water cleavage, either spontaneously or by oxidation[22]. 2-Phenyl-1,3-benzazaphosphole *(17c)* and 2-phenyl-1,3-benzothiaphosphole *(19c)* are formed respectively.

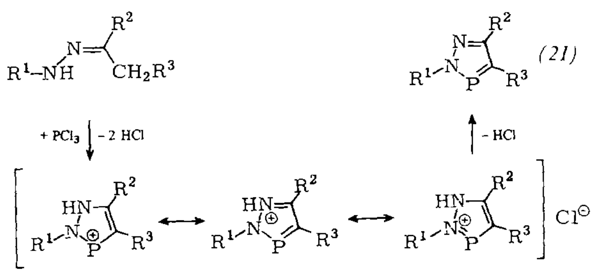


*(17c)*



*(19c)*

Hereby, the palette of elimination reactions was extended to the example of dehydration with dehydrogenation. Finally, the action of *N*-substituted hydrazones with α-CH-acidity on phosphorus trichloride, leading to the new heterocyclic compound *(21)*[26,27], belongs to this group of condensations. The cyclic 6π-electron system of the phosphenium chloride *(20)*[28] could be identified as an intermediate of the dehydrohalogenation.

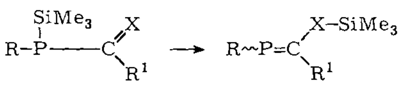


*(21)*

*(20)*

## 2.3. 1,3-Trimethylsilyl Migration

An entirely different principle for the generation of the PC-double bond is based on the migration of a *P*-silyl-group to an element such as nitrogen, oxygen or sulfur which is bonded in the α-position. According to eq. (f) the double bond is hereby shifted to the phosphorus. The driving force of this "silatropy" could be the formation of a very stable N—Si-, O—Si- or S—Si-bond.



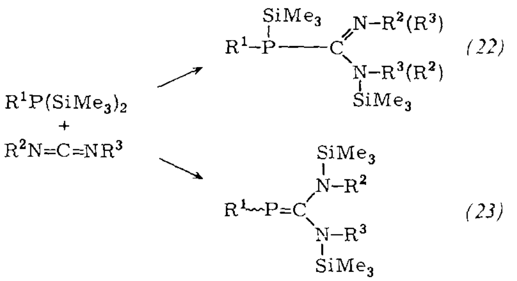
(f)

$X = NR^2, O, S$

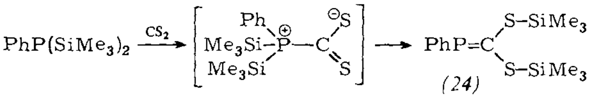
### 2.3.1. Addition with Silyl Migration

To date two examples, in which addition of silylphosphanes to double-bonds takes place prior to the silyl migration, are known. Monoorganobis(trimethylsilyl)phosphanes react with carbodiimides by insertion into the PSi-bond to give phosphaguanidines[29].

Depending on the substituents $R^2$, $R^3$ either the *N,P*-bis-silylated derivatives *(22)* or, by double silyl migration, the isomeric phospha-alkenes *(23)* are formed [*(23a—e)*, see Table 1; $R^2$, $R^3$ should preferably be phenyl].

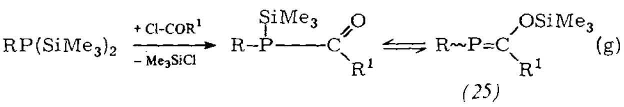


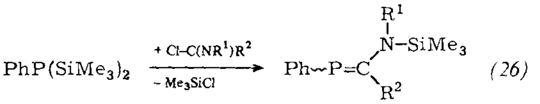
An analogous reaction with formation of a primary adduct was observed when phenyl(bistrimethylsilyl)phosphane was treated with $CS_2$[30]. The phospha-alkene *(24)* is formed.



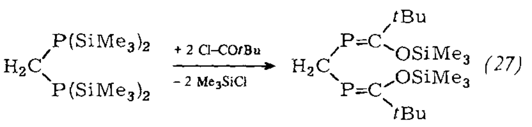
2.3.2. Condensation with Silyl Migration

The very first introduction of a stable PC-double-bond ensued from a halosilane condensation between disilylated phosphanes and carboxylic acid derivatives[11,31,32] and their aza analogues[33]. This synthetic procedure for *(25)* and *(26)* is very advantageous from the preparative point of view because of the ready availability of the starting materials. The primary condensation to the *p*-silylacylphosphane is usually followed by a rapid, irreversible migration of the silyl group with formation of the methylenephosphane structure. Depending on the acyl moiety both silatautomers have occasionally been found in equilibrium[11] [eq. (g)] [*(25a–f)* and *(26a–j)* see Table 1].

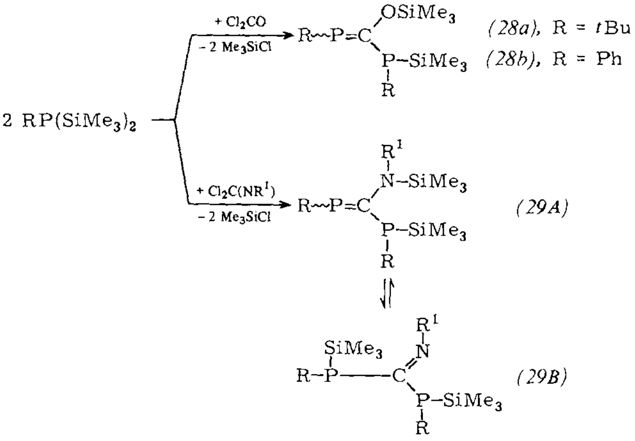




Methylenebis(disilylphosphane) behaves in a similar manner and yields *(27)*, whose structure was determined by X-ray structure analysis[34].



Carbonic acid halides, as *e.g.* phosgene[35,36] and isocyanide dichlorides[37,38] undergo double substitution to give the *C*-phosphinomethylenephosphanes *(28)* and *(29)*, respectively, without isolable intermediates. The isomeric phosphaguanidines *(29B)* can be identified by NMR in minor amounts in solutions of *(29A)*[39] in a similar manner to the acylphosphanes in eq. (g) [*(29a—n)*, see Table 1].



## 3. Properties and Reactivity of Phospha-alkenes

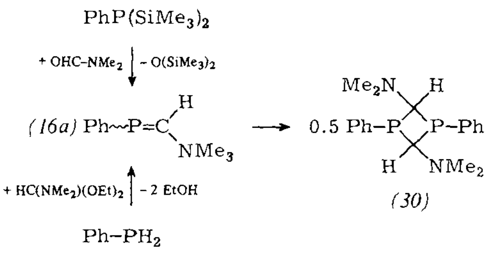
The phospha-alkenes hitherto synthesized on a preparative scale are mainly oily, often yellow-colored substances, which show only a small tendency to crystallize. They are readily or very readily soluble in the usual polar or nonpolar solvents. So far, typical reactions of phosphanes such as oxidations and alkylations, except for the sulfuration of the particularly reactive compound *(12)* (cf. Section 3.3) have not been reported. Up to now no tendency for Wittig-reactions has been be observed.

As far as is known the phospha-alkenes can react in two ways: at the PC-double-bond or at the periphery.

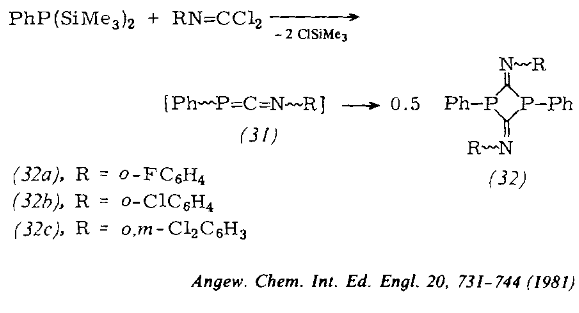
### 3.1. Reactions at the PC-Double Bond

3.1.1. Self-Addition

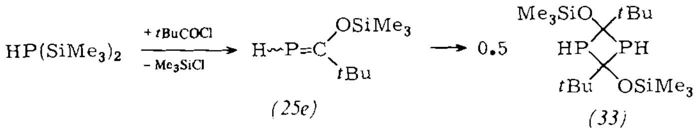
It is well known that molecules with double-bonds have a tendency to dimerize. The phospha-alkene *(16a)* (cf. Section 2.2), which can be prepared *via* different pathways, undergoes [2+2]-cycloaddition (head-to-tail condensation) to give the 1,3-diphosphetane *(30)* according to the expected differences in polarity[22,24].



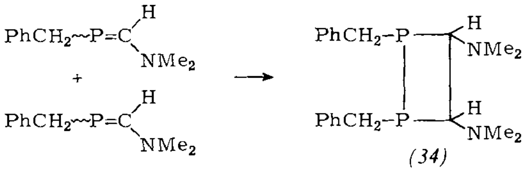
1,3-Diphosphetanes *(32)* are also obtained by reaction of isocyanide dichlorides with disilylphosphanes. The products *(32)* are probably formed by dimerization of the not yet isolated monophosphacarbodiimide *(31)*[38,40].



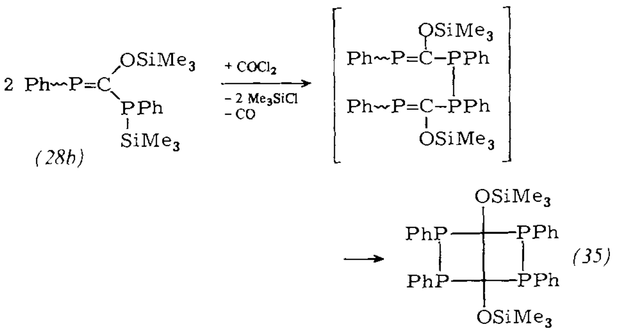
Also *(25e)*, the condensation product of bis(trimethylsilyl)phosphane and pivaloyl chloride, is slowly converted into the 1,3-diphosphetane *(33)* under the influence of light[32].

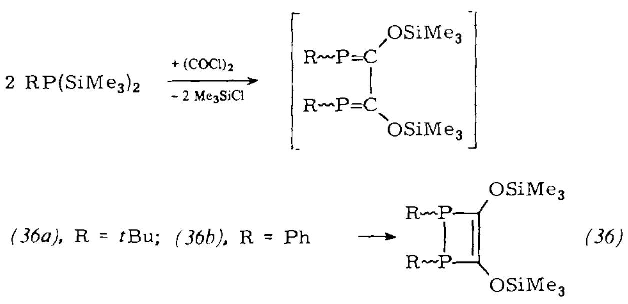


The cyclization of two methylenephosphane-units to the isomeric 1,2-diphosphetanes *(34)* can be observed with the *P*-benzylated aminomethylenephosphane[41].



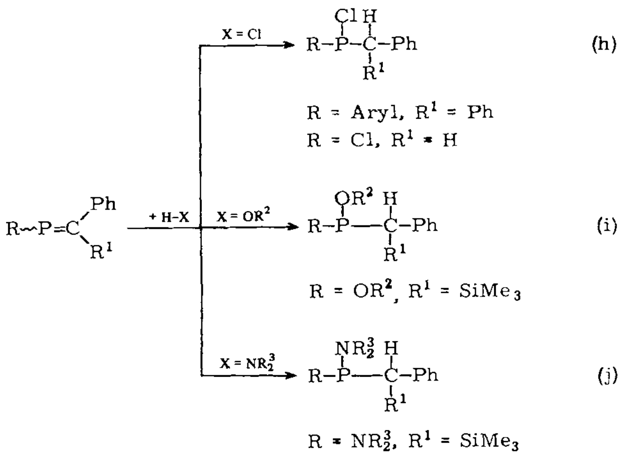
This surprising head-to-head and tail-to-tail addition may also be responsible for the formation of the bicyclo[2.2.0]hexane structure *(35)* when the phosphino-substituted methylenephosphane *(28b)* is treated with phosgene[35,36]. As in the synthesis of the 1,2-phosphetenes *(36)* from disilylphosphanes and oxalyl chloride[42], the corresponding intermediates cannot be isolated.





### 3.1.2. Addition of H-Acidic Reagents

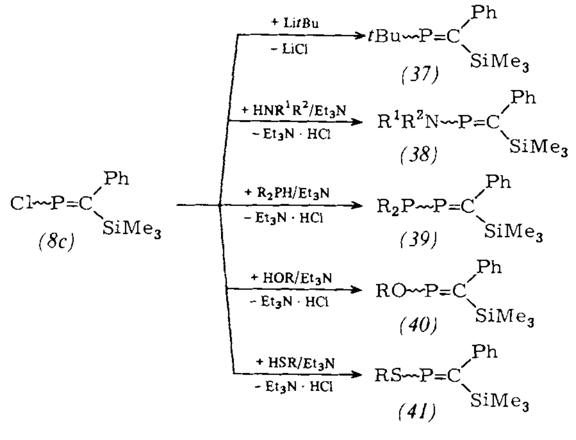
Directed addition reactions of polar reagents to phospha-alkenes have only been investigated to a limited extent up to now and have been restricted to the hydrogen halides[16], alcohols and amines[43]. The anionic part of the HX always adds to the P-atom, while the proton adds to the C-atom [eq. (h)—(j)].



## 3.2. Substitution with Preservation of the PC-Double Bond

### 3.2.1. Derivatization of *P*-Chloro(methylene)phosphanes

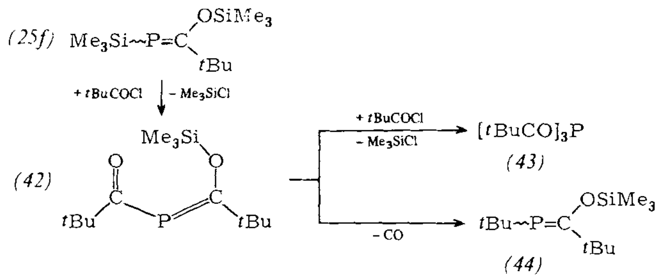
*P*-halogenated methylenephosphanes such as *(8c)*[17] allow derivatization at the phosphorus. They are therefore valuable key compounds for the preparation of a large variety of novel methylenephosphanes, such as the phosphino-, alkoxy- and alkylthio-substituted compounds with unknown atomic sequence[43]. The condensations of *(8c)* with *tert*-butyllithium to give the *P*-organo derivative *(37)*, with secondary amines to give the *P*-amino(methylene)phosphanes *(38)* and with secondary phosphanes to give the group of *P*-phosphino(methylene)phosphanes *(39)* having the diphosphane partial structure may be cited as examples. The alkoxy or alkylthio groups can be introduced by alcoholysis or thiolysis to give *(40)* and *(41)*, respectively [*(38)*, $R^1$, $R^2$=alkyl and/or aryl; *(39a)*, R=*t*Bu; *(39b)*, R=Ph; *(40)*, R=alkyl and/or aryl; *(41)*, R=alkyl; cf. also Table 1].



In this connection *(8c)* has a reactivity which is comparable to that of the secondary chlorophosphanes with the coordination number three. However, it must be borne in mind that after the primary substitution an addition to the PC-double bond has been observed with an excess of the *N,O*-acidic reagents (eq. (i) and (j)).

### 3.2.2. Derivatization of *P*-Silyl(methylene)phosphanes

The silyl derivative *(25f)* with the reversed reactivity (umpolung) of the *P*-chloro(methylene)phosphane *(8c)* oc-

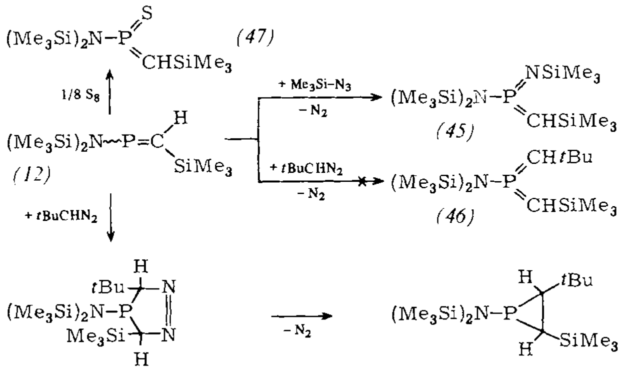


cupies a special position[31]. According to eq. (g), *(25f)* is formed by the reaction of tris(trimethylsilyl)phosphane with pivaloyl chloride. The *P*-acylated derivative *(42)* is formed *via* another halosilane condensation under more vigorous conditions, and reacts in part with further acid chloride to give the triacylphosphane *(43)*, and in part *via* decarbonylation to give *(44)*[31].

### 3.3. Oxidative Extension of the Coordination of the Methylenephosphane Phosphorus

The reaction of trimethylsilylazide or diazaalkanes with the bis(trimethylsilyl)amino(trimethylsilylmethylene)phosphane *(12)*, in order to synthesize the double ylides *(45)* or *(46)* with three coordinated phosphorus was studied; only the imination to *(45)*, however, succeeded[44]. A compound with the skeleton *(45)* had already been obtained by methylenation of the (N—P=N)-system[45a].

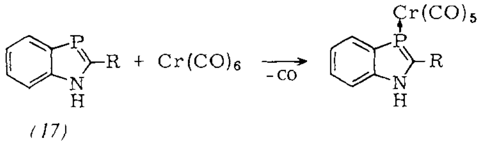
Recently, however, we have succeeded in introducing a second PC double bond at the same P atom[45b]. Starting from *(12)*, instead of the double ylide, only the isomeric phosphirane was formed from the detectable $1,2,4\lambda^3$-diazaphospholidine intermediate *via* $N_2$-elimination[23].



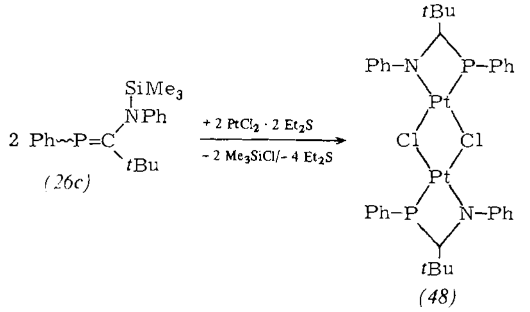
The special position of the methylenephosphane *(12)*, which can be sulfurized to *(47)*, has however been recorded in the literature[45c].

### 3.4. Complexes with Transition Metals

Tertiary phosphanes are valuable and widely used ligands in complex-chemistry. Initial experiments indicate that methylenephosphanes such as *(17)* are also able to displace carbon monoxide from carbonylmetal compounds[22,46]. The question arises whether the complex may be formed only with the lone-pair electrons of the trivalent phosphorus or also with the π-electrons of the double bond. This problem may be elucidated by further studies with varied substitution pattern at the methylenephosphane.



The 1,3-condensation of an amino-substituted phosphaalkene at d$^8$-metal salts (using the stabilizing chelate effect) is demonstrated in eq. (k)[33].



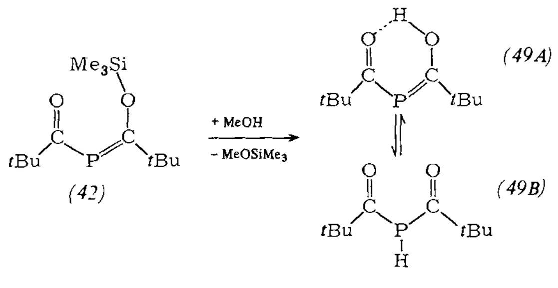
(k)

### 3.5. Reactions at the Periphery

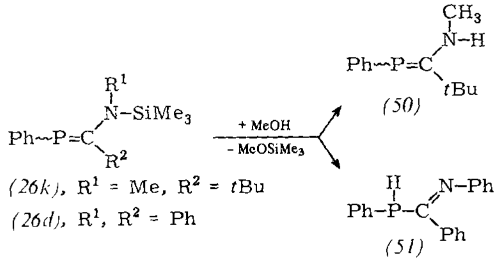
This section deals with reactions at the α-position to the methylene carbon which can affect the double bond. These reactions include cleavage of the *O*-, *N*- or *P*-silyl groups[32,47] with reagents such as methanol and phosgene. Usual derivatizations, such as acylations, in which the molecular structure is retained will not be dealt with here[33].

#### 3.5.1. Desilylations

The cleavage of a silyl group bonded to oxygen or nitrogen, may (but must not necessarily) influence the PC-double bond. Both possibilities have been verified in the keto-enol equilibrium, *(49B)*⇌*(49A)*, after methanolysis of *(42)*[48]. As with the β-diketones, both species are observed in solution; however, according to the X-ray structure determination in the solid state, only the H-bridged enol-form *(49A)* exists.



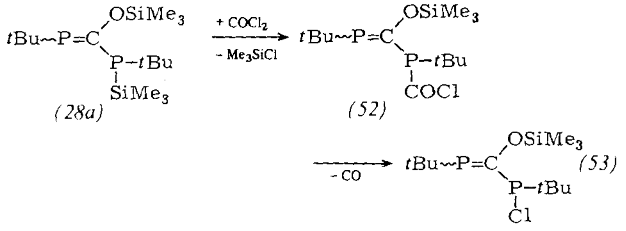
The protonolysis of the silylamino-substituted methylenephosphane is controlled by the competitive basicity of the amino- and phosphino centers of the molecule. In the *N*-methylderivative *(26k)* the position of the double bond remains fixed, even after alcoholysis to *(50)*; in the acidic phenyl derivative *(26d)* the imide *(51)* is formed by an (*N,P*)-prototropy[33].



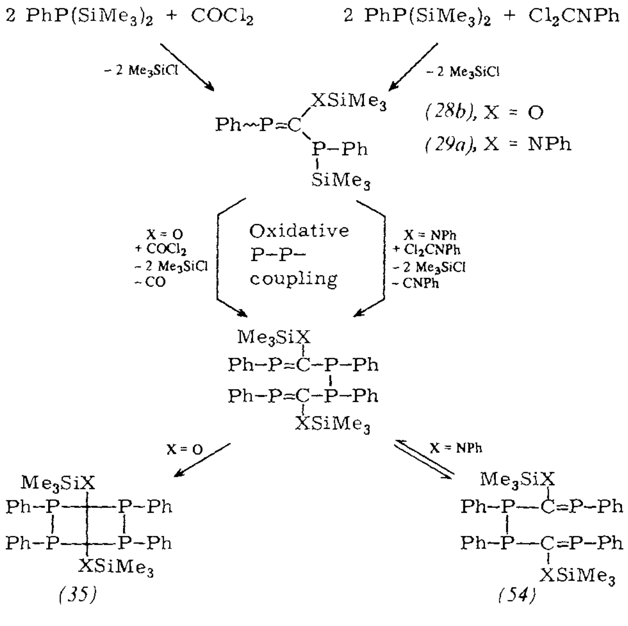
### 3.5.2. Particular Condensations with Phosgene and Isocyanide Dichlorides

The action of phosgene and isocyanide dichlorides on silylphosphino-substituted phospha-alkenes can be distinguished from pure derivatizations which do not affect the methylenephosphane bond and reactions which cause a fundamental change in the bond-system.

$COCl_2$ reacts with the *tert*-butyl compound *(28a)* according to the first pattern, whereby the *P*-silyl function of *(28a)* is converted into the *P*-chloro function of *(53)* following CO-elimination from the detectable mono-condensation product *(52)*[49].



Upon replacing the *tert*-butyl group of *(28a)* by the smaller phenyl group, the phosgenation takes another course. The P—P-linkage in *(28b)* to the 1,3,4,6-tetraphospha-1,5-hexadiene is no longer hindered[37,38]. The bis(siloxy)-analogue of *(54)*, thus obtained, is unstable and undergoes cyclization at the PC-double bond to the stable 2,3,5,6-tetraphosphabicyclo[2.2.0]hexane derivative *(35)*[35,36].



A similar reaction pathway—halosilane condensation and elimination of an isonitrile—is observed up to the penultimate step in the aza-analogues of phosgene, the isocyanide dichlorides. *(54)* shows no tendency to cyclize. It is stable at higher temperatures and undergoes an identical Cope-rearrangement, as discussed in Section 4.3[37,38].

## 4. Structural Characteristics of the PC-Double Bond

Structural problems connected with the PC-double bond are discussed using $^{31}$P-NMR data and X-ray structure determinations.

### 4.1. Influence of the Substitution Pattern on the $^{31}$P-NMR Spectrum

The values of the chemical shifts of the $^{13}$C- or $^{31}$P-atom arise from the state of hybridization of the elements. Both the P- and C-nuclei of the PC-double bond show the characteristic sp$^2$-downfield shift, which is decisively different from that of sp$^3$- or sp-hybridized atoms. The downfield shift of the P-atom of the double bond mainly reflects the deshielding, which probably arises from the lone-pair electrons[50].

Table 1. $^{31}P\{^1H\}$-NMR shifts of phospha-alkenes as a function of the substitution pattern. (A), (B): isomer A or B respectively.

Table 1, classified according to substance classes, shows the effect of the vicinal groups at the PC-double bond on the $^{31}P$-NMR shifts. In this context there are parallels to the $^{13}C$-NMR shifts of the alkenes (α-increments[50]) as well as to the $^{31}P$-NMR shifts of the corresponding phosphanes. These values can be correlated with the corresponding values for the phospha-alkanes, when the electronic interaction of the substituents (H, alkyl, aryl) with the π-system of the PC-double bond is prevented or reduced. Substituents with an electron pair capable of mesomerism (Cl, OR, $NR_2$) at the $P{=}C$ unit, cause a shift to higher field, $Si(CH_3)_3$ however, shifts to lower field[16] (Fig. 1). The $^{31}P$-shifts are not affected if the last mentioned groups are attached to the *P*- or *C*-atom.

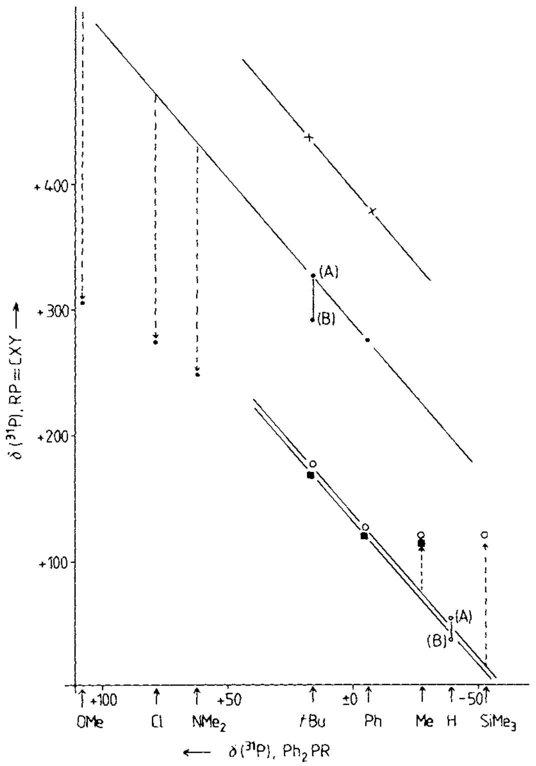

Fig. 1. Correlation of chemical shifts ($^{31}P$-NMR) in phosphanes ($Ph_2PR$) and phospha-alkenes $RP{=}CXY$ with the same substituents R.
x: $RP{=}C(SiMe_3)_2$; ● $RP{=}C(SiMe_3)Ph$, ○ $RP{=}C(OSiMe_3)$ *t*Bu;
■ $RP{=}C[N(SiMe_3)Ph]_2$. (A), (B): isomer A or B respectively.

### 4.2. Geometry of the PC-Double Bond: NMR and X-Ray Results

Taking into account the lone-pair electrons of the two coordinate phosphorus, geometrical isomers analogous to the alkenes are to be expected. In both cases the double bond prevents the mutual conversion of the *cis-trans*-isomers[51]. It is thus possible to obtain both forms (*E/Z*-pairs) and in certain cases to seperate them.

Depending on the substitution pattern the isomeric pairs (summarized in Table 2) can also be detected in the $^{31}$P- as well as in the corresponding $^{13}$C-NMR spectrum.

Table 2. $^{31}$P-NMR shift differences between (*E,Z*)-isomeric pairs.

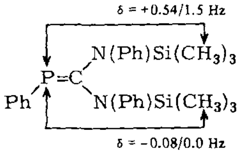
| (*E,Z*)-Phospha-alkene | | $\Delta\delta$ | Ref. |
|---|---|---|---|
| $\mathrm{Cl{\sim\sim}P{=}C(H)Ph}$ | *(8a)* | 2 | [17] |
| $\mathrm{H{\sim\sim}P{=}C(OSiMe_3)}t\mathrm{Bu}$ | *(25e)* | 3 | [35] |
| $\mathrm{PhO{\sim\sim}P{=}C(SiMe_3)Ph}$ | *(40c)* | 32 | [43] |
| $t\mathrm{Bu{\sim\sim}P{=}C(SiMe_3)}Ph$ | *(37)* | 38 | [31] |
| $t\mathrm{Bu{\sim\sim}P{=}C(OSiMe_3)[P(SiMe_3)}t\mathrm{Bu]}$ | *(28a)* | 45 | [49] |
| $\mathrm{Ph{\sim\sim}P{=}C[N(SiMe_3)COOEt][P(SiMe_3)Ph]}$ | *(29n)* | 63 | [39] |
| $\mathrm{Ph{\sim\sim}P{=}C[N(SiMe_3)Ph]Ph}$ | *(26d)* | 81 | [33] |
| $\mathrm{Ph{\sim\sim}P{=}C[N(SiMe_3)}m\mathrm{\text{-}ClC_6H_4][P(SiMe_3)Ph]}$ | *(29g)* | 86 | [38, 39] |

A small shift difference in the $^{13}$C-NMR spectra can also be observed for the corresponding pairs of Schiff-bases and oximes. Differences of up to $\Delta\delta(^{31}P) = 86$ ppm, as in the phospha-alkenes in Table 2 cannot, however, be accounted for in terms of the different position of the substituents at the double bonds.

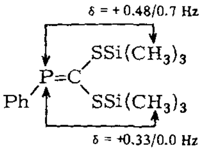
Up to now two theories have been proposed to account for the correlation of the NMR spectroscopic data with the E- and/or Z-isomers defined. From a stereochemical point of view, the phospha-amidines *(26)*, absorbing between $\delta(^{31}P) = +215$ and $+249$ are assigned to the *E*-, and those having signals between $+120$ and $+152$ ppm are assigned to the *Z*-configuration[33].

The structural predictions were also confirmed by the $^{1}$H-NMR parameters.

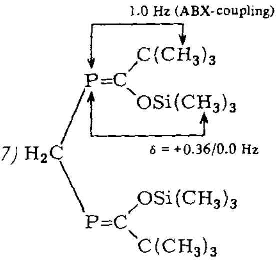
In the case of the phosphaguanidines *(23d)*[29] and of phenylbis(trimethylsilylthio)methylenephosphane *(24)*[30], two signals from the methyl groups are observed; the one at lower field is usually split by coupling with phosphorus. This low field signal is assigned (based on its stereoelectronic properties[29] or on an X-ray structure determination of *(Z,Z)-P,P'*-methylenebis[neopentylidene(trimethylsiloxy)phosphane] *(27)*[34]) to the silyl group on the same side of the double bond as the lone-pair electrons at phosphorus[32].



*(23d)*



*(24)*



*(27)*

This hypothesis has been generalized in later publications and the configuration deduced from the magnitude of the ($^{31}$P-$^{1}$H)-interaction between the P-electron pairs and the coupling group.

The NMR results and several X-ray structure determinations on phosphinomethylenephosphanes *(39a)*[52], *(29e)*[53], *(55)*[54] and *(54A)*[52], studied in our group, restrict the general application of the previously discussed theory.

Hence, no coupling can be detected in the $^{1}$H-NMR spectrum of compound *(39a)* with *E*-configuration, where a *cis*-interaction between the electron pair and the silyl group has been confirmed by X-ray analysis[55]. Similarly, no long range interaction of the methylenephosphane-phosphorus with the *P*-silyl group can be seen in *(29e)*. The doublet from the *N*-trimethylsilyl group results from the phosphano-phosphorus, according to double-resonance experiments.

The hypothesis of a correlation of the $\delta(^{31}P)$-values with the geometry at the PC-double bond is questionable because two other compounds with the comparable substituents exist.

On the one hand, compounds *(29e)* and *(54A)* although having the same configuration, show different $^{31}$P-NMR shifts and, on the other, similar $\delta(^{31}P)$-values are observed with *(29c)* and *(55)* despite different configurations.

These results indicate another factor which influences the $^{31}$P-NMR data far more than the arrangement of the substituents at the double bond: Primarily the interaction between the lone-pair electrons of the group capable of mesomerism and the double bond (see stereoplots) seems to be decisive for the $^{31}$P-NMR shift[16]. If this orbital is orientated approximately parallel to the double bond (*e.g.* *(55)*), a displacement to high field is observed. The $\delta(^{31}P)$-value for the isolated double bond occurs when the overlap is hindered or restricted (Table 3). The downfield shift of *(39a)* results from a double bond which does not overlap with the filled lone-pair orbital of the phosphino phosphorus, as evident from the *trans*-conformation of the diphosphane unit in the stereo pair of *(39a)*[52].

### 4.3. Pericyclic Reactions of Phospha-1,5-hexadiene Derivatives

Another important argument for the existence of real PC-double bonds due to overlap of the C2p- and P3p-orbitals are the pericyclic reactions of the 1,3,4,6-tetraphospha-1,5-hexadiene derivative *(54)*[37]. The $^{31}$P-NMR spectrum of *(54)*, whose analysis leads to these conclusions, will be discussed in more detail because of the crucial importance of this phenomenon for the characterization of the bonding interactions.

At 30 °C the characteristic substructure of a 4-spin-system of the AA'XX'-type is observed. The left signal group at $\delta = +258$ is assigned to the phosphorus atom with the coordination number 2, the right group at $-12.3$ to the trivalent diphosphane phosphorus. In addition a broad sig-

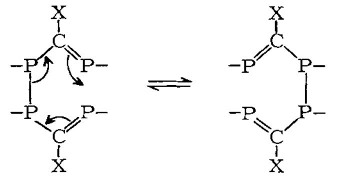
nal at +115.7 occurs which sharpens on heating to 60 °C, while the other signals simultaneously broaden. Cooling to 70 °C results in a splitting of the broad signal. In addition to the signals already present, another 4-spin-system of the same type appears, with the left part arising from the phosphorus with the coordination number 2 and the right hand signals at $\delta = -3.2$ from the diphosphane-phosphorus. Heating the sample to 30 °C results in coalescence of the two inner groups, and the broad absorption reappears at $\delta = +115.8$. This process is reversible.

Upon cooling down to −80 °C or lower, the outer group of signals, designated *(54A)*, disappear completely, since *(54A)* crystallizes out below −80 °C. If the crystals are filtered off at low temperature and redissolved, the spectrum of *(54A)*, followed by the slow conversion of *(54A)* into the *rac*-form *(54B)* can be recorded. At 30 °C the spectrum originally recorded at this temperature is obtained. These results allow the following conclusions to be drawn:

Because *(54)* is homogeneous, according to elemental analysis and molecular mass determination, the compound indicated by the broad absorption at $\delta = +115$ must have the same composition. The splitting of the broad absorption into another AA'XX'-multiplet also indicates that this species must be a diastereomeric tetraphosphahexadiene derivative, since the characteristic signal groups of the diphospane- and the methylenephosphane-phosphorus appear.

These assumptions raise the following questions: what is the reason for the reversible coalescence of the two inner multiplets as a function of temperature and why does only one diastereomer, *(54B)*, show this phenomenon? This may be answered as follows: Only a pericyclic reaction—which is observed at the hexadiene as well and is generally known as the Cope rearrangement—is in complete accord with the coalescence phenomenon [eq. (1)].

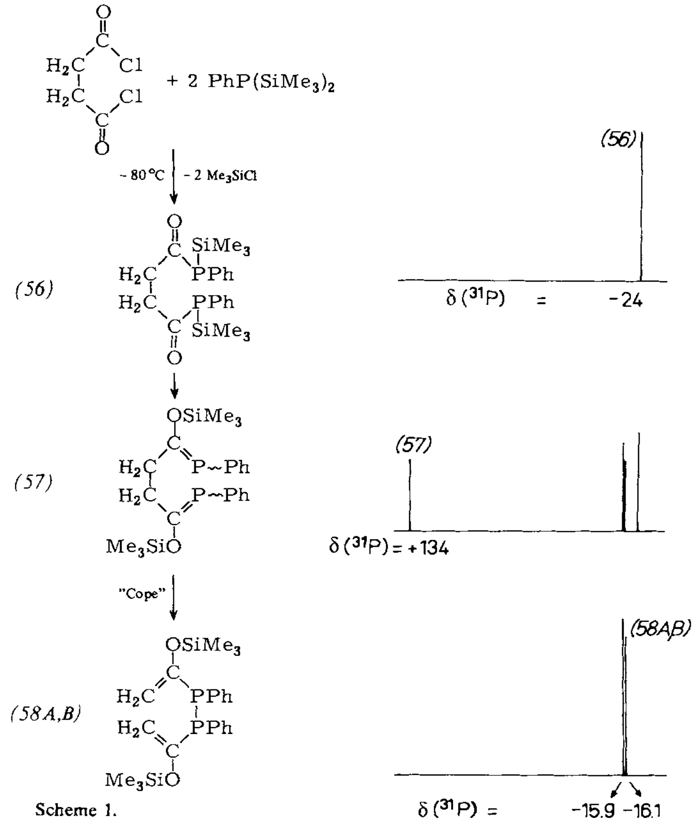
In a [3.3]-sigmatropic reaction the PP-bond in *(54B)* opens and a simultaneous shift of the PC-double bond with formation of a PP-bond takes place. Since the identical rearrangement occurs in *(54B)* and the bonding changes occur on the NMR-time scale, the original signals of the P atoms in *(54B)* with coordination number 2 and 3 coalesce in the middle at room temperature.



(1)

The fact that only one diastereomer shows the coalescence may be explained since it is well known that symmetrical, unequally substituted diphosphanes, which have the same substitution pattern as presented here, have two centers of chirality. The synthesis usually yields a 1 : 1 proportion of the *meso*- and the *rac*-forms, which can be distinguished by their $^{31}$P-NMR shifts. The outer set of multiplets must be assigned to the diastereomer *(54A)*, and the inner set to *(54B)*. The rapid exchange process in the $^{31}$P-NMR spectrum of one isomer at room temperature—which is not observed for the other—leads to the conclusion that only the *rac*-form *(54B)* has a configuration which fulfills the stereochemical demands of the Cope rearrangement. The result of an X-ray structure analysis on the crystals of *(54A)*, filtered off a low temperature and not exhibiting the coalescence phenomenon, is in complete agreement with this assumption. As shown in the stereoplot, this diastereomer presents the *meso*-form with a *trans*-orientation of the substituents at the P—P bond.

The rapid equilibration (compared to carbon compounds) of the *meso*- and *rac*-forms is no exception in phosphorus compounds with chiral, pyramidal P atoms. This has been observed with diphosphanes on several occasions[56].

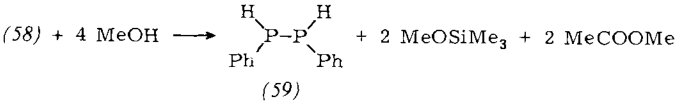


Scheme 1.

Of course, care must be exercised in applying the concepts of pericyclic reactions to elements of the second octet period of the periodic table; nevertheless, interactions are involved between the 2p- and the energetically considerably higher 3p-levels. The bridge connecting the fields of carbon and phosphorus chemistry can, however, be seen in the following experiment.

Succinyl dichloride reacts with bis(trimethylsilyl)phenylphosphane at −80 °C *via* halosilane cleavage to the succinylbis(phosphane) *(56)*. At −10 °C the 1,6-diphospha-1,5-hexadiene *(57)* results from a double 1,3-silyl migration, and at −8 °C a spontaneous [3,3]-sigmatropic rearrangement leads to the corresponding 1,2-diphenyl-1,2-divinyldiphosphane *(58)*[55] (Scheme 1).

The surprising cleavage of a C—C-bond and two PC-double bonds in favor of a P—P-bond, and two olefinic double-bonds, is confirmed not only by unequivocal $^{31}$P-NMR-data but also by a classical decomposition reaction of *(58)*.



$$(58) + 4\,\text{MeOH} \longrightarrow \text{PhHP–PHPh}\ (59) + 2\,\text{MeOSiMe}_3 + 2\,\text{MeCOOMe}$$

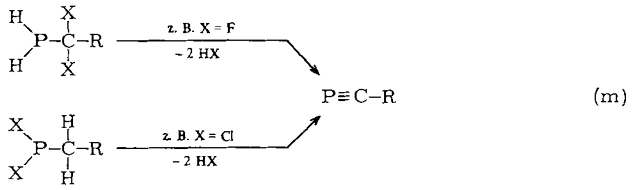
Instead of the $C_4$-unit of succinic acid the methanolysis yields two $C_2$-units (methyl acetate), in addition to the 1,2-diphenyldiphosphane *(59)* and the trimethylsilyl methyl ether.

## 5. Phospha-Alkynes

The early identification of the simplest phospha-alkyne, the phospha-acetylene *(1)*[6], stimulated the search for the more stable phosphorus-carbon combinations with (p-p)π-multiple bonds.

| $P{\equiv}C{-}H$ | $P{\equiv}C{-}F$ | $P{\equiv}C{-}CH_3$ | $P{\equiv}C{-}CF_3$ | $P{\equiv}C{-}C{\equiv}N$ |
|---|---|---|---|---|
| *(1)* | *(60)* | *(61)* | *(62)* | *(63)* |

Besides phospha-acetylene, its derivatives *(60)*[15], *(61)*[57], *(62)*[46] and *(63)*[58] have been reported, all of which were synthesized by repeated hydrogen halide-elimination from primary α-halophosphanes or dihalophosphanes with two hydrogens in α-position. Both pathways are shown in eq. (m).

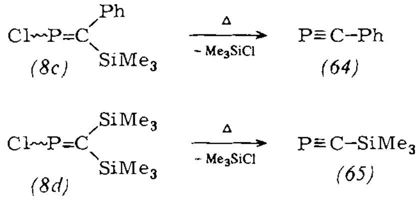


Only the cyanophosphaethyne *(63)*[58] is accessible *via* a condensation reaction.

$$\underset{(1)}{P{\equiv}C{-}H} + N_3{-}CN \xrightarrow[-HN_3]{} \underset{(63)}{P{\equiv}C{-}C{\equiv}N}$$

All the hitherto described phospha-alkynes have been prepared by vapor phase pyrolysis. The phospha-alkynes are obtained as mixtures and identified by their PE-, NMR-, or microwave-spectra; their thermolability, however, has hindered their separation from by-products and their isolation in preparatively useful amounts.

The stepwise synthesis of the triple bond from the double bond of phospha-alkenes suggests itself.

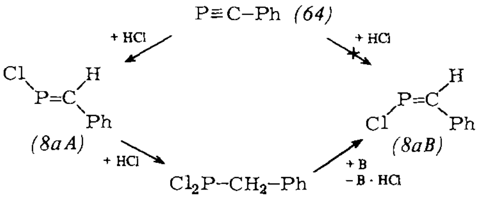


$$\underset{(8c)}{\text{Cl–P=C(Ph)SiMe}_3} \xrightarrow[-\text{Me}_3\text{SiCl}]{\Delta} \underset{(64)}{P{\equiv}C{-}Ph}$$

$$\underset{(8d)}{\text{Cl–P=C(SiMe}_3)_2} \xrightarrow[-\text{Me}_3\text{SiCl}]{\Delta} \underset{(65)}{P{\equiv}C{-}SiMe_3}$$

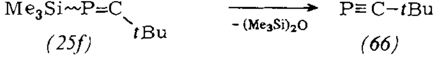
The vicinal chloro- and trimethylsilyl-substituted methylenephosphanes *(8c)* and *(8d)* selectively eliminate chlorotrimethylsilane when heated to *ca.* 700 °C in an Hg-diffusion pump vacuum and the phospha-alkynes *(64)*[18] and *(65)*[19] can be obtained almost quantitatively in a cold-trap placed directly after the pyrolysis apparatus. *(64)* only exists at low temperatures in its monomeric form, above −50 °C slow decomposition takes place. Its half-life, as determined by $^{31}$P-NMR spectroscopy amounted to 7 minutes at 0 °C. As expected, the silyl compound *(65)* is more stable (half-life at room temperature *ca.* 50 minutes).

Apart from the $^{13}$C-NMR data, the presence of a PC-triple bond is confirmed by stepwise HCl-addition.



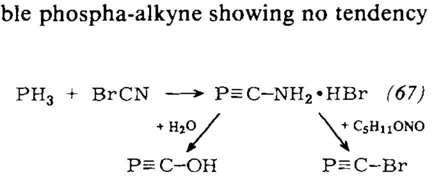
The previously mentioned preparation of *(8a)* *via* dehydrochlorination always yields, besides *(8aA)*, the *Z*-isomer *(8aB)*. After addition of HCl to *(64)*, *(8aA)* is not formed, and this may be explained by a *cis*-addition to the triple bond. Repeated hydrohalogenation leads to benzyldichlorophosphane.

The *tert*-butyl derivative *(66)* with coordination number 1 is stable at room temperature[59]. The PC-triple bond was introduced very smoothly by NaOH-catalyzed siloxane-elimination.



$$\underset{(25f)}{\text{Me}_3\text{Si–P=C(OSiMe}_3)t\text{Bu}} \xrightarrow[-(\text{Me}_3\text{Si})_2\text{O}]{(\text{NaOH})} \underset{(66)}{P{\equiv}C{-}t\text{Bu}}$$

The direct synthesis of the stable hydrobromide *(67)* from phosphane and cyanogen bromide seems to be questionable and conversion to the monomeric hydroxy bromo derivatives very dubious[60], since to date only *(66)* has proven to be a stable phospha-alkyne showing no tendency to polymerize.



Due to the limited number of examples, the hitherto obtained NMR-data cannot be interpreted completely. The effects of the substituents on the $^{31}$P-NMR shifts seem to be similar to those of the phospha-alkenes (Section 4.1).

Compared to *(1)* and *(64)* the silyl substituted phospha-alkyne *(65)* is registrated at a lower field, the halogen derivatives, such as *(60)*, at higher field.

Just as the position of the signal of the phosphorus varies between $\delta = -200$ and $+100$ (rel. to 85% $H_3PO_4$), the values of the methine-C signal vary over a large range and are thereby not significant from a structural point of view. Compared to alkynes or nitriles the phospha-alkyne signals occur at a lower field in the $^{13}$C-NMR.

Table 4. NMR-parameters of phospha-alkynes. $J$ in Hz.

| Phospha-alkyne | | $^{31}P\{^1H\}$ $\delta$ | $^{13}C\{^1H\}$ $\delta(P{\equiv}C)$ | $J$(PC) | Ref. |
|---|---|---|---|---|---|
| PC—H | *(1)* | − 32 | + 154.0 d | 54.0 | [61] |
| PC—*t*Bu | *(66)* | − 69 | + 184.8 d | 38.5 | [59] |
| PC—Ph | *(64)* | − 32 | + 164.9 d | 48.3 | [18] |
| PC—F | *(60)* | − 207 | — | — | [15] |
| PC—SiMe$_3$ | *(65)* | + 96 | + 201.4 d | 13.9 | [19] |

## 6. Summary and Conclusion

Research over the last five years has shown that stable compounds with phosphorus-carbon (p-p)π-multiple bonds can be prepared even without stabilizing mesomeric effects. The introduction of the double bond preferably ensues from 1,2-elimination or from silyl group migration; different methods are available for both pathways.

From the point of view of a preparative chemist hardly any argument can be found against the assumption of real PC-multiple bonds analogous to those of the alkenes and alkynes. The relationship to this type of bond cannot be denied and this is proven by the detection of *E,Z*-stereoisomers, as well as by the existence of a "phospha(keto-enol)-tautomerism". The fluxional structures of the tetraphosphahexadiene derivative *(54B)* may be regarded as completely analogous to the olefinic systems. In agreement with this conception of the double bonds, the $^{13}$C-NMR spectra prove that the methylene carbon atoms of the phospha-alkenes—comparable to the Schiff-bases—are sp$^2$-hybridized.

The reactivity of these new substances is different from that of the homologous CN-compounds, the Schiff-bases and carbonitriles, as demonstrated by the addition of H-acidic reagents to the double bond which occurs in an opposite sense. From this point of view the terms phospha-alkenes and -alkynes, instead of phospha-imines or -nitriles are preferred.

There are some indications that the development of research in the field of (p-p)π-multiple bonds between elements of the first and second octet rows of the periodic table is just beginning. The synthesis of analogous silicon compounds has been repeatedly reported in recent times[62,63]. In a recent report on the synthesis of a stable diphosphaethene RP=PR[64] even a homo-nuclear double-bond between elements of the second octet period can no longer be excluded.

Stimulating topics of future research can only be indicated under keyword headings. They can be found in the field of synthesis of conjugated double bond systems and in the combination of PC-double bonds with olefinic bonds. Can we achieve, for instance, a Diels-Alder synthesis?[*]

Furthermore, it may be worthwhile to use the new structural elements for the synthesis of heterocyclic compounds. In addition, only a small amount of information is available on the field of complex-formation.

Only the future will tell whether these hopes of a new chapter in phosphorus-carbon chemistry will be fulfilled.

*We are indebted to the coworkers mentioned in this article, for their dedicated work and their valuable assistance, and to Dr. M. Halstenberg and Dr. R. Sievers for the X-ray analyses. Financial support was provided by the Deutsche Forschungsgemeinschaft as well as by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, for which we are very grateful.*

# Chemistry and Biochemistry of Microbial α-Glucosidase Inhibitors

**By Ernst Truscheit, Werner Frommer, Bodo Junge, Lutz Müller, Delf D. Schmidt, and Winfried Wingender**[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

α-Glucosidases are among the most important carbohydrate-splitting enzymes. They catalyze the hydrolysis of α-glucosidic linkages. Their substrates are—depending on their specificity—oligo- and polysaccharides. Microbial inhibitors of α-amylases and other mammalian intestinal carbohydrate-splitting enzymes studied during the last few years have aroused medical interest in the treatment of metabolic diseases such as diabetes. Moreover, they extend the spectrum of microbial secondary metabolites which comprises an enormous variety of structures. They also contribute considerably to a better understanding of the mechanism of action of α-glucosidases. These inhibitors belong to different classes of substances. Those studied most thoroughly are microbial α-glucosidase inhibitors which are members of a homologous series of pseudooligosaccharides of the general formula *(4)*. They all have a core in common which is essential for their inhibitory action, a pseudodisaccharide residue consisting of an unsaturated cyclitol unit, and a 4-amino-4,6-dideoxyglucose unit. The—in many respects—most interesting representative of this homologous series is acarbose *(5)*, a pseudotetrasaccharide exhibiting a very pronounced inhibitory effect on intestinal α-glucosidases such as sucrase, maltase and glucoamylase. The present paper will review this new field of microbial α-glucosidase inhibitors which has been studied with particular intensity during the past ten years.

## 1. Introduction

Natural enzyme inhibitors, especially inhibitors of hydrolases are found in many plants and animals as well as in bacteria and fungi. Some of them have been known for a long time. The ubiquitous protease inhibitors[1-4] have been studied most thoroughly with respect to their structure, function and mechanism of action. Publications on protease inhibitors of the serum[5,6] already appeared at the end of last century. Reports on natural α-glucosidase inhibitors date back to the early thirties of this century. In 1933 *Chrzaszcz* and *Janicki*[7] described a protein-like substance

practically insoluble in water which is found in the malts of various kinds of grain, especially in buckwheat malts. Because of its malt α-amylase inactivating properties this substance was called "sistoamylase". Later *Kneen* and *Sandstedt*[8,9] described water-soluble preparations with protein character and α-amylase inhibiting properties which they had isolated from rye and wheat germ flour. These substances were potent inhibitors of α-amylases from human saliva and bacteria. Pancreatic amylase, *e.g.* porcine, was inhibited to a lesser degree. Potent inhibitors of α-amylase were later discovered also in other plants, *e.g.* bean seeds[10-14] and the tuberous root of Colocasia[15], and found to be proteins and glycoproteins. The α-amylase inhibitors of plant origin, especially those from wheat, have been studied very closely by several investigators[16] since about 1970. By means of special methods of isolation using aqueous-alcoholic solutions at acidic pH, preparations were obtained from wheat germ flour or preferably glutens, which proved to be potent inhibitors of both salivary and pancreatic α-amylases[17,18]. Such a preparation was even able to inhibit pancreatic amylase *in vivo*. As was demonstrated by starch loading tests carried out with rats, dogs, and healthy volunteers, the inhibitor, administered orally, reduces the postprandial hyperglycaemia[*] and hyperinsulinaemia dose-dependently[17,19]. These findings provided experimental evidence for a new concept developed by *Puls*[19,20] for the treatment of metabolic disorders such as diabetes mellitus, adiposity and hyperlipoproteinaemia, Type IV, and gave rise to a screening for α-glucosidase inhibitors of microbial origin in the course of which new interesting active substances were isolated from microorganisms of the order *Actinomycetales*[21]. Among these were inhibitors of α-glucosidases found to be members of a homologous series of complex oligosaccharides (pseudooligosaccharides)[22,23].

The wide distribution of microbial α-amylase inhibitors, especially in organisms of the genus *Streptomyces*, has been confirmed by various teams of investigators during the past few years (cf. Table 4). We have found that new methods for microbiological screening tests will lead to new substance classes with interesting biochemical properties so that the spectrum of microbial metabolites, showing a great structural variety and so far exhibiting predominantly antibiotic effects, is extended. Systematic studies which have been carried out by the *Umezawa* group[24] since the second half of the sixties have yielded similar results. These investigators searched and found above all microbial inhibitors of proteases, esterases, aminopeptidases and enzymes involved in the biosynthesis of epinephrine[24-26].

α-Glucosidases are hydrolases that occur ubiquitously in bacteria, fungi, plants and animals. By definition, they catalyze the hydrolysis of α-glucosidic linkages. Depending on their specificity, their substrates are oligo- and polysaccharides.

At present, there is practically no evidence that the microbial inhibitors of α-glucosidases dealt with in this paper have a biological function. However, on the one hand they are of pharmaceutical interest, on the other they contribute decisively to a better understanding of the mechanism of action of α-glucosidases. The inhibitors of this type have so far been studied mainly with regard to the effect on α-glucosidases occurring in the intestinal tract of mammals. Our interest, therefore, centers on α-amylase produced in the pancreas and secreted into the small intestine and also on oligo- and disaccharidases located in the brush border of the small intestine. These glucoamylase, maltase, isomaltase, and sucrase activities may function as reaction partners of microbial α-glucosidase inhibitors.

## 2. Amylases and Enzymatic Starch Hydrolysis

The natural substrate of the amylases is starch, the main storage form of carbohydrate in most of the higher plants. Detailed reviews have been published[27-29] on its structure, which was determined especially by enzymatic methods, and on its metabolism. Starch is composed of two polysaccharides, amylose and amylopectin. Partial molecular structures of these two constituents (generally 15—25% amylose and 75—85% amylopectin) are shown in Figure 1 and their most important properties are listed in Table 1.

Table 1. Properties of starch-type polysaccharides, according to *Manners* [28].

| Property | Amylose | Amylopectin |
|---|---|---|
| General structure | essentially unbranched | branched |
| Average chain length [a] | ≈ $10^3$ | 20—25 |
| Degree of polymerization [a] | ≈ $10^3$ | $10^4$—$10^5$ |
| Conversion into maltose [%] | | |
| a) with α-amylase | ≈ 100 | ≈ 90 |
| b) with β-amylase | 70—100 | ≈ 55 |
| c) with β-amylase after pretreatment with a debranching enzyme [b] | 100 | ≈ 75 |

[a] D-glucose residues. [b] Yeast isoamylase.

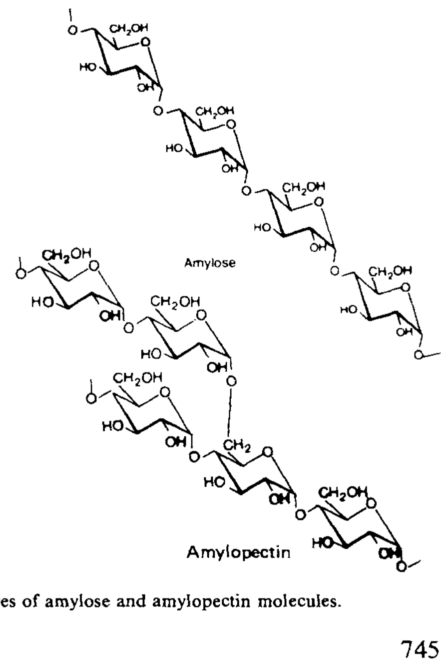

Fig. 1. Partial structures of amylose and amylopectin molecules.

---

[*] postprandial = occurring after a meal; hyperglycaemia = excessively increased blood glucose values; hyperinsulinaemia = excessively increased blood insulin values; adiposity = obesity.

Amylose is a linear (1→4)-α-glucan consisting of helically arranged chains of polysaccharides with an average degree of polymerization of about 1000 glucose residues. Amylopectin, on the other hand, is a branched polysaccharide the molecules of which have a much higher molecular weight (up to about $10^7$). The molecules have a treelike structure[30] consisting of two types of (1→4)-α-glucan chains with an average length of 20 and of over 50 D-glucose residues, resp. that are connected by α(1→6)-linkages. A molecule of amylopectin can contain up to 100000 D-glucose residues and 4000—5000 inter-chain α(1→6)-glucosidic linkages (and the same number of individual chains) (Figs. 1 and 2)[*].

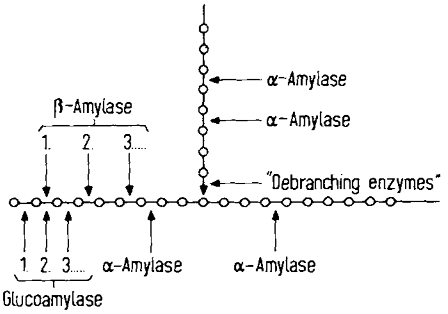

Fig. 2. Sites of action of various starch-degrading enzymes (partial structure of an amylopectin molecule).

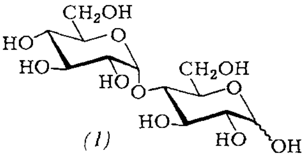
α-Amylases (1,4-α-D-glucan glucanohydrolases, EC 3.2.1.1) attack the substrate molecule—as can be seen schematically in Figure 2 for the example of amylopectin—from inside acting as "endoenzymes", and split off maltose residues released in the α-configuration. Amylose is thus degraded mainly to maltose *(1)* by up to 100%, amylopectin by up to about 90%. In addition, slight amounts of maltotriose and glucose may result.



*(1)*

When amylopectin is degraded, so called α-dextrins[28] (see diagram in Fig. 3) are also formed which still contain the original inter-chain α(1→6)-glucosidic linkages not cleaved by α-amylases.

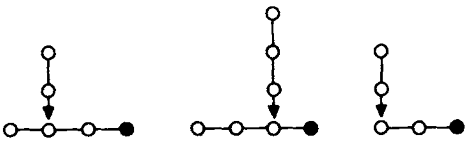


Fig. 3. Typical α-dextrin structures according to *Manners* [28]. ○: α(1→4)-linked D-glucose residue; ↓: α(1→6)-inter-chain linkage; ●: free reducing group.

β-Amylases (1,4-α-D-glucan maltohydrolases, EC 3.2.1.2) are found preferentially in plants but are not produced by the mammalian organism. They act as "exoenzymes", splitting successive maltose residues (which due to inversion are released in the β-configuration) from amylose and amylopectin from the non-reducing end (cf. Fig. 2). The degradation of amylose is sometimes complete only after pretreatment with a so-called "debranching enzyme" (*e.g.* microbial isoamylase, glycogen 6-glucanohydrolase, EC 3.2.1.68) (cf. Table 1)[28] due to the presence of a very small number of branch points. The β-amylolytic degradation of amylopectin, on the other hand, remains incomplete even under these conditions (cf. Table 1), since the outermost branching sites can be neither split nor bypassed[27-29].

Glucoamylases (1,4-α-D-glucan glucohydrolase, EC 3.2.1.3) also known as exo-α-(1→4)-glucosidases, amyloglucosidases or γ-amylases are found preferentially in microorganisms but also occur as enzyme complexes (see Section 3) in the intestinal wall of mammals. They successively split off glucose residues from the non-reducing end (Fig. 2).

The "debranching enzymes" which split α(1→6)-glucosidic linkages in the native amylopectin molecule, occur preferentially in microorganisms and plants. Corresponding enzymes of the mammalian organisms are not active in the intestinal tract. Here the intestinal oligo- and disaccharidases (Section 3) act on the α-(1→6)-glucosidic linkages of degradation products of amylopectin.

The α-amylases, the mode of action of which has already been described, are the starch-degrading enzymes investigated most thoroughly. Highly purified preparations have been obtained from a great variety of microbes, plants and animals and have been biochemically characterized. The main sources for animal α-amylases are pancreatic juice and saliva. Different forms (isoenzymes) of both human salivary amylase[31] of molecular weights between 50000 and 53000 and pancreatic amylase of hogs[32] of molecular weights between 51000 and 54000 have been

Principle of determination according to *Bernfield* [33]:

1) Hydrolysis of soluble starch, 5 min at 35°C, pH 6.9 (0.02 M sodium glycerophosphate buffer, 0.001 M $CaCl_2$).
2) Determination of the reducing groups formed by reaction with 3,5-dinitrosalicylic acid reagent and measurement of the extinction at 540 nm.

Definition of amylase unit (AU):
1 AU = 1 μVal maltose/min.

Definition of amylase-inhibitor unit AIU:
1 AIU: amount of inhibitor which after previous incubation with the enzyme inhibits 2 AU by 50%.

Scheme 1. Activity of α-amylase.

Principle of determination according to F.I.P. [34]; modification of the test according to *Willstätter* (*R. Willstätter, G. Schudel*, Ber. Dtsch. Chem. Ges. *51*, 780 (1918)):

1) Hydrolysis of soluble starch at pH 6.8 and 25°C (in the presence of NaCl).
2) Titration of the reducing groups with iodine in alkaline solution.

Definition of amylase unit according to F.I.P. (FIP-AU):
1 FIP-AU: that amount of enzyme which, under the test conditions, splits starch at such an initial rate that 1 micro-equivalent of glucosidic linkages is hydrolyzed per minute.

Definition of "F.I.P. amylase inhibitor unit (FIP-AIU)":
1 FIP-AIU: that amount of inhibitor which after previous incubation with the enzyme inhibits 2 FIP-AU by 50%.

Scheme 2. Activity of α-amylase.

---

[*] One amylopectin molecule contains only 1 reducing glucose residue.

described. Partial sequences of the polypeptide chain, made up of approximately 470 amino acid residues, are known.

Various methods are used to determine the activity of α-amylases and their inhibitors. We refer to two test methods which are briefly described in Schemes 1 and 2.

The first of these methods introduced by *Bernfeld*[33] is used frequently, though in many modified forms. The second method, the so-called "FIP-Test" is recommended by the "Commission on Enzymes" of the Fédération Internationale Pharmaceutique for the determination of activity of pancreatic α-amylase[34]. The inhibitory tests outlined in Schemes 1 and 2 have been described in detail[21]. Other tests, especially to determine the activity of α-amylase inhibitors of plant origin, have been described in detail by *Whitaker*[35] and *Marshall*[36].

## 3. Intestinal Oligo- and Disaccharidases, Their Substrates and the Determination of Their Activity

While after food intake pancreatic α-amylase is secreted by the pancreas into the duodenum and—apart from a partial adsorption at the intestinal wall—exerts its effect (the initiation of intestinal starch digestion) in the lumen of the small intestine, the intestinal oligo- and disaccharidases are fixed components of the cell membrane of the "brush border region" of the wall of the small intestine. These glycoside hydrolases of the intestinal wall, of which only slight amounts are released into the intestinal lumen, act mainly in a membrane-bound form. Their properties and mode of action and the molecular mechanism of action of sucrase are described in detail in a review by *Semenza*[37]. These enzymes are listed in Table 2.

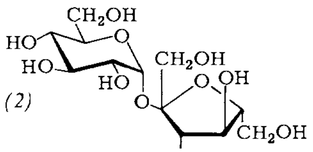
Table 2. Oligo- and disaccharidases of the small intestine [37].

| Designation | EC number |
|---|---|
| 1 Maltases-glucoamylases (γ-amylases) | 3.2.1.20 or 3.2.1.3. |
| 2 Sucrase-maltase | 3.2.1.48 or 3.2.1.20 |
| 3 Isomaltase-maltase | 3.2.1.10 or 3.2.1.20 |
| 4 α-Limit dextrinase [40] | |
| 5 Trehalase | 3.2.1.28 |
| 6 Lactase and hetero-β-glucosidase (phlorizine hydrolase) | 3.2.1.23 and 3.2.1.62 |

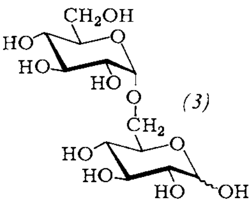
Trehalase, lactase and hetero-β-glucosidase have been included for the sake of completeness.

Like the other membraneous glucosidases, maltase-glucoamylases—also known as γ-amylases—can be obtained in a homogeneous form by solubilization of an intestinal mucosa preparation with papain and subsequent chromatography. A preparation of human origin is a glycoprotein with a carbohydrate content of 32—38% and a molecular weight of the protein portion of about 220000[38]. Substrates are maltose *(1)*, maltotriose and higher α(1→4)-glucans including amylose and amylopectin, *viz.* starch. By cleaving linkages from the non-reducing end (cf. Fig. 2) glucose in the α-pyranose form is produced. The process of splitting is the faster, the smaller the substrate molecule—in contrast to the splitting of poly- and oligosaccharides by pancreatic α-amylase which is already slightly inhibited by maltose. Maltase-glucoamylases thus improve the effectivity of pancreatic amylase. These enzymes are competitively inhibited by 2-amino-2-hydroxymethyl-1,3-propanediol (tris).

The sucrase-isomaltase complex, which among the intestinal oligo- and disaccharidases has been characterized in greatest detail, can be obtained by solubilizing the mucosa material of the small intestine with either proteases (papain) or detergents (Triton X-100, sodium dodecylsulfate (SDS)). This complex is a glycoprotein with a carbohydrate content of 15% and a molecular weight for the protein component of about 220000. The complex can be split into 2 sub-units by various methods: into a sucrase-maltase and an isomaltase-maltase. Both units have an active center with sucrase and maltase specificity and with isomaltase and maltase specificity, respectively. The sucrase-isomaltase complex from the mucosa of human small intestine can be split using β-mercaptoethanol and urea[39]. The 2 sub-units are very much alike: their amino acid composition is similar. Both liberate glucose in the α-pyranose form. The sucrase-maltase complex splits sucrose *(2)*, maltose *(1)*, maltotriose and higher oligosaccharides. Substrates for the isomaltase-maltase sub-unit are, besides maltose *(1)* and isomaltose *(3)*, other oligosaccharides with α(1→6)-glucosidic linkages such as isomaltulose, isomaltotriose, α-dextrins (cf. Fig. 3) and higher limit dextrins.



*(2)*



*(3)*

Both sub-units are competitively inhibited by tris. According to recent studies by *Marshall et al.*[40], a further α-glucosidase activity of the small intestinal wall, designated limit dextrinase, which splits α(1→6)-glucosidic linkages is required in addition to the isomaltase-maltase complex.

The function of the intestinal α-glucosidases described in this section is, on the one hand, the further degradation of oligosaccharides (maltose, maltotriose, α-dextrins, isomaltose *etc.*), that are produced by pancreatic α-amylase from starch, to absorbable glucose which is introduced into the intermediary metabolism. On the other hand, they also break down oligosaccharides such as sucrose ingested with the food to absorbable monosaccharides such as glucose and fructose. *In vivo,* these processes are rather complex and have not yet been clarified in all detail. A recent review by *Semenza*[41] presents a critical evaluation of the present state of knowledge and of open questions in this field.

When determining the activities of intestinal oligo- and disaccharidases and their inhibitors, mostly enzyme preparations obtained by solubilizing mucosa of the small intestine *e.g.* from hogs[42] are used. The specificity of the test applied depends on the substrate (sucrose[23,43b], maltose[44], isomaltose[44], soluble starch[44], "dextrin" (obtained by the exhaustive degradation of glycogen with pancreatic amylase)[45,46]). The methods of determining the activity of sucrase and its inhibition are outlined in Scheme 3[43b].

Principle of determination [43b]:

1) Hydrolysis of 0.2 M sucrose, 20 min at 37 °C, pH 6.25 (0.1 M sodium maleinate buffer).
2) Determination of released glucose, using glucose dehydrogenase reagent (in 0.5 M trisbuffer, pH 7.6), 30 min at 37 °C, and determination of absorption at 340 nm.

Principle of sucrase inhibition test [43b]:
Determination of residual activity after 10 minutes of pre-incubation of the enzyme with the inhibitor at 37 °C, pH 6.25.

Scheme 3. Activity of sucrase.

## 4. Survey of the Occurrence and Composition of Microbial α-Glucosidase Inhibitors

In a screening for microbial α-glucosidase inhibitors started about 10 years ago, inhibitory activities, especially against pancreatic α-amylase and small intestinal sucrase from hogs, were found in almost all genera of the order *Actinomycetales*, of which many strains were available[21,25]. These inhibitors occur especially in strains of the family *Actinoplanaceae*[*], above all of the genera *Actinoplanes*, *Ampullariella* and *Streptosporangium*. Table 3 presents some of the results of these studies[25]. The relatively high frequency of activities for *Actinoplanes* and *Streptosporangium* is striking.

Table 3. Occurrence of α-amylase and sucrase inhibitors in strains of various genera [25].

| Genus | No. of strains tested | Strains active against amylase from hog pancreas | Strains active against sucrase from small intestine of hogs |
|---|---|---|---|
| *Streptomyces* | 85 | 3 | 2 |
| *Actinoplanes* | 220 | 43 | 24 |
| *Streptosporangium* | 161 | 18 | 24 |

Some strains showed effects on individual α-glucosidases, the others were effective against several enzyme activities. The preparation of α-amylase inhibitors resulted in two different groups of active substances[23,25]:

a) inhibitors of a polypeptide character which are heat-labile, hard to dialyze if at all, and can be inactivated by treatment with trypsin, urea or β-mercaptoethanol.
b) inhibitors which are complex oligosaccharides and have been studied most thoroughly (see Section 5). They are stable to heat (at pH 7), acid (up to pH 2), alkali (up to pH 12) and some are dialyzable. Besides α-amylase inhibitors this group includes inhibitors of oligo- and disaccharidases of the mammalian intestinal tract.

The occurrence of α-amylase inhibitors, which will be described in detail in the following sections, has during the past few years been confirmed by various groups of investigators especially for *Streptomycetes sp.* (Table 4).

Table 4. Occurrence and composition of microbial inhibitors of mammalian α-glucosidases (arranged in chronological order of publication).

| Occurrence | Composition | Specificity | Ref. |
|---|---|---|---|
| Actinomycetes of various genera | proteins, complex oligosaccharides | salivary and pancreatic α-amylases, glucoamylases, intestinal oligo- and disaccharidases | [21, 23] |
| *Streptomyces flavochromogenes* | carbohydrate-containing polypeptides (inhibitors A,B,B′,C) | salivary, pancreatic amylase; bacterial α-amylases, *Rhizopus* glucoamylase | [47–50] |
| *Streptomyces diastaticus var. amylostaticus* | N-containing oligosaccharide (amylostatin, S-AI) | salivary, pancreatic amylase;<br>microbial α-amylases, malt amylase, *Rhizopus* amylase | [51–53] |
| *Streptomyces fradiae* | acidic polypeptide, mol. weight ≈6500 (inhibitor X2) | α-amylases | [54] |
| Bacilli, *Streptomyces sp.* | nojirimycin,<br>1-deoxynojirimycin | intestinal mammalian oligo- and disaccharidases;<br>plant and fungal β-glucosidases | [44, 55–63] |
| *Streptomyces sp.* | glucose-containing oligosaccharide, mol. weight ≈600 | salivary α-amylase, glucoamylase | [64] |
| *Streptomyces calidus* | glycopeptide, rich in lysin and glucose | α-amylases, maltase and sucrase of digestive tract | [65] |
| *Streptomyces tendae* | polypeptide, mol. weight ≈7400 | animal α-amylases | [66, 67] |
| *Streptomyces sp.* | N-containing oligo-saccharides ("amino sugars") | α-amylase, sucrase, maltase | [68] |
| *Streptomyces calvus* | N-containing oligosaccharides, mol. weight 950–1050, 650–700 (inhibitors TAI-A and TAI-B, resp.) | microbial and mammalian α-amylases, microbial glucoamylase | [69] |
| *Streptomyces dimorphogenes* | "amino sugar derivatives" (trestatins A, B, C) | α-amylase | [70] |
| *Streptomyces griseosporeus* | proteins, mol. weight ≈8500 (inhibitors Haim I and II) | pancreatic α-amylase | [71,72a] |
| *Streptomyces myxogenes* | weakly basic oligosaccharides (SF-1130-$X_1$, -$X_2$, -$X_3$) | intestinal mammalian α-glucosidase and sucrase | [72b] |

## 5. Acarbose and Homologous Pseudo-oligosaccharidic α-Glucosidase Inhibitors

As mentioned in Section 4 a totally new substance class of secondary metabolites marked by a very pronounced inhibitory effect mainly against intestinal α-glucosidases of mammals has been found in culture filtrates[21–23]. These inhibitors are members of a homologous series of pseudo-oligosaccharides the general formula *(4)* of which is presented in Table 5.

A characteristic of these inhibitors is that they have a core essential for their inhibitory action composed of

---

[*] These strains, until that date hardly exposed to testing for secondary metabolite formation, were isolated by *A. Henssen* and *D. Schäfer*, Fachbereich Botanik, Universität Marburg (Germany).

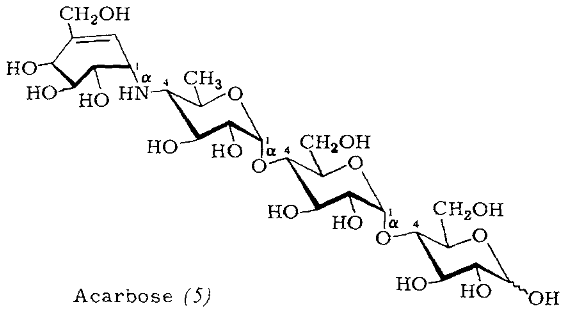
[a] Predominant isomer with $m+n=3$. [b] Predominant isomer with $m+n=4$. [c] Predominant isomer with $m+n=5$.

a cyclitol unit (hydroxymethylconduritol residue) and a 4-amino-4,6-dideoxy-D-glucopyranose unit (4-amino-4-deoxy-D-chinovose residue). This core is linked to a varying number of glucose residues. The linkage of the individual elements is an α(1→4)-linkage as in the natural substrates (*e.g.* amylose, maltose) of the α-glucosidases. In the cyclitol unit the arrangement of the substituents is stereochemically similar to that in an α-D-glucopyranose unit.

Individual members of this homologous series have been isolated either in a homogeneous form or in the form of hardly separable isomer mixtures and been characterized in detail (Table 5). The substance investigated most thoroughly—both with regard to its microbiology[25], chemistry, biochemistry[43b,46,73] and pharmacology[45,74,100] and to its clinical use[75,76]—is component 3 *(5)*. It was given the test designation BAYg5421 and the generic name acarbose[45].



Acarbose *(5)*

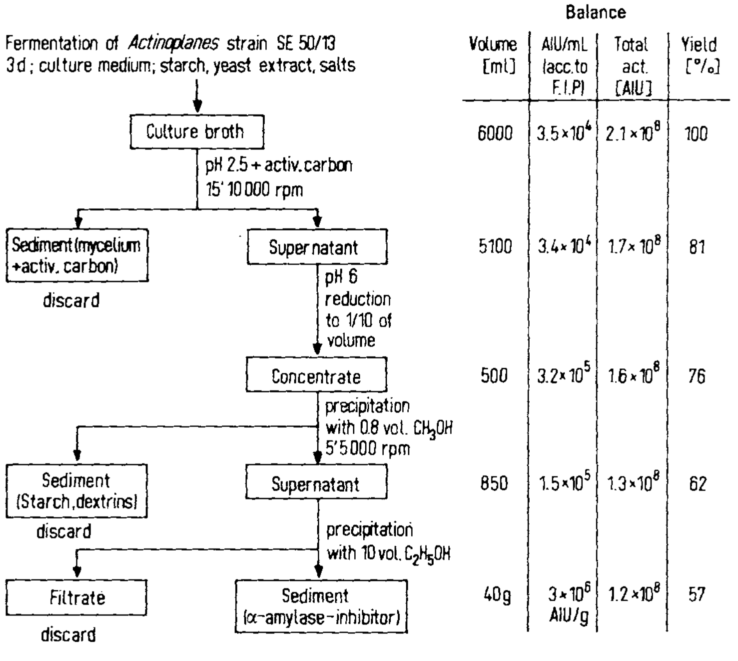
Pseudo-oligosaccharidic α-glucosidase inhibitors were first detected in culture broths of the *Actinoplanes* strain SE 50[*]. Inhibitors of both α-amylase from porcine pancreas and of a sucrase preparation from the small intestinal mucosa of hogs were found. The inhibitory activities of the culture broths against α-amylase or sucrase can vary widely, depending on the conditions of cultivation[25].

As can be seen from Table 6, the composition of the carbon source of the culture medium is of decisive importance for the inhibitory activities produced. Media containing glucose and maltose will yield especially high titers of sucrase inhibition while media containing starch will result in a very high content of α-amylase inhibitors[25]. An amplification of this trend was achieved by the selection of suitable natural variants of the SE 50 strain. In a starch-containing medium, sub-strain SE 50/13 produces amylase inhibitor titers of around 35000 FIP-AIU/mL and only very low sucrase inhibitor activities. Strain SE 50/110, on the other hand, produces sucrase inhibitor titers of around 60 SIU/mL in a maltose-containing medium while producing an amylase inhibitor titer of only about 760 FIP-AIU/mL[25].

Table 6. Influence of carbon source in the medium on inhibitor production of the *Actinoplanes* Strain SE 50 [25].

| Carbon source | Titer after 4 d | | |
|---|---|---|---|
| | SIU/L | AIU/mL | $\frac{\text{SIU}}{\text{AIU}} \times 10^{-3}$ |
| glycerol 3% | 160 | 100 | 1,6 |
| galactose 3% | 1100 | 100 | 11 |
| maltose 3% | 5500 | 1000 | 5,5 |
| cellobiose 3% | 1300 | 220 | 6 |
| glycerol 1% + glucose 2% | 2700 | 120 | 22 |
| galactose 1% + glucose 2% | 2700 | 120 | 22 |
| maltose 1% + glucose 2% | 6600 | 200 | 33 |
| cellobiose 1% + glucose 2% | 2200 | 105 | 21 |

The diagram in Figure 4 shows how a purified inhibitor mixture is obtained which consists mainly of such members of the homologous series of the general formula *(4)* with a very pronounced inhibitory activity against α-amylase. The actinoplanes strain SE 50/13 was cultured in a starch-containing medium. The preparation obtained by fractional precipitation of the culture filtrate with methanol and ethanol inhibits α-amylases from human saliva and pancreas and from hog pancreas to a high degree[25]. This substance (designated BAYe 4609) served, ***inter alia***, as a standard preparation for pharmacological[45,77] and clinical[78] studies. The molecular weight range of this pre-



Balance

| Volume [ml] | AIU/mL (acc. to F.I.P) | Total act. [AIU] | Yield [%] |
|---|---|---|---|
| 6000 | $3.5\times10^4$ | $2.1\times10^8$ | 100 |
| 5100 | $3.4\times10^4$ | $1.7\times10^8$ | 81 |
| 500 | $3.2\times10^5$ | $1.6\times10^8$ | 76 |
| 850 | $1.5\times10^5$ | $1.3\times10^8$ | 62 |
| 40g | $3\times10^6$ AIU/g | $1.2\times10^8$ | 57 |

Fig. 4. Microbiological production of an α-amylase inhibitor standard preparation (BAYe4609) [21, 85].

---

[*] This strain was isolated by *A. Henssen* and *D. Schäfer*, Fachbereich Botanik, Universität Marburg (Germany).

paration is determined by the conditions of precipitation (soluble in 50% $CH_3OH$, precipitable from a mixture of $C_2H_5OH$, $CH_3OH$ and $H_2O$ (84 : 8 : 8)).

The analysis of the oligomer distribution of this mixture consisting of oligosaccharides with inhibitory activity and inert sugars by gel chromatography (using Bio-Gel P-6)[22] resulted in a separation into two fractions with inhibitory activity with different molecular weight ranges[25,46].

The high-molecular fraction with an estimated molecular weight range of 6000 to 8000 has not been examined thoroughly yet. Rechromatography on Bio-Gel P-2 of the low-molecular weight fraction indicated a clear-cut maximum of inhibitory activity for the elution volume of a maltononaose (molecular weight 1477). This portion was shown to consist mainly of a mixture of isomers of component 7 (cf. *(4)*: ($m+n=6$)) and component 8 ($m+n=7$). In addition, it contains small amounts of components 3 to 6 ($m+n=2$, 3, 4, 5)[22]. By re-chromatography of this fraction, using strongly acidic ion exchangers (Dowex 50 W), a preparation of the inhibitor mixture was obtained which is largely free from inert carbohydrates and exhibits a specific activity of $15 \times 10^6$ FIP-AIU/g. This corresponds to about a 5-fold enrichment of the initial material (BAYe4609)[46].

When the crude mixture of this α-amylase inhibitor (BAYe4609) is subjected to a mild acid hydrolysis with 0.5 N hydrochloric acid at 100 °C, a gradual decrease in α-amylase inhibitory activity occurs in the course of hydrolysis which is accompanied by a corresponding increase in sucrase inhibitory activity[23,43b,80]. This sucrase inhibitory activity reaches its maximum about 45 min after the start of hydrolysis after which it slowly falls to minimum values which can be interpreted as a total disintegration of the inhibitors. It was shown by thin-layer chromatography and high-pressure liquid chromatography that with consistent increase of cleavage of glucose residues the whole homologous series of inhibitory components is passed through[43b] in the course of hydrolysis. A solution with a high sucrase-inhibiting and minimal α-amylase-inhibiting activity obtained after one hour of hydrolysis has been studied closely[46].

A separation of the components with inhibitory activity from the other products of hydrolysis (mainly glucose and maltose) was achieved by adsorption on activated carbon and fractional desorption with increasing concentrations of ethanol. Four different pure components (1—4: component 1 from fraction 1, component 2 from fraction 2, *etc.*) were obtained by means of partition chromatography using cellulose (cf. Fig. 5) and after further purification by gel chromatography using Sephadex G-15. The individual components showed different inhibitory effects against sucrase, that of component 1 being very weak. Components 2—4 can—as is shown in Figure 6 by the example of component 3 (acarbose *(5)*)—be converted into the component one unit smaller by further acid hydrolysis, *i.e.* cleavage of one additional glucose residue. The end product of acid hydrolysis, component 1 *(8)*, cannot be transformed further under these conditions[23,46,79].

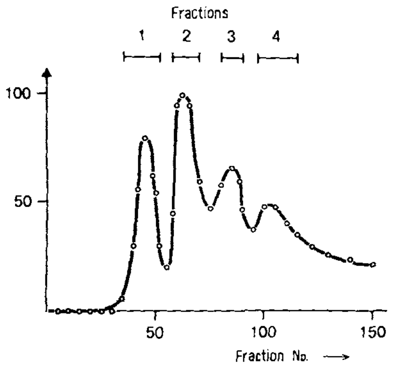


Fig. 5. Chromatography (on cellulose) of a hydrolyzate of the α-amylase inhibitor preparation BAYe4609 [46]. Solvent: pyridine/ethyl acetate/acetic acid/water (36/36/7/21); column: 1.6 × 185 cm; flow rate: 25 mL/h; fractions of 8 mL. Ordinate: Percentage of sucrase inhibition by 10 µL of each fraction.

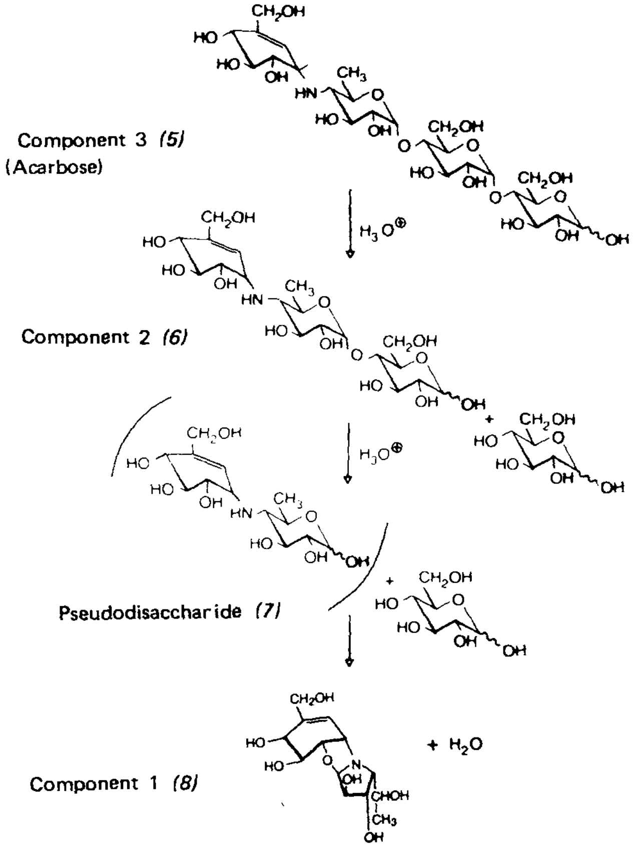

Fig. 6. Acid hydrolysis of component 3 (acarbose) *(5)* [46].

The complete acid hydrolysis of 100 g of the crude preparation BAYe4609 will yield about 500 mg of component 1 *(8)*. The yield of higher components produced after incomplete hydrolysis is within the same range[46]. Component 1 *(8)* is a tricyclic compound, whose structure was determined by degradation reactions, derivatization and spectroscopic analysis[46,73,79]. *(8)* is formed in the following way: after one glucose residue is split off from component 2 *(6)*, the amino sugar *(7)* released is not stable in the pyranose form. It is well known that 4-aminopyranoses such as *(7)* undergo a rearrangement to a pyrrolidine form and readily split off water in acid solution (Fig. 7). The un-

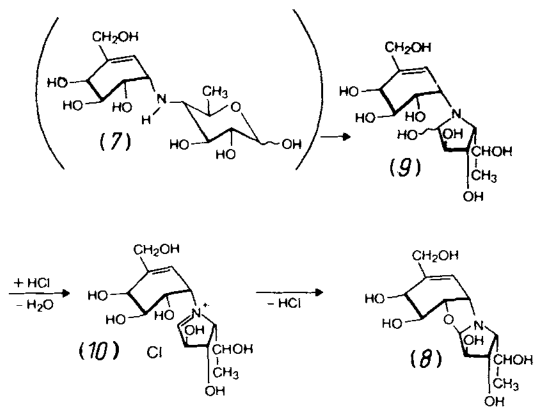

Fig. 7. Conversion of the unstable pseudodisaccharide *(7)* into a pyrrolidine derivative *(9)* and its dehydration to component 1 *(8)*.

saturated compound *(10)* is stabilized by the addition of an adjacent hydroxyl group of the cyclitol unit to the C=N double bond. The non-crystalline tricyclic product of condensation *(8)* is very easily reduced with $NaBH_4$. As a result, the 1,3-oxazolidine ring opens (Fig. 8). The resulting aminocyclitol *(11)* is ineffective against α-amylase and sucrase although the cyclitol unit of the molecule has remained unchanged compared to the highly active components 2—6 of the homologous series. This means that the unsaturated hydroxymethylconduritol unit *alone* will not produce the desired inhibitory effect. The product *(11)* obtained by $NaBH_4$-reduction can be split into the cyclitol unit and the pyrrolidine unit by hydrogenolysis at a platinum contact. The main products thus obtained are validatol *(12)*[81] and the derivative *(13)*[73]. Validatol *(12)* was also obtained by degrading the antibiotic validamycin A *(14)*[81,82].

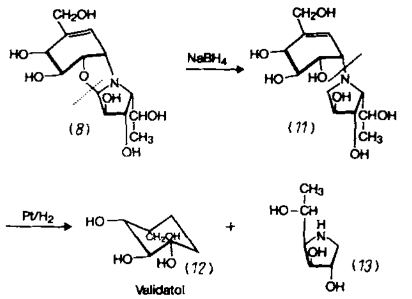

Fig. 8. Reduction of component 1 *(8)* with $NaBH_4$ to an aminocyclitol *(11)* and its catalytic hydrogenation[73].

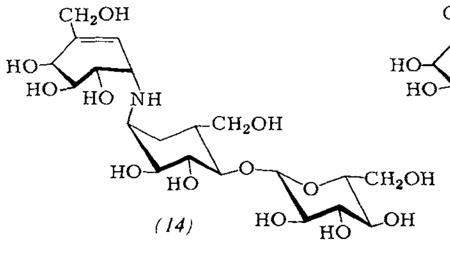
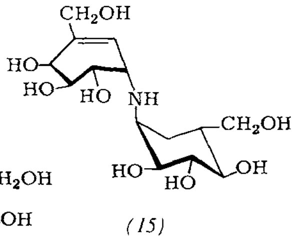
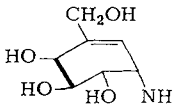


(14)



(15)

Neither validamycin A *(14)* nor validoxylamine A *(15)*[83] inhibit α-amylase or sucrase, although, as constituents of the molecule, they contain the unsaturated hydroxymethylconduritol unit. Valienamine *(16)*[84] obtained by the microbial degradation of validamycin A *(14)* with *Pseudomonas maltophila* proved to be a weak inhibitor of sucrase[73][*].



(16)

By selecting suitable strains and optimizing culture conditions the individual components of the homologous series of pseudo-oligosaccharidic α-glucosidase inhibitors can be obtained much more easily and in higher quantities[25,85,86] than by the acid hydrolysis of the preparation BAY e 4609 described above. The use of glucose or maltose in the culture medium of the *Actinoplanes* strain SE 50/110[86] will result in high sucrase inhibitor titers in the culture broths from which the inhibitors can be adsorbed by activated carbon.

Desorption with successively increasing concentrations of ethanol led to a crude preparation which was purified further by ion-exchange chromatography[46] (Fig. 9). Fractions C to E are partly identical with components 2—4 (obtained by acid hydrolysis of BAY e 4609). The main fraction, approximately 80% of the sucrase inhibitors obtained from this fermentation (Fraction D, Fig. 9), proved to be identical with component 3 (acarbose) *(5)*. The yield of acarbose from fermentation was around 600 mg/L of culture broth. Fraction E was found to have one glucose unit less and identified as component 2. Fraction C has the same composition as component 4 and fractions A and B contain isomeric mixtures of the higher components 6 and 5.

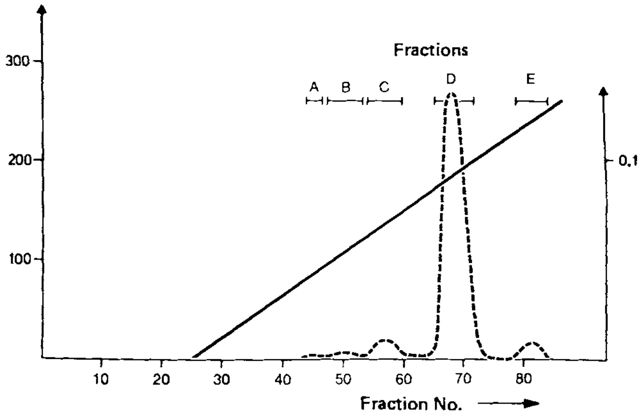


Fig. 9. Ion exchange chromatography of a crude sucrase-inhibitor preparation of the strain SE 50/110 [46]. Dowex 50 W×4H® (200—400 mesh); column: 0.9×60 cm; elution with $10^{-3}$ N HCl up to fraction No. 20; then linear gradient with increasing NaCl concentrations in $10^{-3}$ N HCl; flow rate: 30 mL/h, fractions of 7.5 mL; Left ordinate: SIU/mL (---); Right ordinate: NaCl concentration (M) (——).

Further information about the constituents essential for α-glucosidase inhibition in acarbose and in the other components was provided by hydrogenolysis with $Pt/H_2$, during which the cyclitol residue can be removed by cleaving the C—N bond in allyl position to the double bond without changing the remaining molecule[73]. The basic trisac-

---

[*] For inhibition of other α-glucosidases see [84b].

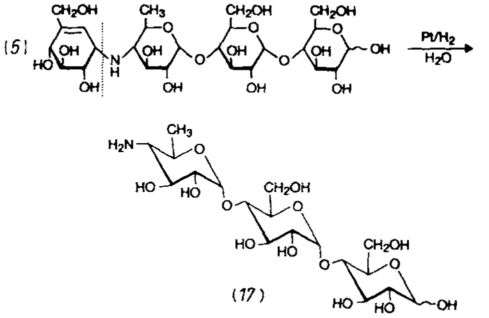

Fig. 10. Hydrogenolytic cleavage of the basic trisaccharide *(17)* during the catalytic hydrogenation of acarbose *(5)* [73].

charide obtained in this way *(17)*[*] has no inhibitory activity against α-amylase or sucrase, which means that the amino sugar *alone* is not essential for the inhibitory effect. As previously mentioned, the unsaturated cyclitol residue alone does not suffice for the inhibitory effect, either.

This leads us to the conclusion that the pseudodisaccharide unit composed of both constituents is essential for the effect. The splitting of the C—N bond in allyl position to the double bond is only one, though preferred, possibility of molecular reaction. The two C—O bonds in allyl position to the double bond are easy to split by hydrogenolysis, too (Fig. 11). Moreover, the double bond is saturated

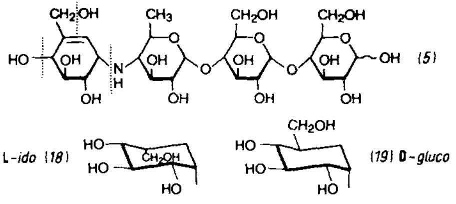

Fig. 11. Possible reactions of acarbose *(5)* during catalytic hydrogenation with maintenance of the pseudotetrasaccharide structure [73].

during hydrogenation. This will result in the formation of two diastereomeric products with an L-*ido* *(18)* or D-*gluco*-configuration *(19)*. Since there may be several of these reactions at the same time, it is easy to imagine how complex a product mixture is obtained by catalytic hydrogenation of acarbose *(5)*. The hydrogenation mixture was first separated into basic and non-basic constituents by fractionation on cation exchangers in the $H^{\oplus}$ form. Each of the two main fractions was then purified further by chromatography.

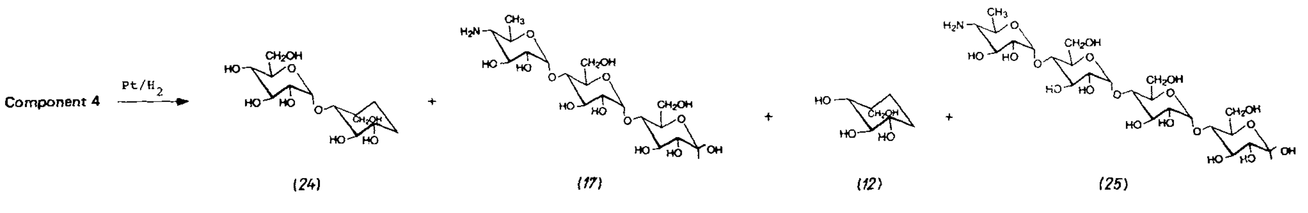

Fig. 13. Catalytic hydrogenation of component 4 [73].

The basic reaction products (Fig. 12) isolated were, apart from the ineffective trisaccharide *(17)* mentioned, two products showing a pseudotetrasaccharide structure which had resulted from simple saturation of the double bond in the cyclitol unit. The compound *(20)* with an L-*ido*-configuration in the cyclitol unit had no inhibitory effect against either α-amylase or sucrase any more, while the other compound with a D-*gluco*-configuration in the cyclitol unit was ineffective against α-amylase but had a very pronounced effect on sucrase. A further product of hydrogenation *(22)* in which the primary hydroxyl group of the cyclitol residue had been additionally removed by reduction had no inhibitory effect on either of the enzymes.

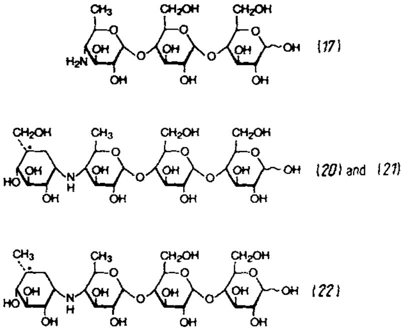

Fig. 12. Basic reaction products of the catalytic hydrogenation of acarbose *(5)* [73].

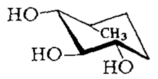
Consequently, the double bond in the cyclitol unit is—quantitatively—important for the effect. The non-basic products were examined by thin-layer chromatography and found to be derivatives of the cyclitol.

Validatol *(12)* and 7-deoxyvalidatol[81] *(23)* were isolated and identified[73].

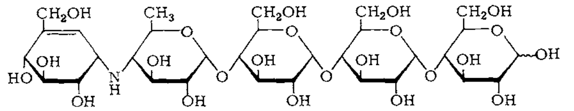


*(23)*

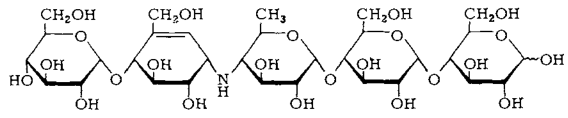
The higher components were also subjected to hydrogenolysis in the form described. As can be seen in Figure 13, "component 4" yields mainly validatol glucoside *(24)* in addition to the basic trisaccharide *(17)* mentioned. However, validatol *(12)* and a basic tetrasaccharide *(25)*[46] are also obtained. Component 4 thus consists of two isomers *(26)* and *(27)*. The isomer with the terminal cyclitol residue *(26)* constitutes only a small proportion. A separation of both isomers was achieved using strongly acidic ion exchangers.

---

[*] *(17)* was acetylated, split into the three monosaccharide constituents by acetolysis and thus correlated to known compounds [73].



(26)



(27)

Both have inhibitory activity against α-amylase and sucrase, isomer *(26)* being slightly more effective. Components 5 and 6 (cf. Table 4) were also found to be isomer mixtures. When the main isomer *(28)* of component 5 is subjected to hydrogenolysis, validatol maltoside *(29)* and the basic trisaccharide *(17)* are formed (cf. Fig. 14).

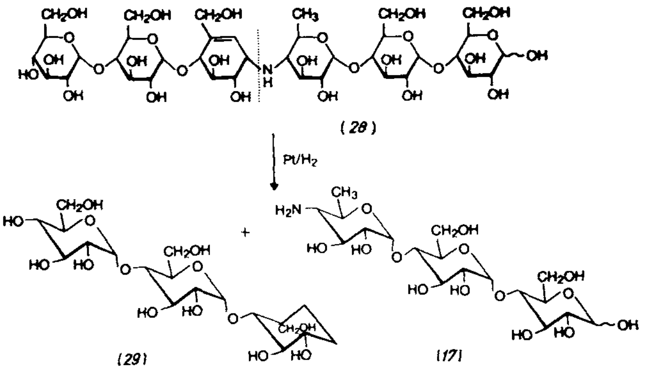


Fig. 14. Catalytic hydrogenation of the predominant isomer *(28)* of component 5 [73].

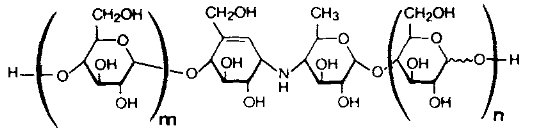
These data relating to the constitution of individual members of the homologous series of pseudo-oligosaccharidic α-glucosidase inhibitors of the general formula *(4)* have been confirmed and extended by reactions of enzyme degradation using β-amylase which is inhibited by the individual components to a much lesser degree than other α-glucosidases. As is shown in Figure 15, a maltose residue is split off from each of the two main isomers *(28)* and *(30)* of the isomer mixtures contained in components 5 and 6. Further products of reaction are component 3 (acarbose) *(5)* and the component 4 isomer *(27)*.

## 6. Inhibitory Spectrum of Acarbose and of Homologous Pseudo-oligosaccharides

The individual components of the homologous series described in detail in the previous Section differ with regard to their inhibitory activities against α-amylase from porcine pancreas and sucrase from hog small intestine (Fig. 16).



(4), m+n = 1-7

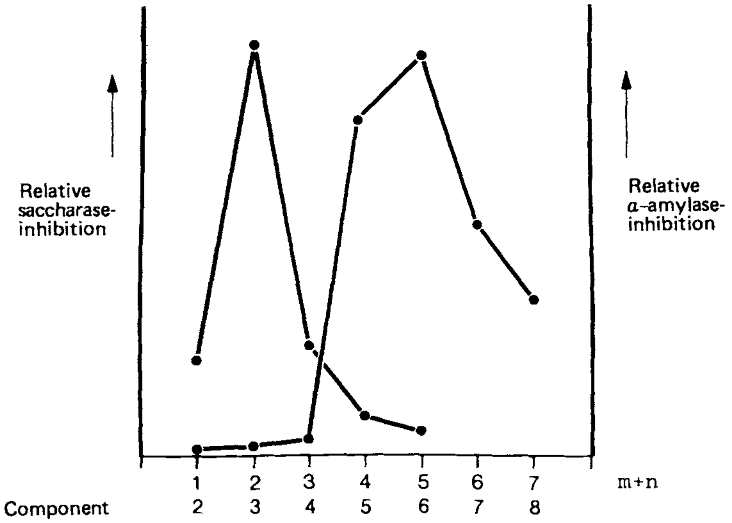


Fig. 16. Relative inhibition of sucrase and α-amylase by "components 2—8" [43].

The highest specific inhibitory activity against α-amylase is exhibited by a component 6 preparation with minimum inhibitor activity against sucrase. (The inhibition of α-amylase by the component 6 preparation is linear up to 70%. By extrapolation the amount of inhibitor for the 100% inhibition can be determined and a 1 : 1 stoichiometric relationship between enzyme and inhibitor is estimated.)

The inhibitory activity against α-amylase decreases with the higher components, while component 3 (acarbose) *(5)* shows maximum inhibitory activity against sucrase (Fig. 16). Table 7 lists the inhibitory activities of different components against α-amylase from porcine pancreas and the intestinal oligo- and disaccharidases from hog small intestine. As a measure of inhibitory activity, that amount of inhibitor is given which produces a 50% inhibition under test conditions. From Table 7 it is obvious that component 3

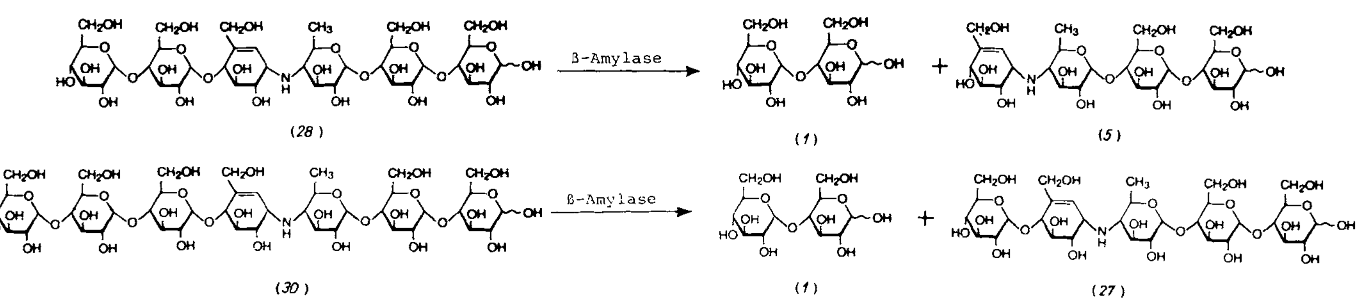

Fig. 15. Enzymatic hydrolysis of component 5 (predominant isomer *(28)*) and component 6 (predominant isomer *(30)*) using β-amylase (sweet potato) [46].

Table 7. Amounts (in ng) of acarbose *(5)* and homologues of the general formula *(4)* [45] necessary for inhibition ($ID_{50}$ [a]) of the activity of intestinal α-glucosides *in vitro* [b].

| Component | No. of glucose residues $m+n$ in *(4)* | Maltase 10 mU [c] | Isomaltase 10 mU | "Dextrinase" 29 mU | Glucoamylase 10 mU | α-Amylase 100 mU | Sucrase 10 mU |
|---|---|---|---|---|---|---|---|
| 2 | 1 | 100 | 43500 | 205 | 83 | 855 | 500 |
| 3 (acarbose) | 2 | 15 | 42000 | 64 | 9.3 | 680 | 74 |
| 4 | 3 | 80 | 54500 | 93 | 39 | 1135 | 455 |

| 6 | 5 | 1000 | ≫ 100000 | 93 | 410 | 2.8 | 700 |
| BAY e 4609 | 7-30 | 8250 | ≫ 100000 | 810 | 8000 | 14.5 | 60000 |

[a] Amount of inhibitor in ng per test, required for 50% inhibition. [b] Assays for glucose-releasing enzymes: Pre-incubate 0.01 ml inhibitor solution in multiple dilutions with 0.1 mL enzyme preparation for 10 minutes, incubate with 0.1 mL substrate solution, stop with 1 mL glucose dehydrogenase reagent in 0.5 M tris-buffer, develop for 30 min for determination of glucose and determine absorption at 340 nm. Substrate solutions and incubation periods: 0.4 M sucrose for 20 min, 50 mM maltose for 10 min, 40 mM isomaltose for 10 min, 5% soluble starch for 20 min. Assay for destrinase: Pre-incubate 0.01 ml inhibitor solution in multiple dilutions with 0.1 ml enzyme preparation for 10 minutes, incubate with 0.1 mL 5% limit dextrin solution for 20 minutes, mix with 0.5 mL dinitrosalicylic acid reagent [33], heat to 95 °C for 5 min, dilute with 1.5 mL water and determine absorption at 540 nm. Assay for α-amylase: Pre-incubate 0.01 mL inhibitor solution in multiple dilutions with 0.2 mL enzyme preparation (α-amylase from hog pancreas) for 10 min, incubate with 0.2 mL 5% starch solution for 5 min, mix with 0.5 mL dinitrosalicylic acid reagent [33], heat to 95 °C for 5 min, dilute with 2.5 mL water and determine absorption at 540 nm. [c] 1 U is that amount of enzyme which converts 1 μmol of substrate per min under standard conditions. 1 U = 16.67 nkat.

(acarbose) *(5)* has the highest specific inhibitory activity also against the other α-glucosidases located in the wall of the small intestine. The isomaltase activity of the enzyme preparation from the small intestine of hogs is inhibited to a very small degree by the lower components (in comparison with nojirimycin and 1-deoxynojirimycin (see Section 8, Table 10)) and practically not at all by the higher components. However, the activity of the enzyme preparation referred to as "dextrinase" (substrate: glycogen degraded to limit dextrins by α-amylase from porcine pancreas) is inhibited to a high degree.

A number of bacterial, fungal and plant enzymes (cf. Table 8) were tested for inhibition by acarbose *(5)*[87]. Table 8 indicates that α-amylases from *Bacillus subtilis* and *Aspergillus oryzea* and glucoamylase from *Aspergillus niger* and α-glucosidase from yeast *(Saccharomyces sp.)* are inhibited. As can be seen from Table 9 glucoamylase of *Aspergillus* origin is the most sensitive of all enzymes tested in this study[87]. Furthermore, cyclodextrin-glucosyl-transferase is inhibited, while muscle phosphorylase is not affected[87].

Table 8. Inhibitory spectrum of acarbose *(5)* for enzymes from bacteria, fungi and plants [87].

| Enzyme | Origin | Substrate | Inhibition [a] |
|---|---|---|---|
| α-amylase | *B. subtilis* | starch | + |
| α-amylase | *A. oryzae* | | + |
| α-amylase | barley malt | | + |
| β-amylase | "sweet potato" | | – |
| β-amylase | B. polymyxa | | – |
| glucoamylase | A. niger | | + |
| invertase | *Saccharomyces sp.* | sucrose | – |
| α-glucosidase | | maltose | + |
| β-glucosidase | almonds | cellobiose | – |
| β-galactosidase | *Saccharomyces fragilis* | lactose | – |
| dextran sucrase | *Leuconostoc mesenteroides* | sucrose | – |
| pullulanase | *Aerobacter aerogenes* | pullulan | – |
| isoamylase | *Cytophaga sp.* | glycogen | – |
| cyclodextrin-glucosyl transferase | *B. macerans* | starch | + |

[a] Inhibition: +, no inhibition: –.

By reacting the reducing glucose unit of acarbose *(5)* a number of semisynthetic glycoside derivatives were produced and tested[73]. In a few cases an increase of up to a factor of three in the inhibitory activity against sucrase was found, but none of the derivatives offered any convincing advantages over acarbose[73]—especially when considering their costly production.

Table 9. Concentrations of acarbose *(5)* required for a 50% inhibition of various α-glucosidases [87].

| Enzyme | Origin | Concentration of inhibitor [μg/mL] |
|---|---|---|
| α-Amylase | "Bacterial saccharifying" | 0.3 |
| | "Bacterial liquefying" | 40.9 |
| | Aspergillus oryzae | 180.0 |
| | Porcine pancreas | 3.8 |
| | Barley malt | 83.5 |
| Glucoamylase | *Aspergillus niger* | 0.04 |
| α-Glucosidase | *Saccharomyces sp.* | 70.0 |

## 7. Further Pseudo-oligosaccharadic α-Amylase Inhibitors

A short time ago microbial α-amylase inhibitors became known from the patent literature which are obviously also members of a homologous series and assumed to have the same "core" as the pseudo-oligosaccharides (acarbose series) (Section 5). Three basic amino sugar derivatives were isolated from culture broths of *Streptomyces dimorphogenes* NR-320-OM7HB and NR-320-OM7HBS. These derivatives, which were separable by high-pressure liquid chromatography, were called trestatins A *(31)*, B *(32)* and C[70]. Their molecular weights as determined by osmometry are 1470, 975 and 1890, respectively. The structures proposed for trestatins A and B on the basis of spectroscopic analysis on the one hand and examinations of products of hydrolysis (4 N HCl, 3 h at 80 °C) on the other are shown in Figure 17.

The products of hydrolysis of the three trestatins are glucose and an amine ($pK_a = 3.9$) of the empirical formula $C_{13}H_{21}NO_7$[*]. All three trestatins have one trehalose residue as a common structural characteristic. Trestatin A *(31)*

---

[*] "Component 1" *(8)* has the same molecular formula.

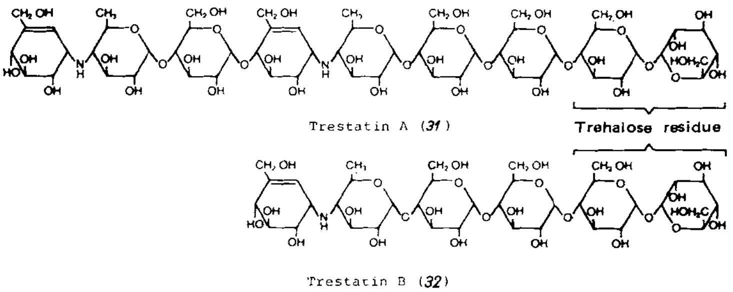

Fig. 17. Proposed structures of trestatins A *(31)* and B *(32)* [70].

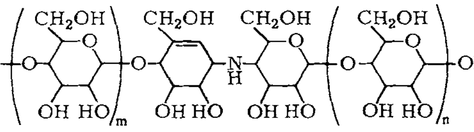
contains two and trestatin C three pseudodisaccharide residues per molecule. Both show relatively high specific inhibitor activity against pancreatic α-amylase from hog ($7.1 \times 10^7$ IU/g and $4.9 \times 10^7$ IU/g, respectively)[*]. Trestatin B *(32)* has only one pseudodisaccharide residue per molecule and a lower specific activity of $1.5 \times 10^6$ IU/g[*].

In a patent application[68] inhibitors of α-glucosidase are described which are also members of a homologous series of the general formula *(33)*. The microorganisms producing these inhibitors are said to be strains of the genus *Streptomyces* (*e.g.* A 2396)[68]. The only structural difference from the acarbose series of the general formula *(4)* is that the 4-amino-4,6-dideoxyglucose residue is replaced by a 4-amino-4-deoxyglucose residue. In the patent application mentioned above[68] amino sugars of the general formula *(33)* with $m = 0$ to 8, $n = 1$ to 8 are claimed, $m+n$ having a value of 1 to 8. The structure of these inhibitors was derived mainly from spectroscopic data. The higher compounds of the homologous series are more effective against α-amylase than the lower ones. Furthermore, inhibitory action on sucrase and maltase is mentioned.



*(33)*

*Murao et al.*[51–53] carried out detailed investigations on a pseudo-oligosaccharidic α-amylase inhibitor (amylostatin, S-AI) isolated from culture broths of *Streptomyces diastaticus subsp. amylostaticus* No. 2476. Its structure has not yet been completely identified, but shows a striking similarity to members of the homologous acarbose series of the general formula *(4)*. This inhibitor was isolated by chromatography followed by purification *via* an enzyme-inhibitor complex with "bacterial liquefying α-amylase" (BLA)[52]. A molecular weight of about 1500 was determined. S-AI *(34)* is called a "substrate analog inhibitor"[53]. Its inhibitory spectrum covers not only human salivary amylase and pancreatic amylase from hogs but also a number of bacterial and fungal α-amylases. Moreover, ***Rhizopus niveus*** glucoamylase and malt α-amylase are inhibited, while mammalian intestinal sucrase, β-amylase of plant origin and a number of microbial α-glucosidases are not. S-AI *(34)* has a reducing terminal glucose residue and five more glucose residues connected by 1,4-glucosidic linkages. Two maltose residues can be split off with β-amylase. The remaining molecule was named "glucosyl-S-AI-X-glucose"[53]. A further derivative, S-AI-XG[72] (molecular weight approximately 500) was obtained from S-AI *(34)* by enzymatic and/or chemical methods. This derivative consists of that part of the molecule containing nitrogen and a reducing glucose residue. Figure 18 shows a schematic attempt at representing the structure[53] of S-AI *(34)*, according to which the active center of BLA interacts with 8–10 glucose residues and the catalytic center of the enzyme "fits" the unknown part of the molecule S-AI-X of S-AI *(34)* which is obviously essential to the inhibitory effect.

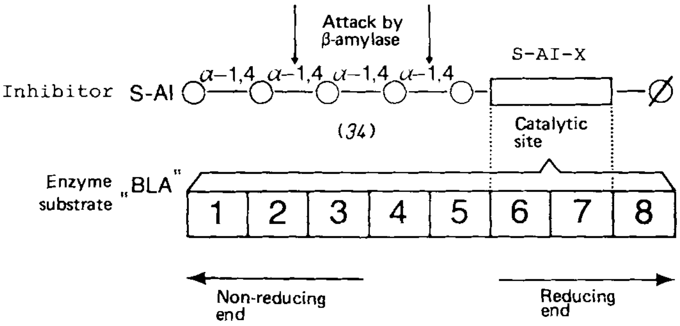


Fig. 18. Structure suggested for the microbial α-amylase inhibitor S-AI *(34)* and postulated binding mechanism between S-AI and "bacterial liquifing amylase (BLA)" according to *Murao* and *Ohyama* [53] (∅: reducing glucose residue).

Additional N-containing oligosaccharidic α-amylase inhibitors, TAI-A and TAI-B, were isolated from culture broths of *Streptomyces calvus* TM-521[69]. These inhibitors have a molecular weight of 950 to 1050 and 650 to 700, respectively, and contain two or several glucose residues and, as a basic residue, probably an amino sugar unit. TAI-A and TAI-B differ from the compounds of the homologous acarbose series of the general formula *(4)* by the absence of methyl groups. Their inhibitory spectrum covers human salivary amylase, porcine pancreatic amylase, ***Rhizopus niveus*** glucoamylase, Taka amylase[*] (only TAI-A) and "bacterial saccharifying α-amylase" but not BLA.

A glucoamylase and α-amylase inhibitor, NCGAI, was isolated from culture broths of *Streptomyces sp.* No. 33[64]. Its molecular weight is approximately 600 and it is assumed to consist mainly of glucose residues. NCGAI exhibits a pronounced inhibitory effect on glucoamylase while inhibiting pancreatic amylase and BLA to a lesser degree.

A short while ago a patent application became known[72a] in which three α-glucosidase inhibitors (isolated from *Streptomyces myxogenes* SF-1130, ATCC 31305) of the general formula *(34a)* are described. They are said to be weakly basic oligosaccharides. Apart from their inhibitory activity against mammalian intestinal α-glucosidase and sucrase, these substances are referred to as antibiotics

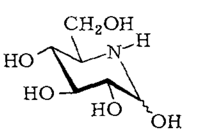
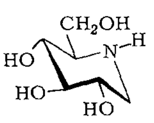
## 8. Nojirimycin and 1-Deoxynojirimycin

Nojirimycin *(35)* was first described as an antibiotic produced by *Streptomyces roseochromogenes* R-468 and *Streptomyces lavendulae*-SF-425[56,58].

(35)





(36)

1-Deoxynojirimycin *(36)* was obtained from *(35)* by catalytic hydrogenation at the platinum contact or by reduction with $NaBH_4$[56,58]. There are also fully synthetic ways to prepare nojirimycin[58] and 1-deoxynojirimycin[57]. Later *(35)* was found to be a potent inhibitor of β-glucosidases (emulsin, fungal β-glucosidases)[59,60]. *(36)* is a much weaker inhibitor of emulsin than *(35)*[59]. *(35)* also inhibits microbial α-glucosidases, but to a much lesser degree than β-glucosidases[59,60].

A screening for inhibitors of intestinal mammalian α-glucosidases reveals that *(35)* and *(36)* are also produced by many strains of the genus *Bacillus*[44,55]. After 4- to 6-day fermentation in nutrient solutions usually containing starch or maltose, culture filtrates with relatively high titers of sucrase inhibitor units were obtained from the strains *B. amyloliquefaciens* (DSM 7), *B. polymyxa* (DSM 365), *B. subtilis* (DSM 704)[*] and *B. subtilis var. niger* (DSM 675). The inhibitors were bound to strongly acidic cation exchangers ($H^{\oplus}$ form) and subsequently eluted with aqueous ammonia. They were purified further by chromatography using CM-cellulose and gel-filtration using Sephadex LH-20. From the concentrated fractions with inhibitory activity, *(36)* crystallized in the form of colorless scales (m.p. 206 °C). *(36)* was also isolated from mulberry tree leaves[61] and called moranoline. Later *(36)* was also obtained by fermentation of the *Streptomyces lavendulae* strains SEN-158[62] and *subsp. trehalostaticus* No. 2882[63]. *(35)* and *(36)* were found to be potent inhibitors of intestinal oligo- and disaccharidases of mammals (Table 10)[44]. Pancreatic α-amylase is practically not inhibited. It was recently discovered that *(36)* is also a potent inhibitor of trehalases (rabbit and *Chaetomium aureum* MS-27) and of *Rhizopus niveus* glucoamylase and *exo*-β-1→3-glucanase *(Penicillium)*[63].

Table 10. Molar concentrations of nojirimycin *(35)* and 1-deoxynojirimycin *(36)* required for a 50% inhibition of intestinal α-glucosidases [44].

| Inhibitor | Sucrase | Maltase | Isomaltase | Glucoamylase |
|---|---|---|---|---|
| Nojirimycin | $5.6\times10^{-7}$ M | $1.7\times10^{-6}$ M | $2.5\times10^{-7}$ M | $7.6\times10^{-7}$ M |
| 1-Deoxynojirimycin | $2.2\times10^{-7}$ M | $1.3\times10^{-7}$ M | $1.3\times10^{-7}$ M | $9.6\times10^{-8}$ M |
| mU Enzyme in 0.21 mL incubation volume at 37 °C | 11.1 | 11.8 | 11.5 | 10.1 |

Assays: Pre-incubate 0.01 mL inhibitor solution in multiple dilutions with 0.1 mL enzyme preparation for 10 min, incubate with 0.1 mL substrate solution, stop with 1 mL glucose dehydrogenase reagent in 0.5 M tris-buffer, develop during 30 min for determination of glucose and determine absorption at 340 nm. Substrate solutions and incubation periods: 0.4 M sucrose for 20 min, 50 mM maltose for 10 min, 40 mM isomaltose for 10 min, 5% soluble starch for 20 min. Nojirimycin is released from the bisulfite adduct using barium hydroxide, determined quantitatively using glucose dehydrogenase reagent and used immediately for the inhibition test.

## 9. Carbohydrate-Containing Polypeptides as Inhibitors of α-Amylase

*Ueda et al.* obtained carbohydrate-containing, peptide-like substances from culture broths of *Streptomyces sp.* No. 280, a variant form of *Streptomyces flavochromogenes*. These crude substances were found to inhibit quite a number of α-glucosidases, glucosyl transferases and phosphorylases (cf. Table 11)[47-50]. By combining several methods of separation (paper chromatography, paper electrophoresis) it was possible to isolate four homogeneous glycopeptide fractions A, B, B′ and C[49]. The carbohydrate portion consists mainly of glucose and the molecular weights range from 1300 (for C) to 4000. In a purified form the inhibitors had different activities against the enzymes listed in Table 11[49].

Recently the authors were able to show that the carbohydrates contained in the inhibitors are degraded enzymatically by *Streptomyces* amylase in the course of culturing the organism (in a medium containing 3% oatmeal)[50]. An additional proteolysis during fermentation cannot be excluded. An amylase preparation was isolated from the inhibitor-producing strain and used for degradation experiments with a crude inhibitor obtained after fermentation for 24 hours (probably glycopeptide fraction A, molecular

Table 11. Enzymes which are inhibited by a crude α-glucosidase inhibitor preparation of *Streptomyces flavochromogenes* [47-50].

| Enzyme | Inhibition |
|---|---|
| Glucoamylase (Rhizopus) | strong |
| α-Amylase (saliva, human) | strong |
| α-Amylase (pancreas, human) | strong |
| α-Amylase (Bacillus) | weak |
| α-Amylase (Bacillus, "bacterial saccharogenic") | strong |
| α-Amylase (Aspergillus) | weak |
| α-Glucosidase (sucrase, intestinal mucosa of rat) | strong |
| α-D-Glucosidase (mucor) | strong |
| α-D-Glucosidase (yeast) | strong |
| Cycloamylose glucosyltransferase | strong |
| Phosphorylase A (rabbit muscle) | strong |
| Phosphorylase (potato) | strong |

---

[*] This strain was isolated by *U. Heber*, Botanisches Institut, Universität Düsseldorf (Germany).

weight approximately 4000). The products of hydrolysis were mainly maltose besides traces of maltotriose and glucose. The inhibitory activity of the resulting "residual inhibitors" remained practically unchanged against *Rhizopus* glucoamylase while slightly decreasing against amylase from hog pancreas and sucrase from rat small intestine. The inhibitory activity against phosphorylase A from rabbit muscle was lost almost completely. This effect thus appears to be dependent to a high degree on the chain length of the carbohydrate unit. Amylase from porcine pancreas and Taka-amylase showed a similar degrading effect on the inhibitor as *Streptomyces* amylase. The above-mentioned glycopeptide inhibitors A, B, B′ and C must therefore be regarded as multiple forms of a native inhibitor formed by bioconversion.

In a patent application[65] a glycopeptide obtained from culture broths of *Streptomyces calidus* DS 26320 and having a molecular weight between 10000 and 20000 is described. This preparation inhibits pancreatic amylase and the sucrase and maltase activities of an enzyme preparation from rat small intestine. Acid hydrolysis yields lysine and monosaccharides consisting mainly of glucose.

## 10. Protein Inhibitors

An inhibitor of mammalian α-amylases (HOE 467), an oligopeptide having a molecular weight of approximately 7400, was isolated from the culture broths of *Streptomyces tendae*[66, 67a]. The inhibition of α-amylase is irreversible. The only lysine residue in the molecule is possibly part of the active center of the inhibitor. Later, the inhibitor was separated into two fractions (A and B) and the amino acid sequence of the fraction HOE467A was elucidated[67b].

Two further very similar protein inhibitors free from carbohydrates and of a molecular weight of approximately 8500, Haim I and II[*], were isolated from culture broths of *Streptomyces griseosporeus* (probable identity) YM-25[71, 72]; they were isolated by precipitation with ammonium sulfate and subsequent chromatography. The inhibitors show about the same specific activity against α-amylase from porcine pancreas. They differ electrophoretically and in their isoelectric points (pH 4.0 and 3.8, respectively). In addition, pancreatic amylases from other species and human salivary amylase are inhibited, while microbial and plant glucosidases are not. The inhibition of amylase from porcine pancreas is linear up to 80% inhibition. There is no complete inhibition. By extrapolation to 100% inhibition a molar ratio of enzyme to inhibitor of 1 : 1 is found. The mechanism of inhibition is explained by a protein-protein interaction, a linkage near to the active center of the α-amylase being assumed. Both inhibitors have a similar arrangement of amino acids and a high content of aspartic acid (15.4 and 15.0 mol%, respectively) and alanine (12.8 and 12.5 mol%, respectively). They contain neither lysine nor methionine.

An α-amylase inhibitor was obtained from culture filtrates of *Streptomyces fradiae* (FERM-P 2303) by precipitation with ammonium sulfate and subsequent chromatography[54]. This preparation designated as X-2 has a molecular weight of approximately 6500 and is a carbohydrate-free acidic polypeptide with *N*-terminal aspartic acid (or asparagine).

## 11. Mechanism of Inhibition of Sucrase by Acarbose, Nojirimycin and 1-Deoxynojirimycin

The most thorough investigations into the inhibition mechanism of α-glucosidase by microbial inhibitors have so far been carried out by *Semenza et al.*[88] on the isolated sucrase-isomaltase complex from rabbit small intestine[89]. Acarbose *(5)* inhibits the sucrase activity of disaccharidase preparations from the small intestine of various species by a fully competitive mechanism[23, 88, 90, 91]. The inhibitor constants ($K_i$ values) listed in Table 12 range, depending on the species, between $10^{-6}$ and $10^{-7}$ mol/L. The $K_i$-value of component 2 *(6)* is $7.0 \times 10^{-7}$ mol/L (sucrase from porcine pancreas; method: "Dixon plot").

Table 12. Sucrase inhibitor constants ($K_i$) of acarbose *(5)*; substrate: sucrose.

| Origin of intestinal disaccharidase preparation | $K_m$ [mol/L] | $K_i$ [mol/L] | pH | Method | Ref. |
|---|---|---|---|---|---|
| Man | $1.9 \times 10^{-2}$ | $1.3 \times 10^{-6}$ | 6 | "Dixon plot" | [90, 91] |
| Hog | $1.9 \times 10^{-2}$ | $2.6 \times 10^{-7}$ | 6.25 | | [23] |
| Rat | | $\sim 4 \times 10^{-7}$ | | | [91] |
| Rabbit [a] | $8 \times 10^{-3}$ | $4.7 \times 10^{-7}$ | 6.8 | "Henderson plot" | [88] |

[a] $K_m$ value according to [92, 93].

Nojirimycin *(35)* and 1-deoxynojirimycin *(36)* are also fully competitive inhibitors of sucrase. Their $K_i$-values (enzyme preparations from rabbit; method: "Henderson plots" ("steady state" rates)) are $1.3 \times 10^{-7}$ mol/L and $3.2 \times 10^{-8}$ mol/L, respectively, at pH 6.8, the optimum of sucrase activity[88]. Consequently, these four substances can be regarded as the, so far, most potent unusually tight-binding sucrase inhibitors. Their affinity for the enzyme is 5 to 6 orders of magnitude greater than that of the substrate sucrose ($K_m$: approximately $8.0 \times 10^{-3}$ mol/L[92, 93]).

According to thorough kinetic studies[88] the reaction of *(5)*, *(35)* and *(36)* with the enzyme is slow: the steady state is reached within five minutes. In view of the structure of these inhibitors and the pH-dependence of their $K_i$-values, an interaction with the active center of the sucrase sub-unit can be assumed which would confirm the mechanism of action of sucrase suggested by *Cogoli* and *Semenza*[92]. The individual steps of the effect of sucrase are shown schematically in Figure 19. In simplified terms we can say that in a first step (A) the substrate molecule which consists of a glucose and a fructose residue is bound by the active center of the enzyme and the glucose pyranose ring is deformed. In a second step (B and C) the glucosidic oxygen function in the 1-position is protonated (possibly by the carboxyl groups in γ-position of a glutamic acid residue in the active center of the enzyme[94]). In a third step (C) the fructose residue is detached and an oxonium/carbenium cation formed which is stabilized by a carboxylate group

---

[*] Haim = hog pancreatic α-amylase inhibitor of microbes.

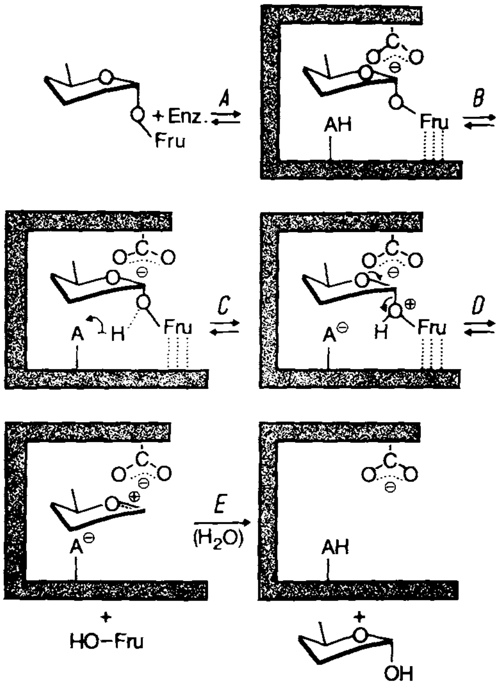


Fig. 19. Mechanism of action of enzymatic hydrolysis of sucrose by intestinal sucrase according to *Cogoli* and *Semenza* [92].

of the active center. In all probability, this is a carboxylate group in β-position of an aspartic acid residue[88,94,95]. In a last step (E) the oxonium/carbenium cation stabilized in the way described reacts with water to form D-glucopyranose—possibly *via* a covalent intermediary stage.

It is most likely that the unsaturated cyclitol unit of acarbose *(5)* interacts with the glucopyranosyl binding center of sucrase, the axially arranged nitrogen atom taking the position of the glycosyl-oxygen atom in the substrate molecule. The 4-amino-4,6-dideoxyglucose unit interacts with the so-called "aglucon" binding center. This interpretation is based on the following facts:

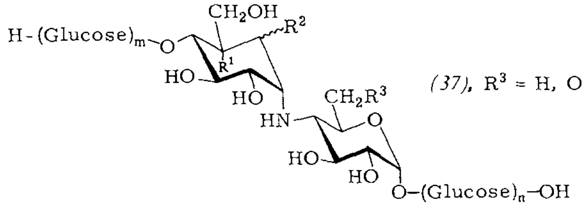
a) The unsaturated cyclitol unit has a half-chair conformation. Three of its four coplanar C atoms correspond with positions C2—C1—O—C5 in the oxonium/carbenium ion (cf. Fig. 19). However, the structural correspondence of cyclitol unit and carbenium cation is not so complete that the saturation of the double bond would lead to a drastic loss of efficacy.

b) Of greater importance for the pronounced inhibitory effect is the replacement of the glycosidic oxygen function of the substrate by the more basic NH function in the inhibitor. The p$K_a$ value of the NH group in *(5)* is about 5[96]. This means that protonation is unlikely to occur at any of the pH values tested (5.85; 6.8; 7.45)[88]. Since this group corresponds with the glycosidic oxygen of the substrate molecule, it will probably interact with the same carboxyl group of the active center. The p$K_a$ value of that group is about 7.3[88]. Actually, the affinity of acarbose *(5)* decreases when the carboxyl group is deprotonated ($K_i$ at pH 6.8: $4.7 \times 10^{-7}$ mol/L compared to $1.0 \times 10^{-6}$ mol/L at pH 7.45)[88].

c) Also important for the high affinity for the enzyme is a marked interaction of the 4-amino-4,6-dideoxyglucose residue in *(5)* with the "aglucon" binding center, for valienamine *(16)* is a weaker inhibitor of sucrase than acarbose by 2 to 3 orders of magnitude. In addition, the α(1→4)-like linkage of cyclitol unit and amino sugar contributes to a specifity of inhibition. Consequently, acarbose inhibits neither the isomaltase sub-unit—which is closely related to the sucrase sub-unit—nor the similarly acting β-glucosidase from almonds to any appreciable degree.

All these findings are consistent with the concept of the mechanism of action of sucrase and demonstrate that the pseudosaccharide "core" of the individual members of the homologous acarbose series is essential to the inhibitory effect.

On account of the results of our own studies (see Section 5) with products of the hydrogenation of acarbose *(5)*[73] and the properties of saturated microbial inhibitors[72b] related to acarbose *(5)* described by Japanese authors, the double bond has probably only quantitative significance. According to the present state of knowledge and further references in the patent literature[68] the general structural formula *(37)* follows for these pseudo-oligosaccharidic α-glucosidase inhibitors; here $R_1 = H$, $R_2 = H$ or OH, or $R_1$ and $R_2$ form a double bond, and $R_3 = H$ or OH.



*(37)*, $R^3$ = H, OH

Nojirimycin *(35)* and 1-deoxynojirimycin *(36)* have a similar molecular size and, to a certain extent, also a structure similar to D-glucose—in contrast to acarbose *(5)*. They inhibit quite a number of both α-glucopyranosidases (including isomaltase from small intestine[*], cf. Table 10) and β-glucopyranosidases[59,60,97,98]. They are likely to react with that part of the active center of sucrase which is the "glucopyranosyl subcenter", and neither with the "aglucon subcenter" nor the carboxyl group that protonates the glucosidic oxygen (p$K_a$ approximately 7.3). Accordingly, the $K_i$ values for both substances are practically equal at pH values 6.8 and 7.45[88]. On the basis of the data availa-

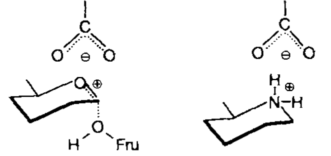


Fig. 20. Binding of the protonated 1-deoxynojirimycin molecule *(36)* to a carboxylate group of the active center of sucrase, in comparison with the stabilization of the oxonium/carbenium cation transition state of the substrate (see also Fig. 19).

---

[*] $K_i$ for 1-deoxynojirimycin *(36)*: $4.8 \times 10^{-8}$ mol/L at pH 6.25 (isomaltase from porcine small intestine, method: "Dixon plot").

ble the mechanism of action of nojirimycin *(35)* and deoxynojirimycin *(37)* is not as easy to explain as that of acarbose *(5)*. After a thorough discussion of all facts, including also the results obtained with other weaker inhibitors of sucrase (such as D-glucono-1,5-lactone and D-glucono-1,5-lactam), and considering hypotheses possibly applicable, *Semenza et al.*[88] arrive at the conclusion that *(35)* and *(36)* are bound to the active center in a non-protonated form and are subsequently protonated. In this case, a diagram as shown in Figure 20 could be drawn up for *(36)*.

## 12. Pharmacological and Clinical Aspects

For a long time dietetic rules have been a basic treatment of metabolic diseases such as diabetes mellitus, obesity or Type IV hyperlipoproteinaemia. As a rule, these regimens require a reduced intake of carbohydrates and a partition of daily meals into many small portions eaten through the day. If these instructions are followed, hyperglycaemia (excessive blood glucose values), hyperinsulinaemia (excessive blood insulin values) and hypertriglyceridaemia (increased triglyceride blood levels) can be prevented in many cases. However, in daily practice the observance of such restrictions is often hindered by unfavorable circumstances and inner resistance[45].

Carbohydrates are a main component of human food, 80—90% consisting of starch and sucrose[99]. In general more than 250 g of di- and polysaccharides—as is described in detail in Sections 2 and 3—must be enzymatically split in the intestinal tract before they can be utilized by the organism. According to the concept by *Puls*[19,20,45]—referred to in the introduction—a pharmacological interference with the intestinal carbohydrate digestion by suitable α-glucosidase inhibitors should be a feasible way to regulate and retard carbohydrate digestion, control the rate of absorption of monosaccharides and by this way influence the intermediary metabolism of the carbohydrates. As already mentioned in the introduction this concept was supported by an α-amylase inhibitor (BAY d 7791), a protein obtained from wheat germ flour[17,18], by experimental and clinico-pharmacological studies[17,19,77], which induced the search for more potent inhibitors of α-glucosidases. The pseudo-oligosaccharidic inhibitors of the general formula *(4)* proved to be particularly suitable. The results obtained with various homologues from *in vivo* experiments with rats are compared to the *in vitro* inhibitory activities against α-amylase and sucrase (Table 13, see also Table 7)[43,45,74,77].

Table 13. Inhibition of α-glucosidase activity *in vitro* and *in vivo* by acarbose *(5)* and homologues of the general formula *(4)* [45].

| Component | *In vitro* 50% inhibition of 100 mU α-amylase [a] [ng] | *In vivo* $ED_{50}$ [b] with starch [mg/kg rat] | *In vitro* 50% inhibition of 10 mU saccharase [a] [ng] | *In vivo* $ED_{50}$ with sucrose [mg/kg rat] |
|---|---|---|---|---|
| 2 | 855 | 1.1 | 560 | 1.0 |
| 3 (acarbose) | 680 | 1.5 | 74 | 1.1 |
| 4 | 1135 | 1.4 | 455 | 3.3 |
| 5 | 4.7 | 1.0 | 700 | 10.0 |
| 6 | 2.8 | 0.4 | 700 | ~25.5 |
| BAY e 4609 | 14.5 | 6.1 | 60000 | >75.0 |

[a] See footnote [b], Table 7. [b] $ED_{50}$ is the dose necessary to reduce the integrated postprandial increase in blood glucose by 50% [100].

The *in vivo* activity of the inhibitors is determined by loading tests with rats using the substrates starch and sucrose. After the administration of a defined amount of carbohydrates postprandial blood glucose concentrations are determined at various times, plotted and integrated.

The blood glucose concentrations of rats treated with physiological saline are used as a baseline. The *in vivo* activity is expressed numerically as $ED_{50}$. Comparison of the data for the *in vivo* activity in the sucrose loading tests for the first five members of the homologous series and the high-molecular preparation BAY e 4609 (given in Table 13) with the *in vitro* data of sucrase inhibitors shows that *in vitro* and *in vivo* activities are very much parallel—with the exception of component 2 *(6)*, the values of which cannot be satisfactorily explained at present.

Acarbose *(5)* stands out against the other compounds as the most effective inhibitor both *in vivo* and *in vitro*. It is striking that—according to Table 13—components 2—6 inhibit the degradation of starch *in vivo* to a very similar degree while there are considerable differences in the inhibition of α-amylases *in vitro* (Fig. 19 and Table 7). We can conclude from this that the *in vitro* inhibition test, using pure α-amylase as the enzyme, does not reflect the real course of the intestinal degradation of starch *in vivo*. As already mentioned in Section 3, the intestinal degradation of starch is a complex process involving a great number of enzymes. Table 7, according to which components 2—5 and especially acarbose *(5)* inhibit maltase, "dextrinase" and glucoamylase to a considerable degree, gives an idea of feasible mechanisms of the *in vivo* effects. If it were possible to exactly define the involvement of the various enzymatic activities in the *in vivo* degradation of starch to glucose, one might be able to explain the mechanism of *in vivo* action of acarbose and its homologues. It can be seen from Table 13 that the $ED_{50}$ for acarbose *(5)* in the starch loading test is 1.5 mg/kg in the rat, thus only slightly higher than the $ED_{50}$ determined in the sucrose loading test. This finding contributed to our selecting acarbose for clinical trials and thus for practical use. On account of its broader spectrum of inhibitory action *in vivo* acarbose proved to be clearly superior to the α-amylase inhibitor BAY e 4609 which was also subjected to in-depth pharmacological[77] and clinical studies[78].

Acarbose does not only produce a dose-dependent inhibition of the postprandial rise in blood sugar values in rats in starch and/or sucrose loading tests, but also inhibits the reactive postprandial hyperinsulinaemia[45,100]. Therapy-related clinico-pharmacological studies on healthy test persons have yielded similar results as the rat experiments described above[45,75,100].

Moreover, acarbose was found to reduce the weight of genetically obese "Zucker" rats that had received a sucrose-containing diet—in a dose-dependent manner—; this can be attributed to a reduced food intake by the animals treated. These animals also had significantly lower serum levels of triglycerides and free fatty acids. The reduction of carbohydrate-induced hyperlipoproteinaemia is considered to be due to a decrease in the excessive secretion of high-triglyceride lipoproteins, the so-called "VLDL fraction", from the liver. Analyses of the animals' trunks (carcasses) revealed a reduced accumulation of fat in the body but unchanged protein content[45,100] in comparison with controls.

Acarbose *(5)* is the clinically most thoroughly tested compound especially in the indication diabetes mellitus. The results of the numerous large-scale studied carried out so far can be summarized as follows[75,76,101]:

Acarbose clearly improves the metabolic condition of insulin-dependent diabetics. Blood glucose levels are lowered so that the dose of insulin can be reduced. However, if there is a deficiency of insulin, acarbose cannot replace insulin. In non-insulin-dependent diabetics the improvement of the metabolic condition is the greater the longer acarbose is administered. On account of its mechanism of action, acarbose may produce transient intestinal symptoms which, however, are usually tolerated by the patient. These symptoms are reduced, *i.e.* tolerability improves, especially when the drug is taken over a prolonged period. Haematological and clinical-biochemical studies have furnished evidence for the preparation's objectively very good tolerability. Acarbose—which has not yet been put on the market—can thus be regarded as a new active principle in the treatment of diabetes mellitus. The efficacy of this preparation in hyperlipoproteinaemia and adiposity is under clinical investigation.

In order to establish additional indications for microbial $\alpha$-glucosidase inhibitors investigations were performed with test persons into the inhibition of oral starch degradation as effected mainly by salivary amylase[102]. It was shown that the addition of the $\alpha$-amylase inhibitor BAY e 4609 to starch results in a reduction of oral starch degradation. After administration of starch, telemetry can be used to follow the rapid drop of pH which is caused by the bacteria within the "plaques" on the teeth. A smaller pH drop was observed in the presence of the amylase inhibitor. This effect was amplified by the combination of BAY e 4609 with acarbose. These results support the idea that microbial $\alpha$-glucosidase inhibitors might reduce the cariogenic potential of starch during its degradation in the oral cavity[102].

We have seen by the example of acarbose and the other $\alpha$-glucosidase inhibitors discussed in this article that new active substances from the far-from-exhausted reservoir of microbial secondary metabolites can be discovered by means of practice-related screening tests.

*We are indebted to Prof. Dr. G. Semenza, Biochemical Laboratory of ETH Zürich, for the extremely valuable discussions of the mechanism of action of the $\alpha$-glucosidase inhibitors and for making his manuscript[88], still unpublished when the present paper was submitted, available to us. We also express our gratitude to Dr. J. J. Marshall, Miles Laboratories Inc., Elkhart, Indiana (USA) for permitting the use of the data listed in Tables 8 and 9 which are part of a manuscript[87] still unpublished when this paper was written.*

# 4-Aryldihydropyridines, a New Class of Highly Active Calcium Antagonists

**By Friedrich Bossert, Horst Meyer, and Egbert Wehinger**[*]

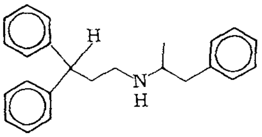
*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

The aryldihydropyridines first prepared by *Hantzsch* almost 100 years ago have recently been found to be highly effective calcium antagonists with suitable pharmacological profiles. An illustrative example is dimethyl-1,4-dihydro-2,6-dimethyl-4-(*o*-nitrophenyl)pyridine-3,5-dicarboxylate (Nifedipine) which is already employed therapeutically. This substance lowers the frequency of attack of angina pectoris and reduces blood pressure. The discovery of the therapeutic activity of this class of substances initiated renewed investigation of the Hantzsch condensation and the synthesis of numerous 4-aryldihydropyridines and related compounds. Qualitative and quantitative structure/activity relationships of these substances can be deduced from their biological data.

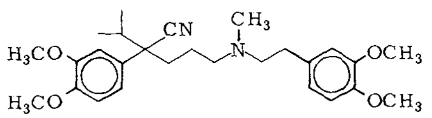
## 1. Introduction: What is a Calcium Antagonist?

"Calcium antagonists" are inhibitors of electromechanical coupling which cause a dose-dependent reduction of transmembranal $Ca^{2+}$ influx into the cells of the contractile system such that the $Ca^{2+}$-dependent myofibril-ATPase converts less phosphate-bound energy into mechanical work. Accordingly, the oxygen demand of the beating heart and the contractile tonus of the coronary and the peripheral resistance vessels are reduced. This mechanism of action results in three fundamental effects[1,2]:

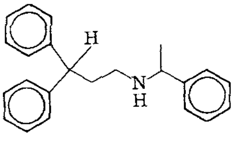
1) the direct damping of myocardial work-load metabolism,
2) an increase in blood supply to the coronary vessels,
3) a reduction in arterial flow resistance.



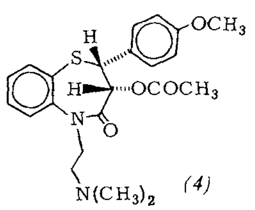
*(1)*



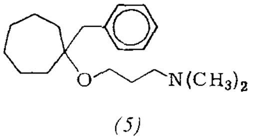
*(2)*



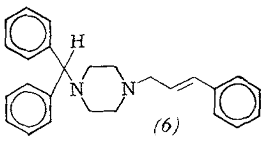
*(3)*



*(4)*



*(5)*



*(6)*

The vasodilating effect of calcium antagonists finds clinical application especially in the treatment of oxygen deficiency diseases of the heart such as angina pectoris. Since they reduce arterial flow resistance, calcium antagonists with suitable pharmacological profiles are also of interest in the treatment of hypertension[3,4,5].

"Specific" calcium antagonists, *i.e.* drugs in which the calcium antagonistic effect is the major one both qualitatively and quantitatively, are prenylamine *(1)*[6,7], verapamil *(2)*[6,7], fendiline *(3)*[8], diltiazem *(4)*[9], bencyclan *(5)*[10] and cinnarizine *(6)*[11].

From a chemist's point of view it is noticeable that all these drugs contain an aryl moiety with a basic alkyl or arylalkyl side chain as essential active structure[12].

## 2. Nifedipine, a Highly Active Calcium Antagonist with 4-Aryldihydropyridine Structure

A completely new, highly active, calcium antagonistic structure without the essential basic side chain was found in the form of the 4-aryldihydropyridines[13].

As a class of chemical compounds 1,4-dihydropyridine-3,5-dicarboxylates have been known since 1882 when *Hantzsch* discovered them as stable intermediates in the pyridine synthesis which bears his name[14,15]. In spite of their ready accessibility and the significance of dihydropyridines as coenzymes of numerous dehydrogenases, this class of compounds found little interest up until the mid-sixties[16]. Then, the vasodilating properties and hence the pharmacological qualities of numerous 4-aryldihydropyridine-3,5-dicarboxylates first became known and widely investigated as a result of work in our laboratories[13] and, independently, at the US pharmaceutical company Smith, Kline & French[17].

One member of this class of compounds, nifedipine *(7)* (Adalat®)[*,18,19] has already passed through clinical trials and is now in therapeutic use in many countries.

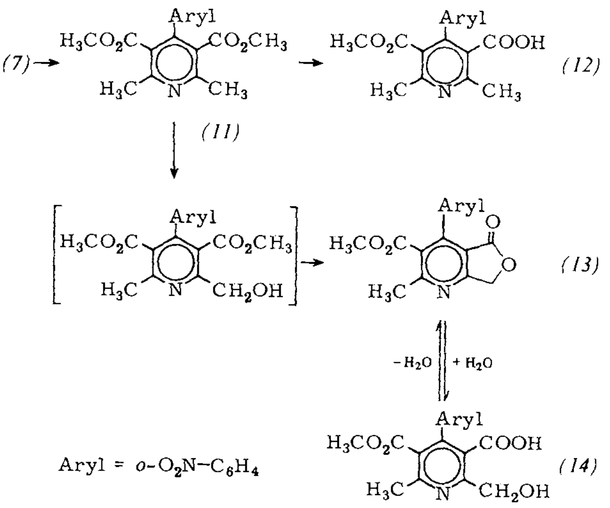
Nifedipine *(7)*

*Fleckenstein et al.* showed that nifedipine is a highly active inhibitor of transmembranal calcium influx, which displays its calcium antagonistic effect in isolated vessels even at dilution levels of a billionth[20]. Clinical studies confirmed the results of animal experiments: well-tolerated by the patient, nifedipine reduces the frequency of attacks in angina pectoris in a highly significant manner at very low doses (individual dose 5—20 mg/person)[21,22]. Furthermore this drug can also be used in the treatment of hypertension[23].

The manufacturing process for nifedipine *(7)* starts with 2-nitrotoluene which, after reaction with diethyl oxalate and subsequent hydrolysis, yields (2-nitrophenyl)pyruvate *(8)*. This product *(8)* can be dihalogenated with technical sodium hyperchlorite and cleaved in a haloform reaction to give 2-nitrobenzal chloride *(9)* in one step. Hydrolysis of *(9)* in sulfuric acid yields 2-nitrobenzaldehyde *(10)*, which is otherwise difficultly accessible on a technical scale[24]. This aldehyde is then condensed with methyl acetoacetate and ammonia in methanol according to *Hantzsch* to give nifedipine *(7)*.

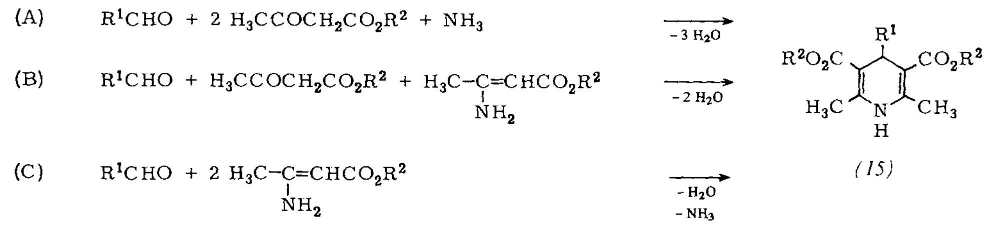


Aryl = $o$-$O_2N$–$C_6H_4$

## 3. Synthesis of 4-Aryl-1,4-dihydropyridines and Related Compounds

### 3.1. Variants of the Hantzsch Condensation

Apart from the classical Hantzsch synthesis, *i.e.* the one-pot condensation of aldehyde and β-ketoester (acetoacetate) in the molar ratio 1 : 2 with ammonia [eq. (A)], two further variations [eq. (B) and (C)] of the synthesis of 1,4-dihydropyridine-3,5-dicarboxylates *(15)* are known[27,28]. The standard conditions are heating under reflux for 6—20 h in a lower alcohol solvent.



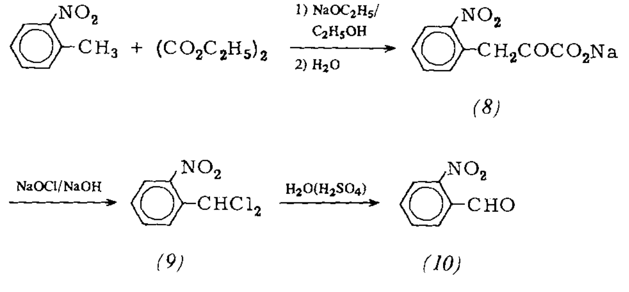
(A) $R^1CHO + 2\ H_3CCOCH_2CO_2R^2 + NH_3 \xrightarrow[-3\,H_2O]{}$

(B) $R^1CHO + H_3CCOCH_2CO_2R^2 + H_3C{-}\underset{NH_2}{C}{=}CHCO_2R^2 \xrightarrow[-2\,H_2O]{}$

(C) $R^1CHO + 2\ H_3C{-}\underset{NH_2}{C}{=}CHCO_2R^2 \xrightarrow[-H_2O,\ -NH_3]{}$

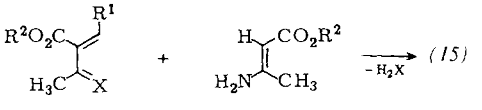
*(15)*

The hydroxycarboxylic acid *(14)*, in equilibrium with the corresponding lactone *(13)*[25], and the 2,6-dimethylpyridinecarboxylic acid *(12)*[26] have been characterized as end-products in the biotransformation of nifedipine. Oxidation to the pharmacologically inactive pyridine derivative *(11)* may be assumed to be the primary step in metabolic degradation.



$(10) + 2\ H_3CCOCH_2CO_2CH_3 + NH_3 \xrightarrow[-3\,H_2O]{} (7)$

The crucial step in all three variations is the cyclizing Michael addition of aminoisocrotonate *(17)* to the Knoevenagel condensation product *(16)*.

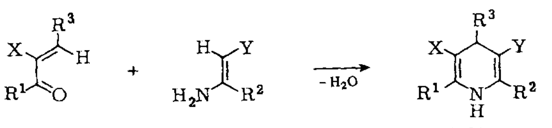


*(16)*, X = O, NH *(17)*

### 3.2. Controlled Cyclizing Michael Addition; Synthesis of Enantiomeric Dihydropyridines

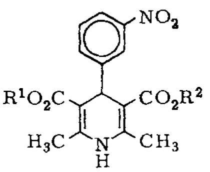
The intermediacy of *(16)* enables the synthesis of 1,4-dihydropyridines *(20)* with non-identical substituents in the 2,6- or 3,5-positions. Apart from the ester function other acceptor substituents such as oxo-, cyano-, sulfonyl-, or nitro-groups can stabilize the 1,4-dihydropyridine system.

The following products under clinical development are examples of 1,4-dihydropyridines with non-identical ester functions, which are accessible *via* cyclizing Michael reac-



(18) (19) (20)

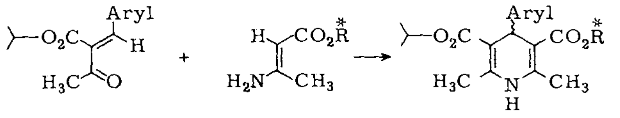
tions: nimodipine (21) (cerebral vasodilator)[29,30], nitrendipine (22) (antihypertensive)[31] and nicardipine (23) (cerebral vasodilator)[32]. Nicardipine is manufactured by the Japanese pharmaceutical company, Yamanouchi Pharm, which has been working intensively in the 1,4-dihydropyridine area since 1973[33].



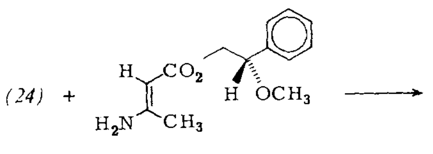
| | $R^1$ | $R^2$ |
|---|---|---|
| (21) | $CH(CH_3)_2$ | $(CH_2)_2OCH_3$ |
| (22) | $CH_3$ | $C_2H_5$ |
| (23) | $CH_3$ | $(CH_2)_2N(CH_3)CH_2C_6H_5$ x HCl |

1,4-Dihydropyridines of the type (21), (22) and (23) possess a chiral center at C-4 and thus can exist in enantiomeric forms. The synthesis of such antipodes will now be illustrated with the enantiomers of (21) as an example[34].

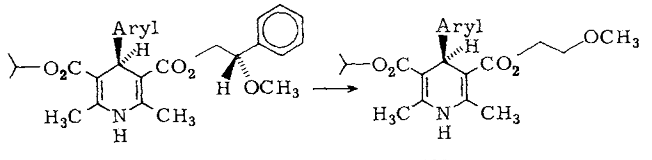
The most expedient route involves the synthesis of a 1,4-dihydropyridine derivative (26) with a chiral ester component. After separation of the two possible diastereomers the chiral ester group is converted into an achiral function



(24) (25) (26)



(27)

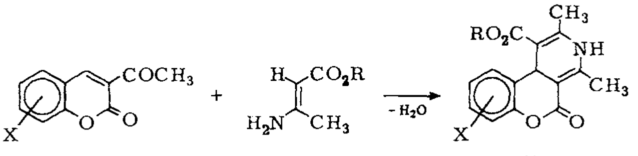


(28) (29)

Aryl = $m$-$O_2N$–$C_6H_4$

by solvolysis. If 2-methoxy-2-phenylethyl 3-aminoisocrotonate (27) is used, the ring-closure to the dihydropyridine occurs diastereoselectively to give the uniformly configurated derivative (28), which can be converted into the optically pure antipode of nimodipine (29) by selective alkanolysis of the chiral ester group. The other antipode of nimodipine is obtainable in an analogous way.

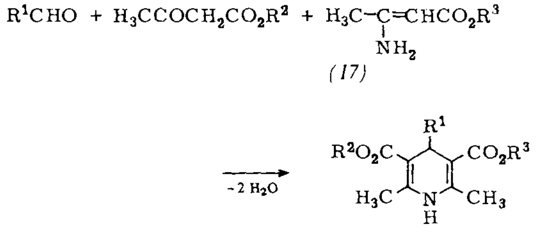
3-Acetylcoumarins (30), readily available from 2-hydroxybenzaldehydes and diketene, can also serve as substrates for the cyclizing Michael addition. They condense with the aminoesters (17) at 150°C without solvent to yield the tricycles (31)[35].



(30) (17) (31)

X = H, Alkyl, Alkoxy, Halogen

If an aldehyde is allowed to react analogously to eq. (B) with acetoacetate and amino esters (17) having non-identical ester functions, then the "mixed" 1,4-dihydropyridines (32) are obtained[36]. The symmetrically substituted dihydropyridines, which could be expected according to eq. (C), are only isolated as by-products in a few cases.

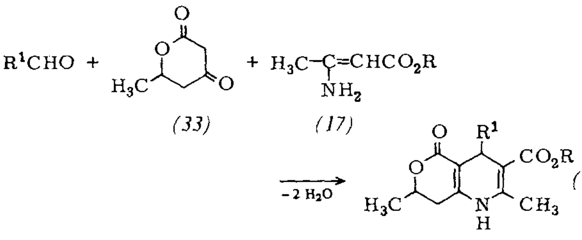


$$R^1CHO + H_3CCOCH_2CO_2R^2 + H_3C\text{–}\underset{NH_2}{C}{=}CHCO_2R^3$$

(17)

(32)

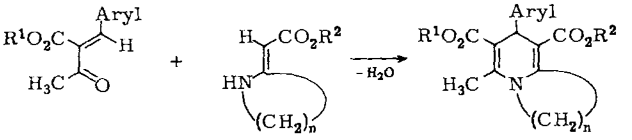
The condensation of aldehydes with β-ketolactones (33) and amino esters (17), which leads to the annelated 1,4-dihydropyridines (34) in high yields, is a further example of this three-component synthesis[37].



(33) (17) (34)

### 3.3. Synthesis of 1,4-Dihydropyridines with a Bridgehead Nitrogen Atom

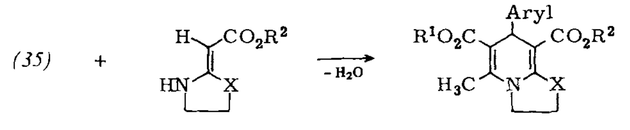
The cyclizing Michael addition of the alkylene bridged 3-aminoisocrotonate (36) to the arylalkylideneacetoacetate (35) yields the bicyclic 1,4-dihydropyridine-3,5-dicarboxylate (37) in high yield[38].



(35) (36) (37)

n = 3, 4, 5

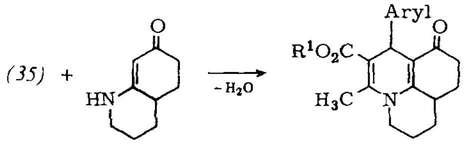
We were able to extend this principle of bridgehead nitrogen heterocycle synthesis to the derivatives (38) which bear a further heteroatom in the 2-position. Oxygen, nitrogen and sulfur could be introduced[38].



(38)

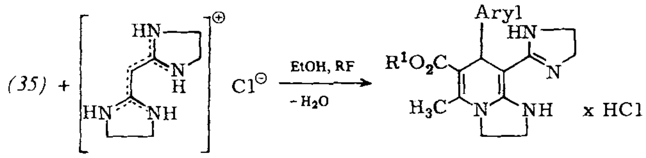
X = O, S, NH

*(35)* reacts with the bicyclic ketone *(39)* in refluxing glacial acetic acid to give the tricyclic dihydropyridines *(40)*[38].

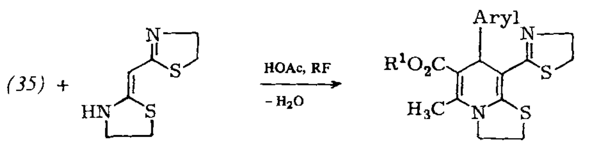


(39) (40)

In the special case of the malonodiimide derivatives *(41)* and *(43)* the imino function is able to exercise both the "push" and the "pull" functions of a donor/acceptor-substituted olefin. The cyclizing Michael addition to *(35)* yields the dihydropyridine derivatives *(42)* and *(44)* bearing a heterocyclic substituent at C-3[39].



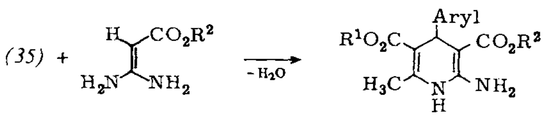
(41) (42)



(43) (44)

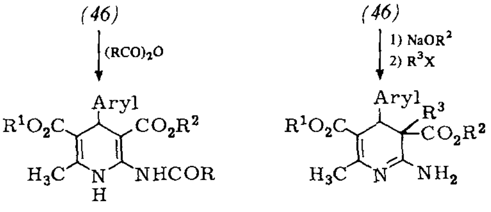
### 3.4. Synthesis of 2-Amino Substituted Dihydropyridines and Their Reactions

The synthetic potential in the dihydropyridine area can be greatly extended by the use of amidinoacetic esters as Michael addends. In their tautomeric enediaminocarbonyl form *(45)* they can be regarded formally as 3-aminocrotonates in which the methyl group has been replaced by an amino group. The cyclizing Michael addition of *(45)* to *(35)* yields the 2-amino-1,4-dihydropyridine-3,5-dicarboxylates *(46)*[40] in good yields, which, as polyfunctional molecules are available for numerous further reactions.



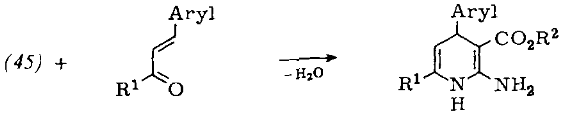
(45) (46)

Only the acylation and alkylation of *(46)* will be mentioned here. Acylation with carboxylic anhydrides occurs, as would be expected, at the exocyclic nitrogen to give *(47)*. In contrast, alkylation occurs at C-3 after deprotonation to give the 3,4-dihydropyridines *(48)*[41]. The regioselectivity of the alkylation contrasts with the *N*-alkylation of 2,6-dialkyl-1,4-dihydropyridine-3,5-dicarboxylates *(15)* under similar conditions[42,43], but is in accordance with *Gompper*'s allopolarization principle which postulates alkylation at the carbon atom for donor substitution of the enamine anion in the 2-position[44].

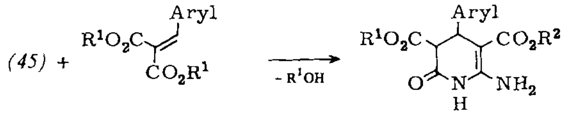


(47) (48)

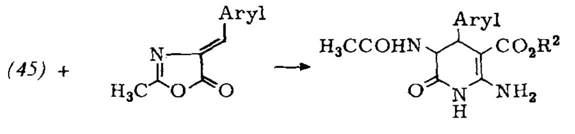
The amidinoacetic esters *(45)* are more reactive partners than 3-aminocrotonates *(17)* in the Michael addition. The condensation of *(45)* with simple α,β-unsaturated ketones *(49)* leads to the 1,4-dihydropyridinemonocarboxylates *(50)*[40], whereas addition to arylalkylidenemalonates *(51)* and 4-aralkylidene-2-methyloxazole-5(4*H*)-ones *(53)* yields the amino and diamino substituted dihydropyridones *(52)* and *(54)*, respectively[45].



(49) (50), $R^1$ = Alkyl, Aryl



(51) (52)

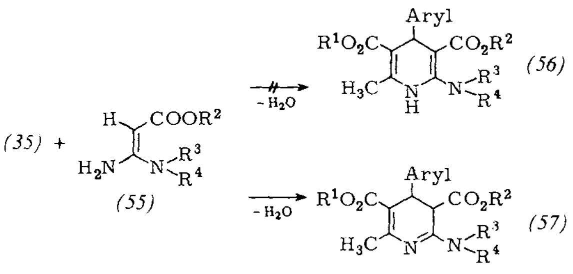


(53) (54)

The *N,N*-dialkyl-substituted enediamines *(55)* do not react as expected with *(35)* to give *(56)*, but instead to give the 3,4-dihydropyridines *(57)*[40], as indicated by the $^1$H-NMR, $^{13}$C-NMR, and mass spectra[46].

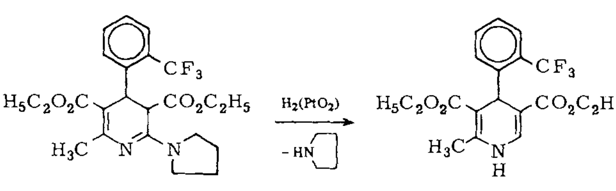
Apparently the highly substituted 1,4-dihydropyridine system switches to the less strained 3,4-dihydropyridine structure when highly hindered substituents are introduced.

Whereas the tautomeric conversion of *(57)* into *(56)* is not possible, the 3,4-dihydropyridines *(57)* can be converted by hydrogenolysis into 1,4-dihydropyridines unsubstituted in the 2-position, which are otherwise difficultly



$R^3$, $R^4$ = Alkyl; $R^3$ + $R^4$ = Alkylene

accessible. For example, the hydrogenation of *(58)* in glacial acetic acid over $PtO_2$ provides the 1,4-dihydropyridine *(59)* in good yield *via* an addition/elimination reaction[47].

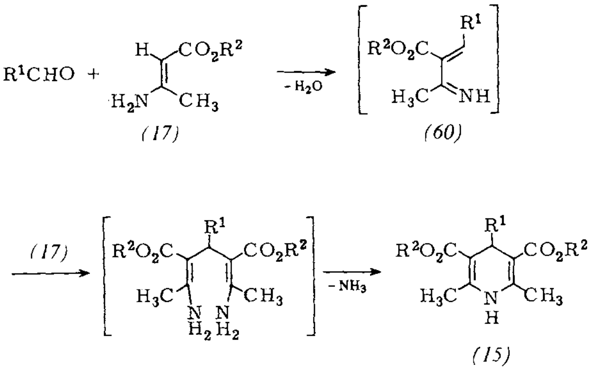


(58) (59)

### 3.5. Synthesis of 2,6-Heterosubstituted Dihydropyridines

In variant (C) of the Hantzsch condensation (see Section 3.1), an aldehyde is condensed with 3-aminoisocrotonate *(17)* in the molar ratio 1 : 2 with elimination of water and ammonia to give the dihydropyridine *(15)*[28].

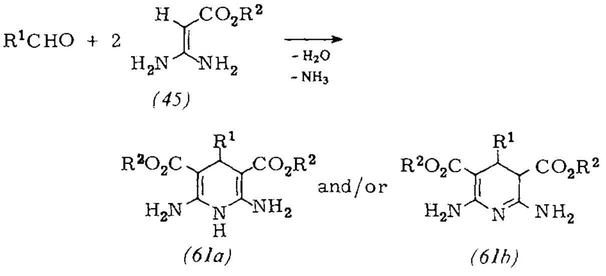
The non-isolable 2-arylalkylideno-3-iminobutanoate *(60)* resulting from a prior Knoevenagel condensation, may be postulated as intermediate in this reaction. The subsequent step would then be the Michael addition of *(17)* to *(60)* followed by the cyclizing condensation to *(15)*.



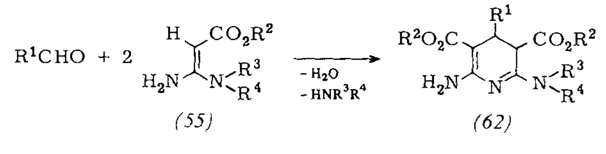
$R^1$ = Aryl, $R^2$ = Alkyl

Reaction of an aldehyde with double molar quantities of the amidinoacetic ester *(45)* in ethanol under reflux leads to the 2,6-diaminodihydropyridine-3,5-dicarboxylates *(61)* by an analogous mechanism[48].

Depending upon the substitution, the double bond isomers *(61a)* and/or *(61b)* are formed. Steric factors [cf. *(57)*] must exercise some influence on the isomer distribution, but are not the sole cause.

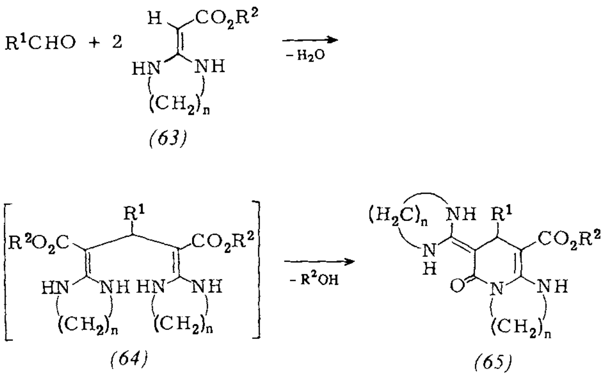


The condensation of aldehydes with the *N,N*-dialkyl-substituted amidinoacetic esters *(55)* to give the 3,4-dihydropyridine derivatives *(62)*[48] clearly shows the steric influence of the dialkylamino group. In this case the dialkylamine-elimination is favored over the alternative cleavage of ammonia.



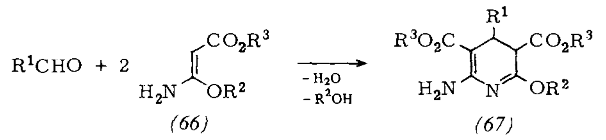
$R^3$, $R^4$ = Alkyl; $R^3$ + $R^4$ = Alkylene

In the analogous reaction of aldehydes with *N,N'*-bridged amidinoacetic esters *(63)* the Michael adducts *(64)* may be formulated as intermediates. Interestingly the amine components are not eliminated here. An alternative ring-closure takes place with the ester function to give the dihydropyridones *(65)*[48].



n = 2,3

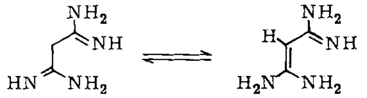
The formal replacement of the methyl group in 3-aminoisocrotonates *(17)* by an alkoxy function leads to the enamino form *(66)*, the imidate derived from cyanoacetate. The enamine form of such compounds postulated by *Cope* from the molar refraction[49] is confirmed by $^1H$-NMR spectroscopy. Condensation of *(66)* with an aldehyde in ethanol (reflux) affords the alkoxy derivatives *(67)*[50].



The structure of *(67)* is ascertained from IR, UV, NMR and mass spectral data, which exclude the alternative 1,4-dihydro form.

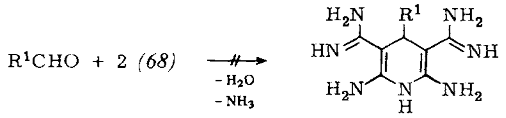
### 3.6. Special Cases of the Hantzsch Condensation

Malondiamidines such as the parent compound *(68)* can be regarded as special cases of an acceptor-substituted enamine. It has been shown that the methylene group in *(68)*



*(68)*

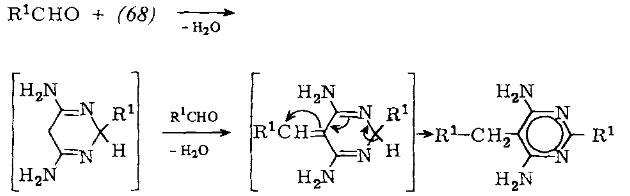
is capable of condensation with carbonyl compounds such as 1,3-diketones[51]. However, the condensation of *(68)* with aromatic aldehydes in the molar ratio 2 : 1 does not lead to the 3,5-diamidino-2,6-diamino-1,4-dihydropyridines *(69)* as would be expected in analogy to the synthesis of *(61a)*



*(69)*

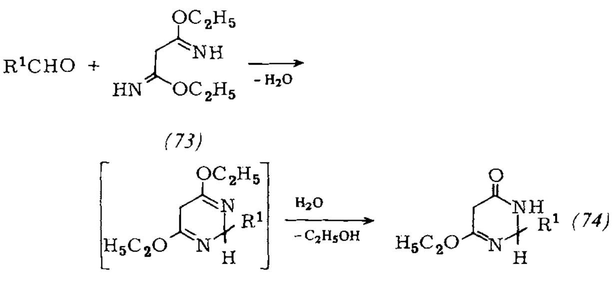
and/or *(61b)*; instead, products are isolated whose molecular weights correspond to the reversed mole ratio of the starting materials after elimination of 2 moles $H_2O$. In fact the condensation of aldehydes with *(68)* in the molar ratio 2 : 1 can be carried out in a widely variable synthesis such that 4,6-diaminopyrimidines *(72)* are formed in high yield[52].

This simple synthesis may be explained by the following multistep process.



*(70)* *(71)* *(72)*

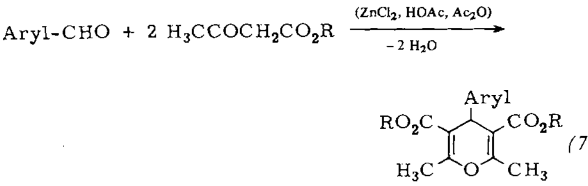
If among 3-iminoenamines such as *(68)* the possibility of a [5+1]-condensation (aminal formation) with aldehydes prevails, then this reaction is apparently favored over that of electrophilic attack at carbon. Aromatic aldehydes confirm to this hypothesis in that they condense with diethyl malonimidate *(73)* to give 6-ethoxy-4-oxo-2,3,4,5-tetrahydropyrimidines *(74)* after hydrolysis of a lactim ether function[53].



*(73)* *(74)*

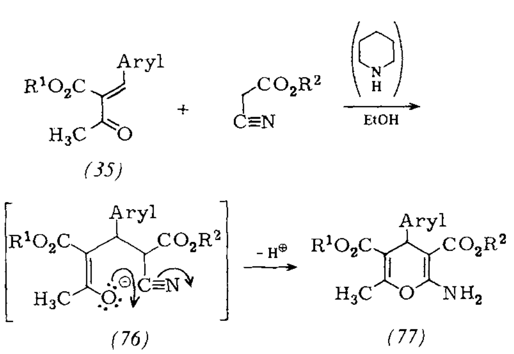
### 3.7. Synthesis of 4-Aryl-4*H*-pyrans, 4-Aryldihydropyridazines and Related Heterocycles

4*H*-Pyran derivatives *(75)* are oxa-analogues of 4-aryl-1,4-dihydropyridine-3,5-dicarboxylates. According to *Wolinsky* and *Hauer*[54] they are accessible by acid condensation of aromatic aldehydes with acetoacetates.



*(75)*

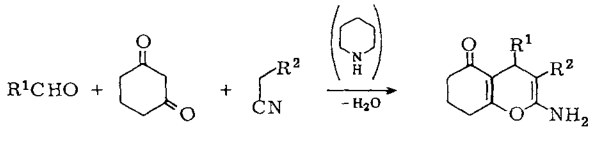
We obtained the corresponding 2-amino-4*H*-pyrans *(77)* by base catalyzed cyclizing Michael addition of cyanoacetates to the arylalkylideno-acetoacetates *(35)*[55].



*(35)* *(76)* *(77)*

The mechanism of this simple formation of the 4*H*-pyran system probably involves nucleophilic attack of the enolate anion of the Michael adduct *(76)* on the nitrile group.

The relationship of this pyran synthesis (cf. also [56]) with the Hantzsch dihydropyridine synthesis is clearly seen in the three-component reaction of aliphatic or aromatic aldehydes, 1,3-dicarbonyl compounds such as cyclohexan-1,3-dione and the nitriles *(78)* with an activated methylene group. 2-Amino-5-oxo-5,6,7,8-tetrahydro-4*H*-chromenes *(79)* are obtained in good yields from a piperidine-catalyzed reaction in ethanolic solution[57].

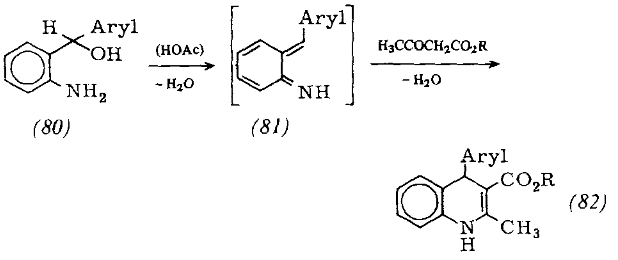


*(78)* *(79)*

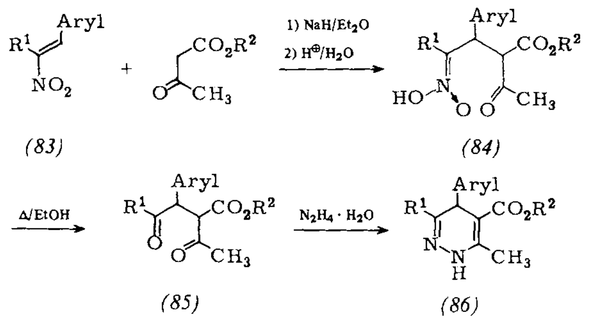
$R^2$ = CN, $CO_2R^3$

1,4-Dihydroquinoline-3-carboxylates *(82)*, are obtainable by condensation of 2-aminobenzyl alcohols *(80)* with β-dicarbonyl compounds in glacial acetic acid[58]. Here again a cyclizing Michael addition to the quinoneimine derivative *(81)* is to be formulated as the key step.

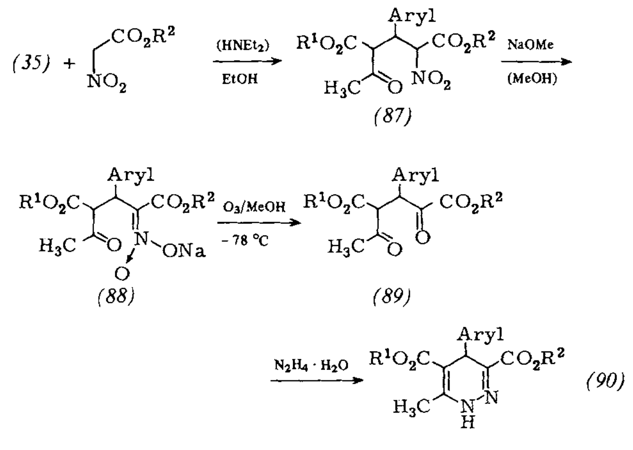
1,4-Dihydropyridazine-5-carboxylates *(86)* with alkyl or aryl substituents in the 3-position *(86)* are accessible by the following reaction sequence[59]. Addition of acetoacetate to



the nitrostyrene or nitrostilbene *(83)* furnishes the nitronic acid *(84)* after mild hydrolysis[60], which is converted into the 1,4-diketone *(85)* by a thermal Nef reaction[61]. A [4+2]-condensation with hydrazine hydrate results in the formation of *(86)*.

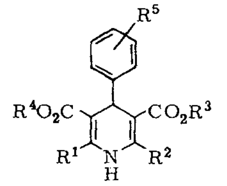


The 1,4-dihydropyridazine-3,5-dicarboxylates *(90)*, pyridazine analogues of the 1,4-dihydropyridines *(15)*, are obtained[59] by an interesting synthetic equivalent of the Nef reaction[62]. Michael addition of nitroacetic esters to the aralkylideno-acetoacetate *(35)* provides the adducts *(87)*, which are converted to the nitronates *(88)* by treatment with sodium methoxide. Low temperature ozonolysis of *(88)* permits the introduction of the carbonyl function in the α-position to give the diketodiester *(89)* which can then be condensed conventionally with hydrazine hydrate to give *(90)*.



## 4. Structure/Activity Relationships

Based on the biological data of a large number of 1,4-dihydropyridines with the general formula *(91)*, which have been synthesized in our laboratories, some qualitative structure/activity relationships can be deduced. Accordingly, an optimum in biological activity (vasodilation, reduction of blood pressure) is to be expected when the following structural parameters are met:



*(91)*

a) 1,4-Dihydropyridines unsubstituted at nitrogen.

b) Lower alkyl groups are optimal substituents ($R^1$, $R^2$) in the 2,6-positions. Replacement of one alkyl group by amino is tolerated.

c) Carboxylate groups are superior to other acceptor substituents such as CN, COR, $SO_2R$, $CONR_2$, $NO_2$ *etc.*, both in the 3- and the 5-position. The alcohol component of the ester group can be saturated, unsaturated, straight-chain or branched. The alkyl chain may be interrupted by heteroatoms or silicon[63,64]. 1,4-Dihydropyridines with non-identical ester groups ($R^3 \neq R^4$) are in many cases superior to the corresponding derivatives with identical substitution[31].

d) A phenyl substituent is superlative in the 4-position of the dihydropyridine even though its replacement by other monocyclic or polycyclic arenes or heteroarenes is possible within limits[17]. Monosubstitution of phenyl ($R^5$) by acceptor substituents such as $NO_2$, CN, $CF_3$ *etc.* in the *ortho-* or *meta*-position has a positive influence. *Para*-substitution, on the other hand, causes a marked reduction in, or even loss of activity.

With the aid of Hansch analysis[65] it was possible to establish a quantitative relationship between physicochemical substituent properties and the negative ionotropic activity[*] on the papillary muscle of the cat for a small selection of 1,4-dihydropyridine derivatives *(91)*[66].

## 5. Prospects

The discovery that intermediates in a named reaction familiar to chemists for almost 100 years have high pharmacological activity has recently awakened the interest of numerous companies and other institutions in the Hantzsch dihydropyridines as a class. The synthetic potential of the Hantzsch reaction thus revealed could also be of value for other branches of heterocyclic chemistry. The progress to date in the chemistry, pharmacology and clinical application of 1,4-dihydropyridines leads one to expect interesting results in the future.

*In conclusion we would like to thank numerous colleagues for the years of fruitful collaboration, in particular Drs. G. Franckowiak, S. Goldmann, H. Horstmann, B. Junge (chemical research), W. Vater, K. Stoepel, S. Kazda, R. To-*

## High Pressure Michael Addition Catalyzed by Fluoride Ions[**]

By *Kiyoshi Matsumoto*[*]

Michael addition and related reactions constitute the most generic synthetic means for the construction of quaternary C atoms[1]. Recently, we described the high pressure Michael addition of components which either do not react or at most react sluggishly at atmospheric pressure[2]. Recent developments in phase transfer[3] catalysis and 'naked' fluoride anion catalyzed reactions prompted us to investigate fluoride catalyzed Michael additions—specifically in homogeneous solution—since high pressures can easily be accomplished under these conditions. The previously reported[2] Michael additions took place in moderate to excellent yields under conditions of $n$Bu$_4$NF catalysis at normal pressure, as summarized in Table 1. However, the reaction of diethyl isopropylmalonate and diethyl phenylmalonate with chalcone was unsuccessful, even in the presence of 'naked' fluoride anions generated by a variety of different methods[4]. This probably arises from the increased steric hindrance caused by substituents in the vicinity of the Michael donor reaction center and concomitant difficulties in the deprotonation step. These problems were expeditiously circumvented *via* recourse to the combined use of $n$Bu$_4$NF catalysis and high pressure, although yields of products were only moderate; *(7)* and *(8)* were obtained in 20 and 28% yield, respectively.

The use of high pressures may be of value in Michael additions and related reactions where the use of 'naked' fluoride anion or strong bases is not appropriate due to side reactions such as elimination[1,5] or fragmentation[6], and where even 'naked' fluoride anion is not powerful enough to induce reaction because of energy barriers imposed by steric and electronic effects.

### *Procedure*

Reaction at normal pressure: Michael acceptor (3 mmol), donor (6 or 15 mmol), and 10 mL of a 1 M solution of $n$Bu$_4$NF in tetrahydrofuran (THF)[7] are mixed under nitrogen and stirred at room temperature (Table 1). The reaction mixture is diluted with 50 mL of benzene and extracted several times with water to remove the catalyst. The organic layer is dried over $MgSO_4$ and worked-up as previously described[2].

Reaction at high pressure: Michael acceptor (3 mmol) and donor (6 mmol) are diluted with a 1 M-THF solution of

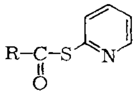
## 1-Phenyl-2-tetrazoline-5-thione, an Effective Reagent for the Synthesis of Macrocyclic Lactones[**]

By *Ulrich Schmidt* and *Manfred Dietsche*[*]

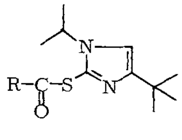
*Dedicated to Professor Arthur Lüttringhaus on the occasion of his 75th birthday*

Methods which have proven useful for the synthesis of macrocyclic lactones from hydroxy acids include the "double activation" method of *Corey* with 2-pyridinethiol esters *(1)*[1] and especially 2-imidazolethiols such as *(2)*[2], as well as the use of onium salts of azaarenes according to the method of *Mukaiyama*[3]. Substantial activation of *(1)* is possible with silver salts[4]. *(1)* and *(2)* are almost always prepared by oxidation-reduction condensation[5]. However, a very disturbing feature[6] is that the reaction products must be separated from pyridinethiol, triphenylphosphane oxide, dipyridyl sulfide, and, in the case of Ag-activation, from excess silver thiolate.

*(1)*

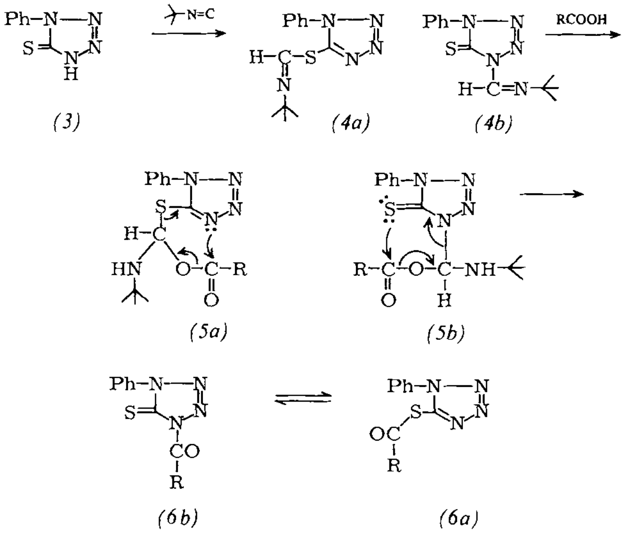


*(2)*

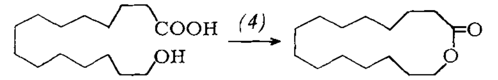


We have now found a very effective cyclization method for hydroxy acids. 1-Phenyl-2-tetrazoline-5-thione *(3)*, which is readily accessible from phenyl isothiocyanate and sodium azide[7], is allowed to react with *tert*-butyl isocyanide to give *(4a)* or *(4b)* which is reacted with the hydroxy acid.

*tert*-Butyl isocyanide reacts within a few minutes with *(3)*, suspended in toluene, to give a solution of the thioformimidate *(4a)* or the formamidine *(4b)*[8], which on treatment with carboxylic acids forms the mixture of the *S*- and *N*-acyl compounds *(6a)*+*(6b)* *via* the intermediates *(5a)* and *(5b)*, resp.[9]. The one rapidly rearranges to the other. The highly active acyl compounds can be used for *C*-acylation, for racemization-free peptide formation at −30 °C, and for ester formation.



The compounds *(6)*, R = ω-hydroxyalkyl, are such strong acylating agents that a silver ion catalyst is superfluous in the lactonization. The 16-, 17-, 18- and 20-membered lactones are formed in over 90% yield (determined gas-chromatographically) without extreme dilution in $3.5 \times 10^{-3}$ M solution in boiling toluene. The 13-membered ring was obtained in only 55% yield, probably because the larger activation energy for the formation of medium-sized rings requires prolonged heating of the thermolabile compounds *(6)*. Work-up is particularly easy when 1-(*m*-dimethylaminophenyl)-2-tetrazoline-5-thione is used for the activation. This reagent can be readily removed from the reaction product by dilute mineral acids.



### Procedure

Pentadecanolide (Exaltolide) *(8)*: To a mixture of *(3)* (124 mg, 1.2 mmol) and anhydrous toluene (5 mL) is added 100 mg (1.2 mmol) of *tert*-butyl isocyanide. After 5 minutes stirring at room temperature the now homogeneous solution is added to 258.5 mg (1.0 mmol) of ω-hydroxypenta-

## Preparation and Structure of Iodocuprates(I) with Tetrahedral Face-to-Face Coupling

By *Hans Hartl* and *Farbod Mahdjour-Hassan-Abadi*[*]

Halometalates, like the oxometalates, exhibit an extremely wide variation in their structural chemistry. Particularly interesting in this respect are compounds with $d^{10}$-electron configuration at the metal, *e.g.* the halocuprates(I) and -argentates(I). These halometalates are, *inter alia,* also of industrial importance, since some of the compounds of this type show ionic conductivity in the solid state[1].

Halometalates $R_mM_nX_p$ (R = organic cation, M = metal, X = Cl, Br, I) are usually prepared by reaction of metal halides with the halides RX in solution or by solid state reactions. We have found that the direct reaction of the metals with triiodides $RI_3$, or with iodine in the presence of the iodide RI in organic solvents, often lead in a simple manner not only to well-known but also to new iodometalates. The composition and structure of the iodometalates isolable by precipitation in these reactions depend on the nature (size, form, charge distribution) of the cations R. Thus, reaction of Cu with $R^1I_3$ = tetramethylammonium triiodide or $R^2I_3$ = dimethyl(3-dimethylamino-2-aza-2-propenylidene)ammonium triiodide[2] led, *inter alia,* to compounds of the composition $R^1Cu_2I_3$ and $R^2Cu_2I_3$, respectively. The triiododicuprate(I) ion in these compounds has a structure which completely deviates from the known types of structure of $Cu_2X_3^-$ (X = Cl, Br, I)[3]: $CuI_4$-tetrahedra linked alternately *via* common edges and faces (!) into ${}^1_\infty(Cu_2I_3^-)$ single chains (Fig. 1). Examples of face to face coupling in tetrahedrally coordinated polyhedra have so far not been described in the literature[5].

$[(C_2H_5)_4N]Cu_2I_3$
$R^1Cu_2I_3$

$[(CH_3)_2N{=}CH{-}N{=}CH{-}N(CH_3)_2]Cu_2I_3$
$R^2Cu_2I_3$

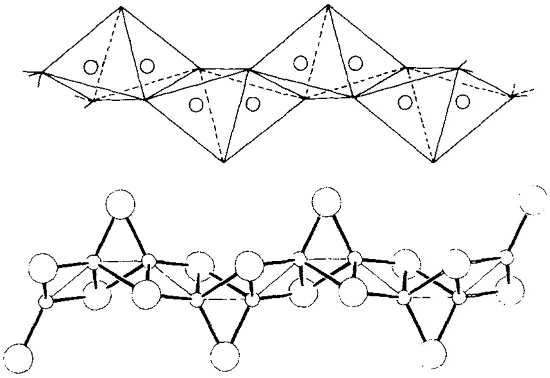

Fig. 1. Structure of the ${}^1_\infty(Cu_2I_3^-)$ anion in the iodocuprate(I)s $R^1Cu_2I_3$ and $R^2Cu_2I_3$. Top: polyhedral model of the chain (Cu: circles); bottom: spherical model of the chain (I: large circles; Cu: small circles).
$R^1Cu_2I_3$, orthorhombic, $Pna2_1$; $a = 842.0(2)$, $b = 1775.5(4)$, $c = 1073.6(2)$ pm. $Z = 4$. 1426 measured reflections, 1123 reflections with $I > 2\sigma(I)$, STOE diffractometer, $Cu_{K\alpha}$-radiation, $R = 0.056$. Symmetry of the ${}^1_\infty(Cu_2I_3^-)$ anion: glide plane. Cu—I 247.5(1)—296.1(1) pm, mean value 270.2 pm; Cu—Cu 250.7(1) and 267.9(1) pm (face- or edge linked); I—Cu—I 95.4(2)—121.4(3)°.
$R^2Cu_2I_3$, monoclinic, $C2/c$; $a = 1572(1)$, $b = 1227(1)$, $c = 850(1)$ pm, $\beta = 108.26(6)$, $Z = 4$. 1336 measured reflections, 985 reflections with $I > \sigma(I)$, SIEMENS diffractometer, $Mo_{K\alpha}$-radiation, $R = 0.034$. Symmetry of the ${}^1_\infty(Cu_2I_3^-)$ anion: twofold rotation axis/glide plane. Cu—I 253.1(2)—291.6(2) pm, mean value 270.2 pm; Cu—Cu 249.1(2) and 269.9(2) pm (face- and edge-linked, resp.); I—Cu—I 99.7(3)—123.1(3)°.

Moreover, the short distances of 249.1 pm and 250.7 pm between the Cu atoms bridged by the three iodine atoms in $R^2Cu_2I_3$ and $R^1Cu_2I_3$, respectively, are remarkable. They are the shortest Cu—Cu distances so far observed in copper-halogen compounds. Shorter distances could only be established in a few organo-copper compounds[6] (for comparison: Cu—Cu in the metal: 256 pm). To what extent the short Cu—Cu contacts are to be ascribed to metal-metal bonding or to the three bridging iodine atoms cannot be established by bond length considerations alone, since comparable values for compounds with analogous Cu—Cu coupling are not known. For the same reason the relationships between Cu—Cu distances and bond energies calculated by *Mehrotra* and *Hoffmann*[7] cannot be considered as evidence for metal-metal bonding in $R^2Cu_2I_3$ and $R^1Cu_2I_3$. The distances between the Cu atoms coupled *via* common edges of iodine tetrahedra (269.9 and 267.9 pm, respectively) are likewise relatively small. The low electrical conductivity of $3 \times 10^{-13}\ \Omega^{-1}\ cm^{-1}$ at 20 °C, measured on pellets of powdered $R^2Cu_2I_3$ would however discount an unambiguous one-dimensional conductivity *via* Cu—Cu—Cu bonds in the direction of the axis of the chain.

What type of relationships exist between the structure of the iodocuprate(I) ions and nature of the cations R cannot be decided on the basis of the present data. The form and charge distribution of the cations $R^1$ and $R^2$ are very different: $R^1$ is spherical with spherical charge distribution; $R^2$ is planar with delocalized π-electron system. Nevertheless, the same type of anion structure ${}^1_\infty(Cu_2I_3^-)$ with only slight differences in the bond lengths and angles is present in both cases (Fig. 1). If one chooses for R the cations *N*-methylpyridinium or methyltriphenylphosphonium, which are comparable with the cations $R^2$ and $R^1$, respectively, so far as type of structure is concerned, then iodocuprates(I) with a Cu : I ratio of 2 : 3 can indeed also be prepared, but the structure depicted in Figure 1 could not be detected[3].

*Procedure*

$R^2Cu_2I_3$: A mixture of $R^2I_3$ (2.55 g, 5 mmol) and Cu powder (1.28 g, 20 mmol) in anhydrous chloroform (40

---

Institut für Anorganische und Analytische Chemie der Freien Universität
Fabeckstrasse 34/36, D-1000 Berlin 33 (Germany)

mL) is heated to boiling solution until the solution decolorizes (*ca.* 2 h). After cooling and filtering, the gray residue is rapidly dissolved in dimethylformamide. Addition of anhydrous benzene to the solution furnishes a white crystalline precipitate of m.p. 189—190 °C.

$R^1Cu_2I_3$: A mixture of $R^1I$ (1.26 g, 5 mmol) and Cu powder (1.27 g, 20 mmol) in acetone (100 mL) is heated together with $I_2$ (1.28 g, 5 mmol) under reflux until the solution turns yellow. On cooling the hot filtered solution, needle-like crystals separate out; m.p. 176—177 °C.

For the preparation of pure crystals it has proven advantageous to work with an excess of copper, since the separation of unreacted $RI_3$ causes difficulties, while unreacted Cu can be filtered off.—Both iodocuprates are readily soluble in dimethylformamide and pyridine but only sparingly soluble in acetone. They are insoluble in benzene, ether, petroleum ether, chloroform, and water.

## Selective CH-Insertion Reactions of Free Arylhalocarbenes[***]

By *Karl Steinbeck* and *Joachim Klein*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Carbenes not only have the ability to form cyclopropanes on reaction with olefinic double bonds but also to react with CH-bonds with insertion. Such insertion reactions, however, usually proceed unspecifically or in very low yields[1]. In continuation of our investigations on the selectivity of reactions of electrophilic carbenes[2] we were able to show that CH-insertion of dichloro- and dibromocarbene (generated in the two-phase system 50% sodium hydroxide/haloform, in the presence of phase transfer catalysts[3]) can proceed selectively, in many cases even specifically, and in good to very good yields. In order to extend this obviously preparatively useful method to the synthesis of C—C bonds we have investigated the behavior of further electrophilic carbenes and report here on the first observed selective CH-insertion of arylhalocarbenes.

Attempts to generate arylhalocarbenes from arylidene halides *(1)* by α-elimination in the liquid-liquid two-phase system with 50% sodium hydroxide failed. According to *Moss et al.*[5] arylhalocarbenoids are formed on reaction of *(1)* with potassium *tert*-butoxide, while reaction with a crown ether such as [18]crown-6 leads to *free* arylhalocarbenes. We have found that only the free carbenes form the expected CH-insertion products. The arylhalocarbenes reacted about as selectively as the dihalocarbenes. Thus, we were able to carry out both the hydroalkylation of free chloro(phenyl)carbene (aryl = $C_6H_5$, X = Cl) with cumene and adamantane to give the 1-chloro-2-methyl-1,2-diphenylpropane *(2a)* and 1-(α-chlorobenzyl)adamantane *(3a)* as well as the hydroalkoxyalkylation with 2-methyltetrahydrofuran to 2-(α-chlorobenzyl)-2-methyltetrahydrofuran *(4a)* and, especially, also the capped hydroacylation with 4,4,5,5-tetramethyl-2-phenyl-1,3-dioxolane to 2-(α-chlorobenzyl)-4,4,5,5-tetramethyl-2-phenyl-1,3-dioxolane *(5a)*, R = $C_6H_5$ (see Table 1).

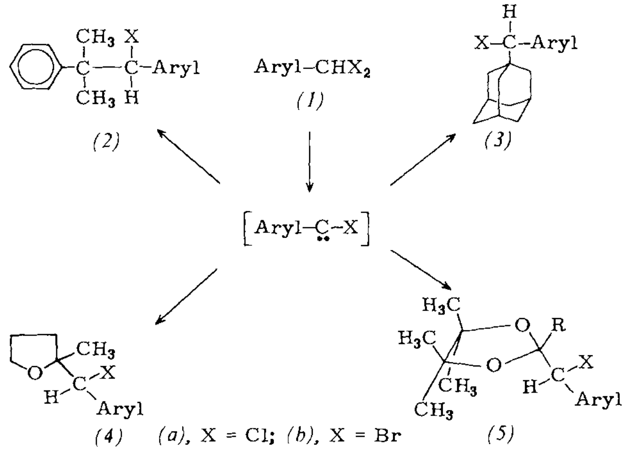

Table 1. Some data of the insertion products *(2a)*—*(5a)*, Aryl = $C_6H_5$, X = Cl.

| Cpd. | Yield [%] [a] | B.p. [°C/torr] | M.p. [°C] | $^1$H-NMR ($CDCl_3$, δ values) |
|---|---|---|---|---|
| *(2a)* | 21 | 115/0.005 | | 1.35 and 1.45 (2s, 6H), 5.03 (s, 1H), 7.0—7.2 (m, 10H) |
| *(3a)* | 10 | | 85 | 1.3—2.1 (m, 15H), 5.75 (s, 1H), 7.3 (m, 5H) |
| *(4a)* [b] | 19 | 95/0.5 | | 1.13 and 1.20 (2s, 3H), 1.40—2.32 (m, 4H), 3.45—3.92 (m, 2H), 4.80 (s, 1H), 7.07—7.40 (m, 5H) |
| *(5a)*, R = $C_6H_5$ | 44 | 130/0.05 | 77 | 0.90 and 0.96 (2s, 6H), 1.30 (s, 6H), 5.07 (s, 1H), 7.03—7.63 (m, 10H) |

[a] Referred to benzylidene chloride *(1a)*. [b] Diastereomeric pair.

*(1a)*, aryl = $C_6H_5$, X = Cl, and 1.5-fold excess of base were allowed to react in the presence of 5 mol-% [18]crown-6 at 80 °C with an excess of the respective substrate. *(2a)*—*(5a)* were the sole isolable products. Excess of unreacted educt could be removed by distillation. The structure of the insertion product is confirmed by NMR and mass spectra as well as by CH analysis.

[*] Priv.-Doz. Dr. K. Steinbeck [**], Dipl.-Chem. J. Klein
Institut für Organische Chemie der Technischen Hochschule
Prof.-Pirlet-Strasse 1, D-5100 Aachen (Germany)

[**] Present address: Bayer AG, FE-FWI Q 18, 5090 Leverkusen (Germany)

[***] Part 6 of the Series, Applications of Phase Transfer Catalysis.—Part 5: *K. Steinbeck*, J. Chem. Res. *1980*, (S) 95; (M) 1163.

These reactions can be applied to other arylhalocarbenes. Thus, reaction with free bromo(phenyl)carbene, from benzylidene bromide *(1b)*, aryl = $C_6H_5$, X = Br, leads to formation of the α-bromobenzyl insertion products *(2b)*, *(3b)*, *(4b)*, *(5b)*, R = $C_6H_5$. The use of aryl groups other than phenyl is usually not very favorable, since substituents either lower the acidity of *(1)* (first step of the α-elimination rendered difficult) or increase the stability of the carbanion (second step of the α-elimination difficult). Positive results were obtained with free chloro(*p*-toyl)carbene.

The methods described above enable selective coupling of an electrophilic carbene with reactive CH compounds and lead, in the case of halogen-containing carbenes and 2,4,4,5,5-pentasubstituted dioxolanes to ketals of α-haloketones [type *(5)*] with defined content and position of the halogen.—An example of the preparative application of the method to other electrophilic carbenes is the selective CH-insertion of the carbene 3-methyl-1,2-butadieneylidene (prepared by reaction of 3-chloro-3-methyl-1-butyne in a two-phase system with 50% NaOH[6]) into the $C^2$—H bond of 1,3-dioxolanes.

*Procedure*

A mixture of *(1a)* (20.5 g, 0.125 mol) and substrate (20 g) is added dropwise within 12 h into a mixture of potassium *tert*-butoxide (21 g, 0.19 mol), [18]crown-6 (1.6 g) and substrate (80 g) at 80 °C. After 48 hours stirring at 80 °C the reaction mixture is diluted with water and extracted with ether. Distillation of the organic phase affords the products *(2a)*-*(5a)* (see Table).

## Synthesis and Reactions of Methylenecyclopropanes; Isolation of a [4+2]-Cycloadduct of Methylenecyclopropene[**]

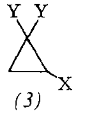
By *Andreas Weber* and *Markus Neuenschwander*[*]

Although numerous derivatives of methylenecyclopropene (triafulvene) *(1)* and cyclopropenylidenecyclopentadiene (pentatriafulvalene calicene) *(2)* have been described, the parent cyclic, crossed conjugated compounds are so far unknown[1]. The intermediary appearance of *(1)* has been implicated in studies on elimination reactions of 1,2-dichloro-1-methylcyclopropane[2], however, a cycloadduct of triafulvene *(1)* could not be isolated.

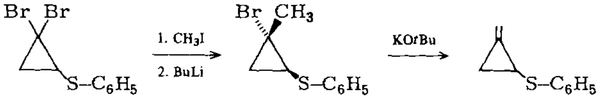
Trisubstituted cyclopropanes of type *(3)* are suitable precursors for *(1)* and *(2)*[3]: by analogy to other 1,1-dihalocyclopropanes[4] it should be possible to metalate and alkylate them[5]. After cleavage of HY, the substituent X could then be converted into a leaving group and be eliminated.

*(1)*

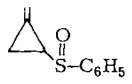
*(2)*



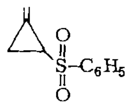
*(3)*



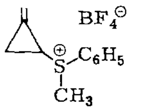
*(4)* *(5)* 93% *(6)* 70%



*(7)* 83%



*(8)* 80%



*(9)* ~95%

This synthetic plan[6] can be simply performed on 1,1-dibromo-2-phenylthiocyclopropane *(4)*[3]: reacting a solution of *(4)* (4 mmol) and methyl iodide (6 mmol) in THF (tetrahydrofuran) with butyllithium (4 mmol) at −95 °C results in the isolation in 93% yield of *trans*-1-bromo-1-methyl-2-phenylthiocyclopropane *(5)*, from which HBr can be eliminated by the action of potassium *tert*-butoxide to give the key intermediate *(6)*.

Table 1. $^1$H-NMR data (80 MHz, $CDCl_3$, δ-values rel. to TMS) of the cyclopropane derivatives *(4)*—*(11)*.

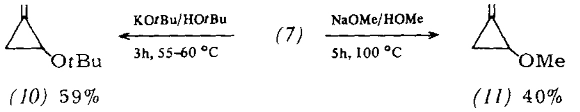
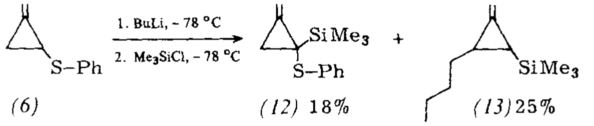
[**] Fulvenes, Fulvalenes, Part 32. Part 31 [5]. This work was supported by the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung (Project No. 2.621-0.80).

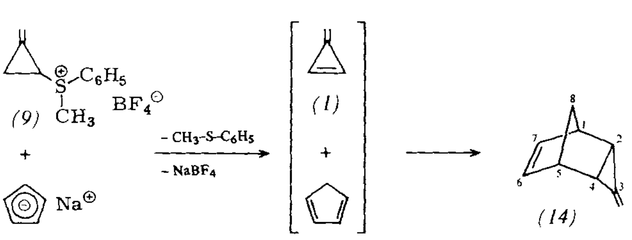
Oxidation with $NaIO_4$ in $CH_3OH/H_2O$ or with $H_2O_2$ in $CH_3COOH$ results in formation of the sulfoxide *(7)* and the sulfone *(8)* in high yield. Alkylation of *(6)* with trimethyloxonium tetrafluoroborate also proceeds almost quantitatively, however the oily diastereomeric mixture of *(9)* is not easily purified.—The structure of the compounds has been verified by analytical and spectroscopic data. The $^1H$-NMR spectra of *(4)* to *(9)* are characterized by the ABX- or AMX-systems of the three-membered ring protons (Table 1).

Both *(7)* and *(8)* react with strong bases, such as potassium *tert*-butoxide or lithium diisopropylamide in THF, between −20 and −78 °C. In this way, diphenyl disulfide (stemming from the initially formed sulfenic acid) is formed from the sulfoxide *(7)*, which indicates that the leaving group is cleaved; however, the expected three-membered-ring products could not be isolated or detected spectroscopically. If the basic elimination of HX from *(7)* is performed in the presence of high concentrations of a protonic trapping reagent, such as *tert*-butyl alcohol or methanol, 1-*tert*-butoxy-2-methylenecyclopropane *(10)*[2] or 1-methoxy-2-methylenecyclopropane *(11)* are isolated in high yield[7]. In addition to the expected product *(12)*, the silylation of *(6)* yields 1-butyl-2-methylene-3-trimethylsilylcyclopropane *(13)* (25%).





Since $S_N2$ reactions on substituted cyclopropanes are hardly possible, these results implicate the intermediate formation of methylenecyclopropene *(1)*. On the other hand, methyl phenyl sulfide can be cleaved off the sulfonium salt *(9)* under extremely mild conditions[8]; this also indicates that *(1)* could occur as an intermediate. Finally, a hydrocarbon with the empirical formula $C_9H_{10}$ is isolated in 13% yield[8] when *(9)* is reacted with an equivalent of sodium cyclopentadienide in furan/THF; the spectroscopic data indicate the structure shown in *(14)*: the number of lines in the $^1H$- and $^{13}C$-NMR spectra (Fig. 1) corresponds to the symmetry of the molecule.



The $^1H$-NMR signals at $\delta = 5.81$ (6-H/7-H) and 3.00 (1-H/5-H) are typical of norbornenes, while the multiplet at $\delta = 4.98$ (methylene groups on C-3) appears at almost the same chemical shift as the exocyclic $CH_2$-group of *(13)* (5.1). The assignment of the signals at $\delta = 1.93$ (2-H/4-H) and 1.84 (8-H/8'-H), as well as the *endo*-configuration of *(14)* follows from decoupling experiments.—In the $^{13}C$-NMR spectrum C-6/C-7 ($\delta = 133.4$) and C-1/C-5 (45.0) absorb in the typical norbornene region, while the signal from C-8 (63.7) is displaced to somewhat higher frequencies[9]; the characteristically low frequency (20.7) of the signals from C-2/C-4 reflects the ring strain of the three-membered ring, and the chemical shifts of the C-atoms of the exocyclic double bond (142.9, C-3 and 102.2, C-9) are also typical.

In summary, investigations of elimination- and trapping-reactions of methylenecyclopropanes, such as *(7)*—*(9)*, provide convincing evidence that the reactive methylenecyclopropene *(1)* occurs as an intermediary.

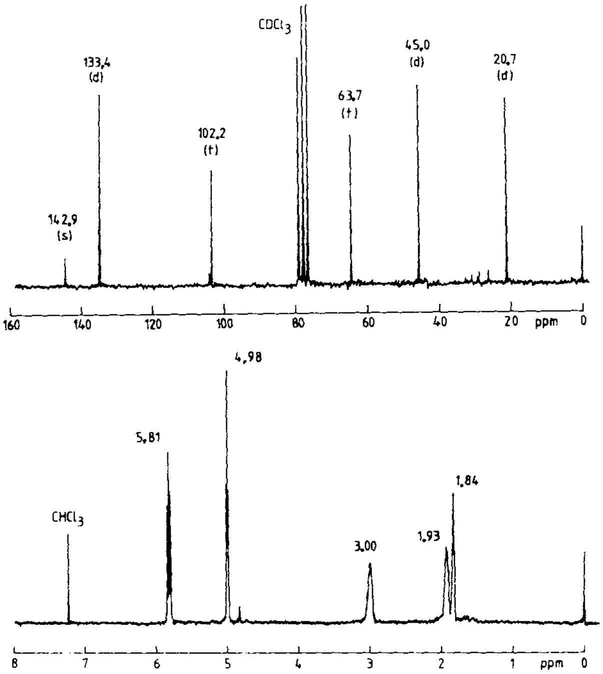


Fig. 1. NMR-spectra of *(14)*. Bottom: $^1H$-NMR ($CDCl_3$, 100 MHz). Top: $^{13}C$-NMR ($CDCl_3$, 25 MHz).

### *Procedure*

*(9)*: A solution of *(6)*[3] (2 mmol) in 2 mL anhydrous $CH_3NO_2$ is dropped into a solution of trimethyloxonium tetrafluoroborate (2 mmol) in 3 mL anhydrous $CH_3NO_2$ under $N_2$ at 0 °C. After stirring for 2 h at 0 °C, the yellow-brown solution is concentrated at 5 torr/20 °C, the residue washed with pentane (3 × 5 mL) and dried under high vacuum at 20 °C: brown oil, yield according to $^1H$-NMR *ca.* 95%.

*(14)*: Sodium cyclopentadienide (3 mmol) in 2 mL anhydrous THF is dropped, within a period of 40 min, into a suspension of *(9)* (2 mmol) in 10 mL anhydrous furan under $N_2$ at room temperature. The initial lemon-yellow, subsequently red-brown reaction mixture (with cloudy precipitate) is stirred for 4 h, and then held for 14 h at 0 °C. Following addition of 10 mL water, the mixture is extracted with pentane (3 × 15 mL); the organic phase is dried over $MgSO_4$ and concentrated at 200 torr/0—20 °C. Chromatography with pentane on 10 g silica gel [*(14)* elutes with the solvent front] and preparative gas chromatography on 10% Carbowax at 60 °C gives analytically pure *(14)*. Yield 13%.

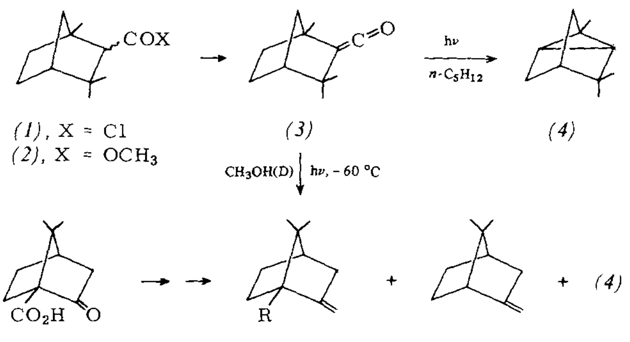
## Photoreactions of Sterically Hindered Ketenes

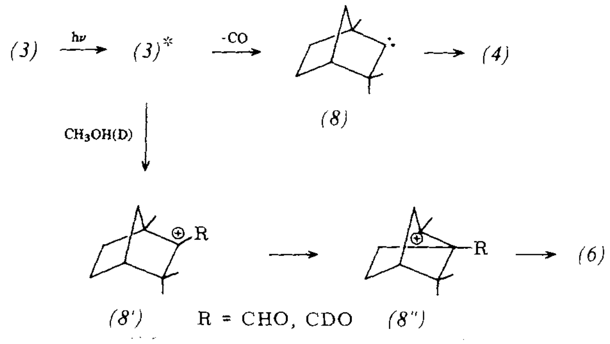
By *Wolfgang Kirmse* and *Walter Spaleck*[*]

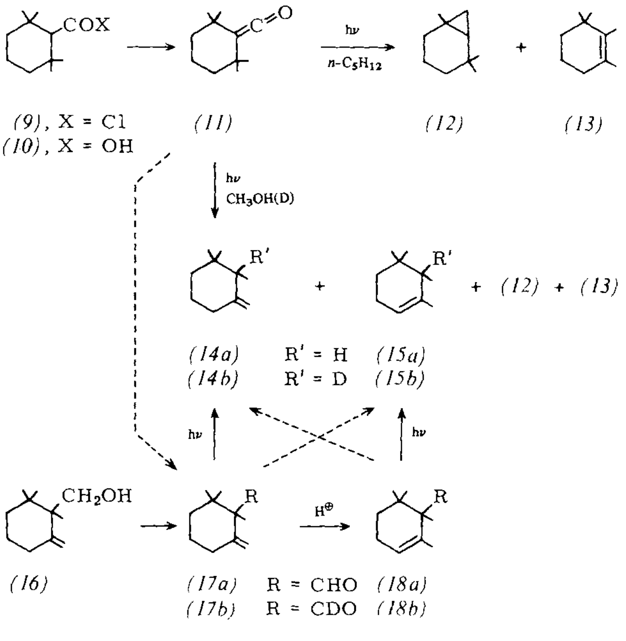
The formation of methylene by gas phase photolysis of ketene has been thoroughly investigated[1]. Ketenes are rarely used in solution as carbene-sources, since they rapidly dimerize and react with nucleophiles. We have found, however, that sterically hindered dialkylketenes, in addition to forming carbenes, undergo novel photoreactions, which indicates an "umpolung" of the excited state.

The acid chlorides *(1)*[2], *(9)*[3] and *(19)*[4], upon treatment with triethylamine (benzene, 130—140 °C, sealed tube), yielded the ketenes *(3)* (19%), *(11)* (30%) and *(20)* (45%) (yields after purification by preparative gas chromatography). Irradiation of a solution of *(3)* in pentane (high pressure Hg lamp, quartz, $N_2$) led to cyclofenchene *(4)*, the typical C—H-insertion product of carbene *(8)*. *(3)* reacts rapidly with methanol at room temperature to give a mixture of the esters *(2)* (*exo* : *endo* = 1 : 10). Photolysis of *(3)* competes with addition of methanol at −60 °C. Hereby, *(4)* and *(6a)* are initially formed in the ratio 1 : 1; at longer periods of irradiation, photodecarbonylation of *(6a)* occurs leading to formation of α-fenchene *(7)*.



The constitution of the surprising photoproduct *(6a)* was verified by independent synthesis from ketopinic acid *(5)*[5] (1. $CH_2N_2$, 2. $Ph_3P{=}CH_2$, 3. $LiAlH_4$, 4. dicyclohexylcarbodiimide/$H_3PO_4$/dimethyl sulfoxide (DMSO), total yield 34%). Formally, *(6a)* is formed from *(3)* by hydrogen transfer from the 1-methyl group to the ketene carbon atom. This does not, however, occur *via* an intramolecular reaction since irradiation of *(3)* in $CH_3OD$ produced *(6b)*. We formulate the novel photoisomerization as a protonation of the excited ketene *(3)** to give the carbenium ion *(8')*, which yields *(8'')* *via* a Wagner-Meerwein rearrangement; finally, deprotonation of *(8'')* leads to the aldehydes *(6a)* or *(6b)*. According to quantum mechanical calculations, the carbonyl carbon of the ketene carries a positive charge in the ground state and a partial negative charge in the excited state ($^3A_2$ and $^1A_2$)[6]. The reaction *(3)**→*(6)* provides experimental verification of this.





Irradiation of ketene *(11)* in pentane yielded *(12)* and *(13)* in the ratio 30 : 1. This result is typical of β-branched carbenes, insertion into the γ-C—H bonds being preferred to alkyl group migration[7]. *(11)* reacts with methanol in the dark only after several days. Photolysis of *(11)* in methanol yields the alkenes *(14a)* (34%) and *(15a)* (15%), in addition to *(12)* (30%) and *(13)* (6%). The aldehyde *(17a)* could—even at −60 °C—only be detected in small amounts (1—2%) after short periods of irradiation. For purposes of comparison, the aldehyde *(17a)* was prepared from *(16)*[8]

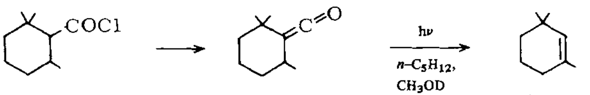
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

(dicyclohexylcarbodiimide/$H_3PO_4$/DMSO, 65%) and isomerized to *(18a)* with 4-toluenesulfonic acid (benzene, 80 °C, 44%). Irradiation of *(17a)* in methanol gave predominantly *(14a)* (70—75%), in addition to *(13)* and *(15a)*; from *(18a)*, predominantly *(15a)* (80—85%), in addition to *(13)* and *(14a)*, were formed. Both aldehydes reacted more rapidly than ketene *(11)* and hence could not be enriched by photolysis. Irradiation of *(11)* in $CH_3OD$ led to *(14b)* with 0.96 D/mol and to *(15b)* with 0.94 D/mol, while *(12)* contained only 0.11 D/mol. These results indicate that a photoprotonation, with concomitant rearrangement, is also probable for *(11)*, *i.e.* formation of *(14)* and *(15)* on the reaction path

$$(11)^* \rightarrow (17) + (18) \rightarrow (14) + (15).$$

In contrast, the irradiation of *(20)* in pentane and methanol resulted, exclusively, in formation of 1,3,3-trimethylcyclohexene *(21)*, the β-C—H shift product of the carbene formed by decarbonylation[7]; *(21)* is formed in $CH_3OD$, without significant deuterium incorporation. Apparently,



*(19)* *(20)* *(21)*

CO cleavage from *(20)** occurs considerably more rapidly than the reaction with methanol.

## Photometry with Laser Diodes: Determination of $D_2O$ and Compounds with OH Groups

By *Martin Wenzel*[*]

Ordinary spectrophotometers deal with the UV/VIS-region up to 800 nm. Only a few spectrometers can, in addition, analyze the near infrared ($\lambda = 800-2500$ nm). Furthermore, this region is also not accessible by conventional IR spectrometers. The near infrared, however, offers interesting analytical possibilities[1], in particular for the determination of compounds with OH- or NH-groups. Compounds having OH-groups show, for example, in addition to a strong absorption in the region of the fundamental vibrations at 2700—2800 nm, harmonics in the near IR in the 1300—1400 nm region[2].

In the following, a new method of analyzing compounds with OH- or NH-groups at 1350 nm is described using an apparatus which neither recquires a monochromator nor a filter for these wavelengths. As light source, the apparatus uses a laser diode ($In_{1-x}Ga_xAs_{1-y}P_y$)[3] which emits light of 1350 nm wavelength and which is normally used for the transmission of information in glass fibers. The laser beam is modulated, passes through the measuring cuvette and is subsequently recorded by a frequency-specific photodetector. Finally, the signal is transformed in the usual way to an extinction value. Since the light emitted from semiconductor lasers is rigorously monochromatic, measurements can be performed on absorption edges without the problems which arise with broadband light sources.

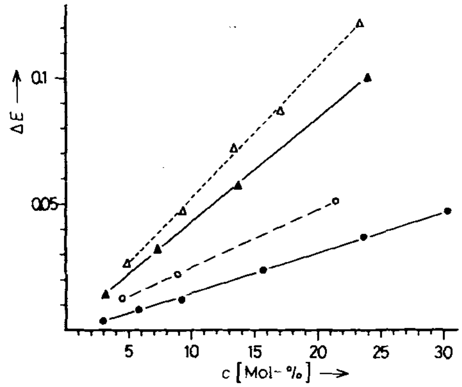

Fig. 1. Concentration dependence of the extinction difference with water and alcohols. (●—●) $C_2H_5OH$ in cyclohexane; (○---○) $CH_3OH$ in acetone; (▲—▲) $H_2O$ in dioxane; (△---△) $H_2O$ in acetone. Measurements made with a laser diode ($\lambda = 1350$ nm); path length: 1 cm; 25 °C; reference cuvette; pure solvent.

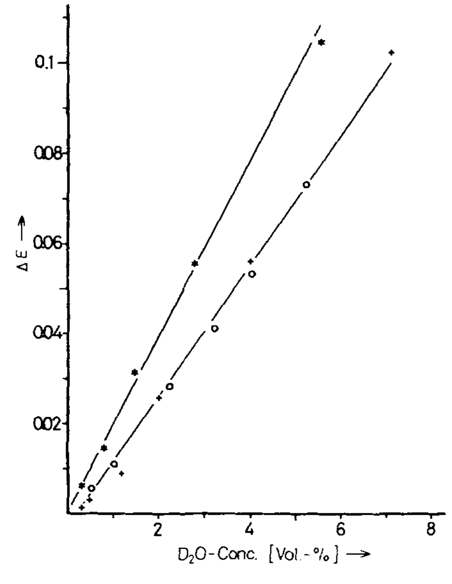

Fig. 2. Concentration dependence of the extinction difference of aqueous samples with different $D_2O$ concentration. (+---+) serum; (○—○) water; (*---*) urine. The serum and urine were treated with the same volume of $H_2O$ (reference cuvette) and $D_2O$ (sample cuvette). All further particulars are as in Fig. 1.

The concentration of compounds with OH-groups can be measured directly using a photometer constructed on this principle with tempered cuvette holders. Figure 1 shows the calibration curves obtained for four mixtures:

Königin-Luise-Strasse 2—4, D-1000 Berlin 33 (Germany)

ethanol and cyclohexane, methanol and acetone, water and dioxane, as well as water and acetone. These curves are linear up to relatively high fractions of the OH-containing compound. Similar calibration curves were obtained with glycine and albumin in water (harmonic of the NH-vibrational frequency).

The $D_2O$ content of water can also be measured, since deuterium oxide only shows a small IR absorption at 1350 nm[4]. The applications for this method in the fields of medicine and biochemistry are particularly interesting, since the $D_2O$ content of native serum or urine can be determined directly. Calibration curves are reproduced in Figure 2. For biological samples it is therefore unneccessary to separate the aqueous component from the constituents *e.g.* by freeze-sublimination.

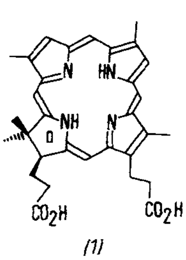
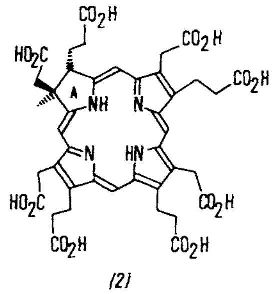
## A Directed Synthesis of the Chlorin System[**]

By *Franz-Peter Montforts*[*]

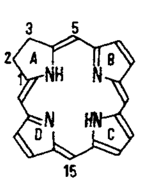
Bonellin *(1)* and the so-called Factor I *(2)* are structurally novel, porphinoid pigments of the chlorin type *(3)*. This fundamental skeletal structure was hitherto known only from its occurrence in the chlorophylls. Bonellin *(1)*, the sex-differentiating pheromone of *Bonellia viridis*, a sea animal of the Echiuroid family and widely distributed in the Mediterranean, has attracted the attention of biologists and chemists because of its unusual physiological properties[1]. In 1978, *Pelter et al.*[1h] were able to establish the constitution of the natural product, already isolated in pure form in 1939[1d], by X-ray structure analysis; however, the absolute configuration of the single center of chirality remained an open question.



*(1)*



*(2)*



*(3)*

The Factor I *(2)* was found in vitamin $B_{12}$-producing microorganisms by *Müller et al.* and *Arigoni et al.*[2] and the reduced form was demonstrated to be a biosynthetic precursor of the sirohydrochlorins and of vitamin $B_{12}$.

Although chlorin syntheses are known[3], selective routes which would provide access to the characteristic structural unit containing the geminal dialkyl groups of the partially

[*] Dr. F. P. Montforts
Institut für Organische Chemie der Universität
Niederurseler Hang, D-6000 Frankfurt/Main 50 (Germany)

[**] This work was supported by the Verband der Chemischen Industrie by a Liebig stipend. I wish to thank Prof. Dr. *A. Eschenmoser* and Prof. Dr. *G. Quinkert* for valuable discussions, and for supplying the necessary substances.

saturated rings D and A in the natural products *(1)* and *(2)* are still lacking.

Paramount in our synthesis is the 2-pyrrolinone *(5)*[4] whose lactam function can be coupled with a geminal dimethylated building block A *(4)*[5] by methods adopted from corrin chemistry, while condensation with the pyrrolaldehyde *(7)*[7] in the 5-position is possible according to the principles of bile-pigment synthesis[6]. Incorporation of the ring D *(6)*[8] is achieved *via* the classical routes of porphin chemistry.

The pyrrolinone *(5)* and the aldehyde *(7)* undergo a base-catalyzed reaction to give the bicyclic lactam *(10)*, which is converted with $P_2S_5/NaHCO_3$[9] into its thio-analogue *(11)*[10].

The thiolactam *(4)* is converted by reaction with the selectively cleavable malonic ester *(8)*[11] *via* sulfide contraction (oxidative variant)[5] into the vinylogous urethane *(9)*.

Coupling of *(9)* and *(11)* *via* a brominating agent[5b] affords the tricyclic sulfide *(13)*, which is converted by a variant of the sulfide contraction, developed by *Rasetti*[11c] for an isobacteriochlorin synthesis, into the CC coupled tricycle *(12)*. Direct hydrolysis of the ester function in *(12)* was of little preparative use, since considerable decyanidation also occurs. Circumvention of this problem was achieved *via* the readily accessible intermediary nickel complex *(14)*, in which the metal atom activates the ester function by participation in the complexation[12], such that a rapid, selective hydrolysis is possible.

The crude product of ester hydrolysis undergoes direct acid-catalyzed condensation with decarboxylation and decomplexation with the bromopyrrolaldehyde *(6)* to give the tetracycle *(15)*. Reaction with potassium *tert*-butyl alkoxide in the presence of zinc(II)[13], which exercises a template effect and can be readily removed acidolytically from the ligand system that is formed, finally leads to cyclization of the tetracycle *(15)* to the chlorin *(16)*[14].

## 4,4-Disubstituted 1,4-Dihydropyridines by Intramolecular Addition of Carbanions to Pyridines

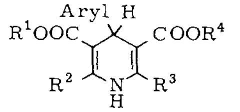
By *Siegfried Goldmann*[*]

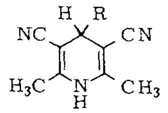
*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

1,4-Dihydropyridines exhibit analgetic[1a] and, above all, coronary dilating and hypertensive activity[1b,c].

Only 1,4-dihydropyridines such as *(1)* and *(2)*, monosubstituted in the 4-position, were previously accessible[1c]—by Hantzsch synthesis or by addition of carbanions to pyridines[2]. All attempts[3] to prepare 4,4-disubstituted derivatives have so far been unsuccessful: Neither the Hantzsch synthesis with ketones[4a] nor preparation *via* the addition of nucleophiles to 4-substituted pyridines[4b] proved useful in this respect.

*(1)*





*(2)*

We have now succeeded, however, in methylating the 4-aryl-substituted pyridine derivative *(3)* exclusively in the 4-position. An alternative route *via* a carbanion attached intramolecularly to the pyridine ring was chosen for this[5].

The dihydropyridine *(3)*, which is readily accessible by the Hantzsch synthesis, was oxidized with chloranil[6] to the pyridine and then with periodate[7] to the sulfoxide *(4)*. Metalation with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at −78 °C affords the carbanion *(5)*, which spontaneously stabilizes as *(6)* at −78 °C. Removal of the "handle" with Raney nickel leads to the 4,4-disubstituted 1,4-dihydropyridine *(7)* in 74% yield.

### Procedure

*(6)*: A solution of diisopropylamine (25.2 mL, 0.25 mol) in anhydrous THF (200 mL) was prepared under $N_2$ and treated with butyllithium (0.25 mol; 15% in hexane) at 0 °C. This solution was then added to a solution of *(4)* (36 g, 0.1 mol) in THF (400 mL) cooled to −78 °C. It was immediately protonated at −78 °C with $CH_3OH$ and

NH$_4$Cl/H$_2$O; after addition of 500 mL of H$_2$O the resulting precipitate was filtered off by suction, washed with water, and dried at 100 °C. Yield 29 g (80%) *(6)*; m.p. 286–289 °C (dec.). $^1$H-NMR (CDCl$_3$/CD$_3$OD): $\delta=2.15$ (s, 3H), 2.2 (s, 3H), 3.2 (s, 3H), 3.3 (s, 3H), 3.4 (d, $J=13$ Hz, 1H), 4.2 (d, $J=13$ Hz, 1H), 7.2–7.5 (m, 3H), 7.6–7.8 (m, 1H).

*(7)*: A solution of *(6)* (12 g, 33 mmol) in aqueous 75% ethanol (600 mL) was treated with Raney nickel (100 g, aqueous suspension) and the mixture boiled under reflux for 5 h. After cooling, the mixture was filtered by suction, the filtrate concentrated in a rotary evaporator, and the residue recrystallized from ethyl acetate. Yield 7.6 g (74%) *(7)*; m.p. 148–150 °C. $^1$H-NMR (CDCl$_3$): $\delta=1.9$ (s, 3H), 2.1 (s, 6H), 3.2 (s, 6H), 5.6 (s, broad, NH), 6.9–7.5 (m, 5H). – $^{13}$C-NMR (CDCl$_3$): $\delta=19.4$, 25.8, 43.5, 50.3, 110.2, 125.0, 127.1, 127.9, 139.8, 150.9, 163.7.

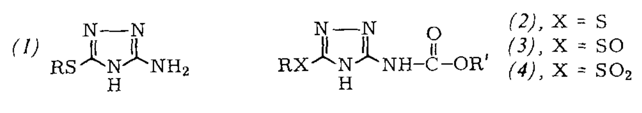
# Carboxylic Acid Derivatives of 3-Alkylthio-5-amino- and 3-Alkylsulfonyl-5-amino-1,2,4-triazoles

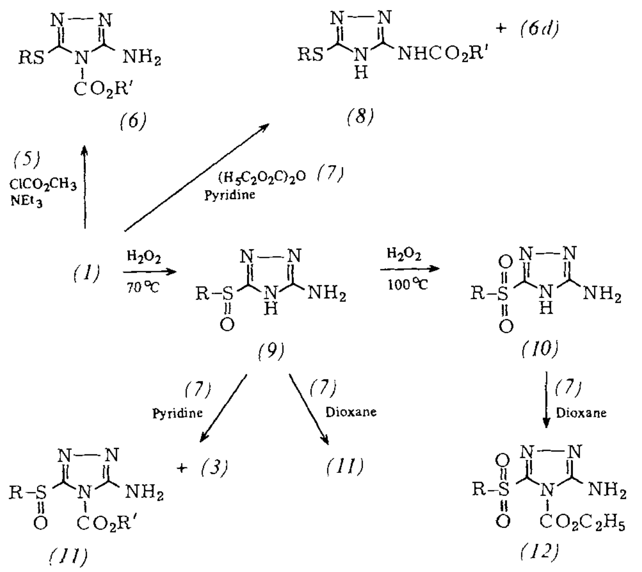
By *Klaus Sasse* and *Harald Niedrig*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Carbamate esters of type *(2)* are of interest from the point of view of biological investigations. We therefore initially studied the acylation of 3-alkylthio-5-amino-1,2,4-triazoles *(1)*, which are readily accessible in good yields *via* the method of *Heitke* and *McCarty*[1]. In α-amino-N-heterocycles the ring N atom[2] is acylated first and only somewhat drastic conditions lead to acylation of the *exo*-orientated amino group. In some cases a thermal rearrangement of the ring *N*-acyl- into the more thermodynamically stable *exo-NH*-acyl-compound occurs.



We found that methyl chloroformate *(5)* reacts with *(1a)* and *(1b, d)* in the presence of triethylamine to give exclusively the 4-methoxycarbonyl derivatives *(6a)*–*(6c)*. Thermal rearrangement of the acyl groups did not occur; only symmetrical urea derivatives were formed upon heating to 150 °C in phenol.



Reaction of *(1a)* with diethyl dicarbonate *(7)* in pyridine produces the isomers *(6d)* and *(8)* (30 : 70), whose structures were assigned by $^1$H-NMR spectroscopy; their separation is straightforward, due to the considerably lower solubility of *(8)* in toluene. Oxidation of the 3-amino-5-propylthio-triazole *(1c)* by H$_2$O$_2$ at 70 °C gave the sulfoxide *(9)* and at 100 °C the sulfone *(10)*. Treatment of the latter species with *(7)* in boiling dioxane produces, exclusively, the ring-acylated compounds *(11)* and *(12)*, respectively; in contrast, both acyl derivatives *(3c)* and *(11)* are formed from *(9)* upon treatment with *(7)* in pyridine (Table 1).

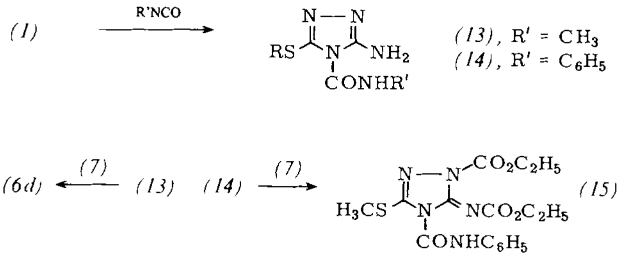
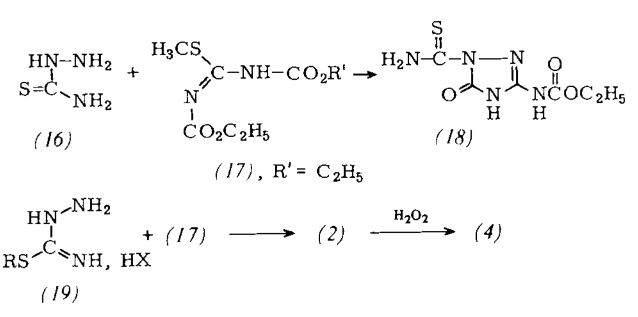
[a] All compounds gave satisfactory $^1H$-NMR-, IR- and mass-spectra. [b] From acetonitrile. [c] From ethyl acetate. [d] From ethyl acetate/ligroin. [e] $^1H$-NMR ($(CD_3)_2SO$): $\delta = 2.48$ (s, $SCH_3$), 3.68 (s, $OCH_3$), 10.5—11.5 (br., NH), 12.5—13.5 (br., NH). [f] From dimethyl formamide (DMF)/methanol. [g] From $n$-propanol. [h] From DMF/ethanol. [i] From methanol. [j] From DMF/propanol. [k] IR (KBr): 1338, 1158 $cm^{-1}$ ($\nu SO_2$); $^1H$-NMR ($(CD_3)_2SO$): $\delta = 3.22$ (s, $SO_2CH_3$), 3.74 (s, $OCH_3$), 11.5 (s, NH), 13.5—14.5 (br., NH). [l] From methanol. [m] From methanol/water (1:1). [n] $^1H$-NMR ($CDCl_3$): $\delta = 2.56$ (s, $SCH_3$), 4.04 (s, $OCH_3$), 6.91 (s, $NH_2$). [p] $^1H$-NMR ($(CD_3)_2SO$): $\delta = 1.31$ (t, $CCH_3$), 2.43 (s, $SCH_3$), 4.34 (q, $OCH_2$), 7.10 (s, $NH_2$). [o] $^1H$-NMR ($(CD_3)_2SO$): $\delta = 1.23$ (t, $CCH_3$), 2.48 (s, $SCH_3$), 4.12 (q, $OCH_2$), 10.5—11.5 (br., NH), 12.5—13.5 (br., NH). [q] $^1H$-NMR ($(CD_3)_2SO$): $\delta = 2.48$ (s, $SCH_3$), 2.75 (d, N—$CH_3$), 7.03 (s, $NH_2$), 7.35—8.0 (br., NH). [r] From toluene. [s] From petroleum ether (85—100 °C).

The selective acylation of the $NH_2$-function after the ring-NH group is previously blocked by a carbamoyl moiety, as in *(13)*, was unsuccessful; the $N$-carbamoyltriazoles *(13)* and *(14)* could be prepared, *via* 1,4-diazabicyclo[2.2.2]octane (DABCO) catalysis, from *(1)* and isocyanates. *(13)* does not react with *(5)*; with *(7)* in boiling dioxane, the carbamoyl groups were exchanged for the ethoxycarbonyl moiety resulting in formation of *(6d)*. Only the thermally stable phenylcarbamoyl compound *(14)* reacted with *(7)* *via* a double acylation procedure to give *(15)*.



We now attempted to introduce the carbamate ester moiety at the triazole synthesis stage: only the triazolinone *(18)* was formed from condensation of the thiosemicarbazide *(16)* with $N,N'$-bisethoxycarbonyl-$S$-methylisothiourea *(17)* in acetic acid. If instead of the thiosemicarbazide its $S$-alkyl derivative *(19)* is used, however, the desired 3-alkoxycarbonylamino-5-alkylthio-1,2,4-triazoles *(2)* are formed, whose oxidation to the sulfones *(4)* with $H_2O_2$ proceedes smoothly (Table 1).



R = $CH_3$, $C_2H_5$, $n$-$C_3H_7$, $n$-$C_4H_9$, $CH_2C_6H_5$;
R′ = $CH_3$, $C_2H_5$, $n$-$C_3H_7$; X = Halogen

## *Procedure*

Yields, melting points and spectroscopic data are given in Table 1.

*(6a)—(6c)*: *(5)* (9.5 g, 0.1 mol) is dropped into a solution of *(1)* (0.1 mol) and triethylamine (10.1 g, 0.1 mol) in 100 mL dioxane at 10—15 °C; the mixture is stirred for 2 h at room temperature, diluted with water, and filtered off.

*(6d)/(8)*: A mixture of *(1a)* (13.0 g, 0.1 mol) in 100 mL dioxane and 25 mL pyridine is heated to boiling with *(7)* (50 g) for 5 h. Insoluble material is filtered off and the filtrate concentrated under reduced pressure. The residue is refluxed in 100 mL toluene and the insoluble material filtered off while still hot. Combined insoluble fractions: 2.8 g *(8)* (14%). The toluene solution is cooled in ice, treated with the same volume of ligroin, recooled, and filtered off. Yield: 6.5 g *(6d)* (32%).

*(9)*: A solution of *(1c)* (15.9 g, 0.1 mol) in 200 mL $H_2O$ and 5 mL $CH_3CO_2H$ at 70 °C is treated, dropwise, with 15 g (0.15 mol) 35% $H_2O_2$, stirred for 2 h at 70 °C and filtered. The filtrate is concentrated under reduced pressure to 1/3 of its original volume and cooled for 24 h on ice. The precipitate is filtered off and recrystallized from a little water. Yield 11 g (63%).

*(10)*: A solution of *(9)* (17.4 g, 0.1 mol) in 120 mL 50% acetic acid at 100 °C is treated dropwise with 15 g (0.15 mol) 35% $H_2O_2$. The mixture is stirred for 3 h at 100 °C, 100 mL water added and cooled for 24 h on ice, before being filtered-off. Yield: 9 g (47%).

*(11)* and *(12)*: 0.1 mol *(9)* or *(10)*, respectively, in 150 mL dioxane is heated to boiling for 5 h with 50 g *(7)* and the solution concentrated under reduced pressure. *(11)*: residue stirred with ether, cooled on ice and filtered-off. Recrystallization from ethyl acetate. Yield: 17 g (69%). *(12)*: Residue recrystallizes from ethanol. Yield: 18 g (69%).

*(3a)*: *(9)* (17.4 g, 0.1 mol) is reacted as described in the preparation of *(6d)/(8)*; the reaction solution is concentrated under reduced pressure. The oily residue dissolves in water and is made weakly alkaline by addition of dilute sodium hydroxide. Pyridine is distilled out using steam; the residue is acidified with dilute hydrochloric acid and concentrated under reduced pressure. The resulting resi-

due is purified by column chromatography on silica gel (eluent: ethyl acetate). Yield: 6 g (24%).

*(13)/(14):* A solution of *(1)* (0.1 mol) in 100 mL dioxane, in the presence of 0.1 g DABCO, is treated with 0.1 mol methyl or phenyl isocyanate; the mixture is stirred for 2 h at room temperature and for 3 h at 40–50 °C; the whole is then cooled, filtered off or concentrated under reduced pressure and recrystallized.

*(18):* A solution of *(17)* (23.4 g, 0.1 mol) and *(16)* (9.1 g, 0.1 mol) in 100 mL acetic acid is gradually heated to boiling. The mixture is refluxed for 4 h, allowed to cool and the crystallizate filtered off. Recrystallization from butanol yields 11.3 g (48.7%) *(18)*, m.p. >250 °C.

*(2):* A solution of 0.1 mol *(17)* and 0.1 mol *(19)* in 100 mL acetic acid is refluxed for 5 h. The cooled reaction mixture is then poured into 400 mL ice-water and the crystallizate filtered off and dried.

*(4):* $H_2O_2$ (21.4 g, 0.22 mol, 35%) is added dropwise to a solution of *(2)* (0.1 mol) in 150 mL acetic acid at 90 °C. After cooling, excess $H_2O_2$ is reduced with conc. $NaHSO_3$ solution. The reaction mixture is concentrated under reduced pressure, and the residue stirred with water, filtered off, and dried.

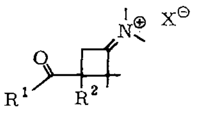
By *Hans-Georg Heine* and *Willy Hartmann*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

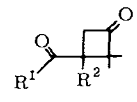
Salts containing the *N,N*-dimethyl-*N*(2-methyl-1-propenylidene)ammonium ion ("keteniminium salts") *(1)* are very reactive compounds owing to an energetically exceptionally low-lying unoccupied molecular orbital of the ammonium ion[1a]. For example, they considerably surpass the ketenes[2] in their readiness to undergo [2+2]-cycloadditions[1b] to simple alkenes and alkynes. Thus, dimethylketene only shows sufficient reactivity with 2-butene above 100 °C[2b], whereas *(1)* ($X = BF_4$) already undergoes smooth reaction at room temperature. We have now found that *(1)* ($X = ZnCl_3$) even adds to α,β-unsaturated carbonyl compounds, thus clearly demonstrating once again the difference in reactivity in comparison with ketenes, [2+2]-cycloadditions of which to relatively electron-poor double bonds are not known[3].

Reaction of *(1)* and methyl acrylate in boiling dichloromethane and subsequent hydrolysis of the primary product *(2a)* affords 3-methoxycarbonyl-2,2-dimethylcyclobutanone *(3a)* in good yields[4]. Its structure is confirmed by the product of the Baeyer-Villiger oxidation—methyl terebinate. The corresponding addition of methyl acrylate to *(1)* leads to *(3b)*, a degradation product of α-pinene[5]. *(1)* reacts even better with methyl methacrylate, giving the cyclobutanone *(3c)*. On the other hand, *(1)* does not react with *trans*-methyl crotonate or with methyl 3-methyl-2-butenoate under the same conditions, not even after 48-60 h. Dimethylamides of acrylic and methacrylic acid are suitable reactants. However, in the addition of *(1)* to methacrylic dimethylamide besides the main product *(3e)*, *ca.* 10% of the regioisomer *(4e)* is formed. Vinyl and isopropenyl methyl ketone behave similarly to the two acrylamides on reaction with *(1)*. Methyl vinyl ketone furnishes exclusively *(3f)*, whose structure is confirmed by degradation to terebic acid, whereas isopropenyl methyl ketone affords *(3g)* and *(4g)* in the ratio 80:20.

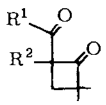
*(1)*



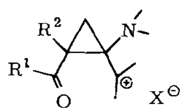
*(2)*



*(3)*



*(4)*



*(5)*

Table 1. Cyclobutanones *(3)* from *(1)* ($X = ZnCl_3$) and α,β-unsaturated carbonyl compounds.

| *(3)* | $R^1$ | $R^2$ | B.p. [°C/torr] | $n_D^{20}$ | Yield [a] [%] |
|---|---|---|---|---|---|
| *(a)* | $OCH_3$ | H | 87–88/12 | 1.4391 | 57 |
| *(b)* | $OC_2H_5$ | H | 93–96/14 | 1.4384 | 60 |
| *(c)* | $OCH_3$ | $CH_3$ | 89–92/12 | 1.4433 | 71 |
| *(d)* | $N(CH_3)_2$ | H | 86–91/0.08 | 1.4750 | 65 |
| *(e)* | $N(CH_3)_2$ | $CH_3$ | 50–51 [b] | – | 20 |
| *(f)* | $CH_3$ | H | 91–92.5/12 | 1.4481 | 48 |
| *(g)* | $CH_3$ | $CH_3$ | 97–103/13 [c] | 1.4548 | 34 |

[a] Polymerization of the α,β-unsaturated carbonyl compounds competes to varying extents with the cycloaddition. [b] M.p. [°C] (ligroin); the 90:10 mixture of *(3e)* and *(4e)* boils at 83–87 °C/0.15 torr, $n_D^{20} = 1.4770$. [c] Isomeric mixture of *(3g)* and *(4g)* (80:20).

The orientation of the substituents in the cycloadducts *(2)* and *(3)*, which does not correspond to the polarity of the components, is remarkable[6]. On reaction with α,β-unsaturated carbonyl compounds *(1)* possibly reacts like a carbene as a 1,1-pull-push reagent[1a]; in a [1+2]-cycloaddition, primarily the cyclopropyldimethylcarbenium ion *(5)* is formed; such intermediates are formulated for the proton-catalyzed rearrangement of *N*-phenylazaspiropentanes to phenylimino-substituted cyclobutanes[7]. Exclusive or preferred migration of the substituted alkyl group then leads to *(2)*.

## *Procedure*

A solution of 1-chloro-1-dimethylamino-2-methyl-1-propene (150.0 g, 1.1 mol) in anhydrous $CH_2Cl_2$ (250 mL) is added dropwise within 30 min to a stirred mixture of methyl acrylate (86.0 g, 1.0 mol) and anhydrous $ZnCl_2$ (165.0 g, 1.2 mol) in anhydrous $CH_2Cl_2$ (200 mL). After 14 hours heating under reflux the reaction mixture is treated with 1000 mL of water, stirred overnight, the phases separated, and the aqueous phase extracted exhaustively with ether in a Kutscher-Steudel apparatus. Subsequent work-up of the organic extract and fractional distillation afford 89.6 g

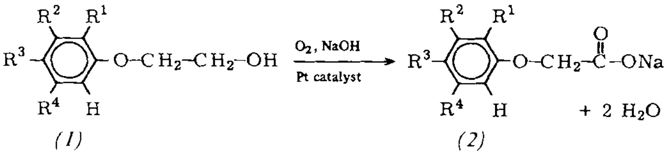
## Activation of Oxidations with Oxygen on Platinum Metals Using the Example of the Conversion of 2-Phenoxyethanols to Phenoxyacetic Acids

By *Helmut Fiege* and *Karlfried Wedemeyer*[*]

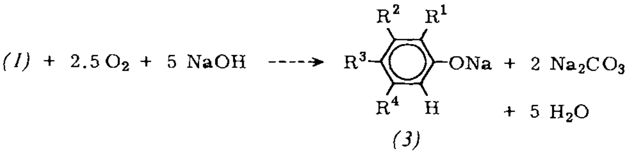
*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Phenoxyacetic acids are valuable organic intermediates and of considerable economic importance as growth-regulating herbicides[1]. They are mainly prepared industrially by heating the corresponding phenols with monochloroacetic acid in aqueous sodium hydroxide[2].

Since alcohols in aqueous alkaline media can often be selectively oxidized by $O_2$ (air) on platinum catalysts to carboxylic acids[3] 2-phenoxyethanols *(1)*, readily accessible from the reaction of phenols with ethylene oxide, could be converted into phenoxyacetic acids *(2)*.



Oxidations of this type have already been intensively investigated[4], however, the efficiency of the catalysts, the reaction conditions required, as well as the yields, were highly unsatisfactory. The transformation of *(1)* into *(2)* was accompanied by an undesired oxidative degradation of the hydroxyethyl group, which led to formation of the phenol *(3)* and $CO_2(Na_2CO_3)$[4b].



We have now found that the reaction can be vastly improved if small amounts of bismuth or lead as activators, and if necessary cadmium as coactivator, are added[5]. By this means, *at normal pressure and at short reaction times, almost quantitative yields* are possible using relatively small amounts of catalyst. The 2-phenoxyethanol concentration can be considerably increased above the levels previously achieved and the catalyst can be used several times without marked reduction in yield[6].

Table 1. Influence of lead-, bismuth- and cadmium-charges on the oxidation of 2-phenoxyethanol (0.1 mol) to phenoxyacetic acid in sodium hydroxide (5 N, 100 mL) on a platinum/active charcoal catalyst (0.65 g with 1% platinum) at 70 °C with $O_2$ at atmospheric pressure.

| Activator [a] | Coactivator [b] | $O_2$-uptake [mol] | t [h] | Yield [c] [%] |
|---|---|---|---|---|
| without | without | 0.0 | 6 | 0 [d] |
| Pb | without | 0.1 | 6 | 34 |
| Bi | without | 0.1 | 6 | 35 |
| Pb | Cd | 0.1 | 3.5 | 98 [e] [f] |
| Bi | Cd | 0.1 | 6 | 53 |
| without | Cd | 0.0 | 6 | 0 [d] |

[a] $5 \times 10^{-4}$ mol lead(II) or bismuth(III) nitrate. [b] $1 \times 10^{-4}$ mol cadmium(II) nitrate. [c] The fraction of $O_2$ not used for phenoxyacetic acid degrades a corresponding amount of 2-phenoxyethanol to phenol. [d] Unchanged 2-phenoxyethanol recovered. [e] M.p. = 98.5—99 °C. [f] Yield at 50 or 60 °C = 100%.

The influence of lead, bismuth and cadmium charges on the oxidation of 2-phenoxyethanol on active charcoal containing plantinum is shown in Table 1. Practically no oxidation occurs at the 1% platinum level. Oxidation first occurs upon addition of lead or bismuth. A further improvement occurs if cadmium, *e.g.* as $Cd(NO_3)_2$, is also added to the reaction mixture. The action of this coactivator in combination with lead is particularly marked. This system almost completely stops the oxidative degradation of the educt and in addition increases the rate of oxidation. The oxidation ceases after uptake of the stoichiometric amount of oxygen required for formation of phenoxyacetic acid.

Table 2. Influence of lead- and bismuth-charges on the oxidation of 2-phenoxyethanol (0.1 mol) to phenoxyacetic acid in sodium hydroxide (1.1 N; 100 mL) on a palladium/medical charcoal catalyst (0.65 g with 5% palladium) at 90 °C with $O_2$ at atmospheric pressure.

| Activator [a] | 0.1 mol $O_2$-uptake in [h] | Yield [%] |
|---|---|---|
| without | 10 [b] | 40 [d] |
| Pb | 1.75 [c] | 93 |
| Bi | 1.5 [c] | 100 |

[a] $5 \times 10^{-4}$ mol lead(II) nitrate or $5 \times 10^{-5}$ mol bismuth(III) nitrate. [b] $O_2$-uptake does not cease after this time. [c] End of $O_2$-uptake. [d] See Table 1, footnote [c].

In the presence of lead or bismuth as activator, an almost quantitative conversion *(1)*→*(2)* can be achieved on palladium—charcoal catalysts without additional dosing with cadmium. In the absence of lead or bismuth the reaction time is considerably longer and the yield poor (Table 2); moreover, the reaction does not stop after uptake of the stoichiometric amount of oxygen required for phenoxyacetic acid formation. Considerable amounts of phenol are formed as by-product.

[a] After acidification to pH = 1, extracted with ether and determined acidimetrically in the extract. [b] Uncorrected M.p. of the extract (crude acid). The compounds gave satisfactory elemental analyses and conclusive IR- and NMR-spectra. [c] Contaminated with 2,6-dichlorophenoxyacetic acid.

The reaction also proceeds in excellent yield with some substituted 2-phenoxyethanols[7], although the conditions have not yet been optimized (Table 3).

### *Procedure*[5]

0.65 g powdered medical charcoal (10%, Pd content), 25 mg $Bi(NO_3)_3 \cdot 5H_2O$, 100 mL 1.3 N sodium hydroxide and 0.05 mol 2-phenoxyethanol are placed in a cylindrical glass vessel (250 mL, 5—6 cm inner diameter), fitted with stirrer, internal thermometer and $O_2$-inlet, which is thermostated by an outer mantel (Table 3).

After air is displaced from the flask by $O_2$, the stirrer (*ca.* 1500 rpm) is switched on, the mixture is heated to 90°C, and $O_2$ is passed in (from a calibrated burette with manostat) at atmospheric pressure until uptake ceases; in general, 0.05 mol $O_2$ are taken up.

After the catalyst has been filtered off from the still warm solution and washed with water, the filtrate is acidified to pH = 1 with 20% sulfuric acid and extracted five times with 50 mL ether. The resulting solution is dried over $Na_2SO_4$ and concentrated, leaving phenoxyacetic acid as residue (Table 3).

[6] In terms of its activity as an activator, it is immaterial which oxidation state, or what type, of bismuth, cadmium or lead compound is added. The activators can be introduced with the catalyst or added directly to the liquid reaction mixture.

[7] Dr. *M. Dietrich*, Bayer AG, Dormagen, is thanked for samples of 2-(4-chloro-2-methylphenoxy)ethanol and 2-(2,4-dichlorophenoxy)ethanol. We prepared the other 2-phenoxyethanols using a method based on that of *E. Becker* and *E. Barthel* (Monatsh. Chem. *77*, 80 (1947)).

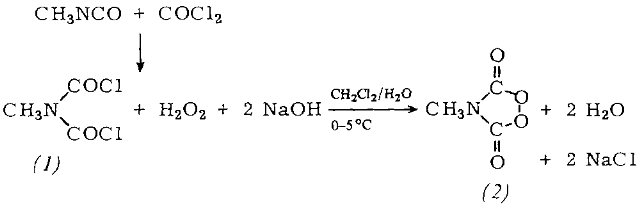
# 4-Methyl-1,2,4-dioxazolidine-3,5-dione, a Cyclic Imidodiacyl Peroxide

By *Hermann Hagemann*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

The easily accessible open-chain diacyl peroxides have long since acquired industrial significance as free radical initiators in polymerizations; cyclic diacyl peroxides are, however, less well known[1].

It has now been found that *N*-methylazamalonyl peroxide *(2)*, the first example of the previously unknown 1,2,4-dioxazolidine-3,5-dione can be particularly easily prepared. The educt *N*-methyliminodicarbonyl dichloride *(1)* was originally synthesized by chlorinating 4-methyl-1,2,4-dithiazolidine-3,5-dione but is now more readily obtainable by addition of phosgene to methyl isocyanate[2].



Solutions of *(1)* in dichloromethane react with 35% $H_2O_2$ and 10% sodium hydroxide at *ca.* 0—5 °C in a smooth cyclization step to the colorless, crystalline product *(2)*, m.p. = 89 °C.

The new cyclic diacyl peroxide *(2)* has an intense, characteristic smell and—as expected—behaves as a powerful oxidizing agent. The crystals are readily soluble in organic solvents *e.g.* $CH_2Cl_2$ or $CHCl_3$ and begin to sublime at *ca.* 50 °C at atmospheric pressure. The constitution of *(2)* has been confirmed from the C=O vibrational frequency at 1785 $cm^{-1}$, elemental analysis, and mass spectrum.

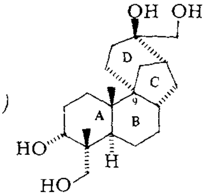
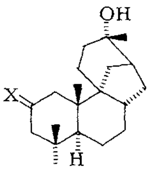
## An Expeditious and Efficient Entry into the Aphidicolin and Related Natural Products Ring Skeleton[**]

By *K. C. Nicolaou* and *Robert E. Zipkin*[*]

The potent antiviral and antimitotic properties of aphidicolin *(1)*[1], coupled with its novel and highly unusual molecular framework present a formidable and important challenge. Of particular interest to the synthetic chemist is the arrangement of the rings B, C, and D. The diterpenes stemodinone *(2)*[2] and stemodin *(3)*[2] are structurally related to aphidicolin *(1)* but differ from it in the stereochemistry of rings C and D. After considerable effort, total syntheses of all three natural products have recently been reported[3]. Although elegant, these syntheses suffer from poor yields and/or because they are multi-step routes, whereby the construction of the C/D ring system was especially problematical.

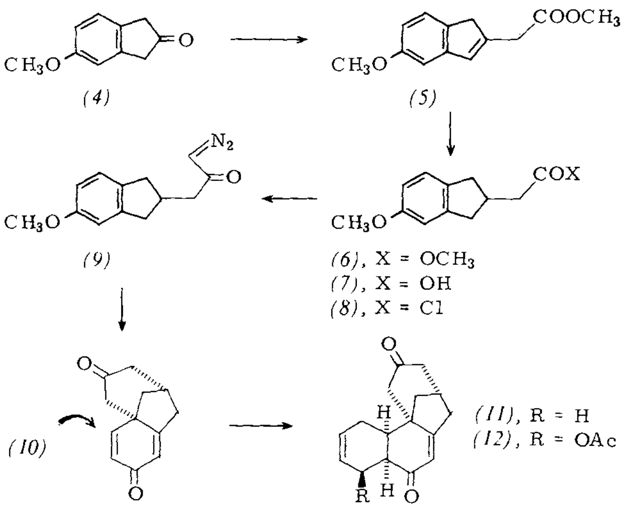


*(1)*



*(2)*, X = O
*(3)*, X = α-OH, H

We report here an expeditious, stereocontrolled and highly efficient construction of the ring structures of compounds *(1)*–*(3)* which is, furthermore, conceptually different from previous methods. The strategy for this new entry into the aphidicolin *(1)* and related structures depends on two key operations; firstly a diazoketone acid-induced cyclization[4] and secondly a regio- and stereocontrolled Lewis acid-catalyzed Diels-Alder reaction.



5-Methoxy-2-indanone *(4)*[5] reacted with $(MeO)_2P(O)CH_2CO_2Me/NaH$ in tetrahydrofuran (THF) (−50 °C→25 °C) to afford a mixture of the unsaturated ester *(5)*, (60–70%, mixture of (*E*)- and (*Z*)- α,β- and β,γ-unsaturated isomers; in the formula scheme only the latter is shown!) which was subjected to catalytic hydrogenation ($Pd/C-CH_3OH$, 25 °C) to afford the methyl ester *(6)* in quantitative yield. Base hydrolysis (LiOH, $H_2O$, $CH_3OH$, 25 °C) of *(6)* led to the acid *(7)* (100%), which was converted to the acid chloride *(8)* (oxalyl chloride-pyridine, $CH_2Cl_2$, 0 °C, 100%), which reacted further ($CH_2N_2$, ether, −20 °C) to give *(9)* (90%). *(9)* reacted with $CF_3COOH$ to give the crystalline dienone *(10)*[6] in 80% yield; this species not only contains the correct BCD ring system of *(1)*, *(2)*, and *(3)*, but also carries appropriate functionality for building on the A ring, *via* a Diels-Alder reaction. Dreiding molecular models clearly suggested a regio- and stereocontrolled approach of a diene component from the "left-side" and from the "top" (arrow). Indeed, it was found that brief exposure of *(10)* to butadiene in $CH_2Cl_2$ at 0 °C in the presence at $SnCl_4$ resulted in a single crystalline product the tetracycle *(11)* (97%). The selectivity of this Diels-Alder reaction was demonstrated by reacting the dienone *(10)* with 1-acetoxybutadiene under whereby the crystalline adduct *(12)* was formed in 90% yield (accompanied by a small amount of an as yet unknown stereoisomer). *(11)* and *(12)* were characterized by spectroscopic and X-ray crystallographic[7] measurements (Table 1 and Fig. 1).

Table 1. Selected physical properties of compounds *(10)*–*(12)*.

*(10)*: m.p. 97.5–98 °C; $^1$H-NMR ($CDCl_3$, 250 MHz): $\delta$ = 1.90–2.20 (m, 3 H), 2.45–2.95 (m, 6 H), 6.15 (d, $J$ = 1 Hz, 1 H), 6.27 (dd, $J$ = 10, 1 Hz, 1 H), 7.06 (d, $J$ = 10 Hz, 1 H); IR ($CCl_4$): $\nu$ = 1725, 1670, 1645 cm$^{-1}$.

*(11)*: m.p. 172–172.5 °C; $^1$H-NMR ($CDCl_3$, 250 MHz): $\delta$ = 1.70–3.10 (m, 15 H), 5.58 (m, 1 H), 5.70 (m, 1 H), 5.87 (s, 1 H); IR ($CCl_4$): $\nu$ = 1725, 1678 cm$^{-1}$.

*(12)*: m.p. 183–184 °C; $^1$H-NMR ($CDCl_3$, 250 MHz): $\delta$ = 1.78–2.80 (m, 11 H), 2.12 (s, 3 H), 3.08 (d, $J$ = 16 Hz, 1 H), 3.45 (t, $J$ = 4 Hz, 1 H), 5.45 (m, 1 H), 5.65 (m, 1 H), 5.77 (s, 1 H), 5.78 (m, 1 H); IR ($CCl_4$): $\nu$ = 1740, 1725, 1670 cm$^{-1}$.

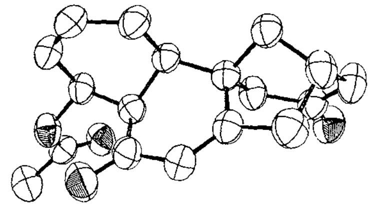


Fig. 1. X-ray crystallographic structure of *(12)*.

These observations clearly qualify this pathway as a rapid and highly efficient entry into the polycyclic ring framework of the natural products *(1)*–*(3)*.

### *Procedure*

*(10)*: A solution of *(9)* (230 mg, 1.0 mmol) in anhydrous $CH_2Cl_2$ (12.5 mL) was added dropwise to a stirred solution of $CF_3COOH$ (25 mL) in dry $CH_2Cl_2$ (12.5 mL) at −20 °C under an argon atmosphere. After 5 min the reaction mixture was diluted with $CH_2Cl_2$ (200 ml) and washed successively with $H_2O$ (3 × 50 mL), saturated $NaHCO_3$ solution (2 × 50 ml) and dried over $MgSO_4$. After evaporation of the solvent and preparative thin layer chromatography (silica gel, 2.5% $CH_3OH$ in ether) *(10)* was obtained as colorless crystals (150 mg, 80%) and was recrystallized from ether/pentane.

*(11)*: *(10)* (188 mg, 1.0 mmol) was dissolved in anhydrous $CH_2Cl_2$ (2 mL), cooled to 0 °C and the solution saturated

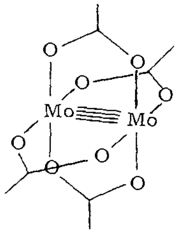
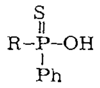
## Determination of the Absolute Configuration of Alkyl(phenyl)thiophosphinic *O*-Acids and of *O*-Alkyl Alkylthiophosphonates from the Circular Dichroism of Their Complexes with $[Mo_2(O_2CCH_3)_4]$[**]

By *Jan Omelańczuk* and *Günther Snatzke*[*]

*In situ* complexes of optically active carboxylic acids with the readily accessible and stable "parent complex" $[Mo_2(O_2CCH_3)_4]$ *(1)* exhibit several Cotton effects between 800 and 300 nm in dimethyl sulfoxide (DMSO); the signs of the two CD bands between 450 and 300 mn could be empirically correlated with the absolute configurations of the acids, which act as bidentate ligands. The sector rule could also be derived non-empirically for the Cotton effect at about 420 nm using qualitative MO theory[1].

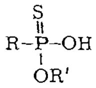


*(1)*



$$R-\overset{\overset{S}{\|}}{\underset{\underset{Ph}{|}}{P}}-OH$$

*(2a)*, R = Me
*(2b)*, R = Et
*(2c)*, R = *t*Bu



$$R-\overset{\overset{S}{\|}}{\underset{\underset{OR'}{|}}{P}}-OH$$

*(3a)*, R = R' = Me
*(3b)*, R = R' = Et
*(3c)*, R = Me, R' = *i*-$C_3H_7$

Of the alkyl(phenyl)thiophosphinic *O*-acids *(2)*, only *(2c)* gave CD bands in DMSO in the presence of *(1)*; surprisingly, however, we were able to observe two or three strong Cotton effects for *(2a—c)* in trifluoroacetic acid. Thus, despite the enormous excess of achiral, potential $F_3CCO_2^-$ ligands, the thiophosphinic acids complex sufficiently enough to yield easily measurable CD curves which retain their shape and magnitude over sufficiently long periods. *(2)* possibly does not occur as bidentate ligand, but as an additional axial substituent at one or both ends of the $Mo_2$ dumbbell. In crystals of $[Mo_2(O_2CR)_4]$-complexes, this position is usually occupied by an oxygen atom[2] of a neighboring molecule. This is also evidenced by the fact that practically no CD could be measured with acids such as phenylalanine in $CF_3CO_2H$.

All (+)-(*R*)-acids give a negative Cotton effect at about 490 nm, a further one about two to three times more positive at about 400 nm, and, at higher concentration, an additional slightly positive Cotton effect can be observed at about 540 nm (Fig. 1). The seleno-analogue behaves in exactly the same way. In the case of the (−)-(*S*)-enantiomers the CD curves are enantiomorphic. Similar Cotton effects are obtained in acetic acid, but they are not so intense.

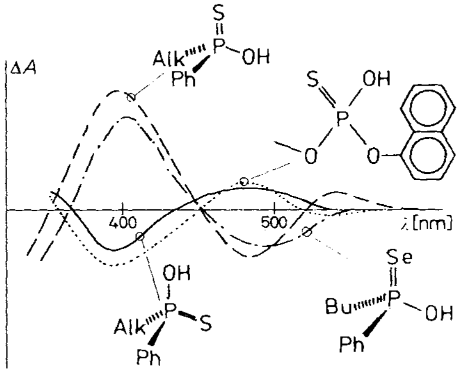


Fig. 1. CD spectra of alkyl(phenyl)thiophosphinic acids [(*R*)- and (*S*)-form] of (*R*)-*tert*-butyl(phenyl)selenophosphinic acid and of methyl α-naphthyl thiophosphate in $CF_3CO_2H$.

In pyridine the Cotton effects were recognizable, but much smaller; they rapidly changed their shape and became weaker. Nevertheless, these CD curves are also characteristic and can be used for the determination of the absolute configuration of *(2)*: the (+)-(*R*)-forms give three broad positive Cotton effects at about 590 nm (weak), 450 nm (strong) and 360 nm (medium). It is well-known that

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and an Alexander-von-Humboldt fellowship grant.

pyridine is incorporated in the complex as additional axial ligand[3].

Optically active *O*-alkyl alkylthiophosphonates *(3)* likewise give Cotton effects with *(1)* in pyridine or trifluoroacetic acid, but not in DMSO. However, in $CF_3CO_2H$ they are also very much smaller and rapidly disappear, probably due to hydrolysis of the ester group. Interestingly, however, we did obtain a clear CD with the (+)-methyl-α-naphthyl diester of monothiophosphoric acid under these conditions (Fig. 1). In pyridine in the presence of *(1)* the (+)-(*R*)-acids give a strong, broad, negative Cotton effect at about 480 nm and a likewise negative but weaker one at about 400 nm; the appearance of a further, positive Cotton effect is recognizable at shorter wavelengths (Fig. 2). *In situ* complexes of the (−)-(*S*)-compounds gave the corresponding enantiomorphic CD curves.

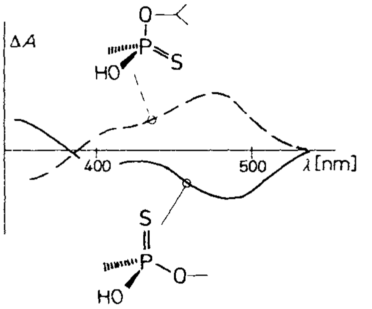

Fig. 2. CD spectra of (+)-(*R*)-*(3a)* and (−)-(*S*)-*(3c)* in pyridine.

*In situ* complexes with *(1)* are not only suitable for the determination of the absolute configuration of optically active carboxylic acids[1], glycols[1] and amino alcohols[4], but also of substituted thiophosphinic acids *(2)* and of esters of the thiophosphonic acid *(3)*. They are even more suitable than direct CD measurements[5], since the Cotton effects lie in a much more conveniently accessible wavelength region and there is no interference by bands of the ligands.

## *Procedure*

The acid[9] (0.5 to 1.5 mg) was dissolved in a solution of *(1)* in $CF_3CO_2H$ or pyridine (about 3 to 5 mM). The CD was immediately measured thereafter in cuvettes of layer thickness 2.00 to 0.10 nm using an ISA-Jobin-Yvon Mark III dichrograph.

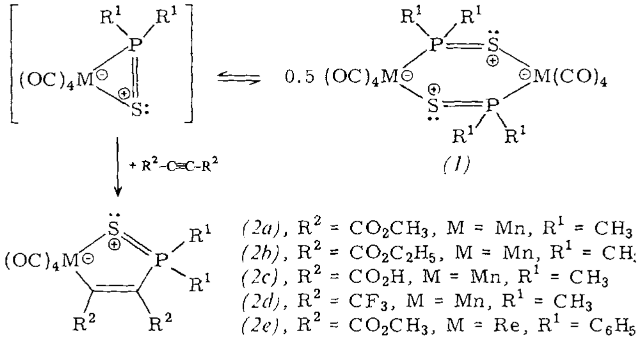
# Thiaphosphametallacyclopentadienes as Intermediates in the Cyclotrimerization of Alkynes with their Phosphorus-Sulfur Analogues[**]

By *Ekkehard Lindner, Axel Rau*, and *Sigurd Hoehne*[*]

Metallacyclopentadienes and $\eta^2$-metallabicyclohept dienes occur as reactive intermediates in the catalytic c clotrimerization and cyclocotrimerization of alkyne These compounds can also be synthesized in a directe manner and their catalytic activity tested[1]. We have no successfully obtained the P═S analogous intermediat products *(2)* by trapping the unstable thiaphosphametalla cyclopropene, which exists in equilibrium with *(1)*[2], wit electron-poor alkynes.



*(1)*

*(2a)*, $R^2 = CO_2CH_3$, M = Mn, $R^1 = CH_3$
*(2b)*, $R^2 = CO_2C_2H_5$, M = Mn, $R^1 = CH$
*(2c)*, $R^2 = CO_2H$, M = Mn, $R^1 = CH_3$
*(2d)*, $R^2 = CF_3$, M = Mn, $R^1 = CH_3$
*(2e)*, $R^2 = CO_2CH_3$, M = Re, $R^1 = C_6H_5$

The yellow (M = Mn) or colorless (M = Re) thiaphosphametallacyclopentadienes *(2)* are highly soluble in polar solvents and thermally stable. They were characterized by complete elemental analysis, mass-, IR-, and NMR-spectra (Table 1); *(2a)* was in addition characterized by crystal structure analysis[3] (Fig. 1). The molecular ions of *(2a)*, *(2b)*, *(2d)*, and *(2e)* were observed in the mass spectra.

Table 1. IR- and NMR-Data of *(2a)* (δ-values, *J* in Hz).

[**] Preparation and Properties of and Reactions with Metal-Containing Heterocycles, Part 14. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 13: *E. Lindner, G. Funk, S. Hoehne*, Chem. Ber. *114*, 2465 (1981).

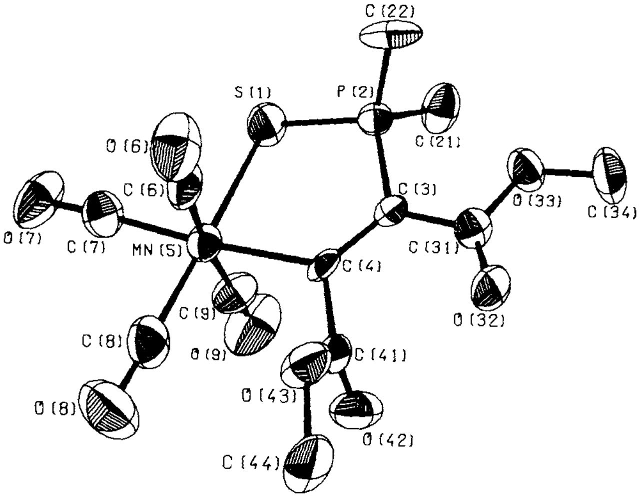

Fig. 1. ORTEP-representation of *(2a)* in the crystal (vibrational ellipsoids with 50% probability).

| Bord lengths | [pm] | Angle [°] | |
|---|---|---|---|
| S1—P2 | 199.6(4) | Mn5—S1—P2 | 99.9(2) |
| P2—C3 | 178.8(9) | S1—P2—C3 | 107.7(3) |
| C3—C4 | 135.6(12) | P2—C3—C4 | 116.9(6) |
| C4—Mn5 | 204.9(8) | C3—C4—Mn5 | 126.3(6) |
| Mn5—S1 | 240.6(4) | C4—Mn5—S1 | 87.4(3) |

The five-membered ring in *(2a)* is almost planar (sum of the internal ring angles 538°). The S1—P2 and C3—C4 bonds (199.6 and 135.6 pm) have considerable π-character. The Mn5—S1 distance is clearly longer than the sum of the covalent radii, and the coordination octahedron at manganese is only slightly distorted.

*(2a)* is kinetically labile and reacts with other alkynes *via* elimination of CO and insertion into the Mn—C σ-bond to produce a metallacycloheptatriene with vacant coordination sites[4], which immediately rearranges *via* reductive C—S-coupling to the λ$^4$-thia-λ$^5$-phospha-η$^2$-manganabicyclo[2.2.1]heptadiene *(3)*. This structural type is already known[5].

With the P═S analogues, the course of the cyclotrimerization of alkynes shows, among other things, that the triply bonded C atoms of the newly incorporated alkyne occupy positions C1 and C6 in *(3)*. In the case of *(3b)*, regiospecific insertion results with exclusive formation of the isomer with R$^3$ at C6. Due to the similar covalent radii and electronegativity of P and S, P═S behaves like a C═C-group. The yellow compounds *(3)*, which are readily soluble in polar solvents, decompose above 130 °C. They were characterized by complete elemental analysis, IR-, mass-, and $^1$H-NMR-spectra[6].

### *Procedure*

*(2a)*: A mixture of 0.58 mol *(1)* and 2.28 mol acetylenedicarboxylic acid dimethyl ester in 100 mL tetrahydrofuran (THF) is heated, under CO atmosphere, to 60 °C for 20 min. The reaction is monitored by thin layer chromatography and is interrupted after *ca.* 15 min by removal of the solvent. Purification is carried out by medium pressure chromatography on silica gel using $CH_2Cl_2$; yield 52%.

*(3b)*: 1.07 mol *(2a)* and 2.12 mol methyl propiolate in 100 mL THF are heated to 66 °C. The solvent is removed after 10 min and the residue chromatographed on silica gel using medium pressure chromatography ($CCl_4$/$CHCl_3$ 2 : 1); yield 64%.

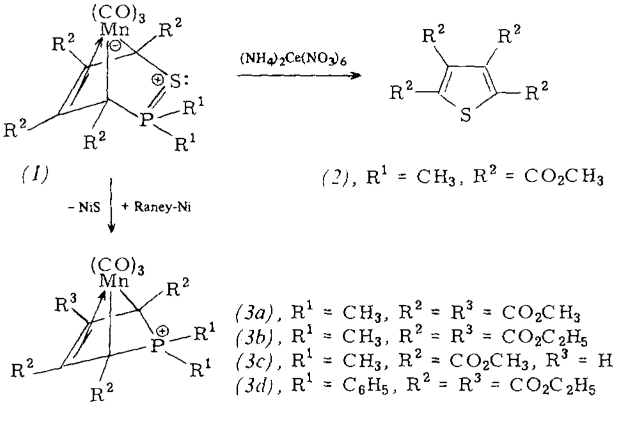
## Syntheses with λ$^4$-Thia-λ$^5$-phospha-η$^2$-manganabicyclo[2.2.1]heptadiene[**]

By *Ekkehard Lindner, Axel Rau*, and *Sigurd Hoehne*[*]

Only a few syntheses of heterocycles using metal catalysis have been described. One of the few examples is the preparation of pyridine derivatives by the action of nitriles and alkynes on cobalt complexes, whereby cobaltacyclopentadienes appear as reactive intermediates[1]. As in the catalytic cyclotrimerization of alkynes, the removal of the metal group from aza-η$^2$-cobaltabicyclo[2.2.1]heptadiene should be the last step in the catalytic cycle.

In the course of investigations on the cyclotrimerization of alkynes with their phosphorus-sulfur analogues[2] we obtained the thiaphosphamanganabicyclo[2.2.1]heptadiene *(1)* which with CO[2b] or Ce(IV) salts[3] underwent cleavage, not only of the Mn(CO)$_3$- but also of the P(CH$_3$)$_2$-group, with almost quantitative formation of the thiophene derivative *(2)*.



*(1)*

*(2)*, R$^1$ = CH$_3$, R$^2$ = CO$_2$CH$_3$

*(3a)*, R$^1$ = CH$_3$, R$^2$ = R$^3$ = CO$_2$CH$_3$
*(3b)*, R$^1$ = CH$_3$, R$^2$ = R$^3$ = CO$_2$C$_2$H$_5$
*(3c)*, R$^1$ = CH$_3$, R$^2$ = CO$_2$CH$_3$, R$^3$ = H
*(3d)*, R$^1$ = C$_6$H$_5$, R$^2$ = R$^3$ = CO$_2$C$_2$H$_5$

Under catalytic hydrogenation conditions with Raney nickel, ring contraction *via* selective sulfur extrusion to the novel λ$^4$-phospha-η$^2$-manganabicyclo[2.2.1]hexene *(3)* occurs.

| C2—Mn6 | 205.0(7) | Mn6—C1—P5 | 91.6(3) |
| Mn6—C3 | 205.0(7) | Mn6—C4—C3 | 65.9(4) |
| | | Mn6—C4—P5 | 91.6(3) |

*(3a)* possesses a crystallographic reflection plane in which Mn6 with one of the three CO, as well as phosphorus with the two methyl-groups, lie. The atoms C1 to C4 (bond length sequence, long-short-long) and P5 form a five-membered ring having an envelope conformation, in which the phosphorus is separated by *ca.* 67 pm from the plane formed by C1—C4. The interplanar angle amounts to 32°. The unusually small value of 88.4° for the C1—P5—C4 angle is due to steric effects. The ester groups on C1 and C4 are only 1.0°, and those on C2 and C3 *ca.* 5.6° rotated out of the plane. Until now only corresponding phosphole complexes with three- or five-bonded phosphorus have been known[5]. The complexes *(3)* are potential educts for the synthesis of difficultly accessible phosphole derivatives.

*Procedure*

*(2):* A solution of 0.38 mmol *(1)* and 0.45 mmol $(NH_4)_2Ce(NO_3)_6$ in 30 mL methanol/tetrahydrofuran (1 : 1) is stirred for 30 min. After removal of the solvent the residue is extracted three times with benzene and filtered. Chromatographic purification on silica gel using ethyl acetate follows; yield 95%.

*(3a, b, d):* 0.38 mmol *(1)* and 19.0 mmol Raney-nickel in 100 mL methanol are stirred. After 24 h the mixture is centrifuged and the solvent removed. Purification using medium pressure chromatography on silica gel with $CHCl_3$ follows: yields 92—98%.

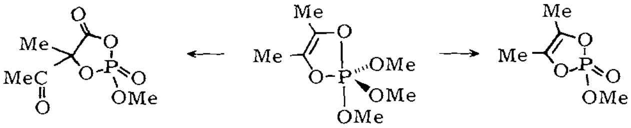
## Synthesis of Highly Reactive Cyclic Enediol Phosphates and Cyclic Acyl Phosphates by Direct Phosphorylating Ring Closure

By *Reiner Schwarz* and *Ivar Ugi*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Oxyphosphorane derivatives such as *(1)* are stabilized by a five-membered ring with O—P—O partial structure, whereas ring strain occurs in analogous cyclic phosphates[1]. Such phosphates react with nucleophiles up to $10^7$ times more rapidly than their open-chain analogues[2] and, moreover, are selective phosphorylating agents[3]. This was observed, in particular, in the case of the cyclic enediol phosphate *(2a)*, the cyclic acyl phosphate *(3)*, and some derivatives obtainable therefrom. Compounds of this type with sp$^2$-hybridized C-atoms in the ring were hitherto accessible only *via* oxyphosphorane derivatives such as *(1)*.



*(3)* *(1)* *(2a)*

We were able to synthesize such cyclic phosphates by direct phosphorylating ring closure.—The results of the reac-

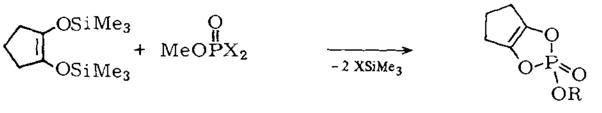
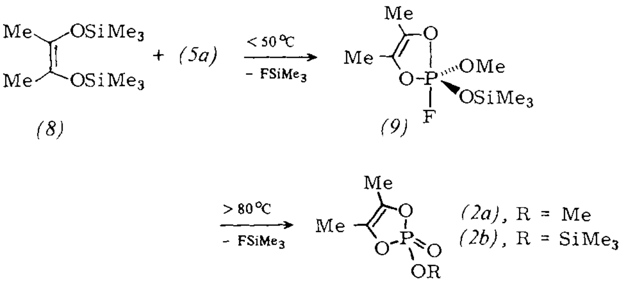
tions of *O*-, *N*- and *S*-silylated compounds with phosphorus halides like PF$_5$[4] stimulated further investigations into whether *O*-trimethylsilylated enediols such as *(4)*[5a] react with methyldihalophosphates *(5)* to give cyclic enediol phosphates. Both on reaction with *(5a)* as well as with *(5b)* we obtained the enediol phosphate *(6)*, in 89 and in 83% yields, respectively. In the case of *(5b)*, 8% of *(7)* was also formed.



*(4)* *(5a)*, X = F *(6)*, R = Me
*(5b)*, X = Cl *(7)*, R = SiMe$_3$

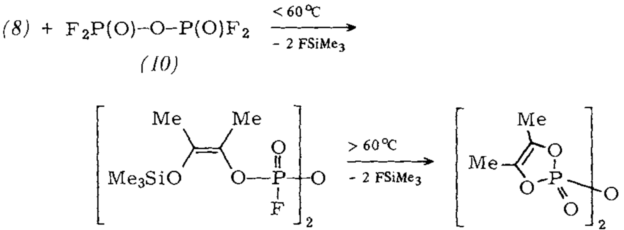
For the analogous synthesis of *(2a)* from acetoin, 3-trimethylsiloxy-2-butanone is first prepared and then deprotonated with LiN*i*Pr$_2$ at room temperature and finally trimethylsilylated. On reaction of the favored product, the *cis*-compound *(8)*, with *(5a)* below 50 °C, *(9)* could be detected by $^{31}$P- and $^{19}$F-NMR spectroscopy. Above 80 °C, *(2a)* is formed in 90% yield. Reaction of *(8)* and *(5b)* at 75 °C affords a mixture of *(2a)* and *(2b)*[2d].



*(8)* *(9)*

*(2a)*, R = Me
*(2b)*, R = SiMe$_3$

When *(8)* is allowed to react with tetrafluorodiphosphate *(10)* below 60 °C, *(11)* can be detected, whereas reaction at higher temperatures leads to formation of *(12)*[5c].

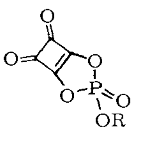


*(10)*

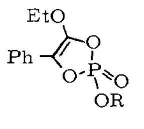
*(11)* *(12)*

Bis(trimethylsilyl) squarate reacts with *(5a)* analogously to *(8)*→*(9)*→*(2a)* at 50 °C *via* a fluorophosphorane as detectable intermediate, whereas *(13a)* is formed at 80 °C. Reaction with *(5b)* affords both *(13a)* (62%) and *(13b)* (29%).

The β-ethoxy-α,β-bis(trimethylsiloxy)styrene, accessible from ethyl mandelate, reacts with *(5a)* to give exclusively *(14a)* (74%)[6] and with *(5b)* to give, aside from *(14a)* (11%) and *(14b)* (8%), mainly unidentifiable products.

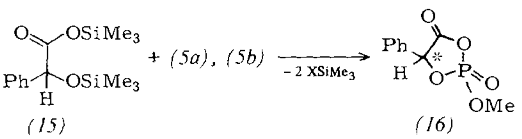


*(13a)*, R = Me
*(13b)*, R = SiMe$_3$

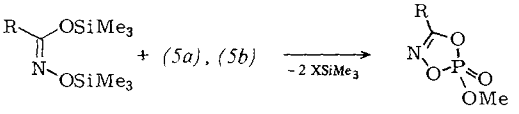


*(14a)*, R = Me
*(14b)*, R = SiMe$_3$

Trimethylsilylated (+)-mandelic acid *(15)* reacts with *(5a)* or *(5b)* to give the cyclic acyl phosphate *(16)* in yields of up to 48%.



*(15)* *(16)*



*(17a)*, R = CF$_3$ *(18a)*, R = CF$_3$
*(17b)*, R = *p*-NO$_2$–C$_6$H$_4$ *(18b)*, R = *p*-NO$_2$–C$_6$H$_4$

The hydroximic acid derivatives *(17a)* and *(17b)*[7], accessible from hydroxamic acids, furnish the 1,3,4,2λ$^5$-dioxazaphosphole derivatives[8] *(18a)* (68%) and *(18b)* (64%), respectively, on reaction with *(5a)* and *(5b)*.—Some NMR data of the products are collected in Table 1.

Table 1. Some NMR data (δ-values) of the synthesized compounds [a].

## *Procedure*

*(8)*: A solution of 3-trimethylsiloxy-2-butanone[9] (32.0 g, 0.20 mol) in dimethylformamide (DMF) (50 mL) is slowly added dropwise to 0.21 mol of LiN*i*Pr$_2$ at room temperature such that the internal temperature of the reaction mixture does not exceed 40 °C. A solution of ClSiMe$_3$ (60.4 g, 0.40 mol) in DMF (25 mL) is then added dropwise to the warm mixture, which is finally stirred for 1 h at 40 °C, filtered, and the separated precipitate is washed three times

with 10 mL of tetrahydrofuran. The combined filtrates are distilled and the crude product is fractionated twice at 60—65 °C/15 torr in a spinning band column. *(8)* [38.6 g (83%)] is obtained as an opalescent liquid, b. p. 64 °C/12 torr.

*(2a):* A solution of *(5a)* (5.57 g, 0.048 mol) in toluene (15 mL) is added dropwise to a solution of *(8)* (11.5 g, 0.048 mol) in toluene (15 mL) at 85 °C. The mixture is then stirred for 30 min at 80 °C, cooled to 60 °C, and distilled in a high vacuum. 7.09 g (90%) of *(2a)* is obtained; b.p. 64—65 °C/0.2 torr).—The other cyclic phosphates are prepared analogously.

## Crystallochemical Correlate to the Anomaly of Hydrofluoric Acid

By *Dietrich Mootz*[*]

The low acid strength of dilute hydrofluoric acid relative to the other hydrohalides and its increasing dissociation with increasing concentration constitute an anomaly in inorganic chemistry, which has been the subject of numerous investigations and discussions. A recent explanation is based on an ion-pair $H_3O^+ \cdot F^-$, indicated by IR-spectroscopy. The ion-pair is held together by an especially strong hydrogen bond, and increasingly dissociates according to $[H_3O^+ \cdot F^-] + HF \rightleftharpoons H_3O^+ + HF_2^-$ only at higher HF concentrations[1].

Results of X-ray structure analyses, which were carried out on compounds $H_2O \cdot HF$, $H_2O \cdot 2HF$, and $H_2O \cdot 4HF$ in the solid-state (melting points between −36 and −100 °C), together with a new determination of the $H_2O$—HF phase diagram[2] now correlate with the anomaly and especially with this explanation. All three structures prove to be those of oxonium salts—$H_3OF$, $H_3OHF_2$ and $H_3OH_3F_4$—with three very strong hydrogen bonds per oxonium ion and with average O···F distances of 2.467, 2.502 and 2.536 Å respectively, appear less tightly bound as the HF content increases.

## Triethanolamine: Dimerization *via* a Ring of Six Hydrogen Bonds

By *Dieter Brodalla* and *Dietrich Mootz*[*]

A special type of dimerization—*via* a ring of six hydrogen bonds to give a cage—was found on analysis of the crystal structure of tris(2-hydroxyethyl)amine.

Growth of a single crystal directly on the diffractometer in a sealed glass capillary in a stream of cold gas was achieved by means of a miniature zone refining method using focussed radiation[1]. The measurements were carried out at 140 K; trigonal rhombohedral crystal system, space group $R\bar{3}$, lattice constants hexagonal $a = b = 1149.1(1)$, $c = 1070.0(1)$ pm and $Z = 6$ molecules in the unit cell[2].

Two triethanolamine molecules facing each other form a cage-like dimer with $C_{3i}$-$\bar{3}$ symmetry (Fig. 1), in which the 2-hydroxyethyl groups enclose the free electron pairs on the nitrogen atoms[3], and the oxygen atoms are bound by six homodromic[4] symmetry-equivalent hydrogen bonds [O···O 270.1(1), O—H 84(1), H···O 186(1) pm, $\sphericalangle$O—H···O 172(1)°], to give a six-membered ring in chair form.

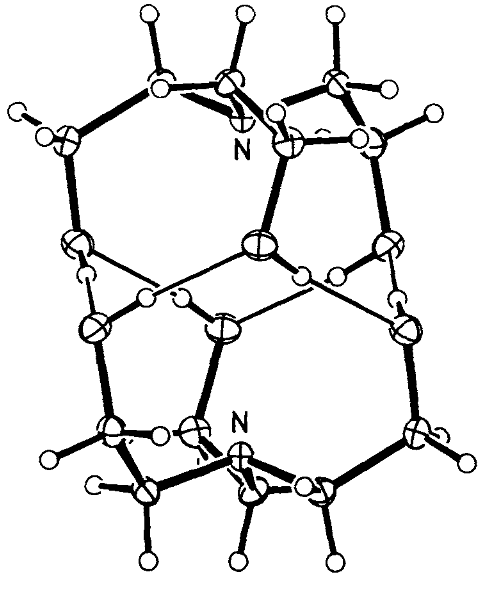

Fig. 1. The cage-shaped dimer of $N(CH_2CH_2OH)_3$ with the ring of six hydrogen bonds (center), ORTEP diagram [5].

The dimeric units in the crystal are arranged according to the principle of cubic close packing. The crystal structures, determined in the same way on mono- and diethanolamine, show cross-linking to give higher associates in which the N-atom also participates in the hydrogen bonding.

## Non-Ergodic Behavior of Excited Radical Cations in the Gas Phase[**]

By *Gisbert Depke, Chava Lifshitz, Helmut Schwarz,* and *Eva Tzidony*[*]

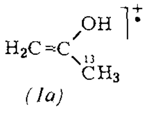
*Dedicated to Professor Hans D. Beckey on the occasion of his 60th birthday*

One of the central questions in reaction dynamics today is whether highly excited molecules behave ergodically[1], *i.e.* whether unimolecular dissociations are slower than intramolecular vibrational energy redistribution. It has been shown for neutral molecules[2] that energy randomization is completed within a few picoseconds and that molecules behave non-ergodically only under special conditions[2a]. If similar non-ergodic behavior were found in ionic systems, then one of the basic assumptions of the quasi-equilibrium theory (QET) of mass spectra[3] would be violated.

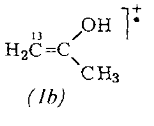
Evidence for the non-statistical behavior of the enol radical cation of acetone *(1)*, through measurements of kinetic energy release distributions *T* of the dissociation fragments, has recently appeared[4]. In that study and in previous ones[5], [$^2$H]-labeled isotopomers of *(1)* were employed and there was the ever present possibility of kinetic isotope effects. In order to circumvent this problem, we have now prepared the [$^{13}$C]-labeled isotopomers *(1a)* and *(1b)*. We report here on the unimolecular dissociation of this radical cation in the gas phase and present evidence indicating that this system is characterized by non-ergodic behavior.

The study of [$^2$H]-labeled ions *(1)*, strengthened by thermochemical arguments[4,5], has shown that the CH$_3$-cleavage from metastable ions *(1)* (lifetimes $\approx 10^{-5}$ s) does not take place by direct α-cleavage ($(1) \nrightarrow (3) + CH_3$), but by dissociation to ion *(5)* following a rate determining [1,3]-H-shift ($(1) \rightarrow (4) \rightarrow (2)$) (Fig. 1). A highly excited intermediate acetone radical cation *(2)** is formed, whose lifetime has been estimated to be $5\times10^{-13}$ s[4].

If *(2)** were to behave ergodically, one would expect, on the basis of the chemical equivalence of the two methyl groups, that the two specifically [$^{13}$C]-labeled ions *(1a)* and *(1b)* would eliminate the radicals $^{13}CH_3^{\cdot}$ and $^{12}CH_3^{\cdot}$ in equal (1 : 1) proportions. Furthermore, the kinetic energy release, *T*, for the $^{13}$CH$_3$- and $^{12}$CH$_3$-eliminations, would be expected to be closely similar. If, however, the internal energy of *(2)** is distributed non-statistically prior to dissociation (*i.e.* the behavior is non-ergodic), then—despite the equivalence of both methyl group—the two $^{13}$CH$_3$ and $^{12}$CH$_3$ radicals would be expected to cleave-off at different rates. Previous data[4,5a] indicate that discrimination against the CH$_3$ group, which is originally present in *(1)*, is to be expected[4,5c] and that the *T*-value for the elimination of this group should be smaller than for the alternative process in which the methyl radical is formed from the original CH$_2$ group and the hydrogen atom of the OH group.



*(1a)*



*(1b)*

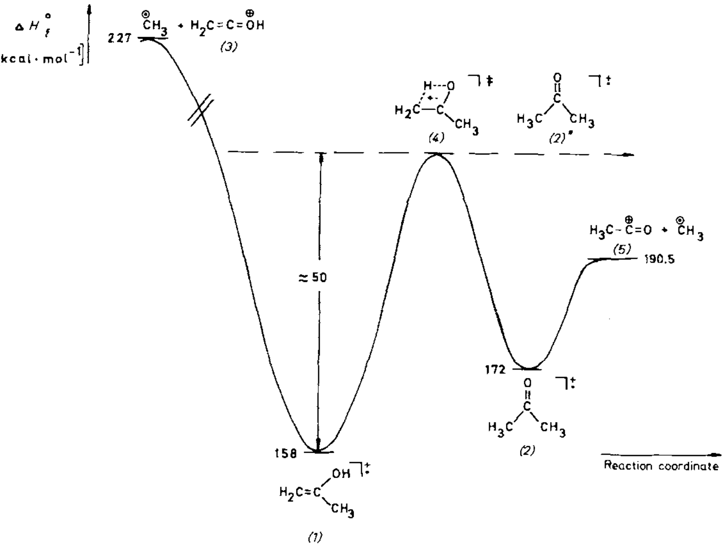


Fig. 1. Energy profile for the isomerization and dissociation of the enol radical cation of acetone *(1)*. The reaction coordinate is complex; it involves a [1.3]-H-shift (*(1)*→*(2*)*), followed by a C—C-cleavage leading to formation of the acyl ion *(5)*.

Table 1. $^{13}$CH$_3$- *versus* $^{12}$CH$_3$-elimination from the radical cations *(1a)* and *(1b)*. The relative intensities were obtained from MIKE-spectra and the translational energy values (calculated from the widths at half-height of the metastable peaks) were obtained from high voltage scans (MAT 311 mass spectrometer at 70 eV ionizing energy; 3 kV acceleration potential, 300 μA emission current) [a].

| Ion | rel. intensity [%] | | *T* [meV] | |
|---|---|---|---|---|
| | $^{13}$CH$_3$ | $^{12}$CH$_3$ | $^{13}$CH$_3$ | $^{12}$CH$_3$ |
| *(1a)* | 42.3 ± 2.5 | 57.7 ± 2.5 | 59.4 | 71.5 |
| *(1b)* | 53.5 ± 1.6 | 46.5 ± 1.6 | 74 | 62.2 |

[a] Details concerning the methodology may be found in [5]. The ions *(1a)* and *(1b)* were produced from the [$^{13}$C]-labelled ketones, [1-$^{13}$C]-2-hexanone and [3-$^{13}$C]-2-hexanone, respectively, *via* McLafferty rearrangements.

The data presented in Table 1 (different loss of $^{13}$CH$_3$ and $^{12}$CH$_3$; $T_{^{13}CH_3} \neq T_{^{12}CH_3}$) demonstrate quite convincingly that the electron impact-induced unimolecular methyl eliminations from the enol radical cation of acetone *(1)* do not behave statistically. Hence, a fundamental assumption of the quasi-equilibrium theory, namely that the distribution of internal energy between the vibrational states is statistical, is apparently violated by *(1)*.

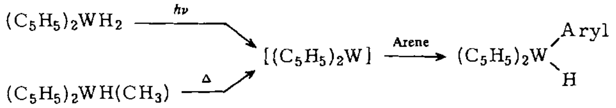
## Synthesis of Hydrido(phenyl)osmium(II)- from Benzeneosmium(0)-Complexes: Intramolecular Insertion of a Lewis Basic Metal Atom into an $sp^2$-C—H Bond[1]

By *Rainer Werner* and *Helmut Werner*[*]

In recent years, considerable interest has been shown in the problem of activating C—H bonds by transition metals. *Green et al.*[2] found that *e.g.* bis(cyclopentadienyl)tungsten ("tungstenocene"), prepared *in situ* by photolysis of $(C_5H_5)_2WH_2$ or thermolysis of $(C_5H_5)_2WH(CH_3)$, can react with arenes by insertion into an $sp^2$-C—H bond.



We recently reported the synthesis of a series of benzeneosmium(0) complexes of the type $C_6H_6OsLL'$[3]. If tertiary phosphanes or phosphites are selected as the ligands L and L′, the compounds obtained, as shown in eq. (a), are thermolabile; they decompose even during attempts to separate off the naphthalene formed as by-product.

$$[C_6H_6OsLL'I]PF_6 + 2\,NaC_{10}H_8 \xrightarrow{THF} C_6H_6OsLL' + C_{10}H_8 + NaI + NaPF_6 \qquad (a)$$

$L = L' = PPh_3,\ P(OMe)_3$

The alkene(trimethylphosphane) complexes $C_6H_6Os(PMe_3)C_2H_3R$ are considerably more stable and are obtained in an analogous way to that shown in eq. (a). They can be isolated in pure form by reaction of the hydrido cations $[C_6H_6OsH(PMe)_3C_2H_3R]^\oplus$ with NaH[3].

$$C_6H_6Os(PMe_3)C_2H_3R \underset{H^\ominus}{\overset{H^\oplus}{\rightleftharpoons}} [C_6H_6OsH(PMe_3)C_2H_3R]^\oplus \qquad (b)$$

*(1)*, R = H
*(2)*, R = Me

Our attempt to synthesize the bis(trimethylphosphane) complex $C_6H_6Os(PMe_3)_2$, which should be an even stronger Lewis base than the homologous $C_6H_6Ru(PMe_3)_2$[4], by exchange of the coordinated alkene in *(1)* or *(2)* for $PMe_3$ was unsuccessful. At room temperature both *(1)* and *(2)* react very slowly with trimethylphosphane; after 24 h only a slight reduction in the concentration of the alkene complex is detected as indicated by NMR spectroscopy. Upon warming the solution ($C_6H_6$) to 70 °C [for *(1)* after 20 h, for *(2)* after 5 h] compound *(3)* is formed practically quantitatively. Instead of the expected exclusive displacement of the alkene, insertion of the osmium into a C—H bond of the benzene also occurs.

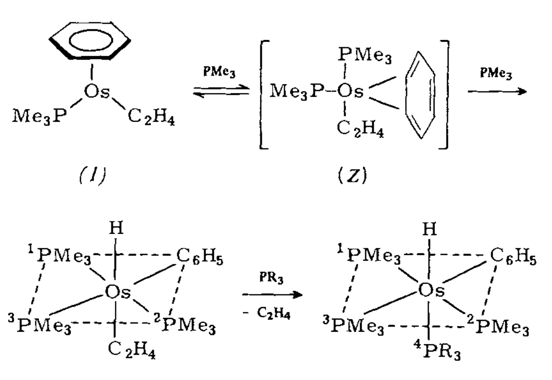
$$(1), (2) + 3\,PMe_3 \xrightarrow[-C_2H_3R]{} cis\text{-}(PMe_3)_4Os{<}^{C_6H_5}_{H} \qquad (c)$$

*(3)*

Repetition of the reaction in $C_6D_6$ indicates that an *intra*molecular oxidative addition has occured; only *(3)*, and no complex containing the $Os(C_6D_5)D$ grouping, is formed. Hence, the insertion of the metal does not proceed *via* a benzene/phosphane exchange.

The changes in the $^1H$-NMR spectrum provide information on the course of the reaction. While no intermediate product is observed in the formation of *(3)* from *(2)*, such a species can be unequivocally detected in the reaction of *(1)* with $PMe_3$. Its spectroscopic data (Table 1) confirm the structure $(C_2H_4)(PMe_3)_3Os(C_6H_5)H$ *(4)*. When the reaction of *(1)* with $PMe_3$ (molar ratio 1 : 4) in benzene is interrupted after 2 h, a mixture of 80% *(4)*, 10% *(1)*, and 10% *(3)* is obtained. Almost pure *(4)* was obtained by recrystallization and this was characterized by mass spectroscopy. In the presence of excess trimethylphosphane, *(4)* reacts completely to give *(3)*. An ethylosmium complex cannot be detected, *i.e.* no insertion of the coordinated ethylene into the Os—H bond occurs. Furthermore, a reductive elimination of benzene from *(3)* in the presence of trimethylphosphane cannot be observed.

In order to clarify the stereochemistry of the final step in the synthesis of *(3)* from *(1)*, *(4)* was reacted with $PMe_2Ph$. The ethylene coordinated in the *trans*-position to the hydride ligand is quantitatively exchanged after 7 h ($C_6H_6$, 70 °C). In a reaction which proceeds with rigorous stereospecificity, the phosphane occupies the alkene-site, which was verified by selective decoupling experiments. The formation of *(3)* and $(PMe_3)_3(PMe_2Ph)Os(C_6H_5)H$ *(5)* from *(1)* can therefore be formulated as follows:



*(3)*, $R_3$ = $Me_3$, *(5)*, $R_3$ = $Me_2Ph$

In the intermediate product *(Z)*, we postulate a $\eta^4$-coordination of the benzene, which is not without precedent in the chemistry of areneruthenium(0) and osmium(0) complexes[5]. The question of whether the hydrido(olefin) compound *(4)* is formed from *(Z)* *via* a one-step reaction or

[a] Exact assignment of both signals to the $PMe_3$ groups in the 3- and 4-positions is not possible. [b] Signals of the $C_2H_4$-protons at $\delta = 1.88$ d × t, $J_{^{1,2}PH} = 3.0$, $J_{^3PH} = 4.5$. [c] Signal lies under the signal of the $PMe_2Ph$ protons.

whether another intermediate species is involved, remains open; the insertion of the metal must result from this.

The activation of C—H bonds has fundamental significance for the comprehension of numerous reactions catalyzed by metal complexes. The cleavage of an sp$^2$-C—H bond by a Lewis basic metal was first described by *Chatt et al.*[6], who obtained the compounds $(dmpe)_2Ru(C_6H_5)H$ and $(dmpe)_2Ru(C_{10}H_7)H$ (dmpe = $Me_2PC_2H_4PMe_2$) by reduction of $(dmpe)_2RuCl_2$ with sodium or potassium in the presence of benzene or naphthalene. The compound $(dmpe)_2Ru(C_{10}H_7)H$ exists in equilibrium with $(dmpe)_2Ru(C_{10}H_8)$[6].

To the best of our knowledge the synthesis of *(3)* from *(1)* or *(2)* is the first proof that the metal atom of a stable $\eta^6$-arene metal complex, after successive addition of further donor ligands, can undergo insertion into an sp$^2$-C—H bond without prior dissociation of the ($\eta^6$-$C_6H_6$) metal bond. An extension to the preparation of other aryl(hydrido) metal compounds appears to be possible.

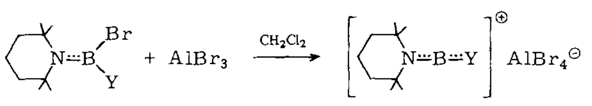
## Boron Cations with a Dicoordinate B Atom

By *Heinrich Nöth* and *Rudolf Staudigl*[*]

Cations of boron with the coordination number 4 are formed on aminolysis of suitable boron halides, on nucleophilic halide-displacement from amine-borohalide adducts with bases, and on electrophilic hydride-exchange in amine-boranes with halogen in the presence of bases[1]; the composition of these salts can be represented by the general formulas $[R_2BLL']X$, $[RXBLL']X$, $[RBL_3]X_2$, and $[BL_4]X_3$ (R = H, Hal; L, L′ = $NH_3$, $NH_2R$, $NR_3$, pyridine; X = Cl, Br, I). Compounds containing triply coordinated cations $[X_2BL]Y$, on the other hand, have so far rarely been described in the literature[2], while dicoordinated cations $[XBX]^{\oplus}$ were hitherto unknown[3]. The latter species formally contain one B atom with an electron quartet; it should therefore be very electrophilic and could correspond to a "superelectrophile".

It is well known that the electron-deficiency in boron compounds can be compensated considerably by $\pi$-back-bonding. Exploiting this principle we have now succeeded in synthesizing salts whose cations contain boron with coordination number 2[4].

Reaction of anhydrous aluminum bromide with a series of 2,2,6,6-tetramethylpiperidinoboron bromides in dichloromethane leads to specific displacement of bromide, which is trapped as tetrabromoaluminate. By formation of this less nucleophilic anion, and owing to the steric and electronic shielding of the B atom by the bulky 2,2,6,6-tetramethylpiperidino-moiety (tmp), dicoordinated boron cations are generated.



| Y = | $N(CH_3)_2$ | $N(C_2H_5)_2$ | $C_6H_5$ | $CH_3$ |
|---|---|---|---|---|
| Salt | *(1)* | *(2)* | *(3)* | *(4)* |
| $\delta(^{11}B)$ | 36.7 | 37.6 | 56.0 | 59.6 |
| $\delta(^{27}Al)$ | 80.7 | 80.7 | 81 | 80.7 |
| $\Delta\nu_{1/2}(^{27}Al)$ | 20 | 20 | 80 | 48 |
| M.p. [°C] | 114 | 90—95 | dec. | dec. |

$^{27}$Al-NMR spectra confirm exclusive formation of the $AlBr_4^{\ominus}$ anion, which, compared to $Al_2Br_6$, is characterized by its substantially sharper signal; the linewidth of $\Delta\nu_{1/2} \approx 20$ Hz observed in *(1)* and *(2)* corresponds to an undistorted tetrahedral $AlBr_4^{\ominus}$. The $^{11}$B-NMR signals of *(1)—(4)* are shifted 6—18 ppm downfield relative to those of the starting compounds tmpB(Br)Y; their linewidths, which are greater by a factor of about 5, are consistent with a *linear* heteroallene structure (for *(1)—(3)*). Also consistent with such a structure are the isotopically split IR bands at

Institut für Anorganische Chemie der Universität
Meiserstr. 1, D-8000 München 2 (Germany)

1850—1900 cm$^{-1}$, which we assign to an antisymmetric $BN_2$ vibration in *(1)* and *(2)*.

The heteroallene structure of *(1)* was confirmed by X-ray structure analysis. The projection onto the *a/c* plane of the monoclinically crystallizing compound (Fig. 1) shows a linear NBN framework ($\sphericalangle$NBN 176(3)°) and orthogonal orientation of the $C_2N$ planes (88°). One of the two BN distances was found to be 130(4) pm. This is the shortest so far recorded[5].

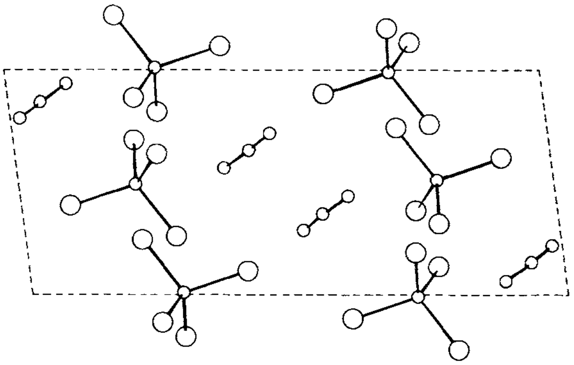

Fig. 1. ORTEP diagram of the unit cell of *(1)*, projection on the *a/c* plane, with omission of the C-skeletal atoms of the tetramethylpiperidino- and dimethylamino-ligands on the boron cation. The shortest Br...B distance is 412 pm. Hence there is no interaction between B and Br atoms.

The B atom of the cation of salt *(4)* can formally be considered as having, at most, an electron sextet. Compared to *(1)* and *(2)* this compound is thermally less stable. The crystals rapidly decompose at room temperature; in $CH_2Cl_2$, decomposition at room temperature is slow enough to enable a definite NMR spectra to be recorded. Less sterically demanding nucleophiles such as $Br^{\ominus}$ (from $[(C_4H_9)_4N]Br$) react with the new boron cations, *e.g.* of *(1)*, to give the educt[6].

The stabilization of these cations of boron by steric and electronic factors is obviously more effective than in the monomeric boron imide $C_6F_5$—B$\equiv$N—$t$C$_4$H$_9$, which also contains a dicoordinated B atom[7] and, in contrast to *(1)—(4)*, undergoes dimerization.

### *Procedure*

Diethylamino(2,2,6,6-tetramethylpiperidino)boron(1+) tetrabromoaluminate *(3)*: A stirred solution of tmp($Et_2N$)Br (2.24 g) in $CH_2Cl_2$ (12 mL) is treated portionwise at −20 °C with 1.92 g of $AlBr_3$. The clear solution is first warmed to room temperature. Subsequent slow cooling to −78 °C affords crystalline *(3)*, while rapid cooling furnishes not quite pure *(3)* as a colorless oil. Yield 3.7 g (90%), m.p. 90—95 °C, rapid decomposition at 130 °C. The equivalent conductivity of a 1.415 M solution in $CH_2Cl_2$ at 20 °C was found to be 31.1 $\Omega^{-1}$ cm$^2$. *(3)* is only slightly sensitive to hydrolysis[8].

## Synthesis of Enantiomerically Pure (*R*)- and (*S*)-α-Hydroxyketones and Vicinal Diols; Asymmetric Nucleophilic Carbamoylation[**]

By *Dieter Enders* and *Hermann Lotter*[*]

*Dedicated to Professor Rolf Appel on the occasion of his 60th birthday*

The use of masked nucleophilic acylation agents is part of the repertoire of organic synthesis[1]. Reagents which bring about direct nucleophilic acylation are also increasing in importance[2]. While enzymatic variants of the cyanohydrin synthesis and the acyloin addition have to a degree been successfully used[3], generally applicable methods for asymmetric CC-coupling using chiral carbonyl-d$^1$-reagents[4] are not yet available[5].

The α-hydroxyamides *(3)* can be obtained in good yield *via* asymmetric nucleophilic carbamoylation by addition of lithium tetramethylpiperidide (Li-TMP) to a mixture of the ketone *(1)* and the chiral formamide *(2)* in tetrahydrofuran (THF), ether, and *n*-pentane (4:4:1) at −100 °C. The chiral carbamoyllithium compounds of type *(4)* ($R=CH_3$) formed as intermediates are highly reactive and the diastereomeric excess of hydroxyamides *(3)* is low (de = 5—20%)[6]. The hydroxyamides can, however, be readily separated into the pure diastereomers *(SS)—(3)* and *(SR)—(3)* by simple column chromatography or, more rapidly, by preparative high pressure liquid chromatography (HPLC). Subsequent reaction with methyllithium permits the preparation of both enantiomers of the α-hydroxyketones *(5)* and the vicinal diols *(6)* in enantiomerically pure form (see Table 1).

In all cases, methyllithium cleavage of the amides *(3)* proceeds to completion; depending on the reaction conditions, either more hydroxyketone *(5)* or more diol *(6)* can be obtained[7]. *(5)* and *(6)* are separated by column chromatography.

Since the diols *(6)* are crystalline, ee-values of >90% can be achieved after two recrystallizations (*n*-pentane), even when the diastereomeric separation step is omitted.

---

[a] Checked by NMR spectroscopy using the chiral shift reagent tris[3-(heptafluoro-1-hydroxybutylidene)-(+)-campherato]europium(III) (ee≥97%). [b] Values in brackets crude yields. [c] Oven temperature during Kugelrohr distillation. [d] The assignment of the absolute configuration follows from an X-ray structure analysis of the hydroxyamide and comparison with literature data [e] [upper line: *(RS)-(3)*, *(R)-(5)* and *(R)-(6)*; lower line: *(SS)-(3)*, *(S)-(5)* and *(S)-(6)*]. [e] *D. J. Cram, L. K. Gaston, H. Jaeger*, J. Am. Chem. Soc. *83*, 2183 (1961): $[\alpha]_D^{25} = +20.34$ ($c=3.2$, EtOH), *(S)*-configuration. [f] In benzene; *(5c)* exhibits mutarotation in ethanol.

Hydrolysis of the amides *(3)* to the acids can only be performed using somewhat drastic conditions (boiling with conc. HCl); *e.g.* 2-hydroxy-2-methyl-3-phenylpropionic acid was obtained in 67% yield from *(3)*, $R^1=C_6H_5CH_2$, $R^2=CH_3$.

The variant described here—CC-coupling, followed by chromatographic separation of the diastereomers—permits the asymmetric nucleophilic acylation or hydroxyalkylation of ketones and is of particular interest if pure samples of both enantiomers have to be prepared.

The optimization of the diastereoselectivity of the asymmetric carbamoylation is current being investigated. For example, use of the lithium compounds *(4)*, $R=CH_2OCH_2CH_2OCH_3$, already doubles the diastereomeric excess (de≈30%)[8].

## *Procedure*

*(SS)- and (RS)-(3):* A solution of 22 mmol Li-TMP in 50 mL THF [prepared from 3.74 mL (22 mmol) 2,2,6,6-tetramethylpiperidine and 13.8 mL 1.59 N *n*-butyllithium solution in *n*-hexane] is cooled to −70 °C and dropped, over 20—60 min, into a solution of 20 mmol *(1)* and 20 mmol *(2)* in 135 mL THF:ether:*n*-pentane=4:4:1 under inert gas atmosphere at −100 °C. The mixture is stirred for 3—5 h at this temperature, allowed to warm up to 0 °C and after acidification of the aqueous phase with dilute HCl, worked-up in the usual way with ether/saturated NaCl solution. The crude diastereomeric mixtures are separated into the pure diastereomers *(SS)*- and *(RS)-(3)* by column chromatography [silica gel, *n*-pentane/THF (5:1, *(3a)*) or ethyl acetate/*n*-pentane (0.5—10:1)] or by preparative HPLC [prep. HPLC-system 830, DuPont, Bad Nauheim, Zorbax SIL-column, 2.4×25 cm, *n*-pentane/THF (5:1), 60 bar *(3a)* or *n*-pentane/ethyl acetate (4—6:1), 60—120 bar], separation factors α=1.5—2.0.

*(S)- or (R)-(5) and (S)- or (R)-(6):* 5 mmol *(SS)*- or *(RS)-(3)*, dissolved in 5 mL THF, is added over 5—10 min to a stirred solution of 22.5 mmol methyllithium (13.6 mL of a 1.65 N solution in ether) in 22.5 mL THF at −10 °C under inert gas atmosphere. The cleavage is complete after 24 h at 20 °C (TLC control). After work-up in the usual way with ether/saturated NaCl solution, the mixture is separated by column chromatography (silica gel, *n*-pentane/ether).

# A Facile Electrosynthesis of 1,2,4-Triazoline-3,5-diones[**]

By *Heinrich Wamhoff* and *Gerhard Kunz*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

1,2,4-Triazoline-3,5-diones *(2a—c)* ("4-R-TAD") are, as extremely reactive dienophiles[1], versatile synthetic building blocks[2]; they can, in general, be prepared by oxidation of the urazoles *(1a—c)* with *tert*-butyl hypochlorite[3a], trichloroacetyl isocyanate[3b], dinitrogen tetroxide[3c] and, particularly easily, with *N*-bromosuccinimide[3d]. While separation from by-products can cause problems in these synthetic methods, the preparative electrolysis of *(1a—c)* at a Pt electrode offers a surprisingly simple and unequivocal route to the triazolinediones *(2a—c)*. In addition, bis(triazolinediones) linked by bridging groups[4] *e.g.* *(4)* are readily prepared in this way (Table 1).

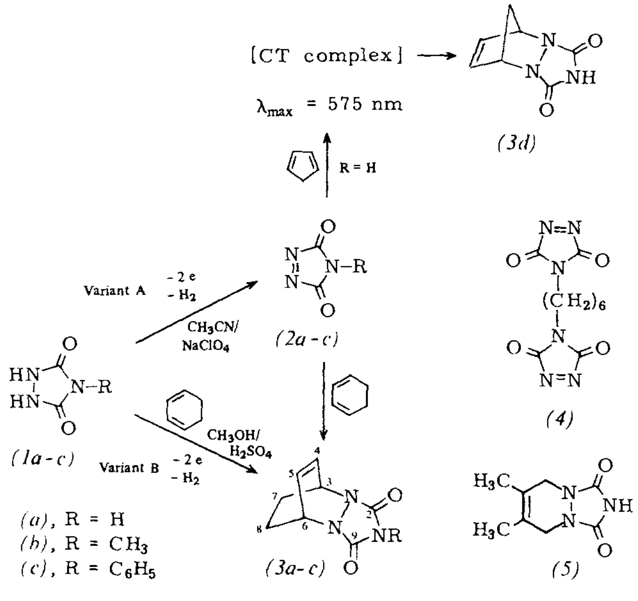

Table 1. Selected properties of the compounds synthesized.

| Compound | Yield [%] A | Yield [%] B [a] | M.p. [°C] | Spectral data |
|---|---|---|---|---|
| *(2a)* | 29 | | | IR($CH_2Cl_2$): 3175, 3070, 2980, 2300, 2250, 1750, 1710, 1375 $cm^{-1}$; UV($CH_2Cl_2$): $\lambda_{max} = 563$, 540, 520, 504 sh nm [b] |
| *(3a)* | 50 | 75 | 202—204 | IR(KBr): 3160, 3060, 2740, 1750, 1700, 1400 $cm^{-1}$; $^{13}C$-NMR($CH_2Cl_2$): $\delta = 157.38$ (C-2, 9), 130.46 (C-4, 5), 49.78 (C-3, 6), 21.90 (C-7, 8) |
| *(3d)* | 35 | | 214—215 [c] | |
| *(4)* | 12 | | 145 [d] | |
| *(5)* | | 62 | 215—216 [e] | |

[a] Variants A and B. [b] Ref. [6a]: $\lambda_{max} = 562$, 539, 518, 500 sh, nm. [c] Ref. [6b]: 214—216 °C. [d] *K. B. Wagener, S. R. Turner, G. B. Butler*, J. Polym. Sci. Polym. Lett. Ed. *1972*, 805. [e] Ref. [6b]: 216—217 °C.

Variant A of this electrochemical method is particularly well suited to the synthesis of the parent compound *(2a)*, which had already been postulated by *Stollé*[5] in 1912 but because of its low stability[6] ("elusive"[6a]) has remained incompletely characterized. Dilute solutions of *(2a)* can be stored for several months at low temperatures[7]. A further advantage with variant B is that *e.g.* Diels-Alder reactions can be carried out, even during the electrooxidation, as titrimetric trapping reactions of the triazolinedione *(2)*, *e.g.* reaction with cyclohexadiene gives *(3a)* and *(3b)* and with dimethylbutadiene *(5)* is produced.

A further simple preparative route to adducts of *(2a)* proceeds *via* metal complexes[8].

## *Procedure*

*Variant A (divided H-cell according to Lund*[9]*)*: *(1a—c)* (2 mmol) are suspended in an electrolyte consisting of 100 mL acetonitrile, 6.1 g sodium perchlorate and a drop of perchloric acid. Electrolysis proceeds at a Pt anode at 0 °C with a current density of 20 mA/$cm^2$ under an inert gas atmosphere. As soon as the color of the solution changes from deep pink to brown, 3 g sodium sulfate are added and after addition of a large amount of $CH_2Cl_2$, all the acetonitrile is removed *in vacuo*. The salts are removed from the red $CH_2Cl_2$ solution, which is then ready for further use; *(2a)*, *(3a)*, *(3d)*, *(4)* see Table 1.

*Variant B (non-divided reaction vessel for simultaneous cycloaddition)*: The conditions used are those described in variant A, however an open beaker is used and the electrolyte consists of 2% methanolic sulfuric acid; two Pt electrodes are used with a current density of 0.3 A/$cm^2$ in the presence of 1,3-cyclohexadiene or dimethylbutadiene. The mixture is worked-up by concentrating to a half of the original volume, the container filled-up with water, the mixture neutralized with sodium carbonate, and then concentrated to a tenth of its volume; the residue is extracted with $CH_2Cl_2$. After drying over magnesium sulfate, the solution is evaporated to dryness; *(3a)* and *(5)*, see Table 1. *(3b)* and *(3)*, R = 4-$ClC_6H_4$ or 3,4-$Cl_2C_6H_3$, are synthesized in an analogous manner.

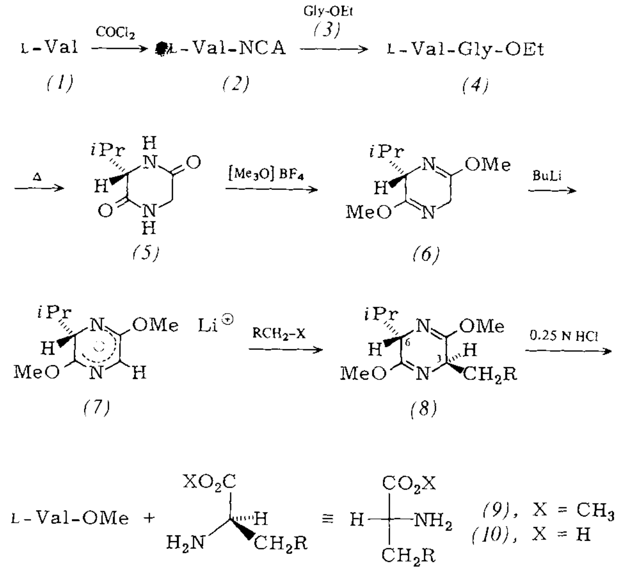
# Enantioselective Synthesis of *(R)*-Amino Acids Using L-Valine as Chiral Agent[**]

By *Ulrich Schöllkopf, Ulrich Groth*, and *Chuanzheng Deng*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

Optically active, non-proteinogenic amino acids are gaining increasing importance in research and application *e.g.* as enzyme inhibitors or pharmaceuticals.

We recently reported the enantioselective[1] synthesis of α-methylamino acids by reaction of the lithiated bislactim ether of *cyclo*-(L-Ala-L-Ala) with electrophiles[2]. We have now found that α-H amino acids [type *(10)*] can also be obtained by the "bislactim-ether method", *e.g.* starting from the mixed bislactim ethers *(6)*, which we obtained from *cyclo*-(L-Val-Gly) *(5)*. *(6)* is metalated regiospecifically in the glycine moiety by butyllithium. The lithium compound (7) (an ion pair) reacts with alkyl halides with, in part, >95% diastereoselectivity to give the adducts *(8)*. The alkyl residue enters *trans* to the isopropyl group on C-6, *i.e.* the (*R*)-configuration is induced at C-3. Hydrolysis liberates the (*R*)-amino acid methyl ester *(9)* as well as the chiral agent, methyl L-valinate. The two esters are separable by distillation. The enantiomeric excess (e.e. in Table 1) of esters *(9)* is determined ¹H-NMR spectroscopically with $Eu(hfc)_3$ on the signal of the ester methyl group. The (*R*)-configuration followed, either from the rotation of the esters *(9)* or of the amino acids *(10)*—insofar as these are configuratively known[3]—and/or from the ¹H-NMR spectrum of the adducts *(8)*.



Scheme 1. NCA = N-carboxyanhydride.

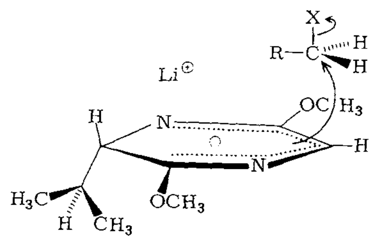
Table 1. Dihydropyrazines *(8)* and methyl (*R*)-α-aminoalkanoates *(9)* prepared from *(6)*.

| | $CH_2R$ | X' | *(8)* Yield [%] | (*R*)-*(9)* Yield [%] [a] | (*R*)-*(9)* e.e. [%] | $[\alpha]_D^{20}$ (EtOH) [b] |
|---|---|---|---|---|---|---|
| *(a)* | $CH_2—C_6H_5$ | Br | 81 | 73 | 91–95 [c] | −24.2 (*c* = 2.2) |
| *(b)* | $CH_2—3,4—(OCH_3)_2C_6H_3$ | Br | 91 | 78 | 85 | −15.0 (*c* = 0.9) |
| *(c)* | $CH_2—CH{=}CH—C_6H_5$ | Br | 90 | 89 | >95 | −18.7 (*c* = 0.9) |
| *(d)* | $CH_2—C{\equiv}C—C_6H_5$ | Br | 92 | 86 | >95 | + 3.3 (*c* = 1.0) |
| *(e)* | $CH_2—C{\equiv}CH$ | Br | 88 | 52 | 60–65 [c] | [d] |
| *(f)* | $CH_2—(CH_2)_5—CH_3$ | Br | 62 | 75 | 75–80 [c] | −19.0 (*c* = 1.1) |
| *(g)* | 2-naphthylmethyl | Br | 89 | 78 | 92 [c] | −15.6 (*c* = 0.9) |

[a] Referred to *(8)*. [b] For the given e.e. values. [c] Rotation of (*R*)- and (*S*)-*(10)* known [3]. [d] Since separation of *(9e)*/Val-$OCH_3$ by distillation is difficult, both esters were hydrolyzed with conc. HCl (1 h); *(10e)* was separated from sparingly soluble *(1)* by crystallization from water. *(10e)* [3]: $[\alpha]_D^{20}$ ($H_2O$) = +18.8 (*c* = 2.4).

We synthesized (*R*)-α-methylphenylalanine in >95% enantiomeric excess in an analogous way, starting from benzyl bromide and the bislactim ether of *cyclo*-(L-Val-L-Ala).

To explain the induction we assume that the lithium compound *(7)* contains a planar dihydropyrazine anion, one diastereotopic side of which is strongly shielded by the comparatively large isopropyl group. *(11)* is the formula proposed for the more favorable of the two transition states which leads to the (3*R*)-configuration of *(8)*. We postulate the "folded" conformation for the transition state, in which R is situated above the heterocyclic anion and thus closely approaches the center of induction. This conformation is stabilized either by a HOMO(anion)-LUMO(R) interaction or by van der Waals attraction.



*(11)*

We were also able to prepare other mixed bislactim ethers, *e.g.* those of *cyclo*-(L-Ala-Gly), *cyclo*-(L-Val-L-Ala), *cyclo*-(L-Val-L-Phe), *cyclo*-(L-Leu-Gly), *cyclo*-(L-*O,O*-dimethyl-α-methyldopa-Gly or -Ala) and *cyclo*-(α-methylphe-Gly) according to the method outlined in Scheme 1.

[**] Asymmetric Syntheses *via* Heterocyclic Intermediates, Part 6.—Part 5: [2c].

*0570-0833/81/0909-0798 $ 02.50/0*

*Procedure*

*(2):* A powerful stream of phosgene was passed into the suspension of *(1)* (46.8 g, 0.4 mol) in tetrahydrofuran (THF) (600 mL) at 40 °C until *(1)* was in solution (*ca.* 30 min). After 1 hours purging with anhydrous $N_2$ the solvent was removed *in vacuo*, the residue taken up in a little THF, and the solvent once again removed by distillation *in vacuo* (removal of hydrogen chloride!). *(2)* was dried for 30 min at 40 °C *in vacuo*; the yield was quantitative.

*(5):* The solution of *(2)* (*ca.* 0.4 mol) in THF (400 ml) was added dropwise to a vigorously stirred mixture of *(3* · HCl) (55.8 g, 0.4 mol), triethylamine (90.9 g, 0.9 mol) and $CHCl_3$ (500 mL) (2L three-necked flask) at −70 to −60 °C. After 3 hours stirring at −70 °C and 30 min at room temperature the triethylamine hydrochloride was separated off by suction, the solvent removed from the solution by distillation *in vacuo* (40 °C bath temperature), and the residue was taken up in 1700 mL toluene. The resulting solution and then suspension was heated for 12 h under reflux with (efficient mechanical) stirring and then cooled to 0 °C; *(5)* was recovered by suction, washed several times with ether, and then dried at 100 °C *in vacuo*. Yield 57 g (91%). For purification, *(5)* can be recrystallized from water. M.p. 254 °C, $[\alpha]_D^{20}=20.2$ ($c=0.9$, $H_2O$).

*(6):* The mixture of *(5)* (9.4 g, 60 mmol; dried for 3 d at 100 °C in a vacuum), $[Me_3O]BF_4$ (22.2 g, 150 mmol) and $CH_2Cl_2$ (200 mL) was stirred for a total of 3d at room temperature (after about 24 h a further 8.9 g (60 mmol) of $[Me_3O]BF_4$ was added[4]. After addition of a solution of $NaH_2PO_4 \cdot 2H_2O$ (28,1 g, 0.18 mol) and $Na_2HPO_4 \cdot 2H_2O$ (106.8 g, 0.6 mol) in water (500 mL), the organic phase was separated-off and the aqueous phase was extracted three times with $CH_2Cl_2$. The combined organic phases were dried over $MgSO_4$, the solvent drawn off *in vacuo*, and the residue distilled; yield 91 g (82%), b.p. 88 °C/8—12 torr, $[\alpha]_D^{20}=106.3$ ($c=1.0$, EtOH).

*(8c): n*-Butyllithium (2 mL of a 1.55 N solution in hexane, *i.e.* 3 mmol) was added (injection syringe) to a stirred solution of *(6)* (0.53 g, 2.9 mmol) in THF (7 mL) at −70 °C. The mixture was stirred for 10 min at this temperature and then treated dropwise with the solution of cinnamyl bromide (0.57 g, 2.9 mmol) in THF (6 mL). After 5 h the temperature of the mixture was allowed to rise to room temperature, the solvent removed in a vacuum, and the residue taken up in ether and extracted with water. The ethereal phase was dried over $MgSO_4$, the ether removed in a vacuum, and the residue distilled (Kugelrohr); yield 0.78 g (90%), b.p. 170—180 °C/0.5 torr.

*(9c):* A suspension of *(8c)* (0.18 g, 0.6 mmol) in 0.25 N HCl (4.8 mL, 1.2 mmol) was stirred for 10 h at room temperature. The mixture was extracted once with ether, which was rejected; the solvent was then removed *in vacuo* and the residue dissolved in a little water, covered with ether, and vigorously shaken with conc. ammonia solution until pH = 8—10. The ether phase was then separated off, the aqueous phase extracted twice with ether, and the combined ether phases dried over $MgSO_4$. The ether was removed in a vacuum and the residue distilled (Kugelrohr); yield 0.11 g (89%), b.p. 90—100 °C/0.1 torr, $[\alpha]_D^{20}=-18.7$ ($c=0.9$, EtOH), e.e. >95%[5]. Only one $OCH_3$ signal was recognizable in the $^1$H-NMR spectrum after addition of $Eu(hfc)_3$.

Schwyzer,* Helv. Chim. Acta *59*, 2181 (1976); *(10f): S. M. Birnbaum, S. J. Fu, J. P. Greenstein,* J. Biol. Chem. *203*, 333 (1953); *(10g): L. Ghosez,* private communcation.

[4] $[Et_3O]BF_4$ is less expensive than $[Me_3O]BF_4$, and, moreover, it reacts more rapidly because it is soluble in $CH_2Cl_2$. On using the method we recommend the bisethoxylactim ether *(6)*, OEt instead of OMe. We used the bismethoxylactim ether *(6)* because the $^1$H-NMR spectra of the products are simpler. The quality of commercial reagents should be checked before use.

[5] We assume >95% d.e. or e.e. if only one diastereomer is recognizable in the $^1$H-NMR spectrum.

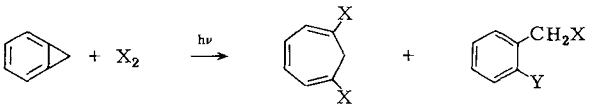
## Synthesis of 1,6-Disubstituted Cycloheptatriene Derivatives from Benzocyclopropene

By *Renji Okazaki, Masaharu O-oka, Norihiro Tokitoh, Yoko Shishido,* and *Naoki Inamoto*[*]

1,6-Disubstituted cycloheptatriene derivatives[1] are important both for the study of the cycloheptatriene-norcaradiene equilibrium[2a] and for the preparation of bridged aromatic heterocycles[2b]. Benzocyclopropene *(1)*[3], which until now has rarely been used as a synthetic building block, proved to be a suitable educt for the preparation of 1,6-dithiocyanato- and 1,6-diiodocycloheptatriene *(2a)* and *(2b)*, respectively, both of which are versatile, useful synthons.



*(1)*
$X_2 = (SCN)_2,\ I_2$

*(2a)*, X = SCN
*(2b)*, X = I

*(3a)*, X = Y = SCN
*(3b)*, X = NCS,
Y = SCN
*(3c)*, X = Y = I

Irradiation of a solution of *(1)* and thiocyanogen in benzene leads to formation of 61% *(2a)*, in addition to 27% *o*-thiocyanatobenzyl thiocyanate *(3a)* and 2% of the isomeric isothiocyanate *(3b)* (Table 1); when the reaction is performed in the dark, but otherwise under the same conditions, only 14% *(3a)* and 9% *(3b)* are formed. The photochemical reaction is inhibited by oxygen and 2,6-di-*tert*-butyl-4-methylphenol, both of which indicate a radical chain mechanism—similar to the reaction of olefins with $(SCN)_2$[4]. The addition of iodine to benzocyclopropene *(1)* also proceeds photochemically; hereby the two diiodides

*(15c)*: $^1$H-NMR: $\delta=3.10$ (s, 2H), 5.18 (d, $J=10$ Hz, 1H), 5.52 (d, $J=17$ Hz, 1H), 6.0—6.9 (m, 5H) [b].
*(16a)*: $^1$H-NMR: $\delta=0.10$ (s, 18H), 1.48—2.44 (m, 4H), 2.24 (s, 2H), 3.24 (s, 6H), 4.32 (t, $J=5$ Hz, 1H), 5.48—6.38 (m, 4H) [b].
*(16b)*: $^1$H-NMR: $\delta=0.10$ (s, 18H), 0.6—1.6 (m, 9H), 2.20 (s, 2H), 5.3—6.2 (m, 4H) [b].

[a] $^1$H-NMR spectra were recorded in $CDCl_3$/TMS. [b] In $CCl_4$/TMS.

A series of reactions showed that the diiodide *(2b)* is also of synthetic interest as an intermediate (Scheme 1). Under nickel(II) catalysis[6a], *(2b)* reacts with one equivalent of *n*-butylmagnesium bromide to give exclusively 1,6-di-*n*-butylcycloheptatriene *(12)*, while under palladium(0) catalysis[6b] with 1.5 equivalents of vinylmagnesium bromide, the mono- and the divinylcycloheptatrienes *(13)* and *(14)*, respectively are formed[7]. Under conditions of copper catalysis[8], *(2b)* reacts with Grignard reagents to give the monosubstituted compounds *(15a)*—*(15c)* in good yield, from which *(15a, b)* were transformed into the amines *(16a, b)*[9] by treatment with copper bis(trimethylsilyl)amide. In addition, the dinitrile *(11)* and the sulfide *(10)*[10] were prepared by nucleophilic substitution in dimethylformamide (DMF).

The method described here is thus a general route for the synthesis of 1,6-disubstituted cycloheptatriene derivatives having halogen, sulfur, nitrogen, and carbon substituents.

## *Procedure*

*(2a)*: A solution of *(1)* (511 mg, 5.7 mmol) and 10 mmol $(SCN)_2$ (from $Pb(SCN)_2$ and $Br_2$) in 100 mL benzene was irradiated for 30 min using an Hg high-pressure lamp. The reaction mixture was chromatographed over silica gel (hexane/ether 2:1) whereupon 715 mg *(2a)* (61%, m.p. 76—77 °C), 316 mg *(3a)* (27%, oil) and 19 mg *(3b)* (2%, oil) were isolated. The reaction proceeded similarly on the 30 mmol scale.

*(5)*—*(9)*: Sodium (98 mg, 4.3 mmol) was added to a solution of *(2a)* (206 mg, 1.02 mmol) in 25 mL liquid ammonia at −78 °C, until a blue color persisted. After evaporation of the $NH_3$, the residue was treated with dilute hydrochloric acid and ether, and after removal of the solvent the ethereal solution yielded 149 mg *(5)* (95%). To synthesize *(6)*—*(9)*, the residue obtained after evaporation of the $NH_3$ was dissolved in 10 mL tetrahydrofuran and 0.5 mL hexamethylphosphoric triamide, and treated with the corresponding alkyl halide.

*(2b)*: A solution of $I_2$ (318 mg, 1.25 mmol) in 100 mL heptane was added over 1 h to an ice cold solution of *(1)* (103 mg, 1.55 mmol) in 80 mL heptane, which was simultaneously irradiated (Hg high-pressure lamp, filter: 0.1% aqueous $K_2CrO_4$ solution 10 °C). After addition of $I_2$ was complete, the solution was irradiated for a further 3 h. 265 mg *(2b)*[5a] (67%) and 16 mg *(3c)*[11] (4%) were isolated from the reaction mixture by chromatography (silica gel, pentane). The reaction can also be carried out on the 40 mmol scale, however, the yield of *(2b)* was reduced to 50—60%.

## Complexes of Iridium with Terminal $PF_2$-Ligands[**]

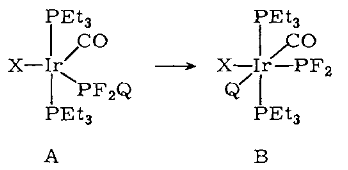
By *E. A. V. Ebsworth, Neil T. McManus,*
*David W. H. Rankin,* and *John D. Whitelock*[*]

Attempts to prepare complexes containing a metal bound to tricoordinated phosphorus have usually produced bridged species. Some derivatives of chromium and tungsten are known in which terminal $PCl_2$-groups are bound to the metal[1], but attempts to prepare $PF_2$-complexes of platinum have led to the production of dinuclear diplatinum complexes[2]. Here we report the synthesis and characterization of some complexes of iridium(III) containing terminal $PF_2$-ligands; these compounds should be suitable for use in the controlled synthesis of mixed-metal bridged complexes.

Reaction of a solution of $PF_2H$ and *trans*-$Ir(CO)I(PEt_3)_2$ at 233 K in toluene leads to the formation of a $PF_2H$-complex of pentacoordinated iridium (type A in Scheme 1). Two signals are observed in the $^{31}P\{H\}$-NMR spectrum (Table 1); a doublet at $\delta = -7$ ($^2J(PP) = 38$ Hz) arising from $PEt_3$, and a wide triplet from the $PF_2$-group at $\delta = 142$ ($^1J(PF) = 1103$ Hz) each line of which is further split into a narrow triplet because of coupling with the P atoms of the two $Et_3P$-groups. In the non-decoupled spectrum, each line of the $PF_2$-signal shows an additional doublet splitting of 415 Hz, a typical value for $^1J(PH)$ in tetracoordinated phosphorus compounds. The $^1H$-NMR spectrum shows a resonance at $\delta = 8.4$ with a doublet splitting of 415 Hz; each line is further split into a triplet [due to $^2J(FH)$] of triplets [due to $^3J(PH)$].

When the solution was allowed to warm to room temperature, the spectra changed. The P resonance of the $PF_2$-group shifts from $\delta = 142$ to $\delta = 378$; this implies a significant alteration in the environment of the $PF_2$-group. Moreover, the magnitude of $^2J(PP)$ becomes smaller and $J(HPF_2)$ drops from 415 Hz to 7.5 Hz. In the $^1H$-NMR spectrum, the resonance at $\delta = 8.4$ disappears and is replaced by a complex multiplet at $\delta = -16$ that must be due to H bound to Ir. It follows that the pentacoordinated iridium complex *(1)* (type A) formed initially has rearranged to give a new complex *(5)* of hexacoordinated iridium(III) (type B in Scheme 1) by oxidative addition of PH, leaving H and a terminal $PF_2$-group bound to the metal.

*trans*-$Ir(CO)(PEt_3)_2X + PF_2Q \longrightarrow$



| X | Q | Type A | Type B |
|---|---|---|---|
| I | H | *(1)* | *(5)* |
| Cl | Cl | *(2)* | *(6)* |
| Br | Br | *(3)* | *(7)* |
| I | I | *(4)* | *(8)* |

Scheme 1.

Similar reactions occur between $PF_2X$ and *trans*-$Ir(CO)X(PEt_3)_2$, X = Cl, Br or I. When X = Cl, the $^{19}F$- and $^{31}P$-NMR spectra show peaks with the multiplet structures expected for a complex of type A; the $PF_2$-chemical shift ($\delta = 97$) is in the same region as that of $PF_2Cl$-complexes. When the solution is allowed to warm to room temperature, the $PF_2$-resonance shifts to $\delta = 364.8$ *i.e.* the signal for *(6)* is similar to that for *(5)*. When X = Br, the concentration of the complex *(3)* (type A) at 193 K is small, and the assignment of the $PF_2$-resonance is doubtful; when X = I, we were unable to identify any of the signals expected for complex *(4)*. In each case, however, there are resonances due to complexes *(7)* or *(8)* (type B); in keeping with the assigned structure, all the $PF_2$-chemical shifts are very similar (Table 1).

Table 1. NMR data for the complexes of types A and B recorded in $[D_8]$toluene at 233 K [*(1)*–*(5)*] and at 298 K [*(6)*–*(8)*]; precision. ±1 to the last figure quoted ($J$ in Hz).

| Complex | Type | $\delta(PEt_3)$ | $\delta(PF_2)$ | $\delta(F)$ | $^1J(PF)$ | $^2J(PP)$ | $^3J(PF)$ |
|---|---|---|---|---|---|---|---|
| *(1)* [a] | A | −7.2 | 142 | −60.8 | 1103 | 38 | [c] |
| *(2)* | A | −6.9 | 97 | 4.9 | 1333 | 42 | 9 |
| *(3)* | A | 0.3 | 110 | 6.2 | 1341 | 45 | [c] |
| *(4)* | A | resonances not observed | | | | | |
| *(5)* [b] | B | −10.8 | 376.7 | −61.5 | 1111 | 25.9 | 17.1 |
| *(6)* | B | −9.3 | 364.8 | −68.3 | 1106 | 9.2 | 11.6 |
| *(7)* | B | −18.1 | 363.1 | −64.8 | 1108 | 8.5 | 11.1 |
| *(8)* | B | −31.9 | 364.8 | −61.0 | 1112 | 8.3 | 10.6 |

[a] $\delta(H) = 8.72$. [b] $\delta(H) = -16.0$; $^2J[HP(Et)] = 10$, $^2J[HP(F)] = 7.5$, $^3J(HF) = 11.5$ Hz. [c] Not resolved.

Complex *(5)* decomposes slowly in solution at room temperature, but complexes *(6)*—*(8)* are stable at room temperature and have been isolated and characterized by elemental analysis, IR-, and NMR-spectroscopy. Addition of $B_2H_6$ to a solution of *(8)* in $C_7H_8$ leads to a shift in the $PF_2$-resonance in the $^{31}P\{^1H\}$-NMR spectrum to $\delta = 250$,

together with a marked broadening of the lines. We interpret these observations as evidence that a bridged complex containing the grouping Ir—$PF_2$—$BH_3$ has been formed; in confirmation of this view, the $^{19}$F-NMR spectrum consists of a broad doublet, due to $^1J$(PF), each line of which is split into a 1 : 3 : 3 : 1 quartet by F—H coupling.

## Cobalt Mediated [2 + 2 + 2]-Cycloadditions: Stereospecific Intramolecular Reactions of Enediynes to Tricyclic Dienes Bearing Angular Methyl Groups[**]

By *Thomas R. Gadek* and *K. Peter C. Vollhardt*[*]

We recently reported on the inter- and intramolecular [2 + 2 + 2]cycloaddition of linear achiral enediynes containing terminal double bonds, using $CpCo(CO)_2$, to give polycyclic diene complexes (cp = cyclopentadienyl)[1]. We now describe similar stereospecific reactions of enediynes which may even be used to incorporate trisubstituted double bonds, producing tricyclic dienes with angular methyl groups. The molecules synthesized constitute good model systems for a variety of polycyclic natural products, particularly vitamin D precursors.

The educts *(1)* were prepared by Wittig reaction of the terminal acetylenic aldehydes or ketones with the appropriate acetylenic ylides[2]. The aldehydes or ketones generally originated from internal propargyl alcohols *via* the "acetylene-zipper" reaction[3], followed by standard structural manipulations. *Cis-* and *trans-(1)* were interconvertible by irradiation in the presence of sensitizer[4] and, if necessary, separated by preparative gas chromatography.

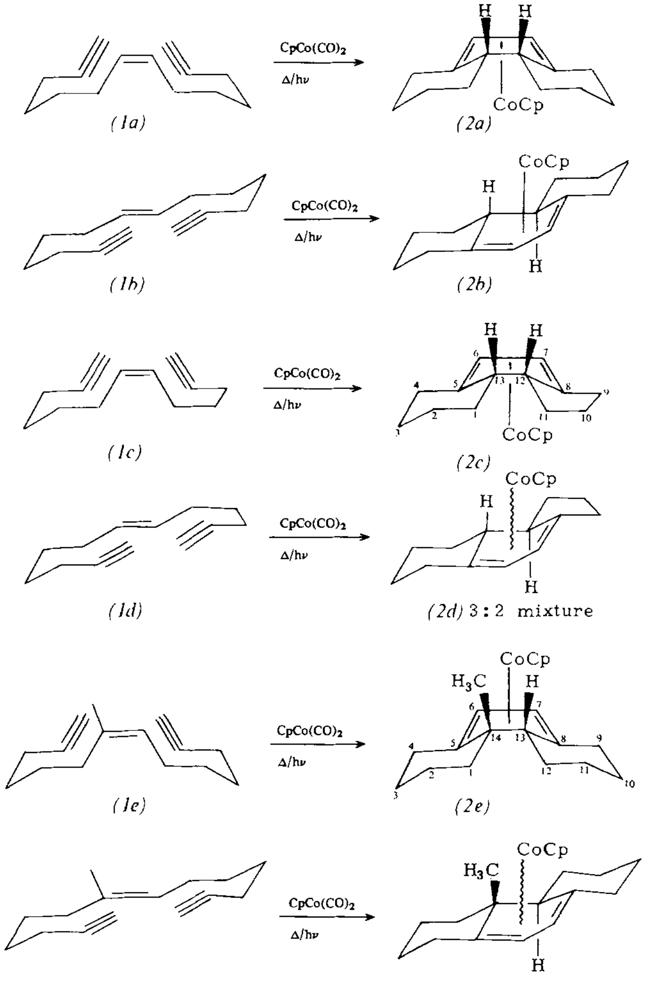
In a typical experiment, a solution of *(1)* and $CpCo(CO)_2$ in boiling *m*-xylene was irradiated to give the red-brown complexes *(2)* (Table 1) in fairly good yield, after chromatography on alumina. Stereochemical and spectral assignments were carried out by comparison with model compounds, utilizing the effect of the anisotropy of cobalt on the NMR spectra[1], symmetry considerations [cf. *(2a)* with *(2b)*], and off-center resonance proton decoupled $^{13}$C-NMR spectroscopy.

Three points of particular interest are:

1. The [2 + 2 + 2]-cycloaddition proceeds with retention of stereochemistry at the original double bond and also with remarkable stereoselectivity with respect to cobalt [cf. *(2a), (2b), (2c), (2e)*]; this might be valuable in asymmetric syntheses with an optically active metal compound.

2. The cyclopentadienylcobalt not only fulfills the function of the mediator of the cyclization but also serves to protect the diene unit from rearrangement and polymerization.

3. The ligands in *(2)*, all of which were either previously unknown - *(2a—d)* - or incompletely characterized - *(2e, f)*[5] - may be liberated as colorless oils in high yield by oxidative demetalation[6] (Table 1). Decomplexation of the mixtures *(2d)* and *(2f)* gave only one product, corroborating the structural assignment of the minor component.



*(2d)* 3 : 2 mixture

*(2f)* 3 : 1 - *endo-/exo*-$CH_3$

The origin of the stereoselectivity observed in the above reactions is not clear at present. It should be noted that trimethylsilylation of the alkyne moieties is detrimental to the successful outcome of the reaction.

Hydrogenated benz[*e*]indanes and phenanthrenes of the type synthesized here are frequent structural features in natural products. The ligands in *(2e)* and *(2f)* are of particular interest since they may be regarded as constituting the ABC-portion of steroids, which function as precursors to vitamin D and valuable steroid hormones. The cobalt mediated [2 + 2 + 2]-cycloaddition approach should provide a simple and effective route to these classes of compounds.

### *Procedure*

A degassed solution of *(1)* (1 mmol) and $CpCo(CO)_2$ (1.1 mmol) in *m*-xylene (50 mL) was refluxed and irradiated (visible light, GE-ENH, 250 W). After 1 h, the solvent was removed *in vacuo* (0.05 torr) and the residue chromato-

# $[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2Hg]_4$, a Compound with an $Mn_4Hg_4$ Eight-Membered Ring and Additional Hg—Hg Bonds

By *Wolfgang Gäde* and *Erwin Weiss*[*]

Numerous examples of mercury-transition metal compounds having linear M—Hg—M bridges are known. We wish to report here on the reaction of $K[\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2GeH_3]$[1] with $Hg^{2+}$ ions in aqueous media, which yields the unexpected Ge-free compound $[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2Hg]_4$ *(1)* (55%); in addition, the Hg-free compound $[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2]_3Ge$ *(2)* (1%) is formed, which contains a GeMn double bond as well as two GeMn single bonds[2]. The course of the reaction is still unknown; the observed elimination of mercury indicates an oxidative action of the $Hg^{2+}$ ions.

An X-ray structure analysis[3] shows a novel ring system with an $Mn_4Hg_4$ eight-membered ring in the Hg-containing compound *(1)*. The molecule possesses a four-fold alternating axis. The four Hg atoms have an almost coplanar

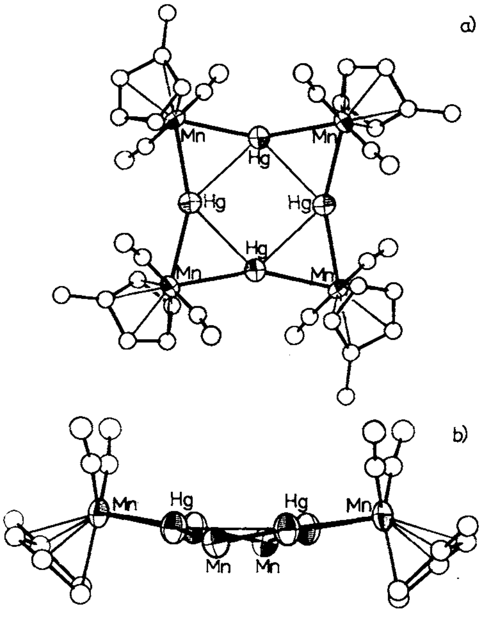

Fig. 1. a) Structure of *(1)* in the crystal, ORTEP-drawing. Mn—Hg 264.0(7), Hg—Hg 288.8(2), Mn—C(CO) 176(7) and 179(8), Mn—C(Cp) 209(9) to 218(5), average 212.4 pm; Mn—Hg—Mn 157.2, Hg—Mn—Hg 66.2(2), Hg—Mn—C(CO) 74(2) and 118(2), C(CO)—Mn—C(CO) 87(3)°. Crystal data: tetragonal space group $I\bar{4}$, $a$=1595.9(2), $c$=768.3(1) pm, $V$=1956.8×10$^{6}$ pm$^{3}$, $Z$=2, $\rho$(calc.) 2.64 g cm$^{-3}$. Mo$_{K\alpha}$-radiation, 986 independent reflections (up to $\Theta$=30°), $R$=0.099 (Mn and Hg anisotropic, C and O isotropic). b) Projection of *(1)* at right angles to the plane of the molecule, two of the Mn atoms shown without ligands.

[*] Prof. Dr. E. Weiss, Dr. W. Gäde
Institut für Anorganische und Angewandte Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

arrangement (deviation from planarity 0.4 pm), while in contrast the Mn atoms exhibit larger deviations (35.9 pm) (Fig. 1).

A similar eight-membered ring system is found in $[CdFe(CO)_4]_4 \cdot 2$acetone[4]; however, in this case a strongly distorted eight-membered ring is present, since two of the four Cd atoms are coordinated by acetone molecules. In contrast to this, metal-metal interaction in the $Hg_4$-ring of *(1)* must be assumed from the short Hg—Hg bond lengths (288.8 pm). For comparison: Hg—Hg bond lengths in $Hg_2X_2$ ($X = F$, Cl, Br, I, $NO_3$) 243—269 pm, in Hg metal 299 (α-form at 78 K), 282.5 and 316 pm (β-form at 77 K)[5]. The nonlinearity of the Mn—Hg—Mn groups, with a markedly small angle at the Hg atom, (157.2°) also indicates metal-metal interaction. The Mn—Hg bond length (264.0 pm) is only slightly longer than in $Hg[Mn(CO)_5]_2$ (261.0 pm)[6] and corresponds to a single bond.

A planar $Hg_4$-ring has also been observed in the alloy $Na_3Hg_2$[7]. Here, the $Hg_4$-unit possesses $D_{2h}$ symmetry; the Hg—Hg bond lengths are 296 and 301 pm. According to a bonding theory treatment due to *Corbett*[8], the actual negative charge is smaller than in the formal $Hg_4^{6-}$ representation.

### *Procedure*

All operations were performed in the absence of air. A solution of $HgCl_2$ (5.4 g, 20 mmol) in 100 mL water is dropped, with constant stirring, into a solution of $K[(\eta\text{-}CH_3C_5H_4)Mn(CO)_2GeH_3]$ (2.4 g, 7.9 mmol) in 50 mL water. After 30 min the gray suspension is extracted several times with ether, the red ether phase dried over $Na_2SO_4$, and concentrated under reduced pressure. The red oily residue is taken up in a little $CH_2Cl_2$. Dark red needles of *(1)* crystallize at *ca.* −25 °C (1.7 g, 1.1 mmol, 55% analytically pure). M.p. > 160 °C (decomp.) IR spectrum: $\nu(CO) = 1905$, 1863 $cm^{-1}$ (in $CH_2Cl_2$). Dark red *(2)* can also be obtained from the mother liquor following subsequent concentration and cooling (50 mg, 0.08 mmol, 1%).

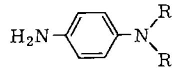
## Colored, Unsymmetric and Light-Sensitive Vesicle Membranes[**]

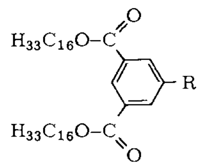
By *Jürgen-Hinrich Fuhrhop, Herbert Bartsch,* and *Detlev Fritsch*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

Vesicles facilitate the localization of three reaction components in aqueous solution: in the hydrophobic membrane interior and in the two water volumes inside and outside the cells[1]. If amphiphiles with reactive head groups are used, then these three reaction spaces can be supplemented by two further reaction centers on the membrane surfaces. First examples of this were monolayer, redox-active bipyridinium membranes[2]. We report here for the first time on bilayer vesicle membranes with phenylenediamine and benzenediazonium head groups, whose exterior surface can be multivariously modified by coupling reactions (color development in color photography; diazotype).



*(1a)*, R = $n\text{-}C_{14}H_{29}$
*(1b)*, R = $n\text{-}C_{16}H_{33}$



*(2a)*, R = $NH_2$
*(2b)*, R = $N^{\oplus}(CH_3)_3\ I^{\ominus}$
*(2c)*, R = $N_2^{\oplus}\ BF_4^{\ominus}$

The phenylenediamine derivatives *(1a)* and *(1b)* were obtained by dialkylation of *p*-aminoacetanilide with *n*-bromotetradecane and *n*-bromohexadecane, respectively, in dimethylformamide and subsequent acid hydrolysis (yield 70%). *(2a)* was accessible from dimethyl 5-aminoisophthalate by transesterification with *n*-hexadecanol in the presence of titanium(IV) butoxide (yield 35%). The free amino group was either permethylated with methyl iodide in dimethyl sulfoxide in the presence of tridodecylamine to *(2b)* (yield 40%) or diazotized in a $CH_2Cl_2/H_2O$ two-phase system with $HBF_4/NaNO_2$ to *(2c)* (yield 50%).

The products *(1a,b)* and *(2a—c)* were sparingly soluble in water, but aqueous suspensions became clear on ultrasonication (Ultrasonics sonicator W 220F, steps 3—4). The solutions of *(1a,b)* rapidly turned red (radical formation) during sonication in air, so they were therefore prepared under inert gas at pH = 3—5. The aqueous solutions of the diazonium compound *(2c)* were unstable above pH = 2; evolution of $N_2$ was accompanied by precipitation of a solid. Surprisingly, at pH = 1—2 no hydrolysis of the ester groups occurred; on the contrary, the vesicles from *(2c)* were now stable for days. The vesicles formed from *(2b)* could also be stored for several days, both in acid as well as in neutral media. Electron micrographs of the suspensions of *(1a,b)* and *(2a—c)* after sonification showed spherical structures of 200—1000 Å diameter. The vesicle interior was also stained on addition of uranyl acetate during the sonification of solutions of vesicles from *(1b)*. The layer thickness of the uncolored membrane was estimated as 50—100 Å. Interestingly, in addition to photographs showing the usual statistical size distribution of the vesicles (Fig. 1, top) (Ø = 250—1000 Å) others were also obtained which showed only microvesicles (Ø = 250—300 Å) (Fig. 1, center). In solutions of *(1a)* we also observed "large" vesicles with cracked surfaces, from which microvesicles were released (Fig. 1, bottom). These photographs are reminiscent of those taken under the optical microscope by *Fox* showing "buds" of microspheres[3], which serve as a model of biological cell division.

If the aqueous solution of *(1)* is treated with iodine and phenol the blue indoaniline dye is formed on the outer surface of the membrane within seconds, while the phenylene diamine residues situated on the interior surface hardly

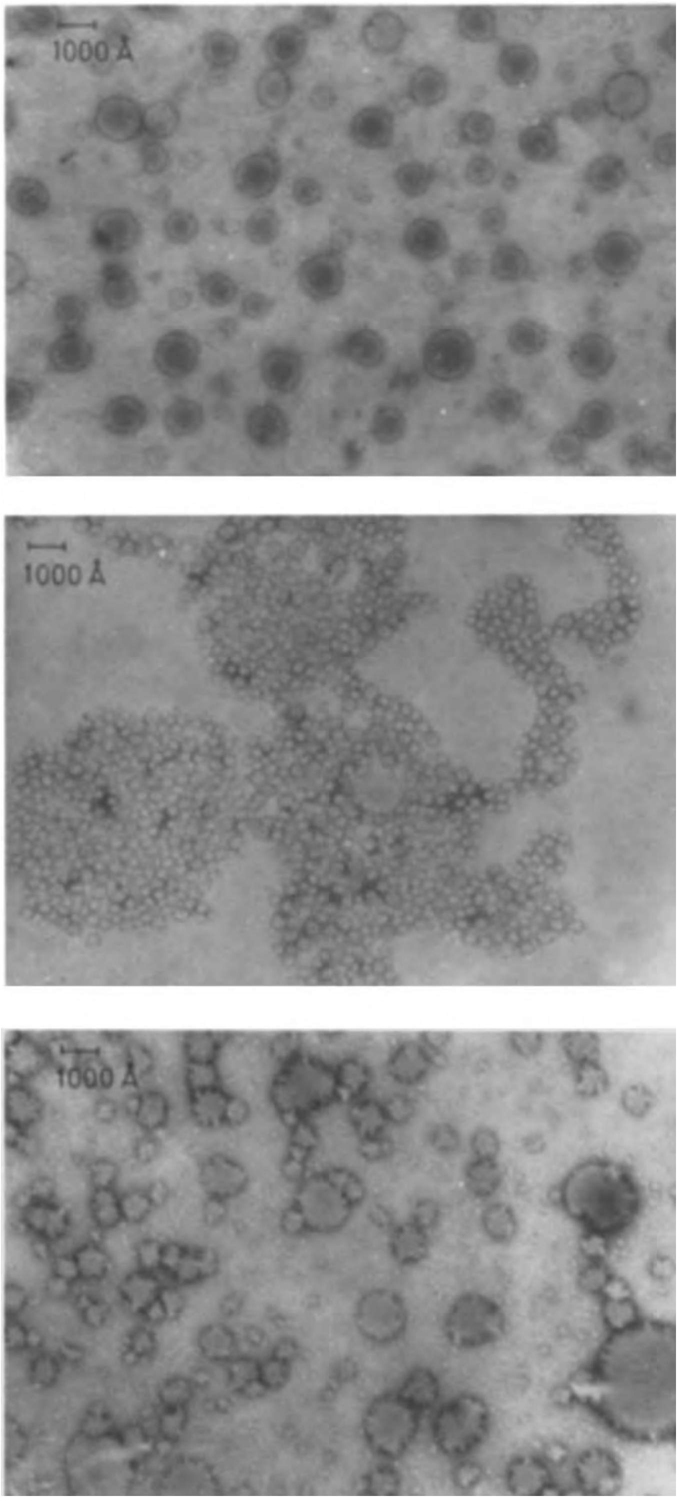

Fig. 1. Various forms of vesicles (see text) from *(1b)* (above and center) and *(1a)* (below). Magnification 40000 × ; stained with uranyl acetate.

react, even within 2 h[4]. In this way, stable soluble vesicles are accessible having an oxidized, colored external surface and an interior surface still in the reduced state. To our knowledge these are the first non-biological cells having an unsymmetrical bilayer membrane (BLM). Benzenediazonium vesicles from *(2c)* could be reacted in the same way with 7-amino-1-naphthol-3-sulfonic acid on the outer surface; the colored vesicles precipitated, though at only 5% conversion they remained in solution.

Finally, the benzenediazonium vesicles could also be decomposed and precipitated with visible light. When traces (*ca.* $10^{-7}$ M) of 5,10,15,20-porphinetetrakis(9-decenesulfonic acid)[5] were added as sensitizer to the vesicular solution of *(2c)* (*ca.* $10^{-4}$ M) the vesicles quantitatively precipitated within 10 min on irradiation with a 60W tungsten lamp; the diazonium salts are converted into chlorobenzene derivatives. The same solution decomposes only slowly (15%/d) in the dark.

[4] The selective reactivity of the outer membrane surfaces was demonstrated by measurements of the difference spectra of the completely reacted compounds in organic solvents [ethanol/water = 20 : 1 for *(1a, b)*, chloroform/methanol = 4 : 9 for *(2c)*] and in vesicular aqueous solution. Several independent measurements gave good reproducibility of these spectra.

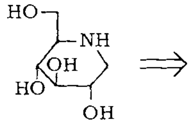
## A Four-Step Synthesis of 1-Deoxynojirimycin with a Biotransformation as Cardinal Reaction Step

By *Günther Kinast* and *Michael Schedel*[*]

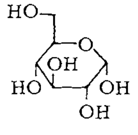
*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Inhibitors of intestinal α-glucosidases have proven to be pharmacologically and clinically effective in the treatment of carbohydrate-dependent metabolic disorders like diabetes mellitus[1]. We were, therefore, interested in the natural product 1-deoxynojirimycin *(1)*.

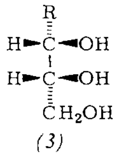
The previously reported methods for the synthesis of 1-deoxynojirimycin[2] involve many steps and necessitate resort to tedious protecting-group techniques; we report here on a short, combined chemical-microbiological synthesis[3] involving reductive conversion of glucose *(2)* into 1-amino-1-deoxy-D-sorbitol *(4a)*[4], which is subsequently transformed by bacteria of the genus *Gluconobacter*, which selectively oxidize the central of the three OH-groups in D-erythro-configurated compounds such as *(3)*[5] into 6-amino-6-deoxy-L-sorbose *(5a)*. Subsequent intramolecular reductive amination of *(5a)* according to the method of *Paulsen* then furnishes *(1)*.



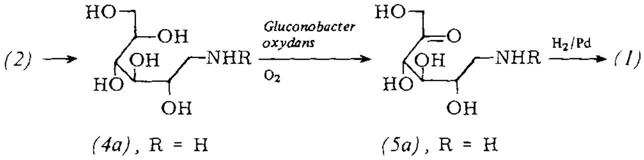
*(1)*



*(2)*



*(3)*



*(4a)*, R = H
*(4b)*, R = $CO_2CH_2Ph$

*(5a)*, R = H
*(5b)*, R = $CO_2CH_2Ph$

---

[*] Dr. G. Kinast, Dr. M. Schedel
Chemisch-wissenschaftliches Labor Pharma und Institut für Biochemie der Bayer AG
Postfach 101709, D-5600 Wuppertal 1 (Germany)

The direct biotransformation of *(4a)* into *(5a)*, however, proceeded in only low yields owing to the instability of the aminoketone *(5a)*, the amino group being free. Protection of the amino function by a benzyloxycarbonyl group proved especially favorable, since both *(4b)* as well as *(5b)* crystallize particularly well and deblocking of *(5b)* can be achieved in one step with ring-closure to give the 1-deoxynojirimycin *(1)*.

Reaction of *(4a)* with benzyloxycarbonyl chloride in water at pH = 8—10 afforded *(4b)*, which could be quantitatively oxidized with *Gluconobacter oxydans* to *(5b)*. The yield was more than 90%, for a conversion of 60—80 g per liter of culture medium. The hydrogenation of *(5b)* in methanol/water led stereoselectively[6], with removal of the protecting group and ring-closure, to 1-deoxynojirimycin *(1)*.

Using the same synthetic sequence, we were also able to prepare some *N*-alkyl-1-deoxynojirimycin derivatives[3] and—starting from D-mannose—the *manno*-isomer of *(1)*, 1,5-dideoxy-1,5-imino-D-mannitol[7] (yield 14%).

### *Procedure*

*(5b)*: 7 L of nutrient medium ($H_2O$, 5% sorbitol, 2% Ohly yeast extract, 0.4% $K_2HPO_4$, pH = 6.5 with KOH) is autoclaved in a 10 L fermenter for 45 min at 121 °C, inocculated with *Gluconobacter oxydans*[8] (250 mL pre-culture, same medium), and incubated for 24 h at 30 °C, 10 L air/min, 500 rpm. The culture is treated 5 times at intervals of 24 h with a hot (80—90 °C) solution of 100 g *(4b)* (m.p. 142—144 °C, from water) in 750 mL of water. After 2d *(5b)* begins to crystallize out, after 6d the fermentation is finished. The precipitate is filtered off by suction, dissolved in 6 L of methanol and the cell residues separated; the solvent is removed in a rotary evaporator and the residue recrystallized from 2-propanol. Yield 455 g (92%), m.p. 107—111 °C.

*(1)*: *(5b)* (50 g) is dissolved with gentle heating in methanol (500 mL) and the solution added to a suspension of palladium/carbon (10 g, 5%) in $H_2O$ (1000 mL) and immediately hydrogenated under a pressure of *ca.* 80 bar: 1 h at 40—50 °C, and finally 2 h at 60 °C. After removal of the catalyst by suction filtration the filtrate is evaporated down in a rotary evaporator and the residue recrystallized from 100 mL of ethanol/water (10 : 1). Yield 19.5 g (75%), m.p. 198—202 °C.

## Reaction of 1-α-Cyano-1-deoxynojirimycin with Grignard Compounds—Complete Exchange of the CN— Group

By *Horst Böshagen, Walter Geiger,* and *Bodo Junge*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

In the reaction of α-aminonitriles with Grignard reagents replacement of the CN group by the organic moiety of the Grignard reagent was observed in some cases alongside the normal addition to the CN bond[1]. This reaction, the mechanism of which was elucidated by *Yoshimura, Ohgo* and *Sato*[2], occurs if the amino group is dialkylated or carries a phenyl- or benzyl-moiety[1b].

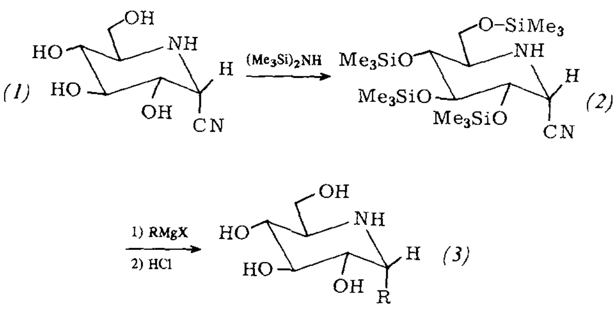

Table 1. Yields, melting points, and some spectroscopic data of the α-isomers of compounds *(3a)*—*(3h)* [a].

| Cpd. | R | Yield [%] | M.p. [°C] [b] | $^{13}$C-NMR (15.04 MHz, δ-values) |

1-Deoxynojirimycin *(3)*, R=H[3], is a highly reactive α-glucosidase inhibitor[4], so our interest was attracted to the synthesis of derivatives substituted in the 1-position.

We therefore prepared from 1-deoxynojirimycin-1-sulfonic acid[5] the 1-α-cyano-1-deoxynojirimycin *(1)*, which was then silylated and subsequently allowed to react with Grignard compounds. This resulted in exclusive replacement of the CN group. As main product we obtained the α-compounds *(3)* as colorless crystals along with small amounts (< 5%) of the non-crystalline β-isomers. Departure of the cyanide and entry of the residue R take place on the same side of the molecule, in agreement with the findings of *Lednicer* and *Babcock*[1d].

α- and β-Isomers of *(3)* differ in the position of their $^{13}$C-NMR resonance signals. Compared to the β-isomers, the α-isomers show $\delta$-values about 3—6 ppm lower for the ring atoms C-1 and C-5 and about 7—8 ppm lower for the methylene α-coupled to the aliphatic moiety R.

### *Procedure*

*(1):* 1-Deoxynojirimycin-1-sulfonic acid (12.2 g, 50 mmol) is transferred to a stirred suspension of $Ba(OH)_2\cdot 8H_2O$ (15.8 g, 50 mmol) in water (50 mL). After addition of NaCN (3.3 g, 75 mmol) the mixture is treated dropwise and slowly at room temperature with 10 mL of 7.5 N hydrochloric acid. After 3 hours stirring the mixture is filtered by suction and the filtrate is concentrated under reduced pressure. The hot syrup is agitated with 100 mL of $CH_3CN/CH_3OH$ (1 : 1). After cooling, the salt is filtered off and the filtrate evaporated to dryness. The crude product is taken up in methanol and re-precipitated by addition of 300 mL of ethanol. Yield 8.75 g (80%) colorless prisms, m.p. 158 °C; IR (KBr): $\nu = 2240\ \text{cm}^{-1}$ (CN).

*(2):* A suspension of *(1)* (3.6 g, 20 mmol) in hexamethyldisilazane (40 mL) is treated with imidazole (0.6 g) and stirred at 60 °C until essentially all is in solution (*ca.* 2.5 h). The mixture is then filtered by suction and the filtrate evaporated to dryness under reduced pressure. The crude product (long prisms) can be used further without purification. Yield 8.5 g (89%); prisms (ligroin), m.p. 105 °C; $^{13}$C-NMR (15.04 MHz, $CDCl_3$): $\delta = -0.55$, 0.32, 1.00, 1.26 ($Si(CH_3)_3$), 52.6 (C-1), 58.1 (C-5), 64.0 (C-6), 71.9, 73.8 (C-2,4), 77.2 (C-3), 117.9 (CN).

Reaction of *(2)* with Grignard compounds: A solution of *(2)* (20 mmol) in anhydrous tetrahydrofuran (100 mL) is treated dropwise with a solution of the Grignard reagent (60 mmol) in anhydrous ether (75—100 mL). The mixture is stirred for 5 h at room temperature. It is then treated with conc. hydrochloric acid (10 mL) and water (200 mL) and stirred for a further 2 h. The aqueous phase is separated off, rendered neutral (pH=7) with 1 N NaOH solution, and evaporated to dryness under reduced pressure. The residue is taken up in methanol, insoluble salts are filtered off, and the filtrate is re-evaporated to dryness. The crude product is dissolved in water (50 mL), transferred to a Dowex 50 WX4 ion-exchange column (*ca.* 300 g exchanger), washed with water (1 L), and fractionally eluted with a 0.25% ammonia solution. The first fraction containing small amounts (< 5%) of β-isomer is followed by the main fraction consisting of pure α-isomer. Yield 40—60% (Table 1). Detection by thin-layer chromatography, silica gel 60 F 254, ethyl acetate, methanol, water, ammonia (100/60/25/1). Spray reagent: 1% aqueous $KMnO_4$ solution.

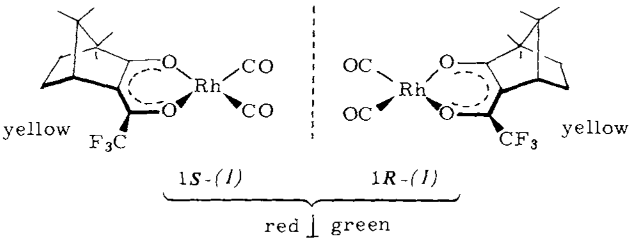
## Chirodichroism of Different Enantiomeric Compositions of a Planar d$^8$-Metal Complex

By *Volker Schurig* [*]

Enantiomeric mixtures of variable composition can exhibit different physical properties in the solid state[1]. A dependence of optical and electrical properties on the enantiomeric composition is to be expected if cooperative phenomena can only occur in a preferred crystal packing. Remarkable differences have been observed between the optical properties of pure enantiomers and racemate in the solid state for the chiral planar d$^8$-metal complex dicarbonylrhodium(I) 3-trifluoroacetylcamphorate *(1)*[2a]—a phenomenon that has been referred to as "chirodichroism"[2b].



The pure enantiomers 1*R*-*(1)* or 1*S*-*(1)* are isolated from *n*-hexane as lemon-yellow crystals (m.p. 134.0 °C (uncorr.)), while the 1 : 1 enantiomeric mixture crystallizes as the deep-red—green dichroic racemate (m.p. 130.5 °C (uncorr.)). When equimolar solutions of the yellow antipodes 1*R*-*(1)* and 1*S*-*(1)* in *n*-hexane are mixed and evaporated to dryness, the red color of the racemate appears spontaneously. This color-effect is especially evident when solutions of the antipodes are added as spots near to each other on filter paper or silica gel plate and chromatographed together: after development of the chromatogram a sharp zone of the red racemate appears at the site of contact, while the regions of the unmixed antipodes remain yellow. The formation of the red racemate can also be followed visually as a solid-state reaction[3] on mixing sublimed samples of the antipodes (10 min). The formation of a red solid phase instantaneously occurs on wetting the yellow mixture with a small amount of solvent ($CHCl_3$).

Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

The diffuse reflection spectrum[4] of the racemate (550, *ca.* 450 sh, 370, 318 nm) differs markedly from that of the pure enantiomer (385, 318 nm); characteristic is the appearance of additional bands at 550 and 450 nm for the racemate[5].

The racemic form of *(1)* proves to be a real stoichiometric binary compound whose melting point is lowered on addition of pure enantiomers (*e.g.* m.p. 127.5 °C for 1R-*(1)*, *ee* = 28%). No differences are discernible in the scalar physical properties of the pure enantiomers and racemic mixture in dilute solution (UV, VIS, NMR, IR)[6]. The melts of the pure enantiomers and of the racemate are all brown-red.

Planar $d^8$-metal complexes (*e.g.* the dicarbonylmetal acetylacetonates of Rh and Ir) form columnar structures in the crystal lattice with intermolecular metal-metal interaction. These compounds therefore show one-dimensional electric effects as well as anisotropic optical properties in the solid state[7]. The chirodichroism described here for *(1)* is attributed to the different crystal packing of the enantiomers and of the racemate. This assumption is confirmed by the X-ray structure analysis[8]: the oppositely configurated molecules of the racemic compound are ideally stacked alternately in a columnar structure, whereby the formation of linear chains of rhodium atoms (Rh—Rh 3.38 Å) parallel to the *z*-axis promotes occurrence of cooperative phenomena. In contrast, identical configuration of the molecules in the pure enantiomer prevents a packing with intermolecular d-d interaction; thus, the rhodium atoms of the molecules, sited in reversed order in the lattice, can only form a zig-zag chain (Rh—Rh 4.32 Å).

The introduction of chirality into the inner coordination sphere of a metal ion proves, therefore, to be an interesting parameter for the investigation of steric influences of ligands of like constitution, but different configuration, on cooperative properties in the solid state. From the findings on *(1)* it follows that the crystal packing has a dominating influence over that of M—M interaction on the formation of columnar structures[9]. The tailor-made reaction of quasi-racemates starting from quasi-enantiomers with ligands of similar constitution or different central atom appears attractive; thus, *e.g.*, highly ordered structures with chains of alternating metal atoms (Rh(*R*)/Ir(*S*)) could be accessible.

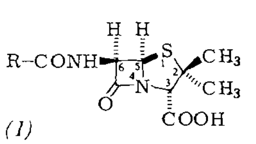
# Stereospecific, One-Step Introduction of a Methoxy Group at C6 in Penicillins and C7 in Cephalosporins

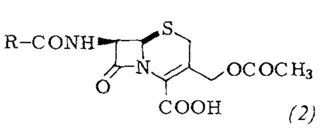
By *Peter Feyen* and *Wilfried Schröck*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

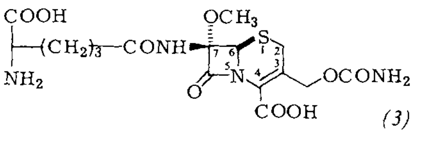
β-Lactam antibiotics such as the penicillins *(1)* and cephalosporins *(2)* are degraded by bacterial β-lactamases. Bacteria which can produce β-lactamase are therefore resistent to derivatives of *(1)* and *(2)*. In cephamycins [*e.g.* cephamycin C *(3)*]—metabolic products of streptomycetes—the cephalosporin ring systems have an α-methoxy substituent at the 7-position which produces improved lactamase stability[1]. In the numerous published syntheses of 7-methoxycephalosporins and 6-methoxypenicillins[2], the carboxy group must always be protected by esterification. The removal of the protecting group—esters have low activity as antibacterial agents—precludes most types of esters in view of the sensitivity of this class of substances[3].



*(1)*



*(2)*



*(3)*

We report here a single-step methoxylation which avoids the use of protecting groups, and which uses penicillinic or cephalosporinic acids with already finished frameworks as starting materials.

The penicillinic or cephalosporinic acids *(1)* and *(2)* are converted into their lithium salts by treatment with lithium methoxide in methanol-tetrahydrofuran (THF) at −50 to −70 °C followed by treatment for *ca.* 30 min at −50 °C with *t*-butyl hypochlorite. Based on earlier investigations on cephalosporin esters[4], the reaction probably proceeds *via* the penicillinic acid *(4)*.

After formation of the acylimine *(6)* from the *N*-chloroamide *(5)*, methanol adds to the sterically less hindered α-side of the molecule with high selectivity (only one methoxy signal in the NMR spectrum). Some methyl penicilloate *(8)* is formed as a by-product *via* direct attack of the methoxide on the β-lactam ring—together with 10—15% other conversion and degradation-products (recognizable by a broad NMR absorption in the region of the signals of the geminal dimethyl groups).

A series of penicillin derivatives, which should have powerful antibacterial activity, were investigated (Table 1). The crude products were purified by crystallization or preparative column chromatography on silica gel.

The 7-methoxycephalosporins were synthesized in an analogous manner. In this way *(9)*[5] was obtained in 60% yield from *(2)*: the crude product contained 75% *(9)* and in addition, 12% of the educt.

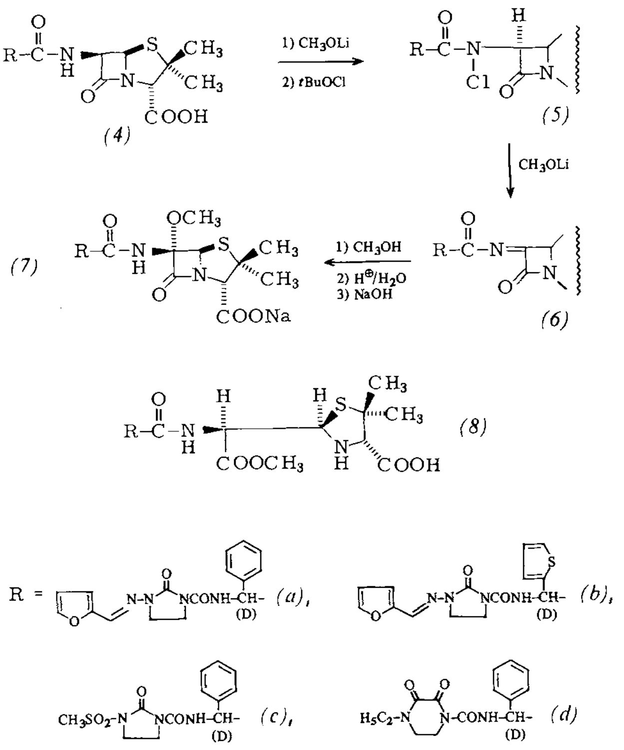


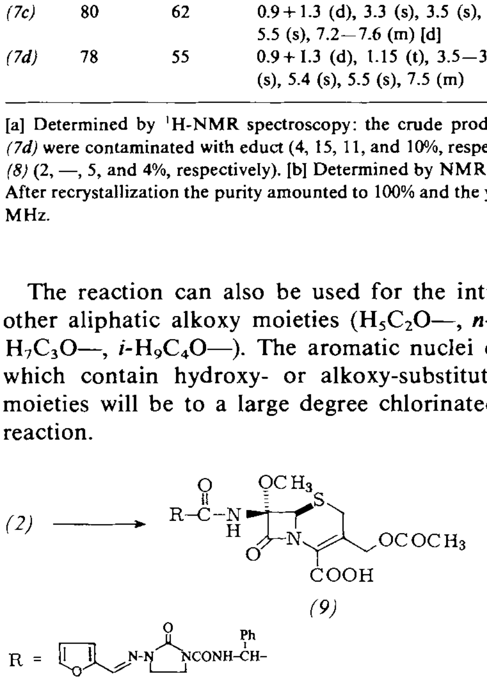
Scheme 1. (D) in substituents *(a)*—*(d)* signifies the asymmetric center to be configuration of the D-amino acid series.

Table 1. Purity, yields and $^1$H-NMR spectroscopic data for *(7a)*—*(7d)*.

| Compound | Product purity [%] [a] | Yield [%] [b] | $^1$H-NMR ($\delta$-value, $CH_3OD$, 100 MHz) |
|---|---|---|---|
| *(7a)* | 84 [c] | 54 [c] | 0.9 + 1.3 (d, $C(CH_3)_2$), 3.5 (s, $OCH_3$), 3.85 (m, —$CH_2$—$CH_2$—), 4.1 (s, 3-H), 5.5 (s, 5-H), 5.55 (s, N—CH—CO), 6.5 (q, $J$ = 3.2 Hz and 1.5 Hz, Furyl-4), 6.85 (d, $J$ = 3.2 Hz, Furyl-5), 7.2—7.6 (m, Furyl-3 + Ph), 7.7 (s, —CH=N—) |
| *(7b)* | 70 | 50 | 1.2 + 1.4 (d), 3.5 (s), 3.9 (m), 4.15 (s), 5.55 (s), 5.85 (s), 6.55 (q), 6.85 (d), 7.0 (d), 7.2—7.4 (m), 7.6 (d), 7.7 (s) |
| *(7c)* | 80 | 62 | 0.9 + 1.3 (d), 3.3 (s), 3.5 (s), 3.85 (m), 4.1 (s), 5.5 (s), 7.2—7.6 (m) [d] |
| *(7d)* | 78 | 55 | 0.9 + 1.3 (d), 1.15 (t), 3.5—3.8 (m, 9H), 4.05 (s), 5.4 (s), 5.5 (s), 7.5 (m) |

[a] Determined by $^1$H-NMR spectroscopy: the crude products from *(7a)*—*(7d)* were contaminated with educt (4, 15, 11, and 10%, respectively) and with *(8)* (2, —, 5, and 4%, respectively). [b] Determined by NMR spectroscopy. [c] After recrystallization the purity amounted to 100% and the yield 38%. [d] 250 MHz.

The reaction can also be used for the introduction of other aliphatic alkoxy moieties ($H_5C_2O$—, *n*-$H_7C_3O$—, *i*-$H_7C_3O$—, *i*-$H_9C_4O$—). The aromatic nuclei of molecules which contain hydroxy- or alkoxy-substituted aromatic moieties will be to a large degree chlorinated during the reaction.



*Procedure*

*(7a)*: A solution of 150 mmol $LiOCH_3$ in methanol at −20 °C is added to a stirred suspension of *(4a)* (50 mmol, 27.7 g) in 550 mL tetrahydrofuran (THF) at −70 °C in such a manner that the internal temperature does not rise above −55 °C. As soon as a clear solution forms, a solution of *t*-butyl hypochlorite (7 g, 65 mmol) in 20 mL $CH_2Cl_2$ is poured in. The temperature rises to −45 °C and is immediately cooled again to −55 °C. The mixture is stirred for 30 min at −55 °C and poured into an ice-cold solution of 75 g $NH_4Cl$ and 10 g $Na_2SO_3 \cdot 10H_2O$ in 750 mL water. Finally, an additional 1000 mL water is added, the pH adjusted to 7—7.5, the mixture washed with ethyl acetate (2 × 500 mL), 500 mL of ethyl acetate added, and the mixture acidified to pH = 2 with HCl. The organic phase is treated with 350 mL water and NaOH is added with constant stirring until the pH = 7. After separation of the ethyl acetate, the mixture is freeze-dried, giving the crude product. Alternatively, the mixture is separated from ethyl acetate, treated with 175 mL acetone, cooled to 5 °C and acidified to pH = 2 with 2 N HCl. During crystallization an additional 150 mL water is added. After 45 min the crystals are filtered-off, suspended afresh in 150 mL water, 2 N NaOH added until the pH = 7 and freeze-dried as the sodium salt. For yield and purity see Table 1.

## 15,16-Dioxo-*syn*-1,6:8,13-bismethano[14]annulene

By *Metin Balci, Rolf Schalenbach,* and *Emmanuel Vogel*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

It had originally been assumed that 11-oxo-1,6-methano[10]annulene *(1)* very readily fragments into naphtha-

---

[*] Dr. M. Balci, Dr. R. Schalenbach, Prof. Dr. E. Vogel

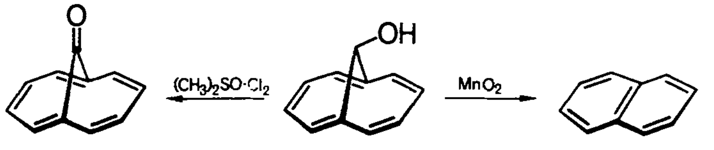
Greinstrasse 4, D-5000 Köln 41 (Germany)

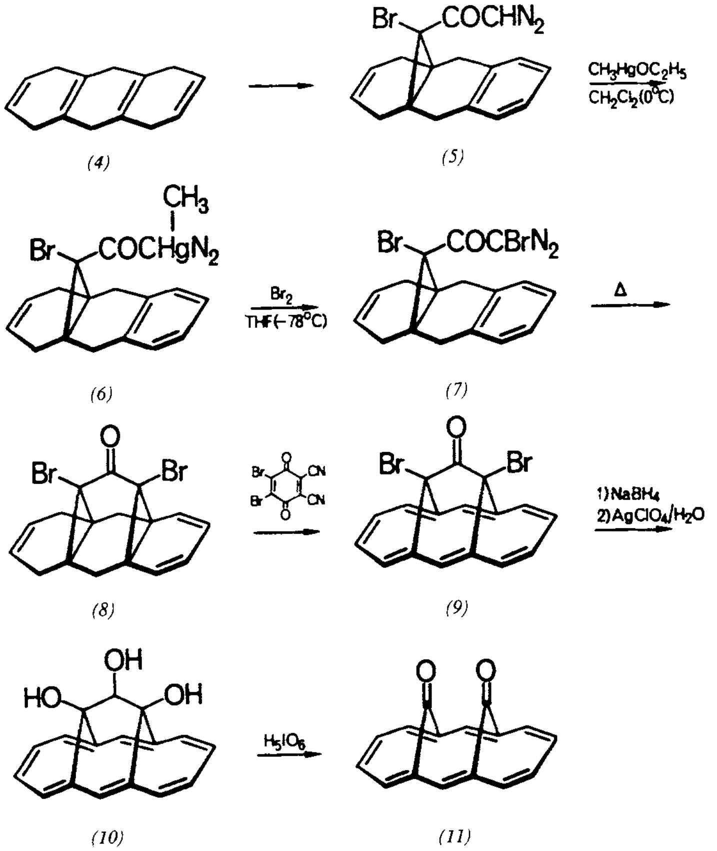
*0570-0833/81/0909-0809 $ 02.50/0*

lene *(3)* and carbon monoxide[1] on heating, since *(3)* was always obtained as reaction product on oxidation of 11-hydroxy-1,6-methano[10]annulene *(2)* with manganese dioxide (in acetone), chromium trioxide-pyridine complex (in dichloromethane) or lead tetraacetate (in pyridine).



In actual fact, *(1)*—first synthesized in 1972 by *Itô et al.*[2] from the [6 + 4]-adduct of tropone and butadiene—is a stable aromatic compound, whose decarbonylation necessitates heating to more than 200 °C! The naphthalene obtained on oxidation of *(2)* with the above mentioned reagents therefore cannot be formed *via (1)* but in all probability arises from tricyclo[4.4.1.$0^{1,6}$]undeca-2,4,7,9-tetraen-11-ol, the valence tautomer of *(2)* containing a cyclopropanol structural unit[3]. It has now been possible to oxidize *(2)* smoothly to *(1)* with the Pfitzner-Moffat reagent as well as with the dimethyl sulfoxide-chlorine complex described by *Corey* (yields 77 and 87%, respectively; no naphthalene formation).

From the properties of *(1)* it could be predicted that its next higher homologue with *syn*-carbonyl groups[4], 15,16-dioxo-*syn*-1,6 : 8,13-bismethano[14]annulene *(11)*, is capable of existence under normal conditions and is distinguished by having aromatic character. True, the annulene ring in *(11)* might be bent as a result of steric and electrostatic repulsion of the carbonyl groups but from experience with the *syn*-1,6 : 8,13-bismethano[14]annulene[5a] no serious loss of resonance is to be expected through this. Possible conjugative interactions between the carbonyl groups and the annulene ring ought to be small, since the $2p_z$ orbitals of the carbonyl groups and the corresponding bridge-base C-atoms are, according to molecular models, arranged almost orthogonally to each other. We have found that these concepts about *(11)* are not at variance and we report here on its synthesis.



The α-diazoketone *(5)*, which has already served as intermediate in the synthesis of 1,6 : 8,13-propanediylidene[14]annulene[5b], is accessible in a five-stage reaction sequence from 1,4,5,8,9,10-hexahydroanthracene *(4)*. The α-bromo-α-diazoketone *(7)* is expediently prepared *via* the mercury compound *(6)*, which is obtained on slow addition of a solution of *(5)* in dichloromethane at 0 °C to a solution of methylmercury ethoxide in ethanol[6]; the compound *(6)* crystallizing out on concentration of the reaction solution is NMR-spectroscopically pure (yield 85—90%). Reaction of *(6)* with an equivalent amount of bromine in tetrahydrofuran (THF) at −78 °C leads to formation of *(7)*, which is not isolated, but, after extensive removal of the original solvent in a vacuum is immediately taken up in hexane (the changeover to this solvent effects precipitation of the Hg-salt) and thermolyzed (reflux, 1 h). Chromatography on silica gel (dichloromethane) furnishes colorless *(8)* [m.p. 189–190 °C (dec.), (from acetonitrile); yield 17%, based on *(5)*]. When a mixture of *(8)* and 2,3-dibromo-5,6-dicyano-*p*-benzoquinone (25% excess) in chlorobenzene is heated for 4 h at 120 °C dehydrogenation of *(8)* takes place to give *(9)*, which is isolated by chromatography on silica gel (dichloromethane) [orange needles (gradual decomposition above 275 °C, from nitromethane); yield 41%]. *(9)* can be smoothly reduced with $NaBH_4$ in THF/methanol (1 : 1) at 0 °C to the alcohol [yellow needles, m.p. 248–250 °C (dec.), from ethyl acetate; yield 90%]. Although, for steric reasons, the bromine atoms of this alcohol should not be very reactive solvolytically, its reaction with an excess of silver perchlorate in acetone/water (3 : 1) leads to almost complete hydrolysis even after 3 hours stirring at room temperature. The main product *(10)* is isolated by transferring the product mixture onto silica gel and successively eluting with dichloromethane (removal of by-products) and ether/methanol (5 : 1) [yellow needles, m.p. 219–221 °C (from ether); yield 56%].

As expected, the triol *(10)* is cleaved by periodic acid in water/acetone, giving *(11)* and not (which had to be reckoned with) a hydrate[7] of *(11)*; it forms air-stable, orange-red rhombic crystals (from acetonitrile), which slowly decompose above 250 °C (yield 51%).

Table 1. Spectral data of *(8)*, *(9)*, *(10)* and *(11)* (cf. also [9]).

*(8)*, $^1$H-NMR ($CDCl_3$): $\delta = 6.23$ and 5.70 (AA′BB′-system, 4 H), 5.58 (m, 2 H), 2.55 (AB-system, 2 × 2 H), 2.33 (m, 4 H); IR (KBr): 1670 $cm^{-1}$ (C=O); MS: $m/z = 396/394/392$ ($M^+$, 5, 10, 5%), 315/313 ($M^+ - Br$, 9), 287/285 ($M^+ - Br, - CO$, 17), 206 ($M^+ - 2Br, - CO$, 100)

*(9)*, $^1$H-NMR ([$D_6$] DMSO): $\delta = 8.10$ (s, 2 H), 7.97—7.54 (AA′BB′-system, 2 × 4 H); UV (dioxane): $\lambda_{max} = 242$ ($\varepsilon = 14250$), 310 (98250), 330 (20600) sh, 362 (9300), 445 (220) sh, 506 nm (1200); IR (CsI): 1750 $cm^{-1}$ (C=O); MS: $m/z = 392/390/388$ ($M^+$, 2, 5, 2%), 311/309 ($M^+ - Br$, 1), 283/281 ($M^+ - Br, - CO$, 1), 202 ($M^+ - 2Br, - CO$, 100)

*(10)*, $^1$H-NMR ($CDCl_3$): $\delta = 7.93$—7.46 (m, 2 × 4 H), 7.78 (s, 1 H), 7.60 (s, 1 H), 1.96 and 1.50 (AB-system, $J = 3$ Hz, 2 H), 0.43 (s, 2 H); UV (dioxane): $\lambda_{max} = 228$ ($\varepsilon = 7700$), 301 (145600), 313 (35550), 252 (7400), 364 (7200) sh, 463 nm (260); IR (KBr): 3500 $cm^{-1}$ (O—H); MS: $m/z = 266$ ($M^+$, 61%), 202 ($M^+ - CO, - 2H_2O$, 36), 178 ($M^+ - C_3H_4O_3$, 100)

*(11)*, $^1$H-NMR ([$D_6$] DMSO): $\delta = 8.53$ (s, 2 H), 8.11 and 7.81 (AA′BB′-system, $J_{2,3} = 9.63$, $J_{3,4} = 9.81$, $J_{2,4} = 0.18$, $J_{2,5} = 0.89$ Hz, 2 × 4 H); $^{13}$C-NMR ([$D_6$]DMSO): $\delta = 194.71$ (C—15, 16), 129.22 (C—7, 14), 129.53, 127.15 (C—2, 3, 4, 5, 9, 10, 11, 12), 125.32 (C—1, 6, 8, 13); UV (dioxane): $\lambda_{max} = 292$ ($\varepsilon = 139100$), 312 (24200), 365 (7550), 442 (80), 509 nm (300); IR (CsI): 1713 (C=O), 1540 $cm^{-1}$ (C=C); MS (120 °C): $m/z = 234$ ($M^+$, 58%), 218 ($M^+ - O$, 2), 206 ($M^+ - CO$, 11), 202 ($M^+ - 2O$, 45), 178 ($M^+ - 2CO$, 100)

The spectra (cf. Table 1) and X-ray structure analysis clearly show that *(11)* is an arene. The $^{1}$H-NMR spectrum, which as expected, consists of a singlet and an AA'BB' system, shows in its parameters—apart from the chemical shifts of H-7, H-14—a qualitative agreement with the partial spectrum of the annulene protons of 1,6:8,13-propanediylidene[14]annulene[5b]. The singlet of H-7, H-14 appears at unusually low field strength, which in the main could be attributed to the fact that these protons are exposed to the inductive effect of both carbonyl groups. The relationship between *(11)* and 1,6:8,13-propanediylidene[14]annulene also extends to the electronic spectrum. Hence, in agreement with model considerations the π-systems of the carbonyl groups and annulene ring in *(11)* are essentially independent of each other. The carbonyl band at 1713 cm$^{-1}$ can be explained in the same terms. As assumed, successive loss of carbonyl groups occurs in the mass spectroscopic fragmentation of *(11)*; interestingly, however, a stepwise cleavage of the two oxygen atoms follows parallel to the decarbonylation and at sample temperatures above 100 °C it even predominates (base peak: $M^{+}-2O$)[8] (this fragmentation pattern is not observed in the case of the *anti*-isomer of *(11)*[9]).

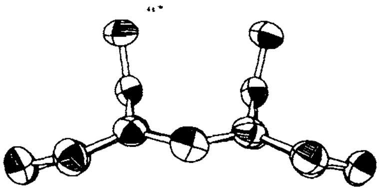


Fig. 1. Longitudinal profile of 15,16-dioxo-*syn*-1,6:8,13-bismethano[14]annulene *(11)*.

The X-ray structure analysis[10] of *(11)* confirms the spectral findings by virtue of demonstrating aromatic CC bonds (lengths 1.376–1.413 Å) in the annulene ring. According to Figure 1 the annulene ring is only slightly bent, even though there must be strong repulsion between the carbonyl groups owing to electrostatic interactions, since the oxygen atoms are forced out of the plane of the corresponding bridge- and bridge-base C-atoms. The bridge bond angle in *(11)* (112.4°) is greater than that in 1,6:8,13-propanediylidene[14]annulene (104.2°), and consequently the transannular distance C1–C6 as well as C8–C13 in *(11)* is greater (2.470 Å) than in the reference compound (2.359 Å).

The outstanding chemical feature of *(11)* is its thermal stability. *(11)* can be subjected to flash pyrolysis at 500 °C in a vacuum without it undergoing fragmentation to anthracene and carbon monoxide or other changes.

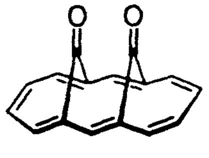
## 15,16-Dioxo-*anti*-1,6:8,13-bismethano[14]annulene

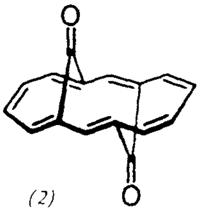
By *Emanuel Vogel, Rudolf Nitsche,* and *Hans-Ulrich Krieg*[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

The properties of the *syn-anti* isomeric 1,6:8,13-bismethano[14]annulenes[1] serve as a typical example for illustrating that the bonding in a cyclically conjugated (4n+2)π-electron system can be decisively influenced by the molecular geometry. The *syn*-isomer[1a] is aromatic, even though it has a bent annulene ring[2], whereas the *anti*-isomer, which has a strongly puckered ring, is an olefinic compound with fluxional π-bonds[3].



*(1)*



*(2)*

We have found that the transition from the aromatic 15,16-dioxo-*syn*-1,6:8,13-bismethano[14]annulene *(1)*[4] to the *anti*-isomer *(2)* is likewise accompanied by a loss in aromaticity.

The synthesis of *(2)* was achieved—following that of the *anti*-1,6:8,13-bismethano[14]annulene[1b]—using 1,4,5,8,9,10-hexahydroanthracene *(3)* as starting material. Reaction of *(3)* with sodium chlorodifluoroacetate in diglyme at 165 °C[5] (molar ratio 1:2.5) afforded a mixture of mono- and bis-(difluorocarbene) adducts, from which *(4)* could be separated by chromatography on silica gel with pentane [colorless rhombs, m.p. 154–155 °C (from ethanol): yield 22%]. *(4)* readily reacts with bromine in dichloromethane at −78 °C to give the tetrabromide (presumably both stereoisomers) [colorless crystals, m.p. 234–236 °C (dec.) (from ethyl acetate), yield 91%]. If the tetrabromide is transferred slowly into a 15% methanolic KOH solution (five-fold excess) and the mixture heated under reflux for 4 h, dehydrohalogenation takes place to give *(5)*, which is obtained in the form of colorless rhombs [decomp. above 270 °C (from ethyl acetate), yield 35%]. On treatment with 70% (vol-%) sulfuric acid and stirring at room temperature (10 d), *(5)* is hydrolyzed to *(6)*[6] *[yield 95% NMR-spectro-*

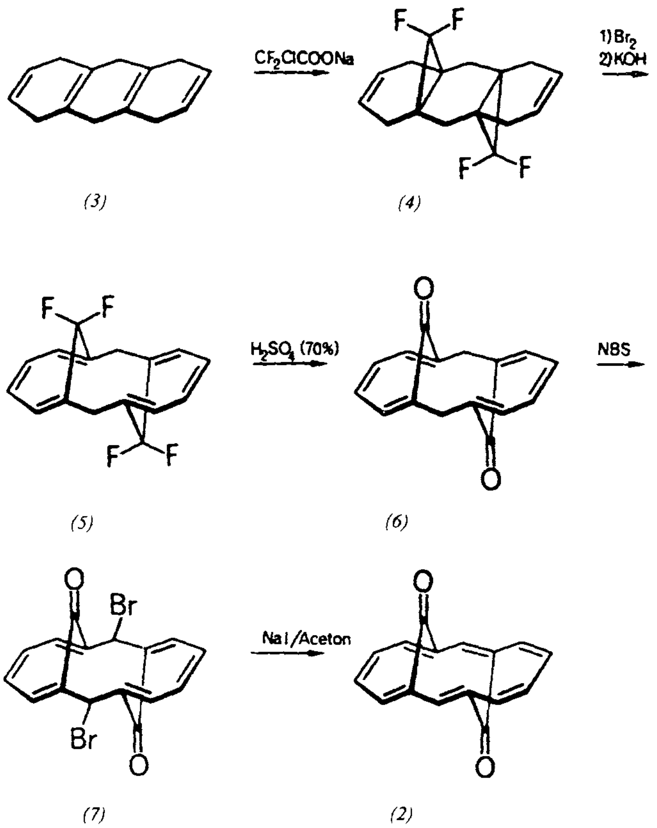
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)



scopically pure *(6)*; colorless rhombs (decomp. above 290 °C, from dichloromethane)]. For the bromination, *(6)* is allowed to react with *N*-bromosuccinimide in boiling benzene in the presence of dibenzoyl peroxide. Subsequent chromatography on silica gel with ether/pentane affords crystalline *(7)* (presumably a mixture of both stereoisomers) in 35% yield, which is immediately dehalogenated by heating (7 h) with an excess of sodium iodide in acetone; after usual work-up and recrystallization from acetone, *(2)* is obtained as carmine-red needles [gradual decomposition above 138 °C, yield 35—45%]. *(2)* very rapidly polymerizes in air and is sensitive to light. It can be stored for some time under argon at *ca.* $-40\,°C$.

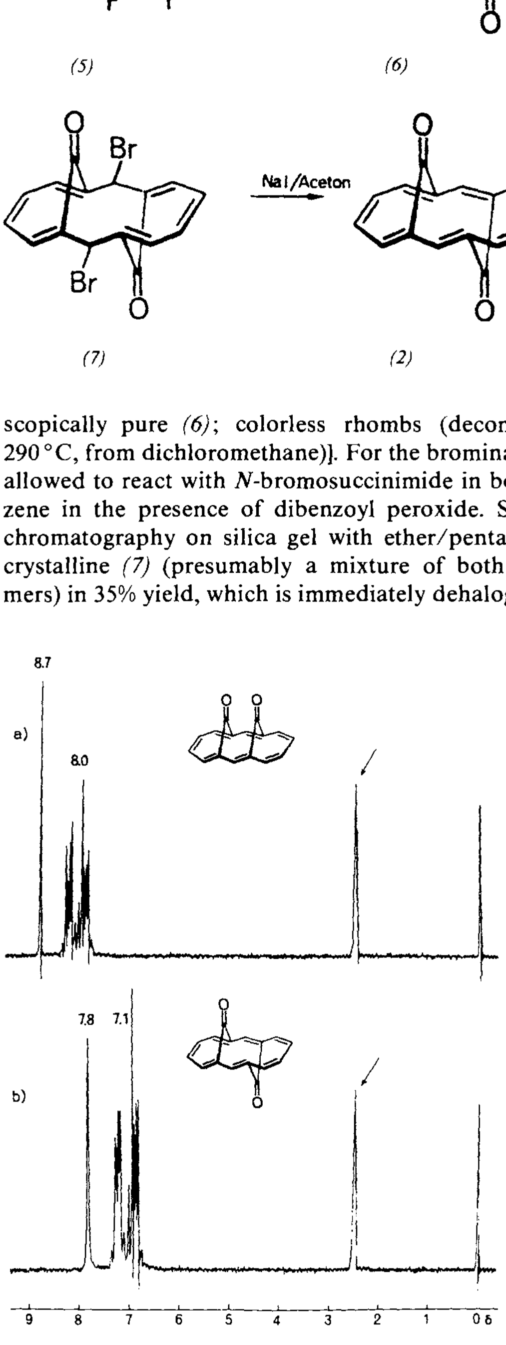


Fig. 1. $^1$H-NMR spectra (90 MHz) of a) 15,16-dioxo-*syn*-1,6:8,13-bismethano[14]annulene *(1)*[4] and b) 15,16-dioxo-anti-1,6:8,13-bismethano[14]annulene *(2)* (both in [D$_6$]DMSO (arrow), TMS as internal standard).

The olefinic nature of *(2)*, suggested by the ready polymerization of the compound, is impressively confirmed by the $^1$H-NMR spectrum. Although this shows the same absorption pattern as that of *(1)* (singlet and AA'BB' system), all the signals are shifted upfield by $\Delta\delta \approx 1$, as is consistent with the transition from an arene to an olefin (Fig. 1). The rapid π-bond shift in *(2)*, inferred from the presence of only one AA'BB' system, has hitherto defied experimental detection. The spectrum remains unchanged at $-130\,°C$[7], the lowest temperature reached, whereas that of the *anti*-1,6:8,13-bismethano[14]annulene already shows strong exchange broadening in the range from $-70$ to $-120\,°C$. The activation energy for the π-bond shift in *(2)* is consequently lower than in the case of the hydrocarbon, which seems plausible, since the opening of the bridge-bond angle effected by the CO group[8] should reduce the torsional angles of the C6—C7 and C7—C8 as well as C1—C14 and C13—C14 bonds. The electronic spectrum of *(2)* has experienced a red-shift compared to that of the hydrocarbon, the main cause of which is to be regarded as a conjugative interaction of the carbonyl groups with the annulene ring, which according to molecular models is sterically possible. However, the CO band at 1695 cm$^{-1}$ is not revealing in this respect. The fragmentation behavior in the mass spectrum is characterized by successive loss of the two carbonyl groups (base peak: $M^+ - 2\,CO$).

Table 1. Spectral data of *(2)*, *(4)*, *(5)* and *(6)*.

*(2)*, $^1$H-NMR ([D$_6$] DMSO): $\delta = 7.78$ (s, 2 H), 7.18 and 6.85 (AA'BB'-system, $J_{2,3} = 9.33$, $J_{3,4} = 10.21$, $J_{2,4} = 0.38$, $J_{2,5} = 0.62$ Hz, 2×4 H); $^{13}$C-NMR [(CD$_3$)$_2$CO]: $\delta = 205.23$ (C-15, 16), 144.89 (C-1, 6, 8, 13), 128.43, 128.29, 125.96; UV (dioxane): $\lambda_{max} = 240$ ($\varepsilon = 27400$), sh, 318 (21800), 384 nm (4400); IR (CHCl$_3$): 1695 (C=O), 1595 cm$^{-1}$ (C=C); MS (120 °C): $m/z = 234$ ($M^+$, 18%), 206 ($M^+ - CO$, 24), 178 ($M^+ - 2\,CO$, 100)

*(4)*, $^1$H-NMR (CDCl$_3$): $\delta = 5.57$ (m, 4 H), 2.70—1.80 (m, 8 H), 1.90 (m, 4 H); IR (KBr): 1675 cm$^{-1}$ (C=C); MS: $m/z = 284$ ($M^+$, 18%), 264 ($M^+ - HF$, 6), 91 ($M^+ - 193$, 100)

*(5)*, $^1$H-NMR (CDCl$_3$): $\delta = 6.80$—6.40 (AA'BB'-system, 2×4 H), 3.85 (br. s, 4 H); UV (MeOH): $\lambda_{max} = 227$ ($\varepsilon = 43400$), 243 (20000), 275 nm (2000); IR (KBr): 1602 cm$^{-1}$ (C=C); MS: $m/z = 280$ ($M^+$, 100%), 178 ($M^+ - 2\,CF_2$, $-H_2$, 47)

*(6)*, $^1$H-NMR (CDCl$_3$): $\delta = 6.74$ (s, 8 H), 4.00 (s, 4 H); UV (dioxane): $\lambda_{max} = 237$ ($\varepsilon = 28000$), 328 nm (3500); IR (KBr): 1670 cm$^{-1}$ (C=O); MS: $m/z = 236$ ($M^+$, 38%), 208 ($M^+ - CO$, 12), 179 ($M^+ - 2\,CO$, $-H$, 100)

The X-ray structure analysis[2,9] of *(2)* surprisingly shows CC bond lengths for the annulene ring like those in arenes. Since the $^1$H-NMR and electronic spectra are clearly consistent with those of an olefin the equalization of the bond lengths is either simulated by crystal defects (most likely case) or confined to the crystalline state of the compound.

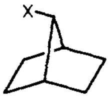
# Intramolecular Interaction between a Tropylium Ion and a Non-Neighboring Cyclopropane Ring[**]

By *Tomoo Nakazawa, Keiji Kubo, Atsuko Okimoto, Jun Segawa,* and *Ichiro Murata*[*]

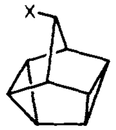
Many examples of remote interaction between a cyclopropane ring and a non-neighboring carbonium ion center are known[1a], the best known example being the solvolysis of the five norbornyl derivatives *(1)*—*(5)*, whose relative rates are 1, 1.7, $10^9$, $10^{10}$, and $10^{12}$, respectively[1]. However, attempts to observe the cation derived from *(5)* directly by spectroscopic methods have been unsuccessful, because the potential precursors are unstable in the acidic media employed[2].



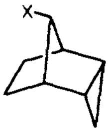
(1)

(2)

(3)

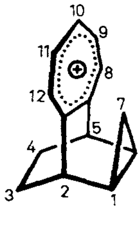


(4)

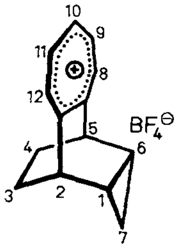


(5)

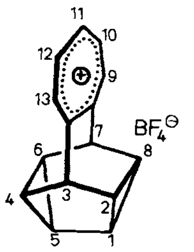
Herein we report the synthesis and some properties of a series of compounds *(6a)*—*(6c)*, in which the tropylium ion and cyclopropane ring are incorporated in a bicyclo[2.2.2]octane. The tropylium ions *(6)* can be synthesized from the benzene derivatives, *(7)* through homologation with diazomethane and a hydride ion abstraction sequence. Thus, for example, cyclopropanation of *endo*-benzotricyclo[3.2.2.$0^{2,4}$]non-6-ene *(7a)*[3a] with $CH_2N_2$ in the presence of CuCl in $CH_2Cl_2$ gave rise to a mixture of two cycloheptatriene isomers *(9a)* and *(10a)* in 28.4% yield. In contrast, the same cyclopropanation of the *exo*-derivative *(7b)*[3a] and 9,10-benzopentacyclo[4.4.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]dec-9-ene (benzosnoutene) *(7c)*[3b] led to a mixture of all three possible isomers, *(8b)*, *(9b)*, and *(10b)* (23%), and *(8c)*, *(9c)*, and *(10c)* (25%), respectively. All of these isomers could be separated by column chromatography on silica gel impregnated with 7% $AgNO_3$ (hexane + benzene) and characterized by $^1$H-NMR spectroscopy.



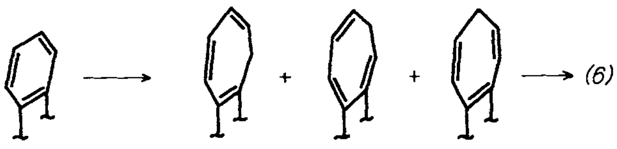
(6a)



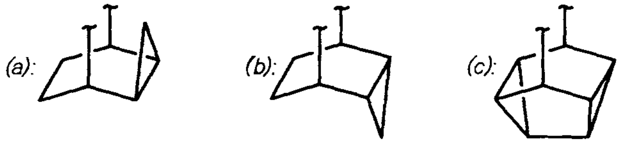
(6b)



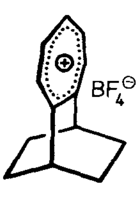
(6c)



(7) (8) (9) (10)

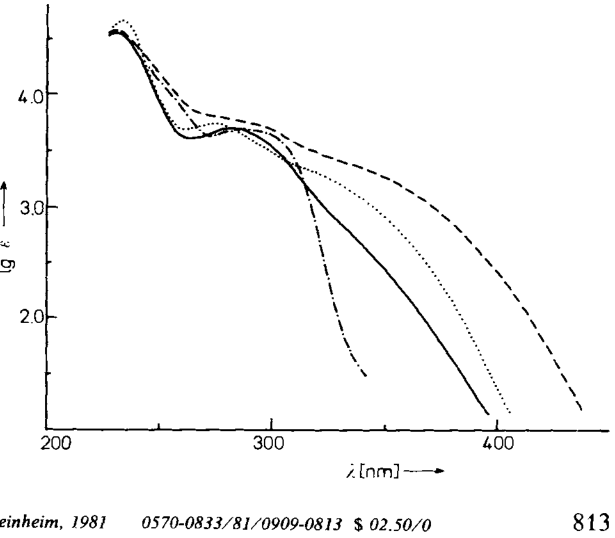


Conversion of these cycloheptatrienes into the desired tropylium ions was readily accomplished using trityl tetrafluoroborate in $CH_2Cl_2$: *(6a)*[4] (yellow leaflets, mp 126—7 °C); *(6b)*[4] (pale yellow prisms, mp 201—3 °C (decomp)); and *(6c)*[4] (lemon-yellow plates, mp 160.5 °C (decomp)).



(11)

In the tropylium ions *(6b)* and *(6c)*, the cyclopropane and tropylium moieties are situated such that interaction can occur *via* an edge of the three-membered ring; this is not the case in *(6a)*. The interactions are evident in the UV/VIS spectra of *(6a)*—*(6c)* (Fig. 1). *(6b)* ($\varepsilon_{350}$ = 900) and *(6c)*



---

[**] This work was supported by a Grant-in-Aid for Scientific Research (No. 343007) from the Ministry of Education, Japan.

($\varepsilon_{350}=2000$) exhibit strong broad end-absorptions in the long wavelength region, tailing out to 400 and 450 nm, respectively; this is not observed in the spectrum of the reference compound *(11)*. These absorptions undergo blue-shifts upon changing the solvent to the more polar acetonitrile[8]. These results, as well as the concentration independence of their intensities, suggest that the absorptions can be assigned to intramolecular charge-transfer (CT) bands[9]. In contrast, *(6a)* only shows a weak absorption ($\varepsilon_{350}=370$) in this region, a result of the weaker interaction of the cyclopropane "side" with the "remote" tropylium ion.

The intramolecular CT-interaction in *(6a)—(6c)* is also reflected in their ground state properties *e.g.* $pK_{R^+}$-values and their reduction potentials (Table 1).

Table 1. $pK_{R^+}$-values and reduction potential data for the tropylium ions, *(6a)—(6c)*, and *(11)*.

| | *(6a)* | *(6b)* | *(6c)* | *(11)* |
|---|---|---|---|---|
| $pK_{R^+}$ [a] | 8.60 | 8.68 | 8.85 | 8.82 |
| $E_{1/2}$ [b] | −0.450 | −0.473 | −0.492 | −0.455 |

[a] Measured spectrophotometrically in 20% aqueous $CH_3CN$. [b] vs. SCE. Measured by polarography at 25 °C in $CH_3CN$ (25 °C, $CH_3CN$, $Et_4NClO_4$ as supporting electrolyte).

Although the dominant factor affecting the thermodynamic stability of the tropylium ion is the inductive effect of the bicyclo[2.2.2]octane skeleton[7, 10], both the $pK_{R^+}$-values and the reduction potentials increase, although only to a small degree, with increasing charge-transfer interaction in the order *(6a)*, *(6b)*, to *(6c)*.

Studies of the possible interactions in the excited states by MCD spectroscopy and MO (CNDO/S) calculations are presently been undertaken[9].

[4] *(6a)*: $^1$H-NMR ($CD_2Cl_2$) $\delta=-1.08$ (1H, dt, $J=7.6$, 3.6 Hz, H-$7_{syn}$), 0.23 (1H, dt, $J=7.6$, 7.6 Hz, H-$7_{anti}$), 1.36—1.71 (4H, m, H-$3_{exo}$, $4_{exo}$, 1,6), 2.62 (2H, m, H-$3_{endo}$, $4_{endo}$), 4.07 (2H, m, H-2,5), 8.90—9.11 (5H, m, H-8—12); $^{13}$C-NMR ($CD_3CN$) $\delta=2.0$ (C-7), 10.3 (C-1,6), 24.0 (C-3,4), 43.2 (C-2,5), 151.5 (C-10), 152.1 (C-8,12), 153.0 (C-9,11), 172.2 (C-5a, 12a). *(6b)*: $^1$H-NMR ($CD_2Cl_2$) $\delta=1.10$—1.50 (4H, m, H-1, 6, $3_{exo}$, $4_{exo}$), 1.57—1.77 (2H, m, H-$7_{syn,anti}$), 1.94—2.19 (2H, m, H-$3_{endo}$, $4_{endo}$), 3.87—4.03 (2H, m, H-2, 5), 9.05 (5H, br, s, H-8—12); $^{13}$C-NMR ($CD_3CN$) $\delta=16.3$ (C-7), 21.2 (C-1, 6), 21.8 (C-3, 4), 42.9 (C-2, 5), 151.5 (C-10), 152.9 (C-8, 12), 153.2 (C-9, 11), 178.7 (C-5a, 12a). *(6c)*: $^1$H-NMR ($CD_2Cl_2$) $\delta=1.96$—2.18 (4H, m, H-2, 4, 6, 8), 2.93 (2H, br. t, $J=5.0$ Hz, H-1, 5), 4.33 (2H, quint, $J=2.9$ Hz, H-3, 7), 8.88—9.11 (5H, m, H-9—13); $^{13}$C-NMR ($CD_3CN$) $\delta=40.5$ (C-2, 4, 6, 8), 41.3 (C-1, 5), 48.9 (C-3, 7), 150.3 (C-11), 151.2 (C-9, 13), 152.2 (C-10, 12), 177.5 (C-7a, 13a); the assignment of signals C-8, 12 and C-9, 11 in *(6a)* and *(6b)*, as well as these of C 9, 13 and C-10, 12 in *(6c)* could also be reversed. Although the $^1$H-NMR spectra of *(6a)*, *(6b)*, and *(6c)* provide no useful information about charge delocalization, the $^{13}$C-NMR data are more informative. Thus, comparison of the $^{13}$C-NMR data for tropylium ions, *(6a)*, *(6b)*, *and (6c)*, with those reported for the corresponding benzo-analogs, *(7a)* [3a], *(7b)* [3b], and *(7c)* [5], indicates that (i) the ethano bridge carbons (C-3 and C-4) of both *(6a)* and *(6b)*, compared with those of *(7a)* and *(7b)*, respectively, are shifted upfield by *ca.* 2 ppm [6], (ii) the signals of C-1 and C-6 in *(6a)* also exhibit slight upfield shifts of 0.9 ppm and (iii) the signals of C-1 and C-6 in *(6b)* and C-2, C-4, C-6, and C-8 in *(6c)* exhibit downfield shifts of 0.7 and 2.8 ppm, respectively. These downfield shifts are indicative of decreased electron densities at these carbon atoms a consequence of the intramolecular CT-interaction in *(6b)* and *(6c)*.

[5] *(7c)*: $^{13}$C-NMR ($CD_3CN$) $\delta=34.5$ (C-1, 5), 37.7 (C-2, 4, 6, 8), 40.9 (C-3, 7), 125.1 (C-10, 11), 124.8 (C-9, 12), 144.1 (C-7a, 12a). The numbering follows that in *(6c)*.

[6] Almost the same high-field shift (1.8 ppm) is observed if the signals of the C atoms in the ethano bridges in *(11)* [7] and in the 6,9-dihydro-6,9-ethanobenzotropylium ion are compared with the signals of the corresponding benzo-annelated derivatives.

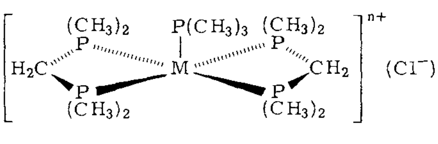
## A Triply Bridged Dicobalt Complex with Odd Number of Electrons ($Co_2^{1+}$)[**]

By *Hans Heinz Karsch* and *Beatrix Milewski-Mahrla*[*]

Dinuclear complexes with bridging ligands and direct metal-metal interaction, which contain an odd number of electrons, are accessible in only a few exceptional cases and/or by directed redox reactions[1]. We report here on the spontaneous formation of a novel, triply bridged dicobalt complex with the "mixed" oxidation state $Co_2^{1+}$.



*(1)*, M = Fe
n = 0
*(2)*, M = Co
n = 1
*(3)*, M = Ni
n = 2

In the series of isoelectronic complexes *(1)—(3)*[2] the orange cobalt(I) compound *(2)* is distinguished by the fact that it disproportionates in tetrahydrofuran (THF) solution—slowly at room temperature, rapidly above 40 °C—to give the cobalt(II) compound *(4)* (green crystals, dec. > 115 °C) and a product *(5)* decrystallizing as red-brown, hexagonal platelets.

$$[(Me_2PCH_2PMe_2)_2(Me_3P)Co]Cl \quad (2)$$

$$\text{THF}\ \Big\downarrow\ +40\,^{\circ}\text{C}$$

$$[(Me_2PCH_2PMe_2)(Me_3P)_2CoCl_2] \quad (4)$$

$$+$$

$$[\{(Me_2PCH_2PMe_2)(Me_3P)Co\}_2PMe_2] \quad (5)$$

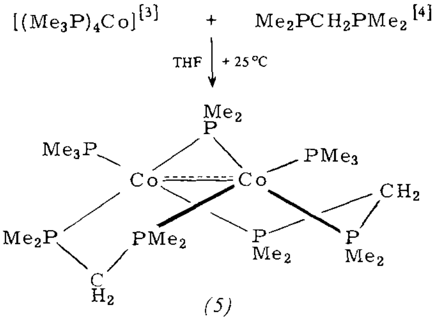
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The paramagnetic complex *(5)*, which is readily soluble in pentane and is moderately sensitive to air in the solid state, should therefore be formulated as a cobalt(0) compound. According to this, *(5)* is also formed spontaneously in the following reaction.



(5)

However, from the mass spectrum (*m/z* 603), the elemental analysis, and the IR spectrum of *(5)*, a dimeric structure could be deduced in which two cobalt atoms with the formal oxidation number $+1/2$ are linked *via* three bridge ligands (two methylenebis(dimethylphosphane)- and one dimethylphosphido-bridge). This surprising observation is confirmed by the X-ray structure analysis[5].

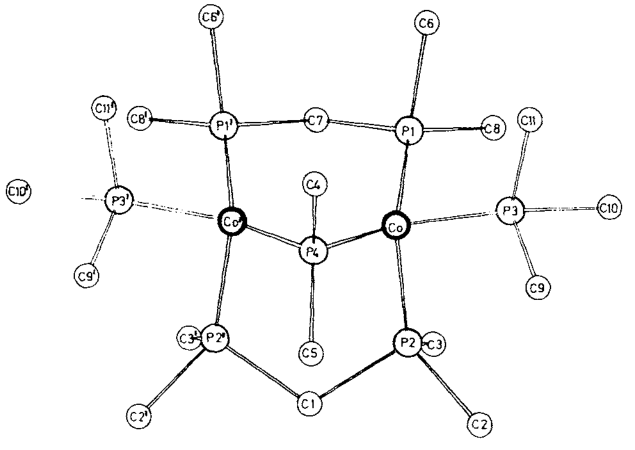


Fig. 1. Structure of the dicobalt complex *(5)* in the crystal. The molecule has a plane of symmetry through C7—P4—C1. Hydrogen atoms not shown. Most important bond lengths and angles: Co—Co 260.3, Co—P1 214.0, Co—P2 217.1, Co—P4 214.4, P1—C7 185.5, P2—C1 184.2 pm; Co—P4—Co' 74.77, P1—C7—P1' 105.43, P2—C1—P2' 113.45, P1—Co—P2 106.65, P1—Co—P3 101.25, P1—Co—P4 137.08, P2—Co—P3 105.39, P2—Co—P4 104.19, P3—Co—P4 98.49, P3—Co—Co' 147.91°.

The distance between the two almost tetrahedrally configurated Co atoms is 260.3(3) pm, a value close to the lower limit in comparable complexes[6]. As model considerations show, a still closer approach of the metal atoms increases repulsion between the bridge- and trimethylphosphane ligands; for minimum repulsion between the bridge ligands only one of the two $CP_2Co_2P$ six-membered rings should adopt a chair conformation, the other a boat conformation; this is in fact observed (Fig. 1). A bond order of 1.5 can be formally assigned to the Co—Co bond (17.5 electrons per Co atom), as is also assumed for the, to our knowledge, hitherto sole comparable complex $[\{(C_5H_5)Co\}_2(\mu\text{-}CO)(\mu\text{-}NO)]$[7]. Regardless of this relationship *(5)* rather corresponds to the "A-frame" complexes[8], whose planar metal coordination (without metal-metal bonding) has now for the first time its tetrahedral pendant (with metal-metal bonding). Whereas the P—C bond cleavage necessary for the formation of *(5)* is not unusual in low-valency phosphanecobalt complexes[6b,9], a "voluntary" reorganization to a bridged molecule with an odd number of electrons is still without example.

## Observations on the Structural Chemistry of the Cyclopentadienyl Bridge[**]

By *Wolfgang A. Herrmann, Gangolf Kriechbaum, Christine Bauer, Ernst Guggolz,* and *Manfred L. Ziegler*

The uniform bonding[1,2] and the consistent structural parameters of all previously investigated $C_5H_4$-bridges have led to their formulation as $\mu(\eta^1:\eta^5)$ ligands, while there are no indications whatever for the alternative $\eta^1$-carbene/$\eta^4$-diolefin coordination. We attempted the realization of this type of structure by employing a precursor compound already containing the $C_5H_4$ ligand, and report here on the carbene addition to metal-metal multiple bonds starting from diazocyclopentadiene.

Reaction of a suspension of the dinuclear nitrosyl complex *(1)*[3], which formally exhibits an FeFe double bond, in tetrahydrofuran (THF), with an excess of diazocyclopentadiene leads with rapid elimination of $N_2$, even at temperatures as low as $-80\,^\circ C$, to the carbene addition product *(3)* which was isolated in pure form in 90—95% yield as air-stable crystals. *(3)* can be stored without decomposition at room temperature and was unequivocally characterized by total elemental analysis and by IR, $^1H$-NMR, $^{13}C$-NMR, and mass spectra (EI and FD) as a $\mu,\eta^1$-cyclopentadienylidene complex[4a]. The smooth formation of *(3)* supports the concept[5] that carbene-transfer with diazoalkanes to sterically accessible metal-metal double bonds com-

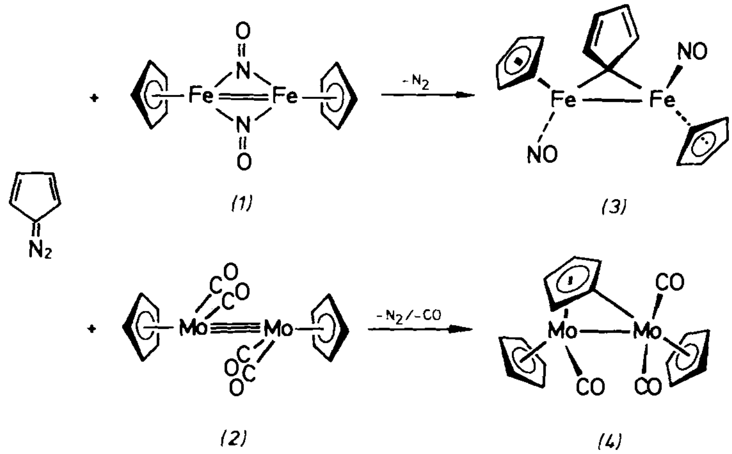
[**] Complex Chemistry of Reactive Organic Compounds, Part 36. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.—Part 35: *W. A. Herrmann, G. Kriechbaum, P. Wülknitz, M. L. Ziegler*, Chem. Ber. *114*, 276 (1981).



prises a straightforward general method for the construction of dimetallacyclopropanes.

By way of contrast, the analogous reaction with the molybdenum compound *(2)*[6], which contains an MoMo triple bond, does not lead to the hitherto unknown dimetallocyclopropenes: the sole isolable product at room temperature in only 35—45% yield formed with with concomitant elimination of $N_2$ and CO is the thermally very stable complex *(4)* (total elemental analysis, FD mass spectrum, IR, $^1$H-NMR spectra[4b]). This unexpected compound formally arises from carbonyl/carbene exchange of the precursor *(2)*. The structural determination (Fig. 1) gave a surprising result:

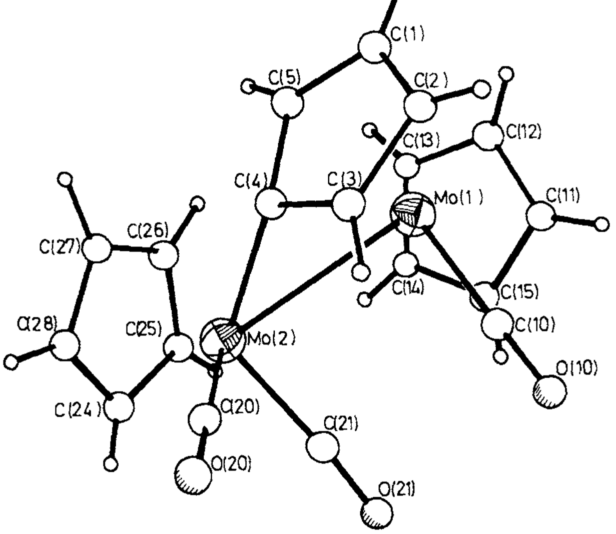


Fig. 1. ORTEP diagram of *(4)* (thermal vibrational ellipsoids drawn with 50% probability).—Monoclinic (from acetone/$CH_2Cl_2$; −35°C), space group $P2_1/n$ ($C_{2h}^5$); $a = 866.66(15)$, $b = 1539.06(35)$, $c = 1222.34(16)$ pm, $\beta = 92.58(1)°$; Syntex P3; $3° \leq 2\theta \leq 70°$; 3966 independent reflections with $I \geq 4\sigma(I)$; $R_{iso} = 0.070$, $R_{aniso} = 0.029$. Selected bond lengths [pm] and angles [°]:

In remarkable contrast to the $\mu,\eta^1$-coordination in *(3)* the $C_5H_4$-group acts as metal-bridging 6-electron ligand with complexation of the entire ring system and concomitant surrender of the MoMo triple bond. The metal-metal distance is about 65 pm longer than in the educt *(2)*[6] and is thus close to the values observed for MoMo "single bonds"[7]. All carbonyl ligands are found to occupy terminal positions; hence for electron balancing reasons (EAN rule), a carbene-diolefin coordination of the bridging ligand is to be expected. However, such a coordination mode is not present on the grounds of the following structural characteristics:

1. The Mo(2)—C(4) bond (211.1(4) pm) is considerably longer than in comparable carbene complexes[8], although a closing up of the two atoms by tilting of the $(C_5H_5)(C_5H_4)$Mo(CO)-fragment in the direction of the second metal atom would encounter no problems, at least geometrically.
2. The Mo(1)—C(4) bond is shorter than the corresponding bond lengths of the remaining ring members of the $C_5H_4$ ligand.
3. The alternance of the C(3)—C(2)-, C(2)—C(1)- and C(1)—C(5)-bond lengths (short, long, short) to be expected for a diolefin-type coordination is not observed. Rather, the C(2)—C(1) bond is significantly shorter than the other CC bonds in the unique cyclic ligand. The observed bond length pattern as a consequence of folding of the $C_5H_4$ ligand about C(3) · · C(5) (3.7°) is also consistent with theoretical calculations[9].

The $\eta^1:\eta^5$-coordination of the cyclopentadienyl bridge thus demonstrated would indicate the formation of a semipolar metal-metal bond of the type Mo(1)→Mo(2), whereby the unequal charge distribution about the metal centers is not mitigated, or alleviated, in the usual way[10] by semibridging, but exclusively by the terminal CO ligands. This is revealed spectroscopically, *inter alia*, by an unusually low-frequency CO vibration[4b] and moreover, is consistent with the significant differences in the Mo—CO and C—O bond lengths, respectively. Some structural details, *e.g.* the markedly acute angle of 59.5° between the plane defined by C(3), C(4), C(5) and the Mo(2)—C(4) vector are in part enforced sterically; nevertheless, the pronounced propensity of the cyclic ring to aromatize appears to be responsible for the general preference of $\eta^1:\eta^5$ complexation over carbene/diolefin fixation, regardless of the method of synthesis, the metal framework, and the electronic nature of the peripheral ligands. As demonstrated by the stability of the compound *(3)* and $(\mu\text{-}C_5X_4)[(\eta^5\text{-}C_5Me_5)Rh(CO)]_2$ (X = H[4a], Cl, Br[11]), the diolefin nature of the $C_5H_4$ bridge is preserved upon carbene-addition to metal-metal multiple bonds if metal-metal single bonds are achieved and/or steric factors or the bonding properties of the additional ligands do not permit further complexation of the ring system. Evidently, cancellation of coordinative and electronic unsaturation of metal-metal multiple bonds plays a pivotal role in determining the final structure of carbene addition products.

## *Procedure*

All operations must be carried out under rigorous exclusion of air and moisture (Schlenk technique).

*(3)*: A suspension of *(1)* (302 mg, 1.0 mmol) in THF (50 mL) is treated at −80°C with *ca.* 5 mmol of diazocyclopentadiene (tosyl azide-free, *ca.* 0.5 M solution in benzene). A color change from olive-green to brown-red occurs, accompanied by immediate evolution of $N_2$; *(1)* goes com-

pletely into solution. The solution is warmed to +25 °C, evaporated down after 20 min *in vacuo*, and the microcrystalline residue extracted with 40 mL of *n*-pentane. The extract is filtered and concentrated to 30 mL. On cooling to −35 °C, *(3)* crystallizes as black needles and/or spear-shaped rods. Decomposition above 184 °C (sealed capillary); very soluble in all common organic solvents, yield 339 mg (93%).

*(4):* A stirred solution of *(2)* (217 mg, 0.5 mmol) in benzene (20 mL) is treated dropwise with 0.5 mmol of diazocyclopentadiene at +25 °C (cf. preceeding preparation). After a few minutes the dark-red solution turns black-brown. Stirring is continued for 12 h and the solution is then evaporated down in a vacuum and the residue chromatographed on silica gel (Merck 7734; Act. II–III; 40 × 1.5 cm column; −20 °C). Unreacted *(2)* (red zone) is first eluted with ether; thereafter the product *(4)* is eluted with $CH_2Cl_2$ as a black-red zone. After recrystallization from acetone/$CH_2Cl_2$ (−35/−80 °C) *(4)* is analytically pure; it forms deep-red prisms which sinter at 155—175 °C and decompose at 222—225 °C (sealed capillary); yield 83—106 mg (35—45%).

# BOOK REVIEWS

**Comprehensive Treatise of Electrochemistry. Vol. 1. The Double Layer.** Edited by *J. O'M. Bockris, B. E. Conway* and *E. Yeager*. Plenum Publishing, New York 1980. xix, 453 pp., bound, $ 49.50.

The first of four volumes deals with the electrochemical double layer. In nine review articles written by well-known authors, the fundamental aspects of this extremely important field are clarified by concentrating on particular points. The contributions run as follows: 1) *R. Parsons:* Thermodynamic Methods for the Study of Interfacial Regions in Electrochemical Systems (thermodynamic description of adsorption), 2) *S. Trasatti:* The Electrode Potential (physical description of the electrode potential, role of the work function, absolute electrode potential), 3) *R. Reeves:* The Double Layer in the Absence of Specific Adsorption (double-layer capacity, classical double-layer model), 4) *M. A. Habib* and *J. O'M. Bockris:* Specific Adsorption of Ions (*inter alia* methods of measurement, adsorption isotherms, partial charge transfer), 5) *A. N. Frumkin, O. A. Petrii* and *B. B. Damaskin:* Potentials of Zero Charge (determination, origin, modification), 6) *Yu. V. Pleskov:* Electric Double Layer on Semiconductor Electrodes (space-charge layer, surface states, capacities. The article deals more with semiconductor surfaces than with the special features of the semiconductor-electrolyte interface), 7) *L. I. Boguslavsky:* Insulator/Electrolyte Interface (short review of problems relating to insulator-electrolyte boundary surfaces), 8) *B. B. Damaskin* and *V. E. Kazarinov:* The Adsorption of Organic Molecules (thermodynamic description, results), 9) *R. J. Hunter:* The Double Layer in Colloidal Systems (charge and potential distribution, electrokinetic effects, colloid stability).

The book gives a very good general picture, is well arranged, and is clearly and attractively written. It will be a welcome reference book not only for the electrochemist but also (and indeed especially) for those working in neighboring areas of research who wish to familiarize themselves with electrochemistry. It will also prove useful for undergraduate and postgraduate students. Electrochemists will realize that some of the chapters have already appeared in other series or monographs, but the advantage of having all together in a single volume must not be underestimated. The shortcomings of the collection are marginal. As always, the combination of various contributions places a strain on consistency. Many important fields are hardly touched upon (electrode kinetics), while other aspects are repeated in at least two chapters. A better account of single-crystal metal electrodes could have been given: recent results in this field (*e.g.* from the French group) would have fitted well into this book. An equally justified treatment of metal electrodes and of semiconductor and insulator electrodes would perhaps have gone beyond the bounds of a single volume, but precisely because of this a much more comprehensive literature collection for these two chapters would have been desirable.

While it is impossible to go here more deeply into the individual contributions, it may be said that the title reflects the contents very well. The first three contributions must be singled out because of their clear and didactic construction; the fourth perhaps suffers somewhat from an excessive linkage of the results with particular workers. Contributions 6, 7, and 9 are a most welcome, even if (too) short, supplement on the electrochemistry of metal electrodes.

The external appearance of the book is attractive, the text and the illustrations are clearly arranged, and, happily, there seem to be few printing errors. The price is moderate and the book can be recommended without reservations for the relevant libraries.

# α,ω-Diisocyanatocarbodiimides, -Polycarbodiimides, and Their Derivatives

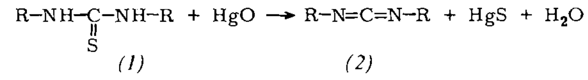
**By Kuno Wagner, Kurt Findeisen, Walter Schäfer, and Werner Dietrich**[*]

*Dedicated to Professor Herbert Grünewald on the occasion of his 60th birthday*

Research in the field of low-molecular weight, oligomeric and polymeric α,ω-diisocyanatocarbodiimides and -polycarbodiimides has been fruitful, not only in connection with these compounds themselves, but also—as so often happens in chemistry—with quite different problems. Novel synthetic methods, discoveries concerning the properties of low-molecular weight carbodiimides and phosphane imide derivatives, as well as results on the fragmentation reactions of four-membered heterocyclic compounds containing oxygen, phosphorus, and nitrogen, and a better understanding of the diisocyanate polyaddition process are among the many by-products of this research. The "high- and low-temperature formation" of polycarbodiimides and the homogeneous and heterogeneous catalysis of this process are described, and the fundamental importance of four-membered ring fragmentation mechanisms resulting in the formation of phosphane imide derivatives is outlined. Interesting building blocks for the diisocyanate polyaddition and polycondensation processes can be synthesized by many derivatization reactions of oligomeric and high-molecular weight polycarbodiimides and polyuretonimines. The *in situ* production of polycarbodiimides *via* matrix reactions in flexible polyurethane foams leads to a cellular arrangement of the material due to the pronounced symmetrical growth processes. Combination-foams with increased carbonation tendencies are formed in this way. Attention is drawn to several industrial applications of α,ω-diisocyanatopolycarbodiimides, of high-molecular weight cross-linked polyuretonimines, and of polycarbodiimide foams.

## 1. Old and New Methods for the Synthesis of Low-Molecular Weight Carbodiimides

The carbodiimide family was first described more than 100 years ago by *Weith*[1]. This was the beginning of an intensive study of these reactive compounds, for the production of which a great variety of methods were subsequently found[2]. The cumulative double bonds make these compounds highly reactive, especially in addition and cycloaddition reactions, with the result that they are versatile building blocks for the synthesis of heterocyclic compounds.



$$\underset{(1)}{R{-}NH{-}\underset{\|}{\overset{}{C}}{-}NH{-}R} + HgO \longrightarrow \underset{(2)}{R{-}N{=}C{=}N{-}R} + HgS + H_2O$$

(1) (2)

Carbodiimides, especially dicyclohexylcarbodiimide, are important dehydrating reagents—in many cases on polymeric carriers (in Merrifield synthesis[4])—in the synthesis of peptides[3].

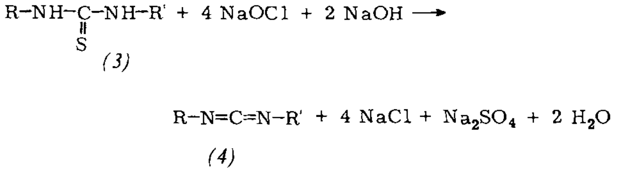
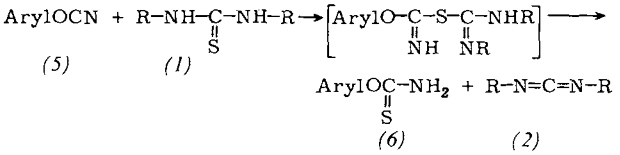
Many methods for the synthesis of low-molecular weight carbodiimides were developed by *E. Schmidt et al.*[5-10]. *N,N'*-dialkylthiourea derivatives *(3)* are oxidized to carbodiimides very efficiently by alkaline hypochlorite solution at temperatures below 0 °C, a reaction which is characterized by a wide range of applications. However, the preparation of oligomeric or high-molecular weight polycarbodiimides with more than two carbodiimide units in the molecule is beset with considerable difficulties, however, even when highly effective phase transfer catalysts are used[11].



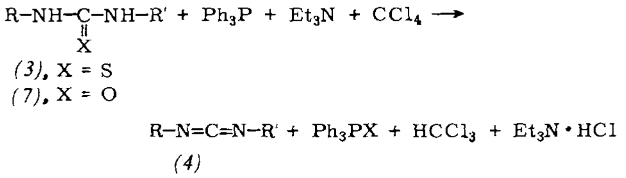
$$\underset{(3)}{\mathrm{R{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH{-}R'}} + 4\,\mathrm{NaOCl} + 2\,\mathrm{NaOH} \longrightarrow \underset{(4)}{\mathrm{R{-}N{=}C{=}N{-}R'}} + 4\,\mathrm{NaCl} + \mathrm{Na_2SO_4} + 2\,\mathrm{H_2O}$$

*Grigat* and *Pütter*[12] succeeded in obtaining high yields of carbodiimides by reacting aromatic cyanates *(5)* with *N,N'*-substituted thiourea derivatives *(1)*.



$$\underset{(5)}{\mathrm{ArylOCN}} + \underset{(1)}{\mathrm{R{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH{-}R}} \longrightarrow \left[\mathrm{ArylO{-}\underset{\underset{NH}{\|}}{C}{-}S{-}\underset{\underset{NR}{\|}}{C}{-}NHR}\right] \longrightarrow \underset{(6)}{\mathrm{ArylO\underset{\underset{S}{\|}}{C}{-}NH_2}} + \underset{(2)}{\mathrm{R{-}N{=}C{=}N{-}R}}$$

As discovered by *Appel et al.*[13], the urea derivatives *(3)* and *(7)* can react with $Ph_3P/Et_3N/CCl_4$ to give carbodiimides in yields exceeding 90%.

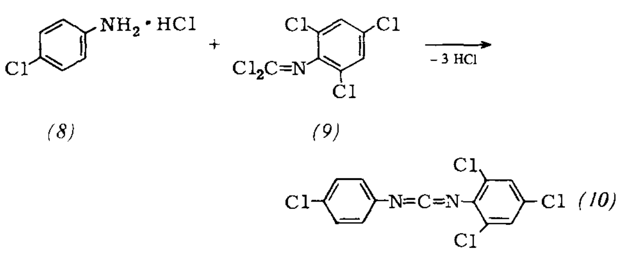


$$\mathrm{R{-}NH{-}\underset{\underset{X}{\|}}{C}{-}NH{-}R'} + \mathrm{Ph_3P} + \mathrm{Et_3N} + \mathrm{CCl_4} \longrightarrow \underset{(4)}{\mathrm{R{-}N{=}C{=}N{-}R'}} + \mathrm{Ph_3PX} + \mathrm{HCCl_3} + \mathrm{Et_3N\cdot HCl}$$

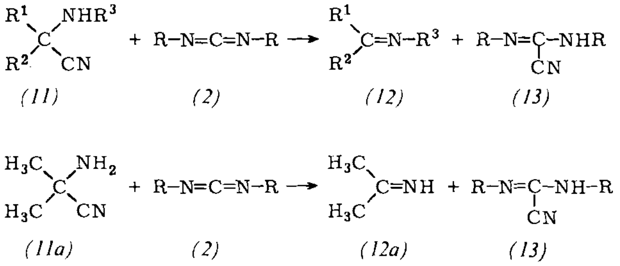
$(3)$, X = S

$(7)$, X = O

One method for the preparation of unsymmetrically substituted carbodiimides, which was subsequently developed by us, is the reaction of isocyanide dichlorides *(9)* with amine hydrochlorides *(8)* in an inert organic solvent[14].



We found that hydrocyanic acid is readily cleaved by aliphatic carbodiimides *(2)* from α-aminonitriles *(11)*[15]. In this way it is possible to obtain the hitherto unknown 2-propanimine *(12a)*, which can be removed by distillation from the simultaneously formed cyanoformamidine derivative *(13)*.



For a variety of reasons, all these methods for the preparation of low-molecular weight carbodiimides were unsuccessful when applied to the synthesis of oligomeric or polymeric polycarbodiimides.

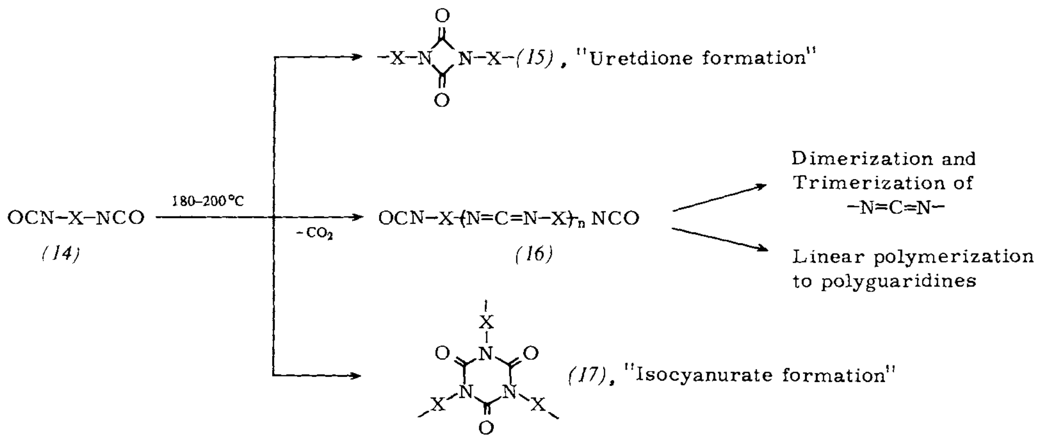
A special study of problems relating to the diisocyanate polyaddition process and an intensive investigation of the side-reactions involved in the preparation of polycarbodiimides from diisocyanates resulted in the development of thermal condensation processes by means of which only low-molecular weight polycarbodiimides with unidentified terminal groups, together with insoluble by-products, were initially obtained.

## 2. Improvements in the Synthesis of Oligomeric α,ω-Diisocyanatocarbodiimides and -Polycarbodiimides

In connection with the diisocyanate polyaddition process, which was devised by *Otto Bayer* in 1937 and subsequently developed by his colleagues[16,17], questions were soon raised about the storage stability of diisocyanatocarbodiimides—questions were even raised concerning their ability to exist at all—as well as about the nature of the side reactions involved in the production of polyisocyanates.

Polyurethane chemistry, the foundations of which were laid by *O. Bayer et al.* more than forty years ago, has since acquired great technical importance throughout the world, polyurethanes now being among the most versatile of plastics. The low-molecular weight and oligomeric building blocks which participate in the diisocyanate polyaddition process form a large group of interesting functional or heterofunctional compounds. *O. Bayer* himself[18] was already interested to ascertain whether isocyanatocarbodiimides could be synthesized and in what manner diisocyanatocarbodiimides, *i.e.* compounds having three cumulative double bond systems in the molecule, can be stabilized by means of cycloaddition processes to form interesting new monomers with heterofunctional groups having different degrees of reactivity. Initially it appeared quite impossible to predict whether a diisocyanate polycondensation process could produce high-molecular weight α,ω-diisocyanatopolycarbodiimides.

It was discovered that monomeric α,ω-diisocyanatocarbodiimides and polymer homologous series of α,ω-diisocyanatopolycarbodiimides could not be formed by thermal condensation of diisocyanates in the presence of highly basic catalysts. The $OH^{\ominus}$-catalyzed reaction leads, *via* the uretedione derivatives *(15)*, to the isocyanurate derivatives *(17)* and to derivatives of *(16)* (Scheme 1).

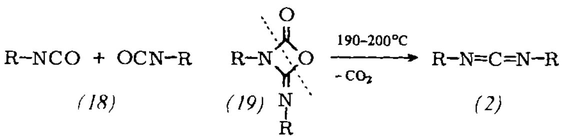


Scheme 1. Side reactions in the production of polyisocyanates; X = aryl, alkyl, or cycloalkyl.

Polyisocyanates are metastable systems having high energy contents; they are only stable and capable of being handled on an industrial scale because the formation of systems *(15)*–*(17)* requires a relatively large amount of activation energy (15–25 kcal/mol[19]).

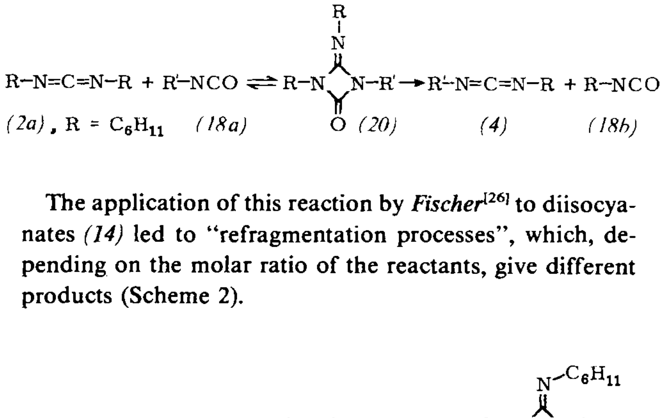
In the absence of diluting agents and in the presence of highly basic catalysts, cross-linked polyisocyanurates (cf. *(17)*) are formed at temperatures between 40 and 210 °C as a result of exothermic reactions which are often violent and in which the NCO groups are trimerized.

One of the best models for the mechanism of purely thermal "high temperature carbodiimidization" was proposed by *Staudinger*[20] in the course of his fundamental work on ketenes[21]. A similar mechanism was postulated independently in 1955 by *Gaylord* and *Snyder*[22]. The symmetrical constitution *(15)* proposed by *Staudinger*[21] for crystalline 1,3-diazetidine-2,4-dione derivatives ("uretediones") was confirmed by X-ray crystallographic analyses performed by *Brown*[23] in 1955. According to *Staudinger*, molten uretediones and liquid monoisocyanates are present, to a small extent, as asymmetrical four-membered ring systems *(19)* at high temperatures; their fragmentation results in the formation of the carbodiimides *(2)*.

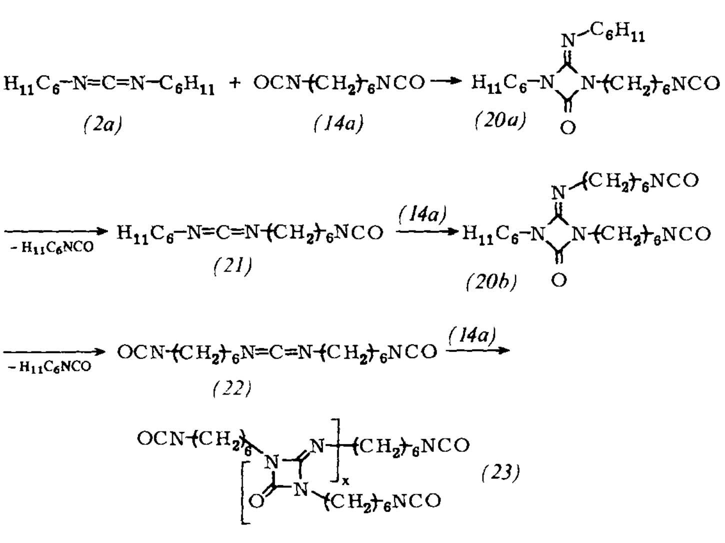


In the course of kinetic investigations we found that the exclusively thermal high-temperature carbodiimidization (at 180–195 °C) of industrially available aliphatic diisocyanates is an extremely slow and entirely unpromising method for the production of low-molecular weight isocyanatocarbodiimides. In the case of hexamethylene diisocyanate, for example, even temperatures of 180–195 °C for 20 h only result in the formation of *ca.* 4–6% of oligomeric isocyanatocarbodiimides. Isocyanatopolyisocyanurates are formed in such reactions, the yield being 18–20%[24].

4-Cyclohexylimino-1,3-diazetidin-2-one-derivatives ("uretonimines") *(20)*, which represent an interesting family of four-membered ring heterocyclic compounds, were first synthesized in the years 1955–1957 by *Hoffmann, Reichle*, and *Moosmüller* in Dormagen, and by *E. Schmidt*[25] in München, from carbodiimides such as *(2a)* and isocyanates such as *(18a)*. *(20)* is formed in an equilibrium reaction which is highly dependent on temperature. This makes it possible[12,13]—when use is made of a mono-isocyanate R′NCO whose boiling point is higher than that of RNCO—for the uretonimine *(20)* to be fragmented in a reversed manner to its formation, provided that RNCO is removed from the reaction mixture by distillation.



The application of this reaction by *Fischer*[26] to diisocyanates *(14)* led to "refragmentation processes", which, depending on the molar ratio of the reactants, give different products (Scheme 2).

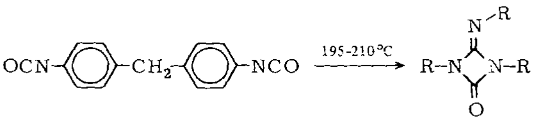


Scheme 2.

The products obtained in this way included polymer-homologous series of uretonimine polyisocyanates *(23)* of hexamethylene diisocyanate *(26)*; they were produced in several addition-elimination steps from *(2a)* and *(14a) via* the uretonimines *(20a)* and *(20b)*, cyclohexyl isocyanate being removed continuously by distillation.

Recent investigations by modern analytical methods, such as gel chromatography, show that, as expected from the laws of *Flory* and *Schultz*, polymolecular mixtures are always obtained. If a large excess of *(14a)* is used the monomeric uretonimine *(23a)*, x = 1, is obtained in the polymer homologous series of the polyuretonimine polyisocyanates at concentrations of up to 60 mol %.

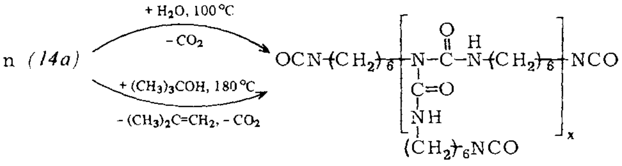
High temperature carbodiimide formation from 4,4′-diisocyanatodiphenylmethane *(14b)* was performed successfully for the first time in 1959, special catalysts being used and solutions of the uretonimine triisocyanate *(24)* being obtained[27,28].



*(14b)* *(24)*, R = $C_6H_4CH_2C_6H_4NCO$

*(24)* is formed in a thermally reversible equilibrium reaction during the cooling phase, through addition of the isocyanate group to the already formed α,ω-diisocyanatocarbodiimide.

Polymer-homologous series of polyisocyanates with the biuret structure *(25)* (Desmodur N, Bayer AG), whose synthesis mechanisms are given in Scheme 3[29–31], are particularly useful non-basic catalysts in the high temperature formation of carbodiimides[28] for the liquefaction of 4,4′-diisocyanatodiphenylmethane.



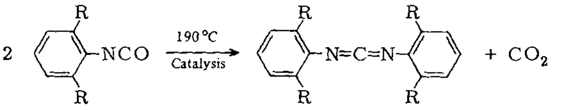
*(25)*, x = 1–6

Scheme 3.

The *in situ* production of the catalysts from aliphatic, cycloaliphatic, or aromatic polyisocyanates can be achieved by adding small amounts of water, *tert*-butyl alcohol, or mono- or diamines.

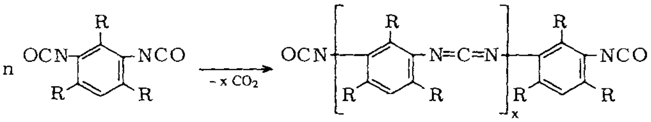
The isocyanatocarbodiimides and polyisocyanatouretonimine synthesized by high temperature carbodiimide formation are, however, contaminated by by-products (isocyanatopolyisocyanourates, isocyanatouretediones), the amounts of which depend largely on the reaction temperature.

Later *Neumann* and *Fischer*[32], using the technique of $OH^{\ominus}$-catalyzed thermal condensation, were also able to synthesize monomeric and oligomeric α,ω-diisocyanatocarbodiimides from mono- and diisocyanates with high degrees of steric hindrance, in a way which excluded side reactions.



*(26)* *(27)*

R = $CH_3$, $C_2H_5$, $CH(CH_3)_2$



*(28)* *(29)*

The bulky isopropyl moieties prevent quantitative formation of uretedione, uretonimine, and polyisocyanurate, as well as the uretonimine cross-linking of the oligomeric diisocyanatopolycarbodiimides formed during the process.

The degrees of polymerization obtainable by this method are, however, low. The oligomeric α,ω-diisocyanatopolycarbodiimides obtained are typical aligomers with mean molecular weights of less than 2000.

A "low temperature polycarbodiimidization" at *ca.* 0—60 °C, in which linear polymers with ten to one hundred —N=C=N-units are obtained, remained impossible until the 1960's.

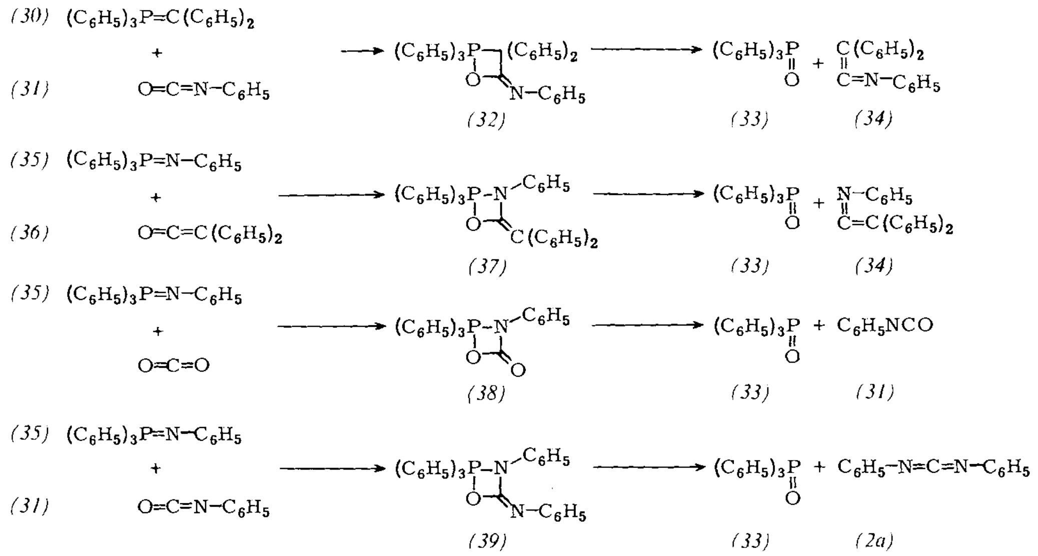
## 3. Catalytic "Low Temperature Carbodiimidization" of Mono- and Polyisocyanates

More than 60 years ago *Staudinger et al.*[33–37] working in Zürich found two important classes of compounds; the substituted phosphorus ylides and the phosphane imides, *e.g.* *(30)* and *(35)* respectively, both of which are characterized by high reactivity towards, *e.g.*, phenyl isocyanate *(31)*.

*(30)* and *(35)* react with reagents containing cumulative double bonds to form four-membered ring heterocyclic compounds (Scheme 4). When heated, these compounds decompose in a manner opposite to that of their formation (a process referred to as "refragmentation"), the decomposition products being the diphenylketenimine derivative *(34)*, the phenyl isocyanate *(31)*, and the diphenylcarbodiimide *(2a)*. Phosphane imides and phosphane oxides play a fundamental part as catalysts in carbodiimidization reactions.

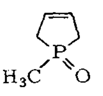
Addition of carbon dioxide to *(35)* to form the heterocyclic compound *(38)* and the fragmentation of the latter to triphenylphosphane oxide and phenyl isocyanate reflect the high energy content of phosphane imide derivatives and the affinity of phosphorus for the oxygen. This is also the key to understanding the four-membered ring mechanism of carbodiimide formation.

"Low temperature polycarbodiimidization" and the formation of polyuretonimines, starting from diisocyanates, were developed in the years following 1959 after *Campbell et al.*[38,39] of DuPont, and *Schliebs* and *Block* of Bayer had synthesized phospholene oxides, which proved highly active as catalysts for the formation of polycarbodiimides.

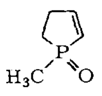


Scheme 4.

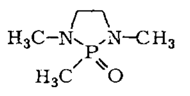
*Schliebs* and *Block* optimized the process by which the isomer mixture was obtained from the 1-methyl substituted phospholene oxides *(40)* and *(41)*, a mixture which was



*(40)*



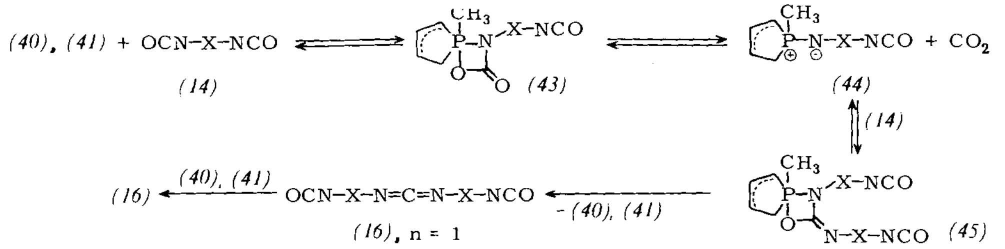
*(41)*



*(42)*

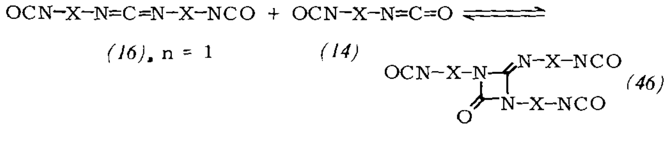
found to be the most effective catalyst of the carbodiimidization in our studies. But the diazophospholidine oxide *(42)*, synthesized by *Däbritz* and *Herlinger*[40], is also an efficient catalyst at temperatures of 60 °C and above.

The mechanism of the polycarbodiimidization, as catalyzed by the mixture of *(40)* and *(41)*, is in accord with the assumptions made by *Staudinger* (Scheme 5).



Scheme 5. Mechanism of formation of polycarbodiimides from diisocyanates. In *(43)*-*(45)* the double bond isomerism is represented by broken lines, X = aryl, alkyl, cycloalkyl.

The isocyanatophosphane imide *(44)*, which is capable of undergoing cycloaddition, is formed just as rapidly as the α,ω-diisocyanatocarbodiimide *(16)*, n = 1, even at temperatures in the vicinity of 0 °C, due to refragmentation.



Repetition of this reaction sequence finally leads to high-molecular weight α,ω-isocyanatopolycarbodiimides.

With aromatic polyisocyanates the polycarbodiimidization with the isomer mixture of the phospholene oxides *(40)*/*(41)* is extremely fast and occurs with continuous elimination of $CO_2$. In the absence of solvents and at a catalyst concentration of about 3% by weight it takes only a few minutes at 20—40 °C. Sterically unhindered aromatic polyisocyanates and oligomeric isocyanate prepolymers react exceptionally rapidly with active phospholene oxides to form polyisocyanatopolycarbodiimides or polyisocyanato(polyurethane)polycarbodiimides. Even when only a few ppm of these catalysts[41] were used we were able to effect the smooth partial carbodiimidization of polyisocyanates. As expected, these carbodiimide isocyanate mixtures undergo changes upon storage. The carbodiimide bands disappear from the IR spectrum, an indication that isocyanatouretonimines such as *(46)* have been formed from the carbodiimides and isocyanates in a thermally reversible equilibrium reaction. The stability of the isocyanatouretonimines in solution is high, and it is possible to deactivate the catalysts adequately with a few ppm of, *e.g.*, anhydrous HCl:

$$(40)/(41) + 2\,HCl \rightleftharpoons [(40)/(41) \cdot 2\,HCl].$$

## 4. Recent Developments

With the advent of highly active phospholene oxide catalysts it become possible for the first time to produce linear, high-molecular weight α,ω-diisocyanatopolycarbodiimides under mild conditions. In this connection we were interested both in the molecular weights obtainable and in the uniformity of the end-groups. Numerous polymer-analogous reactions of high-molecular weight polycarbodiimides appeared to us to be promising, in view of the changes which could be effected in the material properties of the high polymer products. It was also necessary to investigate problems connected with the homogeneous and heterogeneous catalyization. In view of the exceptionally rapid polycarbodiimidization of solventless aromatic polyisocyanates or of highly concentrated solutions of these compounds, we decided to initiate the polycarbodiimide formation in flexible polyurethane foams impregnated with, and swelled by, aromatic polyisocyanates, *i. e.* to perform it as a series of matrix reactions on interconnecting cell walls solvated with polyisocyanates.

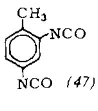
## 5. Rates of Formation of α,ω-Diisocyanatopolycarbodiimides

The α,ω-diisocyanatocarbodiimidization and -polycarbodiimidization from 4,4′-diisocyanatodiphenylmethane *(14b)* and 2,4-diisocyanato-1-methylbenzene *(47)* in toluene occur rapidly at temperatures of 5—40 °C (Fig. 1).

$OCN\text{-}(CH_2)_6\text{-}NCO$

*(14a)*

*(14b)*



*(47)*

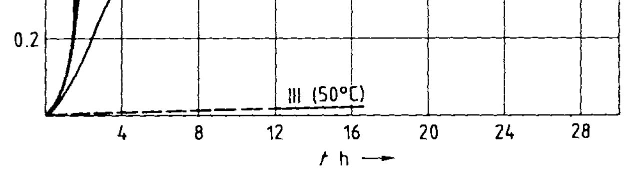


Fig. 1. Carbodiimide formation from *(14b)* (I), *(47)* (II), and *(14a)* (III); *(14b)* and *(47)* were used as 18% solutions in toluene, and *(14a)* as pure substance. The carbodiimide equivalents (calculated from the amount of $CO_2$ released) are plotted as a function of time.

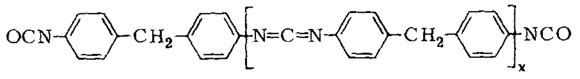
Although we are concerned here with a sterically hindered diisocyanate, the high rate of condensation of *(47)*, both at 40 °C and at 5 °C, and the small differences between the half-lives are remarkable.

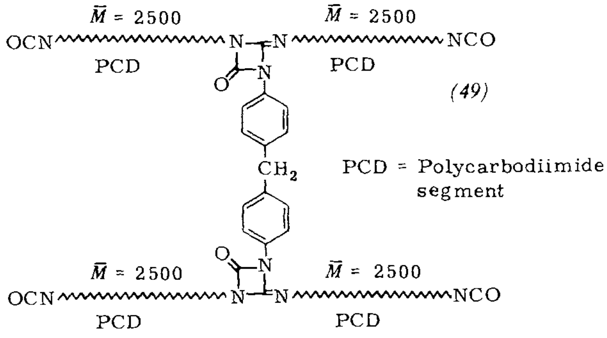
The curve plotted for hexamethylene diisocyanate *(14a)* (III) does not correspond to the actual progress of carbodiimide formation; liberated $CO_2$ reacts immediately, without evaporating, with polar resonance forms of dimeric isocyanatocarbodiimides and of the dimeric hexamethylene diisocyanate even at room temperature (cf. Section 9).

## 6. Linearity of High-Molecular Weight and Oligomeric α,ω-Diisocyanatopolycarbodiimides

In the early part of our investigations we were concerned with discovering whether the powdery polycarbodiimides from 4,4′-diisocyanatodiphenylmethane *(14b)*, which apparently have very high-molecular weights, contained isocyanate end-groups or small amounts of branching and cross-linking sites (uretonimine segments as in *(49)*, and cross-linking isocyanourate or triazine structures, which could have been formed from trimerized carbodiimide units). Since these species are insoluble in all solvents it was at first impossible to determine the average molecular weight. Free NCO groups (1.1—1.4% NCO) were identified using special titration methods. IR spectroscopic data was inconclusive. The oxygen content of 0.4—0.6% found in the elemental analysis was consistent with polymers of the structure shown in *(48)* and *(49)*.



*(48)*, x = 25-27



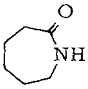
*(49)*

PCD = Polycarbodiimide segment

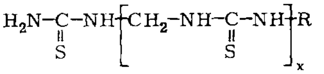
From the NCO content found in the end-group analysis, and from the relations between this content and the amount of $CO_2$ liberated in the polycarbodiimidization, and the oxygen content (high-molecular weight polycarbodiimides with $\bar{M}=25000$ contain only *ca.* 0.13% of oxygen), it was concluded that thermally stable isocyanurate structures could hardly be present in the powdery polycarbodiimides. But the presence of small amounts of cross-linking uretonimine segments could not be excluded.

Thus the highest attainable molecular weights of the white, insoluble polycarbodiimide powders from *(14b)* could only be determined by the classical methods which *Staudinger* had used to investigate the constitution of the polyoxymethylenes. In this connection we were helped by discoveries concerning insoluble polymethylenethioureas which had been made in the 1950's[42,43].

At 80 °C, ε-caprolactam *(50)* is a liquid of low viscosity which readily dissolves polymethylenethioureas of the type *(51)* and *(52)*, which had long been considered to be cross-linked and insoluble.

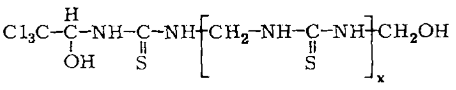


(50), m. p. = 70 °C



$$\mathrm{H_2N{-}\underset{\underset{S}{\|}}{C}{-}NH\left[CH_2{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH\right]_x R}$$

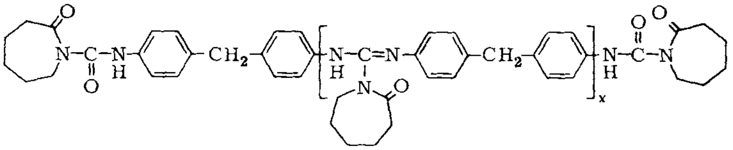
(51), R = H, CH₂OH, x = 4-12



$$\mathrm{Cl_3C{-}\underset{\underset{OH}{|}}{\overset{H}{C}}{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH\left[CH_2{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH\right]_x CH_2OH}$$

(52)

Surprisingly, we found that not only is ε-caprolactam an excellent solvent for the otherwise insoluble high-molecular weight polycarbodiimides of *(14b)*, but also that when it is heated to 120 °C (without polymerization of ε-caprolactam), the lactam in the molten material rapidly adds quantitatively to all the carbodiimide groups and to the isocyanato end-groups of the polymer molecule[44]. In the resulting polymers *(53)* the covalently bound lactam content leads to a dramatic increase (from about 0.6 to 5.7%) in the oxygen content of the powdery final product. The polyaddition product *(53)* melts at 210—214 °C, *i. e.* at a temperature *ca.* 70 °C lower than the melting point of the polycarbodiimide. The lactam ring (acylated guanidine segment), which functions as a spacer in the polymer, now renders the polyaddition product soluble in dimethylformamide or *N*-methylpyrrolidone. In this polymer-analogous conversion, chain cross-linking uretonimine segments are quantitatively eliminated by linearization reactions with ε-caprolactam. The linearized polymers can be isolated by precipitation in acetone. Very little uretonimine cross-linking takes place in carbodiimidization at room temperature, *i. e.* about 6000 segment units, at the most, are formed *per* uretonimine segment. According to *Hoffmann* and *Krömer*[45], the polymers treated with ε-caprolactam have a fairly broad molecular weight distribution and a mean molecular weight of *ca.* 11 000. The highest obtainable molecular weights of powdery α,ω-diisocyanatopolycarbodiimides of *(14b)*, with the idealized constitution respresented in *(48)*, $\bar{x}=30$, are never exceed 6000—7000. The increase in the average molecular weight to 10 000—11 000 in the reaction with ε-caprolactam is in good accord with the oxygen content.



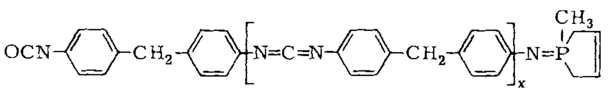
(53), x = 30

Our results on powdery polycarbodiimides can be summarized as follows. The end-groups of these polycarbodiimides are mainly α,ω-NCO groups; but the highest obtainable average molecular weights of the polycarbodiimides, which plastisize at 270 °C, are less than 6000 to 7000. The limiting factors to chain growth ("molecular weight barrier") in many of these compounds are the solvents in which they are synthesized because the solubility limits of the polymers are reached. Even after long reaction times (*e.g.* 40 h at 100—140 °C) the polymers undergo no more chain growth due to topochemical reactions of their end-groups.

## 7. Molecular Weight Jumps in the Melting of High-Molecular Weight α,ω-Diisocyanatopolycarbodiimides

At a temperature of about 180-270 °C the polycarbodiimides described in Section 6 undergo changes which are attributable to the presence of phosphane imide end-groups as impurities in the polymers[44]; structures like *(54)* (where only one phospholene isomer is represented) being present. In the processing of α,ω-diisocyanatopolycarbodiimides as thermoplastics at 270 °C, these polymeric impurities act as catalysts for the molecular weight multiplication. The polycarbodiimide/phopshane imide derivatives with relatively high molecular weights generally have an NCO-content of 1.3%, a P-content of *ca.* 0.05%, and an O-content of *ca.* 0.6%.

The phosphane imide end-groups cause pronounced molecular weight jumps when the powdery polycarbodiimides melt at 240—270 °C, in accord with the mechanism of carbodiimide formation shown in Scheme 5. The processing of these materials to transparent thermally stable linear polymers, *e.g.* as plastics and fibers is difficult because the flowability of these systems decreases continuously, while the softening points rise dramatically; not only do the chain lengths increase, but the materials also undergo cross-linking.



(54), x = 30

At high temperatures, the pronounced polymerization tendencies of the accumulated carbodiimide segments in these powdery polycarbodiimides lead to branching and cross-linking. Transparent molded sheets produced at 270 °C and 250 bar have considerably greater high-temperature bending strength than polycarbonates, but because they have high cross-link densities they have less notched impact strength.

The assumption that cross-linking reactions take place is supported by the fact that polycarbodiimide powders which are molded at 300 °C are no longer soluble in, but are merely swelled by ε-caprolactam. Addition of caprolactam to unpolymerized carbodiimide units is then very difficult.

Thus, the processing of linear α,ω-diisocyanatopolycarbodiimides with average molecular weights of 4000—8000 to produce thermoplastics with the typical characteristics of linear macromolecular materials, *e.g.* with average molecular weights of 20 000—40 000, high degrees of hardness, the ability to cobweb in the molten state, and low brittleness, is prevented by cross-linking polymerization of the numerous carbodiimide groups of the polymer at high temperatures.

The experience gained in connection with polymer-analogous reactions involving ε-caprolactam led us to prepare other polycarbodiimides and mixed condensates with particularly high degrees of thermal stability, *e.g.* mixed condensates from *p*-phenylene diisocyanate and 1,5-naphthylene diisocyanate with softening points of approximately 300 °C. The average molecular weights of these α,ω-diisocyanato mixed polycarbodiimides are very greatly reduced because polymers with three to six carbodiimide units reach their solubility limits in inert solvents, with the result that they do not undergo further condensation. In contrast, ternary mixed carbodiimides from 2,4-diisocyanato-1-methylbenzene *(47)* and the aforementioned aromatic diisocyanates in the ratio 1 : 1 : 1 can acquire average molecular weights of up to *ca.* 3500.

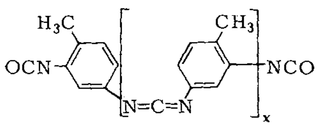
α,ω-Diisocyanato mixed polycarbodiimides can be made elastic with α,ω-diisocyanato polyether—or polyester—urethanes (NCO-prepolymers) and their softening points can be greatly reduced. In aromatic solvent mixtures and isopropanol the chains of polymers containing α,ω-diisocyanatopolyurethane or polyurea groups and having three to four carbodiimide units can be extended with sterically hindered diamines without premature addition of the diamines to the carbodiimide groups, with the result that useful film-forming agents of high-molecular weight are obtained[46].

## 8. Condensation and Polycondensation of 2,4-Diisocyanato-1-methylbenzene in Toluene or Hexane/Petroleum Ether

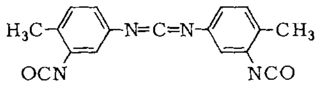
Polymer-homologous compounds of oligomeric α,ω-diisocyanatopolycarbodiimides from 2,4-diisocyanato-1-methylbenzene *(47)*, which are formed at room temperature using phospholene oxides as catalysts, are readily soluble in many chlorinated and aromatic hydrocarbons because of the considerable reduction in mutual association of the chain molecules within certain molecular weight limits. We were also able to show that in such cases the molecular weight is controlled by the solvent. The highest obtainable molecular weight compatible with linearity, which is less than 8000, was determined as described in Section 6; the polymers may be considered to have the constitution given in *(55)*. Using such precipitating agents as cyclohexane and petroleum ether/hexane, we were able to prepare a homologous series of carbodiimides from *(47)*, beginning with the bis(3-isocyanato-4-methylphenyl)carbodiimide *(56)*, using the techniques of fractionating condensation and polycondensation.

These compounds and their addition products to polyethers or polyesters with terminal hydroxy groups, *i.e.* their NCO-containing prepolymers, are useful building blocks in the diisocyanate polyaddition process.

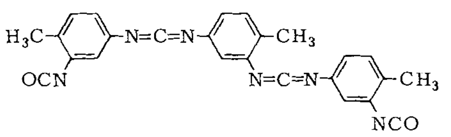
Despite their molecular non-uniformity these polymers are strictly bifunctional; they can be added to all the components used in the diisocyanate polyaddition process by means of selective NCO reactions. Since these powdery products contain 200—400 ppm of phosphane imide end-groups, *i.e.* highly active catalysts, it is necessary to stabilize them with a few ppm of HCl, $BF_3$, or benzoyl chloride.



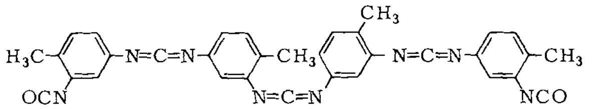
*(55)*



*(56)*, $M$ = 304, % NCO = 27.7



*(57)*, $M$ = 434, % NCO = 19.3



*(58)*, $M$ = 564, % NCO = 14.9

Because the α,ω-diisocyanatocarbodiimides *(56)—(58)* are adequately to freely soluble in many solvents, they have been used for a large number of polymer-analogous reactions[47—52].

These reactions give many interesting polyaddition products with polyurea-, polyisourea-, polyisothiourea-, polyformamidine-, polyacylurea-, polyguanidine-, polyphosphonoformamidine-, and polycyanoformamidine-segments (Table 1).

In this way—through the use of ppm amounts of bases—even such carboxylic acids as acrylic acid and methacrylic acid can readily be added (e in Table 1), without substantial anhydride formation; the polyaddition products obtained being easily polymerizable. Route i in Table 1 leads to *N*-alkoxysilylmethyl-*N*-alkylamino-substituted polyguanidines, which are among the most reactive of those polyaddition products which cross-link *via* siloxane bridges in the presence of atmospheric moisture.

## 9. Possible Errors in the Interpretation of the Reaction Curve for Low-Temperature Polycarbodiimidization of Hexamethylene Diisocyanate

Whereas, we originally thought that only aromatic diisocyanates react at room temperature to form carbodiimides, we later discovered using hexamethylene diisocyanate *(14a)* that this assumption was based on the incorrect interpretation of the respectively determined $CO_2$ balances[53]. Since $CO_2$ was not formed in the phospholene oxide catalyzed reaction of *(14a)* at room temperature, and the characteristic carbodiimide and uretonimine bands were not present in the IR spectra, condensation had not occurred. From the results of NCO-titrations performed at definite time intervals, gel chromatography, and IR spectroscopic investigations of the reaction products, it is clear that ure-

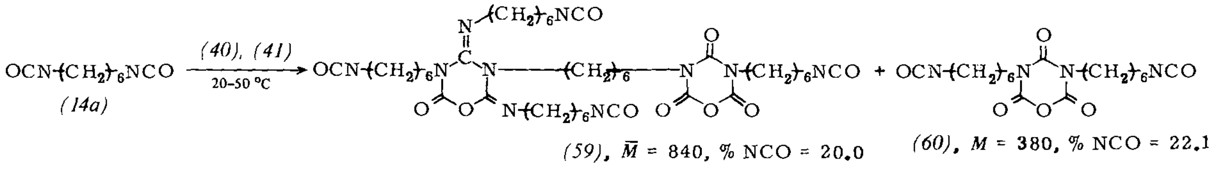
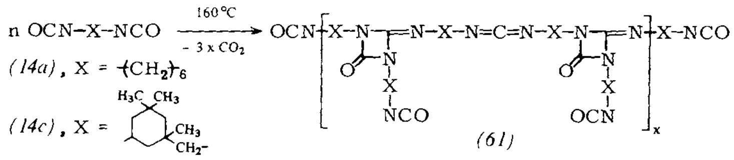
tonimine or carbodiimide units are not found even at room temperature, because the $CO_2$ produced cycloadds immediately after its formation to dimeric, polar intermediates of biscarbodiimides and diisocyanates, leading to compounds with the idealized constitutions given in *(59)* and *(60)*.



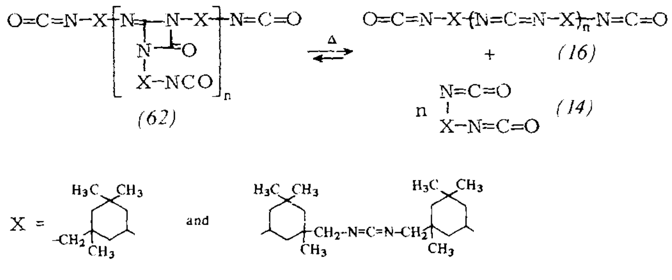
*(59)*, $\bar{M}$ = 840, % NCO = 20.0 *(60)*, *M* = 380, % NCO = 22.1

At temperatures up to 80 °C phospholene oxide derivatives are therefore not selective catalysts of the carbodiimidization; instead they catalyze the oxadiazinetrione ring formation and also the trimerization, thus behaving like phosphane derivatives. The curve reproduced in Figure 1 is therefore misleading with respect to the rate of carbodiimide formation of hexamethylene diisocyanate.

At 150—160 °C, however, even aliphatic polyisocyanates, such as *(14a)* and 3-isocyanatomethyl-3,5,5-trimethylcyclohexyl isocyanate *(14c)* (isophorone diisocyanate) react in the presence of phospholene oxide derivatives to form mainly polycarbodiimides *(61)* with the polycarbodiimide-polyuretonimine structure. Provided that a large excess of monomeric diisocyanate is avoided, these polymers participate in the formation of three-dimensional cross-links, accompanied by uretoneimine formation as



the temperature falls, but, however, readily form polyisocyanates again if the temperature is raised. These systems represent masked polyisocyanates which can be used together with polymerization, polyaddition, and polycondensation products containing Zerewitinoff-active hydrogen for many cross-linking reactions at elevated temperatures[54]. The advantage of these compounds, especially of polycarbodiimide-polyuretonimines from *(14c)* is that volatile decomposition products, which do not participate in the cross-linking, are not formed.



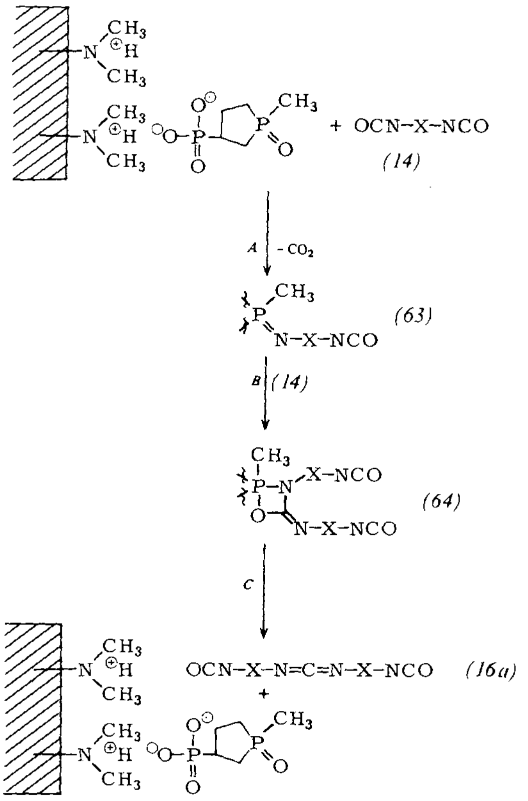
## 10. Heterogeneously Catalyzed NCO Condensations Leading to Oligomeric Isocyanatopolycarbodiimides in Swellable Matrices

With the aid of special phospholene oxide derivatives ionogenically or covalently bound to insoluble but swellable matrices, we investigated whether swellable catalysts are effective in the heteregeneous catalysis of polycarbodiimide formation and how the reaction depends on temperature[55–59]. The high-molecular weight matrix shown in Scheme 6 can be produced by salification of commerical basic ion-exchange resins with phosphonic acid derivatives of the phospholene oxides. Using this matrix those polyisocyanates, which among oligomeric technical polyisocyanates have the lowest molecular weights, can be converted without participation of trifunctional and tetrafunctional polyisocyanates of high molecular weight into isocyanatocarbodiimides provided that they reach the catalytically active anchor group in the matrix. Temperatures of 130 to 165 °C are needed for this purpose.

In the reaction step *C*, the diisocyanatocarbodiimide formed is released from the matrix and hence the high-molecular catalyst is again fully effective.

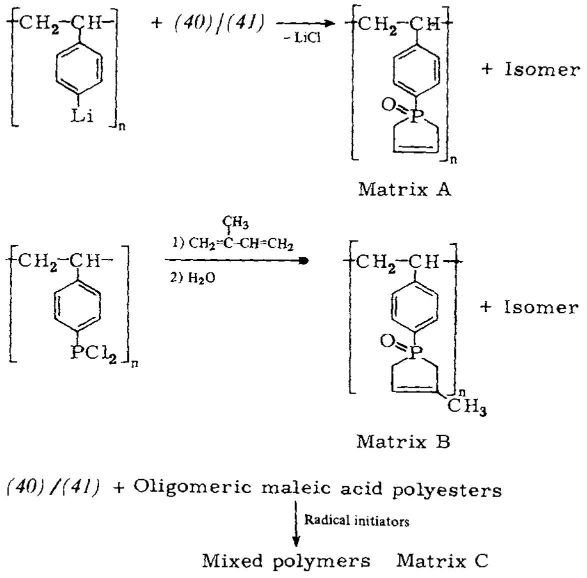
If the process is properly controlled, the oligomeric polyisocyanatocarbodiimides and polyisocyanatouretonimines obtained are completely free of phosphane imide end-groups and can, therefore, be stored.

The use of pore diameters of *ca.* 100—200 Å for the matrices and adjustable porosity, permit the selective formation of the lowest molecular weight polyisocyanatocarbodiimides. Thus, heterogeneous catalysis enables derivatives of polyisocyanate mixtures which are free of phosphane imide end-groups to be produced without loss of catalyst. Another considerable advantage to the process is that the solid catalysts can be removed from the reaction mixture at any time, and can be used again if proper care is taken.



Scheme 6.

Phospholene oxide moieties bound covalently to matrices with pores of 100—200 Å are also catalytically active. They can be produced in the ways indicated in Scheme 7, and also permit the selective formation of polyisocyanatocarbodiimides of low-molecular weight.



Scheme 7.

## 11. High-Molecular Weight Polycarbodiimides and Polyuretonimines in Swellable, Impregnated Flexible Polyurethane Foams

A review article published almost ten years ago[60] reported on growth processes caused by reactions in swellable, cellular matrices and described a universally valid cell arrangement principle which can be applied to any desired organic, cellular substrate and can be effected by any type of organic or inorganic chemical reaction, provided that the reactants exert a sufficient swelling action on the matrices employed. The physical swelling pressure and its irreversible fixation by cellular solid formation were recognized as the driving forces responsible for the observed growth phenomena[61-66].

Results gained so far, indicate that matrix reactions are potentially useful when reactive swelling agents with high energy contents are employed. The essential condition for rapid and irreversible fixation of the state of swelling is that the swelling agents must be able to react very rapidly to form solids in the absence of solvents. For example, since they have high energy contents, flexible polyurethane foam matrices swollen with liquid polyisocyanates, but when previously charged with catalytical amounts of phospholene oxides, need no further energy input to be converted from the cellular, swollen state into a cellular, three-dimensional, and entirely symmetrical solid because of rapid polycarbodiimide formation.

This process gives interesting open-celled, carbonized combination-rigid foams, which show enhanced flame resistance. The interconnecting cell walls of the matrix are considerably stretched by the cellular solid arrangement of the high-molecular weight polycarbodiimides and these forms are fixed irreversibly. It is not until the elongations have acquired the maximum, irreversible degree of fixation that the surfaces of the interconnecting cell walls become—to an increasing extent—the site of the reaction.

A cellular solid arrangement of polyisocyanatopolycarbodiimides arises when the polyurethane matrix is charged with phospholene oxides and then impregnated with any, although preferably aromatic, polyisocyanates and oligomeric and elastifying isocyanate prepolymers of hydroxy-terminated polyethers or polyesters; in this way it is possible to produce rigid or semi-rigid combination-foams whose cells are entirely open and which have carbonization properties and enhanced flame resistance.

## 12. Industrial Applications of Polycarbodiimides, α,ω-Diisocyanatomono-, -Polycarbodiimides, and their Derivatives, and of Polyuretonimines

Through the use of special associates prepared from phospholene oxides and monoalcohols or polyalcohols[67] it has been possible to overcome all the technical difficulties involved in the production of highly cross-linked polycarbodiimide foams with extremely low densities, good high-temperature bending strength, and high degrees of flame resistance. For this purpose it was necessary to specifically increase the stirring, waiting, and rising times of the systems, together with sufficiently short setting times, by systematic variation of the catalyst associates.

The industrial applications of isocyanatocarbodiimides, polycarbodiimides, and uretonimines cover a wide range. This includes anti-hydrolysis agents for polyester-polyurethane plastics and chain extending and cross-linking agents for the diisocyanate polyaddition process. Many of the isocyanato polymers and derivatives described above are interesting diisocyanate liquefiers, reactive fillers, light-fast raw materials for electrostatic powder spraying processes[54], pigment binders, thixotropic agents, starting materials for the manufacture of film[46], coatings[47], or micro-encapsulation devices[68,69], as well as for catalysts used in isocyanate chemistry.

## 13. Conclusion

The chemistry of isocyanates is characterized by the enormous variety of the building blocks that can be used for polyaddition; it can be combined with ring cleavage polymerization and copolymerization processes, and with grafting reactions involving a very wide range of vinyl monomers. In addition, the formation of polycarbodiimides and mixed polycarbodiimides provides a variable polycondensation structural principle; a characteristic of this type of polycondensation is its high rate relative to that of familiar polycondensation processes.

The possibilities of simple *in situ* production of α,ω-isocyanatopolycarbodiimides in monomeric vinyl compounds, together with the ease with which the polymerizable acrylic or methacrylic acid can be added to carbodiimide groups[70,71] to form acylated urea segments, makes interesting polymerizable and graftable polymer combinations feasible.

Owing to the great variability of the diisocyanate polyaddition and diisocyanate polycondensation processes used to produce polycarbodiimides, together with the opportunities for combining these processes with methods involving polymer-analogous reactions on polycarbodiimides, ring cleavage polymerization, copolymerization processes, and with grafting reactions involving many vinyl monomers, solutions to problems encountered in numerous industrially interesting fields of macromolecular chemistry, especially those of polymer blends and multiphase plastics, may be expected.

# Analysis of Low Molecular Weight Homologues of Fiber-Forming Polycondensates[**]

By V. Rossbach[*]

*Dedicated to Professor Helmut Zahn on the occasion of his 65th birthday*

Oligomers belong to the gray area between low molecular weight chemistry and macromolecular chemistry. Although they represent an undesirable "natural impurity" in fiber-forming polycondensates, they serve as useful model compounds for the corresponding polymers in fundamental research. Whereas for many years new classes of oligomers were being made preparatively accessible and the isolation of higher oligomers in pure form was being pursued, at the present time the emphasis is on analysis. By a combination of classical chemical and instrumental methods of analysis from polymer and organic chemistry, the identification of oligomers of unknown structure, the analytical control of their synthesis and the determination of their content in technical polymers has meanwhile become a routine task.

## 1. Introduction

Apart from in a few special processes, the technical synthesis of polymers does not only yield macromolecules. On the contrary, plastics, fibers, varnishes and adhesives often contain low molecular weight precursors of the polymer as "natural impurities". They have the same structure as the corresponding polymer molecules, only the number of repeat units from which they are constructed is smaller. *Van der Want* and *Stavermann*[1] introduced the term "oligomers" for these short-chain homologues of the polymer. *Kern*[2] later narrowed the concept of oligomers to be those low molecular weight polymer homologues which differ sufficiently in their properties so that they can be separated into individual chemical species. This definition is now accepted. Nowadays an oligomer is understood as being a "chemically pure" substance, whereas with a polymer it is tacitly assumed that it can consist of polymer chains of various lengths and frequently also contains oligomer molecules.

In accordance with this definition of oligomers, their classification depends on the efficiency of the methods of separation used. Thus a polystyrene with 38 repeat units, which can be separated chromatographically from its neighboring polymer homologues[3a], would be classified as an oligomer. In the case of the fiber-forming polycondensates (cf. Fig. 1) one would have to speak of polymers at much lower n-values (degree of oligomerization or polymerization), for here the lower polymer homologues with molecular masses of 1000 to 2000 g/mol can no longer be separated. In view of this, the definition by *Zahn* and *Gleitsmann*[3b] appears less ambiguous. They define oligomers as those molecularly uniform initial members of polymer-homologue series which do not yet have the typical physical structure (secondary and tertiary structure) of the particular polymer. The higher members, for which this definition no longer suffices, although they may be prepared in a pure form, can be termed pleionomers. In spite of these various definitions, in this publication oligomers are to be understood quite generally as the lower polymer homologues.

As a result of studies by *Zahn* and his group, considerable experimental material about the oligomers of the fiber-

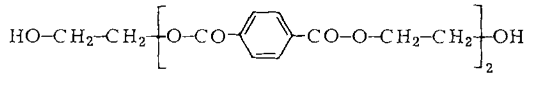
forming polycondensates is available. In the course of three decades, it has been possible to achieve the preparative isolation of the various oligomer classes and to spur on the preparation of pure samples of the higher oligomers[4-8]. In recent times however, the emphasis has shifted towards analysis of these oligomers.

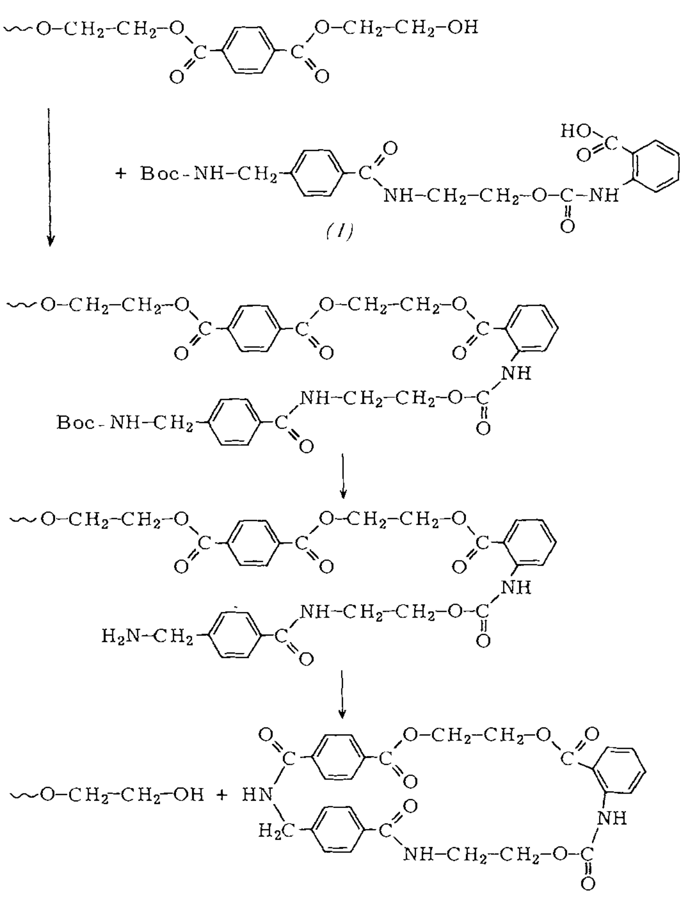
## 2. Importance of Analysis

Analysis of oligomers from fiber-forming polycondensates is, for various reasons, of great scientific and technical significance. Lower polymer homologues serve as model compounds for the elucidation of important textile and polymer properties, such as dyeability, viscosity and melting characteristics[3b,9] as well as secondary and tertiary structure[10] and thermal stability[11]. Furthermore, oligomers are used to calibrate methods of investigation used in polymer chemistry, *e.g.*, as internal standards for gel permeation chromatography[12a] or in the calibration of end-group determinations with polyesters[12b] and polyamides[12c].

Oligomers have also proved to be useful tools for macromolecular chemistry in the development of new analytical procedures. Thus it was possible to show, using the dimeric diol of ethylene terephthalate



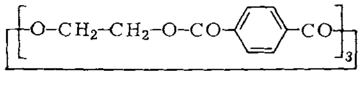
that the reagent *(1)*, m.p. = 181 °C, is suitable for the sequential degradation (and therefore for sequential analysis) of copolyesters containing ethylene terephthalate units[13].



The method for the sequential degradation of ethylene terephthalate oligomers and polymers—binding of the reagent to the hydroxy end groups, cleavage of the Boc protective groups (Boc = *tert*-butyloxycarbonyl), thermal ester aminolysis with ring closure—corresponds to the Edman degradation[14] used in protein chemistry, in that a ring compound (m.p. = 146 °C) is formed which contains the terminal monomer unit. The latter can thus be identified and determined quantitatively. Furthermore, a new hydroxy end group is formed, to which the reagent can again bind. The degradation can thus be repeated. Before this method (the first to allow chemical sequencing of copolyesters) can be used to give satisfactory and complete analyses of products with unknown composition a number of tasks still have to be completed, such as the preparation of molecularly uniform fractions and degradation studies on the corresponding cooligoesters.

It is obvious that, in order to act as model or calibration compounds, oligomers have to be absolutely pure, *i.e.* molecularly homogeneous, which can only be ascertained by efficient analytical methods. Often the task in hand is namely to study changes in certain parameters as a function of chain length.

However, the importance of analysis of oligomers from fiber-forming polycondensates is not confined to producing well-characterized model and calibration compounds for textile and polymer chemistry. On the contrary, the determination of the low molecular weight polymer homologues is important in itself. Thus, for example, by analytical separation of the cyclic oligomers in polyethylene terephthalate[15a], polybutylene terephthalate[15b], polypropylene terephthalate[15b], polyamide 6[16], polyamide 11[17a], and polyamide 12[17] it was possible to come closer to an elucidation of the relationship between the chain conformation of the polymer and its tendency to form cyclic oligomers. There is an increasing tendency to use oligomer analysis in applied problems *e.g.* the clarification of faults in materials. A disproportionately large content of linear oligomers in polyethylene terephthalate is an indication that the material has been subjected to hydrolytic damage[18] and the content of cyclic trimer *(2)* is actually a criterion of quality for polyethylene terephthalate. On account of its low solubility in water the cyclic trimer *(2)* causes difficulties during the processing and finishing of polyethylene terephthalate fibers. During cooling of dye-baths used in high-temperature dyeing, the oligomer *(2)* crystallizes out in the water and on the fiber[19]. The crystalline, sharp-edged deposits which are thereby formed on the fiber surface (cf. Fig. 2) can damage guide rollers during further processing of the fibers. In addition, oligomer crystals which collect on rollers can discharge onto the material and lower its quality.



*(2)*

Although it has been accepted, with resignation, that one "has to live with oligomers"[20], it has recently been shown possible to suppress oligomer formation in polyethylene terephthalate[21] or to remove oligomers once formed[22].

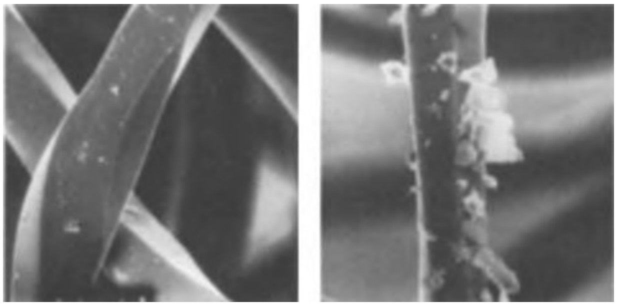


Fig. 2. Surface of a polyethylene terephthalate fiber before dyeing (left) and after dyeing, with considerable oligomer deposition (right) (SEM micrograph from Dr. *P. Kusch*, magnification 450 × ).

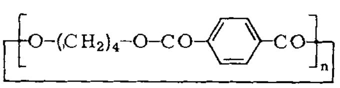
In the case of the other currently important fibrous polymers of the polycondensate type (cf. Fig. 1), oligomers present no very great problems during processing and finishing, since they all exhibit good solubility in water. This is also true for the cyclic oligomers of polybutylene terephthalate, which, surprisingly, are about 3 to 5 times more soluble in water than the sparingly soluble polyethylene terephthalate oligomers[23].



n = 2-5

The (readily soluble) oligomers from fiber-forming aliphatic polyamides can, however, give rise to dust formation if they are present in large quantities in the fiber polymer[24]. In the case of aromatic polyamides such as poly(*p*-phenylene terephthalamide) (Kevlar), oligomer analysis has no direct practical importance since, on account of the manufacturing process used, the commercially available fiber polymers contain no oligomers[25].

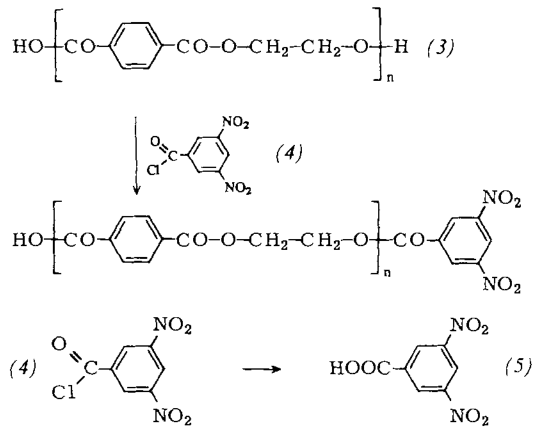
In spite of the great importance which oligomers have as model compounds, calibration compounds, and (undesirable) low molecular weight by-products in fiber-forming polyesters and polyamides, it cannot be overlooked that since about 1970 the number of publications on oligomer preparation has declined steadily. This tendency arises from the fact that in the last decade hardly any new polymers have achieved commercial importance, and the activities of the producers have therefore been concentrated on modifying the polymers already available and optimizing the processing procedures or developing new ones. Parallel to this development in the polymer field, interest in new classes of oligomers is also declining. This development is regrettable in as much as analytical methods are now available which allow even very complicated molecules to be identified and complex oligomer mixtures to be separated. In contrast to this declining activity in the preparative field, there have been numerous publications either touching on, or dealing with, the analytical aspects of oligomer chemistry. However, these are almost entirely restricted to the already well-known oligomer classes[11,15-22,24,26-37].

## 3. Special Aspects of Oligomer Analysis

As polymer homologues with a low degree of polymerization, oligomers occupy a place between monomers and polymers. They are thus, according to a definition of *Lehn et al.*[38], to be classified as "mesomolecules" *i.e.*, they belong neither to the "micromolecules" of organic chemistry (molecular mass $<500$ g/mol), nor to the macromolecules of polymer chemistry and biochemistry (molecular mass $>5000$ g/mol). This special position occupied by the oligomers also holds for their analysis: in many cases they cannot be characterized either by the methods of organic or of macromolecular chemistry.

This may be illustrated by two examples. In organic chemistry, a standard method for the separation of complicated mixtures is gas chromatography. Since, like polymers, oligomers (especially the higher ones) cannot be vaporized without decomposition, this important analytical principle generally cannot be applied to oligomer analysis. Gas chromatography can only be used—as with the corresponding polymer—to analyze monomer units. For example, after trifluoroacetylation of the *N,N'*-diaryldiamines from oligo- and polyamides[39] and trimethylsilylation of ω-amino acids[40] they can be separated and identified, using gas chromatography. The methods of organic chemistry can only be used after the poly- and oligoamides have been converted by hydrolysis into micromolecules.

Similarly, the methods of polymer analysis are also generally not applicable to oligomers. This can be illustrated by an example from polyester analysis. A simple and reliable method for determining the hydroxy end groups in polyethylene terephthalate *(3)* is to react them with an excess of 3,5-dinitrobenzoyl chloride *(4)*, followed by hydrolysis of the excess reagent with pyridine/water to 3,5-dinitrobenzoic acid *(5)*, which is then determined potentiometrically[41].



Before the titration the polymer has to be precipitated from the analysis solution with acetone/water. Otherwise the carboxy end-groups of the polymer would also be titrated, thus leading to erroneous values for the hydroxy end group content. This procedure can only be used with considerable reservations for the oligoesters, since they have different solubility characteristics. In addition, the solubility of the individual members differs considerably, as shown in Table 1 for the dicarboxylic acid dimethyl esters of the polyethylene terephthalate series (cf. also Fig. 3).

Whereas the lower members of this dimethyl ester series are adequately soluble in the solvent dioxane, which is

Table 1. Solubility, melting point and elemental analysis of the dicarboxylic acid dimethyl esters of the polyethylene terephthalate series [42—44]. $n$ = Number of repeat units. DMF = $N,N$-dimethylformamide, TCE = 1,1,2,2-tetrachloroethane.

| 7 | DMF | 250—252 | 62.42 | 4.32 | 62.57 | 4.40 |
| 8 | Dioxane/TCE | 251—253 | 62.43 | 4.30 | 62.22 | 4.21 |
| 9 | TCE | | 62.44 | 4.29 | 62.26 | 4.21 |
| 10 | TCE | 254—256 | 62.44 | 4.28 | 62.36 | 4.39 |

well suited to analytical purposes, the higher members are only soluble in such solvents as $N,N$-dimethylformamide and 1,1,2,2-tetrachloroethane, which for various reasons are less suitable for analytical studies. The higher solubility of the lower oligomers has often been made use of in spectroscopic investigations.

Thus, for example, the UV spectrum of the polyethylene terephthalate oligomers (in solution) was recorded long before the spectrum of polyethylene terephthalate itself[45]. It should be noted, however, that with the discovery of the various fluorinated solvents such as 1,1,1,3,3,3-hexafluoroisopropyl alcohol for polyethylene terephthalate, polyamide 6 and polyamide 6,6 as well as 2,2,2-trifluoroethanol for aliphatic polyamides, suitable solvents are now also available for the most important fiber polymers of the polycondensate type.

The chemistry of low molecular weight polymer homologues, especially their analysis, had its beginnings in peptide chemistry and analysis. *Zahn et al.*[46] described their first synthetic oligoamides as "nylon-peptides". This should not, however, obscure the fact that there are great differences between peptide analysis and oligomer analysis (including oligoamide analysis). These result from the different chemical structure of these classes of compounds. Firstly, peptides consist of *heterogeneous* amino acids, whereas the most important oligoamides and oligoesters are the lower members of the corresponding *homo*polymers (polyamide 6 and 6,6 or polyethylene terephthalate). It is true that cooligoamides are known, *e.g.*, from ε-aminohexanoic acid[*] and ω-aminoundecanoic acid[47], but they are of minor importance. Secondly, among the technically important oligomers of the polycondensate type are some in which — in contrast to peptides — the functional groups leading to chain extension are distributed between two different monomer units. Combinations of practical importance are diamine/dicarboxylic acid and diol/dicarboxylic acid. Such oligomers of the AABB type show a greater variety of structure than the oligomers (and peptides) in which the chain-extending functional groups are contained in the same monomer unit (AB type). Figure 3 illustrates this in the case of the oligomers of ethylene terephthalate.

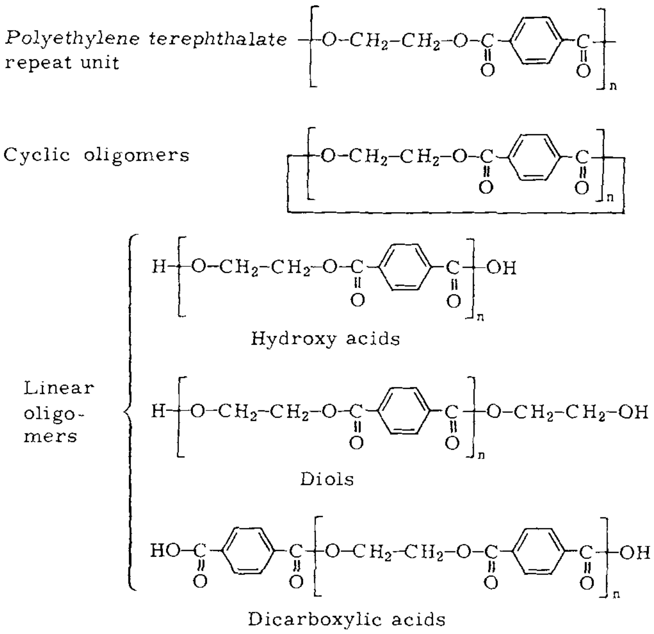

Fig. 3. Structure of the possible oligomers of ethylene terephthalate.

These characteristic differences in the structure of peptides as opposed to the technically important oligoesters and oligoamides have various consequences for their analysis.

On account of the different chemical structure of the individual amino acids, the short-chain peptides differ quite considerably from each other after every coupling step. As a consequence, their purification and the proof of purity do not present any great difficulties. In contrast to this, because of their homogeneous construction, the technically important oligoesters and oligoamides resemble each other chemically to such an extent, after a few coupling steps, that it is hardly possible to purify and separate them using simple methods (*e.g.* recrystallization). The classical criteria of purity (*e.g.* elemental analysis, melting point) also cannot be used (cf. Table 1). For cyclic oligomers this statement is true only with limitations. It is true that elemental analysis is of little value, since all homologues must give the same results, but the melting point determination gives more information, because, in contrast to the linear oligomers, the melting point does not gradually approach that of the polymer (cf. Table 1). As Table 2 shows, in the

Table 2. Melting points, elemental analyses and molecular masses (*via* mass spectroscopy) of cyclic oligomers of butylene terephthalate [23]. $n$ = Number of repeat units.

[*] IUPAC name for ε-aminocaproic acid.

case of the cyclic oligomers of polybutylene terephthalate, the melting points develop discontinuously.

Analysis of the monomer units is much more critical for peptides than for oligomers, since for complete characterization of peptides the sequence and configuration of the amino acids have to be determined in addition to the quantitative composition. In cases where the analysis of the monomer units in oligomers is based on chemical cleavage into these units, it has to be borne in mind that, in the case of the lower cyclic polymer homologues, Flory's principle of equal reactivity of functional groups[48] does not always hold. After ring formation, not only can the lower polymer homologues have a slower rate of hydrolysis compared to the polymer, as has long been known for oligoamides[49,50], but also the reverse can occur: the ester groups in the cyclic trimer of ethylene terephthalate hydrolyze in alkali 50 to 60 times faster than the ester groups in the corresponding polymer[51].

End-group analysis of oligomers with chemical reagents is simplified because, in contrast to peptides, the end-groups in any one series have chemically identical surroundings, independent of the chain length. This means that the reactivity only varies within narrow limits[4,12c].

Peptides are usually synthesized with the aim of obtaining biologically active substances. In these cases, biological activity is the most unequivocal criterion of purity. In the case of the oligomers of technically important polycondensates this aspect does not apply, since they exhibit no biological activity.

Table 3. Eluents for thin-layer chromatographic separation of oligomer mixtures.

| Oligomer Type | Eluent |
|---|---|
| Linear oligomers with free or blocked end groups and cyclic oligomers of polyamide 6- and 6,6-type | *sec*-Butyl alcohol/formic acid/water 75:15:10 ("SBA") or *sec*-butyl alcohol/10% $NH_3$ 85:15 ("SBN") |
| Higher molecular weight linear oligomers of polyamide 6,6-type | Amyl alcohol/formic acid/water 60:30:10 |

## 4. Monitoring the Course of Reaction during Oligomer Synthesis

### 4.1. Synthesis of Oligomers in Solution

Synthesis of oligomers in solution[3b,4] is the most important method for their production besides isolation from the technical polycondensate. The course of the synthesis can be followed easily and rapidly with thin-layer chromatography. A large number of eluents are available for the various oligomer series, some of them having remarkable specificity[18,25,52,53].

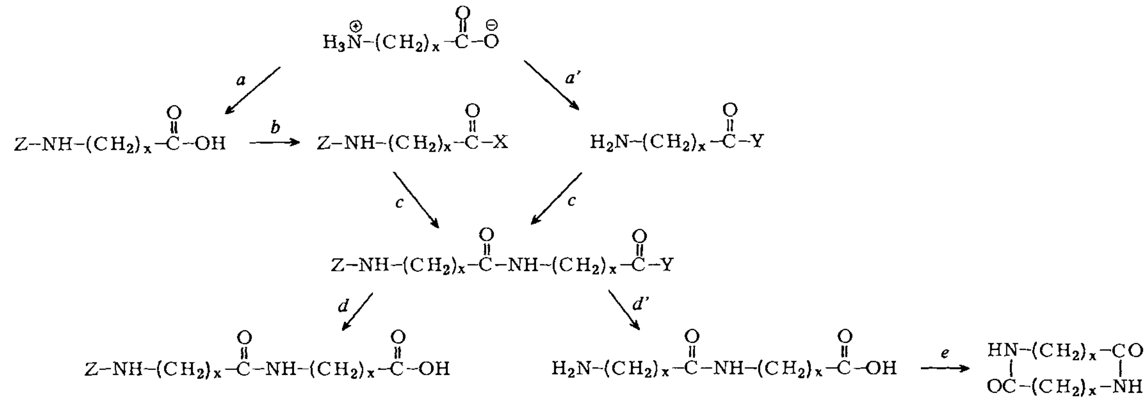

Fig. 4. General scheme for oligomer synthesis in solution, using an oligoamide of the AB type as example. *a,a'*: introduction of the protective group; *b*: activation; *c*: coupling; *d,d'*: removal of protective group; *e*: cyclization.

As Table 3 shows, sufficient eluent mixtures are available for quantitatively following all important steps of an oligomer synthesis, such as introduction of protective groups, coupling, cleavage of protective groups and, if necessary, cyclization (cf. Fig. 4).

In addition to ascending thin layer chromatography, the technique usually used, the descending method is also used for some higher molecular weight oligomers.

There are various possibilities for the detection of the compounds on thin layer chromatograms. If the oligomers contain aryl groups (*e.g.* in the oligomers of ethylene terephthalate, butylene terephthalate, *m*- and *p*-phenylene-terephthalamide), the spots can be detected by quenching of fluorescence under UV light, so long as thin layer plates with a fluorescent indicator are used. In general, the "chlorine" method of *Zahn* and *Rexroth*[54] can be used for oligoamides. If they also contain free amino groups, oligoamides can be detected by spraying with ninhydrin. It has to be remembered however, that with increasing chain length (corresponding to a decreasing amino group content) the detection becomes less sensitive. With both methods the hue and intensity of the colors obtained on the thin layer plates varies quite markedly between the individual oligoamide series.

### 4.2. Oligomer Synthesis on Polymer Carriers

Oligomer synthesis on polymer carriers[6,55] only yields pure oligomers if the reaction steps are kept under strict analytical control. If an *insoluble* carrier resin with chloromethyl groups is used, as in the classical Merrifield peptide synthesis, it is not easy to follow the course of the reaction analytically. For example, in the synthesis of ε-aminohexanoic acid oligomers the following steps (1—4) have to be checked[53].

1. Binding of the first amino acid on the resin:

$$\sim\!\!\sim CH_2{-}Cl + HOOC{-}(CH_2)_5{-}NH{-}Boc \rightarrow \sim\!\!\sim CH_2{-}O{-}CO{-}(CH_2)_5{-}NH{-}Boc$$

(Boc = *tert*-butyloxycarbonyl)

N elemental analysis and Moore-Stein analysis of the total amino-acid carrying resin can be used to follow the reaction analytically.

2. Total blocking with benzyl thioalcohol[56] of excess chloromethyl groups which have not reacted with Boc-ε-aminohexanoic acid:

$$\sim\!\!\sim CH_2{-}Cl + HS{-}CH_2{-}C_6H_5 \rightarrow \sim\!\!\sim CH_2{-}S{-}CH_2{-}C_6H_5$$

This step can be checked by an S elemental analysis.

3. Cleavage of the Boc protective group from the resin-bound ε-aminohexanoic acid with trifluoroacetic acid in $CH_2Cl_2$:

$$\sim\!\!\sim CH_2{-}O{-}CO{-}(CH_2)_5{-}NH{-}Boc \rightarrow \sim\!\!\sim CH_2{-}O{-}CO{-}(CH_2)_5{-}NH_2$$

Various methods are available for determining the resulting free amino groups. *Lee* and *Loudon*[57] recently reviewed their efficacy. In the case of controlled pore glass, the picric acid method is especially suitable. In this method, picric acid initially binds to the amino groups in stoichiometric amounts. The picrate is then cleaved with *N,N*-diisopropylethylamine and the amount of amine-picrate complex formed is determined spectrophotometrically at 358 nm.

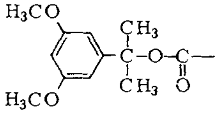
The pyridinium chloride method[58] is also useful. The amino groups bind to the chloride ions of pyridinium chloride. Washing with triethylamine removes the chloride ions, which are then determined potentiometrically.

4. Coupling of the second ε-aminohexanoic acid molecule onto the resin with *N,N'*-dicyclohexylcarbodiimide:

$$\sim\!\!\sim CH_2{-}O{-}CO{-}(CH_2)_5{-}NH_2 + HOOC{-}(CH_2)_5{-}NH{-}Boc \rightarrow \sim\!\!\sim CH_2{-}O{-}CO{-}(CH_2)_5{-}NH{-}CO{-}(CH_2)_5{-}NH{-}Boc$$

Determination of the unreacted amino groups using the methods described above gives a direct estimate of the amount of coupling.

The course of the reaction in the Merrifield synthesis is especially easy to follow if easily identifiable protective groups such as the 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl group are used.



To determine the degree of binding to the polymer, the protective group is cleaved and the carrier material washed until the filtrate shows no UV adsorption. Cleavage and washing are repeated to test completeness of reaction. The combined filtrates are then condensed and the concentration of cleaved protective groups determined by UV spectroscopy[59,60]. To the author's knowledge, this elegant technique has not yet been applied to oligomer synthesis.

Attempts to synthesize ethylene terephthalate oligomers on polymeric carriers have so far been without success[42].

## 5. Determination of Oligomer Content in Polymers

Technical fiber polymers of the polycondensate type almost all contain low molecular weight fractions, present in the individual polymers to quite different extents (Table 4).

Table 4. Content of low molecular weight fractions in some fiber polymers [3b, 23, 25, 61a] (see Fig. 1).

| Polymer | Low molecular weight fraction (wt.-%) | Extraction solvent |
|---|---|---|
| Polyamide 6 | 11—12 | Methanol |
| Polyamide 6,6 | 2.0—2.2 | Glacial acetic acid |
| Polyamide 11 | *ca.* 7 | Glacial acetic acid |
| Qiana polyamide | 2.4 | Butanol |
| Kevlar polyamide | 0 | Various solvents |
| Polyethylene terephthalate | 1.3—1.7 | Dioxane |
| Polybutylene terephthalate | 0.8—1.9 | Dichloromethane, dioxane |

These differences are not only due to the fact that during polymer synthesis the lower polymer homologues are formed in varying amounts, but rather that different technologies are used in their manufacture and processing. Thus the reason no extraction residue is obtained from technical Kevlar polyamide is to be found in the production process for the polymer, using condensation polymerization in solution and wet spinning[25,62].

The oligomers are often separated from the polymer in order to estimate them. This can take place in two ways: by extraction with a solvent for the oligomer or by reprecipitation of the polymer.

Extraction techniques are very common in oligoester and oligoamide analysis and are applied in many different ways. The solvents most often used are listed in Table 4. A special problem, common to all extraction techniques is the *complete* removal of the low molecular weight fraction. As was recently shown in the case of polyamide 6, when determining the content of extractable matter on coarse material (*e.g.* cord and granules) the extraction times are often not sufficient to completely remove the low molecular weight fraction[30]. On the other hand, in some situations it is not required to extract exhaustively. With polyethylene terephthalate it often suffices to extract and determine the surface oligomers, since only these are responsible for problems arising during textile processing and finishing (cf. Section 2). Differentiation between surface oligomer and total oligomer content can be carried out by grading the extraction conditions with respect to solvent, and time and temperature of extraction[31].

The second possibility for separating the low molecular weight fraction consists in dissolving the whole polymer sample (including the oligomers) in a suitable solvent and then precipitating the high molecular weight fraction with a precipitating agent which leaves the oligomer fraction in solution (*i.e.* fractionation). Suitable solvent/precipitant systems are *e.g.* 1,1,1,3,3,3-hexafluoroisopropyl alcohol/dioxane for polyethylene terephthalate[32], and 2,2,2-trifluoroethanol/ethanol for polyamide 6 and 6,6[63]. A problem with all such reprecipitation techniques is that, on addition of the precipitant, the coagulating polymer can occlude oligomers, making them unavailable for analysis.

There are various possibilities for quantitative determination of oligomers in extracts and reprecipitated solutions. The simplest is weighing of the solid residue after evaporation of the solvents (gravimetry). It has to be borne in mind here that foreign matter, such as stabilizers, spinning oils *etc.* is also included in the weighing and can thereby falsify the results. Optical methods are more specific, *e.g.* UV spectroscopy for the oligomers of ethylene terephthalate[64] and refractometry and interferometry for the oligomers of polyamide 6 and 6,6[33]. However, these detection techniques are also liable to interference by foreign substances. In recent times, therefore, preference has been given to analytical methods in which the oligomers are separated from foreign matter before detection, *e.g.* by thin layer chromatography, gel chromatography and adsorption chromatography, in the last case especially as high pressure liquid chromatography (HPLC). These methods have the further advantage that they allow separation of the various oligomers in the mixtures. Information is thus obtained about the content of the individual oligomers in the polymer, which can further be used for the analysis of faults (cf. Section 2). A selection of various chromatographic methods which have been used for analytical problems is given in Table 5.

High pressure liquid chromatography in particular has made it possible to analyze technical extracts of chemically very similar oligomers with great speed and precision. Figure 5 shows this for the monomeric cycloamides of the Qiana-type, which differ only in their configuration.

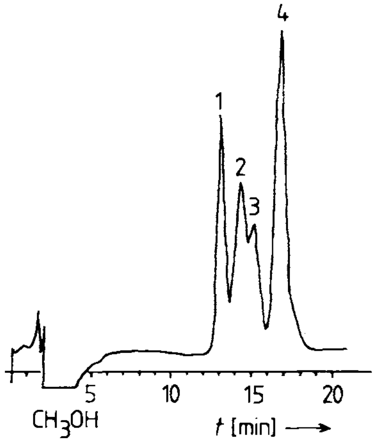


Fig. 5. HPLC chromatogram of an extracted isomeric mixture of the monomeric cycloamides of the Qiana-type [61a]. 1—4, see text.

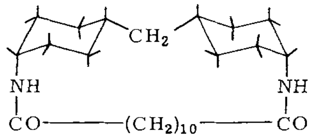
By comparison with synthetically prepared cycloamides, it can be shown that the peaks 1—4 in Figure 5 can be attributed to the isomers *(6a)—(6d)*[61a].

The search for suitable eluting agents is a problem with HPLC. In the case of the ethylene terephthalate oligomers, nano-thin layer chromatography can be used to advantage for this purpose[65].

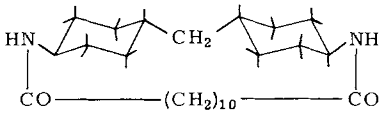
Table 5. Selection of chromatographic methods for quantitative oligomer analysis. GPC = gel permeation chromatography, HPLC = high pressure liquid chromatography, Ads = adsorption chromatography, TLC = thin layer chromatography.

| Area of Application | Principle of Separation | Mobile Phase | Detection | Ref. |
|---|---|---|---|---|
| Linear monomers and oligomers of polyamide 6-, 6,6- and 12-type | GPC after reaction with 1-fluoro-2,4-dinitrobenzene | 0.05 N HCl/Methanol | UV-VIS spectroscopy | [34] |
| Cyclic monomers and oligomers of polyamide 6- and 6,6-type | GPC | 0.1 N HCl | UV spectroscopy | [35] |
| Cyclic monomers and oligomers of polyamide 11- and 12-type | GPC | *o-tert*-Butylphenol | No information | [17a] |
| Isomeric mixtures of the cycloamides of the Qiana-type | HPLC | Methanol/water | Refractometry | [61a] |
| Cyclic trimer of ethylene terephthalate | TLC | Benzene/dioxane | Quenching of fluorescence | [19] |
| Cyclic oligomers of ethylene terephthalate | GPC | Chloroform | Refractometry | [15a] |
| Cyclic oligomers of ethylene terephthalate | Ads. | Chloroform/ether, chloroform/ethanol, $CH_2Cl_2$/hexane | UV spectroscopy | [27, 28] |
| Cyclic oligomers of butylene terephthalate | HPLC | Methanol/water | UV spectroscopy | [23] |
| Cyclic oligomers of ethylene terephthalate | Ads. | Hexane/dioxane | UV spectroscopy | [32] |

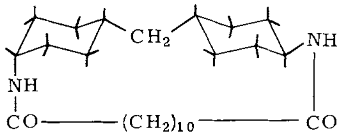


(6a), *cis, cis*, m.p. = 254-257 °C

(6b), probable conformer of (6a)



(6c), *trans, trans*, m.p. = 310-314 °C



(6d), *cis, trans*, m.p.= 269-272 °C

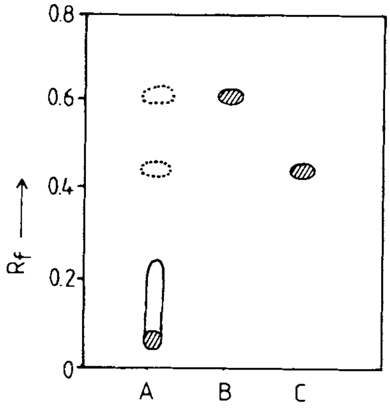


Fig. 6. Thin layer chromatogram of an *N,N*-dimethylformamide extract of poly-(*p*-phenyleneterephthalamide) (A) and the reference compounds *N,N'*-dibenzoylphenylenediamine (B) and *(7)* (C) (Eluent: WESBA, cf. Table 3).

The errors associated with separation of oligomers can be avoided by using techniques which enable the low molecular weight homologues to be determined directly along with the polymer. Examples of this are gas chromatographic[36a] and IR spectrophotometric[29] determination of ε-caprolactam in polyamide 6, or the determination by adsorption chromatography of the cyclic oligomers of ethylene terephthalate[27]. For routine absolute determinations, this method of determining the low molecular weight polymer homologues in the presence of polymer appears particularly promising.

The chromatographic techniques described above can be used in conjunction with authentic reference compounds for the identification of oligomers in polymers. Thus in the *N,N*-dimethylformamide extracts of poly(*p*-phenyleneterephthalamide), manufactured according to the relevant company patent for Kevlar[62], *N,N'*-dibenzoylphenylenediamine and the dibenzoyl derivative *(7)* of the monomeric diamine (m.p. >385 °C) could be identified, along with higher condensed products, by means of thin layer chromatography[25] (cf. Fig. 6).

*(7)*

The formation of these benzoylated low molecular weight homologues can be attributed to the use of benzoic acid, as prescribed in the patent[62], as a molecular weight regulator in the polycondensation.

## 6. Characterization of Oligomers

The methods described above for following the course of reactions in solution (Section 4.1) and for determining the oligomer content of the polymer (Section 5) can also be applied to characterization of the oligomers. They have to be supplemented, however, by further techniques. The methods normally used in organic chemistry, *i.e.* elemental analysis plus UV, IR and NMR spectroscopy, generally are sufficient to assign an oligomer to a certain series. Further information is given by the processes used to determine the monomeric units of the relevant polymers. Table 6 lists a selection of methods for quantitative analysis of monomeric units.

In Table 6 the *N*-propionylpropylamides of ε-aminohexanoic acid and the methyl esters of terephthalic acid have been included as especially useful model compounds ("oligomers free of end groups") for polyamide 6 and polyethylene terephthalate, respectively[3b].

If the chain length and exact oligomer type are to be determined (cf. Fig. 3 in the case of the ethylene terephthalate oligomers) the methods of organic chemistry and polymer chemistry as described above are not sufficient. Fur-

Table 6. Selection of methods for quantitative analysis of monomeric units.

| Area of Application | Preparatory Steps | Principle of Separation | Determination | Ref. |
|---|---|---|---|---|
| Propylamine and propionic acid in *N*-propionyl-propylamides of aminocarboxylic acids, especially ε-aminohexanoic acid | Hydrolysis with $H_2SO_4$ | Distillation | Titration | [66] |
| Various diamines, amino carboxylic acids and dicarboxylic acids from aliphatic polyamides; aromatic diamines from aliphatic-aromatic polyamides | Trifluoroacetylation, methylation or trimethylsilylation after hydrolysis with HCl | Gas chromatography | Retention time (reference compounds) | [39, 40, 67] |
| Methyl ester groups in polyethylene terephthalate | Hydrazinolysis with formation of methanol | Gas chromatography | Retention time | [68] |
| Terephthalic acid units in polyesters | Hydrazinolysis with formation of terephthalic acid dihydrazide and monohydrazide | No separation | Polarography | [69, 70] |
| ε-Aminohexanoic acid units | Hydrolysis with HCl | Ion exchange | Moore-Stein analysis | [71] |

ther chemical and instrumental methods have to be applied.

Although mass spectroscopy was used by *Repin*[72] in 1968 to characterize the cyclic diesters of terephthalic acid and ethylene glycol, it is only in recent years that it has become a standard method in oligomer research. This is due firstly to further refinement of the apparatus[73,74], and also to the fact that since that time reliable data on the fragmentation of the various classes of compounds in the mass spectrometer have become available. This enables the structure of the higher oligomers to be clarified even though they are completely fragmented in the mass spectrometer and hence give no molecular ion.

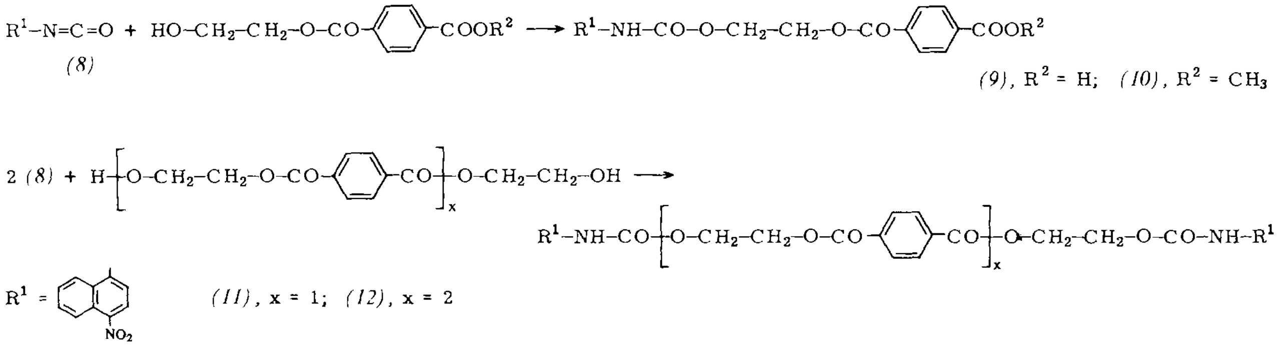
Determination of the molecular mass by identifying the relevant molecular ion is especially applicable to the *cyclic* oligomers, which can be sublimed without decomposition. This technique has been used successfully for the cyclic dimer[36b] and trimer[37a] of ethylene terephthalate, the cyclic oligomers of butylene terephthalate up to the tetramer[23,37b] (cf. Table 2) and the cyclic monomeric and oligomeric amides of various polyamides (Qiana-type[61a], polyamide 6-type[61b], polyamide 4-, 7-, 12- and 4,10-, 6,6-6,10-, 11,6-, 12,12-type[61c]. Mass spectrometry is therefore a useful supplement to the methods of molecular weight determination frequently used in oligomer analysis, *viz.* vapor pressure osmometry and end group analysis[52], since the latter methods are not universally applicable. Vapor pressure osmometry yields values with good reproducibility if the oligomers have a cyclic structure or the end-groups are blocked with non-ionic residues, but it cannot be used for linear oligomers with ionic end groups, *e.g.* for the linear oligomer of ε-aminohexanoic acid and hexamethylene adipamide with unprotected end-groups. However, for these oligomer series a number of chemical and instrumental methods of end-group determination are available, which respond specifically to amino, carboxy and hydroxy end-groups[75].

All these methods have been developed, however, for the corresponding polymers and therefore in some cases they have to be modified before being used with oligomers. Considerable information is obtained from methods of end-group determination which are based on an "oligomer-analogous reaction", *i.e.* a reaction in which, according to *Staudinger*'s criterion, chemical modification takes place without changing the number of repeat units. With this technique it is not only possible to determine the molecular mass according to the following equation:

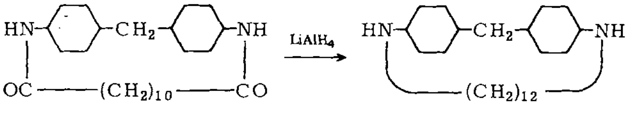
$$M = \frac{2}{E} \times 10^6$$

($E$: end-group content in meq/kg; $M$: molecular mass in g/mol)

In addition, the modified oligomers can be tested for homogeneity using the methods described previously. An example of such a procedure is the reaction of ethylene terephthalate oligomers *(9)–(12)* containing hydroxy groups with 4-nitronaphthyl 1-isocyanate *(8)*, as described by *Nissen*[12b].



The molecular mass of the oligomers can be calculated from the absorption of the introduced chromophore. In addition, information about the homogeneity of the oligomers can be obtained from the melting point, elemental analysis, and chromatographic behavior. Another oligomer-analogous reaction which has proved valuable for analysis is the reduction of cyclic oligoamides to cyclic oligoamines. This was first used by *Spoor* and *Zahn*[76] to determine the oligomers of polyamide 6. In the case of the *cis,trans*-isomeric cycloamides *(6)* of the Qiana-type, this technique proved to be especially useful for characterization since the resulting isomeric diazacycloalkanes *(13)* can, in contrast to the cycloamides, be distinguished by thin layer chromatography[61a].



*(6)* *(13)*

For the identification of known oligomers, *e.g.* in extracts from technical polymers, mention should be made of the clearly arranged table by *Rothe*[77]. This lists physical data and literature references for all oligomers which were characterized up to *ca.* 1970.

*Thanks are expressed to Prof. Dr. H. Zahn for introducing the author to oligomer chemistry. The financial support of the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, Deutsche Forschungsgemeinschaft (Grant No. Ro 432/2) and the Verband der chemischen Industrie is acknowledged with thanks.*

# The Critical Screening and Assessment of Scientific Results without Loss of Information—Possible or Not?

**By Reiner Luckenbach, Reinhard Ecker, and Josef Sunkel**[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

The critical assessment of information as a means of screening and selecting scientific results, leading to a procedure for condensing the flood of data from the primary literature into the secondary literature, is reviewed (here, exemplified for organic chemistry). The criteria for critical assessment without loss of content, developed and tested by the Beilstein Institute on the basis of a hundred years' experience, are presented. The possible extent to which data can thus be reduced is demonstrated for a number of examples.

## 1. Introduction

One of the corner stones of international chemical documentation, Beilstein's Handbook of Organic Chemistry, looks back this year on a hundred years of activity in the field[1-3][**]. The principal objective of this work was, and still is, to provide its user with a comprehensive "concentrate" of the primary literature[**] as a tool for day-to-day research work. This objective can only be attained if the results published in the primary chemical literature are subjected to a scientifically critical appraisal, *i.e.* are checked for their general soundness and consistency with other findings. In addition, it must be ensured that the data reduced by this selective processing reach the user without loss of informational content.

Before discussing the general and specific requirements for attaining this objective, the present-day situation of the "information consumer" will be reviewed.

## 2. The Situation of Scientists Seeking Information Today

The process of communication between scientists—one of the fundamental requirements for all intellectual work—is influenced to an increasing extent these days by the ever greater flood of information. This can become an intolerable burden for the individual scientist who finds it less and less possible to select relevant data from the flood of information reaching him. The number of reports appearing annually in Chemical Abstracts amply demonstrates the extent to which this situation is worsening (Table 1).

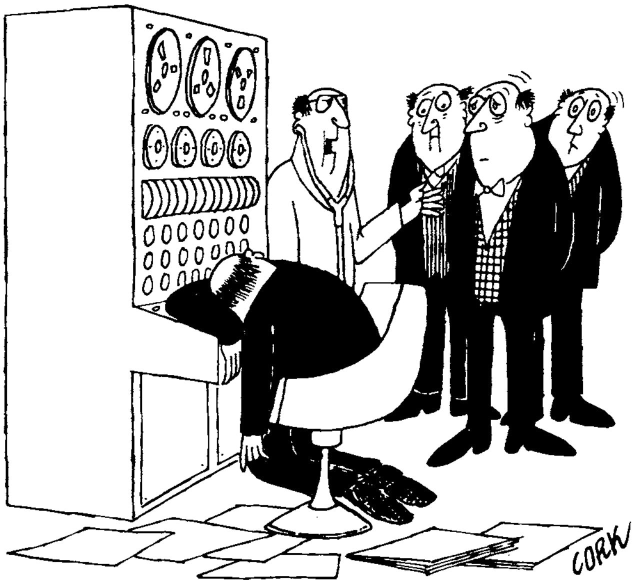

Fig. 1. From *Der Leitende Angestellte 1978* (7), 14: "He died of an overdose of data ...".

Appeals to publish less and to refrain from founding new journals have apparently gone unheeded. As a result, many scientists have adopted the practice of restricting their literature studies to cover only the latest information available at the time. This means that as a result of ignorance of valuable older information numerous duplicate and multiple publications, not infrequently containing already well-known material, have appeared. Scientists specialized in the field of documentation, who made an intensive study of the problems generated by this development, initially believed they had found a solution by the increased use of electronic data processing. Experience has already shown, however, that the non-selective storage of all incoming information once again leads into a blind alley: the percentage of ballast produced in research is con-

Table 1. Number of reports in Chemical Abstracts [5].

stantly on the increase and the end-user is forced to make a time-consuming selection of the relevant information from a large number of ballast-loaded sources (multiple publications, ignorance of long-discovered errors *etc.*). Since this critical screening on any particular subject has to be carried out afresh by every individual seeking information, the entire process must be viewed as making nonsense of any kind of informational economy.

It would thus appear meaningful and rational not to leave it to each individual end-user to rid the material of ballast himself but instead to make the information available after critical screening and assessment by a competent "information analysis center"— a demand which has repeatedly been made over the past years[6] and which has in fact been put into practice by the great chemical handbooks for over a century. More recent attempts to implement this demand have so far mainly failed because of the necessarily high investment costs and the problem of simultaneously avoiding loss of information.

The terminology "critical screening and assessment" is intended to denote the competent scientific appraisal of a piece of information with regard to its soundness (compatibility with generally known facts and analogous material), its novelty, and its general scientific significance. Returning to the experience accumulated during production of the Beilstein Handbook, it will be shown that under certain conditions it is possible, with the aid of this critical scientific screening and appraisal, to make decisive progress in the field of informational economy and accessibility.

## 3. Critical Screening in Science

Critical screening and sifting of information according to quality and usefulness are general reactions of the human intellect towards the flood of information confronting it from day to day. All scientific work also involves critical screening. Before a result is made public, the person or group responsible will normally have filtered out insignificant, uncertain or questionable results since the expenditure required for their publication does not appear to be justified, or further studies are necessary.

Following this rather "subjective" appraisal, the next step is an objective assessment of form and content of the publication or patent application by the editor and referee appointed by the journal, or by the patent attorney. This critical publisher-evaluation of manuscripts submitted to journals has a long tradition in the field of chemistry and is well-illustrated by *Justus von Liebig*'s activities in the course of publication of his "Annalen der Chemie"[7]. In 1871, it was *Friedrich Konrad Beilstein* himself who asked *Emil Erlenmeyer* to referee the increasingly numerous studies submitted to the journals for publication: "... You have now attained the peace of mind necessary to skin the average villain, without the fury of earlier days but in a leisurely and collected fashion over a good cigar ..."[8]. Today too, this critical editorial assessment is frequently exercised in full measure. For example, the editors of the "Chemische Berichte" in 1979 turned down about 17% of the manuscripts submitted and returned just under 50% to the authors for revision (and shortening)[9]. Although it is certain that many of the rejected manuscripts, or parts of them, were subsequently published in other journals, these figures show clearly to what extent potential research ballast is filtered out prior to publication[*]. Once scientific information has become available in the form of a primary publication, it can be taken over by the secondary literature. The function of the secondary literature is to select, analyze, order, and selectively store[10] the information contained in the primary literature.

The greater part of the secondary literature can be subdivided into the *"selective* secondary literature" and that providing *"comprehensive coverage* of the primary literature".

The "selective secondary literature" is intended to provide the user with information of an exemplary nature by grouping scientific results and illustrating common properties of the group in terms of an individual example. The user himself has to bear the risk involved in making analogies with his individual special case. Examples of the "selective secondary literature" are review articles, monographs and textbooks.

The function of the "comprehensive secondary literature" is to provide the user with *all* the information available in the fields covered. The user is thus presented with the individual case itself and all known facts about it.

In addition to the well-established abstracting journals (which provide a comprehensive, mainly uncritical, continuous listing and registration of the contents of the primary literature: a catalogue of all known information) the "comprehensive secondary literature" also includes the scientific handbooks.

If certain rules are observed, these handbooks can be so designed that not only is the primary literature fully covered but also:

- multiple publications with the same content and well-known results are filtered out,
- corrections to earlier findings can be taken directly into account,
- conflicting data on a subject can be recognized and, where possible, clarified,
- individual results on a subject can be correlated with analogous cases and errors brought to light.

Observation of these criteria would satisfy the definition of a critically assessing handbook as a well-ordered, corrected, up-to-date and low-ballast compilation of all known facts. In contrast to the abstracting journal, the handbook does not merely pass on information but is also equipped to recognize and correct mistakes and is thus in a position to exclude ballast.

The absolute necessity of this critical processing was also recognized by *F. K. Beilstein* during preparations for the first edition of his handbook. Here are two further quo-

---

[*] It would of course be unjustified to view publication or non-publication as the sole yardstick of the significance of a scientific result, since frequently there are strong personal, political, military or commercial reasons why the publication of important results is blocked.

tations from his letters to *Erlenmeyer*[8] "... It is truly appalling to see just what has been thrown together so far—the question marks and the inconclusive and contradictory material I have already had to read ...". Elsewhere he deplores that "... a conceited boastfulness is becoming widespread in chemistry, quite insignificant results are blown up into a great discovery, and the publication of watered-down material is becoming the order of the day ...".

## 4. Critical Screening and Assessment as Practised in the Beilstein Handbook of Organic Chemistry

The general criteria outlined above for the compilation of works in the category of "scientific handbooks" are of course also fulfilled by the great handbooks in the field of chemistry (Beilstein, Gmelin, Landolt-Börnstein).

The Beilstein Handbook covers the field of Organic Chemistry *i.e.* it includes a description of all carbon compounds dealt with in the scientific literature (with the exception of CO, $CO_2$ and inorganic carbonates).

In the following discussion it will be shown to what extent it is possible, using a proper scientific approach and methodology to carry out a critical screening and assessment without loss of information.

### 4.1. The Requirements for Critical Screening without Loss of Information

Before the individual criteria for critical screening are discussed, a few general requirements will be mentioned and illustrated in terms of the preparation of Beilstein's Handbook of Organic Chemistry.

#### 4.1.1. Working Procedure

The most important requirement is a suitable working procedure which permits the original literature to be evaluated without informational loss in its first stage and subsequently, after checking, to be stored according to a suitable systematic arrangement. The working procedure includes a number of firm rules for the evaluation of material, established on the basis of many years' experience. Optimal application of these rules is ensured by independent checking of all scientific decisions on at least two levels. This procedure has been supplemented in recent times by a variety of error-determining routines using the most modern data-processing technology (*e.g.* the checking of empirical formulas, checking and standardization of nomenclature *etc.*).

#### 4.1.2. Systematic Classification (Beilstein's System)

In view of the enormous volume of the material to be processed, its classification along strictly logical lines is vital, not only in terms of its later accessibility to the user, but also for those compiling it. The classification of scientific material must ensure that chemically-related compounds be located in close proximity to one another and that all the information available on a compound be immediately retrievable. This in turn ensures that any number of cross-comparisons during compiling of a handbook entry are possible, which again facilitates the uncovering and clarification of any contradictory information which may have been recorded.

These requirements made of the classification system cannot be met by alaphabetical arrangement of the compounds according to their names, nor by arrangement according to their empirical formulas, nor by any other derived or artificial criteria. The Beilstein System is the only system of classification which meets all these requirements for all organic compounds known to date. The basic outlines of the system were developed by Beilstein for the first edition of his handbook, published in 1881, and then refined to their final form, which has stood the test up to the present day, by *B. Prager* and *P. Jabobson*.

The Beilstein System is based on the constitutional formula of the compound as the sole classifying feature and only takes account of the given structural properties ("morphology") of the compound; the essential feature of the system is that it represents a *natural* classification.

The principal classifiable criteria of the system can be summarized as:

A. Main subdivision (acyclic, isocyclic and heterocyclic compounds, the latter of which are further subdivided according to the type and number of the ring heteroatoms),
B. Functional groups (—OH, =O, —COOH, —$NH_2$ *etc.*),
C. Degree of saturation ($C_nH_{2n-x}$),
D. C-number (total number of carbon atoms),
E. Skeletal structure (unbranched, branched, monocyclic, bicyclic, ...).

For further details on the Beilstein System see ref.[11].

#### 4.1.3. Qualifications of the Scientific Editors

Every decision as to whether to include or reject information requires specialized knowledge of the field concerned by the scientific editor. For this reason, more than a hundred scientists (chemists), all of whom participate in continuous further schooling to keep fully up-to-date, are involved in the compilation of the Beilstein Handbook. These scientists are supported by a number of specialists fully familiar with the fields bordering on organic chemistry (*e.g.* biochemistry, organometallic chemistry, physics) or other special areas (*e.g.* nomenclature).

Table 2 shows which of the most important processing stages are absolutely dependent on specialized knowledge, *i.e.* in which processing is carried out by a qualified scientist.

#### 4.1.4. Scientific Aids

Alongside the pre-sorted material, a number of scientific aids are also available to the scientific editors of the handbook. These include, first of all, an extensive library con-

Table 2. Processing stages and compiling editors of the Beilstein Handbook.

| Processing Stage | Compiling Editor |
|---|---|
| Critically selective coverage of the original literature and checking the literature extracts | Specialized scientist (chemist) |
| Arrangement of the abstracts according to the Beilstein System | Chemical documentationalist and/or data processing |
| Preparation of the handbook entries | Specialized scientist (chemist) |
| Checking the entries (in two stages) | Specialized scientist (chemist) |
| Nomenclature and preparation of the indexes | Specialized scientist (chemist) and data processing |

taining all journals and patents as well as a large number of monographs and special publications covering the entire field of organic chemistry. For all important foreign languages translating chemists are available to provide an accurate translation of texts with thorough coverage of the contents.

### 4.2. General Criteria for Critical Screening without Loss of Information

Even today, the fundamental concept developed for the first edition of Beilstein's Handbook provides the basis for the critical processing carried out by the Beilstein editors. *F. K. Beilstein* formulated this concept in the preface to his work as follows[12]: "I have attempted in this work to provide as clear a review as possible of all analyzed organic compounds ... to exclude trivial and superficial information as well as properties and reactions *et cetera* which have not been studied exactly ... to include in its entirety all information which contributes to our precise understanding of substances, such as melting point, boiling point, specific gravity, solubility and so forth as well as precisely studied reactions and rearrangements of the substances ... to extract all data from the *original publications* of the authors ..."

In view of the enormous increases in the number of publications and the progress of chemistry over the last hundred years, the criteria laid down by Beilstein have of course had to be refined, further developed and adapted to keep pace with the advancement of knowledge. The demand for new, reliable and scientifically well-founded information has always been kept in the foreground, and then as now, first priority given to the documentation of all information of interest to the chemist for every organic compound. To combine this objective with simultaneous efforts to achieve maximal data reduction (elimination of redundant information) the criteria for critical screening without loss of content, discussed in the following, must be adhered to.

#### 4.2.1. The Material Correctness of the Information

The first stage of critical screening is to check whether the given information is consistent with current general chemical principles, whether it is compatible with all so far known facts about the compound, and whether contradictions are apparent with regard to data on homologous or analogous compounds. Where discrepancies arise, more detailed research becomes necessary, as a result of which corrections or reservations are noted in the report on the compound involved.

#### 4.2.2. Depth of Information

As experience shows, a depressing feature of the everyday search for information is that the abstracting journals often refer to the primary literature, which, when consulted, proves not to have been worth the effort after all. During compilation of the handbook it is therefore verified that the information possesses a certain "minimal depth" (minimal "content").

If information on a subject is available from *several* publications, it is determined whether some of the data cannot be disregarded in the interests of optimal reduction. A number of factors influencing selection in such cases are considered in the following section.

#### 4.2.3. Completeness of the Information

A publication can be considered as being maximally informative when all relevant details are described exactly, and all important parameters given. This is clearly required if the results given are to be reproducible, which is certainly to be aimed for.

#### 4.2.4. Objectives of the Publication

A further significant criterion for critical selection is consideration of the purpose and objectives of the publication. It is of considerable help in the assessment of a document to know whether the information presented is at the center of the author's interest, and thus of the publication, *i.e.* an essential objective of the work—or is merely an incidental finding. Obviously the "information consumer" is going to give more attention to a result presented in a publication which considers the theoretical background, and larger context, than to one from an otherwise equivalent publication in which the measured result is recorded without comment.

#### 4.2.5. Accessibility of the Information

Although a handbook is primarily concerned with the "documentation of facts" and only serves as a "source of references" for more complex issues, the availability, intelligibility (language) and age of the original publication are also of interest to user and compiler alike. Where more than one publication of comparable informational depth and coverage is available on the same subject, that published in the more easily procurable journal, in the more easily understandable language or of more recent date will generally be preferred.

### 4.2.6. Origin of the Information

A criterion which certainly merits a great deal of caution in its application concerns the competence of the author and the reputation of the journal. However, the knowledge that the author is a known specialist or that the research group involved has considerable experience in the field, and that the publication appeared in a journal with particularly strict rules for acceptance, is—in conjunction with the previously mentioned criteria—sometimes of assistance in making a decision.

## 4.3. Subject-Related Criteria for Critical Screening without Loss of Information

Whereas the criteria reviewed so far include considerations valid for all handbook information, those to be discussed now are more specifically relevant to the factual material dealt with in Beilstein in terms of the most important groups of features used for the description of organic compounds ("compounds meriting inclusion", "preparation", "physical properties", "analysis" and "chemical behavior").

### 4.3.1. Criteria for the Choice of Compounds to be Included

Fundamentally, in a critically assessed collection of chemical data, it would only appear meaningful to describe *isolated* or *definitely identified* compounds of *unambiguous* constitution.

#### *Identity of a Compound*

The most important requirement for the description of a compound—and thus for its nomenclature, documentation and retrievability—is knowledge of its identity, *i.e.* its chemical structure, which is determined by its constitution, configuration and by its conformation.

Compounds of unknown constitution, even when their empirical composition (elemental analysis) has been established with certainty, cannot be described with sufficient unambiguity to permit meaningful classification in the data collection and retrievability with an acceptable degree of effort (*e.g.* "compound $C_8H_{14}O_2$ with m.p. 184—186 °C"). Only where a slight degree of uncertainty exists for an otherwise established constitution (*e.g.* the position of a methyl group in a side chain, or of a C=C double bond) is the retrievability guaranteed to any extent and this condition for the inclusion of a compound fulfilled. (By contrast, the configuration of a species does not necessarily need to be known with certainty; even substances of uncertain or mixed configuration should be retrievable if their constitution is known.)

The constitution or configuration of a compound can be considered as certain when the described mode of formation is unambiguous in terms of general experience and when it has been verified by elemental analysis and physical measurements (*e.g.* spectra) or chemical methods (*e.g.* specific degradation).

Should doubts exist as to the correctness of the assignment of constitution or configuration to a compound, the critical assessment requires a literature search for further data on possible structures. If this research is unfruitful, the search for related compounds whose structure has been verified becomes necessary. This may enable the actual constitution or configuration of the compound in question to be clarified by analogy.

#### *Characterizing Data*

The reporting of the existence alone of a compound is not sufficient to justify its inclusion in the handbook since this information on its own is of little use.

In addition to the verified identity, at least one piece of data, such as details of the method of synthesis used, a characteristic parameter (physical property or information on its chemical behavior) or appropriate information on a salt or derivative should also be available.

The characterizing data must also be meaningful; most important is that the parameter measured is not influenced by existing uncertainties in the molecule itself. For example, data on the optical rotatory power of a compound of non-uniform configuration are just as unsuitable for characterization as the melting point of a mixture of diastereoisomers. The following loosely defined and general criteria can be regarded as a guideline for the inclusion of compounds:

- —Compounds of verified constitution which have been isolated in a configurationally uniform state and for which at least one piece of characterizing data is available are basically suitable for inclusion.
- —Should doubts exist as to a relatively unessential part of the otherwise known constitution of a compound, the configurational uniformity and assignment of the "main part" must be conclusive and adequate characterizing data available, so that where possible comparison with suitable material published at a later date may permit subsequent confirmation.
- —If the constitution of a configurationally non-uniform or questionable substance has been verified, data whose magnitude is not dependent on the configuration should be available.

### 4.3.2. Criteria for the Assessment of Data on Preparation

#### *General*

The information supplied in the primary literature on the preparation of compounds often provides wide scope for rigorous pruning of obsolete material during critical screening.

Thus, the inclusion of modes of formation of no apparent preparative value is invariably suppressed when other useful procedures for the preparation of the compound are already known; strict criteria are to be applied here, particularly for compounds which are frequently described.

Details on already well-known methods of preparation should only be included if an improvement, or at least an equally useful variation of the earlier procedure, is described. Chemical reactions occurring under conditions clearly chosen with a view to isolating another compound are only taken into consideration if no other preparatively useful methods have been described. The question must thus always be asked in assessing a preparational method as to whether the objective of the reaction described was to synthesize a compound, or merely to provide proof of the identity of its precursor by degradation or derivatization.

*Procedure for Critical Screening of Preparational Methods*

Where various methods for the preparation of a compound have been described, it is to be recommended that each individual piece of information be checked in accordance with the scheme shown in Table 3 during critical screening of these data.

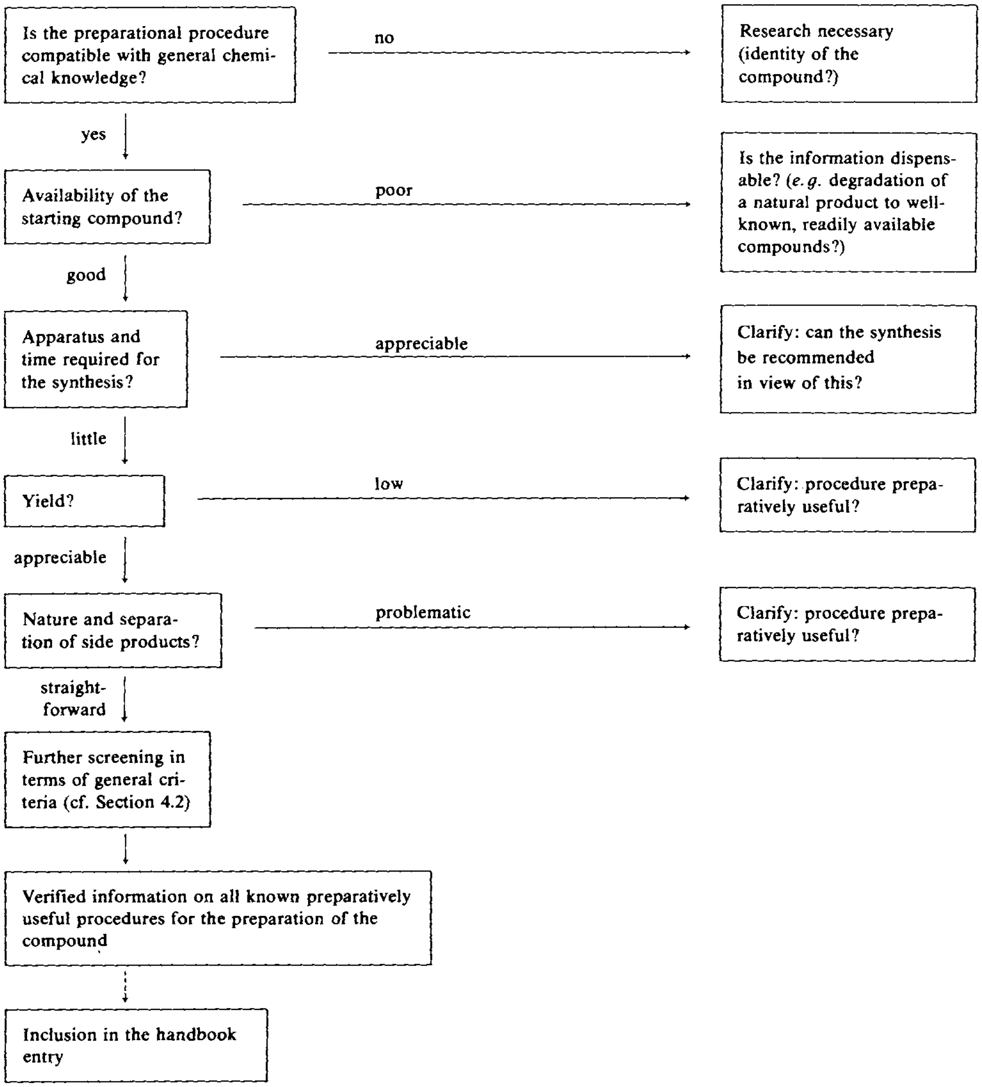
The first question is directed at determining whether the chemical reactions taking place during the synthesis are compatible with general chemical knowledge at all, and thus touches on the problem of the identity of the compound, already discussed in Section 4.3.1. If serious doubts should arise, clarifying research becomes absolutely necessary. If an affirmative response to the first question still leaves a choice of several methods of preparation it must now be examined how readily (relatively) the starting material is available, what experimental effort (apparatus and time) is required for the synthesis, how high the yield is, the nature of the side products and how these can be separated. If this scheme is properly applied, particularly where a large number of preparative methods have been described the best and most important procedures can be determined. A final screening according to the general criteria mentioned in Section 4.2 permits a further selection to be made among multiple publications of the same content.

### 4.3.3. Criteria for the Assessment of Data on Physical Properties

*Purity of the Substance*

The first and most essential criterion for assessment is the purity of the substance (uniformity of constitution and configuration). First indications of this are provided by the elemental analysis. After this, it must be determined

Table 3. Scheme for the critical screening and assessment of information on the preparation of a compound.



whether the author had been at particular pains to isolate the substance in the pure state by recrystallization, distillation, chromatography *etc.*, or whether the substance had been obtained only as an intermediate or crude product for further processing.

*The Method of Measurement and Completeness of the Description of the Experimental Conditions*

First of all, the method of measurement used to determine the physical property under discussion is examined. If a classical, well-known parameter (*e.g.* melting point, boiling point, refractive index *etc.*) is involved, the method of measurement plays a less important role than where the parameter is determined with the aid of a modern technique such as NMR, NQR, ESR spectroscopy *etc.* In the latter case, the stage of development of the instruments used is decisive in assessing the quality of the measurement. A further criterion is provided by the description of the experiment, which, depending on the ease with which it can be performed, permits a more or less exact reproduction.

*Completeness and Accuracy of the Data*

Publication of a physical result is only of value if all the necessary parameters are given. A further indication of the quality of the result is provided by the limits of error, where supplied, as well as a complete and exact description of the units.

*Specific Criteria*

Alongside these general principles—valid for the assessment of all factual information of a physical nature—there also exist a number of specific criteria relating to the nature of the information, which in view of their great number cannot all be mentioned. Three representative examples will show how these detailed deliberations take shape.

a) IR Spectrum: To be taken into account here are the method of preparation of the sample (film, KBr, Nujol or $CCl_4+CS_2$ *etc.*), the resolution of the IR spectrometer used, as well as details of the range of measurement and the way in which the spectrum is reported in the publication (a table of wave numbers or the complete spectrum? Size and precision of reproduction of the spectrum?).

b) Dipole Moment: An important aid to assessment is the method of measurement (microwave spectrum or measurement in solution). It must further be asked which solvents were used (nonpolar or polar) and which method was used for determining the value from the measurements (Debye, Onsager, Kirkwood *etc.*); is the molecule capable of free rotation, and was the resulting temperature dependence of the dipole moment taken into account?

c) Dissociation Constant[13]: Again, the method of measurement is to be considered first of all (*e.g.* determination of the values by potentiometric, conductometric, spectrophotometric or kinetic procedures) since these methods are associated with very different sources of error. It must further be noted whether the ionic strength was taken into account and, in the case of precision measurements, the interface and transport potentials. For measurements carried out in non-aqueous solutions, attention must also be paid to exact definition of the pH value.

Altogether, these three examples show how essential it is that the application of assessment criteria be carried out by capable scientists who are familar with the particular field in question.

### 4.3.4. Criteria for the Assessment of Analytical Data

In view of the increasing use of physical methods in analysis, the criteria mentioned in Section 4.3.3 with regard to physical properties also apply here. It must be added that only properties which relate to the individual substance can be considered; analytical properties which are typical of a certain class of compounds (*e.g.* color reactions of phenols) are not considered. Particular emphasis is laid on the unambiguity and reproducibility of the analytical proof.

### 4.3.5. Criteria for the Assessment of Data on Chemical Behavior

The first thing to be considered here is whether the course of reaction given is consistent with general chemical knowledge, and whether constitution and configuration of the reaction products have been determined with certainty, or whether they have only been conjectured.

Where *qualitative studies* are involved, particular attention must be paid to whether the clarification of the course of the reaction was the object and an essential part of the publication. In studies concerned with the preparation of a compound or determination of the structure (*e.g.* by degradation experiments on natural products), the novelty of the reactions described are used as a criterion. All known reactions can be disregarded if these have already been studied for many other analogous compounds and have thus become general knowledge. By contrast, for *quantitative studies* (kinetics and equilibria) involving substance-specific properties, corresponding data for every compound described should be included. Here again, however, it must also be checked how exact the description is and what relevant parameters are given. In kinetic studies the quality of the measurements and the interpretation of the equation describing the reaction warrant particular attention. The question of configurational uniformity again becomes important here since it almost invariably decisively influences the course of reaction.

## 5. The Significance of Critical Screening and Assessment in Documentation Today and Tomorrow

Following the naming and discussion of the most essential criteria for the critical selection and appraisal of findings in terms of the Handbook of Organic Chemistry, the value of the resulting compacted information is to be considered in conclusion, and an idea of the possibilities for recognition and correction of erroneous information provided, together with a word on the significance of these effects for those seeking information.

### 5.1. Examples of the Extent to Which Data Reduction without Loss of Information is Possible

The efficiency of the system for critical screening and assessment, discussed above, will now be illustrated in terms of its practical application to three compounds, in order to demonstrate just how far data may be reduced by judicious use of the criteria outlined. The results of this test, based on a comparison of the publications cited in an abstracting journal which covers the entire primary literature (Chemical Abstracts), and in the Beilstein Handbook, are summarized in Table 4. (Detailed records of this test can be made available to those interested by the Beilstein editorial staff.)

The test was restricted to material published between 1950 and 1959 for examples 1 and 2, and between 1930 and 1959 for example 3[*]. The information was compared with data already available in earlier volumes of the Beilstein Handbook and checked for its documentational merit. The data in Table 4 show that for the examples chosen a reduction in the number of sources by about one half was possible. It may be added that Beilstein editorial experience shows this reduction by about 50% to be usual for compounds treated with moderate frequency in the literature—between once and 5 times annually. For very frequently discussed compounds, the extent of reduction is considerably higher; in extreme cases, less than 10% of the original citations on a particular category of results are included in the handbook. On the other hand, the situation is necessarily very different for compounds only described in a single original document. In such cases, a critical comparison of data from various sources is not possible and the question of data reduction is limited to a check on whether the conditions for inclusion of the compound are fulfilled at all.

### 5.2. Examples of the Recognition and Correction of Erroneous Primary Literature

As implied in Section 4, the elimination of redundant material is only one aspect of the critical processing of primary information. A further essential feature, of self-evident significance for the user, is the recognition and correction of erroneous data in the original literature. An analysis of Volume 19 of the Beilstein Handbook[*] showed that for more than 2500 compounds, either corrections to the original constitution, given in later publications, had to be taken into account, or, for the first time, unambiguous constitutional assignments had to be made by the Beilstein staff with the aid of analogies or on the basis of genetic relationships to reaction precursors or products. The net result was that critical processing led to a correction or verification of the constitution of almost every tenth compound. A similar situation applies for all other groups of features—particulary for all numerical values.

### 5.3. Significance for the User

The test examples presented in Table 4 demonstrate the efficiency of the procedure described for "critical screening without loss of information". The analysis of the contents of Volume 19 of Beilstein's handbook, mentioned above, shows the significant extent to which errors can be brought to light by critical processing. Application of these procedures represents the greater part of the day-to-day work of the Beilstein scientific staff.

What are the advantages and benefits of a collection of facts and data compiled in this way for those in search of information?

—Improved confidence in the accuracy of the tested data,

—Diminished risk of false conclusions and non-optimal experimental planning as a result of inexact literature results,

—Better possibilities for ballast-free research by concentrating on dependable data,

—Intensive intellectual "reexamination" of selected data unnecessary—greater time saving,

—Guarantee that no relevant information is lost.

In 1880, possibly in premonition of the success of his handbook, *Friedrich Konrad Beilstein*'s "ready tongue", which, in his own words, "God had seen fit to place in his head", formulated the benefits of critical processing in the

Table 4. Extent of information reduction in the Beilstein Handbook by critical screening.

| Name of the compound, Beilstein citation | Number of citations | | Eliminated during Beilstein processing since | | | Reduction in the number of citations in Beilstein [i] | Number of citations only to be found in Beilstein for this compound "*c*" |
|---|---|---|---|---|---|---|---|
| | in Beilstein "*a*" | in Chemical Abstracts "*b*" | contents already known and described in earlier Beilstein series | duplicate publication (prior publication) | does not merit documentation according to other criteria | | |

| 3,6-Dimethoxypyridazine<br>E III/IV *23* 3089/90 | 12 [d] | 15 [d] | 0 [g] | 3 | 1 [h] | 4:3 | 1 |

[a] E IV *5* 2295: Beilstein, Supplementary Series 4, Volume 5, p. 2295. [b] Literature period: 1950—1959. [c] One result on the constitution (tautomerism) and one correction of earlier information on the chemical behavior of the compound from the literature period from 1960—1981. [d] Literature period: 1930—1959. [e] Literature results from the period before 1950, are to be found in the following Beilstein Series: Basic Series, *5*, p. 665; Supplementary Series I, *5*, p. 326; Supplementary Series II, *5*, p. 576; Suplementary Series III, *5*, p. 2134. [f] Literature results from the period before 1950 are to be found in the following Beilstein Series: Basic Series, *3*, p. 654, Supplementary Series I, *3*, p. 228; Supplementary Series II, *3*, p. 423; Supplementary Series III, *3*, p. 1199. [g] No literature results available from the period before 1930. [h] Mainly data given in more detail in other publications. [i] *b*: (*a*—*c*).

---

[*] For the classification of essential features (*e.g.* constitution and configuration) the latest results, appearing in the literature right up to the time of publication of the sub-volume, are taken into account during processing of the Beilstein reports.

[*] Beilstein Supplementary Series III and IV of volume 19 describe about 26000 compounds on over 5000 pages of text. Our thanks are due to Dr. *Th. Schmitt*, Beilstein Institute, for performing the analysis.

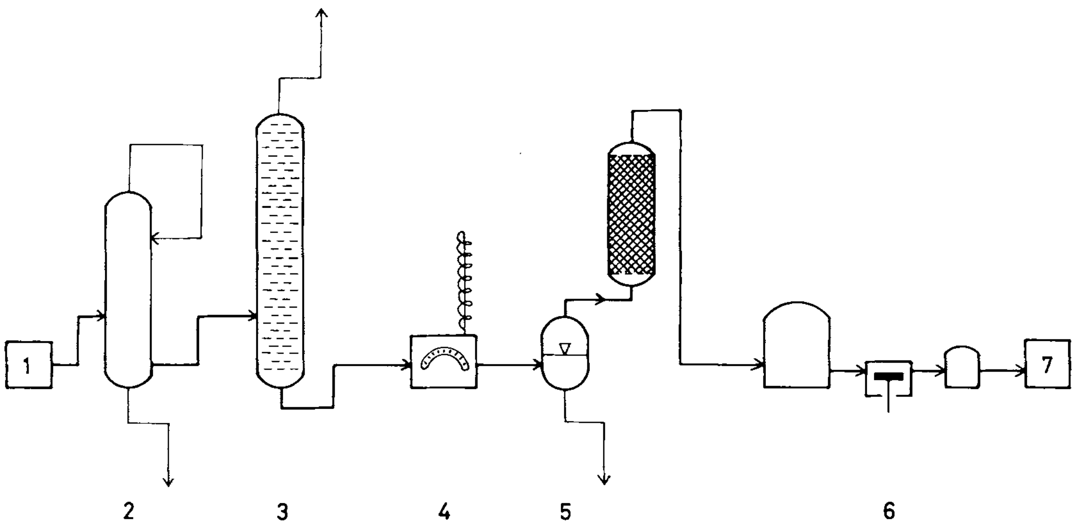

Fig. 2. The procedure of critical screening: In view of its enormous volume, processing of the scientific primary literature has almost reached the dimensions of "industrial" processing. The individual stages of critical assessment are thus readily adapted to the symbolism of industrial technology: 1) primary literature; 2) extraction of the primary literature; 3) "volatile" information distilled off; 4) analysis and evaluation; identification of erroneous data; 5) separation of duplicate information; adsorption of erroneous data; 6) concentration of the information; 7) scientifically assessed information.

following way: "... How delighted such people as *Richter, Wislecenus, Kolbe* and other producers of little books will be, now that everything has been cut to size and they can scoop wisdom by the *bushel* from my well-filled sacks and redistribute it by the *teaspoonful* ..."[8].

### 5.4. Summary and Prospects

In the previous sections, a selection of important considerations, criteria and guiding principles has been reviewed which make it possible for a competent scientist to screen and selectively evaluate data and facts published within his special discipline (here chemistry) and subsequently record and pass them on to the consumer without loss of information. This procedure has not only proved entirely satisfactory for specialized authors of monographs, writing within a narrower field, but also for editors of scientific handbooks, whose task involves critical screening of the literature for an entire discipline (here organic chemistry).

The hundred-year tradition of Beilstein's Handbook of Organic Chemistry testifies to its lasting value and authority, and shows what importance is attached by users to the continuity of the basic concept and the tested dependability of the work. The future task of those entrusted with its compilation will be to retain the well-established conceptual principles of the Beilstein Handbook as a work of critical assessment, but at the same time to remain flexible in the practical business of compilation and able to adapt to current and future developments both in terms of technical innovation and user requirements. It will only be possible to accommodate the steadily increasing volume of data in future if even stricter standards are imposed on the originality and accuracy of results included.

The creation of a computerized "information retrieval" facility for Beilstein is currently under development. It is also being considered to what extent a link-up, useful to the Beilstein user, with other established computer-oriented chemical information systems can and should be implemented.

However, even by stepping up the use of electronic data processing in chemical documentation and information, there is likely to be little change in the significance of the critical screening discussed above. Quite the contrary, sooner or later, in view of the increasing volume of information, critical prior assessment is likely to be of more significance even where data are to be stored in computer information retrieval systems, since this is the only way in which the plethora of data can be reduced. Worthy of note in this connection is that this critical assessment invariably requires the specialized scientist with appropriate training who is able to take into account the criteria and necessary premises on which an acceptance of data depends. Since many of the assessment criteria, with due modification to detail, are certainly of a significance which extends above and beyond the field of chemistry discusssed here, it can be generally said that the procedure of critical screening also provides *one* possibility for other scientific disciplines to direct the current (and future) flood of information into orderly channels.

# Replication and Evolution in Inorganic Systems[**]

By Armin Weiss[*]

Using layer silicates as models, the principle of replication, *i.e.* the spontaneous self-multiplication of a carrier of information, can be shown to be a general property of certain macromolecular systems. Errors in replication and feedback together with environmental influences may lead to mutants with higher or lower replication rates, thus enabling evolution. In the light of these findings, the question of whether or not chemical evolution resulted directly in the nucleic acid/protein system, *i.e.* the genetic principle common to all living systems known up to now, has to be answered. It seems conceivable that as a first step a much simpler replicating system was formed: such a system might then have undergone an evolution of replicating systems, resulting in the final nucleic acid/protein system.

## 1. Introduction

During the course of galactic evolution, the first solid rocks on our earth formed about $4.5 \times 10^9$ years ago. The earth's independent chemical evolution, therefore, stems from this date. Almost all specialists agree that the oldest microfossils are found in rocks which are 3.3 to $3.5 \times 10^9$ years old. These microfossils indicate that biological evolution had already started at this time, and strongly influenced the chemical evolution on earth *via* feedback mechanisms.

In the course of chemical evolution on the prebiological planet, a large number of molecules (amino acids, purines, pyrimidines, fatty acids, and sugars) were synthesized from $H_2$, $H_2O$, $NH_3$, $(CN)_2$, CO, $CO_2$, HCHO, and $H_2S$—the constituents of the primordial atmosphere. Most of these syntheses could have been induced by the action of electrical discharges and UV-radiation from the sun. This radiation was much more intense than that of today, due to the absence of the protecting ozone layer in the stratosphere. Probably, the first free oxygen on earth was generated by photosynthesis of living systems.

Yields obtained in simulation experiments lead to the conclusion that the primordial oceans corresponded to a "chicken broth" with respect to their amino acid content. Normal and selective adsorption may have accumulated many of these compounds in huge amounts. Furthermore, many molecules may have been brought to earth from extraterrestial sources *via* meteors. With increasing concentrations, condensation and polymerization reactions could have become more frequent and macromolecules could have developed. According to *Fox*[1], peptides and protoproteins may also have been formed at this stage. Hydrophobic interactions caused amphiphilic molecules to arrange in structured aggregates or membrane-like systems.

There is a gap in our knowledge concerning the next step. In the course of the chemical evolution of macromolecules and organized molecule aggregates, proteins and nucleic acids, *i.e.* the genetic material, must have been formed. The appearance of the genetic principle is a milestone in the process of chemical evolution: it is chemically the same in all forms of life known to date, and is involved in the replication of information which is fixed in the nucleic acids in the well-known helix or double-helix model; with it, biological evolution could start.

The starting point for our experiments was the question: are nucleic acids the only systems capable of replica-

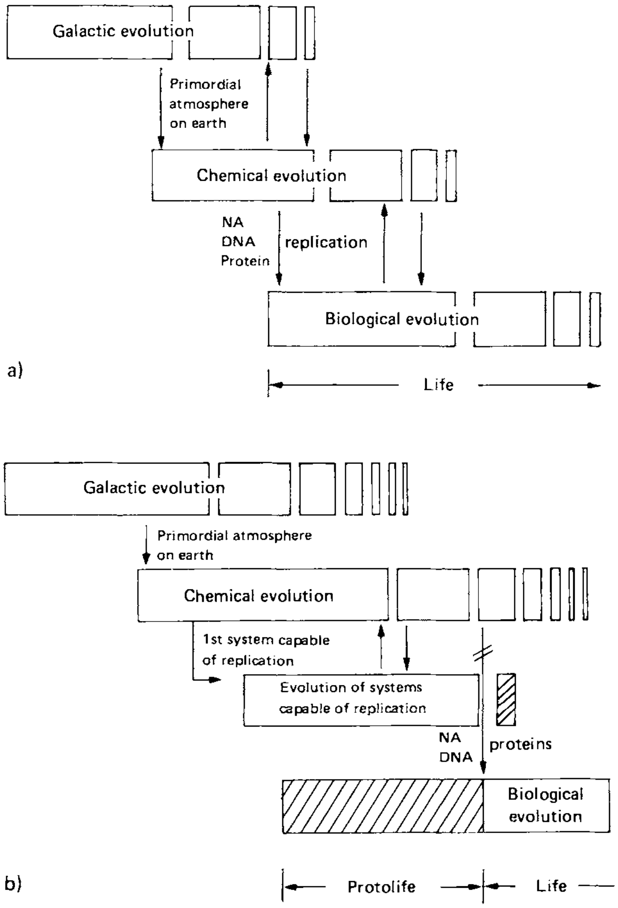

Fig. 1. Scheme of Evolution. a) Direct formation of the genetic nucleic acid (NA)-protein system within the context of chemical evolution; b) between chemical and biological evolution, an evolution of replicative systems (protolife) has been inserted.

tion, *i.e.* was the principle of replication uniquely bound with living systems, or do other replicating systems based on different, perhaps simpler chemistry exist? If replication of a carrier of information is a more general property of chemical systems, the DNA/protein system might only be a highly perfect realization of this principle, far superior to all others with respect to maximum replication rate, entropy production, and adaptability to an environment, changing permanently due to chemical evolution and therefore exclusively used by all life as we know it today.

A consequence of this reasoning leads to the conclusion that further considerations (Fig. 1b) must be added to the previously discussed scheme of evolution (Fig. 1a).

In the course of chemical evolution a primitive replicating system could have developed at a very early stage in the history of the earth[2]. This principle might have undergone an evolution of its own and the evolution of the replicating systems might have culminated in the DNA/protein system. In this case, we would have to concede the existence of alien life not based on DNA/protein. We could refer to this as protolife.

## 2. Conditions for a Simple, Replicating System

A system may be looked upon as replicating, only if it can undergo a spontaneous self-multiplication process in which information is transferred from the mother to the daughter units. The information may be written in full-length or coded in shorthand, as in the DNA/protein system. In practice, the information has to contain either the instructions for the synthesis of a large number of catalysts for the most important chemical reactions like hydrolysis, condensation, oxidation, reduction, and polymerization or has to contain all these catalytic sites in its own replicating structure. These conditions are restricted to macromolecular systems or aggregates. Long-term storage of several pieces of information in isolated small molecules is impossible.

The chemistry of the system should be simple. Synthesis should be possible either with or without ubiquitous catalysts like $H^+$ or $OH^-$: compounds with a macromolecular carbon skeleton are, therefore, eliminated. Bonds and conformations have to be sufficiently stable under the environmental conditions necessary for the self-multiplying process. This also precludes compounds which preferentially adopt pure ionic bonds.

The process of replication, *i.e.* the transfer of information from a matrix onto the replicas, must be precise. Errors may occasionally occur, changing the instructions for the synthesis of at least one catalyst or changing a catalytic property itself. In addition, errors in replication should either accelerate or retard further replication. Retardation can eliminate erroneous replica, acceleration may lead to dominance of the changed information. The chemistry of the system should allow separation of the matrix and replica by an appropriate mechanism, thus enabling the replica to act as matrix on its own.

This latter postulate excludes all simple phenomena of crystal growth. It is well known that many crystals are able to incorporate different information *via* structural defects. For example a screw dislocation which reaches the external surface may decrease the activation energy for many reactions, and act as an active site in catalysis[2]. The distance between these defects, the dislocation density, may alter the catalytic capabilities, quantitatively or even qualitatively. Such a crystal will grow in an appropriate solution and, in general, the screw dislocations will grow along with it, *i.e.* the catalytic capability will be reproduced. However, old and new parts of the crystal cannot be separated by any simple process. Only under the influence of external force, will the crystal be randomly broken into smaller pieces, each of which can act as a growth nucleus for a new crystal. Independent crystals with dislocations will grow from all pieces with dislocations. Their distribution in the different crystals will, however, be random.

Spontaneous separation of matrix and replica, *i.e.* multiplication, requires special mechanisms. In order to store a large number of pieces of information simultaneously, macromolecules or complex systems of small units are required. If these undergo replication, there is strong mutual adherence due to the many sites of contact. This is well known from adsorption and desorption experiments on macromolecules. Usually good separation only becomes possible when the environment is changed; this either alters the surface charge or produces a reversible conformational change.

## 3. Layer Silicates as Models

A simple mechanism of reversible separation, the intracrystalline swelling of montmorillonites and its homologues are silicates with layer structures, and within the indicovered by *U. Hofmann* in 1933, allows the reversible separation of montmorillonite crystals into individual layers of only 9—10 Å thickness[3]. Montmorillonite and its homologues are silicates with layer structures and within the individual crystals the layers are arranged parallel to each other (Fig. 2a). If water is added to such a crystal, water molecules penetrate into the interlayer region, thus increasing the distance between the parallel layers. The equilibrium distance is determined by the electrolyte concentration of the water (Fig. 2b). The lower the ionic strength, the greater the spacings. In the case of 1 : 1 electrolytes the attraction potential approaches the order of the thermal energy at electrolyte concentrations of less than $10^{-3}$ M. The crystals then disintegrate into the individual layers, each of these becoming an independent kinetic unit (Fig. 2c).

Individual layers of a disintegrated crystal, when introduced into an appropriate culture medium containing the necessary ingredients, may act as nuclei for new crystals. Formation of a new layer is highly influenced by the nucleation step. The activation energy for nucleation of montmorillonite layers is decreased by a factor of 0.25—0.35, relative to that for homogeneous nucleation, in the presence of "matrix layers"[*].

---

[*] Experimental determination of the activation energy for nucleation is extremely time-consuming. The degree of error is high when absolute values are to be determined.

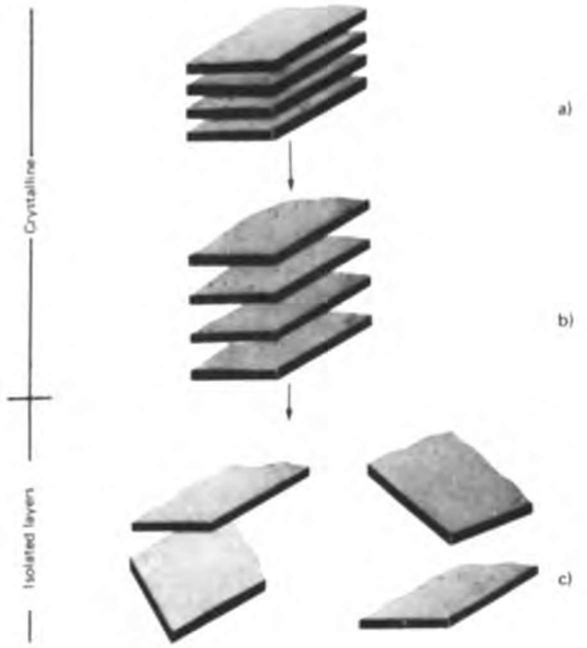

Fig. 2. Scheme for the reversible dissociation of a montmorillonite crystal. a) Layers of a crystal, stacked parallel to each other; b) increase in basal spacing (layer distance), following uptake of water (reduction of electrolyte concentration); c) disintegration of a crystal into individual, kinetically independent layers at low electrolyte concentration ($c \leq 1 \times 10^{-3}$ M of a 1,1-electrolyte).

On decreasing the electrolyte concentration, crystals having newly synthesized layers may also undergo disintegration, thus representing a powerful self-multiplying system. In nature, the external conditions may be provided by each cycle of thawing or by the change from rain to drought. The electrolyte concentration in melting ice is so low that disintegration into individual layers becomes possible. Simultaneously, the suspension of layers becomes highly dilute. As a consequence of the solubility of rocks and soils, and subsequent evaporation of water during drought periods, conditions are created for the synthesis of new layers on the previously existing matrix layers. In addition to cycles of thawing or rain and drought periods, the synthesis requires a distinct ratio of $Mg^{2+}$ and $Ca^{2+}$ to $K^+$ and $Na^+$ ions during the growth phase; the absolute concentrations must not exceed a certain limit. $Mg^{2+}$ and $Ca^{2+}$ limit the uptake of water and expansion of the interlayer distance up to a maximum of *ca.* 12 Å.

As shown in Section 5, individual montmorillonite layers carry quite a number of pieces of different information. If the growth of new layers, nucleated on matrix layers, is connected with the transfer of this information onto the new layers, the self-multiplying montmorillonite could be viewed as a true replicating system. Experiments aimed at investigating the transfer of information in repeated cycles,

disintegration of the matrix into individual layers and subsequent high dilution→

synthesis of new layers on isolated matrix layers→

redisintegration into individual layers and subsequent high dilution→

resynthesis of new layers on isolated matrix layers,

had little success. The transfer of information could not be clearly recognized, even in the first generation. This can, however, be rationalized on the basis of the structure of the individual siicate layers; they have a thickness of *ca.* 9.2 Å and consist of six atomic layers (Fig. 3).

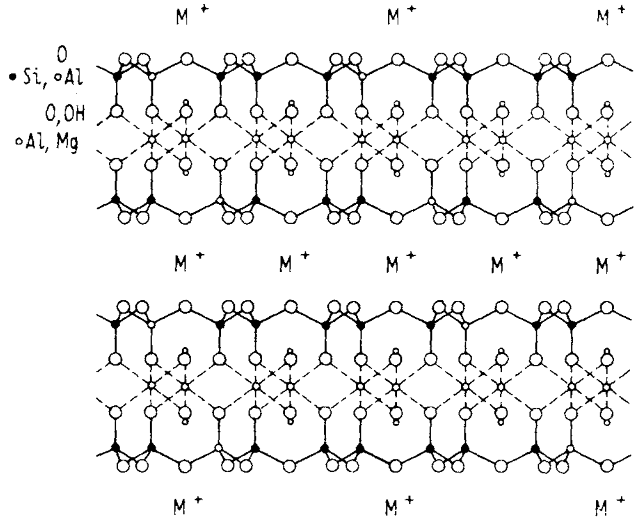

Fig. 3. Structural scheme of a single layer of montmorillonite. $M^+$ = univalent cation.

The Si atoms are tetrahedrally coordinated by four O atoms; neighboring tetrahedrons share common corners, thus forming a two-dimensional $Si_2O_5$-layer. In the idealized structure three of the oxygens, which simultaneously belong to two tetrahedra, lie in one plane. The fourth O atom of each $SiO_4$-tetrahedron protrudes perpendicularly from the layer but is uniformly orientated towards one side of the latter. Two of these tetrahedral layers are interconnected by an octahedral Al(O,OH)-layer. On an atomic scale the information, which should be transferred onto the replica layers during synthesis consits, in general, of isomorphous substitutions of $Si^{4+}$ by $Al^{3+} + M^+$ or of $Al^{3+}$ by $Mg^{2+} + M^+$. A true image of these defects in the replica layers requires long-range forces (up to *ca.* 23 Å, undisturbed by the several sheets of the matrix).

## 4. The Intercalating Synthesis of Silicate Layers

Formally, a different mechanism for a replicating synthesis in such silicates can be postulated. By careful choice of concentration and composition of electrolytes in the growth solution, the interlayer distance can be stabilized at just that value which allows nucleation and growth of new layers in the interlayer region.

From studies of intercalation mechanisms it is well known that the layers can be elastically deformed. Instead of intercalation of small molecules, a newly synthesized layer could grow into the interlayer region, pushing along the frontier of the elastic deformation of the matrix layers (Fig. 4a).

In this way, information on structural irregularities could be transferred from the bottom sheets of the top matrix layer to the top sheets of the new silicate layer, and from the top sheets of the bottom matrix layer onto the bottom sheets of the new silicate layer. Special long-range forces would not be necessary. In principle, this mechanism could be viewed as a primitive two-dimensional analogue of the replication of the double helix of DNA. This is illustrated in simplified form in the scheme in Figure 4b.

varies with water content; appropriate conditions result in total disintegration into individual layers. In contrast to montmorillonite, the smallest kinetically independent units are not single silicate layers, but pairs of layers. Correspondingly, the intercalating synthesis of new layers can only occur in each second interlayer. This permits a simple experimental proof.

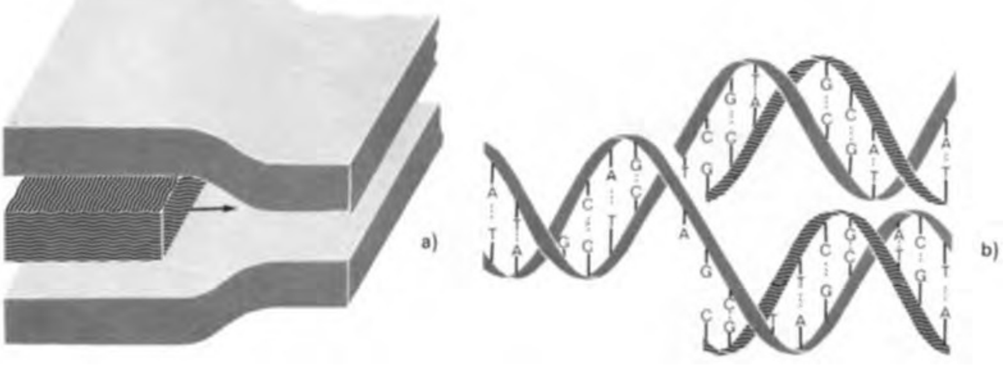

Fig. 4. Comparison of the intercalating synthesis into montmorillonite with the replication of DNA. a) Intercalating synthesis of a silicate layer; b) simplified scheme of the replication of DNA. (Matrix: dark; replica: shaded).

Intercalating synthesis in layer silicates has been known for some time. Under slightly hydrothermal conditions, layers of *e.g.* $Mg(OH)_2$ or $Al(OH)_3$ can be intercalated into the montmorillonite layers, resulting in the formation of chlorites. This synthesis is important in chloritization processes in nature[4].

Unequivocal experimental proof for the intercalating synthesis of montmorillonite silicate layers in montmorillonite, however, meets with considerable difficulties. In those cases where the replica- and matrix-layers are identical, there is no way of differentiating matrix and replica after the synthesis. Moreover, there is no way of distinguishing new layers synthesized either by intercalation or by nucleation on an external basal plane of the matrix. The intercalating synthesis of new montmorillonite layers was eventually unambiguously proven using the rare layer-silicate allevardite[5] as model. The layers of allevardite closely resemble those of montmorillonite; in contrast, however, they are highly asymmetric. The extent of isomorphous substitution of $Si^{4+}$ by $Al^{3+} + M^{+}$ in the two tetrahedral Si—O units of a layer, differs by a factor of three. The stacking of the layers within a crystal is such, that the opposite tetrahedral sheets of adjacent layers have alternately both high or low degrees of substitution. Each replacement of $Si^{4+}$ by $Al^{3+}$ creates an excess negative charge within the layer. For charge balance, cations of equivalent charge have to enter the interlayer space. The typical stacking of the asymmetric allevardite layers thus results in interlayers with regularly alternating very high and very low densities of interlayer cations. The high density corresponds to that of micas. Here the electrostatic attraction between the negatively charged layers and the interlayer cations is of such strength, that under normal experimental conditions hydration of the latter becomes impossible. The interlayer distance is, therefore, fixed at that of closest approach. The low interlayer cation density corresponds to the situation in montmorillonite. The interlayer cations can be hydrated and the interlayer distance

The identity period in allevardite comprises two layers. Therefore, the basal spacing determined by X-ray measurements corresponds to 24.6 Å under normal conditions; 10.2 Å (mica-like part) and 14.4 Å for the montmorillonitic part (silicate layer + 2 layers of $H_2O$) (Fig. 5a). After the intercalating synthesis of one layer in each montmorillonitic interlayer the measured spacing *d* becomes *ca.* 39 Å ($d = 10.2\ \text{Å} + 14.4\ \text{Å} + 14.4\ \text{Å} = 39.0\ \text{Å}$). Shortly after the start of the synthesis, broad first and second order reflections appear. After *ca.* 48 h the original first and second order (001)-reflections disappear, and the new series of reflections become sharper (Fig. 5b). If the synthesis is performed over several weeks another series of (001)-reflections is observed with a spacing of *ca.* 68 Å (Fig. 5c). This results from the intercalation of two additional layers be-

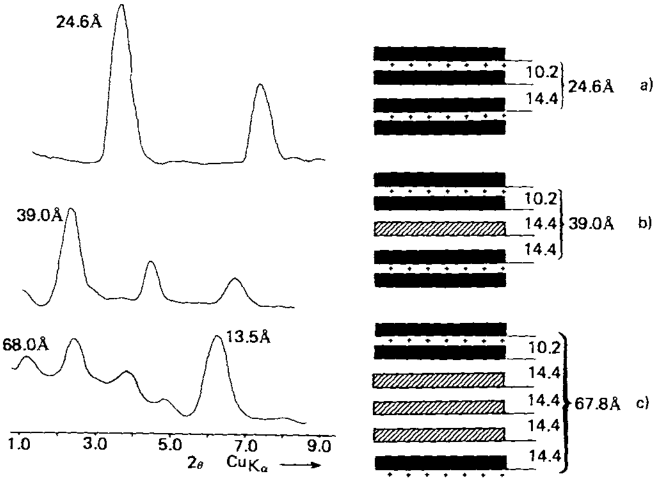

Fig. 5. Evidence for the intercalating synthesis of montmorillonite layers into allevardite. Left: intensities of (001)-reflections in the region $2\theta = 1.0-9.0$ at a water vapor pressure of 6 torr ($Cu_{K_\alpha}$-radiation): right: stacking of layers. The repeat period in the direction normal to the layers is shown in brackets. a) Allevardite, the starting material; b) sample at the end of the intercalating synthesis of the first layer; c) far advanced stage in the synthesis of three new layers (matrix: dark; replica: shaded).

tween the interlayers of the matrix layers and the first intercalated montmorillonite layer ($d = 10.2$ Å + 14.4 Å + 14.4 Å + 14.4 Å + 14.4 Å = 67.8 Å).

To achieve this intercalating synthesis of montmorillonite layers, the experimental conditions must be carefully controlled. We used allevardite from Sarŏspatak (Hungary). The overall electrolyte concentration must not exceed 0.02 N and the ratio of $Na^+ : K^+ : Mg^{2+}$ has to be kept within sharp limits during the synthesis. $Al^{3+}$ was applied as a low charged complex and $SiO_2$ as $Si(OH)_4$.

Systematic experiments have shown that the activation energy for nucleation of a new layer is much smaller in the intercalating synthesis than in synthesis on top of a single matrix layer. The decrease is in the order of one half to one third. Therefore, experimental conditions can be chosen which certainly do not allow homogeneous nucleation from the solution.

## 5. The Information Capacity of a Silicate Layer

The individual silicate layers have only been well characterized structurally but not chemically; they belong to a nonstoichiometric series with a wide range of composition and degree of isomorphous substitution. The substitution of $Si^{4+}$ by $Al^{3+}$, or $Al^{3+}$ by $Mg^{2+}$ creates, in addition to the excess negative charge, a Lewis base site. Such sites are distributed more or less randomly within each layer with areas of higher and lower densities. Correspondingly, there are Lewis acid sites in the interlayer space.

As is well known, Lewis base- and Lewis acid-sites represent sites of high catalytic activity. The different densities of such sites within a layer consitute different catalytic properties. A layer, therefore, might be viewed as a primitive model of a multienzyme complex. The transfer of these catalytic properties from a matrix layer onto the replica would transform the intercalating synthesis into a true replication.

Relations between charge densities and catalytic properties of layers silicates have been studied in detail. In this review article examples have been selected which elucidate the wide variety of catalytic properties stored in the silicate layers.

### 5.1 Dimerization and Oligomerization of Unsaturated Aliphatic Acids

Montmorillonites are widely used as catalysts in industrial processes *e.g.* the dimerization of unsaturated fatty acids to dicarboxylic acids. The annual requirement for this catalyst amounts to several thousand tons. Only a few of the many existing deposits from different localities are highly active, this being governed equally by the charge density and the type of interlayer cations.

In Figure 6 the yield of unaltered oleic acid, $C_{36}$-dimeric, $C_{54}$-trimeric, and $C_{\geq 72}$-oligomeric acids is shown as a function of isomorphous substitution. At high charge densities ($>0.60e/(Si,Al)_4O_{10}$), *cis-trans*-isomerization and redox-disproportioning to diunsaturated $C_{18}$-acids and stearic acid occurs to some extent, but no catalytic dimerization or oligomerization. The oleic acid used as starting material is recovered almost quantitatively as a fraction of $C_{18}$-monocarboxylic acids. At charge densities of 0.28 $e/(Si,Al)_4O_{10}$ the yield of dicarboxylic acids shows a pronounced maximum (*ca.* 66%). The maximum yield of tricarboxylic acids occurs at lower charge density. At still lower densities oligomers, which block the internal surfaces, are formed.

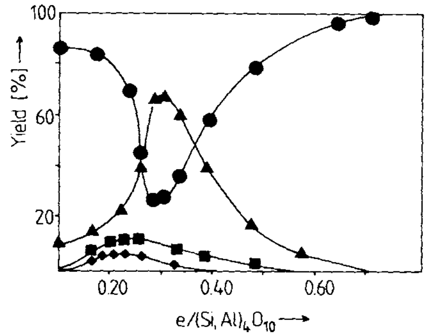

Fig. 6. Oligomerization of oleic acid to di-, tri-, and oligocarboxylic acids with $(CH_3)_4N$-montmorillonite as catalyst as a function of the charge density. Starting material: oleic acid 98%; 0.5 g catalyst per 100 mL oleic acid. ●: Oleic acid + stearic acid ($C_{18}$); ▲: Dicarboxylic acids ($C_{36}$); ■: Tricarboxylic acids ($C_{54}$); ◆: Oligocarboxylic acids ($\geq C_{72}$).

In addition, the effect of charge density on this reaction is interesting because of the influence of the polar end-group of the organic monomer. Only the dimerization of the carboxylic acid is catalyzed, and not that of the corresponding alcohol or nitrile. One would expect the polar end-group not to govern the reactivity of the double bond between C-9 and C-10. All three compounds—acid, alcohol, and nitrile—form intercalation complexes with the montmorillonite catalyst, the only difference being in the structure of these complexes. Alcohols and nitriles have their chains arranged perpendicular or inclined at a large angle to the silicate layers; the $\pi$ bond is, therefore, far removed from the silicate layer and cannot be activated. In the oleic acid complex, the alkyl chain lies flat on the layer; the double bond is in direct contact with the silicate layer and, therefore, can be activated, probably by interaction with an empty 3d orbital on silicon. The charge density provides additional steric effects because the initial intercalation complex is influenced by the interlayer cations $M^+$ which remain in the interlayer region. At high cation density, neighboring acid molecules are separated from each other by the interlayer cations (Fig. 7a). Hence, dimerization cannot occur, although the double bonds are activated. With decreasing interlayer cation density an increasing number of pairs of acid molecules is present. Activation leads to the dimeric acid (Fig. 7b). At still lower cation density, triplets of acid molecules are present, separated from each other by cations. These triplets form trimers. Figure 7c shows a complex with four molecules of acid between the cations, which can react to a tetracarboxylic acid.

### 5.2 Isomerization Reactions

A large number of isomerization reactions are known to occur on and in montmorillonites. A very simple example is the isomerization of cationic complexes, *e.g.*

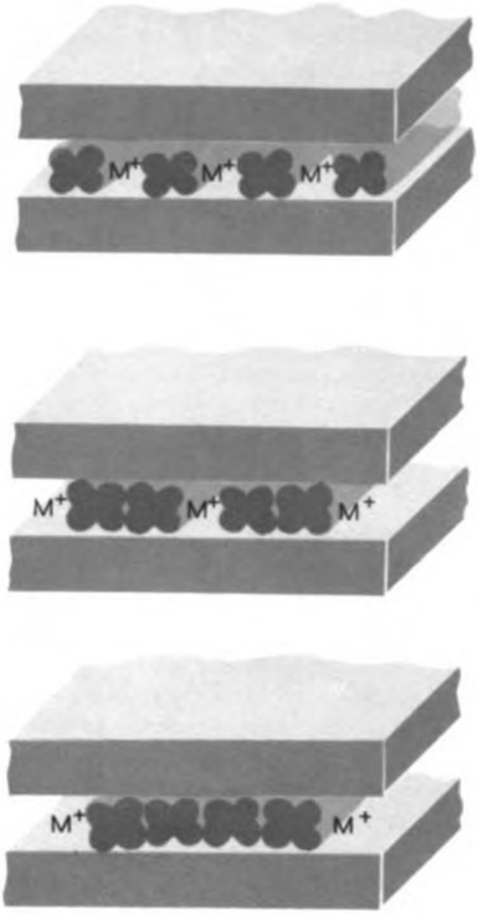

Fig. 7. Effect of the packing density of interlayer cations on the oligomerization of oleic acid (simplified scheme). a) Neighboring molecules in the oleic acid-montmorillonite intercalation complex are separated from each other by interlayer cations: no dicarboxylic acid produced. b) Pairs of acid molecules separated from each other by interlayer cations: maximum yield of dicarboxylic acid. c) Groups of 4 acid molecules separated by interlayer cations: formation of tetracarboxylic acids.

$$[Cr(H_2O)_5Cl]^{2+} + H_2O \rightleftharpoons [Cr(H_2O)_6]^{3+} + Cl^-$$

which can be followed spectrometrically. At high charge densities the complex $[Cr(H_2O)_6]^{3+}$ is stable, at low charge density the stability of $[Cr(H_2O)_5Cl]^{2+}$ is much higher. The behavior is mainly determined by electrostatic interaction. In areas of high charge density, the higher charged interlayer cation is preferred rather than a lower charged one, and the converse. The activation energy for the isomerization reaction varies with charge density by *ca.* 14 kJ/mol.

### 5.3. Redox Reactions

Redox reactions can also be catalyzed by montmorillonites. Industrial applications of this phenomenon are well known, *e.g.* in modern copying papers. The coated front of the paper is filled with an appropriate, mostly acidic montmorillonite, which catalyzes the oxidation of leukobases. The leukobase is fixed on the coated back of the original and is squeezed onto the coated front by the pressure of writing[7]. The oxidizing agent may be any oxidant or oxygen from the air.

The degree of isomorphous substitution is immaterial if the reduced or oxidized compounds are neutral molecules. If cations are involved, however, the charge density becomes a dominant factor, *e.g.* the reaction

$$2CoL_n^{3+} + 2H_2O \rightleftharpoons 2nL + 2Co^{2+} + 2H^+ + H_2O_2$$

In the interlayer space of highly charged montmorillonites the cation with cobalt in the oxidation state +3 is stable, while it is reduced to +2 in low-charged samples. The $H_2O_2$, which develops simultaneously with the cobalt 2+, immediately decomposes to $O_2$ and $H_2O$.

The reduction of the cobalt and the decomposition of the complex are again caused by the electrostatic interaction of the interlayer cations with the fixed negative charges of the layers. At very low charge density, the balance of the excess charges by the complex trivalent cation would imply charge separation.

The effect of charge density on the oxidation of aromatic amines by oxygen of the air is even more pronounced. Aniline, for example, is easily oxidized to a black "polymer" at high charge densities, and at medium densities to a red or blue "oligomer"; at low charge densities it remains unaltered. Correspondingly, the black polymer is hydrolyzed and reduced at low charge densities[8].

### 5.4. Condensation and Hydrolysis

The catalytic action of layer silicates on condensation reactions is not only restricted to montmorillonites. In kaolinite, intercalated ammonium acetate is dehydrated to acetamide even at 60—70 °C. A similar reaction occurs with ammonium salts of amino acids yielding peptides. The same reaction takes place in montmorillonites. The temperature necessary for condensation increases with increasing charge density. In this thermal condensation di-, tri-, and hexapeptides (or other peptides consisting of 3n amino acids) are favored. Similar results were obtained by *Paecht-Horovitz*, *Katchalsky et al.*[9] with activated amino acids and montmorillonite as catalyst. The preference for 3n-peptides is probably related to the pseudohexagonal symmetry of the matrix layers.

Whereas condensation is favored in montmorillonites of low charge density, peptides and proteins can be hydrolyzed at high charge densities if $H_3O^+$ ions are present in the interlayer region. The size of the hydrolysis product of this reaction depends upon the charge density on the silicate layers, and the content of ε-amino- and guanidino-groups of the protein, *i.e.* on the content of lysine and arginine. At a given charge density of the silicate, the more peptide bonds are cleaved the lower the content of lysine and arginine. For a given protein at constant pH, the more bonds are cleaved the higher the charge density of the silicate[8].

There is a simple explanation for this highly selective cleavage of peptide bonds, which is governed by the charge density and its distribution on the silicate. The $H_3O^+$-interlayer cations react with the ε-amino- and guanido groups, forming ammonium ions. In this way the proteins are bound as cations in the interlayer region and spread in layers of 4.5—8 Å thickness. At high charge den-

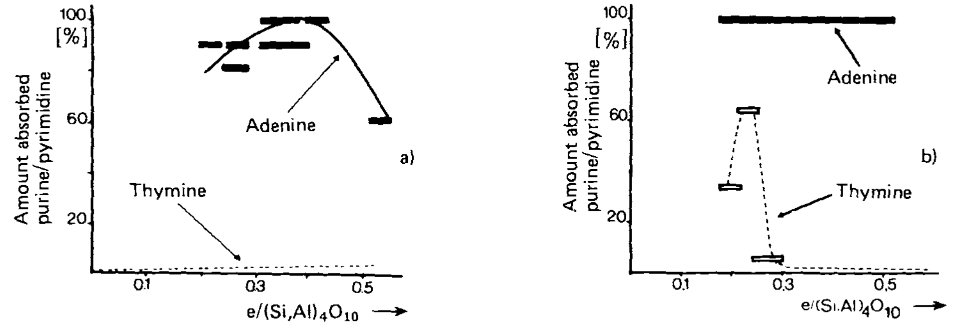

Fig. 9. Adsorption of adenine and thymine on layer silicates of different charge density ($10^{-5}$ M solutions at pH = 4.0). a) Adsorption of pure thymine or adenine; b) Adsorption of mixtures of thymine and of adenine (1 : 1) or adsorption of adenine, followed by adsorption of thymine on the adenine loaded sample.

sity and low lysine and arginine levels, only a fraction of the $H_3O^+$ ions is consumed in ammonium ion formation. The others hydrolyze peptide bonds, which are forced into their neighborhood by the electrostatic interaction of the fixed negative charges and the ammonium groups on the protein. The $H_3O^+$ concentration may correspond to a 10 N acid. Thus, the reaction is a simple acid hydrolysis: the stereospecificity is brought about by the charge density.

### 5.5. Selective Adsorption

In some cases selective catalytic reactions, which depend upon the charge density, are caused by selective adsorption on the silicates. The effect of charge density on such selective adsorptions has been studied with mixtures of amino acids and with mixtures of purines and pyrimidines.

In aqueous solutions of cysteine with another amino acid X, in a molar ratio 1 : 1, one of these is usually adsorbed preferentially. In Figure 8, equilibrium ratios of the adsorbate on the montmorillonite are shown as a function of the charge density.

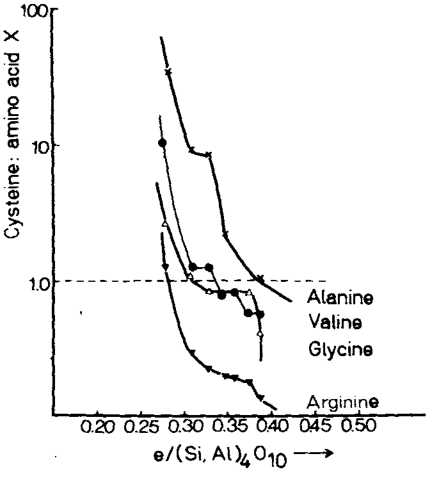

Fig. 8. Effect of charge density on the selective adsorption of amino acids on montmorillonite. Starting mixture; cysteine : amino acid X = 1 : 1 (molar ratio). Ratio in the figure; molar ratio cysteine: amino acid X in the adsorbate at equilibrium. Equilibrium concentration was chosen such that it just reached the plateau of the adsorption isotherm; in every case this is of the Langmuir-type.

At low charge densities the cysteine is enriched, at high charge densities the more basic amino acid accumulates. Similar results have been obtained with many other pairs of amino acids, indicating that the degree of isomorphous substitution has a strong effect on selective adsorption.

The results of adsorption experiments with adenine and thymine, and $10^{-5}$ M solutions of mixtures of these at pH = 4.0[10] also indicate a high sensitivity to charge density. Thymine is bound only to a slight extent, while a broad maximum is observed at medium charge densities in the adsorption of adenine (Fig. 9a).

Adsorption of a mixture of thymine and adenine in the molar ratio 1 : 1, yields quite different results: adenine is adsorbed over the whole range of charge density. In addition, thymine is adsorbed to a high degree at a particular charge density (Fig. 9b). A similar specific adsorption on montmorillonite is found with all corresponding pairs of purines and pyrimidines, but is not observed with non-corresponding pairs.

The particular value of the charge density, at which the specific adsorption is found, is determined by the surface area requirements of the pair. The stronger base is bound as a cation, while the weaker one is chiefly fixed by hydrogen bonds and dispersion forces.

The ring planes of the bases lie parallel to the silicate layers. Hydrogen bonds to the neighboring base are, therefore, only favorable with corresponding pairs. The effect of charge density and charge distribution on the silicate is shown schematically in Figure 10. The cations of the stronger base occupy those sites on the silicate layers which are closest to the fixed negative charges (Fig. 10a). At the particular charge density there is just enough space for pair formation between the cations (Fig. 10b). At higher charge densities, pair formation on the adsorbed monolayer is prevented due to steric effects (Fig. 10c). At lower charge densities the space requirements are sufficient (Fig. 10d). However, in this case the specific adsorption of the pairs is suppressed by kinetic hindrance caused by the strong decrease in the interlayer distance. A state of equilibrium is, therefore, not reached.

From these examples it can be concluded that the areas of different charge densities present in each silicate layer represent, both qualitatively and quantitatively, different catalytic functions and selectivities. Each silicate layer contains a considerable amount of information and corre-

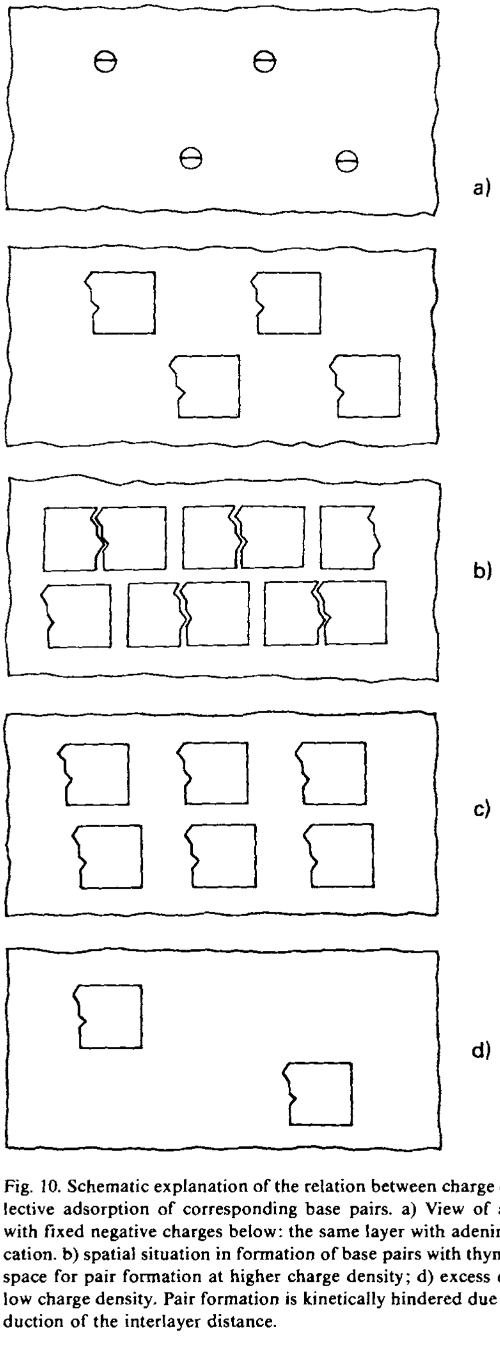

Fig. 10. Schematic explanation of the relation between charge density and selective adsorption of corresponding base pairs. a) View of a silicate layer with fixed negative charges below: the same layer with adenine as interlayer cation. b) spatial situation in formation of base pairs with thymine; c) no free space for pair formation at higher charge density; d) excess empty space at low charge density. Pair formation is kinetically hindered due to a drastic reduction of the interlayer distance.

sponds, at least partially, to multienzyme complexes. Different catalytic capabilities are only partially independent of each other.

## 6. Experimental Proof of Replication

Experiments to establish that every piece of information is transferred from the matrix to the replica layers during the intercalating synthesis were carried out using carefully selected and purified matrix material (montmorillonite from Lower Bavaria and from Cyprus). This matrix material was used as the "parent generation" ($F_0$). Approximately $10^{-8}$ to $10^{-9}$ g of the parent-silicate was added to each run. The breeding solution contained $Na^+$, $K^+$, $Mg^{2+}$, $Al^{3+}$, and $Si(OH)_4$ in concentrations which only resulted in an intercalating synthesis in the model investigations with allevardite, and did not lead to nucleation in the free solution. Concentrations were about half that necessary to cause nucleation in the matrix free solution within three months in the absence of seeds.

The optimum growth rate was determined experimentally by variation of the ionic strength. Part of the $Al^{3+}$ and orthosilicic acid were complexed by pyrocatechol. The intercalating synthesis was interrupted when *ca.* $10^{-5}$–$10^{-6}$ g of new montmorillonite had formed. The product ($F_1$-generation) was examined by X-rays, and characterized chemically by catalytic reactions. The average charge density and its upper and lower limits were determined by the alkylammonium method.

About $10^{-8}-10^{-9}$ g of this $F_1$-generation was used as a matrix for the analogous synthesis of the $F_2$-generation. In order to obtain homogeneous matrix material, the pure $Na^+$ derivative was prepared by a cation exchange reaction and washed with water to an electrolyte concentration less of than $10^{-5}$ N. The $F_n$-generation was bred in the same way, using $10^{-8}-10^{-9}$ g of the $F_{n-1}$-generation as matrix.

The results of such a series of experiments are shown in Figure 11. The composition of the "breeding" solution was such that homogeneous nucleation in the absence of matrix layers, and at twice the concentration, yielded montmorillonites with isomorphous substitution of 0.42 e/$(Si,Al)_4O_{10}$-unit. The matrix layers ($F_0$-generation) had an excess charge of 0.28 e/$(Si,Al)_4O_{10}$.

The distribution of charge densities and its mean value for generations $F_1$ to $F_{22}$ are shown in Figure 11. Up to the 10th generation the spread is low. From the 16th to the 18th generation the number of errors increases rapidly. In

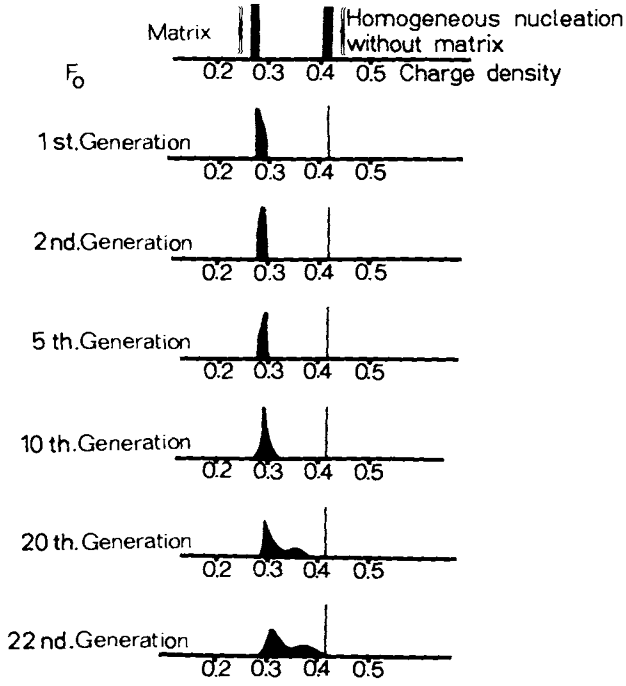

Fig. 11. Charge density distribution in the generations $F_0$ to $F_{22}$. $F_0$-generation: 0.28e/$(Si,Al)_4O_{10}$; the composition of the breeding solution yields 0.43e/$(Si,Al)_4O_{10}$ in the absence of matrix layers at higher concentrations.

the generation $F_{20}$ a significant portion has a charge density higher than 0.33 $e/(Si,Al)_4O_{10}$, and almost no material with the original value of 0.28 $e/(Si,Al)_4O_{10}$ remains; this indicates rapid decay in replication quality.

Results of complementary series of experiments are shown in Figure 12. Here the parent material had a charge density of $0.42e/(Si,Al)_4O_{10}$, while homogeneous nucleation in the solution in the absence of seeds gave densities of $0.26-0.29e/(Si,Al)_4O_{10}$.

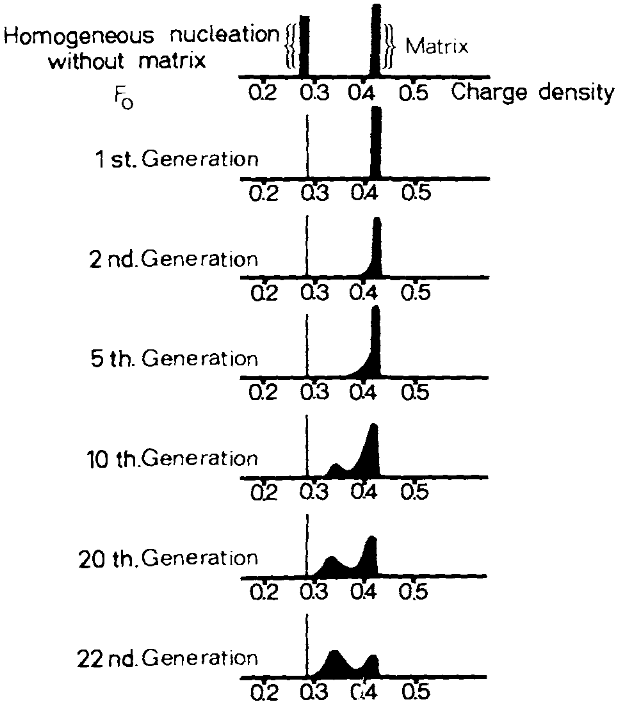

Fig. 12. Charge density distribution in the generations $F_0$ to $F_{22}$. $F_0$-generation: $0.43e/(Si,Al)_4O_{10}$; the composition of the breeding solution yields $0.28e/(Si,Al)_4O_{10}$ in the absence of matrix layers.

In this series, the frequency of replication errors is much higher than in the previous one. By the 10th generation, a second charge density maximum at *ca.* $0.34e/(Si,Al)_4O_{10}$ is observed.

Catalytic activities are affected by errors to a different extent. This is clearly shown in measurements of catalytic activities of individual generations (Fig. 13). These generations were grown under the same experimental conditions as those of Figures 11 and 12. The activities are normalized to samples with maximum activity (=100%). With low charged $F_0$-samples loss of activity for the reduction $Co^{3+} + e \rightarrow Co^{2+}$ is observed, even at the 6th generation. In the 31st generation any influence of the original matrix ($F_0$) has disappeared. With the higher charged $F_0$-matrix ($0.42e/(Si,Al)_4O_{10}$) increased activity for the reduction is clearly displayed after the 20th generation. The activity for oxidation reactions, which was studied using the reaction of aniline with atmospheric oxygen, begins to decrease from the 20th generation in the series with the higher charged $F_0$-generation (Fig. 13b). It increases considerably from the 12th generation in experiments with the low charged $F_0$-matrix.

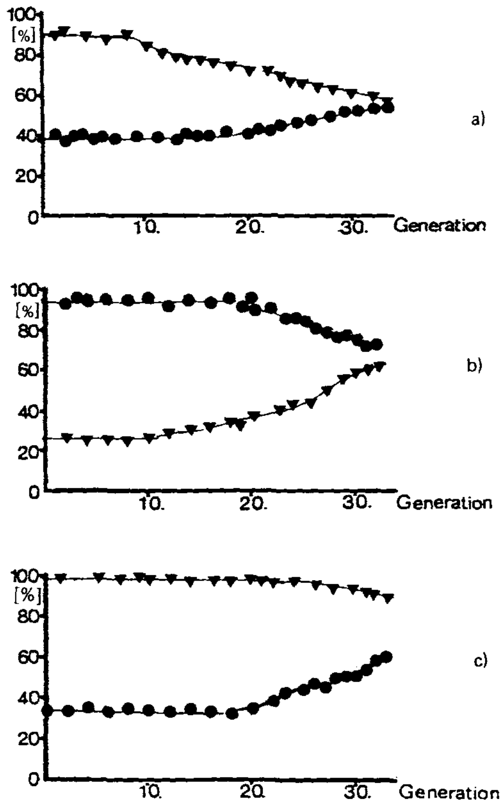

Fig. 13. Change in catalytic activity in the generations $F_0$ to $F_{33}$. a) Activity for reduction of $Co^{3+}$ to $Co^{2+}$; b) activity for the oxidation of aniline; c) activity for the selective adsorption of the pair adenine/thymine. Results from samples, bred according to the conditions described in Fig. 11 (▼) and 12 (●). Charge density ($F_0$): 0.28 or $0.43e/(Si,Al)_4O_{10}$.

The capacity to selectively adsorb the pair adenine/thymine remains unaltered up to the 26th generation in samples which are derived from the lower charged matrix. Improvement becomes significant in the complementary series from the 20th generation onwards (Fig. 13c). Information on distribution and clustering of the errors in replication is obtained from detailed analyses of the data in Figure 13.

The experiments demonstrate that the information contained in the matrix-layer is transferred to the daughter-layers, and prove the intercalating synthesis to be a true replication process. The high margin of error seems to be connected with the two-dimensional nature of the carrier of the information which has many disadvantages compared to a one-dimensional system like DNA. However, it should be borne in mind that our experimental technique[11] may not yet be optimal.

## 7. Replication and Evolution

The results mentioned so far indicate that clay minerals such as montmorillonite, which can swell to a large degree, are capable of replicative self-multiplication. These minerals may, therefore, be looked upon as models for protolife, or possibly for most primitive life; their catalytic capabilities and selectivities can be altered, thus leading to acceleration or retardation of the rate of self-multiplication.

A typical mechanism of retardation becomes active when additional areas of high charge density are produced by the errors. In such areas *e.g.* $K^+$ ions are bound selectively. Beyond a critical concentration of interlayer potassium, the variation of layer distance with variable electrolyte concentration is blocked. Adjacent layers become fixed irreversibly at the distance of closest approach, and water molecules are squeezed out from the interlayer region. In consequence, new layers can no longer be synthesized by intercalation.

Retardation or suppression of the self-multiplication step also occurs if one of the catalytic processes of a mutant leads to a product with much higher molecular weight. This product is bound more or less irreversibly and hence excludes these "mutants" from further replication.

## 8. Differentiation

One of the problems in replication, caused by a two-dimensional carrier of information, is location of the starting point of the replicative synthesis. With a one-dimensional matrix there are only two possibilities. In the two-dimensional system the starting point may occur randomly at the crystal boundary or selectively at distinct charge density sites. Experiments, in which the replicative synthesis was interrupted before the amount of newly synthesized material reached 40% (by weight) of the matrix material, indicate a highly selective start which depends upon the ratio $Na^+ : K^+ : Mg^{2+}$ and the average charge density of the matrix. At relatively high charge density and high $K^+ : Na^+$ ratios, synthesis begins in areas of low charge density, at low $K^+ : Na^+$ ratios in areas of high charge density. Premature interruption of the replication process thus allows the distinct information to be gained. The diameter of the platelets when the synthesis is prematurely interrupted is much smaller than that of the matrix layers. In our experiments the matrix diameter was 600—800 Å; the areas selected by premature interruption were only 80—160 Å in diameter. Unfortunately, these extremely small particles are less stable than the matrix. Therefore, this way of differentiation is very limited in this model system. However, the procedure offers a method of synthesizing highly specific silicate catalysts. Due to their diminished colloid stability, these smaller particles can be flocculated selectively during the self-multiplicating process.

Another disadvantage of our model is the absence of information about the growth of a new layer when the intercalating layer reaches the size of the matrix layers. In nature, this problem seems to be solved in a satisfactory way. The isomorphous substitution obviously induces strain in the lattice. Therefore, when growth reaches the limiting size, nucleation and growth of a new layer becomes energetically more favorable than further growth of the strained layer. In model experiments, however, such information had to be artifically incorporated into the system. This was achieved by reacting the hydroxy groups bound to Si on the edges of the matrix layers with $(CH_3)_3SiCl$, to the produce $(CH_3)_3SiO$ groups. In this way, growth of the matrix layers was prevented and, in addition, growth of the new layers beyond the matrix layer was hindered.

Without the artificial stop-marker in model experiments, the matrix and replica layers would have grown beyond the original size. Thus, the replica layers would obtain all the "genetic" information from the matrix; however, they would acquire additional information in their own genetic index, which is determined by the environment. This newly gained information could be transferred genetically to the next generation. In this way the system would be a simple experimental realization of ***Lamark***'s hypothesis on heritability.

In our experiments, growth of daughter-layers beyond the size of the matrix-layers would have invalidated the results on replication. All experiments were, therefore, interrupted at the earliest possible time; additionally, the trimethylsilyl chloride treatment was administered to the matrix layers of each generation in order to implant the artificial "stop".

## 9. The Possibility of an Evolution of Replicating Systems

With the proof that replication is not restricted to the nucleic acid/protein system, it must be considered whether an evolution of protolife, *i.e.* an evolution of systems capable of replicating, can be inserted between the processes of chemical and biological evolution as shown in Figure 1b.

In a discussion of evolution of the replicating principle, it must first be established whether the principle of a replicating synthesis can be transferred from one system to a chemically different one. In spite of the different chemical composition, the daughter-layer should take over all the information of the matrix.

Information storage implies relatively stable chemical systems, *i.e.* strong bonds and conformational stability: these have to be synthesized in the absence of specific enzymes and hence, the choice of systems is very limited.

For our experiments we chose graphitic acid (graphite oxide), which is obtained from graphite by oxidation with $ClO_2$, $NO_2$, or $Mn_2O_7$[12]. It consists of two-dimensional layers of predominantly $sp^3$-hybridized carbons. Three bonds are used for the carbon layers, the fourth is saturated with a functional group, often OH groups of different acidity. Over a wide range of pH, the layers can be considered as two-dimensional macroanions with interlayer cations for charge balance. With decreasing electrolyte concentration, the interlayer cations form diffuse double layers. The electrostatic repulsion of the latter and simultaneous uptake of water lead to an increase of the interlayer distance, which may lead to the total disintegration into individual, kinetically independent layers as in the case of montmorillonite (Fig. 2). The charge density in graphitic acid can readily be controlled by the pH. In spite of these properties and the very close similarity to montmorillonite, graphitic acid cannot be viewed as a replicating system. There are no catalysts which enable the direct synthesis of two-dimensional layers with carbon-carbon bonds from low molecular weight starting material under conditions in which the crystals are disintegrated into individual layers, or at distances which allow the intercalating synthesis. However, we were able to use graphitic acid as a matrix in the intercalating synthesis of montmorillonite layers.

In the first step, a regular interstratification montmorillonite : graphitic acid = 1 : 1 is formed; at longer reaction times the ratio 3 : 1 is obtained. Finally a montmorillonite with randomly interstratified graphitic acid layers is formed. After the synthesis, the mixed layer crystal was disintegrated into individual layers by lowering the electrolyte concentration to $< 10^{-4}$ M. The effective charge of the graphitic acid layers could be changed by altering the pH, and this enabled the layers to be flocculated into pure montmorillonite and graphitic acid crystals. The separated montmorillonite then was used as a matrix for further intercalating and replicating syntheses of montmorillonite layers.

In this sequence of reactions, the charge density distribution is transferred almost entirely from graphitic acid onto the montmorillonite. Using a breeding solution, which under conditions of homogeneous nucleation and higher concentration would have led to a montmorillonite of mean charge density of $0.25e/(Si,Al)_4O_{10}$, silicate layers with 0.54 or $0.43e/(Si,Al)_4O_{10}$, respectively, were grown in two experiments by intercalating synthesis in different high charged graphitic acid matrices. The charge density on graphitic acid can be varied not only by pH changes, but also by methylation of acidic groups or by acetylation. By use of graphitic acid matrices, whose charge density has been altered in this way, charge density transcription from the graphitic acid onto the montmorillonite layers could also be established.

## 10. Conclusions

The principle of replication and self-multiplication is not restricted to the nucleic acid/protein system; it is a more general property of distinct macromolecular systems. More primitive forms of life or types of protolife, therefore, must also be discussed in the context of the origin of life. Possibly, the question of how nucleic acids and proteins were formed and aptly selected in the course of the chemical evolution has been incorrectly phrased. Both might have developed in the course of the evolution of replicating systems.

The highly-expanding clay minerals are an excellent replicating system model; in the course of an immense number of replications they might have passed on an evolution and a selection, forced on the system by the environment, in just the manner expected for the most primitive forms of protolife.

The question of whether these clay minerals were a real link in the chain of replicating systems, cannot yet be answered. There is no doubt, however, that these clay minerals were abundant on the prebiological earth and were possibly the most abundant macromolecular chemical systems. Certainly, a large number of these would have been excluded from replicating syntheses due to adsorption of basic and neutral C—H—N-compounds, from photochemical reactions, electrical discharges or extraterrestrial sources. This portion was able to accumulate and store labile molecules. The remainder may have propagated replicatively. Each cycle of thawing, or rains and drought could provide the external conditions necessary for one cycle of replication in these systems.

Another indication is obtained, if we assume that *Haeckel*'s postulate "The ontogeny of individuals is an image of the phylogeny" is also valid for protolife systems or the evolution of replicating systems. In this case, three characteristic properties of the clay system may have a deeper meaning:

1) The remarkable $K^+/Na^+$ selectivity,
2) the pronounced selectivity for corresponding pairs of purine/pyrimidine and
3) the possibility of forming ferredoxine-like redox catalysts.

Depending on the charge density, potassium may be accumulated from ratios of 3 : 1 up to 30 : 1 from solutions with $K^+ : Na^+ = 1 : 1$. All living systems known hitherto function within such an accumulation factor.

The corresponding base pairs purine/pyrimidine are fundamental to all types of life based on nucleic acids and proteins, beginning with the most primitive archaebacteria and blue-green algae up to the highly developed mammals.

Ferredoxines represent the biogenetically oldest enzyme system having the same principle: at least two SH groups at a distance which allows formation of metal-sulfur bonds —S—M—S—. Redox properties are mainly determined by the S—M— bond length. These lengths are coerced by the rigid nature of the cysteine groups in the two different peptide helices and the tertiary structure thereof. In models with montmorillonites, the S—M-bond length is determined by the distance of the negative charges, which are fixed in the silicate layers, and the electrostatic interactions between these charges and the $—NH_3^+$ group of cysteine. The selectivity is, therefore, not very pronounced; pair-formation —S—M—S— can occur with all neighboring cysteine units. Their number is higher in the two-dimensional system.

In contrast, the selectivity is higher if the SH groups belong to two different peptide chains, and is still more pronounced if 4 —SH groups are coordinated to a metal ion, as in the phylogenetically younger ferredoxines.

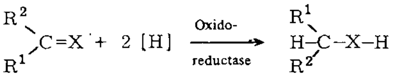
# Electro-Enzymatic and Electro-Microbial Stereospecific Reductions[**]

By *Helmut Simon, Helmut Günther, Johann Bader,* and *Wilhelm Tischer*[*]

*Dedicated to Professor Helmut Holzer on the occasion of his 60th birthday*

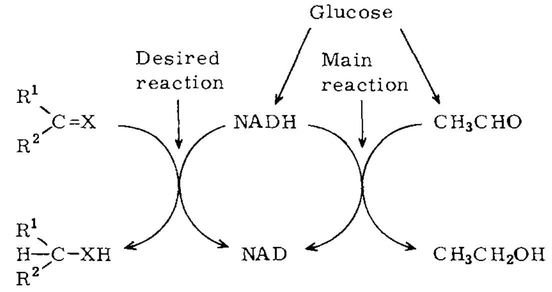
Numerous chiral substances are formed in nature by the reduction of unsaturated compounds with oxidoreductases, which display a relatively large substrate width and complete stereospecificity[1] [eq. (a)]. The two reduction equivalents frequently originate from NADH or NADPH.



$$R^2R^1C{=}X + 2\,[H] \xrightarrow[\text{reductase}]{\text{Oxido-}} H{-}CR^1R^2{-}X{-}H \qquad (a)$$

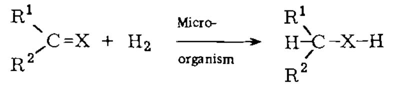
Preparative scale reactions cannot be performed using reduced pyridine nucleotides due to their prohibitively high cost. Therefore, NADH has to be used in catalytic amounts only and regenerated. Reactions of this type have been performed for many years as cofermentations; these have the disadvantage that the desired reaction can principally only occur as a side reaction. Hence, *e.g.*, most of the NADH formed as an intermediate in the fermentation of glucose (electron donor) by yeast is reoxidized in the reduction of acetaldehyde (electron acceptor) [eq. (b)].

We have improved this state of affairs by using $H_2$ as the electron donor[2] in conjunction with anaerobic microorganisms which are provided by a hydrogenase [eq. (c)].



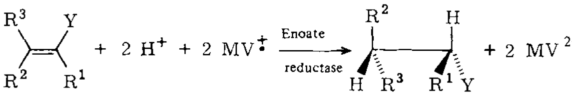
(b)

Reactions of this type are strongly exergonic, and side reactions rarely occur. By this means we have transformed numerous prochiral compounds into chiral species on a preparative scale[2b]. If instead of microorganisms, more or less pure pyridine nucleotide-dependent reductases are used and NAD(P)H is regenerated, systems which are hardly suitable for preparative purposes consisting of two enzymes, two substrates, and two products are formed.



$$R^1R^2C{=}X + H_2 \xrightarrow[\text{organism}]{\text{Micro-}} H{-}CR^1R^2{-}X{-}H \qquad (c)$$

We isolated the enzyme which reduces enoates in Clostridia (anions of α,β-unsaturated carboxylic acids) in an NADH-dependent reaction[3] and have now discovered that this enzyme-type catalyzes two further reactions [eq. (d) and (e)].



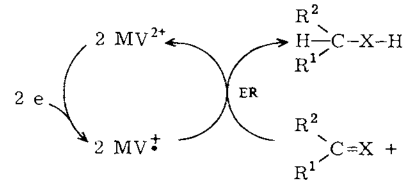
(d)

Y = $COO^-$, CHO;
$R^1$ = H, Me, Et, OMe, NHCHO, F, Cl, Br;
$R^2$ = Alkyl, Aryl, Alkoxycarbonyl (slightly limiting);
$R^3$ = H, Me, Et, etc.

$$2\,MV^{+\cdot} + NAD^+ + H^+ \xrightarrow[\text{reductase}]{\text{Enoate}} NADH + 2\,MV^{2+} \qquad (e)$$

$MV^{+\cdot}$ = Methylviologen radical cation
$MV^{2+}$ = Methylviologen dication
(1,1′-Dimethyl-4,4′-bipyridinium dication)

The dication of the cheap and stable methylviologen can be continuously reduced at an electrode[4]. This produces the system outlined in eq. (f).



(f)

e = Electrons from a cathode; ER = Enoate reductase, $>C{=}X$, the substrate given in eq. (d) or $NAD^+$, eq. (e).

At pH 6.4 even a 0.3 mM solution of $MV^{+\cdot}$ exhibits a half-maximum rate for the reaction described in eq. (d). The

enoate reductase can be used as shown in eq. (f) *(electro-enzymatic reduction),* or in the form of bacterial cells *(electro-microbial reduction).* (2*R*)-2-Methyl-3-phenylpropionate can be prepared in 95% yield using the enoate reductase from *Clostridium* La 1. By analogy, hydrogenations can be carried out using whole cells (50 mg dry weight) or *e.g.* with cells immobilized in polyurethane. The initial rates lie, however, *ca.* 40% and 25%, respectively, below the initial rate of the reaction with the pure enzyme; this decrease in rate results essentially from different diffusion processes.

Not only substrates of enoate reductase can be stereospecifically reduced but also those of all the NAD-dependent enzymes [eq. (e)] which occur in addition to enoate reductase in the cells used.

To date, we have detected enoate reductase in three Clostridia[5]. In this way, using whole cells (*Clostridium sporogenes,* ATCC 3584), we have *e.g.* converted phenyl pyruvate into (2*R*)-phenyl lactate, and other α-keto acids into amino acids by reductive amination. The transformation of phenyl pyruvate can also be achieved using *Proteus mirabilis* (DSM 30115). In properly grown cells, 1—2% of the protein is enoate reductase[3] and 400—500 units of the enzyme can be obtained in a working day, since the method of isolation was simplified[6]. One mg of enoate reductase in the presence of 2 mM $MV^{+\cdot}$ reduces *ca.* 10—12 μmol (*E*)-2-methyl cinnamate *per* minute at 25 °C and pH 6.4. The rates of numerous other enoates lie in the region 5—20 μmol/min.

The question of whether enzymes which catalyze the reaction shown in eq. (e) also occur in aerobic enzymes appeared interesting. We found that *Enterobacter agglomerans*[7] (CDC 1461—67) contains an NADH-dependent fumarate reductase, which can be reduced in the presence of $MV^{+\cdot}$.

A prerequisite for the electro-enzymatic and electro-microbial reductions is that the unsaturated compounds neither react spontaneously at the electrode nor with the reduced mediator. This prerequisite can readily be tested in most cases by means of cyclovoltammetry and by spectrophotometry, and seems to be met in most cases.

We believe that this process, which does not show most of the disadvantages of cofermentations and those which use isolated enzymes with NAD(P)H-regeneration, will enable many chiral compounds to be prepared *e.g.* 21 compounds were reduced using whole cells and hydrogen gas[2b]. Compounds can readily be stereospecifically deuterated using $^2H_2O$ buffers. In cofermentation processes, the quotients, gram glucose/equivalent isolated reduction product, and gram catalyst (*e.g.* microorganisms)/equivalent isolated reduction product, respectively, lie between 500 and 10000[8]; the corresponding values in our process are 10—100 times better.

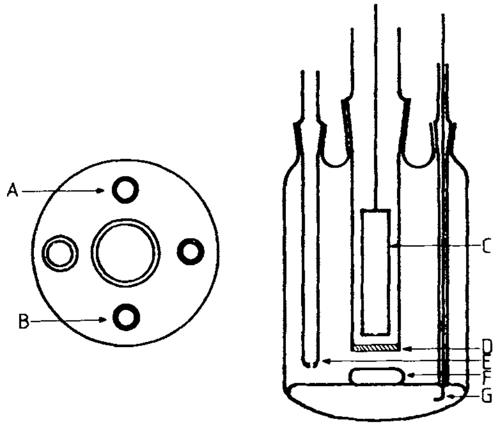

Fig. 1. Side view (right) and plan view (left) of a reaction vessel suitable for electro-enzymatic and electro-microbial reductions; volume 25—160 mL. A = inlet tube, B = outlet tube and sample removal, C = Pt anode, D = diaphragm, E = reference electrode, F = stirrer, G = Hg cathode.

*Procedure*

The cathode compartment of the electrochemical cell (Fig. 1), which contains 85 mL of a solution consisting of 0.1 mol/L phosphate buffer (pH 6.4), 0.1 mmol/L EDTA, 2.5 mmol/L $MV^{2+}$, as well as 40 mg bovine serum albumin (not necessary if the reaction time is less than 20 h), and 1.12 g sodium (*E*)-2-methylcinnamate, is flushed with nitrogen to remove the oxygen. The anode compartment is separated from the cathode compartment by a polyacrylamide plug and is filled with *ca.* 2 mL 0.1 M phosphate buffer (pH 9). The $MV^{2+}$ is prereduced at a −800 mV potential, measured relative to a 0.1 M KCl-calomel electrode, and 0.5 mg eneoate reductase added. By controlling the cathode potential, the reaction proceeds as shown in Figure 2. The pH value of the catholyte is regulated several times by addition of $H_3PO_4/H_2O$ (1 : 1). If Vycor® tips are used as a diaphragm, the anode compartment can be filled with 0.1 M $K_2SO_4$, and adjustment of the pH is unnecessary.

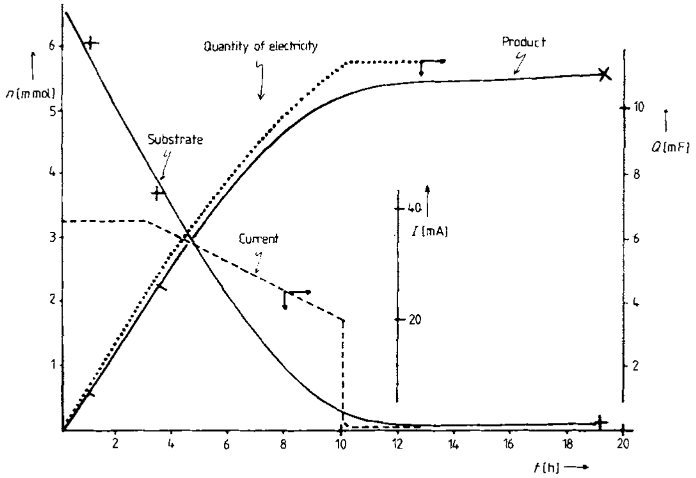

Fig. 2. Course of the electro-enzymatic reduction of (*E*)-2-methyl cinnamate, catalyzed by enoate reductase in the presence of electrochemically continuously regenerated methylviologen radical cation, as a function of time.

The course of the reaction can be followed on the current-curve, or by quantitative high pressure liquid chromatography. After reaction has ceased, the mixture is acidified, extracted with ether, and (*R*)-2-methyl-3-phenylpropionic acid isolated (yield 95%), $[\alpha]^D$ −23.5°; the values for the pure enantiomers have been reported as $[\alpha]^D$ +20.4 and $[\alpha]^D$ −24.6[9].

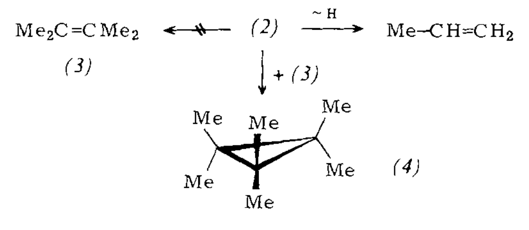
## Cyclopropanation with Dimethylcarbene

By *Peter Fischer* and *Gerhard Schaefer*[*]

Dimethylcarbene, $(CH_3)_2C$: *(2)*, has so far been missing from the broad spectrum of methylene derivatives employed synthetically. Addition of *(2)* to 2,3-dimethyl-2-butene *(3)*, for instance, would be an obvious and elegant route to hexamethylcyclopropane *(4)*[1], which we required in the course of a systematic $^{13}C$-NMR investigation of methylcyclopropanes[2]; the procedures given in the literature afford *(4)* only in low yield[3a] or as a minor by-product[3b].

All attempts at the generation and reaction of *(2)* by thermolysis of 2-diazopropane[4a], dimethylketene[4b] or dimethyldiazirine[4c] yielded only propene. Evidently, intermediary $(CH_3)_2C$: isomerizes much too fast under these conditions for either the dimer *(3)*[4b] or, in the presence of olefins, for cyclopropane derivatives to be formed[4c]. If, on the other hand, 2-diazopropane is decomposed in the presence of NO, the stabilized iminoxyl radical $(CH_3)_2{=}NO^{\ominus}$ can be detected by ESR spectroscopy, and thus the existence of *(2)* established indirectly[5]. So far only the carbenoid, obtainable from 2,2-dibromopropane and chromium(II) salts in DMF/water, has been used with success for $(CH_3)_2C$-addition to olefins which are soluble in this system, *e.g.* allyl alcohol[6].

In principle, α-elimination from 2,2-dihalopropane should also be feasible in a non-polar medium. We have therefore examined the reaction of 2,2-dibromopropane *(1)*[7] in diethyl ether with alkyllithium compounds in the presence of tetramethylethene *(3)* as carbene scavenger (molar ratio 1:1:1). With *n*-butyllithium at −30 °C, the cycloadduct *(4)* could indeed be isolated, apart from unchanged *(3)*; the yield was about 20% with respect to the olefin consumed in the reaction. On the other hand, when methyl- or isopropyllithium were employed as metalating agents, at best traces of *(4)* could be detected by gas chromatography (GC) or GC/MS. These findings are in accord with the gradation of alkyllithium activity reported by *Gilman* for metal-halogen exchange[8].



If, as described by *Schlosser*[9], tetramethylethylenediamine (TMEDA) or potassium *tert*-butoxide is added to the reaction mixture to enhance the metalating potential of the butyllithium, cyclopropanation fails completely since these auxiliary bases themselves react with *(1)*; simultaneous addition of TMEDA and butyllithium does not improve the cyclopropane yield compared to the reaction without auxiliary bases. When, on the other hand, the reaction temperature is lowered from −30° to −70 °C, the yield of *(4)* increases to almost 50% (further reduction giving no further improvement). All further experiments to optimize the cyclopropanation conditions were therefore carried out at −70 °C.

Since in all experiments 35—45% of *(3)* was recovered unchanged[10], the olefin fraction was halved; the yield of *(4)*, relative to the amount of *(3)* consumed, however, remained unchanged. Identical yields of *(4)* (45—50%) were also obtained on doubling the butyllithium fraction or on using a fourfold excess of olefin. In the first case, *n*-octane is formed as by-product, which is much more difficult to separate, while in the second case only half of the excess olefin can be recovered.

Table 1. Addition of dimethylcarbene *(2)* to olefins.

| Olefin | Olefin recovered [%] [a] | Yield relative to olefin consumed [%] [b] |
|---|---|---|
| $(CH_3)_2C{=}C(CH_3)_2$ | 45 | 46 |
| Cyclooctatetraene | 24 | 16 |
| Cyclohexene | 55 | 27 |
| 2-Norbornene | 68 | — |
| $Ph{-}CH{=}CH_2$ | 12 | 44 |
| 1-Dodecene [c, d] | 83 | 9 |
| $Ph{-}CH{=}C(CH_3)_2$ [d] | 86 | 3 |
| $Ph{-}CH{=}CH{-}OCH_3$ [d] | 78 [e] | 6 |

[a] Substrate recovered in pure form by rectification or preparative gas chromatography (in % of total amount employed). [b] All compounds are characterized unequivocally by comparison with authentic material or from their spectral data ($^1H$-, $^{13}C$-NMR, MS). [c] With double solvent volume because of lower solubility at −70 °C. [d] Due to the extremely low carbenation yields, these reactions had to be run with four times the quantities given in the general procedure. [e] The *E/Z*-ratio for the cycloadduct corresponds exactly to that of the styrene precursor (60:40 each).

We have investigated the reaction of dimethylcarbene with a series of other CC-double bond systems, under the conditions optimized for *(3)* (Table 1). The yield decreases drastically on going from *(3)* through cyclohexene to 1-dodecene, indicating that $(CH_3)_2C$-addition puts a rather severe demand on the nucleophilicity of the olefinic substrate. On the other hand, the poor yields obtained in the case of β,β-dimethyl- and β-methoxystyrene (~1% of the olefin employed) are probably due to direct attack of these substrates by butyllithium.

### *Experimental*

A 1.0 M solution of *n*-butyllithium[11] (20 mL) in diethyl ether is added dropwise at −78 °C to a solution of 20 mmol each of elefin and 2,2-dibromopropane[7] in 20 mL of anhydrous diethyl ether; the reaction is carried out under argon atmosphere and with absolute exclusion of moisture, and the rate of addition is so regulated that the internal temperature does not rise above −70 °C to −75 °C (*ca.* 1 h). The reaction mixture is allowed to warm to room temperature (12 h, a colorless precipitate being formed after *ca.* 1 h), 30 mL of water is added, the aqueous phase repeatedly extracted with ether, and the organic phase dried over

$MgSO_4$. The solvent is carefully distilled off, and the residue either fractionated or separated by preparative GC (HUPE APG 402, columns 400 × 1 cm, packed with 10% SE 30 on chromosorb P, carrier gas $N_2$). On reaction of 1.68 g of *(3)*, 0.66 g of *(4)* is obtained, besides 0.73 g of unchanged *(3)* (yield 26%, relative to total amount of *(3)* employed).

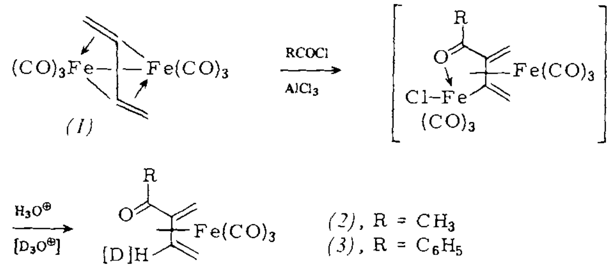
## 2-Acylbutadienes and Their Tricarbonyliron Complexes from Butatriene(hexacarbonyl)diiron Complexes *via* Friedel-Crafts Acylation[**]

By *Michel Franck-Neumann*, *Daniel Martina*, and *Francis Brion*[*]

Butadiene and simple methylated butadienes, as tricarbonyliron complexes, can readily be acylated in the 1-position under Friedel-Crafts conditions[1].

In contrast, open chain 1,3-dienes which carry an acyl group in the 2-position are difficultly accessible[2]; neither 2-acetyl- nor 2-benzoylbutadiene are known.

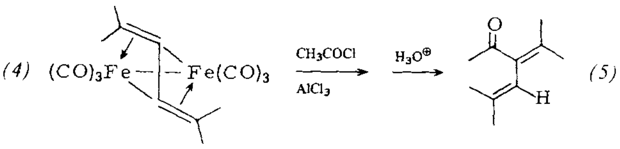
We describe here a route to 2-acylbutadienes, which we required for another purpose[3], using a reaction related to Friedel-Crafts acylation. Reaction of 2-butynes, halogenated in the 1,4-positions, with carbonyliron compounds gives complexes[4a] having the stoichiometry butatriene-$Fe_2(CO)_6$, whose X-ray structural analysis indicates two Fe—C σ-bonds at the 2- and 3-positions[4b]. 2-Substituted butadienes could be formed by electrophilic attack on this species. Indeed, the 2-substituted butadieneiron complexes *(2)* and *(3)*, which were isolated as air stable compounds in 80 and 45% yields, respectively, are formed directly from butatriene(hexacarbonyl)diiron *(1)*[5] and acetyl or benzoyl chloride in the presence of aluminum chloride.



*(2)*, R = $CH_3$
*(3)*, R = $C_6H_5$

The organic ligand of complex *(1)* is not only acylated but also hydrogenated. The latter process most probably occurs during work-up in highly acidic media *via* an insertion complex; a similar reaction pathway has been postulated for the reaction of 2-bromo- or 2,3-dichlorobutadiene with $Fe_2(CO)_9$[6]. This is also corroborated by the fact that both $AlCl_3$ and RCOCl must be used in excess in the reaction and that in the preparation of *(2)*, work-up with $D_2O$ leads to the 3-deuterio analogue of *(2)*.

The tetramethylbutatriene complex *(4)*[7] reacts directly with acetyl chloride and $AlCl_3$ to give the free 3-acetyl-2,5-dimethyl-2,4-hexadiene(2-acetyl-1,1,4,4-tetramethylbutadiene) *(5)* (volatile, therefore only isolated in 40% yield[8]), since the cisoid-configuration necessary for formation of the complex is no longer possible[9].



In contrast, we have been unable to isolate free 2-acetylbutadiene. The dimer *(6)*[10], a colorless liquid, was obtained in 75% yield when the complex *(2)* was cleaved, and in the presence of cyclopentadiene the Diels-Alder adducts *(7)*, *(8)*, and *(9)* were obtained in 95% total yield (see Table 1).

Both of the norbornene derivatives *(7)* and *(8)* undergo rearrangement to the bicyclic ketone *(9)*, whereby *(8)* must only be warmed for a short time (*ca.* 1 h) in benzene at 80 °C; *(7)* reacts more slowly at the same temperature (half-life *ca.* 3 h) and only in the presence of a free radical initiator such as azobisisobutyronitrile (AIBN).

The increased reactivity of 2-acetylbutadiene, which on the one hand may depend on the preferential s-*cis* conformation[11a] and on the other on an extreme radicophilic character[11b], makes it all the more advantageous to have available this diene as a stable tricarbonyliron complex.

### *Procedure*

A solution of *(1)* (8.0 g, 24 mmol) in 50 mL $CH_2Cl_2$ is added dropwise, within 15 min, to a mixture of anhydrous $AlCl_3$ (8.0 g, 60 mmol) and acetyl chloride (8.8 g, 110 mmol) in 120 mL $CH_2Cl_2$ at room temperature. The mixture is stirred for 1 h, cooled to 0 °C, and treated with 100

# Investigation of Valence Isomerism Cyclobutadiene—Bismethylenecyclobutene—[4]Radialene[**]

By *Herbert Meier*, *Toni Echter*, and *Oswald Zimmer*[*]

The short lifetime of highly strained cyclic alkynes often results from di-, tri-, and oligomerization reactions, which *e.g.* occur with cyclohexyne[1a] or 1,2-didehydrocyclooctatetraene[1b].

The 1,5-cyclooctadien-3-yne *(1)*[2], isolated by us, isomerizes to 1,3,5,7-cyclooctatetraene *(2)* at high temperatures. In contrast, at room temperature—by avoiding alkaline media—an almost quantitative dimerization to the cyclobutadiene *(4)* is observed. A 0.3 M solution of *(1)* in chloroform has a half-life of *ca.* 2 h. *(4)* can stabilize itself *via* a conrotatory electrocyclic ring opening process, forming the bicycle *(5)*, a bismethylenecyclobutene, or even the monocycle *(6)*, a [4]radialene. The $^1$H- and $^{13}$C-NMR spectra of the dimeric stage indicate an equilibrium whose position lies almost completely to the side of *(5)*. In contrast to the colorless educt *(1)*, *(5)* is intensely yellow. The 400 MHz $^1$H-NMR spectrum[3] demonstrates that six types of chemically non-equivalent olefinic protons are present. The protons $H_f$ and $H_{f'}$ absorb at the lowest field position ($\delta=6.84$). Their coupling with $H_e$, $H_g$, and $H_h$, and $H_{e'}$, $H_{g'}$, and $H_{h'}$ respectively was ascertained by means of decoupling experiments ($\delta=5.90$, 5.28, 5.17). The protons of the

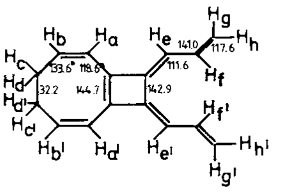
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

intact eight-membered ring approximately form an ABXX' system. $H_a$ and $H_{a'}$ appear as a doublet at $\delta=6.27$, and $H_b$ and $H_{b'}$ as a multiplet at $\delta=6.23$. The chemical equivalence of $H_c$ and $H_{c'}$, as well as that of $H_d$ and $H_{d'}$, is based on an inversion process which occurs at room temperature. The eight $^{13}$C absorptions recorded for *(5)* yield two singlets, four doublets and two triplets under off-resonance conditions. The given assignments shown in the formula are consistent with the $^{13}$C data for bis(methylene)cyclobutene in the literature[4].

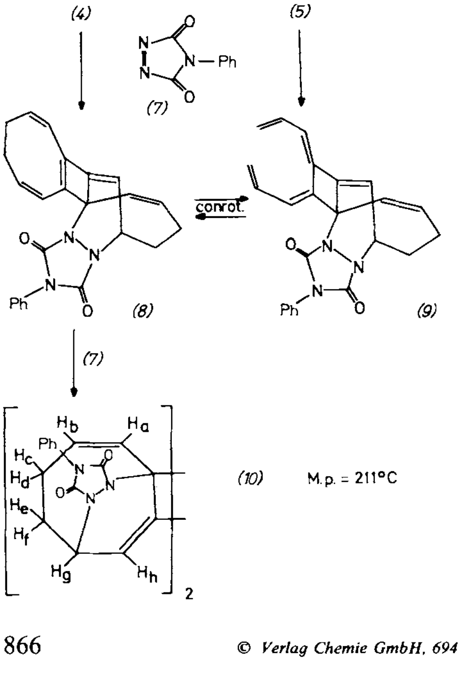


*(5)*

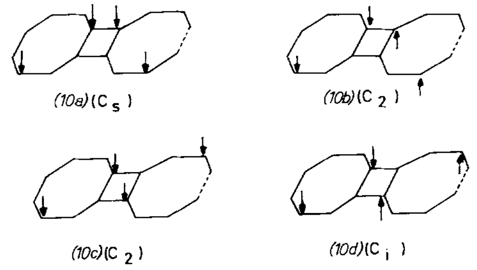
In principal, *(5)* could also be formed *via* an electrocyclic ring opening process of *(1)* to 1,3,4,5,7-octapentaene *(3)*, which reacts with *(1)* in a $[2_\pi+2_\pi]$-cycloaddition step. This route is, however, precluded, since the monomolecular reaction *(1)*→*(3)* would then have to be observed already in the gas phase in the preparation of *(1)*. In the $^1$H-NMR spectrum of a solution of *(5)* in chloroform kept for a few days at room temperature, the signals for protons $H_a$ and $H_b$ become smaller and those of the protons of the open chain become larger. This indicates a further valence isomerization to the radialene system *(6)*. Unfortunately, this process is accompanied by polymerization which makes its investigation difficult.

*cis,cis*-1,3,5,7-Octatetraene undergoes extremely rapid and complete cyclization to 1,3,5-cyclooctatriene[5a]. *Huisgen et al.*[5b] were able to extensively investigate the position of equilibrium and stereochemistry of the dimethyl compounds. The cyclooctatriene was shown to dominate the equilibrium at room temperature. A low energy barrier for this $[_\pi8_s]$-valence isomerization is also indicated by our example. Because of the energetically unfavorable cyclobutadiene structure of *(4)*, the equilibrium lies to the side of *(5)*.

In contrast to *(1)*, the dimeric stage reacts spontaneously with the highly reactive dienophile 4-phenyl-1,2,4-triazolidine-3,5-dione *(7)*. By this means a 20% yield of the bisadduct *(10)*, a derivative of cyclobutadiene *(4)*, is obtained. This can be rationalized in two different ways: either the tricycle *(4)* reacts preferentially *via* the monoadduct *(8)* to *(10)* and thereby displaces the position of the equilibrium *(4)*⇄*(5)*, or the monoadduct *(9)* is formed from *(5)* *via* selective addition to the side of the eight-membered ring, which then is further transformed in an electrocyclic ring closure to *(8)* and hence leads, *via* a second cycloaddition, to *(10)*. The constitution of *(10)* was elucidated using homonuclear double-resonance experiments. Apart from the signals of five aromatic protons ($\delta=7.5$), the $^1$H-NMR spectrum ($CDCl_3$) consists of a doublet for $H_h$ (6.9, $^3J=6.8$ Hz), a multiplet for $H_a$ and $H_b$ (6.0), a multiplet for $H_g$ (5.2), and a broad absorption for $H_c$, $H_d$, $H_e$, and $H_f$ ($1.9\leq\delta\leq2.6$). When all couplings to the saturated protons $H_{c-f}$ are eliminated, residual AB- and AX-systems remain for $H_{a,b}$ and $H_{g,h}$, respectively. The possible structures of *(10)* are obtained by applying one of the following symmetry operations to the half-molecules shown in formula *(10)*: *(10a)*: Reflection in a plane of symmetry σ lying right angles to the plane of the four-membered ring. *(10b)*: Rotation about a $C_2$ axis lying in the plane of the four-membered ring. *(10c)*: Rotation about a $C_2$ axis perpendicular to the plane of the four-membered ring. *(10d)*: Inversion i through the middle of the four-membered ring.

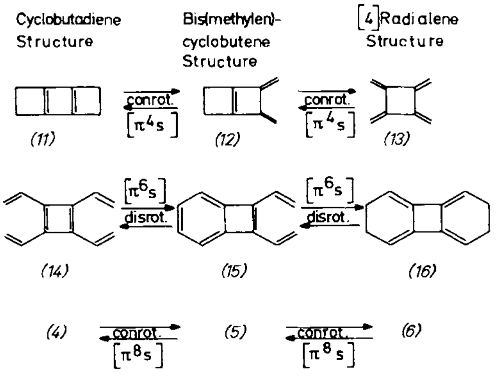


In principle, the double Diels-Alder reaction could lead to four adducts. In this connection it is immaterial whether the direct route *(4)*→*(8)*→*(10)*, or the indirect route *(4)*→*(5)*→*(9)*→*(10)* is followed. The various possible modes of attack of the dienophile *(7)* and the point groups of the resulting adducts are shown in Scheme 1.



Scheme 1.

Apart from the $C_{16}H_{16}$-system with $2\cdot8\pi$- or σ-electrons described here, valence isomerization between cyclobutadiene, bis(methylene)cyclobutene, and [4]radialene systems is also conceivable in the $C_{12}H_{12}$- and $C_8H_8$-systems (Scheme 2). The steric course shown refers to the thermally allowed synchronous reactions. The behavior is reversed under photolytic conditions.



Scheme 2.

The experimental verification of the hypotheses appears to be considerably easier in the $C_{12}H_{12}$ series than with $C_8H_8$[6]. We hope that our investigations will be an impetus to finding further electrocyclic reactions at four-membered rings with four π-centers.

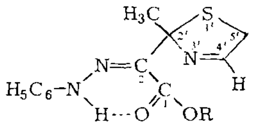
## Reactions of a Heterocyclic System Having Ambidentate Reactivity[**]

By *Johann Gasteiger, Ulrich Strauß*, and *Ulrich Schubert*[*]

α-Phenylhydrazono-2,5-dihydro-2-thiazole acetates *(1)*[1] offer various sites for attack, both by electrophilic[2] and nucleophilic reagents.



*(1a)*, R = $CH_3$
*(1b)*, R = $C_2H_5$
*(1c)*, R = $C(CH_3)_3$

This makes them useful models for the study of ambidentate reactivity. Nucleophilic attack could occur at both C atoms (1 and 2) of the acetic acid system and at C-4′ of the dihydrothiazole ring. A sufficiently basic nucleophile could abstract the NH-proton followed by rearrangement or fragmentation processes. We investigated whether, under these circumstances, the ester group could be hydrolyzed in alkaline solution.

Reaction of *(1a)* with ethanolic potassium hydroxide gave a product in which the methyl group had been lost and an ethyl group had been incorporated. However, the product was not *(1b)*, as its independent synthesis proved, but rather an isomer of *(1b)*. Structure elucidation was aggravated, since $^1$H-NMR spectra showed that the product consisted of a mixture of two compounds which were only moderately soluble in $CDCl_3$.

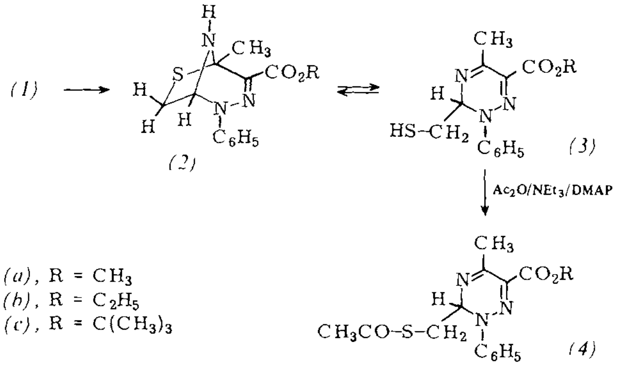
Reaction of *(1c)* with methanolic sodium hydroxide produced a product which was sufficiently soluble in $CDCl_3$ to allow the determination of $^{13}$C-NMR spectra. It was apparent that a *tert*-butyl group was still present, but that a rearrangement had occurred. Hence, in the reaction of *(1a)* with ethanolic potassium hydroxide the incorporation of the ethyl group is not necessarily coupled to the rearrangement reaction, but is rather a secondary process, a transesterification which does not occur with the *tert*-butyl ester.

Additional information on the mechanism was gathered from the reaction of the rearranged methyl ester with acetic anhydride/triethylamine/4-dimethylaminopyridine. By this means, the acetyl derivative *(4)* of the minor component of the product mixture was isolated; sufficient material was collected in this way to allow structural assignments[3]. The constitutional changes express themselves particularly clearly in the $^{13}$C-NMR spectra (Table 1). The course of the reaction is thus as follows: in alkaline media deprotonation of the hydrazono group takes place first, followed by nucleophilic attack at the azomethine group to give the 6-thia-2,3,8-triazabicyclo[3.2.1]oct-3-ene system *(2)*. This compound has a thiohemiaminal structure which can rearrange to the 3-thiomethyl-2,3-dihydro-1,2,4-triazine derivative *(3)*.

Table 1. Selected $^{13}$C-NMR data (in $CDCl_3$; δ-values) of *(1c)*–*(4c)*. C-atoms which are related to each other through the structural changes in the reactions are displayed in the same columns.

| | | | | |
|---|---|---|---|---|
| *(1c)* | 45.9 (C-5′) | 158.3 (C-4′) | 93.1 (C-2′) | 129.0 (C-2) |
| *(2c)* | 43.0 (C-7) | 73.2 (C-1) | 67.7 (C-5) | 140.2 (C-4) |
| *(3c)* | [a] ($CH_2S$) | 71.6 (C-3) | 156.7 (C-5) | [a] (C-6) |
| *(4c)* | 27.9 ($CH_2S$) | 68.2 (C-3) | 157.1 (C-5) | 133.5 (C-6) |

[a] Hidden by lines of *(2c)*.



*(a)*, R = $CH_3$
*(b)*, R = $C_2H_5$
*(c)*, R = $C(CH_3)_3$

The equilibrium *(2)*⇄*(3)* is solvent dependent. At room temperature the amount of *(3c)* in $CDCl_3$ is 25%, in $CD_3COCD_3$ 5%. Acylation of this equilibrium mixture only leads to the acetyl derivative *(4)*.

An X-ray structure determination of the rearranged methyl ester was performed[4], and showed that only *(2a)* was present in the crystal (Fig. 1).

In the thiazolidine ring, the atoms C2, S, C7 and C1 are approximately coplanar (torsion angle C2—S—C7—C1 4.7°). In the six-membered ring, all atoms except N3 are also approximately coplanar. This observation, in conjunction with the bond lengths and the trigonal planar configuration of N2, indicates conjugation of the C=N double bond with N2.

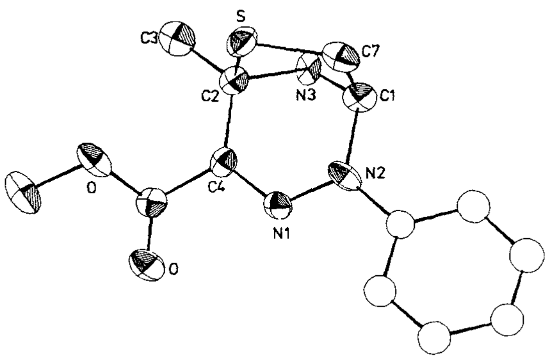

Fig. 1. Structure of *(2a)* in the crystal N1—N2 134.1(6), C4—N1 128.6(6), C1—N2 148.3(6), C1—N3 143.4(6), C2—N3 145.8(8), C2—C4 151.9(7), C2—S 183.8(6), C7—S 181.1(6) pm; C2—S—C7 91.5(3), C2—C4—N1 121.9(5), C4—N1—N2 118.9(4), C2—N3—C1 107.6(4)°.

### *Procedure*

*(2a):* A solution of *(1a)* (6.00 g, 21.6 mmol) in 100 mL dioxane and 40 mL water is treated for 1 h with 21.6 ml 1 N KOH. After dilution with 100 mL ice-water, the mixture is extracted three times with $CH_2Cl_2$. After washing, drying, and evaporation of the solvent, 5.52 g of crude product is obtained from which yellow prisms, 2.36 g (39%) *(2a)*, are isolated by recrystallization from ether and then from acetone.

*(4a): (2a)* (1.80 g, 6.5 mmol) is suspended in benzene and treated with acetic anhydride (8.3 mL, 9.0 g, 88 mmol), triethylamine (3.6 mL, 2.6 g, 26 mmol), and 4-dimethylaminopyridine (0.1 g). Within a few min the solution becomes clear. After 20 h at room temperature, the mixture is washed with sodium bicarbonate solution. After evaporation of the solvent, the product is dissolved in 10 mL methylene chloride, 100 mL cyclohexane added, and the solution concentrated to 50 mL. *(4a)* 1.80 g (87%) crystallizes as fine yellow needles.

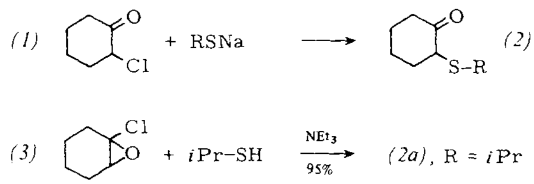
## The 2-Chlorooxirane—α-Chloroketone Reactivity Spectrum[**]

By *Johann Gasteiger* and *Christian Herzig*[*]

α-Hydroxy-[1b], α-amino-[1c], and α-mercaptoketones[1d,2] and their derivatives are important synthetic building blocks. An obvious entry to these classes of compounds is presented by the reaction of α-haloketones with nucleophiles. Thus, 2-alkylthiocyclohexanones *(2)* can be obtained from 2-chlorocyclohexanone *(1)* and thiolates, but only in moderate yields[3].

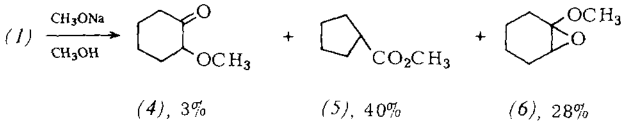


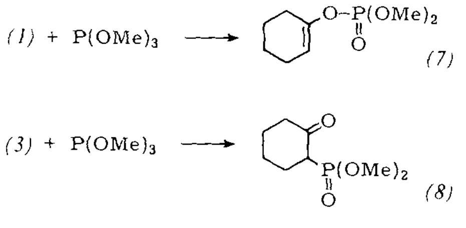
In investigations of nucleophilic substitutions of 2-chlorooxiranes, we found that the α-alkylthioketones *(2)* can be obtained from 1-chloro-7-oxabicyclo[4.1.0]heptane[4] *(3)*, which is isomeric to *(1)*. The reactions proceed under milder conditions, and give higher yields. In comparison with α-chloroketones, 2-chlorooxiranes offer not only the advantage of improved yields, but also might give a different spectrum of products.

Reactions of α-haloketones with nucleophiles often create problems, as a number of side reactions can occur[1]. Thus, 2-chlorocyclohexanone *(1)* only gives minor amounts of 2-methoxycyclohexanone *(4)* with methanolic sodium methoxide. The main reaction is a Favorski rearrangement to *(5)*. In addition, a sizeable amount of 1-methoxy-7-oxabicyclo[4.1.0]heptane *(6)* is formed[5].

Under the same reaction conditions, *(3)* leads to *(4)* in nearly quantitative yield[6].

*(1)* gives 1-cyclohexenyldimethyl phosphate *(7)* with trimethyl phosphite in a Perkov reaction. *(3)*, on the other hand, undergoes a Michaelis-Arbuzov reaction yielding dimethyl 2-oxocyclohexyl phosphonate *(8)*[7].





The reactions of *(1)* and *(3)* with sodium methoxide and with trialkyl phosphites show that in reactions with nucleophiles, 2-chlorooxiranes can follow pathways different from those of α-chloroketones. In other words, reactions of 2-chlorooxiranes do not go through an initial rearrangement to α-chloroketones. This conclusion is supported by the fact that 2-chlorooxiranes have a higher reactivity than α-chloroketones. In the course of the reaction, the strain energy of the three-membered ring is released. Therefore, reactions with nucleophiles occur under mild conditions, and also with less reactive reagents.

To test for the limits of the synthetic utility of 2-chlorooxiranes, *(3)* was reacted with 2-mercaptopropionic acid/triethylamine and with dimethyl sulfide.

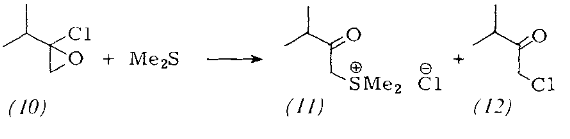
While (9) could be isolated in 88% yield, no reaction between (3) and dimethyl sulfide was observed. In this case only (1), the product of rearrangement of (3), was obtained.

On the other hand, dimethyl sulfide can still be alkylated by 2-chloro-2-isopropyloxirane[4b] (10). The sulfonium salt (11) was isolated in 30% yield. In addition, rearrangement of (10) to (12) (isolated in 60% yield) occurred.



The fact that (12) could be isolated from this reaction mixture underlines particularly well the lower alkylating power of α-chloroketones relative to that of 2-chlorooxiranes. On attempted reaction of the 2-chlorooxirane (3) with dimethyl sulfide, rearrangement is faster than the nucleophilic substitution. In the case of the 2-chlorooxirane (10), the reaction with dimethyl sulfide can still compete with the rearrangement to the α-chloroketone. (10) can even alkylate triethylamine at room temperature; the ammonium salt (13) was obtained in 40% yield.

2-Chlorooxiranes have a higher reactivity than α-chloroketones toward nucleophilic reagents, give products under milder conditions and in higher yields, and over and above lead to different products.

### *Procedure*

*(2a):* A solution of 2-propanethiol (3.14 g, 40 mmol) and of triethylamine (4.04 g, 40 mmol) in 10 mL $CH_2Cl_2$ is added to (3) (2.66 g, 20 mmol) at −10 °C. After 1 h the mixture is allowed to warm to room temperature, and is stirred for an additional 16 h. After evaporation of the solvent at room temperature (12 torr), the residue is digested with ether and filtered. The filtrate is concentrated, and then distilled to give 3.29 g (95%) of (2a) at 59.5 °C/0.5 torr.

*(11):* Dimethyl sulfide (3.10 g, 50 mmol) in 6 mL $CH_2Cl_2$ is added at 0 °C to (10) (1.21 g, 10 mmol). The sulfonium salt (11) precipitates within 1 h in a slightly exothermic reaction, and is isolated in the form of highly hygroscopic crystals after filtration and washing with ether: 0.54 g (30%); m. p. 101 °C. From the reaction solution the chloroketone (12) can be isolated in 60% yield.

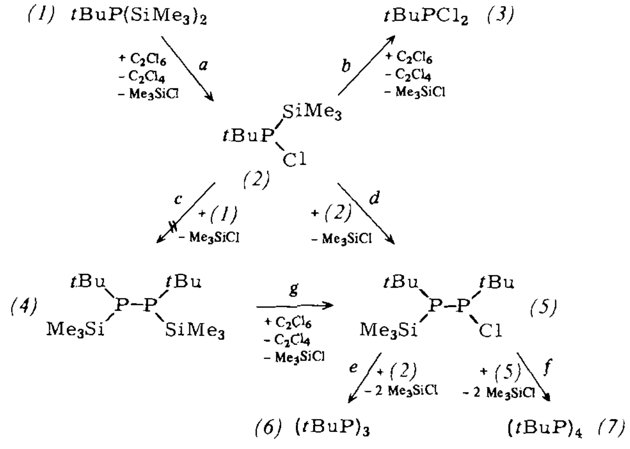
# $Me_3C$—P(Cl)—$SiMe_3$, the First *P*-Halogenated Silylphosphane[**]

By *Rolf Appel* and *Wilfried Paulen*[*]

*Dedicated to Professor Hans-Dieter Beckey on the occasion of his 60th birthday*

Attempts to prepare a *P*-halogen-*P*-silylphosphane have been unsuccessful until now[1]; the halosilane was always cleaved off. To obtain a synthetic building block containing this structurally interesting moiety, however, we reacted *tert*-butylbis(trimethylsilyl)phosphane (1) with the stoichiometric amount of hexachloroethane[2]. The desired product (2) is thus almost quantitatively formed in solution as an unstable intermediate.



As expected, the second silyl function could also be exchanged for chlorine when an excess of $C_2Cl_6$ was used (step *b*). In contrast to the phenyl derivative[3], however, intermolecular condensation (step *c*) of (2) and the educt (1) still present could be observed under the reaction conditions. The formation of the P—P bond in (4) is here kinetically suppressed by the steric demands of the components (1) and (2).

(2) was unequivocally characterized as *tert*-butylchloro(trimethylsilyl)phosphane by elemental analysis, molecular weight (MS), as well as by $^{31}P\{^1H\}$-, $^{13}C\{^1H\}$-, and $^1H$-NMR results[4]. The condensation (step *d*) can be cited as additional proof of the structure. Even at room temperature, (2) reacts slowly in toluene under $Me_3SiCl$-cleavage to produce the novel unsymmetrical diphosphane (5), which in the presence of (2) cyclizes to the cyclotriphos-

Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (Germany)

[**] Phosphorus-Carbon-Halogen Compounds, Part 29.—Part 28: *R. Appel, A. Westerhaus*, Tetrahedron Lett., in press.

phane *(6)*[5], or alternatively undergoes self-condensation to the cyclotetraphosphane *(7)*[6] (steps *e* or *f*, respectively). The dissociation of *(2)* to its thermodynamically stable end-products *(6)* and *(7)* shows a characteristic solvent dependence; a polar medium accelerates formation of the cyclophosphane, and simultaneously causes a shift of the $^{31}P\{^1H\}$ signal of *(2)* to low-field.

The diphosphane *(5)* could not be isolated as a reactive intermediate until now. Its identification by $^{31}P$-NMR spectroscopy in solution (significant AB spectrum[7]) was corroborated by independent synthesis (step *g*) from *(4)* and hexachloroethane using an analogous procedure to that of step *a*.

Silyl- and halogen-functionalized phosphanes are, in addition, suitable educts for gas phase pyrolysis, a process which may hinder the intermolecular condensation discussed here. In this way, *(2)* could form a phosphanediyl[8] *via* a 1,1-elimination and *(5)* an analogue of an azo compound *via* a 1,2-elimination[10].

### *Procedure*

A solution of $C_2Cl_6$ (22.0 g, 93 mmol) in toluene is slowly added to a stirred solution of *(1)*[9] (21.8 g, 93 mmol) in 30 mL toluene under ice cooling. The mixture is stirred for 30 min at room temperature. The toluene solution contains *(2)* in practically quantitative yield. After purification by distillation, *(2)* 3.7 g (20% yield), b.p. 28 °C/0.05 torr) remains in the distillation receiver (−78 °C) (half-life of *(2)* at 34 °C: 13 min from $^{31}P\{^1H\}$-NMR spectrum).

## A Boron-Boron One-Electron π-Bond[**]

By *Hartmut Klusik* and *Armin Berndt*[*]

*Dedicated to Professor Siegfried Hünig on the occasion of his 60th birthday*

The boron-boron one electron π-bond in the radical anion *(2a)* derived from tetraneopentyldiborane(4) *(1a)* represents the simplest B—B π-bond[1–4]. *(1a)*, which is accessible from tetramethoxydiborane(4) and neopentyllithium, can be reduced to a persistent radical. The ESR spectrum of the radical derived from *(1b)*, in which all 36 H atoms of the *tert*-butyl groups have been replaced by D atoms, is shown in Figure 1. The spectrum can be analyzed by hyperfine coupling constants of 0.380 and 0.465 mT for two sets of four equivalent protons and 0.08 mT for two equivalent $^{11}B$ atoms[5]. The assignment of the larger coupling constants to the methylene protons has been experimentally verified by D atom substitution. In the ESR spectrum of the radical derived from *(1a)*, neither the nonequivalence of the methylene protons nor the splitting of the two equivalent boron atoms, which is essential for the proof of the structure, are detectable due to the additional splitting of the *tert*-butyl protons ($a^H = 0.013$ mT).

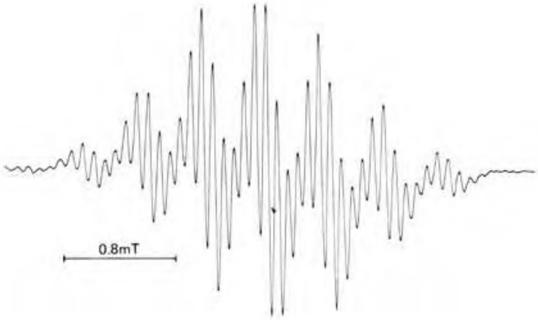

Fig. 1. ESR spectrum of the radical anion *(2b)* in dimethoxyethane at 30 °C.

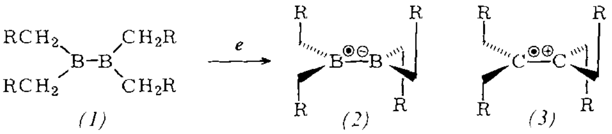
The nonequivalence of the methylene protons indicates that the neopentyl groups adopt a preferred conformation in which the $CH_2$—$C(CH_3)_3$ bond forms a torsion angle of *ca.* 2° with the axis of the p-orbital of the neighboring boron atom[6]. For steric reasons, *(2)* therefore exists in a conformation in which each pair of *tert*-butyl groups of *trans*-standing neopentyl groups shields both boron atoms from above and below.



*(a)*, R = $C(CH_3)_3$; *(b)*, R = $C(CD_3)_3$

This shielding effect, which is reproduced insufficiently in the formula shown, may be one reason for the remarkable persistence of radical *(2)*, which can easily be investigated by ESR spectroscopy up to +140 °C ($t_{1/2} \approx 15$ min). In contrast, *(1)* decomposes, even at +20 °C ($t_{1/2} \approx 20$ min), to produce trineopentylborane and, as yet, unidentified products. The persistence of the reduced diborane(4) is reminiscent of that of tetramethoxydiborane(4) and of tetra(dimethylamino)diborane(4) in which the electron deficiency of the two boron atoms, which must be responsible for the high reactivity of diboranes(4), is partially removed *via* the electron pairs on oxygen and nitrogen. The electron deficiency in *(2)* is decreased by the unpaired electron.

The structure *(2)* is further corroborated by the properties of the isoelectronic radical cation *(3a)*, which we prepared by oxidation of tetraneopentylethylene with $SbCl_5$ in dichloromethane. The nonequivalence of the methylene protons in *(3a)* ($a^H = 0.987$ and 1.040 mT, for each 4 H) es-

tablishes a conformation corresponding to that of *(2)*, which accounts for the notable persistence of *(3a)* ($t_{1/2}\approx 1$ h at +40 °C).

The coupling constant of the methylene protons in *(2)* (*ca.* 0.4 mT) is considerably smaller than in *(3a)* (*ca.* 1.0 mT). This is consistent with the structure of a radical anion: coupling constants of β-protons are always much smaller in radical anions than in the corresponding radical cations[7].

The $^{11}B$ coupling constant of 0.08 mT is surprisingly small[8]. Splittings of this magnitude can remain undiscovered in broad lines of incompletely resolved ESR spectra. Attempts to reduce persistent tetraalkyldiboranes(4) to radical anions were previously interpreted as unsuccessful[9], because the ESR spectra showed no splitting from the two boron atoms. The results found with *(2)*, however, indicate that this could be accounted for by the linewidth of 0.36 mT. The persistence of the radical observed on reduction of 1,2-di-*tert*-butyl-1,2-dineopentyldiborane(4) is comparable to that of *(2)*, indicating that another species with a B—B one electron π-bond is involved.

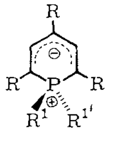
# Novel Reactions of $\lambda^5$-Phosphorins and Their Tricarbonylchromium Complexes

By *Karl Dimroth* and *Hans Kaletsch*[*]

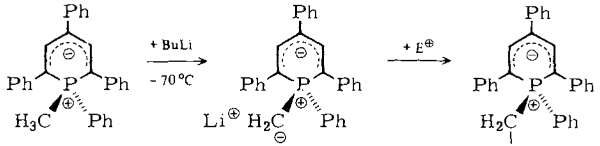
*Dedicated to Professor Sigfried Hünig on the occasion of his 60th birthday*

2,4,6-Trisubstituted $\lambda^5$-phosphorins of type *(1)*[1] are not "non-classical" 6π-heteroarenes, but cyclic phosphorus ylides whose negative charge is delocalized over the pentadienyl moiety and whose positive charge, depending on the substituents $R^1$, $R^{1'}$ is, to a greater or lesser extent, localized on the phosphorus atom[2a]. This can be established from the $^{13}C$-NMR signals of C-2/6 and C-4, and the $^{13}C$-$^{31}P$ coupling constants[2], as well as from the ESR spectra of free radicals formed by the oxidation of *(1)*[3]. We describe the first chemical evidence for the ylide character of *(1)* using a strong base to remove a proton from the α-position of suitable P-substituents (primary or secondary alkyl groups). A "double" ylide *(3)* is obtained which adds electrophiles (E), such as $D^+$, $CH_3^+$, or $PhCH_2^+$, to give *(4)*.

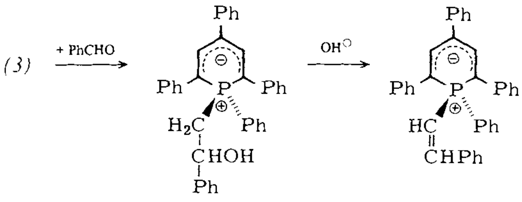
*(4b)*, E = Me, can be deprotonated again, and yields the 1-isopropyl derivative *(4d)* with MeI. Benzaldehyde reacts with *(3)* to give the β-hydroxy compound *(5)*, which forms the olefin *(6)* with alcoholic solutions of sodium hydroxide. No Wittig olefination is observed.



*(1)*, R = Ph, *t*Bu
$R^1$, $R^{1'}$ = Me, Et, Ph,
$NR_2^2$, OMe, SEt, Cl, Br, F, etc.

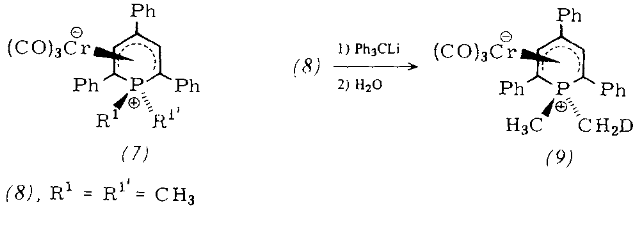


*(2)* *(3)* *(4)*



*(5)* *(6)*

In the nonplanar[4], highly stable[5] *P,P*-substituted tricarbonyl($\eta^5$-2,4,6-triphenyl-$\lambda^5$-phosphorin)chromium derivative *(7)*, the ylide character is strengthened by the electronic buffer-effect of the $Cr(CO)_3$ moiety[6] which leads to increased delocalization of the negative charge. Compounds of type *(7)* are obtained either from reaction of $\lambda^5$-phosphorins with $Cr(CO)_6$, whereby the *larger* residue $R^{1'}$ assumes the *exo*-position[5b], or from tricarbonyl(2,4,6-triphenyl-$\lambda^3$-phosphorin)chromium[7] *via exo*-addition of nucleophiles and subsequent reaction with electrophiles (at the *endo*-position)[8]. If $R^1$ and/or $R^{1'}$ are primary or secondary alkyl groups, the same sequence of deprotonation and addition of electrophiles as in the $\lambda^5$-phosphorins can be performed. However, with the bulky base $Ph_3C^-$ only the *exo*-methyl group of the 1,1-dimethyl complex *(8)* is deprotonated and subsequently deuterated to *(9)* with $D_2O$, while with BuLi both the *exo*- and *endo*-$CH_3$ groups are deprotonated to almost an equal extent. With $D_2O$, therefore, a mixture of *(9)* and its *endo*-$CH_2D$ isomer is obtained. The 1-*endo*-methyl-1-*exo*-phenyl complex, which



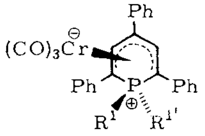
*(7)* *(9)*

*(8)*, $R^1 = R^{1'} = CH_3$

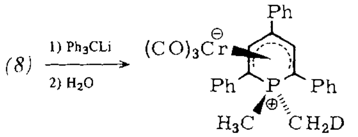
---

[*] Prof. Dr. K. Dimroth, H. Kaletsch
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

produced the "double" ylide complex with BuLi [cf. *(2)*→*(3)*], was thoroughly investigated. $D^+$ and $CH_3^+$ give *(10a—b)*, and benzaldehyde *(11)* from which *(12)* is obtained.



(7)



(9)

(8), $R^1 = R^{1'} = CH_3$

Careful oxidation of the $Cr(CO)_3$ complex resulted in cleavage of the tricarbonylchromium moiety, by analogy to carbocyclic $\eta^6$-tricarbonylchromium benzene complexes[9], whereby $\lambda^5$-phosphorins having the novel substituents $R^1$ and $R^{1'}$ at phosphorus are produced.

*Procedure*

1.2 Stoichiometric amounts of *n*BuLi are added to a solution of *(2)*, or its tricarbonylchromium complex, in anhydrous tetrahydrofuran (THF) under argon, and the mixture stirred for 30 min. $D_2O$, $CH_3I$, $PhCH_2Br$, or PhCHO are then added, and the mixture stirred for a further 30 min, allowed to warm up to room temperature, the solvent removed by evaporation, and the residue chromatographed on $Al_2O_3$ (neutral) using benzene, or in the case of *(10a, b)* on $SiO_2$ using $CH_2Cl_2$/petroleum ether (70—80°C) 1:1; *(12)* is purified by HPLC.

| Comp. | E | M.p. [°C] | Yield [%] | MS ($M^+$, [%]) |
|---|---|---|---|---|
| *(4a)* | D | 169—170 | 70 | 417 (100) |
| *(4b)* | Me | 160—161 | 70 | 430 (81) |
| *(4c)* | $CH_2Ph$ | noncryst. | 60 | 506 (35) |
| *(4d)* | *i*Pr | 173—175 | 70 | 444 (41) |
| *(5)* | | 150—152 | 57 | 522 (55) |
| *(6)* | | 179—181 | 65 | 504 (100) |
| *(10a)* | D | 265—267 | 90 | 553 (44) |
| *(10b)* | Me | 239—241 | 90 | 566 (11) |
| *(11)* | | 205—207 | 50 | 658 (100) |
| *(12)* | | 220 | 50 | 640 (100) |

*(8)* (0.4 g) is treated with the stoichiometric amount of $Ph_3CNa$ in THF and after 30 min, 1 mL of $D_2O$ is added. *(9)*[5b] (0.350 g, 90%, m.p. 276—277°C, MS 491 (13%)) is obtained after chromatography on $SiO_2$.

## Bis(trimethylgermyl)magnesium, the First Organogermylmagnesium Compound Isolated[**]

By *Lutz Rösch*[*]

*Dedicated to Professor Ferdinand Bohlmann on the occasion of his 60th birthday*

Organogermylmagnesium compounds have frequently been postulated as intermediates[1]. We now wish to report the successful isolation of bis(trimethylgermyl)magnesium·2 DME (=dimethoxyethane) *(1)* and hence establish the ability of organogermylmagnesium to exist.

*(1)* is synthesized in an analogous manner to the homologous silyl compound *(2)*[2] (see procedure). The well-formed colorless crystals of *(1)* decompose immediately on contact with the air, however, without the spontaneous ignition observed with *(2)*[2]. Apart from the signals from the coordinated DME, the $^1H$-NMR spectrum of *(1)* in benzene shows only one sharp signal for the trimethylgermyl protons (in the vicinity of the TMS-signals); the ratio DME:$Me_3Ge$ amounts to 1:1. Decomposition of *(1)* with water or $D_2O$ produces trimethylgermane or deuterio(trimethyl)germane, respectively. The results of the elemental analysis were corroborated by the mass spectrum. This shows a weak signal from the molecular ion with the expected isotopic splitting, as well as signals from the expected cleavage products. *(1)* melts at 90°C, accompanied by slight discoloration. A sample which is heated to 100°C for 10 min with dilute HCl yields, apart from trimethylgermane, a small amount of methane. This indicates that dimethylgermanediyl is produced during the decomposition and that the latter proceeds relatively slowly at this temperature.

$Mg[Ge(CH_3)_3]_2\cdot 2C_4H_{10}O_2$ *(1)*

$Mg[Si(CH_3)_3]_2\cdot C_4H_{10}O_2$ *(2)*

*Procedure*

All reactions were conducted under conditions of rigorous exclusion of air and moisture under argon. $(Me_3Ge)_2Hg$ (9 g) is dissolved in 70 mL of anhydrous DME and stirred with Mg (4 g) until the initially formed red color disappears (*ca.* 3 d). The dark solution is then filtered through a glass frit; the volatile fraction of the filtrate is removed using an oil vacuum pump. The solid residue is taken up in *ca.* 40 mL of anhydrous $Et_2O$. The solution is allowed to settle and separated from the undissolved material. Approximately 5 g of colorless *(1)* crystallizes out at −20°C, m.p. ≈90°C (decomp.).

## ENDOR Investigation of a Novel Organic Tetraradical in the Quintet State[**]

By *Burkhard Kirste, Wolfgang Harrer,* and *Harry Kurreck*[*]

*Dedicated to Professor Georg Manecke on the occasion of his 65th birthday*

Little is known about the dipolar coupling and scalar exchange interaction of the unpaired electrons and hyperfine interaction in organic tetraradicals. Reports have appeared in the literature only on ESR investigations of a tetrakisverdazyl[1a], of tetrakisnitroxides[1b], and on the detection of the quintet state of some *m*-dicarbenes and *m*-dinitrenes in the solid state[1c].

Following successful ESR and ENDOR (electron-nuclear double resonance) experiments on diradicals in the triplet state[2a] and on triradicals in the quartet state[2b], we wished to test whether these techniques could also be applied to tetraradicals in the quintet state. The following difficulties must, however, be considered:

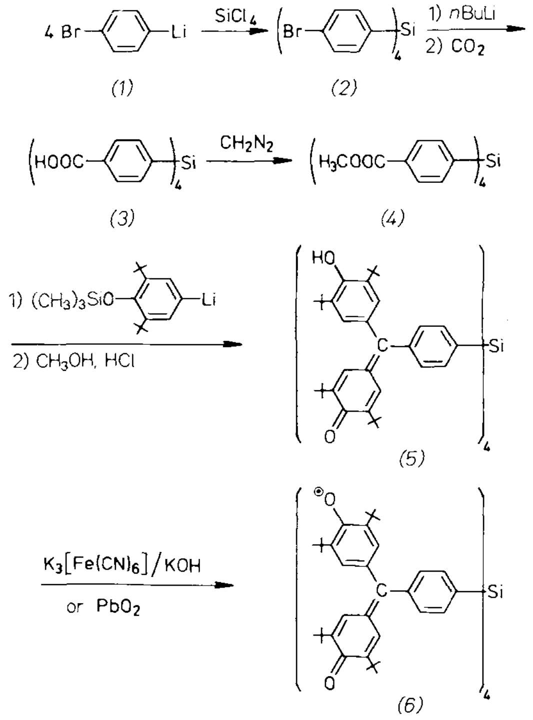
1. If the exchange interaction is large relative to the hyperfine interaction ($|J| \gg |a|$), the number of ESR hyperfine components from the nuclei within the "spin carrier" increase relative to those of the corresponding monoradical.

$$a^{S} = a^{d}/2S \tag{a}$$

Since the separation of the individual ESR lines is accordingly reduced ($a^d$ = coupling constant in the isolated spin carrier (doublet state), $S$ = electron spin quantum number), the total splitting is the same and the resolution of the ESR spectrum becomes poorer. In this connection the ENDOR technique appeared to be promising since it offers a greater resolution compared to ESR spectroscopy.

2. The dipolar interaction of the unpaired electrons—which is measured by the zero field splitting parameter *D*—produces additional relaxation processes, which cause a broadening of the ESR- and ENDOR-lines in liquid solution. As a consequence, the spectral resolution again deteriorates, and according to the theory of ENDOR spectroscopy higher microwave power levels are required[2a]. A tetraradical with *tetrahedral symmetry* should offer two decisive advantages: the exchange interaction is the same between all pairs of spin carriers, hence the formation of a thermally populated quintet state can be assumed and the zero field splitting is roughly zero[3].

The galvinol/galvinoxyl system is a suitable radical type, since the individual oxidation stages, and hence different spin states, can be selectively obtained[4]. The tetrakisgalvinol *(5)* was prepared as follows: reaction of the lithium compound *(1)* with $SiCl_4$, metalation of *(2)* and further reaction with dry-ice yielded the tetracarboxylic acid *(4)*, which was esterified using $CH_2N_2$. The tetraester *(4)* was reacted with (2,6-di-*tert*-butyl-4-lithiophenoxy)trimethylsilane; *(5)* is formed by acidic elimination of the protecting groups[5].



The left side of Figure 1 shows the ESR spectra of the different oxidation states of *(5)*[6]. While the ESR spectrum of the monoradical exhibits the typical quintet pattern of a galvinoxyl radical, the resolution deteriorates with increasing oxidation; the ESR spectrum of the tetraradical *(6)* is completely unresolved.

The ENDOR spectra (Fig. 1, right) can be unequivocally interpreted from the ENDOR resonance condition ($|J| \gg |a|$):

$$\nu_{\text{ENDOR}} = |\nu_n - M_S a^S| \tag{b}$$

($\nu_n$ = free nuclear frequency; $M_S$ = magnetic quantum number of the total electronic spin). It should be noted that the di- and triradical exist in equilibrium with other oxidation states and that, accordingly, lines from other spin states with lower intensity appear in the spectrum[7]. If only the galvinoxyl ring protons, which are viewed as equivalent, are considered, one ENDOR line pair ($M_S = \pm 1/2$) for the monoradical (doublet)[8], three lines ($M_S = \pm 1.0$) for the diradical (triplet), two line-pairs ($M_S = \pm 3/2, \pm 1/2$) for the triradical (quartet), and four equidistant lines ($M_S = \pm 2.0, \pm 1.0$) for the tetraradical (quintet) are expected. It follows from eqs. (a) and (b) that the position of the outermost line-pair is independent of the spin state.

The ENDOR spectrum of the tetraradical *(6)* establishes the presence of a quintet-state molecule. Furthermore, the sample can almost be quantitatively converted into the highest oxidation state. In addition, an electron-nuclear-nuclear triple resonance experiment (TRIPLE)[9] indicates that both line-pairs observed for the galvinoxyl ring-pro-

tons result from transitions belonging to the same hyperfine level diagram ($M_S = \pm 2$ and $\pm 1$ in the S = 2 state) (cf. in this context[2b]).

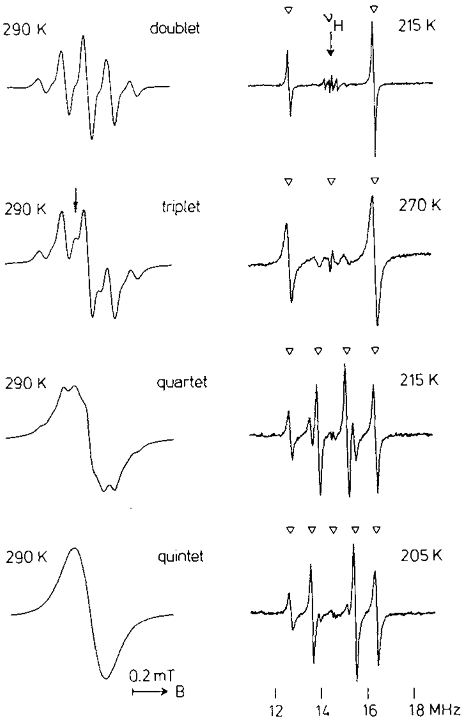

Fig. 1. ESR- (left) and ENDOR-spectra (right) of the different oxidation states of *(5)* in toluene. From top to bottom: mono-, di-, tri- and tetraradical. The symbols (▽) indicate the resonance frequencies calculated for the galvinoxyl ring protons (see also text).

The ENDOR-lines at the free proton frequency ($M_S = 0$), which were predicted for the di- and tetraradical, do not appear. It must, however, be considered that the ESR transitions $|-1\rangle \leftrightarrow |0\rangle$ and $|-0\rangle \leftrightarrow |1\rangle$ are degenerate in liquid solution (averaging of the dipolar coupling by Brownian motion); in consequence, the thermal nuclear spin polarization in the $M_S = 0$ state is not changed by pumping these transitions[10]. If the zero field splitting parameters are different from zero, the ENDOR resonances belonging to the $M_S = 0$ term should show up provided the experiments are performed in a glassy matrix, *e.g.* in toluene at 150 K[2b]. In fact, a $D$ parameter of *ca.* 25 MHz can be estimated from the ESR spectrum of the diradical; consequently, the line at the free proton frequency also appears in the matrix ENDOR spectrum. As can be expected from symmetry considerations the ESR spectrum indicates that its $D$ parameter is too small to be detected. It cannot, however, be exactly zero, since we were also able to detect this ENDOR signal at the free proton frequency for the tetraradical in glassy toluene (or perdeuterotoluene!).

### *Procedure*[11]

*(2):* A solution of 1,4-dibromobenzene (50 g, 0.212 mol) in 200 mL ether is treated within 20 min with 0.212 mol *n*-butyllithium (1.66 M solution in *n*-hexane). After 30 min at 20 °C, a solution of $SiCl_4$ (9 g, 53 mmol) in 15 mL *n*-hexane is slowly (!) added. Addition of 10 mL 50% acetic acid, concentration to dryness, digestion with 50 mL methanol, and filtration yielded 29.4 g crude product, which is purified by dissolving three times in $CH_2Cl_2$ and precipitating with $CH_3OH$; 22.5 g (65%) *(2)*, m.p. 236—239 °C, are produced.

*(4):* A suspension of *(2)* (4 g, 6.13 mmol) in 30 mL of a solution of *n*-butyllithium in *n*-hexane (1.66 M; 50 mmol) is tetrametalated by addition of *N,N,N',N'*-tetramethylethylenediamine (3.56 g, 30.6 mmol) and is finally carboxylated with dry-ice in tetrahydrofuran (THF). After removal of solvent the residue is taken up in water, filtered, acidified and filtered off. Two recrystallizations from methanol/ethyl acetate yield *(3)* (*ca.* 20% yield). *(3)* is esterified with diazomethane, yield 0.56 g (80%) *(4)* after recrystallization from methanol, m.p. 138 °C (lit.[5] 142 °C).

*(5):* A solution of *(4)* (0.5 g, 0.85 mmol) in THF is reacted with (2,6-di-*tert*-butyl-4-lithiophenoxy)trimethylsilane prepared from (2,6-di-*tert*-butyl-4-bromophenoxy)trimethylsilane (5 g, 14 mmol). Crude yield after removal of the trimethylsilyl protecting groups (methanol; 1% HCl) 0.62 g (35%) *(5)*, purification by HPLC and subsequent thin layer chromatography, m.p. 327 °C.

[11] The reaction with organometallic compounds was performed under nitrogen in anhydrous solvents. The spectroscopic data for compound *(5)* are consistent with the suggested structure.

## Stereoisomerization of Aryl-Substituted Cyclopropanes *via* Trimethylene Radical Anions[**]

By *Gernot Boche* and *Helmut Wintermayr*[*]

The *thermal* stereoisomerization of cyclopropanes, which proceeds *via* trimethylene intermediates, is one of the best documented reactions[1a] and, in addition, the *pho-*

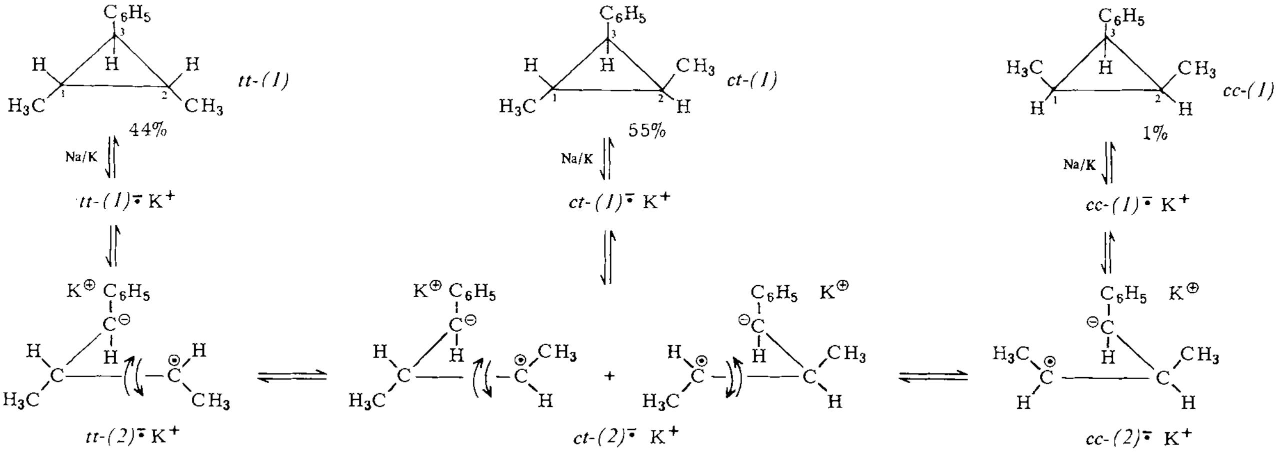
*tochemical* isomerization has also been thoroughly investigated[1b]. We report here on the *electron transfer* (homogeneous: potassium naphthalide ($K^+N^{\cdot-}$); heterogeneous: sodium-potassium alloy (Na/K)) catalyzed reaction. Cyclopropane- and trimethylene-radical anions occur as intermediates.

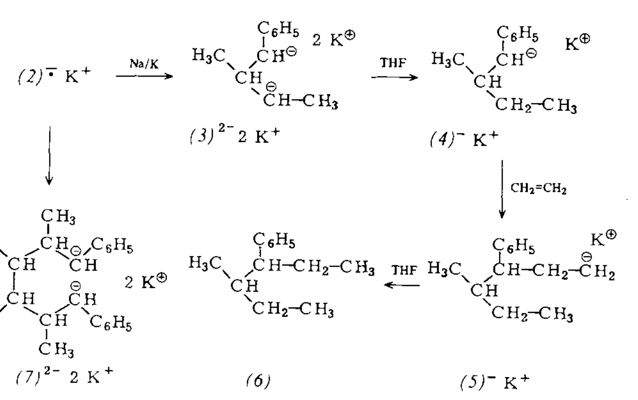
When a mixture of *trans,trans*-1,2-dimethyl-3-phenylcyclopropane *tt-(1)*[2] (146 mg, 1.00 mmol) and Na/K (1 : 1) alloy (621 mg, 20.0 mmol) in 10 mL tetrahydrofuran (THF) is stirred for 16 min at 20 °C, apart from *tt-(1)*, 1,2-*cis,trans*-, and 1,2-*cis,cis*-dimethyl-3-phenylcyclopropane[2], *ct-(1)* and *cc-(1)*, in the ratio 44 : 55 : < 1 are formed in 68% yield (Scheme 1)[3]. Mixtures of *cc-(1)* : *tt-(1)* = 2.47 or 1.71 under similar conditions, produced mixtures having the same ratio, which did not change under continued stirring.



Scheme 1.

This stereoisomerization is considerably different from the *base catalyzed* one conducted by *Closs*[2]: after 17 (!) h at 100 °C (!) a 50 : 1 equilibrium mixture of *tt-(1)* and *cc-(1)* was formed from *cc-(1)* and potassium *tert*-butoxide in dimethyl sulfoxide. Hereby, the intermediate is the benzylic cyclopropyl anion derived from *tt-(1)* and *cc-(1)*.

The formation of *ct-(1)* in the isomerization with Na/K alloy requires bond scission between $C^1C^3$ or $C^2C^3$[4]. This is accomplished by electron transfer from Na/K to form the phenylcyclopropane radical anions $(1)^{\cdot-}K^+$ followed by ring-opening to the trimethylene radical anions $(2)^{\cdot-}K^+$, bond rotation, ring-closure, and retransfer of the electron (Scheme 1), which is corroborated as follows: at long reaction times the yield of *(1)* decreases in favor of three new products. Hence, after 60 h, 16% of $(4)^-K^+$, 47% of *(6)* and 37% of $(7)^{2\cdot-}2K^+$[5] are obtained (Scheme 2).

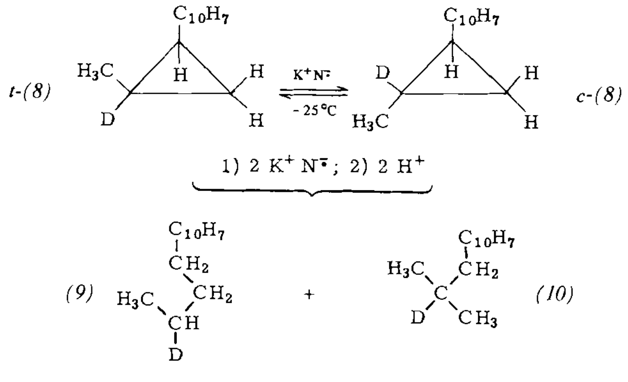


Scheme 2.

$(4)^-K^+$ and *(6)* are formed from the trimethylene radical anions $(2)^{\cdot-}K^+$ *by interaction with Na/K alloy, whereby the dipotassium compound* $(3)^{2-}2K^+$ forms first. The latter compound is spontaneously protonated by THF to the benzylic monoanion $(4)^-K^+$[6,7]. The ethylene[7] thus formed reacts with $(4)^-K^+$, particularly at long reaction times, to give the adduct $(5)^-K^+$, which—by repeated reaction with THF—yields *(6)*[6,8].

$(7)^{2-}2K^+$ is one of three diastereomeric pairs which can be formed by dimerization of the trimethylene radical anions $(2)^{\cdot-}K^+$[9]. Actually, after protonation with methanol—as shown by a gas chromatographic/mass spectroscopic analysis—three "dimers" of mass 294.240 (calc. 294.2348) can be detected; this indicates 1,1-, 1,3-, and 3,3-dimerization processes[10].

If the cyclopropane carries a better electrophore[11a], such as in the cyclopropylnaphthalene *t-(8)*, the stereoisomerization occurs even with the weaker electron transfer agent $K^+N^{\cdot-}$ to give *c-(8)* and *t-(8)* in an 86 : 14 ratio (at −25 °C in 9 h) (Scheme 3). The bimolecular trapping of the intermediate trimethylene radical anion by $K^+N^{\cdot-}$ at 20 °C is also considerably slower than its ring closure; this results from the fact that at this temperature both *c-(8)* and *t-(8)* produce the isomeric deuterium compounds *(9)* and *(10)*[12] in the same ratio (69 : 31).



The reductive cleavage of aryl and acyl substituted cyclopropanes by electron transfer is, above all, well known in protic solvents[11] and *Walborsky*[11h–j], in particular, has pointed out that trimethylene radical anions should occur as intermediates. The reversible formation and dimerization of these species outlined here, establish their existence. Simultaneously, it demonstrates that cyclopropanes of this type can be isomerized under mild conditions[13]; this also occurs with 1-methyl-2-phenyl-, 1,2-dimethyl-1-phenyl-, and 2-methyl-1,1-diphenylcyclopropane, as well as with 2-methyl-spiro[cyclopropane-1,9′-fluorene].

The chemistry described herein goes back to *E. J. Powers*, Dissertation, Florida State University 1969. We are very grateful to Professor *Walborsky* for informing us about this work.

[12] This is in contrast to an observation made by *Staley* [11b], who in the reduction of *cis*-1-methyl- and *trans*-1-methyl-2-phenylcyclopropane with lithium, in ammonia, obtained the corresponding cleavage products in markedly different ratios.

[13] Phenyl cyclopropanes isomerize *thermally* at *ca.* 300 °C [1a].

# Nickel-Induced Coupling and Cleavage of CC-Bonds

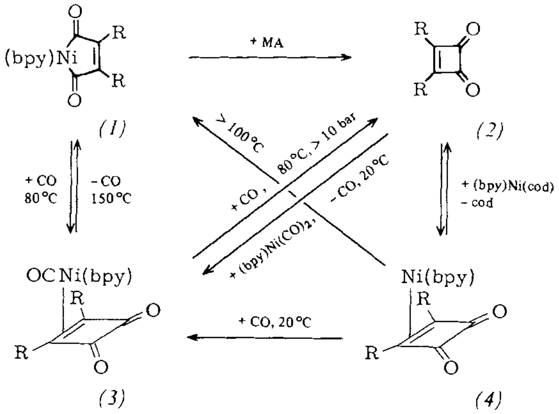
By *Heinz Hoberg* and *Antonio Herrera*[*]

Nickelacyclopentenediones *(1)*, which yield cyclobutenedione derivatives with maleic anhydride (MA) at 20 °C *via* a CC, coupling reaction, are formed from 2,2′-bipyridine (bpy)-stabilized nickel(0) compounds, carbon monoxide, and disubstituted alkynes (R = alkyl, aryl)[1]. In order to gain a detailed insight into the CC-coupling step *(1)*→*(2)* we used ligands other than MA for the reductive elimination ($Ni^{2+} \rightarrow Ni^0$).

Using CO as the reducing agent, an intermediate species could be isolated and hence the CC-coupling and -cleavage reactions rendered reversible.

A solution of *(1)* ($R = C_6H_5$) in toluene at 80 °C first takes up an equivalent of CO, whereby the carbonyl C atoms couple. Compound *(3)* is formed, in which the complex-bound *(2)* is present.

*(2)* is only liberated under a higher CO partial pressure (10 bar) at 80 °C, and simultaneously forms (bpy)Ni(CO)$_2$ and, to a lesser extent, Ni(CO)$_4$.



*(3)* could also be obtained by reaction of *(2)* with (bpy)Ni(CO)$_2$ by CO cleavage at 20 °C, and from *(4)* by reaction with CO. *(4)* is formed from the reaction of *(2)* with (bpy)Ni(cod), (cod = 1,5-cyclooctadiene) (Scheme 1).

*(3)* crystallizes in red leaflets and is diamagnetic. The mass spectrum only contains the fragment ions *m/z* 156 (bpy), 178 (tolan) and 234 *(2)*. The IR spectrum (KBr) shows characteristic bands at 2000 cm$^{-1}$ (Ni—CO) and in the $>$C=O region at 1680 and 1660 cm$^{-1}$. Hydrolysis (2 N $H_2SO_4$, 20 °C) yields *(2)*.

The CC-coupling *(1)*→*(3)* is reversible: upon heating to *ca.* 150 °C, the complex-bound CO cleaves off. Nickelacyclopentene is re-formed in an oxidative addition reaction ($Ni^0 \rightarrow Ni^{2+}$ transition). *(1)* is also formed from the CO-free *(4)* in 3 h at 100 °C.

The X-ray structure analysis[2] shows that the (CO)Ni(bpy) fragment in *(3)* is bonded to the CC double bond of the system *(2)* in such a way that the bpy lies above the carbonyl groups, whereas the CO ligand lies on the same side as the phenyl moieties (Fig. 1).

## *Procedure*

*(3)* from *(1)*: *(1)* (4.04 g, 8.99 mmol) ($R = C_6H_5$[1]) is suspended in 50 mL of toluene and takes up 200 mL (9.0

mmol) of CO at 80 °C and 1 bar within 6 h, thereby forming a red solution. The red crystals, which precipitate after 48 h at room temperature, are filtered off and dried. Yield: 1.68 g (39%) *(3)*.

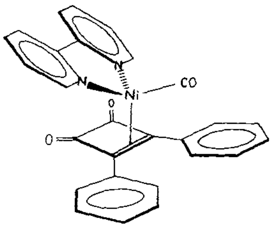

Fig. 1. Structure of *(3)* in the crystal.

*(3)* from *(2)* and (bpy)Ni(CO)$_2$: A solution of *(2)*[1] (1.1 g, 4.7 mmol) in 20 mL tetrahydrofuran (THF) is dropped into a solution of (bpy)Ni(CO)$_2$[3] (1.26 g, 4.7 mmol) in 30 mL of THF at room temperature. The red-violet solution gradually turns red-brown, whereby a precipitate is thrown down with simultaneous evolution of gas. 95 mL (4.2 mmol) of CO is collected within 6 h, and the precipitate is filtered off and dried. Yield: 1.78 g (80%) *(3)*.

*(1)* from *(3)*: *(3)* (1.5 g, 3.2 mmol) is suspended in 50 mL of decalin and heated to 150 °C, whereby evolution of gas is observed. 65 mL (2.9 mmol) of CO is collected within *ca.* 6 h. The precipitate is filtered-off and dried. Yield: 1.34 g (95%) *(1)*.

*(4)* from *(2)*: *(2)*[1] (1.3 g, 5.5 mmol) in 20 mL of THF is dropped into a solution of (bpy)Ni(cod)[4] (1.8 g, 5.5 mmol) in 50 mL of THF. After 24 h the crystals formed are filtered off and dried. Yield: 2.24 g (91%) *(4)*.

*(3)* from *(4)*: A suspension of *(4)* (1.3 g, 2.9 mmol) in 50 mL of toluene takes up 25 mL of CO at 1 bar within 24 h, whereby a solution is formed. The crystals formed after *ca.* 6 d at −20 °C are filtered off and dried. Yield: 0.48 g (35%) *(3)*.

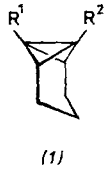
# 1,2,3-Cycloheptatriene by Isomerization of Tricyclo[4.1.0.0$^{2,7}$]-hept-1(7)-ene[**]

By *Hans-Georg Zoch, Günter Szeimies, Roland Römer,* and *Robert Schmitt*[*]

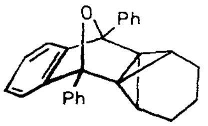
It has been shown by competition experiments that the halides *(1a–c)* react with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at −20 °C to give free tricyclo[4.1.0.0$^{2,7}$]hept-1(7)-ene *(2)*[1]. We have now found that *(2)* is also generated by the elimination method developed by *Chan* and *Massuda*[2] on reaction of *(1e)*[3] and potassium fluoride in dimethyl sulfoxide (DMSO) at 55 °C. In the presence of four equivalents of diphenylisobenzofuran, *(2)* could be trapped up to 56% as the already well-known Diels-Alder adduct *(3)*[4]. Formation of the diene *(4)* (12%)[5] in this reaction was unexpected. Reaction of *(1e)*, KF and four equivalents each of anthracene or 9-methoxyanthracene (MOA) in DMSO at 55 °C proceeded analogously and yielded a mixture of *(5a)*[6] (14%) and *(6a)* (41%) or of *(5b)*[1] (24%) and *(6b)* (48%), respectively.



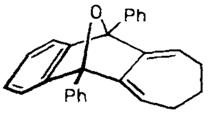
| R$^1$ | Cl | Br | I | Si(CH$_3$)$_3$ | Si(CH$_3$)$_3$ | OC(CH$_3$)$_3$ |
|---|---|---|---|---|---|---|
| R$^2$ | H | H | H | H | Br | H |
| | *(a)* | *(b)* | *(c)* | *(d)* | *(e)* | *(f)* |

*(1)*

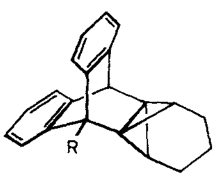
*(2)*



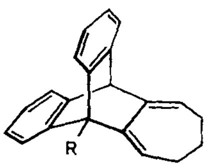
*(3)*



*(4)*



*(5)*



*(6)*

*(a)*, R = H
*(b)*, R = OCH$_3$

*(7)*

Since the dienes *(4)* and *(6)* are not products of the thermal isomerization[4,6] of the propellanes *(3)* and *(5)*, and since the latter are not converted into *(4)* and *(6)* under the reaction conditions used[7] these products must have been formed during the reaction itself. The structure of these dienes would suggest that their precursor is the 1,2,3-cycloheptatriene *(7)*, which is generated according to Scheme 1 by thermal rearrangement of *(2)* and is trapped as the Diels-Alder adduct.

$$\begin{tikzcd}
(1e) \arrow[r, "KF", "DMSO"'] & (2) \arrow[r, "MOA"] \arrow[d] & (5b) \\
& (7) \arrow[r, "MOA"] & (6b)
\end{tikzcd}$$

Scheme 1.

On lowering the concentration of MOA, the yield of *(5b)* should decrease, that of *(6b)* increase. This is in fact the case: The reaction of *(1e)*, KF, and three, two or one molar equivalent(s) of MOA in DMSO at 55 °C afforded *(5b)*/*(6b)*-mixtures of the composition 15% and 54%, 12% and 60%, and 8% and 66%, respectively.

The extent of the rearrangement *(2)*→*(7)* not only depends on the nature and concentration of the trapping agent but also strongly on the temperature. Thus reaction of *(1e)* and KF with tetraphenylcyclopentadienone or 2,5-dimethylfuran in DMSO at 100 °C afforded only the adducts *(8)* and *(9)* (30% and 38%, respectively). Our earlier works, in which *(2)* was formed by elimination of HCl

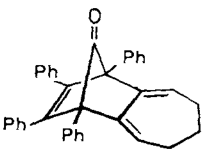
---

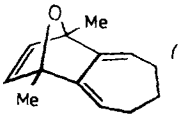
[*] Prof. Dr. G. Szeimies, Dipl.-Chem. H.-G. Zoch, Dipl.-Chem. R. Römer, cand. chem. R. Schmitt
Institut für Organische Chemie der Universität
Karlstr. 23, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

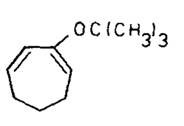
from *(1a)* with LDA at −20 °C in THF, furnished no evidence for the rearrangement *(2)*→*(7)*. However, this isomerization can also be detected when *(1a)* is used as starting material: Thus, on reaction of *(1a)* with 6 equivalents of potassium *tert*-butoxide in THF at 35 °C, the enol ether *(10)* is obtained in 44% yield. Its formation can be explained in terms of the rearrangement *(2)*→*(7)* and subsequent addition of *tert*-butoxide to the reactive double bond C2—C3 of *(7)*. On addition of anthracene to the system *(1a)*/KO-*t*Bu/THF and elevation of the temperature to 65 °C, *(6a)* is formed as well as *(5a)* and *(10)*[8].

*(8)*

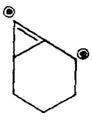




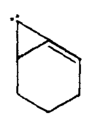
*(9)*



*(10)*



*(11)*



*(12)*

The rearrangement *(2)*→*(7)*, in which two bonds on opposite sides of the bicyclo[1.1.0]but-1(3)-ene moiety in *(2)* are broken, is forbidden as a synchronous reaction according to the Woodward-Hoffmann rules[9]. A stepwise isomerization of *(2)* to *(7)* with the diradical *(11)* or the carbene *(12)* as an intermediate is therefore not ruled out.

[7] If the adduct *(5b)* is included in the reaction of *(1e)*, KF and anthracene, then no *(6b)* can be detected among the end products *(5a)*, *(6a)* and *(5b)*. Reaction of *(1e)*, KF and MOA in presence of *(5a)* leads to an analogous result.

[8] *(10)* cannot be formed by addition of KO-*t*Bu to *(2)* and subsequent isomerization of *(1f)* to *(10)*: On increasing the anthracene concentration in the system *(1a)*/KO-*t*Bu/anthracene/THF (35 °C), the yield of *(5a)* increases, whereas that of *(10)* decreases. On the other hand, there is no change in the yield of *(5a)* or of *(10)* on variation of the KO-*t*Bu concentration. Hence the two trapping agents do not compete for the same intermediate.

# Aldehydes by Formylation of Grignard or Organolithium Reagents with *N*-Formylpiperidine[**]

By *George A. Olah* and *Massoud Arvanaghi*[*]

After having developed methods for electrophilic formylation with formyl fluoride and formic anhydride[1], we turned our attention to nucleophilic formylation *via* Grignard reagents or organolithium reagents, a type of reaction which has represented a long standing challenge[2]. Formyl fluoride reacts with these reagents to give formylated products, but the reaction is not satisfactory and necessitates the use of difficultly available reagents.

In 1976, *Rathke et al.* reported the reaction of (dichloromethyl)diisopropoxyborane with organolithium or organomagnesium reagents[3]; subsequent oxidation with $H_2O_2$ yielded aldehydes. However, the reaction involves four steps, must be carried out in boiling tetrahydrofuran, and only gives low yields of aldehydes.

More recently, *Comins* and *Meyers* reported the use of 2-(*N*-methyl-*N*-formyl)aminopyridine[4] as a formylating agent in similar reactions. The presence of the additional ligand (pyridyl nitrogen) and the ready formation of a six-membered chelate ring was considered to prohibit the release of the aldehyde under the reaction conditions, thus protecting it from further reaction with the organometallic reagent.

We report here on a highly efficient and simple method for the formylation of Grignard or organolithium reagents using readily available and inexpensive *N*-formylpiperidine. In ether or hydrocarbon solvents at room temperature *N*-formylpiperidine reacts with aryl-, alkyl-, vinyl- and ethynyllithium or Grignard compounds and results in formation, upon acidic work-up, of the corresponding pure aldehydes in excellent yields (Table 1). None of the earlier methods show this general utility.

| $C_6H_5C{\equiv}C$—Li | 94<br>93 | *n*-Hexane<br>Ether | 65/0.1 | 65/0.1 |

[a] Yields of aldehydes refer to distilled or recrystallized products; they gave IR and $^1$H-NMR spectra which were identical with those of the authentic compounds. [b] Starting with pure *exo*-norbornyl bromide produces a mixture of *exo*- and *endo*-norbornyl carbaldehyde (3 : 1), which was characterized by $^1$H-NMR spectroscopy.

Piperidine can, if necessary, be easily recovered; it can also be recycled after carbonylation with CO, a fact that can be of importance in reactions on a large-scale.

Since in this system there is no additional ligand group available for chelate formation we suggest that the chelating effect suggested in the case of 2-(*N*-methyl-*N*-formyl)aminopyridine is not a crucial one and perhaps even does not occur.

The formylation of organolithium and Grignard reagents can thus be carried out easily and under mild conditions with inexpensive and readily available reagents.

*Procedure:*

A) Formylation of Grignard compounds: A solution of *N*-formylpiperidine (10 mmol) in diethyl ether (10 mL) is slowly added during 2 min to a stirred solution of freshly prepared Grignard reagent (10 mmol) in either dry diethyl ether or tetrahydrofuran (15 mL), cooled to 0 °C. An exothermic reaction takes place. The reaction mixture is stirred for a further 15 min at room temperature, and then it is quenched by 3 N hydrochloric acid, until the solution becomes acidic. After extraction with diethyl ether, the ethereal solution is washed successively with water, with saturated $NaHCO_3$, and with saturated NaCl solution, and is then dried over anhydrous $Na_2SO_4$. Removal of the solvent affords the corresponding aldehyde in almost pure form, which can be further purified by either distillation or crystallization.

B) Formylation of organolithium compounds: As described under A) a freshly prepared solution of the organolithium compound (10 mmol) in the appropriate solvent (see Table 1), (10 ml) is treated with a suspension or an ethereal solution of *N*-formylpiperidine (15 mL). The reaction is moderately exothermic. The solution is stirred for an additional 10 min, and then worked up following the procedure described under A).

## Cyclobutanone and Cyclobutenone Derivatives by Reaction of Tertiary Amides with Alkenes or Alkynes[**]

By *Jean-Bernard Falmagne, José Escudero, Safia Taleb-Sahraoui,* and *Léon Ghosez*[*]

*Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday*

The utility of *N,N*-dialkyl-*N*-alkylideneammonium (keteneiminium) salts for the synthesis of four-membered rings has been illustrated by the facile cycloadditions of tetramethylketeneiminium salts to alkenes[1a] and alkynes[1b]. However, the method still suffers from an important limitation: whereas "keto" keteneiminium salts generated from α-halo enamines[2] and Lewis acids always cycloadd, "aldo" keteneiminium salts often react faster with the α-halo enamines from which they are formed than with an alkenic or alkynic partner[3]. This limitation should not occur with *non-nucleophilic precursors* of the keteneiminium salts: we anticipated that 1-dialkylaminoalkenyl trifluoromethanesulfonates *(5)* would fulfill this purpose.

The acylation of tertiary amides *(1)* with trifluoromethanesulfonic anhydride *(2)* was found to give a mixture of *O*-acylated (major) *(4)* and *N*-acylated (minor) *(3)* products. The reaction mixture from *(1a)* and *(2)*, for example, showed two pairs of singlets for the protons of the

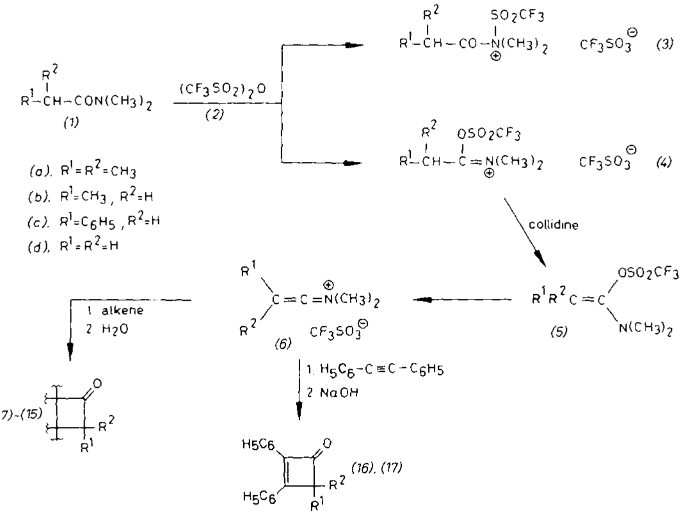
[**] This work was supported by the "Institut pour l'Encouragement de la Recherche Scientifique", the "Administration Générale pour la Coopération au Développement" and the "Service de Programmation de la Politique Scientifique" (Contrat 79/84-13).

$N(CH_3)_3$ groups ($\delta = 3.28$ and 3.37 as well as 3.63 and 3.8) in the ratio 1:4. The most intense low-field signals can be assigned to the *O*-acylated product *(4)*, whereas the high-field signals are most probably due to *(3)*. On hydrolysis, the educt *(1a)* was quantitatively regenerated from the mixture.



When the acylation of *(1)* with *(2)* was conducted in the presence of collidine and an olefin, [2+2] cycloadducts were formed which were directly hydrolyzed to the corresponding cyclobutanones *(7)*–*(15)* (Table 1)[4]. We propose that collidine converts the *O*-acylated intermediates *(4)* into 1-dimethylaminoalkenyl trifluoromethylsulfonates *(5)* which directly ionize to the corresponding keteneiminium salts. Indeed we found no spectroscopic evidence for the presence of substantial amounts of *(5)* while, in certain cases, the presence of *(6)* could be inferred from an IR band around 2020 cm$^{-1}$.

Table 1. Preparation of cyclobutanones and cyclobutenones by reaction of *(1)* with alkenes or alkynes.

| Educts | Products | | Yields [%] [a] | IR ($CCl_4$) [cm$^{-1}$] |
|---|---|---|---|---|
| Styrene + *(1a)* |  | *(7)* | 70 | 1780 |
| Styrene + *(1b)* |  | *(8)* | 60<br>(*cis* + *trans*) | 1785—1790 |
| Styrene + *(1c)* |  | *(9)* | 65 | 1785 |
| Styrene + *(1d)* |  | *(10)* | 77 | 1795 |
| Cyclopentene + *(1b)* |  | *(11)* | 72<br>(2 isomers) | 1760 [b] |
| Cyclopentene + *(1c)* |  | *(12)* | 80 | 1775 |
| Cyclopentene + *(1d)* |  | *(13)* | 50 | 1780 |
| Ethylene + *(1c)* |  | *(14)* | 35 | 1785 [c] |
| Cyclohexene + *(1b)* |  | *(15)* | 48<br>(2 isomers) | 1780 |
| Diphenylacetylene + *(1b)* |  | *(16)* | 80 | 1760 |
| Diphenylacetylene + *(1c)* |  | *(17)* | 62 | 1759 |

[a] The yield was not optimized. [b] In $CHCl_3$. [c] In $CH_2Cl_2$.

Under these conditions, both "aldo" and "keto" keteneiminium salts *(6)* reacted smoothly with olefins. The method also enables the cyclobutenones *(16)* and *(17)* to be prepared from *(1)* and diphenylacetylene. Yields of pure products are generally good. In this respect, the compounds *(6)* are superior to the corresponding ketenes which react only sluggishly with unactivated alkenes or alkynes.

The method described here is thus in general highly suitable for the synthesis of cyclobutanones and cyclobutenones from readily available educts.

### *Experimental*

A 100 mL round-bottomed flask fitted with gas inlet (dry argon atmosphere), dropping funnel and reflux condenser connected to a sulfuric acid trap, is charged with *(1b)* (252 mg, 2.5 mmol), collidine (367 mg, 3 mmol), cyclohexene (4 mL) and $CHCl_3$ (10 mL). A solution of *(2)* (0.5 mL, 3 mmol) in 20 mL of $CHCl_3$ is added to the refluxing mixture over a period of 24 h. Evaporation of the solvent leaves an oil which is washed with ether (3 × 20 mL), and then hydrolyzed overnight in a two phase system (20 mL $CH_2Cl_2$ + 20 mL $H_2O$). Evaporation of $CH_2Cl_2$ and extraction of the aqueous phase with $CCl_4$ gives *(15)* which is chromatographed on silica gel (ethylacetate/petroleum ether 1:5). Yield: 165 mg (48%).

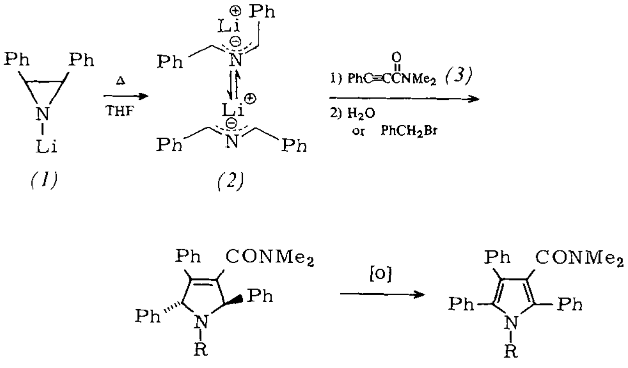
generality of this anionic polar cycloaddition with activated triple bonds, we have now found that reaction of *(2)* with phenylpropiolic acid *N,N*-dimethylamide *(3)* affords 2,4,5-triphenyl-3-pyrroline-3-carboxylic acid *N,N*-dimethylamide *(4a)*, thus indicating that electron-withdrawing groups are not unsuitable[3] for anionic cycloaddition.



*(1)* *(2)*

*(4a)*, R = H
*(4b)*, R = $CH_2Ph$

*(5a)*, R = H
*(5b)*, R = $CH_2Ph$

Ring opening of *N*-lithiated *cis*-2,3-diphenylaziridine *(1)*[1] occurs easily in boiling tetrahydrofuran under argon atmosphere. The anion *(2)* which is formed can be trapped at −70 °C by slow addition of an equimolar amount of the alkyne *(3)*. After complete conversion (5 h, monitored NMR spectroscopically), the pyrroline *(4a)*[4] can be isolated from the hydrolyzed mixture in 46% yield. *(4a)* is very readily oxidized by air to its corresponding pyrrole derivative *(5a)*, partially during subsequent work-up at room temperature in either day-light or darkness, and completely in a chloroform solution in a few hours. From the mixture of cycloadducts, the pyrrole *(5a)* (22% yield) and a polymeric pyrrole (20% yield, mass spectrometric confirmation) are also isolated.

Using the method of *Hill* and *Chan*[5] it could be shown that the 3-pyrroline *(4a)* is *trans*-configurated with respect to C-2 and C-5: as a result of the lack of a plane of symmetry in identically α,α'-*trans*-disubstituted heterocyclic amines, the methylene protons of their *N*-benzyl derivatives are stereochemically and magnetically non-equivalent. The same observation was made in the case of 1,3-isoindolinedicarboxylic acid dimethyl ester[6].

When treated with an equimolar amount of benzyl bromide before hydrolysis, the crude cycloadduct mixture affords 1-benzyl-2,4,5-triphenyl-3-pyrroline-3-carboxylic acid *N,N*-dimethylamide *(4b)* in 20% yield, which is rapidly oxidized by air to the corresponding pyrrole *(5b)*. Its $^1$H-NMR spectrum shows unambiguously a stereochemically pure *trans*-2,5 configuration *(4b)* (Table 1). The large values observed for $J_{2,5}$ coupling constants in *(4a)* and *(4b)* are noteworthy, and are of the same order of magnitude as those previously reported for compounds of this type[7].

Table 1. $^1$H-NMR data of *(4)* and *(5)* (δ values, referred to TMS).

| Cpd. | R | H-2 | H-5 | $NMe_2$ | Solvent |
|---|---|---|---|---|---|
| *(4a)* | 2.40(s) | 5.84(s) | 5.84(s) | 2.15(s), 2.70(s) | $CDCl_3$ |

[a] $J_{2,5} = 5.6$ Hz. [b] $J = 14.2$ Hz.

The present synthetic procedure should be valuable in the stereospecific preparation of substituted 3-pyrrolines which are relatively rare in spite of the promising biological properties of some representative examples[8]. Using this procedure we have also prepared 3-diphenylphosphino-2,4,5-triphenyl-3-pyrroline (31% yield; $^1$H-NMR: $\delta = 5.72$ (d, H-2), 5.24 (d, H-5; $J_{2,5} = 4.5$ Hz)).

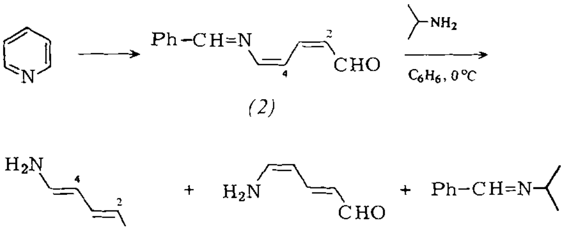
## (*E,E*)-5-Amino-2,4-pentadienal: The First Preparative Synthesis of Hydrolyzed Pyridine

By *Dieter Reinehr* and *Tammo Winkler*[*]

5-Amino-2,4-pentadienal *(1)*, the parent compound of a preparatively important class of compounds[1], has so far never been isolated. *(1)* is formed during the photohydrolysis of pyridine[2a]; it is rather unstable[1] and readily loses water to give pyridine again. *(1)* has been characterized only by its UV spectrum and by trapping reactions[2]. We report here on a simple synthesis of *(1)*, its isolation as a crystalline compound, and on its spectroscopic properties.



*(2)*

*(1a)* *(1b)* *(3)*

Reaction of isopropylamine with the 7-phenyl-6-aza-2,4,6-heptatrienal *(2)*, which is readily accessible from pyridine[3], affords *(1)* in 62% yield. The amine *(1)* is formally replaced by isopropylamine; *(1)* precipitates as yellow crystals which rapidly turn brownish at room temperature and on exposure to air. *N*-Benzylideneisopropylamine *(3)* was isolated from the mother liquor in 58% yield.

*(2)*[3] and *(3)* were characterized by their $^1$H-NMR and IR spectra and elemental analyses and, in the case of *(1)* also by its $^{13}$C-NMR, UV, and mass spectra (Table 1). The UV data of *(1)* are consistent with those of the photohydrolysis product of pyridine[2a]. The absorption maximum of a

Ciba-Geigy AG, CH-4002 Basel (Switzerland)

solution of *(1)* in acidic methanol appears at 339 nm, while the photohydrolysis product absorbs at 340 nm in acid media[2a]. This small difference allows no conclusions about the configuration of the double bond in the photohydrolysis product, as the difference for the *E,E*- and *Z,Z*-isomers of 2,4-hexadienoic acid[4] is also only 5 nm. According to its $^1$H-NMR spectrum, *(1)* is present mainly in the *E,E*-configuration [*(1a)* $J_{2,3}=14$, $J_{4,5}=12$ Hz; cf. analogous dialkylamino compounds[5]]. The 2*E*,4*Z*-compound *(1b)* ($J_{2,3}=14.5$, $J_{4,5}=8$ Hz) is detectable as minor component (5%). Since *(2)* has 2*Z*,4*Z*-configuration[3] ($J_{2,3}=11.5$, $J_{4,5}=7.5$ Hz), an isomerization into the thermodynamically more stable[1] *E,E*-configuration must have taken place during the reaction. This, and the low solubility of *(1)* in benzene, make its isolation possible. Hence this interesting and synthetically important compound[1] is easily accessible.

## Oxidation of Isatins to Anthranilic Acid Esters

By *Gernot Reissenweber* and *Dietrich Mangold*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

The regiospecific Baeyer-Villiger oxidation of isatins by aqueous hydrogen peroxide in glacial acetic acid leads to isatoic anhydrides and with potassium peroxodisulfate in sulfuric acid to 2,3-dioxo-1,4-benzoxazines[1]. The oxidation of isatins by hydrogen peroxide in aqueous alkali metal hydroxides to anthranilic acids has long been used as a preparative route to anthranilic acid derivatives, which are otherwise only accessible with difficulty[2].

We have now found that methyl anthranilates *(2)* can be prepared directly in good yields *via* an exothermic process involving the reaction of isatins *(1)* in methanol with 30 to 50% hydrogen peroxide and sodium methoxide. Their purity after extractive work-up is greater than 96%. The only by-products are the corresponding anthranilic acids (Table 1). Variously substituted methyl anthranilates, which until now have only been accessible indirectly *via* isatoic anhydrides, can therefore be prepared using aniline derivatives as starting materials *via* the readily accessible isatin derivatives[2,3].

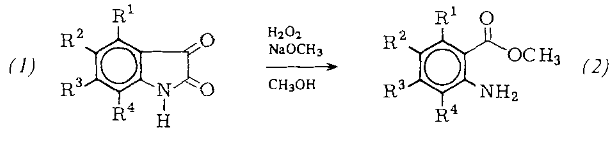

Table 1. Examples for the synthesis of methyl anthranilate esters *(2)* from isatins *(1)* [a].

|  | $R^1$ | $R^2$ | $R^3$ | $R^4$ | *(2)* Yield [%] | B. p. [°C] $n_D^{20}$ |
|---|---|---|---|---|---|---|
| *a* | H | H | H | H | 82 | 1.5818<br>1.5820 [4] |
| *b* | H | H | H | $CH_3$ | 78 | 1.5743 |
| *c* | H | H | H | $CF_3$ | 74 | 1.5042 |
| *d* | H | Cl | H | Cl | 80 | 62—63<br>63—64 [5] |
| *e* | H | Br | H | H | 76 | 73—74<br>74 [5] |
| *f* | H | H | Cl | H | 76 | 69—70 |
| *g* | H | Cl | H | $CH_3$ | 78 | 40—42 |
| *h* | H | H | $CH_3$ | H | 79 | 40 |
| *i* | $CH_3$ | H | H | $CH_3$ | 68 | 34—36 |

[a] All the compounds gave correct elemental analyses as well as satisfactorily IR- and NMR-spectra.

In contrast to the oxidation of isatins *(1)* in aqueous alkali media, the reaction in methanol/sodium methoxide proceeds, based on the results of our investigations, *via* deprotonated isatoic anhydrides *(4)*, which immediately react to the esters *(2)*. There are two possible modes of formation of *(3)*: Route *A* (the water stems from aqueous hydrogen peroxide) and Route *B*.

Furthermore, the reaction is not only limited to the preparation of the methyl esters *(2)*. With ethanol/sodium ethoxide, the ethyl esters can be prepared in equally high yields. A further example: using 1-butanol with sodium hydride as base, *n*-butyl-3-methylanthranilate is formed from *(1b)* in 60% yield.

### *Procedure*[6]

*(1)* (1 mol) is suspended in 1500 mL of methanol. After addition of sodium methoxide (1.5 mol, 30% sodium methoxide solution), hydrogen peroxide (1.2 mol, 50% aqueous solution) is dropped into the cooled mixture (0—10 °C), whereby the initially dark violet solution becomes colorless. The mixture is stirred for 30 min at room temper-

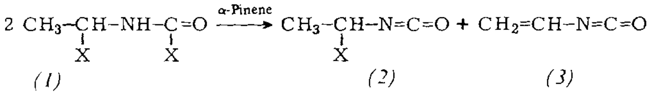
# Vinyl Isocyanate by Thermal Dehydrohalogenation of 1-Haloethylcarbamoyl Halides with α-Pinene

By *Karl-Heinz König, Karl-Heinz Feuerherd, Volker M. Schwendemann*, and *Heinz-Günter Oeser*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

Numerous synthetic routes to vinyl isocyanate *(3)* are known[1]. We have recently synthesized 1-haloethylcarbamoyl halides *(1)* by addition of hydrogen halides to vinyl isocyanate[2], as well as by the halogenation of ethyl isocyanate or ethylcarbamoyl halides[3]. *(1)* shows the tendency to liquefy at room temperature and evolves hydrogen halides. Cleavage of hydrogen halide at room temperature certainly leads at first to 1-haloethyl isocyanate *(2)*. Since, however, considerable amounts of polymeric material are produced in this reaction, presumably at least partial double dehydrohalogenation of *(1)* to the readily polymerizable vinyl isocyanate *(3)* occurs. We have now found that *(1)* and α-pinene react to give a mixture of vinyl isocyanate *(3)* and the, until now unknown, 1-haloethyl isocyanate *(2)*.

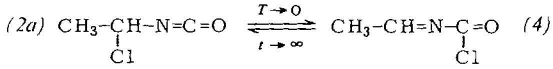


$$2\ \mathrm{CH_3{-}\underset{X}{CH}{-}NH{-}\underset{X}{C}{=}O} \xrightarrow{\alpha\text{-Pinene}} \mathrm{CH_3{-}\underset{X}{CH}{-}N{=}C{=}O} + \mathrm{CH_2{=}CH{-}N{=}C{=}O}$$

*(1)* *(2)* *(3)*

*(a)*, X = Cl; *(b)*, X = Br

With the chloro compound *(1a)*, the fraction of vinyl isocyanate *(3)* in the product mixture of *(2a)* and *(3)* depends on the reaction time. This indicates a mechanism involving intermediates, whereby it can be assumed that a chlorotropic equilibrium between the α-chloroisocyanate *(2a)* and the *N*-alkylidenecarbamoyl chloride *(4)* is involved[4, 5].



$$(2a)\quad \mathrm{CH_3{-}\underset{Cl}{CH}{-}N{=}C{=}O} \underset{t\to\infty}{\overset{T\to 0}{\rightleftharpoons}} \mathrm{CH_3{-}CH{=}N{-}\underset{Cl}{C}{=}O}\quad (4)$$

The formation of vinyl isocyanate *(3)* indicates an azavinylogous dehydrohalogenation of the carbamoyl chloride *(4)*; the position of the equilibrium *(2a)*⇌*(4)* could prevent the rapid formation of vinyl isocyanate *(3)*. In similar chlorotropic equilibria shifts in favor of the α-chloroisocyanate form are known at higher temperatures[4].

*Procedure*

*(2a)* and *(3a)* from *(1a)*: *(1a)* (160 g, 1.13 mol) and α-pinene (537 g, 3.9 mol) were stirred for 2 h while the temperature was increased from 24 to 105 °C; the product mixture was continually distilled out. Total yield 27.6 g (23%). *(2a)* and 34.6 g (44%) *(3)* were purified by preparative gas chromatography[6].

*(3)* from *(1a)*: A mixture of *(1a)* (525 g, 3.7 mol) and α-pinene (1770 g, 13 mol) were heated from 25 to 155 °C over 6.5 h in a stirred flask fitted with a 25 cm packed column and NORMAG distillation head. A distillate of the product was simultaneously collected at reflux ratios of 1 : 15 to 1 : 20; yield 155.5 g (61%) *(3)* with < 1% *(2a)*.

*(3)* from *(1b)*: A mixture of *(1b)* (231 g, 1 mol) and α-pinene (475 g, 3.5 mol) were heated from 23 to 120 °C over 1.5 h in a stirred flask. *(3)* (61.5 g, 89%) in 90% purity was obtained by distillation.

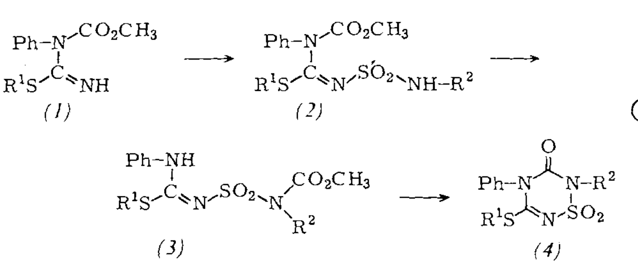
# Thiatriazinones *via* a Novel 1,5-Carboxylic Ester Shift

By *Rolf-Dieter Acker*, *Gerhard Hamprecht*, and *Erich Hädicke*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

Heterocycles with N—$SO_2$—N substructures show a wide range of biological activity[1,2]. The combination of the uracil ring with the sulfonamide element leads to thiatriazinone structures whose synthesis is interesting because of their potential biological activity. A route to the novel 2-alkyl-5-(alkylthio)-4-phenyl-2*H*-1,2,4,6-thiatriazin-3-(4*H*)-one 1,1-dioxides *(4)* was accomplished *via* an unusual 1,5-carboxylic ester shift.

The educts used were the *N*-carboxymethyl-*N*-phenylisothioureas *(1)*[3], which can be readily converted into the sulfamides *(2)* by the action of *N*-alkylsulfamoyl chlorides[2] (Table 1)[4]. Direct cyclization of *(2)* to *(4)* was not possible; however, under mild conditions (2 N NaOH, 20 °C, 30 min, yield 70—80%) the ester group migrated to the alkyl substituted nitrogen atom to form *(3)*. *(3)* cyclized in aqueous alkali (1—2 N NaOH, 50—90 °C, yield 20—40%, depending on the nature of the substituents) to the thiatriazinones *(4)* (Table 1).



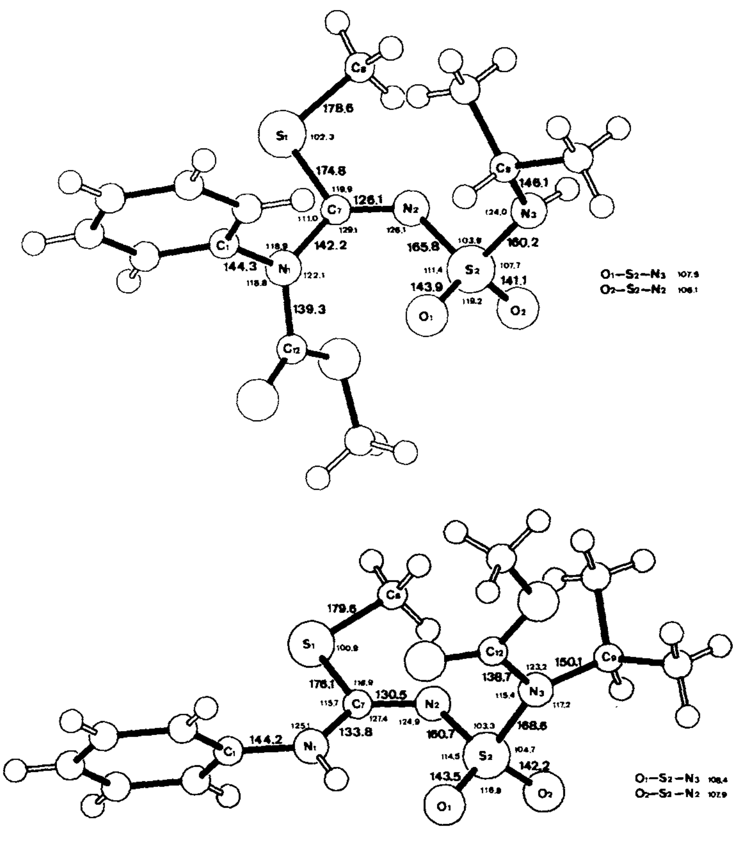


Fig. 1. Molecular structures of *(2a)* (above) and *(3a)* (below) in the crystal. Standard deviations (without hydrogen atoms) 0.2 to 0.7 pm and 0.1 to 0.4° [5].

Table 1. Synthesized products of the type *(1)*—*(4)*.

[a] 4 : 1 mixture of *(3b)* and *(2b)*. [b] Cyclization of *(4c)* commenced at room temperature; *(3c)* was not isolated but could be detected in the reaction mixture.

The surprising rearrangement of *(2)* to *(3)* was confirmed by X-ray structure analyses[5] of *(2a)* and *(3a)* (Fig. 1).

The results of these studies indicate that *(2a)* and *(3a)* have *syn*-configurations (relative to N1—S2) and can readily undergo cyclization. An explanation for selectivity of *(3)* in cyclization reactions is provided by the structural data. The N2—S2—N3 bond lengths in *(2a)* and *(3a)* are considerably different (166 and 160 pm, and 161 and 169 pm, respectively); the marked double bond character of the N1—C7 bond in *(3a)*, relative to that of *(2a)*, is indicated by shortening of this bond from 142 to 134 pm. The different position of the carboxylic ester group causes a shift in the bonding electron density in *(3a)*, which in the N1-to-N3-section of the molecule leads to alternating long and short bonds. This influences the nucleophilicity and increases the acidity at N1. Moreover, the thermolability of the isomer *(2)* in the basic media is presumably important: decomposition of *(2)* begins even at 40 °C.

The $^1$H-NMR spectra are in accord with the molecular geometries of *(2)* and *(3)*. A considerably larger low-field shift of the *N*-alkyl protons in *(3)* relative to those of *(2)* is observed; the same, but less intense effect is observed with *S*-alkyl protons[6].

The structural assignment of the thiatriazinones *(4)* is supported not only by the NMR data (significant low-field shift of the *N*-alkyl protons (Table 1), which is comparable to that of previously known thiatriazinones[7]), but also by IR- (*inter alia* an NH-bond is absent) and mass-spectroscopy.

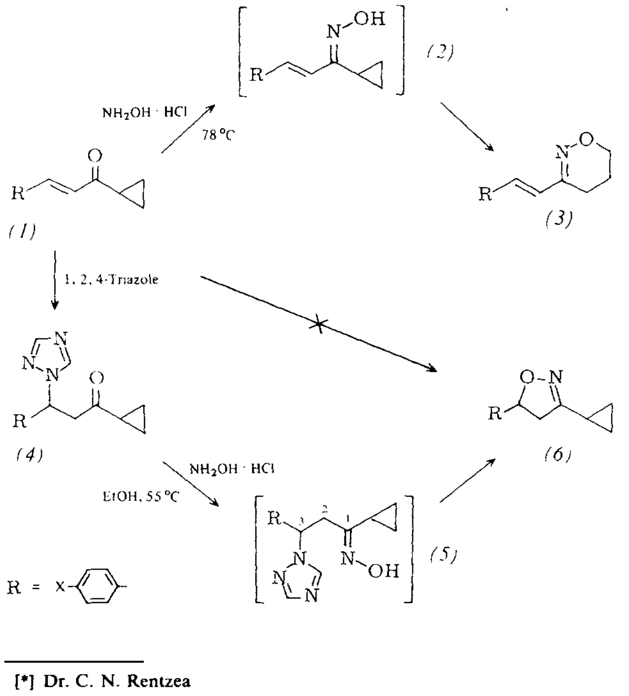
## 4,5-Dihydroisoxazoles from Cyclopropyl Ketone Oximes[**]

By *Costin N. Rentzea*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

Cyclopropyl styryl ketones *(1)* and the corresponding oximes *(2)* rearrange to 5,6-dihydro-4*H*-1,2-oxazines *(3)* on heating in the presence of hydroxylammonium chloride[1]. Cyclizations of *(1)* or *(2)* to give isoxazole derivatives have not so far been observed under these conditions.



We have, however, been able to prepare the 4,5-dihydroisoxazoles *(6)* in the following way: (i) by addition of 1,2,4-triazole to the double bond of *(1)* to give *(4)*[2] [*(4a)*, X=$CH_3$, m.p. 65 °C; *(4b)*, X=Cl, m.p. 82 °C], and (ii) reaction of the *p*-substituted 1-cyclopropyl-3-phenyl-3-(1,2,4-triazol-1-yl) 1-propanone *(4)* under mild conditions (1 h at 55 °C in ethanol; *(4)*: $NH_2OH\cdot HCl=1:1.5$) to give the corresponding *p*-substituted 3-cyclopropyl-5-phenyl-4,5-dihydroisoxazoles *(6)* (see Table 1).

Table 1. Some data of the dihydroisoxazoles *(6)* obtained from the ketones *(4)*. IR in KBr, $^1$H-NMR in $CDCl_3$, TMS int.

*(6a)*, X=$CH_3$; yield 46%, m.p. 160 °C; $^1$H-NMR: $\delta=0.65$ (s, 2 H), 0.9 (s, 2 H), 1.75 (m, 1 H), 2.25 (s, 3 H), 2.5 (AB system, 2 H), 4.1 (split. d, 1 H), 6.9—7.5 (m, 4 H); IR: 1556, 1248, 976, 945, 808 $cm^{-1}$.
*(6b)*, X=Cl; yield 50%, m.p. 152 °C; $^1$H-NMR: $\delta=0.75$ (s, 2 H), 0.85 (s, 2 H), 1.7 (m, 1 H), 2.6 (AB system, 2 H), 4.05 (split d, 1 H), 7.1—7.5 (m, 4 H); IR: 1482, 1222, 1084, 985, 950, 805 $cm^{-1}$.

During the course of the reaction *(4)*→*(6)* the intermediary oximes *(5)*[3] appear on the thin-layer chromatogram ($CHCl_3$ : acetone = 9 : 1). The triazole ring in *(5)* is protonated even more rapidly than the cyclopropane ring. Hence an extremely good leaving group exists on C-3 which is subsequently readily replaced by the oxime oxygen with formation of the dihydroisoxazole *(6)*.

## Base Catalyzed Asymmetric Induction of the Reaction of Methyl(phenyl)ketene with 1-Phenylethanol: Method of Obtaining Hydratropic Acid in High Enantiomeric Purity

By *Joachim Jähme* and *Christoph Rüchardt*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

Chiral, secondary alcohols can react stereoselectively with non-symmetrically substituted ketenes to yield esters[1,2]. Asymmetric induction also occurs if the ketene is reacted with methanol or other achiral alcohols, catalyzed by chiral tertiary amines such as acetyl quinine[2,3].

We now report on the stereoselective formation of the 1-phenylethyl hydratropate ester *(3)* from methyl(phenyl)ketene *(1)* and 1-phenylethanol *(2)*, and on the novel drastic increase in the stereoselectivity caused by addition of achiral bases such as pyridine and 1,4-diazabicyclo[2.2.2]octane. This discovery enables hydratropic acid *(4)* to be obtained in high enantiomeric purity.

(*S*)-(–)-*(2)* or *rac-(2)* and the base were dissolved in toluene or ether under an argon atmosphere in one limb of a

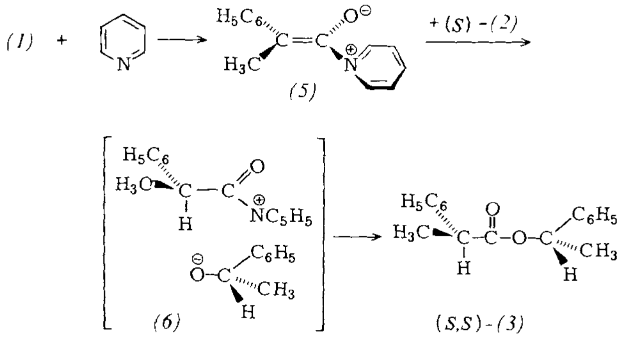
[a] Py = Pyridine; DABCO = 1,4-Diazabicyclo[2.2.2]octane; 4-Pic = 4-Picoline; $NEt_3$ = Triethylamine; DMA = *N,N*-Dimethylaniline; DIEA = Diisopropyl(ethyl)amine; 2,6-Lu = 2,6-Lutidine; DMPP = Dimethyl(phenyl)phosphane. [b] (*R,R*)+(*S,S*):(*R,S*)+(*S,R*). [c] Inverse reaction conditions: base and *(1)* were mixed and then treated with *(2)*. [d] Experiment with (*S*)-(−)-*(2)*. [e] Experiment in diethyl ether.

The results are shown in Table 1. In all cases, the *threo*-diastereomer [(*S,S*)- and/or (*R,R*)-configuration] is formed in higher yield than the *erythro*-compound [(*R,S*)- and/or (*S,R*)-diastereomer].

Whereas the stereoselectivity of the non-catalyzed reaction of *(1)* and *(2)* is dependent both on the initial concentrations (experiments 1 and 2) and on the ratio of *(1)*:*(2)* (experiments 1 and 3), it was only slightly influenced by the same parameters under pyridine catalysis, which also has a large rate enhancing effect (cf. experiments 8 and 9, 5 and 12). The diastereomeric ratio of *(3)* hardly changed when the reaction was conducted under inverse conditions (cf. experiments 5 and 6, as well as 13 and 15) or when a deficiency of base was used. The reaction proceeded more selectively at low temperatures (experiments 13—18) than at 25 °C; changing the solvent from toluene to ether (experiments 26—28) has no marked influence. Use of (*S*)-(−)-*(2)* results in the same diastereomeric ratio as found with racemic *(2)* (cf. experiments 13 and 14, 17 and 18 as well as 27 and 28). The stereoselectivity depends largely on the catalytic base (experiments 19—25). In nitrogen bases, bulky groups and low basicity can be recognized as factors which reduce the selectivity. The use of dimethyl(phenyl)-phosphane as base leads to low selectivity.

When the reaction of (*S*)-(−)-*(2)* ($c_0$ = 0.064 mol/L) with *(1)* and pyridine was conducted in toluene in the molar ratio 1:1:1.1 at 0 °C, the diastereomeric mixture of *(3)* was isolated in 77% yield (by GC (*S,S*):(*R,S*) = 88:12), from which the pure (*S,S*)-diastereomer *(3)* was obtained by one recrystallization from *n*-pentane. Hydrolysis of the crude product with conc. HCl yielded (*S*)-(+)-hydratropic acid (*S*)-(+)-*(4)* with $[\alpha]_D^{22}$ (acetone) + 69.9[5]. This corresponds to 73.2% optical purity, or to an enantiomeric ratio of 87:13 which is in accord with the results in Table 1. Since (*S*)-(−)-1-phenylethanol *(2)* can be reisolated, it serves merely as an optically active auxiliary agent: hydratropic acid can be obtained in this way in high enantiomeric purity by a single recrystallization from *(3)*. In addition, the isolation of the unstable ketene *(1)* can be avoided if it is prepared *in situ* from hydratropaoyl chloride and triethylamine in toluene (molar ratio 1:1, 2 h, 25 °C), and then treated with pyridine and (*S*)-*(2)* (molar ratio 1:1:1) at 0 °C. After 1 h, 59% *(3)* in the diastereomeric ratio (*S,S*):(*R,S*) = 79:21 was isolated.



The fact that almost the same stereoselectivity was obtained with racemic 1-phenylethanol *(2)* as with optically active *(2)*, suggests that the transfer of the proton and the alcoholate to one molecule of ketene *(1)* proceeds from one and the same molecule *(2)* and, hence, that the proton transfer is the descisive enantioselective step. We assume that an enolbetaine, which presumably has the configuration *(5)*, is initially formed from *(1)* and pyridine. This takes over a proton from (*S*)-*(2)* preferentially "from below", forming the ion-pair *(6)*, which by analogy to ion-recombination is acylated to *(3)* in a fast consecutive step. Even in the polar solvent ether dissociation of the ion-pair *(6)* apparently does not compete; in the reaction of *rac-(2)* this ion pair dissociation would lead to a change in stereoselectivity[6] because the acylation step would then be selectivity determining. At present we are investigating the scope of the application of this method and the possibility of applying the principle of stereoselective proton transfer[8] to other molecules.

# Experimental Electron Density Determination of a Dimetallacyclopropane-Type μ-Methylene Complex[**]

By *Dore Augusto Clemente, Bernard Rees, Giuliano Bandoli, Marina Cingi Biagini, Barbara Reiter,* and *Wolfgang A. Herrmann*[*]

There is now firm evidence that bridging methylene units play a pivotal role in the metal surface catalyzed gas-phase decomposition of diazomethane; even more importantly, reactive μ-methylene surface complexes appear to dominate the mechanism of the Fischer-Tropsch synthesis[1,2]. *Hofmann et al.*[3a,b] and *Lichtenberger et al.*[3c] have presented detailed MO calculations, according to which the methylene bridge carbon atoms carries a high negative charge.

In order to substantiate this prediction, we have now carried out an experimental X-ray diffraction electron density determination of the prototype dimetallacyclopropane compound *(1)* first prepared by us in 1975[4].

The molecule *(1)* (Fig. 1, Table 1) consists of two equivalent fragments related by a $C_2$ axis passing through the C(3) atom and the middle of Mn—Mn. Each cyclopentadienyl ring is planar within experimental accuracy, and is situated on one side of the dimetallacyclopropane plane, while the carbonyl atoms C(1) and C(2) lie on the other side at 120 and 137 pm, respectively, from this plane. The angles C(1)—Mn—$C_c$, C(2)—Mn—$C_c$, C(3)—Mn—$C_c$ are practically identical (122.0, 121.3 and 121.0°, respectively),

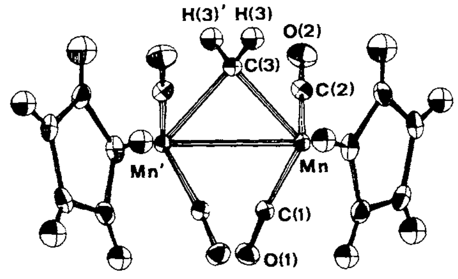

Fig. 1. Molecular Structure of μ-Methylene-bis[dicarbonyl($\eta^5$-cyclopentadienyl)manganese] *(Mn—Mn)* at 130°K. Two crystals were cut into spheres of 0.28 and 0.33±0.02 mm diameter, covered with Loctite®, and sealed in a Lindeman glass capillary. Low-temperature X-ray diffraction data were collected on a Philips PW-1100 diffractometer ($Mo_{K\alpha}$ radiation, Leyboldt Heraeus NCD-1 cooling device). The temperature at the crystal (Chromel/Alumel thermocouple) was maintained at 130°K by means of a stream of $N_2$ gas; space group Pccn, unit cell parameters $a$ = 716.1(4), $b$ = 1517.7(6), and $c$ = 1270.3(6) pm (mean of two crystals). *Ca.* 7500 and 14000 reflections were measured with the two spherical crystals, respectively (for the second, at least two symmetry equivalents for each reflection), and averaged to 6986 independent reflections. The intensities, corrected for Lorentz, polarization and absorption effects, were correlated with each other using least-squares techniques. The structure was solved by repeated Fourier and Patterson syntheses and refined by least-squares methods, using the 4283 reflections with $I \geq 3\sigma(I)$; positional and thermal parameters were refined for all atoms (isotropic parameters only for H atoms); a secondary isotropic extinction dominated by mosaic spread with a Lorentzian distribution function was assumed, but the corresponding $g$ parameter proved to be very small and was later disregarded. Final $R$ values for the full set of data: $R(F)$ = 0.040, $R(F^2)$ = 0.059, and $S(F^2)$ = 1.89.

[**] Transition-Metal-Methylene Complexes, Part 21. This work was supported by CNR Grant No. 780.176.803 and the Deutsche Forschungsgemeinschaft.—Part 20: *Ch. Bauer, W. A. Herrmann*, J. Organometal. Chem. *209*, C 13 (1981).

while the angle Mn—Mn′—$C_c$ is 126.7°. Thus, the overall geometry very much resembles that of the related $(\eta^5\text{-}C_5H_5)Mn(CO)_3$ compound[5].

To ascertain if there is an accumulation of electron density between the two metal centers or whether the two mononuclear fragments are bonded *via* multicentered linkages between the metal atoms and the methylene bridge[3c], we have calculated a preliminary *X*—*X* deformation density map in the Mn—C(3)—Mn′ plane (Fig. 2). The subset consisting of low order *(LO)* reflections up to $\sin\vartheta/\lambda = 0.71$ Å$^{-1}$ ($\vartheta_{max} = 30°$) was used in the calculations of deformation densities computed with the Fourier coefficients $\Delta F = F_0(LO) - F_c(HO)$; the atomic parameters of the structural model used in the calculation of $F_c(HO)$ ($HO$ = high order) were obtained from high-order ($30° < \vartheta < 50°$) refinement. Interestingly, the deformation density map shows no accumulation of density along the Mn—Mn′ vector — being near to zero ($-0.02$ eÅ$^{-3}$) between the Mn atoms, in contrast to quantum chemical calculations which indicate direct bonding interactions between the two metal atoms of dimetallacyclopropane-type frameworks[3,6]. This is quite analogous to the observation made for $Mn_2(CO)_{10}$[7] and is probably related to insufficient overlap of the corresponding metal orbitals in a long metal-metal bond[8]. On the other hand, a significant charge gradient is found along the Mn—C(3) bond, with a region of charge accumulation close to the bridging carbon atom. In this respect the $CH_2$-bridged compound *(1)* hardly differs from the CO-bridged compound $(\mu\text{-}CO)_2[(\eta^5\text{-}C_5H_5)Fe(CO)]_2$[9], except that in *(1)* the charge accumulation in the carbon lone pair region appears smaller. A possible explanation is that the position of C(3) determined by least-squares refinement does not coincide exactly with the actual position of this atom. By way of contrast, a smaller shift is expected for a carbonyl bridge, the "lone pair" charge accumulation being compensated by the strong charge accumulation on the CO bond.

The finding that the methylene carbon is situated in a region of high charge density is in accord with earlier MO calculations and is also consistent with NMR results on dimetallacyclopropanes[1]. An effective charge transfer from the metal center to the methylene ligands is evident from parameter-free Fenske-Hall calculations which yield a methylene carbon atomic charge of $-0.526$ eÅ$^{-3}$[3c]; a similar value ($-0.78$ eÅ$^{-3}$) results from a SCCCMO treatment of *(1)*[6]. The latter method attributes a charge of $-0.92$ eÅ$^{-3}$ to the entire $CH_2$ fragment. These results, and those obtained from the EHMO analysis performed by *Hofmann*[3a,b], appear quite consonant and emphasize that nucleophilic reactions at the methylene bridge must come to the fore unless the reactivity of these systems is governed by the nature of the metal-metal bond itself[10].

[8] The lack of charge density accumulation on the Mn—Mn bond is most probably associated with the small value of the metal 3d density at the center of the bond. Assuming for example a bonding orbital of the form $(2+2S)^{-1/2}(d+d')$, where $S$ is the overlap between the orbitals $d$ and $d'$ centered on the two metals, the density associated with this at the midpoint would be $4(1+S)^{-1}d^2$ and the deformation density with five 3d electrons of the Mn atom: $2\frac{1-S}{1+S}d^2$. This is only of the order of 0.03 eÅ$^{-3}$. There is also circumstantial NMR evidence for M—M bonds in complexes of this type [1b, c].

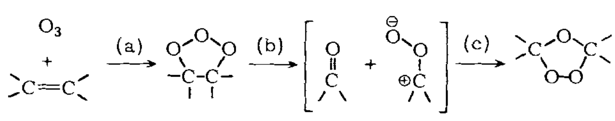
## Stereochemistry of the Ozonolysis of Alkenes: Ozonide- *versus* Carbonyl Oxide-Control

By *Dieter Cremer*[*]

The reaction of ozone with alkenes in non-polar, aprotic solvents essentially proceeds according to the three-step mechanism proposed by *Criegee*[1], namely: (a) formation of primary ozonide *(1)*, (b) decomposition of *(1)* to aldehyde *(2)* and carbonyl oxide *(3)*, (c) recombination of the decomposition products to give the final ozonide *(4)*.



*(1)* *(2)* *(3)* *(4)*

Of particular interest is the reaction step (b), whose energetics and stereochemistry could hitherto not be investigated because of the instability of *(1)* and *(3)*. Whereas *(1)* and *(4)* are each formed in a strongly exothermic reaction, the sign of the energy of reaction step (b) depends upon

Table 1. *Ab-initio* energies of reaction (in kcal/mol) calculated for the ozonolysis of alkenes [a].

| Reaction step | Ethene | Propene | 2-Butene *trans* | 2-Butene *cis* |
|---|---|---|---|---|
| (a) | −49.2 | − 50.5 | − 50.7 | − 51.2 |
| (b) | 13.7 | 6.4 [b] | 1.2 | − 0.2 |
| (c) | −63.1 | − 58.3 | − 55.9 | − 55.1 |
| (a + b + c) | −98.6 | −102.4 | −105.3 | −106.5 |

[a] Correlation-corrected calculations with augmented 6-31G* basis according to the Møller-Plesset perturbation method (2nd order). The absolute energies for the parent compounds are: −224.87683 (ozone), −78.29431 (ethene), −303.34952 *(1)*, −114.17494 *(2)*, −189.05283 *(3)*, −303.32834 Hartree *(4)*. The alkyl effects were calculated according to the Hartree-Fock method. [b] Calculated for the formation of methylcarbonyl oxide and formaldehyde. The formation of acetaldehyde and carbonyl oxide is 2.3 kcal/mol more endothermic.

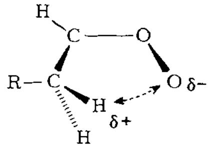
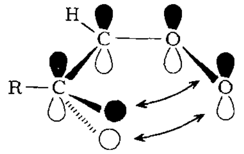
the substituents at the alkene double bond. *Ab initio* calculations (Table 1) show that step (b) in the ozonolysis of ethene proceeds endothermally. The endothermic character of step (b) decreases on going to propene and 2-butene; in the case of 2,5-dimethyl-3-hexene, step (b) is distinctly exothermic[2]. The change in energy of reaction results from the different stabilization of *(1)*, *(2)* and *(3)* by alkyl groups[3-5].

If one assumes, in accord with the Hammond postulate[6], that the transition state is influenced by the product in endothermic reactions but by the educt in the case of exothermic reactions, then two alternatives can be distinguished for reaction step (b).

1) In the case of lower alkenes (ethene, propene, 2-butene) the stereochemistry of step (b) is essentially determined by the electronic properties of the carbonyl oxide that is formed. Quantum-chemical calculations on alkylcarbonyl oxides[4] show that, despite apparently unfavorable repulsion, the *syn*-isomers are 3—4 kcal/mol more stable than the corresponding *anti*-forms. This is ascribed to the attraction between a negatively charged terminal oxygen and positively charged H-atoms of the alkyl substituents. Through space π-bonding interactions (formation of a homoaromatic 6π-system) also contribute to stabilization of the *syn*-form[4].





This effect should also play a role in the transition state of step (b) and should lead—irrespective of the configuration of *(1)*—to preferred formation of *syn-(3)*.

2) In the case of higher alkenes the conformational properties of the primary ozonide *(1)* determine the stereochemistry of step (b). The rules put forward by *Bailey et al.*[7] and *Kuczkowski et al.*[8] can be applied, namely *cis-(1)* preferably decomposes to *anti-(3)*, *trans-(1)* preferably to *syn-(3)*.

According to experimental[1,7,8] and theoretical findings[2] the following statements can be made about the stereochemistry of steps (a) and (c): The formation of *(1)* proceeds stereochemically with retention of the alkene configuration. The final ozonide *(4)*, on the other hand, is formed stereoselectively, *syn-(3)* being preferably incorporated in *trans-(4)*, *anti-(3)* preferably in *cis-(4)*.

The proportion of *cis-* and *trans-(4)* in the product mixture of the ozonolysis is substantially influenced by the stereochemistry of step (b). In the case of "carbonyl oxide-control" (ozonolysis of lower alkenes) predominantly *trans-(4)* is formed—irrespective of the configuration of the alkene[9]. In the case of "ozonide-control" (ozonolysis of higher alkenes) the *cis(trans)*-configuration of the alkene is essentially transferred to the final ozonide *(4)*. These quantum-chemical predictions explain the unusual stereochemistry of the ozonolysis of lower alkenes[1].

## On the Structure of the Helical N-Terminus in Alamethicin—α-Helix or $3_{10}$-Helix?[**]

By *Thomas Butters, Peter Hütter, Günther Jung, Norbert Pauls, Heribert Schmitt, George M. Sheldrick*, and *Werner Winter*[*]

In lipid bilayer membranes the polypeptide antibiotics alamethicin *(2)*, suzukacillin and trichotoxin form potential-dependent, ion-conducting pores having discrete conductance values[1]. The study of these model systems could possibly contribute to a better understanding of excitation in nerve membranes, if the molecular structure of the pores made up of oligomers were to be known.

CD and $^{13}$C-NMR spectra of the natural peptide antibiotics and of synthetic analogues have revealed a strongly solvent-dependent α-helix content of 20—40%[2]. A structural prerequisite for pore formation and hemolytic action is the presence of a non-helical C-terminal segment of 6 or 7 amino acid residues together with an N-terminus of 10—12 amino acid residues[3]. Alternating sequences, *e.g.* (Aib-Ala)$_n$ containing the conformationally very restrictive α-aminoisobutyric acid form a very stable α-helix dipole on the polypeptide antibiotics, especially in lipophilic environment.

In several recent works it has been suggested that a $3_{10}$-helix could also be present in alamethicin[4]. For example, an X-ray structure analysis of the N-terminal tetrapeptide of *(2)*, Z-Aib-L-Pro-Aib-L-Ala-OMe has shown that this short peptide forms one turn of a $3_{10}$-helix. The X-ray structural data of Tos-(Aib)$_5$-OMe and Z-(Aib)$_5$-O*t*Bu, each with three type-III β-turns[9], seem also to indicate the presence of a $3_{10}$-helix in the antibiotics[4]. On the other hand, on the basis of conformational calculations, *Burgess* and *Leach*[5] designate Aib as an "obligatory α-helicogenic residue".

Since we have previously been unable to obtain useful single crystals of the natural peptide antibiotics, owing to their microheterogeneity, for spectroscopic and X-ray purposes we have synthesized the model *(1)* of the N-terminal alamethicin helix containing eleven amino acid residues[6].

Helical undecapeptide *(1)*:
Boc-L-Ala$^1$-Aib$^2$-Ala$^3$-Aib$^4$-Ala$^5$-Glu(OBzl)$^6$-Ala$^7$-Aib$^8$-Ala$^9$-Aib$^{10}$-Ala$^{11}$-OMe

Alamethicin *(2)*:
Ac-Aib$^1$-L-Pro$^2$-Aib$^3$-Ala$^4$-Aib$^5$-Ala(or Aib)$^6$-Gln$^7$-Aib$^8$-Val$^9$-Aib$^{10}$-Gly$^{11}$-Leu$^{12}$-Aib$^{13}$-Pro$^{14}$-Val$^{15}$-Aib$^{16}$-Aib$^{17}$-Glu$^{18}$-Gln$^{19}$-Pheol$^{20}$

Aib = α-aminoisobutyric acid (2-methylalanine), Pheol = L-phenylalaninol, Ac = acetyl, Boc = *tert*-butyloxycarbonyl, Bzl = benzyl, Me = methyl

Single crystals of *(1)* could be grown from dichloromethane/hexane, but they disintegrated within seconds in absence of the mother liquor. However, with two "surviving" crystals we were able to collect several data sets with a four-circle diffractometer[7]. After numerous unsuccessfull attempts with the usual program systems, solution of the structure by direct methods ($P2_1$, 90 atoms other than hydrogen) was achieved with a new random phase refinement + E-Fourier recycling program[8]. The present state of the isotropic structure refinement is $R = 0.12$ (4327 reflections with $F \geqslant 3\sigma(F)$, 6 dichloromethane solvent molecules per unit cell).

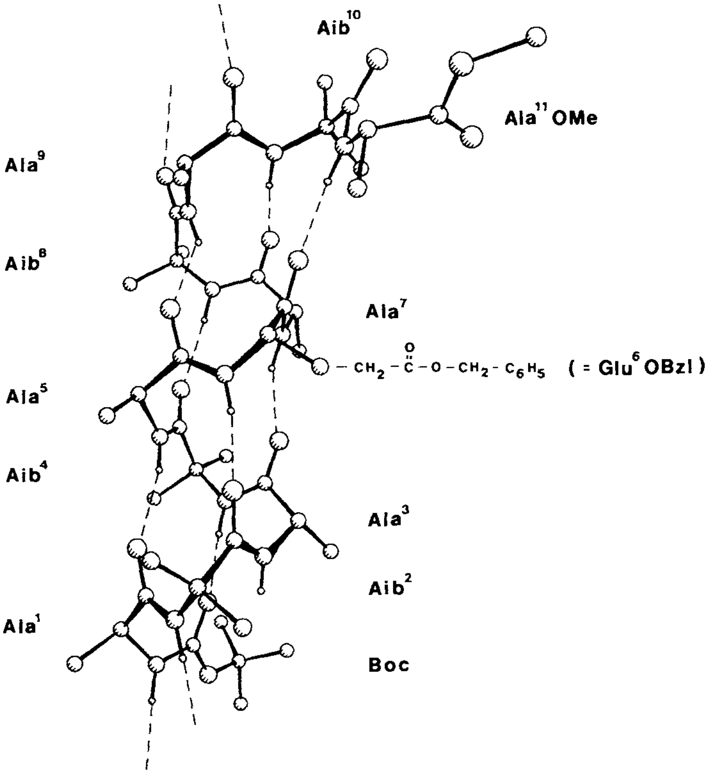

Fig. 1. Perspective view of the peptide skeletal framework of *(1)*. For sake of clarity, the atoms of the Glu$^6$(OBzl) side chain have been omitted. Intra- and intermolecular H-bonding is shown by dotted lines.

Nine of the eleven amino acids of *(1)* are part of an α-helix, only the two C-terminal amino acids Aib$^{10}$ and Ala$^{11}$ are bent away by a β-turn (Fig. 1). The carbonyl groups of Aib$^8$ and Ala$^9$ are thereby situated on the periphery of the molecule and act as acceptors for intermolecular H-bonding with the NH-groups of Ala$^1$ and Aib$^2$ of a neighboring molecule. The α-helices coupled head-to-tail in this way form antiparallel chains.

On the basis of the crystal structure of *(1)* we can assume that no $3_{10}$-, but α-helix conformations are present in the antibiotics alamethicin, suzukacillin and trichotoxin. Only the last three N-terminal amino acids of *(2)*, Ac-Aib$^1$-Pro$^2$-Aib$^3$-, can close the α-helix like a β-turn[2,3].

The CD spectrum of undecapeptide *(1)* in solution showed the typical Cotton effects for a α-helix, and the $^{13}$C-NMR spectrum showed the pronounced magnetic non-equivalence of the geminal Aib-$C_\beta$ atoms due to the helix dipole, which was also observed in the natural peptides and their analogues[2,3,6]. An antiparallel arrangement of the helices of aggregated alamethicin molecules is also possible in the lipid membrane; the opening of an ion-conducting pore could be caused by high local field strengths occurring during an action potential and may include a parallel arrangement of the helices. In experiments with planar lipid membranes, beside the potential-dependent pore formation, an additional but only weak potential-dependent conductivity was observed[1]. This could be explained in terms of aggregates of parallel helices.

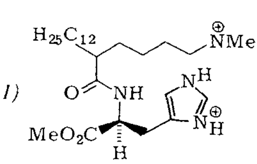
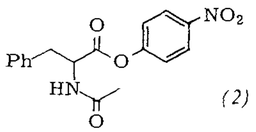
[**] This work was supported by Procter and Gamble, U.K. (partial support for *R. L. E.* and *C. G. G.*) and the Deutsche Forschungsgemeinschaft (Project He 880/6).

nitrophenyl ester *(2)* is hydrolyzed three times faster than the *R*-enantiomer. The absolute configuration at C-5 in *(1)* was unknown and subsequent work[2] has concentrated on varying the histidine moiety. We now report the synthesis of both diastereomers of an analogue of *(1)* and their catalysis of the hydrolysis of the enantiomers of *(2)*.



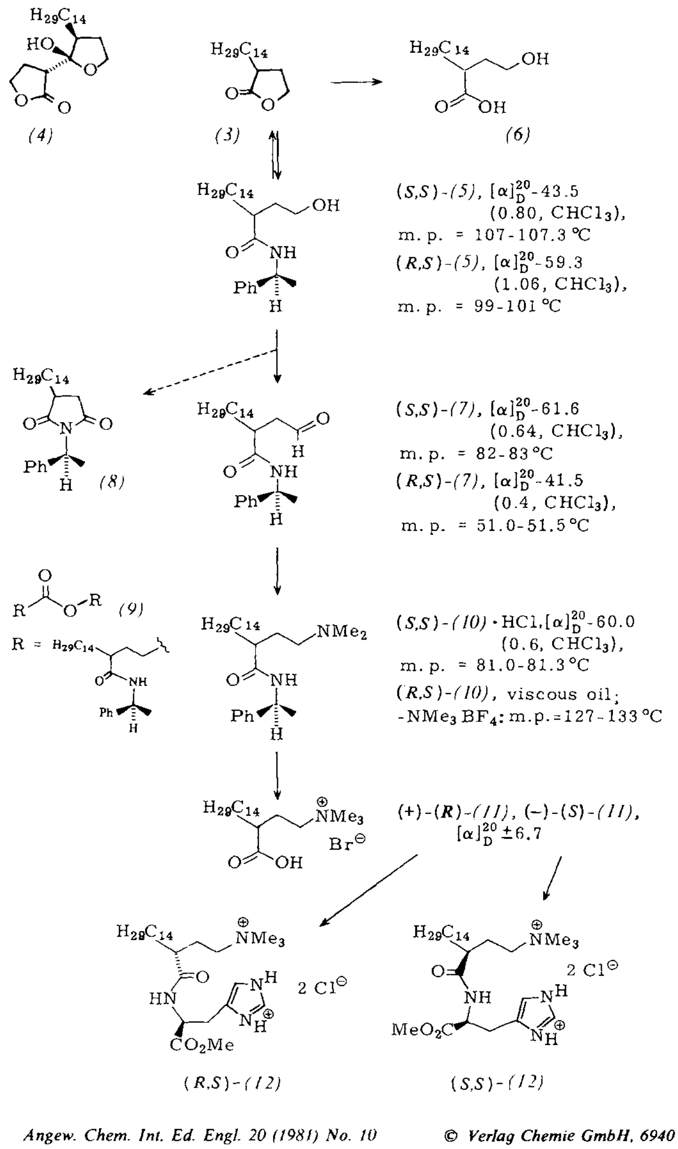
*(1)*



*(2)*

Racemic α-tetradecyl-γ-butyrolactone *(3)* was prepared by alkylation of butyrolactone (lithium diisopropylamide, tetrahydrofuran/hexamethylphosphoric triamide 1 : 1, −40°, $C_{14}H_{29}Br$) and separated from by-product *(4)*[3]. It was efficiently resolved by medium-pressure liquid chromatographic or flash chromatographic[4] separation of the diastereomeric hydroxyamides *(5)* formed by reaction of *(3)* with (−)-(*S*)-α-phenylethylamine and reconversion[5] [(+)-(*S*)-*(3)*: $[\alpha]_D^{20} = +8.17°$ ($c = 10.2$, $CHCl_3$), (−)-(*R*)-*(3)*: $[\alpha]_D^{20} = -8.13$ ($c = 10.0$, $CHCl_3$)]. The absolute configurations are assigned by the resolution method on the basis of many corollaries[5]. All attempts to convert optically pure lactones *(3)* to hydroxycarboxylic acids *(6)* under mild conditions (*e.g.* KOH, MeOH, 0 °C, 30 s) led to partially racemized compounds[6]. Thus the following approach was devised. The diastereomerically pure hydroxyamides *(5)* were oxidized with pyridinium chlorochromate[7] giving the corresponding aldehydes (*R,S*)- and (*S,S*)-*(7)*, purified chromatographically in each case to remove *ca.* 20% of the succinimide *(8)*. Similar results were obtained when $CrO_3$-pyridine was employed but now *(9)* was the major impurity. The tertiary amines (*R,S*)-and (*S,S*)-*(10)* were prepared by reductive amination of the aldehydes [$NaBH_3CN$, $NH(CH_3)_2$][8]. Methylation ($CH_3Br$) and hydrolysis gave rise to the two enantiomeric quaternary ammonium salts *(11)*[9]. The final reaction step was carried out as previously described[1] and gave the diastereomeric histidines (*R,S*)- and (*S,S*)-*(12)* as amorphous solids. These were shown to be chemically and stereochemically pure by $^{13}C$-NMR spectroscopy, with distinct carbonyl resonances (75.47 MHz, $D_2O$, δ(CO), (*R,S*)-*(12)*: 176.2, 171.7, (*S,S*)-*(12)*: 176.5, 172.0).

(*R*)- or (*S*)-*(2)* was allowed to react in aqueous phosphate buffer in the presence of both diastereomeric catalysts *(12)* and the rate profiles thus obtained are recorded in Figure 1. The curves are typical of nucleophilic catalysis in homomicelles[10]. The fastest reaction is shown for the combination (*S,S*)-*(12)* and (*S*)-*(2)*, which is 2.5 times more reactive than (*R*)-*(2)* in the plateau region. Thus, by analogy, the configuration of *(1)* must be (*S,S*). The other diastereomer, (*R,S*)-*(12)*, surprisingly shows opposite selectivity, for (*R*)-*(2)* reacts 1.5 times faster than (*S*)-*(2)* in the plateau region. This requires that the chain is intimately involved in stereochemical control of catalysis, which imposes severe limits on possible models for the reaction transition-state.



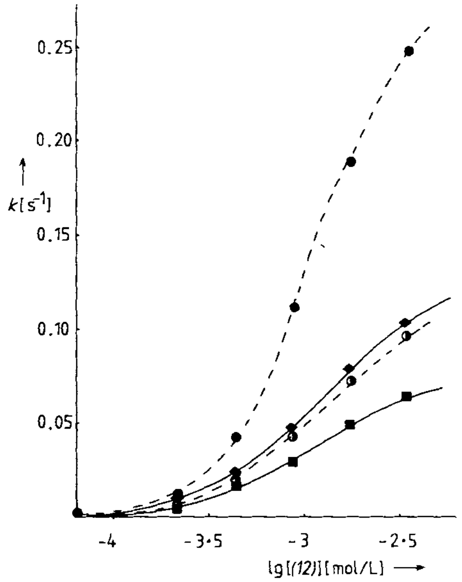


Fig. 1. Rate profile of the hydrolysis of the ester *(2)* catalyzed by *(12)*; pH 7.26±0.04, 0.02 M phosphate buffer, $[(2)] = 5 \times 10^{-5}$M, 0.47 vol.-% acetone in water. ● (*S,S*)-*(12)*, (*S*)-*(2)*; ◑ (*S,S*)-*(12)*, (*R*)-*(2)*; ◆ (*R,S*)-*(12)*, (*R*)-*(2)*; ■ (*R,S*)-*(12)*, (*S*)-*(2)*.

The pH-rate profile (Fig. 2) is equally instructive. In phosphate buffer below pH 8, reaction proceeds predominantly through neutral imidazole nucleophilic catalysis and little variation in stereoselectivity is observed. In borate buffer, where the reactive nucleophile is an imidazolide anion[11], at least in part, reactivities are much less vari-

0570-0833/81/1010-0891 $ 02.50/0

able (Figure 2). This places further constraints on asymmetric catalysis: (a) only the neutral histidine is effective, and (b) phosphate buffer (predominant counterion $HPO_4^{2-}$ at pH 7.5) is more efficacious than borate buffer (predominant counterion $Cl^-$ rather than $H_3BO_4^-$ at pH 9). A model which displays these features is presented by formula *(13)*.

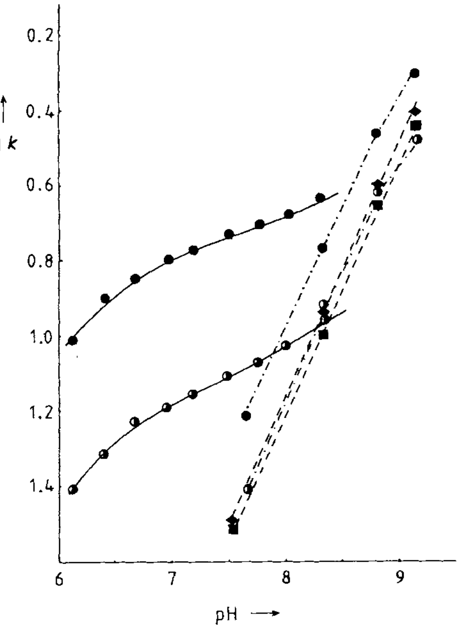

Fig. 2 Dependence of lg *k* on the pH of the solution in the hydrolysis of *(2)* catalyzed by *(12)*; $[(12)] = 1.08 \times 10^{-3}$M, $[(2)] = 5 \times 10^{-5}$M, [buffer] = 0.02 M, 0.47 vol.-% acetone in water; ● (*S*,*S*)-*(12)*, (*S*)-*(2)*, ----- borate buffer; —— phosphate buffer; ■ (*R*,*S*)-*(12)*, (*S*)-*(2)*, — — — borate buffer; ◑ (*S*,*S*)-*(12)*, (*R*)-*(2)*, -·-·- borate buffer, ——— phosphate buffer; ◆ (*R*,*S*)-*(12)*, (*R*)-*(2)*, — — — borate buffer.

## A Mild and Effective Method for the Reactivation or Maintenance of the Activity of Heterogeneous Catalysts[**]

By *Helmut Tiltscher, Helmut Wolf,* and
*Joachim Schelchshorn*[*]

*Dedicated to Professor Franz Patat on the occasion of his 75th birthday*

There is considerable current interest in investigations of highly compressed fluid mixtures in the critical or supercritical region chiefly due to their significance in new separation processes[1]. The effect of increase of pressure at the supercritical region can change the course of homogeneous and heterogeneous reactions as a result of the drastic change in material properties. Apart from a few, previously reported investigations[2] hardly any systematic studies are known.

By measuring the isomerization of 1-hexene on γ-$Al_2O_3$ with 2-chlorohexane as cocatalyst we found that a catalyst, which was deactivated under gaseous or liquid phase reaction conditions, can be reactivated by increasing the pressure and/or temperature until a supercritical state is reached. The method can be employed in the case of loss of catalytic activity, whether caused by deposition of substances of low volatility, (catalyst 'coking', 'fouling') or by specific compounds ('poisoning'). The deactivation phenomena of the mentioned types can be avoided by applying higher pressures under supercritical reaction conditions at the initial stages of heterogeneous, catalytic conversions.

A continuously operating high pressure apparatus, which allowed kinetic measurements to be made, was used[3]. The main part of the system consists of a novel type of high pressure differential recycle-reactor[4,5].

For the kinetic measurements the high pressure reactor was charged with 7.5 g of a freshly synthesized shell catalyst (γ-$Al_2O_3$/Al-metal, particle diameter: 0.6—0.75 mm, catalytically active specific surface: 4.95 $m^2/g$). As shown in Figure 1a (bottom curve), the theoretically expected degree of conversion of 1-hexene (24%) cannot be achieved

[**] Chemical Reactions at High Pressures, Part 5. We thank Prof. Dr. *K. Dialer* for his valuable comments and generous support of this work. – Part 4: H. Tiltscher, Y. K. Wang, H. Wolf, High Temperatures - High Pressures *9*, 529 (1977).

with a gaseous reaction phase[6] at 15 bar and 523.2 K after stationary conditions had been established within the reactor (ca. 4 h = four times the mean residence time). The resulting curve is typical of a conversion upon which a deactivation process is superimposed. In the colorless product solution only the hexene isomers 1-hexene, *cis*-2-hexene, *trans*-2-hexene, *trans*-3-hexene could be detected by capillary gas-chromatography, GC/MS, and $^{13}$C-NMR-analytical methods.

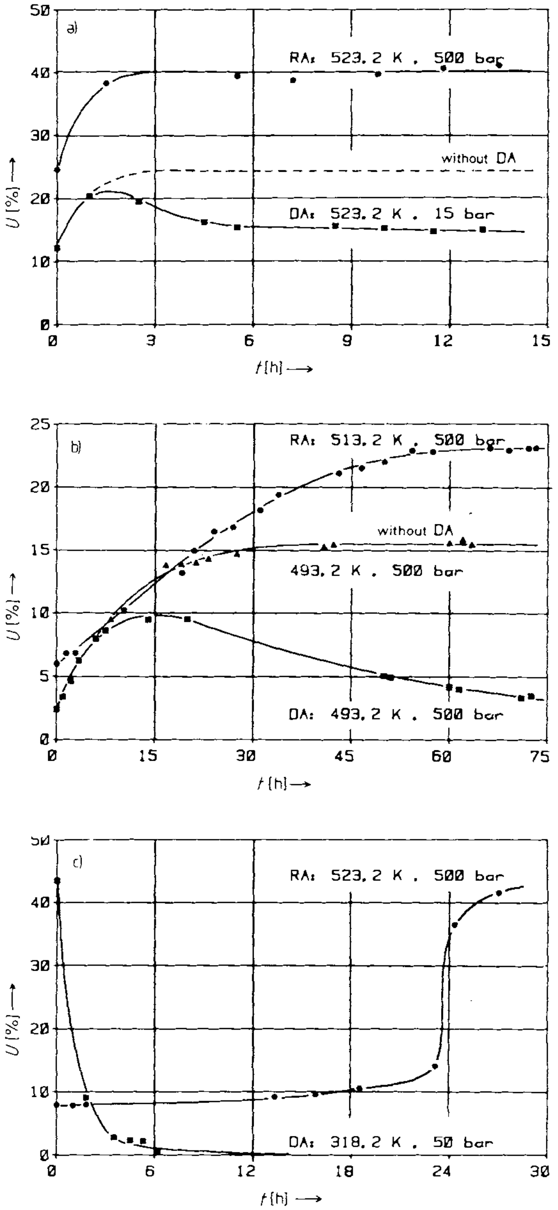

Fig. 1. Isomerization of 1-hexene in the presence of 2-chlorohexane (molar ratio 500:1) on $\gamma$-$Al_2O_3$. Units see text. a) Deactivation (DA) of the catalyst by side reactions, and reactivation (RA) in the supercritical region under gas phase reaction conditions. Residence time $\tau = 1.08 \times 10^5$ s·g/mol. b) Deactivation (DA) of the catalyst by $MoS_2$ under liquid phase reaction conditions and reactivation (RA) under supercritical conditions. Middle: Measurements with reactivated catalyst. Residence time $\tau = 1.89 \times 10^5$ s·g/mol. c) Deactivation (DA) of the catalyst by poisoning of the catalytic active acid sites with pyridine under liquid phase reaction conditions and reactivation (RA) at supercritical conditions. Residence time $\tau = 1.08 \times 10^5$ s·g/mol. $U$ = conversion.

An increase of pressure, at the same temperature, to a value higher than the critical pressure $p_c$, *e.g.* 500 bar, produces an immediate dark brown coloration of the product solution, which gradually brightens again. After the stationary conditions have been re-established, the conversion corresponds to the expected values. As seen in the upper curve even at extremely long reaction times the catalyst does not decay, despite the essentially higher reactivity. The dark brown oily product solutions which were sampled immediately after pressurization, contained, besides the hexene isomers, considerable amounts of oligomers ($C_{12}$ to $C_{30}$). Under gaseous reaction phase conditions, these oligomeric compounds remain on the catalyst surface due to their markedly lower volatility relative to the hexene isomers and finally cause complete coking. After reactivation only a small constant residual amount of hexene-dimers could be detected in the product solution.

Whilst pressurization at a constant temperature of a gaseous reaction phase usually favors sorption processes in heterogeneous catalytic conversions and thus hinders desorption of low volatile compounds, increase of pressure in the supercritical region causes the opposite effect. Distinct influences for practical applications can even be obtained at pressures of 50 to 150 bar. Based on the present kinetic measurements it can be concluded that the applied pressure is the higher, the less volatile the deposited substances and the faster the reactivation should occur.

The advantages of supercritical reaction conditions also apply to catalyst fouling caused by the introduction of compounds of low volatility. Hence, a small amount of finely dispersed $MoS_2$ was introduced into the reactor under liquid phase reaction conditions ($T = 493.2$ K; $p = 500$ bar) again resulted in a conversion-time curve, which is typical for a heterogeneous catalytic reaction with catalyst decay (Fig. 1b, bottom curve). Catalytic activity could not be regained under liquid phase conditions, not even after an extremely long operation period (75 h). By raising the temperature to 513.2 K at the same pressure the supercritical region was reached, resulting in an increase of the degree of conversion (upper curve). Finally the isomerization could be studied under liquid phase conditions by means of the reactivated catalyst, without catalyst decay (middle curve).

The ability of compressed supercritical reaction phases to reactivate poisoned catalysts is shown in Figure 1c. For this purpose, the active acidic sites of the catalyst were initially poisoned at a pressure of 50 bar and a temperature of 318 K by continuous addition of a $6.4 \times 10^{-2}$ M solution of pyridine in 1-hexene over a period of twelve hours. The conversion decreases rapidly as shown by the deactivation curve. At 493.2 K and 500 bar in the liquid phase, the catalyst could not be reactivated even after an extremely long reaction time. Only after a further increase of the temperature to 523.2 K at constant pressure and supercritical conditions had been reached, was a degree of conversion of about 8% achieved; this level increased with time, until the original value was obtained after *ca.* 24 h. A white deposit of pyridinium chloride was isolated from the product solution.

The use of highly compressed supercritical fluid reaction phases for the reactivation of heterogeneous catalysts thus has considerable advantages over the usual methods employed in heterogeneous catalytic syntheses:

1. The reactivation conditions are relatively mild.
2. The reactivation or maintenance of the activity is performed by the fluid reaction phase itself; no other substances have to be added to the reaction system.
3. The reactivation can be easily carried out *in situ*.

4. The heterogeneous catalyst can be used over long working periods with constant catalytic activity.
5. At constant residual catalytic activity, more drastic reaction conditions can be used and higher space-time yields are obtainable.

The heterogeneous catalyst used in our kinetic measurements loses its activity completely within a 14 day period of operation under gaseous reaction conditions (*e.g.* $T = 523.2$ K; $p = 15$ bar). However the experiments described here could be performed with a single catalyst charge without any loss of catalytic activity for a period of four months by periodical reactivation at supercritical conditions. Thus, the ratio of volume of the reactants passed through the catalyst to the volume of the catalyst ($1.2 \times 10^6 : 1$) reached an order of magnitude desirable for many industrial syntheses.

# Synthesis of Glycopeptides: Selective Carboxy-Deblocking of Completely Protected Glucosylserine Derivatives[**]

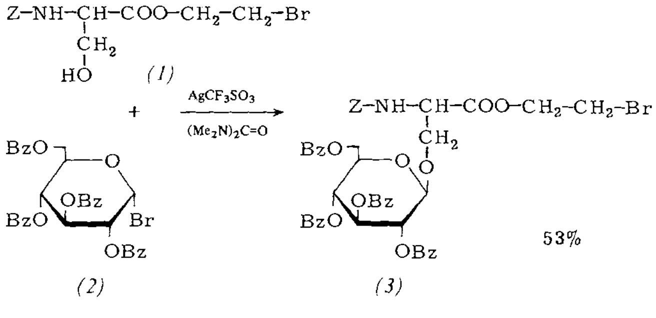
By *Horst Kunz* and *Michael Buchholz*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

In the glycoproteins of connective tissue and mucins[1a], as also in other physiologically important glycoproteins, *e.g.* in blood-group active sialoglycopeptides of human erythrocytes[1b], the carbohydrate moiety is linked *O*-glycosidically with the protein moiety. In many globulins, *e.g.* in immunoglobulins of the rabbit[2], *O*-glycosidic linkage to serine and to threonine is found in addition to the more frequently met *N*-acetylglucosamine-asparagine linkage. The *O*-glycosidically bound serine and threonine residues are not only sensitive to acid, but are also characteristically unstable towards alkalis: β-elimination of the sugar residue readily occurs[3], with formation of unsaturated amino acid derivatives[1a,4].

Model compounds such as benzyloxycarbonyl(Z)- or dinitrophenyl(Dnp)-serine and threonine methyl or benzyl esters[5], which have been used to study the β-elimination, are not particularly suitable for a directed glycopeptide synthesis, since selective cleavage of the N- and C-terminal protecting groups cannot be achieved. According to *Garg* and *Jeanloz*[6] predominantly the *O*-glycosidic linkage is cleaved during acidolytic cleavage of the Z-group of glycosyl-Z-serine methyl esters; alkaline hydrolysis likewise proves unsuccessful, since β-elimination leads to decomposition of the glycoside.

We report here the selective deblocking of the C-terminal of glucosyl-Z-serine esters using the 2-bromoethyl ester protecting group[7]. Fundamental for this synthetic pathway is the finding that the Z-serine-2-bromoethyl ester *(1)* reacts with 2,3,4,6-tetra-*O*-benzoyl-α-D-glucopyranosyl bromide *(2)* according to the "triflate method"[8] to give the fully protected β-glucosyl-Z-serine-2-bromoethyl ester *(3)*[9].



Bz = Benzoyl

Under these conditions the 2-bromoethyl ester is not attacked by $CF_3SO_3Ag$. The only feature which lowered the yield was the partial hydrolysis of the 1-bromo sugar *(2)*. In analogous reactions of the acetobromoglucose with *(1)*, according to either the classical Koenigs-Knorr method with $Ag_2CO_3$ or $Ag_2O$ or to the more recent variants *e.g.* with silver salicylate[10] or with mercury salts, we recorded low yields and several by-products, among which the corresponding ortho ester represented the main part. Position and splitting of the signal of the anomeric proton in the $^1$H-NMR spectrum and the $^{13}$C-NMR signal for C-1

($\delta = 101.2$)[11] afford proof of the β-configuration of the glucoside *(3)*. The C-terminal protection of the serine glucoside *(3)* is selectively removed by initially converting the 2-bromoethyl ester with sodium iodide in acetone (60 min, room temperature) into the iodoethyl ester *(4)*, which is then reductively fragmented with zinc (48 h, 40—50 °C) to yield *(5)*[9] in a one-pot procedure.

For the purpose of identification the iodoethyl ester may be isolated. In some experiments educt *(4)* is still found in the heterogeneous mixture after 48 h, irrespective of the quality of the zinc used. The N-terminal protecting group Z is not attacked, nor is the glucosidic bond cleaved; hence this process, which proceeds under neutral conditions, enables selective deblocking of the polyfunctional serine glucoside *(4)* to give the free carboxylic acid *(5)*. Coupling of *(5)* with alanine 2-bromoethyl ester using ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ) affords the glucodipeptide ester *(6)*.

The 2-haloethyl ester accordingly offers a possibility of directed lengthening of the C-terminal of glycopeptides; lengthening of the N-terminals is achieved *via* the selective cleavage of the 2-triphenylphosphonioethoxycarbonyl (Peoc) protecting group[12].

### *Procedure*

*(3)*: A solution of freshly prepared $AgCF_3SO_3$ (5.1 g, 0.02 mol) in anhydrous $CH_2Cl_2$ (10 mL) is treated dropwise at −30 °C under $N_2$ (exclusion of moisture!) with a solution of *(1)*[7] (6.85 g, 0.02 mol), *(2)*[13] (10.6 g, 0.016 mol) and tetramethylurea (2.3 g, 0.02 mol) in anhydrous $CH_2Cl_2$ (30 mL). The mixture is stirred for 2 h at −30 °C and 5 h at room temperature, filtered to remove the precipitated AgBr, and the filtrate is washed with 50 mL each of 0.05 N HCl, $H_2O$, 1% $NaHCO_3$ solution, and finally with water again. After drying over $Na_2SO_4$ and removal of the solvent by evaporation the residue is purified by preparative high-pressure liquid chromatography (petroleum ether/ethyl acetate, 2 : 1). Yield 7.8 g (53%) of the analytically pure amorphous solid *(3)*, $[\alpha]_D^{20} = +18.2$ ($c = 2.4$, $CHCl_3$).

*(4)*: A solution of *(3)* (0.5 g, 0.54 mmol) in anhydrous acetone (5 ml) is treated with NaI (0.3 g, 2 mmol) and the mixture stirred for *ca.* 1 h at room temperature. (The separation of NaBr is then complete.) Zinc powder (0.26 g, 4 mmol), freshly treated with HCl and dried, is then added to the mixture, which is stirred at 40—50 °C until no more *(3)* can be detected in the thin layer chromatogram (toluene/ethanol (9 : 1), silica gel 60) (*ca.* 48 h). After filtration and evaporation to dryness the residue is taken up in $CHCl_3$ (20 mL), filtered again, and the organic phase is washed with 10 mL each of 0.05 N HCl, 10% $Na_2S_2O_3$ solution and $H_2O$. After drying over $Na_2SO_4$ the solution is evaporated to dryness under reduced pressure and the residue is taken up in toluene/ethanol (9 : 1) and filtered through a short column of silica gel 60. The free acid *(4)* is eluted with ethanol. 0.24 g (54%) of *(4)* is obtained as analytically pure amorphous solid; $[\alpha]_D^{20} = +7.8°$ ($c = 2.37$, $CHCl_3$).

## Synthesis of Glycopeptides: Selective Amino-Deblocking of 2-Phosphonioethoxycarbonyl-Protected Asparagine *N*-Acetylglucosamine Moieties[**]

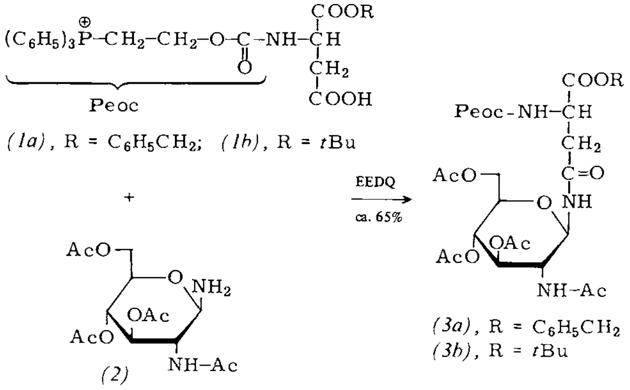
By *Horst Kunz* and *Hermann Kauth*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

Glycoproteins[1] have important biological functions. Unlike in peptide synthesis, in the synthesis of glycopeptides the functional groups of the carbohydrate moieties must also be taken into consideration. The reactions are rendered difficult by the glycosidic bond between the carbohydrate and the peptide moieties, since this bond is sensitive to acids, thus making the acid-cleavable protecting groups used in peptide synthesis unsuitable[2].

Therefore we have used the base-sensitive 2-triphenylphosphonioethoxycarbonyl(Peoc) protecting group[3] for amino-blocking of *N*-glycosidically bonded asparagine moieties. The *N*-glycosidic linkage is more stable than the *O*-glycosidic bond, both towards acids as well as bases[1,4]; thus these compounds are suitable for model experiments.

For preparation of the glycosylamines *(3a)* and *(3b)* *N*-Peoc aspartic acid α-benzyl- or *tert*-butyl-ester is allowed



*(1a)*, R = $C_6H_5CH_2$; *(1b)*, R = *t*Bu

*(2)*

*(3a)*, R = $C_6H_5CH_2$
*(3b)*, R = *t*Bu

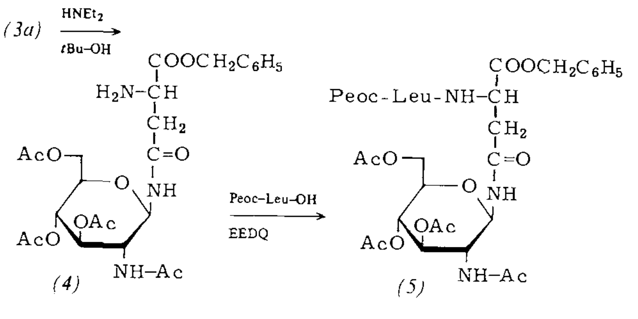
---

[*] Prof. Dr. H. Kunz, Dipl.-Chem. H. Kauth
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18—20, D-6500 Mainz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

to react with 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosylamine *(2)*[4a,6] in the presence of ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ)[5].

The structure of *(3a)* and *(3b)* is confirmed by IR and $^1$H-NMR spectroscopy. The selective cleavage of the Peoc-protecting group proceeds quite smoothly in a *ca.* 5% solution of diethylamine in *tert*-butyl alcohol.



After 30 minutes at room temperature, *(3a)* affords the crystalline deblocked benzyl 4-*N*-glycosylasparaginate *(4)* in 67% yield. Under these conditions the primary ester at C-6 of the glucosamine is not attacked.

In the case of glycosyl peptides the Peoc-protecting group has three advantages in comparison to the frequently employed benzyloxycarbonyl (Z)-moiety:

1) In the case of a Z-protected compound analogous to *(3a)*, the hydrogenolysis leads to unselective deblocking of the *N*- and *C*-terminals[7a].

2) During the basic cleavage of the benzyl ester in the presence of the Z-group the *O*-acetyl groups are removed[4a]. At the same time there is the likelihood of rearrangement in the asparagine moiety—as is also likely under acid conditions[7].

3) *N*-Glycoside coupling *via* Z-aspartic anhydride and hence separation of the desired 4-amide from the 1-amide of the aspartic acid formed in the same way can thus be avoided[8].

In the case of *(3a)*, not only selective cleavage of the Peoc-protecting group is possible but also hydrogenolytic deblocking of the C-terminal with intact ester groups on the carbohydrate moiety.

The peptide chain can be elongated on the free amino group of *(4)*; thus, with Peoc-leucine[3], *e.g.* in dichloromethane in the presence of EEDQ, the Peoc-glycodipeptide ester *(5)* can be synthesized in *ca.* 60% yield.

## *Experimental*

*(3a)*: To a solution of *(1a)*[3] (6.7 g, 12 mmol) in anhydrous $CHCl_3$ (80 ml) cooled to −10 to −5 °C are added first a solution of *(2)* (4.2 g, 12 mmol), likewise cooled to −10 to −5 °C, and then solid EEDQ (3.26 g, 13.2 mmol). The mixture is stirred overnight and allowed to warm to room temperature. The solution is then washed three times each with 50 ml 0.5 N HCl and with $H_2O$, and dried over $Na_2SO_4$; after removal of the solvent under reduced pressure, the crude product is chromatographed on 300 g of silanated silica gel, 70—230 mesh (Merck), with chloroform/methanol (25 : 1). Yield 7.2 g (65%), amorphous, decomp.: 100—110 °C.

*(4)*: A solution of *(3a)* (6 g, 6.5 mmol) in *tert*-butyl alcohol (150 ml) is treated with a 20% solution of diethylamine in *tert*-butyl alcohol and the mixture stirred for 30 min at room temperature. After removal of the solvent under reduced pressure the residue is taken up in 100 mL of $CH_2Cl_2$, washed three times with 50 ml of water and dried over $Na_2SO_4$. Renewed evaporation of the solvent and recrystallization from chloroform/ether affords 2.4 g (67%) of crystalline, analytically pure *(4)*, m.p. 149—150 °C (dec.).

# BOOK REVIEWS

**Analytiker Taschenbuch. Band 1.** (Analytical Pocketbook. Vol. 1). Edited *H. Kienitz, R. Bock, W. Fresenius, W. Huber* and *G. Tölg.* Springer-Verlag, Berlin 1980. vii, 439 pp., bound, DM 78.00.

If, as is planned, a volume of the "Analytiker Taschenbuch" actually appears every two years, the analytical community can truly congratulate itself, particularly if the high level of the publications can be maintained. The great novelty value lies in that apart from the subdivision into Fundamentals, Methods, and Applications there is no scheme of structure and treatment laid down beforehand and references are made to current needs. The editors have been able to secure the services of well-known and excellent authors and to achieve a high standard.

In the Fundamentals, the chapter on sampling, data processing, and evaluation methods must be specially singled out. The Methods section is particularly valuable because of the clear nomenclature in electrochemical processes, corresponding to the IUPAC rules, the exhaustive tables for gas chromatography, and—for the air-monitoring environmental analyst—a summary of the testing tubes available for monitoring working premises and for industrial gas analyses. Also noted with pleasure is the introduction to chiroptical methods and, particularly, the table of Cotton effects covering many examples.

It is likewise appropriate to mention the valuable hints on sources of error in measurements with ion-selective electrodes. Of modern physical methods of analysis, a very good chapter on X-ray spectral analysis in SEM has been included. The methodological part is completed by a contribution on surface analysis, which—with the exception of the now widely used ATR-FT-IR methods—gives an excellent review of this important field.

The third part, dealing with application techniques, begins with a relatively new but increasingly important field, enzymatic analysis, and shows how widespread the direct determination of various substances with comparatively specific enzymes in the presence of complex mixtures has already become. Since there is no doubt about the extreme importance of the determination of mycotoxins, and especially aflatoxins, the corresponding contribution, made more valuable by the schemes of analysis, is greatly welcomed. It will prove particularly valuable for the foodstuffs and feedstuffs researcher. The qualitative investigation of dyestuffs as such and on the fiber has undoubted practical importance.

Methods of detecting and determining environmentally relevant products and compounds are now in constant demand, and this has been taken into account. Thus, in addition to methods for the detection of narcotics and dopes, the determination of mercury compounds (including organomercury compounds) in water and the analysis of plutonium are given.

Summarizing, volume 1 of the pocketbook is indeed heterogeneous. It is also very informative and up to date, and the chemists and analysts not dealing directly with the individual subject fields now have at their disposal a very valuable guide.

**X-Ray Analysis and the Structure of Organic Molecules.** By *J. D. Dunitz.* Cornell University Press, Ithaca 1979, 528 pp., bound, £ 33.00.

*Dunitz*'s monograph is based on a series of lectures and is therefore very personal in style and presentation. For this reason alone, it is worth reading. This naturally also applies to its contents, which are organized in two large sections, crystal structure analysis (I) and molecular structures (II), relieved by historical observations on the development of X-ray structure analysis. Diffraction, symmetry, methods of structure determination, refinement processes, and above all treatment of the results are dealt with in Part I. The direct juxtaposition of theory and practise, instead of a chronological exposition, is particularly successful. The detailed examples thus make the material understandable even to readers with little mathematical training. Part II is not just a compilation of results, but begins with a unique reference to the aspects decisive for the chemist that can be demonstrated from the wealth of known molecular structures. The sections on structural analysis and chemistry, electron density in molecules, topological limitations in cyclic systems, and treatment of conformations with symmetry groups open up a fascinating field of molecular events far beyond that achievable by drawings of molecules and statements of distances.

The book may be recommended most heartily to anyone who would like to know how molecular structures are determined and what can be deduced from them apart from their topology. The author is evidently a great admirer of the method and its results. The reviewer would agree that "cooking" is not the only way to bring chemically relevant knowledge to light.

*Hans Georg von Schnering* [NB 549 IE]

## Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

**The Heterocyclic Chemistry of Phosphorus. Systems Based on the Phosphorus-Carbon Bond.** By *L. D. Quin.* John Wiley & Sons, Chichester 1981. xiii, 434 pp., bound £ 27.05.—ISBN 0-471-06461-0

**The Inorganic Chemistry of Biological Processes.** By *M. N. Hughes.* John Wiley & Sons, Chichester 1981. 2nd edit. ix, 338 pp., bound, £ 9.90.—ISBN 0-471-27815-7

# Hybrid Orbitals and Their Applications in Structural Chemistry

By Werner A. Bingel and Wolfgang Lüttke[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

A uniform, systematic, and complete review is given on s-p hybrid orbitals with which a central atom Z enters into $\sigma$ bonds with two to four ligands L. All possible cases of symmetry are treated: in four-coordination from $T_d$ symmetry in $ZL_4$ molecules to the asymmetric case of four different ligands; in three-coordination from $D_{3h}$ symmetry in $ZL_3$ molecules to $C_s$ symmetry for $ZLL'L''$ molecules. For some cases the formulas are given for the first time. In this connection it is shown that the most general $sp^3$ and $sp^2$ hybrids still contain three and two free parameters, respectively. The appearance of hybrid orbitals on changing from a *"delocalized"* to a *"localized"* description of the bonding situation is illustrated with examples. Finally, possible applications in the description of the bonding relationships of molecules and the interpretation of the results of spectroscopic methods for the determination of molecular structure are indicated and likewise illustrated by examples.

## 1. Introduction

The s-p hybrid orbitals with which a central atom Z binds two, three, or four *identical* ligand atoms L should be known to any chemist. Diagrams of their spatial arrangement, often together with formulas by which they are expressed through the s and the three p atomic orbitals (AO's) of the central atom Z, are nowadays given in many introductory textbooks of general, inorganic, and organic chemistry[1]. These are the well-known *special digonal* or sp, *trigonal* or $sp^2$, and *tetrahedral* or $sp^3$ hybrid AO's, introduced already in 1928 by *Pauling* to explain the directed valence in linear $ZL_2$, planar $ZL_3$, and tetrahedral $ZL_4$ molecules[2].

These orbitals are called *special* because the *valence* or *interorbital* angles[3] are all equal and have the special values of 180°, 120°, and 109.5°, respectively. Since at the same time the percentage s or p character is also fixed (see below), these special hybrids contain *no other free parameters* of any kind. They are also characterized by the fact that for reasons of symmetry their bond *and* valence angles[3] must coincide.

If, on the other hand, the central atom Z binds *different* ligands, L, L', L'', *etc.*, the bond angles will deviate from these special values to a greater or lesser extent, depending on the nature of the ligands in question. Consequently, *more general* hybrid orbitals are now needed, in which the parameters (valence angle and s or p character) are—within certain limits—still freely variable to be able to adapt them to the particular molecule.

Several of such hybrid orbitals for planar $ZL_2L'$ molecules such as $F_2C{=}O$ or pyramidal $ZL_3L'$ molecules such as $CH_3Cl$ can indeed be found scattered among the literature of the 'thirties to 'fifties[4-6,88].

What is still lacking is a *coherent* and *comprehensive* account, and this is the aim of the present review.

In the second section the formulas for arbitrary hybrids with s and p orbitals will be summarized, including the auxiliary conditions that the parameters appearing in the hybrid orbitals must satisfy. It will be shown that the *most general* $sp^3$ orbitals, which contain the maximum possible number of still *freely variable* parameters, have not been known before. They are therefore given for the first time in Sections 2.1—2.11; here also are given, for the sake of completeness, results for the *most general* sp and $sp^2$ hybrid orbitals, which are already well known. A review of all possible cases (with examples) is given in Table 1 (Section 2).

To clarify the concepts, it may be mentioned at this point that, for example, the designation $sp^2$ does not indicate, as is often incorrectly done, only the three special *trigonal* hybrid orbitals, but also those three general hybrid orbitals, for the construction of which a total of one s and two p AO's are used. The distribution of, for example, the s AO's over the three hybrid orbitals is *uniform* in the *special* case (with 33% each), but it is *nonuniform* in the *general* case[7].

The hybrid AO's of Z discussed here are necessary for the formation of localized Z—L σ-bonds with the ligands L. In addition, of course, π-bonds (localized or delocalized) between Z and its ligands can also be formed, provided that suitable orbitals and valence electrons are still available in both the central atom and its ligands.

In addition, one or more σ-bonds between Z and the ligands L can be replaced by lone or "free" electron pairs E on Z. Thus, the hybrid AO's of $ZL_2L'_2$ molecules can naturally also be used for the bonds in $ZL_2E_2$ molecules such as $H_2O$, those of $ZL_3L'$ molecules can similarly be used for $ZL_3E$ molecules such as $NH_3$, and so on.

The reader may well ask whether in present-day quantum chemistry hybrid orbitals are still of such importance that an article devoted to this rather special subject is justified. Hybrid orbitals play an important role as basis functions in molecular calculations by the "valence bond" or VB method[8-10]. However, in the MO methods used almost exclusively today they are not normally used as basis orbitals; the molecular orbitals or MO's so obtained are, rather, expressed in terms of unhybridized atomic orbitals or AO's of the atoms involved. These MO's are *delocalized, i.e.* they extend over the whole molecule, even in the case of *saturated* compounds. If, however, the results of such calculations are to be brought into harmony with the usual chemical ideas, the MO's must be *localized* by a suitable transformation[11-14] (see below). In this way, by analogy with the valence bonds of the chemist, we obtain localized two-center MO's which are now expressed in terms of hybrid AO's of the neighboring atomic centers, together with localized one-center hybrid orbitals for the "lone" or "free" electron pairs. This localization can in general be carried out just for *those* molecules whose bond situation is described by the chemist by means of a *single* valence-bond formula.

The fact that in such cases the localized and the delocalized descriptions are almost completely *equivalent* was recognized even in the early period of theoretical chemistry, but the reason *why* this is so does not appear to be generally known to this day. Consequently, an attempt will be made using simple examples to make this equivalence at least *plausible.* More far-reaching presentations of this problem can be found in the literature of theoretical chemistry[15,16].

### 1.1. Localization of Orbitals

As the first example, let us consider the nitrogen molecule N≡N; here the chemist expects to find the following *localized* orbitals: 1) For each of the two K shells one 1s AO for each of the two atoms; 2) two hybrid AO's for the two "free" electron pairs; 3) one σ and two π MO's which together describe the triple bond. This gives the following MO configuration (the exponent 2 shows the *double occupation* of each orbital):

$$(1s_a)^2(1s_b)^2(n_a)^2(n_b)^2\sigma^2\pi_x^2\pi_y^2 \tag{1}$$

On the other hand, an MO calculation gives a different, more *delocalized* description by so-called "canonical" MO's, which are *all* two-centered:

$$(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2\pi_x^2\pi_y^2(3\sigma_g)^2 \tag{2}$$

Nevertheless, all chemical properties of the $N_2$ molecule are described by (1) or (2) in a completely *equivalent manner.* For example, let us consider the contribution of the two lowest-energy orbitals to the *electron density.* In the delocalized description (2), the orbitals are given to a good approximation by the LCAO forms

$$\begin{aligned} 1\sigma_g &= (2)^{-1/2}\cdot(1s_a + 1s_b) \\ 1\sigma_u &= (2)^{-1/2}\cdot(1s_a - 1s_b) \end{aligned} \tag{3}$$

and their contribution to the electron density is twice the sum of the squares

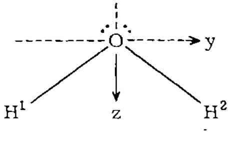
$$\Delta\rho = 2(1\sigma_g^2 + 1\sigma_u^2) \tag{4}$$

By substituting Eq. (3) in Eq. (4) and using the algebraic identity $(a+b)^2+(a-b)^2=2a^2+2b^2$, it is found that the contribution (4) is identical with

$$\Delta\rho = 2(1s_a^2 + 1s_b^2) \tag{5}$$

However, this is precisely the part of the charge density $\rho$ that the two K-shells of (1) contribute to $\rho$. It can also be shown for the remaining orbitals of Eqs. (1) and (2) that they can be converted into one another by a generalization of the transformation equations (3) in such a way that *their* contribution to the charge density is also the same for both pictures.

As a second example, consider the water molecule. The *localized* description corresponding to the valence-bond formula



(6)

is described by the MO configuration

$$(1s_0)^2(b_1)^2(b_2)^2(n_1)^2(n_2)^2 \tag{7}$$

in which $b_1$ and $b_2$ are the two-center orbitals of the two OH bonds and $n_1$ and $n_2$ are the one-center hybrid orbitals for the two lone electron pairs on the O atom.

An SCF-MO calculation, on the other hand, gives five doubly occupied MO's which belong to one of the four symmetry types of the symmetry group $C_{2v}$ of (6), which, instead of (7), leads to the MO configuration

$$(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2 \tag{8}$$

In a so-called "minimal" AO basis these canonical MO's have the LCAO forms

$$1a_1 \approx 1s_0 \tag{9a}$$
$$na_1 = \alpha_n \cdot 2s_0 + \beta_n \cdot 2p_z + \gamma_n \cdot (1s_1 + 1s_2) \qquad n = 2, 3 \tag{9b}$$
$$1b_2 = \delta \cdot 2p_y + \varepsilon(1s_1 - 1s_2) \tag{9c}$$
$$1b_1 = 2p_x \tag{9d}$$

The lowest-energy $1a_1$ MO is, according to (9a), to a good approximation identical with the 1s orbital of the oxygen atom, and the $1b_1$ MO is, for reasons of symmetry, *exactly* identical with the $2p_x$ AO of the O atom which is oriented perpendicularly to the plane of the molecule [cf. Eq. (6)]. According to Eqs. (9b, c), on the other hand, the remaining three MO's are *completely delocalized, i.e.* they extend over all three atoms. By means of a transformation generalizing Eq. (3), however, these three MO's together with the $1b_1$ "MO" of Eq. (9d) can be replaced by four *substantially localized* MO's, which are *almost* identical with the four "highest" MO's of the localized description (7). More accurately, one obtains in this way one of the OH bonding orbitals in the form

$$B_1 = (\alpha h_1 + \beta 1s_1) + \gamma 1s_2 \tag{10}$$

and an equivalent orbital for the other OH bond ($B_2$), which follows from Eq. (10) by the interchange $1 \leftrightarrow 2$, as well as two one-center hybrid AO's $N_1$ and $N_2$ for the two lone electron pairs. The limitation "almost" shows up in a comparison of $B_1$ and $b_1$: 1) The *hybrid* AO $h_1$ in Eq. (10) deviates somewhat from the direction of the $OH^1$ bond, *i.e.* the interorbital or valence angle is, in general, not identical with the bond angle $\sphericalangle H^1OH^2$ ("bent" bonds, see below), and 2) $B_1$ is not *completely* localized in the $OH^1$ bond; an—albeit smaller—*"localization defect"* exists, which is expressed by a value of the coefficient $\gamma$ for the "false" H orbital in Eq. (10) that is small but does not vanish.

If these, generally small, corrections are ignored, then in this example the localized and delocalized descriptions of the bond situation are again completely equivalent.

Passing from the special to the general, it can be said that this equivalence is valid for all states—not necessarily ground states—of molecules with an even number of electrons and closed shells, *i.e.* purely doubly-occupied MO's that can be described by a *single* valence-structural formula. If the double occupation of the delocalized MO's in such molecules is partially lost by ionization or excitation of an electron, a localized description is generally no longer possible for the states of the resulting molecular ion or excited molecule. An example of this is the ESCA spectrum of $H_2O$[17]. In the three states of $H_2O^+$ that arise through the ionization of an electron from one of the three delocalized MO's $2a_1$, $1b_2$, and $3a_1$ of (8), a transformation to localized MO's of $H_2O^+$ can no longer be performed. The reason can be illustrated more simply with the state of $N_2^+$ that corresponds to the 1s "peak" in the ESCA spectrum of $N_2$[17]. Here ionization takes place from one of the two lowest MO's of (2) which have very similar energies (separation $\approx 0.1$ eV). The resulting highly-excited $N_2^+$ is then in one of the states

$$(1\sigma_g)^1(1\sigma_u)^2 \cdots {}^2\Sigma_g^+ \tag{11}$$

or

$$(1\sigma_g)^2(1\sigma_u)^1 \cdots {}^2\Sigma_u^+ \tag{12}$$

with the following contributions to the electron density for (11) and (12), respectively:

$$\begin{aligned} \Delta\rho &= 2 \cdot 1\sigma_g^2 + 1 \cdot 1\sigma_u^2 \\ \Delta\rho &= 1 \cdot 1\sigma_g^2 + 2 \cdot 1\sigma_u^2 \end{aligned} \tag{13}$$

The same simple substitution that led from Eq. (4) to Eq. (5) for neutral $N_2$ now gives

$$\Delta\rho = 1s_a^2 + 1s_b^2 + 1\sigma_u^2 \quad \text{and} \quad 1s_a^2 + 1s_b^2 + 1\sigma_g^2 \tag{14}$$

*i.e.* two electrons are localized in the now *singly*-occupied K-shells, while in both cases the third occupies a delocalized two-center MO. This state of affairs can also be explained by valence bond formulas: the two states (11) and (12) of $N_2^+$ can no longer be described by a single valence structure. Rather, there are *two* structures (*A*) and (*B*) with only one electron in one of the two K-shells:

$$(A) \quad \overset{+}{N}\equiv N \qquad N\equiv\overset{+}{N} \quad (B)$$

The "resonance" or mesomerism between these two structures then leads to the VB wave functions $(A)+(B)$ and $(A)-(B)$, which correspond to (11) and (12), respectively.

This digression on the relationship between delocalized and localized descriptions of chemical bonds in molecules will also serve as an illustration of the above-mentioned necessary occurrence of hybrid orbitals on localization. Consequently, even in present-day quantum-chemical calculations hybrid AO's have a firm place because they allow their interpretation in a language with which the chemist is familiar.

In addition to this, hybrid AO's are used in the interpretation of the results of spectroscopic methods of *structure determination:* in NMR spectroscopy, the percentage s character of the hybrid orbitals of the bonds concerned is deduced from measured CH and CC coupling constants[18]; bond angles and the percentage ionic character of bonds are determined from measured nuclear quadrupole coupling constants using hybrid orbitals[19]. Hybrid orbitals are also involved in the discussion of bond lengths[20], force constants, and dipole moments[21], and of other molecular constants.

While it is true that the relationships between experimentally measured values and theoretical bond quantities that are used in these cases have often only an approximate validity, they are the only possible means of interpretation in all those cases—and they are the overwhelming majority—in which a direct quantum-mechanical *ab-initio* calculation of these measured values with sufficient accuracy is still impossible. These applications will be discussed in closer detail in Section 3.

### 1.2. Construction of s-p Hybrid Orbitals

The central atom Z makes available its s orbital and the three p orbitals of its valence shell. The three real and normalized p AO's

$$p_x = R(r)\frac{x}{r}, \quad p_y = R(r)\frac{y}{r}, \quad p_z = R(r)\frac{z}{r} \tag{15}$$

are transformed under rotations like unit vectors in the three axial directions. Consequently, the $p_i$ orbital, whose axis of symmetry coincides with an arbitrary *valence direction i* described by the unit vector $\boldsymbol{n}_i$, can be written as

$$p_i = \boldsymbol{p}\cdot\boldsymbol{n}_i = \frac{R(r)}{r}\,\boldsymbol{r}\cdot\boldsymbol{n}_i \qquad \boldsymbol{p} = (p_x, p_y, p_z) \tag{16}$$

*i.e.* as the scalar product of $\boldsymbol{n}_i$ with the "vector" $\boldsymbol{p}$. In Figure 1, this construction is illustrated for the special case of a p orbital lying in the xy plane.

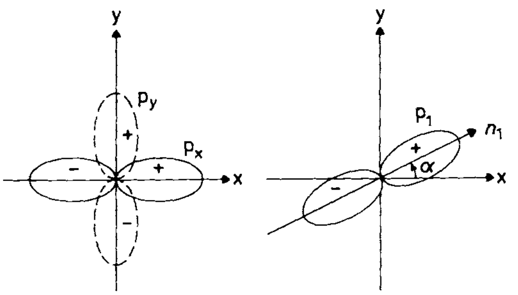


Fig. 1. p-Orbital in the xy plane with its valence direction $\boldsymbol{n}$ forming the angle $\alpha$ with the x axis. Here Eq. (16) has the special form $p = p_x\cos\alpha + p_y\sin\alpha$.

An s-p hybrid in direction $i$ is then of the form

$$h_i = (s + \lambda_i p_i)/\sqrt{1+\lambda_i^2} \tag{17}$$

with the *hybridization parameter* $\lambda_i \geqslant 0$[22], the s contribution $1/(1+\lambda_i^2)$, and the p contribution $\lambda_i^2/(1+\lambda_i^2)$[23]. The square root normalizes $h_i$ to 1. The smallest possible value $\lambda_i = 0$ gives the pure s orbital, and $\lambda_i = \infty$ gives the pure, *i.e.* unhybridized, p orbital. In this way, four hybrid AO's (17) with four different valence directions ($i = 1, 2, 3, 4$) can be formed from one s and three p AO's.

If the central atom Z is imagined to be at the center of a unit sphere, the tips of the four valence direction vectors $n_i$ whose origin is at Z lie on this sphere and form the corners of a spherical quadrilateral.

The angle between the valence directions $i$ and $j$ is the valence angle $\theta_{ij}$, which can be represented by a side or diagonal of this spherical quadrilateral (Fig. 2).

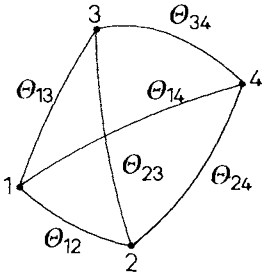

Fig. 2. The spherical quadrilateral formed by the four valence directions $i$ and the six valence, *i.e.* interorbital, angles $\theta_{ij}$.

Of the four hybrid AO's $h_i$ in (17) we must demand that they—just like the unhybridized s and p AO's—are *orthogonal* to one another, *i.e.* that the integral over the whole of space vanishes

$$\iiint h_i h_j \,dx\,dy\,dz = 0 \quad \text{for all} \quad i \neq j \tag{18}$$

Because of (17) and the normalization of the AO's it follows from this that

$$1 + \lambda_i\lambda_j \iiint p_i p_j \,dx\,dy\,dz = 0 \quad \text{for all} \quad i \neq j \tag{19}$$

The integral in Eq. (19) is equal to $\cos\theta_{ij}$, which follows from Eq. (16). In this way one obtains the *six* orthogonality relations (abbreviated to OR)

$$\cos\theta_{ij} = -1/\lambda_i\lambda_j \quad \text{for all} \quad i \neq j \tag{20}$$

Two further auxiliary conditions are obtained from the requirement that the sum of all the s contributions and the sum of all the p contributions in the four hybrid AO's must add up to 1 and 3, respectively [Eq. (21a, b)].

$$\sum_{i=1}^{4} \frac{1}{1+\lambda_i^2} = 1 \tag{21a}$$

$$\sum_{i=1}^{4} \frac{\lambda_i^2}{1+\lambda_i^2} = 3 \tag{21b}$$

A preliminary assessment might be made in the following way: There are six $\theta$ values and four $\lambda$ values, *i.e.* a total of ten parameters. But these parameters must satisfy the six OR's of Eq. (20) and the two conditions of Eqs. (21a and b). Thus, 10—6—2 or 2 independent parameters should remain.

This reasoning is erroneous in several respects: in the first place, even a *general* spherical quadrilateral (Fig. 2) is determined not by six but by only five parameters: the four sides and one diagonal in Figure 2 are sufficient to fix the second diagonal. In the second place, even in a molecule ZLL′L″L‴ with four different ligands there are not five but only three independent valence angles $\theta_{ij}$. The special form of the OR's of Eq. (20) means in fact that *van Vleck*'s identity[4]

$$\cos\theta_{12}\cos\theta_{34} = \cos\theta_{13}\cos\theta_{24} = \cos\theta_{14}\cos\theta_{23} = (\lambda_1\lambda_2\lambda_3\lambda_4)^{-1} \tag{22}$$

must be satisfied. This condition represents *two* additional constraints on the valence angles $\theta_{ij}$, which explains the above reduction from five to three.

On the other hand, there are likewise not $4-2=2$ independent values for $\lambda$ but again three of them. The two auxiliary conditions (21a, b) are in fact not independent of each other. When one holds, the other is automatically satisfied too, as may be easily verified.

If it is now possible to determine, on the one hand, from three mutually independent valence angles $\theta$ the remaining three angles and all values for $\lambda$ and, on the other hand, when three independent values for $\lambda$ are specified to determine the fourth and all six angles $\theta$, the *most general* $sp^3$ hybrid orbitals should contain *three independent* parameters in each case. The fact that this is actually so will be shown in Section 2.1.

In addition to the equations (20) to (22), the hybridization parameters $\lambda_i$ must also satisfy the following *inequalities*

$$\lambda_i \geq 0 \quad \text{for all} \quad i \tag{23}$$

$$\lambda_i \lambda_j \geq 1 \quad \text{for all pairs} \quad i,j \quad \text{with } i \neq j \tag{24}$$

Inequality (23) has already been introduced before as a convention[22]. Inequality (24) follows from Eq. (20), since the cosines of real angles $\theta$ can only assume values between $-1$ and $+1$. This limits the permissible values of $\lambda$ to certain intervals of the positive $\lambda$-axis. Finally, it follows from Eqs. (20) and (24) that $\cos\theta_{ij}$ must be negative and therefore the valence angle $\theta_{ij}$ must be $\geq 90°$.

Knowing the above relationships, we will now in the following sections derive the most general hybrids and their special cases.

All the possible cases so arising are summarized in Table 1.

Table 1. Summary of all possible cases of hybridization with the numbers of *independent* bond angles ($\alpha$), valence angles ($\alpha^{\text{val.}}$), and hybridization parameters ($\lambda$).

| Hybridization | Case [b] | Symmetry | Molecule | No. of independent values for $\alpha$ | $\alpha^{\text{val.}}$ | $\lambda$ | Examples |
|---|---|---|---|---|---|---|---|
| sp | 1 | $C_{\infty v}$ | LZL′ | 0 | 0 | 1 | OCS, $N_2O$, HCN |
| | 2 | $D_{\infty h}$ | LZL | 0 | 0 | 0 | OCO, $N_3^-$ |
| $sp^2$ | 3 | $C_s$ |  | 2 | 2 | 2 |  |
| | 4 | $C_{2v}$ |  | 1 | 1 | 1 | $H_2C$ $CH_2$, $H_2C$ ·O |
| | 5 | $D_{3h}$ |  | 0 | 0 | 0 | $CO_3^{2-}$, $BF_3$ |
| $sp^3$ | 6 | $C_1$ |  | 5 | 3 | 3 |  |
| | 7 [a] | $C_1$ |  | 4 | 3 | 3 | ? |
| | 8 | $C_s$ |  | 3 | 2 | 2 | $CH_2ClBr$ |
| | 9 | $C_{2v}$ |  | 2 | 1 | 1 | $CH_2Cl_2$ |
| | 10 | $C_{3v}$ |  | 1 | 1 | 1 | $CH_3Cl$ |
| | 11 | $T_d$ |  | 0 | 0 | 0 | $CH_4$, $NH_4^+$, $C(Me)_4$ |

[a] In this (hypothetical?) case the dihedral angle between the LZL‴ and the L′ZL″ planes is 90°. [b] The designations of the cases correspond to the appropriate paragraphs of Section 2.

## 2. Types of Hybrid Orbitals

### 2.1. The Most General Digonal sp Hybrid Orbitals of Symmetry $C_{\infty v}$

The form of two *general, i.e.* nonequivalent collinear hybrids has been known for a long time[2]. The hybrid orbital

$$h_1 = (s + \lambda_1 p_z)/\sqrt{1+\lambda_1^2} \tag{25a}$$

*i.e.* $p_1 = p_z$, is complemented by the so-called "ortho-hybrid" with $p_2 = -p_1$ and $\lambda_2 = 1/\lambda_1$ (only *one* free parameter)

$$h_2 = (\lambda_1 s - p_z)/\sqrt{1+\lambda_1^2} \tag{25b}$$

in such a way that the s and p contributions of the two each add up to 1. The two p AO's of the central atom Z that have not yet been involved, $h_3 = p_x$ and $h_4 = p_y$, are still available for the formation of π-bonds with the two ligands in linear LZL′ molecules such as, *e.g.*, OCS. It may be shown that because $\lambda_3=\lambda_4=\infty$ for the pure p AO's (see Section 1.2), the six OR's [Eq. (20)], the two auxiliary conditions (21a, b), and the inequalities (23) and (24) are all satisfied. Thus, with the linear arrangement present here the valence angles in Eqs. (20) and (22) are $\theta_{12}=180°$ and $\theta_{ij}=90°$ for all other pairs.

### 2.2. Special Digonal sp Hybrid Orbitals of Symmetry $D_{\infty h}$

With two *identical* ligands, as in the $CO_2$ molecule, the symmetry group rises to $D_{\infty h}$, and the two hybrid AO's (25a, b) must become *equivalent, i.e.* $\lambda_1=1/\lambda_1$ or $\lambda_1^2=1$, which, in view of Eq. (23), has the consequence $\lambda_1=+1$. In this way we obtain

$$\mathrm{di}_1=\frac{1}{\sqrt{2}}(s+p_z) \tag{26a}$$

$$\mathrm{di}_2=\frac{1}{\sqrt{2}}(s-p_z) \tag{26b}$$

### 2.3. The Most General $sp^2$ Hybrid Orbitals of Symmetry $C_s$

They occur in planar molecules with *three different* ligands (ZLL′L″). The three hybrid AO's in the x,y plane (Fig. 3a) are all of the form of Eq. (17); and in addition $h_4=p_z$, *i.e.* $\lambda_4=\infty$ (see Section 2.1). Consequently, the three OR's

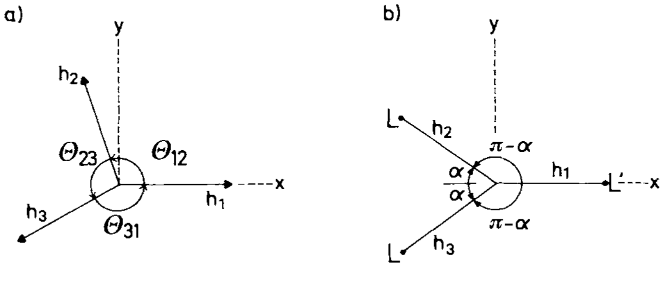

Fig. 3. a) The three most general planar $sp^2$ hybrids with $C_s$ symmetry. b) Special $sp^2$ hybrids for $L_2ZL'$ molecules with $C_{2v}$ symmetry.

$$\cos\theta_{i4}=0,\quad i=1,2,3$$

just like the *Van Vleck* identity [Eq. (22)], are satisfied automatically. Of the remaining three OR's

$$\cos\theta_{12}=-1/\lambda_1\lambda_2 \tag{27a}$$
$$\cos\theta_{23}=-1/\lambda_2\lambda_3 \tag{27b}$$
$$\cos\theta_{31}=-1/\lambda_3\lambda_1 \tag{27c}$$

only two are independent, since

$$\theta_{12}+\theta_{23}+\theta_{31}=360°.$$

Because $\lambda_4=\infty$, the conditions (21a, b) now take the form

$$\sum_{i=1}^{3}\frac{1}{1+\lambda_i^2}=1\qquad\sum_{i=1}^{3}\frac{\lambda_i^2}{1+\lambda_i^2}=2 \tag{28a, b}$$

We therefore have only *two* independent hybridization parameters, *e.g.* $\lambda_1$ and $\lambda_2$. If these are given initially, the three valence angles are determined from Eqs. (27a–c).

If, conversely, two independent valence angles $\theta$ are known, the three $\lambda$ values can be determined from the expressions[24]:

$$\lambda_1^2=-\cos\theta_{23}/\cos\theta_{12}\cos\theta_{13} \tag{29a}$$
$$\lambda_2^2=-\cos\theta_{31}/\cos\theta_{23}\cos\theta_{21} \tag{29b}$$
$$\lambda_3^2=-\cos\theta_{12}/\cos\theta_{31}\cos\theta_{32} \tag{29c}$$

which are obtained by solving Eqs. (27) for the individual $\lambda_i$ values. All three $\lambda$ values obtained in this way then satisfy the auxiliary conditions (28a, b). This proves the statement given in the introduction that the most general $sp^2$ hybrid AO's contain *two* free parameters.

An explicit expression for the most general hybrid orbital $h_1$ can also be derived from Eq. (29):

$$h_1=\left(s-\frac{\cos\theta_{23}}{N}p_1\right)\cdot(\mathrm{ctg}\,\theta_{12}\,\mathrm{ctg}\,\theta_{31})^{1/2} \tag{30a}$$

with the abbreviation

$$N=(-\cos\theta_{12}\cos\theta_{23}\cos\theta_{31})^{1/2} \tag{30b}$$

The expressions for $h_2$ and $h_3$ follow from Eqs. (30a, b) by a single or double cyclic permutation of the subscripts $1\rightarrow2\rightarrow3\rightarrow1$.

### 2.4. The $sp^2$ Hybrid Orbitals for $L_2ZL'$ Molecules with $C_{2v}$ Symmetry

This special case with *two equivalent* hybrid AO's for the two identical ligands is obtained from the formulas given in Section 2.3 with $\lambda_2=\lambda_3=\lambda$. It then follows from Eqs. (27a–c) that $\theta_{23}=2\alpha$ and $\theta_{12}=\theta_{31}=180°-\alpha$, *i.e.* that the two equivalent hybrid orbitals $h_2$ and $h_3$ form the same angle with the axis of symmetry (see Fig. 3b). In total, for these one-parameter hybrid AO's we have the explicit formulas[5]:

$$h_1=(\cos\alpha\cdot s+(-\cos2\alpha)^{1/2}p_1)/\sin\alpha \tag{31a}$$
$$h_i=((-\cos2\alpha)^{1/2}\cdot s+p_i)/\sqrt{2}\sin\alpha\qquad i=2,3 \tag{31b}$$

### 2.5. The Special Trigonal $sp^2$ Hybrid Orbitals with $D_{3h}$ Symmetry

These are obtained from Eqs. (31a, b) for $\alpha=60°$. They no longer contain free parameters. Their form is[2]:

$$\mathrm{tri}_i=\frac{1}{\sqrt{3}}(s+\sqrt{2}p_i)\qquad i=1,2,3 \tag{31c}$$

### 2.6. The Most General $sp^3$ Hybrid Orbitals of Symmetry $C_1$

Equations (20) to (22) of Section 1.2 apply to these orbitals. It was also shown in Section 1.2 that there are only *three* independent valence angles $\theta_{ij}$ or hybridization parameters $\lambda_i$. It still remains to be shown that when one of these two sets of parameters is given, all the remaining parameters can be determined unambiguously. In some cases, however, there may be more than one solution.

When the four $\lambda$ values, which must satisfy the one auxiliary condition (21a) and the inequalities (23, 24), are given beforehand, all six valence angles can be determined from the OR's of Eq. (20). The identity (22), which is a consequence of the special form of the OR's, is thereby automatically satisfied.

If, conversely, *three* valence angles, such as $\theta_{12}$, $\theta_{23}$, and $\theta_{31}$, are given, the values for $\lambda$ can be determined from the following generalized form of Eqs. (29a—c):

$$\lambda_i^2 = -\cos\theta_{jk}/\cos\theta_{ij}\cos\theta_{ik} \tag{32}$$

Here the triad of subscripts *i, j, k* is any combination of three numbers from the index set 1, 2, 3, 4. The remaining three valence angles $\theta_{i,4}$ with $i = 1, 2, 3$ are then obtained from the OR's according to Eq. (20).

*More special* $sp^3$ hybrids can easily be derived from Eqs. (20) to (22) and (32). This is done in Sections 2.7—2.11.

### 2.7. General $sp^3$ Hybrid Orbitals for "Perpendicular" ZLL′L″L‴ Molecules with $C_1$ Symmetry

This sub-case in which the two planes LZL‴ and L′ZL″ are perpendicular to each other is mentioned only for the sake of completeness. No examples are known to the authors, and therefore no formulas are given here. Formulas can be obtained—if necessary—from those of Section 2.6 when the two "digonal" valence angles $\theta_{14}$ and $\theta_{23}$ of Figure 2 intersect each other at 90°.

A *possible* realization would be given by the $L_2ZL'L''$ molecules of the next section if the two identical ligands L are not—as assumed there—mirror-images, but lie *unsymmetrically* with respect to the plane determined by L′, Z, L″. In spite of only three different types of ligands, such a central atom would then be *chiral*; with a symmetrical position of the two identical ligands it would be *prochiral*.

### 2.8. $sp^3$ Hybrid Orbitals for $L_2ZL'L''$ Molecules with $C_s$ Symmetry

Normally, the two identical ligands L will lie in *mirror-image relationship* with respect to the plane defined by L′, Z, and L″, *i.e.* they will assume *equivalent* positions in the molecule. The spherical quadrilateral of Figure 2 then assumes the special form of Figure 4a, from which it can be seen that $\theta_{12} = \theta_{13} = \theta$ and $\theta_{24} = \theta_{34} = \vartheta$. Of the six OR's of Eq. (20), there are two identical pairs:

$$\cos\theta = -1/\lambda_1\lambda_2 = -1/\lambda_1\lambda_3 \tag{33a}$$
$$\cos\vartheta = -1/\lambda_2\lambda_4 = -1/\lambda_3\lambda_4 \tag{33b}$$

*i.e.* $\lambda_2 = \lambda_3 = \lambda$.

Naturally, equivalent hybrid AO's must be assigned to the two identical ligands. The two free parameters are the two angles $\theta$ and $\vartheta$, from which the value of $\lambda_i$ can be determined according to Eq. (32) with Eq. (21a) satisfied. If, on the other hand, two of the $\lambda$'s are known the two angles are obtained from Eq. (21a) and Eqs. (33a, b).

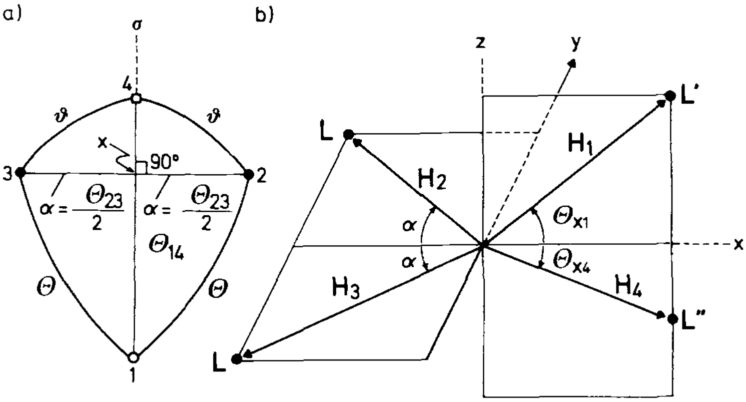

Fig. 4. $sp^3$ hybrids for $L_2ZL'L''$ molecules with $C_s$ symmetry. a) The valence angles in the spherical quadrilateral. The L, L′, and L″ ligands are located at corners 2 and 3, 1, and 4. b) Spatial orientation of valence directions *i* in an xyz coordinate system.

However, this route is unsuitable for a *calculation*, since in each case the two other angles $\theta_{14}$ and $\theta_{23}$ must also be determined by trigonometric transformations. Our aim is achieved faster if one starts from the explicit formulas (31a, b) for $L_2ZL'$ molecules. The $h_1$ hybrid of Eq. (31a) is then mixed unsymmetrically with the $p_z$ AO, which was not used there, *i.e.* the *new* hybrid orbitals

$$H_1 = \cos\beta \cdot h_1 + \sin\beta \cdot p_z$$

and

$$H_4 = \sin\beta \cdot h_1 - \cos\beta \cdot p_z$$

with the mixing parameter $\beta$ (which is *not* a valence or bond angle!) are introduced by analogy to Eqs. (25a, b). They are represented by capital letters to distinguish them from the $h_i$ of Eq. (31a, b).

Substitution of (31a) gives, after a short calculation, the following two *nonequivalent* hybrid orbitals:

$$H_1 = (\cos\beta \cdot s + \sqrt{tg^2\alpha - \cos^2\beta} \cdot p_1) \cdot ctg\,\alpha \tag{34a}$$
$$H_4 = (\sin\beta \cdot s + \sqrt{tg^2\alpha - \sin^2\beta} \cdot p_4) \cdot ctg\,\alpha \tag{34b}$$

The valence directions $\boldsymbol{n}_1$ and $\boldsymbol{n}_4$ of the two orbitals lie in the xz plane (see Fig. 4b), which is the mirror plane of the molecule, but they form *different* angles with the x-axis:

$$tg\,\theta_{x1} = tg\beta \frac{\sin\alpha}{(-\cos 2\alpha)^{1/2}} \tag{35a}$$

$$tg\,\theta_{x4} = -ctg\beta \frac{\sin\alpha}{(-\cos 2\alpha)^{1/2}} \tag{35b}$$

The two *equivalent* hybrid orbitals are taken over unchanged from Eq. (31b) and are now denoted by capital letters in order to have agreement with (34a, b):

$$H_i = ((-\cos 2\alpha)^{1/2} \cdot s + p_i)/\sqrt{2}\sin\alpha \qquad i = 2, 3 \tag{34c, d}$$

Their valence directions $\boldsymbol{n}_2$ and $\boldsymbol{n}_3$ lie in the xy plane in mirror-image relationship to the $\sigma_{xz}$ mirror plane (see Fig. 4b).

In Appendix II of a paper from 1951[6], *Torkington* stated that, "there is no set of four $sp^3$ hybrid orbitals with $C_s$ symmetry". The fact that this statement and the proof given for it are incorrect is shown by Eqs. (34), which explicitly give just such a set. This set also contains—as stated—two parameters, namely the bond angle $LZL=\theta_{23}=2\alpha$ and the mixing parameter $\beta$ (which can be limited to the range 0 to 45°).

For the valence angle $\theta_{14}$ of Figure 4b we obtain from Eqs. (35a, b):

$$\mathrm{tg}\,\theta_{14}=-2\,\mathrm{tg}\,\alpha\sqrt{\mathrm{tg}^2\alpha-1}/\sin 2\beta \tag{36}$$

The following special cases for particular values of the mixing parameter $\beta$ are of interest, and also provide an opportunity to check the correctness of the formulas derived:

1) $\beta=0$, *i.e.* no mixing of $h_1$ and $p_z$, restores the original $sp^2$ hybrid orbitals (31) and the $p_z$ orbital:

$$H_1\rightarrow h_1,\ H_4\rightarrow p_z,\ H_2=h_2 \text{ and } H_3=h_3$$

2) $\beta=45°$; here $H_1$ and $H_4$ are *equivalent* and according to Eqs. (35a, b) make the same angle with the x-axis. One thus obtains the hybrid orbitals of Eq. (39) for $L_2ZL'_2$ molecules.

## 2.9. $sp^3$ Hybrid Orbitals for $L_2ZL'_2$ Molecules with $C_{2v}$ Symmetry

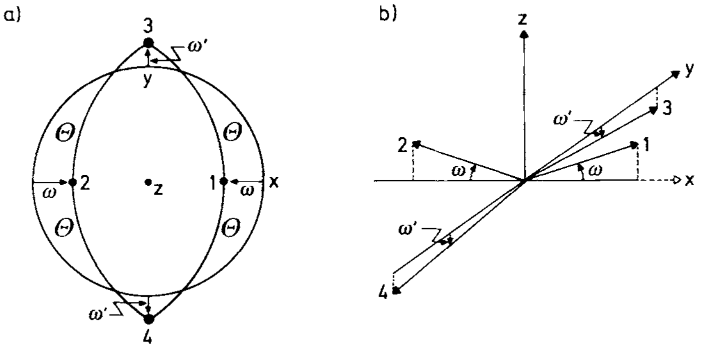

Fig. 5. $sp^3$ Hybrids for $L_2ZL'_2$ molecules with $C_{2v}$ symmetry. a) Representation of the spherical quadrilateral; $\theta_{12}=180°-2\omega$, $\theta_{34}=180°-2\omega'$. b) Spatial representation (*van Vleck*'s $\omega$-model [4]).

Here *two* pairs of two equivalent hybrid AO's each are required. Consequently, we put $\lambda_1=\lambda_2=\lambda$ and $\lambda_3=\lambda_4=\mu$ and obtain from Eq. (21a) the relations:

$$\mu=\left(\frac{\lambda^2+3}{\lambda^2-1}\right)^{1/2} \quad\text{and}\quad \lambda=\left(\frac{\mu^2+3}{\mu^2-1}\right)^{1/2} \tag{37}$$

Of the six OR's only three are left, one for each of the two ZL and ZL′ bonds (see Fig. 5a, b)

$$\cos 2\omega=1/\lambda^2 \tag{38a}$$
$$\cos 2\omega'=1/\mu^2 \tag{38b}$$

and one *between* the two groups, *i.e.* for $\sphericalangle LZL'=\theta$

$$\cos\theta=-1/\lambda\mu \tag{38c}$$

A fairly long calculation gives the final formulas[5]

$$h_i=\begin{cases}((\cos 2\omega)^{1/2}\cdot s+p_i)/\sqrt{2}\cos\omega & i=1,2 \quad (39a)\\ ((\cos 2\omega')^{1/2}\cdot s+p_i)/\sqrt{2}\cos\omega' & i=3,4 \quad (39b)\end{cases}$$

and also the angular relationship derivable from Eqs. (37) and (38)

$$\cos\theta=-\sin\omega\cdot\sin\omega'=-(\cos 2\omega\cos 2\omega')^{1/2} \tag{40}$$

from which it also follows that

$$\mathrm{tg}^2\omega+\mathrm{tg}^2\omega'=1 \tag{41}$$

Again, everything is determined by *one* angle, such as $\omega$. One should note that according to Eq. (41) $|\omega|$ and $|\omega'|$ must be less than 45°, which again shows that valence angles <90° cannot be constructed from hybrids of s and p AO's (see Section 1.2), which is already well known.

The angles $\omega$ and $\omega'$ are defined—differently from *van Vleck*[4]—in such a way that they are *both* positive. In Figure 5b, therefore, *one* hybrid pair must point in the direction of the negative z axis[25].

If the hybrid orbital $h_1$ of Eq. (31a) is mixed *symmetrically* with the $p_z$ AO, the two new orbitals $(h_1+p_z)/\sqrt{2}$ and $(h_1-p_z)/\sqrt{2}$, together with $h_2$ and $h_3$ of Eq. (31b), must give the same result (39a, b) as the above derivation.

If we put $\lambda=\mu$, Eq. (37) gives the common value $\sqrt{3}$, and we obtain the special case described in Section 2.11 of the tetrahedral $sp^3$ hybrid AO's with no free parameters ($\mathrm{tg}\,\omega=\mathrm{tg}\,\omega'=1/\sqrt{2}$).

## 2.10. $sp^3$ Hybrid Orbitals for $L_3ZL'$ Molecules with $C_{3v}$ Symmetry

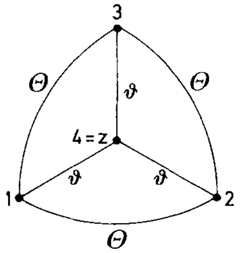

Fig. 6. $sp^3$ Hybrids for $L_3ZL'$ molecules with $C_{3v}$ symmetry. Here $2\cos\theta=3\cos^2\vartheta-1$.

This case requires three equivalent hybrid orbitals. If, therefore, we put $\lambda_1=\lambda_2=\lambda_3=\lambda$ and $\lambda_4=\mu$, Eq. (21a) gives

$$\mu=\left(\frac{3}{\lambda^2-2}\right)^{1/2} \quad\text{and}\quad \lambda=\left(\frac{3+2\mu^2}{\mu^2}\right)^{1/2} \tag{42}$$

Of the OR's [Eq. (20)], two sets of three are identical; with $\theta_{12}=\theta_{23}=\theta_{31}=\theta$ and $\theta_{i4}=\vartheta$ for $i=1, 2, 3$, we obtain

$$\cos\theta=-1/\lambda^2 \tag{43a}$$
$$\cos\vartheta=-1/\lambda\mu \tag{43b}$$

and also from (42) and (43a, b) the relation

$$2\cos\theta=3\cos^2\vartheta-1 \tag{44}$$

which can be read off from the spherical triangle 1, 2, 4 of Figure 6. After a short calculation, we obtain[4]

$$h_i = \left[(1-2\,\mathrm{ctg}^2\vartheta)^{1/2}\cdot s + \frac{\sqrt{2}}{\sin\vartheta}\cdot p_i\right]/\sqrt{3} \qquad i=1,2,3 \tag{45a}$$

$$h_4 = [-\sqrt{2}\,\mathrm{ctg}\,\vartheta\cdot s + (1-2\,\mathrm{ctg}^2\vartheta)^{1/2}\cdot p_4] \tag{45b}$$

Therefore all quantities are expressed in terms of the *one* valence angle $\vartheta$, the other is obtained from Eq. (44). If, conversely, one of the two hybridization parameters $\lambda$ or $\mu$ is given, the other is obtained from Eq. (42) and the two angles from (43a, b)[25]. If now we put $\lambda=\mu=\sqrt{3}$, the above equations specialize to the tetrahedral $sp^3$ hybrid orbitals (see Section 2.11), since according to Eq. (43) we have $\cos\theta=\cos\vartheta=-1/2$.

### 2.11. The Special Tetrahedral $sp^3$ Hybrid Orbitals for $ZL_4$ Molecules of Symmetry $T_d$

These may be obtained by the specialization given at the end of Section 2.10. They have the well-known form:

$$h_i = \frac{1}{2}(1+\sqrt{3}\,p_i) \qquad i=1,2,3,4 \tag{46}$$

where the p orbitals of the central atom point toward the vertices of a tetrahedron.

## 3. Applications: Examples and Possibilities

Since the structural properties of a molecule are determined by its electron distribution, and since the constituent atoms approximately retain their individuality in the molecular association ("atoms in molecules"[26]), each atom Z contributes to the overall structure of the molecule according to the hybridization of its electron arrangement. All structural quantities (particularly geometry, energetics, charge distribution and, consequently, also reactivity) should therefore be capable of being described by the nature of the hybrid orbitals involved in the bonds[10,16,27].

### 3.1. Molecular Geometry

Covalent molecules are characterized by a definite geometric structure which manifests itself in the appearance of directed bonds and definite interatomic distances. The reason for this is that in each case a minimum energy is associated with a certain spatial arrangement of the nuclei and the electrons.

To the extent that the *stereochemistry* of a molecule is given by its *bond angles*, it is described by the relationships between the s or p character of the hybrid orbitals and the valence angles as summarized in Section 1.2. As is well known, according to these relations the angles of the bonds issuing from an atom Z become larger, if the s character of its hybrid orbitals increases. According to recent theoretical investigations[27,28], for sterically unstrained compounds the bond angles are very close to the valence angles or are practically equal to them.

In molecules with ring strain, however, according to both calculation and experiment, the directions of the hybrid orbital axes differ substantially from those of the lines linking the atoms ("bent bonds"[29]); thus in cyclopropane and its derivatives, for example, angular deviations of about 22° have been calculated[27,29-32], or measured in X-ray studies[33-36] of the so-called *deformation densities* of the electrons. It is thus obvious to try to relate the magnitudes of these angular deviations to the ring strain energy.

The occurrence of definite CC and CH *bond lengths* in organic compounds, especially hydrocarbons (but different for different substance classes), was ascribed first by *Coulson*[37] and then with particular emphasis by *Dewar* and *Schmeising*[38] to the fact that the C atom has a so-called *covalent radius* $R_c$ which depends on its status of hybridization: $R_c$ is the smaller, the greater is the s character of the C orbital involved in the bonding. A rule of thumb is that the length decreases by about 0.04 Å in each case on passing from $sp^3$-$sp^3$ to $sp^2$-$sp^2$, and finally, to sp-sp bonding; if the CC $\sigma$-bonds are also accompanied by one or two $\pi$-bonds, an additional contraction takes place, which in conjugated compounds occurs to a weaker degree even in normal single bonds.

According to *Coulson*[37], the following expression describes the dependence of the covalent radius $R_c$ of an atom on the hybridization parameter $\lambda$:

$$R_c\,[\text{Å}] = \mathit{Const.}\cdot\frac{1+(4/3)\sqrt{3}\cdot\lambda+(3/2)\cdot\lambda^2}{1+\sqrt{3}\cdot\lambda+\lambda^2} \tag{47}$$

This relation applies only to the CC bonds of unstrained compounds; it does not give the unusually short bonds of strained compounds with their anomalous hybridization (*e.g.* those of cyclopropane or bicyclobutane); consequently, *Maksić* and *Eckert-Maksić*[39] proposed a different type of equation for the latter case, which approximates the distance along the "bent bonds" by a parabola. Other relations for $R_c=f(\lambda)$ have been given by *Brown*[40], *Somayajulu*[41], *Zeil et al.*[20a,42], *Bak et al.*[20b,43,44], *Mikhailov*[45], *Dewar* and *Schmeising*[38], *Bastiansen* and *Traetteberg*[46], and others. For further information reference may be made to the symposium report "An Epistologue on Carbon Bonds"[47].

### 3.2. Bond Energy

The fact that not only the molecular geometry but also the *energies* of the individual bonds depend on the character of the hybrid orbitals of the atoms involved in the bonding was shown by *Förster*[8] as early as 1939, for strained and unstrained hydrocarbons. *Förster* recognized as the cause of the different bond energies the different electron densities, after hybridization, between the bound atoms: stronger and less stretchable CC and CH bonds should correspond to a higher percentage s character. This can be explained as a consequence of the principle of maximum overlap of hybrid orbitals (cf. [16,48]). What is particularly convincing is *Förster*'s analysis of the observation that the energies of CH bonds, and therefore their CH force constants and vibrational frequencies[49,50], are also determined by the hybrid nature of the orbitals of the C atoms involved in bonding.

### 3.3. Bond Polarity

Another fundamental property of chemical bonds is their *polarity*[16,51,52]. The polarity is substantially determined by the *electronegativities* of the atoms involved. As was shown by *Walsh*[53] in 1948 and has been demonstrated experimentally by *Zeil*[20a], the electronegativity that an atom exhibits in a bond is the higher, the greater is the s character of its hybrid orbital involved in the bond. According to *Hinze* and *Jaffé et al.*[54,55], the electronegativity of a C orbital increases linearly with its s character. To this principle—recently confirmed by quantum-chemical analysis[56]—corresponds the fact that when a polar substituent is added to a carbon atom, the latter's hybrid orbitals become polarized in such a way that the p character of the C orbital directed toward this substituent increases. According to Eq. (21a), the p character of the other hybrid orbitals of this C atom must then decrease correspondingly, *i.e.* their s character must increase. Because of this, not only the polarities but also the corresponding bond angles and lengths undergo a change. Using a large volume of data, *Domenicano, Vaciago,* and *Coulson*[57,58] have confirmed this convincingly for variously substituted benzene derivatives.

### 3.4. NMR Coupling Constants

Hybridization also substantially affects the characteristic quantities of *nuclear magnetic resonance spectra.* Thus, the $^1$H- and $^{13}$C-NMR signals of organic compounds are concentrated on the basis of their chemical shifts in characteristic regions determined by the hybridization of the C atom. This applies analogously to the HH, CH, and CC coupling constants and is due to the fact that the spin-spin coupling is brought about to a substantial extent by the s contribution of the bonding electrons at the position of the nucleus. Correspondingly, according to Eq. (48) $^1J_{CH}$ is proportional to the s character of the hybrid orbital of the C atom involved in the CH bond[59,60], and according to Eq. (49) $^1J_{CC}$ is proportional to the product of the s characters of the hybrid orbitals of the C atoms involved in the CC bond[28,61-63]. A theoretical substantiation of these relationships has been given by *Pople et al.*[18,64-66].

$$^1J_{CH} = \frac{500}{1+\lambda^2} \quad [\mathrm{Hz}] \qquad (48)$$

$$^1J_{C\text{-}1,C\text{-}2} = A\,\frac{1}{1+\lambda_1^2}\cdot\frac{1}{1+\lambda_2^2} - B \quad [\mathrm{Hz}] \qquad (49)$$

Other structural properties connected with hybridization cannot be considered here; reference may be made to reviews[67,68].

Up to this point it has been shown how structural properties can be explained by the particular hybridization involved. Now the inverse aim must be considered, namely a quantitative characterization of the electron distribution with the aid of experimentally determined structural quantities. To this end explicit relationships between chemical structure and $\lambda$'s (or s characters) are necessary, permitting numerical values relating to, for instance, the s character of all the hybrid orbitals of a central atom Z or the discrepancy between bond and valence angles to be obtained from experimental results.

Corresponding quantitative relations such as Eq. (47)—partly of an empirical nature and partly substantiated by theory—have long been known for many important and readily measured structural quantities, although not for all. Information on the corresponding values of $\lambda$ is obtained from bond lengths with the aid of formulas such as (47), and from bond angles by the formulas of Section 2. Here it is best to use the CCH, HCH, or $CH_3$ bond angles, because even in strained compounds, *inter alia,* these differ only slightly from the corresponding valence angles which are related to the hybrid character.

The widest range of variation of the results when the accuracy of measurement is good is found in the NMR coupling constants $^1J_{CH}$[59,60] and $^1J_{CC}$[18,63]; of these, the CH coupling constants are preferred as hybridization indicators, since they are determined almost solely by the *Fermi* contact term, which depends on the C hybridization[59,66], while all three possible coupling mechanisms act on $^1J_{CC}$[69-72].

Thus, $^1$H-NMR measurements on molecules with natural $^{13}$C abundance give coupling constants $^1J_{CH}$ proportional to the s contribution $1/(1+\lambda^2)$ of the sp hybrid orbital of the C atom for the localized CH bond[59,60,66], in astonishingly good agreement with the empirical relation (48). In this way *experimental values of* $\lambda$ are obtained from which by means of the formulas summarized here experimental valence angles $\alpha^{\mathrm{val}}$ are obtained, which can then be compared with the bond angles $\alpha$ obtained from other experiments.

Similarly—within the above-mentioned limitations—conclusions about the product of the s character of the two hybrid AO's involved in the CC bond can be drawn from measured CC coupling constants of directly linked C atoms[61-63,70].

Hybrid-orbital data that are obtained experimentally in such a fashion can be used to test theories of chemical bonding and the associated methods of calculation if they are compared with the corresponding data obtained by quantum-chemical calculations (for example, by the Maximum Overlap process[72], by the INDO method[14], or by an *ab-initio* method with subsequent localization[27]).

In the search for relationships between structure and hybridization, small-ring hydrocarbons and, among them, the bi-, tri-, and tetra-cycles have always evoked the interest of theoreticians[27], spectroscopists, and preparative chemists[73-81], since they provide the opportunity to change hybridization within wide limits, even up to "abnormal" values, by varying the ring size. Substitution by polar groups can serve as another "structure variable"; according to *Walsh*[53,56], their effects on $\sigma$-bonds can also be explained by changes in hybridization.

The requirement that all molecular structural quantities are determined by the electron distribution and thus by the hybrid nature of localized orbitals can finally also help to clarify empirical correlations between experimental quantities and theory, some of which have been known for a long time, and thus make them more applicable.

The empirical rules of *molecular spectroscopy* of diatomic molecules, also applicable to the corresponding groups of polyatomic molecules, have been comprehensively discussed by *Müller* and *Bräuer*[82]. For CH bonds, *McKean*[83] has worked out various correlations valuable for structure determinations between vibrational frequencies, bond lengths, dissociation energies, and coupling constants. The relationship recently found by *Kamienska-Trela*[84] between CC force constants and the CC coupling constants $^1J_{CC}$ deserves particular attention.

### 3.5. Bond Angles and Valence Angles

So far as concerns the *bond angles* and their relationship to the *valence angles*, the cases summarized in Table 1 can be divided into three groups:

1) In the first group there are the special hybrids of cases 2, 5, and 11. As mentioned in the introduction, they no longer contain free parameters. Furthermore, for reasons of symmetry their bond angles $\alpha$ must coincide with their valence angles $\alpha^{val}$ and take the special values 180°, 120°, and 109.5°[85]. Only in these cases can we be sure that the bonds are not strained.

In all other cases there is at first no convincing reason for an exact equality of these two angles. As already mentioned, one must reckon here with greater or smaller deviations $\delta\alpha = \alpha - \alpha^{val}$, which correspond to "bent" bonds[29].

Such deviations *must* naturally always occur when bond angles $\leq 90°$ appear in the equilibrium geometry of a molecule, as for example in the small-ring hydrocarbons $(CH_2)_3$ and $(CH_2)_4$.

Deviations—even if small ones—are to be expected also in molecules with highly *polar* bonds such as $CH_2Cl_2$ and $CH_2Br_2$ (Nos. 3 and 1 in Table 2). Steric hindrance will also lead to deviations of this type. If, however, none of these reasons exists, a substantial equality of the bond and valence angles is to be expected, as in example No. 8 of Table 2, propane.

2) The second group includes cases 3, 4, and 10 with two or one free parameter and the *same* number of independent bond and valence angles. Consequently, the formulas given here at first provide no help in determining whether a certain molecule of this group has "strained" bonds. Rather, to begin with, values for $\alpha^{val}$ must be obtained by a different route. This can be done theoretically by subjecting quantum-chemical MO calculations optimized for the energetically most favorable configuration of the particular molecule to a localization process[12-15] (see Section 1). The hybrid AO's of the atoms concerned can then be read off from the resulting localized bond orbitals and the orbitals of lone electron pairs. However, this procedure is applicable only to a limited extent, since—particularly for molecules with low symmetry—it does not always provide *unambiguous* results[86]. For larger molecules of chemical interest sufficiently accurate MO calculations are still not yet available in many cases.

3) Finally, the third group includes cases 6—9 with one to a maximum of three free parameters, in which the number of *independent* bond angles is *larger* than the number of independent valence angles. Here again, of course, the methods described for the second group can be used. In addition to this, however, it is also possible in this case to deduce the presence of strained bonds from the experimentally determined bond angles *alone*. Consider as an example the $L_2ZL'_2$ molecules given in Table 2.

Table 2. Bond angles and their deviations from the valence angles for some $L_2ZL'_2$ molecules.

| No. | Molecule $L_2ZL'_2$ | No. according to [a] | $\sphericalangle LZL = \alpha$ | $\sphericalangle L'ZL' = \beta$ | $\delta\beta'$ [b] |
|---|---|---|---|---|---|
| 1 | $H_2CBr_2$ | 68 | 113.6 | 112.7 | 6.9 |
| 2 | $(NH)_2S(CH_3)_2$ | 316 | 135.0 | 101.2 | 5.8 |
| 3 | $H_2CCl_2$ | 70 | 113.0 | 111.8 | 5.5 |
| 4 | $H_2C(SiH_3)_2$ | 140 | 108.1 | 114.4 | 3.5 |
| 4 | $(SiH_3)_2CH_2$ | 140 | 114.4 | 108.1 | 2.9 |
| 5 | $H_2CF_2$ | 74 | 113.7 | 108.3 | 2.6 |
| 5 | $F_2CH_2$ | 74 | 108.3 | 113.7 | 3.0 |
| 6 | $O_2S(CH_3)_2$ | 299 | 121.0 | 103.3 | 2.3 |
| 7 | $Cl_2Si(NCO)_2$ | 152 | 107.7 | 113.0 | 1.7 |
| 7 | $(NCO)_2SiCl_2$ | 152 | 113.0 | 107.7 | 1.4 |
| 8 | $H_2C(CH_3)_2$ | 428 | 106.1 | 112.8 | −0.4 |
| 8 | $(CH_3)_2CH_2$ | 428 | 112.8 | 106.1 | −0.7 |
| 9 | $H_2Ge(CH_3)_2$ | 314 | 108.5 | 110.0 | −0.5 |
| 9 | $(CH_3)_2GeH_2$ | 314 | 110.0 | 108.5 | −0.5 |
| 10 | $(CN)_2CH_2$ | 350 | 109.4 | 108.7 | −0.8 |
| 10 | $H_2C(CN)_2$ | 350 | 108.7 | 109.4 | −0.9 |

[a] The experimental bond angles in the fourth and fifth colums have been taken from *K. H. Hellwege, A. M. Hellwege: Landolt-Börnstein,* Neue Serie Vol. 7. Springer-Verlag, Berlin 1976. [b] Calculated deviations of the angles (see text) arranged in order of decreasing values.

In case 9 of Table 1 (cf. Section 2.9) the two *bond angles* $\alpha$ and $\beta$ are independent of each other. On the other hand, there is only one independent *valence angle*, since $\alpha^{val} = 180° - 2\omega$ and $\beta^{val} = 180° - 2\omega'$ (cf. Fig. 5) are linked through the following relation which follows from Eq. (41):

$$\operatorname{ctg}^2\frac{\alpha^{val}}{2} + \operatorname{ctg}^2\frac{\beta^{val}}{2} = 1 \qquad (50)$$

This relationship is shown graphically in Figure 7.

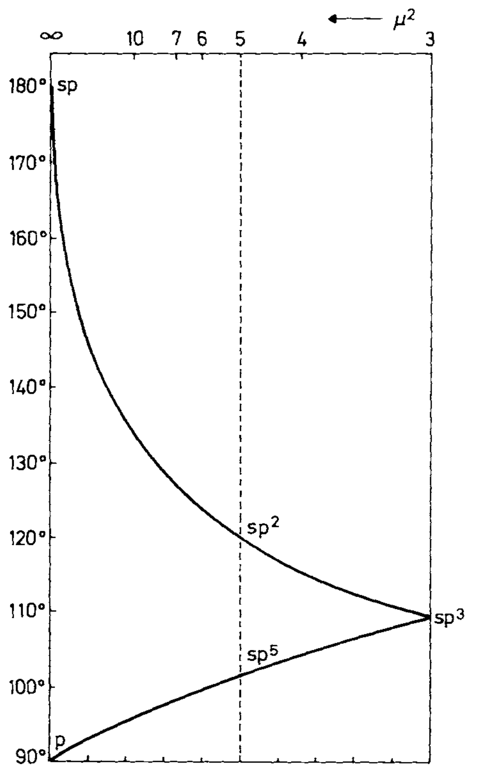

Fig. 7. The two valence angles $\alpha^{val} = \theta_{12}$ and $\beta^{val} = \theta_{34}$ of Figure 5 as functions of $\lambda^2$ ($=\lambda_1^2 = \lambda_2^2$) and $\mu^2$ ($=\lambda_3^2 = \lambda_4^2$).

It can be seen that—starting from the common value $\alpha^{\mathrm{val}}=\beta^{\mathrm{val}}=109.5^\circ$ (right-hand side of Fig. 7)—an increase in one angle automatically results in a decrease in the other. Therefore in examples 1 and 3 of Table 2, in which *both* bond angles are larger than the tetrahedral angle of 109.5°, the existence of "strained" bonds can be deduced directly from the experimental values of the bond angles without any quantum-chemical calculations of the valence angles[87]. In the other examples of the table it is possible to tell whether unstrained bonds are present by using the corresponding bond angles $\alpha$ and $\beta$ collected in Table 2 in connection with Figure 7. The bonds are unstrained only if the two points $\alpha$ and $\beta$ of the two branches of the curve lie vertically one above the other, *i.e.* belong to the *same* value of the lower abscissa $\lambda^2$. This, together with the value of the upper abscissa $\mu^2$, then gives the s contribution for the ZL and ZL′ bonds.

If this construction is impossible, deviations in at least one—and probably both—bond angles $\delta\alpha$ and $\delta\beta$ must occur. The *sum* of the deviations can be obtained in the following manner:

$\alpha^{\mathrm{val}}$ is first put equal to $\alpha$ from the fourth column of Table 2 (*i.e.* one puts $\delta\alpha=0$) and the corresponding value of $\beta^{\mathrm{val}}$ is calculated from Eq. (50). The difference between the latter and the bond angle $\beta$ from column five then gives the value shown in the sixth column $\delta\beta'=\beta-\beta^{\mathrm{val}}$. By splitting this value equally between the two angles one obtains approximate angular deviation values $\delta\alpha=\delta\beta=\delta\beta'/2$. If it is desired to avoid the unsymmetry associated with this procedure, the above simple calculation can be repeated with $\alpha$ and $\beta$ interchanged (which has been done for Nos. 4, 5, and 7—10) and averaging the two results.

The results in Table 2 confirm, in general, the statements made above relating to the reasons for "strained" bonds. As expected, propane (No. 8) and the analogous Ge compound (No. 9) have the smallest $\delta\beta$ values. But even with these compounds, which are usually regarded as certainly unstrained, small deviations lying outside the limits of error of the bond angle can be found.

### 3.6. Conclusion

In conclusion, it may be said that in the interpretation of his results by means of hybrid AO's the experimentalist must take into account the possibility illustrated here of bonds that are strained to at least some extent, even in cases in which he perhaps does not expect them to be so.

On the whole, the use of localized hybrid orbitals has proved useful on the one hand by giving the formalism of quantum chemistry an embodiment corresponding to the way of thinking of experimental chemists and on the other hand by opening up a theoretically based and at the same time descriptive correlation of experimental magnitudes of structural chemistry.

*We thank Dr. B. Klahn (Göttingen) for his most valuable help with the numerical calculations and literature search and Professor M. Klessinger (Münster) for critical perusal of the manuscript. Thanks are also due to the Fonds der Chemischen Industrie for continued support of our work.*

# Anodic and Cathodic CC-Bond Formation

## By Hans J. Schäfer[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

Electrolysis allows the reactivity of a substrate to be changed, or its polarity to be reversed ("*redox umpolung*"). The carbon skeleton and the functional groups of a synthetic building block can thus be utilized more economically, and at the same time the number of reaction steps in multistage syntheses can be reduced. The tools necessary for an electrolytic process are a cell, a power source, electrodes, and an electrolyte, the latter being chosen in accordance with the reduction or oxidation potential of the substrate. A series of electroanalytical methods provides information on the electrode reaction mechanisms. At the *anode,* arenes, phenolic ethers, and electron-rich olefins dimerize *via* intermediate radical cations. In the Kolbe electrolysis, carboxylic acid anions decarboxylate to form radicals which can couple to form *e.g.* long chain alkene derivatives having pheromone activity, or add to olefins. At the *cathode,* activated olefins hydrodimerize *via* radical anions or, in the presence of appropriate reagents, can be acylated, alkylated, and carboxylated. Pinacols, crossed hydrodimers, and cyclic and arylated compounds are accessible *via* the cathodically produced radicals, while the formation of strained small rings or the reductive addition of halides to carbonyl compounds takes place through intermediate carbanions.

## 1. Introduction

In the course of electrolysis a substrate is subjected to the removal *(anodic oxidation)* or addition *(cathodic reduction)* of electrons. The reactive intermediates formed anodically can be radical cations, radicals, and carbenium ions, while those formed cathodically can be radical anions, radicals, and carbanions. The transfer of electrons changes the reactivity, or leads to an *umpolung*[1] of the substrate. The carbon skeleton and the functional groups of a given synthesis unit can thus be utilized in several different ways—as a nucleophile, a radical, or an electrophile. Bond formation between reactants of the same polarity, usually

*Angew. Chem. Int. Ed. Engl. 20, 911-934 (1981)* *0570-0833/81/1111-0911 $ 02.50/0*

possible only after several steps, can be brought about electrochemically in a single step by a preceeding *"redox umpolung"*. Thus, in the hydrodimerization of acrylonitrile[2], a one-step coupling of the two electrophiles is achieved by reducing one reactant to a Michael donor[3]. The nucleophilic styrene dimerizes, after the oxidation of one olefin molecule, to the radical cation[4].

An electrode has *advantages* over chemical redox reagents. Compounds with several electroactive groups *(electrophores)*, whose half-wave potentials differ by 200 mV, can be converted selectively due to the continuously adjustable voltage of the working electrode[5], whereas the restricted number of chemical redox reagents permits this only to a limited extent. Solubility and work-up problems, frequently encountered with inorganic redox reagents are diminished, and the appearance of ecologically objectionable end-products can be avoided. Finally, electrolysis is cheaper, since it does not require the often expensive chemical electron-transfer agents (*e.g.* $OsO_4$, Li, or $Pb(OAc)_4$), but transfers the electrons directly.

The *disadvantages* are the often longer reaction times and, because of the required conductivity, the necessity of using polar solvents; both of these factors promote undesirable competing side reactions. The frequent and troublesome problem of electrode coverage *(passivation)* can often be overcome by changing the electrolyte or the electrode material, or by pulsing the voltage[6].

The present review is restricted to preparative CC-bond formation at the anode and cathode. Functional group interconversion will be dealt with in a later review. Electroanalytical methods are described only when they refer to syntheses; studies of electrode mechanisms and the reactivities of electrolytically produced radicals and radical ions have been largely omitted.

Up to the beginning of the seventies there were only a few textbooks[7-10] dealing with organic electrochemistry. The classic representative of them is *Fichter*'s book[8], which even today is a treasure-house for many interesting reactions. Several monographs then appeared within a few years[11-20], of which those by *Baizer*[16], *Beck*[17], and *Weinberg*[18] are the most comprehensive. There are also shorter[21-29] or more exhaustive[30-34] reviews, annual surveys[35,36], and a bibliography of the field[36a]. Besides these, more specialized articles have been published dealing with the electrochemistry of functional groups[37-49], with biologically active compounds[50], with electroorganic syntheses of natural products[51,52], with anodic[53-55] and cathodic[56-63] reactions, and also with electrode mechanisms and the properties of radical ions[64-70].

The present review will be limited essentially to electrosyntheses published since 1973.

## 2. Procedure

### 2.1. The Requirements for Electrolysis

Let us begin with the *electrode*. This must be mechanically stable and chemically inert, and have the least possible tendency toward passivation. Many materials can be used as cathodes[71-73]: the platinum metals (low hydrogen overvoltages), copper, silver, iron, aluminum, and titanium (medium hydrogen overvoltages), and mercury, lead, cadmium, tin, lead- and cadmium-amalgams, and graphite (high hydrogen overvoltages). In contrast, the selection of materials for anodes is much smaller[71,74,75]: platinum is used in sheet form or as a foil on steel, carbon, or titanium; gold is usable only to a limited extent; graphite is employed as synthetic carbon, glassy carbon[76], graphite felt, or carbon paste electrodes[77]. Lead dioxide[78-80] on graphite or titanium, and ruthenium-dioxide-activated titanium anodes[81-84] can also be used, though no organic electrosyntheses with the latter have so far been described.

Electrodes with chemically modified surfaces have so far mainly been investigated electroanalytically[85,86] for their suitability as electrocatalysts, sensitizers in photoelectrochemistry, or as electrosensors. Stable derivatives of platinum are produced by the adsorption of surface-active compounds[87], by coating with electro-active polymers[88], or through the reaction of chemically activated hydroxy-, carboxy-, or oxo-groups at oxidized platinum, graphite, ruthenium dioxide, or stannic oxide electrodes with cyanuryl chloride[86], chlorosilanes[89,90], amino acids[91-94], amines[95], carboxylic acids[95], or cyclodextrins[96]. Their applications in organic electrosyntheses are still minor. 2-Acetylpyridine and phenylglyoxylic acid have been reduced with 10% asymmetric induction at a graphite electrode chirally modified with phenylalanine[91-93], but other authors have been unable to reproduce these results[94]. At a surface-oxidized graphite cathode the carbinol : pinacol ratio in the reduction of acetophenone is reversed[94]. The anodic chlorination of anisole at a cyclodextrin-modified anode leads, like the corresponding chemical chlorination[97], preferentially to *p*-chloroanisole[96]. The advantages of the electrochemical method consist in a small consumption of cyclodextrin and an easier separation of the product.

The *electrolyte*, consisting of a solvent and a conducting salt (supporting electrolyte), should have a high conductivity, be a good solvent for the substrate, should be easily separable, and should moreover exhibit a high anodic or cathodic decomposition potential. Essential data and methods of purifying electrolytes are summarized in [98-102]. The decomposition potentials of some electrolytes are shown in Table 1.

Table 1. Decomposition potentials of selected electrolytes [103].

| Electrolyte (Solvent/conducting salt) | Decomposition potential in Volts [a] cathodic | anode |
|---|---|---|
| Methanol/$Bu_4NClO_4$ | −2.2 (Hg) | +1.3 (Pt),<br>+1.9 (Glass-C) |
| Acetonitrile/$Bu_4NClO_4$ | −2.6 (Pt) | +2.7 (Pt) |
| *N,N*-Dimethylformamide/$Et_4NClO_4$ | −2.8 (Hg) | +1.9 (Pt) [104] |
| Dichloromethane/$Bu_4NClO_4$ | −2.3 (Pt) | +2.45 (Pt) [105] |
| Tetrahydrofuran/$Bu_4NClO_4$ | −3.75 (Pt) | +1.75 (Pt) [106] |
| Pyridine | −2.2 (Hg) | +3.3 (Pt) [104] |
| Nitromethane/$LiClO_4$ | −2.8 (Pt) | +2.7 (Pt) [107] |

[a] Relative to the saturated calomel electrode (SCE). In the chamber working electrode. Glass-C signifies glassy carbon.

An electrolyte consisting of dichloromethane/trifluoroacetic acid/$Bu_4NBF_4$[108], and amounts of trifluoroacetic anhydride and alumina[108, 109], have proved satisfactory for investigations of radical cations; a salt melt of aluminum chloride and *n*-butylpyridinium chloride at +40°C has also been used in the formation of radical cations[110]. For oxidations at high anodic potentials, trifluoromethanesulfonic acid[111], ethylene carbonate[112], sulfolane[113], and sulfur dioxide[114], with high anodic decomposition potentials, are also available in addition to dichloromethane/trifluoroacetic acid. Even the nonpolar solvents chlorobenzene and benzene can be used in cyclic voltammetry, although only at microelectrodes; they are characterized by a wide potential range and stability to radical ions[115]. Liquid ammonia is suitable for the production of radical anions[116]; ethylenediamine can also be used as a solvent for reductions[117]. The electrolyte consisting of dimethylformamide and $Bu_4NBF_4$ can be purified so well by a recycling apparatus with an alumina column that even aromatic dianions remain stable[118].

Optical activity can be induced by using chiral electrolytes. This is best done by the addition of catalytic amounts of surface-active chiral compounds[119-122], an optical yield of almost 50% being achievable in the case of strychnine. With chiral supporting electrolytes[123, 124], in spite of numerous variations in the structure of the supporting electrolyte, the pH, the potential, and the temperature, the inductions are below 15% in protic electrolytes, though somewhat higher in aprotic media[125]. In the case of reduction in chiral solvents, activities of only up to 6% are induced[126].

The potential of the working electrode is kept constant relative to a *reference electrode* with the aid of a potentiostat[127]. Various reference electrodes have been described for protic and aprotic solvents[101, 128-130].

To prevent unwanted reactions of the educt and product at the counterelectrode, particularly in reductions, the cathode and anode compartments are separated by a clay, porous glass, unglazed porcelain, Teflon, or polyethylene *diaphragm*, or by an ion-exchange membrane[131-134].

Cells with and without diaphragms have been developed for a wide variety of applications[135-139]; cells have been described for voltammetry and coulometry, for working under pressure or under high vacuum[140], with rotating[141a], vibrating[141b], continually scraped[141c], or three-dimensional electrodes[142], together with cells for low-temperature voltammetry[143], or for a combination of electrochemical methods with ESR[144] or UV spectroscopy[145]. The capillary gap cell, an undivided cell with a small electrode distance, avoids high cell resistances and permits good space-time yields. It is used in the form of a stacked cell[146] or a concentric version[147-149] for hydrodimerizations, acetoxylations, Kolbe electrolyses, or for the preparation of propylene oxide. An interesting new development is the "Swiss roll" cell consisting of rolled-up metal gauzes and an insulating plastic fabric[150]. Various divided cells have been described by *Horner et al.*[151], *Cauquis et al.*[152], *Bard et al.*[153a], and others[153b].

For a preliminary laboratory experiment the following setup, which can be set up quickly and inexpensively, suffices in most cases: a beaker is fitted with a clay cylindrical diaphragm and with electrodes made of suitable material, and the potential at the working electrode is measured with a pH-meter against an Ag/AgCl electrode (a chlorinated silver wire in saturated KCl solution) and adjusted through a rectifier with a variable transformer.

### 2.2. What are the Requirements for a Successful Electrolysis?

The first information needed is the approximate oxidation or reduction potential of the substrate; some potential ranges are given in Figure 1.

The potentials of many classes of substances have been summarized in the literature[11, 18] and also specifically for

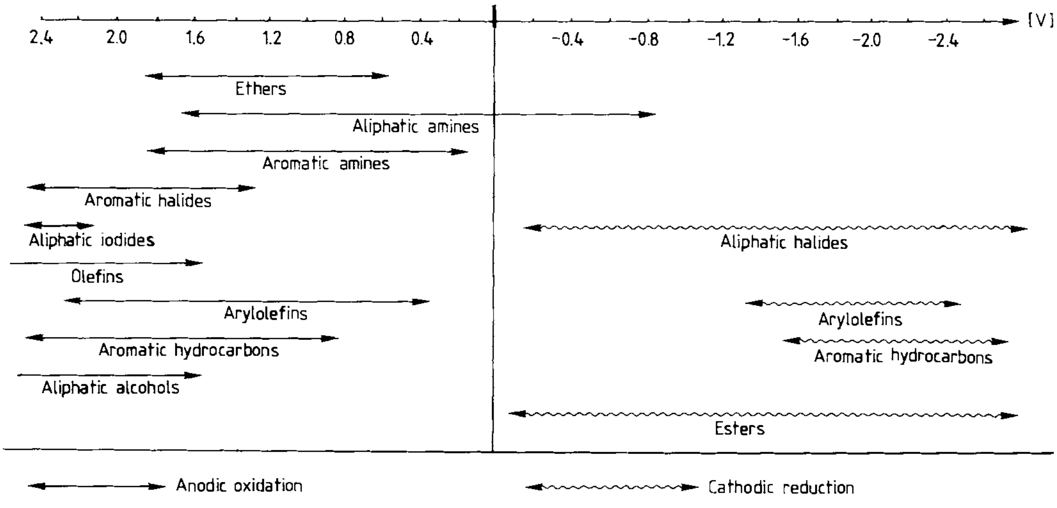

Fig. 1. Potential ranges for the oxidation and reduction of some electrophores (against SCE, after [18]).

alkanes[154], alkenes[155], arenes[156], amines[157], phenolic ethers, and phenols[158]. The anodic oxidation potentials and photoelectronic ionization potentials correlate in a remarkably linear manner in many cases, *e.g.* for dienes[159], arylalkenes[4], cyclopropanes[160], and other substrates[161], since both are determined by the energy of the highest occupied molecular orbital (HOMO).

The *electrolyte* is selected on the basis of the known reduction or oxidation potential. Its decomposition potential should, in oxidations, be *ca.* 200 mV more anodic, and in reductions more cathodic than the half-wave potential of the substrate; in addition, the electrolyte must be a good conductor, must dissolve the substrate well, and be readily separable from the product by distillation.

The *electrode material* must show minimum passivation, resist corrosion, and have a high overvoltage for decomposition of the electrolyte.

### 2.3. What Information can be Obtained about the Reaction Mechanism?

The electroanalytical methods available for elucidating reaction pathways have been summarized in several monographs[162-172] and reviews[173-176]. The first indication of the mechanism is given by the number of electrons transferred. This is determined by comparing the limiting current from cyclic voltammetry ($i_L$) or at a rotating disk electrode with those of standard compounds (*e.g.* ferrocene) or, more accurately but also more laboriously, by coulometry at a controlled potential[177]. Whether the reaction in the limiting current region is diffusion-controlled is shown polarographically from the relation $i_L \approx \sqrt{h}$[178] (where $h$ is the height of the Hg level above the capillary opening), voltammetrically from the relation $i_L \approx \sqrt{v}$[179] (where $v$ is the scan rate in V/s), or at the rotating disk electrode from the relation $i_L \approx \sqrt{\omega}$[180] (where $\omega$ is the angular velocity of the disk). The reactants which are involved in the rate-determining electrochemical step are shown by the electrochemical order of the reaction $\nu$[181].

Information on the lifetime of the electrochemically produced intermediate stages is supplied by cyclic voltammetry[182] from the ratio of the anodic and cathodic peak currents ($i_{p,a}$ and $i_{p,c}$, respectively). Thus, $i_{p,c}/i_{p,a} = 1$ indicates that an oxidatively produced intermediate product is long-lived[183]. A difference of 59 mV between the anodic and cathodic peak potentials ($E_{p,a}$ and $E_{p,c}$, respectively) shows that the electron transfer takes place rapidly[184]. The chemical reaction rate $k$ of the intermediate $B^{+\cdot}$ with a nucleophile $Nu^-$

$$A \xrightarrow{-e} B^{+\cdot} \xrightarrow[k]{Nu^-} \dot{B}\text{—}Nu$$

can be determined from the change in the anodic peak current $i_{p,a}$ at different scan rates[185a]. By analog differentiation of the cyclovoltammetric current/voltage curves, the peak potentials can be determined accurately even for very rapid scan rates[185b]. Conclusions concerning the reaction mechanism can be drawn from their kinetic displacement[185c], so that by this method even very fast follow-up reactions can be analyzed. Cyclic voltammetry can also be performed at low temperatures (−80 °C)[143], and has thus been used for conformational analysis studies[186]. At the rotating disk electrode[174, 187] or the rotating ring-disk electrode[188] the kinetics of the reactive intermediates can be determined from the dependence of the limiting current[189] or the collection efficiency $i_R/i_D$[190] (R = ring, D = disk) on the rate of rotation. Spectro-electrochemical methods afford additional information about the structure of the intermediates. The following spectroscopic methods have been used so far: absorption spectroscopy (UV-VIS-NIR)[191], ESR[192], IR[193], resonance Raman[194], NMR[195], and mass spectroscopy[196].

It has been possible to determine the redox potentials of short-lived free radicals by a combination of pulsed radiolysis with polarography[197]. The adsorption of organic compounds on the electrode can be determined by means of electrocapillary curves[198a], capacity measurements[198b], isotopic labeling[199], the change in the roughness of the electrode (polaromicrotribometry)[200a], and other techniques[200b].

## 3. Preparative Applications: CC-Coupling Reactions at the Anode

It appears advantageous to arrange the methods for CC bond formation, not according to the type of educt or product but rather according to the reactive intermediates. This makes the broad scope of the reaction and new possibilities of application more obvious, though a disadvantage is that this arrangement is not free from some arbitrariness, since the mechanisms of many electrosyntheses are not accurately known.

### 3.1. Radical Cations as Intermediates

Alkylarenes[201] yield biphenyl and/or diphenylmethane derivatives, depending on their substitution pattern (Table 2). The cation radical *(1)* first formed reacts either with the educt to give the biphenyl *(2)* (route *a*) or is deprotonated to the benzyl radical (route *b*), which, after oxidation, reacts with the educt to give a diphenylmethane *(3)*.

A low charge density on an unsubstituted C atom of *(1)* favors route *a*, whereas a low charge density on a substituted C atom favors route *b*. The intermediate radical cations become increasingly more stable when the positive charge density is uniformly distributed (as in perylene) or the reactive sites are blocked, as in *e.g.* 9,10-diphenylanthracene and rubrene[202].

Unsymmetric biphenyl derivatives can be obtained in moderate to good yields by the coelectrolysis of naphthalene with mesitylene (13%) or with tetra- (42%) or pentamethylbenzene (56%)[203]. Correspondingly, unsymmetric diphenylmethanes can be obtained in yields of 5—81% by the electrolysis of hexamethylbenzene in the presence of benzene, toluene, *p*-xylene, or mesitylene[204]. [2.2]-*m*-Cyclophanes can be coupled intramolecularly to give pyrene derivatives[205]. The oxidation of phenols has been compre-

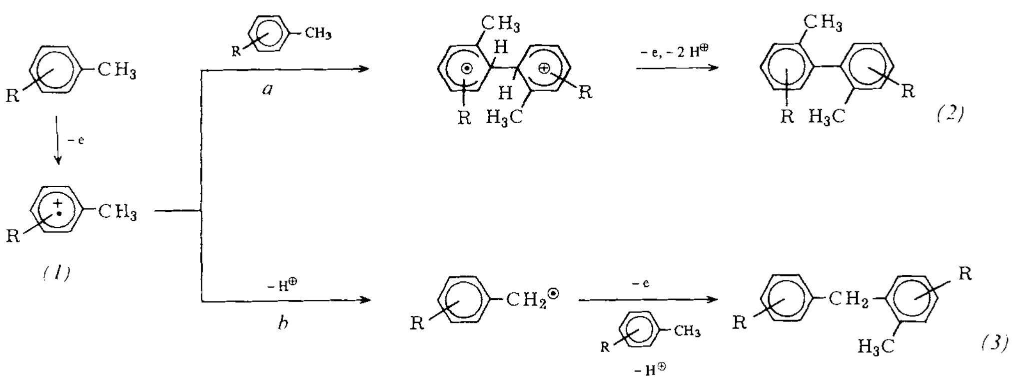

Table 2. Anodic coupling of alkylarenes *via* radical cations *(1)* [201].

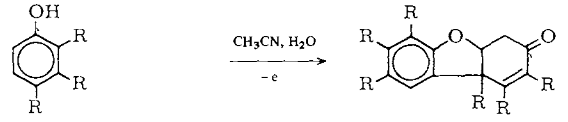
| Alkylarene | *(2)* : *(3)* | *(2)*+*(3)*, Yield [%] |
|---|---|---|
| 1,4-Dimethylbenzene | 1 : 99 | 10 |
| 1,2,4-Trimethylbenzene | 46 : 54 | 38 |
| 1,3,5-Trimethylbenzene | 100 : 0 | 63 |
| 1,2,4,5-Tetramethylbenzene | 0 : 100 | 32 |

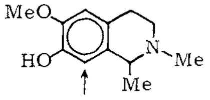
hensively reported[40,206]; they dimerize[*] *via* neutral radicals, cation radicals, and cations. In basic electrolytes, phenoxides give rise to phenoxy radicals; these react to form CC- and CO-dimers, which are easily oxidized further, leading to less useful product mixtures[207]. Blocking the 2-, 6-, or 4-position makes the couplings more selective. Thus, the phenol *(4)* dimerizes in good yield to the enone *(5)*[208].

2,4,6-Tri-*tert*-butyl phenoxide can be oxidized reversibly to the phenoxy radical (aryl-O·) at −0.2 V, while at the higher potential of +1.0 V the phenoxylium ion (aryl-$O^+$) is formed irreversibly[209]. Phenolic benzylisoquinolines couple inter- and intramolecularly with CC and C—O bond formation[207,210], and under these circumstances *(6)* only forms one diastereomer as a coupling product[211]. It has thus been deduced that *(6)* is adsorbed on the anode *via* the benzene ring and the nitrogen, and that the transition state is sterically most favorable when two configurationally identical radical cations couple.



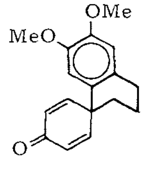
*(4)*, R = H, $CH_3$, $C_2H_5$ *(5)*

In neutral or acidic media, phenoxylium ions are formed from phenols that react intermolecularly *via* CC-coupling with anisole to give anisylcyclohexadienone[212] or intramolecularly in 1,3-diarylpropanes to give the spirodienone *(7)*[213]. The phenoxylium ion *(8)* can be detected cyclovoltammetrically starting from phenol or the phenoxy radical, or be prepared from the quinol by the action of acid[214]. In the oxidation of the phenol *(9)*, the intermediate phenoxylium ion *sym*-proportionates to phenoxyl radicals, which couple in 95% yield to give the quinhydrone *(10)*[215].

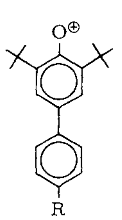


*(6)*

Unblocked phenols give good yields of dimers only after they are etherified[216]. A mixture of dichloromethane/trifluoroacetic acid (2 : 1) has proved to be a satisfactory electrolyte for these oxidations, since it protects the product against oxidative degradation[217]. Moreover, the addition of alumina and of trifluoroacetic anhydride has proved to be advantageous[108,109]. Methoxybiphenyls can be coupled intramolecularly in low yield in acetonitrile but in almost quantitative yield in 4 : 1 dichloromethane/trifluoroacetic acid[218,219]. 1,n-Bis(3,4-dimethoxyphenyl)alkanes *(11)* cyclize almost quantitatively when n = 1—4, but when n = 6—10 only in moderate yields, and then intermolecularly[219,220].

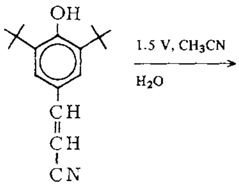


*(7)*, 73%

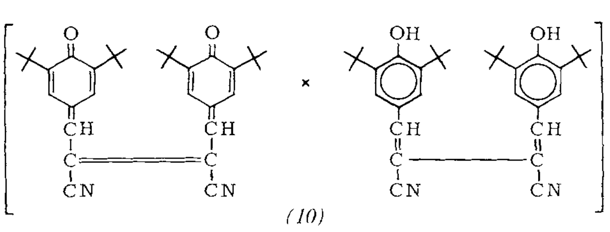


*(8)*, R = $OCH_3$, $N(CH_3)_2$

The cyclic voltammograms of unsymmetrically methoxylated diphenylalkanes exhibit two oxidation potentials, at



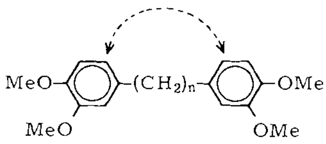
*(9)*



*(10)*

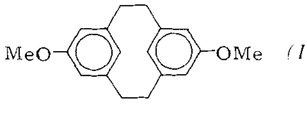
---

[*] The term "dimerize" here only refers to the molecular skeleton.



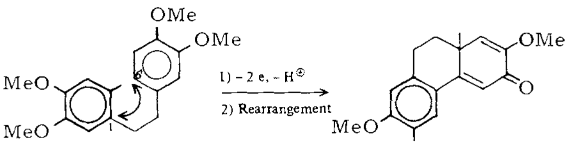
(11)

which either intramolecularly—or intermolecularly—formed products arise, permitting some conclusions to be drawn about the dimerization mechanism[221]. In the case of the [2.2]-*m*-cyclophane *(12)*, two anisyl radical cations couple in 90% yield to give the tetrahydropyrene derivative[222].



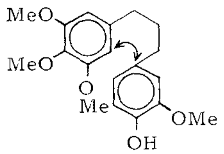
(12)

The tetramethoxybibenzyl derivative *(13)* cyclizes in an anodic 1,6′-coupling reaction, with a subsequent dienone/phenol rearrangement, to give an 88—98% yield of the dihydrophenanthrone *(14)*, which contains the essential structural elements of the B, C, and D rings of steroids[223].

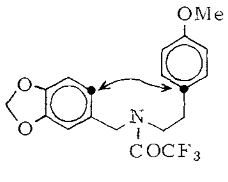


(13) (14)

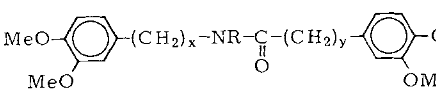
With the corresponding dimethoxybibenzyl derivative, ring closure takes place to form a structure analogous to the A, B, and C rings[224], but the yield is only moderate (22%) because of the lower activation of the arene system. Similar intramolecular aryl couplings as in *(15)*[225] and *(16)*[226] have been used in a synthesis of colchicine and for the preparation of (+)-oxocrinine respectively and of (+)-cryptopleurine[227]. Diarylamides *(17)* can be cyclized when the amide is tertiary and the carbonyl and amino groups are not conjugated with the aromatic system ($x,y \neq 0$)[228].



*(15)*, 80%

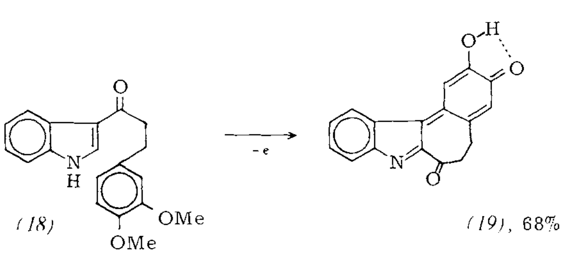


*(16)*, 62%



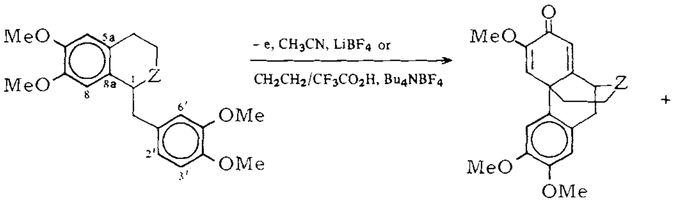
(17)

In a series of indole and dihydroindole derivatives only *(18)* couples intramolecularly to give *(19)*[229], this reaction probably being favored by a six-membered transition state[230]; the other indoles usually dimerize intermolecularly.

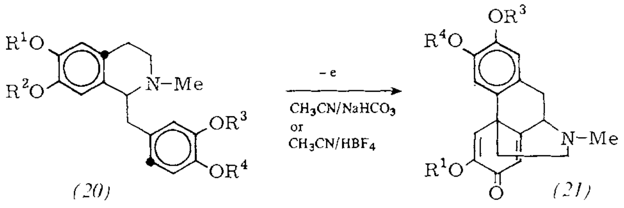


*(18)* *(19)*, 68%

The anodic cyclization of benzyltetrahydroisoquinolines *(20)* to the morphinane skeleton is particularly interesting from the preparative point of view, since it cannot be achieved satisfactorily with chemical oxidants. *(21a)* and *(21b)* can be obtained in good yield in acetonitrile/sodium bicarbonate using a divided cell[224,231-233]; *(21c—e)* can even be obtained under less mild conditions in an undivided cell and in acidic electrolytes[234].



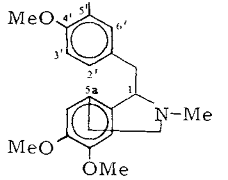
*(24)* *(25)*



*(20)* *(21)*

| | | |
|---|---|---|
| *(21a)*, $R^1 = R^3 = R^4 = CH_3$; *O*-methylflavinantine | | (52-85%) |
| *(21b)*, $R^1 = R^3 = CH_3$, $R^4 = PhCH_2$; *O*-benzylflavinantine | | (43-63%) |
| *(21c)*, $R^1 = R^3 = CH_3$, $R^4 = H$; flavinantine | | (63%) |
| *(21d)*, $R^1 = R^4 = CH_3$, $R^3 = H$; pallidine | | (50%) |
| *(21e)*, $R^1 = CH_3$, $—R^3—R^4— = —OCH_2O—$; amurine | | (80%) |

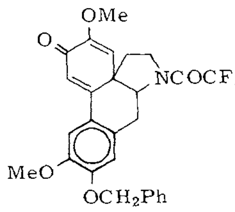
However, it is disadvantageous that in *(22)*, because of the −I-effect and the steric hindrance of the 5′-methoxy group, a C2′—C5a coupling to the flavinanthine type of compound takes place, and not a C6′—C5a coupling to the desired morphine type.



(22)

Attempts to enforce the "morphine type" of coupling have so far been unsuccessful[235,236]. 2′-Bromo *(22)* cyclizes at C2′ with debromination[224]; 2′-chloro[224,235], 2′-nitro- and 2′-N-acetylamino[236] substituents lead to cleavage at Cl; 3′-bromo or 3′-iodo substituents hardly hinder the C2′

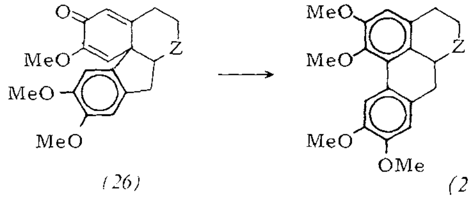
ring closure (3'-Br: 89%; 3'-I: 29%)[224,235]. 3'-Methoxy *(22)*, in which the C2'- and C6'-couplings are identical, forms



*(23)*

35—55% of the cyclization product[232,235]. *N*-Acyl substituents considerably affect the formation of products; while *N*-formyl *(22)* is cleaved at C1, *N*-trifluoroacetyl *(22)* gives the dienone *(23)* in good yield[236].

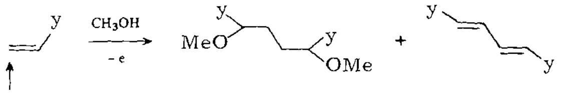
Carbon analogs (*(24)*, Z=$CH_2$) of benzyltetrahydroisoquinolines[237] couple at C2' and C5a in good yield to give



*(26)* *(27)*

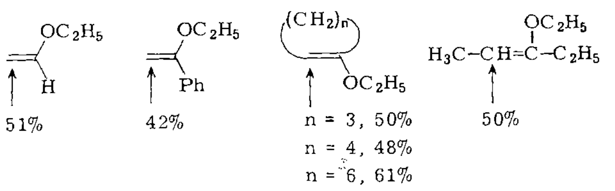
*(25)* or at C8a to give *(26)*; in acidic electrolytes ($CF_3CO_2H/CH_2Cl_2$), the intermediate product first formed by cyclization at C2'—C8a rearranges to give *(27)*.

Olefins *(28)* with electron donating substituents Y (alkoxy, acylamino, phenyl, or vinyl) can be dimerized in methanol to give 1,4-dimethoxy compounds *(29)* and/or dienes *(30)*.



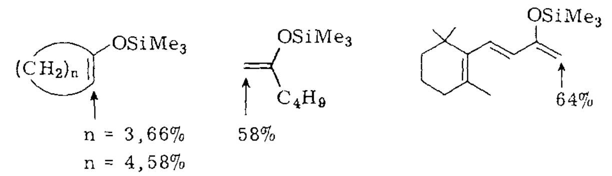
*(28)* *(29)* *(30)*

Enol ethers (*(28)*, Y=OR) with half-wave potentials between $E_{1/2}=+1.2$ and $+1.8$ V (Ag/AgCl) couple in methanol/2,6-lutidine at a graphite anode to give the acetals of 1,4-dicarbonyl compounds[238,239].

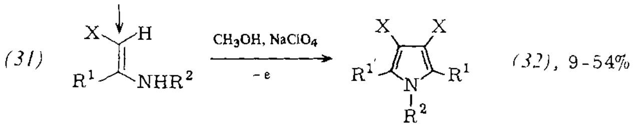


The tail-to-tail coupling of the dimers and the electrochemical reaction orders $\nu_{\text{enolether}} \approx 1$, $\nu_{\text{methanol}}=0$, suggest coupling *via* the radical cation. Silyl enol ethers (*(28)*, Y=$OSi(CH_3)_3$) can also be dimerized to 1,4-dicarbonyl compounds in good yields[240]:

Unsymmetric ketones can be linked uniformly in this way in the α- or α'-position, since the corresponding silyl enol ethers can be prepared regioselectively[241]. Enamino ketones or enamino esters *(31)* yield *via* the radical cations



by subsequent ring closure, and pyrrole derivatives *(32)*[242].

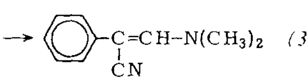


*(31)* *(32)*, 9-54%

X = $CO_2CH_3$, $COCH_3$, CN;

$R^1$ = $CH_3$, H, 4-$CH_3O$–$C_6H_4$; $R^2$ = H, $CH_3$, $CH_2$–$C_6H_5$, $C_6H_5$

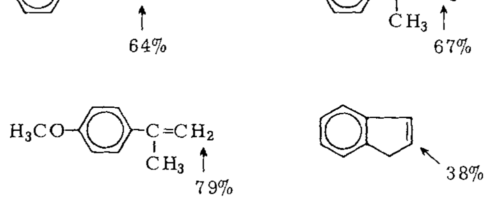
In the case of the enamino nitrile *(33)* coupling through the phenyl ring is observed[243].



$$\rightarrow C_6H_5\text{–}\underset{\displaystyle CN}{C}\text{=CH–N}(CH_3)_2$$

*(33)*

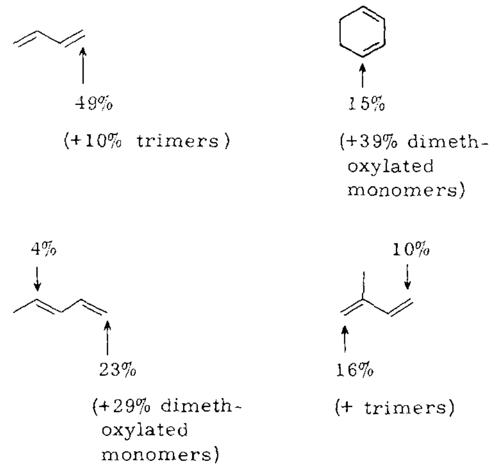
Styrene- and indene-derivatives (*(28)*, Y=aryl) are dimerized to 1,4-dimethoxy-1,4-diphenylbutane derivatives or 1,4-diphenylbutadiene derivatives[238,244]:



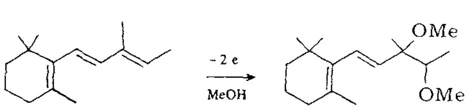
The product distribution is in some cases decisively affected by the anode potential and the supporting electrolyte. β-Alkyl substituents decrease the yield of dimers drastically and favor the formation of dimethoxylated monomers. For the dimerization of 4,4'-dimethoxystilbene it has been possible to prove spectro-electrochemically[245] and at the rotating ring-disk electrode[246] that the product is formed by the radical dimerization of the intermediate radical cations. When methanol is replaced by aqueous dichloromethane or by aqueous acetonitrile as solvent, styrene[247a] and α-methylstyrene[247b] yield 2,5-diphenyltetrahydrofurans. On anodic acetoxylation, presumably in a chain reaction *via* the radical cation[248a], 5,6-dimethoxyindene yields a [2+2]-cycloadduct as by-product[248b].

Dienes *(28)* (Y=vinyl) are dimerized to dimethoxyoctadienes or are dimethoxylated to dimethoxybutenes at graphite, platinum, or glassy carbon anodes in a methanol/sodium perchlorate electrolyte[238,249]:

Dimerization is favored by graphite- or carbon-cloth anodes, by high olefin concentrations, and by terminally unsubstituted dienes[249,250]. Butadienyl acetate and the β-ionone derivative *(34)* could not be dimerized but yielded dimethoxylated monomers, whereby *(34)* regioselectively forms 73% of the α,β-dimethoxy product[249].

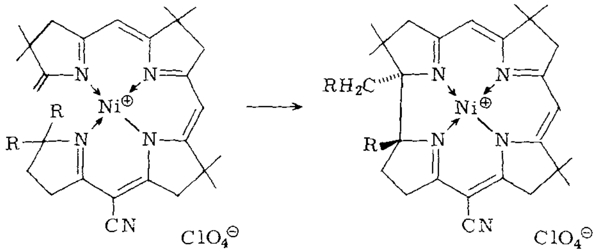


The polyene derivative *(35)* can be cyclized to form the nickelcorrin complex *(36)* if it is first oxidized to the radical cation, which undergoes a 1,16-hydrogen shift and then



*(34)*

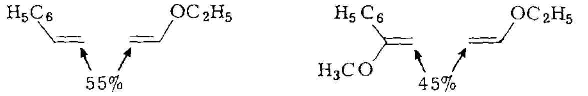
couples intramolecularly through cathodic reduction[251] (Conditions: +1.22 V, −0.3 V; Pt/LiClO$_4$, CH$_3$CN, Ac$_2$O, HOAc; yield 18% with R = H).



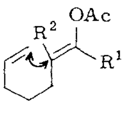
*(35)* *(36)*

Alkenes without +M-substituents can be coupled only if they are dialkylated at one carbon atom of the double bond and are unsubstituted at the other—a further indication that the dimerization of radical cations responds sensitively to steric hindrance[252]:

Unsymmetric dimers are accessible through the coelectrolysis of different olefins[253].



Unsaturated enol acetates *(37)* can be cyclized to cyclohexenyl ketones in yields of 18—40%[254].



*(37)*

### 3.2. Radicals as Intermediates

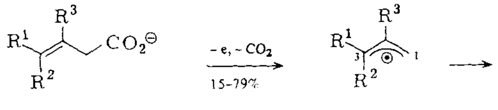
#### 3.2.1. Coupling of Radicals

Radicals can be generated in preparative amounts by an experimentally simple procedure using the Kolbe electrolysis; for reviews see [16-18,20,37,53,255]. Here, carboxylic acid anions are decarboxylated to radicals *via* 1e-oxidation or to carbenium ions *via* 2e-oxidation. The radicals couple or react with olefins to give "additive" dimers and/or monomers (see Section 3.2.2); alcohols, amides, esters, alkenes, and rearranged products are formed from the carbenium ions. The radical route is favored by platinum anodes and sometimes also by those of glassy carbon or sintered graphite[256], *i.e.* electrode materials with smooth surfaces, and also by a high current density, by an acidic electrolyte in which only 5—10% of the acid is neutralized, by methanol as solvent, and finally, by hydrogen or electron-attracting substituents on the α-carbon atom of the carboxylic acid[257]. Some selected Kolbe dimerizations are listed in Table 3.

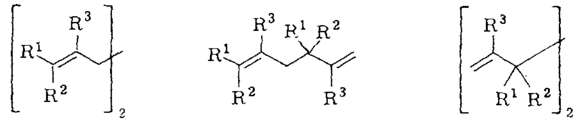
Table 3. Some examples of the Kolbe electrolysis of carboxylic acids.

| Carboxylic acid | Yield of dimers [%] | Ref. |
|---|---|---|
| H$_3$C(CH$_2$)$_n$CO$_2$H, n = 5-15 | 60-90 | [53b] |
| RO$_2$C(CH$_2$)$_n$CO$_2$H, n = 4-16 | 45-95 | [53b] |
| (CH$_3$)$_2$CH—CH(CO$_2$Et)CO$_2$H | 67 | [258] |
| AcO(CH$_2$)$_n$CO$_2$H, n = 3-5 | 73-83 | [259] |
| F(CH$_2$)$_n$CO$_2$H, n = 4-10 | 45-70 | [260] |
| EtCO(CH$_2$)$_4$CO$_2$H | 75 | [261] |
| Oleic acid | 75 | [262] |
| R$^1$CO—CR$^2$R$^3$CO$_2$H | ≈35 | [263a] |
| F$_2$CCl—CO$_2$H | 45 | [263b] |

Anions *(38)* of β,γ-unsaturated carboxylic acids can be coupled in methanol *via* allyl radicals *(39)* to the isomeric 1,5-dienes *(40)*—*(42)* in satisfactory yields[264,265].



*(38)* *(39)*

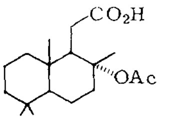


*(40)* *(41)* *(42)*

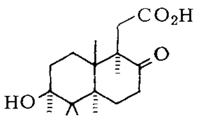
R$^1$ = H$_3$C(CH$_2$)$_7$, (CH$_3$)$_2$CHCH$_2$, MeO$_2$CCH$_2$, (CH$_3$)$_2$CH, (CH$_3$)$_3$C
R$^2$ = H, CH$_3$
R$^3$ = H
—R$^1$—R$^2$—, —R$^1$—R$^3$— = —(CH$_2$)$_4$—

In this process, the configurations of the double bonds are almost totally (≈90%) retained; terminal double bonds sometimes migrate if the electrolyte becomes alkaline[264]. The diene *(40)* is formed more and more selectively with increasing size of $R^1$, $R^2$, and $R^3$, presumably due to the steric shielding of C3 in the allyl radical *(39)*. The passivation that is frequently observed can be diminished and the yield increased reproducibly if the carboxylic acids are neutralized with tributylamine or triethylamine[266]. In the case of 4-alkene-6-ynoic acids[267] or 6-heptenoic acid[264] a more or less pronounced cyclization to cyclopropylmethyl or cyclopentylmethyl radicals is observed.

If a target compound can be divided into two symmetrical fragments, Kolbe electrolysis is a favorable method for its synthesis. For example, in the dimerization of *(43)* or *(44)* it is the key step in syntheses of pentacyclosqualene[268] and of α-onocerin[269], respectively.



*(43)*, 34%



*(44)*, 40%

Unsymmetric compounds can also be prepared *via* mixed Kolbe electrolyses of different carboxylates. The disadvantageous but unavoidable formation of symmetric dimers can be reduced to one by-product if the cheaper carboxylic acid is used in 5- to 10-fold excess. Hydrogenated carotenoids, saturated and unsaturated fatty acids, optically active ω-hydroxy carboxylic acids, and intermediates for the preparation of muscone and humulene have been obtained in this way[53b]. The method has recently been applied to the synthesis of pheromones[255]. For example, muscalure *(45)* has been synthesized in yields of 40%[270] or even 80%[271], and its antagonist (*Z*)-11-heneicosene[271], looplure *(46)*[272], (*E*)-7-dodecenyl acetate *(47)*[273], brevicomin *(48)*[274], disparlure *(49)*[275], the attractant *(50)* of the German cockroach[276], and optically active *(51)*, a *Trogoderma* pheromone[277a], have also been synthesized (the arrows indicate the positions where coupling occurs). In addition, alkynecarboxylic esters having different chain lengths, which can be hydrogenated at will to (*E*)- or (*Z*)-pheromones, can be obtained[271]. C-Analogs of cystine peptides have been prepared from glutamic acids protected in various ways[277b]. A further selection of mixed Kolbe electrolyses is summarized in Table 4.

It is quite certain that the intermediate "Kolbe radicals" react as free radicals and are not bound to the anode. This follows from the formation of completely racemic products in electrolyses with carboxylic acids whose α-carbon is a center of chirality *e.g.* 2-methyloctadecanoic acid[285] or ethyl ethylmethylmalonate[286]. Moreover, the *cis*- and *trans*-4-*tert*-butylcyclohexanecarboxylic acids yield the three stereoisomeric 4,4'-di-*tert*-butylcyclohexanes *(aa, ae, ee)* in the statistical ratio 1 : 2 : 1)[287]. Furthermore, addition of methoxycarbonylmethyl radicals from malonic acid hemiesters to β-methylstyrene produces additive dimers and monomers in the same ratio as in their reductive preparation in homogeneous solution from the $H_2O_2$ adduct of dimethyl acetonedicarboxylate[288].

In addition to the carboxylates, other anions can also be dimerized at anodes, presumably *via* radicals. Anionized 1,3-dicarbonyl compounds and heteroanalogs of CH acids couple in satisfactory yields[289]. With some substrates, the yield is substantially improved with iodide as supporting electrolyte; probably an indirect electrolysis takes place here, with iodine as an electrocatalyst. In one of the rare examples in which a useful product is obtained simultaneously at the working electrode and the counter electrode

*(coupled electrosynthesis)*, diethyl malonate dimerizes at the anode to give tetraethyl ethanetetracarboxylate and ethyl acrylate dimerizes at the cathode to give diethyl adipate in yields of over 90% in each case[290,291]. Furthermore, anions of nitroaliphatic compounds are coupled to give vicinal dinitroalkanes[292], Grignard compounds[293] and borates[294] couple to give alkanes, acetylides give diacetylenes[295], and amides give azoalkanes[296].

### 3.2.2. Addition of Radicals to Double Bonds

If anions $R^{\ominus}$ are oxidized in the presence of olefins, additive dimers *(53)* and substituted monomers *(54)*, *(56)*, and *(57)* are obtained (Table 5):

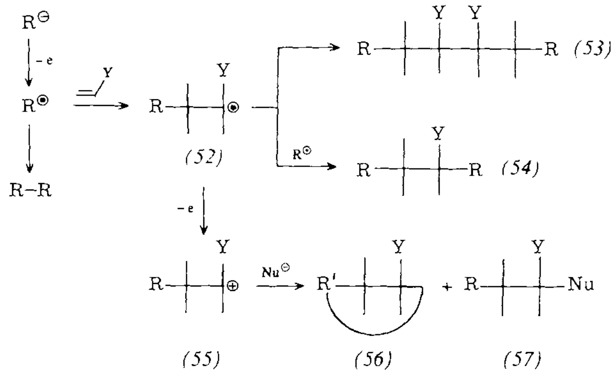

Table 5. Addition of anodically generated radicals to alkenes to give adducts of the type *(53)*, *(54)*, *(56)* and *(57)*. Y = Vinyl, Alkyl, Phenyl, Alkoxy; $Nu^{\ominus} = CH_3O^{\ominus}$.

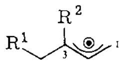
[a] For purposes of comparison an alkyne was taken.

The following pathway appears to be plausible: the radical $R^{\bullet}$ obtained by a 1e-oxidation from the anion $R^{\ominus}$ adds to the alkene to give the primary adduct *(52)* which dimerizes to give the additive dimer *(53)* with regiospecific head-to-head linkage of the two olefins, or couples with $R^{\bullet}$ to give the additive monomer *(54)*. If the substituent Y in the olefin can stabilize a carbenium ion, *(52)* is oxidized to the cation which reacts intra- or intermolecularly with nucleophiles to give *(56)* or *(57)*.

Satisfactory to good yields of adducts have been found for styrenes (Y = phenyl), conjugated dienes (Y = vinyl), and enol ethers (Y = alkoxy) particularly if they are unsubstituted at the β-carbon atom. Nonactivated alkenes react less satisfactorily. In vicinal disubstituted styrenes, upon addition of the Kolbe radical $MeO_2CCH_2^{\bullet}$, the yields of adducts decrease with increasing size of the β-substituent: H = 42%, Me = 27%, Et = 11%, *i*Pr = 5%, *t*Bu = 2%[288]. The yields also depend on the radical's reactivity: thus, cyclohexene gives 18% of adducts with the $N_3^{\bullet}$ radical[309] but only 9% with $EtO_2C^{\bullet}$[302], while the stable $NO_2(CH_3)_2C^{\bullet}$ radical no longer adds[299b]. The additive dimer *(53)* : monomer *(54)* ratio can be affected to some extent by the current density ($\bar{i}$). With butadiene and ethyl oxalate (Table 5, No. 9), *(53)* : *(54)* = 15.6 for $\bar{i}$ = 0.025 mA/cm², but only 0.67 for $\bar{i}$ = 0.66 mA/cm². Obviously, at low current densities the radicals $R^{\bullet}$ are mainly trapped by the olefin to give *(52)* [→ 1/2 *(53)*], a process which no longer occurs at higher current densities, *i.e.* higher radical concentrations, so that now the mixed coupling to give *(54)* is favored. In the oxidation of anionized 1,3-dicarbonyl compounds (Table 5, Nos. 1—4) between 0.6 and 1.4 V (SCE) in the presence of butadiene only the additive dimer *(53)* is obtained, while with ethyl vinyl ether only the disubstituted monomer *(56)* or *(57)* arises, and with styrene both types of products *(53)* and *(56)* are formed. This result makes it probable that the primary adduct *(52)* is oxidized to the carbenium ion as a ethoxymethyl radical (Y = OEt) below 0.6 V, as an allyl radical (Y = vinyl) above 1.4 V, and as a benzyl radical (Y = phenyl) within this potential range[297]. Addition to butadiene forms an allyl radical *(58)*, which couples at C1 and C3 to give isomeric 1,5-dienes [cf. *(40)*—*(42)*]. It follows from the higher proportion of 1,1′-linked dimers that C1 reacts about 2.7 times faster as C3, probably due to the greater steric shielding of C3[297].



*(58)*

Taking the different reactivities of the allyl radicals into account indicates that they couple almost statistically to form the 1,1′-, 1,3′-, and 3,3′-dimers[297]. With more bulky substituents, *e.g.* $R^1 = NO_2(CH_3)_2C$ and $R^2 = CH_3$, the C1 : C3 reactivity ratio may rise to greater than 15[299b]. In the addition of the Kolbe radicals $MeO_2C(CH_2)_{n-1}CH_2^{\bullet}$ to butadiene (Table 5, Nos. 9 and 13), the distribution of the isomers is independent of the chain length (n = 0 to 4, respectively). Reports that adipic acid hemiesters only give unbranched additive dimers[305] have not been confirmed[310].

The preparative advantages of anodic addition comprise simpler reaction conditions and short routes to complex compounds. The disadvantages are the formation of isomers by parallel reactions and the non-regioselective coupling of the intermediate allyl radicals. The one-step preparation of dihydrofurans (Table 5, No. 1), of the diene diesters (Nos. 9 and 13), of the 1,4-dicarbonyl compounds (No. 15), and of the diazides (Nos. 16 and 18) could be of preparative interest.

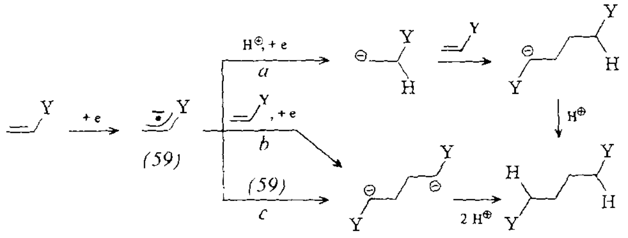
## 4. Preparative Applications: CC-Bond Formation at the Cathode

At the cathode it is possible to obtain radical anions, carbanions, and neutral radicals, whose reactions with electrophiles or whose coupling leads to the formation of new CC-bonds.

### 4.1. Radical Anions as Intermediates

Olefins that are activated by electron-attracting substituents form tail-to-tail linked hydrodimers at the cathode, presumably *via* radical anions. This hydrodimerization[12,16-18,61,62] has been developed, particularly by *Baizer*, into a large technical-scale synthesis of adipodinitrile[311,312], has been extended to numerous olefins[313], and has been applied in mixed couplings and intramolecular cyclizations[57,59,61]. Some examples of these reactions are summarized in Table 6.

The intermediate radical anion *(59)* can dimerize in three ways:



$Y = -\underset{|}{C}=O,\ -CO_2R,\ -C\equiv N$

Tabelle 6. Hydrodimerization of activated olefins at the positions shown by the arrows.

| Olefin | Yield [%] [a] | Ref. |

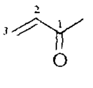
|  | (93) | [321] |
|  R = H, CH₃ | | [322] |

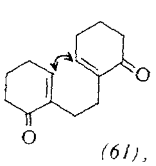
[a] Current yield; the material yields are given in parentheses.

Route *a*, protonation and reduction to a β-substituted carbanion, is assumed for the hydrodimerization of acrylonitrile[62]; route *b*, the Michael addition of the radical anion to the educt, has been suggested for the cathodic hydrocyclization[323]; finally, route *c* has been shown to be probable for the radical dimerization of the dimethyl maleate radical anion[324].

α,β-Unsaturated ketones and aldehydes *(60)* usually yield 3,3′-coupled dimers in neutral media (Table 6), while in acidic media larger amounts, up to 100%, of the 1,1′- and 1,3′-dimers are formed[325]. The dienedione *(61)*, which

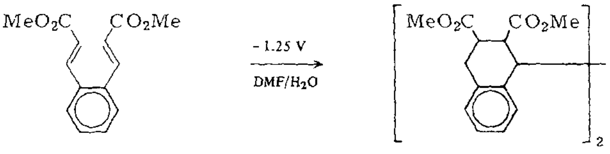


*(60)*



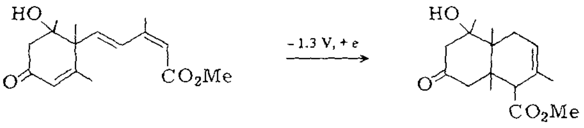
*(61)*, 80%

can be obtained by the Kolbe dimerization of Hagemann's ester, yields, in a regio- and stereospecific reaction, the potential steroid-building block *trans,trans*-perhydrophenanthrene[326]. An intramolecular ring closure followed by dimerization is observed for the dienic diester *(62)* in dimethylformamide/water[327].



*(62)* 29%

Methyl abscisate *(63)* likewise cyclizes intramolecularly in a 6-*exo-trig* reaction[328] to give the decalin derivative *(64)*[329]:



*(63)* *(64)*, 51%

In cyclopropyl ketones only the carbonyl group is hydrogenated or coupled to form the pinacol; only if the three-membered ring is additionally phenyl-substituted can it also undergo hydrogenative cleavage[330].

Acylations, carboxylations, and alkylations of activated alkenes are possible by reaction of the intermediate radical anions with the corresponding electrophiles E (Table 7).

The radical anion *(59)* reacts in a CEC step[*] to give an acylated or dicarboxylated monomer[332,333,341] (route *a*); didecarboxylated dimers arise in route *b* from diactivated double bonds, or by reduction of olefins which can be reduced in two steps at the potential of the first step[342]. If the reduction potential of the olefin is more cathodic than the reduction potential of $CO_2$ ($E_{1/2} = -2.3$ V), the latter can be reduced to the anion radical and react with the olefin as an electrophile. While with $CO_2$ dicarboxylations are the rule, diacylations *e.g.* diformylation are the exception[336]. Acylations can be classified as *umpolung* reactions of type d³[1].

---

[*] C = chemical, E = electrochemical.

(59)

E = RCOX, $CO_2$; Y = $-\underset{|}{C}{=}O$, $-CO_2R$, –Aryl

The reductive alkylation of double bonds with alkyl halides or 'onium salts takes place largely *via* a transfer of electrons to the solution (SET = solution electron transfer)[347a, 358]:

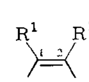
$$Su \xrightarrow{+e} Su^{\cdot-}$$

$$RX + Su^{\cdot-} \longrightarrow Su^{\cdot-} + RX^{\cdot-}$$

$$RX^{\cdot-} \longrightarrow R^{\cdot} + X^{\ominus}$$

$$R^{\cdot} + Su^{\cdot-} \longrightarrow R{-}Su^{\ominus} \xrightarrow{H^{\oplus}} R{-}Sn{-}H$$

The substrate radical anion $Su^{\cdot-}$ reduces the alkyl halide to $RX^{\cdot-}$ which dissociates to the alkyl radical, and this couples with $Su^{\cdot-}$ to give the alkylation product. An $S_N2$ substitution with $Su^{\cdot-}$ as the nucleophile can be excluded, since the best yields are obtained with *tert*-butyl halides[344], and in the case of mixed 'onium salts containing the *tert*-butyl residue only this is transferred[349]. Activated double bonds *(65)* with $R^1$ = alkyl, $R^2 = CO_2Et$, or $R^1$ = phenyl, $R^2 = SO_2Me$ are alkylated selectively at C1, while with $R^1$ = phenyl, $R^2 = CO_2Et$, alkylation takes place only nonspecifically[346, 347a, 351].



(65)

Schiff's bases[353] and quinoline[354] react with primary halides by an ECEC mechanism:

$$-CH{=}N- \xrightarrow{+e} \overline{-\overset{\cdot}{C}H{-}\overset{-}{N}-} \xrightarrow{RX} -\overset{\cdot}{C}H{-}\overset{R}{\underset{}{N}}- \xrightarrow{+e} -\overset{\ominus}{C}H{-}\overset{R}{N}- \xrightarrow{RX} -\overset{R}{C}H{-}\overset{R}{N}-$$

Reductive alkylations merit preparative interest particularly for the tertiary alkylation of aromatics and double bonds and for the preparation of α-alkylated amino acids and nitrogen heterocycles.

The reductive oligomerization of $CO_2$ is also industrially of potential interest for the synthesis of large carbon units, and has therefore been treated fairly frequently. Reduction in aqueous electrolytes leads to formic acid[359]. The preparation of longer-chain hydroxy carboxylic acids[360] is not always reproducible[359], but other workers[361] have managed to obtain 70% of malic acid at pH 10 with a mercury cathode. In partly aprotic media, formic and oxalic acids or, by subsequent reduction, glycolic, glyoxylic, tartaric, and malic acids are formed[359,362]. Up to 90% yield of oxalic acid is formed in aprotic media[359,363].

### 4.2. Radicals as Intermediates

Aldehydes and ketones can be hydrodimerized cathodically to form pinacols; in acidic media hydroxyalkyl radicals are probable intermediates in this process[364]. While with aromatic carbonyl compounds good yields of pinacols are generally obtained, yields are only moderate with aliphatic compounds, because of the competing reduction to alcohols and hydrocarbons. Formation of pinacols is favored by a high concentration of the carbonyl compound, an acidic medium, and cathodes with a low hydrogen overvoltage[365]. Older investigations have been described in [366], while more recent results are summarized in Table 8.

Table 8. Cathodic formation of pinacols from carbonyl and analogous reactions of Schiff's bases at the positions marked wich arrows, as well as crossed hydrodimerization and cyclization reactions.

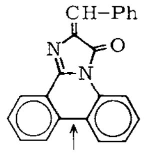
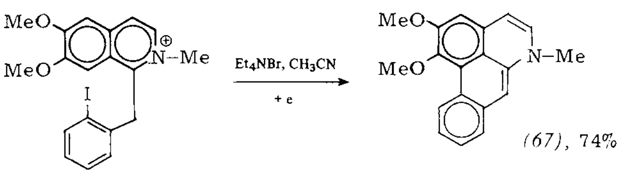
[a] Intramolecular reaction. [b] Reaction product 9,10-dihydrophenanthrene-9,10-diol.

Tetrahydrophenanthrones (Table 8, No. 1) couple more or less preferentially to give *R,R*- or *S,S*-diols, due to adsorption of the intermediate radicals (see also [211]). While ketones with heterosubstituents in the α-position do not form pinacols in aqueous acidic media but eliminate the hetero substituents, pinacols are formed in aprotic (acetonitrile), neutral, or weakly basic media (Table 8, Nos. 2 and 3). 1,3-Diketones react intramolecularly in aprotic media[372], and in weakly acidic and protic solutions to cyclopropanediols; two alkyl substituents in position 2 are favorable, but not essential, conditions to this end (Table 8, No. 5). An α-hydroxy carbanion which adds nucleophilically to the carbonyl group, has been discussed as an intermediate here. In acidic media 1,8-dibenzoylnaphthalene (Table 8, No. 6) forms a *cis*-acenaphthenediol stereoselectively, which can be explained by the formation of a hydrogen bond; the formation of the *trans*-diol in basic media is explained by electrostatic repulsion of the intermediate ketyls. α,β-Unsaturated carbonyl compounds generally hydrodimerize to 1,6-diketones (Table 7), but if the double bond is sterically shielded, as in β-ionone or in retinal, they couple to form 1,2-diols (Table 8, No. 8a, 8b). The yields can be increased by the addition of chromium(III) salts[376], which probably act as complexing agents, but still better by the replacement of the coelectrolyte acetic acid by the weak CH-acid diethyl malonate[377a]. The crossed hydrodimerization between a carbonyl compound and a second electrophile discovered by *Baizer*[379] (Table 8, Nos. 9—13b) takes place particularly well in strongly acidic media, while the yields fall in weakly acidic or neutral electrolytes. Radical[380] and nucleophilic[378a] additions of $R_2(HO)C^{\ominus}$ or $R_2(HO)C^{\ominus}$ to the electrophile have been proposed for the reaction mechanism. As an alternative to the mixed electrolysis of ketones[382c], unsymmetric pinacols can be obtained by the coelectrolysis of aromatic ketones and enolic esters (Table 8, No. 14). The cyclization of δ- or ε-unsaturated ketones to cyclopentanols or cyclohexanols with alkyl groups in the *cis*-position takes place remarkably stereoselectively and is of preparative interest (Table 8, No. 15). The reaction mechanism is assumed to be a radical attack of the ketyl on the double bond. Correspondingly, *exo*-cycloalkenols are formed with ketoalkynes (Table 8, No. 16). Schiff's bases hydrodimerize to form diamines or undergo a crossed reaction with carbonyl compounds to give α-amino alcohols (Table 8, Nos. 17–19).

Benzyl, allyl, and even alkyl bromides are dimerized *via* indirect electrolysis with chromium(II) chloride[385] or by using iron 2,4-pentadionate[386] as electron carrier, presumably *via* radical intermediates. Suitable aryl halides can be cleaved to σ-radicals, which cyclize by intramolecular aryl addition to azaphenanthrenes *(66)*[387a] or aporphines *(67)*[387]. The latter synthesis is claimed at present to be the shortest route to this biologically active class of compounds.

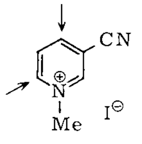


*(66)*

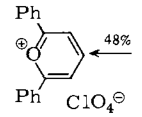


*(67)*, 74%

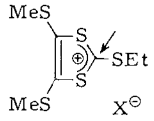
Cations are reduced cathodically to give radicals, which then dimerize. The nicotinamide model *(68)* thus gives four stereoisomeric hydrodimers[388], and 2,6-diphenylpyrylium perchlorate *(69)* gives the corresponding substituted bipyranyl[389].



*(68)*



*(69)*



*(70)*

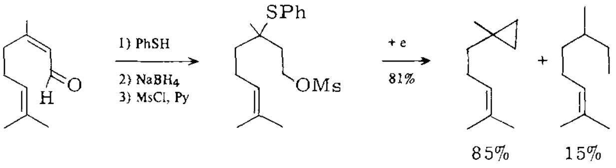
Tropylium tetrafluoroborate gives a quantitative yield of 7,7-bitropyl[390], and the sulfonium salts *(70)* can be coupled to tetrathiafulvalene precursors[391]. Diazonium salts of 2-aminophenylcinnamic acids are reduced, with the elimination of nitrogen, to phenyl radicals which cyclize to phenanthrene derivatives with a better yield (>90%) than in the alternative Pschorr reaction[392a]. Benzyl-, cinnamyl-, and polyenyl-substituents in phosphonium salts can be dimerized in yields of 6—56%[392b].

### 4.3. Carbanions as Intermediates

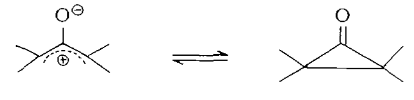
Carbanions are usually obtained by the cathodic cleavage of carbon-halogen bonds and are used for the preparation of small rings by intramolecular substitution, for additions to carbonyl compounds and activated double bonds, or as bases for deprotonations.

Cathodic 1,3-eliminations have repeatedly proved their value for the preparation of cyclopropanes[393]. α,β-Unsaturated carbonyl compounds can also be converted into cyclopropanes by this principle, if they are previously modified by the addition of thiophenol, reduction of the carbonyl group, and mesylation[394].

The tetramethyl cyclopropanone *(72)* should be accessible from 2,4-dibromo-2,4-dimethyl-3-pentanone by a 1,3-

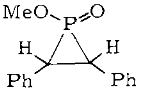


elimination, but in spite of numerous variations of the reaction conditions and trapping reagents, a complex mixture of products was formed in acetonitrile/ethanol, which was ascribed to the intermediate zwitterion *(71)*[395]. In contrast to this, the methyl hemiacetal of *(72)* was obtained in almost quantitative yield starting from the same dibromide in methanol[396]. This difference in results has been explained by a solvent-dependent position of the equilibrium: *(71)*⇄*(72)*.



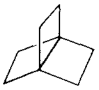
*(71)* *(72)*

A cyclic phosphinate *(73)* has been assumed to be an intermediate in the reduction of the corresponding α,α′-dihalophosphinate to *cis*- and *trans*-stilbenes[397].



*(73)*

The results on the mechanism of the 1,3-elimination are controversial. While the fact that the reduction potentials of the 1,3-dihalides are more anodic than those of the monohalides indicates a synchronous mechanism[398a], the stereochemistry of the cyclopropane formation supports the idea of a two-step pathway *via* a carbanion and an $S_N2$ substitution reaction[398b]. For the cyclization of *endo,endo*-2,6-dibromonorbonane to tricyclene, where an $S_N2$ substitution is sterically impossible, a diradical has been proposed as intermediate[399]. Some strained, reactive hydrocarbons have been prepared by 1,n-eliminations. While the synthesis of [2.2.1]propellane *(75)* was unsuccessful[400], [2.2.2]-propellane *(74)* was obtained from 1,4-dibromobicyclo[2.2.2]octane, although only in 12% yield[401]. [2.2.0]Bicyclohexene *(76)*, prepared by the electrolysis of 1-bromo-4-chlorobicyclo[2.2.0]hexane, has been trapped as the cyclopentadiene adduct[402].



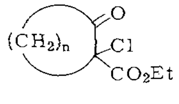
*(74)*

*(75)*

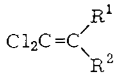
*(76)*

A 1,4- and a subsequent 1,2-elimination in xylylidene tetrabromide led to benzocyclobutadiene, which was isolated as the Diels-Alder dimer[403]. Cyclic dicarboxylic acid diesters are obtainable in satisfactory to good yields from 2,(n−1)dibromo alkanedioates, n=3 (74%), 4 (32%), 5 (52%), 6 (60%), 7 (20%)[404]. Hexamethyldisilane can be obtained from trimethylsilyl chloride, probably *via* a 2e-reduction to the silyl anion[405]. By reductive 1,1-elimination and α-elimination with cathodically produced bases, it is possible to obtain dichlorocyclopropanes[406] and bromofluorocyclopropanes[407] from carbon tetrachloride, chloroform, and tribromofluoromethane with alkenes in current yields of up to 80%; a considerable improvement over the original adduct yields of only 8%[408a]. A Fritsch-Buttenberg-Wiechell rearrangement of 1,1-diaryl-2,2-dihaloethylenes can be initiated cathodically, giving 1,2-diarylacetylenes in yields of 85—92%[408b]. Tosyl-[409] and alkoxycarbonyl-nitrenes[410] are accessible cathodically from the corresponding dichloro precursors and can be trapped as insertion products with dioxane in yields of 2—32%.

Carbanions obtained cathodically from halides have been treated with carbonyl compounds, activated double bonds, or other electrophiles. With acetone, allyl halides form isomeric homoallyl alcohols, the product distribution depending slightly on the electrode material[411]. With aldehydes and ketones, carbon tetrachloride and 1,1,1-trichloroethane yield 2,2,2-trichloroethyl alcohol[412a,418b] and 2,2-dichloropropyl alcohols[412b]; the yields are considerably increased in some cases by additions of magnesium perchlorate[413]. With ethyl trichloroacetate and cyclic ketones, the β-keto esters *(77)* are formed *via* ring expansion[412a]. The dichloroolefins *(78)* or α-chloroacrylic esters can be prepared in a Wittig-Horner reaction, without the use of bases, by the reduction of trichloromethyl phosphonates or dichloro(ethoxycarbonyl)methyl phosphonates in the presence of carbonyl compounds[414].



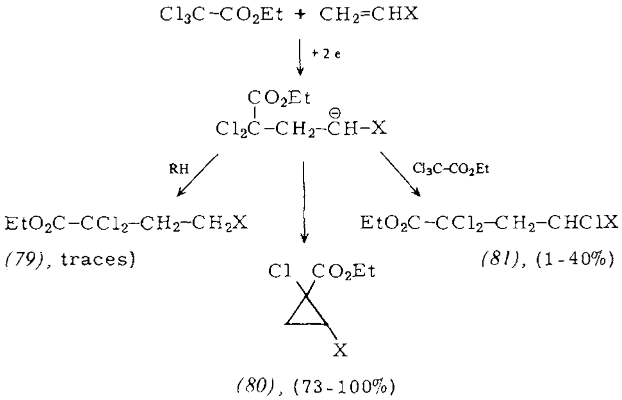
*(77)*, n = 3 (43%)
n = 4 (27%)



$Cl_2C{=}C(R^1)(R^2)$

*(78)*, $R^1$ = 4-$CH_3OC_6H_4$, $R^2$ = H (40%)
$R^1$ = $CH_2{=}\underset{CH_3}{\underset{|}{C}}{-}$, $R^2$ = H (45%)
$R^1$, $R^2$ = $-(CH_2)_5-$ (52%)

β-Halogeno esters[415] and α,β-unsaturated esters[416] can be added cathodically in the presence of trimethylsilyl chloride to aldehydes and ketones to give γ-lactones in satisfactory to good yields. Benzyl chlorides are acylated by acid chlorides to form benzyl ketones[417]. Ethyl trichloroacetate adds cathodically to activated double bonds forming, in addition to the adduct *(79)*, the cyclopropane esters *(80)* by intramolecular substitution and the trichlorinated ester *(81)* by nucleophilic attack on the educt[418a].



*(79)*, traces)
*(81)*, (1-40%)
*(80)*, (73-100%)

With ethyl dichloroacetate, electrolysis initiates a chain addition[418a], a principle which was later applied to the addition of chloroform to carbonyl compounds[418b]. Acrylic esters are alkylated by alkylboranes in undivided cells with very good yields[419a]. Here it is assumed that the boranes react with iodine, produced anodically from the sodium iodide supporting electrolyte, to give alkyl iodides which add cathodically to the activated esters. Under catalysis by vitamin $B_{12}$, bromomethylenecyclohexenones can be cyclized cathodically in good yield[419b].

While the reaction of dichloromethane with dialkylboranes forms dialkylmethanols reductively in good yield[420], the corresponding reaction of benzylidene chloride and $CO_2$ gives mandelic acid in low yield[421].

A series of nucleophilic substitutions, eliminations, and additions of preparative interest can be achieved with cathodically produced bases. For example, nitro aliphatic compounds[422], nitriles[423], and terminal alkynes[424a] are alkylated by trialkylboranes in undivided cells. As discussed above, it is considered that the alkylboranes form alkyl iodides with anodically produced iodine and alkylate the cathodically anionized CH acids. Reduction in the presence of alkyl halides yield the corresponding products[424b]. The cyanomethyl anion reacts with benzaldehyde and phenyl ketones to give phenylated-propionitriles and -glutaronitriles[425]. Esters and amides react analogously[426]. While allylphosphonium salts are mainly cleaved by direct reduction with a cathodically produced base such as the radical anion of 9-(dicyanovinylidene)fluorene, they can be deprotonated to ylides and react with carbonyl compounds to form polyenes[367a]. 2,2′-Di-*tert*-butylazobenzene and tetrabutyl ethylenetetracarboxylate are favorable probases which, when reduced cathodically to dianions, deprotonate weak CH acids. Thus, it has been possible to carboxylate ethyl phenylacetate and 9-phenylfluorene with $CO_2$ in high yields. The dianions are substantially protected against the attack of the electrophile by steric hindrance (*tert*-butyl and *n*-butyl groups), and the protonated bases can be regenerated to the probase by aerial oxidation or anodically[427]. With the above probases, for example, diglycolic acid N-methylimide has been carboxylated in 85—88% yield to *O*-carboxymethyltartronic acid, a potential detergent[428].

## 5. Final Remarks

Distinct *advantages* can be seen if electrochemical methods of forming CC bonds are compared with the chemical methods. The reactivity of a building block for synthesis can be changed without altering its functionality only by the transfer of electrons, which decreases the number of reaction steps. Polyfunctional compounds can be transformed potential-selectively. Scaling-up the reaction is usually no problem. On the other hand, there are *disadvantages* that must be taken into account and for which long-term solutions must be found. In electrolysis, the substrate frequently reacts with the product formed by its *umpolung*, which makes selective couplings to unsymmetric compounds difficult. The required conductivity demands polar solvents whose proton activity, electrophilicity, and nucleophilicity can lead to difficulties in the case of reactive anionic or cationic intermediates. Transformations at low temperatures, which, particularly with organometallic reactions can lead to remarkable selectivity, are usually possible in preparative electrolyses only at temperatures down to −50 °C. Short reaction times and therefore reduced non-electrochemical competing reactions are in principle possible in new types of cells; likewise, passivation can be effectively suppressed. Here too, however, the practical solution may raise problems in individual cases.

*The author's own work described here was made possible by the assistance of committed co-workers and the effective support of the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Arbeitsgemeinschaft Industrieller Forschungsvereinigungen, to all of whom thanks are gratefully extended.*

# Transition Metal Thiometalates: Properties and Significance in Complex and Bioinorganic Chemistry

**By Achim Müller, Ekkehard Diemann, Rainer Jostes, and Hartmut Bögge**[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

In their highest oxidation states the early transition metals V, Nb, Ta, Mo, W, and Re form tetrahedral, strongly colored thioanions endowed with some remarkable properties. Thiometalates can be formed by solid-state reactions or in solution from the oxometalates. Polythiometalates with mixed valences can be produced by new types of intramolecular condensation-redox reactions from thioanions. The metal-sulfur bonds can react either nucleophilically or electrophilically, and in the case of the Mo—S bonds this is of biochemical interest. It is important to mention the applications of thiometalates as ligands in complex chemistry (generation of multi-metal complexes, versatile coordination behavior, unique electronic properties of the ligands), in which thiometalato complexes with a variety of electron populations can exist because of the marked electron delocalization. Apart from this, $MoS_4^{2-}$ has a significance in bioinorganic problems, *e.g.* the nitrogenase problem and Cu—Mo antagonism.

## 1. Introduction

On account of their range of colors, the thioanions of the early transition metals have long been of interest to the chemist. For example, at the beginning of nineteenth century *Berzelius*[1] investigated their formation by passing $H_2S$ into aqueous solutions of $MoO_4^{2-}$ or $WO_4^{2-}$. However, their true composition was not established until the turn of the century. Both the thiometalate and the selenometalate ions formed from V, Nb, Ta, Mo, W, and Re in their highest oxidation states exhibit interesting properties. Anions of nearly any color can be produced by varying the chalcogen. The reactivities of the thiometalates and their application in complex chemistry are especially interesting, since they display unique ligand properties. For example, these anions can be used to produce multimetal complexes (heterothioanions), which are either interesting from a structural point of view, or have unusual electronic properties. Some of the complexes comprise four-membered metal-sulfur ring systems $M'S_2M$ with very different formal valences of the M and M′ atoms and metal-metal interactions. Moreover, poly(thiometalates) with mixed valences can be produced from the thiometalates by new types of condensation-redox reactions. In addition, the thiomolybdate and thiotungstate anions are currently of interest since they play a part in certain problems in the domains of bioinorganic chemistry (cf. the existence of polymetallic centers), nutrition physiology, and veterinary medicine. (Several years ago we had already indicated the possible relevance of the Fe thiometalato complexes to the nitrogenase problem.) In the present article we shall review the chemistry and bioinorganic chemistry of certain thiometalates which we have investigated systematically (preparation, reactions, and electronic structure) and introduced as ligands in complex chemistry.

## 2. Discrete Thiometalate Ions

### 2.1. Formation of Thiometalate Ions in Solution and Preparation of the Salts

Table 1 shows the known transition metal thioanions with a $d^0$ configuration of the central atom, and the salts that can be prepared easily from them, together with some characteristic data. The corresponding selenoanions are also shown, since they are important for understanding the electronic properties.

The chalcogenometalates are prepared either by reactions in the solid state from the constituent elements themselves (*e.g.* $K_3VS_4$[45] or $Tl_3MX_4$ [M = V, Nb, Ta; X = S, Se[10]]), or by the reaction of $H_2S$ (or $H_2Se$) with an aqueous solution of the corresponding oxometalate. Only the solid-state reaction is effective when the oxometalate in question cannot exist in solution, or only in a very strongly alkaline medium (except in the isolation of $NbO_2S_2^{3-}$ with organic cations[46]). Most of the known chalcogenometalates have only been isolated in pure form within the last fifteen years (*e.g.* the salts of the anions $MoOS_3^{2-}$ [21], $WOS_3^{2-}$ [21], $MoO_3S^{2-}$ [14a], and $ReS_4^-$ [42] and nearly all the Se compounds) or detected in solution (Table 1). The pre-

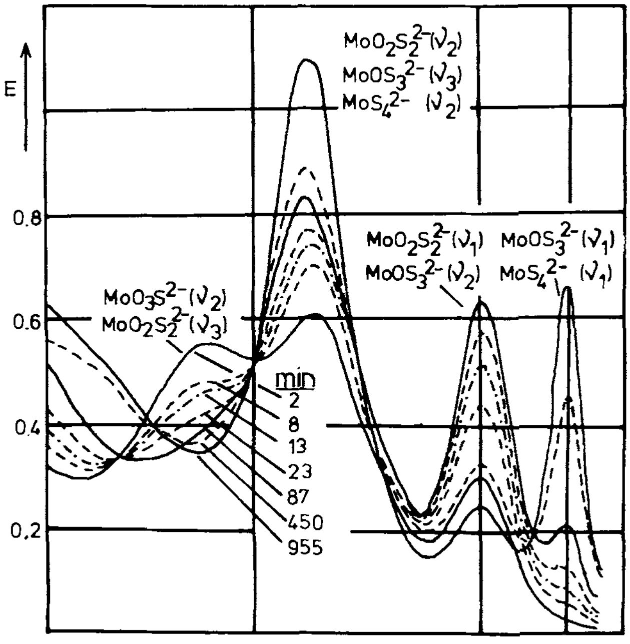

Fig. 1. Electronic absorption spectra of the reaction products from $MoO_4^{2-}$ and $H_2S$ in aqueous solution, as a function of time.

Table 1: Discrete thio- and seleno-anions of V, Nb, Ta, Mo, W, and Re.

| Anion or comp. | Color in solution | VIS/UV [$10^3$ cm$^{-1}$] [c] | Preparation of M'salt from solution M' | IR/Ra [cm$^{-1}$] [b] | Typical M—S(Se) bond length (average) [Å] |
|---|---|---|---|---|---|

[a] Reflectance, in $MgSO_4$. [b] Band maxima sequence: $\nu_1(A_1)$, $\nu_2(E)$, $\nu_3(F_2)$, $\nu_4(F_2)$ (in some solid state spectra $\nu_2$ and $\nu_4$ do not coincide [76]). [c] In brackets values of log $\varepsilon$ for $\nu_1$ [44]. [d] Tl salt. [e] *J. Lapasset, N. Chezeau, P. Belougne,* Acta Crystallogr. *B 32,* 3087 (1976). [f] The deviations of the mean bond lengths in salts with other cations such as $Cs^+$, $PPh_4^+$, and guanidinium cannot be significantly interpreted (structure investigations see [24]).

paration of the selenometalates, and particularly of the mixed thioselenometalates, is difficult (*inter alia* because of their high sensitivity to $O_2$).

The salts with organic cations are important, since they can be used for the synthesis of multimetal complexes in organic solvents. Most of them can be obtained simply from aqueous solutions of their alkali metal salts. While compounds with $Tl^+$ ions can still be regarded as salts[47], in copper compounds such as $NH_4Cu(MoS_4)$ the Cu—S interaction is so strong that the thiometalate ions are no longer isolated (cf. Section 4).

Since all the chalcogenometalates have strong and characteristic absorption bands in the UV/VIS region, the reactions in which they are formed and decomposed can be readily followed by spectrophotometric methods (Fig. 1)[48-51] (see also in Table 1 the literature cited concerning anions that could only be detected in solution). When hydrogen sulfide is passed into an aqueous solution of an oxometalate the electronic spectrum changes, the bands of all the species $MO_{4-n}S_n^{m-}$ (n = 1—4; M = V, Mo, W, Re) appearing in succession. From the existence of isobestic points it follows that almost only two species can coexist in the solution at any one time[50]. Thus, to isolate a chalcogenometalate a cation that will form a sparingly soluble salt with only one of the two anionic species must be added.

The rate of formation of thiometalates depends markedly on the nature of the central atom; the greater the electron density on the oxygen the higher the rate (see Section 2.4). Thus, thiomolybdates form more rapidly than thiotungstates[51]. The rate falls markedly as the sulfur content of the anion (with the same central atom) is increased[51]. It is therefore difficult to isolate the monothiomolybdate and the monothiotungstate. (For example, various workers have attempted in vain to produce a monothiomolybdate[14a]. The contamination of $MoO_3S^{2-}$ by other molybdates can, for instance, clearly be detected by determining the $^{95}$Mo-NMR spectra in water[14b]).

The kinetics of thiomolybdate formation were recently investigated quantitatively by *Sykes*[52,53], using the assumption that $SH^-$ was the reacting agent. We had already concluded on the basis of qualitative observations that this could not be the doubly negative ion $S^{2-}$ but that $H_2S$ is probably also involved[51]. Equilibrium investigations of the systems $MO_4^{2-}/H_2X$ (M = Mo, W; X = S, Se) have also been carried out[54]. The formation of the $MoS_4^{2-}$ ion in solution can also be utilized for the qualitative and quantitative determination of Mo[55] (for analytical applications cf. also [81]).

Besides $MoS_4^{2-}$ there are two other interesting sulfur-rich thiomolybdates (Fig. 2): $Mo_2S_{12}^{2-}$[56] (the only known complex with exclusively $(S_2)^{2-}$ ligands) and $Mo_3S_{13}^{2-}$[57] (the first discrete metal-sulfur cluster). Both complexes can be obtained in almost quantitative yields[58] by reducing $MoO_4^{2-}$ with ammonium polysulfide (which should contain a high proportion of $(S_2)^{2-}$), and have been characterized comprehensively by physical measurements and structural analyses[59,60]. The formation of these thiomolybdates, as well as of the complexes $[Mo_4(NO)_4S_{13}]^{4-}$ and $[Mo_4(NO)_4S_{12}O]^{2-}$ in $H_2O$ (see Section 2.5) bears witness to the high affinity of Mo (in various valence states) for S, and particularly for $(S_2)^{2-}$ (see [58,59]). $(NH_4)_2Mo_2S_{12}\cdot 2H_2O$ contains enantiomeric complex anions[61] (ideal symmetry $D_2$, crystallographic $C_2$). Thermal decomposition of $(NH_4)_2Mo_3S_{13}\cdot nH_2O$ (n = 0—2) yields $MoS_2$[62a], and when $Cs_2Mo_2S_{12}$ is thermally decomposed $S_2$ is formed even at relatively low temperatures in a reductive elimination step[62b].

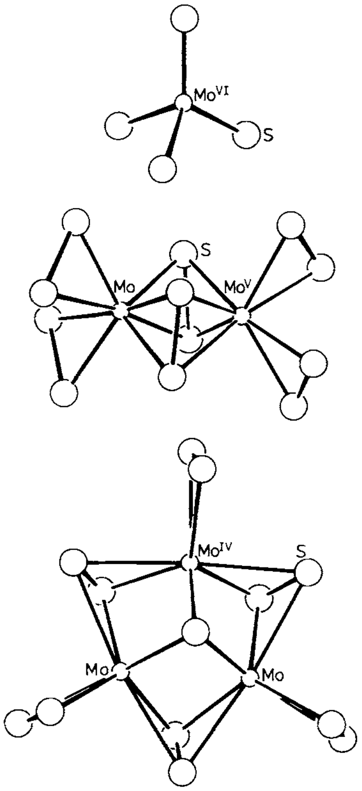

Fig. 2. Thioanions of molybdenum: $MoS_4^{2-}$, $Mo_2S_{12}^{2-}$, and $Mo_3S_{13}^{2-}$.

## 2.2. Behavior in Solution

Thiometalates are not very stable in aqueous solution, especially at low pH. Their decomposition may either be caused by hydrolysis to oxometalates, by intramolecular redox processes (Section 3), or by their marked tendency to form sulfides. With molybdates and tungstates the stability decreases with increasing oxygen content and increasing electron density on the ligands. When they decompose in acid media, binary sulfides (or with selenometalates, selenides) such as $MoS_3$[63] are formed. The decomposition kinetics of the $MoS_4^{2-}$ ion at low pH have been investigated semiquantitatively[64,65], as has its hydrolysis in neutral and weakly alkaline solutions[66]; in this range, the hydrolysis is found to be independent of the pH. No intermediate hydrolysis products, for example mixed oxothiometalates, are detected in dilute solutions[66]. $^{95}$Mo-NMR spectra[67,68] of concentrated solutions of $MoO_2S_2^{2-}$, however, also show signals due to $MoO_3S^{2-}$ and $MoOS_3^{2-}$[14b] (in ref.[67] the signal of $MoO_3S^{2-}$ had erroneously been assigned to that of $MoS_4^{2-}$[14b]).

A protonated species, $(PPh_4)[WS_3(SH)]$ (the only known hydrothio salt), can be isolated from an aqueous solution of $WS_4^{2-}$[69]. $[WS_3(SH)]^-$ reacts in solution with bases such as $N(CH_3)_3$ to give $WS_4^{2-}$. In nonaqueous systems, for example dimethyl ether/HCl, the acids corresponding to the ions are probably present[70,71]. This can be utilized, for example, for the extraction of tungsten[72].

### 2.3. Properties of Solids with Discrete Thiometalate Ions

Most of the alkali metal and ammonium thiomolybdates and thiotungstates crystallize in the $\beta$-$K_2SO_4$ type[73,74a] (cf. Table 1) (except for the monothio salts, salts of the type $A_3(MOS_3)Cl$[74b] (A = K, Rb) and $(NH_4)_2MO_2S_2$ (M = Mo, W), in which strong hydrogen bonds are present[75]). Little is known about the structures of salts with other cations, *e.g.* $Tl^+$[10]. In the structures of solids containing both sulfur and selenium in the anion the respective positions of the two elements are occupied statistically[74a]. A review has been published[76] on the vibrational spectra of solids, which yield information about the cation-anion interactions.

On heating, the ammonium salts of the tetrachalcogenomolybdates and -tungstates decompose to give $NH_3$, $H_2S$ (or $H_2Se$), and the corresponding X-ray amorphous trisulfide (or triselenide) (see [12,77-79a] and the literature cited therein), which *via* release of one mole of the chalcogen forms the dichalcogenide at higher temperatures[78,79a]. From $(NH_4)_3VS_4$ one can obtain the amorphous $V_2S_5$, whose structure we recently investigated[79b]. The decomposition reactions of $(NH_4)_2MoO_2S_2$ and $(NH_4)_2WO_2S_2$ are complex, and the original assumption that $MoOS_2$ is formed as an independent compound[80] has not yet been clearly confirmed[77].

The alkali metal and ammonium salts are soluble in water (the solubility decreasing from $Na^+$ to $Cs^+$), and the $XR_4^+$ salts (X = N, P, As; R = aryl or alkyl) are soluble in various organic solvents. The ammonium salts are relatively unstable even at room temperature *(vide supra).*

### 2.4. Spectroscopic Investigations and Chemical Bonding

Chalcogenometalate ions are distinguished by characteristic high-intensity absorption bands in the UV/VIS region (see Table 1); they can also be traced by IR and Raman spectroscopy (characteristic stretching vibrations: $\nu$(MO): $\approx 800-1000$, $\nu$(MS): $\approx 400-500$, $\nu$(MSe): $\approx 250-350$ $cm^{-1}$; for reasons of space, Table 1 shows only the frequencies for the high-symmetry ions with $T_d$ symmetry). Total assignments and normal coordinate analyses are available for many of the species[81] (also with recourse of isotope shifts[81], as in the case of $^{92/100}MoO_2S_2^{2-}$[19], $^{92/100}MoOS_3^{2-}$[82], or $^{92/100}MoS_4^{2-}$[83]). The vibrational spectra of transition metal-chalcogen compounds have been reported in a review[81].

The first indication of the type of bonding is given by the metal-sulfur bond lengths (Table 1), which are significantly shorter than the sum of the ionic or covalent radii, and thus suggest a bond order $>1$ *i.e.* the involvement of $\pi$ bonds. The MoS bond length in $MoS_4^{2-}$ or $MoOS_3^{2-}$ lies between those for a double and single bonds. (Both bond types are present in the $Mo_2S_4$ moiety; cf. Fig. 13).

The involvement of $\pi$-bonding MO's is also demonstrated by various physical measurements and by MO-calculations [for the $MS_4^{m-}$ ions with $T_d$ symmetry from the stretching-force constants[81] (some of which have been determined fairly reliably[83] from the vibrational spectra of isotopically substituted compounds), from the Raman intensities of $\nu_1(A_1)$[85], from MO-calculations[86,87], and from the oscillator strengths of the $\nu_1(t_1 \rightarrow 2e)$ electronic transitions[88]]. Both calculations and empirical findings, *e.g.* the linear relationship between the energy of the longest-wavelength electronic transition $\nu_1$ and the stretching force constants[89], demonstrate that there is a stabilization of the strongly $\pi$-bonding MO 1e (see Fig. 3). The MO-coefficients for 1e and 2e MO's can be determined from the measured oscillator strengths (2e has mainly metal AO character)[88]. The proportion of $\pi$-contributions in the respective metal-sulfur bonds of analogous species increases in the sequence V < Mo < W < Re. It is also appreciably higher than in the thioanions of the main group elements such as $PS_4^{3-}$, $AsS_4^{3-}$, and $SbS_4^{3-}$[84].

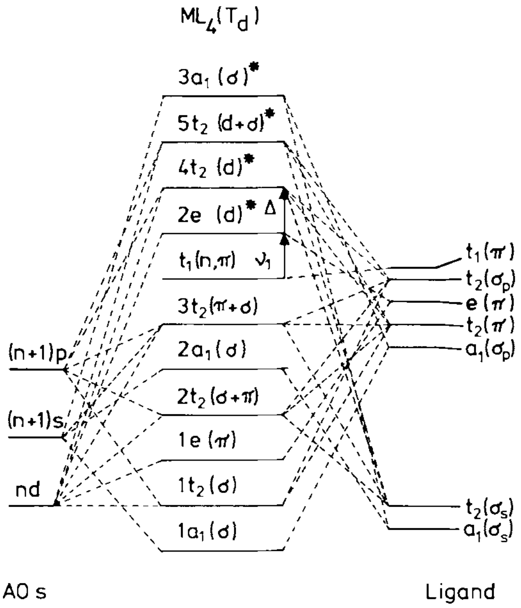

Fig. 3. Simplified MO scheme for $MS_4^{m-}$ ions with $T_d$ symmetry.

The band maxima of the allowed electronic transitions are shown in Table 1. Unambiguous assignments are only possible for the longest-wavelength bands of ions with $T_d$ and $C_{3v}$ symmetry[44]. However, from our own investigations on a large number of anions (Table 1)[44] all bands can be assigned qualitatively to metal reduction transitions (from MO's with predominantly ligand character to ones essentially localized on the central atom). Empirically, this follows *e.g.* from the practically linear relationship between the transition energy and the optical electronegativity of the central atom (for a given ligand) or of the ligand (for a given central atom) (Fig. 4). For ions with $T_d$ symmetry the assignment $t_1 \rightarrow 2e$ (Fig. 3) for the longest-wavelength transition is, furthermore, clearly demonstrable by means of MCD measurements[90]. (In the case of the tetrathiometalates well-defined MCD spectra whose interpretation is beyond question can be obtained: see Fig. 5;

MCD = magnetic circular dichroism). On the basis of empirical considerations[90] and of our investigations of the influence of various coordination centers on the UV/VIS bands of $MoS_4^{2-}$, the assignments $\nu_2 \triangleq 3t_2 \rightarrow 2e$ and $\nu_3 \triangleq t_1 \rightarrow 4t_2$ are probable (see Section 5.2). The positions of the metal reduction bands can also be related to the redox behavior (see Sections 2.5 and 3).

Photoelectron spectra[47,91] have also been used to characterize the electronic structure of these compounds. (For

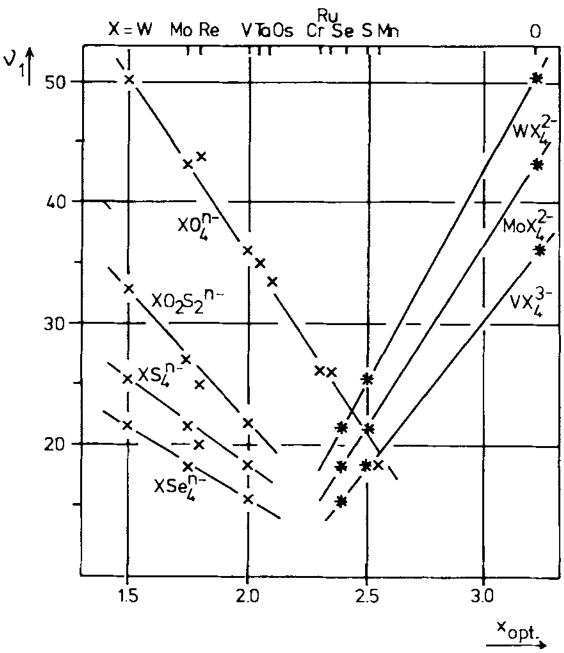

Fig. 4. $\nu_1(t_1 \rightarrow 2e)$ transition energies of species with $T_d$ symmetry, (together with corresponding data for the dithiometalates) as a function of the optical electronegativity of the central atom or the ligands O, S, and Se ($\nu_1$ in $10^3$ $cm^{-1}$).

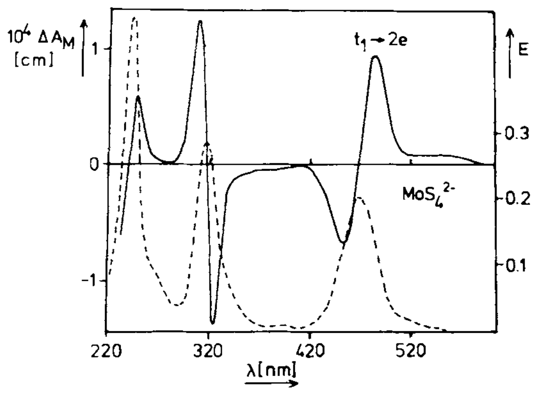

Fig. 5. MCD spectrum (broken line: electronic absorption spectrum) of the $MoS_4^{2-}$ ion.

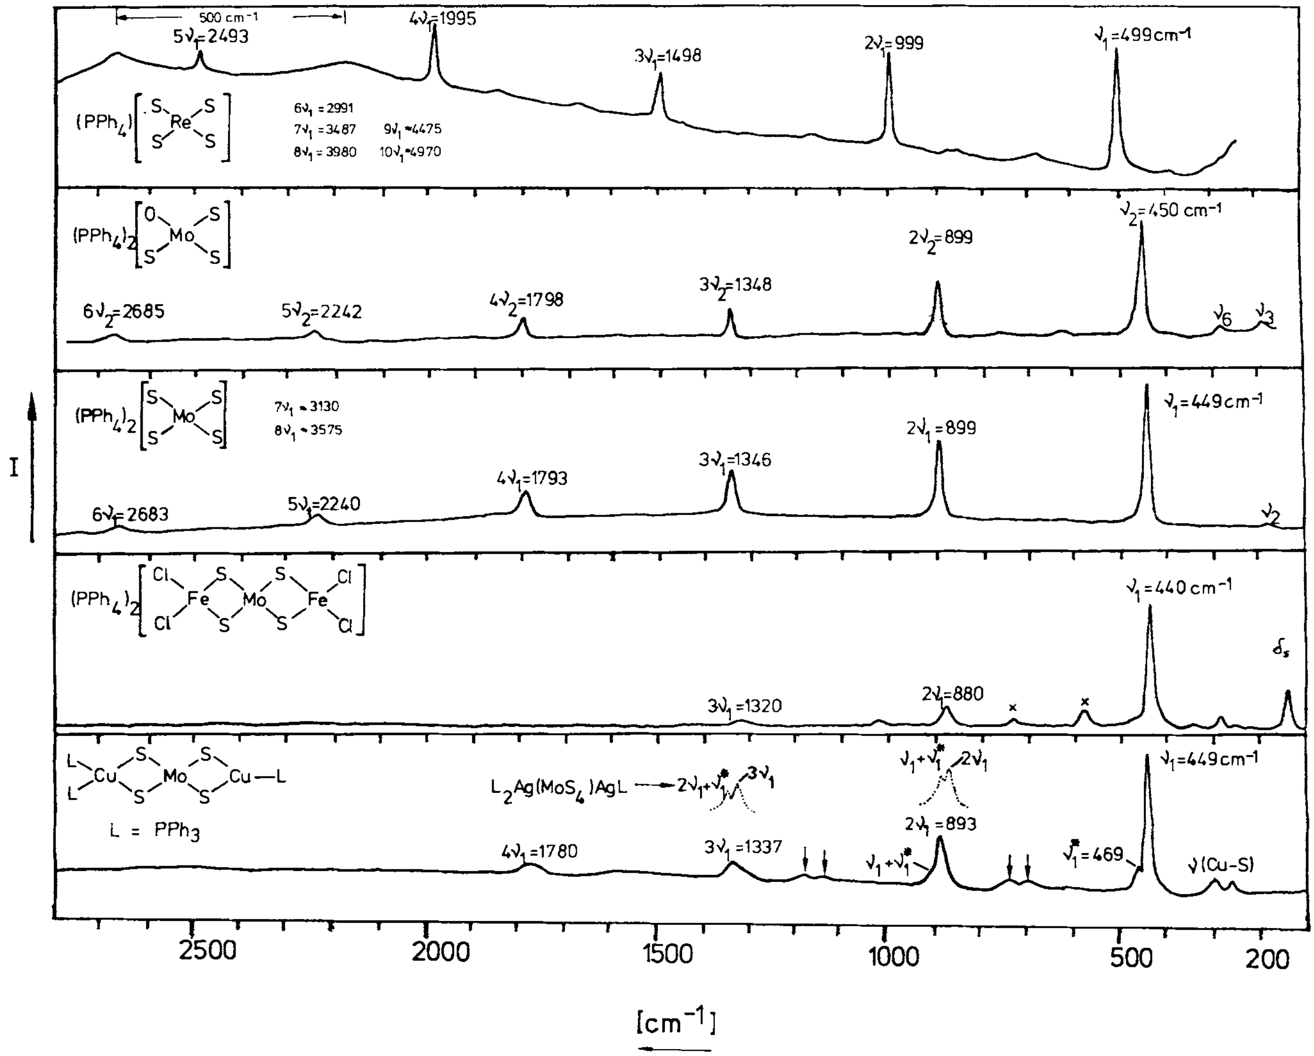

Fig. 6. Resonance Raman spectra of $MoS_4^{2-}$, $MoOS_3^{2-}$, and $ReS_4^-$ and of some thiomolybdato complexes with doubly-bridging $MoS_4^{2-}$ ligands ↓: combination bands of $n\nu_s(MoS)$ with $\nu(CuS)$; × : further combination bands of stretching and bending vibrations [94, 155].

a more complete discussion of the spectra, the electronic structures, and the higher-energy absorption bands, see [44].)

The longest-wavelength bands of the $MOX_3^{2-}$ species $MoOS_3^{2-}$ and $WOSe_3^{2-}$ can be unambiguously assigned to $\pi(X)\rightarrow d(M)$ (or $a_2\rightarrow e$) transitions, since in the resonance Raman spectra (excitation line within the band in question) only the intensities of the lines corresponding to vibrations in corresponding $MX_3$ chromophores are enhanced[92,93,94] (Fig. 6, showing a much better spectrum than the earlier reported one). Resonance Raman spectra could also be obtained for $MoS_4^{2-}$[81,94] (Fig. 6; a particularly fine example, also of biochemical interest) and for $VS_4^{3-}$[94,95], $MoSe_4^{2-}$, $WSe_4^{2-}$[94,96], and $ReS_4^-$[94] (Fig. 6). Particularly informative spectra are obtained from $PPh_4^+$ salts (or those with other bulky organic cations with small anion-anion interaction), since the number of observed overtones and combination tones is particularly large[94] *e.g.* in the spectra of the corresponding compounds with $ReS_4^-$ and $MoS_4^{2-}$, where the series of combination tones $\nu_2+n\nu_1$ could be observed up to $n=7$ and 4, respectively. In the spectrum of $ReS_4^-$ the fluorescence band of the $t_1\rightarrow 2e$ transition is clearly perceptible (*ca.* 18000 $cm^{-1}$ with $\nu_1(A_1)\approx 500$ $cm^{-1}$), together with a non-uniform intensity pattern of the bands of the higher harmonics (to some extent comparable with a resonance fluorescence spectrum). The anharmonicity of the $\nu_1(A_1)$ vibration of the thioanions is clearly smaller than in the case of the oxometalates such as $MnO_4^-$ (see [81]). (Anharmonicity constants: $x_{11}(MoS_4^{2-})=-0.4\pm0.3$;
$x_{11}(ReS_4^-)=-0.3\pm0.2$ $cm^{-1}$[94]).

### 2.5. Reactions

M$\overset{\cdots}{=}$S groups with $\pi$-bond contributions (*e.g.* in the thiometalates) can react either with nucleophiles *(Nu)* or electrophiles *(E)*:

$$\mathrm{Mo}^{r}\overset{\cdots}{=}\mathrm{S} + Nu \rightarrow \mathrm{Mo}^{r-2} + Nu\mathrm{S} \qquad \text{(a)}$$

(abstraction of S/two-electron reduction)

$$\mathrm{Mo}^{r}\overset{\cdots}{=}\mathrm{S} + E \rightarrow \mathrm{Mo}^{r} + E\mathrm{S}^{2-} \qquad \text{(b)}$$

(abstraction of $S^{2-}$).

A further important type of reaction corresponds to an intramolecular redox process:

$$\mathrm{Mo}^{r}(\mathrm{S}^{2-}) \rightarrow \mathrm{Mo}^{r-2}(\mathrm{S}^{0}) \qquad \text{(c)}$$

or

$$\mathrm{Mo}^{r}(\mathrm{S}^{2-})_2 \rightarrow \mathrm{Mo}^{r-2}(\mathrm{S}_2^{2-}) \qquad \text{(d)}$$

The formation of $(S_2)^{2-}$ can formally occur *via* the intramolecular reaction of $(S^0)$ (produced according to eq. (c)) with $S^{2-}$ (Section 3). Until recently, the fact that this type of reaction is of decisive importance for molybdenum-sulfur chemistry (and probably in various catalytic and biochemical problems as well) had been overlooked. (For the formation of polysulfide ligands *vide infra.*) Electron-transfer reactions in $Mo(SR)_2$ groups with partial disulfide formation are probably significant in biochemistry[97a]. For type (a) a number of reactions with $Nu=CN^-$ are known and these are significant for problems in the bioinorganic[97a] and prebiotic[98] fields (*i.e.* in connection with the evolution of primitive Mo enzymes). For example, the following type of reaction has a relevance for the deactivation of xanthine oxidase by $CN^-$[99]:

$$\mathrm{Mo}^{r}{=}\mathrm{S} + \mathrm{CN}^- \rightarrow \mathrm{Mo}^{r-2} + \mathrm{NCS}^- \qquad \text{(e)}$$

*i.e.* a sulfur-atom-transfer reaction with a two-electron reduction of the central atom.

$MoO_3S^{2-}$ and $MoO_2S_2^{2-}$ react with $CN^-$ by two- or four-electron reductions to form cyano-complexes, which no longer contain any sulfur, and $SCN^-$[100,101]. In general, a briding sulfide ligand ($\mu_2$ or $\mu_3$) is better protected against attack by $CN^-$. This can be demonstrated with the $Mo_3S_{13}^{2-}$ "thiomolybdate", which reacts with $CN^-$ to form $[Mo_3S_4(CN)_9]^{5-}$, where the triangular $Mo_3S_4$ system with sulfur bridges between the Mo atoms and the apical sulfur atom are not attacked[102], and also by the reaction of $Mo_2S_{12}^{2-}$ to $[Mo_2S_2(CN)_8]^{6-}$[103]. In this last process a central $Mo_2S_4^{2+}$ unit of an intermediate product may react according to reaction type (a)[103].

The reactions of oxoanions with $H_2S$ in the presence of cyanide may also proceed according to type (a) (though up to now, thiometalate ions as intermediate products have not been detected). These reactions are interesting because they lead either to new types of $\mu_n$-thio(cyano) complexes or to cyano complexes whose preparation is otherwise difficult.

The reaction of $VO_4^{3-}$ with $H_2S$[104] in the presence of cyanide leads to $[V(CN)_7]^{4-}$[105-107]; if the system also contains hydroxylamine, then $[V(NO)(CN)_6]^{4-}$ will be produced[105,108,109]. $MoO_4^{2-}$ reacts with $H_2S$ and $CN^-$ to give $[Mo_2S_2(CN)_8]^{6-}$[100,110], $[(CN)_6MoSMo(CN)_6]^{6-}$[111] (Fig.

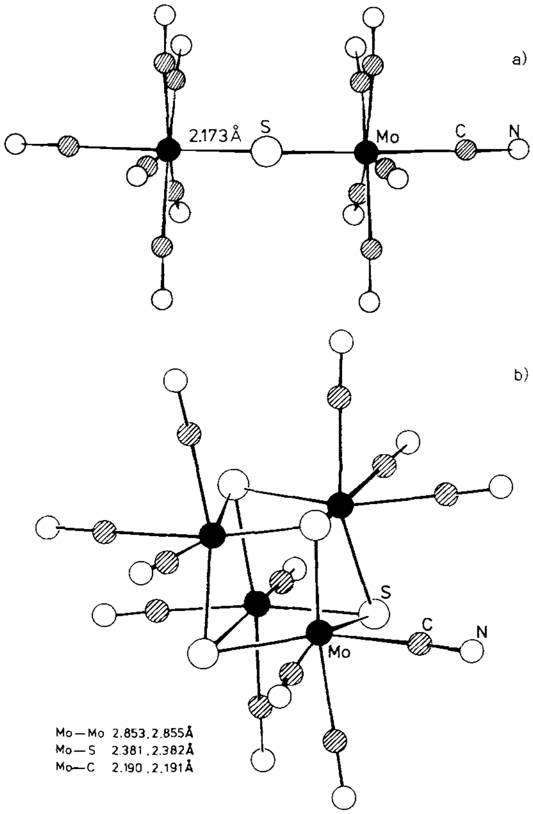

Fig. 7. Structure of a) $[(CN)_6MoSMo(CN)_6]^{6-}$ [111, 114] and of b) $[Mo_4S_4(CN)_{12}]^{8-}$ [223] with cubane-like structure.

7a), $[Mo_4S_4(CN)_{12}]^{8-}$[223] (Fig. 7b), but also to $[Mo(CN)_7]^{5-}$[100]. Under suitable conditions $ReO_4^-$ or $WO_4^{2-}$ form $[Re_2S_2(CN)_8]^{4-}$[112] and probably a cyano(thiocyanato)tungstate, respectively[113].

It is interesting that in $[(CN)_6MoSMo(CN)_6]^{6-}$ there is a nearly linear MoSMo bridge with very short bond lengths (Fig. 7a)[114]. Our own MO-calculations on this complex show that there are π-MO's delocalized over the three centers. The remarkable π(S)→d(Mo) donation induces a decrease of electron density on the sulfur and are thus responsible for an unusual CT transition Mo→S (band at 27 100 $cm^{-1}$).

The thio(cyano)metalates are regarded as a key species in the evolution of metal enzymes[98]. For example, the last of the above mentioned complexes, first reported by us, is also formed when freshly precipitated $MoS_2$ is treated with $CN^-$[98,101]. It is important in this connection that in cyanomolybdates the $CN^-$ can be easily substituted by sulfur-containing ligands[210].

Thus, while with vanadium the preferred process is abstraction of sulfur, in the case of Mo the high sulfur affinity leads mainly to the formation of complexes that still include bridging $S^{2-}$ ligands. In this connection we should also mention the remarkable species $[Mo_4(NO)_4S_{13}]^{4-}$[59,115a] and $[Mo_4(NO)_4S_{12}O]^{2-}$[116] (Fig. 8), produced using similar conditions as $[V(NO)(CN)_6]^{4-}$.

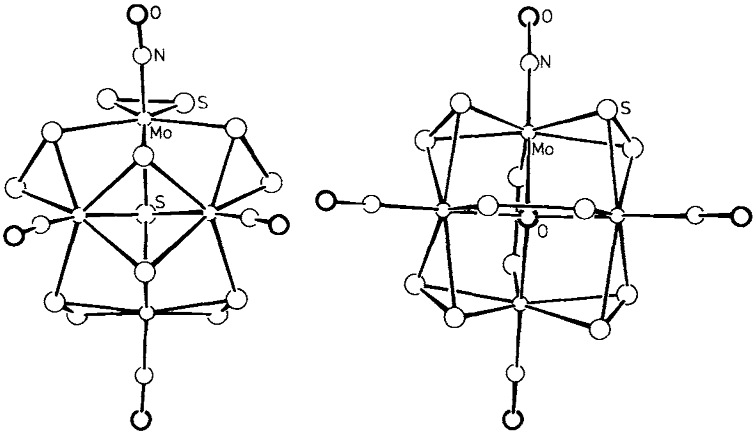

Fig. 8. Structure of $[Mo_4(NO)_4S_{13}]^{4-}$ and $[Mo_4(NO)_4S_{12}O]^{2-}$, two unusual polynuclear complexes with four different types of coordinated $S_2^{2-}$ ligands [59, 115a, 116].

The complexity of the mode of formation of these compounds mentioned is well known, and certain proposals have been suggested for the system $MoO_4^{2-}/H_2S/CN^-$[114].

The reaction of $MoS_4^{2-}$ with $H^+$ to give $MoS_3$ formally takes place according to type (b). This reaction type (*i.e.* $E{=}S_x$) also seems relevant to the reaction of $MoS_4^{2-}$[115b] or $MoOS_3^{2-}$[115c] with sulfur to form $S_4^{2-}$ ligands. In the formation of $[Mo^{IV}O(S_4)_2]^{2-}$ (see Fig. 12) from $MoOS_3^{2-}$ and $S_8$, the reduction probably takes place according to eq. (c) or (d) with r = 6+. The possible intermediate product $\{OMo^{IV}(S_2^{2-})S^{2-}\}^{2-}$ (or $\{OMo^{IV}S^0(S^{2-})_2\}^{2-}$) may react with the sulfur *via* ring expansion (or ring formation). $[Mo_2O_2S_2(S_4)_2]^{2-}$[115c] is also formed as a by-product (or from $[MoO(S_4)_2]^{2-}$) (cf. Fig. 12). In the interpretation of this it is important in this context that in solution $MoOS_3^{2-}$ "decomposes" rapidly already at room temperature, even without the addition of sulfur, in a process involving intramolecular condensation-redox process[115c]. In this case binuclear complexes of the type $[Mo_2X_2S_2(S_2)_2]^{2-}$ (with $X_{term}$) are formed (probably *via* the intermediates mentioned) (see Fig. 12) with the X-positions occupied randomly by O and S ($PPh_4^+$ salts characterized by crystal structure analysis[115c]), as well as trinuclear complexes of the type $M_3OX_8^{2-}$ (see Fig. 9)[115c].

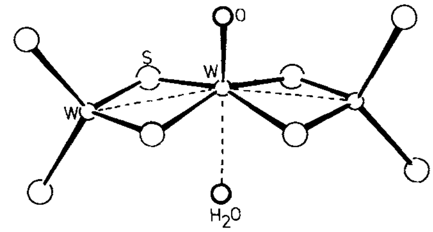

Fig. 9. Structure of $[W_3OS_8(H_2O)]^{2-}$) ($Cs^+$ salt [120]).

## 3. Formation of Poly(thiometalates); Chalcogenometalates with Mixed Valences

While a great deal of research has been done on condensations of oxometalates in aqueous solutions, there has been little such work on thiometalates (cf. [117]). In the interpretation of the results, those authors who have approached the subject have not considered the fact that intramolecular redox processes may take place in addition to the condensation reactions[118,119]. The condensation reactions subsequent to protonation of thiometalate ions take place at a lower pH than that of the oxoanions, since the proton affinity of S is appreciably lower than that of O. Investigations of the condensation behavior of thiometalate ions are made more difficult, since various complex decomposition processes are also involved. For example, no definite condensation products has yet been isolated from an aqueous solution containing $MoS_4^{2-}$.

The behavior of $WS_4^{2-}$ is again different from that of $MoS_4^{2-}$ and of the oxothiometalates, since protonation only takes place at relatively low pH values (the proton affinity of $WS_4^{2-}$ is lower than that of $MoS_4^{2-}$, since the electron density on the sulfur atoms in $MoS_4^{2-}$ is larger; see Section 2.4). When an aqueous $WS_4^{2-}$ solution is acidified, condensed species are formed besides $[(HS)WS_3]^-$ (Section 2.2). $[W_3OS_8(H_2O)]^{2-}$ or $W_3OS_8^{2-}$ ions (Fig. 9) (a species with mixed valences) can be precipitated from the solution by various cations, such as $Cs^+$[120], $PPh_4^+$[121], and $NMe_4^+$[118,122,225].

$[W_3OS_8(H_2O)]^{2-}$, which can also be formulated as $W_3OS_8^{2-}$[212] since the very weakly bound $H_2O$ can also be regarded as water of crystallization, formally contains $2\,W^{VI}$ and $1\,W^{IV}$, in common with $W_3S_9^{2-}$[123], and is possibly formed as follows:

$$WS_4^{2-} + 2H_2O \rightarrow WO_2S_2^{2-} + 2H_2S$$

$$WO_2S_2^{2-} + H^+ \xrightarrow{aq} OW(OH)S_2(aq)^-$$

$$OW^{VI}(OH)S_2(aq)^- \rightarrow OW^{IV}(OH)(S_2)(aq)^- \qquad \text{(f)}$$

$$OW^{IV}(OH)(S_2)(aq)^- + 2WS_4^{2-} \rightarrow [OW(WS_4)_2(H_2O)]^{2-} + OH^- + (S_2)^{2-}$$

The condensation takes place after partial hydrolysis. The pure sulfur compound $W_3S_9^{2-}$ (Fig. 10) probably cannot be obtained directly from aqueous solution but, *e.g.* quite simply by heating a solution of $(NH_4)_2WS_4$ in an organic solvent[124]. The homologous species $W_4S_{12}^{2-}$ (Fig. 11) was also recently isolated[125]; this formally contains the central unit $W_2^{V}S_4^{2+}$ and two $W^{VI}S_4^{2-}$ ligands. The "$WS_4^{2-}$ ligands" can be abstracted from $W_3S_9^{2-}$ and $W_4S_{12}^{2-}$ with $FeCl_2$ to give $[Cl_2Fe(WS_4)]^{2-}$[211]. While the $Mo_2^{V}X_2S_2^{2+}$ units (X = O, S) are characteristic species for the chemistry of $Mo^{V}$ (Figs. 12 and 13), little is known as yet about the corresponding W units. $W_3OS_8^{2-}$ can be obtained easily from $W_3S_9^{2-}$ in organic solvents containing a little water[211], and this must be borne in mind in the latter's preparation (by heating $WS_4^{2-}$ in organic solvents). There is a marked tendency for the formation of these trinuclear poly(thiometalate).

EH-SCCC-MO calculations on the new types of polythiometalates $W_3XS_8^{2-}$ (X = O, S) also show that these can be described approximately as coordination compounds of $W^{IV}X^{2+}$ with $WS_4^{2-}$ ligands. An occupied MO is about 50% localized on the central W atom, but owing to the appreciable participation of orbitals of the outer W atom there is a clear metal-metal interaction[126]. After diamagnetic correction for the W centers a weak paramagnetism is found. Correspondingly, there is a metal-metal bond in the central $W_2^{V}S_4^{2+}$ unit of $W_4S_{12}^{2-}$[126].

Mixed oxothiometalates should show a particularly characteristic and marked tendency toward polymerization, because of the appreciably higher proton affinity of oxygen compared to sulfur. For example, $MoO_2S_2^{2-}$ ions are only stable at high pH. In near-neutral aqueous solutions, "decomposition" or condensation takes place quite rapidly with the probable involvement of the following intramolecular redox processes (see Section 2.4):

$$2\,S^{2-} \xrightarrow{\text{ox}} (S_2)^{2-} \qquad \text{(g)}$$

$$Mo^{VI} \xrightarrow{\text{red}} Mo^{IV} \qquad \text{(h)}$$

$$(Mo^{VI} + Mo^{IV} \rightarrow 2\,Mo^{V})$$

Here too, the first step of the reaction should be a protonation of the oxygen atom. This protonation favors both condensation and an intramolecular redox process, since it reduces the effective electron density on the Mo center by decreasing the Mo—O-π bond order, and thus enhances the oxidizing action of the Mo atom. Similar redox-condensation reactions of $MoOS_3^{2-}$ in methanol, which also lead to the formation of polythioanions, are mentioned in Section 2.5.

The $[Mo_2O_2S_2(S_2)_2]^{2-}$ anion (see Fig. 12) has already been isolated from a solution of $MoO_2S_2^{2-}$[127], and in this reaction an $(S_2)^{2-}$ ligand is thus formally generated by oxidation of two $S^{2-}$ ligands (with reduction of Mo). In the presence of other sulfur-containing ligands complexes with the central $Mo_2O_2S_2^{2+}$ unit, such as $Mo_2O_2S_2(dtc)_2$[119], are formed.

In recent years there have been many investigations of $Mo^{V}$ complexes with the central unit $Mo_2X_2S_2^{2+}$ (X = O, S), principally with bio-relevant ligands such as cys-

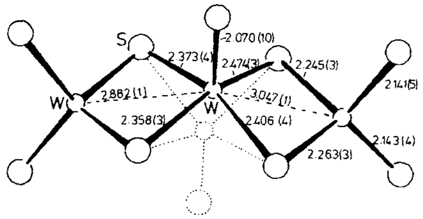

Fig. 10. Structure of $W_3S_9^{2-}$ ($PPh_4^+$ salt) [124] (the central $WS_5$ unit is disordered, the midpoint of the W—W vector lies at the center of symmetry (see [120, 123, 124]).

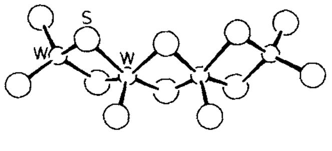

Fig. 11. Structure of $W_4S_{12}^{2-}$ [125].

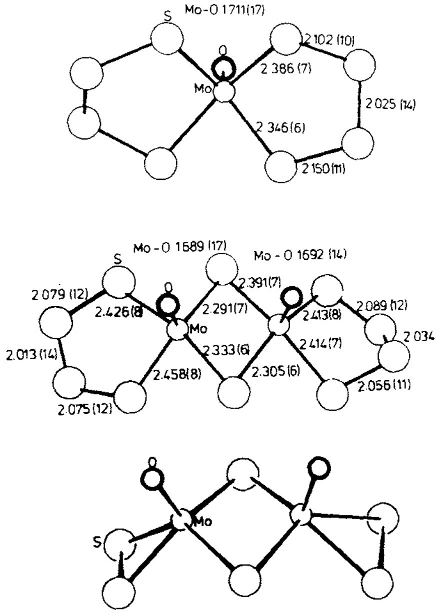

Fig. 12. Species with $S_n^{2-}$ ligands in whose formation from thiomolybdates intramolecular redox processes are involved: $[MoO(S_4)_2]^{2-}$ [115c], $[Mo_2O_2S_2(S_4)_2]^{2-}$ [115c] ($PPh_4^+$ salts), and $[Mo_2O_2S_2(S_2)_2]^{2-}$ [127].

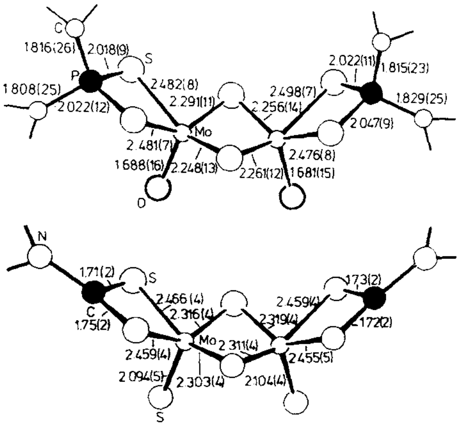

Fig. 13. Structure of $[Mo_2O_2S_2(S_2PPh_2)_2]$ [129b] and $[Mo_2S_4(dtc)_2]$ [129a]; dtc = diethyldithiocarbamate.

teine[128]. The unit, in which X = O, is significant for the chemistry of $Mo^V$ because of its high tendency to be formed. The unit with X = S appears, for example, in the reactions of thiomolybdate $Mo_2S_{12}^{2-}$ with S-bearing ligands such as $dtc^-$[129a] in organic solvents. Figure 13 shows the structure of $Mo_2O_2S_2(S_2PPh_2)_2$[129b] and $Mo_2S_4(dtc)_2$[129a] with the corresponding bond lengths. In the second of these, there are bond lengths characteristic of Mo—S single and Mo—S double bonds, longer and shorter than the bond length in $MoS_4^{2-}$ respectively (Section 2.4).

## 4. Multimetal Complexes with Thiometalate Ligands

Thioanions have remarkable ligand properties, *e.g.* versatile coordination behavior and very low-lying unoccupied orbitals. Thus, the complexes show strong metal-ligand interactions (see [144]). We first described complexes with such ligands about ten years ago[117, 130]. It is worth noting that there are multimetal complexes of this type with a variety of electron populations (see Section 5.2) and with coordinatively unsaturated metal centers *e.g.* $[Fe(WS_4)_2]^{2-}$ (possible catalytic significance). Some of the complexes catalyze the photoreduction of water[213].

The reaction of various divalent transition metal cations with thiometalates in solution (*e.g.* in $H_2O$) takes place as follows:

$$2XR_4^+ + 2MO_{4-n}S_n^{2-} + M' \rightarrow (XR_4)_2[M'(MO_{4-n}S_n)_2] \qquad \text{(i)}$$

M' = Fe, Co, Ni, Pd, Pt, Zn, Cd, Hg; M = Mo, W; n = 2, 3, 4;
X = P, As

leading to the formation of bis(thiometalato) complexes (multi-metal complexes with bidentate ligands), which can be isolated *e.g.* as quaternary phosphonium salts (cf. Table 2, exception: the combination M' = Fe, M = Mo). Spectroscopic investigations show that in solution other species may be present before the precipitation: for example, solutions of $Co^{2+}$ and $WO_{4-n}S_n^{2-}$ (n = 4, 3) in water do not show the characteristic electron absorption spectra of $[Co(WO_{4-n}S_n)_2]^{2-}$ complexes[131] (although they do in organic solvents); from an orange solution of $Fe^{2+}$ and $WS_4^{2-}$ in $H_2O$ a green precipitate of $(PPh_4)_2[Fe(WS_4)_2]$ is obtained.

Table 2: Complexes of the types $[M'(MO_{4-n}S_n)_2]^{m-}$ and $[LM'(MS_4)_n]^{2-}$, and their properties [a], term = terminal, br = bridged.

[a] M = Mo, W; M' = Fe, Co, Ni, Pd, Pt, Cu, Zn, Cd, Hg; n = 2, 3, 4. [b] The assignment of the electronic spectra is only approximate when the M'—L interactions are strong (see text). [c] Possibly a band of type d(M')→L*. [d] *W. E. Newton*, personal communication; *W. E. Newton, A. Müller*, unpublished results. [e] Solid-state reflectance spectra. [f] *A. Müller, M. C. Chakravorti, H. Dornfeld*, Z. Naturforsch. *B 30*, 162 (1975). [g] The spectra given in [192a] for the complexes $[M'(MS_4)_2]^{2-}$ (M' = Ni, Pd, Pt) are not all correct, since some $NEt_4^+$ salts decompose rapidly in solution (*e.g.* $(NEt_4)_2[Ni(MoS_4)_2]$, for which, therefore, the weak longest-wavelength band maxima not given in [192a] are difficult to measure). The band maxima given by us for the spectra in solution agree with those of the solid-state reflectance spectra. [h] Representative for complexes of the type $[X_2Fe(MS_4)]^{2-}$ (see Table 3). [i] $PPh_4^+$ salt. [j] Measured on $NMe_4^+$ salts (see Fig. 23 and text). [k] See also Table 1 (isotope data and normal coordinate analysis: *A. Müller, E. Krickemeyer, W. Jaegermann, Sun Che*, unpublished results). [l] The isotope data relate to the IR frequences; see the corresponding literature. [m] Unless otherwise indicated, the unpublished spectra were measured on $PPh_4^+$ salts in $CH_2Cl_2$ or $CH_3CN$ (often only the main absorption maxima are given). [n] The $PPh_4^+$ salt is isostructural with the corresponding Co complex [144]. [o] Cyclovoltammetric values of the Ni- (see also [192a], $Co^-$, and Fe-complexes: $PPh_4^+$ salts in dimethyl formamide ($10^{-3}$ M); supporting electrolyte $NEt_4I$ or $NPr_4(PF_6)$; Pt electrode; versus Ag/AgCl/LiCl(sat.)EtOH ($E_N = +0.143$ V); 200 [mV/s]; Pd complexes versus SCE [191, 192a]; $E^{I}_{1/2}$values correspond to eq. (I). [p] $\nu(M'S)$: ≈ 270–330 cm$^{-1}$. [q] $PPh_4^+$ salt/Nujol; $\nu(WS)$ with $\Delta\nu = \nu(^{58}Ni) - \nu(^{62}Ni) \approx 0$; $\nu(NiS) = 315.0$ ($\Delta\nu = 6.1$) and 322.5 (1.3) cm$^{-1}$.

Particularly with tetrathiometalate ions—due to the high electron density on the S atoms—species in which the ligand acts as a doubly bridging entity can form[227a]. (This property of the ligand is demonstrated by the existence of the well characterized species $[Cl_2Fe(MoS_4)FeCl_2]^{2-}$[132] (see also[150]) and $NH_4Cu(MoS_4)$[133], which will be discussed later). In some cases inhomogeneous and X-ray-amorphous products with polymeric ions can also be formed. For example, in the case of $Ni^{2+}$, the reaction in $H_2O$ produces not only the species $(XR_4)_2[Ni(MS_4)_2]$ (M = Mo, W), but also amorphous products which, in contrast to the complex, are insoluble in nitromethane and so can be separated off[134, 136]. However, only the complex is produced in $CH_3CN/H_2O$[192a]. If dioxodithiometalates are used, then as expected, no by-products are produced in water. However, it is necessary to work very quickly in this case, because of the high decomposition rate of the dithioanions (see Section 3)[135].

In all complexes of Table 2, $MO_{4-n}S_n^{2-}$ ions coordinate as bidentate ligands to the metal atom[137-139]. Figure 14 shows the types of structures we found earlier with the aid of spectroscopic methods in bis(thiometalato) complexes

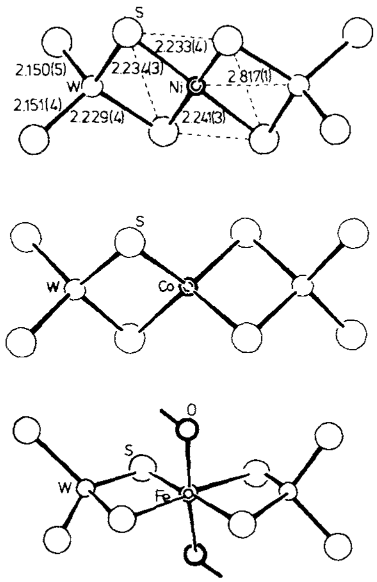

Fig. 14. Bis(tetrathiometalato) complexes: $[Ni(WS_4)_2]^{2-}$ ($AsPh_4^+$ salt), $[Co(WS_4)_2]^{2-}$, and $[Fe(dmf)_2(WS_4)_2]^{2-}$ ($PPh_4^+$ salt) with square planar, tetrahedrally or octahedrally coordinated central atom resp. (cf. Tables 2 and 3) [121, 142, 178, 180].

[n] The structures of the Ag complexes, having the same stoichiometry [167] with the ligands $MOS_3^{2-}$ (M = Mo, W) and $WO_2S_2^{2-}$ have not yet been determined, due to lack of suitable single crystals. [o] *A. Müller, H. Bögge, U. Schimanski, T. K. Hwang*, Inorg. Chim. Acta, in press.

with various coordinations of the central M′ atom. (These have been confirmed by single-crystal structure analyses in the cases of $[Ni(MoS_4)_2]^{2-}$[140], $[Co(WS_4)_2]^{2-}$[142], $[Ni(WS_4)_2]^{2-}$[121], $[Zn(WS_4)_2]^{2-}$[141], and $[Hg(WS_4)_2]^{2-}$[143] (cf. Table 3)).

There are some bis(thiometalato) complexes with different electron populations, for example $[Co(WS_4)_2]^{n-}$ (n = 2, 3, 4) and $[Fe(WS_4)_2]^{n-}$ (n = 2, 3). The Fe complexes can be isolated in crystalline form. That $[Fe(WS_4)_2]^{3-}$ should exist was to be expected, since in a cyclic voltammogram the doubly-negative anion shows a reversible one-electron reduction with only a relatively small negative $E^{I}_{1/2}$ value (Section 5.2)[227b].

The reactions in the system $Fe^{2+}/MS_4^{2-}/H_2O$ (M = Mo, W), which is of bioinorganic interest, are complicated. Whereas $[Fe(WS_4)_2]^{2-}$ (as also *e.g.* $[Co(WS_4)_2]^{2-}$ and other complexes with a double negative charge (Table 2)) can be isolated from aqueous media[144], the corresponding reaction between $Fe^{2+}$ and $MoS_4^{2-}$ according to eq. (i) generally gives variable products whose composition depend on the nature of the precipitation conditions[144, 145] (approximate composition $(PPh_4)_2\{Fe(MoS_4)_2\}$); according to our data[144] these samples do not contain the discrete $[Fe(MoS_4)_2]^{2-}$ ion, however they could not be clearly characterized because of their amorphous state. The Mössbauer spectrum (Section 5.2, Fig. 26[149]) of the frozen solution shows that in the $Fe^{2+}/MoS_4^{2-}/H_2O$ system, the anion $[Fe(MoS_4)_2]^{3-}$ with a triply negative charge is formed[147], which until now could only be obtained from Fe complexes with S-containing ligands and $MoS_4^{2-}$[148] (the UV/VIS spectrum of the solution proves the existence of $MoS_4^{2-}$ in equilibrium). This indicates the high stability of $[Fe(MoS_4)_2]^{3-}$, and demonstrates that sulfur-containing organic ligands are not necessary for the reduction, as was previously assumed[148, 221]. It was also, therefore, possible to isolate the $[Fe(MoS_4)_2]^{3-}$ ion in high yield as the $NMe_4^+$ salt from a solution of $(NH_4)_2MoS_4$ and $FeSO_4 \cdot 7H_2O$ in $CH_3CN/H_2O$ (1:1) (precipiation after filtration and addition of isopropanol)[149]. (The reduced species is also formed by the reaction of a suspension of $Fe(C_2O_4)$ in dimethyl formamide with $MoS_4^{2-}$[149].) While the greater stability of the triply negatively charged compared to the doubly negatively charged complex can be understood on the basis of the MO scheme (Section 5.2), the mechanism of reduction has not been clarified. (In the reaction of $Cu^{II}$ with $MoS_4^{2-}$ or with $WS_4^{2-}$, $Cu^{I}$ complexes are also formed.) This result is also of interest in relation to attempts to prepare FeSMo clusters with low-valence Mo (Section 6), since the one-electron reduction in the above system takes place in the absence of any additional reducing agent.

The tendency of the $MoS_4^{2-}$ ligands to form bridges ("further" coordination occurs easily as a result of the high $Fe \rightarrow MoS_4$ electron delocalization, see Section 5) is illustrated by the reaction[150]:

$$[Cl_2Fe(MoS_4)]^{2-} + \{FeCl_2\} \rightarrow [Cl_2Fe(MoS_4)FeCl_2]^{2-} \qquad (j)^{[150]}$$

In the trinuclear complex, $MoS_4^{2-}$ acts as a doubly bridging ligand (Fig. 15) (and also in the first two complexes of Fig. 18).

Whereas the discrete bis(tetrathiomolybdato) complex of $Fe^{II}$ (formally) is unstable, the following corresponding mixed ligand complexes of the type $[X_2Fe(MS_4)]^{2-}$ (M = Mo, W) have been isolated. They also contain $Fe^{II}$ and a thiometalate ligand (because the lower energy group of orbitals with predominantly d-character is destabilized relative to the corresponding orbitals in pure thiometalato complexes; see Fig. 25 and Section 5.2): $(NEt_4)_2[(PhS)_2Fe(MoS_4)]$[151, 152], $(PPh_4)_2[(S_5)Fe(MoS_4)]$[153], $(PPh_4)_2[(S_5)Fe(WS_4)]$[153], $(PPh_4)(N(C_7H_7)Me_3)[Cl_2Fe(MoS_4)]$[154, 157] (see Fig. 16); $(NEt_4)_2[Cl_2Fe(MoS_4)]$[152], $[Fe(dmso)_6][Cl_2Fe(MoS_4)]$[155], $[Fe(dmso)_6][Cl_2Fe(MoOS_3)]$[156], $(PPh_4)(N(C_7H_7)Me_3)[Cl_2Fe(WS_4)]$[157], and $[Fe(dmso)_6][Cl_2Fe(WS_4)]$[158]. (For the preparation of $(NEt_4)_3[(PhS)_2FeS_2Fe(MoS_4)]$ see [159]). All these compounds (except for the last) have been characterized by single-crystal structure analysis (see Table 3). $MS_4^{2-}$ (M = Mo, W) acts as a bidentate ligand in all these complexes (see Fig. 16). Owing to their high Fe content, the compounds containing $[Fe(dmso)_6]^{2+}$ may be of interest as starting substances for the preparation of MoFeS clusters.

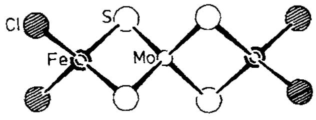

Fig. 15. Structure of $[(Cl_2Fe)_2(MoS_4)]^{2-}$: a complex with a doubly bridging $MoS_4^{2-}$ ligand (see also Fig. 18) [132].

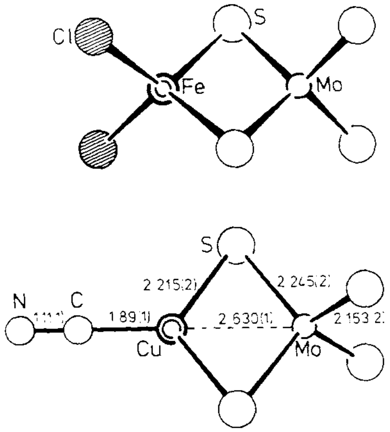

Fig. 16. Structure of $[Cl_2Fe(MoS_4)]^{2-}$ and $[NCCu(MoS_4)]^{2-}$: simple dinuclear complexes with one bidentate $MoS_4^{2-}$ ligand [152, 155, 157].

The reaction of $Cu^{2+}$ with $MS_4^{2-}$ ions (M = Mo, W) leads to the formation of reaction products with polymeric anions, for example $NH_4Cu(MoS_4)$[133] and $NH_4Cu(WS_4)$[160]. In the solid-state structures of these compounds there are chains of $CuS_4$- and $MS_4$-tetrahedra connected *via* the edges. Here, the thiometalate ion acts formally as a doubly bridging ligand (cf. also a further chain-forming complex with $Cu^+$ and $MoS_4^{2-}$ ions in Fig. 17).

$CuX_4$ and $MX_4$ tetrahedra connected *via* the edges are also present in $Cu_3MX_4$[161-163] (M = V, Nb, Ta; X = S, Se) with sulvanite structure.

The "polymerization" of a copper thiometalate system can be inhibited by additional ligands at the Cu atom, such as $PPh_3$ or $CN^-$. In the reaction system $M'^+/MO_{4-n}S_n^{2-}/PR_3$ (M' = Cu, Ag, Au; M = Mo, W; n = 4, 3; $R_3 = Ph_3$, $(C_7H_7)_3$, $MePh_2$) the following types of compounds are formed, which are interesting from the standpoint of structural chemistry, containing doubly, triply, and quasi-quadruply bridging thiometalate ligands:

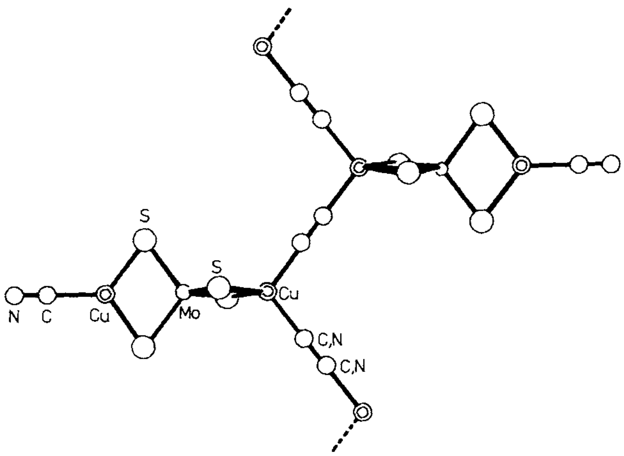

Fig. 17. Structure of the polymeric anion in the compound $(NMe_4)_2NCCu(MoS_4)\{CuCN\}$[174].

a) *Compounds with a central cubic unit* $\{Cu_3MS_3Cl\}(PPh_3)_3X$ *(M = Mo, W; X = S, O):* These have a strongly distorted cube as their central unit (see Figs. 18 and 19). The $MXS_3^{2-}$ ligand here is triply bridging. The coordination polyhedra of the three Cu atoms are not equivalent: while one Cu atom is enclosed in a distorted tetrahedron, in the case of the other two atoms there is a transition to trigonal planar coordination (cf. Table 3).

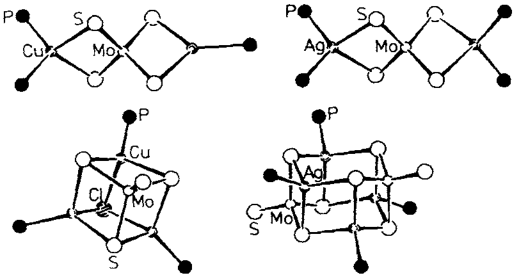

Fig. 18. Examples of multimetal complexes in the system $M'^+/MO_{4-n}S_n^{2-}/PPh_3$ (n = 3, 4; M' = Cu, Ag; M = Mo, W): $(PPh_3)_3Cu_2(MoS_4)$,
$(PPh_3)_4Ag_2(MoS_4)$, $\{Cu_3MoS_3Cl\}(PPh_3)_3S$, and $\{Ag_4Mo_2S_6\}(PPh_3)_4S_2$ (cf. references in Table 3).

b) *Compounds with a novel type of cage structure of composition* $\{M'_4M_2S_6\}(PR_3)_4X_2$ *(M' = Cu, Ag; M = Mo, W; X = S, O; $R_3 = Ph_3$, $(C_7H_7)_3$, $MePh_2$):* The central unit is a new type of cage, formally arising from a fusion of two $MS_2M'_2S$ rings (see Figs. 18 and 19). Here, the $MXS_3^{2-}$ ligand acts as a quasi-quadruple bridge (bonds to all four M' atoms) (see Table 3).

c) *Trinuclear complexes of composition* $(PR_3)_nM'_2(MS_4)$ *(M' = Cu, Ag, Au; M = Mo, W; $R_3 = Ph_3$, $MePh_2$; n = 2, 3, 4):* In these compounds each pair of M' atoms is connected *via* a doubly bridging $MS_4^{2-}$ ligand. The M' atoms each carry one or two $PR_3$ ligands, and hence for n = 4 both atoms are surrounded by distorted tetrahedra, for n = 2 both have almost trigonal planar configurations, and for n = 3 one atom is coordinated tetrahedrally while the other has a trigonal planar environment (see Fig. 18 and Table 3). The structures of the compounds with n = 4 ($(PPh_3)_4Ag_2(WS_4)$[168], $(PPh_3)_4Ag_2(MoS_4)$[155, 169], and $(PMePh_2)_4Ag_2(WS_4)$[170]) have not yet been confirmed by single-crystal structure analyses, but the structure type shown in Figure 18 has been established from spectroscopic investigations ($^{31}P$-NMR[170], IR, Raman, and in particular resonance-Raman spectroscopy[155, 171]).

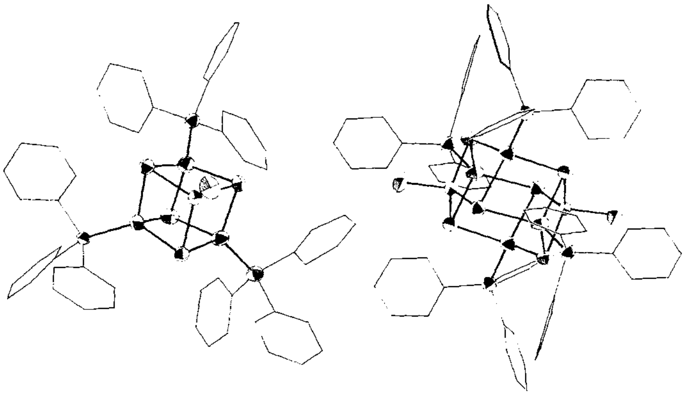

Fig. 19. ORTEP plot of the total molecular structure of $\{Cu_3WS_3Cl\}(PPh_3)_3S$ and $\{Ag_4W_2S_6\}(PPh_3)_4S_2$ with $PPh_3$ ligands (cf. Fig. 18).

In the compounds with cage structures it is worth noting that one thiometalate ligand provides six bonds to Cu or Ag atoms (see Fig. 18 and 19).

Since the compound types a) to c) above have roughly the same tendencies to form, in a given reaction different compounds can easily appear side by side[167, 172, 173]: slight variations of the concentration ratios of the reactants can shift the equilibrium strongly in favor of one of the compounds. For example, if the Cu concentration is reduced, the formation of $\{Cu_4W_2S_6\}(PPh_3)_4O_2$ becomes preferred over that of $\{Cu_3WS_3Cl\}(PPh_3)_3O$[172], as would be expected on the grounds of the different compositions.

In the $Cu^+/MoS_4^{2-}/CN^-/XR_4^+$ system there are also at least two different compounds:
$(PPh_4)_2[NCCu(MoS_4)]$[214] (Fig. 16) and
$(NMe_4)_2NCCu(MoS_4)\{CuCN\}$ (Fig. 17). The latter is worth noting, since here the complex $[NCCuMoS_4]^{2-}$ is coordinated to the Cu atoms of an infinite zigzag CuCN chain[174] (Fig. 17). (It is also interesting that $MoS_4^{2-}$ can be coordinated to a CuCN molecule as well as to a CuCN chain).

Thiometalate ligands are usually coordinated *via* sulfur to *soft cations* such as $Cu^+$, $Ag^+$, and $Au^+$. Thus, it has not yet been possible to prepare any compound of the structural type c) with $MOS_3^{2-}$ ligands. Following this principle, using oxotrithiometalates, we have deliberately prepared certain compounds with a cubane-like structure[164].

Up to now the only non-polymeric thiotungstates with elements of group Ib *without* additional ligands that have been isolated are $[Au_2(WS_4)_2]^{2-}$[175] and $[Au_2(WOS_3)_2]^{2-}$[176], *i.e.* pure metal-sulfur ring systems without organic ligands. In each case the anions consist of two Au atoms bridged by two thiotungstate ligands (see Fig. 20).

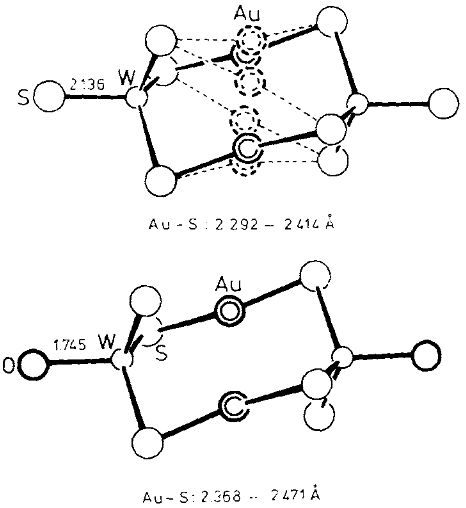

Fig. 20. Structure of $[Au_2(WS_4)_2]^{2-}$ and $[Au_2(WOS_3)_2]^{2-}$. In both ions there is a statistical disorder with the Au atoms distributed over three positions [175, 176].

Compounds with thiometalate ligands involving elements of the 4th main group are also known. In the novel polynuclear complexes of the type $[M'_2(MS_4)_4]^{4-}$ ($M' = Sn$, Pb; $M = Mo$, W) there are nonequivalent, bridging, and terminal bidentate ligands (Fig. 21). Corresponding anions are very probably present in the compounds $(PPh_4)_4[Pb_2(MOS_3)_4]$[177, 178].

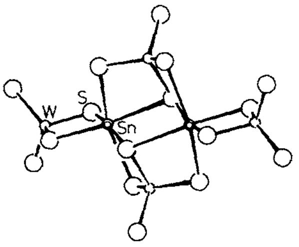

Fig. 21. Structure of $[Sn_2(WS_4)_4]^{4-}$ [177].

Only one[226] *selenometalato complex*, namely $[Zn(WSe_4)_2]^{2-}$, has so far been reported[134, 179].

The bis(thiometalato) complexes of Co and particularly of Fe show a high affinity for the coordination of ligands[144, 178, 180]. ($[Fe(WS_4)_2]^{2-}$ *e.g.* to $N_3^-$ or $NCS^-$, with dmf it forms $[Fe(dmf)_2(WS_4)_2]^{2-}$[178, 180], whose structure, established from vibrational and Mössbauer spectra, is shown in Figure 14). The weak splitting of the bands due to the $\nu(WS)$ stretching modes is a proof that the Fe—$WS_4$ interaction is weaker than in the other complexes in Fig. 14 (no characteristic $\nu(WS_{term})$ and $\nu(WS_{br})$ vibrations; Table 2). The orange $[Fe(H_2O)_x(WS_4)_2]^{2-}$ may be present in aqueous solution. $[Fe(WS_4)_2]^{2-}$ and $[Co(WS_4)_2]^{2-}$ react unusually rapidly with NO to give the mononitrosyl complexes $[M'(NO)(WS_4)_2]^{2-}$[144, 181]. Their $PPh_4^+$ salts are isostructural[181].

## 5. Spectroscopic Investigations and Chemical Bonding in Thiometalato Complexes

Spectroscopic studies were carried out, both to determine the molecular structure, and to investigate the interesting electronic properties (see Table 2).

### 5.1. Vibrational Spectra and Molecular Structure

The structures of complexes of the type $[M'(MO_{4-n}S_n)_2]^{2-}$ have been determined by IR spectroscopic investigations[117, 134–139]. The isotope-substitution technique ($^{54}Fe/^{56}Fe$, $^{58}Ni/^{62}Ni$, $^{63}Cu/^{65}Cu$, $^{64}Zn/^{68}Zn$, $^{92}Mo/^{100}Mo$) has made it possible to produce detailed information of the spectra of the complexes $[Ni(MoS_4)_2]^{2-}$[182], $[Ni(WS_4)_2]^{2-}$[81, 183], $[Ni(WO_2S_2)_2]^{2-}$[180, 184], $[Zn(MoS_4)_2]^{2-}$[81, 185], $[Zn(WS_4)_2]^{2-}$[141], $[NCCu(MoS_4)]^{2-}$[186a], and $[Cl_2Fe(MoS_4)]^{2-}$[186a], and to show that the $\nu(MS_{br})$ and especially the $\nu(MS_{term})$ vibrations are relatively characteristic[182, 183, 185, 186] ($\nu_{as,term}$ is the most, and $\nu_{s,br}$ the least characteristic vibration). Thus, the presence of corresponding bonds can easily be detected from the vibrational spectra (see Fig. 22).

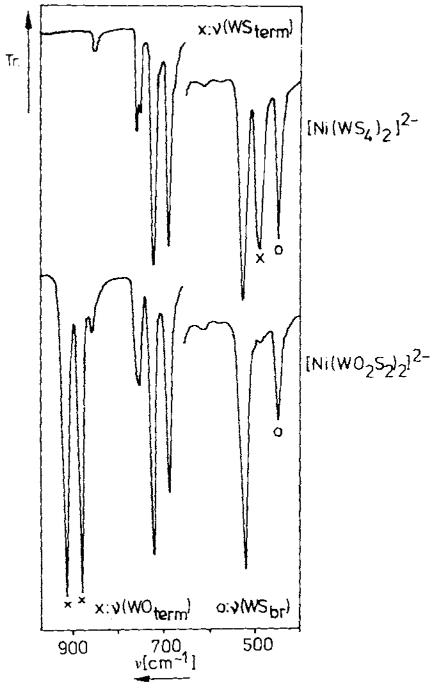

Fig. 22. IR spectra of $(PPh_4)_2[Ni(WS_4)_2]$ and $(PPh_4)_2[Ni(WO_2S_2)_2]$ in the region of the WO and WS stretching vibrations (demonstrating the bidentate nature of the ligands and the S-coordination).

Since the ligand internal transitions in thiomolybdato complexes correspond roughly to those of free $MoS_4^{2-}$, one can obtain resonance Raman spectra[150, 155] also from nearly all the complexes in Tables 2 and 3 (see also [193a]). In these spectra the lines due to the totally symmetric vibrations of the $MoS_4$ chromophore (usually $\nu(MoS)$ stretching vibrations) are significantly intensified. The resonance Raman effect is a sensitive probe for the detection of $MoS_4^{2-}$ ligands, for example at Cu or Fe centers in biological systems (see Section 6). Among other things, significant distinctions can be made between bridging and bidentate ligands[155]. This method offers a unique and sensitive probe for doubly bridging ligands (Fig. 6).

### 5.2. Electronic Structure and Stability

Various physical measurements have demonstrated that in thiometalato complexes with central atoms possessing open d-shells, there are strong metal-ligand interactions, *i.e. delocalized molecular orbitals*. Thus, the assignment of the electronic-transition bands (Table 2) for such systems can only be approximate. The electronic interactions in $M'S_2M$, systems is interesting due to its relevance in the bioinorganic field (Section 6).

The known complexes of the type $[M'(MO_{4-n}S_n)_2]^{2-}$ ($M'$ = Fe, Co, Ni, Pd, Pt) show characteristic absorption bands whose positions are only roughly comparable to those in free thiometalates (*i.e.* $L \rightarrow L^*$ assignment). The reduction of the symmetry due to complex formation often leads to splitting of the bands, whereas the total intensity remains virtually unchanged. However, because of the strong M—L interactions, the spectra in the region of the ligand internal transitions depend markedly on the nature of the central atom (*i.e.* the influence is quite noticeable). For example, there is a characteristic splitting of the $\nu_1$ band of $WS_4^{2-}$ (Table 2) in the Ni complex. In contrast, the longest-wavelength band in $[Ni(MoS_4)_2]^{2-}$ is strongly shifted in the direction of longer wavelengths. This demonstrates different interactions, which should be particularly large in the $MoS_4^{2-}$ complex.

According to EH-SCCC-MO calculations, strong $3d_{xz}$(Ni)- and $3d_{yz}$(Ni)-$\pi$ interactions with the ligand orbitals occur in the $[Ni(MS_4)_2]^{2-}$ complexes (M = Mo, W)[126]. In the trimetallic complexes with square-planar coordination of the central atom, the coordination geometry gives rise to a considerable perturbation of the electronic structure of the ligands. Since the opposite S bridge atoms of the two thiometalate ligands are separated by only *ca.* 2.8 Å, the energies of the occupied nonbonding 3p(S) ligand orbitals are in part markedly increased. Particularly in the $MoS_4^{2-}$ complex, the Ni-ligand interaction is so strong that it can no longer be accurately formulated as a $Ni^{II}$—$Mo^{VI}$ complex, and one must think in terms of a formal reduction of the Ni center and a partial disulfide bond between the bridging S atoms.

The spectra of complexes with $d^{10}$ central atoms[222] show essentially ligand internal transitions corresponding to those of the free thiometalate ions. It is worth noting that, for example in $[NCCu(MoS_4)]^{2-}$ and $[Zn(MoS_4)_2]^{2-}$, of the three longest wavelength bands the first ($\nu_1$) and the third ($\nu_3$) are clearly changed in their structure by complex formation, while the second ($\nu_2$) is practically unaltered in its position, intensity, and half-width (see Fig. 23)[186b]. (The fact that this is not true for $MoS_4^{2-}$ complexes with open d shells, for example those of Fe and Ni, can be explained in terms of MO theory[126]). MO calculations show that on complex formation the $t_1$ orbitals of the $MS_4^{2-}$ ligands, as expected, are much more strongly disturbed than the $3t_2$, 2e, and $4t_2$ MO's[126]. It follows that in the transition corresponding to the $\nu_2$ band in $MoS_4^{2-}$, the $t_1$ orbital is not involved; this lends support to the assignments[90] $\nu_2 \triangleq 3t_2 \rightarrow 2e$ and $\nu_3 \triangleq t_1 \rightarrow 4t_2$[186b]. This probably constitutes an essential contribution to the old assignment problem of the electron transfer transitions of tetrahedral transition-metal chalcogenometalates[44]. It is also interesting to note that the type of perturbation of the $\nu_2$ band of complexes with open-shell metal ions reflects the type of $\pi$-M′-L interaction.

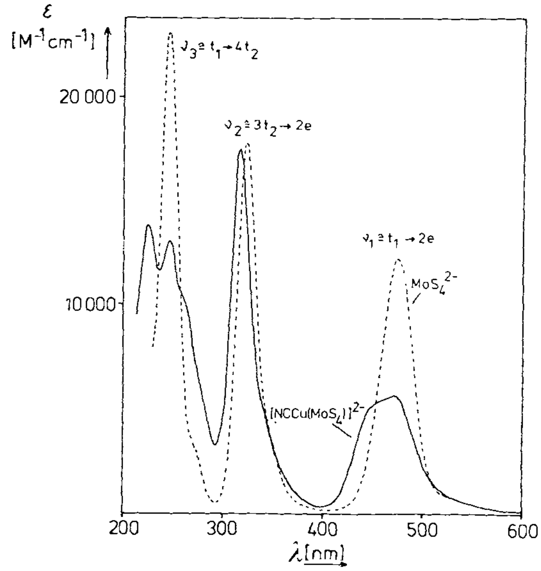

Fig. 23. Influence of a coordination center on the longest-wavelength bands of $MoS_4^{2-}$; electronic spectra of $(NMe_4)_2[NCCu(MoS_4)]$ and $(NMe_4)_2MoS_4$ (in acetonitrile).

The Fe and Co complexes of the above type show a remarkable band of high intensity ($\varepsilon \approx 10^3 - 10^4$ [$M^{-1}$ $cm^{-1}$]) in the NIR/VIS region (Table 2, Fig. 24), which is not present in classical complexes without strong metal-ligand interactions. An assignment can be achieved on the grounds of empirical relations and from MO calculations. For analogous complexes, the transition energy decreases as follows[187]:

Fe > Co complex ($X_{opt}$(Fe) < $X_{opt}$(Co))
Tungstato > molybdato complexes (k)
Dithiometalato > trithiometalato > tetrathiometalato complexes.

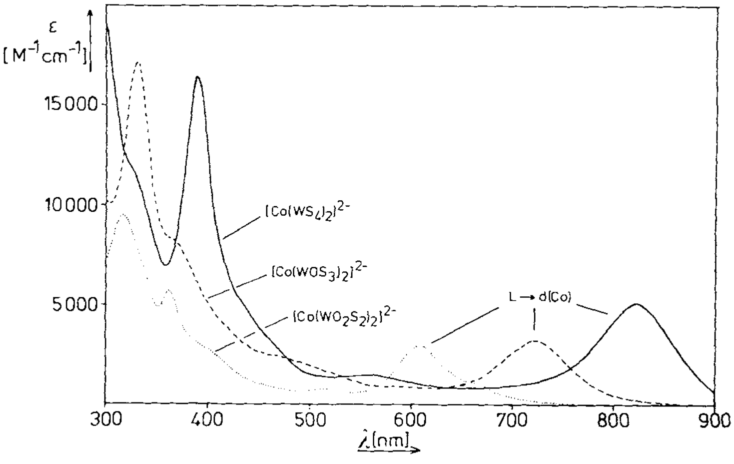

Fig. 24. Electronic absorption spectra of the complexes $[Co(WO_{4-n}S_n)_2]^{2-}$ in $CH_2Cl_2$ ($PPh_4^+$ salts).

Furthermore, there is a linear relationship between the transition energies of the $[Co(MoO_{4-n}S_n)_2]^{2-}$ complexes and those of the corresponding $[Co(WO_{4-n}S_n)_2]^{2-}$ complexes. These findings indicate that the intense bands should be assigned to charge-transfer transitions of the type L→d(M').

This assignment is supported by EH-SCCC-MO calculations on corresponding Co and Fe complexes[126], which lead to the qualitative MO scheme shown in Figure 25[126, 154, 180, 187]. (The problem of the sequence of the MO's in these complicated systems is evident: however, the MO scheme given here can provide answers to certain interesting questions of stability (Section 4 and below)). In this scheme the following classes of MO's with approximately similar energies are included: 1. Nonbonding L—MO's with a predominantly 3p(S) character, 2. Closed or open shell MO's of predominantly 3d(M) character (corresponding to the e and $t_2$ orbitals in a crystal field theory description). 3. Unoccupied L*-MO's of predominantly 4d(Mo) or 5d(W) character (corresponding to the 2e-MO's of the free thiometalate ions[44, 117]). Charge-transfer transitions of the type d(M')→L* should probably be expected at higher energies, possibly in the region of the first ligand internal transitions. (However, as indicated in Table 2, the band assignment is only approximate, because of the strong central-atom ligand interaction; this also applies to the assignments to d→d transitions given in Table 2).

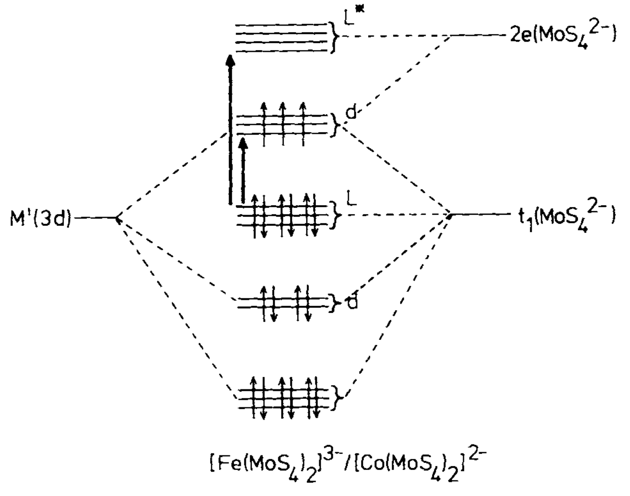

Fig. 25. Qualitative MO scheme of the isoelectronic complexes $[Fe(MoS_4)_2]^{3-}$ and $[Co(MoS_4)_2]^{2-}$, and analogous bis(thiometalato) complexes of Fe and Co with half-occupied and completely occupied "d levels", resp. The braces link together MO's of approximately the same energy; for the probable sequence of the MO's in other Fe and Co complexes, see text.

The remarkable properties of thiometalate ligands can also be demonstrated by calculations: the MO coefficients of the 3d(M')-type MO's show a high electron delocalization (which increases with increasing sulfur content of the ligand), and hence a strong π-acceptor ability (which can be explained by the low-lying unoccupied L* orbitals). Since the 3d(M') level is at an energy comparable to that of the nonbonding MO's of the ligands ($t_1$ of the free $MS_4^{2-}$ ions[44, 117]), it also follows that there is a remarkable M'—L-σ interaction. The overlap integrals between the 3d(M') and 4d(M), or 5d(M) functions show that at an M'—M separation of *ca.* 2.8 Å direct metal-metal interactions should also be taken into consideration.

The calculations also show that due to complex formation the electron density on the M' (M' = Fe, Co) center is diminished, while that on the M center is increased, relative to the free $MS_4^{2-}$. The electron density on the terminal S atoms is hardly altered by electron delocalization compared to that of the free $MoS_4^{2-}$, especially in Fe—Mo complexes. This explains the ability of this anion to function as a bridging ligand (*e.g.* in $[Cl_2Fe(MoS_4)FeCl_2]^{2-}$).

Delocalized (occupied) MO's over the metal centers M' and M occur particularly clearly in complexes with $M'S_2MS_2M'$ units (*e.g.* M' = Fe, and notably also when M' = Cu with a closed d shell[126]; *cf.* the resonance Raman spectrum results mentioned below).

As expected, the electronic spectra of complexes of the type $[X_2Fe(MoS_4)]^{2-}$ (X = Cl[152, 154, 188], PhS[151, 152], *p*-$CH_3C_6H_4S$[152], $1/2\,S_5$[153], where the M'-L interaction is smaller than in the trimetallic species, are very similar. The same is true of the $[X_2Fe(WS_4)]^{2-}$ complexes. For example, the Fe→$WS_4^{2-}$ electron delocalization is greater in $[Fe(WS_4)_2]^{2-}$ than in $[Cl_2Fe(WS_4)]^{2-}$. In the first of these complexes, this is responsible for a lower energy both for the longest-wavelength ligand internal transition and for the L→d(Fe) charge-transfer transition (Table 2).

The stability of the complexes[180] $[Fe(MS_4)_2]^{n-}$ and $[Co(MS_4)_2]^{2-}$ (M = Mo, W), and the special behavior of the Fe species can be explained as follows: the low-energy MO's of the 3d(M') type in the Co complexes (these are occupied here, in contrast to those of the Fe complexes with n = 2) and in $[Fe(MoS_4)_2]^{2-}$ are situated at a lower energy, and in the case of $[Fe(WS_4)_2]^{2-}$ at about the same energy, as the nonbonding L orbital (Fig. 25). Thus, the unstable, discrete $[Fe(MoS_4)_2]^{2-}$ is stabilized by taking up one electron to form $[Fe(MoS_4)_2]^{3-}$, and $[Fe(WS_4)_2]^{n-}$ exists with n = 2 and 3.

The $^{57}$Fe Mössbauer spectra of complexes of the type $[X_2Fe(MS_4)]^{2-}$ show unusually low values for the isomer shift (IS) of the order of 0.5 mm·s$^{-1}$[152-154, 188] (all values relative to α-Fe at room temperature). This also demonstrates the strong electron delocalization Fe→$MS_4^{2-}$. As expected, this delocalization is greater in the Mo complexes than in the analogous W complexes[188]. The effect of a thiometalate ligand is clearly illustrated by the fall of the IS values in the series $[Cl_2FeCl_2]^{2-}$ (IS = 0.76 mm·s$^{-1}$[189a]), $[Cl_2Fe(WS_4)]^{2-}$ (IS = 0.52 mm·s$^{-1}$[188]), $[(WS_4)Fe(WS_4)]^{2-}$ (IS = 0.43 mm·s$^{-1}$[189b]). The Mössbauer spectrum of $[Fe(MoS_4)_2]^{3-}$, with an isomer shift of 0.38 mm·s$^{-1}$, shows that the electron density on the Fe center is much lower than would be expected for a formal oxidation state of +1[148], and is almost identical to that of a frozen solution of $Fe^{2+}$ and $MoS_4^{2-}$ in $H_2O$ (Fig. 26, explanation in Section 4).

The $^{197}$Au Mössbauer spectrum of $[Au_2(WS_4)_2]^{2-}$[175] can be interpreted as indicating that for Au$^{I}$, with a closed d shell, the π-acceptor ability of the $WS_4^{2-}$ ligand does not carry much weight.

The ESR spectrum of $[Fe(MoS_4)_2]^{3-}$ is similar to that of the MoFe cofactor of nitrogenase[148], and that of

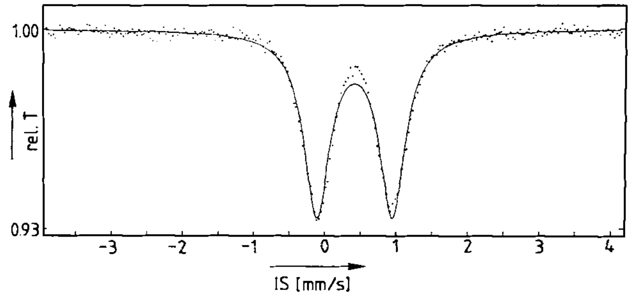

Fig. 26. $^{57}$Fe Mössbauer spectrum of a frozen solution of $Fe^{2+}$ and $MoS_4^{2-}$ in water [146] (1.2 mmol $(NH_4)_2MoS_4$, 0.5 mmol $FeSO_4\cdot 7H_2O$, 10 mL $H_2O$, 77 K. IS = 0.423 ± 0.035 mm/s; QS = 1.060 ± 0.070 mm/s).

$[Co(WS_4)_2]^{2-}$ in $(PPh_4)_2[Zn(WS_4)_2]$ gives a $g_\perp$ value of *ca.* 4.1[190].

Various complexes of the type $[M'(MO_{4-n}S_n)_2]^{2-}$ (M' = Fe, Co, Ni, Pd) and also $[(FeCl_2)_2MoS_4]^{2-}$[180] show a reversible redox behavior[135, 180, 187, 191, 192a]. According to cyclic voltammetric investigations, these complexes can be reduced reversibly in a one-electron process (I), and some also in a second one-electron process (II) (see Fig. 27):

$$[M'(MO_{4-n}S_n)_2]^{2-} \overset{\text{I}}{\underset{-e}{\overset{+e}{\rightleftharpoons}}} [M'(MO_{4-n}S_n)_2]^{3-} \overset{\text{II}}{\underset{-e}{\overset{+e}{\rightleftharpoons}}} [M'(MO_{4-n}S_n)_2]^{4-} \qquad (I)$$

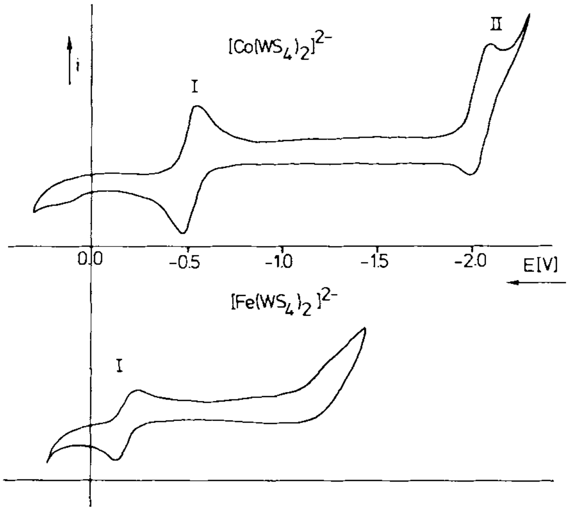

Fig. 27. Cyclic voltammograms of $[Co(WS_4)_2]^{2-}$ [187] ($NEt_4^+$ salt in dimethyl formamide/$NEt_4I$) and $[Fe(WS_4)_2]^{2-}$ [180] ($PPh_4^+$ salts in $CH_3CN/NPr_4(PF_6)$) versus Ag/AgCl/LiCl(sat)EtOH electrode.

(The second process is often only quasi-reversible or irreversible.) Since in the Fe and Co complexes the half-step potential $E^I_{1/2}$ is significantly ligand-dependent, it is likely that the additional electrons are taken up by levels that besides a 3d(M') character also exhibit a ligand component. In the oxothiomolybdato and oxothiotungstato Co complexes, the energy of the L→d charge-transfer transition (see (k)) increases approximately linearly with increasing $|E^I_{1/2}|$. (Due to S→O substitution, the highest energy occupied ligand orbitals are stabilized, and the incompletely occupied orbitals with 3d(Co) character are destabilized because of decreasing delocalization). In the Ni complexes, the corresponding half-wave potentials are somewhat less L-dependent (however, the second reduction step is more markedly ligand-dependent than the first). In this case the first reduction occurs predominantly in the chromophore $NiS_4$, the charge density on the S atoms also being increased (leading to a reduction of the partial disulfide character; see MO calculation results, above).

Correspondingly, $[Fe(MoS_4)_2]^{3-}$ shows a single, reversible reduction[148] which only formally corresponds to the $Fe^I \rightarrow Fe^0$ transition.

These experimental findings also illustrate the marked electron delocalization $M' \rightarrow MO_{4-n}S_n^{2-}$ (M' = Fe, Co), since the stabilization of the formal 0 and +1 oxidation states of the metals M' can only be explained by pronounced π-acceptor properties of the thiometalato ligands.

Resonance Raman spectroscopy allows, for example, an investigation of the kind of bonding in complexes. Whereas in the Raman spectra of tetrathiometalato complexes ($[M'(WS_4)_2]^{2-}$ with M' = Pt, Zn in Fig. 28), the intensities $I_R$ of the $\nu$(MS) bands are basically given by

$$I_R[\nu(MS_{term})] > I_R[\nu(MS_{br})]$$

(reason: higher π-bond-order in $MS_{term}$), the preresonance and resonance Raman spectra can exhibit clear deviations from this rule. (In the interpretation of the spectra it should be borne in mind that $\nu(MS_{term})$ vibrations are more characteristic than $\nu(MS_{br})$, *e.g.* $\nu_s(MS_{br})$ contains a clear $\nu_s(MS_{term})$ component[186a]). The preliminary results will be briefly summarized here[192b].

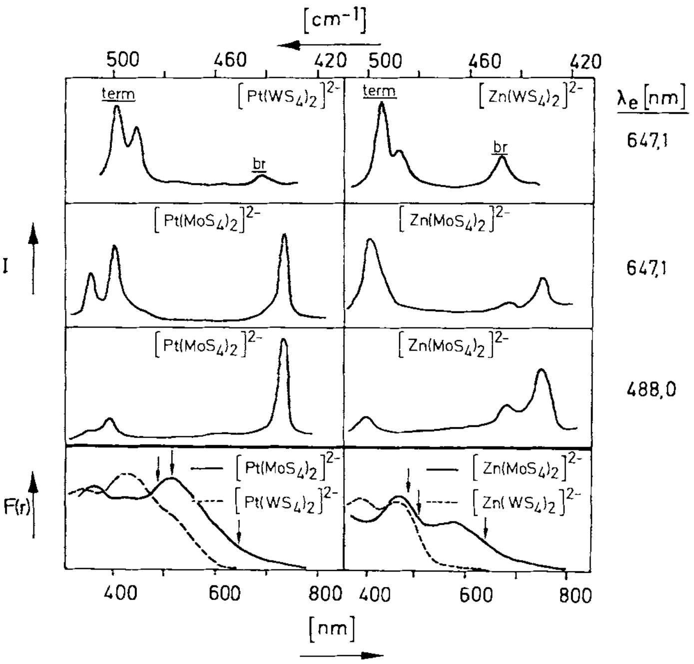

Fig. 28. Raman-, pre-resonance, and resonance Raman spectra (the latter without the overtone region) and reflectance electronic spectra of the $PPh_4^+$ salts of $[M'(MS_4)_2]^{2-}$ complexes (term = $\nu(MS_{term})$, br = $\nu(MS_{br})$).

If an excitation line within the shorter-wavelength band of the $\nu_1$ doublet in the case of $[Zn(MoS_4)_2]^{2-}$ is used, or in the case of $[Ni(MoS_4)_2]^{2-}$ and $[Pt(MoS_4)_2]^{2-}$ within the longest-wavelength bands or their tails (or with the 514.5 nm line; not shown in Fig. 28) an altered intensity relationship will be observed. In contrast, if a line is used within the tail region of the low-energy band of the $\nu_1$ doublet of $[Zn(MS_4)_2]^{2-}$ (M = Mo, W), the intensity relationship given above will be found. This indicates that in the Zn complexes the bands of the doublet can be roughly assigned to transitions in the two chromophores $MS_2$(term) and $MS_2$(br), respectively. Measurements of an excitation profile may contribute toward a final clarification. In $[Ni(MoS_4)_2]^{2-}$ and $[Pt(MoS_4)_2]^{2-}$ it is not possible to distinguish between the corresponding chromophores. The electronic transitions responsible for the resonance Raman effect observed here should, however, be localized mainly in the central $MoS_2M'S_2Mo$ portion[192b]. The resonance Raman spectrum of $[Pt(MoS_4)_2]^{2-}$ (488.0 nm) also contains intensified bands of the following symmetric vibrations: $n\nu(MoS_{br})$, $\nu(PtS)$, $\nu(MoS_{br})+\nu(MoS_{term})$, and $\nu(MoS_{br})+\nu(PtS)$[192b], again indicating the presence of a strongly delocalized bonding system.

The occurrence of intercombination bands of $\nu$(CuS) with $n\nu_s$(MoS) in Cu complexes with bridging $MoS_4^{2-}$ ligands demonstrates that delocalized MO's are present in the $Cu^IS_2MoS_2Cu^I$ fragment itself, as confirmed by the MO calculation (see above) (Fig. 6)[155, 192b].

Magnetic measurements have mainly been used to clarify the structures of the Ni and Co complexes. The isolated Ni complexes are diamagnetic, as would be expected for pseudo-square-planar coordinated $Ni^{II}$. The magnetic moments of the Co complex are essentially closer to spin-only values than to values of "typical" compounds with a tetrahedral $CoS_4$ chromophore[135, 180, 187], because of the strong electron delocalization $M'\rightarrow MO_{4-n}S_n^{2-}$. This behavior is still more clearly expressed in $[Fe(MoS_4)_2]^{3-}$[148].

## 6. The Significance of Thiometalates, and Especially of $MoS_4^{2-}$ for Bioinorganic Problems

### 6.1. Relevance to the Nitrogenase Problem

Sulfur-containing ligands play a dominant part in all Mo enzymes[97a, 97b, 193a], and this is particularly true for the nitrogenases, in which the Mo atom is probably surrounded only by S ligands[97a]. This enzyme is responsible for the fixation of atmospheric nitrogen, which apart from photosynthesis is the most important elementary process for life on Earth. With the help of this enzyme various microorganisms reduce nitrogen to ammonia, more or less in accordance with the following scheme:

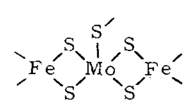
$$\{\text{Fe-protein[MgATP]MoFe-protein}\} \rightarrow \{\text{Fe-protein}_{ox}[\text{MgADP} + P_i]\text{MoFe-protein}_{red}\}$$
$$N_2 + 8e^- + 8H^+ \rightarrow 2NH_3 + H_2$$

As early as 1930 *Bortels*[97c] recognized that *Azotobacter* could not fix $N_2$ in the absence of Mo. However, the exact biochemical significance of the molybdenum is not known, though in recent years important information has been accumulated which is relevant to the subject of this review[216, 217].

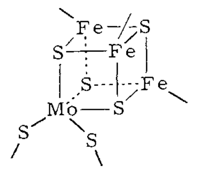
Nitrogenase consists of two separate proteins, an MoFe protein (the reaction carrier) and an Fe protein (the electron carrier)[97d, 193b]. The latter is a dimer with identical subunits and a molecular weight of about 60000. Each subunit comprises a 4Fe—4S cluster[97d, 193b]. The MoFe protein, with a molecular weight of *ca.* 220000, is a tetramer with two pairs of different subunits (with 2 Mo, *ca.* 32—33 Fe, and 27—32 acid-labile S atoms per tetramer)[97d] and was obtained in crystalline form from *A. vinelandii*[194]. The following additional facts seem to be of key importance for the elucidation of the active center. *Shah* and *Brill*[195] were able to isolate a low-molecular, *N*-methyl formamide-soluble MoFe cofactor (MoFe-co) with Fe : Mo : S ≈ 8 : 1 : 6, from MoFe protein (obtained from various microorganism) (or, according to more recent work, about 7 : 1 : 4[216, 217], which on the basis of ESR[198] and EXAFS studies[196, 197] can be regarded as the active center of the protein[198]. This is confirmed by the fact that the MoFe-co is able to reactivate the denaturated MoFe protein, and catalyzes the reduction of acetylene to ethylene[199]. About 50% of the iron content of the nitrogenase (and all of the Mo) is contained in MoFe-co, and probably most of the rest in the 4Fe—4S clusters.

On the basis of EXAFS data, *Cramer et al.*[196, 197] proposed the following models for the surroundings of the Mo atoms (3—4 shorter Mo—S distances of about 2.36 Å, 2—3 Fe atoms at 2.72 Å); however, the nature of the short range order of the Mo surroundings has not yet been clarified[216, 217]:

(1)



(2)

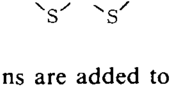


Furthermore, *Zumft*[200] was able to show that $MoS_4^{2-}$ is obtained, among other products, when the protein undergoes acid-base hydrolysis.

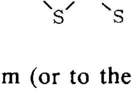
Some groups are now attempting to synthesize MoFeS clusters (and, because of the Mo—W antagonism, WFeS clusters as well) with structures similar to that of MoFe-co, and if possible to use them for the reactivation of the denaturated protein. In all the methods of synthesis published so far, the $MoS_4^{2-}$ ion has been used as the starting material. However, in principle it is also possible to use other Mo—S compounds, such as $[Mo(SR)_4]$[220].

Fe complexes in which the $MS_4^{2-}$ ligand (M = Mo, W) is intact (*e.g.* $[Fe(WS_4)_2]^{2-}$) were prepared for the first time by *Müller et al.*, and later by *Averill et al.*, *Coucouvanis et al.*, and *Newton et al.* (see Section 4 and [144]). These compounds were regarded as ***precursors*** for MoFe-co[97a]. Particular attention should be paid to the unit *(3)*, since it can be obtained from complexes with the moiety *(4)* (see Section 4).

(3)



(4)



When electrons are added to the system (or to the Mo atom) the coordination number of Mo can increase. Thus, in the reaction system $MoS_4^{2-}/3$—3.5 $FeCl_3/9$—12 NaSR in methanol the double-cubane-cluster anions, are formed[201] $[(MoFe_3S_4)_2S(SR)_8]^{3-}$ (type 1), $[(MoFe_3S_4)_2(SR)_9]^{3-}$ (type 2), $[(MoFe_3S_4)_2Fe(SR)_{12}]^{3-}$ (type 3), and $[(MoFe_3S_4)_2Fe(SR)_{12}]^{4-}$ (type 4), which can be isolated in the form of the quaternary ammonium salts (see Fig. 29). (The W analogs of various compounds have also been obtained[201l]). The EXAFS spectrum of (1) agrees quite well with that of the MoFe protein obtained from *C. pasteurianum*[201a]. The clusters can be reversibly reduced in several one-electron steps. In all the species, $MoFe_3S_4$ clusters are connected in various ways. On the basis of $^{57}Fe$ isomer shifts, the following formal electronic descriptions of the central clusters have been given: $[Mo^{4+}Fe_2^{3+}Fe^{2+}S_4]^{4+}$ + $[Mo^{3+}Fe_2^{3+}Fe^{2+}S_4]^{3+}$ (for type 1), and $2[Mo^{3+}Fe_2^{3+}Fe^{2+}S_4]^{3+}$ for types 2, 3, and 4[201].

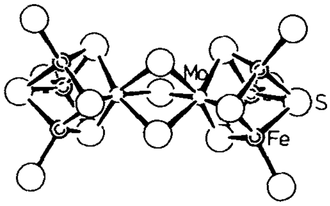


Fig. 29. The skeleton of $[(RS)_3Fe_3MoS_4(\mu\text{-}SR_3)Fe_3MoS_4(SR)_3]^{3-}$.

The reduction of the $Mo^{VI}$ in $MoS_4^{2-}$ probably takes place both by reaction with the nucleophile $SR^-$ and by an intramolecular reaction [according to Section 2.5; reaction type (a), (c), or (d)]. In this connection it is worth noting that S-containing ligands can reduce $Mo^{VI}$ (*e.g.* $(S_2)^{2-}$ reduces $Mo^{VI}$ to $Mo^V$ and $Mo^{IV}$ (Section 2.1)).

In future, an attempt must be made to obtain compounds in which the valence state of the Mo lies between that in the cluster with double-cubane structure and that in the thiomolybdato complexes, and which contain coordinatively unsaturated Mo centers, if it is assumed that $N_2$ is coordinated to Mo in the enzyme.)[218,219]

A recent report deals with non-nitrogenase-like MoFeS proteins[202], isolated from *Desulphovibrio* bacteria. Interestingly enough, the electronic spectrum of such a protein resembles that of complexes of the type $[X_2Fe(MoS_4)]^{2-}$[97a].

### 6.2. Cu—Mo Antagonism

Ruminants pastured on soils rich in Mo show symptoms of disorders (anemia, diarrhea, and retarded growth) that can be traced to a deficiency of Cu[203-209,224] (*"secondary trace-element deficiency"*[207]). In many parts of the world, this deficiency causes a substantial loss of livestock[207], which can only be remedied by a greater intake of Cu. The following facts are known about this Cu—Mo antagonism:

Table 4: Tissue residues of Cu and Mo in rats after various doses of $CuCl_2$ and $(NH_4)_2MoS_4$ [205] [a].

| *Influence of various doses of Cu in food on the residual dietary Mo (6 mg Mo/kg feed)* | | | |
|---|---|---|---|
| Dietary Cu [mg/kg] | 3 | 8 | 16 |
| Carcass retention of $^{99}Mo$ [fraction of oral uptake] | 0.40±0.02 | 0.22±0.01 | 0.15±0.02 |
| Total liver Mo [mg/kg dry weight] | 1.2 | 0.8 | 0.4 |
| *Influence of various doses of Mo (as $MoS_4^{2-}$) in food on the residual dietary Cu (3 mg Cu/kg feed)* | | | |
| Dietary Mo [mg/kg] | 0 | 12 | |
| Carcass retention of $^{64}Cu$ [fraction of oral uptake] | 0.34±0.02 | 0.04±0.01 | |
| Total liver Cu [mg/kg dry weight] | 23 | 12 | |

[a] The rats were given either $^{99}Mo$ (as $(NH_4)_2{}^{99}MoS_4$) or $^{64}Cu$ (as $^{64}CuCl_2$), after having been fed for at least a week on a Cu- or Mo-enriched semisynthetic diet.

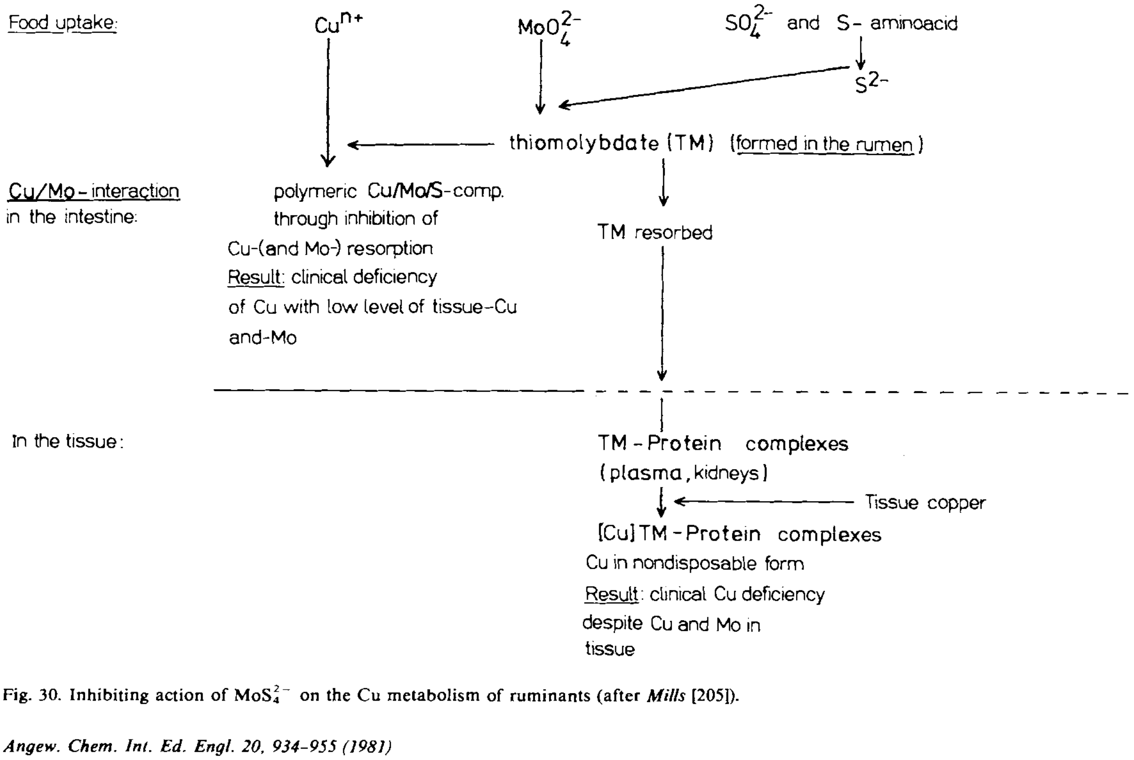

Fig. 30. Inhibiting action of $MoS_4^{2-}$ on the Cu metabolism of ruminants (after *Mills* [205]).

$MoS_4^{2-}$, which is believed to be the strongest Cu antagonist[207], is formed in tests *in vitro*, under physiological conditions, in a medium consisting of rumen contents (18 h at 39 °C) from ammonium molybdate and ammonium sulfate, or organic sulfur compounds[208]. The antagonistic interaction between $Cu^{n+}$ and $MoS_4^{2-}$ has been impressively demonstrated by determining the tissue levels of Cu and Mo in rats given various amounts of radioactive $^{64}CuCl_2$ or $(NH_4)_2{}^{99}MoS_4$ in their food[205] (see Table 4). Since these investigations show that Mo interferes with the Cu metabolism both before and after the resorption (Fig. 30), it is difficult to explain the interaction. According to *Mills*, the latter is due to the formation of a "[Cu]TM-protein complex" (TM = thiomolybdate)[205], which makes the Cu unavailable for metabolic purposes. This is supported by the observation that clinical signs of a Cu deficiency are observed in animals after resorption of $MoS_4^{2-}$, in spite of a high plasma Cu level. Thiomolybdato complexes of Cu are therefore, of interest (Section 4).

*We wish to thank the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie for their financial support.*

[130] The first published complex was $[Ni(WS_4)_2]^{2-}$ [136].

[131] Complexes of the type $[Co(MO_{4-n}S_n)_2]^{2-}$ ($n=3, 4$) are formed from $CoCl_2$ and $(PPh_4)_2MO_{4-n}S_n$ in dimethyl formamide or dimethyl sulfoxides. The complex formation (unambiguously proved with $WO_{4-n}S_n^{2-}$) can be detected by recording the NIR/UV/VIS-spectra and the cyclic voltammogram; *A. Müller, R. Jostes*, unpublished results.

[144] *A. Müller, S. Sarkar*, Angew. Chem. *89*, 748 (1977). Angew. Chem. Int. Ed. Engl. *16*, 705 (1977). The first thiometalato complexes of iron were described in this work (*e.g.* $(PPh_4)_2[Fe(WS_4)_2]$), and were isolated in pure form with discrete complex anions; the possible relevance to the nitrogenase problem was pointed out for the first time. Moreover, the strong $M' \rightarrow MS_4^{2-}$ electron delocalization was pointed out, which explains for example the tendency of the Fe and Co complexes to accept more ligands.

[145] *E. Ahlborn*, Diploma thesis, Göttingen 1971. (The UV/VIS spectrum of $[Fe(MoS_4)_2]^{3-}$ is pictured, but no assignments could be made).

[146] *A. Müller, A. Trautwein, U. Bender*, unpublished results.

[147] The $[Fe(MoS_4)_2]^{3-}$ present in equilibrium does not precipitate as a $PPh_4^+$ salt.

[225] In a recently published paper (*F. Sècheresse, S. Lavigne, Y. Jeannin, J. Lefebvre,* J. Coord. Chem. *11,* 11 (1981)), the preparation and structural characterisation of $(PPh_4)_2W_3OS_8$, which contained impurities of $W_3S_9^{2-}$ (too long W=O distance) was described. According to the reported bond distances and a $\nu$(WO) at 800 $cm^{-1}$ (see also [215]) the $[N(^nC_4H_9)_4]_2W_3OS_8$ (*K. Hahnewald, G. Kiel, G. Gattow,* Z. anorg. allg. Chem. *478,* 215 (1981)) is also not pure, which leads to wrong crystallographic assumptions. However, we could obtain the pure $W_3OS_8^{2-}$ ion as the $Cs^+$ salt [212]; the crystal structure determination will be published in detail [120].

[226] $(PPh_3)_3Cu_2(WSe_4)$, having the same structure as the corresponding S analogue, could also be isdated (*A. Müller, J. Schimanski,* unpublished results).

[227] a) We have recently isolated complexes of general formula $PPh_4M'(MS_4)$, (M' = Fe, Co, Cu, Ag), which contain symmetrically coordinated $MS_4$ units, as for example in the chain-like structure of $(NH_4)(MoS_4)$ [133]. b) $[Co(WS_4)_2]^{3-}$ could also be isolated crystalline solid by us.

# COMMUNICATIONS

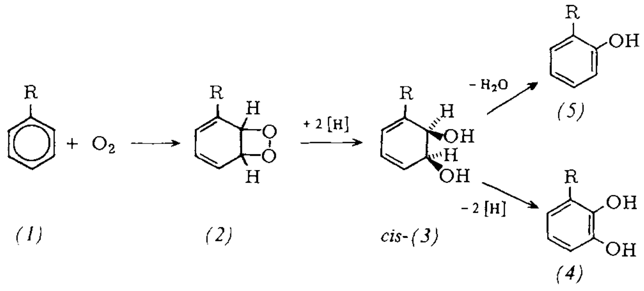
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## Initial Steps in the Degradation of Chlorobenzene Derivatives by *Pseudomonas putida*[*]

By *Karlheinz Ballschmiter* and *Charlotte Scholz*[*]

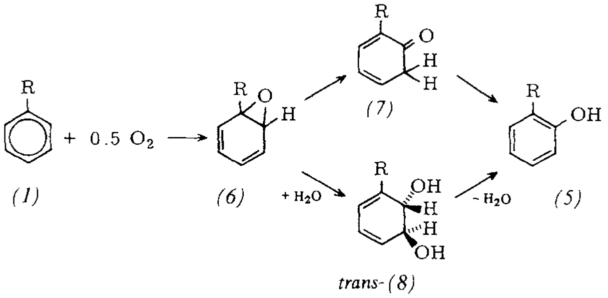
The initial step in the bacterial degradation of arenes is generally accepted to be a reaction with a dioxygenase[1].

A dioxetane *(2)*, which is presumed to be an intermediate, reacts *via* a—in many cases isolated—*cis*-cyclohexadienediol *(3)* to give the pyrocatechol *(4)*[1].



In contrast on benzene-selected mixed cultures of soil bacteria, phenols are formed from lipophilic substituted benzene- and biphenyl-derivatives[2]. 1-Naphthol is the main metabolite formed when naphthalene is treated with a species of blue algae (cyanobacterium)[3].

Phenols could be formed either by enzymatic or spontaneous dehydration of the *cis*-cyclohexadienediols *(3)*, or by transformation or hydration of arene oxides (oxiranes) following attack of monooxygenases. An indication that *(6)* is involved as a precursor is provided by the migration of substituents (NIH-shift) to cyclohexadienone *(7)*[4]. This NIH-shift was detected in the bacterial formation of chlorophenol from chlorobenzene derivatives[2a]. The hydroxylation of chlorophenols to chloropyrocatechols by *Pseudomonas sp.* has been described[2c, 5].



The three *Pseudomonas* species (see experimental), after 100 h incubation at 30°C, produced the following results: 2,3-, 3,4-, and 2,6-dichlorophenol are formed from 1,2-dichlorobenzene. Chlorophenol could not be detected. Only 2,4,6-trichlorophenol is produced from 1,3,5-trichlorobenzene, even upon incubation with a soil mixture culture which had been benzene-selected. Incubation with rat liver microsomes in a pH 7.6 buffer in the presence of NADPH under aerobic conditions, also led to formation of the same product. Dichlorophenols are not produced. When biphenyl is used as substrate in a culture medium with benzene as C source, with pentafluorobenzyl bromide as a derivatizing agent, of the three possible hydroxybiphenyl derivatives only the 2-hydroxy compound is detected, apart from phenol itself.

The $H^+$-catalyzed dehydration of a 5,6-dichlorocyclohexan-3,5-diene-1,2 diol yielded, after *ca.* 70% conversion of the diol, the 2,3-, 3,4-, and 3,5-dichlorophenols in the ratio 4 : 17 : 1.

[**] Microbial Degradation of Chlorinated Arenes, Part 7.—Part 6: [2c].

© *Verlag Chemie GmbH, 6940 Weinheim, 1981* *0570-0833/81/1111-0955 $ 02.50/0*

The dehydration of the dichlorocyclohexadienediol isolated from the bacterial synthesis[8] does not completely simulate the degradation of this compound by *Pseudomonas sp*. The same intermediate occurs in the dehydration of the diol from the *cis*- as well as from the *trans*-form after protonation and cleavage of $H_2O$[2c]; apart from kinetic differences in the course of the reaction, the same secondary products should be formed[1g]. The 3,5-dichlorophenol formed by dehydration could arise *via* an allyl rearrangement of the intermediate carbenium ion; it was, however, not detected in the bacterial degradation. The formation of 2,6-dichlorophenol from 1,2-dichlorobenzene in the bacterial degradation indicates a rearrangement of an α-dichloroepoxide.

Further evidence for a monooxygenase attack is provided by the formation of 2,4,6-trichlorophenol from 1,3,5-trichlorobenzene, even when no NIH-shift of the chlorine atom occurs. Moreover, the same results were obtained with pseudomonads and rat liver microsomes, indicating that the same enzymatic reactions are involved. Finally, only the direct detection of epoxides or dioxetanes would indicate that *one* primary reaction occurs—with the prerequisite that *only one* exists[1g]; even the use of $^{18}O_2$ labels in reactions having a parallel course does not enable clear statements to be made[3].

*Experimental*

Pure cultures of the arene degrader *Pseudomonas putida* (No. 50802, No. 50222, and No. 548 from the Deutsche Sammlung von Mikroorganismen, Grisebachstrasse 8, D-3400 Göttingen) were used. The degradation was performed in parallel with a benzene-selected soil mixed culture, as well as with phenobarbital-induced rat liver microsomes. 1,2-Dichlorobenzene, 1,3,5-trichlorobenzene, and biphenyl ($10^{-6}$ M) were used in conjunction with benzene as the primary C source. These compounds were introduced into the standard culture salt medium by diffusion from hard paraffin[6]. The metabolites were identified as the pentafluorophenyl ethers or acetates by comparison of the retention indices with those of authentic compounds. After high resolution capillary gas chromatography using an electron capture detector[6] reliable identification, even in the nanogram range[7] is possible.

Epoxides or cyclohexadienediols should hardly rearrange during the work-up of the culture mixtures by extractive derivatization of the phenolacetates from aqueous $K_2CO_3$ solution (0.1 M). 5,6-Dichlorocyclohexa-3,5-diene-1,2-diol—obtained by degradation of 1,2-dichlorobenzol with a *Pseudomonas* mutant[8]—was $H^+$-catalytically dehydrogenated at 23 °C in 2 M HCl within 24 h.

## Do All Eight Diastereomeric Bacteriochlorophylls Exist in Nature?

By *Bernd Scholz* and *Karlheinz Ballschmiter*[*]

Numerous anaerobic bacteria, *e.g.* the *Rhodospirillaceae*, are able to perform photosynthesis. They contain tetrahydroporphyrins; the green plant chlorophyll a and b (CHL a and b) are dihydroporphyrins. We have investigated bacteriochlorophyll ap (BCHL ap) and bacteriochlorophyll agg (BCHL agg)—together designated, in general, as BCHL a—as well as BCHL b (Fig. 1). Because of the different arrangements of substituents at C3, C4, C7, C8, and C10, eight diastereomers of BCHL a, and four diastereomers of BCHL b should occur. Until now only for BCHL a has the epimeric compound BCHL a' been detected[1]. The BCHL a epimers have—relative to the position of the substituents at C7—different configurations at C10.

The ready separation of the C10 epimers of CHL a and b by reversed phase high pressure liquid chromatography (RP-HPLC)[2] leads one to expect that the BCHL a diastereomers can also be separated using this method. The thin layer chromatographic separation of an unknown blue compound from commercial samples of BCHL ap is a further indication of other diastereomers[3].

The isolation of bacteriochlorophylls from cultures of *Rhodospirillum rubrum* (BCHL agg), *Chromatium* D, *Rhodospirillum fulvum* (BCHL ap), and *Rhodopseudomonas viridis* (BCHL b), as well as the resolution of the compounds into diastereomers by RP-HPLC are described in [4]. Under optimized separation conditions, each of BCHL ap and BCHL agg can be resolved into eight bands of largely different intensities using RP-C18 HPLC (Fig. 2A + 2C).

For BCHL a, the assignment of the diastereomers shown in Scheme 1 is possible. The configuration of the substituents at C7 and C8 (ring IV), as well as at C3 and C4 (ring II) is *trans* from earlier results[5]. Diastereomers which are present at the 10—20% level cannot be assigned by NMR spectroscopy[5c]. In contrast, components which are only present at the 1% level can be detected at 365 nm in the Soret region and also at 780 nm in the infrared after liquid chromatographic separation.

The isolation of the components separated by HPLC and their oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ)[6] enables peak 6 to be assigned to 2-devinyl-2-acetyl-proto-CHL agg (rings II and IV dehydrogenated); peak 6 is therefore not detected at 780 nm. Peaks 1—5, 7, and 8 were rearranged by treatment with DDQ to 2-devinyl-2-acetyl-CHL agg (peak 16) and by excess DDQ to

Fig. 1. Structure of various chlorophylls and bacteriochlorophylls ($R^5 = CO_2CH_3$).

2-devinyl-2-acetyl-proto-CHL agg (peak 6) (Fig. 2B), *i.e.* the components 1—5, 7, and 8 are all diastereomers of BCHL agg. By analogy, these results also apply to the BCHL ap diastereomers. Furthermore, it should be noted that the *Chromatium* D bacteria, in addition to the main compound BCHL ap, contain small amounts of BCHL agg.

Scheme 1. Systematology of the possible diastereomers of bacteriochlorophyll ap and agg. The absolute configuration of the main component of bacteriochlorophyll agg was determined as BCHL agg12 [5a]. The C10 epimer pertaining to this is the BCHL a'gg12 [1]. By analogy the statements also apply to BCHL ap: n.d. signifies not detected; $hR_f$-value is the $R_f$ value times 100.

The DDQ oxidation of the diastereomers separated by RP-C18-HPLC also proves that the side chain at C7 is the same in both classes of compounds. In other cases, the peaks from more than each of two oxidized bacteriochlorophylls would have to appear in the chromatogram.

The combination of thin layer (TLC) distribution chromatography[3] and RP-C18-HPLC enables the assignment of the separated BCHL agg diastereomers, reproduced in Scheme 1, to be made. All the compounds contained in the three TLC spots produce the compounds devinyl-2-acetyl-CHL agg and 2-devinyl-2-acetyl-proto-CHL agg after reaction with DDQ *i.e.* intact BCHL agg diastereomers are also involved here.

From the result that $k'$ BCHL a$<k'$ BCHL a'—the $k'$ value is the quotient of the net retention time, and the retention time of the solvent front is a measure of the interaction time and hence for the interaction strength of the compounds with the stationary phase—it can be derived that in RP-C18-HPLC the retention time of diastereomers with increasing screening from both sides of the porphyrin plane is lowered with *transoid* orientated substituents. The smaller retention time of BCHL a, relative to that of BCHL a', implies a better solvation in the eluent acetonitrile/water (80:20). Generalization of this result leads *e.g.* to the expectation of a shorter retention time for BCHL a11 than for BCHL a12. Furthermore, diastereomers with *trans*-orientated groups at C3 and C4 should be preferred to those with *cis*-orientated groups, and this facilitates the assignment of the BCHL a diastereomers.

Accordingly TLC spot 1 can, at most, contain one BCHL a'. Therein, the components 1, 2, and 3, which can probably be assigned to BCHL a11, BCHL a'11, and BCHL a21, respectively, can be detected by RP-C18-

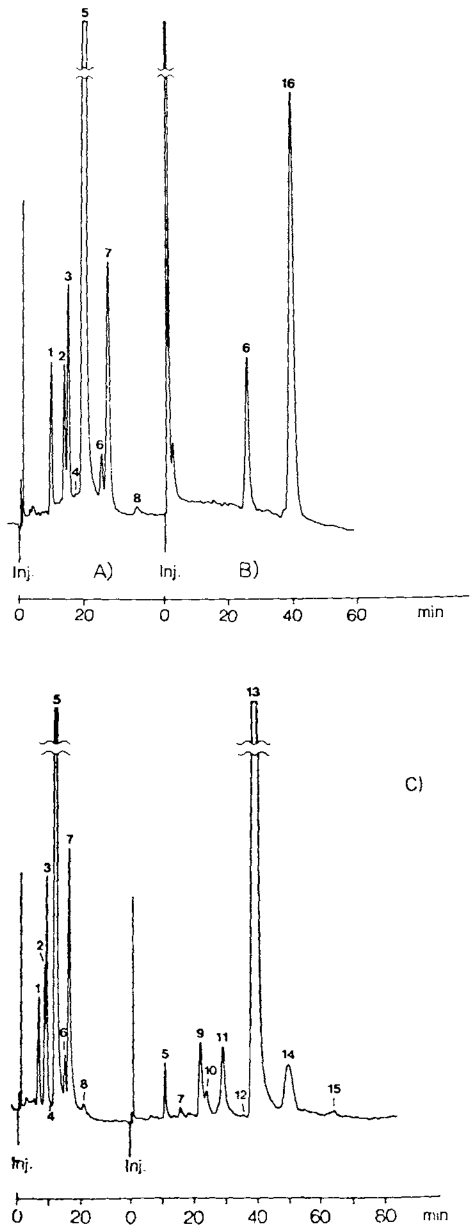

Fig. 2. A) HPLC chromatogram of BCHL agg at maximal resolution. Mobile phase: acetonitrile/water, 80/20 (V/V), stationary phase: Lichrosorb RP-18, 5 μm. Detection at 365 nm. B) HPLC chromatogram of 2-devinyl-2-acetyl-proto-CHL agg (peak 6) and 2-devinyl-2-acetyl-CHL agg (peak 16) after oxidation of the BCHL agg diastereomers (peak 1—8) with DDQ. Conditions as in A). C) HPLC chromatogram of BCHL agg (peaks 1—8) and BCHL ap (peaks 9—15). Mobile phase: acetonitrile/water 88/12 (V/V), stationary phase: Lichrosorb RP-18, 5 μm. Detection at 365 nm.

HPLC. The main peak in the HPLC chromatogram is assigned the usual structure BCHL a of the diastereomer BCHL a12. The *cisoid*-arrangement of the groups at C4/C7 also corresponds to the retention behavior in TLC (spot 2). TLC spot 3 contains the HPLC peaks 7 and 8 with a small amount of 5, *i.e.* because of its retention behavior, this compound should have an optimally unrestricted porphyrin plane. This occurs in the diastereomers BCHL a'12 and BCHL a22, as well as in BCHL a'22 and BCHL a'21. From the composition, the HPLC peak 7 corresponds to BCHL a'12; unequivocal assignment of the HPLC peak 8 cannot be made, however it probably arises from BCHL a22. The composition BCHL a11 (5.5%), a12 (71), a21 (8.5), a'11 (5.5), a'12 (8.5), a22 (0.8), a'21—peak 4—(0.2) is consistent with the assumption that by analogy to ring IV, on the basis of the biosynthesis of the bacteriochlorophylls at ring II, a *trans*-hydrogenation between C3/C4 is preferred. In an analogous way, the structural assignments also apply to the BCHL ap diastereomers (Fig. 2C), *i.e.* peak 9 = a11, 10 = a'11, 11 = a21, 12 = a'21, 13 = a12, 14 = a'12, and 15 = a22 (Scheme 1).

Although it has thus far not been possible to isolate sufficient amounts of the individual BCHL a diastereomers for an NMR-spectroscopic investigation, and final proof for the proposed structural assignment is still lacking, the presence of the different diastereomers in the photosynthetic units of the given microorganisms has been unequivocally established. The structure-related evaluation of the retentions using the combination of RP-DC and RP-C18-HPLC provide more than an indication for the correct characterization of the individual BCHL a' diastereomers.

## A New Cationic Hydrido-Bridged Rhodium(I)-Iridium(III) Complex[**]

By *Alberto Albinati, Alfredo Musco, Ralph Naegeli,* and *Luigi M. Venanzi*[*]

The formation of homometallic hydrido-bridged dinuclear complexes having two alike metal atoms has frequently been observed in catalytic hydrogenations[1,2]; dinuclear species containing one five-coordinate rhodium(I) and one six-coordinate rhodium(III) of the type $[L_2Rh(\mu_2\text{-}H)_3RhHL_2]$ ($L = P(OR)_3$) have been postulated as intermediates in catalytic hydrogenation[2].

During a study of dinuclear hydrido-bridged complexes[3] we isolated complex *(1)*, which is related to the above mentioned type and contains a five-coordinate

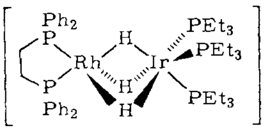
[**] This work was supported by the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung.

rhodium(I) and a six-coordinate iridium(III). The dark green complex *(1)* was obtained by the reaction of $[Rh(diphos)(MeOH)_2][BF_4]$ with *mer*-$[IrH_3(PEt_3)_3]$ followed by



$[BPh_4]$ *(1)*

precipitation of the dinuclear cation with $Na[BPh_4]$. Whereas *(1)* in crystalline form is air-stable, its solutions decompose on exposure to air.

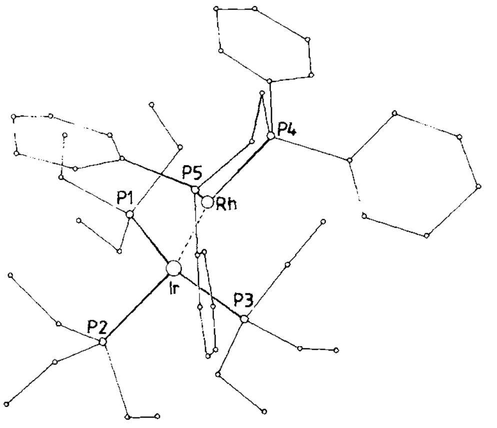


Fig. 1. Molecular structure of the cation of *(1)* in the crystal. Bond lengths [Å]: Ir···Rh 2.636(2), Ir—P1 2.352(4), Ir—P2 2.299(6), Ir—P3 2.334(4), Rh—P4 2.157(6), Rh—P5 2.194(6); Bond angles [°]: P1—Ir—P2 101.4(2), P2—Ir—P3 100.5(2), P1—Ir—P3 98.6(1), Rh—Ir—P(1) 111.6(1), Rh—Ir—P2 122.0, Rh—Ir—P3 118.9(1), P4—Rh—P(5) 83.2(2). Torsion angles [°] (ay. errors *ca.* 0.6°): P2—Ir—Rh—P4 −178.8, P2—Ir—Rh—P5 1.6, P1—Ir—Rh—P4 61.2, P3—Ir—Rh—P5 127.9.

The molecular geometry of the cation *(1)* is shown in Figure 1[4]. The hydride ligands could not be located. From the positions of the heavy atoms one can postulate a distorted octahedral coordination around the $Ir^{III}$ center with P1, P2, P3, and the three hydride ligands as donor atoms. The positions of the heavy atoms are also consistent with the presence of three bridging hydride ligands and thus a five-coordinate rhodium(I). The differences in the P—Rh—Ir and Rh—Ir—P bond angles and in the Rh—P and Ir—P bond lengths indicate that the $Rh(\mu_2\text{-}H)_3Ir$ unit is not symmetrical in the solid state.

The presence of hydride ligands in compound *(1)* is indicated by its $^1H$-NMR spectrum, which shows a complex multiplet centered at $\delta = -12.0$ (Table 1). This multiplet simplifies to a doublet of triplets on selective decoupling of P1, P2, and P3. The number of hydride ligands was confirmed by integrating the hydride region of the $^1H$-NMR spectrum of *(1)* relative to that of a known amount of *trans*-$[PtHCl(PEt_3)_2]$ which had been added to the solution. The $^1H$- and $^{31}P$-NMR spectra were unaltered by addition of this species.

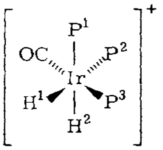
Table 1. Selected NMR data for *(1)*—*(3)*. 90 MHz $^1H$-NMR and 36.43 MHz $^{31}P$-NMR in $[D_6]$acetone.

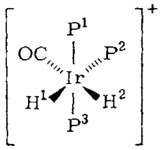
*(1)*. $^1H$-NMR: $\delta = -12.0$ (m, H 1,2,3, $^1J(Rh, H\,1,2,3) = 22$ Hz, $^2J(P4,5, H\,1,2,3) = 10$ Hz); $^{31}P\{^1H\}$-NMR: $\delta = 80.0$ (dq, P4,5, $^1J(Rh, P4,5) = 178$ Hz, $^4J(P4,5, P1,2,3) = 8.3$ Hz), −8.5 (dt, P1,2,3, $^3J(Rh, P1,2,3) = 6.8$ Hz)
*(2)*. $^{31}P$-NMR: $\delta = -16.7$ (P3, $^2J(P1, P3) = 22.3$ Hz), −27.8 (P1,2); $^1H$-NMR: $\delta = -12.4$ (H1,2, $^2J(P3, H1,2) = 7.5$ Hz)
*(3)*. $^{31}P$-NMR: $\delta = -9.6$ (P1,3, $^2J(P1,3, P2) = 15.4$ Hz), −21.7 (P2); $^1H$-NMR: $\delta = -11.3$ (H2, $^2J(P1,3, H2) = 17.0$ Hz, $^2J(P2, H2) = 17.0$ Hz, $^2J(H1, H2) = 4.5$ Hz), −12.7 (H1, $^2J(P1,3, H1) = 19.3$ Hz, $^2J(P2, H1) = 109$ Hz)

The $^{31}P\{^1H\}$-NMR spectrum of *(1)* is also consistent with the proposed structure (Table 1). The $^1H$- and $^{31}P$-NMR spectra are temperature-independent over the range 200—330 °K.

In the IR spectra (nujol) of *(1)* and of $[(diphos)Rh(\mu_2\text{-}D)_3Ir(PEt_3)_3][BPh_4]$, the H—M and D—M stretching vibrations, respectively, occur as fairly sharp, intense bands at 1686 and 1200 cm⁻¹ and broad bands centered at *ca.* 1800 and 1300 cm⁻¹.

*(2)*





*(3)*

The cation of *(1)* reacts irreversibly with CO to give *fac*-$[IrH_2(CO)(PEt_3)_3]^+$ *(2)*, which slowly rearranges to its *mer*-isomer *(3)* and an unidentified rhodium complex. Structures *(2)* and *(3)* were assigned from $^1H$- and $^{31}P$-NMR data (Table 1). The isomer with *trans*-hydride ligands has been obtained from the reaction of $[(PEt_3)PhPt(\mu_2\text{-}H)_2IrH(PEt_3)_3]^+$ with CO[6].

The isolation of a compound related to complexes of type $[L_2Rh(\mu_2\text{-}H)_3RhHL_2]$ is probably due to the inertness caused by the six-coordinate iridium(III) center in *(1)*. Preliminary investigations indicate that *(1)* is not a hydrogenation catalyst under standard conditions.

## *Experimental*

A solution of $[Rh(nbd)(diphos)][BF_4]$ (nbd = norbornadiene) (623 mg, 1 mmol) in methanol (40 mL) was hydrogenated for 2 h at atmospheric pressure. A solution of *mer*-$[IrH_3(PEt_3)_3]$ (549 mg, 1 mmol) in methanol (5 mL) was then added and a dark green color developed. *(1)* was precipitated from solution by addition of $Na[BPh_4]$ (342 mg, 1 mmol) and the solid recrystallized from acetone/methanol. Yield 1.1 g (88%).

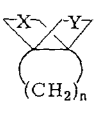
## Synthesis of Dithiapropellanes with Annelated Benzene Rings—Precursors for Molecules with the Benzene-Dewar Benzene Structure[**]

By *Klaus Weinges, Peter Günther, Wolfgang Kasel, Georg Hubertus,* and *Petra Günther*[*]

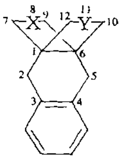
*Dedicated to Professor Karl Freudenberg on the occasion of his 95th birthday*

For some years we have investigated the thermal and photochemical behavior of 1,4-polymethylene Dewar benzene derivatives *(5)* prepared from dithiapropellanes *(1a)*[1-3]. The limit to their thermal valence isomerization is reached in the rearrangement of 1,4-hexamethylene Dewar benzene *(5)*, n = 6, to [6]paracyclophane (1,4-hexamethylenebenzene)[4]; [5]paracyclophane cannot be prepared in this way from *(5)*, n = 5[5].

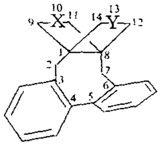
We have now prepared the hydrocarbons *(6)–(8)*, with benzene-Dewar benzene structure, using synthetic methods already tried and tested for 1,4-polymethylene Dewar benzene derivatives *(5)*, and also recently for pterodactyladiene[6]. The dithiapropellanes *(2a)–(4a)* were used as educts (Table 1). Work published by *Jamrozik*[7a] and *Ripoll*[8], who have described the dioxapropellanes *(2c)* and *(4c)*, respectively, prompted us to publish a preliminary account of our results although they are, at present, incomplete.



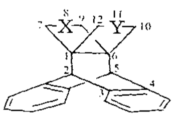
(1)



(2)

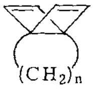


(3)

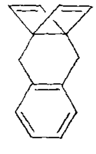


(4)

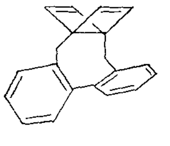
*(a)*: X, Y = S; *(b)*: X = O, Y = S; *(c)*: X, Y = O



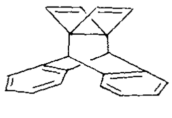
(5)



(6)



(7)



(8)

We found that 3,4-benzo[4.2.2]propella-7,9-diene *(6)* obtained from *(2a)* is stable up to 120 °C, whereas irradiation produced an isomerization product of, as yet, unknown constitution. The benzene ring must participate in this photochemical reaction, since aromatic protons can no longer be detected by $^1$H-NMR spectroscopy.

The valence isomerization of the Dewar benzene derivative *(7)*, preparable from *(3a)*, is interesting because of the effect of the cyclooctadiene ring on the previously mentioned valence isomerization of *(5)* (n = 6) to [6]paracyclophane. Moreover, the diheteropropellanes *(3)* are chiral, which is also apparent from the $^1$H- and $^{13}$C-NMR spectra of *(3a)* (see Table 1). It should be possible to separate the racemic forms present, which from a consideration of models appear to be stable, and hence to obtain the first chiral 1,4-bridged Dewar derivative *(7)* from the enantiomers of *(3a)*; however, initial attempts to resolve the racemates of *(3a–c)* on acylated cellulose[9] have been unsuccessful to date. The Dewar benzene derivative *(8)* has already been prepared by another route and ought to be stable up to *ca.* 700 °C[10]. Its photochemical behavior was not investigated.

The most important intermediate products in the synthesis of the dithiapropellanes *(2a)*, *(3a)*, and *(4a)* are the tetraethyl 1,1,2,2-tetracarboxylates *(9)*, each of which must be prepared by a different route[1,2b].

The esters *(9d)* and *(9e)*, respectively, are prepared by condensation of the disodium or dipotassium salts of tetraethyl 1,1,2,2-ethanetetracarboxylate with the corresponding bis(bromomethyl) compounds[7], whereas *(9f)* is obtained, *via* a diene synthesis, from anthracene and tetraethyl 1,1,2,2-ethenetetracarboxylate[8]. The additional reaction steps follow our previously described procedure[1,2]: LiAlH$_4$ reduction of *(9)* in tetrahydrofuran (THF) led to the tetrols *(10)*, which yielded the readily crystallizing tetrakis(methanesulfonyl) derivatives *(11)*. *(11)* is reacted with sodium sulfide nonahydrate in anhydrous dimethyl

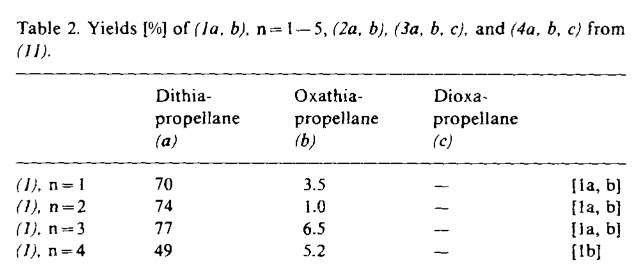


Table 1. Selected physical data for *(2a)*, *(3a)*, and *(4a)*.

*(2a)*: M.p. = 108 °C (Methanol); $^1$H-NMR (300 MHz, CDCl$_3$): $\delta = 7.08$, 7.16 (2m, 4 arom. [**] Condensed Ring Systems, Part 14.—Part 13: [3b].

sulfoxide (DMSO) or hexamethylphosphoric triamide (HMPA). Whereas from *(9)*, $Z=(CH_2)_n$, in general, the dithiapropellanes *(1a)* are found as the major products, in addition to smaller amounts of the oxathiapropellanes *(1b)*, the product ratio is different from the diheteropropellanes *(2)*—*(4)* (see Table 2). In the analogous reaction starting from *(11f)* in DMSO, *Ripoll*[8] neither obtained the dithiapropellane *(4a)* nor the oxathiapropellane *(4b)*, but only the dioxapropellane *(4c)* in very high yield. The different results presumably originate from the different water contents of the solvent and reagent.

## Decomposition of the Yellow Form of Thiamine[**]

By *Rudolf F. W. Hopmann* and *Gian Pietro Brugnoni*[*]

When thiamine (vitamin $B_1$) is dissolved in strongly alkaline media, a yellow color, which slowly fades, immediately develops; this is due to the "yellow form" $YF^{\ominus}$, which has been investigated spectroscopically[1] and kinetically[2,3]. We propose here a novel mechanism for the alkali-induced transformation of thiamine.

The decay of $YF^{\ominus}$ can be followed in the time-dependent UV spectra (Fig. 1). The spectrum of $YF^{\ominus}$ is designated as A1 and the thiol form $TS^{\ominus}$ as A9. In alkaline solution $TS^{\ominus}$ is the thermodynamically stable product of the alkali-induced transformation of thiamine, whose spectrum (curve B) is shown in Figure 1. The time-dependent UV spectra pass through isosbestic points indicating that no intermediate is formed in significant amounts.

The rearrangement from $YF^{\ominus}$ to $TS^{\ominus}$ is a pseudounimolecular reaction. A Lorentz curve is formed upon plotting the logarithm of the rate constants $k_{obs}$ against the pH value, in agreement with previous results[1] (Fig. 2, lower part). The observation that the rate of transformation at low pH is limited by the OH ion concentration and at high pH by the $H^{\oplus}$ ion concentration is not supported by the frequently investigated thiazolium hydrolysis[4] at pH values between 9.0 and 11.5 represented by the ascending branch of the Lorentz curve. The Lorentz curve must, therefore, be interpreted as indicating a change in the reaction mechanism. The only information on the decay of $YF^{\ominus}$ at high pH values that can be deduced from the decreasing branch of the Lorentz curve is a rate constant of $8\times10^9\ M^{-1}\ s^{-1}$, which would correspond to a diffusion-controlled proton transfer reaction[5]. The amplitudes observed (upper part of Fig. 2) provide no information on this reaction step, since they are assignable to the much more rapid formation of $YF^{\ominus}$.

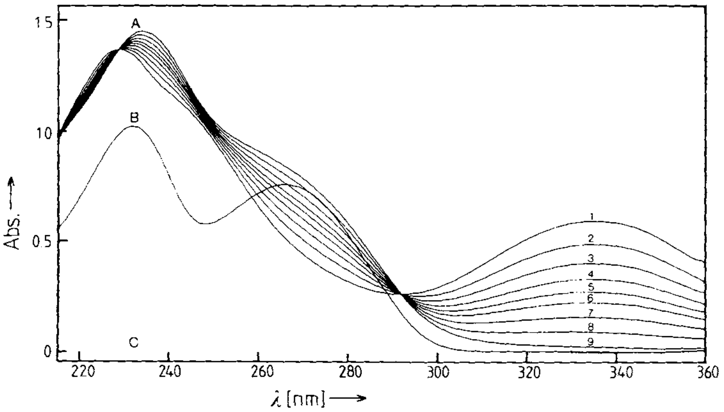

Fig. 1. Time-dependent spectra for the dissociation of the yellow form of thiamine. Thiamine concentration: $9.3\times10^{-5}$ M in 0.1 N NaOH, pH = 12.61. Curves A1—A9: recording begins after 0, 100, 200, 300, 400, 500, 700, 1000, and 1750 s, respectively (forward and reverse together take 100 s). Curve B: same concentration of thiamine in $HPO_4^{2-}/H_2PO_4^-$ buffer, pH = 6.95. Temperature: 22.5 °C, Cary 118 CX, damping 1 s, scan rate 2 nm $s^{-1}$, 0.5 mm slit width, autogain.

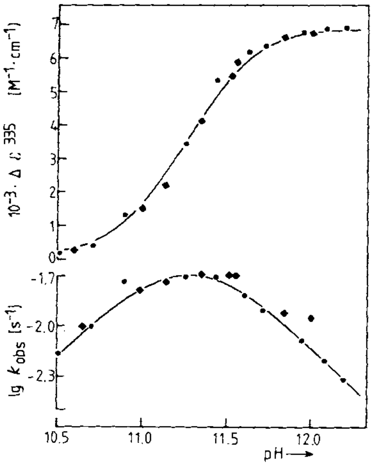

Fig. 2. pH-Rate profile and amplitudes of the decomposition of the yellow form of thiamine. Buffers: ◆ borate, ● glycinate, ionic strength 0.1 M, 22 °C. $\Delta\varepsilon^{335}$ is the change of the absorbancy ($\Delta\varepsilon=\varepsilon_{product}-\varepsilon_{educt}$) at 335 nm.

The reaction is almost independent of the buffer concentration, but depends on the ionic strength $\mu$. From the equation[6]:

$$\log k_{obs}=\log k^0+1.018\,z_A z_B A\sqrt{\mu}$$

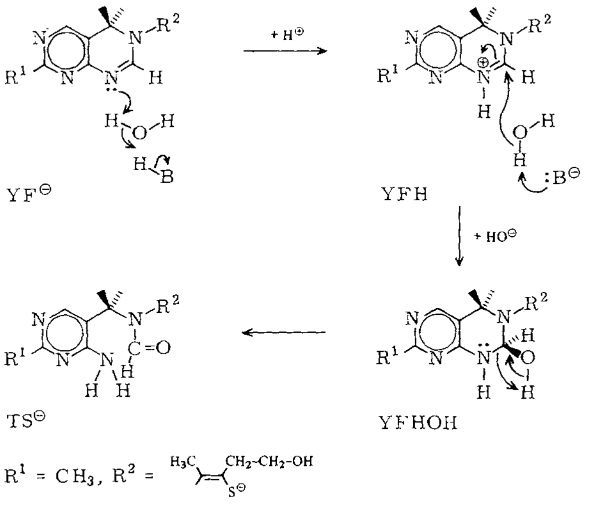
[**] Thiamine Catalysis, Part 3.—Part 2: [2].

where $k^0$ is the reaction rate extrapolated to an ionic strength of zero, $z_A$ and $z_B$ are the respective charges of the reactants, and A is a constant, we found: $k^0 = 0.0254\ s^{-1}$, $z_A \cdot z_B = -1$, and $A = 0.115$ (arsenate buffer, $4 \times 10^{-4}$ M, pH 11.55, $\mu$ adjusted with NaCl/$H_2O$ at constant buffer concentration). Since $z_A z_B$ is negative, and $YF^{\ominus}$ possesses a negative charge, the reaction partner must be positively charged: it is the proton. By synthesizing the ring skeleton of $YF^{\ominus}$ ($R^1 = R^2 = CH_3$), by its methylation, and by determining the p$K$ values of this and other compounds it was concluded that the nitrogen N1 of the dihydropyrimidine ring is probably the proton acceptor[7]. A p$K$ value of 6.38 was found, whereas the p$K$ values of the pyrimidine ring in $TS^{\ominus}$ and thiamine are 6.13[7] and 4.85[8], respectively.

It was assumed that $YF^{\ominus}$ is the product of kinetic control, and $TS^{\ominus}$ the product of thermodynamic control in the transformation, whereby thiamine exists in equilibrium with $YF^{\ominus}$ (p$K_{av}$ = 11.4), and that thiamine can rearrange to $TS^{\ominus}$ at any pH value by hydrolytic cleavage of its thiazolium ring[1]. We postulate that $YF^{\ominus}$ can be directly transformed in an acid catalyzed reaction into $TS^{\ominus}$.

A distribution of the reactants in equilibrium with each other (thiamine, $YF^{\ominus}$, and YFH) at a given pH value can be calculated from the p$K$ values of the protolytic reactions involved, and from the corresponding rate constants the rates for the pathways suggested by *Maier* and *Metzler*[1], as well as ourselves, can be estimated[9]. A ratio of *ca.* $10^{-10}:1$ results, whereby the calculated rate for the direct transformation of $YF^{\ominus}$ into $TS^{\ominus}$ is of the order of magnitude of the measured rates. This strongly supports our proposition.



Scheme 1.

Since $TS^{\ominus}$ and $YF^{\ominus}$ are negatively charged, but $YF^{\ominus}$ is protonated to yield YFH, the protonation must be followed by a deprotonation. This also formally corresponds to the addition of an $OH^{\ominus}$ ion (formation of the pseudobase YFHOH). Consequently $YF^{\ominus}$ decays *via* a similar ring opening step as the thiazolium salts. In fact, in dihydropyrimidopyrimidine, the dihydropyrimidine ring is readily opened by hydrolysis[7].

Because of the low basicity and nucleophilicity of the $NH_2$ group in $TS^{\ominus}$, the re-formation of thiamine from $TS^{\ominus}$ *via* $YF^{\ominus}$ is not possible. The sequence $YF^{\ominus} \rightarrow TS^{\ominus}$ is therefore, quasi-irreversible.

## $[Ga_6Se_{14}]^{10-}$: A 1900 pm Long, Hexameric Anion

By *Hans-Jörg Deiseroth* and *Han Fu-Son*[*]

The reaction of caesium with gallium monoselenide leads—similar to that which we recently found in the analogous rubidium/indium monosulfide system[1a]—to an unexpected disproportionation of the monochalcogenide. Thereby, apart from elemental gallium, a ternary selenide of trivalent gallium having the composition $Cs_{10}Ga_6Se_{14}$ forms from Cs and GaSe. The crystal structure of this solid is distinguished by the until now unknown linear, *ca.* 1900 pm long, hexameric anion $[Ga_6Se_{14}]^{10-}$ and is, to our knowledge, the first ternary compound in the Cs/Ga/Se system whose single crystal structure has been investigated.

For the preparation of the novel compound, Cs and GaSe in the molar ratio 1:1 were reacted at 200 °C (24 h)[1b] using a previously described procedure[1a]. The reaction mixture, which is liquid at 750 °C, is held at the latter temperature for 1 h to ensure complete homogenization, before being slowly cooled (2 °C/h) to 580 °C and tempered at this temperature for 24 h. The product predominantly consists of pale-yellow, transparent, leaf-shaped crystals of $Cs_{10}Ga_6Se_{14}$, which are intermingled with droplets of Ga, and decompose and turn brown in air. DTA cooling plots show a sharp signal at 610 °C (exotherm) which is assigned to the crystallization of the ternary compound. Presumably $Cs_{10}Ga_6Se_{14}$ is thermodynamically stable in the $Cs_2Se/Ga_2Se_3$ system.

The most significant structural element of this compound is the anion $[Ga_6Se_{14}]^{10-}$, which consists of six, linear, edge-linked $GaSe_4$ tetrahedra. These unusually long, discrete anions with $C_{2h}$ point group symmetry are orientated along $[10\bar{1}]$ in the crystal (Fig. 1). The bond lengths and angles of the individual $GaSe_4$ tetrahedra correspond in order of magnitude to the values found for $TlGaSe_2$[2]. The special geometry of the limited edge-coupling leads in the hexameric $[Ga_6Se_{14}]^{10-}$, however, to pronounced gradation from the center to both ends of the anion. The coordination of the cations $Cs^+$ is marked by average Cs—Se distances of between 359 and 388 pm (CN: 5—8).

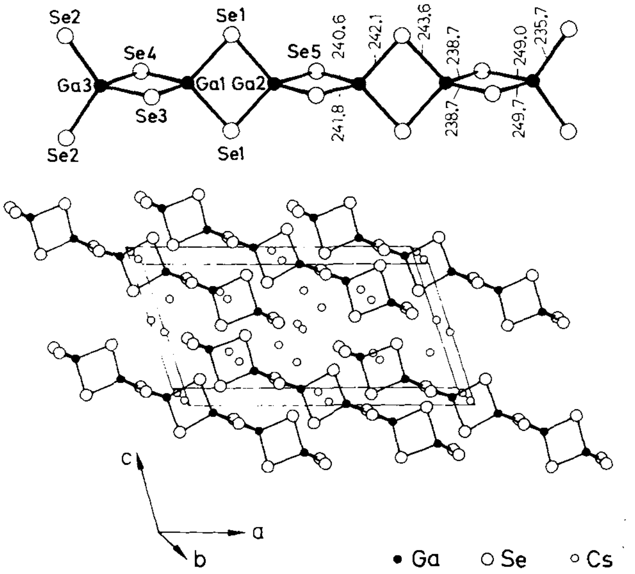

Fig. 1. $[Ga_6Se_{14}]^{10-}$ anion (distances in pm) and projection of the atomic arrangement of $Cs_{10}Ga_6Se_{14}$. Crystallographic data ($T=293$ K): C2/m, $a=1823.3(7)$, $b=1288.9(5)$, $c=966.8(3)$ pm, $\beta=108.20(3)°$, $Z=2$; $R=0.047$, $R_w=0.053$ (1907 reflections with $I>2\sigma(I)$). The Ga—Ga distances are: Ga2—Ga2 313.9, Ga1—Ga2 317.8, Ga1—Ga3 323.0 pm.

Structurally, $[Ga_6Se_{14}]^{10-}$ represents a link between the one-dimensional infinite edge-linked tetrahedral chains of type $SiS_2$ and isolated double-tetrahedra such as in $Al_2Cl_6$. Until now, the larger chalcogenic anions of elements of the third and fourth main groups have only been obtained from aqueous solutions. These possess, however, exclusively adamantane-type structures with corner-linked $MX_4$ tetrahedra, such as *e.g.* $[In_4S_{10}]^{8-}$[3], and not the limited one-dimensional edge-coupling found in $[Ga_6Se_{14}]^{10-}$. The only comparable species to $[Ga_6Se_{14}]^{10-}$ is the linear, tetrameric unit $[Zn_4O_8]^{8-}$ found in $Rb_2ZnO_2$ and $Cs_2ZnO_2$[4].

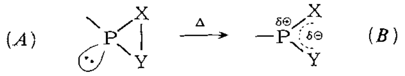
## 1,2,3λ³-Diazaphosphiridines— Synthesis, Molecular Structure and Ring Opening[**]

By *Edgar Niecke, Klaus Schwichtenhövel,*
*Hans-Günther Schäfer*, and *Bernt Krebs*[*]

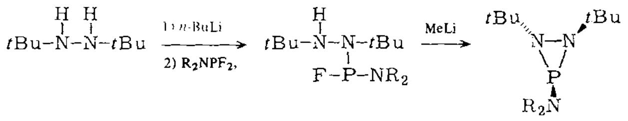
*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

Because of their high energy content, three-membered ring heterocycles (*A*) with λ³-phosphorus and heteroatoms of high electronegativity, should be good sources of the phosphorus ylides (*B*).

The combination of the elements with nitrogen ($X=Y=NR$), which through careful steering of the steric effects of the heteroatom ligands affords a sufficient kinetic stabilization of (*A*) *versus* the open ring (*B*), appeared the most promising to us.



Bearing in mind the expected thermolability of (*A*), as well as experience gained in the synthesis of 1,2λ³,3λ³-azadiphosphiridines[1], we selected as precursors the fluorophosphanes[2] *(1)*, accessible by metalation of 1,2-di-*tert*-butylhydrazine followed by reaction with amino(difluoro)phosphanes. Elimination of "HF" by methyllithium then led to the 1,2,3λ³-diazaphosphiridines *(2)*, which are colorless, remarkably air-stable solids. Their composition and constitution were confirmed by elemental analysis, mass spectroscopy[3], NMR data (Table 1), and for *(2a)* also by X-ray structural analysis (Fig. 1).



*(1)* *(2)*

*(a)*, R = *i*Pr; *(b)*, R = SiMe₃

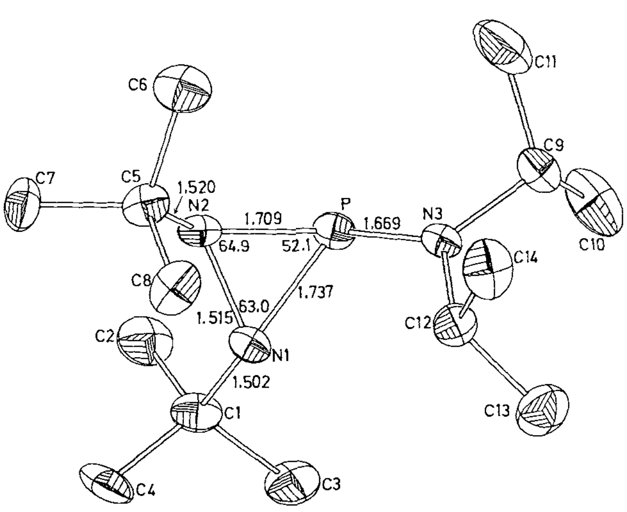


Fig. 1. Structure of *(2a)* in the crystal with the most important bond lengths [Å] and angles [°] (without H atoms). Standard errors: P—N 0.005 Å, N—N, N—C 0.007 Å.

The ¹H- and $^{13}C\{^1H\}$-NMR spectra of *(2a)* and *(2b)* at 303 K indicate free or hindered rotation, respectively, about the exocyclic PN bond, as well as groups of signals expected from the $C_2$ or $C_s$ molecular symmetry for the peripheral isopropyl- or bis(trimethylsilyl)-ligands and *tert*-butyl substituents. Lower temperatures lead in *(2a)* to a different stereochemistry for both isopropyl ligands, ($T_{c(rot)}=268\pm5$ K)[4]. Correspondingly, $^3J_{HP}$ and $^{2,3}J_{CP}$ change significantly, which by analogy to the values of $^2J_{SiP}$ and $^3J_{CP}$ in *(2b)*, respectively, arise from the different positions of these groups relative to the free electron pair on

[**] Part 22 of Phosphazenes of Coordination Number 2 and 3. This work was supported by the Fonds der Chemischen Industrie.—Part 21: [4b].

the phosphorus atom[5]. The broadening of the signals of the *tert*-butyl groups in the $^1$H-NMR, or their doubling in the $^{13}$C-NMR, indicate the *trans*-orientation of these ligands in the ground state of the molecules *(2a, b)*; the apparent stereochemistry simulated at room temperature is a consequence of a nitrogen inversion process[6] [$T_{c(inv)} = 238 \pm 5$ K *(2a)*, $240 \pm 5$ K *(2b)*]. The now chiral phosphorus atom explains the appearance of four groups of signals for the methyl ligands of the now prochiral isopropyl moieties in the $^{13}$C-NMR spectrum of *(2a)*.

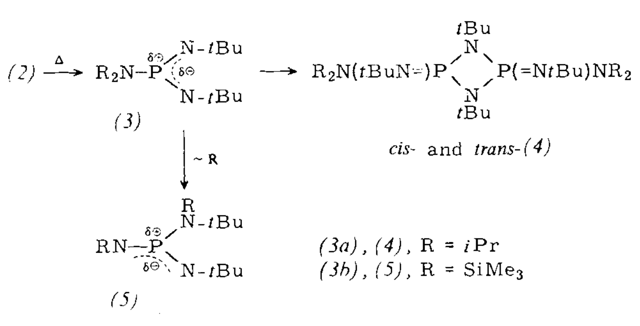
[a] 30% solution in CDCl$_3$ ($^1$H-NMR) or [D$_8$]toluene ($^{13}$C-NMR) with TMS as internal standard at 303 K. Values in brackets measured at 223 K. [b] $^{29}$Si-NMR: $\delta = 5.1$, 6.6, $^2J_{SiP} = 7.9$, 22.2 Hz. [c] Covered by the signal of the *tert*-butyl group at $\delta = 27.4$.

The strong deshielding of the phosphorus in the diazaphosphiridines [$\delta = -9.8$ *(2a)*; $-0.6$ *(2b)*] is surprising in view of the previously described three-membered ring systems with λ$^3$-phosphorus[7], particularly with respect to the 1,2λ$^3$-azaphosphiridine[8] ($^{31}$P-NMR: $\delta = -73.3$), which is isoelectronic to *(2a)*.

The crystal structure of *(2a)*[9] confirms the NMR spectroscopic results. Both *tert*-butyl substituents adopt the sterically favorable *trans*-positions, whereby the interaction between the "lone pairs" on the N atoms is also minimized. The almost coplanar arrangement of the atoms C5—N2—P—N3 in the crystal is possibly due to steric effects. The PN bonds in the ring are almost as long as in 1,3,2λ$^3$,4λ$^3$-diazadiphosphiridines[10]. In contrast, the NN distance of 151.5 pm is unusually large and is an indication of a high charge density at the N atoms.



In toluene at 50 °C the diazadiphosphiridines *(2)* isomerize slowly, and at 100 °C within a few minutes, to the valence isomeric diiminophosphoranes *(3)*; these react further to give the *cis*- and *trans*-[2+2]-cycloadducts *(4)* and the diiminophosphorane *(5)*, respectively[11].

The results of these investigations enable us to presume that further highly reactive phosphorus-element ylide systems are accessible *via* kinetically stabilized three-membered rings with λ$^3$-phosphorus and oxygen and/or carbon as heteroatoms by electrocyclic ring opening reactions.

## *Procedure*

*(2a, b)*: *N,N*-Di-*tert*-butylhydrazine[12] (14.4 g, 50 mmol) dissolved in *n*-hexane (100 mL) is metalated using the equivalent amount of *n*-C$_4$H$_9$Li (15% in *n*-hexane). The solution is treated dropwise with diisopropylamino(difluoro)phosphane (8.8 g, 50 mmol) or bis(trimethylsilyl)amino(difluoro)phosphane and stirred at room temperature, under $^{31}$P-NMR control, until the difluorophosphane has completely reacted (*(2a) ca.* 90 h; *(2b) ca.* 180 h).

After addition of 50 mmol of CH$_3$Li (5% in *n*-hexane), the greater part of LiF is separated off either, [*(2a)*] by filtration through a G4 frit, or [*(2b)*] using 2 equivalents of BF$_3$·Et$_2$O, bound as LiBF$_4$; solvent is thoroughly removed from the filtrate. The crude product thus obtained is recrystallized from a little *n*-hexane at 0 °C. *(2a)*: 8.2 g (60%), M.p. = 60—63 °C; *(2b)*: 4.2 g (25%), decomp. 50—55 °C.

## Structural Properties of Phosphorus Oxides in the Solid Aggregation State[**]

By *Martin Jansen, Marlen Voss,* and *Hans-Jörg Deiseroth*[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

The series of phosphorus oxides $P_4O_{6+n}$ (n = 0—4) is ideally suited for the study of the mutual influence of tri- and penta-valent phosphorus, having practically the same environment, on their bonding properties (*e.g.* by comparison of the bond lengths and angles). In this context the crystal structures of the end-members $P_4O_{10}$ and $P_4O_6$, the phosphorus(III) oxide being the last binary phosphorus oxide whose structure has not been investigated in the solid state, are of particular interest. Measurements on the $P_4O_6$ molecule in the gas phase[1] are not immediately comparable with the previously determined crystal data of $P_4O_7$[2], $P_4O_8$[3], and $P_4O_9$[4].

Single crystals of $P_4O_6$ (m. p. = 23 °C) were grown *in situ* on a diffractometer[5]. For this purpose a capillary tube (Ø = 0.3 mm) was filled with the liquid sample to a height of approximately 20 mm, under an atmosphere of dry argon, and attached to the diffractometer, which was equipped with a low temperature device. The top of the capillary protruded through a small hole at the center of a heated (+30 °C) metal screen into a cold nitrogen gas stream (−20 °C). Crystal growth was achieved by slowly moving the screen, thus introducing the whole capillary into the gas stream. Data collection was performed at −5 °C.

The crystal structure[6] consists of molecular units $P_4O_6$ with site symmetry m, having the mirror planes passing through P1, P2, O1, and O4 (cf. Fig. 1). Geometrical analysis of the molecular structure, however, reveals that within the limits of experimental error the point-group is $T_d$. The bond lengths, both uncorrected and corrected for the effect of librations of the rigid group, are significantly larger than those determined for $P_4O_6$ in the gas phase[1]. This is presumably caused by intermolecular interactions which seem to be of the van der Waals type as indicated by the smallest intermolecular contacts [$d$(O—O) = 319 pm] in the solid state. Within the series $P_4O_6$, $P_4O_7$, and $P_4O_8$ the P—O distances in the $P^{III}$—O—$P^{III}$ bridges decrease monotonically from 166 through 164 to 163 pm, and the bonds $P^V$—O (terminal) shorten similary from $P_4O_7$ (145 pm) to $P_4O_9$ (141 pm). This structural feature may be explained either in terms of increasing effective charges on the trivalent phosphorus atoms with increasing number of pentavalent phosphorus atoms in the molecule, or by decreasing effective charges on $P^V$ with increasing amounts of $P^{III}$. The interpretation suggested here is supported by $^{31}$P-NMR signals determined for the species $P_4O_6E_n$ (E = O, S, Se; n = 1—4)[7].

It is remarkable that $P_4O_6$, a perfect example of a "sheathed" compound, with its relatively low melting point and a high vapor pressure, forms no plastic phase: completely ordered $P_4O_6$ crystallizes immediately below the melting point (23 °C) This presents a marked, at first inexplicable contrast to $P_4$, which despite a higher melting point (44 °C) exists over a broad temperature range as a plastic-crystalline species.

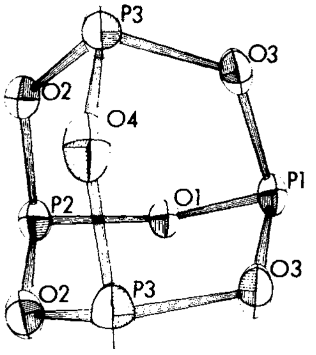

Fig. 1. Perspective view of a $P_4O_6$ molecule. Bond lengths [pm] and angles [°] in $P_4O_6$ (maximum standard deviation 0.4 pm). a) Solid state: P1—O1(O3) = 165.8 (165.8); P2—O1 (O2) = 165.9 (165.9); P3—O2 (O3) = 165.9 (164.6); P3—O4 = 165.6 (corrected for rigid body motion); P—O—P 127.0, O—P—O 99.5.—b) Gaseous state [1]: P—O = 163.8; P—O—P = 126.4; O—P—O = 99.8.

## CC Bond Formation Between "Electron-Rich" and "Electron-Deficient" Alkenes[**]

By *Bernd Giese* and *Gerhard Kretzschmar*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

Formation of CC bonds is an important synthetic procedure in organic chemistry. We have now succeeded in reductively coupling "electron-rich" alkenes *(1)* with "electron-deficient" alkenes *(2)*, in a one-pot process using mild conditions, to give the products *(3)*. The synthesis proceeds *via* the steps 1. Hydroboration of the alkenes *(1)* to the trialkylboranes *(4)*[1], 2. Mercuration of *(4)* to form the organomercury salts *(5)*[2], and 3. Reduction of *(5)* with sodium tetrahydridoborate in the presence of the alkenes *(2)*, whereby the products *(3)* are formed *via* a radical chain reaction[3].

---

[*] Prof. Dr. B. Giese, Dipl.-Ing. G. Kretzschmar
Institut für Organische Chemie und Biochemie der Technischen Hochschule

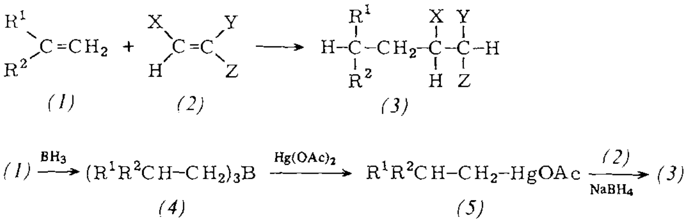
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.



(1), (2), (3), (4), (5)

$$(1) \xrightarrow{BH_3} (R^1R^2CH{-}CH_2)_3B \xrightarrow{Hg(OAc)_2} R^1R^2CH{-}CH_2{-}HgOAc \xrightarrow[NaBH_4]{(2)} (3)$$

Alkyl-, aryl-, and alkoxy-groups serve as suitable substituents $R^1$ and $R^2$ for the "electron-rich" alkenes *(1)*; halogen atoms, carboxylic acid esters, sulfonic acid esters, hydroxy[4], and vinyl groups that are less reactive in hydroboration reactions[1] remained unchanged.

In order to direct the attack of the boron with >98% regioselectivity towards the vinylic $CH_2$ group of *(1)*, $(cC_6H_{11})_2BH$ (Method A) was used for the hydroboration instead of $BH_3$/THF (Method B), particularly with monosubstituted alkenes ($R^1 = H$). The regioisomers of *(4)* do not lead to impurities in the reaction products *(3)*, because only bonds between primary alkyl groups and boron are cleaved by $Hg(OAc)_2$[2].

For acrylonitrile, the total yields over the three reaction steps in this one-pot synthesis vary between 50 and 70% (Table 1). Cyano groups, as well as carboxylic acid ester-, ketone-, anhydride-, and imide-moieties prove to be highly suitable X-, Y-, and Z-substituents for the "electron deficient" alkenes *(2)*; yields are considerably lower with chlorine atoms and phenyl groups (Table 2)[5]. This reflects the reactivity gradation of the alkenes *(2)* in reactions with alkyl radicals[6].

Table 1. Reductive CC coupling of alkenes *(1)* with acrylonitrile to give products *(3)*, X = Y = H, Z = CN.

## *Procedure*

*Method A:* A solution of cyclohexene (1.81 g, 22 mmol) in 5 mL of tetrahydrofuran (THF) is added over 5—20 min to a solution of $BH_3$ (11 mmol, 11 mL of a 1 M solution in THF) under $N_2$ at 0 °C. After 2 h, alkene *(1)* or *(6)* (10 mmol) is added, left to react for 12 h at 20 °C, and the mixture then treated with $Hg(OAc)_2$ (3.18 g, 10 mmol). The resulting mixture is stirred for 5—30 min and mixed with alkene *(2)* (20—50 mmol). Rapid addition of $NaBH_4$ (450 mg, 12 mmol), suspended in 1 mL of water, leads to precipitation of metallic mercury within 5 min. Separation of the organoboron compounds follows by chromatography on silica gel, or by oxidation with $H_2O_2$[1]. The analytically pure products *(3)* and *(7)*, respectively, are obtained by distillation.

*Method B:* $BH_3$ (3.5 mmol, 3.5 mL of a 1 M solution in THF) is added to a solution of alkene *(1)* (10 mmol) in 10 mL of THF under $N_2$ at 0 °C. After 45 min, $Hg(OAc)_2$ (3.18 g, 10 mmol) is added, and the mixture allowed to react for 30 min at 20 °C. The resulting mixture is diluted with $CH_2Cl_2$ (20 mL) and mixed with alkene *(2)* (20—50 mmol). Rapid addition of $NaBH_4$ (450 mg, 12 mmol) suspended in 1 mL of water leads to precipitation of metallic mercury within 5 min. Analytically pure *(3)* is obtained by distillation.

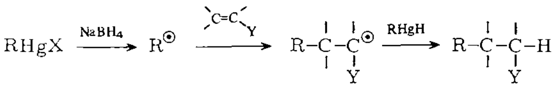
## Steric Effects in the Addition of Alkyl Radicals to Alkenes[**]

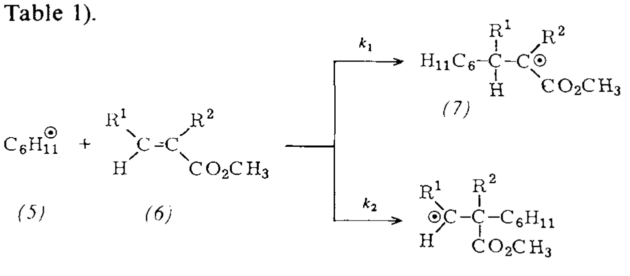
By *Bernd Giese* and *Stephen Lachhein*[*]

The alkyl radicals *(2)*[1], generated by reduction of alkylmercury salts *(1)* with sodium tetrahydridoborate, form the adduct radicals *(3)* in the presence of "electron-deficient" alkenes[2]. The complete reaction of *(3)* to the H-captured products *(4)* enables the relative rate constants to be determined using the competitive kinetic method[3]. Steric effects, which have a considerable influence on the reactivity and selectivity of addition of alkyl radicals to alkenes in polymerizations, can, therefore, be quantitatively measured for the first time[4].



*(1)* *(2)* *(3)* *(4)*

If the cyclohexyl radicals *(5)* are generated from cyclohexylmercury salts[2,3] in the presence of pairs of acrylates *(6)*, the relative rate constants $k_1$ and $k_2$ can be determined from the products formed by the radicals *(7)* and *(8)* (see Table 1).



*(5)* *(6)* *(7)* *(8)*

Table 1. Influence of the alkyl substituents R$^1$ and R$^2$ on the relative rate constants $k_1$ and $k_2$ (average error ± 10%) for the reaction of cyclohexyl radicals *(5)* with acrylate esters *(6)* in $CH_2Cl_2$ at 293 K.

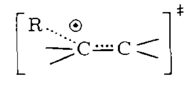
| | R$^1$ | R$^2$ | $10^3\,k_1$ | $10^3\,k_2$ | $k_1 : k_2$ |
|---|---|---|---|---|---|
| *(a)* | H | H | ≡1000 | 2.0 | 99.8 : 0.2 |
| *(b)* | $CH_3$ | H | 11 | 1.0 | 92 : 8 |
| *(c)* | $C_2H_5$ | H | 6.6 | 0.9 | 88 : 12 |
| *(d)* | $i C_3H_7$ | H | 1.5 | 0.5 | 75 : 25 |
| *(e)* | H | $CH_3$ | 710 | [a] | |
| *(f)* | H | $C_2H_5$ | 550 | [a] | |
| *(g)* | H | $i C_3H_7$ | 430 | [a] | |
| *(h)* | H | $t C_4H_9$ | 250 | [a] | |

[a] $k_2$ is smaller than $10^{-3}$ and could not be measured.

Alkyl groups having similar polarity but substantially different steric effects were selected as substituents R$^1$ and R$^2$ for the alkenes *(6)*. The data in Table 1 show that steric influences depend markedly on the position of the shielding group on the alkene *(6)*. A substituent at the vinylic C atom undergoing attack reduces the rate from $R^1 = H$ *via* $CH_3$ to $iC_3H_7$ by factors of 90 and 670, respectively (α-effect). In contrast, the same variation at the C atom not undergoing attack only produces factors of 1.4 and 2.3, respectively (β-effect). From the correlation with steric substituent parameters[5] the nonmeasurable effect of a *tert*-butyl group can be estimated as 3000, whilst its β-effect is only 4 (Table 1).

The small β-effect is also reflected in the rate constants $k_2$ shown in Table 1. Hence, the isopropyl derivative *(6d)* is only attacked 4-times slower at the methoxycarbonyl-substituted vinylic C atom than the unsubstituted acrylate *(6a)*. In consequence, the regioselectivity decreases with increasing bulkiness of the alkyl moiety R$^1$ from 99.8 : 0.2%, in unsubstituted acrylate esters *(6a)* *via* 92 : 8% ($R^1 = CH_3$, $R^2 = H$), and 88 : 12% ($R^1 = C_2H_5$, $R^2 = H$), to 75 : 25% for the isopropyl derivative *(6d)* (Table 1).

The vast difference between the steric α- and β-effects can be viewed as experimental confirmation of calculations[6] in which an unsymmetrical transition state *(9)* for the addition of alkyl radicals to alkenes was postulated.



*(9)*

In contrast to electrophilic addition, nucleophilic alkyl radicals do not initially attack alkenes at the center of the double bond, but approach the π-system from the side. This can be understood in terms of the Frontier Orbital theory[3b,7] for addition of nucleophilic alkyl radicals, since the overlap of the singly occupied orbital of the radical (SOMO) with the unoccupied orbital of the alkene (LUMO) is decisive. An approach of the radical from the side is, however, only hampered by substituents which are located at the vinylic C atom being attacked. This difference in magnitude of the steric α- and β-effects is of decisive importance for the regioselectivity of radical additions[8].

[**] Contributions to the Chemistry of Phosphorus, Part 107. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.— Part 106: *M. Baudler, F. Saykowski*, Z. Anorg. Allg. Chem., in press.

sizes[1a,b]. In the presence of $PCl_3$, polycyclic organophosphanes $P_mR_n$ ($n < m$)[2a,b] are formed. We report here the synthesis and properties of tetra-*tert*-butylhexaphosphane *(1)*, a bicycle having an unexpected structure.

*(1)* is formed by dehalogenating a mixture of *tert*-butyl(dichloro)phosphane and $PCl_3$ with magnesium using widely variable mixture ratios of both phosphorus-halogen compounds

$$4\,t\mathrm{BuPCl_2} + 2\,\mathrm{PCl_3} + 7\,\mathrm{Mg} \rightarrow \underset{(1)}{t\mathrm{Bu_4P_6}} + 7\,\mathrm{MgCl_2}$$

In addition, $t\mathrm{Bu_6P_8}$[2b], $(t\mathrm{BuP})_4$[3a], and $(t\mathrm{BuP})_3$[3b] are formed together with small amounts of the polycyclic phosphanes $t\mathrm{Bu_3P_9}$[3c], $t\mathrm{Bu_5P_9}$, $t\mathrm{Bu_5P_7}$, $t\mathrm{Bu_4P_8}$, and $t\mathrm{Bu_6P_{10}}$. The product distribution is strongly dependent on the reaction conditions: the best initial yield of *(1)* is obtained by performing the reaction rapidly, and using a molar ratio $t\mathrm{BuPCl_2} : \mathrm{PCl_3} = 3:2$ (not 2 : 1!) in boiling tetrahydrofuran (THF). Analytically pure *(1)* can be isolated by column chromatography.

The hexaphosphane *(1)* forms colorless, lamellar crystals (m.p. = 121 °C, sealed tube) which are stable under inert gas at room temperature, and can be sublimed in high vacuum. They are readily soluble in hydrocarbons and THF, but, in contrast, only moderately soluble in methanol. In the solid state at room temperature, *(1)* is stable for some time against atmospheric oxygen, but in solvents is rapidly oxidatively attacked. In the mass spectrum (field ionization, 100 °C), apart from $M^+$ ($m/z$) = 414; rel. int. 100), a single fragment $M^+ - C_4H_9$ (357; 2) appears. The vibrational spectra show bands in the P—P stretching- and deformation-regions[4].

The NMR data (Table 1) unequivocally show that of the four possible structures for the phosphorus skeleton, *(1a)*—*(1d)*[5], the structure assigned as *(1d)* is present; *(1)* is therefore a 2,3,4,6-tetra-*tert*-butylbicyclo[3.1.0]hexaphosphane.

[a] 30% solution in $C_6H_6/C_6D_6$ at 303 K ($^{31}$P) and 306 K ($^{1}$H, $^{13}$C). [b] The assignment follows from the relative intensities and the characteristic high-field of the signals for the substituents on the three-membered ring; the results were confirmed by $^{31}$P-partial decoupling experiments.

The $^{31}P\{^1H\}$-NMR spectrum (four complex multiplets in the ratio 1 : 2 : 2 : 1 at $\delta \approx +145, +115, -45$, and $-135$) establishes that the signal group at high-field stems from $P_D$ in the three-membered ring, and that both closely neighboring low-field signal groups stem from $P_B$ and $P_C$ in the five-membered ring. The configuration follows from the chemical equivalence of $P_A$ and $P_{A'}$, as well as $P_B$ and $P_{B'}$; moreover, the large $^2J_{P_BP_D}$ coupling constant[6] indicates that the lone pairs of electrons at $P_B$ and $P_D$ are directed towards each other. In consequence, the three-membered ring is strongly inclined relative to the five-membered ring, and the arrangement of the substituents is *all-trans*. In contrast to other polycyclic organophosphanes, further configurational isomers do not occur[2a,7]. The X-ray structural analysis[8] (Fig. 1) confirms that *(1d)* has a chair-like phosphorus skeleton. Because of the influence of the substituents, the five-membered ring adopts an unusually flat, only slightly twisted envelope conformation in the crystal; the endocyclic bond angles are comparatively large. The slightly distorted three-membered ring stands almost at right angles to the five-membered ring.

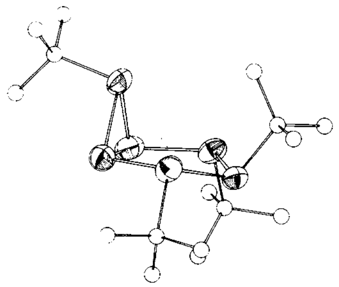

Fig. 1. Molecular structure of *(1)* in the crystal; values and average values of important bond lengths [pm], bond angles and torsional angles [°]: $d$(P—P) = 219.2, 220.2, 220.8, 219.5 (five-membered ring); 219.5 (zero bridge); 217.8, 219.2 (three-membered ring); $\sigma$(P—P) = 0.4; $\varphi$(P—P—P) = 108.4, 106.7, 107.4, 106.8, 107.7 (five-membered ring); 99.6, 97.9 (three-membered ring/five-membered ring); 60.2, 60.3, 59.5 (three-membered ring); $\sigma$(P—P—P) = 0.2; $\tau$(P—P—P—P) = −1.8, 11.7, −17.3, 16.2, −8.9 (five-membered ring); 88.9, −90.7 (five-membered ring/three-membered ring over the zero bridge); $\sigma$(P—P—P—P) = 0.2; $\bar{d}$(P—C) = 189.5(6); $\bar{d}$(C—C) = 153.2(10); $\bar{\varphi}$(P—P—C) = 102.1(18); $\bar{\varphi}$(P—C—C) = 105.9(9) (twice respectively), 115.5(12) (once respectively); $\bar{\varphi}$(C—C—C) = 109.8(12).

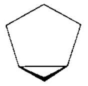
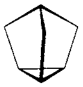
The ring system *(1d)* formally arises from the particularly stable $P_7$-cage *(2)*[7,9] when one of the three one-atom bridges is removed.



*(1d)*



*(2)*

A consideration of molecular models indicates that $t\mathrm{Bu_4P_6}$ does not adopt the framework *(1b)* or *(1c)* with a four-membered ring because of the strong transannular interactions between the *tert*-butyl groups. With smaller substituents, *(1d)* could be destabilized relative to *(1b)* and *(1c)*.

### Procedure

A solution of $t\mathrm{BuPCl_2}$ (31.8 g, 0.20 mol) and $PCl_3$ (18.3 g, 0.13 mol) in 60 mL of THF is added dropwise, with rigorous stirring, over 30 min to a suspension of magnesium turnings (10.0 g, 0.41 mol), which had been etched by evaporating a few grains of iodine, in 400 mL of boiling THF. The yellow mixture is refluxed for 30 min, whereby it turns dark red-brown. Finally, the solvent is completely removed under reduced pressure at room temperature. The residue is taken up in 500 mL *n*-pentane and the undissolved material filtered off, washed with pentane (4 x 20 mL), and the solvent removed from the combined filtrates. The yellow, viscous residue is dissolved in the minimum amount of pentane and chromatographed on $Al_2O_3$ using pentane with $^{31}P\{^1H\}$-NMR spectroscopic control (column length: 50 cm; inner diameter: 5.8 cm; filling material: $Al_2O_3$ neutral according to *Brockmann*, particle size 0.063—0.200 mm, thoroughly heated *in vacuo*, and gassed with Ar; amount of solvent: 4500 mL; duration: 10—12 h). The fractions having the highest content of *(1)* are combined, the pentane is removed, and the white residue is taken up in 50 mL of boiling methanol (made absolute over Mg). After rapidly filtering off the undissolved part while still warm, and allowing the filtrate to slowly cool to room temperature, large, translucent crystals of *(1)* precipitate out; yield 3.3 g (16%). If necessary, ($^{31}P$-NMR spectroscopic control of purity) they can be recrystallized again.

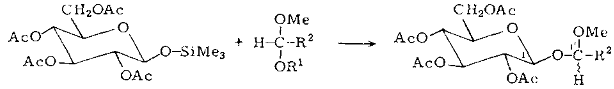
# Stereoselective Synthesis of β-Glucosides with 1,1'-Diacetal Structure[**]

By *Lutz-F. Tietze* and *Roland Fischer*[*]

*Dedicated to Professor George Büchi on the occasion of his 60th birthday*

The stereoselective preparation of glycosides is one of the most exacting synthetic tasks in natural product chemistry[1]. Particularly difficult is the synthesis of glucosides having 1,1'-diacetal structure, such as those present in the 1,1-coupled disaccharides or iridoid glycosides[2]. We have now found a simple, highly stereoselective method for the synthesis of this type of compounds.

2,3,4,6-Tetra-*O*-acetyl-1-*O*-trimethylsilyl-β-D-glucopyranose *(1)*[3] is used as educt for the synthesis of β-glucosides. Reaction of *(1)* with the acetals *(2a—h)* in the presence of catalytic amounts of trimethylsilyl trifluoromethanesulfonate[4] at −70 °C affords the β-glucosides *(3a, c—h)* in very good yields. α-Glucosides are not formed at all under these conditions. As expected, in the reaction with formaldehyde acetal *(2a)* the homogeneous product *(3a)* is obtained, whereas reaction with the prochiral acetals *(2c—h)* leads to a *ca.* 1 : 1 mixture of the C-1' epimers. In the case of the methyl(phenyl) acetal *(2b)*, exclusive cleavage of the phenoxy group takes place (Table 1).



*(1)* *(2)* *(3)*

Table 1. Synthesis of the β-glucosides *(3)* from the educts *(1)* and *(2)*.

| Educts *(1)*+*(2)* | $R^1$ | $R^2$ | Products *(3)* | Yield [%] | $^1H$-NMR [a] *(3)*, H instead of Ac |
|---|---|---|---|---|---|
| *(2a)* | Me | H | *(3a)* | 75 | 4.58 |
| *(2b)* | Ph | H | | 88 | |
| *(2c)* | Me | $CH_2—Ph$ | *(3c)* [b] | 84 | 4.57, 4.67 |
| *(2d)* | Me | *n*-$C_3H_7$ | *(3d)* [b] | 78 | 4.47, 4.59 |
| *(2e)* | Me | $CH_2—CH(OMe)_2$ | *(3e)* [b] | 79 | 4.63, 4.71 |
| *(2f)* | Me | $CH_2—OMe$ | *(3f)* [b] | 77 | 4.57, 4.67 |
| *(2g)* | Me | $CH_2—Cl$ | *(3g)* [b] | 75 | 4.63, 4.71 |
| *(2h)* | Me | $CH_2—Br$ | *(3h)* [b] | 78 | 4.63, 4.71 |
| *(2i)* | Me | Ph | — | | |

[a] $[D_6]$Acetone/$D_2O$, δ-values for 1-H; $J_{1,2} = 7.5$ Hz. [b] Mixture of the C-1' epimers (*ca.* 1 : 1).

We assume that the reaction proceeds *via* a silylation of one acetal oxygen of *(2)* with formation of an oxonium ion[5], which then undergoes a kind of $S_N2$ reaction[6] with the trimethylsilylglucoside *(1)* at −70 °C with retention of configuration at C-1. Ketals such as cyclohexanone- and acetonedimethyl acetal, as well as the dimethyl acetals of aromatic aldehydes [*e.g.* *(2i)*][7], do not react with *(1)*.

The work-up and purification of the products is accomplished by chromatography on silica gel. For determination of the selectivity of the reaction and of the configuration at C-1 the glucosides were liberated from the unpurified and purified acetyl derivatives *(3)* by solvolysis with methanol/sodium methoxide (yield >90%).

## *Procedure*

A 0.1 M solution of trimethylsilyl trifluoromethanesulfonate (0.2 mL) in $CH_2Cl_2$ is added to a solution of *(1)* (105 mg, 0.25 mmol) and *(2c)* (83.0 mg, 0.50 mmol) in anhydrous $CH_2Cl_2$ (3 mL) under inert gas at −70 °C and the mixture stirred at this temperature (TLC monitoring; silica gel, hexane/ethyl acetate = 1 : 1) for *ca.* 20 h. After addition of 0.1 mL triethylamine the reaction mixture is washed with saturated $NaHCO_3$ and NaCl solutions and dried over $Na_2SO_4/Na_2CO_3$ (1 : 1). Removal of the solvent *in vacuo* affords 115 mg (95%) of crude product which is almost homogeneous. Further purification can be achieved by chromatography on silica gel; yield 101 mg (84%) *(3c)*.

## Synthesis of [10-$^{13}$C]Secologanin[**]

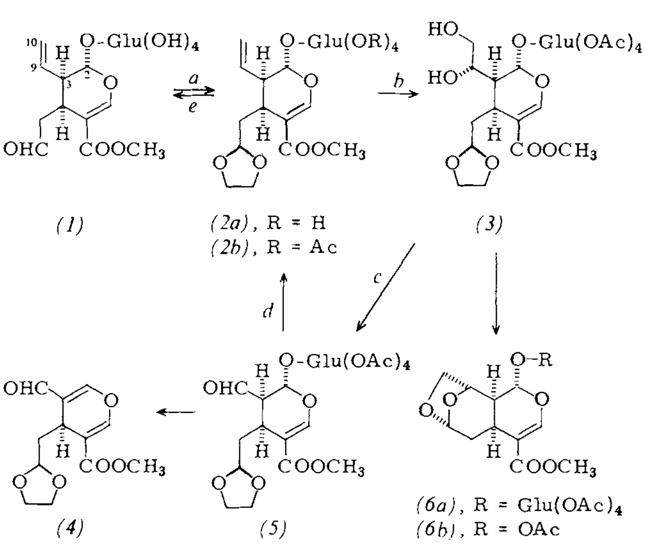
By *Lutz-F. Tietze* and *Stephan Henke*[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

The monoterpeneglycoside secologanin *(1)* assumes a key position in the biogenesis of the indole, cinchona, ipecacuanha and pyrroloquinoline alkaloids[1] and the secoiridoids[2]. Most biosynthetic investigations in this field have been carried out with [$^{3}$H]- and [$^{14}$C]-labeled precursors. However, identification of unisolated intermediates is generally impossible by this method. This necessitates monitoring the reactions of [$^{13}$C]-labeled precursors with cell-free enzyme systems or isolated enzymes by means of $^{13}$C-NMR spectroscopy[3].

We now describe a method for the synthesis of [10-$^{13}$C]secologanin [10-$^{13}$C]-*(1)* from natural secologanin *(1)*[4]. C-10 was chosen for labeling, since this center participates in most biological transformations of *(1)*.

Acid-catalyzed reaction of *(1)* with ethylene glycol to give *(2a)*, followed by acetylation with acetic anhydride/pyridine, affords almost quantitative yields of the peracetylated acetal *(2b)*. The analogously prepared dimethyl acetal is not stable enough for the following reactions. Oxidation of *(2b)* with equimolar amounts of osmium tetraoxide[5] in pyridine leads to the diol *(3)* in 31% yield. The other diastereomer is not formed. Other products of the reaction include tetraacetylglucose[6] (30%) and *(6a)* together with educt *(2b)* (29%). For determination of the configuration at C-9, *(3)* is converted with perchloric acid/acetic acid into the tricyclic compound *(6a)*, which, on solvolysis, glycoside-cleavage and acetylation, affords the acetate *(6b)* (m.p. 119 °C) in 82% overall yield. *(6b)* is identified by comparison with authentic material[7].



Scheme 1. *a*: 1. $HOCH_2CH_2OH$, $CH_3CN$, IR 120 ($H^{\oplus}$), $Na_2SO_4$, 5 °C/24 h, 94% *(2a)*; 2. $Ac_2O$/pyridine, 20 °C/24 h, 91% *(2b)*, m.p. 131.5 °C.—*b*: $OsO_4$/pyridine, 20 °C/72 h; $NaHSO_3$, 5 min, 31% *(3)*, m.p. 138 °C; 30% tetraacetylglucose; 29% *(2b)*; 3% *(6a)*.—*c*: $Pb(OAc)_4$, $CHCl_3$, 60 °C, 30 min, 96% *(5)*, m.p. 145 °C.—*d*: $Ph_3\overset{\oplus}{P}CH_3$ $I^{\ominus}$, *n*BuLi, THF, −30 °C/30 min, 20 °C/3 h, 60 °C/12 h, 20% *(2b)*, m.p. 131.5 °C; 48% *(4)*.—*e*: 1. MeOH/NaOMe, 20 °C/6 h, 96% *(2a)*; 2. $H_2O$, $CH_3CN$, IR 120 ($H^{\oplus}$), 5 °C/6 d, 81% *(1)*.—The yields refer to isolated and analytically pure products.

Oxidative cleavage of *(3)* with lead tetraacetate furnishes the aldehyde *(5)* in 96% yield, which very readily loses tetraacetylglucose with formation of the pyran *(4)*. For introduction of the labeled C$_1$-unit, *(5)* is allowed to react with (triphenylphosphonio)[$^{13}$C]methanide, which can be easily prepared from triphenylphosphane and [$^{13}$C]$H_3I$[8]. The desired [10-$^{13}$C]-*(2b)* can be obtained under a wide variety of reaction conditions, albeit in only 20% yield; the pyran *(4)* is always the main product. Base-solvolysis of the acetate groups in [10-$^{13}$C]-*(2b)* and subsequent acid-catalyzed cleavage of the acetal affords [10-$^{13}$C]secologanin [10-$^{13}$C]-*(1)* in 78% yield (Scheme 1).

Introduction of the C$_1$-unit[9] into *(5)* can also be accomplished in 45% yield *via* a Grignard reaction with methylmagnesium iodide. The secondary alcohol formed, however, reacts after conversion into the methanesulfonate with 1,5-diazabicyclo[4.3.0]non-5-ene to give an *E*-configurated isomer of *(2b)* having a double bond between C-3 and C-9 (38% yield).

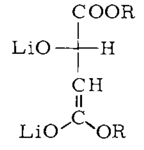
# Alkylation of Amino Acids without Loss of Optical Activity: α- and β-Alkylation of an Aspartic Acid Derivative

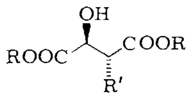
By *Dieter Seebach* and *Daniel Wasmuth*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

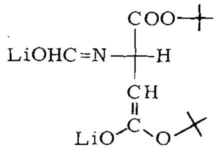
Double deprotonation of dimethyl or diethyl malate by two equivalents of lithium diisopropylamide (LDA) generates the dilithio derivative *(1)*, which is converted into *erythro*-products *(2)* with a variety of electrophiles[1]. We have now tried to extend this *α-alkylation of β-heterosubstituted carbonyl compounds* to di-*tert*.-butyl (*S*)- or L-(+)-*N*-formyl-aspartate[2]. Unlike LDA, lithium diethylamide effected a clean double deprotonation (THF, −78 °C, 2 h) to give *(3)*, which was alkylated by iodomethane, iodoethane, allyl bromide, or benzyl bromide (−78 °C, 12 h) to furnish a mixture of β- and α-substituted aspartic acid derivatives *(4)* and *(5)* in the ratio of *ca.* 7 : 2 and in total yields ranging from 60 to 70%. The pairs of isomers *(4)/(5)* can be separated chromatographically (silica gel, diethyl ether/pentane). According to their chromatographic behavior, to their melting points and/or their specific rotations, and to their $^1$H- and $^{13}$C-NMR spectra, the β-alkylated α-amino acid esters *(4b)—(4e)* thus obtained are diastereomerically and enantiomerically pure. However, their solutions, like those of the starting material *(4a)* itself, contain two rotamers[3].—To our surprise, the α-alkylated α-amino acid derivatives *(5b)—(5e)* are also optically active. Enantiomeric enrichment by fractional crystallization was possible with *(5c)—(5e)*. From the highest specific rotations thus observed, and from $^1$H-NMR measurements with chiral shift reagent Eu(tfc)$_3$ we deduce enantiomeric excesses of *ca.* 60% in the originally formed samples of *(5)*.—Table 1 lists some characteristic data of the products *(4)* and *(5)*.



*(1)*

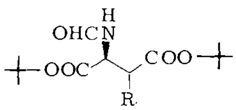


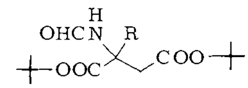
*(2)*



*(3)*

*(4)*





*(5)*

*(a)*, R = H; *(b)*, R = CH$_3$; *(c)*, R = C$_2$H$_5$; *(d)*, R = CH$_2$CH=CH$_2$; *(e)*, R = CH$_2$C$_6$H$_5$

Table 1. Characteristic physical data of the analytically pure β- and α-alkylated aspartates *(4)* and *(5)*, respectively, after crystallization or distillation. Except in the case of *(5b)*, the specific rotations are given of products *(5) after* separation of the racemic components.

| Compound | B.p./torr [a] or M.p. [°C] | $[\alpha]_D^{20}$ (*c*, CHCl$_3$) |
|---|---|---|
| *(4a)*≡*(5a)* | 130/0.01 | +44.4 (1.14) |
| *(4b)* | 84—85 | +16.8 (1.22) |
| *(5b)* | 140/0.01 | −15.3 (1.27) [b] |
| *(4c)* | 150/0.005 | + 1.0 (1.36) |
| *(5c)* | 150/0.01 | −17.0 (1.07) |
| *(4d)* | 140/0.005 | +24.6 (1.05) |
| *(5d)* | 77—78 | +17.2 (1.00) |
| *(4e)* | 102—103 | +43.0 (1.45) |
| *(5e)* | 106 | +61.1 (1.05) |

[a] Air bath temperatures during Kugelrohr distillations. [b] As obtained as a colorless oil by chromatography, *without* enrichment of the enantiomeric purity.

The configuration of *one* of the products *(4)*, the methyl derivative *(4a)*, was established by hydrolysis of the ester and amide groups to give *erythro*- or (2*S*,3*R*)-3-methylaspartic acid *(6)* ($[\alpha]_D^{20}$ = +38.7 (*c* = 1.83, 5 N HCl; ref.[4] $[\alpha]_D^{24}$ = +35 (*c* = 2, 5 N HCl)). We tentatively assign *erythro*-configuration to *all* alkylation products *(4)*. This is compatible with the rule (cf. *(7)*, R$^1$ = H, R$^2$ = CO$_2$*t*Bu, X = NCHOLi, Y = C(OLi)(O-*t*Bu)), proposed previously for reactions of other donor double bonds[1a,5].—The α-alkylation of the *N*-formyl-aspartate shows that the dilithio-derivative *(8)* has been formed besides the desired enolate *(3)*. Further experiments will be necessary to decide, why *(8)* leads to optically active α-alkylated products; two possibilities are: (a) the 6-atom-8-electron π-system[6] is axially chiral [see the bond emphasized by an arrow in *(8)*], (b) the achiral *(8)* forms mixed aggregates[7] with the chiral dilithio-derivative (3). If the interpretation (a) should turn out to be valid, simple amino acids might also be alkylated *via* derivatives of type *(8)* (R instead of CH$_2$CO$_2$-*t*Bu) without racemization[8].

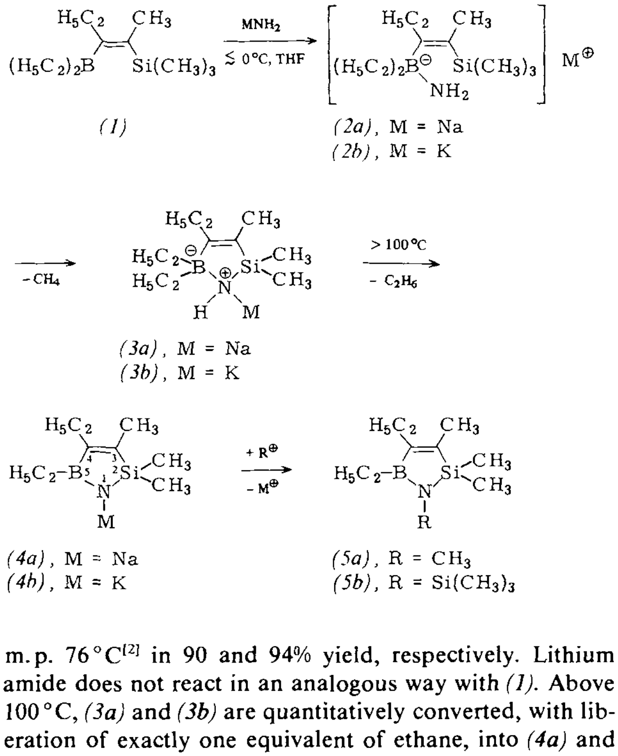
## Novel Five-Membered $C_2BNSi$-Rings[**]

By *Roland Köster* and *Günter Seidel*[*]

We have prepared novel five-membered ring heterocycles by a new type of ring-closure reaction. The (*E*)-diethyl(2-trimethylsilyl-2-penten-3-yl)borane *(1)*[1], which is readily accessible by reaction of sodium triethyl-1-propynylborates with chloro(trimethyl)silane, can easily be converted into the *N*-metalated pentaalkyl-$\Delta^3$-1,2,5-azasilaborolines *(4)* and the *N*-methylated or *N*-trimethylsilylated $\Delta^3$-1,2,5-azasilaborolines *(5a)* or *(5b)*, respectively.

Reaction of *(1)* in toluene or tetrahydrofuran (THF) at $\leq 0\,^\circ C$ with sodium or potassium amide leads to formation of the thermally unstable, $^{11}$B-NMR spectroscopically detectable alkali-metal amino(triorgano)borates *(2a)* or *(2b)*. In THF solution, aminolysis of a methyl residue of the trimethylsilyl group leads to loss of exactly one equivalent of methane, in the case of *(2a)* at 25 °C, in the case of *(2b)* already at 0 °C. This unexpected, rapid and completely smooth reaction affords the previously unknown five-membered ring heterocycles *(3a)*, m.p. > 120 °C (dec.) and *(3b)*, m.p. 76 °C[2] in 90 and 94% yield, respectively. Lithium amide does not react in an analogous way with *(1)*. Above 100 °C, *(3a)* and *(3b)* are quantitatively converted, with liberation of exactly one equivalent of ethane, into *(4a)* and *(4b)*[2], which are colorless solids that melt without decomposition at 154–156 and 262 °C, respectively. The intramolecular aminolysis of the borates *(2)* takes place exclusively at the SiC bond and not—as is otherwise usual—at the BC bond. The regiospecificity of the aminolysis can be ascribed to the *cis* orientation of the trimethylsilyl group in the borates *(2)*, for dialkyl(amino)-substituted vinyl borates free of silyl groups are thermally preferably cleaved at the $BC_{vinyl}$ bond[3]. *(4a)* and *(4b)* readily react with electrophiles, *e.g.* with iodomethane or chloro(trimethyl)silane to give very good yields (80–90%) of the heterocycles *(5a)* and *(5b)*, which can be distilled without decomposition[2].



*(4)* and *(5)* are suitable for the preparation of a variety of transition metal complexes[3].

*Procedure*

*(3a)*: *(1)*[1] (8 g, 38 mmol) is added dropwise within 0.5 h at 0 °C to a suspension of sodium amide (1.9 g, 49 mmol) in THF (80 mL) and the mixture stirred for *ca.* 1 h [*(2a)* $^{11}$B-NMR: $\delta = -7.8$] before removing the cooling-bath. On warming to over 25 °C (up to boiling) 852 mL (100%) methane is evolved within 1.5 h. After removal of *ca.* 0.9 g of $NaNH_2$ (excess) by filtration, evaporation to dryness at 12 torr, and drying ($10^{-3}$ torr/60 °C), 8 g (90%) of *(3a)* is obtained.—IR (Nujol): $\nu_{NH} = 3355, 3300$, $\nu_{C=C} = 1535$ cm$^{-1}$; $^{11}$B-NMR: $\delta = -2.3$ ($\Delta = 65$ Hz).

*(4a)*: *(3a)* (50.8 g, 218 mmol) is heated to 120–130 °C; 4.8 L (98%) of ethane is liberated within *ca.* 2 h. There remain 44 g (98%) of *(4a)*.—IR (Nujol): $\nu_{C=C} = 1550$ cm$^{-1}$; $^{11}$B-NMR: $\delta = 48$.

*(5a)*: Iodomethane (24.2 g, 171 mmol) is added dropwise within *ca.* 50 min to a solution of *(4a)* (30.3 g, 149 mmol) in THF (250 mL), whereupon the mixture warms to *ca.* 45 °C. After 4 hours boiling under reflux and removal of 18.2 g of NaI by filtration, the solvent is distilled off at 12 torr. 5.3 g of residue and 25.2 g (87%) of *(5a)* are obtained. *(5a)*: b.p.$_{12}$ = 67–68 °C.—IR: $\nu_{C=C} = 1560$ cm$^{-1}$; $^{11}$B-NMR: $\delta = 46.4$ ($\Delta = 190$ Hz).

## Simple Metal-Catalyzed Synthesis of Functionalized Pyrimidines from Dicyanogen and 1,3-Dicarbonyl Compounds[**]

By *Benedetto Corain, Marino Basato,* and *Hans-Friedrich Klein*[*]

Conventional pyrimidine syntheses are based on the ring closure reactions A—C[1], the desired functionalization generally being carried out in the synthetic building blocks *prior to* cyclization—which occasionally meets with difficulties.

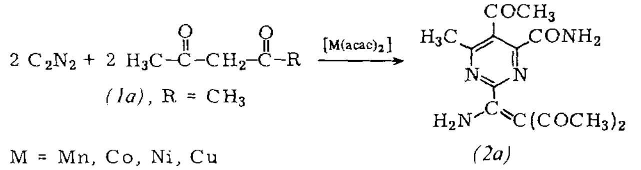
We have recently reported the preparation of the highly functionalized pyrimidine derivative *(2a)*[2] by reaction of dicyanogen and 2,4-pentanedione under mild conditions in the presence of catalytic amounts of metal acetylacetonate.



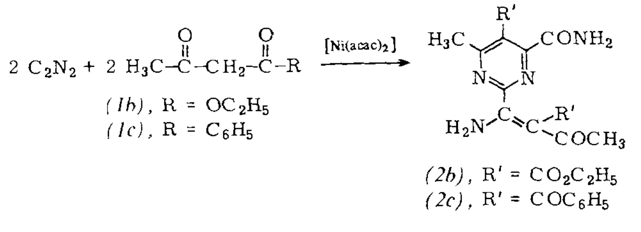
*(1a)*, R = $CH_3$

M = Mn, Co, Ni, Cu

*(2a)*

In the new pyrimidine synthesis, which is carried out as a one-pot reaction under mild conditions, the heterocycle is formed by way of the schematic ring-closure reaction D.

We have found that other readily accessible 1,3-dicarbonyl compounds can also be used for the preparation of functionalized pyrimidines. The simplicity of the procedure and the high yields make the catalytic pyrimidine synthesis a very promising method (Table 1).



*(1b)*, R = $OC_2H_5$

*(1c)*, R = $C_6H_5$

*(2b)*, R' = $CO_2C_2H_5$

*(2c)*, R' = $COC_6H_5$

Table 1. Conditions, yields, and conversions for the synthesis of pyrimidine derivatives *(2)* in 1,2-dichloroethane.

| Educt *(1)* [a] | Catalyst [b] | *t* [h] | Yield of *(2)* [%] [c] |
|---|---|---|---|
| *(a)* | $Ni(acac)_2$ | 24 | 78 (100) |
| | | 140 | 100 (100) |
| *(a)* | $Cu(acac)_2$ | 24 | 58 (100) |
| | | 288 | 100 (100) |
| *(b)* | $Cu(acac)_2$ | 288 | 20 (44) |
| *(b)* | $Ni(acac)_2$ | 288 | 41 (49) |
| *(c)* | $Ni(acac)_2$ | 288 | 22 — |

[a] 0.35 mol $L^{-1}$; $[(CN)_2]$ 0.40 mol $L^{-1}$. [b] $1.2\times10^{-3}$ mol $L^{-1}$. [c] Isolated product. In brackets: yields with respect to converted educt.

The new pyrimidine derivatives are characterized by elemental analysis, NMR, IR, UV/VIS, and mass spectra. In the case of *(2a)* and *(2b)* the structure could also be determined by an X-ray structure analysis.

*(1b)* and *(1c)* cyclize with dicyanogen in the presence of Cu and Ni complexes more slowly and less selectively than *(1a)* (Table 1). If the yield of *(2)* with respect to initial amount of educt used in the presence of $Ni(acac)_2$ is higher than in the case of $Cu(acac)_2$ then it is of about the same order of magnitude with respect to amount of educt converted. Hence, longer reaction times are necessary in order to obtain high yields of pyrimidines.

*(2a)* is formed particularly rapidly (80% conversion after 1 h) at the following concentrations: 2 mmol $Cu(acac)_2$ in 20 mL 1,2-dichloroethane, 0.30 mol $L^{-1}$ acacH, and 0.80 mol $L^{-1}$ $(CN)_2$; vigorous stirring is necessary and the reaction must be interrupted after 1 h, because otherwise a secondary precipitation of green bis[1-cyano-2-(1-iminoethyl)-1,3-butanedionato]copper will contaminate the product *(2a)*.

The catalytic pyrimidine synthesis proceeds in two steps: base-catalyzed addition of dicyanogen to the 1,3-dicarbonyl compounds[3]—which can also be carried out with malonic esters—followed by the metal-catalyzed cyclization, which only takes place if at least one keto-function is present in the substrate.

### *Procedure*

*(2b):* $Ni(acac)_2$ (10 mg) is dissolved with stirring in 40 mL of a standardized 0.6 M solution of dicyanogen in 1,2-dichloroethane. *(1b)* (2.5 mL, 19.2 mmol) is pipetted into the orange colored solution and the mixture stirred slowly (*ca.* 100 r.p.m.) at 20 °C. After 12 d the resulting yellow precipitate is filtered off from the supernatant red solution, washed twice with 10 mL of 1,2-dichloroethane, and air-dried. Yield: 1.5 g of yellow powder, 41% referred to *(1b)*. Recrystallization from 100 mL of hot 1,2-dichloroethane affords 1.3 g of analytically pure *(2b)*, m.p. 206–208 °C. IR (nujol, $cm^{-1}$): 3485, 3450, 3345, 3245 $\nu_{NH}$; 1740, 1705, 1680, 1610 $\nu_{C=O}$, $\nu_{C=C}$, $\nu_{NH_2}$.

## A New Onium Salt: Synthesis and Characterization of the Difluorophosphonium Ion, $PH_2F_2^+$ [**]

By *Herbert W. Roesky, Karl-Ludwig Weber,* and *Jürgen Schimkowiak*[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

Ammonium salts have been known since the 14th century[1]. The homologous cation of phosphorus, first prepared in 1870 as $PH_4I$[2], is stable only with large anions. $NF_4^+$ salts[3] are also thermally more stable than $PF_4^+$ salts[4]. By way of contrast, we have now found that $PH_2F_2^+$, which, unlike $NH_2F_2^+$ does not decompose explosively at room temperature[5], can be isolated in the reaction

$$PH_2F_3 + AsF_5 \rightarrow PH_2F_2^+AsF_6^- \qquad (1)$$

in high yields as the hexafluoroarsenate.

The new salt *(1)*, a finely crystalline, colorless solid, decomposes on warming, with elimination of HF and formation of red phosphorus. The compound cannot be stored for longer than 12 h at room temperature in glass vessels; in polyethylene vessels no noticeable decomposition occurs, even after several days. In contrast to $PF_4^+Sb_3F_{16}^-$[4], *(1)* shows no measurable decomposition pressure at 20 °C in a vacuum.

We assume the $PH_2F_2^+$ cation to have a tetrahedral skeletal structure ($C_{2v}$ point group). The nine normal vibrations are classified as $4A_1+A_2+2B_1+2B_2$. Apart from the torsional vibration $\nu_5(A_2)$, which is only Raman-active, all other vibrations should appear in both the IR as well as the Raman spectrum. The bands of the antisymmetric ($\nu_6$) and symmetric ($\nu_1$)$PH_2$ valence vibrations at 2600 and 2538 $cm^{-1}$, respectively, can be assigned by comparison with the valence vibrations of the isoelectronic compound $SiH_2F_2$[6]; tentative assignment of the remaining bands [$cm^{-1}$]: $\delta$(HPH) 1096 w, $\delta$(HPF) 1055 s, $\nu_{as}$(PF) 1010 s, $\nu_s$(PF) 950 s, $\delta$(HPF) 885 w, $\delta$(FPF) 835 s. Absorptions were observed at 695 and 645 $cm^{-1}$ for the $AsF_6^-$ anion. NMR investigations have so far proved impossible, since no suitable solvent for *(1)* has yet been found.

## *Experimental*

$H_2PF_3$[7] (0.64 g, 7 mmol) and $AsF_5$ (1.2 g, 7 mmol) are condensed together at − 196 °C in a metal apparatus. The mixture is allowed gradually to warm to room temperature and the volatile components are removed by suction, leaving behind 1.7 g (6.5 mmol) (93%) as crystalline, analytically pure salt *(1)*.

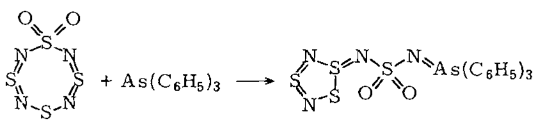
# Synthesis and Structure of a Non-Polymeric Molecule Containing Eleven Alternating Sulfur- and Nitrogen-Atoms[**]

By *Michael Witt, Herbert W. Roesky, Mathias Noltemeyer, William Clegg, Martin Schmidt,* and *George M. Sheldrick*[*]

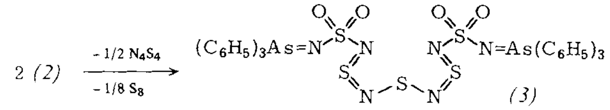
*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

We recently reported[1] a ring contraction in the eight-membered ring $S_4N_4O_2$ *(1)*, which leads to the five-membered ring system *(2)*, a triphenylarsane adduct, in high yields.



*(1)* *(2)*

*(2)* forms crystals (space group $P2_1/n$) which are stable towards air and hydrolysis. We have now found that *(2)* slowly loses $S_4N_4$ and sulfur in acetone solution, and is converted into the condensation product *(3)*.



*(3)*

This reaction can be explained mechanistically in terms of an intermediate formation of a dimer of *(2)* containing a central ten-membered ring system $S_6N_4$.

The molecular structure of *(3)* was determined by X-ray diffraction analysis on a single crystal[2]. *(3)* proves to be the longest non-polymeric sulfur-nitrogen chain synthesized so far, with eleven alternating atoms. The compound cannot be sublimed without decomposition. The largest fragment appearing in the mass spectrum is $(C_6H_5)_3AsS$ at $m/z=338$.

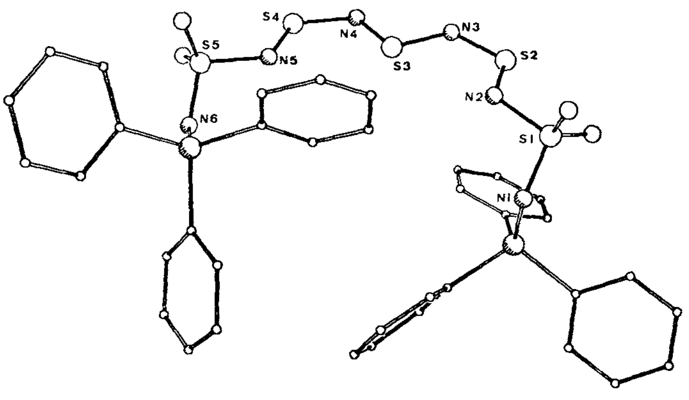


Fig. 1. Structure of the molecule *(3)* in the crystal.

Bond lengths [Å]: N1—S1 1.576(10), S1—N2 1.684(10), N2—S2 1.544(10), S2—N3 1.574(11), N3—S3 1.632(11), S3—N4 1.645(13), N4—S4 1.602(11), S4—N5 1.629(12), N5—S5 1.655(11), S5—N6 1.559 (11); N1—As1 1.756(12), N6—As2 1.779(13), S—O (mean value) 1.438(12), As—C (mean value) 1.892, C—C (mean value) 1.376

Bond angles [°]: As1—N1—S1 120.8(7), N1—S1—N2 105.1(6), S1—N2—S2 116.1(5), N2—S2—N3 110.4(6), S2—N3—S3 119.5(7), N3—S3—N4 96.3(6), S3—N4—S4 117.0(8), N4—S4—N5 113.7(7), S4—N5—S5 115.3(8), N5—S5—N6 104.3(6), S5—N6—As2 118.9(9)

The SN bond lengths (and angles) in the two halves of the molecule of *(3)* differ considerably; the average SN bond length 1.602 Å, however, is similar to the corresponding value of 1.611 in $(SN)_x$[3]. Nevertheless, shorter and longer SN bonds occur in *(3)* than in $(SN)_x$ (1.593 and 1.628 Å). The greater variation in the bond lengths in *(3)* appears to be a result of arbitrary folding of the molecule in the solid state.

## *Procedure*

A solution of $AsPh_3$ (7.6 g, 25 mmol) in benzene (50 mL) is added dropwise to a solution of *(1)* (5.4 g, 25 mmol) in benzene (100 mL) and the mixture briefly heated to boiling. After cooling, the intense yellow precipitate is filtered off, dried, and extracted with acetonitrile. At room temperature, blood-red crystals of *(2)* precipitate out from the extract. After filtration, the mother liquor is stored for a few

days in a refrigerator. A mixture of sulfur, $S_4N_4$ and *(3)* separates out on the wall of the flask; after decanting off the solvent, the crystals of *(3)* can be separated manually from the mixture and recrystallized from $CH_3CN$ or benzene. *(3)* crystallizes from benzene with 3 molecules of solvation (m.p. 87 °C, dec.), from $CH_3CN$ without any molecules of solvation (m.p. 146 °C, dec.), as translucent orange needles.

## Synthesis of Dithiophosphinato Complexes with Bis(diorganothiophosphoryl)disulfanes: $Mo_3S_7$-Cluster Dithiophosphinates

By *Helmut Keck, Wilhelm Kuchen, Jürgen Mathow, Beate Meyer, Dietrich Mootz,* and *Hartmut Wunderlich*[*]

Dithiophosphinate ions *(1)* reduce some metals according to eq. (a); simultaneously, they are themselves oxidized according to eq. (b) to bis(diorganothiophosphoryl)disulfanes *(2)*. $Cu^{2+}$ reacts analogously to give $R_2PS_2Cu$. Presumably, dithiophosphinato chelates of the higher valence metal $R_2PS_2M/m$[1] are formed as intermediates. On the other hand, the disulfanes *(2a)* and *(2b)* can oxidize metals according to reversed eq. (b), being themselves reduced to chelate ligands *(1)*. Thus, *e.g.*, on heating *(2a)* with $Cr(CO)_6$, tris(diethyldithiophosphinato)chromium(III)[2a] is formed according to

$$3\ \underset{(1)}{R_2PS_2^-} + M^{m+} \longrightarrow R_2PS_2M/n + R_2P(S){-}S_2{-}P(S)R_2 \qquad \text{(a)}$$

$$(2a),\ R = C_2H_5$$
$$(2b),\ R = n\text{-}C_3H_7$$

e.g. M = Au, Tl: m = 3, n = 1

$$2\ R_2PS_2^- \underset{+2e}{\overset{-2e}{\rightleftharpoons}} R_2P(S){-}S_2{-}P(S)R_2 \qquad \text{(b)}$$

$$Cr(CO)_6 + 3/2\,(2a) \rightarrow (Et_2PS_2)_3Cr + 6\,CO$$

$Ni(CO)_4$ and $Fe(CO)_5$ react analogously to give $(Et_2PS_2)_2Ni$[2b] and $(Et_2PS_2)_3Fe$[2b], respectively; $SnCl_2$ is oxidized to $(Et_2PS_2)_2SnCl_2$[2c].

We have found that this reaction of the disulfanes can be used for the synthesis of $Mo_3S_7$-cluster chelates of type *(3)*, and of dinuclear tungsten(V) complexes *(4)*. On reaction with carbonyl complexes $M(CO)_6$ of these metals they additionally act as sulfur transferring agents with conversion into monosulfanes $R_2P(S){-}S{-}P(S)R_2$.

Thus, reaction of $Mo(CO)_6$ with *(2a)* or *(2b)* affords the $Mo^{IV}$ compounds *(3a)* and *(3b)*, respectively:

$$[Mo_3S_7(R_2PS_2)_3]^+[R_2PS_2]^-$$

*(3a)*, R = Et, orange-red, decomp. above 260 °C
*(3b)*, R = *n*Pr, copper-red needles, decomp. above 200 °C

The cluster structure of the 1 : 1 electrolytes *(3a)* follows from the elemental analysis, the $^{31}P\{^1H\}$-NMR spectrum ($\delta_P = 110.1$ and 73.5; intensity ratio 3 : 1, saturated solution in $CH_2Cl_2$, relative to 85% $H_3PO_4$), the field-desorption (FD) mass spectrum ($[Mo_3S_7(Et_2PS_2)_3]^+$ $m/z$ 977, ref. to $^{98}Mo$), and the X-ray structure analysis (Fig. 1). *(3b)* exhibits similar properties and a better solubility in many organic solvents. Reaction of *(3a)* with triphenylphosphane affords the sulfur-deficient chelate complex $Mo_3S_4(Et_2PS_2)_4$, a non-electrolyte, which forms deep-black, shiny crystals.

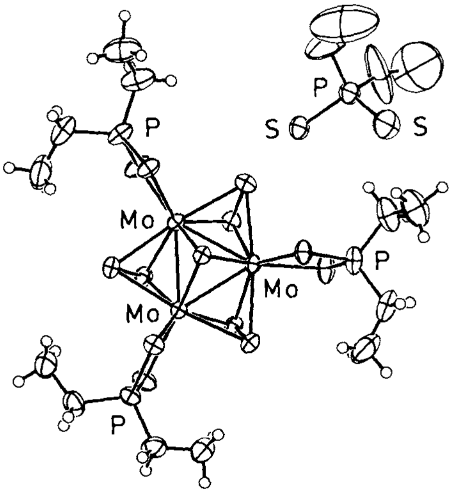

Fig. 1. Crystal Structure of the $Mo^{IV}$ cluster *(3a)* [6]. The orientation and assignment of cation and anion are arbitrary. A disorder in the anion cannot be ruled out. *(3a)* crystallizes in two modifications with the lattice constants $a=2065.1(3)$, $b=1015.2(2)$, $c=1901.9(2)$ and $a=2012.8(2)$, $b=1565.5(2)$, $c=1260.8(1)$ pm, respectively. The corresponding orthorhombic space groups are $Pca2_1$ and Pnma, each with $Z=4$. The structure determinations with 2886 and 3414 significant measured diffraction intensities (ω-scan, $Mo_{K\alpha}$, $2\theta_{max}=54°$) lead to $R$ values of 0.058 and 0.045, respectively. In the latter case anion and cation have a crystallographic mirror plane. In both structures the Mo atoms form an equilateral triangle with an average bond length of 273.7 pm. Each of these bonds is bridged by a vertically oriented $S_2$-dumbbell on one side of the triangle, a single S atom trigonal-pyramidally coordinates the Mo triangle from the other side. This $Mo_3S_7$ cluster was first observed in $Mo_3S_7Cl_4$ [4a]. To each of the three Mo atoms a dithiophosphinato ligand is bonded *via* both S atoms. The two modifications differ in the conformation of the organic moiety and in the arrangement of anions and cations.

Molybdenum-sulfur clusters are of topical interest because of their importance as model substances in bioinorganic chemistry[3]. The method described here provides the first convenient access to $Mo_3S_7$ clusters modified by organo groups[4]. Thus, not only a high solubility in organic solvents is achieved, but the functionalization of these compounds by suitable choice of substituents R is also possible.

Reaction of $W(CO)_6$ with *(2)* affords the tungsten complexes *(4a, b)*.

We postulate a dinuclear structure for these non-electrolytes. *(4a)*: $^{31}P\{^1H\}$-NMR: $\delta_P = 135.6$ (saturated solution in 1,2-dichloroethane); electron-impact induced (EI) MS:

(4a), R = $C_2H_5$, bordeaux red, m.p. 238 °C (dec.)
(4b), R = $n$-$C_3H_7$, cinnabar red, m.p. 248 °C (dec.)

$m/z$ 802 ($M^+$, ref. to $^{184}W$); IR (Nujol): $\nu_{W=S} = 528$ $cm^{-1}$[5]. *(4b):* $^{31}P\{^1H\}$-NMR: $\delta_P = 130.3$ (saturated solution 1,2-dichloroethane); EIMS: $m/z$ 858 ($M^+$ ref. to $^{184}W$); IR (Nujol): $\nu_{W=S} = 530$ $cm^{-1}$. Accordingly, *(2)* also functions here as an oxidizing agent under chelate formation and sulfur transfer.

*Procedure*

*(3a):* A mixture of $Mo(CO)_6$ (2.6 g, 10 mmol), disulfane *(2a)* (9.2 g, 30 mmol), and toluene (50 mL) is heated under reflux in an argon atmosphere. The initial clear, colorless solution turns dark-brown with evolution of CO. After *ca.* 1 h an orange-yellow precipitate is formed which after 4 h is filtered off and washed with toluene and ether. For further purification, *(3)* is precipitated from boiling $CH_2Cl_2$ by slow addition of $CH_3OH$. Yield 65%, soluble in $CHCl_3$ and $CH_2Cl_2$, air-stable.

*(4a):* A mixture of $W(CO)_6$ (8.8 g, 25 mmol), disulfane *(2a)* (19.2 g, 63 mmol) and 1,2,4-trimethylbenzene is heated under reflux for 2 h. On addition of 400 mL of ligroin (100—120 °C) to the red-brown solution a red solid is precipitated, which is washed several times with hot methanol. Yield 82%; the bordeaux-red crystals (1,2-dichloroethane) are moderately soluble in acetone, chloroform or benzene.

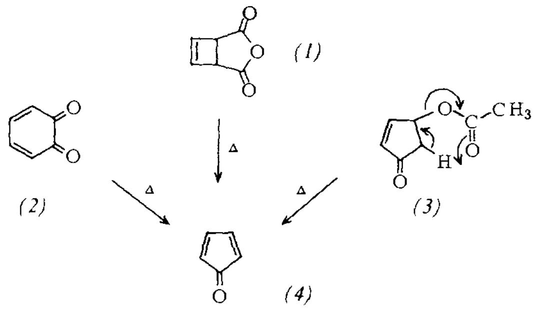
## Trimethylsilylated Cyclopentadienones[**]

By *Günther Maier, Hans Werner Lage,* and
*Hans Peter Reisenauer*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

The use of cyclopentadienone *(4)* in syntheses is rendered difficult by its strong tendency to dimerize. Monomeric *(4)* is obtainable in substance only by matrix isolation[1]—*e.g.* in combination with the vacuum flash pyrolysis of *(1)*, *(2)*, or *(3)*[2]. Trimethylsilylated derivatives of *(4)*, whose protective groups can easily be cleaved at a later stage, should be far more suitable as synthetic building blocks. A recent publication on this topic prompted us to report the results of our experiments, in which we attempt to open up an entry to unsubstituted tetrahedrane[5] *via* silylated precursors.



Trimethylsilylmaleic anhydride *(6)* is accessible by addition of trimethylsilane to di-*tert*-butyl acetylenedicarboxylate[6a] in the presence of $PdCl_2(PPh_3)_2$[6b] and heating the primary adduct to 190 °C. Photolysis of *(6)* and bis(trimethylsilyl)acetylene *(5)*[7a] in acetone smoothly affords the [7b] anhydride *(7)*. On direct irradiation, photofragmentation of *(7)* leads to the structurally isomeric tris(trimethylsilyl)cyclopentadienones *(8)* and *(9)*[8] (Table 1). *(8)* completely dimerizes within a week at room temperature, whereas *(9)* is stable under these conditions.

Table 1. Data for compounds *(6)*—*(12)*: Yields, physical and spectroscopic properties. IR [cm$^{-1}$]; NMR (CDCl$_3$): $\delta$ values rel. TMS (all signals are singlets); UV (cyclohexane) [nm] ($\varepsilon$). All substances gave correct elemental analyses.

*(6)*: 65%; colorless oil, b.p. 50 °C/10$^{-2}$ torr.—IR (Film): 1853, 1815, 1760 (anhydride); $^1$H-NMR: −0.13 (9H), 6.72 (1H); $^{13}$C-NMR: 2.42, 145.28, 157.54, 166.98, 169.80

*(7)*: 80%; colorless crystals, m.p. 54 °C.—IR (Film): 1840, 1760 (anhydride); $^1$H-NMR: 0.24 (27H), 3.72 (1H); $^{13}$C-NMR: 0.77, 2.36, 2.60, 55.55, 58.80, 170.35, 172.58, 177.16 (2C); UV: 220 (1290), 240 (850)

*(8)*: 32%; red-orange oil.—IR (Film): 1690 (C═O); $^1$H-NMR: 0.27 (18H), 0.35 (9H), 5.80 (1H); $^{13}$C-NMR: 0.47, 1.38, 1.61, 133.30, 143.61, 169.18, 174.87, 210.16; UV: 230 (sh), 395 (190)

*(9)*: 13%; red-orange crystals, m.p. 36—37 °C.—IR (Film): 1690 (C═O), 1570 (C═C); $^1$H-NMR: 0.16 (9H), 0.22 (9H), 0.28 (9H), 7.28 (1H); $^{13}$C-NMR: −1.28, −0.15, 0.84, 133.23, 145.86, 160.60, 167.61, 210.61; UV: 227 (1040), 400 (180)

*(10)*: 17%; red crystals, m.p. 81—83 °C.—IR (CDCl$_3$): 1700 (C═O), 1530 (C═C); $^1$H-NMR: 0.25 (9H), 0.35 (9H), 0.40 (9H); $^{13}$C-NMR: 0.31, 0.76, 1.64, 129.13, 145.65, 162.66, 181.34, 198.31; UV: 250 (sh), 445 (350)

*(11)*: 41%; yellow-orange crystals, m.p. 50 °C.—IR (CDCl$_3$): 1685 (C═O), 1545 (C═C); $^1$H-NMR: 0.30 (18H), 0.46 (9H); $^{13}$C-NMR: 0.77, 1.66, 2.23, 130.65, 148.57, 161.49, 168.40, 206.06; UV: 250 (6590), 405 (495)

*(12)*: 49%; orange crystals, m.p. 132—133 °C.—IR (KI): 1670 (C═O); $^1$H-NMR: 0.24 (18H), 0.35 (18H); $^{13}$C-NMR: 1.13, 2.36, 146.82, 181.09, 204.81; UV: 423 (290)

Bromination of *(8)* with pyridinium perbromide at −78 °C in pentane and subsequent dehydrobromination with 1,5-diazabicyclo[5.4.0]undec-5-ene affords 2-bromo-3,4,5-tris(trimethylsilyl)cyclopentadienone *(10)*, while bromination of *(9)* at 0 °C followed by HBr-elimination furnishes the structurally isomeric bromodienone *(11)*.

The fourth trimethylsilyl group can be incorporated by reaction of the reactive Michael acceptor *(11)*[9a] with LiSiMe$_3$ in the presence of CuI[9b].

The resulting tetrakis(trimethylsilyl)cyclopentadienone *(12)* behaves completely different compared to the analogous fourfold *tert*-butyl substituted derivative[5b] on photochemical excitation. The final product of the photolysis (Hg low-pressure lamp, Rigisolve matrix, 77 K, 200 h) is not the tetrahedrane *(15)*[10], but tetrakis(trimethylsilyl)butatriene *(13)* (65%)[11]. On irradiation in an argon matrix (10 K, 35 h) with 313-nm light, the allenylketene *(14)* (IR: 1890, 2080 cm$^{-1}$) can be detected as intermediate. Further irradiation at a wavelength of 254 nm (10 K, 10 h) leads to loss of CO and formation of the butatriene *(13)* (1543 cm$^{-1}$).

The new trimethylsilyl compounds *(9)* and *(12)* constitute the first cyclopentadienone-equivalents available as synthons, which are stable at room temperature.

## Enantioselective Synthesis of (*R*)-α-Vinylamino Acids[**]

By *Ulrich Schöllkopf* and *Ulrich Groth*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

α-Vinylamino acids of type *(6)* have gained increasing importance as potential enzyme inhibitors[1]. Although several methods are available for their preparation in racemic form[2], enantioselective syntheses, which would provide access to these compounds in, if possible, the most optically pure form and with defined configuration have so far not been described in the literature.

We describe here the enantioselective synthesis of almost optically pure (*R*)-2-amino-3-phenyl-3-butenoic acid methyl ester *(6)* (β-methylenephenylalanine methyl ester), which has previously been prepared in racemic form[3]. This demonstrates that our bislactim-ether method[4] is also suitable for the asymmetric synthesis of α-vinylamino acids. The bislactim ether *(1)*[5] of cyclo-(L-Val-Gly) is converted with butyllithium into its lithium derivative *(2)*, which on reaction with acetophenone affords the adduct *(3)* (*ca.* 90% yield) with extremely high diastereoselectivity. The carbonyl compound enters *trans* to the isopropyl group at C-6, *i.e.* the (*R*)-configuration is induced at C-3 (use of D-valine would result in the (*S*)-configuration). The configuration was assigned on the basis of the $^1$H-NMR spectrum. Since the adduct *(3)* has the "aryl-inner" conformation[6], the hydrogen atom 6-H falls into the shielding anisotropic region of the phenyl ring and its NMR signal experiences a strong upfield shift.

Reaction of thionyl chloride/2,6-lutidine with *(3)* affords a mixture (80:20) of the two olefins *(4)* and *(5)*, which on hydrolysis with hydrochloric acid give, aside from L-Val-OCH$_3$, the (*R*)-α-vinylamino acid ester *(6)* and the α-keto ester *(7)*. The keto ester *(7)* can be extracted from the acidic aqueous solution. The amino acid ester *(6)*, which can be separated from L-Val-OCH$_3$ by distillation, is >95% optically pure[7].

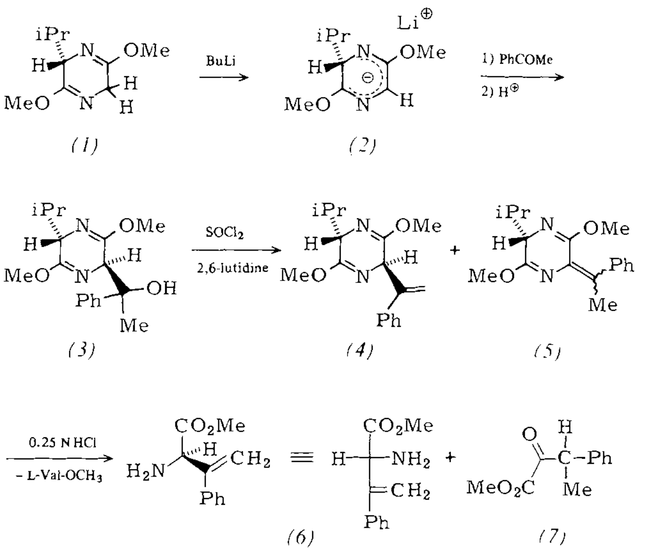
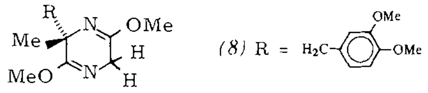
[**] Asymmetric Synthesis *via* Heterocyclic Intermediates, Part 9.—Part 8: [4].





The bislactim ether *(8)*[8] of [(*S*)-(*O,O*-dimethyl-α-methyldopa)-Gly] is also suitable as starting compound for the enantioselective synthesis of α-vinylamino acids. Reaction of the lithium compound of *(8)* with acetone, followed by elimination of water and hydrolysis, affords the (*R*)-2-amino-3-methyl-3-butenoic acid methyl ester (type *(6)*, Me instead of Ph)[9] with *e.e.* ≈ 88% (determined $^1$H-NMR spectroscopically with Eu(hfc)$_3$ on the OCH$_3$ signal.

### *Procedure*

*(3)*: A 1.55 N solution of *n*-butyllithium (4.2 mmol) in hexane (2.7 mL) was added dropwise (under $N_2$, injection needle) at −70 °C to a solution of *(1)*[5] (0.74 g, 4 mmol) in dimethoxyethane (8 mL). The mixture was stirred for *ca.* 10 min at −70 °C and then treated with the solution of acetophenone (0.50 g, 4.2 mmol) in dimethoxyethane (5 mL). After *ca.* 4 h the mixture was rendered neutral with a solution of glacial acetic acid (0.25 g, 4.2 mmol) in dimethoxyethane (2 mL), allowed to warm to room temperature, and the solvent removed under reduced pressure. The residue was taken up in *ca.* 10—15 mL of ether, washed with about 20 mL of water, and the aqueous phase extracted twice with 20 mL of ether. The combined ether extracts were dried over $MgSO_4$, the ether removed under reduced pressure, and *(3)* was distilled in a Kugelrohr apparatus. Yield 1.1 g (91%) *(3)*, b.p. 140—150 °C/0.1 torr.

*(4)* and *(5)*: A solution of $SOCl_2$ (0.37 g, 3.1 mmol) in toluene (4 mL) was added to a solution of *(3)* (0.91 g, 3 mmol) and 2,6-lutidine (0.66 g, 6.2 mmol) in toluene (10 mL) at room temperature. After 16 h the mixture was treated with *ca.* 20 mL of ether, washed with *ca.* 15—20 mL of water, dried over $MgSO_4$, the solvent removed under reduced pressure, and the residue distilled in a Kugelrohr apparatus. Yield 0.75 g (88%) *(4)* and *(5)* in the ratio 80 : 20, b.p. 130—140 °C/0.1 torr.

*(6)*: A solution of *(4)* plus *(5)* (0.52 g, 1.8 mmol) in 0.25 N HCl (14.4 mL, 3.6 mmol) was stirred for 30 h and then extracted with ether. The aqueous phase was evaporated down under reduced pressure to *ca.* 1-2 mL (bath temperature 60—80 °C), covered with *ca.* 10 mL ether, and treated with conc. ammonia solution with vigorous shaking until the pH was 8—10. The ether phase was separated off and the aqueous phase extracted a further three times with ether. The combined ether extracts were dried over $MgSO_4$, the ether removed under reduced pressure, and *(6)* distilled in a Kugelrohr apparatus. Yield 0.22 g (64% referred to the isomeric mixture of *(4)* and *(5)*), b.p. 100—110 °C/0.1 torr, $[\alpha]_D^{20} = -62.1°$ ($c = 0.6$, ethanol), enantiomeric purity >95%[7]; $^1$H-NMR ($CDCl_3$): $\delta = 1.83$ (s, $NH_2$), 3.71 (s, $OCH_3$), 4.54 (s, α-H), 5.34 and 5.43 (2 s, C=$CH_2$), 7.25—7.49 (m, $C_6H_5$).

## CC-Coupling and Reversible γ-H Abstraction in the Tantalum Complex Cl($\eta^5$-Cp)($\eta^3$-$C_9H_7$)Ta(CHCMe$_3$)

By *Anton W. Gal* and *Harry van der Heijden*[*]

Coordinatively unsaturated cyclopentadienyl(Cp)-tantalum-neopentylidene complexes have been shown to be useful precursors for reactive tantalum olefin compounds[1a]. They generally react with olefins to give tantalacyclobutane intermediates, which rearrange *via* β,α hydrogen migration to give the corresponding tantalum olefin complexes[1a,c]. However, coordinatively saturated neopentylidene complexes, such as Cl($\eta^5$-Cp)$_2$Ta(CHCMe$_3$)[1d], do not react with olefins. In an attempt to enhance the reactivity of Cl($\eta^5$-Cp)$_2$Ta(CHCMe$_3$) we have now replaced one $\eta^5$-Cp group by an $\eta^3$-indenyl group ($\eta^3$-$C_9H_7$) to obtain Cl($\eta^5$-Cp)($\eta^3$-$C_9H_7$)Ta(CHCMe$_3$) *(2)*[2].

The $\eta^3$-indenyl complex *(2)* is prepared by reaction of one equivalent of indenylsodium with $Cl_2$CpTa(CHCMe$_3$) *(1)* (molar ratio 1 : 1) in benzene[3]. If excess of indenylsodium (>2 : 1) is used *(3)* is the only product (Scheme 1).

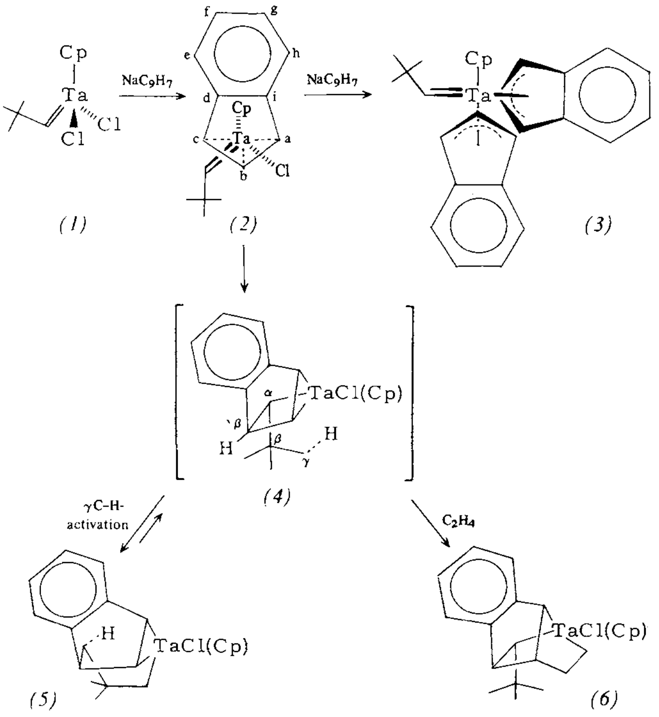


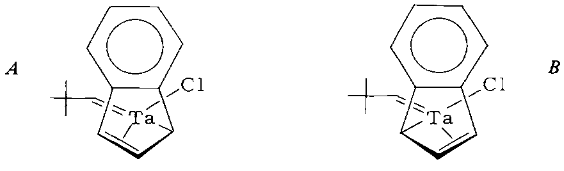
Scheme 1.

The structures assigned to *(2)* and *(3)*, are based on their $^1$H- and $^{13}$C-NMR spectra. The $^{13}$C-NMR signals ($C_6D_6$, TMS) of the bridgehead carbon atoms $C_d$ and $C_i$ in both *(2)* ($\delta = 129.8$)[3] and *(3)* (137.0 and 140.4) are shifted downfield relative to those for $C_d$ and $C_i$ in $\eta^5$-($C_9H_7$) complexes (*e.g.* ($\eta^5$-$C_9H_7$)$_2$Fe: $\delta = 87.0$)[4a]. Comparison of the chemical shifts of $C_a$, $C_b$, and $C_c$ in compounds *(2)* ($\delta = 82.9$, 118.0, and 98.7 resp.) and *(3)* (77.1, 134.4, and 97.2 resp.) with those of the corresponding carbon atoms in Ni($\eta^3$-$C_9H_7$)$_2$ (67.6, 106.6, and 67.6 resp.)[4a] and $Me_3Sn$($\eta^1$-$C_9H_7$) (45.8, 135.3 126.6 resp.)[4b] clearly indicates that the indenyl group is $\eta^3$-coordinated. The $^{13}$C-NMR spectrum of compound *(3)* at room temperature shows broad resonances due to carbon atoms $C_a$, $C_b$, $C_c$, $C_d$, and $C_i$, which are thought to represent the collapsed signals due to two rapidly exchanging nonequivalent $C_9H_7$ groups.

The coordinatively saturated 18e species *(3)* can be formally considered as a pseudo-octahedral complex in which each of the asymmetrically coordinated[5] $\eta^3$-$C_9H_7$ groups occupies two coordination sites. As expected, *(3)* does not react with ethylene. The coordinatively unsaturated 16e species *(2)* can be regarded as a pseudo-tetragonal pyramidal complex. It reacts slowly with ethylene in benzene at room temperature. $^1$H-NMR spectroscopy indicates that the neopentylidene originally present in *(2)* is quantitatively converted within 2.5 h into the homologous olefins 4,4-dimethyl-1-pentene and *trans*-4,4-dimethyl-2-pentene in a molar ratio of 1 : 1[6].

In the absence of ethylene, compound *(2)* has a half-life of *ca.* 1 d at room temperature, and is quantitatively converted to the tantalum bicycloheptane derivative *(5)* (Scheme 1). We presume that this reaction occurs *via* the tantalum bicyclopentane derivative *(4)* as intermediate. The structure assigned to compound *(5)* is based on $^1$H- and $^{13}$C-NMR spectroscopic evidence. The most salient features in the $^1$H-NMR spectrum, on going from *(2)* to *(5)*, are the disappearance of the singlet of the *tert*-butyl group ($\delta = 1.20$) in *(2)* accompanied by the simultaneous appearance of both singlets of the methyl groups of *(5)* (1.64 and 1.31). This clearly demonstrates the involvement of the *tert*-butyl group in the reaction.

CC bond formation in *(2)* can only occur when the two carbon atoms involved are in a *cis*-position to each other.



Scheme 2. Two resonance structures of *(2)*; Cp is not shown.

Dependent on the relative contributions of resonance structures *A* and *B*, the coupling between the neopentylidene and the asymmetrically coordinated $\eta^3$-$C_9H_7$ ligand can be formulated in two ways: 1) coupling of the neopentylidene fragment and the $\pi$-coordinated double bond to give a tantalacyclobutane ring; 2) insertion of the neopentylidene fragment into the Ta—$C_9H_7$ $\sigma$-bond. At present we cannot discriminate between the two possibilities. Both types of reaction have their precedents in tantalum chemistry[1a, b].

Dreiding molecular models of intermediate *(4)* suggest that the isomer shown in Scheme 1 is the most attractive one from the point of view of steric interactions. This isomer has to arise from the conformer of *(2)* containing an *endo*-oriented $\eta^3$-$C_9H_7$[7a, b] and an *exo*-oriented neopentylidene ligands[7c] (Scheme 1). The geometrical constraints in the highly coordinatively unsaturated 14e species *(4)* prevent $\beta$-H abstraction ($C_{\beta'}$—H) from the indenyl skeleton and provoke $\gamma$-H abstraction from a methyl in the *tert*-butyl group. This $\gamma$-H abstraction is unique in the sense that a

Table 1. $^1$H- and $^{13}$C-NMR data for *(5)* and *(6)* [a, b].

*0570-0833/81/1111-0979 $ 02.50/0*

γ-H is abstracted by $C_\alpha$ of the same alkyl group[8]. Whether this "γ,α-hydrogen shift" actually involves oxidative addition of $C_\gamma$-H to a Ta atom, followed by reductive elimination of $C_\alpha$-H[8], or a four centered transition state (see α-H abstraction in $ClTa(CH_2CMe_3)_4$)[1d] remains to be determined.

The result of the hydrogen shift is an expansion of the tantalacyclobutane ring to a less strained tantalacyclohexane ring in the boat conformation (*(5)*, Scheme 1). In this conformation the C—H bond formed is still close to the metal center and γ-H abstraction and ring expansion should be easily reversible. Several conformers of *(5)* can be envisaged. Dreiding molecular models reveal that of all the possible conformations, the skew boat form of *(5)* (Table 1) is the only one that involves both the energetically favored coordination of the double bond of the indenyl fragment parallel to the Cp group[6a] *and* a dihedral angle of *ca.* 90° between $C_c$—$H^4$ and $C_d$—$H^5$, since $J_{H^4H^5} \approx 0$ (Table 1). This conformation may well be the one prevailing in solution at room temperature.

The reversibility of the γ-H abstraction discussed above is shown by the reaction of *(5)* with ethylene in toluene at 70 °C: within 3 h, compound *(5)* is quantitatively converted into the tantalanorbornane derivative *(6)* *via* incorporation of 1 mol of ethylene (Scheme 1). The most striking change in the $^1$H-NMR spectrum upon conversion of *(5)* into *(6)* is the reappearance of a *tert*-butyl singlet: ($\delta = 1.04$) since $J_{H^7H^x} = 0$ (Table 1) the *tert*-butyl group must be in the *endo*-position, in accordance with the proposed mechanism. Treatment of *(5)* with $C_2D_4$ indicates that no significant H/D exchange occurs during $C_2D_4$ incorporation: only the signals and couplings due to $H_1$, $H_2$, $H_3$, and $H_4$ disappear in the $^1$H-NMR spectrum.

Both conversions *(2)→(5)* and *(5)→(6)*, described above, are highly specific and quantitative. They clearly demonstrate the high potential of organotantalum complexes in the C—C coupling and hydrogen-shift reactions involved in rearrangements of complex, unsaturated hydrocarbons.

### *Procedure*

*(2):* Solid $NaC_9H_7$ (360 mg, 2.6 mmol) was added over 1 h to a stirred solution of *(1)* (1.00 g, 2.6 mmol) in 20 mL of $C_6D_6$ at 6—10 °C. After warming up to room temperature over 30 min and filtration to remove the precipitate of NaCl, the solution was concentrated by partial evaporation of $C_6D_6$. The $^1$H-NMR spectrum indicated virtually quantitative conversion of *(1)* to *(2)*, with small amounts of *(1)* and *(3)* present.

*(3):* Solid $NaC_9H_7$ (0.10 g, 0.72 mmol) was added to a stirred solution of *(1)* (0.07 g, 0.18 mmol) in 4 mL of $C_6D_6$. After 1 h, the solution was filtered to remove NaCl and excess $NaC_9H_7$. The $^1$H-NMR spectrum of a sample of this solution indicated that quantitative conversion of *(1)* to *(3)* had occurred. Evaporation of the $C_6D_6$ resulted in formation of a brown oil, which we have not been able to crystallize.

*(5):* A sample of the crude solution of *(2)* was allowed to stand for 3 d at room temperature. The $^1$H-NMR spectrum indicated complete conversion of *(2)* into *(5)*. The brown oil obtained upon evaporating $C_6D_6$ was dissolved in *n*-hexane, and activated carbon added. After being stirred for 1 h and filtration, the solution was concentrated. Cooling at −20 °C gave brownish purple needles of *(5)*.

*(6):* A solution of *(5)* (1.5 g, 3.2 mmol) in 150 mL of toluene was heated at 70 °C under an ethylene pressure of 0.3 bar. The color of the solutions slowly changed from brown to red. After 3 h the solution was concentrated to 20 mL, and 35 mL of hexane and activated carbon were added. After being stirred, filtration of the mixture resulted in a clear red solution. Evaporation of the solvents produced *(6)* as a red oil. Upon recrystallization of this oil from hexane, analytically pure solid *(6)* was obtained.

[3] One of the signals from $C_d$ and $C_i$ in *(2)* is hidden by $C_6D_6$ signals.

[4] a) *F. H. Köhler*, Chem. Ber. *107*, 570 (1974); b) *G. A. Taylor, P. E. Rakita*, J. Org. Magn. Reson. *6*, 644 (1974).

[5] In *(2)* and *(3)*, the different ligands which are *trans* to $C_a$ and $C_c$ of the allylic part of the indenyl ligand cause a localization of the π-electron density between either $C_a$ and $C_b$ or $C_b$ and $C_c$, which is clearly shown in the $^{13}$C-NMR spectrum (see text).

[6] a) This ratio is different from that observed in the reaction of *(1)* with $C_2H_4$. 4,4-Dimethyl-1-pentene : *trans*-4,4-dimethyl-2-pentene = 0.97 : 0.03 (*S. J. McLain, C. B. Wood, R. R. Schrock*, J. Am. Chem. Soc. *101*, 4558 (1979)); b) we have been unable to characterize the Ta complexes formed, since they are difficulty soluble and their NMR spectra exhibit broad lines (probably due to the formation of paramagnetic compounds).

[7] a) *exo-* and *endo*-Indenyl are defined by analogy to *exo-* and *endo*-allyl (*B. E. R. Schilling, R. Hoffman, J. W. Faller*, J. Am. Chem. Soc. *101*, 592 (1979); b) a single crystal X-ray study of the pseudo-tetragonal pyramidal species $(\eta^5\text{-}C_9H_7)(\eta^3\text{-}C_9H_7)W(CO)_2$ revealed a dihedral angle of 26° between the allylic part ($C_a$, $C_b$, $C_c$) and the aromatic ring of the *exo*-coordinated $\eta^3$-indenyl ring. *endo*-Coordination of the $\eta^3\text{-}C_9H_7$ ligand is prevented since the six-membered rings of $\eta^3\text{-}C_9H_7$ and $\eta^5\text{-}C_9H_7$ would then be extremely close together. *J. A. N. Nesmeyanov, N. A. Ustynyuk, L. G. Makarova, V. G. Andrianov, Yu. T. Struchkov, S. Andrea, Yu. A. Ustynyuk*, and *S. G. Malyugina*, J. Organometal. Chem. *159*, 189 (1978). *endo*-$\eta^3\text{-}C_9H_7$ coordination would however be feasible if, as is the case for *(2)*, $\eta^5$-Cp were present instead of $\eta^5\text{-}C_9H_7$. c) In *exo*-neopentylidene the *tert*-butyl group is directed away from the Cp fragment; in *endo*-neopentylidene the *tert*-butyl group is turned towards the Cp fragment.

[8] In $(Et_3P)_2Pt(CH_2CMe_3)_2$ a γ-H atom of one neopentyl group is abstracted by the $C_\alpha$ atom of the second neopentyl group. γ-H abstraction by $C_\alpha$ of the same neopentyl group was not observed; *P. Foley, G. M. Whitesides*, J. Am. Chem. Soc. *102*, 6713 (1980).

## Palladation of sp$^3$-Carbon Atoms: Preparation of *N*-Palladiomethylthioamides[**]

By *Yoshinao Tamaru, Masahiro Kagotani*, and *Zen-ichi Yoshida*[*]

Many studies on the *ortho*-palladation of aromatics which possess a benzylic heteroatom (N, P, S, *etc.*) substituent have been reported[1]. Although the reaction of *N,N*-dimethylthiobenzamide *(1a)* with $PdCl_2$ in refluxing $CH_3OH$ is analogous to the *ortho*-palladation of thiobenzophenone[2a] and thiopivaloylferrocene[2b], the product *(2a)* which is C-metalated at the N—$CH_3$ group is quantitatively formed; no *ortho*-palladation product was detected.

[a] In HMPA in 80 °C.

The structure of *(2a)* (acac complex), which is characterized by its five-membered ring (Pd—C($sp^3$)—N—C=S), follows from IR- and $^1$H-NMR spectra, and X-ray crystal structure analysis (Fig. 1)[3]. *(2a)* is thermally stable and does not decompose in air or in the presence of moisture.

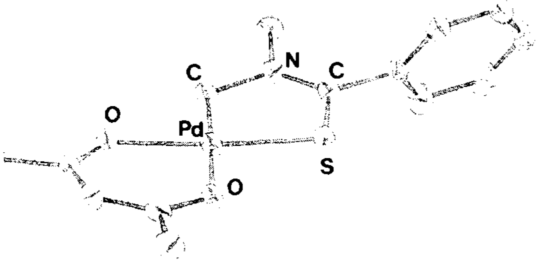

Fig. 1. ORTEP plot of *(2a)* (acac complex) in the crystal.

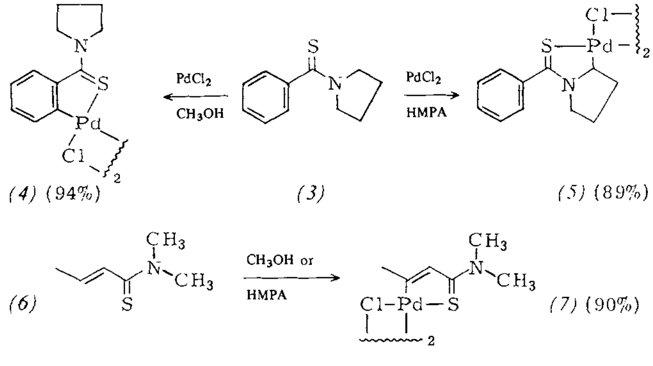
The reaction *(1)*→*(2)* is reminiscent of the lithiation of the $NCH_3$ groups of *N,N*-dimethylthioamides[4a] or *N,N*-dimethylcarbamates[4b]. While metalation with Li is restricted to compounds whose thiocarbonyl groups are protected against attack of organolithium compounds, the present metalation with Pd indicates the high structural flexibility of many thioamides[5].

Selected results are summarized in Table 1, which reveals that not only thiobenzamides but also thioalkylamides can react to give *N*-palladiomethyl derivatives *(2)* with similar ease: hereby thioalkylamides with bulky alkyl groups react particularly easily (Table 1)[6].

The *N*-methyl group is much more reactive than the *N*-ethyl or pyrrolidino groups, as shown *e.g.* by the selective palladation of the $NCH_3$ group in *(1c)*. The *N*-isopropyl group could not be metalated with Pd. Hexamethylphosphoric triamide (HMPA) is found to be a better solvent for less reactive substrates.

The regioselectivity (palladation of the *N*-alkyl group in the α-position *versus ortho*-palladation) largely depends on the reaction conditions and/or the structural features of the thioamides. While *N*-thiobenzoylpyrrolidine *(3)* is metalated by $PdCl_2$ at the $CH_2$ group neighboring the nitrogen in HMPA to give *(5)*, the similar reaction in $CH_3OH$ leads to a selective *ortho*-palladation producing *(4)* in quantitative yield. Similarly *N,N*-dimethylthiocrotonamide *(6)* reacts both in HMPA and in $CH_3OH$, whereby an $sp^2$-C atom is also metalated; this is in marked contrast to the selective palladation of *N,N*-dimethylthiocinnamamide *(1i)* and *N,N*-dimethyl-1-cyclohexenethioamide *(1j)* (where only an $sp^3$-C atom is attacked.



## *Procedure*

*(2a):* A suspension of $PdCl_2$ (1 mmol) and *1a* (1.2 mmol) is magnetically stirred and refluxed in $CH_3OH$ for 10 h, during which time a pale yellow solid gradually precipitates. When the reaction mixture has cooled to room temperature, the precipitate is filtered and washed with ether. Yield 90—100% (based on Pd). The acetylacetonato complex of *(2a)* is obtained as follows: A solution of *(2a)* (1 mmol) in 20 mL of $CH_3CN$ is treated with Tl(acac) (1.2 mmol) at room temperature for 4 h. After evaporation of the solvent, the residue is dissolved in benzene, filtered through a 2 cm long cellulose column, and then chromatographed on a silica gel column ($C_6H_6/CH_2Cl_2$). Recrystallization (EtOH/$CH_2Cl_2$) provides a pale yellow solid (50—60%). IR (KBr disk): 1595 (s), 1575 (s), 1520 (s), 1405 (br. s), 764 (m), and 604 (m); $^1$H-NMR ($CDCl_3$): $\delta = 1.97$ (s, 6 H), 3.13 (s, 3 H), 4.56 (s, 2 H), 5.30 (s, 1 H), and 7.47 (br. s, 5 H).

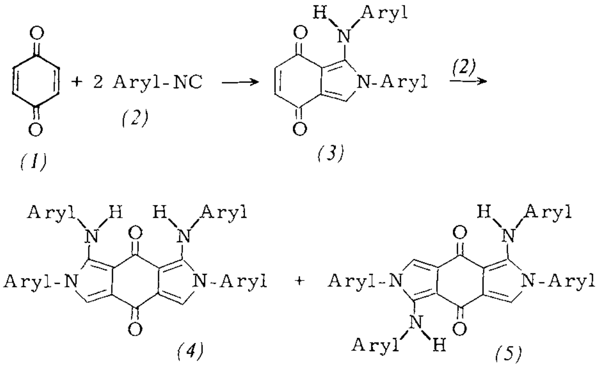
# Addition of Aryl Isocyanides to 1,4-Quinones: Synthesis of Novel Deep-Blue Dyes

By *Walter Ott* and *Victor Formacek*[*]

Although quinones and isocyanides have each been the subject of numerous investigations, nothing has so far been mentioned about how they react with each other[1-3]. We have now found that on heating a mixture of 1,4-benzoquinone *(1)* and 2.5 equivalents of 4-methylphenyl isocyanide *(2)* in toluene, a deep-blue solution is obtained from which the products *(3)*, *(4)*, and *(5)* can be isolated. *(3)* is apparently a precursor of *(4)* and *(5)*, since reaction of pure *(3)* with *(2)* under the same conditions also affords *(4)* and *(5)*. According to elemental analyses and mass spectra *(3)* is a 1:2 adduct, *(4)* and *(5)* are 1:4 adducts of the quinone *(1)* and the isocyanide *(2)*.



Aryl = 4-Methylphenyl

Table 1. Melting points and spectroscopic data of the compounds *(3)*, *(4)*, and *(5)*.

[a] In 1,2-dichloroethane. [b] In Nujol. [c] In $CDCl_3$, 250 MHz. [d] In $CDCl_3$, 62.89 MHz. Quoted multiplicities taken from the off-resonance decoupled $^{13}$C-NMR spectra.

The spectra of *(3)*, *(4)* and *(5)* verify the close similarity of the compounds (see also Table 1). According to the $^1$H-NMR spectrum *(3)* contains two different aryl moieties and two *cis*-vinyl protons, which are absent in the case of *(4)* and *(5)*. All spectroscopic data of the 1:2 adduct are consistent with it being the 4,7-dioxo-4,7-dihydroisoindole *(3)*. According to the $^{13}$C-NMR spectra, *(4)* has $C_{2h}$ symmetry (16 $^{13}$C-NMR signals) and *(5)* has $C_{2v}$ symmetry (15 $^{13}$C-NMR signals). It follows, therefore, that the 1:4 adducts, which are also formed from *(3)*, must have the structures *(4)* and *(5)*, the basic skeletal unit of which was recently synthesized *via* an alternative route[4]. Noteworthy is the deep-blue color of the compounds *(3)*, *(4)* and *(5)*, which is reminiscent of the color of the diamino-1,4-benzoquinones[5]. Annelation of the second pyrrole ring on *(3)* hardly influences the position of the longest wave absorption maximum, only the extinction becomes larger.

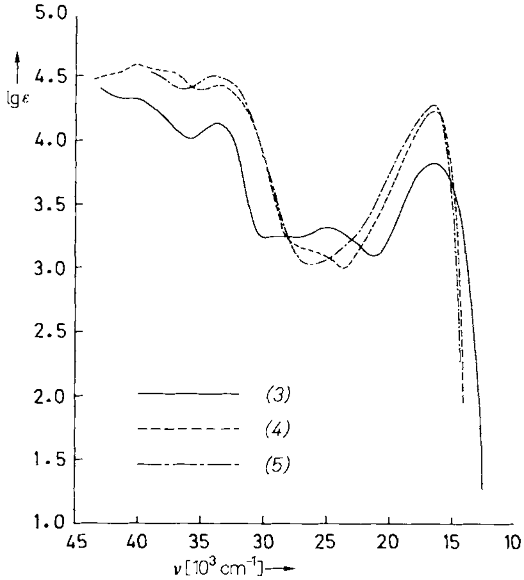

Fig. 1. UV/VIS spectra of the dyes *(3)*, *(4)* and *(5)* in 1,2-dichloroethane.

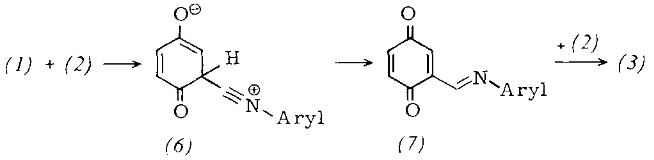
We assume the first step of the reaction sequence leading to *(3)* to be a formal insertion of the isocyanide C atom into a CH bond of *(1)*, in which the dipole *(6)* occurs as intermediate. [4+1]-Cycloaddition of a second isocyanide molecule to the heterodiene *(7)* and stabilization of the cycloadduct by prototropy leads to the 1:2 adduct. [4+1]-Cycloadditions of isocyanides to electron-deficient heterodienes have been described on numerous occasions[6]. Phenyl isocyanide and 4-substituted aryl isocyanides containing residues other than methyl likewise give 1:2 and 1:4 adducts.



### *Procedure*

A solution of *(1)* (1.08 g, 10 mmol) and *(2)* (2.93 g, 25 mmol) in toluene (30 mL) was heated under reflux until no more *(1)* was present (4 h, TLC monitoring, silica gel, chlo-

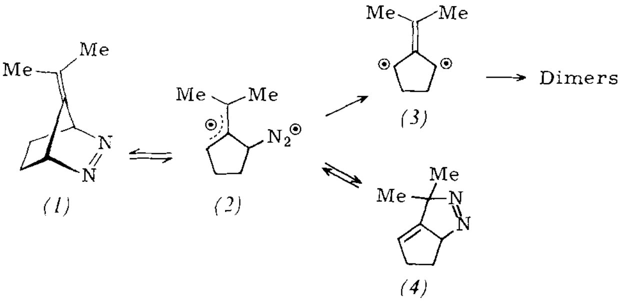
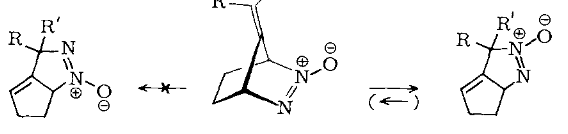
## Rearrangement of Bridged Diazene *N*-Oxides: Selective Cleavage of the C—NO Bond[**]

By *Henrik Olsen* and *Jean F. M. Oth*[*]

It has been shown recently by *Berson et al.* that thermal loss of $N_2$ from the bridged diazene *(1)* is accompanied by a rearrangement to the isomer *(4)*[1a]. Kinetic investigations combined with MO calculations suggest that the thermolysis proceeds *via* the diradical *(2)*[1]. We report here on the thermal isomerization of the analogous diazene *N*-oxides *(5)*—*(7)*.





*(8b)*, R = R' = Me
*(5)*, R = R' = Me
*(6a)*/*(6b)*, R = Me/Ph, R' = Ph/Me
*(7)*, R = R' = Ph
*(8a)*, R = R' = Me
*(9a)*/*(9b)*, R = Me/Ph, R' = Ph/Me
*(10)*, R = R' = Ph

Pyrolysis of degassed solutions of *(5)* in sealed pyrex ampules yielded quantitatively the isomer *(8a)*, the structure of which was established unequivocally by an X-ray analysis[2]. A mixture of the diastereomers *(6)* underwent thermal rearrangement to give a mixture of the diastereomers *(9)*[3]. Although the spatial arrangement of the phenyl and methyl groups in *(6)* and *(9)* could not be specified, the $^1$H-NMR spectra recorded before and after thermolysis indicate that each stereoisomer rearranges to give a single product: in all cases the molar ratio of the products was found to be identical to the molar ratio of the educts. In contrast, thermolysis of *(7)* yields equilibrium mixtures of *(7)* and *(10)*[3] ($K_{(10)/(7)} = 1.75$ at 134.6 °C).

Table 1. Rate constants and free energies of activation for the isomerization of *(5)*—*(7)* in $[D_8]$dioxane at 134.6 °C.

| Compound | $k \times 10^5$ [s$^{-1}$] | $\Delta G^{\neq}$ [kcal/mol] |
|---|---|---|
| *(5)* | 2.6 | 32.6 |
| *(6a)* | 3.8 | 32.3 |
| *(6b)* | 4.9 | 32.1 |
| *(7)* | 9.6 | 31.6 |

Table 2. The effect of solvent and temperature on the thermal Rearrangement of *(5)*.

| Solvent | $E_t$ | $k \times 10^5$ [s$^{-1}$] [a] | $\Delta H^{\neq}$ [kcal/mol] [b, c] | $\Delta S^{\neq}$ [cal mol$^{-1}$K$^{-1}$] [b, c] |
|---|---|---|---|---|
| $[D_8]$toluene | 33.9 | 21.6 | — | — |
| $[D_8]$dioxane | 36 | 12.0 | 33.6 ± 1.9 | 8.9 ± 4.4 |
| $CD_3CN$ | 46 | 4.5 | — | — |

[a] At 150.5 °C. [b] At 25 °C. [c] The values are given with standard deviations.

The rate constants for the rearrangements of *(5)*—*(7)* were determined at 134.6 °C in $[D_8]$dioxane; the effects of temperature and solvent on the isomerization *(5)*→*(8a)* are shown in Table 2. The rate of disappearence of the substrate was found to be first order by $^1$H-NMR spectroscopy.

Several pathways for the rearrangement are conceivable: apart from a concerted process, diradical *(11a)* or zwitterionic intermediates *(11b)* and *(11c)*, respectively, deserve consideration. However, the following evidence makes it probable that the diradical *(11a)* is involved: 1) isomerization of *(5)* is insensitive to solvent polarity *i.e.* zwitterionic intermediates are improbable; 2) the entropy of activation for the rearrangement of *(5)* is strongly positive ($\Delta S^{\neq} = 8.7$ cal mol$^{-1}$K$^{-1}$); this is more consistent with a flexible,

than with a pericyclic transition state; 3) finally, the rates of rearrangement (at 140 °C) of *(5)*—*(7)* are practically the same as those of the triazolidinedione derivatives *(12)*—*(14)*, thus indicating a similar mechanism. The isomerizations of *(12)*—*(14)*, which are also first order reactions, leads *via* a common diradical intermediate to two products: a fused isomer and an isomer formed by H-abstraction[4].

All NMR data recorded during the thermal isomerization of *(5)* indicate that only *(8a)* is formed; if *(8b)* is also formed its yield must be less than 1%. This implies that the rate of cleavage of the C—NO bond is at least 100 times faster than the rate of cleavage of the C—N bond ($\Delta\Delta G^{+} = \Delta G^{+}(\text{C—N}) - \Delta G^{+}(\text{C—NO}) > 3.9$ kcal/mol at 150.0 °C). Preferential cleavage of the C—NO bond may be attributable to the differences in stability between the two diradicals *(11a)* and *(15)*. *(11a)* is stabilized by the "three-electron-bonding" effect, which is precluded in *(15)*. This effect has recently been invoked by *Greene et al.* as an important factor in the stabilization of diazenoxyl radicals[5].

Comparison of the rearrangement of the diazene *(1)* with that of the analogous *N*-oxide *(5)* is instructive. The ratio of the rate constants[6] $k_{\text{diazene}}/k_{\text{diazene }N\text{-oxide}} = 44000$ (at 50 °C), corresponding to $\Delta\Delta G^{+} \simeq 7$ kcal/mol. This difference in reactivity between *(1)* and *(5)* is considerably smaller than the observed difference between $N_2$ and $N_2O$ extrusion in diazenes and their corresponding *N*-oxides: diazenes normally eliminate $N_2$ *ca.* $10^{17}$ times faster than the rate at which the related *N*-oxides extrude $N_2O$ ($\Delta\Delta G^{+} > 26$ kcal/mol)[7]. This dramatic difference in reactivity has been related to the fact that loss of $N_2$ is much more exothermic than loss of $N_2O$ ($\Delta\Delta H_{\text{react.}} = \Delta H_{\text{react.}}$(diazene) $- \Delta H_{\text{react.}}$(diazene *N*-oxide) $= -32$ kcal/mol; $\Delta H_f^0(N_2O, g) = 19.4$ kcal/mol)[7]. The enthalpy of reaction for the *(1)*→*(4)* and *(5)*→*(8a)* transformations should be very similar. Since the group increment for the enthalpy of formation of the *cis*-azoxy group is 13 kcal/mol smaller than that of the *cis*-azo group[7], the energy profiles for the reactions *(1)*→*(2)* and *(5)*→*(8a)* would be expected to be mutually displaced by this amount. Actually the transition states differ by 6 kcal/mol[7]. Hammond's postulate[8] suggests that the resemblance between the diazenyl diradical and the transition state leading to it is closer than the resemblance between the diazenoxyl diradical *(11a)* and its corresponding transition state.

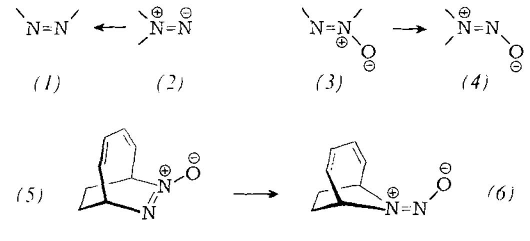
# Valence Isomerization of a *cis*-Diazene-/Isodiazene-*N*-Oxide: Thermolysis of 7,8-Diazabicyclo[4.2.2]deca-2,4,7-triene *N*-Oxide[**]

By *Henrik Olsen*[*]

Both experimental evidence[1a] and *ab initio* calculations[1b] indicate that *cis*-1,2-diazenes *(1)* are thermodynamically more stable than their 1,1-isomers *(2)*. *cis*-1,2-Diazene *N*-oxides, on the other hand, are expected to be less stable than their 1,1-isomers [*(3)*: $\Delta H_f^0 \simeq 35-40$ kcal/mol[2a]; *(4)*: $\Delta H_f^0 \simeq 30$ kcal/mol[2b]]. However, no evidence for the occurrence of the rearrangements *(2)*→*(1)* and *(3)*→*(4)* has, to date, been found[3]. We now wish to report on the thermolysis of 7,8-diazabicyclo[4.2.2]deca-2,4,7-triene *N*-oxide *(5)*, which to our knowledge represents the first example of an isomerization of the type *(3)*→*(4)*.



Pyrolysis of degassed solutions of *(5)*[4] in toluene sealed in pyrex ampules yielded, after 500 min at 185 °C, isomer *(6)*[5] (65%, m.p. = 61—62°, lit.[6] 62—63 °C). The rate of disappearence of *(5)*—a first order reaction—was studied at different temperatures and in different solvents by ¹H-NMR spectroscopy (Table 1). However, the formation of *(6)* was not strictly first order, since it slowly decomposes at the temperatures at which the isomerization *(5)*→*(6)* can be observed ($k_6 = 1.15 \times 10^{-5}$ s$^{-1}$; $k_5 = 2.04 \times 10^{-4}$ s$^{-1}$ at 184.6 °C)[7].

Table 1. Influence of solvent and temperature on the thermal isomerization *(5)*→*(6)*.

| Solvent | $E_t$ | $\delta$ | $k \times 10^5$ [s$^{-1}$] [a] | $k_{\text{rel}}$ [a] | $\Delta G^{+}$ [kcal/mol] [a] | $\Delta H^{+}$ [kcal/mol] [b, c] | $\Delta S^{+}$ [cal mol$^{-1}$ K$^{-1}$] [b, c] |
|---|---|---|---|---|---|---|---|
| [D₈]Toluene | 33.9 | 8.9 | 5.24 | 4.6 | 34.9 | 36.8 ± .8 | 4.2 ± 1.8 |
| [D₈]Dioxane | 36 | 9.8 | 3.10 | 2.7 | 35.4 | 38.0 ± .6 | 6.0 ± 1.4 |
| $CD_3CN$ | 46 | 11.8 | 1.15 | 1.0 | 36.2 | | |

[a] At 169.9 °C. [b] At 25 °C. [c] Tolerances given are standard deviations.

*A priori* two mechanistic pathways must be considered for the rearrangement *(5)*→*(6)*: a) a one-step concerted 1,2-sigmatropic shift, which according to frontier orbital considerations[8] is a forbidden reaction, and b) a two-step sequence *via* the diradical *(7)* or the zwitterions *(8a)* or *(8b)*.

The following arguments indicate that the isomerization probably proceeds *via* the intermediate diradical *(7)*: 1)

The observed rate dependence on solvent polarity (Table 1) is consistent with a polar ground state which rearranges *via* a less polar transition state, suggesting a concerted or diradical process. 2) Solvent effects are also to be expected if the substrate molecular volume changes on moving from the ground to the transition state. According to *Abraham*[9] the volume of activation $\Delta V^{\neq}$ can be estimated by fitting the data to a linear equation of the form

$$\ln k_{rel} = -(\Delta V^{\neq}/RT)\delta^2 + c_0$$

where $\delta$ is the Hildebrand solubility parameter. The dependence of the rate constant on $\delta^2$ ($r=0.996$) is consistent with a positive value for $\Delta V^{\neq}$ and is therefore in agreement with a two-step process. 3) The positive entropy of activation (Table 1) is more consistent with a flexible than with a pericyclic transition state. 4) Finally, replacement of the butadiene bridge by a tetramethylene group decreases the rate dramatically. The relative rate of decomposition $k_5/k_9$ is 1750 at 250°C ($\Delta\Delta G^{\neq}=7.8$ kcal/mol)[10]. Since the pentadienyl radical has a stabilization energy of *ca.* 20 kcal/mol[11] the observed $k_5/k_9$ ratio constitutes further evidence for a diradical mechanism.

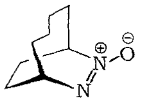
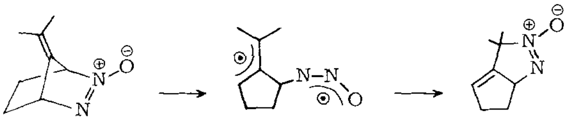
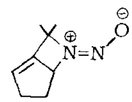
*(8b)*, *, † = ⊖, ⊕



*(9)*



*(10)* *(11)* *(12)*



*(13)*

Thermolysis of the bridged diazene *N*-oxide *(10)* leads, *via* the diradical *(11)*, to isomer *(12)*[12]. The ring closure of *(11)*→*(12)* is preferred, since the 1,1-diazene *N*-oxide *(13)* is thermodynamically unstable (ring strain). The relative rate of rearrangement of *(10)* and *(5)* in toluene at 150°C is 28 ($\Delta\Delta G^{\neq}=2.8$ kcal/mol). These values suggest that release of strain, together with stereoelectronic factors appear to strongly influence the reactivity[13].

# Chemical Applications of NMR Isotope Effects: Ring Inversion and Conformational Equilibrium in [$^2$H$_1$]Cyclohexane[**]

By *Rafet Aydin* and *Harald Günther*[*]

Secondary isotope effects of heavy nuclei on the NMR chemical shift of neighboring nuclides have been known for some time[1], however, chemical applications of this parameter are, until now, rare. In particular, the $^1$H/$^2$H isotope effect on the chemical shift of the $^{13}$C nucleus is of interest to the organic chemist, not least because the vicinal isotope effects ($^3\Delta$) are stereospecific[3a]. Since NMR isotope effects can be relatively easily determined using high-field NMR spectrometers, structurally interesting information thus becomes readily accessible.

We report here the possibility of detecting dynamic phenomena by means of stereospecific $^1$H/$^2$H isotope effects through *one* bond ($^1\Delta$), and of investing these kinetically with the aid of $^{13}$C-NMR spectroscopy. At high field, the $^1$H-decoupled $^{13}$C-NMR spectrum of [$^2$H$_1$]cyclohexane *(1)*[3b] shows the expected triplet for C-1, ($\Delta\delta=0.41$ ppm relative to C-4) caused by $^1J(^{13}\text{C},^2\text{H})$ coupling, whose lines broaden upon coaling and which below −80°C—the ring inversion process *(1a)*⇄*(1b)* is slow on the NMR time scale—Split into doublets (Fig. 1). The superposition of *two* triplets observed at this temperature signifies that the situation $^1\Delta_a \neq {}^1\Delta_e$ must apply to the isotope effect (Table 1). The assignment $^1\Delta_a > {}^1\Delta_e$ is based on the coupling constants $^1J(^{13}\text{C},^2\text{H})$, for which we found values of 18.89 and 19.49 Hz for the axial (a) and equatorial (e) C—$^2$H bonds, respectively. According to the results of *Sergeyev* on [$^2$H$_1$]cyclohexane, the larger coupling originates from the equatorial deuterium[4].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We are indebted to Dr. *J. R. Everett* for helpful comments.

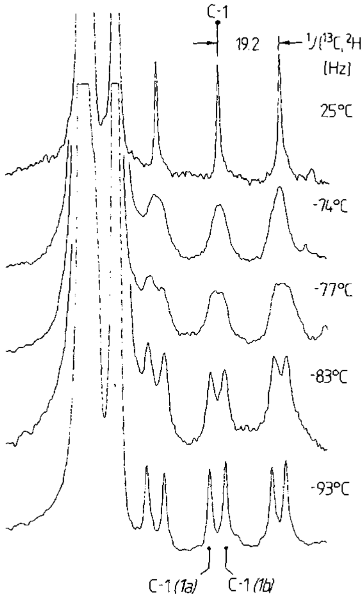

Fig. 1. $^{13}$C-NMR spectrum of [$^{2}H_{1}$]cyclohexane *(1)* at different temperatures; measuring frequency 100.61 MHz, $^{1}$H-broad-band decoupling, Bruker WH-400 FT spectrometer.

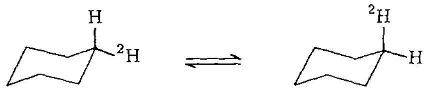
Table 1. $^{1}H/^{2}H$ Isotope effects $^{n}\Delta$ through n bonds (in Hz at 100.61 MHz measuring frequency) for the $^{13}$C resonances in [$^{2}H_{1}$]cyclohexane *(1)* and [1,1,$^{2}H_{2}$]cyclohexane *(2)*.

| Comp. | $T$ [°C] | $^{1}\Delta$ | $^{2}\Delta$ | $^{3}\Delta$ | Measuring conditions [a] |
|---|---|---|---|---|---|
| *(1a)* | −80 | 39.64 | — | — | $CS_2/CD_2Cl_2$ (4:1) |
| *(1b)* | −80 | 44.49 | — | — | 1 M; exp. error ±0.04 Hz |
| *(1)* | *ca.* 20 | 42.02 | 10.41 | 2.50 | as above; exp. error ±0.02 Hz |
| *(1)* | *ca.* 20 | 41.32 | 10.47 | 2.56 | $CCl_4$, 1 M; $^{19}$F lock |
| *(2)* | *ca.* 20 | 82.98 | 21.07 | 5.07 | $C_6F_6$ int.; exp. error ±0.02 Hz [b] |

[a] The experimental errors were determined from the digital resolution using error propagation for difference measurements; upper limit values are therefore involved. [b] As shown by measurements with internal $^{19}$F lock ($C_6F_6$), solvent effects of 1–2% can occur in the $^{1}\Delta$-values.



*(1a)* $\rightleftarrows$ *(1b)*

The coalescence of the two C-1 triplets is observed over a narrow temperature range of *ca.* 4° (Fig. 1). Since the frequency difference between the triplet components for the same $^{2}$H spin state differ because of the different couplings[5], the individual doublets merge successively; the reaction rate constants $k$ and the $\Delta G^{+}$ values can be determined from the coalescence temperatures using known methods[6a]. At −75°C we obtained $\Delta G^{+} = 42.68$ kJ/mol, which is in excellent agreement with the best literature value (42.85 kJ/mol)[6b].

For the equilibrium *(1a)*$\rightleftarrows$*(1b)* it is interesting whether an isotope effect on the position of the equilibrium (isotopic perturbation of degeneracy[2a]) can be determined. This would not be unexpected[7] in view of the different sizes of the C-$^{2}$H and C-$^{1}$H groups[6c].

From the isotope effects measured for *(1a)* and *(1b)* at low temperatures (for experimental errors, see Table 1) an average value of 42.07 Hz for $^{1}\Delta$ is calculated for an equilibrium constant $K = 1.0$ at room temperature. Experimentally we found 42.02 Hz. It must however, be borne in mind that $^{1}\Delta$ increases with temperature[8a]. The effect of temperature on $^{1}\Delta$ was determined on [1,1-$^{2}H_{2}$]cyclohexane *(2)*[8b] at −80 and +25°C. Using the value of $+0.07 \pm 0.03$ Hz thus obtained, $^{1}\Delta$ (corrected) is found to be 41.95 Hz and is hence smaller than the average value expected for $K = 1.0$ Accordingly, conformer *(1a)* predominates in the equilibrium.

Independent confirmation of this result, which was desirable because of the small magnitude of the effect, was achieved by studying a mixture of cyclohexane, [$^{2}H_{1}$]cyclohexane, and [1,1-$^{2}H_{2}$]cyclohexane. From the simplified spectrum obtained by $^{1}$H- and $^{2}$H broad-band decoupling[8c], we measured the following $^{1}\Delta$-values [relative to $\delta(C_6H_{12})$]: *(1)* 41.32 Hz; *(2)* 82.98 Hz. Since isotope effects are additive[8a,9], we would have expected a value of 82.98/2 = 41.49 Hz for *(1a)*$\rightleftarrows$*(1b)* with $K = 1.0$. Finally, additional confirmation of the result was possible from $^{2}$H-NMR low-temperature measurements on *(1)*. Integration and line-shape analysis of the signals observed for the equatorial and axial deuterium atoms at −88°C (measurement frequency 61.42 MHz, $\Delta\nu$ 29.4 Hz) produced $K = 1.060 \pm 0.014$, which is consistent with the other results. On the other hand, from the $^{1}\Delta$-values we obtained $K = 1.100 \pm 0.037$. In consequence, the conformation *(1a)* is favored by *ca.* 200 J/mol at room temperature.

Our result can be understood if it is assumed that the vicinal *gauche*-$^{1}$H, $^{1}$H-, and $^{1}$H,$^{2}$H-interactions are decisive for the relative energies of conformers *(1a)* and *(1b)*[10]. In order to avoid unfavorable H,H-interactions, the system takes up conformation *(1a)*, and the C—$^{1}$H group, *i.e.* the "larger substituent", preferentially adopts the axial position by way of exception.

# Cleavage of Water by Visible-Light Irradiation of Colloidal CdS Solutions; Inhibition of Photocorrosion by $RuO_2$[**]

By *Kuppuswamy Kalyanasundaram, Enrico Borgarello, Dung Duonghong,* and *Michael Grätzel*[*]

The conversion of light into electricity or chemical fuels in photoelectrochemical devices equipped with semiconductor electrodes is of great current interest[1]. A serious problem associated with the use of materials with valence-band gaps appropriate for solar energy exploitation, is their inherent instability. For example, n-type CdS or GaP are subject to undesirable decomposition upon irradiation[2]. Holes ($h^+$) produced in the valence band upon irradiation migrate to the surface where photocorrosion occurs:

$$CdS + 2h^+ \rightarrow Cd^{2+} + S \qquad (1)$$

$$GaP + 3H_2O + 8h^+ \rightarrow Ga^{3+} + PO_3^- + 6H^+ \qquad (2)$$

This undesired process may be prevented in the presence of suitable reducing agents such as, $Fe(CN)_6^{4-}$, $S^{2-}$, $SO_3^{2-}$, or hydroquinone[3] which scavenge the hole at the semiconductor/electrolyte interface before lattice dissolution can occur. However, in order to be effective, the hole-transfer across the interface requires a large driving force which consumes a significant fraction of the absorbed light energy.

In investigations of microheterogeneous systems capable of decomposing water into $H_2$ and $O_2$ by visible light[4a], we discovered that ultrathin layers of $RuO_2$ on CdS inhibit photocorrosion[4b]: reaction *(1)* is replaced by oxidation of water.

$$4h^+(CdS) + 2H_2O \xrightarrow{RuO_2} O_2 + 4H^+ \qquad (3)$$

We now describes the design and performance of *colloidal* CdS microelectrodes which exhibit surprisingly high activity as water-cleaving catalysts.

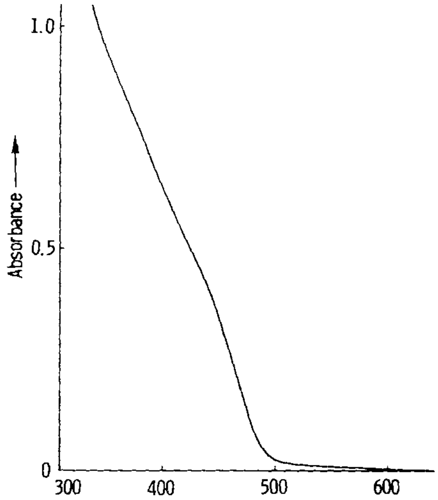

Fig. 1. Absorption spectrum of the colloidal CdS solution (330 mg/L), optical path length 0.2 cm.

Precipitation of CdS from aqueous solutions of $Cd^{2+}$ and $(NH_4)_2S$ in the presence of maleic anhydride/styrene copolymer produces a perfectly transparent, intensely yellow colored sol, whose absorption spectrum is shown in Figure 1. Noteworthy is the upper band limit at 520 nm, whose position coincides with the 2.4 eV band gap of CdS. The band rises towards the UV in a very steep fashion, typical of electronic transitions in semiconductors[5]. From these characteristics it is concluded that microcrystalline CdS particles of colloidal dimensions are present in solution.

The CdS particles themselves do not afford photodecomposition of water. Active catalysts are obtained only after they have been loaded with Pt and $RuO_2$[6]. Sustained water cleavage by visible light ($\lambda > 400$ nm) was observed with such colloidal solutions, *e.g.* from a 25 mL solution (2.75 mg of CdS, 1 or 0.5 mg of Pt and 0.2 mg of $RuO_2$) a total of 2.8 mL of $H_2$ and 1.4 ml of $O_2$ was produced after 44 h of irradiation (cf. Fig. 2); this corresponds to turnover numbers of 6, 25, and 85 for CdS, Pt, and $RuO_2$, respectively. Clearly the reaction is catalytic with respect to all three constituents. In particular, no appreciable photodegradation of CdS occurs. To further confirm this surprising and important effect we examined carefully the $Cd^{2+}$ concentration before and after 72 h of photolysis. Polarographic analysis showed no detectable increase in ion concentration during this period, which precludes any significant contribution of the anodic dissolution reaction (1) to the overall photoprocess. Since, on the other hand, the generation of oxygen by photolysis can be demonstrated readily and unambiguously it can be inferred that oxidation of water occurs exclusively, and at the expense of photocorrosion.

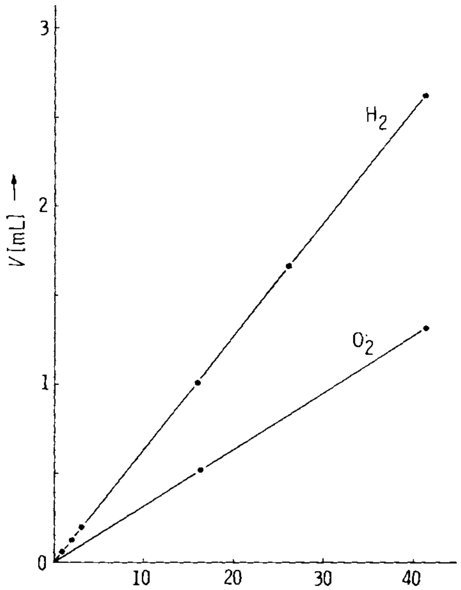

Fig. 2. Production of $H_2$ and $O_2$ by irradiation of a $8.4 \times 10^{-4}$ M CdS sol at room temperature. Particles loaded with Pt and $RuO_2$. $O_2$ determined by flow procedures [11].

Further experiments established that the stabilization of CdS is brought about by the $RuO_2$ catalyst. Particles only loaded with Pt decompose rapidly under illumination with formation of sulfur. A similar observation was made with dispersions of commercial CdS powders[4b].

*0570-0833/81/1111-0987 $ 02.50/0*

The reaction temperature has a decisive influence on the efficiency of the light induced water cleavage. Thus, at 75 °C the rate of $H_2$ formation (0.1 mL/h) is approximately twice as fast than at room temperature.

Compared to a macrodispersion, decreasing the particle size to colloidal dimensions increases the yield of $H_2$ per unit mass of catalyst by a factor of 50. These observations may be rationalized in terms of electron/hole pair-formation in the colloidal CdS particles under band gap excitation. The electrons migrate to Pt sites where $H_2$ production from water occurs. The flat band potential of CdS is located at *ca.* −900 mV (*vs.* standard $H_2$ electrode at pH = 7), which is sufficiently cathodic for water reduction. On the other hand the valence band edge of n-type CdS is *ca.* + 1.5 V and holes trapped by $RuO_2$ sites on the surface are subsequently used to produce oxygen from water: since the driving force for water oxidation is therefore more than 600 mV this process is sufficiently fast[7] to compete with surface corrosion. Thus, the role of the $RuO_2$ is to promote the transfer of holes from the valence band to the aqueous solution where $O_2$ evolution occurs.

Moreover, we have found that the catalytic properties of the CdS sols (also *without* Pt!) described here are also particularly suitable for the photolytic decomposition of $H_2S$ into $H_2$ and sulfur[9b].

Our results clearly identify the decisive influence of $RuO_2$ on valence band processes in irradiated semiconductor particles. In the case of CdS a striking augmentation of the photoactivity is observed when the particle size is reduced to colloidal dimensions[8]. Work is now in progress to substitute these microsystems by polycrystalline semiconductor electrodes by covering the electrode with an ultrathin layer of $RuO_2$ and by coupling it to a Pt counterelectrode, such a device should afford local separation of the $H_2$- and $O_2$-generating reactions[9a].

## *Experimental*

100 mg of maleic anhydride/styrene copolymer (50/50, TNO, Utrecht) is dissolved in 100 mL of alkaline water (pH = 10, adjusted with 1 N NaOH) under constant stirring at 50 °C for several hours. When dissolution is complete, 0.15 mL of a 10% (W/V) solution of $(NH_4)_2S$ is added. A stock solution of $CdSO_4$ (2 g/L) is prepared, and 10 mL is slowly (microsyringe!) injected. After being stirred for *ca.* 1 h the appearance of an intense yellow color indicates formation of the CdS sol. The pH of the solution is subsequently adjusted to 3 (HCl), and excess sulfide removed as $H_2S$ by slushing the solution with $N_2$ overnight. The final concentration is 110 mg CdS/L ($8.4 \times 10^{-4}$ M).

CdS is loaded with $RuO_2$ *via* decomposition of $RuO_4$ ($RuO_4 \rightarrow RuO_2 + O_2$) by injecting 0.5 mL of a stock solution of $RuO_2$ in water (0.5 g/L) into 20 mL of the CdS solution. An ultrathin deposit of $RuO_2$ is formed when the mixture is stirred for 30 min. $H_2PtCl_2$ (3 mg) and 1 mL of a 40% aqueous solution of formaldehyde are subsequently directly added to the CdS/$RuO_2$ solution. After deoxygenation, Pt is deposited onto the CdS particles *via* photoplatinization[4, 10] and excess formaldehyde is subsequently removed under *in vacuo*. The final concentrations are 40 mg/L Pt, 8 mg/L $RuO_2$, and 110 mg CdS/L.

Photolysis experiments were carried out with a xenon lamp (Osram XBO-450W; filter for IR region and $\lambda < 400$ nm) in a pyrex flask (25 mL of solution) equipped with optically flat entry- and exit-windows. $H_2$ production was monitored by gas chromatography (GOW MAC, carbosieve column, 35 °C, $N_2$ carrier gas). $O_2$ was analyzed using a Teledyne $B_1$ oxygen specific microfuel cell[11].

**An Introduction to Synthesis Using Organocopper Reagents.** By *G. H. Posner*. J. Wiley & Sons, Chichester 1980. xvii, 140 pp., bound, £ 12.50.

The subject of the monograph and the author's name could give rise to misunderstanding: it is in no way a review like *Posner*'s two contributions that appeared in "Organic Reactions" [*19*, 1 (1972) and *22*, 253 (1975)]. The principal aim here is to show how an organic synthesis is planned and on what basis a choice between several possible solutions is made. The reader takes part in a course of instruction organized from beginning to end on the basis of practical examples. About 30 syntheses of aromas and flavors, growth substances, pheromones, alkaloids, sugars, phenols, lactones, sesquiterpenes, prostaglandins, and steroids are dealt with one by one. The copper reagents enjoy a privileged role as a means to this end, but occasionally another organometal compound may prove to be more useful and often in fact a quite different approach may well be superior.

The examples have been carefully chosen and are expertly explained. Slight uncertainties appear to exist on stereochemical questions. Thus, in connection with a synthesis of muscalure, the sex attractant of the housefly, it is assumed that the Wittig reaction permits its preparation only with *Z/E* ratios of about 85 : 15 (p. 69), while since 1966 a procedure has been known which ensures more than 99% *cis*-selectivity. In discussing manicon, an ant pheromone, an important point is left unmentioned (p. 81): the compound contains an asymmetric carbon atom. Any synthesis will be judged beforehand on how it handles the problem of leading to a pure enantiomer.

To stimulate the reader toward more basic reading and independent study, about a dozen references are given at the end of each example. No single synthesis is given in all its details; in each case only the basic features of possible strategies are explained. In view of this policy, it is surprising to find at the end of the monograph, as an appendix, four small detailed experimental procedures. The historical review given in the introduction also falls somewhat outside the framework of the book. With a length of under ten lines, it is not exhaustive. Several studies that together with others probably gave the impetus to the later extensive systematic investigation of copper reagents have passed unquoted (*e.g. G. Köbrich et al.*, J. Organomet. Chem. *6*, 194 (1966); *T. Kaufmann et al.*, Angew. Chem. *79*, 101 (1967); Angew. Chem. Int. Ed. Engl. *6*, 85 (1967); *G. Wittig et al.*, Justus Liebigs Ann. Chem. *704*, 91 (1967)).

The monograph is short but lively, careful, and intelligent. An exhaustive subject and author index facilitates reference to the literature. With excellent presentation and illustrations, the publishers have done their part toward contributing to the great pleasure with which one leafs through the book. It will please anyone who can wax enthusiastic about synthesis, and it will probably prove particularly suitable as a basis for group seminars.

*Manfred Schlosser* [NB 547 IE]

# Pyramidal Carbocations[**]

By Helmut Schwarz[*]

*Dedicated to Professor Ferdinand Bohlmann on the occasion of his 60th birthday*

Pyramidal cations are discussed with reference to their role as the connecting link between organic and inorganic chemistry. The electronic structure of these ions is treated with respect to their physical and chemical properties, namely charge distribution, geometry, and quenching reactions with nucleophiles. The chemistry in the gas phase of certain carbenium ions, in particular the scrambling of carbon atoms, is readily explicable by invoking transition states or intermediates of pyramidal structure. Moreover, the behavior of unimolecular processes can be understood in terms of transition states in which a hydrogen molecule is positioned as a "side-on" or an "end-on" ligand.

## 1. Introduction

Carbocations are now seen as *the* logical bridge between organic and organometallic chemistry[1]. Although as hydrocarbons, carbocations are unquestionably organic, nonetheless their valence properties and structural features, not least of which is the coordination number of carbon, owe much to organometallic compounds. In most organic compounds the coordination number is never greater than *four*. However, in carbaboranes and cluster compounds[2], a central carbon atom having *five* or *six* ligands is not unusual and carbonium ions are, by definition, at least *penta*coordinate. *Wilson et al.*[3] first suggested that a C atom could also be pentacoordinated. Subsequently, *Winstein*[4], *Olah*[5], *Hogeveen*[1a,6], and others[7] developed and refined the theory of carbocations. Experimental confirmation for it was forthcoming from studies on protonated alkanes—such as $CH_5^\oplus$ *(1)*—in both the gas phase[8] and in superacid media[9], as well as by indications of the existence of nonclassical carbenium ions *e.g.* the norbornyl cation *(2)*[10] and other ions such as *(3)*[11] and *(4)*[12]. These cations can be adequately described in terms of 2-center/2-electron (2z/2e) and 3z/2e bonds[13]. Examples of 3c/2e bonds are provided *e.g.* by the boranes[14]. The structural similarity between carbocations and organometallic compounds is even more apparent in the *pyramidal* carbocations $(CH)_5^\oplus$ *(5)* and $(CH)_6^{2\oplus}$ *(6)*. In these species the C atoms of interest are not only five- and six-coordinated, respectively, but the structural topology of the $(CH)_n^\oplus$ compounds finds its counterpart in organometallic chemistry. Consequently, compounds *(5)* and *(6)* are analogous to ferrocene *(7)*, since they both have semisandwich structures. Following the more general approach to cluster theory formulated by *Wade*[2c], *Williams*[2d], and *Rudolph*[2e] compounds *(5)* and *(6)* could be described as *nido*-clusters since they have the same topology and are isoelectronic with the carbaboranes[2]. For example, formal replacement of the apical cationic $C^\oplus$ ion of *(5)* by the isoelectronic B atom, and exchange of the four basal C atoms by the isoelectronic BH fragment produces, directly, the known borane $B_5H_9$ *(8)*[15]. Similarly, the carbaborane *(9)* can be generated from the dication *(6)* by replacement of the apical and one basal C atom by two B atoms. In fact, the hexamethyl derivatives of *(6)* and *(9)* have been identified[16,17], while the unsubstituted *(9)* has been characterized by its

microwave spectrum[18]. As we will see in Section 2, the bonding in pyramidal cations *(5)* and *(6)*, unlike cations *(1)*–*(4)*, can no longer be described by a set of 2c/3e or 3c/2e bonds, but requires a more complex description. Recourse to graph theory[19] has recently provided a useful general model for seemingly different types of complexes.

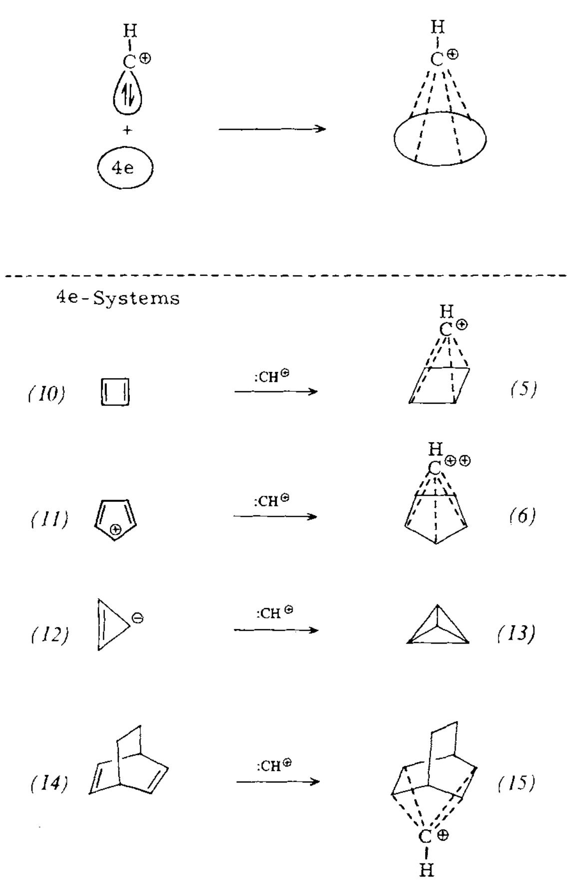
## 2. Bonding Properties and Theoretical Aspects

### 2.1. Formal Construction of Pyramidal Ions from $CH^\oplus$ and 4e Systems

Pyramidal cations such as *(5)* can formally be considered as being the result of the interaction of the $CH^\oplus$ fragment (protonated C atom) with a 4e system such as cyclobutadiene *(10)*[20]. The only requirements are that the interacting orbitals of the molecular fragments be of similar energy and of appropriate symmetry. Furthermore, the segment forming the base must supply *four* electrons while the $CH^\oplus$ fragment provides *two* electrons and two empty orbitals[20,21]. The interaction diagram (Fig. 1a), which should not be mistaken for a correlation diagram for the central linear approach of $CH^\oplus$ to cyclobutadiene, clearly describes the electronic nature of *(5)*. The $a_1$ and e orbitals of $CH^\oplus$ on combination with *(10)* furnish three bonding molecular orbitals containing *six* electrons (two from $CH^\oplus$ and four from *(10)*). In analogous fashion, the pyramidal dication *(6)* may be described as a *nido*-cluster resulting from combination of $CH^\oplus$ and the antiaromatic cyclopentadienyl cation *(11)* (Fig. 1b). Here again, six electrons are accomodated in three stabilized molecular orbitals[22].

The foregoing treatment also accounts for the fact that certain carbocations and carbanions cannot be stable if pyramidal geometry is adopted. Thus, the pyramidal $C_5H_5^\ominus$ anion *(16)* requires that the extra pair of electrons be placed in an antibonding orbital (Fig. 1a). This constitutes an unfavorable situation, and in fact there is neither theoretical nor experimental evidence for the existence of *(16)*[20]. Similarly, the pyramidal $C_7H_7^\oplus$ cation *(20)* is unstable[26], although it has been postulated as an intermediate in the solvolysis of C7-substituted norbornadienyl derivatives *(17)*[27] and in the carbon scrambling of the benzyl *(19)* and tropylium cations *(21)*[28], and contains *eight* electrons, (six from benzene and two from the $CH^\oplus$ fragment, two of which have to be placed in orbitals of high energy). Nature arranges things differently; solvolysis of *(17)* generates a cation which is better described by *(18)*, in which 3c/2e bonding occurs, than by *(20)*[29]. Carbon atom scrambling between *(19)* and *(21)* proceeds *via* a sequence of orbital symmetry allowed isomerizations in which *(20)* is not involved[26]. In principle, structures of type *(20)* are possible, provided they possess two electrons less, as exemplified by the $C_7H_7^{3+}$ cation *(22)*. Obviously, structure *(22)* is unredistic for electrostatic reasons[30]. Nonetheless, the structurally analogous carbaborane $C_4B_3H_7$ *(23)* should be an excellent candidate for a neutral molecule possessing a ***heptacoordinated*** apical carbon atom[31].



Scheme 1. Formal construction of pyramidal cations from 4e systems and $CH^\oplus$.

If the 4e component of the diene is unsymmetric, then interaction with the $CH^\oplus$ cap does not create a cation of pyramidal structure, but gives instead an ion with 3c/2e bonds. Examples are provided by *Coates'* $C_9H_9^\oplus$ cation *(4)* which must have $C_{3v}$ symmetry: the pyramidal alternative *(24)* should not be favored[12]. However, the isomeric $C_9H_9^\oplus$ ion *(26)* ought to be pyramidal as it is lower in energy than the 3c/2e structure *(28)*, which according to MINDO/3 calculations does not correspond to a minimum on the energy hypersurface[24]. Similarly, cation *(3)*[1a] and the bishomocyclopropenyl cation *(33)*[32] are better described by 3c/2e bonding than by the greater charge delocalization needed for the pyramidal cations *(29)* and *(31)*.

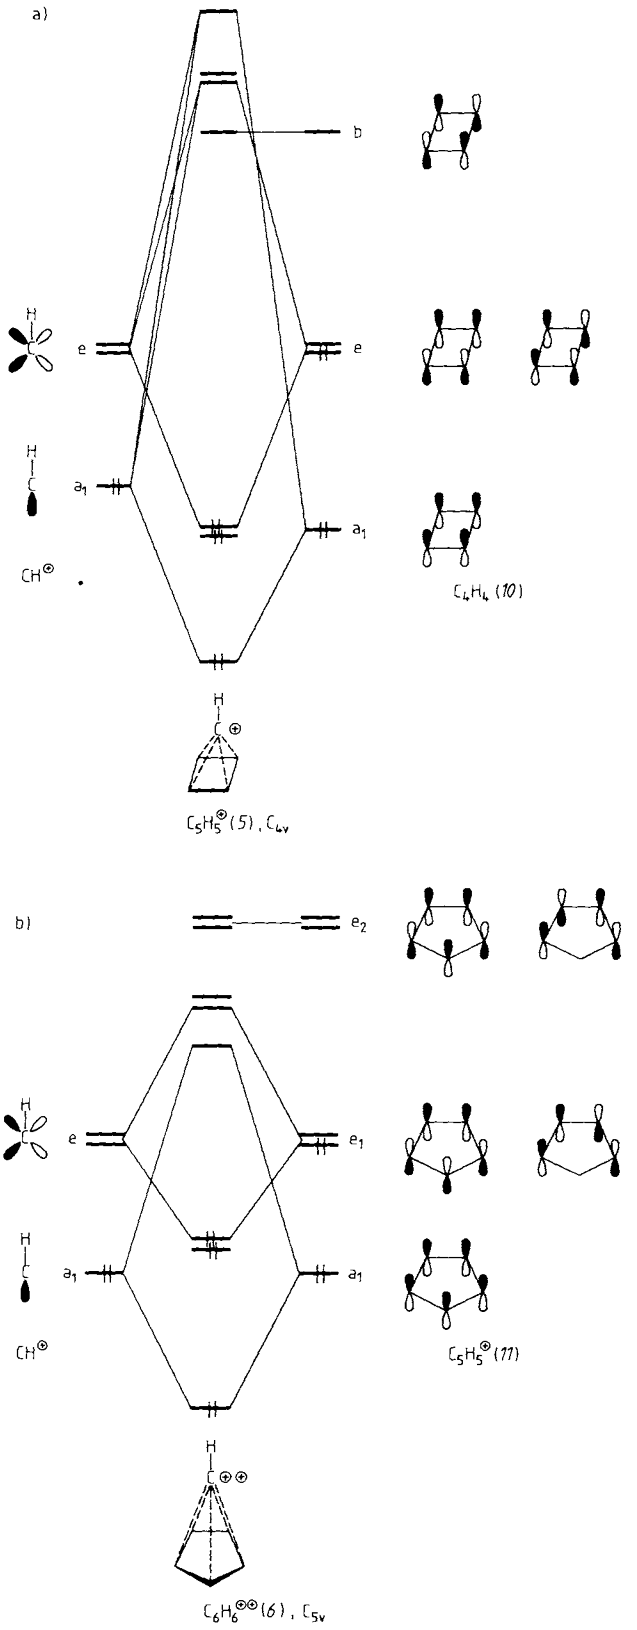


Fig. 1. Interaction diagram for the construction of a) $C_5H_5^{\oplus}$ *(5)* from $CH^{\oplus}$ and cyclobutadiene, b) $C_6H_6^{2+}$ *(6)* from $CH^{\oplus}$ and $C_5H_5^{\oplus}$.

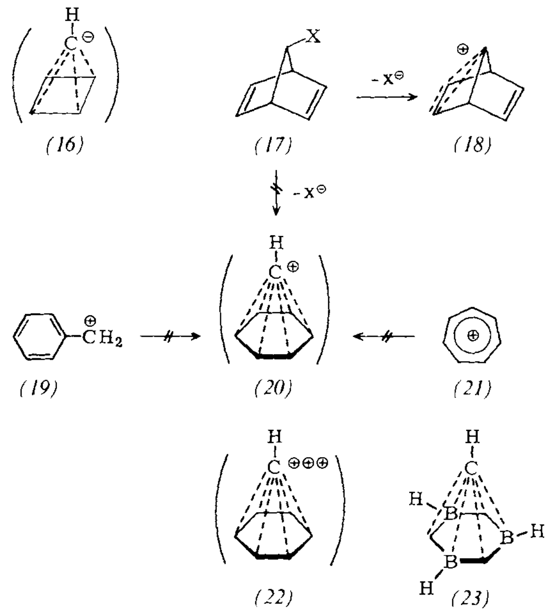
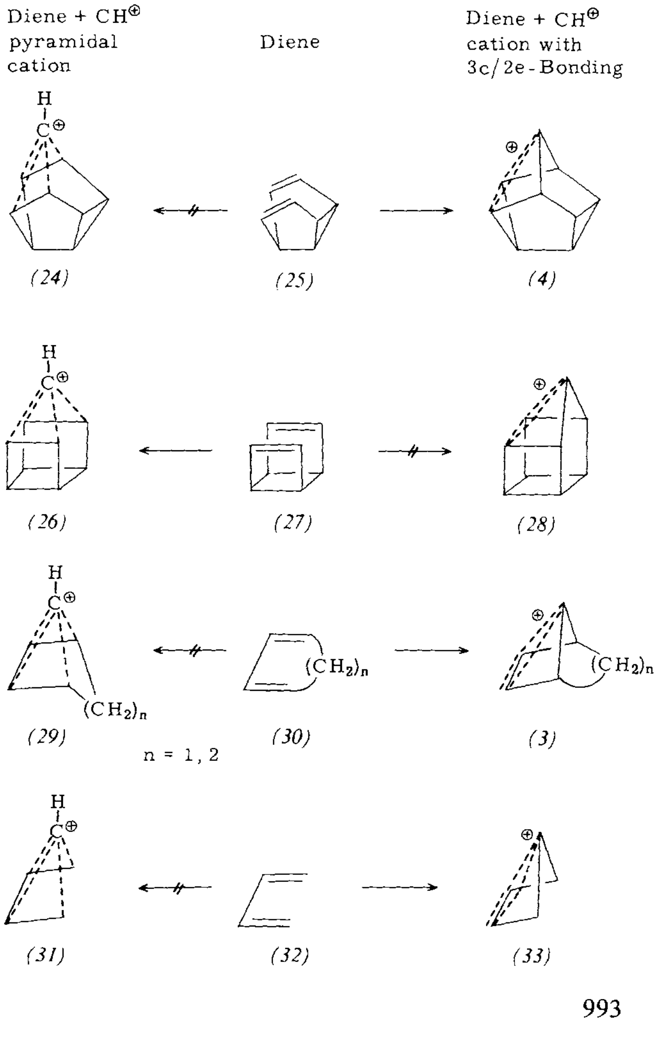
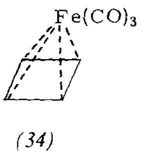


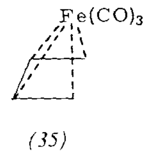
The reason why 3c/2e bonds contend energetically with pyramidal structures is that cations such as *(26)*, and others, contain a diene component *(27)* which is symmetrically substituted. On the other hand, cations such as *(3)*, *(4)*, and *(33)* require unsymmetric diene components *(30)*, *(25)*, and *(32)*, respectively. Presumably in the case of unsymmetrically substituted dienes the interaction of $CH^{\oplus}$ is more favorable with one set of terminal carbon atoms than with



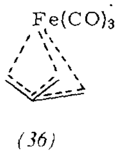
the other, thereby leading to a less symmetric distribution of charge. This suggests that transitions between classical 3c/2e bonding and that required by pyramidal ions can be brought about with the proper choice of diene. It is entirely possible that the $C_5H_7^{\oplus}$ ion (formed under the conditions of ion cyclotron resonance by β-protonation of cyclopentadiene) possesses a structure which can be considered as a 3c/2e system or an *arachno*-cluster ion *(31)*[32].



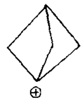
*(34)*



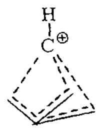
*(35)*



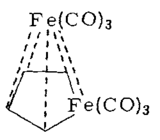
*(36)*



*(37)*

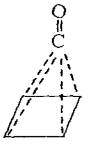


*(38)*

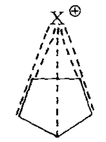


*(39)*

The idea that pyramidal cations are made up of molecular fragments allows us to replace $CH^{\oplus}$ by similar fragments which are *isolobal* with $CH^{\oplus}$, namely fragments X having the same or similar properties regarding the number, symmetry, shape, and energy of the relevant frontier orbitals[33], *e.g.* BH and $Fe(CO)_3$. Consequently, it is not surprising that clusters of $Fe(CO)_3$ combined with 4e systems are well known[34]. Of the many examples it is sufficient to mention only the complexes of $Fe(CO)_3$ with cyclobutadiene *(34)*[34], butadiene *(35)*[35], and trimethylenemethane *(36)*[36]. *(34)* and *(35)* correspond to the pyramidal cations *(5)* and *(31)*, whereas *(36)* finds its carbocation counterpart in the 1-bicyclo[1.1.1]pentyl cation *(37)*. The latter can also be considered as a $CH^{\oplus}$-trimethylenemethane cluster *(38)*[37]. The pyramidal dication *(6)* also has an organometallic cluster counterpart, namely compound *(39)*[33,34]. This complex is formally obtained by replacing the apical and one basal $CH^{\oplus}$ group of *(6)* by the *isolobal* $Fe(CO)_3$.



*(40)*



*(41)*, X = Sn, Ge

The structure of the carbonylcyclobutadiene cluster *(40)* is readily obtained by the interaction of CO and cyclobutadiene[20]: the appropriate interaction diagram resembles Figure 1a. In *(40)* the HOMO of carbon monoxide, in which the lone pair of electrons is more or less localized axially on the carbon atom, replaces the axial lone pair of $CH^{\oplus}$. The role of the p-orbitals of the $CH^{\oplus}$ is taken up by the π* orbitals of the carbonyl group. In other words, *(40)* is the carbonyl complex of cyclobutadiene.

Clusters can also be constructed having a metal ion such as $Sn^{2+}$ or $Ge^{2+}$ at the apex. Unambiguously characterized examples have been obtained from the cyclopentadienyl *anion* and its permethyl derivative *(41)*[38]. The cations *(41)* can also be considered as *nido*-clusters of pentagonal pyramidal symmetry in which the electronic and orbital requirements are completely fulfilled. The MO diagram (Fig. 2) shows that in *(41)*, X = Sn, the interaction of the orbitals of the apical metal atom with the π MOs of the cyclopentadienyl moiety gives a typical closed-shell electronic structure. Apart from the six electrons located in the $1a_1$ and $1e_1$ molecular orbitals, the "lone pair" is essentially localized in a high lying orbital on the Sn atom having considerable p-character. An octet of electrons formally fills the valence shell of the main group element, thereby occupying the $1a_1$ to $2a_1$ molecular orbitals of *(41)*. This description satisfactorily accounts for the unusual stability of these cations.

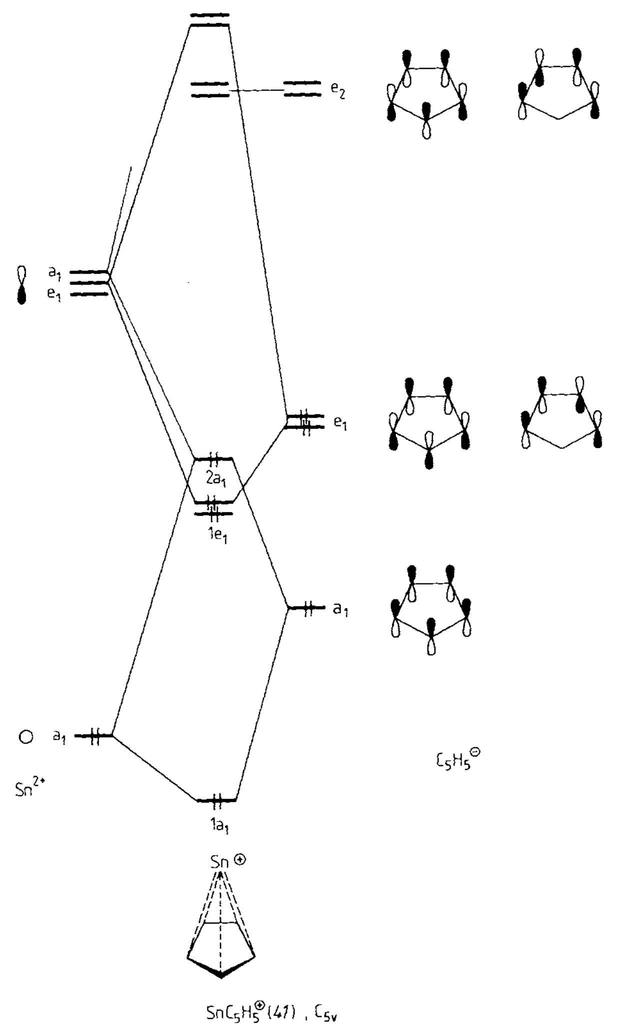


Fig. 2. MO diagram for the interaction of $Sn^{2+}$ with $C_5H_5^{\ominus}$ to form *(41)*.

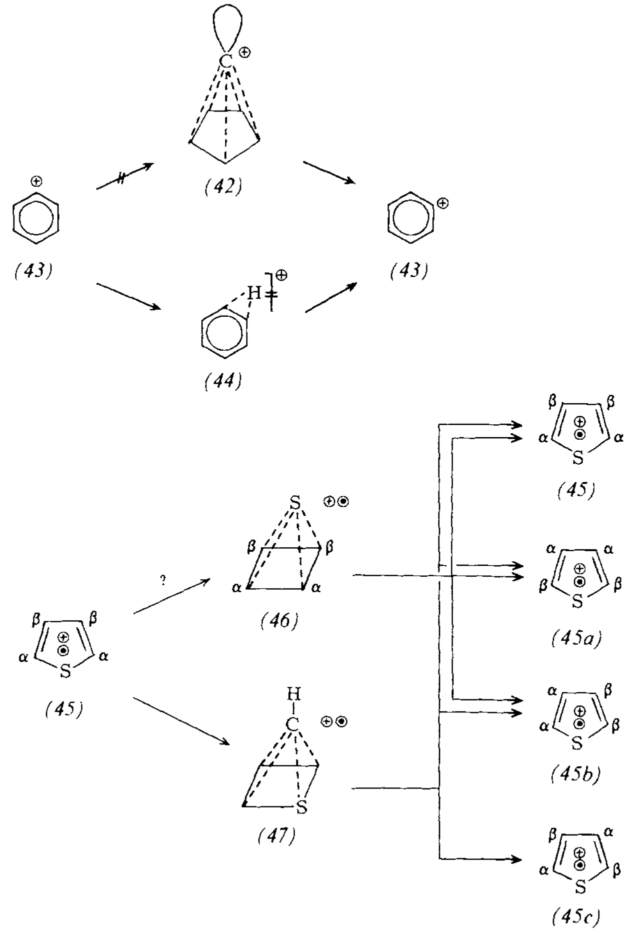
From studies of the gas phase automerization of *(43)* *via* H-migration[39a], it can safely be concluded that the pyramidal cation *(42)* is not involved. The degenerate isomerization of *(43)* presumably proceeds *via* *(44)* (Scheme 2)[*]. However, MINDO/3 calculations[39b] clearly reveal that

---

[*] In this article, the symbol ‡ is used in formulas, schemes, and figures to denote the transition state.

*(42)* is involved in the dissociation of the phenyl cation *(43)* to $C_4H_3^{\oplus}$ and $C_2H_2$. The activation energy for the process *(43)*→*(42)* has been calculated to be 69 kcal/mol, which is substantially lower than the activation energy for loss of $C_2H_2$ from *(43)* (108 kcal/mol). In consequence it is to be expected that *(43)* undergoes complete carbon scrambling prior to dissociation: this is in fact observed[39c].

Further studies are needed to decide whether the partial scrambling of carbon atoms preceding the molecular decay of the radical cation of thiophene *(45)* passes through the *nido*-cluster intermediate *(46)* having sulfur at the apex. Intermediate *(46)* cannot account for complete scrambling of carbon since the fourth product *(45c)* is inaccessible from *(46)*. A possible intermediate, which has not been considered or detected so far, is *(47)* which could decay to all four degenerate thiophene radical cations.



Scheme 2. Examples of automerization reactions which do *not* [in *(43)*] or only probably [*(45)*] involve pyramidal intermediates.

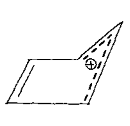
## 2.2. Quantum Mechanical Calculations on the Pyramidal $(CH)_5^{\oplus}$ Ion

Many of the current quantum chemical methods for calculating the stability of pyramidal carbocations give widely different results. The pyramidal cation *(5)* provides a typical illustration. Extended Hückel calculations[20] show that *(5)* constitutes the global minimum on the energy hypersurface for the family of $C_5H_5^{\oplus}$ ions. These findings were confirmed by CNDO/2[41] and by modified CNDO calculations[42]. Calculations by *Smith et al.*[42] further showed that structure *(48)* also constitutes a minimum, but that it is located some 45 kcal/mol higher in energy than the minimum for *(5)*. MINDO/3 calculations[43] confirm that both *(5)* and *(48)* lie at minima on the energy hypersurface, but that *(5)* is *ca.* 14 kcal/mol less stable than *(48)*[44]. *Ab initio* calculations at the STO-3G/4-31G level indicate that *(48)* is more stable than *(5)* by *ca.* 55 kcal/mol[45]. This enormous difference in stability is understandable in view of the electronic structure of the pyramidal cation *(5)* in which three pairs of electrons are spacially closely packed together, holding the $CH^+$ and cyclobutadiene fragments in place. The difference between the enthalpies of formation of *(5)* and *(48)* should be substantially smaller in *ab initio* calculations when the effects of electron correlation are accounted for. When these are taken into account[46], enthalpy differences between *(5)* and *(48)* agree fairly well with those computed by MINDO/3.

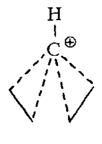
Despite the discrepancies concerning the absolute stability of $C_5H_5^{\oplus}$ isomers, all methods indicate that *(5)* and *(48)* are separated by high potential barriers. For example, the barrier for the isomerization *(5)*→*(48)* according to MINDO/3 calculations, amounts to 43 kcal/mol[43], which indicates that the pyramidal cation *(5)*, once formed, should enjoy considerable stability.

## 2.3. Substituent Effects

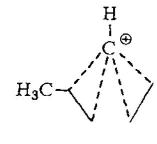
The effect of methyl and phenyl groups on the relative stability of structures *(5)* and *(48)* was estimated by *ab initio* calculations using isodesmic reactions[*][45]. It was found that phenyl substituents stabilize the cyclopentadienyl structure *(48)* over the pyramidal form *(5)*. Moreover, substitution by phenyl and methyl groups at the base of *(5)* turned out to be more favorable than at the apex. This difference *vide infra* is due to the charge distribution in the pyramidal cations. Calculations reveal that placing both methyl groups on the base, rather than one on the base and one at the apex, is energetically more favorable by 1.7 kcal/mol. This result is consistent with the findings for mono-substitution of pyramidal cations. However, neither Hückel calculations[47] nor experiment[21,48] confirm this tendency. Complete substitution by methyl, exemplified by the permethyl derivatives of *(5)* and *(49)*, results in stabilization of both structures with a slight preference for the pyramidal form. MINDO/3 and MNDO calculations indicate that pyramidal cations of type *(48)*, $C_5H_9^{\oplus}$[49], prefer to be substituted by methyl at the base *(50)* rather than at the apex *(51)*. (MINDO/3: $\Delta\Delta H_f^0 = 18$ kcal/mol, MNDO = 9 kcal/mol)[49-50].



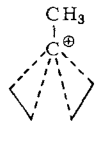
(48)



(49)



(50)

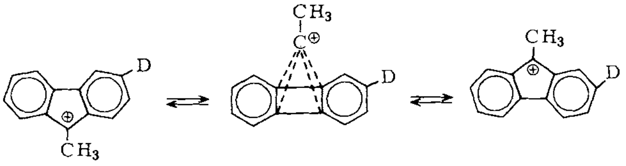


(51)

---

[*] For definition of isodesmic, see *W. J. Hehre, R. Ditchfield, L. Radom, J. A. Pople*, J. Am. Chem. Soc. 92, 4796 (1970), as well as *L. Radom, J. A. Pople, P. von R. Schleyer, ibid. 94*, 5935 (1972).

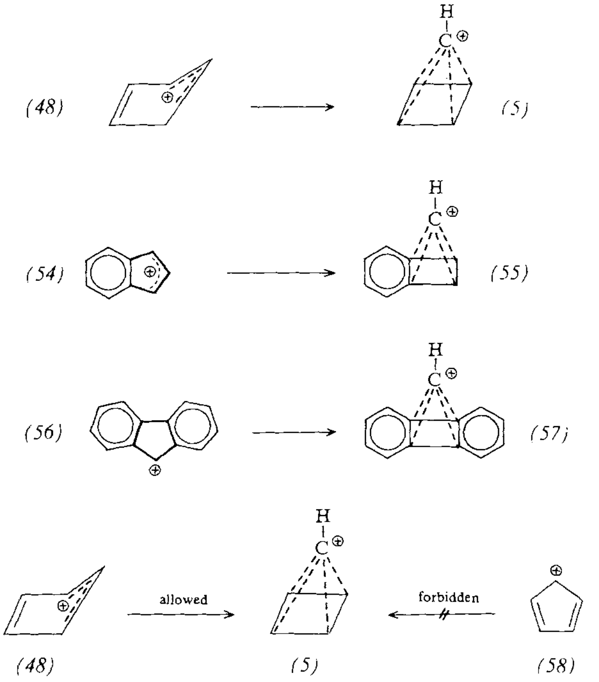
The influence of benzannelation on the relative stabilities of classical *versus* pyramidal cations has been discussed by *Olah* and *Schleyer et al.*[52] in relation to whether 9-substituted 9-fluorenyl cations, *e.g.* *(52)* undergo degenerate isomerization [*(52)*⇄*(52a)*] *via* intermediates having pyramidal structures such as *(53)*.



(52) (53) (52a)

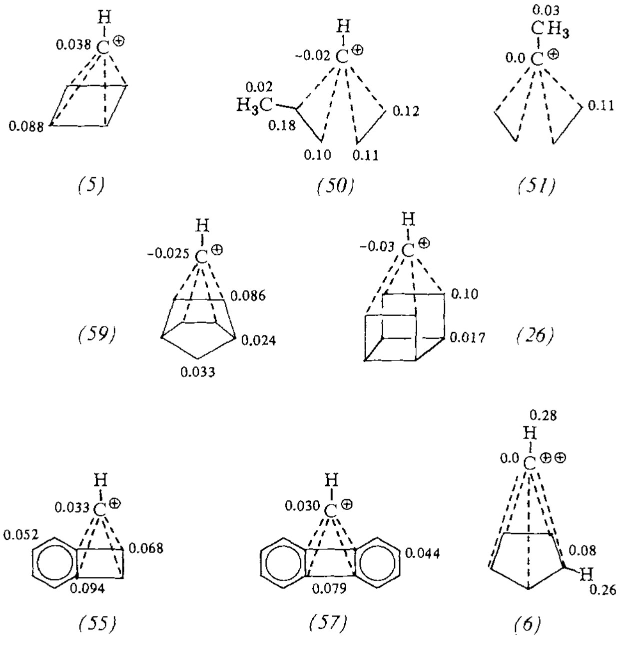
Scheme 3. Degenerate isomerization of the 3-deuterio-9-methyl-9-fluorenyl cation.

Numerous MINDO/3 calculations[52] clearly show that the pyramidal structures *(5)*, *(55)*, and *(57)* are destabilized upon increasing annelation compared to the classical structures *(48)*, *(54)*, and *(56)*, ($\Delta\Delta H_f^0$ = 14.4, 49.1, and 73.0 kcal/mol, respectively). There are two reasons for this substantial increase in energy difference. Firstly, the antiaromatic character of the classical structures is diminished upon increasing benzannelation, *i.e.* *(56)* is more stable than *(54)*, which is in turn more stable than *(48)*. Secondly, the stability of the pyramidal structures decreases in the order *(5)*>*(55)*>*(57)*. The differences are readily apparent from the "complexation energies" arising from the hypothetical reaction: olefin + $CH^{\oplus}$ → pyramidal cation. The relevant values for the formation of *(5)*, *(55)*, and *(57)* are −176.2, −153, and −131.9 kcal/mol, respectively[52]. As the complexation energy arises from the interaction of the doubly degenerate p-LUMO of the $CH^{\oplus}$ fragment with the π orbital of the diene, the observed trend becomes understandable; increasing annelation diminishes the π energy and at the same time decreases the coefficients of the carbon centers involved in the coordination. Another factor responsible for the non-occurrence of the reaction *(52)*⇄*(53)*⇄*(52a)* is the electronic situation in *(56)* and *(57)*. Although the process *(48)*→*(5)* is symmetry allowed, the reaction *(56)*→*(57)* is forbidden, the reason being that the electronic structure of *(56)* is not comparable to that of *(48)*, but rather to that of *(58)*. Furthermore *(58)*, which is a lumomer[*] of *(48)*, cannot isomerize to *(5)* for symmetry reasons[20].



## 2.4. Charge Distribution in Pyramidal Cations

For many pyramidal carbocations it has been found that the apical C atoms bear only a small positive charge or even a slight negative charge (Scheme 4)[54]. The apical C atom in *(5)* carries only 3.8% of the total charge, whereas the basal C atoms carry 35%[52]. Similar distributions have been obtained for cations *(50)* and *(51)*[50]. The apical C atom in *(50)* is slightly negative (−2%), whereas in *(51)* it is almost charge-free. As far as the H atoms are concerned, computation reveals that the basal part of *(50)* supports 99% of the charge and the apex only 1%. In the case of *(51)* the base possesses 91% of the charge and the $CH_3C$ apex 9%. In the pyramidal $C_8H_9^{\oplus}$ and $C_9H_9^{\oplus}$ ions *(59)*[55] and *(26)*[24] a slightly negative charge is found at the apical C atoms (−2.5 and −3%, respectively), whereas the basal C atoms share 34.4 and 40% of the positive charge, respectively. In *(59)* the H atoms carry a total of 59.7% of the charge and 56.3% in *(26)*. These results mean that the carbyne carbon atom is practically neutral, with the charge being strongly deflected to the periphery. This is an electrostatically favorable state of affairs which is a characteristic of the polyhedral structure. The analogy with the distribution of charge on a spherical surface is obvious.



Scheme 4. Charge distribution on the carbon atoms of pyramidal cations [54]. For the dication *(6)*, the charge distribution on C and H atoms is given.

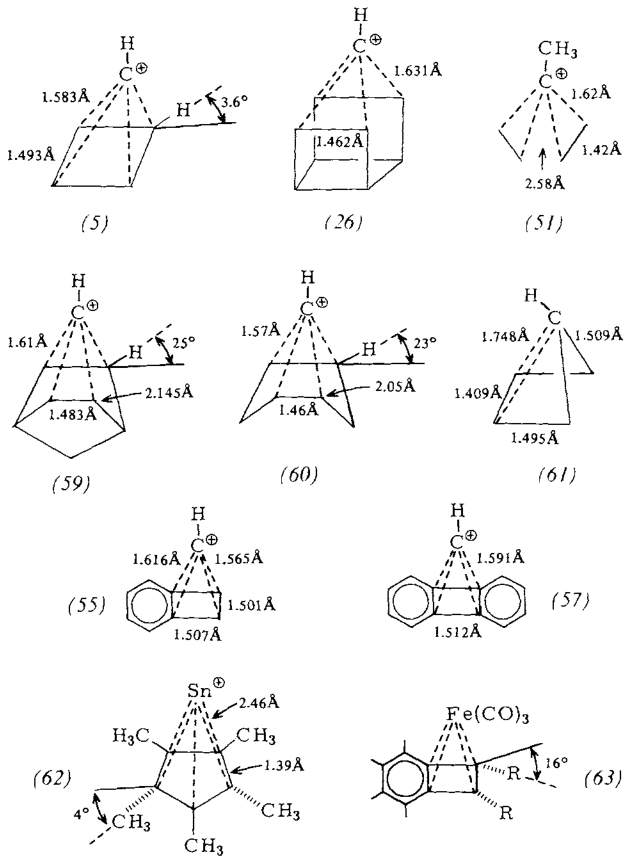
---

[*] Lumomers are isomers which are predominantly distinguished from each other by their LUMO.

The apical C atoms in the ions *(55)* and *(57)* are also only partially charged (3.3 and 3.0%, respectively)[52]. The dication *(6)* presents an interesting case. Its charge distribution was computed by *ab initio* methods[56] and it was found that the apical CH group only possesses 0.29 charge units (corresponding to 14.5%), whereas the entire basal region possesses 1.71 units (85.5%). An interesting insight into the nature of the electronic interaction underlying the formal combination of the $CH^{\oplus}$ and $C_5H_5^{\oplus}$ fragments is provided by analysis of the valence configuration of $CH^{\oplus}$. Starting from a $\sigma_{CH}^2\pi^2\sigma^0$ configuration for the free $CH^{\oplus}$ fragment, a $\sigma_{CH}^2\pi^{1.76}\sigma^{0.96}$ configuration is obtained for the CH-partial structure in *(6)*. This can be interpreted as follows. The five-membered ring donates 0.96 electrons to the empty σ orbital of $CH^{\oplus}$, whereas 0.24 electrons from the π orbital of $CH^+$ are donated back to the five-membered ring. This type of bonding is commonplace for organometallic compounds[33,34b].

### 2.5. Geometry of Pyramidal Ions

Only the more significant structural parameters of pyramidal cations will be discussed here. 1) The distance between the apical C atom and the basal C atoms corresponds to that of an elongated CC-single bond (1.6 Å). 2) The original CC-double bonds of the diene moiety are lengthened from 1.35 to *ca.* 1.48 Å on complexing with $CH^{\oplus}$. 3) The four basal atoms interact with each other in such a way as *not* to form a substituted cyclobutane ring. In fact, the distance between the opposing $C_2$ units is 2.58 Å in *(51)*[50], 2.15 Å in *(59)*[55], and amounts to 2.05 Å[21,57] in the analogously substituted $C_7H_9^{\oplus}$ ion *(60)* (Scheme 5). Similar results have been obtained for *(49)* and *(50)*[49,50]. For unsymmetrically substituted cations such as *(55)*[52], *(31)*, and *(33)*[32] the situation is more complicated: the single bonds in the basal region and those to the apical C atom differ in length. This is exemplified by the bishomocyclopropenyl cation *(61)*. This cation is intermediate in structure between 3c/2e bond species *(33)* and a distorted pyramid[32]. It is worth mentioning that the SnC separation in the cluster ion *(62)*, as determined by X-ray analysis, is significantly shorter compared to that of the $(Cp)_2Sn$ derivatives (from *ca.* 2.6 to 2.46 Å. 4) Pyramidal cations have similar shapes. The basal CH bonds of cations *(5)*, *(59)*, and *(60)* are all bent upwards towards the apex[20,21,41,43,45,55,57]. This probably allows better overlap of the molecular orbitals of the diene with those of the $CH^{\oplus}$ fragment. An analogous conformation is found in $B_5H_9$ *(8)*[15a]. On the other hand, the methyl groups on the five-membered ring of the permethyl-substituted cluster *(62)* are bent out of the plane of the five-membered ring by 4° *away* from the metal[38]. This out-of-plane bending is also encountered in the $Fe(CO)_3$ complex of benzocyclobutadiene derivatives *(63)*. X-ray analysis reveals that the plane of the annelated benzene ring and the two substituents ($R = t\text{-}C_4H_9$) are bent away from the $Fe(CO)_3$ center by 5° and 16°, respectively[58]. A satisfactory explanation of these configurational differences between carbocations and boranes on one hand, and organometallic cluster compounds on the other has recently been provided[83].



Scheme 5. Some geometric data of pyramidal cations.

## 3. Studies of Pyramidal Cations in the Condensed Phase

### 3.1. $(CX)_5^{\oplus}$ Derivatives (X = H, Cl, Ph, Aryl)

All attempts to generate and characterize the prototype of pyramidal cations *(5)* have, so far, been unsuccessful. The unsubstituted $C_5H_5^{\oplus}$ ion *(65a)* obtained from *(64)*, according to low temperature ESR studies, exists as a triplet[59]. A triplet state has also been assigned to the perchlorinated ion $C_5Cl_5^{\oplus}$ *(65b)*[60], whereas the derivatives *(65c)* exist as singlets in their ground states[60b,61]. It is no surprise that *(64)* gives the cyclopentadienyl derivative *(65a)* and not the pyramidal structure *(5)*. Theory[42,43] indicates that *(64)* and *(66)* should give *(65a)* or its lumomer *(48)*, respectively. Potential precursors for the pyramidal cation *(5)* are *(67)* and *(68)*. Unfortunately, experimental confirmation is still lacking.

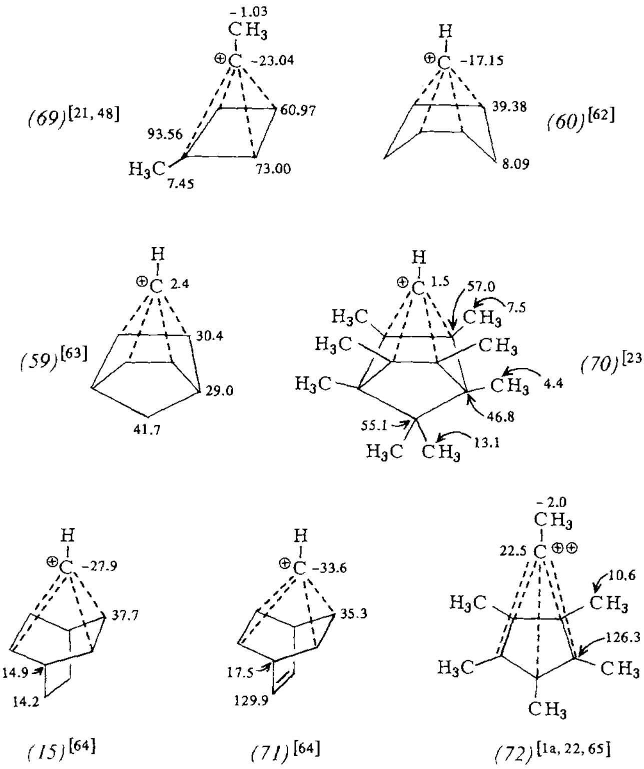
### 3.2. $^{13}$C-NMR Spectroscopic Investigations

Several cations *(15)*, *(59)*, *(60)*, *(69)*-*(72)* have been generated in superacid media and characterized as stable species. The dominant feature of the $^{13}$C-NMR spectra of these cations is the appearance of the resonance of the apical C atom at unusually high field (Scheme 6). Although the shift is certainly influenced by strain effects and steric crowding—*e.g.* in *(70)*—its value essentially arises because the apical C atom hardly bears any positive charge and that it is largely sp-hybridized. Most of the charge (see Section 2.4) is delocalized on the basal region and, in consequence, these atoms display a corresponding downfield shift. The sp-hybridization of the apical C atom is also evident from the $^{13}$C—$^{1}$H coupling constants, these being sensitive to hybridization[66]. The apical C atom in *(70)* has a $^{13}$C—$^{1}$H coupling constant of 220±5 Hz[67]: This value is entirely characteristic of a pyramidal structure and an sp-hybridized apical center[68].



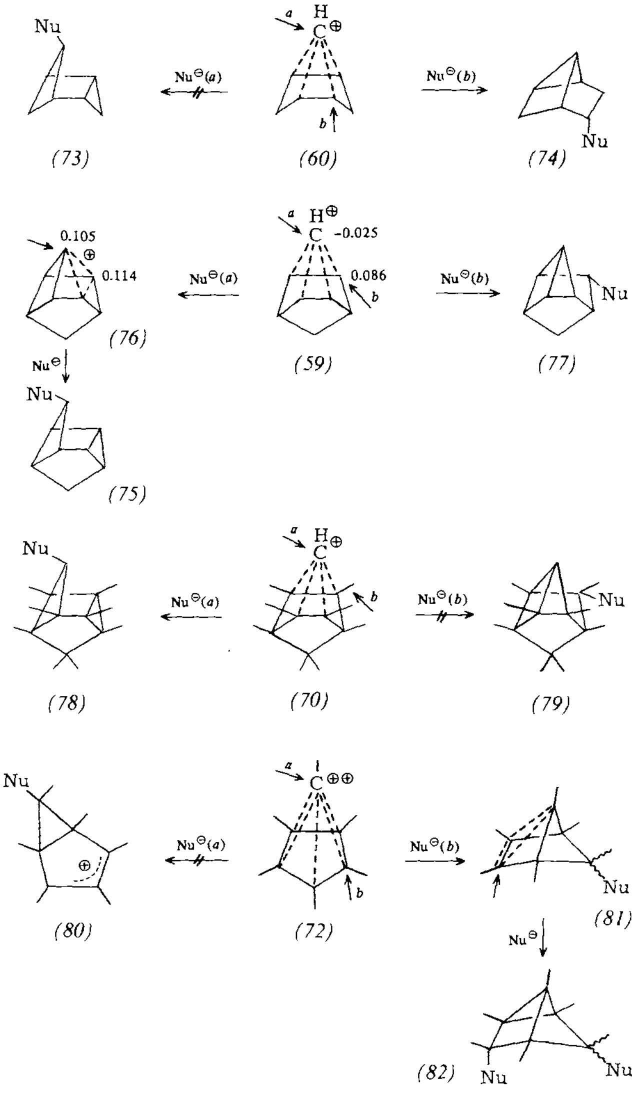
Scheme 6. $^{13}$C-NMR data (δ-values) of some pyramidal cations.

### 3.3. Quenching by Nucleophiles Nu$^{\ominus}$

The charge distribution discussed in Section 2.4 leads one to expect that attack by nucleophiles Nu$^{\ominus}$ under conditions of kinetic control should occur preferentially at the basal center. Indeed, Nu$^{\ominus}$ attacks *(60)* exclusively from the *endo*-side yielding *(74)*[21,62]. Attack at the apex to give *(73)* is not observed. A similar pattern of reactivity is to be expected for the homologous $C_8H_9^{\oplus}$ ion *(59)*. Almost equal amounts of *(75)* and *(77)* are formed[62,69], *i.e.* *(59)* is nucleophilically attacked at both the base and apex. This result can be rationalized if the principle of microscopic reversibility is taken into account[55], and if the reaction course is examined in more detail.

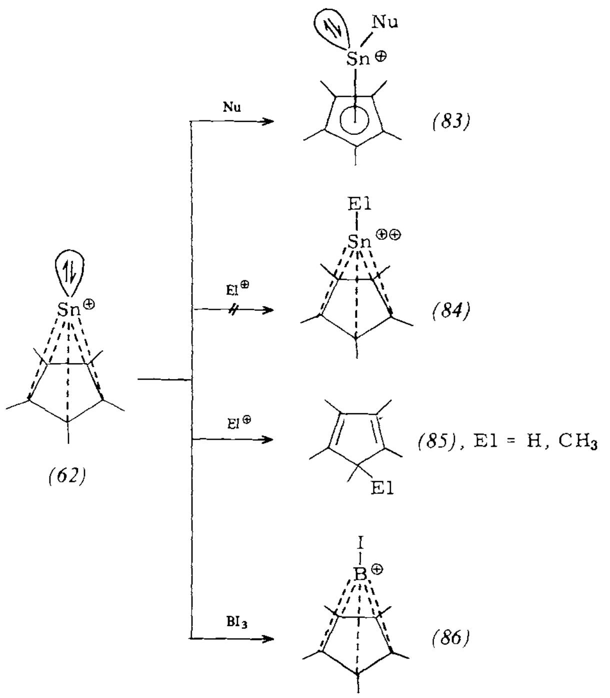
Reaction of *(75)* (Nu = OTs) with $CH_3CO_2H$[69a] and its solvolysis (Nu = Cl) in superacidic media[70] lead to the trishomocyclopropenyl cation *(76)*, which according to MINDO/3 calculations[55] is separated from the pyramidal cation *(59)* by a barrier of only 0.2 kcal/mol. A nucleophile could therefore "displace" the apical carbon atom away from the $C_2$ axis of *(59)*. This distortion redistributes the charge in *(76)*, thereby favoring attack at the apical C atom. Clearly, other factors may be important in controlling the approach of the nucleophile, *inter alia* different substitution patterns at the basal and apical carbon atoms. This is clearly seen by comparing *(59)* with its permethylated derivative *(70)* which reacts exclusively with nucleophiles at the apical C atom [*(70)*→*(78)*]. The product expected from *endo*-attack at the base, *viz.* *(79)*, was not detected[23,72].

Interestingly, the dication *(72)* undergoes nucleophilic attack exclusively at the basal C atom. *(72)*→*(82)* is unfavorable for steric and electronic reasons[1a,16,65]. Reaction of *(72)* with Nu$^{\ominus}$ occurs *via* the intermediate configurationally unstable monocation *(81)* to give the tricycle *(82)* (Scheme 7).



Scheme 7. Quenching of pyramidal cations by nucleophiles Nu$^{\ominus}$.

The behavior of the organometallic cation *(62)* towards electrophiles and nucleophiles is worth mentioning[38b]. Despite their topological similarity, *(62)* and the pyramidal cation *(72)* have completely different chemistries (Scheme 8). Nucleophiles attack the cluster at the tin atom [*(62)*→*(83)*]. Although the cluster-type bonding is lost, the *pentahapto*-structure *(83)* nevertheless remains intact. Electrophiles $El^{\oplus}$ do not attack the lone pair of the tin atom. In contrast to the formation of $(CCH_3)_6^{2+}$ *(72)* from the corresponding monocation, the dication $(CCH_3)_5SnR^{2+}$ *(84)* is not detected. Instead, the cluster either undergoes degradation [*(62)*→*(85)*], exchange of the apical tin atom [*(62)*→*(86)*], or attack of $El^{\oplus}$ at the counterion[38b].



Scheme 8. Reactions of the cluster ion *(62)* with nucleophiles (Nu) and electrophiles (El).

## 4. Pyramidal Carbocations in the Gas Phase

### 4.1. Carbon Atom Scrambling and Alkene Elimination

An increasing number of theoretical and experimental studies in recent years have shown that pyramidal cations play a central role in gas phase reactions of cations. The following examples are typical.

Metastable $C_5H_9^{\oplus}$ ions, generated from several precursors by dissociative ionization, lose ethylene in a unimolecular fashion to give an allylic cation. $C_5H_9^{\oplus}$ ions doubly labeled with $^{13}C$ have been shown to undergo complete scrambling of their C atoms prior to elimination of ethylene[49].

Model studies and quantum mechanical calculations[49] show that C atom scrambling in the cyclopentyl ion *(90)* can be accounted for in two ways; either by a bisected cyclobutylcarbinyl cation *(91)* or by the pyramidal cation *(49)*. Ethylene elimination, however, occurs only with the pyramidal cation *(49)*. Electronic reorganization in *(49)* leads to a transition state $TS_3$, whose structure *(92)* corresponds to a partially opened cyclopropyl cation "solvated" by an ethylene molecule[74].

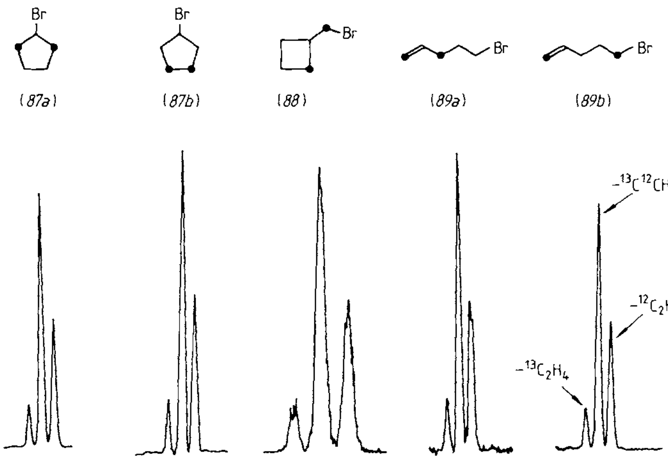


Fig. 3. Unimolecular ethylene elimination from the $[M-Br]^{\oplus}$ ions of *(87)*—*(89)*. $^{13}C$ label indicated by (•). Spectra were recorded by the MIKES method[73]. For complete C atom equilibration, the relative intensities for fragments obtained by loss of $^{13}C_2H_4$, $^{13}C^{12}CH_4$, and $^{12}C_2H_4$ are respectively 10%, 60%, and 30%, respectively.

Alternative mechanisms for the process $C_5H_9^{\oplus} \rightarrow C_3H_5^{\oplus}$ *(93)* $+ C_2H_4$, the cycloreversion [*(91)*→*(93)*] or two-step reactions involving acyclic $C_5H_9^{\oplus}$ ions, have been found by calculation to be energetically unfavorable.

Similar results were obtained for the homologuous $C_6H_{11}^{\oplus}$ ion which decomposes unimolecularly to the 1-methylallyl cation and ethylene[50]. It is seen from the doubly $^{13}C$-labeled $C_6H_{11}^{\oplus}$ cations, generated from *(94)*—*(97)* by

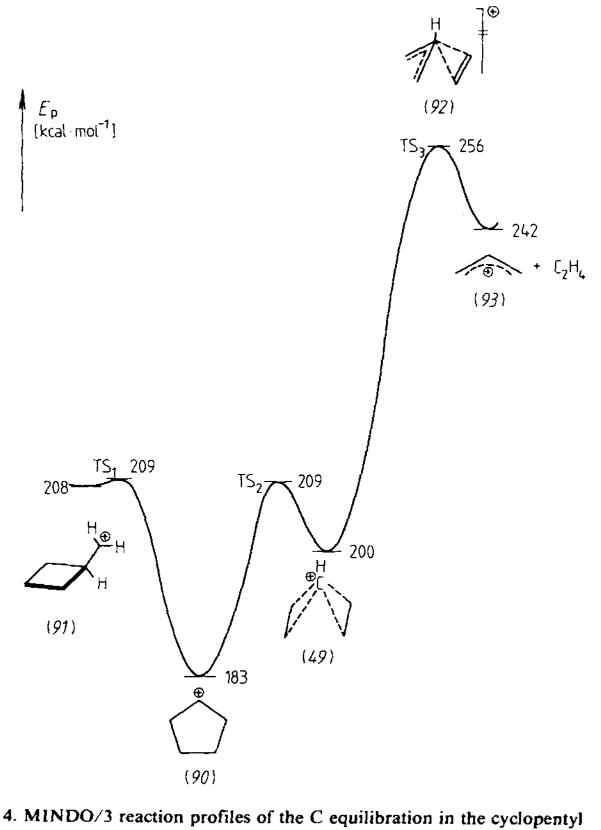

Fig. 4. MINDO/3 reaction profiles of the C equilibration in the cyclopentyl cation *(90)* and for the reaction $C_5H_9^{\oplus} \rightarrow C_3H_5^{\oplus} + C_2H_4$.

dissociative ionization, that complete C scrambling occurs (Fig. 5). Moreover, the constitution of the molecular ions (five- or six-membered ring derivatives) has no effect on the scrambling pattern. The nature of the neutral part X to be eliminated (X = COOH or Br) and the initial position of the $^{13}C$ label (1,2- or 1,3-assignment) are also without effect. Accordingly, the scrambling of C atoms is best described by an equilibrium between the cyclohexyl *(98)* and the 1-methylcyclopentyl cations *(99)*, involving both protonated cyclopropane derivatives *(100)*[75] and the pyramidal cations *(50)* and *(51)* (Scheme 9)[50]. Ethylene elimination, however, proceeds most favorably from the transition state *(101)*. According to MNDO calculations[50], *(101)* is at least 11 kcal/mol more stable than its isomeric form *(103)*, and is expected to decay to ethylene and $C_4H_7^{\oplus}$ (Scheme 10). Numerous experimental methods confirm that the $C_4H_7^{\oplus}$ ion has the 1-methylallylic structure *(102)* and not the 2-methylallyl cation structure *(104)*[50,76].

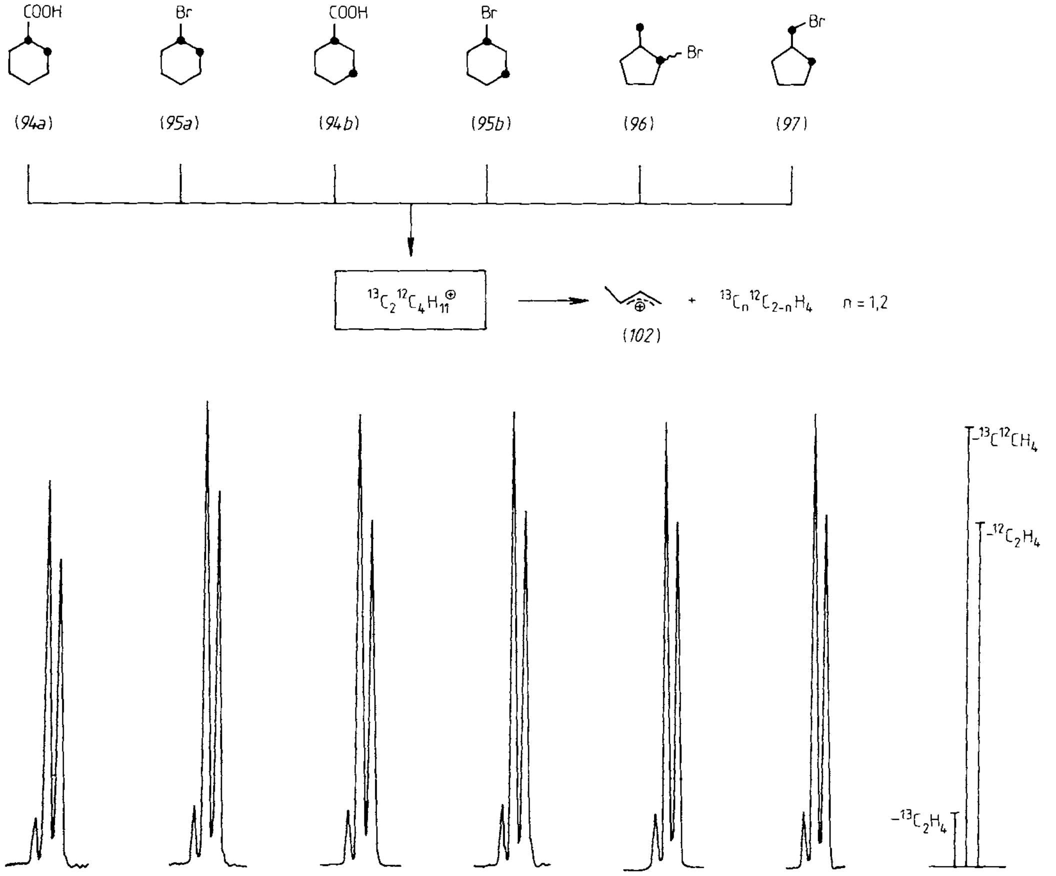

Fig. 5. MIKE spectra of the unimolecular ethylene elimination from doubly $^{13}C$ labeled $C_6H_{11}^{\oplus}$ ions obtained from *(94)*–*(97)*. $^{13}C$ label indicated by (●).

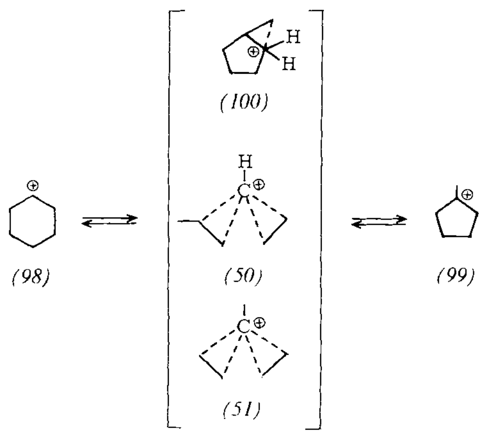
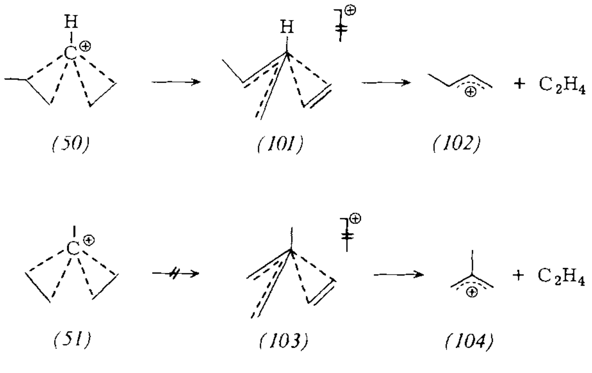
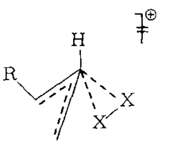


Scheme 9. Isomerization of the cyclohexyl- *(98)* and 1-methylcyclopentyl-cations *(99)*.



Scheme 10. Unimolecular ethylene elimination from $C_6H_{11}^{\oplus}$.

Elimination of $C_2H_4$ from $C_5H_9^{\oplus}$ and $C_6H_{11}^{\oplus}$ is mechanistically similar to the unimolecular elimination of $H_2$ from



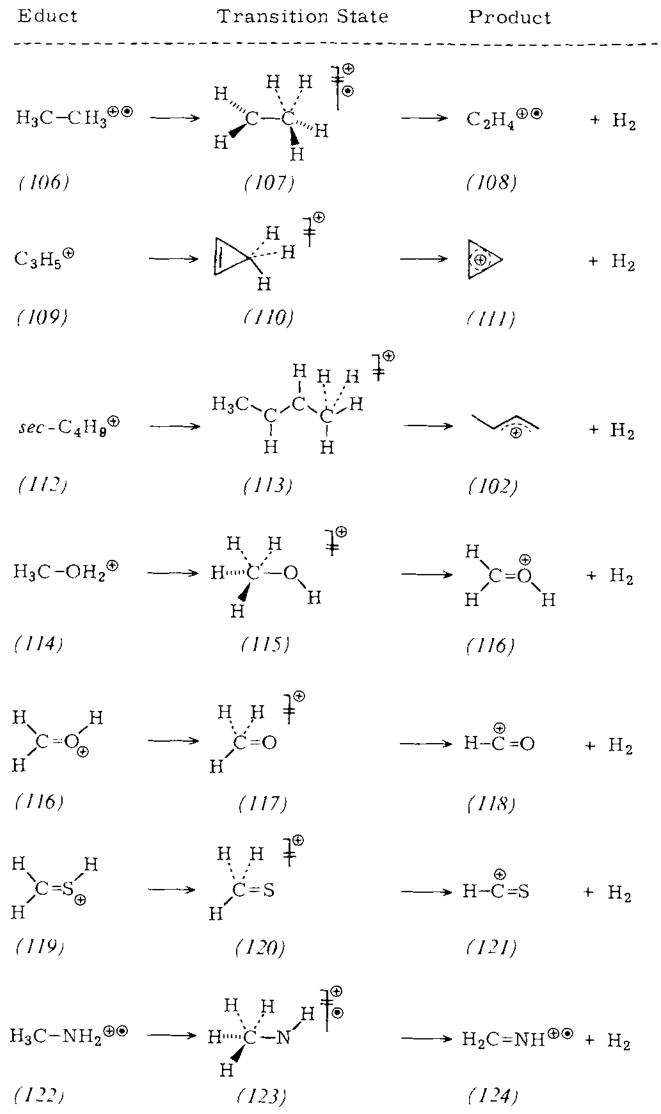
(105)

| R | X | Reaction | Lit. |
|---|---|---|---|
| H | H | $C_3H_7^{\oplus} \rightarrow C_3H_5^{\oplus} + H_2$ | [77] |
| H | $CH_2$ | $C_5H_9^{\oplus} \rightarrow C_3H_5^{\oplus} + C_2H_4$ | [49] |
| $CH_3$ | $CH_2$ | $C_6H_{11}^{\oplus} \rightarrow C_4H_7^{\oplus} + C_2H_4$ | [50] |

$C_3H_7^{\oplus}$, which also produces the allyl cation[77]. Once again, experiments and calculations both show that the transition state *(105)* (X = H, R = H) exhibits the properties of a partially opened cyclopropyl cation which is "solvated" by $H_2$. Indeed, the reaction $C_3H_7^{\oplus} \rightarrow C_3H_5^{\oplus} + H_2$ is the first example of *two* coupled symmetry allowed processes, namely the opening of a cyclopropyl cation to the allyl cation and the simultaneous cheletropic elimination of hydrogen[77].

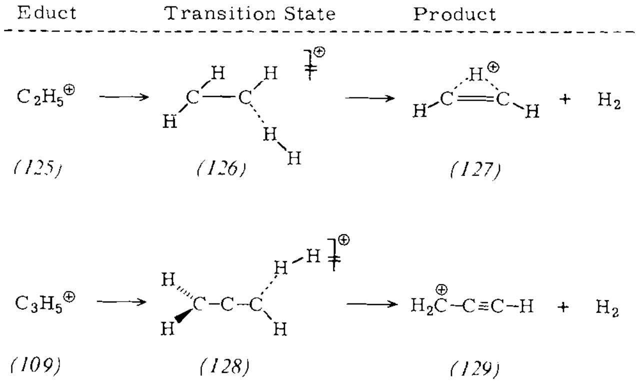
### 4.2. $H_2$ "Solvated" Transition States

Transition states like *(105)* represent the formal "solvation" of cations by $H_2$ and have been discussed for numerous unimolecular gas-phase reactions[79]. The unimolecular decomposition of such solvated cations displays a common feature, a [1,2] $H_2$ shift combined with a [1,1] elimination of $H_2$ (Scheme 11). The transition state for elimination can be described by a side-on complexation of the cation with $H_2$. The resulting species correspond to deformed derivatives of the methonium ion $CH_5^{\oplus}$ (with the exception of *(117)* and *(120)*). In all these processes (Scheme 11) the translational energy ($E_T$)[79], released in the unimolecular decomposition process, is found to represent a substational fraction of the energy of activation of the reverse reaction[79b–d, 80]. This is probably a direct consequence of the repulsive nature[81] of the corresponding transition states and the inefficient coupling of the imaginary normal vibrational modes between the ionized and neutral parts of the complex.



Scheme 11. Unimolecular elimination of $H_2$ from side on complexed transition states.

Transition states leading to the vinyl cation *(127)* and the propargylium ion *(129)* are completely different from the side-on coordinated transition states discussed in Scheme 11. Instead of a pentacoordinated C atom, a complex in which the hydrogen molecule is positioned end-on is necessary[78] (Scheme 12).

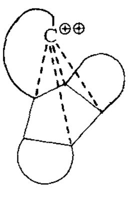


Scheme 12. Unimolecular elimination of $H_2$ from end-on complexed transition states.

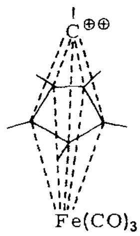
## 5. Future Prospects

There is considerable support for the view that pyramidal cations constitute *the* essential bridge between organic and inorganic chemistry. By an appropriate choice of conditions these ions can be prepared either as stable species in superacid media, where they can be conveniently studied by spectroscopic methods, or as transient species formed by solvolysis. Lastly, and perhaps most importantly, they can be easily prepared in the gas phase. Under these latter conditions, the polyhedral shape and the associated favorable "spherical" charge distribution clearly make these pyramidal cations sufficiently long-lived and hence amenable to study. Carbon atom scrambling reactions of several carbocations, which were previously not properly understood, can now be conveniently rationalized in terms of pyramidal cations. For example, seemingly different processes such as the unimolecular elimination of σ (such as $H_2$) or π ligands (alkenes) are seen to have much in common if intermediates and transition states involving pyramidal structures are admitted.

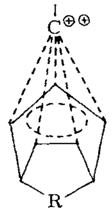
There is no doubt that these novel pyramidal structures provide a stimulus to the ingenuity of chemists. As examples of compounds which have not been synthesized up to now we may cite the neutral carbaboranes containing hypervalent carbon, *e.g. (23)*[31], futuristic structures possessing polycyclic skeletons, *e.g. (130)* and inverted sandwich structures *(131)*[1,82], and to complete the list of this exotic series, pyramidal dications having fluxional properties, *e.g. (132)*[19] (R=CH=CH, *o*-$C_6H_4$, *etc.*).



*(130)*



*(131)*



*(132)*

Although not all carbocations have pyramidal structures neither do they have "rococo" topology[15], which has aroused the skepticism of some chemists. Analysis by graph theory has already predicted that no *closo-* or *arachno* clusters are to be expected for carbonium ions. Moreover, calculation[24] has demonstrated that the stability order for pyramidal *versus* classical structures can be easily upset by solvation by the simple act of passing from the gas to the condensed phase. In other words, from the ideal solvent-free state to the real situation.

*I wish to acknowledge the generous support by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (project Schw 221/5, 6-2), the Gesellschaft von Freunden der Technischen Universität Berlin, and Schering AG. Work in our laboratory has been accomplished essentially by my co-worker Dipl.-Chem. Wilfried Franke, to whom I express my gratitude. An Overseas Fellowship awarded by Churchill College, Cambridge, England (1981) allowed me to write this report. I also greatly appreciate many stimulating discussions with R. G. Cooks (Purdue), T. Gäumann (Lausanne), P. von R. Schleyer (Erlangen), and D. H. Williams (Cambridge). Translated from the German by Drs C. W. Jefford and U. Burger, Université de Genève, Switzerland.*

[22] *Hart* [23] suggests that the interaction of $CH^{\oplus}$ with any 4e system might generally produce a "stable" molecular arrangement. Tetrahedrane *(13)* could be considered as the covalent form of the interaction of $CH^{\oplus}$ with the antiaromatic cyclopropenyl anion *(12)*. Further, the $C_{4v}$ symmetry of the methonium in *(1)* might result from the interaction of $CH^{\oplus}$ with two $\sigma_{H-H}$ bonds.
The rules which have been suggested for the nomenclature of pyramidal cations suggested by *Jorgensen* [24] follow closely those proposed by *Cotton* [25] for use with organometallic complexes. For example, the positions of the $CH^{\oplus}$ groups are followed by the term *"tetrahapto"* ($\eta^4$), then the name of the 4e system, finally followed by the name of the apical fragments. *(5)* is therefore named the tetrahaptocyclobutadienemethinyl cation. Similarly, *(6)* is termed the *pentahapto*-cyclopentadienylmethinyl cation. The cluster *(15)*, obtained from $CH^{\oplus}$ and bicyclo[2.2.2]octadiene *(14)* would be termed 2,3,5,6-*tetrahapto*-bicyclo[2.2.2]octadienemethinyl cation.

# Physical Methods for the Microanalysis of Solids—General Significance, Recent Developments, and Limitations

By Manfred Grasserbauer[*]

The characterization of solid systems by physical methods ("physical analysis") is one of the most important future-orientated areas of analytical chemistry. Important developments are the increase of the informational content of analytical signals by application of mathematical methods, the investigation of extremely small amounts (microanalysis), as well as concentrations (trace analysis). New developments in analytical methodology and strategy in micro and surface analysis permit, for example, the direct identification of compounds in individual phases in the solid state, the quantitative elemental analysis of aerosol particles in the submicrometer region (identification of asbestos fibers), and highly sensitive distribution analysis of trace elements in semiconductors. Important technological-scientific problems can be explained in this way.

## 1. Definition, Significance and General Characteristics of Physical Methods of Microanalysis

On the basis of *Malissa*'s[1] division of analytical chemistry into chemical, physical, and biological sectors and of the definition of analytical chemistry recommended by a group of the Working Party on Analytical Chemistry (WPAC) of the Federation of European Chemical Societies (FECS)[2], it can be said that "Physical analysis is the science of extracting and evaluating chemical information on material systems with the aid of physical reagents".

The prefix "micro" in front of "physical analysis" indicates either that only very small quantities of the sample are used and determined (as in the general concept of microanalysis), or that microregions of nanometer to micrometer dimensions are characterized.

The "reagents" currently used in the realm of physical microanalysis are photons, electrons, protons, neutrons, and free ions.

To permit a general description of the part played by physical microanalysis in the characterization of solids the very term "characterization" must be more rigorously defined. A very good definition has been produced by the US National Academy of Sciences[3]:

"Characterization describes *those features* of the *composition* and *structure* of a material that are *significant* for a *particular preparation, study of properties* or *use* and *suffice* for *reproduction of the material*".

This means that the characterization of a solid includes information on
its average chemical composition,
the distribution of elements and phases,
the geometric structure, and
the electronic structure.

Figure 1 gives a synopsis of the most important and the most commonly used methods for obtaining this information. These are predominantly physical micromethods.

This is not to say chemical analysis has become obsolete. It still has a major role to play, especially for bulk analyses. Chemical methods, often being more accurate, are used for calibration, and when applied to the separation and concentration of trace elements significantly broaden the scope of physical methods; finally they are significant for a wide range of elements and substance groups for which only chemical techniques are applicable. Whereas in the last few decades chemical have rather tended to be eclipsed by physical methods, a renaissance of chemical analytical techniques now seems to be underway. This can be ascribed largely to a combination of chemical preparation steps with physical methods of determination, as impressively demonstrated by *Tölg*[4].

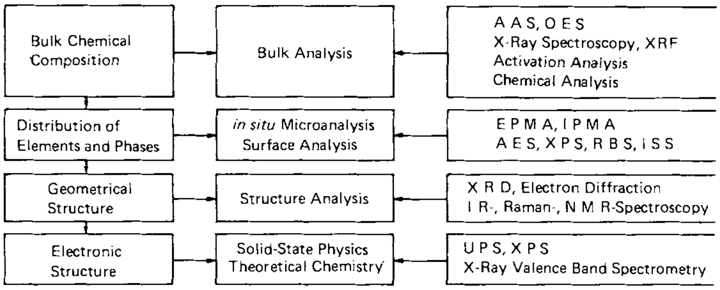

Fig. 1. Analytical characterization of solids. Abbreviations:

AAS = Atomic Absorption Spectrometry
OES = Optical Emission Spectrometry
XRF = X-Ray Fluorescence Analysis
EPMA = Electron Probe Microanalysis
IPMA = Ion Probe Microanalysis (also denoted by SIMS—Secondary Ion Mass Spectrometry)
AES = Auger Electron Spectrometry
XPS = X-Ray Photoelectron Spectrometry
RBS = Rutherford-Backscattering Spectrometry
ISS = Ion Scattering Spectrometry
XRD = X-Ray Diffraction Analysis
UPS = UV Photoelectron Spectrometry

In spite of these important new developments, in general it can be said that the advances in the analysis of solids achieved in recent decades can be traced to the application of physical micromethods.

0570-0833/81/1212-1004 $ 02.50/0

The most important characteristics of physical methods are as follows:

1. High information content: suitable methods are available for bulk analyses, for studies of distributions, and for structural analyses. The information is directly concerned with elementary particles, whose nature, number, and arrangement determine the properties of a given substance (valence electrons, core electrons, atomic nuclei).
2. High absolute detection power: typical absolute detection limits are, for example, $10^{-6}$ to $10^{-12}$ g. In extreme cases the absolute detection limit can be as low as $10^{-20}$ g (microanalysis).
3. High relative detection power: typical relative detection limits are in the range mg/g to ng/g. In individual cases pg/g can be directly detected, or fg/g after concentration (trace analysis).
4. High selectivity, and generally even specificity of the analytical signal: this permits direct, unambiguous qualitative and quantitative analyses of complex systems of substances, usually without preliminary separation.
5. Small dimensions of the analytical volumes: by the selection of suitable (focusable) "reagents", signals, and conditions of excitation, regions from nm to µm can be selectively investigated and analyzed in solids (*in situ* micro- and surface-analysis).
6. Automazation: this enables the rapidly increasing number of analyses with tolerable expenditure of time, costs, and personnel to be coped with for the first time.

## 2. Trends in Development of Methods for Physical Microanalysis

Starting out from the characteristics of physical microanalysis, the targets of the most important development studies and trends, can be summarized thus:

1. Increase of the informational content of the analysis to obtain further-reaching (more detailed) information (*e.g.* compound-specific analysis of microregions in a solid with X-ray valence band spectroscopy or laser-Raman microdomain analysis[5]).
2. Elevation of the absolute detection power (reduction of absolute detection limits) of methods to enable the characterization of still smaller samples or smaller regions in the solid samples (*e.g.* phase analysis in the submicrometer range, characterization of surface layers in the nm range, and *in situ* micro-surface analysis with scanning Auger electron spectroscopy[6]).
3. Elevation of the relative detection power by the development of more sensitive trace-analysis techniques, by combination with chemical concentration methods (*e.g.* Hg in water or air[7]) or by the application of *in situ* trace methods such as ion-beam microanalysis (*e.g.: in situ* micro-trace analysis, trace analysis of surfaces, or thin layers).
4. Enhancement of the specificity of the analytical signals by mathematical signal processing (*e.g.* peak deconvolution, factor analysis, clustering techniques, general; incorporation of chemometrics[8]).
5. Increasing degree of automation of analytical systems by further development of computerized multielement techniques (*e.g.* ICP-Optimal Emission Spectrometry in process analysis[9]).

## 3. New Developments in *in situ* Micro- and Surface-Analysis

A substantial part of the present-day development of the analysis of solids, and also of analytical chemistry, falls into the sphere of *in situ* micro- and surface-analysis, two areas that are becoming increasingly important.

Since it would be impossible even to approximately describe all the important advances of the last few years in detail, three examples of the further development of microdomain and surface analysis have been selected. These examples are intended to illustrate the strategy and systematics that can be applied in analytical research in this field, but also to reflect the present state of the individual subareas.

On the basis of specific results, the selected themes will concentrate on the fundamental problems relating to
direct compound-specific *in situ* micro-analysis of solids by X-ray valence band spectroscopy;
quantitative X-ray microanalysis in the submicrometer range, and
quantitative characterization of trace element distributions.

### 3.1. Compound-Specific Analysis by X-ray Valence Band Spectrometry

The direct compound-specific analysis of microdomains (phases) of solids is of fundamental interest for clarifying the question of the maximum obtainable informational content of an X-ray spectrum, but also of practical significance for the identification of inclusions containing light elements that are difficult to quantify (*e.g.* B, N, C, O), or which are smaller than the analytical volume of the electron microprobe (a few micrometers in diameter).

The principle of this analytical method consists of an evaluation of the fine structure of the X-ray valence band spectrum excited in a microdomain of the sample with an electron microprobe. The spectrum reproduces in its intrinsic form the density of states of valence-band electrons taking part in the transition and thus, because of the dependence of the density of states on the type and arrangement of the atoms, constitutes a clear fingerprint of the excited compound. The intrinsic X-ray signal therefore contains not only clear information on the excited atom but also on its chemical bonding and hence on the compound in question[10].

In comparison with the intrinsic X-ray valence band spectrum, the measured spectrum is distorted by convolution with the absorption function of the X-ray radiation in the sample and the spectrometer function (constant), and has a high noise level due to the low signal intensity with the conventional analog (spectrometer scanning plus analog intensity measurement) recording techniques.

This can be clearly seen in the example of the $O_K$ spectra of $Cu_2O$, CuO, $2CuCO_3 \cdot Cu(OH)_2$, and $CuCO_3 \cdot Cu(OH)_2$ (Fig. 2). Direct compound identification is limited to a restricted number of systems with large differences in the spectral structure. To increase the number of these systems it is necessary to achieve a more precise reproduction of the fine structure by further development of the measurement techniques and to look for mathematical procedures which allow characterization of very slight differences in the fine structure.

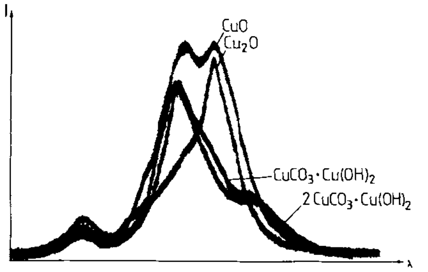

Fig. 2. X-Ray valence band spectra ($O_K$ bands) of various copper compounds and their characteristic structural parameters.

| Compound | $\lambda_{max}$ [Å] | Free-width at half maximum [Å] | Asymmetry factor |
|---|---|---|---|
| $Cu_2O$ | 23.662 | 0.14 | 1.1 |
| CuO | 23.658 | 0.25 | 0.8 |
| $2CuCO_3 \cdot Cu(OH)_2$ | 23.554 | 0.17 | 1.9 |
| $CuCO_3 \cdot Cu(OH)_2$ | 23.575 | 0.17 | 2.2 |

The improvement in the reproduction of the fine structure can be achieved by the application of digital recording with computer control of the spectrometer, and smoothing the spectra with the aid of a 5-point polynomial (after *Savitzky* and *Golay*[11]). The $Cu_{L\alpha}$ spectra of 14 copper compounds are shown in Figure 3[12]. Each spectrum was recorded in 512 measurement steps, each of 2 sec.The accuracy of the determination of the peak maximum wavelength (as a characterization parameter of the fine structure, *i.e.* the chemical shift) is 0.04 pm ($=4 \times 10^{-4}$ Å), but because of the small shift differences between similar compounds, an exact determination of this wavelength is insufficient for a definite identification of each individual compound on the basis of the $Cu_{L\alpha}$ spectrum: the different shapes of the bands should also be taken into account.

For this purpose it is necessary to quantify the differences in the spectral structure as accurately and objectively as possible, since mere optical distinction is insufficient and, moreover, a numerical description of the fine structure is necessary for storage in a spectrum data bank.

The principle of structure characterization of the X-ray valence band spectrum is that the form of the spectrum is represented by a nine-dimensional (band) vector (Fig. 4) which represents the signal width as a function of the intensity (signal height) at nine points and reproduces very clearly small differences in shape, as can be seen by comparing the Lα signals of Cu, $Cu_2O$, and CuO. Since according to this concept, the fine structure of a peak is represented as a point in (abstract) nine-dimensional space, it is sensible to transform the information, with least possi-

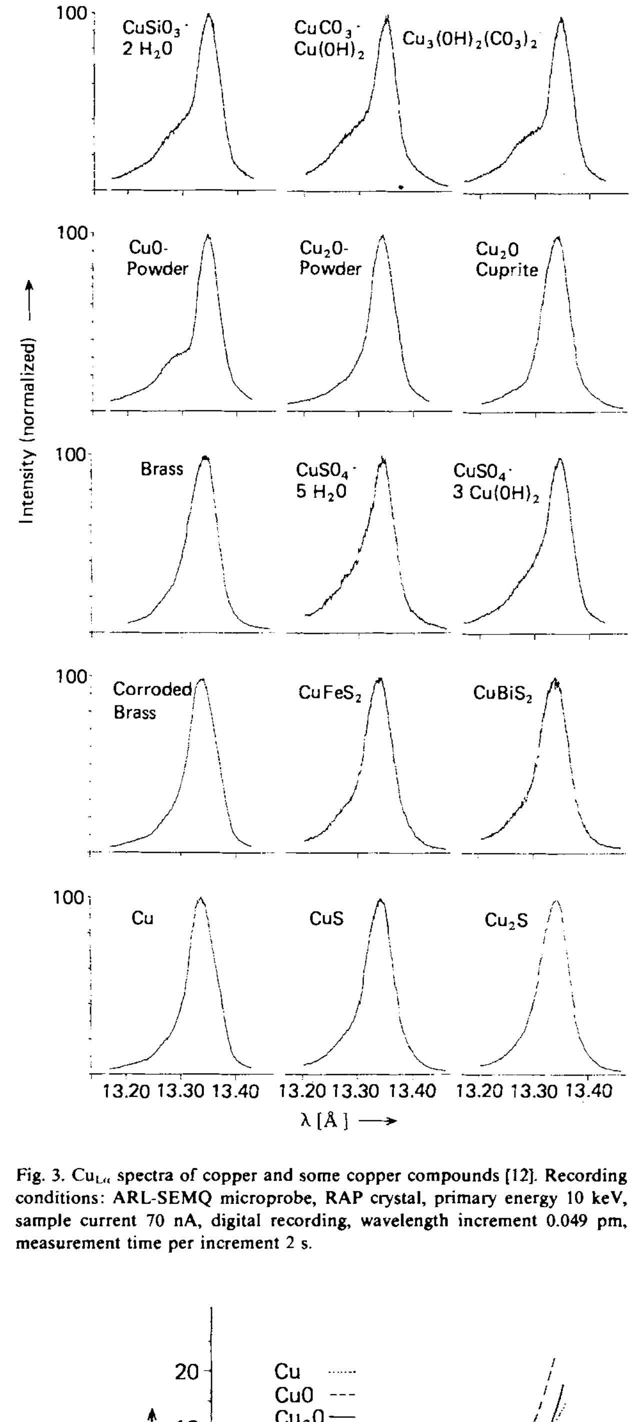

Fig. 3. $Cu_{L\alpha}$ spectra of copper and some copper compounds [12]. Recording conditions: ARL-SEMQ microprobe, RAP crystal, primary energy 10 keV, sample current 70 nA, digital recording, wavelength increment 0.049 pm, measurement time per increment 2 s.

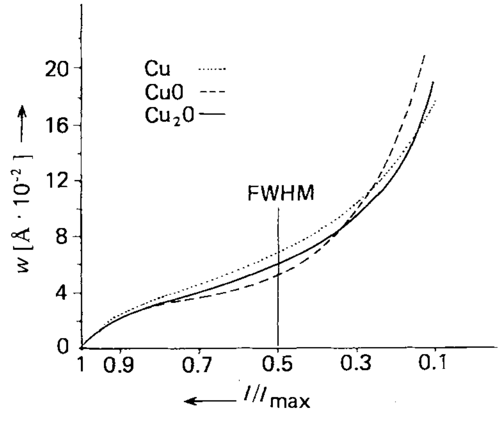

Fig. 4. Characteristic band lines of $Cu_{L\alpha}$ spectra of Cu, $Cu_2O$, and CuO [12]. $w$ = width, FWHM = free-width at half maximum.

ble information losses, into the easily pictured two-dimensional space. The representation space transformation method described by *Lin* and *Chen*[13] is suitable for this purpose. In this method, the distances of the points in nine-dimensional space from two suitably selected auxiliary functions (Gaussian functions) are determined in two directions and used as x, y-coordinates in a two-dimensional representation. These new coordinates $p_1^*$ and $p_2^*$ now give the shape of the signal in the two-dimensional representation (Fig. 5). The fine structure of a spectrum, and thus the identity of a given compound is represented as a point. The reproducibility of the fine structure measurement is shown by a circle (five measurements, 3 s value, 99% confidence interval). The distances between the circles correspond to differences in the spectral structure measured, and hence to the distinguishability of the compounds from other (similar) ones.

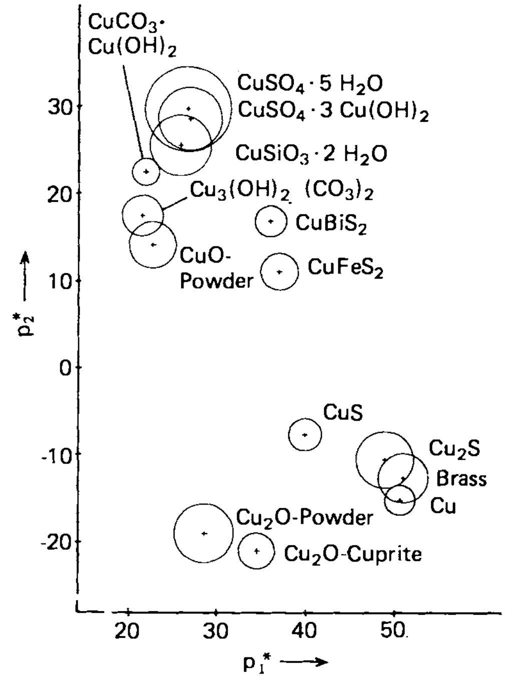

Fig. 5. Characterization of copper compounds on the basis of structure of the $Cu_{L\alpha}$ valence band spectrum in representation space. The circle diameters correspond to a confidence interval of 0.99 [12].

As the example shows, with the aid of this method even compounds with very slight differences in fine structure can be clearly identified simply from an evaluation of the X-ray valence band spectrum. Even compounds of very similar composition such as $CuCO_3 \cdot Cu(OH)_2$ and $2CuCO_3 \cdot Cu(OH)_2$ can be clearly distinguished. Differentiation with an electron microprobe on the basis of elementary analysis would be very difficult, because of the similar copper contents (55.1 and 57.2 wt-%).

The system described has also been used successfully for the characterization of iron compounds[14].

### 3.2. Quantitative X-ray Microanalysis in the Submicrometer Range

Quantitative X-ray microanalysis of inclusions and phases in solids can usually be carried out with an electron microprobe with an accuracy of a few relative percent[15], and has now joined the ranks of routine methods. The lateral resolution of the method is a few microns, because of scattering of the primary electrons in the bulk of the sample, and for many problems this limitation prevents the analysis of phases that, although smaller, still have a bearing on the properties, since when they are excited the matrix material is also determined. Quantitative analysis of submicrometer regions in bulk samples is virtually impossible. To identify such small particles it is necessary for them either to be isolated from the matrix as individual particles on an electron-transparent substrate, or at least to be available as thin-film samples. Both these preparation techniques are used with varying degrees of success.

The second basic limitation of this analysis is that, because of the small volume analyzed, extremely low X-ray intensities are produced.

The electron microprobe and the conventional scanning electron microscope are not suitable for quantitative analyses in the submicrometer range. It was only the introduction of the scanning transmission electron microscope, enabling highly sensitive generation and measurement of X-ray spectra because of high primary electron currents with very small beam diameters (nA at 10 nm, due to the special design of the objective lens) and large semiconductor detectors at very small distances from the sample (detector area 30 $mm^2$) that permitted the penetration of quantitative X-ray analysis into the submicrometer range[16].

Since some of the problems involved in analysis in the submicrometer range are completely different from those encountered in the microrange analysis of bulk samples, a careful analytical process development must be undertaken for each problem, and an appropriate strategy devised. This will be illustrated in greater detail using the example of a very difficult and complex analytical problem, namely the identification of asbestos fibers[17].

Asbestos fibers are found in dust fractions entering the lungs in cities (from brakes in motor vehicles, from the facades and roofs of buildings) in concentrations of a few $ng/m^3$, and in substantially higher concentrations in the asbestos-processing industry, in the vicinity of asbestos mines, and in certain cases in drinking water (Duluth, Lake Superior, taconite mining in Silver Bay)[18].

Although contradictory statements have been made about the influence exerted by such asbestos contents, it has been established that the prolonged effects of higher doses can give rise to lung cancer. It is agreed unanimously that suitable, highly sensitive analytical methods must be devised to allow chemical identification of fiber-like particles in water, air, and the soil and thus to show whether or not asbestos is present, and if so, what type and in what amount. The strategy of asbestos analysis is thus determined by the statement of the problem and by the boundary conditions (Fig. 6). The boundary conditions for the analyst are the normally very low concentrations of asbestos fibers in a sample, which rules out the application of a compound-specific averaging analysis such as X-ray diffractometry, and the small size of the fibers (thickness *ca.* 20—500 nm, length *ca.* 100 nm to 10 μm).

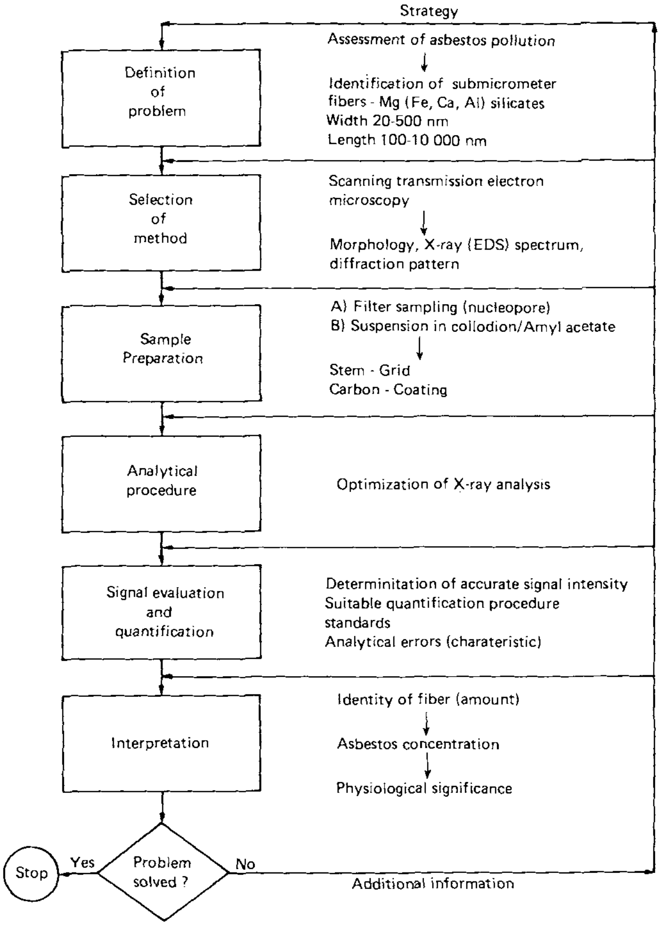

Fig. 6. Analytical strategy for the identification of asbestos fibers.

Thus, the only analytical method left is scanning transmission electron microscopy (STEM), which permits a detection of fibers in the particle conglomerate (Fig. 7), and an identification of the individual fibers by quantitative X-ray microanalysis and electron diffraction.

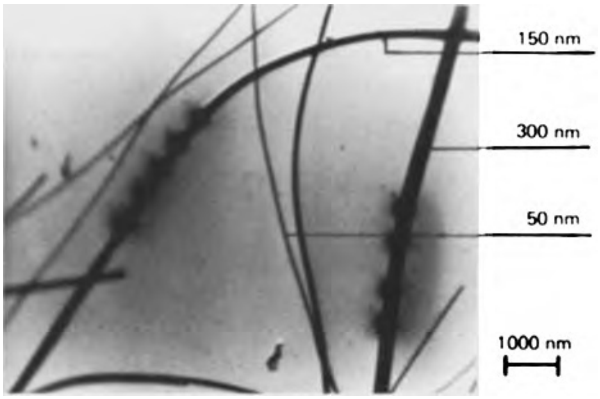

Fig. 7. STEM micrograph of asbestos fibers (chrysotile).

For the STEM investigation, the particles must be separated from one another on an electron-transparent substrate. Depending on the nature of the sample, various techniques of sample collection have been optimized for this purpose, such as extraction from air or water with Nuclepore® filters or transfer to carbon TEM grids from suspensions in collodion and amyl acetate.

The next step is optimization of the X-ray microanalysis—essentially in the direction of highest sensitivity and reproducibility of the results. The excitation energy ($E_0=40$ keV), the beam current ($i_s \approx$ nA), the angle of incidence of the primary beam ($\alpha=55°$), the recording angle ($\vartheta=24°$), and the distance of the detector from the fiber (20 mm) are all optimized.

Measurement of a fiber under the optimized conditions produces an X-ray spectrum characterized by a fairly high signal-to-background ratio (Fig. 8). From this X-ray spectrum the characteristic intensities must be picked out by suitable mathematical techniques with the highest possible accuracy. For this purpose, several steps are necessary—

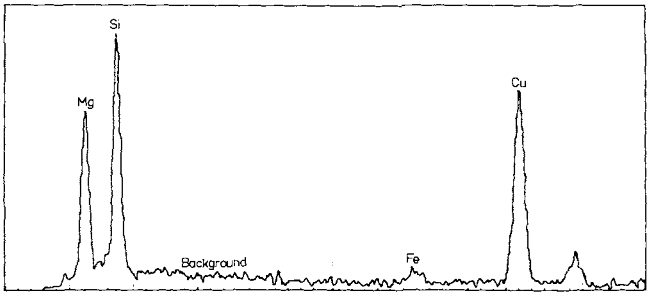

Fig. 8. X-Ray spectrum of an asbestos fiber (chrysotile), diameter 200 nm (Jeol 100C, excitation energy $E_0=40$ keV, measurement time t=200s).

1. Smoothing of the background
2. Subtraction of the background by linear interpolation
3. Signal integration.

In addition, the systematic and statistical errors must be calculated in the determination of the characteristic X-ray intensity. Systematic errors may arise from the following sources:

During excitation:

1. Excitation of the copper grid—not important for asbestos
2. Beam artefacts—loss of alkali or $H_2O$—low with asbestos
3. Contamination (Fig. 9)—radiation absorption, dependent on the fiber diameter; maximum 3%.

Fig. 9. Scanning transmission electron microscope photograph of olevine particle Contamination cone; for conditions see Fig. 8.

During evaluation:

1. Nonlinear background
2. Nonoptimized integration width

Statistical errors which must be considered are:

1. Statistical uncertainty of the X-ray intensity—especially in the case of elements present in low concentration
2. Statistical fluctuations of the background.

Evaluation of all these errors reveals that in the determination of the X-ray intensity of the principal elements occurring in asbestos fibers (Mg, Si, Ca, Al, Fe) the statistical errors are predominant (200 nm chrysotile fibers: Si 4 rel-%, Mg 10 rel-%, Fe 37 rel-%).

In the quantification it must be borne in mind that the X-ray intensities measured are dependent on the particle size, since the number of electrons penetrating the fiber, the energy they lose in the fiber, and the absorption of the generated X-ray intensity on exit under constant analytical conditions are all a direct function of the fiber diameter (Fig. 10).

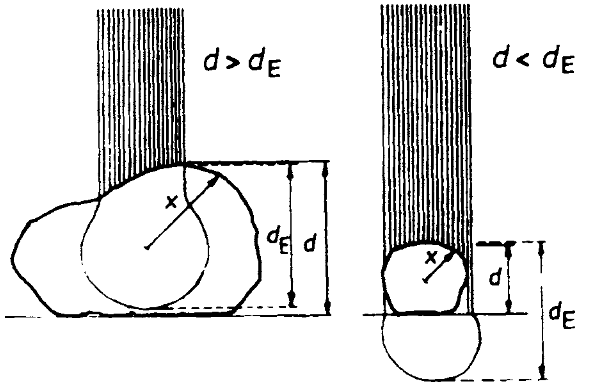

Fig. 10. Generation of the X-ray signal in submicrometer particles in comparison with large particles [16].
For large particles

$c_A \approx (I_A/I_A^*) c_A^*$ applies,

for submicro particles,

$I_A = f(d)$

$N_e$, transmission, and absorption are considered

$I_A = I_A^0 \cdot e^{-(\mu/\rho)\rho \cdot x}$

$I_A$, $I_A^*$ = (measured) characteristic X-ray intensities of element A in the sample and standard

$c_A$, $c_A^*$ = concentrations of element A in the sample and standard

$d$ = particle diameter

$d_E$ = depth of penetration of the primary electrons in a bulk sample (a few microns)

$N_e$ = number of electrons on the particle

$x$ = exit path length of the X-rays produced [cm]

$I_A^0$ = characteristic X-ray intensity of A excited within the particle

$\mu/\rho$ = mass absorption coefficient [cm$^2$ g$^{-1}$]

$\rho$ = density [g cm$^{-3}$].

Thus, the only method of quantification available is a ratio method in which the intensity ratios of the elements in the fiber are connected with their concentration ratios by a sensitivity factor ($k_{A/B}$)[19]:

$$\frac{c_A}{c_B} = k_{A/B} \cdot \frac{I_A}{I_B}$$

For a specific pair of elements (A and B) this sensitivity factor depends only on the fiber diameter and on the matrix, whereby the influence of the matrix on the main elements of asbestos fibers is slight in comparison with the dependence on the fiber diameter. Well-defined homogeneous standard substances (pure asbestos fibers) must be used for the determination of $k_{A/B}$ as a function of fiber diameter.

The values for a given fiber diameter are used for the analysis of the unknown fibers having the same diameter. The standard substances (chrysotile, crocidolite) are characterized by atomic absorption spectroscopy (AAS).

The accuracy of the analysis is determined above all by the statistical error of the determination of the X-ray intensities and by the accuracy of the reference analysis, *i.e.* by homogeneity of the calibration substances, since with the AAS *ca.* 100 mg of sample analyzed and with is STEM only *ca.* $10^{-12}$ mg.

When all the factors have been taken into account in accordance with the error propagation theorem, a relative analytical error of *ca.* ±25 rel-% is found for the quantitative analysis of the main elements in asbestos fibers *ca.* 200 nm thick. This is in sufficiently good agreement with the reference analyses (AAS) (Table 1).

Table 1. Comparison of the analytical values of asbestos fibers determined by the two methods.

| Methods | $c_{Mg}/c_{Si}$ | $c_{Fe}/c_{Si}$ |
|---|---|---|
| Atomic Absorption Spektrometry (AAS) | 1.040 | 0.096 |
| Scanning Transmission Electron Microscope (STEM) | 0.726 | 0.108 |
| Difference | −30.2% | +12.5% |

STEM analysis thus yields an often sufficiently accurate value for concentration ratios of measurable elements in the fiber and permits the determination of a stoichiometric empirical formula (oxygen is assigned in accordance with the oxidation state of the cations, $H_2O$ or OH are not determinable). This in turn determines (like the intensity ratios themselves) the type of the asbestos, in spite of a considerable mixing range (Table 2).

The identification of asbestos fibers in dust or water samples is supplemented by electron diffraction, which provides typical patterns (especially for chrysotile). This

Table 2. Current types of asbestos: empirical formulas, as well as characteristic concentration and X-ray intensity ratios of the main elements. Exitation energy $E_0 = 40$ keV, current $i_S = 10$ nA, fiber diameter $d = 200$ nm.

| Type of asbestos | Empirical formula | Conc. ratio | Int. ratio |
|---|---|---|---|
| Chrysotile | $Mg_3Si_2O_5(OH)_4$ | Mg : Si = 0.73 | 0.69 ± 0.06 |
| Crocidolite | $Na_2Fe_3^{II}Fe_2^{III}Si_8O_{22}(OH,F)_2$ | Fe : Si = 1.15 | 0.72 ± 0.08 |
| Amosite | $(Mg,Fe^{II})_7Si_8O_{22}(OH)_2$ | Mg : Si = 0.21 | 0.19 ± 0.03 |
| | | Fe : Si = 0.88 | 0.55 ± 0.05 |
| Tremolite | $Ca_2Mg_5Si_8O_{22}(OH,F)$ | Ca : Si = 0.22 | 0.26 ± 0.04 |
| | | Mg : Si = 0.27 | 0.25 ± 0.04 |
| Anthophyllite | $(Mg,Fe^{II})_7Si_8O_{22}(OH,F)_2$ | Mg : Si = 0.31 | 0.29 ± 0.04 |
| | | Fe : Si = 0.41 | 0.26 ± 0.03 |

$k_{Mg/Si} = 1.06 \pm 0.1$; $k_{Fe/Si} = 1.59 \pm 0.18$; $k_{Ca/Si} = 0.81 \pm 0.12$.

permits the construction of a scheme of identification based on a combination of data relating to the fiber's morphology (ratio of length to width), structure (electron diffraction), and elemental composition (Fig. 11).

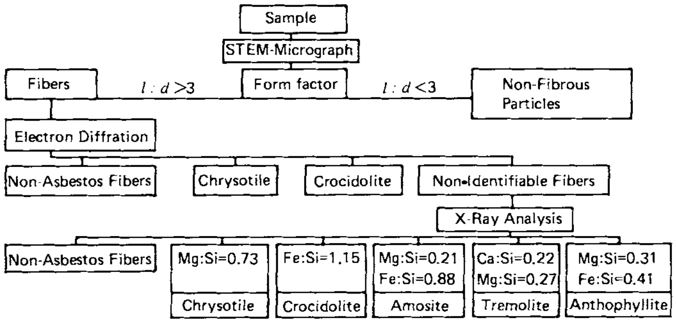

Fig. 11. Identification scheme for asbestos fibers in STEM (Concentration ratios were derived from X-ray-analytical data; l = length, d = diameter).

The quantity of the asbestos fibers, or their concentration, is determined from STEM pictures or stereometric processes. Although this analytical technique is very laborious, it constitutes the only method that yields results of sufficient accuracy for an evaluation of asbestos pollution.

### 3.3. Quantitative Distribution Analysis of Trace Elements

In many branches of materials science, characterization of the distribution of the trace elements (concentrations $\leq 0.01\%$) is one of the essential tasks of analytical chemistry, since trace amounts may exert a decisive influence on the properties of the material (*e.g.* in hard metals or steel), or may yield important information about the system under examination from their quantity and distribution (*e.g.* in the case of geological samples, information can be obtained on the rock-forming processes, age, and geochemical prospecting parameters).

If the trace elements are locally enriched to above *ca.* 0.1—1%, their distribution can be determined with the aid of electron probe microanalysis. Quantitative microdomain analysis gives the local concentration, while a stereometric evaluation, *e.g.* using the principle of X-ray micro-linear analysis or an automated area analysis[20,21] reveals their average content and distribution. In the event of an enrichment of the trace elements on the surfaces of the solid samples surface analysis methods, such as Auger electron spectrometry (AES), X-ray photoelectron spectrometry (XPS), and ion-scattering can be successfully applied. The characterization of the distribution of locally enriched trace elements has already become largely routine.

A distribution analysis of the trace elements when these are not locally enriched is substantially more difficult. The methods then used for the characterization must have, besides a high lateral resolution, a high detection capacity for microdomain analysis. At present, ion probe microanalysis (IPMA) is the most appropriate method for the *in situ* micro-trace analysis of solid samples[22]. This method has a lateral resolution of a few microns, a depth-resolution in the nanometer range, and (for many elements) detection limits of µg/g to ng/g.

In spite of these outstanding characteristics for *in situ* microtrace analysis, only a limited number of problems have so far been solved. This is essentially due to the fact that practical difficulties are encountered, caused primarily by interference between the analytical ions and the molecular ions, and only the present generation of instruments has offered some prospect of eliminating these problems (at least in part). In addition, full details of the interaction between primary ions and solids have not yet been adequately explained, and hence considerable quantification problems still remain for many elements and matrices. The greatest progress has undoubtedly been in the analysis of the distribution of dopants in semiconductors.

Knowledge of the total concentration and the distribution of the dopant elements is of major significance to semiconductor technology. In addition, the total dopant concentration must also be determined. Whereas the concentration of the electrically active fraction determines the maximal current, and the depth distribution of the active fraction determines the amplification factor of a transistor, the inactive fraction influences the diffusion behavior of the dopant elements during manufacture (*e.g.* by cluster formation). For the quite customary high dopant concentrations of more than $10^{21}$ atoms/cm$^3$ (*e.g.* for MOS transistors), the electrically inactive fraction is sometimes several times greater than the active fraction.

For this reason, the mathematical models used today to describe the diffusion behavior are really only accurate for concentrations below $5\times10^{19}$ atoms/cm$^3$[23]. At higher doping levels, the concentration dependence of the diffusion coefficients must first be exactly determined and incorporated into the model. The construction of a sufficiently accurate diffusion model is therefore of significance, because in this way it is also possible to control lateral (x,y-direction) diffusion processes occurring in the thermal treatment of semiconductor components during their manufacture. Because of the small size of the lateral structure ($\leq 1$ µm), analytical characterization of the lateral distribution is practically impossible; yet it is necessary to known this. At present, only the determination of the dopant distribution in planar semiconductors with relatively large surface areas has been determined analytically (*e.g.* implanted Si disks, with or without diffusion treatments).

Characterization of semiconductor components must include a quantitative (depth) distribution analysis of the total dopant concentration, and a separate distribution analysis of the electrically active fraction, since the inactive fraction can be determined only by difference. It is necessary to determine both profiles with a high degree of accuracy (regarding the scales of concentration and depth), and both should cover the widest possible range of concentration. Since the currently customary limits of (local) dopant element concentrations range from *ca.* $5\times10^{21}$ to *ca.* $10^{14}$ atoms/cm$^2$, an extremely wide dynamic range of $5\times10^7$ and very high sensitivity are required.

As an example of the possibilities and limitations of the distribution analysis of trace elements in semiconductors, only the situation with the most important dopants for silicon semiconductors—boron and arsenic—will be described. The analytical characteristics of the most common methods for the analysis of the electrically active fraction and for the total dopant concentration are summarized in Table 3.

Table 3. The most important methods used for the distribution analysis of dopants in semiconductors and their characteristics. NAA = Neutron Activation Analysis.

| Methods | Sensitivity limit [atoms/cm$^3$] | Depth resolution [nm] |
|---|---|---|
| 2-point resistance measurement | $10^{14}$ | 40 |
| 4-point resistance measurement | $10^{17}$-$10^{18}$ | 15 |
| NAA $^{10}B(n,\alpha)^7Li$ | $10^{14}$-$10^{15}$ | 20 |
| NAA $^{75}As(n,\gamma)^{76}As$ | $10^{17}$ | 20 |

The distribution of the electrically active fraction is determined by measuring the surface conductivity. The depth distribution is obtained either by measurements on tapered sections with an angle of inclination of 1° (2-point resistance measurement) or by repeated measurements on a planar sample after chemical dissolution of the topmost layer (*ca.* 10—50 nm) by specific anodic oxidation and with 30% hydrofluoric acid (4-point resistance measurement).

The advantage of 2-point resistance measurements is the high sensitivity ($10^{14}$ atoms/cm$^3$). The disadvantages are the considerable problems associated with the preparation of a polished section with a 1° angle of taper. The 4-point resistance measurement, on the other hand, while being very time-consuming is essentially easy to perform; however, its sensitivity is considerably lower (*ca.* $10^{17}$ atoms/cm$^3$).

Elemental analysis methods can be used to determine the distribution of the total dopant concentration. To date, neutron activation analysis of the dopant element in combination with repeated chemical removal of the topmost layer has been used most frequently for this purpose. Apart from the fact that the method is extremely lengthy, neutron activation analysis (with the usually readily available flux density) does not often have the sensitivity required and the necessary dynamic range of *ca.* $10^7$.

A second possibility is to record the depth profiles by an ion microprobe technique[24-29]. This method has *a priori* the great advantage that the depth profiles can be recorded directly within a short time. However, the depth profiles are given in the form of intensity of the measured secondary ion current *versus* time, and hence must be calibrated. This in turn requires the development of quantification processes characterized by a high degree of accuracy. The second disadvantage until recently was that the sensitivity was not sufficient for some dopant elements.

Progress in direct dopant-distribution analysis only came about as a result of the development of a new generation of instruments (*e.g.* CAMECA IMS-3F) with high primary-ion intensities (a few μA with a beam diameter of 50 μm), more sensitive secondary-ion measurements (focusing of the secondary ions emitted from the sample surface into the entrance slit of the mass spectrometer, and a low-noise detection system), and possibilities of separating the analytical ion (the dopant) from interfering molecular ions (silicon-oxides and -hybrides) by energy filtering or by high-resolution mass spectrometry[30].

Under optimized working conditions it is possible, for example, to measure the depth distribution of boron with the necessary depth resolution of 10 to 50 nm (in the case of profile depths of 500—1000 nm) down to a minimum concentration of $10^{14}$ atoms/cm$^3$ ($\triangleq$ 1 ng/g) (Fig. 12a).

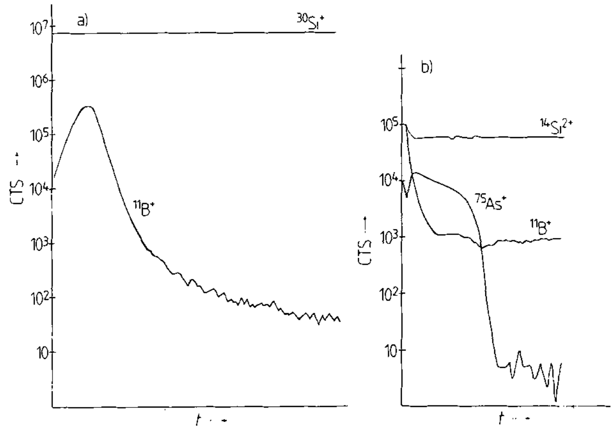

Fig. 12. a) Depth profile of boron in a silicon semiconductor, recorded with the ion microprobe. Primary ions $O_2^+$, primary ion current $i_P = 1000$ nA, excitation energy $E_0 = 10$ keV; $c_B = 5.8 \times 10^{19}$ atoms/cm$^3$, diameter $d = 1800$ nm; b) depth profile of arsenic in a silicon semiconductor, recorded with the ion microprobe. Primary ions $O_2^+$, primary ion current $i_P = 4000$ nA, excitation energy $E_0 = 13.0$ keV; $c_{As} = 4 \times 10^{19}$ atoms/cm$^3$, CTS signifies counts per unit time.

The distribution analysis of As is substantially more difficult, since this ion interferes with a silicon oxide ion ($^{75}As^+$ and $^{29}Si^{30}Si^{16}O^+$). This interference is eliminated by energy-filtering the atomic ion $^{75}As^+$ from the molecular ion, making use of the fact that atomic ions have a broader kinetic energy distribution than molecular ions. By selecting a carefully optimized energy threshold level, the molecular ions can be filtered out before entering the mass spectrometer. Thereby a fraction of the atomic ions (the fraction having energies lying in the range of kinetic energies of the molecule-ions) is also removed and is not measured. Loss of intensity by a factor of *ca.* 20 is, however, counterbalanced by an increase of the dynamic range by a factor of $10^4$.

Using energy filtering in a double-focusing mass spectrometer, a detection limit of *ca.* $10^{16}$ atoms/cm$^3$ ($\triangleq$0.5 μg/g) can be reached for the distribution analysis of As in Si (Fig. 12b). In comparison with the methods of elementaal analysis used up to now, this represents an improvement by a factor of 10-100.

Conversion of the time scale into a depth scale uses the sputter rates that can be calculated for the oxide layer and silicon using ellipsometry and interference microscopy.

In principle, quantification of the intensity axis can be carried out using measurements on an external standard. Sufficiently homogeneous standards of this kind are available for silicon samples, since doping can already be carried out during the manufacture of the single crystal. By normalizing the dopant intensity to a matrix ion ($^{28}Si^{2+}$) it is possible using this method, which corresponds to quantification with relative sensitivity factors, to determine maximum concentrations with an accuracy of *ca.* 5–10 rel-%.

For implanted semiconductor samples use can also be made of the integration method. The integrated intensity of a depth profile is directly proportional to the total dopant concentration. When the implantation dose (total concentration) is known, the proportionality factor can be determined after integration of the profile using a suitable polynomial. With this factor, the depth profile can be calibrated.

This method of integration yields highly accurate depth profiles (error 5—10 rel-%), as shown by comparative determinations with neutron activation analysis and electrical measurements (in this case with negligible cluster formation) (Fig. 13).

In principle, the use of ion beam microanalysis constitutes an essential improvement for characterizing dopants in semiconductors, and hence of *in situ* microtrace analysis in general.

In spite of this, the method still suffers from limitations, *e.g.* regarding the sensitivity towards As and the elimination of the chemical matrix effect. Despite the use of reactive oxygen primary ions, a sharp increase in the yield of secondary ions occurs in oxide layers, which can indicate spurious enrichment of the dopant element in the oxide layer (Fig. 13). One of the essential future tasks will be to improve the existing models for the quantitative determination of the matrix effects, or to develop new models. Since ion-beam microanalysis so far constitutes the only really feasible method for *in situ* trace analysis it is of considerable general significance.

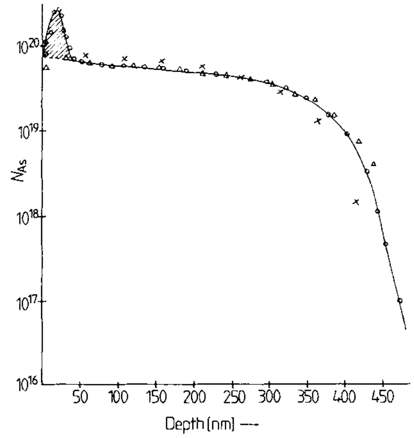

Fig. 13. Distribution of arsenic in a silicon semiconductor: comparison of the quantified IPMA profile (○) with results of electrical measurements and neutron activation analysis. (4 point resistence measurement) (△) and neutron activation analysis (×). The hatched area indicates the signal increase in the oxide layer. IPMA: Primary ions $O_2^+$, primary ion current $i_P = 1000$ nA, excitation energy $E_0 = 10$ keV.

## 4. Summary and Outlook

Advances in the field of physical microanalysis permit increasingly closer insight into the structure of matter. Most of the information necessary for the characterization of properties can be obtained, in the present state of the art, from "ideal" or simple substance systems, but there are still large gaps and problems in the characterization of "real", more complex systems, such as are encountered in most cases in technology. This applies, for example, to the sphere of (extreme) trace analysis of complex mixtures, such as airborne dusts, or to the surface characterization of industrial solids such as catalysts.

Reasons for this is that for many problems adequate methods do not exist and that not all the possibilities of deriving information by a combination of physical and chemical methods have yet been exhausted. The number of analytical laboratories equipped with the necessary instruments is small, even in the most highly industrialized countries.

Moreover, in many cases, the physical, mathematical, or information-theoretical foundations are still inadequately incorporated into the process of obtaining chemical analytical data. The integration of new concepts or of unifying principles, both in analytical chemistry as a whole[31,32] and for substances or partial regions such as surfaces[33], seems to be both sensible and potentially useful. The task of physical methods of analysis in the characterization of solids will further increase in future, above all in the wake of the burgeoning development of new technologies. Particularly important future fields of application will probably be energy research (*e.g.* characterization of photovoltaic solar cells and of materials for fusion reactors), the further development of semiconductor components (*e.g.* thin-film and surface analysis of optoelectronic elements), prospecting for raw materials (*e.g.* the application of "teleanalytical" methods for prospecting on seabeds), and, as ever, environmental questions (compound-specific analysis of physiologically active trace elements).

# COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## $Gd_5Cl_9C_2$: A Structure with Two Condensed Metal Octahedral and Interstitial $C_2$ Groups

By *Arndt Simon, Eberhard Warkentin*, and *René Masse*[*]

The structures of metal rich lanthanoid halides $LnX_y$ $(1 \leq y \leq 2)$ are characterized by the occurrence of isolated and condensed metal clusters[1]. In $Ln_7I_{12}$ $(=Ln_6I_{12}\cdot Ln)$ single octahedral $Ln_6$ clusters are found which are linked to infinite chains, double chains, or layers in the more metal rich compounds.

In the search for new compound types with condensed clusters we obtained the compound $Gd_5Cl_9C_2$. Its structure is surprising in two different ways. On the one hand a novel cluster consisting of two condensed metal octahedra occurs, and on the other an occupation of the octahedral centers of lanthanoid cluster compounds is shown for the first time.

The crystal structure consists of a close packed arrangement of quasimolecular $Gd_{10}Cl_{18}(C_2)_2$ clusters (Fig. 1). The cluster contains two $Gd_6$ octahedra ($d_{Gd-Gd}=321$ to 409 pm) which are connected *via* a common edge. Cl atoms lie in front of unconnected edges, as in the well-known $M_6X_{12}$ clusters ($d_{Gd-Cl}=261$ to 326 pm). The double octahedron is the first step in the condensation of $Ln_6X_{12}$ clusters *via* octahedral edges which—involving only *trans*-edges—leads to a series of general composition $Ln_{2+4n}X_{6+6n}$ (n is the number of $Ln_6$ octahedra involved). From this series only the first member $(n=1)$ and the last $(n=\infty)$ were previously known. The infinite $Ln_2X_3$ chain occurs as structural unit in the compounds $Tb_2Br_3$[2], $Er_4I_5$[3], and in the $Sc_5Cl_8$ type structures[4]. The *trans*-edge linked chain of $M_6X_{12}$ clusters also occurs in $NaMo_4O_6$[5]. Close relations to the clusters $Mo_9Y_{11}$ (Y = chalcogen[6]) exist which contain two face sharing octahedral clusters of the $Mo_6Y_8$ type.

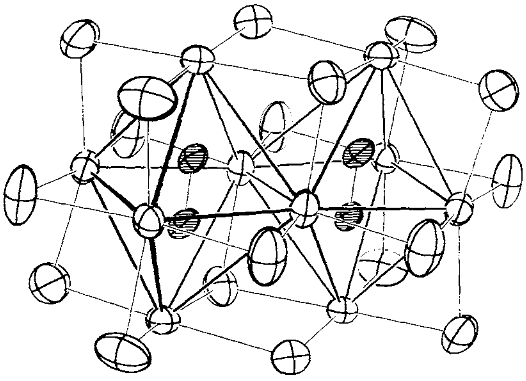

Fig. 1. "Dimeric" $Gd_{10}Cl_{18}C_4$ cluster. The metal atoms of the double octahedron are connected by bold lines; the C atoms are hatched.

Both octahedral centers in the $Gd_{10}Cl_{18}$ cluster are occupied by $C_2$ groups. The distance observed $d_{C-C}=146.5$ pm corresponds to a bond order of between 1 and 2. The distances $d_{Gd-C}$ are 221 pm to the apices and 248 or 266 pm to the atoms in the octahedral bases. A comparable $C_2$ group derived from ethane ($d_{C-C}=148$ pm) has already been found in the large low-symmetry cluster containing twelve metal atoms in the compound $Rh_{12}C_2(CO)_{25}$[7].

$Gd_5Cl_9C_2$ is formed by electrolysis of fused $GdCl_3$ in a graphite crucible (Gd anode, 1020 K, 700 mV) as black crystals which grind to a reddish powder[8]. The synthesis can also be prepared according to $2\,Gd_2Cl_3+GdCl_3+2\,C \rightarrow Gd_5Cl_9C_2$ in welded tantalum capsules at 970 K. The composition is proved by elemental analysis[9a], X-ray fluorescence and X-ray structure analyses[9b].

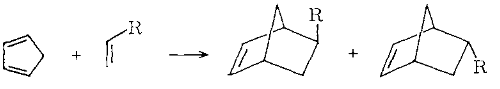
## Diels-Alder Reaction of Cyclopentadiene with Acrylic Acid Derivatives in Heterogeneous Phases

By *Harun Parlar* and *Rotraud Baumann*[*]

In the addition of the acrylic acid derivatives *(1a)*—*(1c)* to cyclopentadiene in homogeneous phases, the isomeric ratio of the products is hardly influenced by solvents or catalysts[1]; for the dienophiles acrolein *(1a)* and methyl acrylate *(1b)*, the ratio of *endo-* to *exo*-adducts is *ca.* 3 : 1, and, in contrast, *ca.* 3 : 2 for acrylonitrile *(1c)*.



*(1)* *(2)* *(3)*

*(a)*, R = CHO; *(b)*, R = $CO_2CH_3$; *(c)*, R = CN

Table 1. Percentage composition of the product mixtures of the Diels-Alder reaction of cyclopentadiene with acrylic acid derivatives absorbed on various activated surfaces. The values in brackets refer to reactions on non-activated surfaces [a].

| *(1)* | Silica gel | | Montigel [b] | | $Al_2O_3$ (neutral) | | Sea sand | | Cellulose | |
|---|---|---|---|---|---|---|---|---|---|---|
| | *(2)* | *(3)* | *(2)* | *(3)* | *(2)* | *(3)* | *(2)* | *(3)* | *(2)* | *(3)* |
| *(a)* | 22.0 | 77.7 | 27.7 | 68.9 | 43.9 | 47.3 | 31.3 | 68.0 | 25.1 | 73.9 |
| | (19.2) | (80.1) | (20.4) | (79.6) | (48.8) | (51.2) | (22.6) | (76.5) | (26.7) | (72.8) |
| *(b)* | 10.5 | 87.5 | 6.6 | 90.7 | 2.9 | 93.7 | 23.5 | 71.1 | 24.3 | 71.4 |
| | (13.2) | (84.3) | (12.9) | (83.4) | (2.8) | (93.8) | (24.2) | (72.2) | (23.6) | (72.5) |
| *(c)* | 32.8 | 50.4 | 25.9 | 67.2 | 37.0 | 60.3 | 37.5 | 59.0 | 36.5 | 57.0 |
| | (35.8) | (60.1) | (32.0) | (65.0) | (38.3) | (58.1) | (38.0) | (57.5) | (36.7) | (58.4) |

[a] In homogeneous phases (2 h at 60 °C), cyclopentadiene and *(1a)*, *(1b)*, or *(1c)* give the following product ratios: *(2a)*:*(3a)* = 24.4 : 75.3; *(2b)*:*(3b)* = 24.2 : 71.5; *(2c)*:*(3c)* = 40.2 : 58.2. [b] Montigel is a natural montmorrillonite.

We have managed to achieve an isomer ratio of almost 1 : 1 in a purely heterogeneous reaction of cyclopentadiene with acrolein *(1a)* on non-activated neutral $Al_2O_3$. In the addition of acrylonitrile *(1c)* to cyclopentadiene on activated Montigel, considerably more *endo*-isomer *(3c)* is formed than in the same reaction under homogeneous conditions. Even more impressive is that the formation of the *exo*-isomer is almost completely blocked in the reaction of methyl acrylate *(1b)* with cyclopentadiene on non-activated $Al_2O_3$ (Table 1). The isomer ratios are almost independent of temperature (40—70 °C). Mutual condensation of the adducts can be excluded, since these are stable under the same reaction conditions.

Measurements of the absorption behavior of the starting materials at a maximal covering density of $10^{15}$ particles/$cm^2$ on a variety of surfaces, over different pressure and temperature ranges, indicate that the chemical composition of the absorbent only influences the covering density to a small extent (the bond strength is 25 kcal/mol); any special interaction of the educt with the surface, which could result in reduction in the intramolecular interactions, is therefore precluded[2]. Presumably, a small fraction of the molecules is strongly adsorbed on the surface. Under these conditions one of the two transition states is stabilized over the other by symmetry-controlled secondary orbital interactions[3].

*Procedure*

Solutions of cyclopentadiene (0.05 mol), prepared by thermolysis of dicyclopentadiene, and of the freshly distilled acrylic acid derivatives (0.05 mol), each in 50 mL of diethyl ether, are taken up successively on 30 mg of one of the carrier substances at 20 °C. After cautious evaporation of the solvent at 35 °C at atmospheric pressure, the heterogeneous mixture is warmed up to 50 °C for 4 h under constant stirring, and subsequently extracted (5 x 200 mL) with acetone in a Soxhlet apparatus over 6 h. After removal of the acetone under reduced pressure, the product mixture is purified by passage through a short silica gel column (silica gel 60, Merck, $l=15$ cm, $d=4$ cm, petroleum ether 60—90 °C). The product mixtures are analyzed by gas chromatography (glass column: 2 m, $d=0.4$ cm, 3% OV 17 on Chromosorb W-AW-DMCS 80—100 mesh, $T=60$ °C, carrier gas: $N_2$, 50 mL/min).

## Electrophilic Addition of a Sulfur, Selenium, and Tellurium Atom as well as of an $SO_2$ Molecule to a Metal-Metal Bond[**]

By *Werner Hofmann* and *Helmut Werner*[*]

We have recently shown that the dinuclear complex *(1)* is nucleophilic[1a]. It reacts rapidly with $CF_3COOH$, even at room temperature, to give the cation *(2)* which has a symmetric, bent CoHCo bridge. The CoCo bond lengths in *(1)* and *(2)* (determined as $BPh_4$ salt) are closely similar [*(1)*: 2.544 Å; *(2)*: 2.517 Å][1b]. This indicates that the metal-metal interaction is little influenced by the protonation,

---

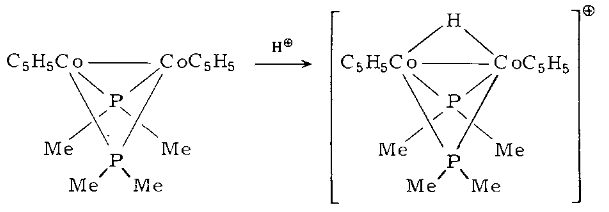
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

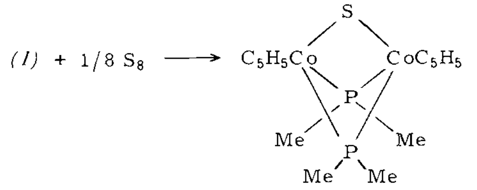
[**] Basic Metals, Part 26. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and, through a gift of chemicals, by BASF AG, Ludwigshafen. *E. Wittmann* is thanked for experimental work.—Part 25: *R. Feser, H. Werner,* Angew. Chem. *92,* 960 (1980); Angew. Chem. Int. Ed. Engl. *19,* 940 (1980).

and that the electronic interaction in the $Co_2H$ moiety can be described by a cyclic (3c,2e) bond.



(1) (2)

Rupture of the Co—Co bond should occur if the electrophile *El* added to *(1)* possesses free electrons available for bonding which can form two covalent M—*El* bonds with the electrons of the metal-metal bond. Atoms of main group VI satisfy this prerequisite. Thus, *(1)* reacts with cyclooctasulfur, under similar conditions as with $CF_3COOH$, to give the dinuclear complex *(3)*. The composition is confirmed by elemental analysis and mass spectra.

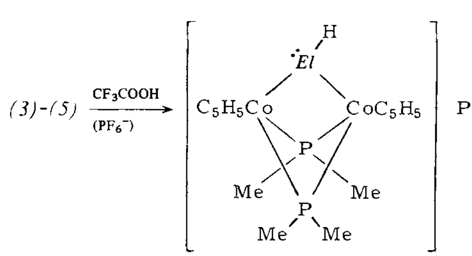


(3)

The selenium and tellurium compounds *(4)* and *(5)* are obtained analogously, but are formed considerably slower than *(3)* so that good yields are only obtained using a large excess of Se or Te, respectively. Gray selenium reacts more rapidly than the black allotrope with *(1)*.

$$(1) + 1/n\mathit{El}_n \rightarrow (C_5H_5Co)_2(\mu\text{-}PMe_2)_2(\mu\text{-}\mathit{El})$$
*(4)*, *El* = Se; *(5)*, *El* = Te

The bridge-forming chalcogen atoms in *(3)—(5)* are nucleophilic. In consequence, the dinuclear complexes react with $CF_3COOH$ upon addition of $NH_4PF_6$ to give the red-brown, air-stable salts *(6)—(8)* which show the conductivity of 1 : 1-electrolytes in nitromethane. To the best of our knowledge this is the first example of a dinuclear transition-metal compound with a bridging TeH ligand[2].



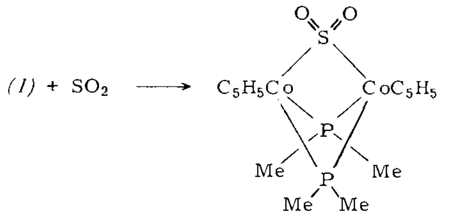
(6), *El* = S
(7), *El* = Se
(8), *El* = Te

Addition of a methyl cation to the chalcogen bridge is also possible. For example complex *(9)*, which forms from *(5)* and methyl iodide even at room temperature, was synthesized.

$$(5) + CH_3I \rightarrow [(C_5H_5Co)_2(\mu\text{-}PMe_2)_2(\mu\text{-}TeCH_3)]I$$
*(9)*

The ¹H-NMR spectra of the cations of *(8)* and *(9)* (Table 1) indicate that a lowering of the symmetry results from protonation or methylation, *i.e.* the chalcogen atom of the *El*H- or $\mathit{El}CH_3$-bridge is coordinated pyramidally and not in a trigonal planar fashion. In contrast to *(7)* and *(8)*, *(6)* shows only two NMR signals for the $PMe_2$ protons at room temperature, indicating a rapid inversion process at sulfur. The rate of this process decreases along the series S > Se > Te and follows the trend expected from the position of these elements in the periodic table.

The nucleophilicity of *(1)* is also demonstrated by its rapid reaction with $SO_2$ to give *(10)*. The black-brown, air-stable crystals are considerably less soluble than *(1)* in nonpolar solvents, which is in accord with the expected higher polar character of the (μ-$SO_2$) complex.



(10)

The reactivity of dinuclear transition-metal complexes having a metal-metal *double bond* with electrophiles, particularly with $CH_2$ and carbenes, has recently been investigated for the rhodium complex $[C_5Me_5Rh(\mu\text{-}CO)]_2$ by ***Hermann et al.***[3a], ***Shapley et al.***[3b], and ***Stone et al.***[3c]. Reactions of this compound with sulfur, selenium, tellurium, or $SO_2$ have not been studied. According to ***Balch et al.***[4a] and ***Brown et al.***[4b], the dinuclear complexes $[ClM(\mu\text{-}dpm)]_2$ (M = Pd, Pt; dpm = $Ph_2PCH_2PPh_2$), which contain an M—M *single bond*, are able to add a sulfur atom and $SO_2$. On the basis of our results obtained to date, we presume that *(1)*—and possibly also the analogous compounds $[C_5H_5Co(\mu\text{-}PPh_2)]_2$[5] and $[C_5H_5Co(\mu\text{-}SMe)]_2$[6]—have a similarly marked reactivity as the above mentioned palladium and platinum complexes towards electrophiles. The activation of small molecules by coordination to *two* metal centers is, above all, in catalysis[7]—particularly in model studies of the Fischer-Tropsch synthesis[8]—of current interest.

Table 1. ¹H-NMR data of complexes *(3)—(5)* and *(8)—(10)* (δ-values, TMS int.; *J* in Hz).

| Complex | Solvent | $C_5H_5$ | μ-$PMe_2$ δ | *J* (PH) | μ-*El*R |
|---|---|---|---|---|---|
| *(3)* | $C_6H_6$ | 4.40 s | 2.45 vt [a] | | |
| | | | 1.47 vt [b] | | |
| *(4)* | $C_6H_6$ | 4.37 s | 2.50 vt [a] | | |
| | | | 1.46 vt [b] | | |
| *(5)* | $C_6H_6$ | 4.37 s | 2.61 vt [a] | | |
| | | | 1.40 vt [b] | | |
| *(8)* | $CD_3NO_2$ | 4.94 s | 2.36 d (6 H) | 12.0 | [c] |
| | | | 1.94 d (12 H) | 11.0 | |
| | | | 1.83 d (6 H) | 11.0 | |
| *(9)* | $CD_3NO_2$ | 4.74 s | 1.88 d (6 H) | 12.0 | 1.70 [d] |
| | | | 1.85 d (12 H) | 12.0 | |
| | | | 1.64 d (6 H) | 12.0 | |
| *(10)* | $CD_3NO_2$ | 4.39 s | 2.50 vt [a] | | |
| | | | 1.85 vt [b] | | |

[a] *N* = 14.0 Hz. [b] *N* = 12.0 Hz. [c] Signal covered by $PMe_2$ signals. [d] Signal overlaps with the signals of the $PMe_2$ protons.

## *Procedure*

*(3)—(5)*: A solution of *(1)* (1.97 g, 5.3 mmol) and $S_8$ (172 mg, 0.67 mmol) in 25 mL of $C_6H_6$ is stirred for 1 h at room temperature. The solvent is completely removed *in vacuo*,

the residue extracted with tetrahydrofuran (THF), and the product precipitated with hexane. Purification occurs by column chromatography on silica gel using ether. *(3)*, red-brown crystals, decomp. = 116—118 °C, yield 1.19 g (53%).—For the preparation of *(4)* a five-fold excess of selenium, and for the preparation of *(5)* a 25-fold excess of tellurium, is used (both finely ground). The reaction times are 36 h (Se) and 48 h (Te), respectively. *(4)*, red-brown crystals, decomp. = 135 °C, yield 55%; *(5)*, red-brown crystals, decomp. = 170 °C, yield 50%.

*(10)*: A solution of *(1)* (432 mg, 1.17 mol) in 5 mL of $C_6H_6$ is stirred for 5 min in an atmosphere of $SO_2$. The solvent is completely removed *in vacuo* and the residue recrystallized from THF/hexane. *(10)*, black-brown crystals, m.p. = 176 °C—178 °C, yield 380 mg (75%).

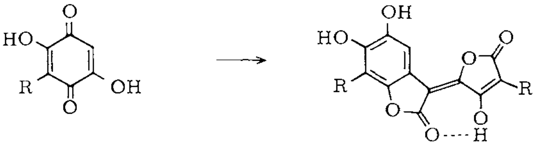
# Polyamide-Catalyzed Dimerization of 2,5-Dihydroxybenzoquinones to 4-Ylidenetetronic Acids; a Model for the Biosynthesis of Bovilactone-4,4[**]

By *Erhard Jägers* and *Wolfgang Steglich*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

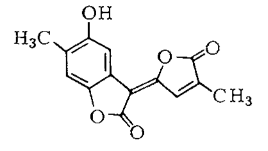
The fungal pigments bovilactone-4,4 *(2b)*[1a] and variegatorubin[1b] contain a 4-ylidenetetronic acid chromophore[2] (tetronic acid is 3-hydroxy-2-butene-4-olide). We found that the parent compound *(2a)* could be readily synthesized by heating 2,5-dihydroxybenzoquinone *(1a)* with acetylated polyamide-6 in inert solvents. The dilactone *(2a)*[3] was obtained in 68% yield after 2 d by performing the reaction in boiling ethyl acetate. Hereby, 17% unconverted *(1a)* could be reisolated, which in the more rapid dimerization with polyamide-6 powder [(10 h, 68% *(2a)*] is impossible because of irreversible bonding to the polymer[4]. Performing the reaction with acylated polyamide at room temperature resulted in the isolation of 8% *(2a)* after stirring for 14 d.



*(1a)*, R = H
*(1b)*, R = Geranylgeranyl

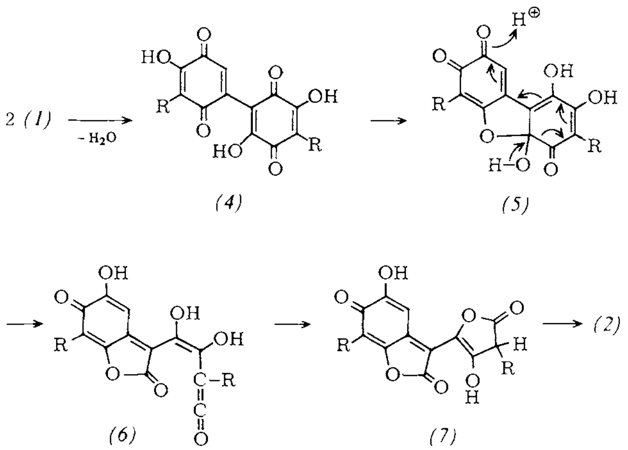
*(2a)*, R = H
*(2b)*, R = Geranylgeranyl

The absorption spectrum of *(2a)* is consistent with that of the dilactone *(3)*[3] prepared by *Posternak*[5]; careful analysis of the ¹³C-NMR spectrum confirms the given constitution[1a].



*(3)*

The initial step in the formation of *(2a)* is presumed to be condensation of *(1a)* to give the dibenzoquinone *(4)*, which then undergoes a Posternak rearrangement[5]. Thereby, the dienone *(5)*, the ketone *(6)*[6], and the tautomer *(7)* can be formulated as intermediates.



*(4)* *(5)*

*(6)* *(7)*

The nature of the polyamide catalysis is still unknown. Since the dimerization also proceeds with freshly reacetylated acetylated polyamide, the activity cannot only stem from basic centers. In this connection it is interesting to observe that *(2a)* is slowly formed when *(1a)* is heated in organic solvents with the difunctional catalyst 2-pyridone[7], but not upon addition of triethylamine, piperidine, or hydrochloric acid.

The mutual occurrence of *(2b)* and boviquinone-4 *(1b)*[8] in the sporophores of *Suillus bovinus* allows one to presume that the reaction course proposed is also of importance in the biosynthesis of *(2b)*. In fact, *(2b)* is obtained in a smooth reaction by boiling *(1b)* with polyamide-6 in ethyl acetate; a turnover of up to 28% requires 3 d[9].

## *Procedure*

A solution of *(1a)* (0.56 g) in 15 mL of ethyl acetate is refluxed for 2 d with acetylated polyamide-6 (MN-polyamide SC 6-AC, Macherey & Nagel, Düren). After evaporation of the solvent and extraction of the residue with ethyl acetate in a Soxhlet apparatus, 0.079 g of unreacted *(1a)* is reisolated together with 0.35 g of *(2a)* upon chromatography on acetylated polyamide using ethyl acetate.

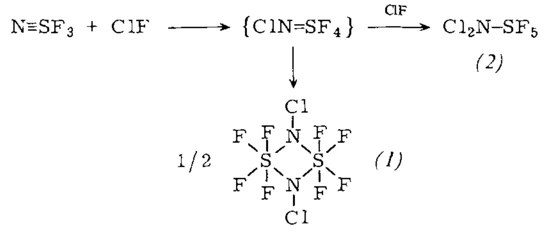
## Dimeric *N*-Chloroiminosulfur Tetrafluoride, a Cyclodiaza-λ$^6$-thiane with Hexacoordinated Sulfur[**]

By *Alfred Waterfeld* and *Rüdiger Mews*[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

The previously known cyclodiaza-λ$^6$-thianes[1] contain exclusively tetracoordinated sulfur atoms. However, by reacting $NSF_3$ and ClF we were able to isolate the novel cyclodiaza-λ$^6$-thiane *(1)* with hexacoordinated sulfur atoms, in addition to the previously described product of this reaction, *N,N*-dichloroaminosulfur pentafluoride *(2)*[2].



Whether the four-membered heterocycle is formed by direct dimerization of the *N*-chloroaminosulfur tetrafluoride or *via* ionic intermediates is still at present not clear. *N*-alkylaminosulfur tetrafluorides, such as *e.g.* $CH_3NSF_4$, do not dimerize[3].

The colorless compound *(1)* melts at 4 °C, and its vapor pressure at 20 °C is 7 torr. Whereas *(1)* decomposes in glass vessels at room temperature, it appears to be stable in passivated metal flasks.

*(1)* was characterized by elemental analysis and spectroscopic methods. Apart from the molecular ion at *m/z* 314 (36%), the EI mass spectrum (70 eV, cold source) shows peaks from the fragments $(M-ClF)^+$ 260 (20), $ClNSF_4^+$ 157 (85), $ClNSF_3^+$ 138 /34), $SF_5^+$ 127 (40), $NSF_3^+$ 103 (12), $SF_3^+$ 89 (100). In the FI mass spectrum, a peak for $(M-ClF)^+$ was found in addition to that of $M^+$. The IR and Raman spectra exhibit no coincidences[4], and hence the molecule is probably centrosymmetric with a *trans*-orientation of the two chlorine atoms. The NMR data can be interpreted using an $A_2B_2$ system as a simplification: $\delta(F_A) = 76.1$, $\delta(F_B) = 49.4$, $J(AB) = 140.8$ Hz.

### *Procedure*

ClF (22.9 g, 0.42 mol) and $NSF_3$ (21.8 g, 0.212 mol) are condensed into a Monel cylinder at −196 °C. The reaction mixture is slowly warmed up to −78 °C, and then to room temperature (Care! Warming too rapidly leads to violent explosions). Fractional condensation (−50, −95, −196 °C) using an oil-pump vacuum yields *(1)* (1.2 g, 3.6% yield) in the first cold trap and *(2)* (5.3 g, 11.8%)[2], together with small amounts of impurities[5], in the second.

## Cyanation of Tertiary Alkyl Chlorides: A Novel Method for the Geminal Dialkylation of Ketones[**]

By *Manfred T. Reetz* and *Ioannis Chatziiosifidis*[*]

The ambidentate cyanide ions[1] react with $S_N2$-active primary and secondary alkyl halides at the C atom to form nitriles[4] in accord with the Kornblum rule[2] and the HSAB principle[3]. In the case of tertiary alkyl halides only elimination of HX is observed[5]. Under $S_N1$ conditions, *N*-alkylation occurs *via* the Ritter reaction[6]. In order to solve the classic problem of the cyanation of tertiary alkyl halides [*(1)*→*(3)*], we reacted these with the readily accessible trimethylsilyl cyanide[7] *(2)* in the presence of catalytic amounts of $SnCl_4$.

$$\underset{(1)}{R_3C{-}Cl} + \underset{(2)}{(CH_3)_3SiCN} \xrightarrow{SnCl_4} \underset{(3)}{R_3C{-}CN} + \underset{(4)}{(CH_3)_3SiCl}$$

As shown in Table 1, the desired tertiary nitriles are readily obtained. Noteworthy is the CC coupling reaction of *exo*-2-chloro-2-methylnorbornane *(1j)*, which leads to the *exo*-nitrile *(3j)* with 100% stereoselectivity. Furthermore, the strict chemoselectivity in the reaction of *(5)* is notable: the tertiary nitrile *(6)* is formed exclusively.

The present CC coupling reaction is of synthetic interest, because the products can be variously modified *e.g.* by Grignard addition or reduction, leading to the otherwise

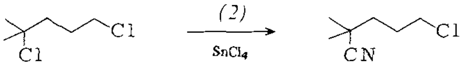
Table 1. Cyanation of *tert*-alkyl chlorides.

| *tert*-Alkyl chloride | Nitrile | Yield [a] [%] |
|---|---|---|
| 2-Chloro-2-methylpropane *(1a)* | 2-Methyl-2-propacarbonitrile *(3a)* | 75 (64) |
| 2-Chloro-2-methylbutane *(1b)* | 2-Methyl-2-butacarbonitrile *(3b)* | 80 (75) |
| 2-Chloro-2-methylheptane *(1c)* | 2-Methyl-2-heptacarbonitrile *(3c)* | 78 (70) |
| 5-Chloro-5-methylundecane *(1d)* | 5-Methyl-5-undecacarbonitrile *(3d)* | 80 (70) |
| 1-Chloro-1-methylcyclopentane *(1e)* | 1-Methylcyclopentacarbonitrile *(3e)* | 75 (67) |
| 1-Chloro-1-ethylcyclopentane *(1f)* | 1-Ethylcyclopentacarbonitrile *(3f)* | 87 (82) |
| 1-Chloro-1-methylcyclohexane *(1g)* | 1-Methylcyclohexacarbonitrile *(3g)* | 60 (38) |
| 1-Chloro-1-methylcycloheptane *(1h)* | 1-Methylcycloheptacarbonitrile *(3h)* | 85 (76) |
| 1-Chloro-1-methylcyclododecane *(1i)* | 1-Methylcyclododecacarbonitrile *(3i)* | 75 (60) |
| *exo*-2-Chloro-2-methylnorbornane *(1j)* | *exo*-2-Methyl-2-norbornacarbonitrile *(3j)* | 90 (84) |

[a] The values reflect the $^1$H-NMR spectroscopically estimated amounts; the data in brackets are the yields of isolated products. The structures of all products were confirmed analytically and spectroscopically.

not easily accessible neopentylamines. Since tertiary alkyl halides are *inter alia* conventionally accessible from ketones, the cyanation also provides a novel method for geminal dialkylation of ketones[8,9].



*(5)* *(6)*, 72%

### *Procedure*

$SnCl_4$ (25 mol%) is added slowly to a constantly stirred solution of the *tert*-alkyl chloride (10 mmol) and trimethylsilyl cyanide *(2)* (13 mmol) in 30 mL of anhydrous $CH_2Cl_2$ at room temperature under $N_2$. After 24—38 h the solution is poured onto ice-water and shaken vigorously. The organic phase is separated off, the aqueous phase washed twice with $CH_2Cl_2$, and the combined organic phases washed with a 10% solution of $NaHCO_3$. The solution is dried over $Na_2SO_4$, concentrated, and either distilled or recrystallized.

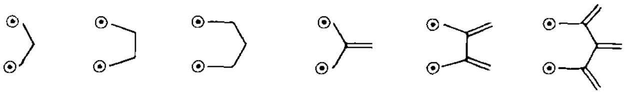
## First Detection of a π-Coupled 1,5-Diradical *via* Cycloaddition[**]

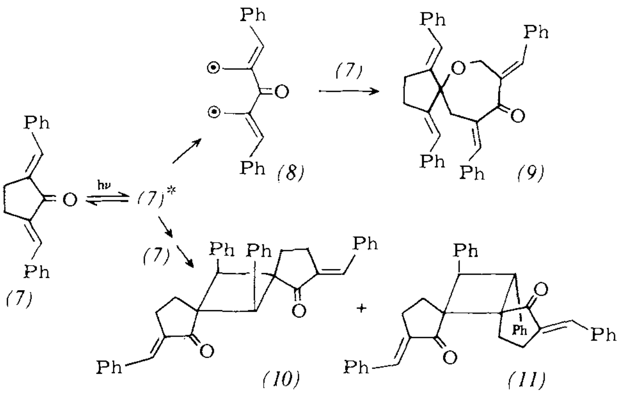
By *Gerd Kaupp* and *Inge Zimmermann*[*]

Diradicals such as *(1)*, *(2)*, *(3)*[1], *etc.* establish a homologous series. This has to be differentiated from a homologous series of π-coupled diradicals *(4)*[2], *(5)*[3], *(6)*, *etc.* We report on a cycloaddition of the first π-coupled 1,5-diradical. Thus, the formation and cycloaddition of *(8)* to a keto group competes favorably with [$2\pi+2\pi$]-dimerizations of electronically excited *(7)*.



*(1)* *(2)* *(3)* *(4)* *(5)* *(6)*

Irradiation of the crystalline dienone *(7)*, which is readily accessible from cyclopentanone and benzaldehyde, and which is used as a cosmetic light protection agent (UV-A range)[4], results in formation of the spiroheterocyclic compound *(9)* *via* cleavage of the five-membered ring and subsequent cycloaddition to the C=O-bond of a second molecule of *(7)*. Furthermore *(7)* dimerizes *via* the exocyclic double bonds to give the dispirocyclobutanes *(10)* and *(11)*. The product ratios *(9)*:*(10)*:*(11)*$=26:38:8$ do not change, whether or not *(7)* is crystallized slowly from methanol, or rapidly from dichloromethane, and whether or not air is excluded during irradiation. However, neither *(9)* nor *(10)*, but almost exclusively the head to head dimer *(11)* is formed in solution (dichloromethane; $\lambda > 380$ nm)[5] upon irradiation of *(7)*.



The structures and compositions of the dimers *(9)*, *(10)* (with mirror symmetry), and *(11)* (with rotational symmetry) were established by elemental analyses as well as by IR-, UV-, and $^1$H-NMR spectra (see Table 1). *(10)* and *(11)* are characteristically different from their centrosymmetric stereoisomer[6].

It is unusual that several products are stereoselectively formed with comparable yields upon irradiation of crystalline *(7)* (cf. *e.g.*[6]; further products which appeared in yields of <4% were not investigated). The formation of *(9)*,

[a] Centrosymmetric stereoisomer of *(10)* and *(11)*: M.p. = 250.5—251.5°C; δ = 7.34 (22H, m); 4.50 (2H, s); 3.1—2.6 (6H, m); 2.0—1.5 (2H, m) [6].

which gives preparatively good yields, is the first example of addition of a π-bond to a σ-bond of a five-membered ring. Usually such $[2\sigma+2\pi]$-additions proceed only if cyclopropane derivatives are involved, *via* intermediates of type *(1)* or *(4)*[2,7]. Therefore, it should be pointed out that upon light absorption the short-lived diradical *(8)* is formed in proximity to trapping molecules *(7)*, which are apparently favorably oriented. There is no interfering solvation envelope which has to be penetrated prior to the trapping by *(7)* to produce *(9)*. This, and the fact that no solid-state *E*/*Z*-isomerizations are observed suggest that further (also homologous) intermolecular additions of diradicals to double bonds upon irradiation of suitable crystals should be investigated. These should include intermolecular $[2\sigma+2\pi]$-additions of alkenes to non-additionally strained cyclopropane derivatives[1d,2], or to cyclopropane itself, which failed in solution.

### *Procedure*

*(7)* (1.04 g, 2.0 mmol) is evenly spread on the inner wall of a mirrored Dewar vessel (diameter 14 cm, height 20 cm) with some dichloromethane. After heating to 80°C for 1 h the crystalline film is irradiated from within for 3.5 h at 30-35°C using a mercury high-pressure lamp (Hanovia, 450 W) through a 5% solution of benzophenone in benzene (5 mm; λ > 380 nm). From the $^1$H-NMR-analysis are formed 400 mg (38%) *(10)*, 275 mg (26%) *(9)*, and 85 mg (8%) *(11)*. By preparative TLC (200g SiO$_2$, dichloromethane) and by crystallization (1,2-dichloroethane, toluene, and methanol, resp.) these products are isolated, purified, and separated from 190 mg (18%) of unreacted *(7)* and by-products.

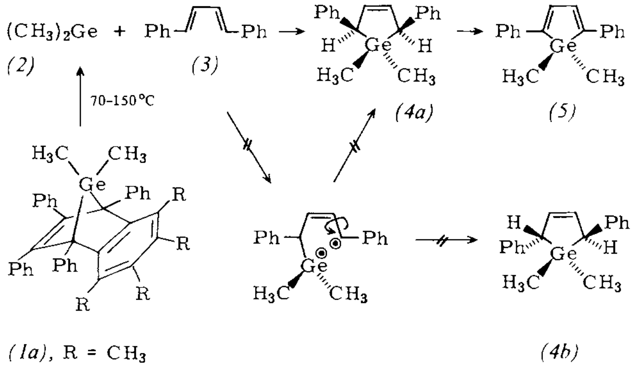
# Carbene-Analogous Germylenes (Germandiyls): Singlets or Triplets?— The First Stereospecific Cycloadditions of $R_2Ge$ to Conjugated Dienes[**]

By *Michael Schriewer* and *Wilhelm P. Neumann*[*]

Singlet carbenes add stereospecifically, triplet carbenes non-stereospecifically to olefins. Much less is known about silylenes $R_2Si$ in this respect, discussions are still continuing[2]. No experiments, however, have been reported concerning the singlet-triplet problem of germylenes $R_2Ge$ until now.

The smooth thermal generation of 7-germanorbornadienes, *e.g.* *(1)*, enables germylenes to be obtained at 70—150°C[3]. We now examined whether germylenes obtained in this way *e.g.* dimethylgermylene *(2)* reacts as a singlet or triplet in 1,4-additions to conjugated dienes[4].

Reaction of *(2)* with (*E,E*)-1,4-diphenylbutadiene *(3)* gave exclusively the *cis*-adduct *(4a)* (Table 1), whose dehydrogenation leads to *(5)*. The *trans*-isomer *(4b)* is not formed. The isomerization *(4a)* ⇌̸ *(4b)* is observed only upon UV irradiation of pure *(4a)*.



Similarly, pure (*E,E*)-3,4-diphenyl-2,4-hexadiene *(6)* and *(2)*, generated from *(1a)*, give only the *cis*-product *(7a)* (Table 1) and no detectable amounts of the *trans*-isomer *(7b)*.

The stereospecific preparation of *(4b)* or *(7b)*, respectively, starting from the corresponding (*Z,E*) isomers *(3)* or *(6)* was unsuccessful. The use of (*E,Z*)-1-phenyl-1,3-pentadiene also gave no reaction.

---

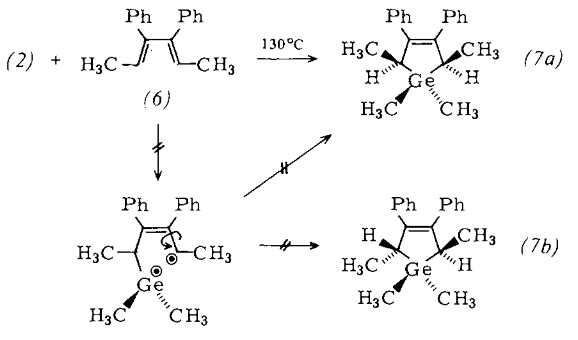
[a] Somewhat broadened.

Unequivocal proof was made with the isomer-free *meso*-diallene *(8a)*[5]. Under mild conditions it reacts to give only the *(Z,Z)/(E,E)*-pair of isomers *(9a/9b)* (Table 1) as expected for a thermal [2+4]-cheletropic reaction of the germylene. The addition is disrotatory and is not influenced by steric hindrance of the phenyl groups since approach from both sides (routes *a* and *b*) is almost equally favored. The isomer *(9c)*, which should also be found in a stepwise addition *via* an intermediate biradical, was not found.



In this case a cross-check was successful: We prepared the previously unknown D,L form of the diallene *(8b)*, which gave exclusively the *(Z,E)* isomer *(9c)* (isomeric purity ≥98%, Table 1).

We therefore concluded that the dimethylgermylene *(2)*, generated thermally, reacts as a singlet species $^s(CH_3)_2Ge$: that is with paired electrons.

This conclusion is in accordance with the results of quantum chemical calculations, from which the singlet states for $H_2Ge$ and $(CH_3)_2Ge$ are lower in energy than the triplet states by 19 and 14 kcal/mol, respectively[6,7]. $H_2Sn$[6] and $H_2Si$[8] are also found to be more stable in the singlet state, whereas for the carbenes $H_2C$ and $(CH_3)_2C$ the ground state is the triplet state[1].

### *Procedure*

All experiments are carried out under argon. All reaction mixtures were checked ($^1$H-NMR) whether the corresponding isomers are present or not.

*(4a)*: *(1a)* (2.75 g, 4.6 mol) and *(3)* (2.30 g, 10 mmol) are heated for 1.5 h at 150 °C. After cooling, the mixture is pulverized and stirred for 0.5 h with 25 mL of EtOH. The filtrate is evaporated to half its volume *in vacuo* and residual *(3)* precipitates out, followed by 0.50 g (30%) of pure *(4a)* as colorless crystals (m.p. = 52 °C) upon cooling in a $CO_2$ bath. A further 50% (still impure) was obtained.

*(5a)*: A sample of *(4a)* is stirred in benzene with an equimolar amount of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone for 15 min at 25 °C, yielding *(5)* which is precipitated from $CH_2Cl_2$ with EtOH; m.p. = 128 °C[9].

*(7a)*: Prepared by analogy to *(4a)* from *(1a)* (2.0 g, 3.4 mmol) and *(6)* (2.3 g, 10 mmol) for 3 h at 130 °C. After evaporation of the EtOH filtrate, the residue is dissolved in a little $CH_2Cl_2$, and residual *(6)* is trapped as its adduct by adding tetracyanoethylene (NMR). Chromatography on a silica gel layer (pentane/$Et_2O$ 19 : 1) gives *(7a)* (from MeOH), m.p. = 65 °C; yield 100 mg (pure product).

*(9a)+(9b)*: *(1b)* (1.5 g, 2.8 mmol) and *(8a)* (1.1 g, 4.3 mmol) are heated for 3 h at 70 °C in 10 mL of anhydrous benzene and then almost evaporated to dryness *in vacuo*. The residue is taken up in 10 mL of pentane, filtered through 10 cm silica gel, evaporated to two thirds, and mixed with the same volume of EtOH. Upon cooling, *ca.* 300 mg *(9a)+(9b)* precipitates out (58% : 42%) in 3 fractions, the first being almost pure *(9a)*.

*(9c)* is synthesized analogously to *(9a)+(9b)* from *(1b)* and *(8b)*. *(8b)* is prepared analogously to *(8a)*[5] from *(Z,E)*-2,5-diphenyl-2,4-hexadiene and characterized by the $^1$H-NMR of its $SO_2$ adduct.

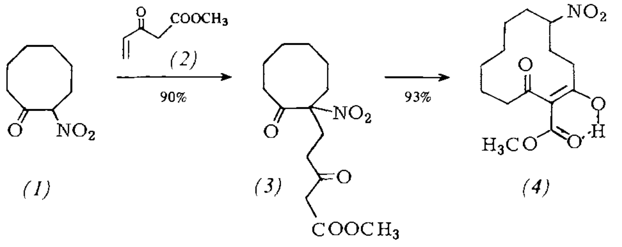
## The Carbon Zip Reaction: A Method for Expanding Carbocycles[**]

By *Yoshihiko Nakashita* and *Manfred Hesse*[*]

We have previously reported the ring expansion of *N*-alkylated lactams *via* the Zip reaction[1]. Using this reaction we have now also been able to expand carbocycles. The reaction principle, which has already been demonstrated in open-chain systems[2], is also applicable to cyclic systems for use in ring expansions, as exemplified here by an eight-membered ring: cyclooctanone was reacted with amyl nitrate, in the presence of K-*tert*-butoxide, to give 2-nitrocyclooctanone *(1)*[3].



Reaction of *(1)* with methyl 3-oxo-4-pentenoate *(2)*[4] in the presence of tetrabutylammonium fluoride (TBAF) in tetrahydrofuran (THF) yielded the Michael condensation product *(3)*, which in $CDCl_3$ is present mainly as the keto form[5]. Treatment of *(3)* with TBAF in THF (30 min, 0 °C/7 h, 20 °C) produced methyl 2-hydroxy-5-nitro-12-oxo-1-cyclododecenecarboxylate *(4)* (colorless needles from ethyl acetate/hexane) [m.p. = 81.1-81.8 °C; IR (KBr): 1678, 1652, 1580, and 1548 $cm^{-1}$]. The $^1H$-NMR spectrum indicates that four conformers are present [$\delta = 13.34 + 13.32$ (*ca.* 0.5 H) + 13.28 + 13.26 (*ca.* 0.2 H) dd-like, enol H; 4.97-4.50 (*ca.* 0.6 H) and 4.40-3.97 (*ca.* 0.4 H), 2 m, H-5; 3.9-3.7 (1 main signal at $\delta = 3.83$ and 4 smaller signals), $CH_3$]. The EI mass spectrum of *(4)*, like those of analogous compounds (cf. [2]), is not highly informative [$M^{+\cdot}$: $m/z$ 299 ($\ll 1$ rel%)]. The structure *(4)* was confirmed by X-ray structure analysis (Fig. 1).

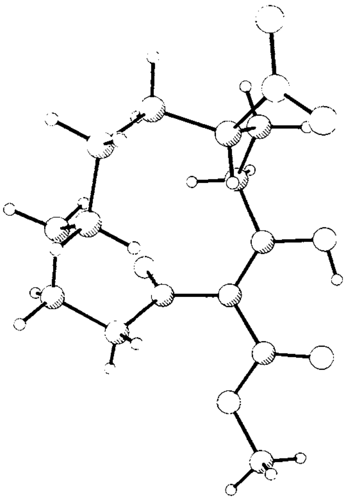


Fig. 1. Structure of *(4)* in the crystal [6].

The method described here is generally suitable for the synthesis of ring compounds by expansion[7].

## Isobenzofulvene[**]

By *Gerhard Gross, Reinhard Schulz, Armin Schweig*, and *Curt Wentrup*[*]

In spite of several attempts[1] to prepare the parent isobenzofulvene (2-methylene-2*H*-indene) *(4)*, the molecule has never been directly observed. We now report the preparation and characterization of this long-sought compound[2].

2-1*H*-Indenylmethyl acetate *(2)* was obtained by flow pyrolysis of the diacetate *(1)*[3] through a 30 × 2 cm quartz tube at 550 °C using $N_2$ as carrier gas (1.8 torr). Flash vacuum pyrolysis of either *(1)* or *(2)* at 650 °C ($10^{-4}$ torr) resulted in a blue compound collected on a cold finger (−196 °C). The blue color disappeared on warming to *ca.* −100 °C, and after opening the apparatus, acetic acid and a mixture of $C_{20}H_{16}$ dimers could be isolated. The major dimer[4a] was purified by preparative layer chromatography and identified as the *endo*-dimer *(3)* from its $^1H$-NMR spectrum[1e].

When the flash pyrolysis of either *(1)* or *(2)* was carried out at temperatures above 700 °C, naphthalene *(5)* was obtained together with the blue compound and its dimers. At 800 °C the product was almost exclusively naphthalene.

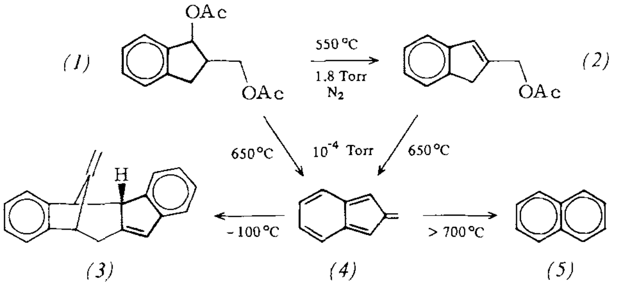
[**] Part 94 of "Theory and Application of Photoelectron Spectroscopy". This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 93: *J. Kreile, A. Schweig, W. Thiel*, Chem. Phys. Lett. *79*, 547 (1981).

The same result was obtained when at 650 °C the pressure was increased using $N_2$ as carrier gas (*i.e.* increased contact time). These results indicate that the blue compound is isobenzofulvene *(4)* which isomerizes to naphthalene at elevated temperatures in the gas-phase, and dimerizes to *(3)* at low temperatures in the condensed state. When the products of the 650 °C flash pyrolysis were led directly into the source of a mass spectrometer, the spectrum of a compound $C_{10}H_8$ ($m/z$ 128 base peak) was obtained[4b].



Direct identification of the blue $C_{10}H_8$ compound as isobenzofulvene was achieved using variable temperature photoelectron spectroscopy (VTPES)[5a]. In this case *(2)* was pyrolyzed immediately above the ionization region of a photoelectron spectrometer (*ca.* $5\times10^{-2}$ torr, contact time *ca.* 0.1 s[5b]) and the spectra recorded as a function of temperature. Figure 1a shows the spectrum of the starting material *(2)* at 25 °C with prominent $^2A''(\pi)$ bands at 8.18 and 8.95 eV (vertical IP's) characteristic of indenes. Figure 1b gives the spectrum of the 590 °C pyrolyzate which, apart from bands due to *(2)*, shows a new low-energy band at 7.32 eV. Attempts to remove the starting material *(2)* by further temperature increase (> 650 °C) resulted in formation of *(5)* as indicated by the appearance of a sharp band at 8.15 eV. The spectrum of the pure new compound *(4)* between 7 and 10.5 eV was obtained by spectral subtraction[6] and is shown in Figure 1c (the spectrum beyond 10.5 eV is inaccessible due to the presence of acetic acid). On the basis of LNDO/S-PERTCI spectral calculations[7a,b,c] using a molecular geometry optimized with MNDO[7d] (Fig. 2), and comparison with the photoelectron spectra of 2*H*-indene derivatives *(6)*[8] and *(7)*[6], the new experimental bands at 7.32, 9.10 and 9.90 eV (Fig. 1c) can be unambiguously assigned to isobenzofulvene *(4)*.

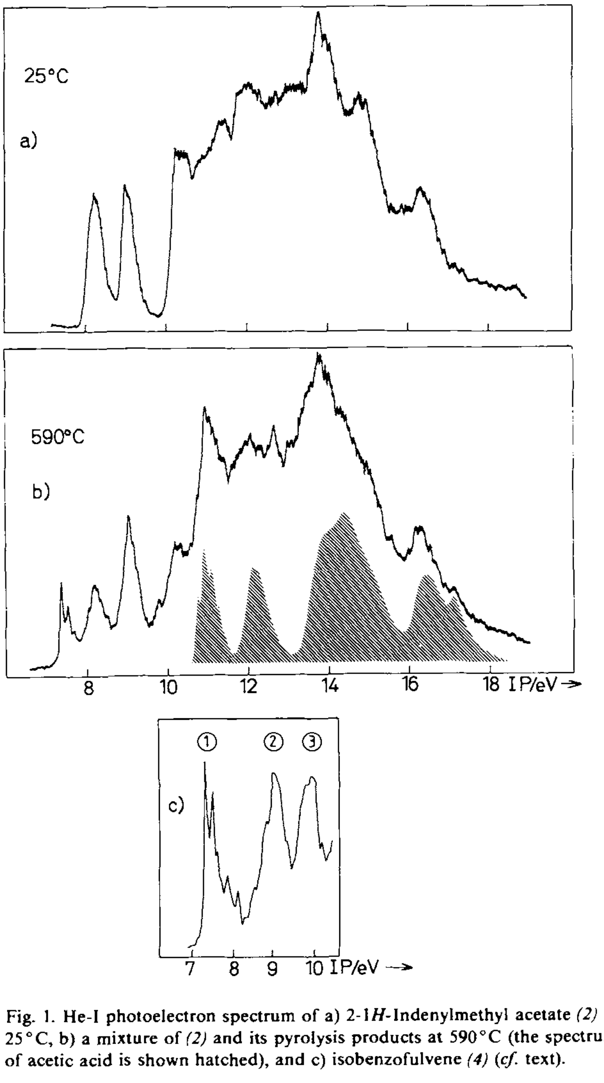


Fig. 1. He-I photoelectron spectrum of a) 2-1*H*-Indenylmethyl acetate *(2)* at 25 °C, b) a mixture of *(2)* and its pyrolysis products at 590 °C (the spectrum of acetic acid is shown hatched), and c) isobenzofulvene *(4)* (*cf.* text).

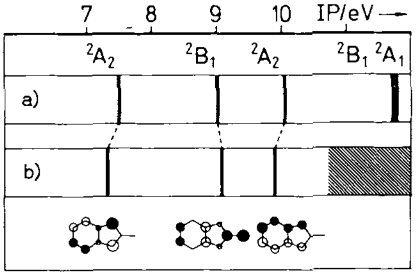

Fig. 2. a) Calculated (LNDO/S-PERTCI) and b) measured vertical ionization potentials (IP) for isobenzofulvene *(4)*.

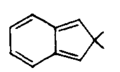
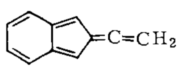
*(6)*





*(7)*

Table 1. Excitation energies [eV] and oscillator strengths (in parenthesis) for isobenzofulvene *(4)*.

| | LNDO/S-PERTCI | CNDO/S-SECI | PPP-SECI |
|---|---|---|---|
| $^1B_2(\pi\rightarrow\pi^*)$ | 2.63 (0.03) | 2.42 (0.16) | 2.27 (0.03) |
| $^1A_1(\pi\rightarrow\pi^*)$ | 4.20 (0.35) | 4.17 (0.29) | 4.21 (0.10) |
| $^1B_1(\pi\rightarrow\sigma^*)$ | 4.35 (0) | 5.08 (0) | — |
| $^1B_2(\pi\rightarrow\pi^*)$ | 4.66 (0.09) | 4.36 (0.11) | 4.27 (0.06) |
| $^1A_2(\pi\rightarrow\sigma^*)$ | 4.83 (0) | 5.31 (0) | — |

The UV/VIS absorption data of *(4)*, calculated using the LNDO/S-PERTCI[7a,b], CNDO/S-SECI[9a], INDO/S-SECI[9b], and PPP-SECI[9c] methods (Table 1), are in accord with an azulene-like spectrum. The calculated absorption spectra are strongly dependent on geometry. In particular, a small reduction in bond alternation causes a significant long-wave shift of the first $^1B_2(\pi\rightarrow\pi^*)$ absorption; the ionization energies are hardly influenced, however.

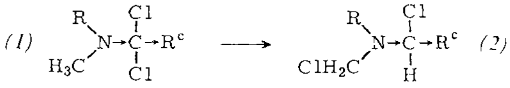
## Intramolecular 1,3-Cl/H Exchange in $F_3CCCl_2N(CH_3)_2$ and $Cl_3CCCl_2N(CH_3)_2$[**]

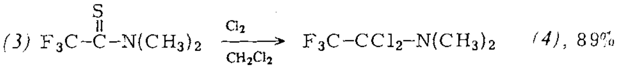
By *Monique Rover-Kevers, Luc Vertommen, Fabienne Huys, Robert Merényi, Zdenek Janousek,* and *Heinz Günther Viehe*[*]

*Dedicated to Professor Werner Reif on the occasion of his 60th birthday*

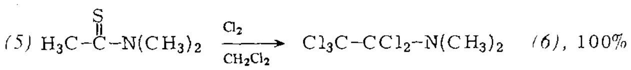
Compounds where the central $—CCl_2—$ moiety is flanked by an electron donor (amino group) and an electron acceptor (capto-dative, cd-substitution) undergo a 1,3-Cl/H exchange[1,2]. The rate of this rearrangement is very sensitive to the extent of the simultaneous electron-donation and -withdrawal properties of the substituents.



Thus, *(1a)* ($R=CH_3$, $R^c=ClC{=}\overset{\oplus}{N}(CH_3)_2$ can only be trapped at −60°[2]; *(1b)* ($R=CH_3$, $R^c=CO_2Et$, rearranges



$$(3)\ F_3C-\overset{\overset{\displaystyle S}{\|}}{C}-N(CH_3)_2 \xrightarrow[CH_2Cl_2]{Cl_2} F_3C-CCl_2-N(CH_3)_2 \quad (4),\ 89\%$$



$$(5)\ H_3C-\overset{\overset{\displaystyle S}{\|}}{C}-N(CH_3)_2 \xrightarrow[CH_2Cl_2]{Cl_2} Cl_3C-CCl_2-N(CH_3)_2 \quad (6),\ 100\%$$

completely after 1 h at 20°[3]; with *(1c)* ($R=C_6H_5$, $R^c=CO_2C_2H_5$) the process takes 5 d at 20°[3]. This reflects the fact that the N-methylanilino group is significantly less electron donating than the dialkylamino group. We now report the reaction of dimethylamino compounds *(4)* and *(6)*, the amide chlorides of trifluoro and trichloroacetic acid; here the electron attracting substituents are $CF_3$ and $CCl_3$, respectively. *(4)* and *(6)* were prepared by chlorination of the thioamides *(3)*[4] and *(5)*.

The amide chlorides *(4)* and *(6)* are, for all pratical purposes, stable at room temperature, but rearrange quantita-

[**] Capto-dative Substitution. Part 10. This work was supported by the Fonds National de la Recherche Scientifique and the Service de Programmation de la Politique Scientifique.—Part 9: *L. Stella, F. Pochat, R. Merényi,* Nouv. J. Chim. *5*, 55 (1981).

tively upon heating to give the new compounds *(8)* and *(16)*, respectively. Moreover, since *(4)* and *(6)* are very reactive towards C, N, O, and S nucleophiles, they constitute valuable synthons for introducing. —$CF_3$ and —$CCl_3$ groups, respectively, into various substrates as shown in the synthesis of compounds *(9)*, *(11)* and *(12)* as well as of *(15)*, *(17)* and *(18)*[5] (Schemes 1 and 2).

The rearrangement product *(14)* cannot be isolated since it eliminates HCl to give trichloroenamine *(16)*.

In order to gain some insight into the mechanism, we measured the kinetics of rearrangement of *(4)* in benzene, dioxane, and nitrobenzene at different temperatures. The plots show that the process is unimolecular and does not depend upon the polarity of the solvent. This precludes polar pathways and confirms that the process is intramolecular. Although no radicals have been detected to date by ESR spectroscopy, we consider a homolysis leading to a tight radical pair $[CF_3\underset{\odot}{C}ClN(CH_3)_2Cl]$ as very likely; a concerted process cannot, however, be excluded.

Table 1. Kinetics of the 1,3-Cl/H exchange *(4)*→*(8)*.

| Solvent | $T$ [°C] | $k \times 10^5$ [$s^{-1}$] | $A \times 10^{-13}$ [$s^{-1}$] | $E_a$ [kcal/mol] |
|---|---|---|---|---|
| Benzene | 72.5 | 1.14 | | |
| | 81 | 3.57 | 7.9 | 29.76 |

| | 82.5 | 6.88 | 3.82 | 28.9 |
| | 91.5 | 19.60 | | |

### *Experimental*

*(4)* and *(6)*: Solutions of *(3)*[4] and *(5)* in $CH_2Cl_2$ are chlorinated by passing a rapid stream of chlorine through the solutions until the exothermic reaction has subsided. *(4)* is a colorless liquid b.p. = 25 °C/12 torr; $^1$H-NMR ($CDCl_3$): $\delta = 2.66$ ppm; $^{19}$F-NMR ($CDCl_3$): $\delta = -73.5$ ppm.—Solid *(6)* is obtained by evaporation of the $CH_2Cl_2$ and is purified by sublimation at 65 °C/0.02 torr. $^1$H-NMR ($CDCl_3$): $\delta = 2.83$.

*(8)*: *(4)* is heated to 100 °C over 4 h and distilled at 55 °C/10 torr. $^1$H-NMR ($CDCl_3$): $\delta = 2.66$ (s, 3 H), 5.03 (s, 2 H) and 5.36 (q, 1 H).

*(16)*: A solution of *(6)* in $CHCl_3$ is refluxed for 18 h. Crude *(16)* is purified by Kugelrohr distillation 35 °C/0.2 torr. $^1$H-NMR ($CDCl_3$): $\delta = 2.76$ (s, 3 H) and 5.15 (s, 2 H). When the transformation is performed in the presence of $Cl_2$, *(18)* is obtained.

### *Kinetic Measurements*

A solution of 0.1 g of *(4)* in 0.5 mL of the solvent was prepared in a NMR tube, which is then heated in a thermostated bath for a definite time. The rate constants were determined at various temperatures by $^1$H-NMR spectroscopy. An Arrhenius plot gives the values for the $A$ factor and the activation energy $E_a$, in each solvent.

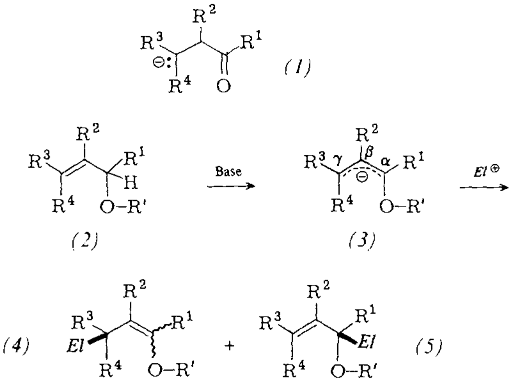
1-Oxyallyl anions *(3)*, R' = alkyl[1], aryl[1] or trialkylsilyl[2,3] are synthetic equivalents of the unknown aldehyde- and ketone-homoenolates *(1)*; their scope of application, however, is very limited: 1) Anions of type *(3)* are indeed selectively γ-alkylated to enol ethers *(4)*; however, on addition of carbonyl compounds the α-adducts *(5)* predominate[1,2,4]. 2) Because of inadequate acidity only those allyl ethers *(2)* which bear at most one alkyl group can be deprotonated (in the absence of stabilizing M-substituents)[1,2]. 3) Wittig rearrangements and related reactions often take place, even at low temperatures[3,5].



We report here on a novel type of 1-oxyallyl anions[6] which does not suffer these limitations: *N,N*-dialkylcar-

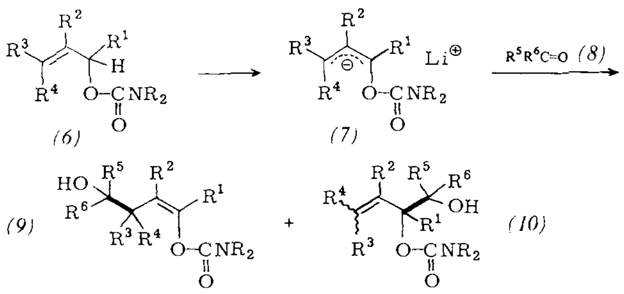
[**] Metalated Nitrogen Derivatives of Carbonic Acid in Organic Synthesis, Part 20. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Delivered in part at the Chemiedozenten-Tagung in Tübingen, March 25, 1981.—Part 19: *R. Hanko, D. Hoppe*, Angew. Chem. *93*, 115 (1981); Angew. Chem. Int. Ed. Engl. *20*, 127 (1981).



bamic acid allyl esters (6)—prepared from allyl alcohols and *N,N*-dialkylcarbamoyl chlorides[7]—are rapidly deprotonated to the lithium compounds (7) with *n*-butyllithium in diethyl ether/*N,N,N',N'*-tetramethylethylenediamine (TMEDA) at −78 °C (Table 1). The carbamoyl group of (6) is not attacked by butyllithium, even in the case of the 1,2,3-trialkylated allyl ester (6f). Solutions of (7) are stable up to *ca.* −50 °C. Hence, highly substituted 1-oxyallyl anions with a large variety of structural features are now accessible for the first time.

Unlike (3) the lithium compounds (7) take up aldehydes and ketones (8) predominantly at the γ-position to give the δ-hydroxyenolcarbamates (9); small amounts of the less polar allyl isomers (10) are easily separated by chromatography (Table 1). With exception of *E*-(9e) ($^1$H-NMR ($CCl_4$): $^3J_{1,2}=13$ Hz) and (9g), *Z*-enol esters are obtained [(9a), (9d) and *Z*-(9e): $^3J_{1,2}=6$ Hz; (9b) and (9c): $^4J_{1',2}=1.1$ Hz[5a]]. Thus, whenever it is sterically suitable the reacting species (7) prefers the 1-*Z*-configuration[1,2].

We presume that (7) is present as tight ion pair, in which the lithium cation is held at the α-C atom by the complexing carbamoyl oxygen (Fig. 1a): as a result the carbonyl compound (8) reacts with (7), *via* a six-membered transition state[8,9] (Fig. 1b), in the γ-position.

Solvolysis of (9) with $TiCl_4/H_2O$ or $CH_3OH$ affords the δ-hydroxycarbonyl compounds (homoaldols) (11) as lac-

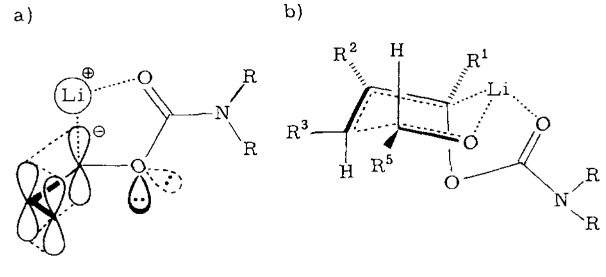


Fig. 1. a) (7) as tight ion pair. b) Transition state of the addition of carbonyl compounds to (7).

Table 1. Addition of aldehydes and ketones (8) to 1-oxyallyl anions (7) generated from (6). R = *i*Pr.

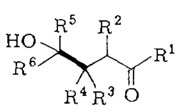
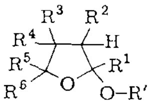
[a] Structure secured by $^1$H-NMR and IR spectra and by CH analysis; Cb = C(=O)N(*i*Pr)$_2$. [b] Pure (9) after chromatography. [c] Determined by isolation of the compounds or $^1$H-NMR spectroscopically. [d] *threo*-(9d):*erythro*-(9d) = 85:15, cf. [9].,[e] Contains *ca.* 5% *Z*-(9e) ($^1$H-NMR: $^3J_{1,2}=6$ Hz). [f] Prepared from (−)-myrtenol. [g] Cb = C(=O)NEt$_2$; (3*S*,5*S*)-(9g):(3*R*,5*S*)-(9g) = 92:8, determined by $^{13}$C-NMR spectroscopy.

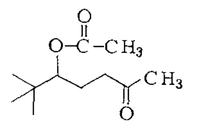
tols *(12)* or as lactol ethers *(13)*. After protection of the hydroxy group in *(9)*, deblocking leads to preparatively useful homoaldol derivatives with free carbonyl groups. Thus, the acetate of *(9b)* gives the γ-acetoxyketone *(14)* in 94% yield.



*(11)*



*(12)*, R′ = H
*(13)*, R′ = CH$_3$



*(14)*

*Procedure*

*(9)*: All operations must be carried out under N$_2$ with rigorous exclusion of moisture. A 1.60 N solution of butyllithium (3.40 mL, 5.50 mmol) in hexane is transferred within 15 min at −78 °C through a syringe cooled with dry-ice into a solution of *(6)*[7] (5.00 mmol) and TMEDA (0.83 mL, 5.50 mmol) in diethyl ether (15 mL). After 0.25—5 h (Table 1), a solution of *(8)* (5.30 mmol, 1.06 equiv.) in a few mL of ether is added to the mixture at −78 to −70 °C; after 2 hours stirring at this temperature the mixture is neutralized with glacial acetic acid (0.90 g, 15 mmol), allowed to warm, and worked-up in the usual way with ether/water. Chromatography on *ca.* 60 g silica gel with ether/petroleum ether (1 : 1) furnishes pure *(9)*, $R_f = 0.1-0.3$ [*(10)*: $R_f = 0.3-0.5$].

# Total Synthesis of Zizyphin A and *N*-Acetylzizyphin B[**]

By *Ulrich Schmidt, Albrecht Lieberknecht, Hilmar Bökens*, and *Helmut Griesser*[*]

Until now, attempts to synthesize ansapeptides have only been partially successful[1]. Over the last ten years *ca.* 80 of these "peptide alkaloids", which complex with alkali earth metal ions and function as ionophores in plants, have been isolated and characterized[2]. Most peptide alkaloids show activity against gram-positive bacteria and lower funghi. Some inhibit energy transfer processes in chloroplasts.—We report here the first total synthesis of two peptide alkaloids—zizyphin A *(1)* and *N*-acetylzizyphin B *(2)* from *Zizyphus oenoplia*[3]—with a 13-membered ring having a 10-membered "handle", using a cyclization method previously developed by us[4].

By means of the route worked out for the preparation of *trans*-3-phenoxyproline[5], the methyl ester of 3-bromodehydroproline was reacted with sodium 3-*tert*-butoxycarbonyl-4-methoxyphenolate[6], the methoxycarbonyl group was saponified, and the dehydroproline derivative was reduced with dimethylaminoborane. The resulting mixture of *cis*- and *trans*-phenoxyproline derivatives could be separated by recrystallization. The *trans*-compound *(3)* was acylated at the proline nitrogen and finally converted into the methyl ester *(4)* by diazomethane. After cleavage of both *tert*-butyl groups and acylation of the proline nitrogen to give *(5)* [yield 21% relative to the methyl ester of bromodehydroproline], we synthesized the aminoacetyl group from the aromatic carboxy group.

Reaction[7] of the imidazolide of *(5)* with the magnesium salt of monobenzyl malonate led to the benzyl acetylacetate *(6)* [yield 97% from *(5)*]; oximation of *(6)* to *(7)* [yield 91%], followed by catalytic hydrogenation of the oxime group, simultaneous catalytic debenzylation of the ester and decarboxylation of the keto acid formed the amino ketone *(8)*, which upon treatment with *N*-benzyloxycarbonylproline hydroxysuccinimide produced the diastereomeric amides *(9a)* and *(9b)* [yield 56% from *(7)*]. Reduction of the carbonyl group on C-1 with NaB(CN)H$_3$ to give *(10)*[8] [100 % yield], saponification of the methyl ester [yield 95%] and formation of a mixture of the four diastereomeric pentafluorophenyl esters *(11a—d)* [pentafluorophenol/dicyclohexylcarbodiimide; yield 83%] yielded the starting material for the ring-closure step which, after 5 h catalytic hydrogenation on palladium/charcoal using dilution techniques[4], produced the four diastereomeric alcohols *(12a—d)* in 80% yield.

It should be possible to form the double bond between C-1 and C-2 from the corresponding bromides *via* an elimination step. To preserve the acid-sensitive Boc protecting group, we reacted the mixture of alcohols *(12a—d)* with 1-bromo-*N*,*N*-2-trimethylpropenylamine[9] to produce a mixture of the diastereomeric bromides *(13a—d)*. Even this re-

sulted in the formation of small amounts of olefin. Reaction of the bromides with 1,5-diazabicyclo[5.4.0]undec-5-ene at 80 °C in acetonitrile led to a mixture of the diastereomeric olefins *(14a)* and *(14b)* in only 5% yield; accordingly only two of the four bromides *(13)* readily underwent hydrohalide elimination. Using 2,4,6-collidine and lithium bromide in diglyme at 100 °C, we obtained 50% yields, relative to *(12a–d)*. Thereby, the higher reaction temperature and lower reaction rate led to a greater population of conformers capable of elimination. Additionally, lithium bromide converts the sluggish diastereomers into more reactive species by reversing their configurations.

It is more advantageous to convert the mixture of alcohols into the mixture of selenides (tributylphosphine/p-nitrophenylselenocyanate) and to form the olefins by oxidation-elimination. By this means we obtained the mixture of the two pure olefins in 70% yield.

Both of the diastereomeric cyclopeptides *(14a)* and *(14b)* can be readily separated by chromatography on silica gel. In this case the ring compound with the "correct" (*SSS*)-configuration [*(14a)*]—as in all the natural products having this structure—has a large negative optical-rotation value (Table 1). After cleavage of the Boc group with trifluoroacetic acid (TFA), amine *(15a)* is firstly reacted with Boc-isoleucine hydroxysuccinimide ester, and after cleavage of the protecting group (TFA) is treated with activated dimethylisoleucine to give *(1)*. The synthetic product [38% from *(15a)*] is identical in every respect with zizyphin A *(1)*.—For the synthesis of *N*-acetylzizyphin B *(2)*, the amine *(15a)* was coupled with Boc-isoleucine as described above and after cleavage of the Boc group, reacted with the hydroxysuccinimide ester of *N*-methyl-*N*-acetyl isoleucine to give *(2)* [45% yield from *(15a)*].

[8] Ring closure using the ketone *(9)*, $R^3 = C_6F_5$ only proceeds with poor yield and with partial reduction of the keto-to-hydroxy group. The hydroxy group required for the later elimination was therefore prepared *before* the ring closure step.—The introduction of a hydroxy group, which is eliminated at the final stage of the synthesis, increases the number of diastereomers to four due to the non-stereoselective formation of a new asymmetric center, and hence leads to difficultly purifiable mixtures; the yields of subsequent steps, particularly in the ring closure are, however, so high that this disadvantage is more than balanced out.

## [3 + 2]-Cycloadditions of Allyl Cations – Synthesis of Permethylcyclopentene and Other Highly Substituted Cyclopentenes[**]

By *Herbert Klein* and *Herbert Mayr*[*]

Whereas [3 + 4]-cycloadditions of allyl cations to 1,3-dienes represent one of the most widely used synthetic approaches to seven-membered carbocycles[1a], only little attention has been paid to [3 + 2]-cycloadditions of allyl cations. Concerted [$3^+_s + 2_s$]-cycloadditions are thermally forbidden by orbital symmetry rules[1b] and a stepwise process involves a cyclization step *(5)*→*(7)* (Scheme 1), which is predicted to be unfavorable by the Baldwin rules[1c].

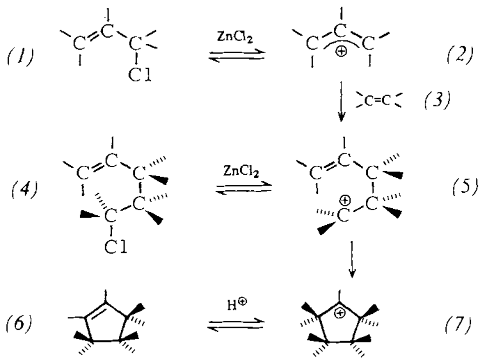
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and, by gifts of chemicals, by Hoechst AG and BASF AG. Dr. *E. Wilhelm* is thanked for the NMR-spectra.

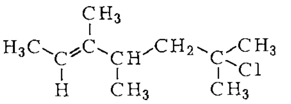


Scheme 1.

Apart from cyclopentanone syntheses with 2-siloxy[2d] or carbonyliron stabilized 2-oxyallyl cations[2a], [3+2]-cycloadditions of allyl cations to CC double bonds have previously only been observed in the gas phase[2b] or as minor reaction from 2-oxyallyl cations and 1,3-dienes[2c]. *Miller* and *Moore* obtained linear and cyclic products from the $ZnCl_2$ catalyzed reaction of prenyl chloride (1-chloro-3-methyl-2-butene) with alkynes[3a]. In contrast, the corresponding reaction with alkenes gives acyclic products exclusively[3b].

We have now found the reactions of 2-alkyl-substituted allyl cations of type *(2)* with alkenes *(3)* to present an easy access to highly substituted cyclopentenes. Isobutene *(3a)* and allyl chloride *(1a)* react at −78 °C in dichloromethane under $ZnCl_2$—$Et_2O$ catalysis[4a] to give the linear addition product (*E*)-6-chloro-3,4,6-trimethyl-2-heptene *(4a)*[5] in 81% yield.

In spite of the three-fold molar excess of isobutene used for this reaction, the 1:1-addition product *(4a)* is formed selectively, since *(1a)* dissociates faster than *(4a)*[3b,4b]. At room temperature, *(4a)* cyclizes in the presence of Lewis acids to yield the pentamethylcyclopentenes *(6a)* and *(6b)* (Scheme 1, Table 1). Additional methyl groups in *(4)* accelerate the cyclization reactions (*gem*-dialkyl effect[6]) and the reaction of *(1a)* with tetramethylethylene gives cyclopentene *(6d)* even at −78 °C. In many cases, mixtures of cyclopentenes and chlorocyclopentanes or acyclic products are obtained at −78 °C, which give the cyclopentenes shown in Table 1 when treated with Lewis acid at 0−25 °C. Sometimes, the cyclopentene yields can be increased if a slow stream of hydrogen chloride is bubbled through the reaction mixture during cyclization; this procedure probably prevents hydrogen chloride elimination from *(4)*.



$$H_3C{-}CH{=}C(CH_3){-}CH(CH_3){-}CH_2{-}C(CH_3)_2Cl$$

(4a)

Ethyl vinyl ether polymerizes when reacted with allyl chloride *(1a)* and $ZnCl_2$, since the initially formed α-chloro ether *(4)* reacts faster with vinyl ether than allyl chloride *(1a)*[3b,4b]. In contrast, high yields of 1:1 products are obtained from 1-ethoxy-2-methyl-1-propene *(3d)* and these allyl chlorides. Now, the cyclization *(5)*→*(7)* is accelerated by the *gem*-dialkyl effect and the intramolecular reaction becomes faster than polymerization.

These results are in accord with the stepwise addition mechanism depicted in Scheme 1. From the cyclopentene substitution pattern it can be deduced that unsymmetrical allyl cations are primarily attacked at the less substituted terminus[8]. Unsymmetrical olefins react in the Markovni-

kov sense. In spite of contrary predictions[1c] cyclization *(5)→(7)* readily takes place, if a tertiary carbenium ion is formed[9]. The deprotonation of cyclopentyl cations *(7)* is reversible so that only the thermodynamically most stable elimination products *(6)* are isolated.

### *Procedure*

$ZnCl_2$ (2.2 g) was dissolved in ether (2.6 mL), diluted with 45 mL of $CH_2Cl_2$ and cooled to −78 °C. Successively, solutions of *(3c)* (5.30 g, 63.0 mmol) and *(1b)* (2.64 g, 19.9 mmol) each in 10 mL of $CH_2Cl_2$ were added dropwise. After 7.5 h at −78 °C the catalyst was extracted with conc. aqueous $NH_3$ and the organic phase was dried over $CaCl_2$. The crude product, obtained after evaporation of the solvent and excess alkene, was added to a solution of $ZnCl_2$ (4.4 g) in ether (5.2 mL) and $CH_2Cl_2$ (90 mL) at 25 °C. A stream of dry HCl was bubbled through the solution for *ca.* 1 min. After 35 min at 25 °C, the mixture was worked-up with aqueous ammonia as described above. Distillation yielded 2.50 g (70%) of pure octamethylcyclopentene *(6f)*.

## Dodecamethyl-1λ$^3$,4λ$^3$-diphospha-2,3,5,6,7,8-hexastannabicyclo[2.2.2]octane, a Highly Symmetrical Cage Molecule[**]

By *Martin Dräger* and *Bernd Mathiasch*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

The reaction of white phosphorus with tin hydrides can be used to form SnP bonds[1]. In addition to the phosphane, we obtained the title compound *(1)* by reacting 1,1,2,2-tetramethyldistannane[2] with phosphorus *in the dark*.

$$3\,(CH_3)_4Sn_2H_2 + P_4 \xrightarrow[0\,°C,\ darkness]{Et_2O} \underset{(1)}{[(CH_3)_2Sn]_6P_2} + 2\,PH_3$$

Under the *action of light (1)* disproportionates to the norbornane-analogous *(2)*[1] and dimethylstannanediyl, which can be trapped as iodotrimethylstannane by reaction with $CH_3I$.

$$\underset{(1)}{[(CH_3)_2Sn]_6P_2} \xrightarrow{h\nu} \underset{(2)}{[(CH_3)_2Sn]_5P_2} + (CH_3)_2Sn:$$

The novel compound *(1)* forms as bright yellow crystals from benzene. The X-ray structure analysis[3] indicates, within the standard deviations, a chiral molecule with $D_3$ symmetry (six equivalent Sn atoms, two equivalent P atoms and six equivalent C atoms; cf. Fig. 1). The bicycle $Sn_6P_2$ is constructed from three $Sn_4P_2$ six-membered rings which share three bonds with each other and adopt the conformation of a boat, twisted by 26°.

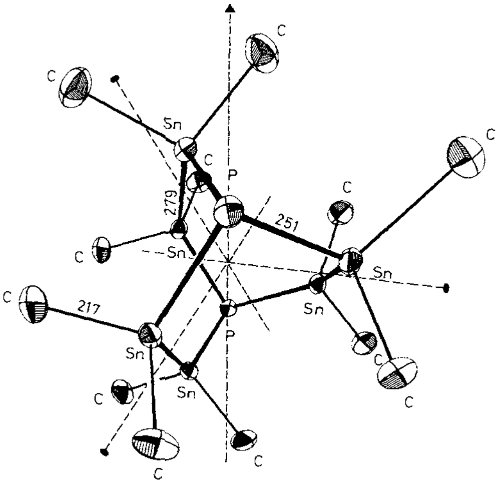

Fig. 1. Molecular structure of *(1)* in the crystal with average bond lengths [pm] (P···P distances; intramolecular 518, intermolecular 371 pm) and symmetry elements. Average bond- and torsion-angles [°]: Sn—P—Sn 98, P—Sn—Sn 117, C—Sn—C 107, Sn—Sn—C 109, P—Sn—C 107; PSn—SnP +26, SnSn—PSn −62, SnSn—PSn′ +37.

In solution at room temperature *(1)* has, on average, $D_{3h}$ symmetry: The NMR signals of all the methyl groups show a joint doublet arising from $^{31}$P-coupling[4]. The coupling constants $^3J$(PSnCH) and $^2J$(PSnC) confirm the previously found dependence on the torsion angle of the phosphorus lone pair of electrons and the coupling nuclei in *(2)*[1].

### *Procedure*

All operations are performed under argon, using solvents saturated with Ar: $Me_4Sn_2Cl_2$ (4 g, 10.9 mmol) is reduced to $Me_4Sn_2H_2$ at room temperature by $LiAlH_4$ in 70 mL of $Et_2O$. The solution is cooled to 0 °C and ice-water added under stirring. The ether layer is separated off, dried over $MgSO_4$, and poured onto white phosphorus (0.3 g, 9.7 mmol, less than the stoichiometric amount). The reaction vessel is kept dark and immediately cooled (0 °C). After 48 h the phosphorus is consumed, and the crystals formed are separated from the $Et_2O$ solution by suction and re-

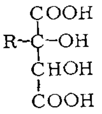
## Direct Diastereoselective Alkylation of Tartaric Acid Through an Enolate

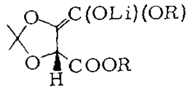
By *Reto Naef* and *Dieter Seebach*[*]

The usefulness of (+)- and (−)-tartaric acid as chiral starting materials (pool of chiral building blocks[1]) for syntheses would be greatly enhanced, if direct alkylation to give *(1)* could be achieved. Depending upon the stereochemical course of such a process, natural products with *erythro-(1)* structures[2], such as piscidic acid, fukiic acid, or loroglossine, which have hitherto been synthesized only as (±)-mixtures by elaborate routes, might become readily accessible in enantiomerically pure form.

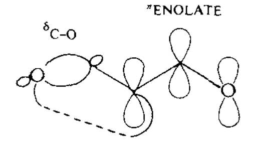
We have now succeeded in finding conditions for generating lithium enolates *(2a)* and *(2b)* from (*R*,*R*)-tartrate acetonides[3]. Alkylation with highly reactive electrophiles leads to pentasubstituted *trans/cis*-dioxolanes *(3)/(4)* in yields ranging from 40 to 80% (Table 1); the diastereomeric ratios of *ca.* 80 : 20 can be determined from the $^1$H-NMR spectra. The stability of the enolates *(2a)* and *(2b)*, sufficient for allylations and benzylations but not for *n*-alkylations, can be rationalized by assuming, that the rigid acetonide skeleton holds the enolate π-system and the C—O σ bond at an "aldol distance", perpendicular to each other [*(2c)*[4]], thus preventing β-elimination.



*(1)*

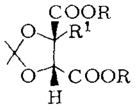


*(2a)*, R = $CH_3$
*(2b)*, R = $CH(CH_3)_2$



*(2c)*

The enolate *(2a)* also adds to the carbonyl group of acetone: A 4 : 1-mixture of a diester of *(4f)* and of the lactone ester *(5)* (M. p. = 96—97 °C, $[\alpha]_D^{20} = -11.0$ ($c = 0.95$, $CHCl_3$)), which spontaneously crystallizes, is isolated in 60% yield. The minor component *(5)* must be a *cis*-bicyclo[3.3.0] system formed from an adduct of type *(3)* with *trans*-configuration. Thus, acetone has approached the enolate *(2a)* from the *Re*-face preferentially [see *(4f)* in Table 1]. In contrast, the *p*-methoxy-benzylation of *(2a)* must have occurred from the *Si*-face: the diastereomeric mixture *(3e)/(4e)* was hydrolyzed with 0.1 N HCl (methanol/water 1 : 1) to give the dihydroxyester, the major isomer of which was obtained by crystallization. According to the $^1$H- and $^{13}$C-NMR spectra, supported by measurements in the presence of a chiral shift reagent, and comparison with an authentic sample[2a, 5], the major product is the 97% enantiomerically pure *threo*-isomer *(6)* (m. p. = 107.0—107.5, $[\alpha]_D^{20} = -26.3$ ($c = 0.57$, $CHCl_3$)), while natural piscidic acid is *erythro-(7)*. By analogy, we assume that all main products of allylation and benzylation of *(2)* have the *trans*-configuration (Table 1), *i. e.* that the substitution of the α-proton of tartaric acid occurs with *retention* of configuration.



*(3)* *(a)*, $R^1 = CH_3$
*(b)*, $R^1 = CH(CH_3)_2$

### *Procedure*

*(3d)/(4d)*: To a solution of dimethyl (*R*,*R*)-tartrate acetonide (3.27 g, 15 mmol)[3] and benzyl bromide (3.06 g, 18 mmol) in 50 mL of tetrahydrofuran (THF)/10 mL of hexamethylphosphoric triamide, stirred under argon at −78 °C, is added within 30 min a solution of lithium diisopropylamide (16 mmol) in 50 mL of THF cooled at −70 °C. The temperature is allowed to rise to −10 °C over 6 h, the reaction mixture poured into 300 mL of diethyl ether, the resulting solution washed with water (5 × 200 ml), dried over magnesium sulfate, and the solvent removed by evaporation. Kugelrohr distillation (165 °C/0.005 torr) gives 2.5 g (54%) of the mixture *(3d)/(4d)* (84 : 16) as a yellow resin.

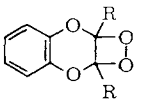
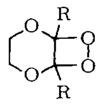
## Dihydrodioxetobenzodioxins: Synthesis and Chemiluminescence[**]

By *Waldemar Adam, Omar Cueto, Ernst Schmidt,* and *Kiyoshige Takayama*[*]

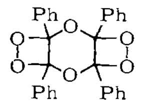
In our search for novel "high-energy" molecules for the thermal generation of electronically excited products, we undertook the preparation of the dioxetanes *(1)* derived from 1,4-benzodioxins *(4).* By analogy to the perhydrodioxetodioxins *(2)* and the bisdioxetane *(3),* which on thermolysis afford electronically excited ethylene glycol diester[1] and benzoic anhydride[2], respectively, in high yield, it was expected that electronically excited pyrocatechol diesters should be formed in high yields from 2a,8a-dihydro-1,2-dioxeto[3,4-*a*][1,4]benzodioxin *(1)*[3]. Herewith we report the preparation, characterization, and chemiluminescence of the novel dioxetanes *(1).*



*(1)*



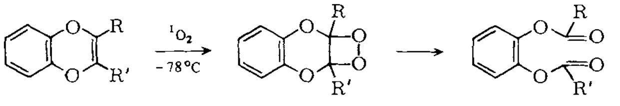
*(2)*



*(3)*

Photosensitized singlet oxygenation of a 0.03 M $CH_2Cl_2$ solution of the 1,4-benzodioxins *(4)*[4] at −78 °C, using polymer-bound Rose Bengal as sensitizer and a 400 W sodium street lamp as radiation source[5], led to complete consumption of the dioxins within 2 h, as evidenced by NMR monitoring. For example, with *(4a)* the olefinic proton at $\delta = 6.41$ disappeared with simultaneous appearance of the dioxetanyl proton at $\delta = 6.33$. On heating to 20 °C this signal also disappeared; in its place an aldehydic proton—as expected for *(5a)*—appeared.

The dioxetane *(1a),* was isolated by column chromatography (Florisil, −60 °C, $CH_2Cl_2$) and characterized spectroscopically[6]. On heating, pure *(1a)* quantitatively gave the pyrocatechol diester *(5a)*[7] with concomitant light emission.



*(4)* *(1)* *(5)*

*(a),* R = Ph, R′ = H; *(b),* R = Ph, R′ = Me; *(c),* R = R′ = Me

Photooxygenation of 2-methyl-3-phenyl and 2,3-dimethyl-1,4-benzodioxins, *(4b)* and *(4c),* respectively, afforded the corresponding dioxetanes *(1b)*[8] and *(1c)*[9] which upon heating were quantitatively transformed into the pyrocatechol derivatives *(5b)*[10] and *(5c)*[11], respectively, with light emission.

On thermal decomposition, the dioxetanes *(1)* chemiluminesce; however, the emission intensity was too weak to be useful for quantitative determination of the singlet quantum yields ($\Phi^{S}$). We therefore used the energy-transfer chemiluminescence to assess the quantum yields[3]. The activation parameters $\Delta H^{+}$ and $\Delta S^{+}$, and the singlet ($\Phi^{S}_{DPA}$) and triplet ($\Phi^{T}_{DBA}$) quantum yields, respectively, are collected in Table 1.

Table 1. Activation parameters and quantum yields for thermolysis of the dioxetanes *(1).*

| | *(1a)* | *(1b)* | *(1c)* |
|---|---|---|---|
| $\Delta H^{+}$ [kcal/mol] [a] | 23.8 ± 1.0 | 25.1 ± 1 | 26.2 ± 1 |
| $\Delta S^{+}$ [cal/mol/K] [a] | −5.1 ± 2 | −5.7 ± 2 | −3.7 ± 2 |
| $\Delta G^{+}$[kcal/mol] [b] | 25.7 ± 1 | 26.9 ± 1 | 27.3 ± 1 |
| $10^3\ \Phi^{S}_{DPA}$ [%] | 1.1 ± 0.3 | 1.6 ± 0.2 | 0.09 ± 0.02 |
| $\Phi^{T}_{DBA}$ [%] | 0.6 ± 0.06 | 3.5 ± 1.3 | 0.02 ± 0.01 |
| $\Phi^{T+S}$ [%] | 0.6 ± 0.06 | 3.5 ± 1.3 | 0.02 ± 0.01 |
| $\Phi^{T}/\Phi^{S}$ | 500 ± 300 | 2200 ± 700 | 200 ± 100 |

[a] Determined by isothermal kinetics using DBA-enhanced chemiluminescence. [b] At 293.2 K.

The activation parameters show that the dioxetanes *(1)* are of comparable stability to that of tetramethyl-1,2-dioxetane (TMD)[3]. As expected, the disubstituted dioxetanes *(1b)* and *(1c)* are more stable than the monosubstituted derivative *(1a),* but there is no difference in stability due to phenyl *versus* methyl substitution. From the quantum yields it is seen that, as with TMD, n,π* triplet states can be selectively generated from the dioxetanes *(1), i. e.* all derivatives *(1a)*—*(1c)* give very low yields of n,π* singlet states. Surprising is the very low total quantum yield of dioxetane *(1c).* The possibility of introducing substituents into the benzene ring and at the 2,3-positions should make derivatives assessible which exhibit high singlet excitation yields through intramolecular electron exchange[1].

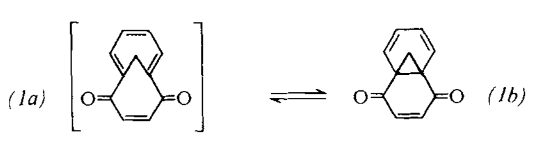
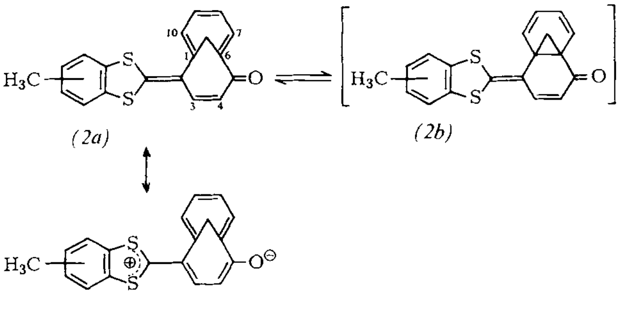
## Donor-Acceptor-Stabilized 1,6-Methano[10]annulene Derivatives[**]

By *Richard Neidlein* and *Hartmut Zeiner*[*]

*Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday*

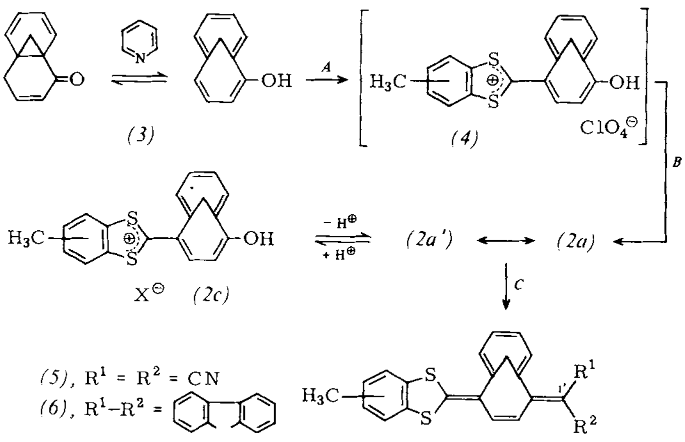
The diketo derivative *(1a)* of 1,6-methano[10]annulene, a homologue of 1,4-naphthoquinone, cannot be synthesized[1] since it is thermodynamically less stable than its valence isomer *(1b)*.





In contrast, however, the bicyclic quinoid structure is considerably more stable than the tricyclic structure if it is incorporated into an integral part of a "push-pull" system as in *(2a)*. No evidence that the valence isomer *(2b)* exists has been obtained to date[2]. To the best of our knowledge, *(2a)* is the first "push-pull"-stabilized quinomethide whose quinoid partial structure is not derived from a benzoid aromatic system.

The synthetic route to *(2a)* starting from the tautomeric/valence isomeric mixture *(3)*[3] is outlined in Scheme 1.



Scheme 1. *A:* 5-methyl-1,3-benzodithiolylium perchlorate [4], anhydrous $CH_3CN$, $N_2$, 20 °C, 12 h; *B:* $NEt_3$, $CH_2Cl_2$, 20 °C; *C:* Reaction to give *(5)* or *(6)*: dicyanoketene [5] or 9-carbonylfluorene [6], anhydrous toluene, $N_2$, 1.5—2 h.

The bicyclic cycloheptatriene structure of *(2a)* is based on spectroscopic evidence: in the $^1$H-NMR spectrum, the $CH_2$-bridge protons form an AX system with geminal coupling $^2J_{AX} = 10.7$ Hz; in contrast, 4—5 Hz would be expected for a tricyclic norcaradiene structure such as in *(2b)*[7]. A further index for *(2a)* is provided by the absorption of H-7 to H-10[8] (ABCD system at relatively low field strength ≥ 6.7). The "push-pull" effect in *(2a)* produces a carbonyl absorption at conspicuously low wavenumber, as well as a relatively high basicity; the negative solvatochromism of the longest wavelength UV bands indicates a marked contribution of the polar mesomeric structure *(2a')* to the ground state.

Conversion of the basic *(2a)* into the conjugated red-violet acid *(2c)* (Scheme 1) shifts the absorption of the $CH_2$-bridge protons (AB signal) 1.18 ppm upfield. With

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

$\delta_{ABc}=0.79$ ($CF_3COOD$) they lie close to the characteristic high-field region of disubstituted 1,6-methano[10]annulenes ($\delta=-0.5$ to $+0.5$). Furthermore, aromatization of the $C_{11}$ bicycle in *(2c)* is also indicated by the paramagnetic shift of the low-field multiplet by 0.67 ppm, as well as the reduction of $^3J_{3,4}$ by ca. 1.6 Hz, suggesting a decrease of the bond order between C-3 and C-4.

Similar results are obtained with the "push-pull" stabilized quinodimethanes *(5)* and *(6)*, which are readily accessible from *(2a)* (Scheme 1); however, only *(6)* can be protonated at the exocyclic double bond (C5—C1′).

## Potassium Metal Dispersed on Silica: A Versatile Reagent in Organic Chemistry[**]

By *Jaacov Levy, Dov Tamarkin, Henry Selig,* and *Mordecai Rabinovitz*[*]

In recent years there has been much interest in reagents supported on silica gel[1,2], on graphite[3], and on alumina[4]. We report here the preparation and some reactions of a new reagent in this class—potassium metal dispersed on silica gel.

Silica gel (1.500 g, BDH, 70—100 mesh, dried for 3 weeks at 100—120 °C) was heated to 170 °C and stirred under argon with metallic potassium (0.780 g, 0.02 mol, BDH, washed with petroleum ether, and 1-butanol in petroleum ether) for 20 min, and cooled to room temperature. A gray free flowing, relatively air stable powder *(1)* was obtained. X-ray powder diffraction studies show the material to be amorphous. Quenching *(1)* with water released hydrogen gas from whose volume it was determined that 85—90% of the potassium is in elemental form.

Several investigations were carried out in order to study the reactivity of *(1)*. Addition of benzophenone (1.82 g, 0.01 mol) in petroleum ether to *(1)*, prepared as above from 0.02 mol potassium under argon at room temperature, produced a strong blue coloration after 5 min. After 8 h at room temperature the mixture was quenched with water: isolation of the organic products afforded benzopinacol (1,1,2,2-tetraphenyl-1,2-ethanediol) (m.p. 179—180 °C, 72% yield, 1.3176 g, 0.0036 mol); and benzhydrol (m.p. 65—68 °C, 8% yield, 0.1450 g, 0.0008 mol). In contrast, no reaction was observed at room temperature with potassium metal; when heated to reflux a reaction took place which yielded a 1 : 1 mixture of benzopinacol and benzophenone in 60—80% total yield.

*(1)*, prepared from 0.02 mol potassium was reacted with bromobenzene (1.490 g, 0.0095 mol) in diethyl ether and petroleum ether to afford biphenyl (m.p. 65 °C, 82% yield, 0.603 g, 0.00389 mol); no polyphenylenes were observed. Similarly, iodobenzene afforded 81% biphenyl. The Fittig reaction of aryl halides with metallic potassium takes place at higher temperatures, and yields only 20—30% biaryls[5].

These examples show that the dispersion of potassium on silica *(1)* has greater reactivity and different selectivity than metallic potassium. The tendency of *(1)* to facilitate formation of "dimers" (benzopinacol, biphenyl) as exemplified by its reactions with benzophenone, bromobenzene and iodobenzene, may originate from the proximity of two reaction centers on the surface of the silica; on average 4.5—5 active sites per 100 Å$^2$ are found[6].

## $[Fe_3S(S_2C_{10}H_{12})_3]^{2-}$: The First Synthetic Trinuclear Iron-Sulfur Cluster Compound

By *Gerald Henkel, Wolfgang Tremel,* and *Bernt Krebs*[*]

Preliminary results of an X-ray structure analysis by *Stout et al.*[1] as well as Mössbauer spectroscopic investigations by *Emptage et al.*[2] on a ferredoxin-like iron-sulfur protein ("iron-sulfur protein III") from *A. vinelandii*, first described by *Shethna*[3] and *Yoch* and *Arnon*[4] about 10 years ago, would suggest that the center with the low redox potential of −420 mV represents a novel type of trinuclear cluster.

*Stout et al.*[1] interpret this cluster as a 3Fe—3S center, whose structure can be derived from the dimeric $Fe_2S_2$ unit of the 2Fe—2S ferredoxins by insertion of a distorted planar $FeS_4$ group.

---

[*] Prof. Dr. B. Krebs, Dr. G. Henkel, Dipl.-Chem. W. Tremel
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

We report here on a novel trinuclear iron-sulfur cluster with tetrahedral coordination of the Fe atoms, which could be isolated for the first time as the $Fe_3S(SRS)_3^{2-}$ anion in the compound $[(C_2H_5)_4N]_2[Fe_3S_7C_{30}H_{36}]\cdot CH_3OH$ *(1)* and corresponds to the previously unknown central member in the series of tetrahedrally coordinated Fe—S cluster compounds $(Fe_nS_{4+n})^{z-}$ ($n=2$, 3, 4) with cubane-analogous structure of the terminal member.

The compound *(1)* is obtained as blackish-brown crystals on reaction of 1,2-bis(mercaptomethyl)-4,5-dimethylbenzene and sodium methoxide with iron(III) chloride and *p*-thiocresol in anhydrous methanol and subsequent precipitation with $N(C_2H_5)_4Cl$.

The structure of *(1)* was determined from single crystal diffractometer data (Syntex $P2_1$, $Mo_{K\alpha}$ radiation, graphite monochromator, scintillation counter, $2\theta$-$\theta$ scan, 4016 symmetry-independent reflections, $2\theta_{max}=44°$, $T=-133\,°C$) and refined to $R=0.068$ (Fig. 1). *(1)* crystallizes in space group $P\bar{1}$ of the triclinic system with two formula units per unit cell, the lattice constants, determined at $-133\,°C$, being $a=10.226(3)$, $b=16.505(4)$, $c=16.777(5)$ Å, $\alpha=81.97(3)$, $\beta=73.69(3)$, $\gamma=86.59(3)°$.

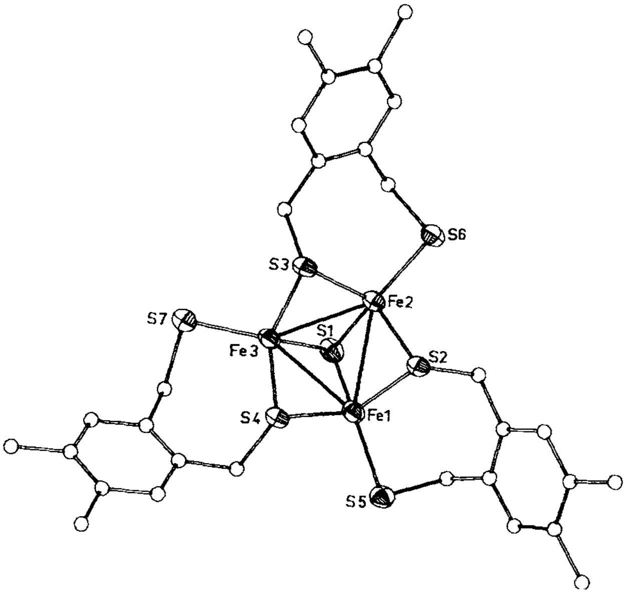

Fig. 1. Structure of the $[Fe_3S(S_2C_{10}H_{12})_3]^{2-}$ ion in crystals of *(1)* with vibration ellipsoids of the central $Fe_3S_7$ skeleton (50% probability level).

The structure of the Fe—S center derives from the $Fe_4S_4(SR)_4$ cubane structure, with one of the four tetrahedral iron positions not being occupied. The Fe atoms form a completely bonded triangle and are each surrounded by a tetrahedron of S atoms which is somewhat distorted from idealized symmetry. This tetrahedron consists of an inorganic S atom above the center of the metal triangle and three mercapto S atoms, two of which form slightly asymmetric bridges to neighboring Fe atoms.

The average lengths of equivalent Fe—S bonds are 2.303 Å (Fe1—S1, Fe2—S1, Fe3—S1), 2.345 Å (Fe1—S2, Fe2—S3, Fe3—S4), 2.350 Å (Fe1—S4, Fe2—S2, Fe3—S3) and 2.293 Å (Fe1—S5, Fe2—S6, Fe3—S7) with standard deviations of the individual values of 0.004 Å. The average distance between the Fe atoms of the cluster is 2.799 Å and thus lies in the upper range of Fe distances, as have been observed in the centers of the 4Fe—4S and 2Fe—2S ferredoxins[5] and their synthetic analogues—*e.g.*, 2.746 Å in $(Et_4N)_2[Fe_4S_4(SC_7H_7)_4]$ *(2)*[6] and 2.698 Å in $(Et_4N)_2[Fe_2S_2(S_2C_8H_8)_2]$ *(3)*[7]. The significance of the metal-metal interactions has already been pointed out, both in the case of the dinuclear as well as of the tetranuclear clusters[6,7]. Considering the formal oxidation states of iron (+2 in *(1)*, +2.5 in *(2)*, and +3 in *(3)*) a nearly linear correlation between oxidation states and metal-metal distances becomes clearly evident.

The IR spectrum of *(1)* shows three poorly resolved Fe—S vibration bands at 355, 320, and 298 $cm^{-1}$ (KBr disk). Preliminary results from Mössbauer spectroscopic investigations ($IS=0.58$ mm $s^{-1}$, $EQ=3.08$ mm $s^{-1}$, $T=293$ K) show good agreement with the values found for *tetrahedrally* coordinated iron(II)-sulfur complexes[5].

The central $Fe_3S_7$ unit of *(1)* with the six potential coupling sites is the first model for trinuclear iron-sulfur centers in proteins, whose existence could only recently be demonstrated[1,2]. The assumption of a more general significance of trinuclear iron-sulfur centers in biological processes is supported by results of investigations on aconitase[2,8] and ferredoxin from *Desulfovibrio gigas*[2].

Engl. *20*, 963 (1981).

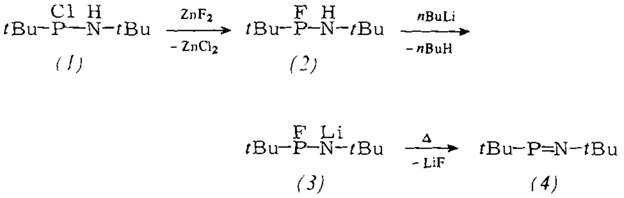
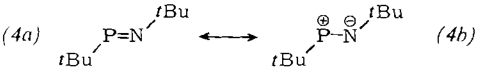
few days at −40 °C. The monomeric structure of *(4)* follows from the doublet-splitting of the $^{1}$H- and $^{13}$C{$^{1}$H}-NMR signals of the two *tert*-butyl groups. The magnitude



of $J_{CNP}$ (13.4 Hz) indicates the energetically more favorable *trans*-form[2]. The $^{31}$P-NMR signal of *(4)* ($\delta = 472$) shows a drastic deshielding of the phosphorus compared with iminophosphanes of type *(A)* ($\delta = 290-330$[1,3]), which can be ascribed to considerable contribution of *(4b)* to the ground state of *(4)*[4].



When *(4)* is warmed to above 0 °C, it dimerizes within a few minutes (within a few hours in solution) by [2 + 1]-cycloaddition to give the 1,2$\lambda^3$,3$\lambda^5$-azadiphosphiridine *(6)*—a pale-yellow, viscous liquid (only *one* diastereomer). The thermodynamically favored [2 + 2]-cycloaddition[5] to the 1,3,2$\lambda^3$,4$\lambda^3$-diazadiphosphetidine *(5)* does not take place. Also remarkable is the chelotropic fragmentation of *(6)* under mild conditions, which makes this heterocycle an ideal source of iminophosphane *(4)*.

Table 1. Some spectroscopic data of compounds *(2)*, *(4)*, *(6)* and *(8)* [a]. In the case of *(2)*, *(4)* and *(8)* *m/z* 57 ($t$Bu$^+$) is the base line.

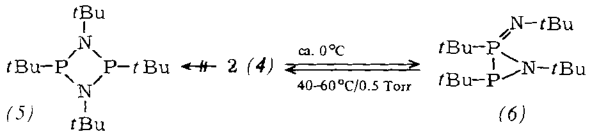
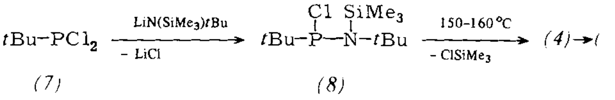
[a] 30% solution in CD$_2$Cl$_2$ [*(2)*, *(6)*, *(8)*] or [D$_8$]toluene [*(4)*] with H$_3$PO$_4$ as external ($^{31}$P) or TMS as internal standard ($^{1}$H, $^{13}$C); 300 K [*(2)*, *(6)*, *(8)*] or 237 K [*(4)*]. [b] $J_{PF} = 965$, $J_{HNPF} = 1$, $J_{HCNPF} = 1.2$, $J_{CCPF} = 1.8$, $J_{CPF} = 12.0$, $J_{CCNPF} = 2.0$, $J_{CNPF} = 3.4$ Hz. [c] Data for the preferred rotamer with the SiMe$_3$ group arranged elliptically to the "free" electron pair of the P atom. [d] For *(6)*: $|J_{HP} + J_{HP'}|$. [e] For *(6)*: $|J_{CP} + J_{CP'}|$.



A more direct route to *(6)* has proven to be the thermally-induced elimination of chlorosilane from [*tert*-butyl(trimethylsilyl)amino]-*tert*-butyl(chloro)phosphane *(8)*, which is obtainable from *tert*-butyldichlorophosphane *(7)* and lithium *tert*-butyl(trimethylsilyl)amide.



The difference in reaction behavior of iminophosphane *(A)* and *(B)* is consistent with results of MNDO calculations[6], according to which both systems have two high level σ(P)- and π-orbitals with energy differences o $E_\sigma - E_\pi = 0.3$ eV in *(A)* and −1.1 eV in *(B)*, respectively giving the frontier orbitals π,π*, for *(A)* and σπ* for *(B* The latter corresponds to the orbital sequence characteristic for carbenes and, together with the high electrophilicity of the phosphorus, explains the carbene-analogous behavior of *(4)*.

The composition and constitution of *(6)*, as well as of the precursors *(2)* and *(8)*, are confirmed by elemental analysis, mass spectra [*(2)*, *(8)*], cryoscopic molecular weight determination [*(6)*] and NMR-data (Table 1).

## *Experimental*

All experiments were carried out under inert gas and with rigorous exclusion of moisture. The solvents were purified and dried by column chromatography on Al$_2$O$_3$ (Super I, basic).

*(2)*: A mixture of *(1)*[7] (39.1 g, 0.2 mol) and anhydrous ZnF$_2$ (41.3 g, 0.2 mol) is stirred for 10 min at 140 °C. The resulting crude product is separated from any ZnCl$_2$ and is then distilled from a 10 cm Vigreux column, yield 27 g (76%) as water-clear, mobile liquid, b.p. 48–50 °C/12 torr.

*(8)*: A mixture of LiN(SiMe$_3$)$t$Bu (15.1 g, 0.1 mol) in THF (100 mL) is added dropwise at 40 °C to a stirred solution of *(7)*[8] (19.6 g, 0.1 mol) in 20 mL of THF. After stirring for 2h at 50 °C, filtration, and removal of solvent, the residue is fractionally distilled; yield 16 g (59%) as pale yellow liquid, b.p. 58—60 °C/0.2 torr.

*(4)* from *(2)*: A solution of *n*-butyllithium (2.3 mL, 0.05 mol; 23% in *n*-hexane) is slowly added dropwise at −78 °C to a stirred solution of *(2)* (9 g, 0.05 mol) in pentane (50 mL) and diethyl ether (20 mL). After stirring for 1h at −78 °C the solvent is removed by slowly warming to −10 °C. The residue (mainly *(3)* and the by-product $t$Bu($n$Bu)P—NH$t$Bu[9]) is pyrolyzed at 50—60 °C/0.5 torr; the volatile products are collected in two cold traps (0 °C/−78 °C) mounted in series. After 4 h, 3.6 g of *(4)* together

with *ca.* 10% of the by-product are collected in the −78 °C trap; double re-condensation leads to 2.4 g (32%) of pure *(4)*.

*(6)* from *(8)*: 13.4 g (0.05 mol) of *(8)* is pyrolyzed in a 10-cm Vigreux column at 40 torr and 160—170 °C, the temperature of the column not being allowed to exceed 40 °C; yield: 4.7 g (60%) (oil).

*(4)* from *(6)*: 3.1 g (0.01 mol) of *(6)* is heated to 60—70 °C at 0.1 torr. The volatile *(4)* thus formed is collected in a micro-trap cooled to −196 °C; yield: >90%.

## *gem*-Bis(halooxy) Compounds from *cis*- and *trans*-Tetrafluordioxotellurium(VI) Acid, $(HO)_2TeF_4$[**]

By *Brigitte Pötter, Dieter Lentz, Hans Pritzkow,* and *Konrad Seppelt*[*]

*Dedicated to Professor Oskar Glemser on the occasion of his 70th birthday*

In octahedral compounds of the nonmetals, *cis-/trans*-isomers are only rarely observed[1]; often only one isomeric form occurs. Until now $(HO)_2TeF_4$ could be detected only spectroscopically along with $(HO)_xTeF_{6-x}$ derivatives[2]. $Na_2TeO_2F_4$, a salt of the *cis*-acid, forms as a thermodynamically stable product in the pyrolysis of $NaTeOF_5$[3].

Fusing a mixture of $HOTeF_5$ and $Te(OH)_6$ in an autoclave gives a mixture of $(HO)_xTeF_{6-x}$ from which *cis*- and *trans*-$(HO)_2TeF_4$ can be sublimed out at room temperature as major products [yield 76.5%] as colorless, difficultly volatile crystals; *cis*:*trans* ≈ 2.25 : 1 (from statistical theory 4 : 1). The isomers can readily be separated *via* the silyl esters whose melting and boiling points differ significantly.

$$cis/trans\text{-}(HO)_2TeF_4 + 2\,Me_3SiCl \xrightarrow{60\,^\circ C} cis/trans\text{-}(Me_3SiO)_2TeF_4 + 2\,HCl$$

*cis*-$(Me_3SiO)_2TeF_4$ is a clear, stable liquid; M.p. = −10 °C, b.p. = 79 °C/20 mbar and the $^{19}$F-NMR spectrum shows a typical $A_2B_2$ pattern ($\delta_A = 28.59$, $\delta_B = 35.51$, $J_{AB} = 161.4$ Hz). *trans*-$(Me_3SiO)_2TeF_4$ is a colorless solid, m.p. = 47.0 °C, b.p. = 77.5 °C/20 mbar and only one sharp line occurs in the $^{19}$F-NMR spectrum ($\delta = 32.56$). Its structure was confirmed by X-ray diffraction analysis (Fig. 1).

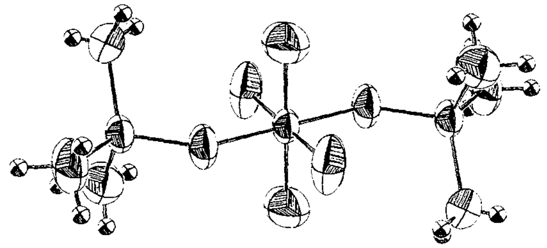

Fig. 1. Molecular structure of *trans*-$(CH_3)_3SiO_2TeF_4$ in the crystal. $P2_1/n$, $a = 1035.0(3)$, $b = 1127.0(3)$, $c = 636.0(2)$ pm, $\beta = 90.132°$; 2222 reflections. All atoms except H were refined anisotropically. $R_w = 0.025$; ∢ TeOSi = 137.4°.

Interestingly, pure *cis*-$(Me_3SiO)_2TeF_4$ can be prepared from $Me_3SiOTeF_5$ by reaction with disiloxane.

$$Me_3SiOTeF_5 + Me_3SiOSiMe_3 \xrightarrow{100\,^\circ C} cis\text{-}(Me_3SiO)_2TeF_4 + Me_3SiF$$

Its formation is obviously kinetically controlled (NMR limit of detection for the *trans*-isomer < 1%).

From the isomerically pure silyl ester, the isomerically pure acids are obtained by reaction with HF.

$$(Me_3SiO)_2TeF_4 + 2\,HF \rightarrow (HO)_2TeF_4 + 2\,Me_3SiF$$

*cis*-$(HO)_2TeF_4$ is a colorless, sublimable solid, m.p. = 106 °C; $^{19}$F-NMR: $A_2B_2$ spectrum ($\delta_A = 34.33$, $\delta_B = 42.37$, $J_{AB} = 149.47$ Hz). Likewise, *trans*-$(HO)_2TeF_4$ is a colorless, sublimable solid, m.p. = 116 °C; $^{19}$F-NMR: sharp singlet ($\delta = 39.65$). Both acids are thermally stable well above 100 °C, they do not interconvert, and are soluble in water without decomposition.

The structure also remains intact in simple chemical reactions:

$$cis\text{-}(HO)_2TeF_4 + 2\,ClF \xrightarrow{-78\,^\circ C,\ CFCl_3} 2\,HF + cis\text{-}(ClO)_2TeF_4$$

$$cis\text{-}(ClO)_2TeF_4 + Br_2 \xrightarrow{-78\,^\circ C} Cl_2 + cis\text{-}(BrO)_2TeF_4$$

$$trans\text{-}(HO)_2TeF_4 + 2\,ClF \xrightarrow{0\,^\circ C,\ CFCl_3} 2\,HF + trans\text{-}(ClO)_2TeF_4$$

$$trans\text{-}(ClO)_2TeF_4 + Br_2 \xrightarrow{-78\,^\circ C} Cl_2 + trans\text{-}(BrO)_2TeF_4$$

Compounds with vicinal bis(halogenoxy) groups were, to our knowledge, unknown. Both bis(chloroxy)tellurium tetrafluorides are yellow liquids: *cis*-$(ClO)_2TeF_4$, m.p. = −77.8 °C, b.p. < 20 °C/$10^{-2}$ mbar, $^{19}$F-NMR: $A_2B_2$ spectrum ($\delta_A = 51.71$, $\delta_B = 57.37$, $J_{AB} = 159.7$ Hz);

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

*trans*-$(ClO)_2TeF_4$, m.p. = −66.7 °C, b.p. <20 °C/$10^{-2}$ bar, $^{19}F$-NMR: singlet ($\delta = 54.65$). They are moisture and light sensitive. *cis*-$(BrO)_2TeF_4$, a red liquid, is thermally highly unstable and decomposes at *ca.* 0 °C (m.p. = −31.5 °C); the *trans*-isomer is more stable, (m.p. = 23 °C, $^{19}F$-NMR: singlet at $\delta = 51.60$).

Starting from *cis*-$(HO)_2TeF_4$, a polymeric xenon compound is obtainable:

$$cis\text{-}(HO)_2TeF_4 + XeF_2 \xrightarrow[20\,^\circ C]{C_4F_9SO_2F} 2\,HF + (\text{—}Xe\text{—}OTeF_4O\text{—})_n$$

This faintly yellow solid is insoluble in all common solvents and decomposes above 80 °C vigorously with evolution of xenon.

All new compounds were identified by elemental analyses as well as by IR spectroscopy.

# $CH_3\text{—}SF_4^+SbF_6^-$, a "Sulfuranonium" Salt[**]

By *Gert Kleemann* and *Konrad Seppelt*[*]

The kinetic stability of sulfur hexafluoride against all chemical attack is widely known and can be explained by the almost perfect shielding of the sulfur atom by the six fluorine ligands. The alkyl derivatives $CH_3\text{—}SF_5$ and $C_2H_5\text{—}SF_5$, likewise, are inert towards concentrated bases or lithium alkyls even at higher temperatures. When attacked by Lewis acids, however, the abstraction of a fluoride ion in the primary step is readily possible.

Methyl- and ethylsulfur pentafluoride were prepared according to:

$$CH_2{=}SF_4 \xrightarrow[-78\,^\circ C]{HF} CH_3\text{—}SF_5{}^{[1]}, \qquad \text{B.p.} = 26\,^\circ C$$

$$ClCO\text{—}CH_2\text{—}SF_5{}^{[2]} \xrightarrow[\text{1. ether 2. } H_2O]{LiAlH_4} HOCH_2CH_2\text{—}SF_5 \xrightarrow[CH_2Cl_2,\ \text{pyridine}]{TosCl}$$

$$Tos\text{—}OCH_2CH_2\text{—}SF_5{}^{[3b]} \xrightarrow[(nC_4H_9)_2O]{LiAlH_4} C_2H_5\text{—}SF_5, \qquad \text{B.p.} = 61\,^\circ C$$

Both react readily at low temperatures with $AsF_5$ or $SbF_5$, forming colorless solids that decompose irreversibly at room temperature.

$$RSF_5 + EF_5 \xrightarrow{-70\,^\circ C} RSF_4^+EF_6^- \xrightarrow{20\,^\circ C} SF_3^+EF_6^- + RF$$

The intermediate products and their decomposition reactions were investigated by NMR spectroscopy in the $CH_3SF_5/SbF_5$ system with $SO_2$ as solvent (cf. Fig. 1).

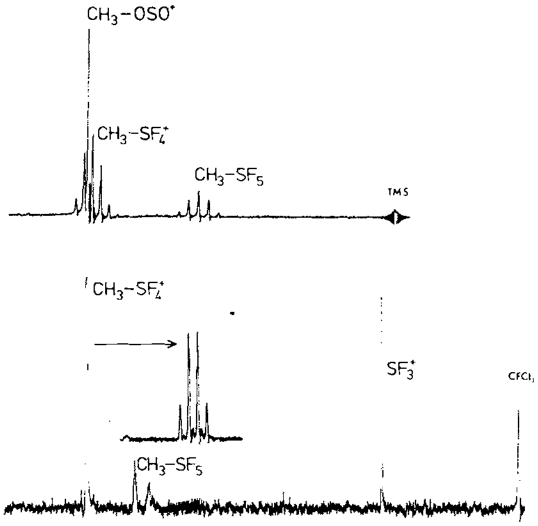

Fig. 1. $^1H$- and $^{19}F$-NMR spectra (below) of a $CH_3SF_5$ and $SbF_5$ solution in $SO_2$ at −80 °C.
$CH_3SF_5$: $\delta_H = 3.4$, $\delta_{FA} = -84.0$, $\delta_{FB_4} = -70.5$, $J_{HF} = 10.25$ Hz, $J_{AB_4} = 150$ Hz; $CH_3SF_4^+$: $\delta_H = 5.28$, $\delta_F = -80.7$, $J_{HF} = 8.6$ Hz; $CH_3OSO^+$: $\delta_H = 5.35$ (cf. [4]); $SF_3^+$: $\delta_F = -25.5$.
In the $^{19}F$-NMR spectrum several broad peaks for the Sb—F atoms are additionally observed at $\delta = +100$ to $+150$.

Besides the known peaks of the starting compound $CH_3\text{—}SF_5$[2], a quintet appears in the $^1H$-NMR spectrum and a quartet in the $^{19}F$-NMR spectrum, which are assigned to the $CH_3\text{—}SF_4^+$ cation. This interpretation presumes the magnetic equivalence of the fluorine atoms through rapid intramolecular exchange. Further peaks indicate the decomposition ot the "sulfuranonium" ion, thus

$$CH_3\text{—}SF_4^+ \xrightarrow{SO_2} CH_3\text{—}OSO^{+[3]} + SF_4 \xrightarrow{SbF_5} SF_3^+SbF_6^-$$

whereby $CH_3^+$ could be formed as intermediate.

Our results indicate that:

- either the displacement of a fluorine atom in $SF_6$ by the sterically similar methyl or ethyl group leads to a drastic change in the electronic properties of the molecule, in particular it causes an increase in the basicity of the remaining fluorine atoms,
- or the reactivity of $SF_6$ in the presence of the strongest Lewis acids has not been sufficiently explored to date.

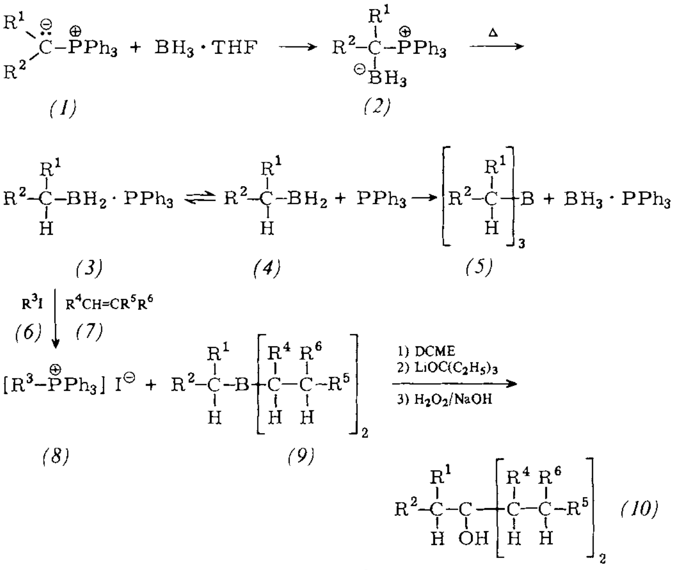
# Monoalkylboranes from Alkylidene(triphenyl)phosphoranes and Borane; Combination of Ylide Reactions and Hydroboration[**]

By *Hans Jürgen Bestmann, Kurt Sühs,* and *Thomas Röder*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

Alkylidenetriphenylphosphoranes *(1)* add $BH_3$ (as adduct with ether, tetrahydrofuran or amines) to give the stable phosphonioborates *(2)*[1]. *Köster* and *Rickborn*[2] found that when *(2a)* and *(2e)* (Table 1) are heated in boiling chlorobenzene a clear solution is formed which on treatment with acids liberates two moles of hydrogen per mole of *(2)*; on the strength of this they concluded that *(3)* is formed. Consistent with this conclusion, trialkylboranes *(5)* and triphenylphosphane–borane are formed on heating *(2)* in boiling decalin.



*(6a), (8a)*: $R^3 = CH_3$; *(6b), (8b)*: $R^3 = C_6H_5CH_2$
DCME = $Cl_2HCOCH_3$

We have now been able to confirm the rearrangement of *(2)* to *(3)* with numerous examples. The reaction (in chlorobenzene) was followed $^{31}$P-NMR spectroscopically. The adducts *(3)*, which can be isolated in a crystalline or an oily state, do not disproportionate; on acid hydrolysis they evolve two moles of hydrogen per mole of *(3)*. The reactions carried out by us are listed in Table 1.

In solution an equilibrium exists between the adducts *(3)* on the one hand, and the monoalkylboranes *(4)* and triphenylphosphane on the other; this equilibrium lies predominantly on the side of *(3)* at room temperature. If a solution of *(3)* in tetrahydrofuran is treated with methyl iodide *(6a)* or, better, benzyl iodide *(6b)*, then triphenylphosphane is removed as the sparingly soluble phosphonium salt *(8)*, and the free monoalkylboranes *(4)* remain in solution. We have thus found a simple entry[4] to the preparatively very useful[5] compounds *(4)*; monoalkylboranes *(4b–d)* with unbranched chains, as well as monomethyl- *(4a)*, monobenzyl- *(4e)* and monoisopropylborane *(4f)*, can be prepared without difficulty. If the monoalkylboranes *(4)* obtained from *(3)* are liberated by reaction with *(6)* in the presence of an olefin *(7)* at room temperature, a hydroboration takes place, leading to the "mixed" trialkylboranes *(9)*, which can be converted by known methods[6a], *e.g.* into the tertiary alcohols *(10)*. We usually employed the dichloromethyl methyl ether–$LiOC(C_2H_5)_3$–$H_2O_2$ (DCME) method[6b]. Table 2 lists some examples.

Table 2. Tertiary alcohols *(10)* obtained by reaction of the adducts *(3)* with methyl iodide *(6a)* in the presence of an olefin *(7)* in tetrahydrofuran at room temperature and subsequent conversion, by the DCME method, of the borane *(9)* formed. The reaction times *(t)* can be shortened by use of benzyl iodide *(6b)* instead of *(6a)*.

Ring closure takes place on reaction of diolefins with monoalkylboranes, as has already been demonstrated in the case of monotectylborane[6a,c]. Reaction of the adducts *(3)* with *(6)* in the presence of 1,5-cyclooctadiene leads to formation of the bridged boranes *(11)*, which can be converted by the DCME-method[6b] into the corresponding tertiary alcohols *(12)* [*(12a)* from *(3b)* on using *(6b)*; *(12b)* from *(3c)* on using *(6a)*; reaction times 24 h and 78 h, b.p. 80–85 °C/0.01 torr and 96–100 °C/0.05 torr[8], yield 41% and 50%, respectively[7]].

Table 1. Phosphonioborates *(2)* from phosphorus ylides *(1)* and borane, and triphenylphosphane—monoalkylboranes *(3)* by rearrangement of *(2)*.

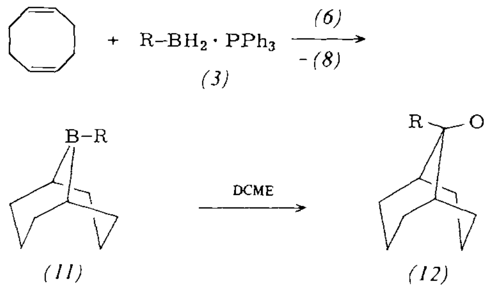
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (Germany)

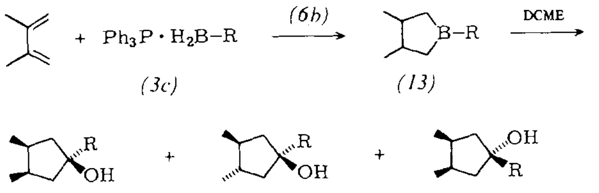
[**] Delivered in part in a lecture at the International Symposium "Metallo-Organics in Organic Synthesis", July 14—17, 1980 in Swansea (Wales).—We thank Prof. *G. Wilke*, Mülheim-Ruhr (Germany) for supplying (*Z*)-1,2-divinylcyclobutane.



(11) (12)

(12a): R = $C_2H_5$; (12b): R = $n$-$C_6H_{13}$

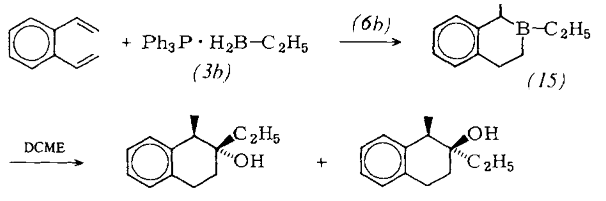
(13). Reaction of (13) according to the DCME method, followed by oxidation, furnishes a 55 : 43 : 2 mixture of three alcohols (b.p. 69–73 °C/0.02 torr, yield 43%[7]), which, according to GC/MS and NMR spectra, are the isomeric cyclopentanols (14). The product formed in least yield is assigned the all-*cis* structure (14c).



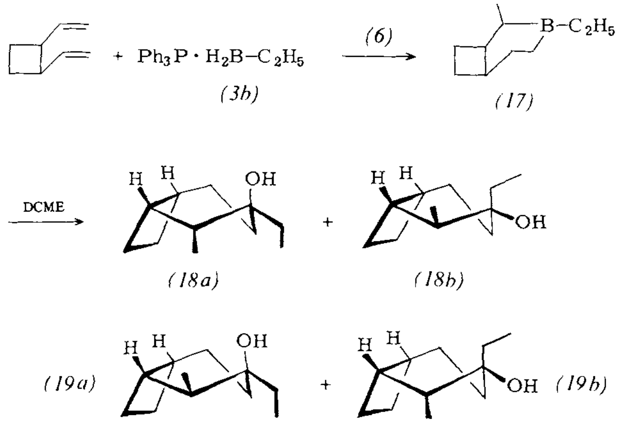
(14a) (14b) (14c)

R = $n$-$C_6H_{13}$

*o*-Divinylbenzene[9], which is readily accessible from phthalaldehyde and methylenetriphenylphosphorane, reacts with (3b) in the presence of (6b) to give a cyclic product, which on treatment by the DCME method gives three isomers (GC/MS) in the ratio 52 : 44 : 4 by weight (b.p. 79–83 °C/0.01 torr, yield 46%[7]). The $^{13}$C-NMR spectrum of the two main compounds is reconcilable only with a mixture of the dialkyltetrahydronaphthols (16a) and (16b). (The constitution of the third isomer is still unclear.) This means that the cyclizing hydroboration of *o*-divinylbenzene with (3b) proceeds largely regiospecifically with formation of a six-membered ring to give (15).



(16a) (16b)



With the same regioselectivity, reaction of (3b) with (*Z*)-1,2-divinylcyclobutane should afford the borabicyclooctane derivative (17) whose conversion by the DCME method would lead to four isomers. We found four alcohols and a still unidentified compound (38 : 22 : 19 : 17 : 4). On GC/MS analysis, the alcohols (proportion 96%, b.p. 69–73 °C/0.01 torr, yield 40%[7]) gave the same mass spectrum. A gas chromatographic separation of the isomers (14a) and (14b), (16a) and (16b), as well as (18a, b) and (19a, b) on the preparative scale, which would enable an unambiguous assignment of the isomers to the GC peaks, has so far met without success.

The Wittig reaction enables the synthesis of olefins from carbonyl compounds and phosphorus ylides. The general method described here for the conversion of ylides into monoalkylboranes and their subsequent reaction with olefins provides a combination of ylide reactions and hydroboration, whose scope of application still remains to be investigated in detail.

## Alcoholate Clusters ("Aggregates") and Their Role in Alkyne-Forming Elimination Reactions[**]

By *Manfred Schlosser* and *Tran Dinh An*[*]

Consistent with an earlier prediction[1], unusual reaction orders have been found for potassium *tert*-butoxide when used as a dehydrohalogenating reagent in solvents of low polarity. The values for the indices *n* in the rate equation, which reflect the influence of the base concentration on the reaction rate, lie between 0.5 and 0.75 in the case of *syn*-eliminations (*cis*-1,2-dichlorocyclodecane in toluene: 0.5[2a]; *meso*-3,4-dichloro-2,2,5,5-tetramethylhexane in tetrahydrofuran or *tert*-butyl alcohol: 0.5 and 0.7, respectively[2b]), and between 0.75 and 1.2 in the case of *anti*-eliminations (*cis*-1,2-dichlorocyclodecane in toluene: 0.75[2a];

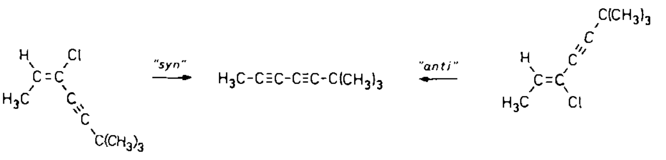
---

[*] Prof. Dr. M. Schlosser, Dipl.-Chem. Tran Dinh An
Institut de Chimie Organique de l'Université
Rue de la Barre 2, CH-1005 Lausanne (Switzerland)

[**] This work was supported by the Schweizerischen Nationalfonds zur Förderung der wissenschaftlichen Forschung (Project 2.128.0-78). Special thanks are due to Prof. *J. F. Bunnett*, Santa Cruz (Calif.) for his hospitality and numerous valuable discussions; the greater part of this work was carried out in his laboratory.

*meso*-3,4-dibromo-2,5-dimethylhexane in toluene: 1.0[2a]; *meso*- or *dl*-4,5-dichlorooctane in benzene 0.75[2a]; *meso*-3,4-dichloro-2,2,5,5-tetramethylhexane in tetrahydrofuran or *tert*-butyl alcohol: 0.8 and 1.2, respectively[2b]). Making the sound[3], but not strictly proven assumption, that potassium *tert*-butoxide exists predominantly as a tetrameric "aggregate" in solvents of low polarity, these reactions are mainly induced by dimeric and trimeric and, occasionally, by tetrameric base associates.

We decided to extend our investigations to *acetylene*-forming eliminations, since these differ in several respects from the *olefin*-forming ones. (*Z*)- and (*E*)-3-chloro-6,6-dimethyl-2-hepten-4-ynes *(1)* were chosen as model substrates, because interfering side-reactions like *E2cb* processes[7] or allene formation[8] may then be ruled out. Indeed, on reaction with base, 6,6-dimethyl-2,4-heptadiyne *(2)* was formed as sole product.



*E-(1)*   *(2)*   *Z-(1)*

The reaction orders (see Fig. 1 and Table 1) are approximate by 0.6 for the *syn*-elimination in three different solvents and about 0.8 (in tetrahydrofuran and toluene) or 1.1 (in *tert*-butyl alcohol) for the *anti*-elimination. According to the "variable transition state model"[9] the mechanisms of acetylene-forming eliminations are much more like *E1cb* processes than those of olefin-forming eliminations. Nevertheless, here also, dimeric, trimeric or—more rarely—tetrameric alcoholate aggregates participate in the rate-determining step. They exert a push-pull action on the reacting halide and initiate a closed cyclic electron- and particle-*motion* ("conveyor belt mechanism"), as indicated, *e.g.* in *syn-(3)* and *anti-(3)*.

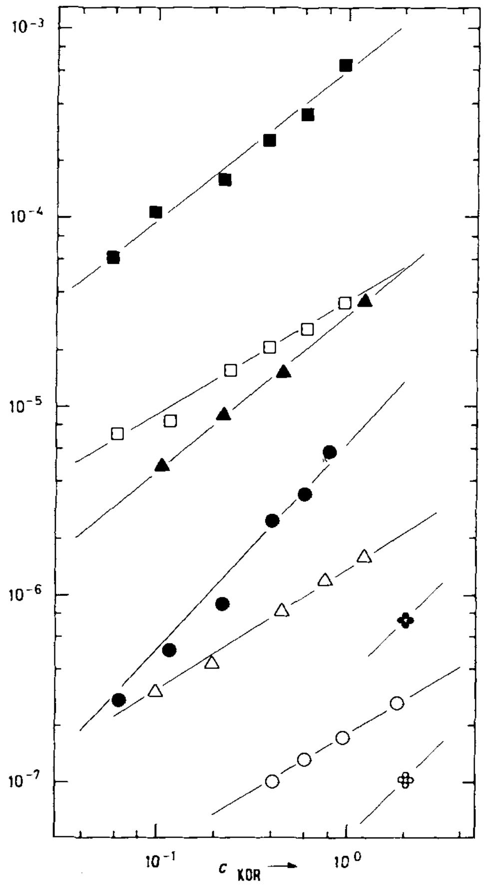


Fig. 1. Double logarithmic plot of the pseudoconstants $k_1^{\psi}$ $s^{-1}$ against the "formal" alcoholate concentration [mol/L]. Light and dark symbols designate *syn*- and *anti*-eliminations, respectively; squares, triangles, and circles: with potassium *tert*-butylalcoholate in tetrahydrofuran, toluene, and *tert*-butyl alcohol, respectively; rosettes: with potassium ethoxide in ethanol.

Table 1. Rate of the *syn*- and *anti*-periplanar cleavage of hydrogen chloride from (*E*)- and (*Z*)-3-chloro-6,6-dimethyl-2-hepten-4-yne with potassium *tert*-butylalcoholate or potassium ethoxide: Effect of solvent and base concentration.

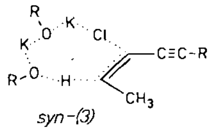
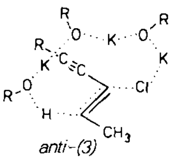
[a] In the first column $c_{KOR}$ denotes the "formal" or "titratable" concentration of the alcoholate; it is found by titrimetric determination of the hydroxide concentration (mol/L) after hydrolysis. The second column contains pseudoconstants $k_1^{\psi}$ for a 1st order reaction (dimension: $s^{-1}$), which are obtained on plotting the chlorodimethylheptenyne concentration as a function of the reaction time; in order to obtain true reaction rate constants the pseudoconstants must be divided by the—unknown—concentration of "active base". In the third column the tangent (tan) is given, which defines the slope of the straight line through the points on plotting the pseudoconstants $k_1^{\psi}$ against the respective formal concentrations $c_{KOR}$ (Fig. 1). This data multiplied by the degree of aggregation of the potassium *tert*-butoxide in the ground state gives the number of the base molecules which are jointly active in promoting the reaction.—[b] This measurement, obviously erroneous is not taken into account in Fig. 1.—[c] The *syn/anti* reactivity ratio for the elimination of HCl from *trans*- and *cis*-propenyl chloride, instead of being around 70, as here, approaches 800 [*S. I. Miller*, J. Org. Chem *26*, 2619 (1961)].—[d] Since, at least in this concentration range, potassium ethoxide exists to a very large extent as dissociated free ions (and also reacts as such) a reaction order of 1.0 with respect to the base is to be expected, unless salt effects (cf. [2b]) intervene.



*syn-(3)*



*anti-(3)*

There is no point in comparing stereo- or regiochemically different routes which are accessible to a given elimination reaction as long as it is unknown whether the same reagents (such as monomeric, dimeric or oligomeric potassium *tert*-butoxide) are always involved. Therefore, before listing *syn/anti* or Hofmann/Saytzeff ratios, one should first measure each reaction order with respect to the base.

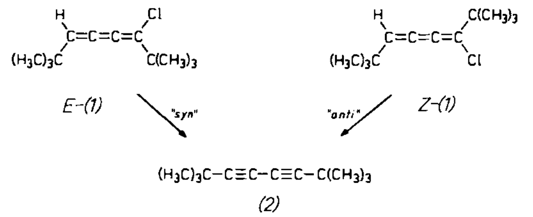
# Base-Promoted 1,4-Elimination Reactions: On the Origin of an Eventual *syn*-Stereoselectivity[**]

By *Manfred Schlosser, Claudio Tarchini, Tran Dinh An, Renzo Ruzziconi*, and *Paul J. Bauer*[*]

The mechanism of base-promoted elimination reactions remains an ever fascinating problem[1]. A currently intriguing question is how concertedness and stereoselectivity are affected on going from 1,2- to 1,3- or 1,4-elimination processes[2], thus separating the two reaction centers by insertion of one or two carbon units. So far, investigations of 1,4-conjugate eliminations have been confined to cyclic models which may be expected to favor a boat-shaped transition state facilitating a *syn*-, and discriminating against an *anti*-mode of cleavage[3]. We have now devised and prepared a linear model system, which has allowed us to study the fundamental features of a 1,4-conjugate elimination mechanism in what we had hoped to be a more unambiguous way.

Starting with 2,2,7,7-tetramethyl-4-octyn-3,6-diol[4] (*meso/dl*-mixture), 3,6-dichloro-2,2,7,7-tetramethyl-4-octyne (*meso/dl*-mixture, b.p. 58—60 °C/0.2 torr)[5] was obtained by treatment with triphenylphosphane and tetrachloromethane. The dichloro derivative was stirred with potassium *tert*-butoxide in pentane at −50 °C and converted into a 3 : 1 mixture of (*Z*)- and (*E*)-3-chloro-2,2,7,7-tetramethyl-3,4,5-octatriene *(1)* (30%, b.p. 63—64 °C/2 torr)[5,6], separable by gas chromatography[7]. When heated with alcoholates both isomers underwent 1,4-dehydrochlorination affording 2,2,7,7-tetramethyl-3,5-octadiyne *(2)*[5] in quantitative yield.

The decrease in concentration of *(1)* as a function of time was monitored by UV measurements (*Z*- and *E-(1)*: $\lambda_{max} = 248$ nm, ε 48000), NMR spectroscopy (using the



*tert*-butyl signals as an internal standard) or gas chromatography (45 m C-20M "SCOT" glass-capillary column, 80 °C). In addition, the relative rates $k_{syn}/k_{anti}$ ($=k_E/k_Z$) were measured in competition experiments using substoichiometric amounts of base. In the polar solvents methanol and dimethyl sulfoxide, or in the presence of the macrocyclic polyether 1,4,7,10,13,16-hexaoxacyclooctadecane ([18]crown-6) the reactivity of both isomers was virtually the same. On the other hand, in *tert*-butyl alcohol, tetrahydrofuran, or benzene *(E)-(1)*, was converted, with *syn*-elimination, into the diacetylene *(2)* at least 35 times faster than the (*Z*)-isomer (see Table 1).

Table 1. Dehydrohalogenation of (*E*)- and (*Z*)-3-chloro-2,2,7,7-tetramethyl-3,4,5-octatriene *(1)*: relative rates of *syn*- and *anti*-elimination ($k_{syn}/k_{anti}$).

| Base/Solvent system [a] | In the presence of [18]crown-6 | In the absence of [18]crown-6 |
|---|---|---|
| $KOCH_3/CH_3OH$ | — | 3.2 |
| $KOC(CH_3)_3/(CH_3)_2SO$ | 0.95 | 0.96 |
| $KOC(CH_3)_3/(CH_3)_3COH$ | 1.8 | 35 |
| $KOC(CH_3)_3/C_4H_8O$ | 2.0 | >35 |
| $KOC(CH_3)_3/C_6H_6$ | 2.4 | >35 |

[a] Alkoxide and substrate *(1)* concentrations roughly 0.6 and 1.2 M, respectively. The reaction was run in methanol at 50 °C and in all other cases at 25 °C.

In $CH_3OD$, $(CH_3)_3COD$ or $(CD_3)_2SO$, the chlorocumulenes did not incorporate any deuterium. Moreover, no (*Z/E*)-isomerization[8] of *(1)* was detected under the reaction conditions. Thus, in methanol and dimethyl sulfoxide either an irreversible E1cb process or a concerted, although still E1cb-like mechanism should be operative[9]. We favor the second hypothesis since the rate constants of (*Z*)- and (*E*)-*(1)* in methanol, when compared to related substrates[10], are fairly high. The low stereoselectivity may then be explained by the increasing distance between the reaction centers when going from acetylene-forming 1,2- to 1,4-eliminations. In this way, the differences in orbital interactions and hence the discrimination between the *syn*- and *anti*-mode vanish.

The reappearance of stereoselectivity in solvents of low polarity must be attributed to special factors. As demonstrated already in several other cases[11] oligomeric alcoholate species, so-called "aggregates" or fragments thereof, are now the effective reagents. Indeed, in the reaction between (*Z*)- or (*E*)-*(1)* and potassium *tert*-butoxide in *tert*-butyl alcohol, the "formal" base concentration was also found to enter the rate equation with an exponent of 0.8. This points at the action of a trimeric entity on both isomers (see [11]). Two complex ions[12] $[(H_3C)_3COK_2]^{\oplus}$ and $[(H_3C)_3COKOC(CH_3)_3]^{\ominus}$, cooperatively effecting the elimination through transition states *syn*- and *anti-(3)* would be in perfect agreement with this conclusion. The observed *syn*-stereoselectivity should then be a consequence of enhanced concertedness due to the pull-effect of the cation[13]. This, however, would be inconflict with the common belief that replacement of methoxide by *tert*-butoxide, a stronger base, will inevitably render the elimination

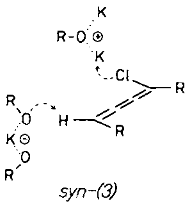
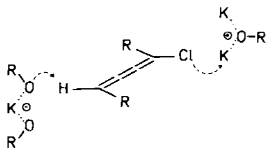
mechanism more, not less, E1cb-like. Therefore, we prefer to postulate again a "conveyer belt" process[11] as defined by transition states *syn*- and *anti-(4)*. The *syn*-mode would then be privileged for obvious and trivial geometrical reasons.

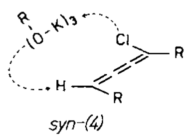


*syn-(3)*

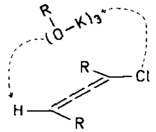


*anti-(3)*

R = C(CH$_3$)$_3$



*syn-(4)*



*anti-(4)*

Perhaps also the stereoselectivity of vinylogous substitutions ($S_N2'$ reactions), electronically related to 1,4-conjugate eliminations, depends more on external factors than on inherent orbital-control. This would explain why sometimes the *syn*- and sometimes the *anti*-mode are dominant[14].

[3] Cf. [2c]: Dehydroanthracenes prefer a boat-conformation already in the ground-state; overlap between electrons of the incipient carbanion (E1cb-type mechanism!) and the neighboring aromatic rings should still enhance this tendency. The conformational requirements of the transition state of 2-cyclohexenol dichlorobenzoates are less safely predicted; since, however, a *bona fide* monomeric base in a non-dissociative solvent (toluene) was involved, a cyclic group transfer mechanism (privileging *syn*-elimination) appears highly probable.

[4] *W. B. Sudweeks, H. S. Broadbent*, J. Org. Chem. *40*, 1131 (1975).

[5] Correct NMR, UV, IR and mass spectra as well as combustion analytical data have been obtained for all new or otherwise important compounds.

[6] Dipole measurements alone allowed an unequivocal assignment of configurations (*P. J. Bauer*, unpublished work). *(Z)-(1)* ($\delta(^1H) = 5.47$, 1.18 and 1.01 in benzene) melts between −8 and −6 °C, whereas *(E)-(1)* ($\delta(^1H) = 5.36$, 1.19 and 0.98), which has a longer retention time on Carbowax columns, only becomes more and more viscous and finally glassy below −40 °C. Incidentally, the sterically related (*E*)- and (*Z*)-isomers ($\delta(^1H) = 5.50$ and 1.09 or 5.45 and 1.12, respectively, in CDCl$_3$) of the non-halogenated "di-*tert*-butylbutatriene" (prepared from *meso*- and *dl*-3,6-dichloro-2,2,7,7-tetramethyl-4-octyne by treatment with zinc and separated by gas chromatography) melt at 64—65 °C and 21—23 °C, respectively. These melting points have so far not been reported by other authors (*H. Yamazaki*, J. Chem. Soc. Chem. Commun. *1976*, 841; *M. Tigchelaar, H. Kleijn, C. J. Elsevier, J. Meijer, P. Vermeer*, Tetrahedron Lett. *1981*, 2237) who also claim the isolation of one or both of these isomers.

[7] 6 m glass column, 30% diethyleneglycol succinate on Chromosorb WAW 60/80, 10 min 120 °C, then 3 °C/min up to 200 °C, injector and detector temperature 150 °C.

[8] Allenyl and butatrienyl anions should rapidly invert or even be linear, as some of the isoelectronically related ketenimines are (cf. *J. J. Daly*, J. Chem. Soc. *1961*, 2801).

[9] The acidity of the methine group, occupying both an olefinic and allylic position, may just reach the threshold pK$_a$-value of 28 (*S. Andreades*, J. Am. Chem. Soc. *86*, 2003 (1964)) required for methoxide-mediated carbanion formation.

## Molecular Structures of Tri-*O*-acetyl-D-glucal and Ethyl-4,6-di-*O*-acetyl-2,3-dideoxy-α-D-erythro-2-hexenopyranoside

By *Wolfgang Voelter, Wolfram Fuchs, John J. Stezowski,* and *Petra Schott-Kollat*[*]

*Dedicated to Professor Karl Folkers on the occasion of his 75th birthday*

2,3-Unsaturated pyranoses are intermediates frequently used for the synthesis of derivatives of rare natural carbohydrates, *e.g.* amicetose (2,3,6-trideoxy-*erythro*-hexose)[1]. Biologically important amino sugars, *e.g.* ossamine (4-dimethylamino-2,3,4,6-tetradeoxy-*threo*-hexose)[2], its *erythro*-isomer forosamine[3] and tolyposamine (4-amino-2,3,4,6-tetradeoxy-*erythro*-hexose)[3] can be obtained by $S_N$ reactions at C-4. The most elegant method for the preparation of 2,3-unsaturated pyranosides such as *(2)* is the boron trifluoride-ether catalyzed reaction of glycals such as *(1)* with alcohols[4]. To clarify the course of this reaction we carried out X-ray structural analyses on tri-*O*-acetyl-D-glucal *(1)* (obtained by reaction of 2,3,4,6-tetra-*O*-acetyl-α-D-glucosyl bromide with zinc[5]) and the ethyl-4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-2-hexenopyranoside *(2)* prepared therefrom (Fig. 1, Table 1).

With exception of the C—O ester bond C3—O3 in *(1)* (1.454(2)) and C4—O4 in *(2)* (1.458(2)) adjacent to the double bond, the molecules exhibit normal atomic distances: the two ester bonds are about 0.01 Å longer than in analogous ester groups of the sugars. According to the dihedral angles[8] both unsaturated sugars exist in the half-chair form. All ester groups are *trans* oriented.

Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

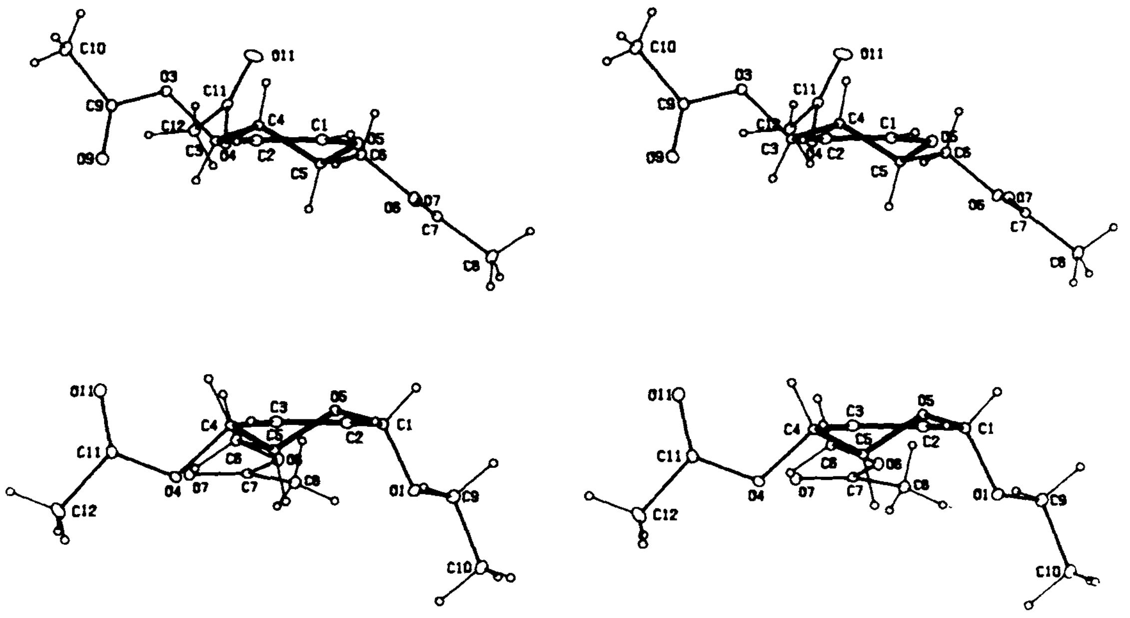

Fig. 1. Stereoscopic diagram of the half-chair conformation of the unsaturated sugars *(1)* and *(2)* in the crystal. Crystallographic data: *(1)*: space group $P2_12_12_1$; $Z=4$; cell constants at 120 K: $a=5.2210(7)$, $b=15.234(2)$, $c=16.307(1)$ Å; *(2)*: space group $P2_12_12_1$; $Z=4$; $a=5.3320(4)$, $b=14.571(1)$, $c=16.479(2)$ Å.—The sets of high-resolution data ($2\theta_{max}=75°$ for *(1)* and 80° for *(2)*, monochromatic $Mo_{K\alpha}$ radiation, $\lambda=0.71069$ Å) are corrected for Lorentz and polarization effects, and were recorded according to the "ω"-scan method. The original crystal structure models [6] were refined to $R=0.046$ and $R_w=0.052$ for *(1)* and to $R=0.041$ and $R_w=0.048$ for *(2)* (3220 and 3922 reflections, respectively) [7].

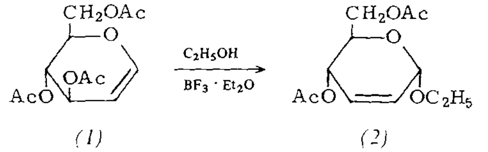

*(1)* *(2)*

Table 1. Bond lengths, bond angles and dihedral angles of *(1)* and *(2)*

| Bond lengths [Å] | | *(1)* | *(2)* | |
|---|---|---|---|---|
| C1—C2 | | 1.327(2) | 1.506(2) | |
| C1—O5 | | 1.369(2) | 1.427(2) | |
| C2—C3 | | 1.500(2) | 1.331(2) | |
| Bond angles [°] | | | | |
| C2—C1—O5 | | 125.0(1) | 111.9(1) | |
| C1—C2—C3 | | 121.9(1) | 121.9(1) | |
| Dihedral angles [°] | | | | |
| O5—C1—C2—C3 | | − 3.2(3) | 12.1(2) | |
| C1—C2—C3—C4 | | − 13.9(2) | 1.9(2) | |
| C2—C3—C4—C5 | | 45.8(2) | 17.3(2) | |
| C3—C4—C5—O5 | | − 65.0(2) | − 50.0(1) | |
| C4—C5—O5—C1 | | 48.4(2) | 68.1(1) | |
| C5—O5—C1—C2 | | − 15.1(2) | − 48.0(1) | |
| C2—CX—OX—C9 | X = 3 | − 78.5(2) | − 175.6(1) | X = 1 |
| CX—OX—C9—C10 | X = 3 | 174.6(1) | − 178.3(1) | X = 1 |
| C5—C4—O4—C11 | | − 104.7(1) | − 141.4(1) | |
| C4—O4—C11—C12 | | 178.1(1) | 176.1(1) | |
| C4—C5—C6—O6 | | − 173.9(1) | 177.1(1) | |
| C5—C6—O6—O7 | | 152.0(1) | 159.8(1) | |
| C6—O6—C7—C8 | | 177.7(1) | 171.7(1) | |

The numbers in brackets are estimated standard deviations to the last eignificant figure.

It is clear from this X-ray structure analysis that the $BF_3$-catalyzed reaction *(1)*→*(2)* essentially takes place in one plane and is stereospecific, since the C-atoms 1—3 are planar oriented, both in the educt as well as in the product.

## Heterogeneous Hydrogenation of Organic Halogen Compounds by Carrier-Supported Organotin Hydrides[**]

By *Herbert Schumann* and *Bernd Pachaly*[*]

Organotin hydrides, especially tributylstannane, are indispensable as hydrogenating agents in organic synthesis[1]. Thus, for example, they convert alkyl halides into the corresponding hydrocarbons, the organotin hydride itself being converted into an organotin halide, which must be separated from the product of reduction. This separation can, however, be circumvented by using polymeric insoluble reagents, such as organotin hydrides supported on polysty-

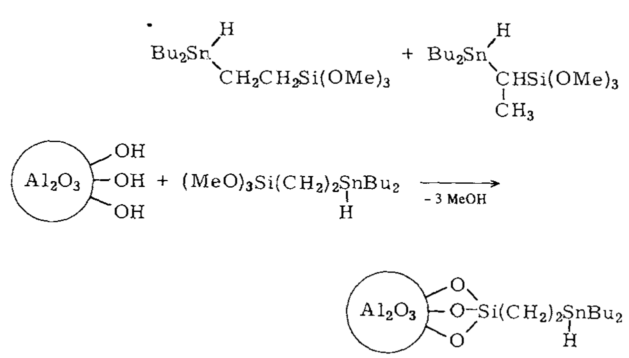
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Paul Rauschert KG.

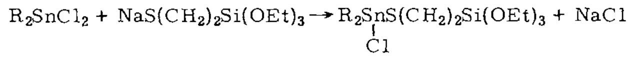
rene[2]. To improve the method—and particularly the stability and regeneratability of the reagent—we supported soluble organotin hydrides on solid *inorganic* carriers.

Hydrostannation of trimethoxy(vinyl)silane with dibutylstannane affords an isomeric mixture of dibutyl(1- and 2-trimethoxysilylethyl)tin hydride, which reacts with aluminum oxide or silica gel with cleavage of methanol:

$$Bu_2SnH_2 + CH_2{=}CHSi(OMe)_3 \xrightarrow{AIBN}$$

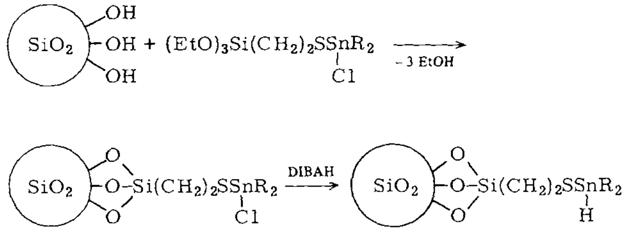


A second possibility is the incorporation of terminal triethoxysilylated organotin halides onto silica or alumina and subsequent hal/H exchange with diisobutylaluminum hydride (DIBAH):



$$R_2SnCl_2 + NaS(CH_2)_2Si(OEt)_3 \rightarrow R_2\underset{Cl}{Sn}S(CH_2)_2Si(OEt)_3 + NaCl$$

R = Bu, b.p. = 185-189°C/13 torr
R = Ph, b.p. = 190°C/10 torr



The amount of substance incorporated was found to average 1.3 molecules of organotin compound per nm$^2$ surface area of solid (gravimetric determination), *i.e.* within the range (0.5 to 1.5 molecules/(nm)$^2$ carrier) already quoted for such incorporation of reagents[3]. The reactive hydrogen was determined indirectly by reaction with CH$_3$I (measurement of amount of CH$_4$ liberated) and was found to average 48% of active organotin hydride referred to the amount of supported substance. Table 1 lists the yields of hydrocarbon that could be achieved on reduction of alkyl halides with the modified reagent at 40°C in cyclohexane after 2 h. 1,1-Dichloro-2,2-diphenylcyclopropane (DCDPCP) is completely reduced to 1,1-diphenylcyclopropane (DPCP) (NMR detection) within 24 h.

Table 1. Reduction of alkyl halides with carrier-supported organotin hydrides.

| Reducing agent (active amount in mmol) | Substrate g (mmol) | Product mL (% conv. ref. to t inhydride) |
|---|---|---|
| SiO$_2$—Si(CH$_2$)$_2$SSnBu$_2$H | CH$_3$I | CH$_4$ |
| (15.6) | 4.5 (32) | 140 (40) |
| SiO$_2$—Si(CH$_2$)$_2$SSnPh$_2$H | C$_4$H$_9$Br | C$_4$H$_{10}$ |
| (0.27) | 3.0 (22) | 2.4 (40) |
| Al$_2$O$_3$—Si(CH$_2$)$_2$SnBu$_2$H | CH$_3$I | CH$_4$ |
| (8) | 1.5 (11) | 85 (48) |
| Al$_2$O$_3$—Si(CH$_2$)$_2$SnBu$_2$H | DCDPCP | DPCP |
| (2) | 0.43 (2) | 100% |

*Procedure*

Di-*n*-butyltin dihydride (2.73 g, 13 mmol), trimethyl(vinyl)silane (1.93 g, 13 mmol) and azoisobutyl nitrile (AIBN) (100 mg) are stirred together for 24 h at 60°C. The reaction mixture ($\nu$SnH 1795 cm$^{-1}$) is dissolved in ether (200 mL) and heated under reflux with 29 g of dried Al$_2$O$_3$ for 24 h. Removal of the solution by filtration, washing with ether, and drying, furnishes 33.8 g of loaded Al$_2$O$_3$. A trial test with CH$_3$I showed the proportion of active organotin hydride to be 0.17 nmol/g carrier material.

The polymer-supported reducing agents (with 6 mL cyclohexane/g) were allowed to react with alkyl halides (Table 1). Evolution of gas was complete after 2 h at 40°C. The incorporated organotin halides can be reconverted into the organotin hydrides by reaction with diisobutylaluminum hydride in ether/toluene (loss of activity 57%).

## Di-*tert*-butylthia- and -selenadiphosphirane[**]

By *Marianne Baudler, Horst Suchomel,*
*Gabriele Fürstenberg,* and *Ulrike Schings*[*]

*Dedicated to Professor Leopold Horner on the occasion of his 70th birthday*

Cyclic compounds containing the P$_2$X moiety (X = C[1a], Si[1b], B[1c], As[1d], Ge[1e], Sn[1f]) have become preparatively accessible in the past few years. In all cases a considerable kinetic stabilization of the P$_2$X moiety was achieved by bulky substituents on the three ring atoms. We have now examined whether analogues with unsubstituted ring members, such as sulfur or selenium, are also capable of existence and can be isolated.

Small amounts of 2,3-di-*tert*-butyl-1,2,3-thiadiphosphirane *(1)* (about 1 mol-%) could be identified $^{31}$P-NMR spectroscopically for the first time in the reaction of tri-*tert*-butylcyclotriphosphane[2] with sulfur (1 : 3, boiling te-

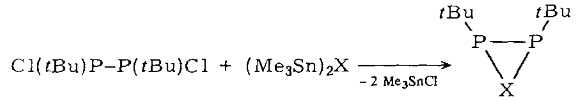
[**] Contributions to the Chemistry of Phosphorus, Part 108. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 107; *M. Baudler, Y. Aktalay, K.-F. Tebbe, Th. Heinlein*, Angew. Chem. *93*, 1020 (1981); Angew. Chem. Int. Ed. Engl. *20*, 967 (1981).

trahydrofuran (THF)); an enrichment compared to the main products $(t\mathrm{BuPS})_3$[3a] and $[t\mathrm{BuP(S)S}]_2$[3b] could not be achieved, however, by varying the reaction parameters. All the more surprising was the finding that *(1)* is obtainable in 36% yield (99% purity) by high-vacuum distillation after removal of the solvent and thermolysis of the product mixture at 130 °C. The formation is apparently achieved by ring contraction of higher-membered phosphorus-sulfur heterocycles.

Larger amounts of *(1)* could be detected $^{31}$P-NMR spectroscopically in the reaction of sulfur dichloride with 1,2-di-*tert*-butyldiphosphane[4] (1 : 1, boiling toluene) or with the diphosphasilirane $(t\mathrm{BuP})_2\mathrm{SiPh}_2$[1b] (1 : 1 : 1, boiling dioxane).

A particularly suitable preparative approach is the [2+1]-cyclocondensation of 1,2-di-*tert*-butyl-1,2-dichlorodiphosphane[5] with bis(trimethylstannyl) sulfide[6] (1:1, boiling THF). With bis(trimethylstannyl) selenide[7], the 2,3-di-*tert*-butyl-1,2,3-selenadiphosphirane *(2)* is obtained. The four-membered ring compounds $(t\mathrm{BuP})_4$ and $(t\mathrm{BuP})_3\mathrm{X}$ as well as the five-membered heterocycle with an exocyclic chalcogen atom $(t\mathrm{BuPX})_3$ are formed as by-products; in the case of *(2)* the five-membered ring compound $(t\mathrm{BuP})_4\mathrm{Se}$ is also formed. The product pattern depends on the concentration of the reactants, the reaction time and the quantities used; under suitable conditions the proportion of *(1)* or *(2)* is about 60 mol-%. The compounds can be isolated by high-vacuum distillation, in the case of *(2)* with subsequent low-temperature crystallization.



*(1)*, X = S
*(2)*, X = Se

*(1)* and *(2)* are, respectively, pale and bright yellow, viscous, evil-smelling liquids which are stable for weeks at −30 °C when not exposed to air and light. They readily dissolve in organic solvents, but the solutions—above all, of *(2)*—are less stable. The composition of *(1)* and *(2)* is confirmed by correct elemental analyses (C, H, P, S, and Se, respectively) as well as mass spectra with high relative intensity of the $M^+$ ions [*(1)*: $m/z = 208$ (100%); *(2)*: 256 (88%)]. The constitution follows from the $^{31}\mathrm{P}\{^1\mathrm{H}\}$-NMR spectra, which in each case show a singlet in the characteristic high-field region for phosphorus three-membered ring compounds[8] [*(1)*: $\delta = -91.5$ (THF, 301 K); *(2)*: $\delta = -76.9$, $J(\mathrm{P}^{77}\mathrm{Se}) = 135.2$ Hz (pentane, 213 K)]. The downfield shift of *(2)* in comparison to *(1)* is ascribed to the larger P—Se bond length and the resultant widening of the P—P—Se angles. The high-field position of the respective singlets in the $^1\mathrm{H}\{^{31}\mathrm{P}\}$-NMR spectra is also typical for substituents on the three-membered ring [*(1)*: $\delta = 0.94$ (benzene, 298 K; *(2)*: 0.97 (benzene, 300 K)]. The configuration cannot be deduced from the NMR spectra; but *tert*-butyl groups should be *trans*-oriented as in other $\mathrm{P_2X}$ compounds[1b,c,e,9].

Compared to analogous phosphorus three-membered ring compounds, *(2)* and, in particular, *(1)* are astonishingly stable towards heat and towards polar solvents such as THF. This high kinetic stability is apparently caused by the steric shielding of the *tert*-butyl substituents and by the free electron pairs on the heteroatoms.

### *Procedure*

*(1)*: 1,2-Di-*tert*-butyl-1,2-dichlorodiphosphane (14.1 g, 57.1 mmol) and bis(trimethylstannyl) sulfide (20.6 g, 57.3 mmol) in 300 mL THF are allowed to react to completion at the boiling temperature with stirring (about 187 h, $^{31}$P-NMR monitoring). After removal of the solvent trimethyltin chloride is condensed at 0.45 torr and maximum bath-temperature of 35 °C over a 10 cm Vigreux column fitted with an air-cooled bridge into a receiver cooled with liquid nitrogen. Distillation of the residue over a Zincke apparatus at 0.15 torr and bath-temperature of 70—75 °C yields 5.1 g (43%) of *(1)*, b.p. 45—46 °C/0.15 torr, which solidifies to a colorless solid at −78 °C; purity >99% ($^{31}$P-NMR).

*(2)*: A mixture of 1,2-di-*tert*-butyl-1,2-dichlorodiphosphane (6.4 g, 25.9 mmol) and bis(trimethylstannyl) selenide (10.47 g, 25.8 mmol) in 120 mL THF is heated under reflux for about 36 h. Since the amount of *(2)* passes through a maximum, $^{31}$P-NMR control is frequently necessary. After removal of solvent and trimethyltin chloride as in *(1)* the orange-yellow, liquid residue is distilled at $5 \times 10^{-4}$ torr at a bath-temperature of 110 °C through a Zincke apparatus, fitted with a 5 cm extension, into a receiver cooled to −78 °C; yield 2.85 g (43%), b.p. 57—58 °C/$5 \times 10^{-4}$ torr, purity 97% (rest $(t\mathrm{BuP})_3\mathrm{S}$, $^{31}$P-NMR). Dissolution in *n*-pentane (5 mL) and cooling to −78 °C yields, after 3 d, 2.19 g (33%) of almost colorless crystals, which after removal of the mother liquor are washed with 2 mL of cold pentane; purity 100%.

## A Ternary Crown Ether "Supercomplex": X-Ray Structure Analysis of the 1 : 1 : 1 Adduct of Dibenzo-[18]-Crown-6, Potassium Iodide, and Thiourea[**]

By *Rolf Hilgenfeld* and *Wolfram Saenger*[*]

X-ray structural analyses have made a decisive contribution[1b] to the investigation of the complexing properties of

Hermann-Rein-Str. 3, D-3400 Göttingen (Germany)

[**] Structures of Polyether Complexes, Part 18.—Part 17: *R. Hilgenfeld, W. Saenger*, Z. Naturforsch. *B 36*, 242 (1981).

cyclic crown ethers and their open-chain analogues towards metal ions[1a]. Oligoethers also form inclusion complexes with ionic or neutral guest molecules[2a], and are therefore considered, *inter alia*, as simple enzyme models[2b]. According to X-ray crystallographic findings the interactions between host and guest in such adducts can mainly be ascribed to N—H...O or C—H...O hydrogen bonding[3].

In 1971, *Pedersen* obtained crystalline ternary complexes between crown ether, metal salt, *and* thiourea in the molar ratio 1:1:1, 2:1:1, 1:1:4, and 1:1:6[4] on reaction of some metal-salt complexes of benzo-[15]-crown-5 and dibenzo-[18]-crown-6 with thiourea (in methanol). Such "super complexes" are potential models for transition states of reactions assisted by crown ethers, *e.g.* nucleophilic substitutions in which stereospecificity has been observed[5]. The existence of loose adducts, in which the crown ether cation complex as well as substrate and anion participate would afford an explanation for this effect. Since no information on the structures of the ternary adducts was available, we decided to determine the structure of the 1:1:1-complex of dibenzo-[18]-crown-6, potassium iodide and thiourea[6].

The crystal structure is found to be polymeric (Fig. 1). The potassium ion is situated at the center of the crown ether cavity and is in contact with all six ether oxygen atoms with $K^+$...O distances between 2.71 and 2.80 Å; the sevenfold coordination is completed by the iodide ion ($K^+$...$I^-$ 3.57 Å) to give a hexagonal pyramid. This part of the complex is similar to that in the 1:1 adduct of dibenzo-[18]-crown-6 with KI, the crystals of which are found to contain two independent complex molecules[7]: in one, the apical $K^+$ coordination site is occupied by a water molecule, in the second (as in the present case), it is occupied by the $I^-$ anion.

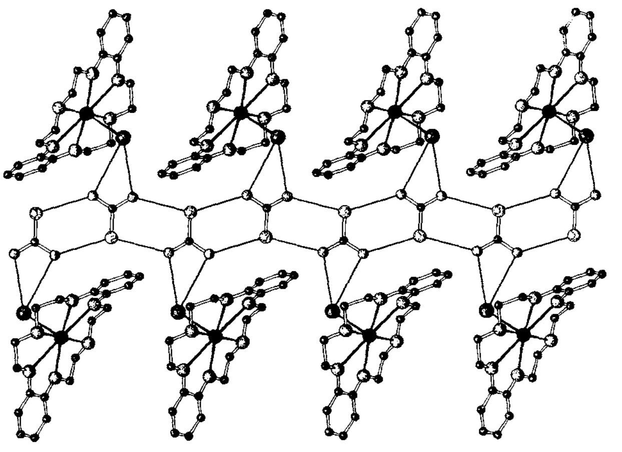

Fig. 1. Polymeric structure of the 1:1:1 complex of dibenzo-[18]-crown-6, potassium iodide, and thiourea (hydrogen atoms not shown). Hydrogen bonds are indicated by thin lines. Atomic spheres symbolize, with increasing radius, C, N, O, S, and I; the $K^+$ ions are shown in black. We thank Dr. *E. Keller*, Freiburg (Germany), for the computer plot programm SCHAKAL.

The thiourea neither participates in the complexation of the metal ion, nor has it any contact with the polyether ligand; instead, it forms polymeric chains coupled by hydrogen bonds which run through the crystal structure in the direction of the *c*-axis. One hydrogen atom of each amino group is in contact with the sulfur atom of the neighboring (symmetry generated) thiourea molecule (N...S 3.43(1) and 3.49(1) Å), while the other participates in N—H...$I^-$ hydrogen bonding. The two H-bonds of this latter type formed by each thiourea molecule are of different strength with lengths of 3.55(1) and 3.85(1) Å; the respective I—N—C angles are 110.3(8) and 95.7(7)°. The hydrogen atoms of the thiourea molecule could not be determined with certainty from the difference Fourier synthesis.

The anion plays an important role as hydrogen bond acceptor and as a link between crown-ether complex and thiourea chains. It is therefore of interest to investigate whether anions other than the readily polarizable $I^-$ ion form such complexes. *Pedersen* has also obtained ternary complexes with $SCN^-$[4], which is as soft as $I^-$. On the other hand, we were unable to prepare the corresponding adduct with the hard $F^-$ ion; this is also explainable in terms of the high KF lattice energy, which prevents formation of a crystalline crown-ether complex. Presumably the "supercomplexes" are formed only with sufficiently soft anions.

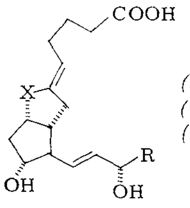
[**] Prostaglandin Analogues, Part 4.—Part 3: *W. Skuballa*, Tetrahedron Lett. *21*, 3261 (1980).

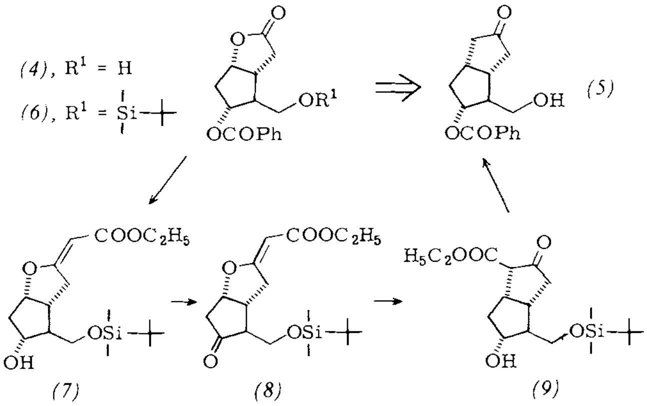
limited due to the extreme instability of the enol-ether function[1]. In the search for stable and biologically active analogues an essential target molecule was the 6a-carbacyclin *(2)*[2].



*(1)*, X = O, R = $n$-$C_5H_{11}$
*(2)*, X = $CH_2$, R = $n$-$C_5H_{11}$
*(3)*, X = $CH_2$, R = $CH(CH_3)$-$CH_2$-$C{\equiv}C$-$CH_3$

We describe here a novel and economic entry to this class of substances using as example the synthesis of the 6a-carbacyclin *(3)*, modified in the lower side-chain and selected for clinical testing.

Our aim, starting from the commercially available, optically active "Corey lactone" *(4)*[3], was to synthesize the versatile, optically active intermediate *(5)* by formal replacement of the ring oxygen atom by a methylene group.



Scheme 1.

The ease of preparation and high stereoselectivity of the reaction pathway shown in Scheme 1 permits the general synthesis of bicyclo[3.3.0]octane derivatives.

After protection of the alcohol function in *(4)* ($ClSiMe_2tBu$, dimethylformamide, imidazole), reaction of the silyl ether *(6)* with lithiated ethyl acetate in tetrahydrofuran (THF) at −70 °C, acid-catalyzed dehydration (TsOH, toluene, 25 °C), and subsequent cleavage of the benzoate ($K_2CO_3$, methanol, 25 °C) afford the α,β-unsaturated ester *(7)* in 70% yield. After Collins- or Jones-oxidation of *(7)* to give the ketone *(8)*, a one-pot reaction with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) at 0 °C in THF[4] and subsequent addition of $NaBH_4$ and $CH_3OH$ furnishes regio- and stereoselectively the bicyclo[3.3.0]octane derivative *(9)* (yield 70%, starting from *(7)*). Decarbethoxylation of *(9)* with 1,4-diazabicyclo[2.2.2]octane (toluene, $H_2O$, 110 °C)[5], evaporation to dryness, benzoylation of the residue (PhCOCl, 0 °C, 10 min), and cleavage of the silyl ether ($AcOH/H_2O/THF$ 65 : 35 : 10, 25 °C) lead to the ketone *(5)* in 88% yield.

After ketalization of *(5)*, *(10)* is oxidized to the aldehyde *(11)* ($CrO_3 \cdot 2C_5H_5N$, $CH_2Cl_2$, 0 °C) and the crude product condensed with 3-methyl-2-oxo-5-heptynylphosphonic acid dimethyl ester[6] (NaH, dimethoxyethane, 0 °C) in a Wittig-Horner reaction to give the α,β-unsaturated ketone *(12)*. Reduction of *(12)* ($NaBH_4$, $CH_3OH$, −40 °C) yields a mixture of the alcohols *(13)* and *(14)*; chromatographic separation of the more polar β-alcohol *(14)* affords the allyl alcohol *(13)*, which is converted by transesterification ($K_2CO_3$, $CH_3OH$) into *(15)*. Cleavage of the ketal function to give *(16)*, followed by treatment with dihydropyran furnishes the tetrahydropyranyl (THP) derivative *(17)*. Wittig reaction of the ketone *(17)* with $Ph_3P{=}CH(CH_2)_3COONa$ (DMSO, 45 °C) affords, after chromatographic separation, the (*E*)-isomer *(18)* and the less polar (*Z*)-isomer *(19)*, which are converted after cleavage of the tetrahydropyranyl moiety into *(3)* and *(20)*, respectively[7].

# 18,19-Didehydrocorrinoids—Possible Intermediates in the Biosynthesis of Vitamin $B_{12}$

By *Bernd Dresow, Ludger Ernst, Lutz Grotjahn*, and *Volker B. Koppenhagen*[*]

Under cobalt-deficient conditions nonsulfur purple bacteria release considerable amounts of metal-free corrinoids into the medium[1,2]. Thus, up to 3 mg/L of a mixture of isomer-free hydrogenobyrinic acid *c*-amide *(1)* and hydrogenobyrinic acid *a,c*-diamide can be isolated from the culture filtrate of *Rhodopseudomonas sphaeroides*. These compounds do not appear to be biogenetic precursors of the cobalt-containing corrinoids. Incorporation of the central $Co(CN)_2$-group into the crude product *(1)* yields cobyrinic acid *c*-amide *(2)* and a small amount (4%) of a blue cobalt-

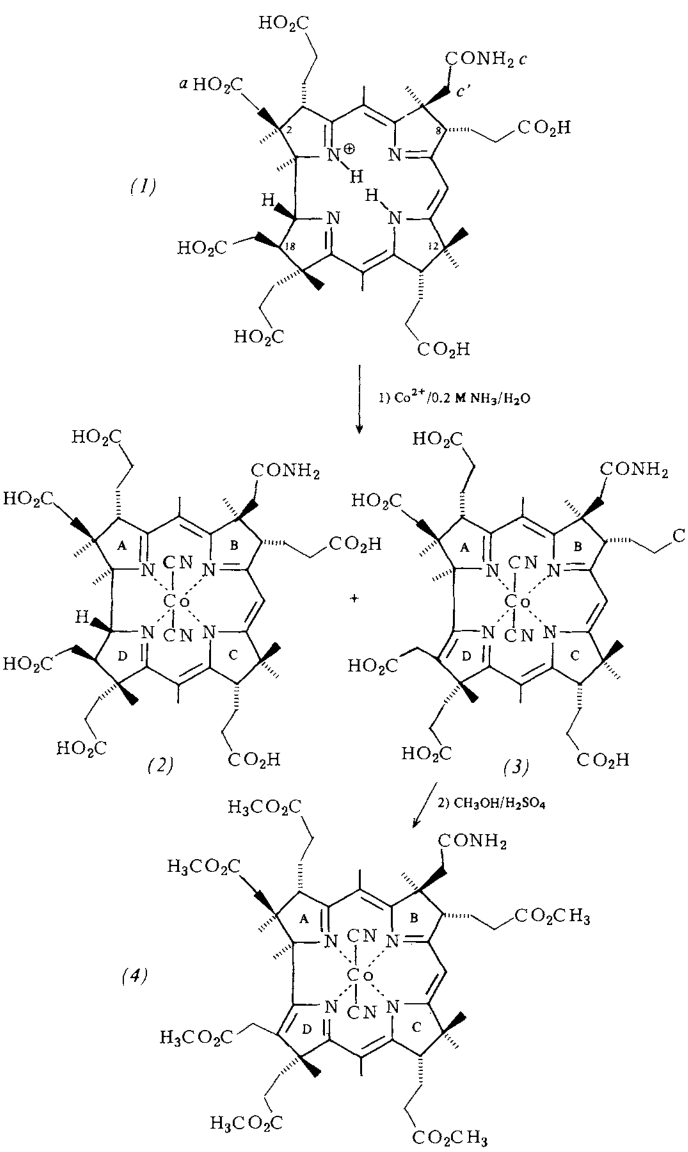

Table 1. NMR spectroscopic data of *(4)*.

[a] The resonances of the quaternary and the methoxy carbons could be identified on the basis of their low intensities. The relative intensities between $\delta$ = 178 — 170 could not be determined with absolute certainty because of the low signal-to-noise ratio. No signal was found for C-7; by analogy to the spectrum of cobester *c*-amide in $CDCl_3$ (unpublished) it is expected at $\delta$ = 51-52, presumably hidden under other resonances in this region. $CDCl_3$: $\delta$ = 77.05.

[*] Dr. V. B. Koppenhagen, Dr. B. Dresow, Dr. L. Ernst, Dr. L. Grotjahn
Gesellschaft für Biotechnologische Forschung mbH
Mascheroder Weg 1, D-3300 Braunschweig-Stöckheim (Germany)

containing by-product, for which we have proposed the structure 18,19-didehydrocobyrinic acid *c*-amide *(3)*[2]. Such a compound is of interest in its metal-free, non-amidated form as the connecting link between metal-free and cobalt-containing corrinoids in the biosynthesis of vitamin $B_{12}$[2]. We have now unambiguously proved the structure of the hexamethyl ester of *(3)* as dicyano-18,19-didehydrocobyrinic acid hexamethyl ester *c*-amide *(4)*.

The absorption spectrum of *(4)* shows the typical α,β,γ-structure of cobalt-containing corrinoids. The substantial bathochromic shift of the main absorption bands (369→396 nm, 545→590 nm, and 584→626 nm) compared to those of the heptamethyl ester of dicyanocobyrinic acid ("cobester") indicates a lengthening of the corrin chromophore.

The presence of the same peripheral groups as in the hexamethyl ester of *(2)* follows from the $^1$H-NMR spectrum, which contains the signals of the protons of one amide group and of six methoxy- and eight angular methyl groups. An AB system ($J$ = 16.7 Hz) appears at $\delta$ = 3.47/3.38 which is assigned to the methylene group of a $CH_2CO_2Me$ moiety adjacent to a double bond. The position of this double bond and that of the amide function follows from the $^{13}$C-NMR spectrum, which was recorded despite the small amount of substance available (*ca.* 2 mg = *ca.* 2 μmol, recording time 64 h for 351000 accumulations). The deshielding of C-5, 7, and 8 and of C-*c'* by 3—5 ppm in *(4)* (relative to "cobester"[3]) and the shielding of C-6 by *ca.* 2 ppm are consistent with a *c*-amide group. In cobester[3] the signals of C-18 and C-19 appear at $\delta$ = 39.2 and 74.7, respectively; in *(4)* they are shifted into the olefinic region, presumably to $\delta$ = 124.6 and 151.5, respectively. The signals of C-17 ($\delta$ = 58.3→65.2), C-1 ($\delta$ = 82.5→84.7) and 17-$CH_3$ ($\delta$ = 18.3→20.4) are also clearly shifted downfield. The above data indicate that *(4)* is the $\Delta^{18}$-olefin.

The molecular ion in the FD mass spectrum ($M^+$ = 1071) is consistent with the empirical formula ($C_{53}H_{70}N_7O_{13}Co$). The base peak (1019) corresponds to $M^+ - 2CN$.

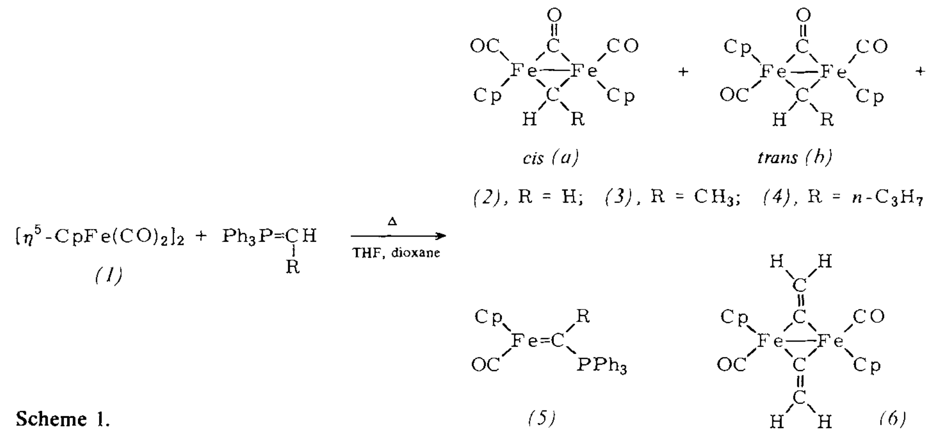
## Novel Reactions of Phosphorus Ylides with Carbonyl(cyclopentadienyl)metal Complexes: Preparative Access to μ-Alkylidene Complexes and Unexpected Acylations[**]

By *Richard Korswagen, Reinhold Alt, Dieter Speth,* and *Manfred L. Ziegler*[*]

Phosphorus ylides $R_3P{=}CR'R''$ prove to be astonishingly versatile in their reactions with metal complexes. Essentially three types of reaction have already been reported: 1) ligand exchange with formation of products in which the ylide carbon atom functions as σ-donor[1]; 2) ligand exchange and transylidation whereby a hydrogen atom attached to ylide carbon is replaced by an organometallic group[2]; 3) peripheral ligand reactions in which CO groups of the complex participate[3].

We have now discovered two further different types of reaction which take place between phosphorus ylides and organometallic substrates.



Scheme 1.

On reaction of the iron complex *(1)* with ylides $PH_3P{=}CHR$ (Scheme 1) we obtained μ-alkylidene complexes as major products (50—60%). The μ-methylene complex *(2)* is formed in both *cis*-form *(2a)* as well as the *trans*-form *(2b)*; both isomers can be isolated in the pure state by means of low-temperature chromatography. The same holds for the μ-ethylidene complex *(3)*. The *cis*- and *trans*-isomers differ slightly in their solubility in apolar solvents (as expected the *trans*-form is the more soluble). *(2a)* and *(2b)* are found to be in equilibrium (≈3 : 1) in solution at room temperature; at −80 °C the solutions of the pure isomers are stable. *(2a)* exists in two modifications in the solid state [*(2a)* and *(2a')*] whose $^1$H-NMR spectra are identical. The compounds *(2)*—*(4)* were characterized by elemental analysis and by their IR, $^1$H-NMR, $^{13}$C-NMR and mass spectra[4], and, in the case of the *cis*-isomer *(2a)*, also by X-ray structure analysis (Fig. 1)[5].

Besides the μ-alkylidene complexes we were able, in each case, to isolate organometal-substituted ylides *(5)*; the species *(6)* could be detected only by mass spectroscopy. The preparation of μ-alkylidene complexes *via* phosphorus ylides is new (syntheses with diazaalkanes[6] or dihaloalkanes[7] are known).

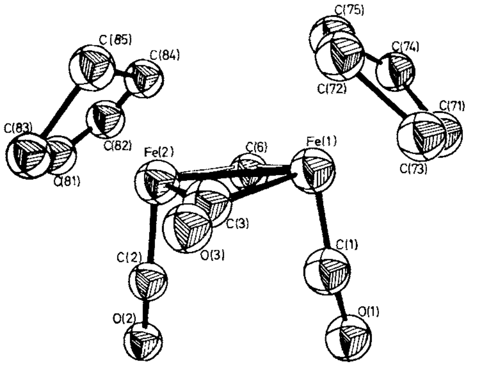

Fig. 1. ORTEP diagram of the μ-methylene complex *(2a)*: the thermal ellipsoids correspond to a probability of 50%.

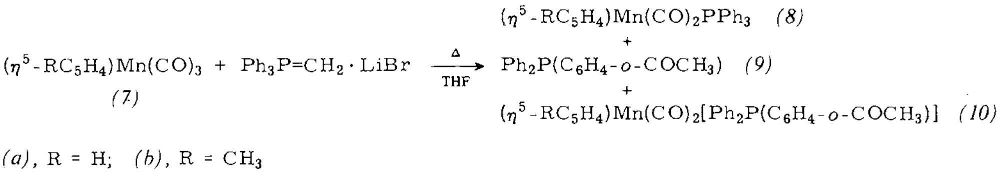
The manganese complex *(7b)* reacts with methylene- or benzylidenephosphoranes in a ligand exchange reaction to give $(\eta^5\text{-CH}_3\text{C}_5\text{H}_4)\text{Mn(CO)}_2\text{—CHRPR}'_3$[1b] and with trimethyl(methylene)phosphorane, after photolysis of an intermediate formed by peripheral ligand substitution at a CO group, to give $(\eta^5\text{-CH}_3\text{C}_5\text{H}_4)\text{Mn(CO)}_2\text{—CH}_2\text{PMe}_3$[3b]. We have now reacted the complexes *(7)* under reflux in tetrahydrofuran (THF) with $\text{Ph}_3\text{P}{=}\text{CH}_2$ (Scheme 2).



$$(\eta^5\text{-RC}_5\text{H}_4)\text{Mn(CO)}_3 + \text{Ph}_3\text{P=CH}_2\cdot\text{LiBr} \xrightarrow[\text{THF}]{\Delta} \begin{array}{l} (\eta^5\text{-RC}_5\text{H}_4)\text{Mn(CO)}_2\text{PPh}_3 \quad (8)\\ \quad + \\ \text{Ph}_2\text{P(C}_6\text{H}_4\text{-}o\text{-COCH}_3) \quad (9)\\ \quad + \\ (\eta^5\text{-RC}_5\text{H}_4)\text{Mn(CO)}_2[\text{Ph}_2\text{P(C}_6\text{H}_4\text{-}o\text{-COCH}_3)] \quad (10)\end{array}$$

*(7)*

*(a)*, R = H; *(b)*, R = $\text{CH}_3$

Scheme 2.

The compounds *(9)* and *(10)* were characterized by elemental analysis and by IR, NMR and mass spectra[8]; in the case of complex *(10b)* also by an X-ray structure analysis[9]. In the course of their formation a phenyl ring of the $\text{Ph}_3\text{P}$ unit was acylated in the *ortho*-position; the acylation product *(9)* is present, both bonded as ligand in *(10)*, as well in the free state.

The phosphane-complexes *(8)* were identified on the basis of data in the literature. The mechanism of the reaction is still unclear. Participation not only of the ylide but also of a CO group is evident.

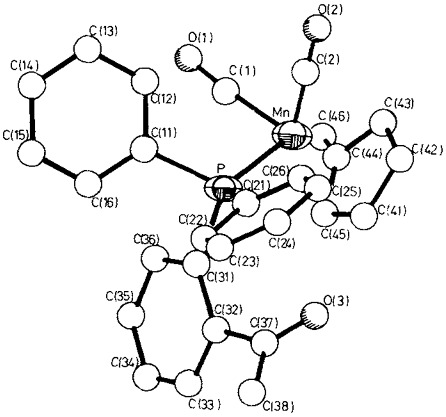


Fig. 2. ORTEP diagram of the peripherically acylated phosphane-complex *(10b)*; the thermal ellipsoids correspond to a probability of 50%.

*Procedure*

Preparation of *(2a)* and *(2b)*: A suspension of $[\text{Ph}_3\text{PCH}_3]\text{Br}$ (2 g, 5.65 mmol) in anhydrous THF (100 mL) under an atmosphere of $\text{N}_2$ is treated dropwise with a 15% solution of *n*-butyllithium in *n*-hexane until a clear orange solution is formed. After addition of 1 g (2.82 mmol) of *(1)* the mixture is heated under reflux for 24 h (10 h with dioxane as solvent). 10 g silica gel (0.05—0.2) is added to the solution, which is then evaporated down in a rotary evaporator. The brown residue is extracted with 200 ml of diethyl ether and the deep-red solution "prechromatographed" on a column ($\text{Al}_2\text{O}_3$ neutral, activity 1; 20 × 3.5 cm, ether). The first, yellow fraction contains $\text{Ph}_3\text{P}$ and a little ferrocene. The second, violet and third, orange-red zones are rechromatographed ($\text{Al}_2\text{O}_3$ neutral, activity 1, 25 × 2.5 cm, ether) together at −20 °C. Elution of a small amount of $\text{Ph}_3\text{P}$ is followed by a violet, second zone containing *(2b)*, whose eluate is collected under $\text{N}_2$ at −50 °C. The bright-orange, third zone contains *(5)*, R = H, the red-orange, fourth zone *(2a)*, which is eluted under the same conditions as *(2b)*. Each of the solutions is evaporated down to *ca.* 25 mL under high vacuum at −50 °C and treated with 25 mL *n*-pentane. After a few days over dry ice, red-violet and cherry-red crystals of *(2a)* and *(2a')*, respectively, and dark violet crystals of *(2b)* separate out. The complexes are air-stable at room temperature; the total yield of *(2a)* and *(2b)* [m.p. 168—170 °C (dec.)] is 600 mg (63%).

Preparation of *(10a)* [*(10b)* analogously]: *(7a)* is allowed to react with the ylide, as described for *(1)*. After prepurification on the column the filtrate still contains unreacted *(7a)* besides the products *(8a)*, *(9)* and *(10a)*. The ether solution is evaporated down to 50 mL and, after addition of 50 mL of *n*-pentane, cooled to −60 °C; besides *(10a)* mainly *(7a)* and *(9)* crystallize out (the mother liquor contains *(7a)* together with *(8a)* and $\text{PPh}_3$). The mixture of crystals is dissolved in ether (10 mL) and separated by preparative TLC (20 × 20 × 0.2 cm, silica gel 60, cyclohexane/diethyl ether ≈ 1 : 1). The yellow, first zone contains *(7a)* and *(8a)*, the yellow, second zone *(9)*, and the likewise yellow, third zone *(10a)*.—The air-stable crystals of *(10a)* and of *(10b)* melt at 168 and 170 °C, respectively, with decomposition; *(9)* melts at 143 °C. The yields of *(10a)* and *(10b)* are 2 and 6%, respectively.

## Second Sphere Coordination of Cationic Platinum Complexes by Crown Ethers—

## The X-Ray Crystal Structure of $[Pt(bpy)(NH_3)_2\cdot Dibenzo[30]crown\text{-}10]^{2+}[PF_6]^-_2\cdot xH_2O$ ($x\approx 0.6$)[**]

By *Howard M. Colquhoun, J. Fraser Stoddart, David J. Williams, John B. Wolstenholme*, and *Ryszard Zarzycki*[*]

Since the possibility of second sphere coordination[2] of transition metal complexes was first alluded to by *Werner*[1] in 1913, it has become apparent[3] that the binding of an outer layer of ligands to transition metal (M) ammine complexes is usually a result of (N—H···X) hydrogen bonding between the $NH_3$ ligands and electron donor atoms (X) present in counterions, solvent molecules, or other ligands. The fact that [18]crown-6 (18C6) and dibenzo-[18]crown-6 (DB18C6)[4] form strong adducts with primary alkylammonium ($RNH_3^+$) ions through multiple hydrogen bonding suggested[5] to us that coordinated ammonia ($M—NH_3^{\delta+}$) should bind to crown ethers in a similar manner. Indeed, we have been able to isolate[6] the crystalline adducts, [*trans*-$PtCl_2(PMe_3)NH_3\cdot$DB18C6] and [{*trans*-$PtCl_2(PMe_3)(NH_3)$}$_2\cdot$18C6], and have demonstrated[6] that the macrocyclic polyethers serve as second sphere ligands *via* (N—H···O) hydrogen bonding to $NH_3$ ligands in the first sphere.

We now report on the ability of the $[Pt(bpy)(NH_3)_2]^{2+}$ ion to form 1 : 1-adducts with 18C6, DB18C6, DB24C8, DB30C10, and DB36C12[7]. In addition to the expected (N—H···O) hydrogen bond formation between the *cis*-$NH_3$ ligands on $Pt^{II}$ having a square planar environment and polyether components of these crown ethers, the benzene rings (π-donors) in DB24C8, DB30C10, and DB36C12 all enter into stabilizing charge-transfer (CT) interactions with the aromatic rings of the bipyridyl ligand (π-acceptor).

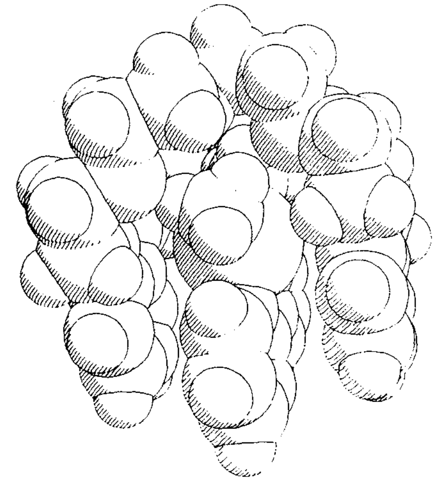

Fig. 1. Computer drawing of a space-filling molecular model based on the crystal structure of the 1 : 1-adduct formed between $[Pt(bpy)(NH_3)_2]^{2+}$ and DB30C10. Direct visual comparison with the representation of the structure shown in Figure 2 is necessary in order to appreciate the structural detail. Crystals of $[Pt(bpy)(NH_3)_2(DB30C10)]^{2+}[PF_6]^-_2\cdot$*ca.* $0.6\,H_2O$ are monoclinic; space group $P2_1/n$, $a=16.081(2)$, $b=15.912(2)$, $c=18.718(2)$ Å, $\beta=101.34(1)°$, $V=4696$ Å$^3$, $Z=4$, $\rho_c=1.74$ g cm$^{-3}$, $\mu(Cu_{K\alpha})=72$ cm$^{-1}$. Of the 5250 independent reflections ($\theta\leqslant 50°$, $Cu_{K\alpha}$ irradiation), 453 were classified as unobserved. The structure was solved by the heavy atom method and refined anisotropically with absorption corrected data to $R=0.053$.

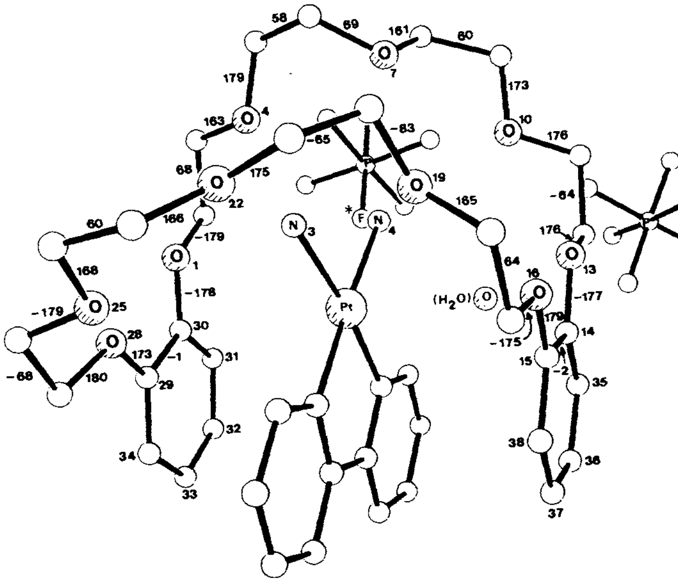

Fig. 2. Crystal structure of $[Pt(bpy)(NH_3)_2(DB30C10)]^{2+}[PF_6]^-_2\cdot$*ca.* $0.6\,H_2O$. Bond lengths [Å] in the host molecule: C—C (excluding $C_{Aryl}$—C), 1.39—1.45; $C_{Aryl}$—O, 1.35—1.37. Bond angles [°] in the host molecule: COC (excluding $C_{Aryl}$OC), 110—115; $C_{Aryl}$OC: 116—118. Torsion angles [°] (OCCO and CCOC) in the host are shown beside the relevant CC and CO bonds in the structure. Hydrogen bond distances, $R_{N\cdots X}$ Å; angles ($\theta_N$ and $\theta_H^0$) between COC planes and a) the NO vectors and b) the HO vectors: $R_{N4\cdots O4}=3.02$, a) 36, b) 37; $R_{N4\cdots O10}=2.90$, a) 0, b) 14; $R_{N3\cdots O19}=2.99$, a) 15, b) 24; $R_{N4\cdots F}=3.20$ (hydrogen atoms were located unambiguously). (In the case of N4, a rigid body refinement of the $NH_3$ ligand was possible. Since the thermal parameters were anisotropic for N3, rigid body refinement of the $NH_3$ ligand was not possible; however, the H atom involved in hydrogen bonding to O19 was identified from the difference map.) Separations [Å] between aromatic rings in the guest and host: bpy-benzene ring (14/38) = 3.45 (minimum), 3.47 (average); bpy-benzene ring (29/34) = 3.48 (minimum), 3.52 (average). Angles [°] between the planes of the aromatic rings: bpy-benzene ring (14/38) = 0.9; bpy-benzene ring (29/34) = 2.2; benzene ring (14/38)-benzene ring (29/34) = 1.4.

Addition of diethyl ether to a dichloromethane solution containing equimolar amounts of $[Pt(bpy)(NH_3)_2]^{2+}[PF_6^-]_2$ *(1)*[8] and DB30C10 resulted in the formation of a crystalline 1 : 1-adduct which proved amenable to X-ray structural analysis (Fig. 1 and 2). Undoubtedly, the most fascinating features of this structure—apart from the hydrogen bonding between three of the ten O atoms in the crown ether and three of the six hydrogen atoms associated with the $NH_3$ ligands in the complex, are the π-π stabilizing interactions[9] between the two benzene rings in the host molecule and one of the two pyridine rings of the 2,2′-bipyridyl ligand in the guest complex. At first glance, the involvement of relatively few hydrogen bonds with respect to both host and guest is remarkable. However, the relative geometries essential for effective CT-interaction between these two species militate against the involvement of the four "phenolic" O atoms[10] in the hydrogen bonds. Also, one of the H atoms on one of the two $NH_3$ ligands forms a hydrogen bond to an F atom in one of the $PF_6^-$ counterions. Although the structure was found to incorporate *ca.* 0.6 $H_2O$, the water molecule does not enter into any hydrogen bonding interactions with the crown ether[11]. Notable features of the gross conformation of the crown are: 1) The absence of any molecular symmetry, and 2) the departure from a conformation where the sequence of torsion angles in the two polyether loops reads $ag^+a\ ag^-a$ (*a* signifies *anti* with *ca.* 180°, and *g gauche* with *ca.* ±65°); exceptions are provided by C5—C6—O7—C8 and C18—O19—C20—C21 which have values of +69° and −83°, respectively.

The manner in which the crown ether envelopes the transition metal complex is quite remarkable and the question arises: What is the structure and stability of the 1 : 1-adduct in solution? The UV spectrum of a solution of *(1)* in $CH_3CN$ (Fig. 3) is essentially unchanged upon addition of 1 equivalent molar amount of 18C6; however, in the presence of the same amount of DB30C10, the intensities of the $\pi \rightarrow \pi^*$ absorptions of the bipyridyl ligand[12] at $\lambda_{max} = 306$ and 318 nm are significantly reduced. A band at 275 nm, characteristic[4a] of the annelated benzene rings of DB30C10 is also evident, but more importantly, a broad absorption appears in the charge-transfer region ($\lambda_{max} \approx 350$ nm). Solutions of *(1)* become visibly more strongly colored on addition of DB30C10.

Comparison of the $^1H$-NMR spectra of 18C6, DB18C6, DB24C8, DB30C10, and DB36C12 recorded in $CD_2Cl_2$ with those of the corresponding 1 : 1 adducts with *(1)* (Table 1) reveals that the mutual influences of ring currents (associated with the benzene rings in the host molecules and the pyridine rings of the bpy ligand in the guest complex) on the chemical shifts of the aromatic protons manifest themselves most noticeably in the *(1)*·DB30C10 adduct. In particular, the appreciable upfield shift of 0.52 ppm for the protons on the benzene rings on 1 : 1-adduct formation is accompanied by equally dramatic upfield shifts of 0.38 and 0.68 ppm, respectively, for the 3,3′-H and 6,6′-H in the bpy ligand. Inspection of space-filling molecular models confirms that both hydrogen bonding and CT-interactions should be optimized in *(1)*·DB30C10 (Fig. 1).

Thus, appropriate crown ether derivatives can enter into second sphere coordination with suitable transition-metal

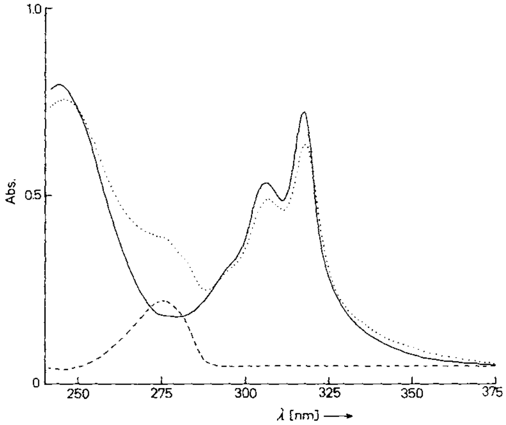

Fig. 3. UV spectra ($CH_3CN$, $4 \times 10^{-5}$ M, $d = 1$ cm) of a) DB30C10 (----) ($\lambda_{max} = 275$ nm; $\varepsilon = 4250$), b) *(1)* and *(1)*·18C6 (—) ($\lambda_{max} = 245$, 306, 318 nm; $\varepsilon = 18750$, 12000, 16750), and c) *(1)*·DB30C10+18C6 (······) ($\lambda_{max} = 246$, 275, 307, 318 nm; $\varepsilon = 17500$, 8500, 11000, 14750).

[a] The spectra were recorded at room temperature ($CD_2Cl_2$, TMS) with a 220 MHz spectrometer (Perkin Elmer R 34). [b] The values in brackets indicate how strongly the respective signals are shifted relative to the corresponding signals in *(1)*·18C6. [c] The values in brackets indicate how strongly the signal is shifted in relation to the corresponding signal of the respective crown ethers.

complexes in solution and in the crystalline state *via* CT-interactions, as well as by hydrogen bonding.

## *Experimental*

*(1)*·18C6: *(1)* (330 mg, 0.43 mmol) and 18C6 (230 mg, 0.87 mmol) were dissolved in $CH_2Cl_2$ (30 mL) and $Et_2O$ added dropwise until the first trace of permanent cloudiness was evident. The solution was allowed to stand overnight and the resulting yellow crystals were filtered off, washed with $Et_2O$, and dried. Yield 270 mg (61%); m.p. = 231 °C; IR (Nujol): 3200 m (NH), 1620 m (NH), 1105 s (CO), 820 vs (PF) $cm^{-1}$.

*(1)*·DB30C10: The corresponding crystalline 1 : 1-adduct with DB30C10 was prepared similarly using equimolar proportions of complex and crown. Elemental analysis and IR spectroscopy indicated the presence of just under 1 molar equivalent of water (cf. X-ray crystal structure). Yield 30%; m.p. = 191°; IR (Nujol): 3660 m, 3590 m (OH), 3200 m (NH), 1630 m, 1610 m, 1595 m (OH and/or NH), 1100 s (CO), 820 vs (PF) $cm^{-1}$.

So far, attempts to isolate crystalline 1 : 1-adducts of *(1)* with DB18C6, DB24C8, and DB36C12 have not been successful.

# Does a Molecule have the Same Conformation in the Crystalline State and in Solution? Comparison of NMR Results for the Solid State and Solution with those of the X-ray Structural Determination

By *Horst Kessler, Gottfried Zimmermann, Hans Förster, Jürgen Engel, Gerhard Oepen,* and *William S. Sheldrick*[*]

The exact conformation of compounds in the crystalline state may be relatively easily determined by means of X-ray structural analysis. Does this conformation also exist in solution or do the interactions of the molecule with its surroundings—lattice forces[1], on the one hand, and solvation on the other—lead to structural changes? Since it has recently become possible to obtain high resolution NMR spectra from solids as well, it is now feasible to compare structures in the crystal and in solution using *one* method alone.

We wish to report here two examples in which the most stable conformation in solution is not that which exists in the crystal structure, namely the *Z,E*-isomerism at a partial CN double bond and at a CC double bond. The second case is a configuration isomerism, which, however, displays a smooth transition to a conformation isomerism[2]. In the first example, two conformations exist in the crystal (as demonstrated by X-ray structural analysis and solid state NMR spectroscopy), whereas in solution only an average conformation is observed, which, however, equili-

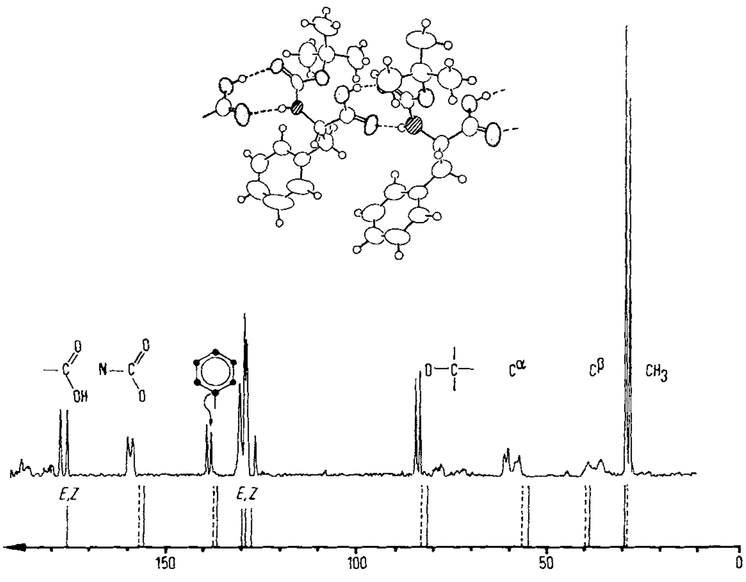

Fig. 1. Crystal structure and 75.46 MHz $^{13}C$-CP-MAS-NMR spectrum (δ-values, CP-MAS stands for "Cross Polarization-Magic Angle Spinning") of crystalline *(1)* [4]. $^{13}C$-signals for a $CDCl_3$ solution are given in the line spectrum below: solid lines: (*E*)-conformer; broken lines: (*Z*)-conformer.

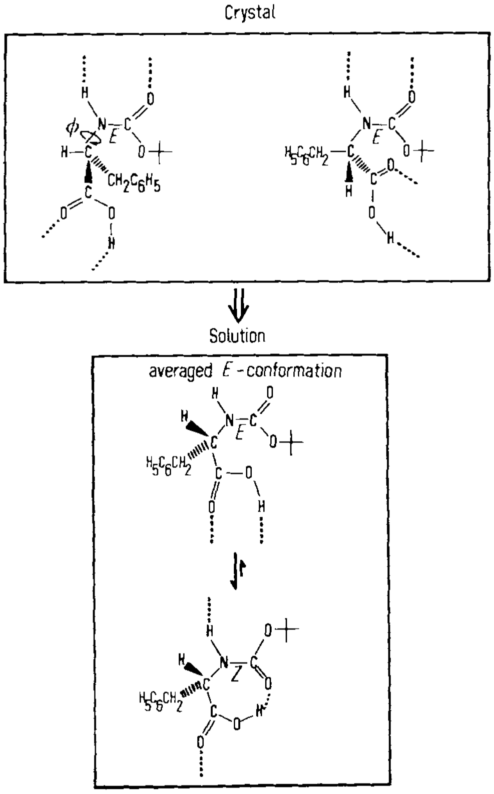
brates to another structure. In the second example, one crystal conformation is converted upon dissolving into several primary conformations, which are then transformed to a further stable solution conformation.

We were previously able to show that Boc-Phe-OH (*tert*-butoxycarbonyl phenylalanine) *(1)* exists as a rotamer with an *E*-configurated urethane bond in the crystal, which, however, contains two conformers in the unit cell, whose significant difference lies in the torsion angle $\phi$ (NH—C$^\alpha$H)[3].

The solid state $^{13}$C-NMR spectrum (Fig. 1) clearly shows a doubling of all signals in the ratio 1 : 1. If the crystals are dissolved at $\leqslant -50\,^\circ$C in $CD_2Cl_2$ and the NMR spectrum immediately recorded, only a single set of signals of the *E*-conformer is identified. The *E*-conformer is almost completely transformed within a few hours at $-50\,^\circ$C into the Z-conformer, which is more stable in solution (Scheme 1). The interpretation of the $^{13}$C chemical shifts of the crystalline compound is difficult. Nevertheless, it may be clearly recognized that the signals of C$^\alpha$ and those of the quaternary C atoms of the *tert*-butyl group and the urethane carbonyl group are shifted to low field, because the urethane group participates in two intermolecular hydrogen bonds. The associated reduction in the electron density of the urethane group is also observed for the *Z*-conformer in solution (formation of an intra- and an intermolecular hydrogen bond)[3,5]. As a result, the chemical shifts of the *Z*-conformer in solution are more similar to those of the *E*-conformer in the crystal, rather than those of the non-associated *E*-conformer in solution.



Scheme 1. Conformations of *tert*-butoxycarbonylphenylalanine *(1)* in the crystal and in solution.

On the basis of an X-ray structural analysis, the vinylogous amide $H_{11}C_6COCH{=}CHNHCH_3$ *(2)*[6] has an *E*-configuration at the CC double bond and a *Z*-configuration at the partial CO—C= and =C—N double bonds. The molecules of *(2)* form relatively weak NH...O hydrogen bonds of length 2.90 Å in the crystal lattice. The solid state $^{13}$C-NMR spectrum (Fig. 2) shows only a single set of signals. If the solid is dissolved in $CD_2Cl_2$ at low temperature ($\leqslant -80\,^\circ$C), the NMR spectra indicate the presence of two conformers (*ca.* 4 : 1); on the basis of the olefinic coupling constants of the protons, both have the *E*-configuration at the double bond ($^3J_{HH} = 13.3$ Hz). At higher temperatures

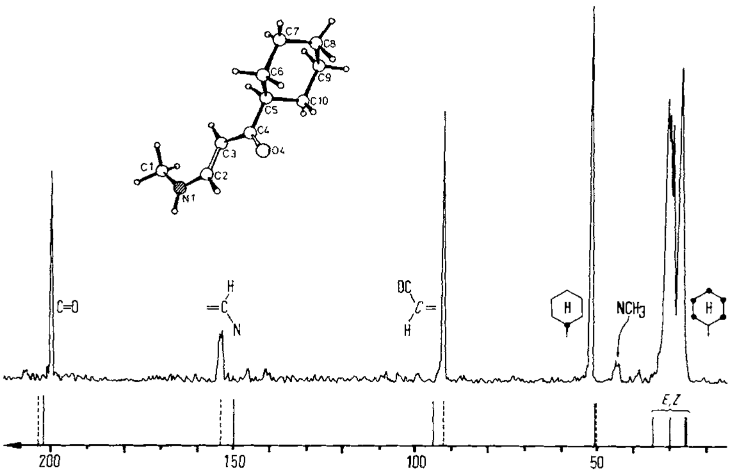


Fig. 2. Crystal structure and 75.46 MHz $^{13}$C-CP-MAS-NMR spectrum (δ-values) of crystalline *(2)* [4]. $^{13}$C-signals for a $CD_2Cl_2$ solution are given in the line spectrum below: solid lines: *E*-conformer; broken lines: *Z*-conformer.

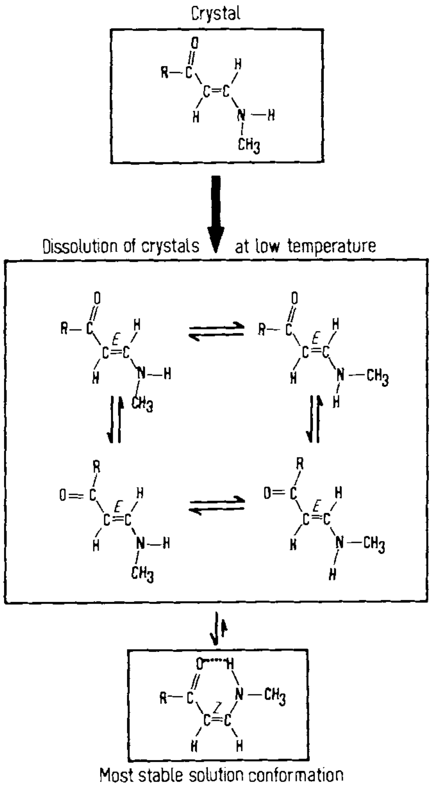

Scheme 2. Conformations of 1-methylamino-1-nonen-3-one *(2)* ($R = C_6H_{11}$) in the crystal and in solution.

the line-shape changes allow the detection of two different dynamic processes, which may be assigned to inhibited rotations about the partial CC and CN double bonds of the *E*-isomers (Scheme 2).

Above *ca.* 0 °C conversion into the isomer with *Z*-configurated CC double bond, which contains an intramolecular hydrogen bond ($\delta_{NH}=9.7$ in $CD_2Cl_2$ at 0 °C), is observed within a few minutes; in comparison, $\delta_{NH}=4.9$ ppm for the *E*-isomer. Once again the chemical shifts for the *Z*-isomer in solution are similar to those of the *E*-isomer in the crystal. As was discussed for *(1)*, changes in the chemical shifts are essentially due to hydrogen bonding. After allowing the solution to stand at room temperature for several days the equilibrium lies at 7% *E*- and 93% *Z*-isomer. A vinylogous amide, in which the *N*-methyl group in *(2)* is replaced by an *N*-phenyl group, behaves in a completely analogous manner.

*(1)* and *(2)* represent clear examples in which the crystal structure is not consistent with the most stable conformation in solution. It could be argued that this state of affairs is only observed when intra- and/or intermolecular hydrogen bonds compete with one another. An example contrary to this assumption, which we have studied, is *cyclo*-($Pro_2$-Bzl-Gly), whose crown conformation in the crystal[7] equilibrates to 90% to a new boat conformation when dissolved in $CD_2Cl_2$[8]. The NMR spectroscopic demonstration of this inconsistency is only possible when the conversion of the crystal conformation into a different solution conformation is slow on the NMR time scale. Conformational differences between crystal and solution will more readily ensue the more polar a molecule is and the greater its tendency to form hydrogen bonds, by means of which interactions with the surroundings (crystal effects, solvation, association) may become stronger than intramolecular forces.

It therefore follows that conclusions on the conformations of polar molecules in solution, which are based on either molecular structure calculations ("isolated" molecules) or on X-ray structural analyses (molecule in a "rigid" crystal lattice), must be drawn with reservation.

## Ring-Opening Reactions of 2-Lithio-1,3-dithiane and 2-Lithio-1,3,5-trithiane with Carbene Complexes of Chromium and Tungsten

By *Helgard G. Raubenheimer, Ernst Otto Fischer, Ulrich Schubert, Carl Krüger,* and *Yi-Hung Tsay*[*]

Reactions of lithiothioacetals with hexacarbonyl complexes of chromium and tungsten, involving CO insertion and affording heterometallocyclic carbenethioether chelates, are well established[1]. Alkoxycarbene(pentacarbonyl) complexes of the same metals are also highly susceptible to nucleophilic attack[2] and the carbene carbon atom has been shown to react, among others, with organolithium compounds[3] and phosphanes[4]. No reaction with diorgano sulphides is known. We have found that alkoxycarbene complexes such as *(1)* react with 2-lithio-1,3-dithiane or -1,3,5-trithiane and that carbene carbon atoms add to the negatively charged carbon atom and a neutral sulphur atom of the heterocycle. Subsequent removal of one alkoxy group leads to novel molecular rearrangements which involve two types of ring-opening in the parent sulphur-containing compounds.

The metalated thioacetals, $LiCH(SR)_2$ (R = Me, Ph), reacted with the complexes *(1)* (M = Cr, W) at −60 °C in ether to yield either extremely thermolabile dark yellow oils, or (with M = Cr, R = Ph) light yellow precipitates. All these compounds were insoluble in tetrahydrofuran (THF) and turned red again above −20 °C due to the re-formation of the complex *(1)*. The presumed formation of 1 : 1-adducts was substantiated for solid products by elemental analysis. These results indicated the possibile formation of sulphur ylide complexes in the reaction of carbene complexes with lithiothioacetals in which the Lewis basicity of the sulphur atoms is increased due to the negative charge on the adjacent carbon atom.

Reaction of the carbene complexes *(1)* with 2-lithio-1,3-dithiane or 2-lithio-1,3,5-trithiane in ether/THF at −60 °C produced salt-like compounds, which upon treatment with $SiO_2$[3b] afforded the thiocarbene compounds *(2)*—*(4)*, and *(5)* and *(6)*, respectively (Scheme 1).

The chromium analogue of *(4)* was detected, but not isolated in pure form, since it always contained small quantities of *(2)*. The sulphide complexes *(7)* and *(8)* had been described before[1]. The new phenyl(thiocarbene) complexes *(2)*—*(6)* were characterized by elemental analyses and spectroscopic measurements (Table 1); the molecular structures of *(5)* and *(6)* were defined by single crystal X-ray diffraction studies[5] (Fig. 1 and 2). Bond lengths and angles in corresponding parts of the molecules are the same in both complexes, as is also the arrangement of the substituents at the carbon-carbon double bond. With $(CO)_5CrC(Me)SPh$[6] there is good correspondence concerning the bonding parameters of the carbene carbon atom.

Table 1. Some physical data of the new thiocarbene complexes *(2)*—*(6)* [a].

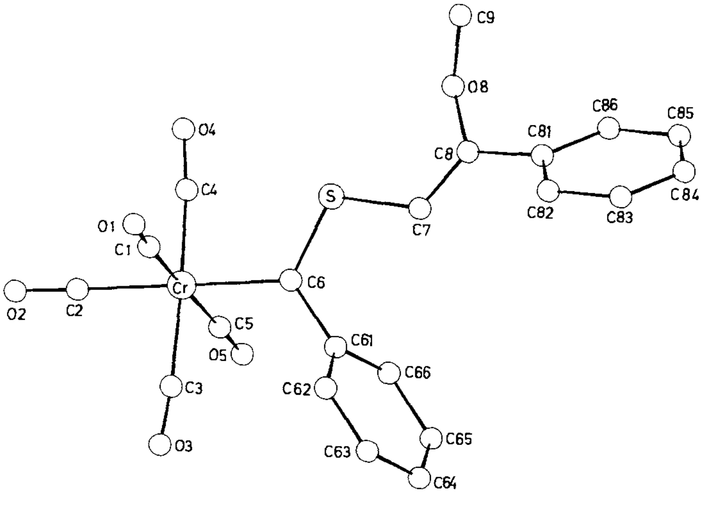

Fig. 2. Molecular structure of *(6)* in the crystal. Cr—C6 202.9(10), C6—S 167.1(10), S—C7 175.9(11), C7—C8 131(2), C8—O8 137(1) pm. Cr—C6—S 119.0(6), Cr—C6—C61 122.9(7), C6—S—C7 109.2(5)° [8].

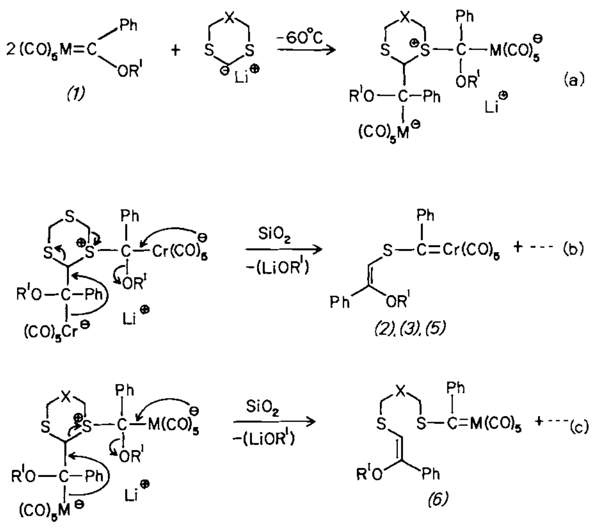
The first step in the synthesis probably involves the formation of a 2:1-adduct which contains both a metal ylide carbon atom and a metal alkyl carbon atom (Scheme 2a). The formation of the main products can then be explained in terms of the rearrangements given in Schemes 2b and 2c. The latter is the most important route to trithianes, whereas β-elimination is the dominant mode of decomposition for the dithiane derivatives. In the case of dithiane it was found that the $(CO)_5M$-moieties then react with the uncoordinated sulphur atom of the product to form the complex *(4)*; the metal-sulphur bond in *(4)* is very labile.



Scheme 2.

The formation of all the new carbene complexes, which provide examples of the involvement of two metal centers in unusual ring-opening reactions, is also especially interesting in view of the current interest in thiovinyl derivatives[7]. In each case, the olefinic phenyl group is situated *trans* to the sulphur atom.

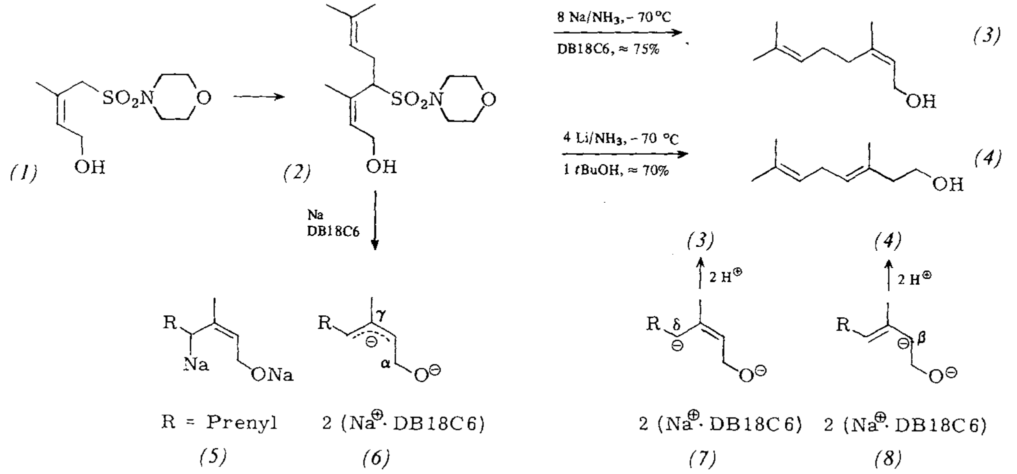
# Crown Ether-Assisted Change of Regioselectivity in the Reductive Cleavage of Allylsulfonamides

By *Alexander M. Moiseenkov, Evgeni V. Polunin,* and *Alexei V. Semenovsky*[*]

The widely used two-step carbon chain elongation reaction in isoprenoids *via* alkylation of a sulfur-stabilized allyl anion has the main disadvantage that both during the alkylation[1] as well as during the subsequent reductive desulfurization[2,3] procedures formation of double bond isomers is possible. Although the regioselectivity of such alkylations (α *vs.* γ) has been frequently studied, little attention has been directed toward improving this step at the desulfurization stage.

We discuss here one of the possible approaches towards solving this problem, exemplified by the reductive desulfonylation of nerylsulfonamide *(2)*. The latter was found to be the only (α)-prenylation product derived from the hydroxysulfonamide *(1)* (as its dilithium salt) which we have recently proposed for the $C_5$-homologation of isoprenoids[4].



Reduction of *(2)* under a variety of conditions such as with amalgams, electrochemically, or with dissolving metals in amines, results in a mixture of nerol *(3)*, isogeraniol *(4)*[3,4], and $C_{10}$-hydrocarbons, the whole process being highly selective with respect to isogeraniol *(4)*. Hence, with Li in $NH_3$ in the presence of *t*BuOH (molar ratio 1 : 4 : 1) at −70 °C, the regioisomers *(3)* and *(4)* are formed in the ratio 7 : 93 in 70% yield. Reaction with Na in $NH_3$ at −70 °C under these conditions gives *(3)* : *(4)* ≈ 15 : 85. In order to avoid the unwanted hydrogenolysis process the known mode of conversion of the alcohol into its alcoholate[3,5] (with *n*BuLi in the molar ratio 1 : 2 in tetrahydrofuran (THF) at 0 °C) was tried. In this case, however, although the yield of the alcohols did not enhance markedly, the relative portion of isogeraniol *(4)* was found to be substantially diminished in favor of nerol *(3)*. Thus, reduction of the alcoholate of *(2)* with Li in $NH_3$ at −70 °C gave *(3)* and *(4)* in the ratio 30 : 70. Pretreatment of *(2)* with NaH (1 : 1) and subsequent reaction with Na in $NH_3$ at −70 °C led to a similar result.

In the second case, the observed effect can be explained by increased polarization of the O—Na bond in the probable key disodium intermediate *(5)* (or in the corresponding intimate ion pairs). It was, therefore, reasonable to expect that the yield of nerol *(3)* would increase due to the additional ionization of the polarized C—Na and O—Na σ-bonds in such an intermediate (or in the corresponding intimate ion pairs). This could arise by introducing into the reaction sphere a macrocyclic polyether capable of complexing $Na^\oplus$ ions[6]. As expected, reduction of *(2)* with Na in $NH_3$ at −70 °C in the presence of dibenzo-[18]crown-6 (DB18C6) (molar ratio 1 : 8 : 0.1) gives, with a reproducible yield of ~75%, nerol *(3)* containing no more than 4% of isogeraniol *(4)*.

The above result may be interpreted in terms of preferential δ-protonation of the free ion pairs *(6)* specifically solvated by participation of the polyether. Of the two mesomeric forms *(7)* and *(8)*, *(7)* is favored due to the better separation of the negative charge[7].

Thus, the crown ether-assisted regiospecific reductive desulfonylation opens up the possibility of employing the hydroxysulfonamide *(1)* as an effective cisoid isoprenoid synthon for the stereospecific construction of polyprenols. Using this procedure, we have recently successfully synthesized (2*Z*, 6*Z*, 10*Z*, 14*E*, 18*E*)-farnesylfarnesol.

## *Experimental*

To a solution of Na (370 mg, 16 mmol) in $NH_3$ (50 mL) containing DB18C7 (72 mg, 0.2 mmol) at −70 °C under Ar was added a solution of *(2)* (605 mg, 2 mmol) in THF over 5 min with constant stirring. After an additional 2 min, the excess Na was decomposed with $NH_4Cl$, $NH_3$ evaporated off, and the residue treated with water and extracted with hexane. The usual work-up gave 290 mg of product which was chromatographed on silica gel (30 g). Gradient elution, hexane→ether (up to 50 vol.% of ether) yielded 230 mg (75%) *(3)*, b.p. = 105 °C/10 torr, contaminated with 2—4% *(4)*.

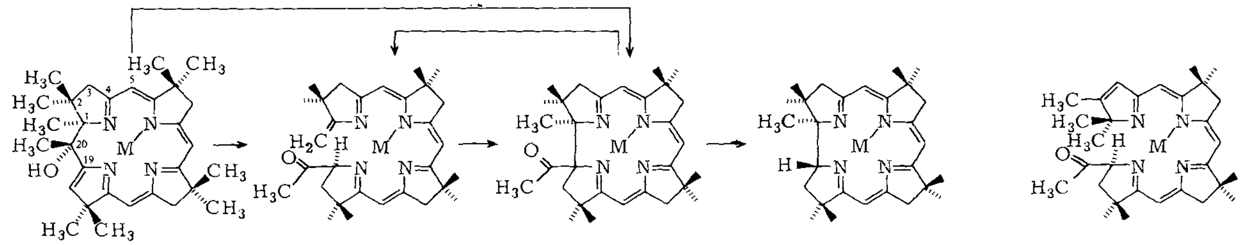
# The Dihydrocorphinol→Corrin Ring Contraction: A Potentially Biomimetic Mode of Formation of the Corrin Structure[**]

By *Vittorio Rasetti, Kurt Hilpert, Alexander Fässler, Andreas Pfaltz,* and *Albert Eschenmoser*[*]

Recently we reported[1] the synthesis of the octahydroporphinoid (dihydrocorphinoid) metal complexes *(1a)* and *(1b)*, their thermal rearrangements to the 19-acetylcorrin complexes *(3a)* and *(3b)*, respectively ("dihydrocorphinol[2] → corrin ring contraction"), and the deacylation of *(3a)* by hydroxide ions to give the nickel(II) nonamethylcorrinate *(4a)*. These transformations point to a possible mechanism for the formation of the characteristic corrinoid (A—D) ring connection in vitamin $B_{12}$ biosynthesis. The corphinoid structure *(1)* of the starting material for the ring contraction was inspired by the structure of "Factor III"[3]; the latter is the most advanced intermediate in corrin biosynthesis to be isolated to date. The ring contraction *(1)→(3)* is closely related, both structurally and mechanistically, to our 1-methylidene-1,19-secocorrin→corrin cycloisomerization[4], especially to the non-photochemical (A→D)-cyclization of a 1-methylidene-19-formyl-1,19-secocorrin reported in 1977[4c, 5]. The earlier conditions necessary for the conversions *(1a, b)→(3a, b)* (melting at 295° and 260°, respectively) were unsatisfactory with regard to the intended role of the reaction as a potentially[6] biomimetic model. We now describe further properties and variants of the reaction, among which are conditions that permit the ring contraction to proceed even at room temperature.



*(1a)*, M = $Ni^+(ClO_4^-)$
*(1b)*, M = $Co(CN)_2$
*(1c)*, M = $Zn^+(ClO_4^-)$
*(1d)*, M = $H(H^+/CF_3COO^-)$

*(2a)*, M = $Ni^+(ClO_4^-)$
*(2c)*, M = $Zn^+(ClO_4^-)$

*(3a)*, M = $Ni^+(ClO_4^-)$
*(3b)*, M = $Co(CN)_2$
*(3c)*, M = $ZnCl$
*(3d)*, M = $H(H^+/ClO_4^-)$

*(4a)*, M = $Ni^+(ClO_4^-)$

*(5a)*, M = $Ni^+(ClO_4^-)$

Scheme 1. Summary of the reaction conditions (RT = room temperature). All compounds were isolated crystalline and characterized spectroscopially (UV/VIS, IR, $^1H$- and $^{13}C$-NMR, MS). For experimental details: *K. Hilpert,* Dissertation, ETH Zürich (in preparation).

| Reactions | Reaction conditions and yields |
|---|---|
| *(1a)→(3a)* | cf. [1] |
| *(1b)→(3b)* | cf. [1] |
| *(3a)→(4a)* | cf. [1] |
| *(1c)→(2c)* | evacuated tube, in the dark, 220 °C (70 s), yield 33%, apart from 28% educt and 13% *(5a)*, isolated as Ni complex; or: visible hν (150 Watt) in $CH_2Cl_2 + CF_3COOH$ ($7 \cdot 10^{-4}$ M), 40 °C, yield 50% |
| *(2c)→(2a)* | $CF_3COOH$, $Ni(OAc)_2 \cdot 4H_2O$ in $CH_3CN$, RT, yield 88% |
| *(2a)→(3a)* | $CH_3COOH/(C_2H_5)_3N$ (4 : 1) in toluene, 100 °C, 2 h, evacuated tube, yield 90% [a] |
| *(2c)→(3c)* | hν visible (150 Watt) in benzene/$CH_2Cl_2$ (6 : 1) (degassed), 25 °C, yield 75% [b] |
| *(3c)→(3d)* [c] | $CF_3COOH/CH_3CN$ (1 : 100), 0 °C, 30 min, argon, in the dark, 62% *(3d)* + 20% educt |
| *(3c)→(2a)* | a) $CF_3COOH/CH_3CN$ (1 : 10), RT, 16 h in the dark; b) $Ni(OAc)_2 \cdot 4H_2O/NaOAc$, RT, 3 h, yield 81% |

[a] In the 19-formyl model series [4c], the analogous ring closure occurs within hours at room temperature (cf. *A. Pfaltz,* Dissertation ETH No. 6184, Juris-Verlag Zürich 1978, p. 167). [b] *(3c)* was isolated crystalline as the chlorozinc(II) complex (m. p. = 230 °C). [c] 19-Acetyl-1,2,2,7,7,12,12,17,17-nonamethylcorrinium perchlorate, orange crystals, M. p. = 139 °C. — UV/VIS ($C_2H_5OH$): $\lambda_{max} = 263$ ($\log\varepsilon = 4.47$), 292 sh (4.22), 307 sh (4.41), 321 (4.53), 371 (3.72), 392 sh (3.56), 458 sh (3.76), 488 sh (4.06), 512 (4.10) nm. — $^1H$-NMR ($CDCl_3$/300 MHz): 9 $CH_3$ singlets between $\delta = 1.02$ and 1.46, 1.99 ($CH_3CO$), 1.88/2.65 (AB/$J = 14$/2 H-18), 2.92/3.11 (AB/$J = 19$/2 H-3), 2.89/2.91 (ABX/$J_{AB} = 19$; $J_{BX} = 1.8$/2 H-13), 2.83/2.87 (AB/$J = 19$/2 H-8), 5.43 (t/$J = 1.8$/H-15), 5.63/5.64 (2 s/H-5 and H-10), 11.86/13.17 (2 s br., 2 NH) ($J$ in Hz). — $^{13}C$-NMR ($CDCl_3$, 75 MHz): $\delta = 19.5-29.2$ (8 q/10 $CH_3$), 42.6—52.0 (4 t/4 $CH_2$), 43.2—52.2 (4 s/C-2,7,12,17), 78.8 (s/C-1), 91.1 (s/C-19), 91.4—93.3 (3 d/3 CH), 155.8—193.5 (6 s/6 $>$C=N), 210.8 (s/$>$C=O).

Melting the *metal-free* ligand *(1d)* (as the crystalline trifluoroacetate, m. p. = 194 °C) for one minute in an evacuated tube at 215 °C did not lead to ring-contraction. Instead, ring-opening occurred (evidently followed by skeletal rearrangement) to give the ligand system of *(5a)*, which was isolated as the crystalline nickel(II) complex. The same occurred with *(1d)* in pure trifluoroacetic acid (TFA) at 80 °C in 1 h (though the reaction was not observed even

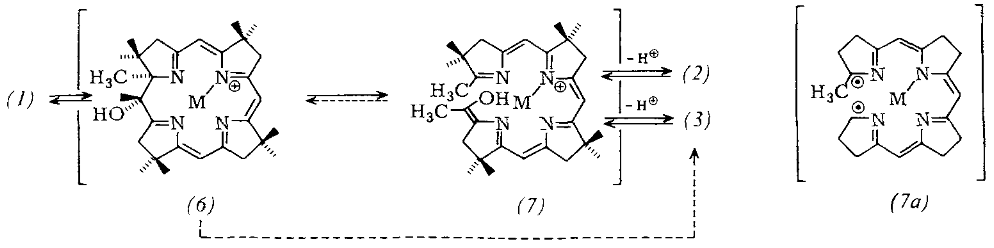
after days at room temperature)[7]. With the zinc(II) complex *(1c)*, careful control of the melting conditions (see Table 1) enabled the undesired skeletal rearrangement to be largely avoided in favor of formation of the zinc(II) 19-acetyl-1-methylidene-1,19-secocorrinate *(2c)*. The same dihydrocorphinol→secocorrin ring-opening occurred at room temperature upon irradiation of the zinc complex *(1c)* with visible light in dichloromethane under conditions of strict oxygen exclusion in the presence of traces of TFA. In the absence of TFA, but otherwise under the same conditions, *(1c)* was photostable; this supports the notion that protonation of the starting material to give the iminium derivative *(6)* is a prerequisite for the (electrocyclic) ring-opening step, *(1)→(2)* (cf. Scheme 2).



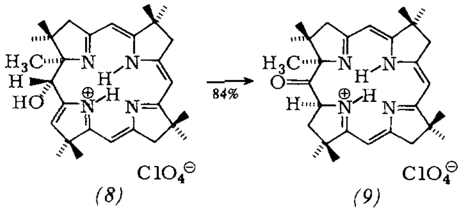
Scheme 2. Intermediates in the dihydrocorphinol → corrin ring contraction [8].

The nickel(II) 19-acetylsecocorrin complex *(2a)*, readily accessible from *(2c)* by metal exchange, cyclized in a manner closely analogous to the 1,19-secocorrin → corrin cycloisomerization in the 19-formyl model series[4c]. Cyclization of *(2a)* to the 19-acetylcorrin complex *(3a)* in acetic acid/triethylamine (4:1)/toluene was almost quantitative within 2 h at 100 °C. The reaction also occurred at room temperature, but required weeks (cf. Scheme 1).

The metal-free form of the 19-acetylcorrin *(3d)* could be obtained by photochemical (A→D) cycloisomerization of the zinc complex *(2c)*, followed by (very careful) decomplexation of the zinc(II) corrinate *(3c)* with TFA in acetonitrile at 0 °C (see Scheme 1). Decomplexation of *(3c)* at room temperature followed by recomplexation with Ni$^{II}$ led exclusively to the nickel(II) secocorrinate *(2a)*. *This is the first time we have encountered an (A→D) ring opening of a corrin to an A/D-secocorrin.* Mechanistically, this transformation can be interpreted as the acid-catalyzed reversal of the (acid/base-induced) (A→D) cyclization of 19-acyl-1-methylidene-1,19-secocorrins, and, as such, it requires an angular acyl group at C-19 (or C-1).

The results communicated here demonstrate the existence of kinetically readily accessible transitions[8] between the structural types of 1,20-dimethyl-1,20-dihydro-20-corphinol *(1)*, 19-acetyl-1-methylidene-1,19-secocorrin *(2)* and 19-acetyl-1-methylcorrin *(3)*. In this context, the secocorrin structure *(7)* assumes the role of a "transit structure" (cf. Schemes 1 and 2). At the same time, *(7)* corresponds to the primary dissociation product in the fragmentative reaction variant of the ("semibenzoin") rearrangement[1], which provides a direct link between the dihydrocorphinols *(1)* and 19-acetylcorrins *(3)*. It remains experimentally uncertain whether the ring contractions *(1a, b)→(3a, b)* described in [1] are direct rearrangements (either fragmentative or concerted) or whether they proceed *via* secocorrinoid intermediates of type *(2)*.

We find it noteworthy that the species formally derived by deprotonation of the hydroxyl group of *(7)* is of the same structural type as the (still hypothetical) intermediate *(7a)* in the photochemical A/D secocorrin → corrin cycloisomerization described in 1969[4b]. The latter was the starting point for our search for potentially biomimetic versions of the (A→D) cyclization.



Scheme 3. Model investigation in the 20-demethyl-series. The configurational assignments are tentative (see [1]). For experimental details: *A. Fässler*, Dissertation ETH Zürich (in preparation).

The tertiary nature of the hydroxyl group at C-20 or, from the biosynthetic point of view, the presence of a methyl group at this bridging carbon atom, seems to be a prerequisite of the dihydrocorphinol → corrin transformation. If this methyl group is absent from the model system, an alternative reaction occurs under mild conditions (Scheme 3). Thus, triethylammonium acetate in benzene irreversibly tautomerized the 20-demethyl derivative *(8)*[9] at room temperature to give the isomeric ketone *(9)*; under analogous conditions, *(1d)* was stable up to 90 °C. This difference in behavior between the 20-methyl- and 20-demethyl-model series should be viewed in relation to the *raison d'être* of the methylation at C-20 in the biosynthesis of vitamin B$_{12}$.

Acta *60*, 2653 (1977).

[5] The cyclization studies in the formyl series were based on the knowledge then current, *i.e.* that C-20 of uroporphyrinogen III is eliminated in the course of the biosynthesis of cobyric acid ("obviously as a C$_1$-fragment").

[6] The reaction type responsible for the ring contraction in the biosynthesis of vitamin B$_{12}$ is still not known. For the present state of knowledge cf. *C. Nussbaumer, M. Imfeld, G. Wörner, G. Müller, D. Arigoni*, Proc. Natl. Acad. Sci. USA *78*, 9 (1981); *L. Mombelli, C. Nussbaumer, H. Weber, G. Müller, D. Arigoni, ibid. 78*, 11 (1981); *A. R. Battersby, M. J. Bushell, C. Jones, N. G. Lewis, A. Pfenninger, ibid. 78*, 13 (1981).

[7] With acetic acid/triethylamine (4:1 to 1:1.5) in nonpolar solvents at 100–125 °C, *(1d)* yielded complex mixtures from which (after complexation with $Ni^{II}$) neither *(3a)* nor *(2a)* could be isolated.

[8] The reaction arrows in Scheme 2, leading from *(6)* to *(3)* and from *(7)* to *(6)* are mechanistically plausible, but the corresponding conversions have not yet been experimentally demonstrated.

[9] Synthesized from the corresponding carbonyl compound (cf. [1]) by (diastereoselective) reduction of the chlorocadmium complex with $ZnBH_4$ in $CH_2Cl_2$ at 0 °C, and subsequent (careful) decomplexation with $CF_3COOH/CH_3CN$ (1:50) at room temperature.

## Stabilization of Diphosphorus Tetrabromide as the Bis(pentacarbonylchromium) Complex

By *Axel Hinke, Wilhelm Kuchen,* and *Jürgen Kutter*[*]

In solutions of *(1)* there exists the equilibrium

$$n\,RP(X){-}P(X)R \rightleftharpoons (RP)_n + n\,RPX_2$$

*(1)*

R = alkyl, aryl; X = Br, I

whose position at a given temperature is a function of, R, X and solvent[1]. Disproportionation of *(1)* can be prevented by coordination to metal(0) centers, *e.g.* as in complexes of type *(2)*[2,3].

$$(CO)_5CrRP(X){-}P(X)RCr(CO)_5$$ *(2)*

$R = C_6H_5$, 4-$CH_3OC_6H_4$,

Analogous disproportionations also occur with the diphosphorus tetrahalides $P_2Cl_4$ and $P_2I_4$[4,5], and presumably particularly fast, with the as yet unknown $P_2Br_4$.

We have now succeeded in stabilizing diphosphorus tetrabromide as a ligand in complex *(4)*, which we have obtained *via* three routes:

1) from the products of the reaction of $(CO)_5Cr\cdot THF$ with $PBr_3$, whereby $(CO)_5CrPBr_3$ is principally formed,
2) by the partial reduction of $(CO)_5CrPBr_3$ with magnesium,
3) from the tetraaminodiphosphane complex *(3)*[6] thus

$$(CO)_5Cr{-}(Et_2N)_2PP(NEt_2)_2{-}Cr(CO)_5 \xrightarrow[-\,Et_2NH\cdot HBr]{+\,HBr}$$

*(3)*

$$(CO)_5Cr{-}Br_2PPBr_2{-}Cr(CO)_5$$

*(4)*

*(4)* forms orange-yellow crystals that are relatively air-stable, and readily soluble in chlorohydrocarbons, benzene, and toluene, but however, only sparingly soluble in pentane. The structure of *(4)* was derived from the elemental analysis and spectroscopic data. The IR spectrum, therefore, shows the characteristic pattern of bands for the $(CO)_5CrL$ groups in the $\nu$(CO) - (2081 m, 2001 s, 1995 vs, 1964 vw $cm^{-1}$ (*n*-pentane)), $\delta$(CrCO)- and $\nu$(CrC)-regions. The $^{31}P$-NMR spectrum shows a singlet at $\delta = 178.0$ (0.03 M in toluene, standard: 85% $H_3PO_4$). Apart from the intense signal for the molecular ion *m/z* 762 (47%), fragments, corresponding to a successive loss of all the CO ligands, occur in the EI mass spectrum; only the $M^+$ ion occurs in the FD mass spectrum. The molecular weight (754±3%) was determined cryoscopically in benzene.

Evidence for the formation of free diphosphorus tetrabromide was obtained from the reduction of $PBr_3$ with magnesium in tetrahydrofuran (THF) or with $(C_6H_5P)_5$ in $CS_2$, as well as from the reaction of white phosphorus with $PBr_3$, and of $(Et_2N)_4P_2$ with HBr. In all cases the coupled $^{31}P$-NMR spectrum of the reaction solution temporarily shows a singlet at $\delta \approx 145$ (for comparison: $P_2Cl_4$: $\delta = 155$[7]; $P_2I_4$: $\delta = 106$[5]). A transient signal observed at $\delta = 150$ (in $PBr_3$) in the system $C_2H_4/PBr_3/AlBr_3$ had previously been assigned to $P_2Br_4$[8]. The appearance of the signal in the above mentioned reactions strongly supports the assignment to $P_2Br_4$. Moreover, the low-field shift upon coordination has the expected order of magnitude[3,9].

### *Procedure*

All operations were performed under conditions of rigorous oxygen- and moisture-exclusion.

*(4)*: $Cr(CO)_6$ (5.50 g, 25 mmol) in 370 mL of THF is irradiated in a quartz photoreactor (Fa. Normag, Lampe TQ 150 Original Hanau) for 5.5 h. After dropwise addition of $PBr_3$ (6.77 g, 25 mmol) in 10 mL of benzene over 30 min and being stirred for 2 h, solvent and excess $Cr(CO)_6$ are removed *in vacuo* at room temperature. Toluene (20 mL) is added to the residue, the mixture is cooled to −30 °C for some hours before being filtered at −35 °C. The crystals are washed with a little toluene, and dried *in vacuo* at room temperature; yield 1.3 g, decomp. above *ca.* 130 °C, black coloration at *ca.* 150 °C.

*(4)*: Using liquid-nitrogen cooling, hydrogen bromide (*ca.* 250 mL) is condensed into a solution of *(3)* (804 mg) in 300 mL of toluene. The reaction mixture is stirred constantly and gradually warmed up to room temperature, filtered, concentrated to *ca.* 40 mL, and refiltered. Pentane is added until the solution becomes turbid. Then the mixture is cooled to −35 °C and the crystals are filtered off after 24 h. Total yield (after concentration and recooling of the filtrate) 762 mg (90%).

sorption—was demonstrated by *Mills* by determining the tissue levels of Cu and Mo in rats which had been given various amounts of $^{64}CuCl_2$ and $(NH_4)_2{}^{99}MoS_4$ in their diet[1].

Our previous investigations showed that a variety of structurally interesting polynuclear Cu complexes are formed[2-4] from $MoS_4^{2-}$ and $Cu^{n+}$ in the presence of triphenylphosphane (and also with $MoOS_3^{2-}$, $WS_4^{2-}$, $WOS_3^{2-}$ and $Ag^+$[2,3]). We have now found that $MoS_4^{2-}$ may also coordinate directly to neutral Cu compounds such as the "CuCN molecule" or an infinite CuCN chain, resulting in the binuclear complex $(Ph_4P)_2[(CuCN)MoS_4]$ *(1)* (Fig. 1) and the *catena*-complex $(Me_4N)_2(CuCN)_2MoS_4$ *(2)* (Fig. 2) with a novel solid-state structure. *(1)* and *(2)* were characterized by full crystal structure determinations[5,6]. The new reactions show that the triphenylphosphane ligand is not essential for the formation of thiomolybdato complexes of copper, which we consider to be models for the $Cu^{n+}$-TM interaction[2,3].

The molecular structure of the binuclear complex anion of *(1)* is shown in Figure 1. It contains a linear Mo···Cu···CN arrangement with almost trigonal-planar coordination of Cu and tetrahedral coordination of Mo.

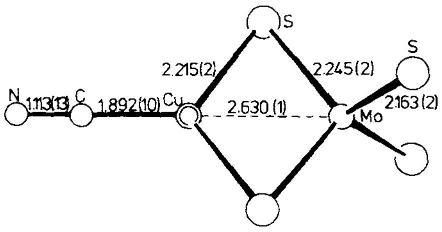

Fig. 1. Structure of the complex anion in crystals of *(1)* (distances in Å).

Infinite chains of complex anions are aligned parallel to the x-axis in the novel solid-state structure of *(2)*. A bidentate $MoS_4^{2-}$ ligand is coordinated to each Cu atom of a zigzag ...CuCNCuCN... chain (angle of fold 107.2(5)°). A further "CuCN molecule" is attached to the free *S*-coordination sites of the thiomolybdate ligand. This results in distorted tetrahedral or trigonal-planar environment for the non-equivalent Cu atoms. The Cu···Mo···CuCN fragment is linear and lies along a crystallographic $C_2$-axis parallel to the z-axis. The complex anion in *(2)* may also be described as a CuCN chain with the binuclear anionic complexes of *(1)* as ligands. The geometrical parameters of the corresponding parts of *(1)* and *(2)* are thus very similar, and have not been given in Figure 2.

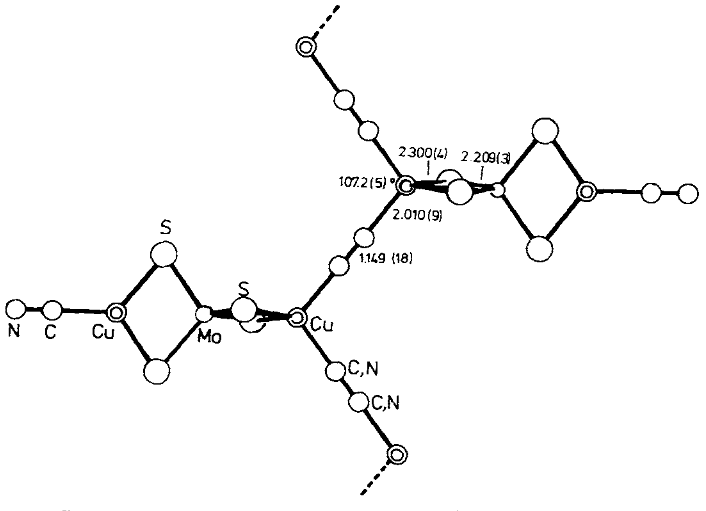

Fig. 2. Partial structure of the complex *catena*-anion in crystals of *(2)*.

The structure may prove illuminating for Cu-Mo-antagonism, because it has been indicated that this arises from the formation of a [Cu]TM-protein complex[1] (blocking of Cu for metabolism by coordination of $MoS_4^{2-}$ to a Cu-carrying protein).

### *Experimental*

*(1)*: $(Ph_4P)_2MoS_4$ (1.6 g) is added to a suspension of CuCN (0.18 g) in 50 mL of $CH_3CN/CH_2Cl_2$ (1 : 1). The reaction mixture is stirred for *ca.* 10 min (until an almost clear solution results). The solution is filtered and *ca.* 28 mL of $Et_2O$ is added (until a slight cloudiness appears). *(1)* precipitates slowly on cooling to *ca.* 5 °C. The red crystals are filtered off, washed with 5 mL of ice-cold $CH_2Cl_2$ and 10 mL of $Et_2O$, and dried in air; yield 1.0 g[7].

*(2)*: $(Me_4N)_2MoS_4$ (0.28 g) and CuCN (0.135 g) in 50 mL of $CH_3CN/CH_2Cl_2$ (1 : 1) are stirred for 60 min in a sealed Erlenmeyer flask. After addition of 5 mL of $Et_2O$, the filtrate is allowed to stand for 2 d in a sealed vessel. The dark brown crystals which precipitate are filtered off, washed with 5 mL of ice-cold acetonitrile and 10 mL of dimethyl ether, and dried in air; yield 0.22 g.

Postfach 8640, D-4800 Bielefeld 1 (Germany)

onism[3] has frequently been pointed out. We report here the syntheses of new tetrathiomolybdato (TM) complexes of iron and silver and the structural characterization of these and related complexes by the Resonance Raman Effect (RRE). Using this method the ***influence of the nearest and next nearest neighbors on the vibrations of the ligand chromophore*** is investigated. For this purpose, TM complexes can be regarded as particular textbook examples (high symmetry of the free ligand, which has a very intense electronic transition in the VIS range and unique electronic properties[1,2]).

Apart from $MoS_4^{2-}$, species with $FeS_2MoS_2$ groups are probably also formed upon hydrolysis of the MoFe protein of nitrogenase[1a]. For the synthesis of the cofactor[1a], precursors with high Fe content, *e.g.* $[Fe(DMSO)_6][(Cl_2Fe)MoS_4]$ *(1)* are probably particularly suitable. In the $M^+$ ($M^+ = Cu$, Ag)/$PPh_3$(=L)/TM system, various multinuclear complexes are formed[1b,2], but only with $Ag^+$ the "symmetrical" trinuclear complex[2] $L_2AgMoS_4AgL_2$ *(2)* (with a doubly bridging TM ligand), the synthesis of which is described here for the first time.

Figure 1 shows the resonance Raman spectra (cf. [4]) of *(1)* and *(2)* as well as those of $L_2CuMoS_4CuL$ *(3)*[2] and $(Me_4N)_2(CuCN)_2MoS_4$ *(4)*[5]. The spectra of the compound $L_2AgMoS_4AgL$ *(5)*[2], which is analogous to *(3)*, as well as those of $(Ph_4P)_2[(CuCN)MoS_4]$ *(6)*[5] were recorded. The intensities of bands due to the totally symmetric vibrations of the TM ligands[8] were strongly enhanced (solid samples, rotating cell technique) using the 488 nm line of an Ar ion laser which lies within the absorption bands of the ligand internal charge-transfer transitions of the $MoS_4^{2-}$ chromophores[2,6] (for all the complexes and for $MoS_4^{2-}$ [7] at *ca.* 470 nm[6]). Using the same excitation line, resonance Raman spectra can also be obtained for $MoOS_3^{2-}$ and $ReS_4^-$ [2,7] and their complexes.

The intensity enhancement as well as the number of overtone bands is especially remarkable for complexes with high local ligand symmetry (especially for *(2)*, but also for *(3)*, *(4)*, and *(5)*) (Fig. 1). In *(5)* one finds $\nu_1 = 442$, $2\nu_1 = 882$, $3\nu_1 = 1320$, $4\nu_1 = 1760$, $5\nu_1 = 2200$, $\nu^* = 460$, $\nu_1 + \nu^* = 900$, $2\nu_1 + \nu^* = 1340\,cm^{-1}$ (see below). The structures or structural fragments in Figure 1 result from the analysis of the spectra.

*Influence of the nearest neighbors:* The spectra of species with only one coordinated metal atom (local $C_{2v}$ symmetry of the $MS_2MoS_2$ fragment), as in *(1)* or *(6)*, show characteristic bands due to the totally symmetric vibrations of the terminal *and* bridging $MoS_2$ groups[9] (stretching ($\nu$), as well as bending vibrations ($\delta$)), and also of the corresponding combination and overtone bands. The complexes with two coordinated metal atoms, *i.e.* with equivalent (as in *(2)*) or almost equivalent Mo—S bonds (as in *(3)* to *(5)*), *i.e.* with local $D_{2d}$ symmetry of the $MS_2MoS_2M$ fragment, show (as expected) strong symmetrical stretching vibration bands ($\nu$) as well as bands of the corresponding overtones (cf. Fig. 1).

*Influence of the next nearest neighbors:* The deviation from "$D_{2d}$ symmetry" (nearly $C_{2v}$ for the extended fragment $P_2MS_2MoS_2MP$) can clearly be recognized in the compounds *(3)* and *(4)*, which are unsymmetrically substituted at Cu and Ag, respectively, (therefore *and* because of the stoichiometry *(4)* should crystallize in a novel solid-state structure with unsymmetrically coordinated Cu atoms[5]), and especially in *(5)* (cf. hatched overtones in Fig. 1) but not in *(2)*, since on the high energy side of the bands of the different overtones weak features appear that can approximately be assigned to combination bands of the type $n\nu_1(A_1) + \nu^*(A_1)$ (assuming $C_{2v}$ symmetry for the

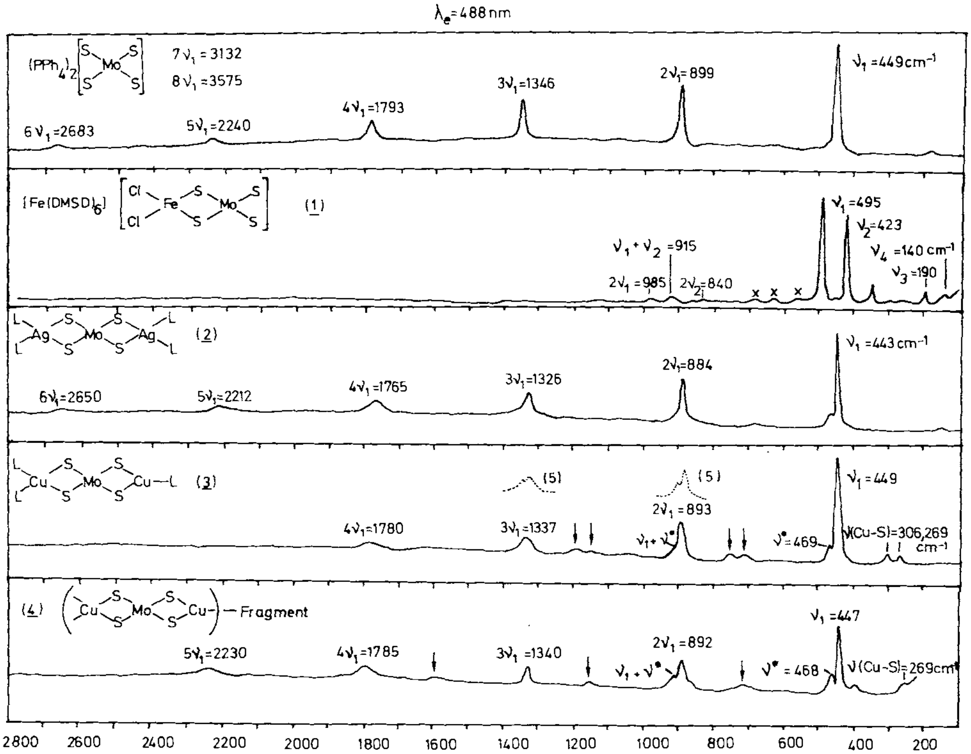

Fig. 1. Resonance Raman spectra of $MoS_4^{2-}$ (without overtones and combination bands [2, 7]), *(2)*, *(3)*, and *(4)* with symmetrically and unsymmetrically coordinated $MS_2MoS_2M$ moieties (local $D_{2d}$ symmetry; $\Gamma_{sym}(\nu) = 1A_1$; $\nu_1 = \nu_s(MoS)$) as well as of *(1)* [9] with an $MS_2MoS_2$ moiety (local $C_{2v}$ symmetry; $\Gamma_{sym}(\nu,\delta) = 4A_1$; $\nu_1 = \nu_s(MoS^t)$, $\nu_2 = \nu_s(MoS^b)$, $\nu_3 = \delta(MoS_2^t)$, $\nu_4 = \delta(MoS_2^b)$. ×: combination bands of $\nu$ and $\delta$, ↓: combination bands of $\nu_s(CuS)$ with $n_i\nu_1(MoS)$ [10].

extended fragments; for the transition $D_{2d} \rightarrow C_{2v}$ the correlation $B_2 \rightarrow A_1$ holds). Unnambiguous proof of the structure of the symmetrically coordinated trinuclear complex *(2)* (Fig. 1), for which suitable single crystals for a crystal structure determination could not be obtained, was therefore acheived[10].

### *Experimental*

*(1):* $FeCl_2 \cdot 4H_2O$ (1.2 g) is added to a stirred solution of $(NH_4)_2MoS_4$ (0.52 g) in 50 mL of dimethyl sulfoxide (DMSO). The solution is heated to 40°C for 5 min, then cooled to room temperature. After addition of 5 mL of $CH_2Cl_2$, the solution is filtered and the filtrate kept in the refrigerator for 12 h, whereby deep red crystals separate out; these were filtered, washed with $CH_2Cl_2$, and dried over $P_4O_{10}$. Yield 1.2 g [Space group $P\bar{1}$, $a = 855.8(2)$, $b = 999.5(2)$, $c = 1035.0(2)$ pm, $\alpha = 86.89(2)$, $\beta = 89.78(2)$, $\gamma = 89.62(2)°$, $Z = 2$; 3500 observed reflections, $R = 0.069$; Fe—Mo 277.5 pm; statistical disorder[2] of $X_2M'S_2MX'_2$ ($X'/X = Cl, S$; $M'/M = Fe, Mo$): Fe(Mo)—$S_{br}$ 226.8 pm].

*(2):* A solution of $(NH_4)_2MoS_4$ (0.22 g) in 100 mL of $H_2O$ is extracted with a solution of 0.21 g $AgNO_3$ and 0.73 g $PPh_3$ in 25 mL of $CH_2Cl_2$ for 3 min. The organic phase is filtered off and $PPh_3$ (6 g) added. A mixture of acetone/*n*-pentane (10 mL/50 mL) is slowly added to the $CH_2Cl_2$ so that two layers result. After 2 d, red needles of *(2)* separate out. Yield 0.25 g.

[5] *A. Müller, M. Dartmann, C. Römer, W. Clegg, G. M. Sheldrick*, Angew. Chem. *93*, 1118 (1981); Angew. Chem. Int. Ed. Engl. 1060 (1981).

[6] *A. Müller, E. Diemann, C. K. Jørgensen*, Struct. Bonding *14*, 23 (1973).

[7] The spectrum of $MoS_4^{2-}$ shows more details than those previously published by us and other authors [2], since an optimal RRE can be observed with $PPh_4^+$ salts or salts of this type with bulky cations (*e.g.* for $Ph_4P(ReS_4)$ overtones up to $10\nu_1(A_1)$ [2] and for $(Ph_4P)_2MoS_4$ also several combination band progressions with $\lambda_e = 488$ nm excitation which was also used for all other spectra of Fig. 6 in [2]).

[8] *K. H. Schmidt, A. Müller*, Coord. Chem. Rev. *14*, 115 (1974).

[9] The spectrum of *(6)* ($\nu_1 = 482$, $\nu_2 = 418$, $\nu_3 = 205$, $\nu_4 = 151$, $\nu(CuS) = 288$ $cm^{-1}$) corresponds to that of *(1)* with regard to the sequence of the main bands. The presence of $(Ph_4P)_2MoS_4$ (in a probably distorted crystal lattice), for which the RRE is considerably stronger (see text), leads to a band at 447 $cm^{-1}$.

[10] The interpretation of other features (combination bands of the $MoS_4^{2-}$ chromophore, weak bands of other vibrations *e.g.* of $\nu(CuS)$, and especially of combination bands of the type $\nu(CuS) + n_i\nu_1(MoS)$) for the investigation of the electronic structure of these multi-metal complexes is also interesting. The appearance of the combination bands of the latter type proves impressively the strong electronic interaction of $Cu^+$ and $MoS_4^{2-}$ in *(3)*, *(4)*, and *(6)*, which also follows from EH-SCCC-MO-calculations.

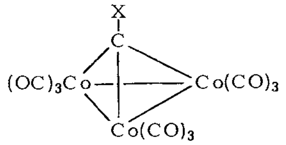
---

## Hydroformylation of Alkylidyne(nonacarbonyl)tricobalt Clusters: Model Reaction for the Direct Conversion of Synthesis Gas into $C_1$- and $C_2$-Oxygenated Compounds[**]

By *Giuseppe Fachinetti, Raffaello Lazzaroni,* and *Sergio Pucci*[*]

The spectroscopic and structural properties[1] of $(CO)_9Co_3C—OH$ *(1)* define this compound as a member of the well known family of alkylidyne(nonacarbonyl)tricobalt clusters[3], which have previously been photochemically hydrogenated[2]. *Bergman* and *Stuhl*[4] have shown that the complex $(CO)_9Co_3CR$ is thermally converted by hydrogen into alkanes, alkenes, $Co_4(CO)_{12}$ and traces of cobalt metal. These observations and the fact that *(1)* exists in equilibrium with $HCo(CO)_4$ and $Co_2(CO)_8$[5] persuaded us to assume *(1)* as being a possible intermediate in the hydrogenation of CO in the homogeneous phase, in the presence of carbonylcobalt compounds, carried out by *Rathke* and *Feder*[6].

In an attempt to gain support for this hypothesis, we investigated the reactions of the alkylidene complexes *(2)*—*(4)*[7] with synthesis gas at high temperatures and pressures in the presence of $Co_2(CO)_8$: like *(1)*, compounds *(2)*, do not react with $CO/H_2$ to give alkenes and, hence, have been considered by us to be model compounds for the labile *(1)*.



*(1)*, X = OH
*(2)*, X = $OCH_3$
*(3)*, X = H
*(4)*, X = D
*(5)*, X = $CH_3$
*(6)*, X = *n*-$C_4H_9$

The methoxy derivative *(2)*, whose IR spectrum in the CO stretching region is superimposable on that of *(1)*, reacted completely with $CO/H_2$ (xylene, $Co_2(CO)_8$, *ca.* 115 bar, 10 h, 120°C). No precipitate was observed, the only carbonyl compounds detected at the end of the reaction being $HCo(CO)_4$ and $Co_2(CO)_8$. The organic products were identified as dimethyl ether and 2-methoxyethanol (1:10)—apart from varying amounts of 2-methoxyethyl formate—corresponding to methanol and ethylene glycol, respectively, two of the products of the catalytic CO-hydrogenation[6].

$$(2) \xrightarrow[Co_2(CO)_8]{CO/H_2} H_3COCH_3 + H_3COCH_2CH_2OH + H_3COCH_2CH_2OCHO$$

These results indicate that the intermediary occurrence of the hydroxymethylidyne cluster *(1)* in the CO hydrogenation could not only explain the formation of methanol

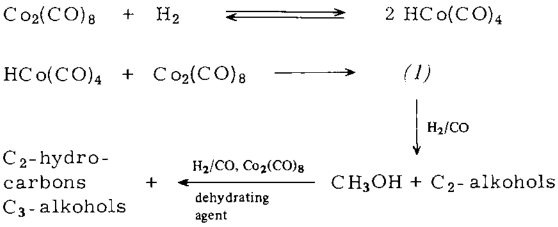
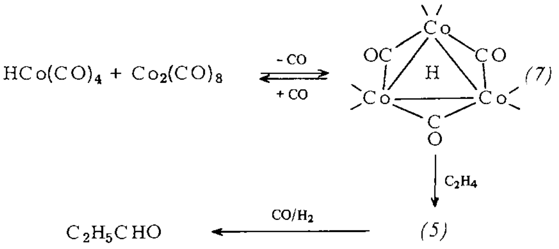
but also that of $C_2$-alcohols; higher homologues could form in the presence of a dehydrating agent and under oxo-synthesis conditions (Scheme 1).



Scheme 1. Possible mechanism for the Fischer-Tropsch reaction: a sequence of hydroformylation steps.

A sample withdrawn after 4 h contained methoxyacetaldehyde, presumably the precursor of 2-methoxyethanol. In addition, the reaction of *(3)* and *(4)* with syngas, which proceeds under milder conditions, affords $CH_3CHO$ and $CH_2DCHO$ in quantitative yields, thus confirming that aldehydes and, under more drastic conditions, alcohols and alkanes are generated from alkylidine complexes without the intermediacy of alkenes. The previously reported formation of propionaldehyde[8] from $Co_3CH_3C(CO)_9$ and syngas could be considered as a special case of the general reaction.

The unsaturated 46e trinuclear cluster $HCo_3(CO)_9$ *(7)* reacts with acetylene[9] and—presumably with $H_2$ evolution — with ethylene to give $(CO)_9Co_3CCH_3$ *(5)*; with terminal alkynes and alkenes[10], *(7)* reacts to give the corresponding alkylidine complexes. *(7)* can also be obtained from $HCo(CO)_4/Co_2(CO)_8$ solutions[5]. On these grounds the following multi-step hydroformylation of alkenes is plausible.



Scheme 2. Possible mechanism for the hydroformylation of alkenes (oxo synthesis).

The reaction of the pentylidene clusters *(6)*[12] with syngas yield, apart from 5% *n*-pentane, 76% of oxygenated $C_6$-products, whereby the ratio normal : branched is 3.4—a value similar to that found for the hydroformylation of 1-pentene by carbonylcobalt compounds[11]. This result can be interpreted in several ways: 1) Alkenes and the corresponding alkylidynes generate, under oxo synthesis conditions, the same reactive intermediate. 2) The hydroformylation of alkylmethylidynes proceeds *via* alkenes. 3) Alkylidyne complexes occur as intermediates in the oxo synthesis. Further investigations are necessary to verify these hypotheses.

## *Procedure*

All investigations were carried out in a 50 mL steel autoclave equipped with a siphon to withdraw liquid samples: the vessel was charged with 15 mL of a *p*-xylene (toluene for *(6)*) solution containing 3 mmol of the alkylidyne complex $Co_2(CO)_8$ (1.5 mmol), and syngas. The disappearance of the alkylidyne complex was followed by thin layer chromatography (silica gel, *n*-hexane). The carbonyl complexes were identificated by IR spectroscopy and the organic products by mass spectroscopy (GC-MS). Yields of organic products were obtained by GC-comparison with standard solutions. *(2)—(4)* were prepared and purified as described in [7]. *(6)*, prepared as described in [12] was purified by chromatography (silica gel/*n*-hexane) and then sublimed.

## *Reaction of (2)—(4) and (6) with syngas:*

*(2):* The reaction was complete after 15 h at 120 °C and *ca.* 115 bar syngas. A sample withdrawn after 4 h contained — apart from traces of $CH_3OCH_2CH_2OH$ — $CH_3OCH_2CHO$, $CH_3OH$, and $CH_3OCH_3$ (10 : 1 : 1). The final composition of the solution was $CH_3OCH_2CH_2OH$ (60% yield), $CH_3OCH_3$ (6%), $CH_3OCH_2CH_2CHO$ (10%). The products must be analyzed immediately after sampling, since the concentration of alcohols rapidly decreases upon exposure to air. The possible presence of small amounts of $CH_4$ was not checked.

*(3):* The reaction was complete after 45 min at 100 °C and *ca.* 95 bar syngas. $CH_3CHO$ was produced as final product in quantitative yield.

*(4):* Conditions similar to *(3)*. On the basis of the mass spectra the maximum amount of non-deuterated aldehyde is 30%; $CH_3CDO$ was not formed.

*(6):* The reaction was complete after 15 h at 120 °C and 120 bar syngas. A sample withdrawn after 3 h contained 1-hexanal and 2-methylpentanal (3.4 : 1). At the end of the reaction the product composition was thus: 1-hexanol (58% yield), 2-methylpentanol (17%), *n*-pentane (5%), 1-hexanal (1%), and 2-methylpentanal (trace).

**Molecular Shapes—Theoretical Models of Inorganic Stereochemistry.** By *J. K. Burdett*. J. Wiley & Sons, Chichester 1980. x, 287 pp., bound, £ 15.75.

Qualitative comprehensive concepts for the theoretical understanding and systematization of the structure and stereochemistry of molecules are certainly as important as the further development of "exact" quantum-chemical methods of calculation. A clearcut example are the Woodward-Hoffmann rules and all their consequences for development and cross-fertilization of organic and theoretical chemistry.

*Burdett*'s interesting little book, written in response to the explosively growing number of structure determinations and structural types, attempts a review of the most important qualitative and semiquantitative theoretical concepts for describing the bonding relationships and stereochemistry of inorganic and organometallic molecules. The author does not address himself so much to specialists, *i.e.* theoreticians or structural chemists (for whom, however, the book can serve as a useful synopsis) as to experimental chemists, teachers, and advanced students. Mindful of the need for "simple" theories on the basis of qualitative MO concepts and relying on arguments of perturbation theory and symmetry considerations as method-independent as possible, *Burdett* gives a review that is successful in its total impression without succumbing to the danger of losing sight of the limits of application and the often limited informative value of the various simple theoretical approaches. The reader is assumed to have little general basic theoretical knowledge, and the material is presented with the help of numerous examples.

After a brief introduction into the fundamentals of perturbation theory and MO theory (description of simple approximate MO methods) and the angular overlap model (which the author considers particularly useful), the first main part of the book (Chapters 3—7) deals with model ideas of structure theory for main-group molecules $AY_n$. Following a description of the VSEPR (valence shell electron pair repulsion) model and the well-known VB description of molecular geometries with directed hybrid orbitals, stereochemical statements are developed on the basis of qualitative one-electron MO's and Walsh diagrams. This chapter has been kept relatively short, and probably deliberately so, as a really exhaustive treatment of the subject can be found in a recent book by *Gimarc*. After a quite detailed and clear description of the Jahn-Teller effect of first and second order on molecular geometry, there is a chapter explaining simple semiquantitative derivations of molecular structures from the angular overlap model. Critical evaluations of bonding concepts in structural isomerisms, comments on σ-bonding effects and steric influences, and also a glimpse at some results of quantitative MO calculations complete the main-group part of the book. The author then turns to the stereochemistry of transition-metal systems (Chapters 8—13), presents the principles of crystal field theory, and uses for describing transition-metal-ligand interactions and their stereochemical consequences the methods already used for main-group molecules. The geometry of excited states, σ- and π-bonding effects in transition-metal complexes, and thermodynamic properties are interpreted on the basis of MO theory. Particularly worth reading is Chapter 13, in which with readily understandable PMO analyses based on the results of quantitative calculations, a substantially more detailed picture of the molecular orbitals of transition-metal complexes or of common metal-ligand fragments is developed than would be possible with the angular overlap model. Statements on electronic structure and stereochemistry are then derived from shape (hybridization) and energy of the valence orbitals.

The last two chapters of the book deal with the structure of rings, cage compounds, clusters, and solids; the author's results cited here form a connection with the ideas of MO theory developed on and applied to simple molecules.

Apart from the often somewhat small figures, *Burdett*'s book is very readable and free from ballast. The construction is clear. Each chapter is preceded by a short summary and statement of its aims. The book can certainly fulfil its purpose stated in the preface, which in itself is well worth reading, namely to contribute to the qualitative understanding of molecular structures with the aid of simple theoretical models. It would be desirable to give the book a firm place in chemical education.

*Peter Hofmann* [NB 546 IE]

**Recent Books**

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

**Polymer Chemistry.** An Introduction. By *R. B. Seymour* and *C. E. Carraher, Jr.* Marcel Dekker, Basel 1981. xvi, 564 pp., bound, SFr. 80.00.—ISBN 0-8247-6979-1

**Synthetic Reagents. Vol. 4.** Mercuric Acetate, Periodic Acid and Periodates, Sulfuryl Chloride. Edited by *J. S. Pizey*. John Wiley & Sons, Chichester 1981. 426 pp., bound, £ 32.50.—ISBN 0-470-27133-7

**Progress in Pesticide Biochemistry. Vol. 1.** Edited by *D. H. Hutson* and *T. R. Roberts*. John Wiley & Sons, Chichester 1981. xi, 346 pp., bound, £ 24.00.—ISBN 0-471-27290-X

**Handbuch der Präparativen Anorganischen Chemie, Vol. 3.** Edited by *G. Brauer*. Enke Verlag, Stuttgart 1981. 3rd Edit. xiv, pp. 1407—2113, bound, DM 288.00 (all three volumes must be orded).—ISBN 3-432-87823-0

**Oxygen and Life. Second BOC Priestley Conference.** Issued by The Royal Society of Chemistry, London 1981. Special Publication No. 39. xii, 224 pp., bound, £ 11.00.—ISBN 0-85186-825-8

**Aliphatic and Related Natural Product Chemistry. Vol. 2.** Senior Reporter: *F. D. Gunstone*. The Royal Society of Chemistry, London 1981. xiii, 265 pp., bound, £ 40.00.—ISBN 0-85186-652-2.—A volume of the series "Specialist Periodical Reports"

**Inorganic Biochemistry. Vol. 2.** Senior Reporter: *H. A. O. Hill.* The Royal Society of Chemistry, London 1981. xiv, 347 pp., bound, £ 40.00.—ISBN 0-85186-555-0.—A volume of the series "Specialist Periodical Reports"

**Messen, Steuern und Regeln in der Chemischen Technik.** Edited by *J. Hengstenberg, B. Sturm,* and *O. Winkler.* Springer-Verlag, Berlin 1981. 3rd revised edit. xii, 500 pp., bound, DM 210.00.—ISBN 3-540-10092-X

**Methoden der Organischen Chemie.** In 16 volumes. Vol. IV/1d: Reduktion, Teil II. Edited by *H. Kropf.* Thieme Verlag, Stuttgart 1981. 4th completely new edit. *Ca.* 1000 pages, bound, *ca.* DM 780.00.—ISBN 3-13-201104-5

**Elektrochemie II.** Elektrodenprozesse, Angewandte Elektrochemie. Taschentext 42. By *C. H. Hamann* and *W. Vielstich.* Verlag Chemie, Weinheim 1981. xv, 428 pp., bound, DM 52.00.—ISBN 3-527-21081-4

**Lexikon alchemistisch-pharmazeutischer Symbole.** By *W. Schneider.* Verlag Chemie, Weinheim 1981. 2nd edit. 140 pp., bound, DM 38.00.—ISBN 3-527-25898-1

**Polarographische Analyse.** By *M. Geissler.* Verlag Chemie, Weinheim 1981. 1st edit. 194 pp., bound, DM 73.00.—ISBN 3-527-25887-6

**Hazards in the Chemical Laboratory.** Edited by *L. Bretherick.* The Royal Society of Chemistry, London 1981. 3rd edit. xxi, 567 pp., bound, £ 15.00.—ISBN 0-85186-419-8

**Reactivity of Metal-Metal Bonds.** ACS Symposium Series No. 155. Edited by *M. H. Chisholm.* American Chemical Society, Washington 1981. 327 pp., bound, $ 39.00.—ISBN 0-8412-0624-4

**Handbook of Automated Analysis.** Continuous Flow Techniques. By *W. A. Coakley.* Marcel Dekker, Basel 1981. xii, 144 pp., loose-leaf SFr. 55.00.—ISBN 0-8247-1392-3

**Dielectric Properties of Binary Solutions.** A Data Handbook. By *Y. Y. Akhadov.* Pergamon Press, New York 1981. 475 pp., bound, $ 112.50.—ISBN 0-08-023600-6

**Analytical Chemistry of Polycyclic Aromatic Compounds.** By *M. L. Lee, M. V. Novotny,* and *K. D. Bartle.* Academic Press, New York 1981. xi, 462 pp., bound, $ 60.00.—ISBN 0-12-440840-0

**A Guidebook to Mechanism in Organic Chemistry.** By *P. Sykes.* Longman, London 1981. 5th edit. 397 pp., bound, £ 6.95.—ISBN 0-582-44121-8

**Im Schatten der Sensation—Leben und Wirken von Fritz Strassmann.** Portrayed by *F. Krafft* after documents and records. Verlag Chemie, Weinheim 1981. xvii, 541 pp., bound, DM 150.00.—ISBN 3-527-25818-3

**Natural Products as Medicinal Agents.** Edited by *J. L. Beal* and *E. Reinhard.* Hippokrates Verlag, Stuttgart 1981. 528 pp., bound, DM 98.00.—ISBN 3-7773-0540-5

**Structure and Bonding, Vol. 45: Breakdown of the One-Electron Pictures in Photoelectron Spectra.** By *G. Wendin.* Springer-Verlag, Berlin 1981. vii, 130 pp., bound, DM 66.00.—ISBN 3-540-10584-0

**Air Pollution Control Equipment.** By *H. Brauer* and *Y. B. G. Varma.* Springer-Verlag, Berlin 1981. vii, 388 pp., bound, DM 196.00.—ISBN 3-540-10463-1

**Analytiker-Taschenbuch Band 2.** Edited by *R. Bock, W. Fresenius, H. Günzler, W. Huber,* and *G. Tölg.* Springer-Verlag, Berlin 1981. viii, 351 pp., bound, DM 78.00.—ISBN 3-540-10338-4

**Tabellen zur Strukturaufklärung organischer Verbindungen mit spektroskopischen Methoden. Anleitungen für die chemische Laboratoriumspraxis, Band 15.** By *E. Pretsch, T. Clerc, J. Seibl,* and *W. Simon.* Springer-Verlag, Berlin 1981. 2nd edit. ix, 316 pp., bound, DM 39.80.—ISBN 3-540-10556-5

**Bioorganic Chemistry.** A Chemical Approach to Enzyme Action. By *H. Dugas* and *C. Penney.* Springer-Verlag, Berlin 1981. xii, 508 pp., bound, DM 59.00.—ISBN 3-540-90491-3

**Annual Reports on NMR Spectroscopy. Vol. 11A.** Edited by *G. A. Webb.* Academic Press, London 1981. x, 282 pp., bound, £ 35.00.—ISBN 0-12-505311-8

**Lectins—Biology, Biochemistry, Clinical Biochemistry. Vol. 1.** Proceedings of the Third Lectin Meeting. Edited by *T. C. Bog-Hansen.* W. de Gruyter, Berlin 1981. xii, 418 pp., bound, DM 120.00.—ISBN 3-11-008483-X

**Der historische Weg der Chemie, Band I und II.** By *W. Strube.* VEB Deutscher Verlag für Grundstoffindustrie, Leipzig 1981. Band I: 3rd edit. 192 pp., bound, DM 21.00; Band II: *Ca.* 224 pp., bound, *ca.* DM 23.50.
