# Condensed Metal Clusters

By Arndt Simon[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

The chemistry of metals in low valence states is marked by the frequent occurrence of metal clusters, which are easily recognizable when they occur as molecular units. Many metal-rich compounds of transition metals with p-elements (3rd to the 6th main groups) are closely related to the corresponding halides, since they are built up from metal clusters of the same type. The clusters are however, linked together (condensed) by metal-metal bonds. This principle of construction holds particularly well in the case of the novel reduced halides of the lanthanoids.

## 1. Introduction

The chemistry of compounds of transition metals in low oxidation states with main group elements is full of examples showing unusual compositions in terms of traditional valence rules. Above all, 4d- and 5d-elements are capable of using the remaining valence electrons to form metal-metal bonds. The occurrence of M—M bonds rationalizes the coincidental integer values of the oxidation state of many transition metals, and has resulted in the replacement of the old scheme of classification of simple compounds of these elements by oxidation numbers, by one involving structural elements.

M—M bonds can be restricted to a few directly coupled atoms, which leads to clearly defined bonded groups ("clusters"). Such clusters occur in discrete molecules or in quasi-molecular units joined by bridging ligands. Frequently, however, infinitely extended regions of bonded metal atoms result. The first group of cluster compounds have been the subject of numerous studies in the last twenty years and have been described in a series of review articles[1-15], which are already difficult to list completely; detailed descriptions are to be found in text books of inorganic chemistry. The following study is concerned with the structural relationship between cluster compounds of this sort and compounds containing extended regions of M—M bonding, which occur in the metal-rich binary compounds of transition metals as well as lanthanoids, with the elements of the seventh to the third main groups.

Conditions for the formation of metal clusters are particularly favorable when the non-metal involved, donates as many valence electrons as possible to the metal atoms on the one hand and, is present in a proportion which is sufficient to fully surround the cluster, on the other hand. As a result, the M—M bond has been most thoroughly studied in discrete clusters of the halides of the transition metals. In the case of compounds with elements of the 6th to the 3rd main groups the two above conditions cannot be readily met simultaneously. High valence electron concentration (VEC) for the metals normally demands a low non-metal content so that the resulting metal clusters do not show up as isolated (and easily recognizable) units. Metal-rich compounds of transition metals with the above elements are therefore as a rule, characterized by extended regions of M—M bonds, and the coordination of non-metal by metal atoms becomes the dominant structural feature. The structures of metal-rich compounds of the transition metals with elements of the 6th to

Heisenbergstrasse 1, D-7000 Stuttgart 80 (Germany)

the 3rd main groups have therefore been repeatedly reviewed in terms of characteristic coordination polyhedra of non-metal atoms and the way in which they link together[16–18]. The interaction between the metal atoms, which in these compounds is also extremely important, has not received so much attention[18, 19], although its significance in the structural chemistry of the halides had been recognized much earlier. A detailed analysis in fact shows that the same atomic arrangements as in the halide clusters, play an important role in a vast number of metal-rich compounds of transition metals with multivalent non-metals. The basic principle is simple; when the number of non-metal atoms in a compound is not sufficient to completely surround the metal cluster, the latter link up *via* direct M—M bonds, *i. e.* they "condense".

Cluster-condensation closely corresponds to the stepwise transition from benzene to graphite *via* intermediate carbon-rich polycyclic compounds. A second analogy can be found in the structural chemistry of silicates, which is dominated by various arrangements of condensed $SiO_4$-tetrahedra. This comparison in particular, illustrates the main difficulty in applying the concept of condensed metal clusters. Because of the exclusive presence of $SiO_4$-tetrahedra and their linkage *via* vertices, the structural principles of silicates are relatively simple.

On the contrary, the large variety of existing isolated metal clusters is further extended in systems with condensed clusters. Furthermore, the kind of linkage between clusters is variable and, finally, the bond lengths in metal clusters may fluctuate within a large range. These difficulties explain the prolonged hesitation in presenting the still qualitative concept[20–24] in a comprehensive version. The encouragement to give a more extensive description has been provided by some of the most recent results; compounds containing two or three condensed $Mo_6S_8$ clusters have been recognized as intermediate species on the way to the infinite $Mo_3S_3$-chain (*cf.* Section 3.3) and it has become evident that the novel chemistry of metal-rich halides of the elements Sc, Y, and the lanthanoids can be readily explained by application of this concept (*cf.* 3.2.2).

This review article has two objectives; firstly an attempt is made to reach a unified description and an understanding of the underlying structural principles of a wide range of metal-rich compounds of the transition metals, by considering characteristic M—M contacts (together with M—X contacts). Secondly, it is desirable to demonstrate the essential unity of "molecular" and "solid state" inorganic chemistry. It is also hoped that a contribution will be made to the understandig of an important class of substances, which fall equally under the headings of molecular compounds and coordination compounds as well as intermetallic phases.

## 2. General Approach to the Concept of Condensed Clusters

What boundary conditions determine the existence of a particular isolated metal cluster? This question has been treated several times, particularly for carbonyls and organometallic compounds[25–27]. In the present discussion on halide cluster compounds, only qualitative aspects will be considered. For this purpose, the number of valence electrons on the metal atom (VEC) which are available for M—M bonding for some binary compounds and anions are plotted in Figure 1 against the halogen/metal ratios (X/M). In the ionic limit, the value of VEC for the compound can be obtained from the VEC of the appropriate free metal ($VEC_0$) according to:

$$VEC = VEC_0 - n \cdot (X/M)$$

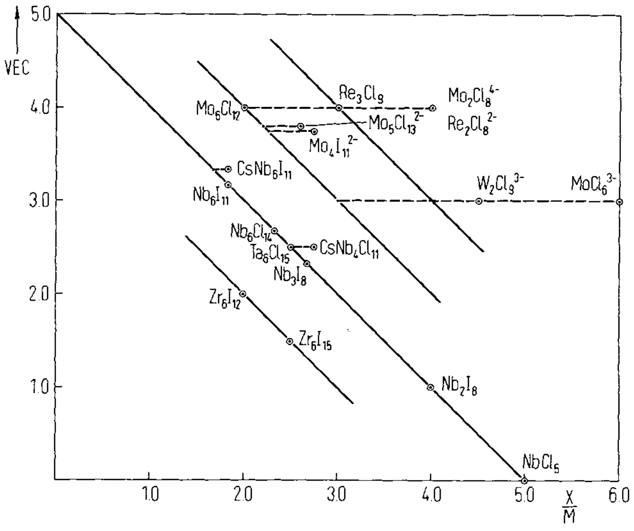

Fig. 1. Influence of valence electron concentration at the metal atom (VEC), and non-metal/metal ratio (X/M) on the size of a metal cluster in the halides of Zr, Nb, Ta, Mo, W, Re (see text).

This type of treatment is valid for the halides ($n = 1$) in general, and is still applicable with certain restrictions, for the chalcogenides ($n = 2$). Basic differences exist, however, from other procedures for "counting electrons"[28]. An extension of this approach to compounds of transition metals with elements of the 5th and 4th main groups is however not possible in this simple form. The X atom will certainly, however, remain the anionic counter-ion and it also behaves structurally much as a chalcogen, as will be seen from the comparisons discussed in the next chapter.

From the examples given in Figure 1, the following trivial conclusions can be drawn:

(a) Lowering the oxidation state of a transition metal (and with it an increase in VEC) in one of the halide compounds which lies on the line (solid) of gradient −1, leads to larger metal clusters; $NbCl_5$ contains isolated Nb atoms[29], $Nb_2$ pairs are present in ($\alpha$)-$Nb_2I_8$[30] and $Nb_3I_8$ contains $Nb_3$ clusters[31]. The $M_6X_{12}$ cluster is formed in the compounds $Nb_6F_{15}$[32] and $Ta_6Cl_{15}$[33], and is first retained as the oxidation number is lowered further in $Nb_6Cl_{14}$[34] but is finally replaced by the $M_6X_8$ cluster when the oxidation number is further lowered in $Nb_6I_{11}$[35] and $CsNb_6I_{11}$[36]. Interestingly enough, the $M_6X_8$ cluster only appears in a small area of Figure 1. It is not formed as an isolated cluster by Zr; the VEC is apparently too small. For Re halides, on the other hand, X/M (or VEC) is too large. As expected, however, the $Re_6S_8$ cluster exists[37]. In contrast to the $M_6X_8$ species, the $M_6X_{12}$ cluster turns out to be less sensitive to the VEC, occurring not only at very low values in the compounds $Zr_6I_{12}$ and $Zr_6Cl_{15}$[38], but also at extremely high values in $Pt_6Cl_{12}$[39] and corresponding Pd halides (M—M bonds absent). According to MO calculations[40,41], there may be 16 bonding electrons in this cluster (VEC = 2.67). A low X/M value is apparently more important in these species for the formation of the $M_6X_{12}$ cluster than special values of VEC. The influence of the VEC can be clearly seen in a comparison of the compounds $Nb_3Br_8$[39], $Nb_3Se_4$[50] and $Mo_6Se_8$[51]. In $Nb_3Br_8$, trigonal $Nb_3$ clusters are found; a trigonal $Nb_3$ grouping is also present in $Nb_3Se_4$ with the same VEC. In contrast, the compound $Mo_6Se_8$, with the same composition as the last compound but higher VEC, contains isolated $Mo_6Se_8$ clusters.

(b) The dominating effect of the X/M ratio on the cluster size can be seen from the examples in Figure 1, and is easily understood, since, with increasing cluster size, the number of non-metal atoms which can coordinate to metal atoms becomes smaller. The following examples demonstrate in an interesting way how the cluster shrinks through raising the X/M ratio. While the VEC is the same in $Nb_6F_{15}$, $Ta_6Cl_{15}$ and $CsNb_4Cl_{11}$[42] only $Nb_4$ clusters occur in the latter[42]. In the case of divalent molybdenum the dimeric anion $Mo_2X_8^{4-}$ forms, on raising the value of X/M[43], instead of the very stable $Mo_6X_8$ cluster. In this ion and in the isoelectronic $Re_2X_8^{2-}$ ion, the high VEC leads to a fourfold bond between the metal atoms[44]. The metal atoms in the $Mo_6X_8$- and $W_6X_8$-clusters can be oxidized up to the oxidation number +3[45,46], but the resulting compounds are thermodynamically unstable. In contrast, the stable compounds $[(C_4H_9)_4N]_2Mo_5Cl_{13}$[47] and $[(C_4H_9)_4N]_2Mo_4I_{11}$[48] contain clusters which result structurally from the removal of one or two Mo atoms from the $Mo_6X_8$ cluster. In the case of $K_3MoCl_6$, the "dilution" of the transition metal is so high that, despite the high value of VEC = 3, M—M bonding is no longer possible[49].

On studying the structures of $Nb_3Br_8$ and $Nb_3Se_4$, a problem becomes apparent which plays an important role in condensed metal cluster systems which will be treated later; the M—M distances inside a cluster are very variable. This is known for isolated clusters, but holds most strongly for clusters which can form bonds to M atoms of adjacent clusters. In the halide $Nb_3Br_8$, three $NbBr_6$ octahedra are joined by common *edges* (Fig. 2a). The M—M bond is recognizable by the shift of the Nb atoms towards the center of the cluster. Depending on the particular halogen atoms around the cluster, the Nb—Nb bond lengths are 281, 288 and 300 pm respectively in $Nb_3Cl_8$[52], $Nb_3Br_8$ and $Nb_3I_8$[31]. It is natural to attribute the variation in bond lengths to the matrix effect of the differently-sized halogen atoms.

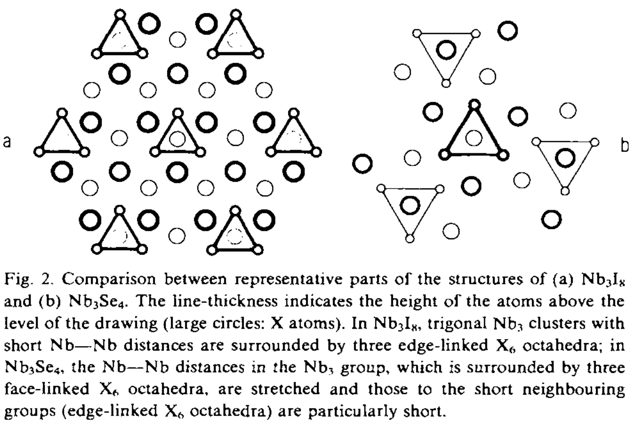

Fig. 2. Comparison between representative parts of the structures of (a) $Nb_3I_8$ and (b) $Nb_3Se_4$. The line-thickness indicates the height of the atoms above the level of the drawing (large circles: X atoms). In $Nb_3I_8$, trigonal $Nb_3$ clusters with short Nb—Nb distances are surrounded by three edge-linked $X_6$ octahedra; in $Nb_3Se_4$, the Nb—Nb distances in the $Nb_3$ group, which is surrounded by three face-linked $X_6$ octahedra, are stretched and those to the short neighbouring groups (edge-linked $X_6$ octahedra) are particularly short.

In the chalcogenide $Nb_3Se_4$, three $NbSe_6$ octahedra are joined by common *faces* to form trigonal $Nb_3$ groups (Fig. 2b). The resulting $Nb_3Se_{11}$ groups are, however, connected to each other *via* octahedral *edges* with bonds between similar surrounding groups, and the Nb atoms are shifted in the direction of the shared edges—as in the halides $Nb_3X_8$. For $Nb_3S_4$[53], $Nb_3Se_4$[50] and $Nb_3Te_4$[54], this interaction leads to an enlargement of the $Nb_3$ groups to 337, 347 and 365 pm, respectively, while particularly short Nb—Nb bonds form between atoms of the adjacent $Nb_3$ groups (288, 280 and 297 pm respectively). This can be explained by an improved orbital overlap for the Nb atoms *via* the edges of the coordination octahedra[55].

In summary, it can be stated that compounds with isolated $M_6X_8$ or $M_6X_{12}$ clusters form the boundary at low values of X/M in Figure 1. It was presumed therefore that clusters of the $M_6X_8$-type would maintain their importance as structural units on further reduction of the X/M ratio. This assumption has, in fact been confirmed in an impressive manner by the discovery of the stepwise condensation of $M_6X_8$ clusters (*cf.* Section 3.3).

The structure of $Nb_3Se_4$ makes it clear that the configurations of clusters should also be taken into account when analyzing the structural principles of metal-rich transition metal compounds, even if the M—M bond lengths within the cluster are not the shortest in the structure. There is of course a possible danger of setting up a scheme which ignores the core of the structure, namely the chemical bonds. On the other hand, it is a fact that every structural classification system is based on idealized structures. This is just as true for the "Frank-Kasper" concept[56] as for "lattice complexes"[57] or "chemical twinning"[58]. The ideal structure relaxes and only this relaxed structure is observed. A considerable amount of interpretation is already introduced when reconstructing the ideal arrangement. Two arguments speak in favour of considering the topology of a cluster even in the case of large M—M distances. On the one hand, it is only possible to describe the chemical bonding in an isolated cluster by taking the X atoms into account. Such multi-center bonds are also of importance in condensed bonding systems, as long as the geometry of the metal cluster is, in principle, retained. On the other hand, it should also be noted that no generally valid relationship exists between interatomic distance and bond order. Widely held concepts[59] are contradicted, *e.g.*, in the cases of metal-rich alkali metal oxides[60] and alkaline earth nitrides[61-63], as the bonding M—M distances are considerably larger than the non-bonding distances.

## 3. Principles of Cluster Condensation

The conclusion may be drawn from Section 2 that the $M_6X_8$ and $M_6X_{12}$ clusters, which tend to form isolated units down to X/M ratios of 1.33 and 2.00 respectively, will be retained as structural units on further reduction of X/M. The present study is chiefly concerned with those compounds which contain condensed octahedral $M_6$-groups, and concludes with compounds containing some further types of condensed clusters. Of course, only a certain proportion of the compounds with condensed clusters can be discussed.

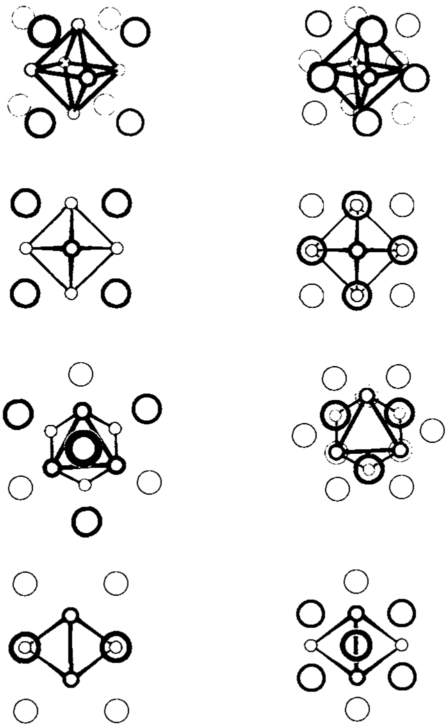

Fig. 3. $M_6X_8$ and $M_6X_{12}$ clusters shown three-dimensionally and as projections along the 4-, 3- and 2-fold axes.

The $M_6X_8$ and $M_6X_{12}$ clusters are shown three-dimensionally and in various projections in Figure 3, to explain the graphical representations which are used in a standardized way in this work. When such clusters are condensed, not only M atoms but also X atoms are shared by adjacent clusters. Positions which are occupied by X atoms in the isolated cluster can often, for steric reasons, no longer be occupied in the condensed cluster system[*]. Up to now, relatively few examples of condensed systems of $M_6X_{12}$ clusters are known. On the other hand, many structures exist in which $M_6X_8$ clusters (or fragments of these clusters) are present.

### 3.1. Vertex-Linked $M_6$ Clusters

The condensation of $M_6X_8$ clusters *via* opposite M atoms leads to a *one-dimensional* column with the composition $M_4M_{2/2}M_{8/2} = M_5X_4$ (Fig. 4a). A large number of transition metal compounds exist, which contain infinite one-dimensional structural elements of this type. The $Ti_5Te_4$-type structure[64] consists entirely of such columns arranged parallel to each other (Fig. 5a)[**]. This interpretation of the structure has already been mentioned[65,66]. On looking at further compounds of the same structural type, such as $V_5Sb_4$[67], $V_5S_4$[68], $V_5Se_4$[69], $Nb_5Sb_4$[70], $Ta_5Sb_4$[71], $Nb_5Se_4$[54], $Nb_5Te_4$[54] and $Mo_5As_4$[72], one is struck by the wide range of the values $2.4 \leq VEC \leq 3.6$. It may be concluded that the VEC is less important for the existence of this structure than the observance of certain size ratios between the atoms X and M, which have the same repeat distance along the c-direction. Band structure calculations show, however[73], that the stability is maximized at the values VEC = 2.6 and 3.4. The agreement with the experimental findings shows that the VEC also influences the choice of structure type.

In $Ti_5Te_4$, the chains are ordered in such a way relative to each other that the X atoms of one chain are close to the M atoms of a neighbouring chain. The marked compression of the M octahedra in the c-direction is certainly caused by additional bonding between the chains; in $Ti_5Te_4$, 8 octahedral edges are 284 pm long, while the 4 edges which form the base in the ac-plane, are 322 pm, and thus even longer than the Ti—Ti distances between neighbouring chains (294 pm). The other examples of this type exhibit the same geometrical details.

The structure of $Ti_5Te_4$ contains voids formed by the X atoms between neighbouring chains (Fig. 5a). By filling these voids, interesting structural variants result. In the simplest case the composition $M_5X_4 \cdot M \triangleq M_3X_2$ is obtained. Figure 5b shows the projection of the structure of $V_3As_2$, which corresponds to a "filled" $M_5X_4$-type. This relationship has already been established in the first discussion of the structure[74]. The function of the additional metal atoms in the structure is obviously to complete the (preferred trigonal prismatic) coordination of all X atoms by M atoms. Certainly, the tetragonal distortion of the M-octahedra remains, but the M—M distances in the octahedral bases are smaller or almost as long as the distances between the M atoms of neighbouring chains. The "expansion" of the $Ti_5Te_4$ structure discussed for $V_3As_2$ is continued with different stoichiometries. In this way, the atomic arrangement in $Nb_7P_4$ (*cf.* Fig. 5c)[75] is easily constructed from the $Ti_5Te_4$ structure by double occupation of the anionic voids according to $M_5X_4 \cdot M_2$. The additional M atoms again lead to the formation of trigonal prismatic coordination of the metal by the X atoms. Besides this, the intermediate M atoms arrange themselves in a very special way. This aspect will be treated in more detail in Section 3.4.3. A particularly striking form of an expanded $Ti_5Te_4$ structure is found in the compound $Nb_5Cu_4Si_4$[76]. As shown in Figure 5d, 4 M′ atoms (Cu) per formula unit occupy the spaces between the chains. Despite the resulting increase in volume, atomic distances can be found which are directly comparable with those in the basic $Ti_5Te_4$ structure; the octahedra in the $Nb_5Si_4$ chains are compressed, the Nb—Nb distances being 299 pm (vertex-base) and 338 pm (base). The Nb—Nb distances in the octahedron base are again slightly longer than those between neighbouring columns.

The fact that no binary compounds of the $Ti_5Te_4$-type exist with the elements of the 4th main group indicates that the VEC of the transition metal atoms is too small in such compounds; the role of the Cu atoms as electron donors in $Nb_5Cu_4Si_4$ becomes evident. This fact establishes a relationship with the intercalated cluster compounds $Mo_6X_8Cu_y$, in

---

[*] Although the X coordination is incomplete in this case, the use of the terms $M_6X_8$ and $M_6X_{12}$ cluster will be continued as long as the X atoms lie above the (remaining) faces and edges respectively.

[**] Except where otherwise noted, the following applies to the structural projections shown. The unit cell is indicated by broken lines; the shortest axis is the projection direction and the cluster atoms shown with differing line thickness lie at the heights 0 and 1/2. The lattice directions have not been entered in the drawing; the assignment is easy to make with the help of the collected crystal data at the end of the work (Table 3). From Figure 4 onwards, all drawings were made with the atomic parameters given in the references to Table 3 using the computer centre of the Max Planck Institutes in Stuttgart (ORTEP program), and completed with connecting lines to clarify the structural principles.

In preparing the graphical representations, I have deliberately avoided showing only those regions of the structure which can be described in terms of condensed clusters. The reproduction of the whole crystal structure is intended to put the reader in a position to follow the statements made in the text.

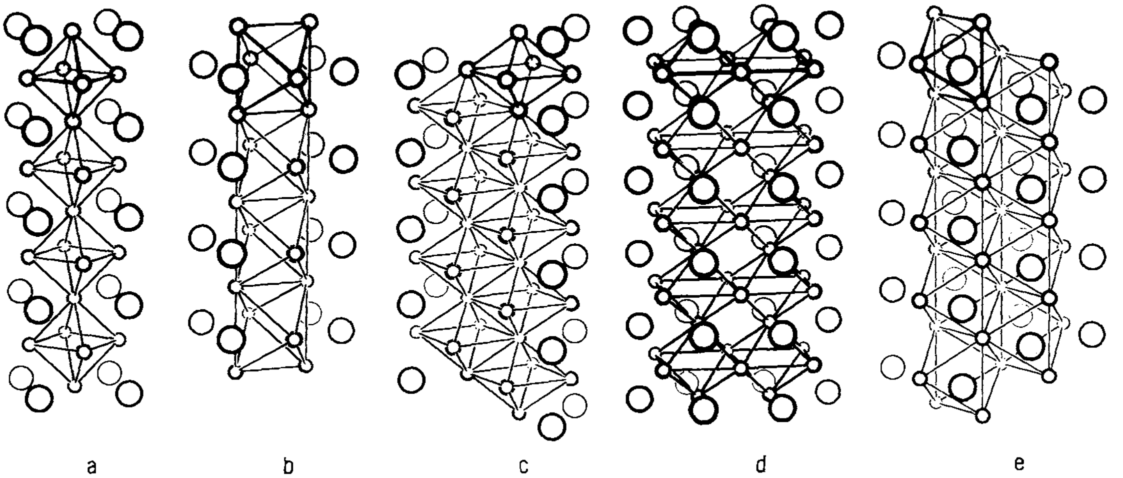

Fig. 4. Three-dimensional representations of the structural units present in compounds with condensed $M_6X_8$ clusters. (a) *trans* vertex-linked chain in $Ti_5TE_4$; (b) *trans* edge-linked chain in $Gd_2Cl_3$; (c) *cis* edge-linked chain or double chain of two edge-linked $M_5X_4$ units in $Nb_2Se$; (d) double chain of edge-linked $M_5X_4$ units in $Ti_2S$ ($Ta_2P$); (e) double chain of edge-linked $M_6X_8$ clusters in $Sc_7Cl_{10}$.

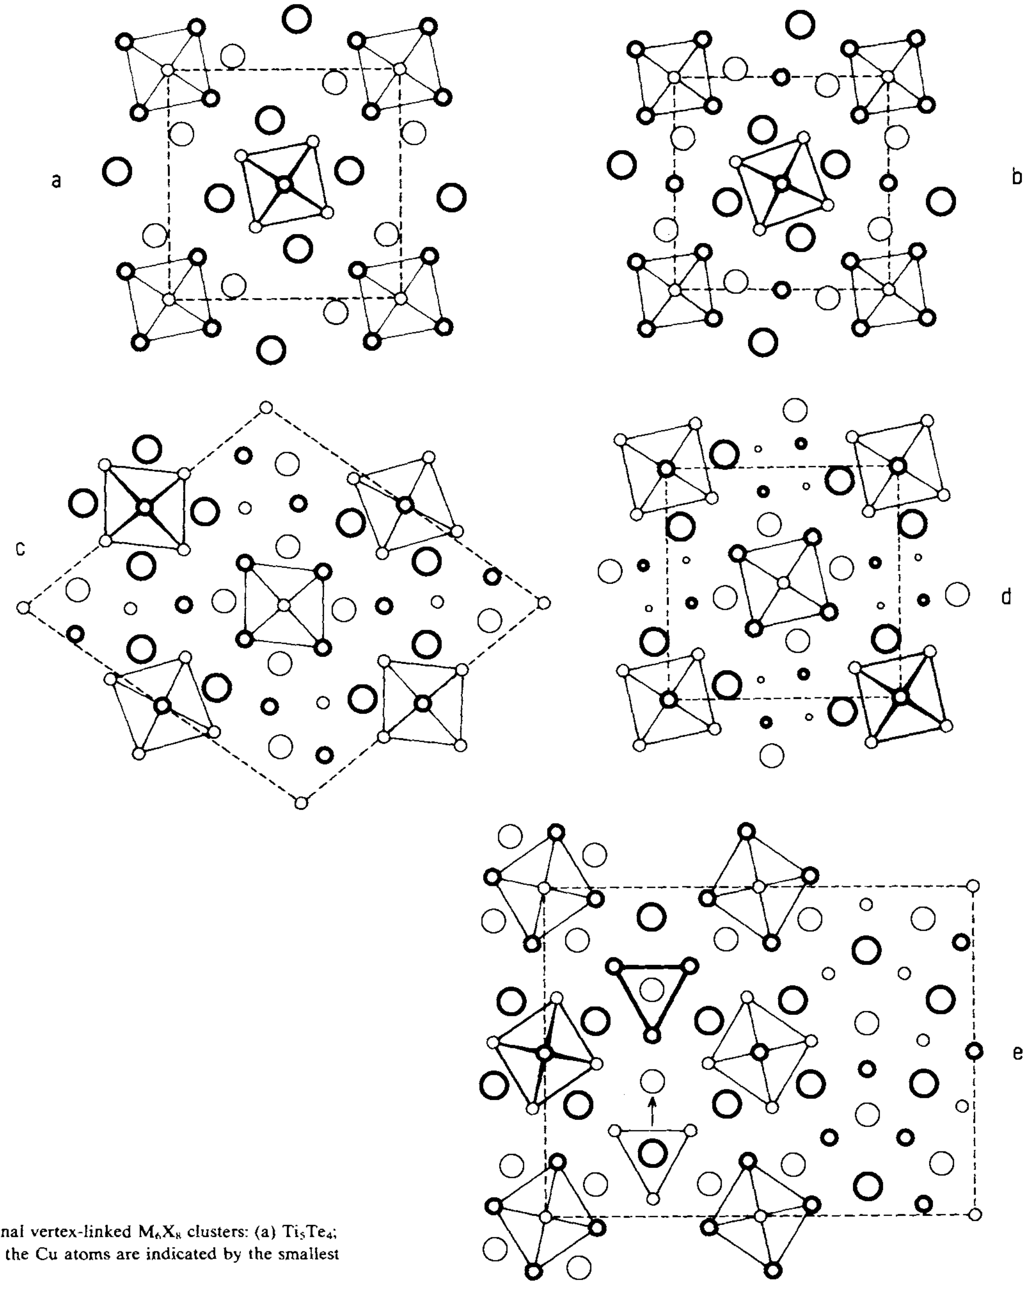

Fig. 5. Structures with one-dimensional vertex-linked $M_6X_8$ clusters: (a) $Ti_5Te_4$; (b) $V_3As$; (c) $Nb_7P_4$; (d) $Nb_5Cu_4Si_4$, the Cu atoms are indicated by the smallest circles; (e) $Nb_4As_3$.

which such electron transfer has been proved in detailed studies[77-79]. From these considerations a series of questions arises, which appear worthy of experimental investigation. Is it possible to stabilize $Ti_5Te_4$ variants by intercalation, *e.g.* $Ti_5As_4Cu_4$, $Ti_5Si_4Zn_4$? Are there phase widths in the sense of optimum VEC values? The existence of the recently discovered[80] compounds $Ta_5Ni_4P_4$ and $Nb_5Ni_4P_4$ points to an influence of the relative atomic sizes.

From the point if view of an "expansion" of the $Ti_5Te_4$ structure, only those compounds which have additional M atoms inserted, have been treated up to now. These compounds may be contrasted with others in which X atoms, as well as M atoms, have been introduced into the host lattice. A particularly interesting case of this type is given by the structure of $Nb_4As_3$[81] (cf. Fig. 5e), which is also adopted in the low-temperature form of $V_4As_3$[82] (α-form). The spaces between the $M_5As_4$ chains are occupied by $M_3$-groups, whose atoms contribute to the trigonal prismatic coordination of the As atoms around the chains, and in a similar way surround the As atoms which lie above the center of gravity of the $M_3$-groups. The coordination of the other As atom (indicated by an arrow in the drawing) is, however, very unusual, but can be understood by comparing Figures 2b and 5e. This As atom contributes to a coordination of the $Nb_3$ group as it is found in $Nb_3Se_4$. Thus, the characteristic structural elements of $Nb_5Se_4$ and $Nb_3Se_4$ alternate in a systematic way in the compound $Nb_4As_3$. The agreement holds right down to the details; in $Nb_4As_3$ the $Nb_3$ group is also considerably expanded. Further structural correlations of this type of chemically motivated "chemical intergrowth" will be treated in Section 3.4.3.

Starting from the $M_5X_4$ column as the simplest (infinitely extended) unit of vertex-linked $M_6X_8$ clusters, more complicated condensed structures can be built up by further condensing such columns. The condensation of $M_5X_4$ chains can be continued exclusively *via* further vertex-links or also include edge-linkage. The former case will be treated first.

Linkage *via* opposite vertices (as in the $M_5X_4$ chain itself) represents the simplest way of continuing the condensation, and leads to an assemblage whose composition is described by the general formula $M_{4n+1}X_{2n+2}$, where $n$ is the number of interconnected $M_5X_4$ chains. Intermediate members of this series are apparently unknown. The limiting case with an infinity of $M_5X_4$ chains is formed in the *two-dimensional* assemblage of the $Ti_2Bi$ structure[83], which is shown as a projection along the layers in Figure 6a. It is notable that the ordering of the $Ti_2Bi$ layers to each other, with regard to the M—M and M—X contacts, follows identical packing principles as in $Mo_6Se_8$ (for isolated clusters) and $Ti_5Te_4$ (for cluster-chains). The condensation of the $Ti_2Bi$ layers *via* the still unlinked *(trans)* octahedral vertices leads finally to a *three-dimensional* structure of linked $M_6X_8$-clusters, which is described by the formula $M_{6/2}X_{8/8} = M_3X$. An example within the range of elements chosen here is given by the structure of $U_3Si$ (Fig. 6b)[84,85], which has a tetragonally-distorted $Cu_3Au$ structure. The linkage of the $M_6X_8$ clusters *via* vertices in all three dimensions thus leads to a structure, which is observed in hundreds of intermetallic phases. This result is hardly surprising, since if X = M, the $M_6X_8$ cluster represents the unit cell of the cubic face-centered lattice. In the $Cu_3Au$-type structure the consequences of directed M—M or M—X bonds as well as the tendency to form a close-packed arrangement of atoms, when directed bonds are absent, must be borne in mind. It may be supposed that the specific distortions in representatives of the $Cu_3Au$ family give an indication of some specific type of chemical bonding[86]. In $U_3Si$, the Si atoms have an unusual coordination. The rotation of the columns relative to each other, as displayed by the structure of $U_3Si_2$ (Fig. 6c)[84], allows the Si atoms to have a trigonal prismatic coordination, and is in fact a type of coordination which is specially favored (*cf.* $V_3As_2$).

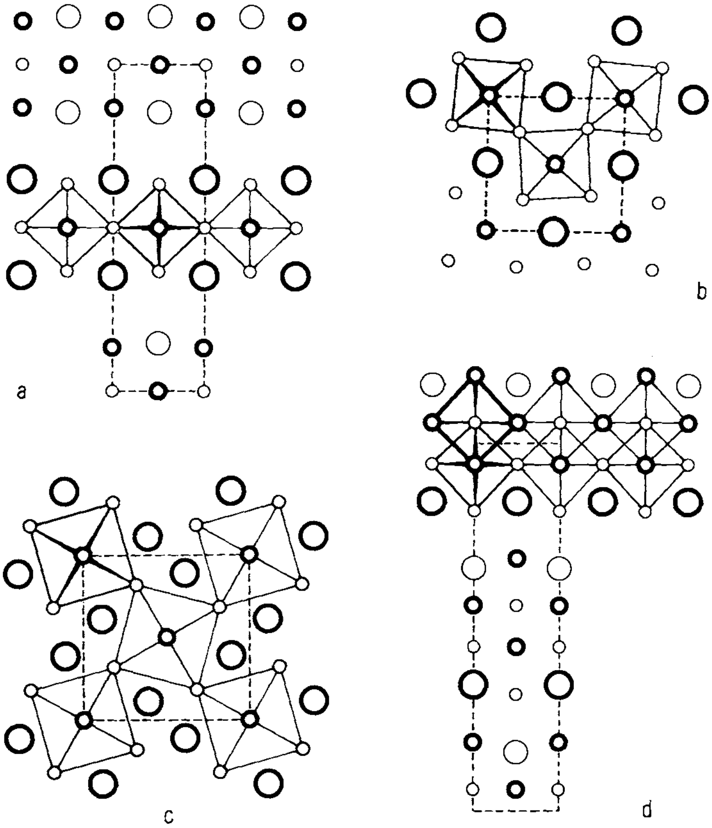

Fig. 6. Structures with two- and one-dimensional vertex-linked $M_6X_8$ clusters: (a) $Ti_2Bi$; (b) $U_3Si$, cell content shown up to z = 1/2, atomic positions z = 0 and 0.25; (c) $U_3Si_2$; (d) combined vertex- and edge-linkage in the structure of $Mn_3As$.

Compounds with condensed $M_6X_{12}$ clusters are, as mentioned in Section 3 comparatively rare, although NbO was recognized as such some time ago[1]. NbO crystallizes in a NaCl-type structure with ordered vacancies in the Nb and O sublattices. The specific order is understood in terms of a close packing of O-bridged "spherical" $Nb_6O_{12}$ clusters. The

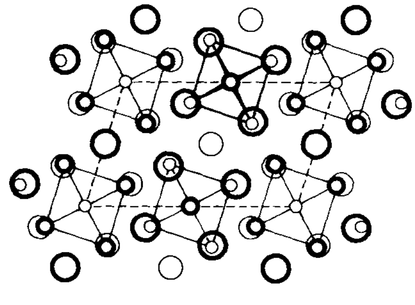

Fig. 7. Interpretation of the ordering of vacancies in the structure of TiO with the presence of *trans* vertex-linked $M_6X_{12}$ clusters (*cf.* Fig. 3, Table 3).

unusual thing about this point of view is that "spheres" and "vacancies" are geometrically identical in this packing; the compound can be described with the formula $Nb_{6/2}O_{12/4}$[1]. Both NbO and $U_3Si$ are, in principle, based on the same framework of three-dimensionally vertex-linked $M_6$ octahedra, which are edge-centered by X atoms ($M_6X_{12}$ cluster) in NbO, while in $U_3Si$ they are face-centered ($M_6X_8$ cluster).

Even under high pressure one observes practically no change in the concentration of vacancies or in their arrangement in NbO[87]; the clusters are very stable. Many other oxides, nitrides and carbides of transition metals with the composition MX, crystallize in NaCl defect-structures, without any recognizable ordering of the defects as in NbO. It may be supposed that an ordering of the defects in these high-melting compounds often does not take place for kinetic reasons. In this respect the structural studies on TiO are important. The homogeneous phase ranging from $TiO_{0.9}$ (O-vacancies) to $TiO_{1.25}$ (Ti vacancies) crystallizes in the NaCl structure. An ordering of both types of defects takes place for the composition TiO below 990 °C, forming the structure shown in Figure 7[88]. The analysis reveals chains of *trans* vertex-linked $Ti_6$ octahedra which are surrounded by O atoms in the same way as in the $M_6X_{12}$ cluster. An isolated chain of this sort (analogous to $M_5X_4$) has the composition $M_{2/2}M_4X_{8/2}X_4 = M_5X_8$. In the ordered TiO structure such chains are linked in a complicated way *via* shared O atoms; the composition can be described by the formula $Ti_{2/2}Ti_4O_{6/3}O_{6/2}$. The alteration of the linkage pattern leads to different compositions. It is possible that the homogeneous "TiO" phase splits into single phases with slightly different compositions upon ordering the defects, as found for the principally comparable oxide block structures[89].

Figure 6d shows the combination of vertice- and edge-coupling in the structure of $Mn_3As$ (see Section 3.2.1).

### 3.2. Edge-Linked $M_6$ Clusters

Edge-linkage differs from vertex-linkage in that not all the X positions around the $M_6$ cluster can be occupied. The missing X positions are partly occupied by M atoms of the neighboring cluster.

#### 3.2.1. Edge-Linked $M_5X_4$ Chains

There are two possible ways of connecting two $M_5X_4$ chains *via* edges: a) Each $M_6$ octahedron has one shared edge with a neighbouring octahedron. b) Each $M_6$ octahedron shares two *(cis)* edges with neighbouring octahedra. Case a) leads to an infinitely extended unit with the composition $M_{4/2}M_2X_{6/2} = M_4X_3$, case b) results in a unit with the composition $M_{3/3}M_3X_{4/2} \triangleq M_2X$. Both types of structural unit occur in a series of compounds. As an example for a), the structure of $Ta_2P$ is reproduced in Figure 8a[90]; the compounds $Ta_2As$[91], $Ti_2S$[92], $Ti_2Se$, $Zr_2S$, $Zr_2Se$[93], $Hf_2P$ and $Hf_2As$[94] are isostructural. The $M_4X_3$ chains run parallel; the regions between them are occupied by additional M atoms. The structure is directly comparable to that of $Nb_5Cu_4Si_4$, in so far as the single chains $M_5X_4$ (in the latter compound) are replaced by double chains. The structure of $Ti_2S$ ($Ta_2P$) can therefore be formulated as $M_8X_6 \cdot M_4$. This formulation raises the question of whether the M atoms which serve to complete the trigonal prismatic coordination of the X atoms could be replaced by suitable heteroatoms M′. The $M_6$ octahedra in the $Ta_2P$ structure type are strongly distorted, as in the $M_5X_4$ compounds; only the distances from the vertex atoms to the base atoms of the octahedra are shorter than 300 pm.

Figure 8b shows the structure of $Nb_2Se$[95], as an example of the structural unit b). This compound is at present the only known example which consists entirely of these type of *cis* edge-linked octahedral chains. In principle, the $M_6$ octahedra exhibit the same distortions as in the single chain $M_5X_4$ itself; all the distances within the octahedral base are more than 300 pm long (318 to 340 pm); the distances from base to vertex atoms are, in contrast, all short (282 to 294 pm). In particular, the edges shared by two octahedra are 286 pm long. The fact has already been mentioned that, because of the edge-linkage of the $M_6$ octahedra, the X-coordination remains incomplete, or is partly replaced by M atoms. This is quite evident in the $Nb_2Se$ structure; externally the $M_6$ octahedra are coordinated in the "normal" way by Se atoms at distances of 262 to 280 pm, while inside the chain the remaining X positions are occupied by M atoms at a distance of 290 pm. Short M—M distances are also found between adjacent double chains (297 to 311 pm). Besides regions of direct M—M contact between adjacent double chains, there are others which are only marked by van der Waals contacts between Se atoms. It should be possible to fill the resulting spaces with additional M atoms, as in the $Ti_5Te_4$ structure, which then leads to trigonal prismatic coordination of the Se atoms. In this context, the interesting question may be raised of whether the double chain could also be obtained with other elements (*e.g.* $Nb_8P_4 \cdot M_4$ by analogy with $Nb_5Si_4Cu_4$).

Apart from the short M—M distances between the double chains in $Nb_2Se$, the structural units are present in an unconnected form. The structure of $Mn_3As$[96] represents a particularly impressive example of vertex-linkage between units of this sort (Fig. 6d). With respect to the double chain, the structure forms the two-dimensional infinite case of (one kind of) *trans* vertex-linkage of these units. A similar approach applied to the simple $M_5X_4$ chain leads to the $Ti_2Bi$ structure (Fig. 6a, *cf.* Section 3.1). The structure of $Mn_3As$ can therefore also be discussed as the first step in the condensation of the simple octahedron layers in $Ti_2Bi$ *via cis* edges, which finally leads to the three-dimensional atomic arrangement of a cubic metal lattice.

Four possible ways of linking three $M_5X_4$ chains together *via* edges emerge. The linkage type a) for two chains ($Ta_2P$) can be extended linearly or at an angle of 90° and yields, if all X positions are filled, structural units with the compositions $M_{11}X_8$ and $M_{11}X_7$, respectively. The construction principle a) can, however, be combined with b) in two possible ways and then leads to chains with the compositions $M_{11}X_6$ and $M_2X$. The metal-rich niobium sulphide $Nb_{14}S_5$[97], whose structure is projected in Figure 8c, is an example of the last case. As indicated by the connecting lines, the network of condensed clusters contains not only the double chain with partially substituted X coordination known from the $Nb_2Se$ structure, but also the unit formed from three $M_5X_4$ chains. The units are linked to each other by vertex atoms with further M atoms occupying the spaces between the triple chains.

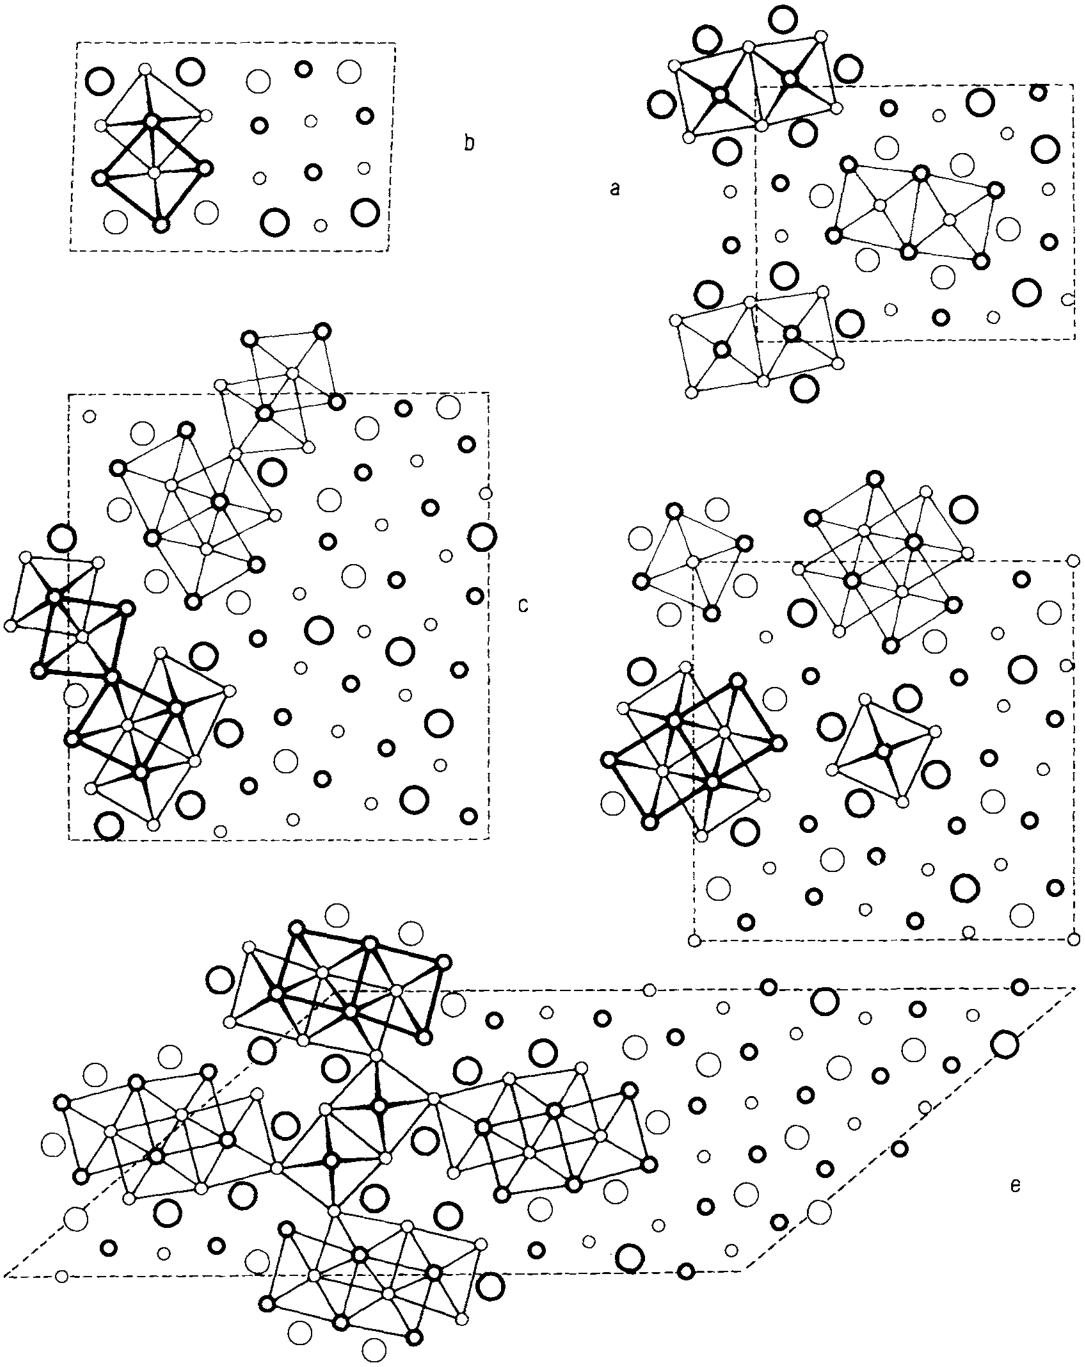

Fig. 8. Structures with edge-linked $M_5X_4$ chains: a) double chains in $Ti_2S$ ($Ta_2P$ type); b) double chains in $Nb_2Se$; c) triple chains in the structure of $Nb_{14}S_5$, linked with double chains as occurring in $Nb_2Se$; d) quadruple chains in $Nb_{21}S_8$ together with single $M_5X_4$ chains; e) quadruple chains in $Ti_8S_3$, linked to double chains in the manner of $Ti_2S$ (half the cell drawn up to $x = 1/2$).

The structure of $Nb_{21}S_8$[98] appears at first sight to be extraordinarily complicated, but from the point of view of condensed $M_6X_8$ clusters, it can be reduced to a simple pattern. It is obvious from Figure 8d that the compound consists of two kinds of building block, which are not mutually connected. On the one hand, $M_5X_4$ isolated chains occur, and on the other, units built up from four $M_5X_4$ chains which have the composition $M_{12/2}M_6X_{4/2}X_2 = M_{12}X_4 \hat{=} (M_3X)$. Additional M atoms fill the voids between these structural elements, and contribute once again to the trigonal prismatic coordination of all the S atoms. According to the structure, therefore, $Nb_{21}S_8$ can be described as $Nb_5S_4 \cdot Nb_{12}S_4 \cdot Nb_4$. The same construction principle is found in $Zr_{21}S_8$[99]. It is interesting that the octahedra in the $Nb_5S_4$ chain are considerably distorted, as they are in the compounds with the $Ti_5Te_4$ structure. The bond lengths within the quadruple chain are in accordance with expectation; the vertex-base distances in the octahedra are among the shortest in the structure (282 to 294 pm), while some of the atoms in the base are further apart (320 pm and more) from one another than they are from Nb atoms which do not belong to the same unit.

A variation of the unit formed from four $M_5X_4$ chains occurs in the structure of $Ti_8S_3$[100], which is shown in Figure 8e. The units containing two $M_5X_4$ chains are the same as in $Ta_2P$ (and $Ti_2S$). These are linked *via* vertices to form aggregates of four $M_5X_4$ chains, which are the condensation product of two double chains. Both kinds of double chain, a) and b), are contained in the quadruple chain. The same is true for the fourfold chain in $Nb_{21}S_8$.

Considering the many possible ways of varying both the number of chains which are condensed to form a unit, and the way in which different types of unit can be combined, the few known examples of compounds containing edge-linked $M_5X_4$ chains seem to be like the tip of an iceberg. Further studies are urgently needed to extend the classification scheme of this highly interesting class of compounds.

The condensed cluster concept reaches the field of intermetallic phases again with the structure of $Nb_{21}S_8$. The fourfold octahedron chains in the $U_6M$ structure (M = Ni, Co, Fe, Mn)[101] are the same as those which form the core of the $Nb_{12}S_4$ chains in $Nb_{21}S_8$. Curiously, the limit of the concept is also reached with sulphides. The structures of the compounds $Ta_6S$[102], $Ta_2S$[103] and $Zr_9S_2$[104] cannot yet be explained in terms of the known isolated clusters of these transition metals, but chains of interpenetrating metal icosahedra are present in the structures of these compounds. This amounts to a quasi one-dimensional variant of the Frank-Kasper principle[56], which has been realized in many intermetallic compounds.

### 3.2.2. *Trans* Edge-Linked $M_6$ Clusters

The attempt has been made in the previous sections to collect a fairly large number of known compounds and discuss them within the concept of condensed clusters. This approach has shown itself to be a useful aid to memory in treating a series of complicated structures as well as a scheme of classification for the structures of metal-rich transition metal compounds. The concept, however, also represents a useful starting point for opening up new groups of substances, as shown in the following, with the newly discovered metal-rich halides of Sc, Y and the lanthanoids. These metals occur in solid state compounds predominantly with the oxidation state +3; salt like dihalides are known, in particular for Eu and Yb where they have been understood for a long time on the basis of the particular stability of the $4f^7$ and $4f^{14}$ configurations[105], but also for Nd, Sm, Dy and Tm[106]. Oxidation states below +2 were however unknown until recently, although the existence of the metallic diiodides of La, Ce, Pr, Gd already demonstrated a way of obtaining low (formal) oxidation states; $Ln^{3+}$ ions are present, and the surplus valence electrons establish M—M bonds according to the formula $Ln^{3+}(I^-)_2e^-$[106]. In the metallic conducting $LaI_2$, all the La—La distances between neighbouring atoms are the same. In the case of $PrI_2$ (modification V), on the other hand, the M—M bonding produces discrete tetrahedral $M_4$ clusters[107], as have been recognized for some time in MoSBr[108].

$Gd_2Cl_3$ was the first lanthanoid compound to have an oxidation number less than +2. The structure[110-112] contains parallel chains of *trans* edge-linked $Gd_6$ octahedra, which on including the surrounding halogen atoms can be discussed in terms of condensed $M_6X_8$ clusters[20,21]. This structural principle, characteristic for such a wide variety of compounds of the d-metals, suggested the existence of a similar variety of reduced Ln halides. Investigations have led to the presently known compounds, summarized in Table 1; structurally, they correspond to the metal-rich halides of Sc and Y which have been discovered simultaneously. These results confirm the correctness of the original idea, which was based on the structure of $Gd_2Cl_3$ alone; a) all halides with $X/M \leq 1.6$ contain characteristic structural elements consisting of chains of *trans* edge-sharing $M_6$ octahedra, which are surrounded by halogen atoms centered over the edges of the octahedra faces as in the $M_6X_{12}$ or $M_6X_8$ cluster. The chains may be isolated or condensed with others. b) On the one hand, the compounds $NaMo_4O_6$[113] and $KMo_4O_6$[114] also contain chains of *trans* edge-linked $Mo_6O_{12}$ clusters; the cations $Na^+$ or $K^+$ are situated between the units formulated as $Mo_2Mo_{4/2}O_2O_{8/2}$ (*cf.* Fig. 9a). These compounds form a link from Sc, Y, and the lanthanoids, to the element Mo, whose structural chemistry is particularly strongly characterized by the presence of discrete octahedral clusters. c) On the other hand, compounds have also been isolated in the meantime which contain discrete $M_6X_{12}$ clusters of Sc and the lanthanides, which are the starting units of condensed systems. The structures of these compounds have also been discussed and reviewed elsewhere[115-117] in terms of condensed clusters.

The metals Sc, Y and the lanthanoids are distinguished by a particularly low VEC compared to the transition metals which have been treated up to now. Their distinct tendency to form M—M bonds is therefore all the more surprising. The "expansion" of the cluster structures by additional M atoms, which has already been discussed in detail, assumes special significance here due to their electron donor function. If one assumes that these M atoms are present as $M^{3+}$ ions in the anionic vacancies of the structures, the VEC in the cluster regions is raised correspondingly. The VEC values given in brackets in Table 1 have been calculated using this assumption. While the X/M ratio correlated only approximately with the degree of cluster condensation, the regions of M—M bonding become step by step larger as the VEC values increase—starting from the isolated cluster and proceeding *via* one-dimensional structures up to the two-dimensional layer structure. In complete contrast to the transition metal compounds with isolated $M_6X_8$ and $M_6X_{12}$ clusters, one finds that there is no particular preference for one or the other cluster type in the condensed structures because of the VEC.

The compounds with the formula $M_7X_{12}$, whose structural principle was first clarified for $Sc_7Cl_{12}$[38] and which in the meantime has been found in a series of Ln iodides, essentially play the role of a "missing link". The structure contains isolated $M_6X_{12}$ clusters, which are ordered according to a close-packing of "spheres" as in $Zr_6I_{12}$. Further M atoms occupy some of the octahedral voids formed by X atoms. The VEC is already extraordinarily low for $Zr_6I_{12}$ (12 electrons per cluster instead of 16); for the hypothetical $Sc_6I_{12}$ it would have the value 6. The gain of 3 additional electrons *per* cluster by inserting M atoms leads to a VEC identical to that found in the compound $Zr_6Cl_{15}$[38]. All representatives of the composition $M_7X_{12}$ contain considerable defects, so that to date only the principle of the structure is certain[119,120].

Chains of *trans* edge-linked octahedra form at the same value of VEC = 1.5, but with a lower X/M ratio. Figure 9b shows the projection of the structure of $Gd_2Cl_3$, which is found in the chlorides and bromides of yttrium, as well as a series of rare earth metals. The halogen atoms are centered

Table 1. Structurally characterized halides $MX_n$, with $n < 2$, of the metals Sc, Y and the lanthanoids; references in parentheses; further explanations *cf.* text.

| VEC | Formula | Cluster type | Linkage principle | X/M | Compounds |
|---|---|---|---|---|---|
| (1.50) | $M_6X_{12} \cdot M$ | $M_6X_{12}$ | discrete | 1.71 | $Sc_7Cl_{12}$ [38], $La_7I_{12}$, $Ce_7I_{12}$, $Pr_7I_{12}$, $Gd_7I_{12}$, $Tb_7I_{12}$, $Er_7I_{12}$, $Lu_7I_{12}$ [119, 120] |
| 1.50 | $M_2X_3$ | $M_6X_8$ | single chain | 1.50 | $Y_2Cl_3$, $Y_2Br_3$ [118, 122], $Gd_2Cl_3$ [110—112], $Gd_2Br_3$, $Tb_2Cl_3$, $Tb_2Br_3$, $Er_2Cl_3$, $Tm_2Cl_3$, $Lu_2Cl_3$ [121] |
| 1.50 | $(M_2X_3)$ | $(M_6X_{12})$ | single chain | 1.50 | $[Tb_2^{II}Br_3]$ [121] |

| 1.75 | $M_4X_5$ | $M_6X_{12}$ | single chain | 1.25 | $Er_4I_5$ [124] |
| (1.83) | $M_6X_{10} \cdot M$ | $M_6X_{12}$ | double chain | 1.43 | $Er_7I_{10}$ [124] |
| (1.83) | $M_6X_{10} \cdot M$ | $M_6X_8$ | double chain | 1.43 | $Sc_7Cl_{10}$ [115] |
| 1.83 | $M_6X_7$ | $M_6X_{12}$ | double chain | 1.17 | $Tb_6Br_7$, $Er_6I_7$ [125] |
| 2.00 | MX<br>ZrCl-Typ<br>[128, 129] | $M_6X_8$ | layers | 1.00 | YBr [122], LaBr, PrBr, GdBr, TbBr, HoBr, ErBr [127], CeBr, NdBr, DyBr, HoCl, ErCl, LuBr [121], t-GdCl, t-TbCl [21, 127] |
| | ZrBr-Typ [130] | | | | ScCl [126], YCl [122], LaCl, CeCl, PrCl [121], h-GdCl, h-TbCl [127] |

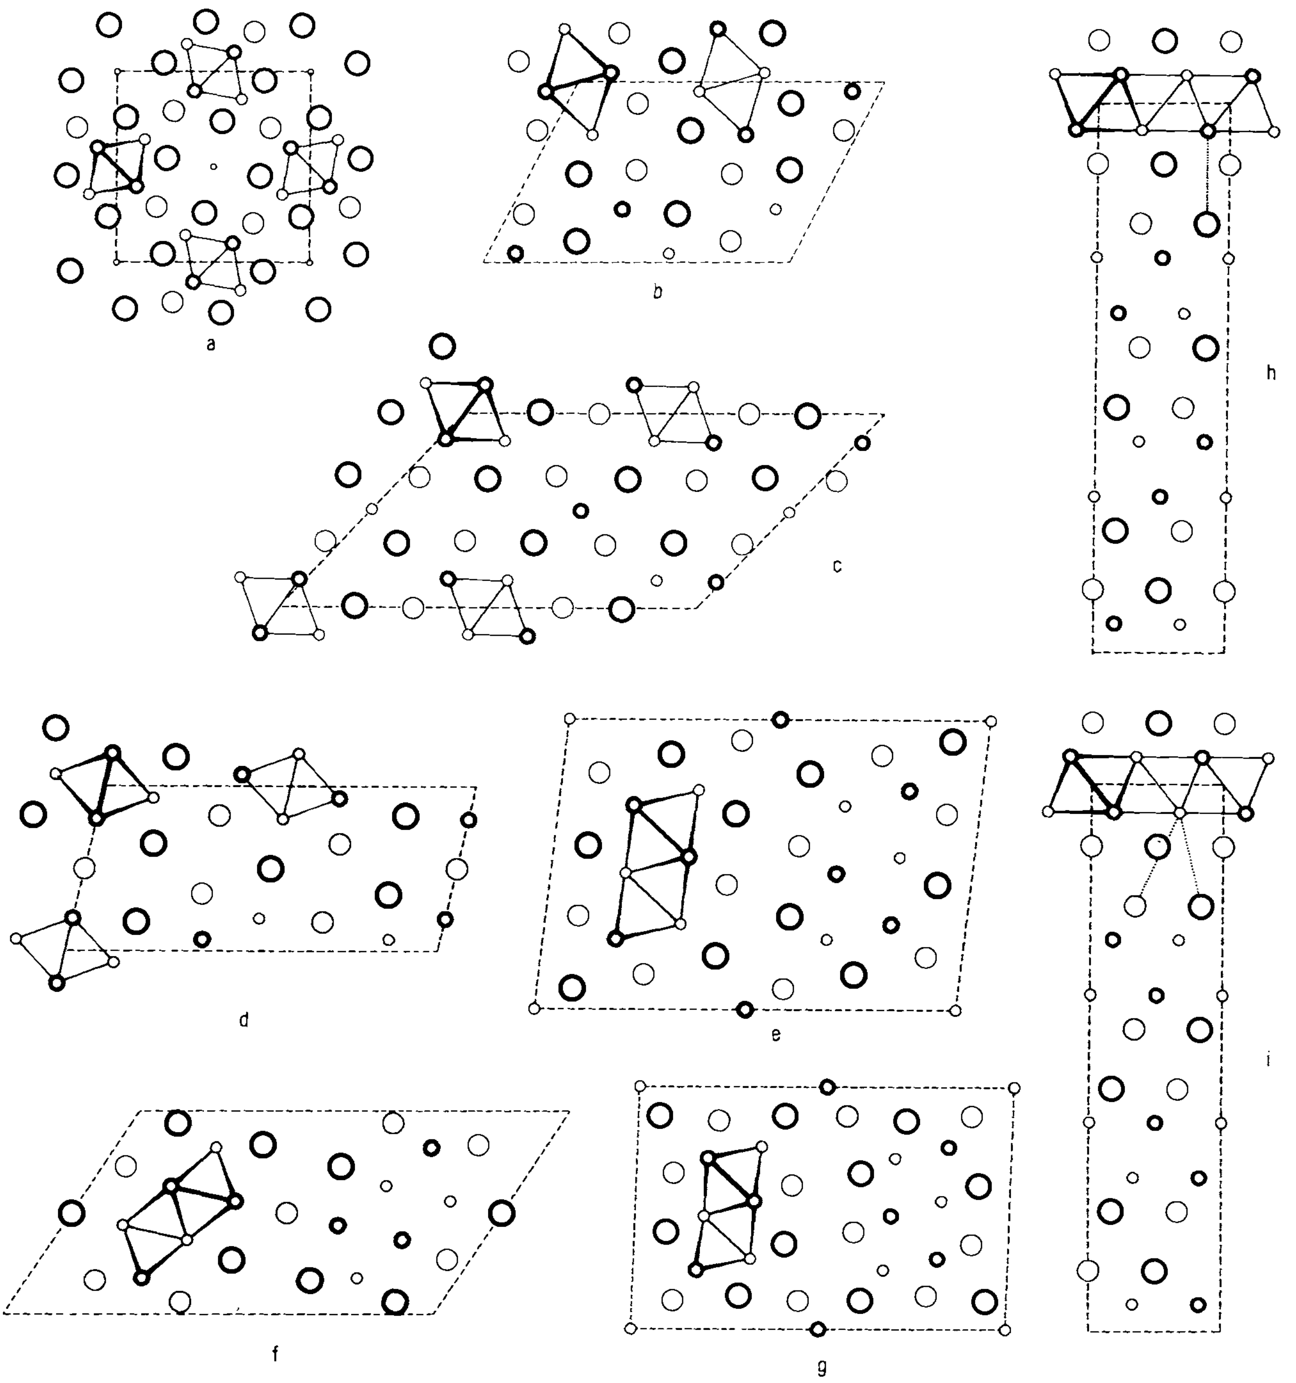

Fig. 9. *Trans* edge-linked chains of $M_6X_8$ and $M_6X_{12}$ clusters and structures derived from them (Table 1): a) chains of $M_6X_{12}$ clusters in $NaMo_4O_6$ (smallest circles correspond to Na positions); b) chains of $M_6X_8$ clusters in $Gd_2Cl_3$; c) chains of $M_6M_{12}$ clusters in $Tb_5Br_8$ and d) $Er_4I_5$; e) double chains of $M_6X_{12}$ clusters in $Er_7I_6$ and f) $Er_7I_{10}$; g) double chains of $M_6X_8$ clusters in $Sc_7Cl_{10}$; h) layers of linked $M_6X_8$ clusters in *h*-TbCl (ZrBr) and i) *t*-TbCl (ZrCe).

over the octahedral faces; however, only the outer faces are coordinated by X atoms, while the X atoms above the inner faces (between adjacent octahedra) are replaced by the M atoms of the next octahedron. Further X atoms lie approximately above the octahedral vertices. The composition is correspondingly $M_2M_{4/2}X_4X_2$. The M—M distances in the octahedron differ widely. Because of this, the bridging edges in $Gd_2Cl_3$ are, at 337 pm, shorter than the M—M bond lengths in the metal itself, while the distances in the chain direction are 389 pm. According to the Pauling relationship[59] $d_n = d_1 - 60\lg n$, the short distances correspond to single bonds, whereas the long distances indicate a bond order $n \approx 0.1$. These direct or indirect interactions are apparently also of critical importance to the entire structure (cf. Section 2).

Measurements made on the easily accessible compounds $Gd_2Cl_3$ and $Tb_2Cl_3$ allow first conclusions to be drawn about the character of the M—M bonding. Both are semi-conductors[131] in agreement with the results of a band structure calculation[132] and the findings of photoelectron spectroscopy[133]. Both the magnetic behaviour[134] and $^{155}$Gd-Mössbauer spectra[135] of $Gd_2Cl_3$ indicate the presence of a $4f^7$ core, as expected for $Gd^{3+}$. The additional 1.5e/Gd have (s,p)d-character. The lanthanoids behave therefore like d-metals with regard to the formation of M—M bonds in metal-rich halides.

Besides the normal form of $Tb_2Br_3$ which crystallizes in the $Gd_2Cl_3$ structure type, crystals have been obtained[121] with a structure very similar to that of $NaMo_4O_6$ (*cf.* Fig. 9a). The same framework of *trans* edge-linked $M_6X_{12}$ octahedra (composition $M_2M_{4/2}X_{8/2}X_2$) is probably present, without the large voids between the chains being filled. It is certainly a metastable form, because of the poor space-filling. But the structure of $NaMo_4O_6$ is of a "pathological" nature too, because the $Na^+$ ions possess extremely high Debye-Waller factors ($B \approx 24$ Å$^2$)[136]; $KMo_4O_6$ on the other hand behaves normally[114].

The compounds $M_5X_8$ also contain *trans* edge-linked $M_6X_{12}$ clusters (Fig. 9c). The halogen atoms which lie above the octahedral edges belong solely to one chain. Further X atoms lie exactly above the octahedral vertices. The chain structure can be described by the formula $M_2M_{4/2}X_{8/2}X_2X_2$; "expansion" by additional atoms in the octahedral sites between the X atoms yields $M_4X_8 \cdot M = M_5X_8$. The arrangement of the X atoms around the octahedron chain corresponds to that in $NaMo_4O_6$. The variation in bond length within the $M_6$ octahedra is nearly the same as in $Gd_2Cl_3$, with 333 pm for the shared edge, and 386 pm for the edge in the chain direction. It is interesting however, that the M—M distances of the atoms of the octahedral base to the vertex atoms in $Tb_5Br_8$ are equal within one standard deviation, while they differ significantly in $Gd_2Cl_3$ (373 and 378 pm). This difference in behavior is easily explained by the differing arrangements of X atoms around the octahedron chain, which only possess the chain symmetry in the case of $Tb_5Br_8$. This comparison gives clear evidence for the easy adaptation of the weak M—M bonds to their environment (*cf.* MX). The fact that distances between functionally very different pairs of M atoms are equal, is an important aspect of the $M_5X_8$ structure, especially when attempts to correlate atomic distances and bond orders are made. The distances between the isolated $M^{3+}$ ions are (for crystallographic reasons) just as large as the repeat distances within the cluster chain, whose (weak) bonding interaction is assumed in the concept of condensed clusters but, of course still has to be proved.

The structure of $Er_4I_5$ is, at first glance, surprising (*cf.* Fig. 9d). Despite the small ratio $X/M = 1.25$ only single chains of *trans* edge-linked octahedra are found, which are surrounded by X atoms in the manner of $M_6X_{12}$ clusters. If the VEC available for M—M bonds is taken into account, however, $Er_4I_5$ is found to be on a level with the $M_5X_8$ halides. The cluster chains, together with the entire arrangement of X atoms are, in fact, identical in the two compounds. The higher metal content in $Er_4I_5$ comes from sharing of I atoms (as $X^{i-i}$ or $X^{i-a}$)[1] between adjacent chains; $Er_4I_5 = Er_2Er_{4/2}I_{8/2}I_{2/2}$.

Further reduction of the X/M ratio to the value 1.17 leads to an increase in the degree of condensation. As shown in Figure 9e, the structure of $Er_6I_7$ contains units which are formed by the condensation of two *trans*-linked octahedron chains; the "fusion" takes place *via* two edges of each octahedron. X atoms lie above the remaining free edges as in the $M_6X_{12}$ cluster. The environment of the double chain corresponds exactly to that of the single chain, as for example in $Er_4I_5$. The agreement between the two structures is so marked that with $Er_6I_7$ some of the I atoms serve the same linking function ($I^{i-i}$ or $I^{i-a}$) as in $Er_4I_5$. The close relationship between the two structures will be discussed once more later.

The octahedra in $Er_6I_7$ (and $Tb_6Br_7$) are, as expected, considerably distorted, due to the differing environments of the individual M atoms. The shortest M—M distances are found for those edges which are shared between two octahedra (329 and 343 pm), while the distances parallel to the direction of the double chain are comparatively long (387 pm), as in the single chain. A comparison between the M—M distances in $Er_6I_7$ and $Tb_6Br_7$ leads to the same result as for $Gd_2Cl_3$ and $Gd_2Br_3$; although the matrix effect of the larger anions produces a lengthening of the M—M bonds affected, a shortening of other M—M bonds largely compensates for this, *i.e.* the average bond order in the M—M bonded part of the structure is maintained.

The compound $Er_7I_{10}$ (Fig. 9f) takes up the correct place in Table 1 regarding the degree of condensation, despite the high value of $X/M = 1.43$. As shown in the projection of the structure, double chains of condensed metal octahedra are present and besides these, single Er atoms with octahedral iodine coordination. Assuming that these are $Er^{3+}$ ions, one finds the same VEC for the M—M bonded regions as in $Er_6I_7$, and, correspondingly, the occurrence of the same structural element in both cases is not surprising. While the degree of condensation is apparently closely related to the VEC, there is no recognizable correlation between VEC and the environment around the halogen atoms. In the structure of $Er_7I_{10}$, the arrangement of the halogen atoms corresponds to that in the $M_6X_{12}$ cluster, while the double chains in the structure of the isoelectronic $Sc_7Cl_{10}$ (Fig. 9g) are surrounded as in the $M_6X_8$ cluster. The discovery that all the M—M distances in $Er_7I_{10}$ are on average *ca.* 45 pm longer than in $Er_6I_7$ has not yet however been explained.

The highest degree of condensation found up to now in the compounds of Sc, Y and the lanthanoids occurs in the layer structures of the monohalides MX. As can be seen in Figures 9h and 9i, the structure represents the final members in the series of (parallel) condensed *trans* edge-linked octahedron chains following the structure principle $M_{6/3}X_2$. The halogen atoms lie above the two remaining "free" octahedral faces *i.e.* their arrangement corresponds to that in the isolated $M_6X_8$ cluster. The remaining coordination sites of each octahedron are geometrically identical to that in the isolated cluster; six M atoms of the adjacent cluster occupy the sites which are otherwise occupied by X atoms.

As yet no evidence has been found for the existence of a form of the monohalides derived from the $M_6X_{12}$ cluster, in whose structure the halogen atoms lie above the unshared octahedral edges. Such hypothetical modifications are conceivable and appear in the final members of two series of compounds whose first members are already known; $M_5X_8$, $M_7X_{10}$ and $M_4X_5$, $M_6X_7$, respectively. These relationships are sketched in Figure 10[124]. The structure of $Er_4I_5$ shows a specific substitution of parallel rows of atoms in a cubic close-packed lattice of iodine atoms by *trans* edge-linked Er octahedra. Replacement of two adjacent rows of atoms by octahedron chains leads to the structure of $Er_6I_7$. The continuation of this structural principle, while maintaining the environment of the iodine atoms, leads to a series with the general formula $M_{2a+2}X_{2a+3}$; *a* is the number of interconnected octahedron chains. The structure of $Tb_5Br_8$ is derived in an analogous way from a hexagonal close-packed lattice of Br atoms, rows of which are substituted by *trans* edge-linked Tb octahedra in such a way that the remaining Br atoms coordinate only one octahedron chain; octahedral voids in the halogen packing are occupied by single Tb atoms. Raising the degree of condensation leads stepwise *via* the $Er_7I_{10}$ structure to hypothetical compounds with the general formula $M_{2a+3}X_{2a+6}$, whose structures, although predictable in detail

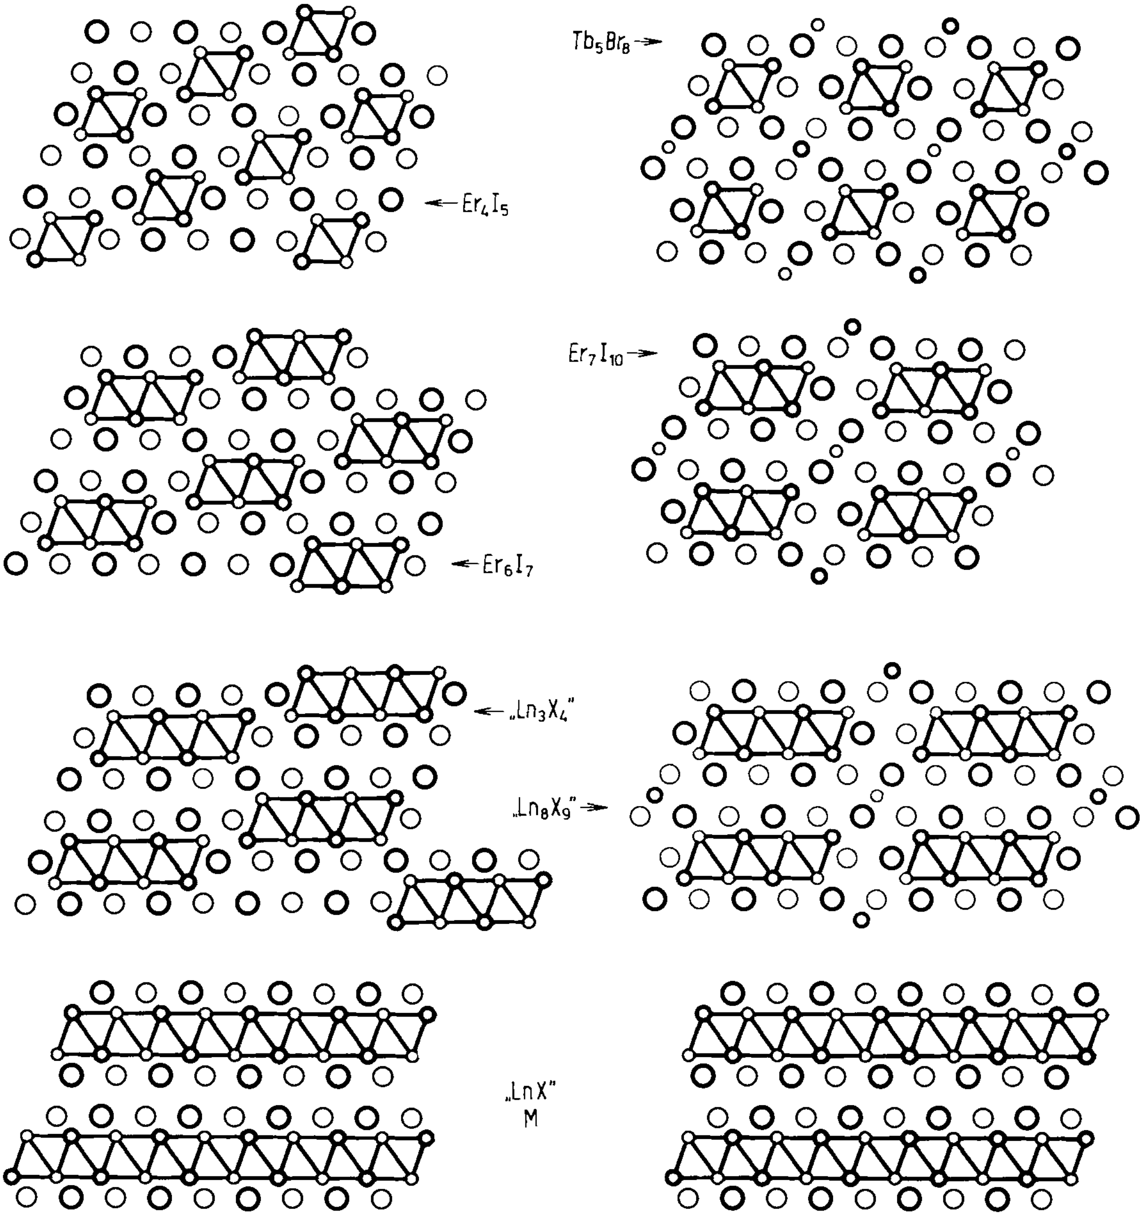

Fig. 10. Structural relationships between $Er_4I_5$, $Er_6I_7$ and $Tb_5Br_8$, $Er_7I_{10}$. The continuation of the structural principle leads to the series of compounds $M_{2a+2}X_{2a+3}$ and $M_{2a+3}X_{2a+6}$ respectively. Here "*a*" represents the number of linked octahedron chains in the structure. Hypothetical members of this series are shown in inverted commas.

have not yet been discovered. At the end of this series is, once again, a monohalide derived from the $M_6X_{12}$ cluster.

The layer structures of the monohalides of Sc, Y and the lanthanoids are closely related to a series of metal-rich compounds of the 4d and 5d metals; they are isostructural with ZrCl[129] or ZrBr[130] and, like these, they behave physically as two-dimensional metals[118]. A comparison of the bond lengths in various compounds which crystallize with these structures allows interesting conclusions to be drawn. a) As in the isolated chains of *trans* edge-linked $Ln_6$ octahedra, the shared edges are shorter (by about 7%) than the unshared edges. The Ln—Ln distances parallel to the octahedron layer become larger of course with increasing anion size (379 pm in TbCl, 384 pm in TbBr). The non-existence of corresponding monoiodides—the metals should form low oxidation states preferentially with iodine—may be attributed to the large size of the anion. The difference between the Zr—Zr distances in the structure of ZrCl is even more pronounced (about 11%). Of course, this effect can be expected because of the higher VEC, but can also be caused by the smaller interatomic distance arising from the size of the anions. b) ZrCl and ZrBr form layer structures, in which closely packed double layers of metal atoms are surrounded by halogen layers; such X—Zr—Zr—X layers are stacked in different ways[127]. The different mechanical properties of the crystals can be explained by assuming more pronounced interactions between Zr atoms and halogen atoms of the next layer but one, in ZrBr (*cf.* Fig. 9h and 9i)[130]. The M—M bond serves here as an indicator which clearly reveals the presence of such interactions; TbCl develops both stacking variants as temperature polymorphs. In the modification with ZrBr structure, in which additional interactions between Tb atoms and second-nearest Br atoms may be postulated, the distance between the Tb layers is significantly enlarged[127].

Further close relationships exist between the layer structures of the monohalides and those of other metal-rich compounds of d-metals. The MX structure represents the analogy (two-dimensional edge-linkage) to the structure of $Ti_2Bi$ (two-dimensional vertex-linkage of $M_6X_8$ clusters), which has been discussed in Section 3.1. The extension of the condensation *via* edges into three dimensions leads finally to the fcc lattice of a metal. An even more direct similarity exists between the MX structures and the structures which are formed by occupation of every second layer of octahedral sites in the close-packed metal lattice and which therefore correspond to the formula $M_2X$. Examples of this group are given by the metallic compounds; $Ti_2O$[137], $Ag_2F$[138], $Ta_2C$[139] (*anti* $CdI_2$-type) and the subcarbides $Y_2C$ and $Ln_2C$ (*anti* $CdCl_2$-type)[140, 141]. The behavior of $Y_2C$ is particularly interesting. Above 900 °C it exists with a wide range of homogeneity; the C atoms are statistically distributed in a rock salt structure. Below 900 °C it becomes ordered and the low temperature phase can be easily discussed in terms of condensed clusters. The compound thus resembles TiO (*cf.* Section 3.1, Fig. 7). The compounds listed above are formulated as $M_{6/3}X_{2/2}$ within the concept of condensed clusters, since the double layers of X atoms in the halides MX are replaced by single layers whose atoms function as bridges between neighboring layers of condensed M octahedra. It is noteworthy, in connection with the compound $Ag_2F$ mentioned above, that the isolated $Ag_6$ cluster is also known[142]. An interesting variant of the $M_2X$ layer structures is formed in $Hf_2S$. In this case, the condensed cluster layers are shifted relative to each other, in such a way as to give the S atoms a trigonal prismatic Hf atom coordination (*anti* $NbSe_2$ structure)[143]. A direct comparison of the bonding in $Hf_2S$ and in the MX layer structures is possible since the structure of the corresponding compound HfCl has been thoroughly studied[144]. For these two compounds, having the same VEC and containing anions almost equal in size, the M—M distances are identical within the accuracy of their determination.

The present section indicates that *trans* edge-shared $M_6$ octahedra occur above all in the halides of Sc, Y and the lanthanoids, producing a large number of compounds of almost unlimited variety. This may be caused by low VEC of these metals, which in particular with halogens as X atoms, allow the formation of M—M bonds. The comments made on discrete metal clusters in the introduction hold therefore for condensed aggregates as well. Such aggregates are easily recognizable because of the relatively high X content, and the halogen atoms tend to form markedly anisotropic bonds to the M atoms, which can be clearly seen in the substantial structural differences between isoelectronic pairs of compounds like TiO/ScCl or NbO/ZrCl.

The compounds $AMo_4O_6$ ($A = Na$, K) show how the specific properties of the halogens mentioned above can also be simulated by multivalent X atoms, through the formation of ternary compounds. These may be expected to be the first members of a whole family of ternary compounds containing low-dimensional regions of condensed clusters, in which, in addition to the transition metal in a low oxidation state, multivalent anions and large cations of the electropositive metals are to be found.

### 3.3. Face-Sharing $M_6$ Clusters

The *trans* face-linkage of an infinite number of octahedral $M_6$ clusters leads to a chain with the composition $M_{6/2}X_{6/2} \mathrel{\hat{=}} MX$ for $M_6X_8$ clusters and $M_{6/2}X_6 \mathrel{\hat{=}} MX_2$ for $M_6X_{12}$ clusters, respectively. With this kind of linkage the same restrictions hold as for edge-sharing; X positions which lie above those faces shared between two octahedra ($M_6X_8$ cluster) or above the shared edges ($M_6X_{12}$ cluster) must remain unoccupied for spatial reasons.

A large number of transition metal compounds with elements of the 4th to 6th main groups, especially intermetallic compounds, have been known for some time to contain MX chains as structural units derived from the $M_6X_8$ cluster[24]. A discussion of these units in terms of condensed clusters is, however, not without problems. The arrangement of the atoms in the MX chain corresponds to a section of the (hexagonal) close-packing, so that the occurrence of the structural unit, particularly in intermetallic phases, is hardly surprising. The same remarks hold as in the case of the $U_3Si$ structure (*cf.* Section 3.1, Fig. 6b). The recently discovered Mo cluster compounds, which will be discussed next, are therefore of special importance.

The approach sketched at the end of the previous section has, in principle, been adopted. Intercalation experiments with $Mo_6Se_8$ and In (see Fig. 11a), led to a compound with the approximate composition $In_3Mo_{15}S_{19}$. This compound produced the first evidence for a $M_9X_{11}$ cluster[145], shown in

Figure 11b, which consists of two face-linked $Mo_6$ octahedra, each surrounded by X atoms in the same way as the single $M_6X_8$ cluster. In the meantime, further compounds have been found containing this cluster (always together with $Mo_6X_8$ clusters)[146-150].

The $Mo_6X_8$ and $Mo_9X_{11}$ clusters are the first two members of a series which can be formulated as $M_{3n+3}X_{3n+5}$, where $n$ is the number of (linked) $M_6$ octahedra. The next member of the series, the $M_{12}X_{14}$ cluster, built up from three octahedra (Figure 11c), has been found in the compounds $K_2Mo_9S_{11}$[149] and $Tl_2Mo_9S_{11}$ together with the $M_6X_8$ cluster[151,152]. The final member, the infinite MX chain, was discovered in an independent investigation of the structure of $TlFe_3Te_3$[153,154]. The chain is shown in Figure 11d and the projection of the $TlFe_3Te_3$ structure in Figure 12a.

Meanwhile, isostructural ternary chalcogenides of molybdenum such as $KMo_3S_3$[149] have become known, together with the compounds $AMo_3X_3$ (A = In, Tl; X = Se, Te)[155]. Table 2 lists the known potassium compounds of the cluster series $M_{3n+3}X_{3n+5}$, whose structures in general show the expected relationship between X/M ratio and degree of condensation, but nevertheless cause surprise due to the joint occurrence of different types of cluster.

Table 2. Condensed $Mo_6S_8$ clusters in the ternary compounds $K_xMoS_y$ [149].

| Compounds | X/M | VEC | Structure |
|---|---|---|---|
| $K_{\approx 0.5}Mo_3S_4$ | 1.33 | ≈3.50 | $K_{\approx 1}[Mo_6S_8]$ |
| $K_2Mo_{15}S_{19}$ | 1.26 | 3.60 | $K_2[Mo_6S_8][Mo_9S_{11}]$ |
| $K_2Mo_9S_{11}$ | 1.22 | 3.78 | $K_4[Mo_6S_8][Mo_{12}S_{14}]$ |
| $KMo_3S_3$ | 1.00 | 4.33 | $K{}^1_\infty[Mo_3S_3]$ |

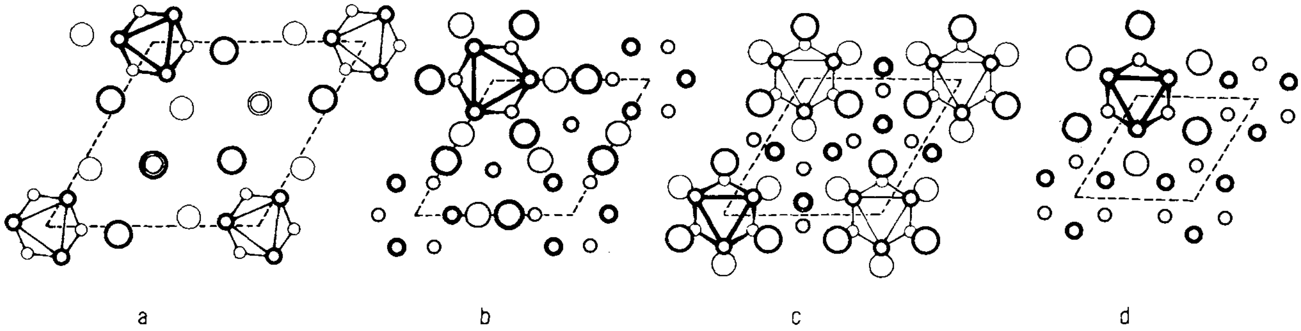

Fig. 12. *Trans* face-linked chains of $M_6X_8$ clusters: a) $TlFe_3Tl_3$, the Tl atoms are marked by double rings; b) $Mn_5Si_3$; c) $Ru_7B_3$ and d) $Ni_3Sn$.

General considerations[155] regarding the chemical bonding in the cluster structures $M_{3n+3}X_{3n+5}$ reveal that $6(n+1)$ bonding molecular orbitals or bands *per* cluster are available for M—M bonding; such cluster systems form preferentially about VEC = 4.0. The assumption signifies that the degree of condensation is, to a first approximation, independent of the VEC and therefore substantially controlled by the X/M ratio, or the cationic counterparts in the compounds. This proposal is in agreement with commonly accepted ideas about the single cluster[1,40] and leads to a quantitative understanding of the M—M distances in $TlFe_3Te_3$ (259 and 260 pm[154]) and $TlMo_3Te_3$ (275 and 262 pm[155]). In the limit of an ionic model, taking into account $Tl^+$, $Te^{2-}$, the values VEC = 6.33 and 4.33 respectively are obtained for the two compounds. This result explains the elongation of the Fe—Fe bonds (although in absolute terms shorter than in the Mo compound) with respect to the single bond lengths of Fe, by the occupation of anti-bonding states. Details of this approach, however, still require refinement. The assumption of an optimal value of VEC = 4 for all types of cluster $M_{3n+3}X_{3n+5}$ cannot explain the behavior of $In_xMo_{15}S_{19}$, which exhibits a range of homogeneity. As the content of In acting as a donor increases, the $Mo_6S_8$ clusters shrink, but the $M_9S_{11}$ clusters, which are also present, expand[148], although the average VEC (cf. Table 2) is still significantly below the value 4.0.

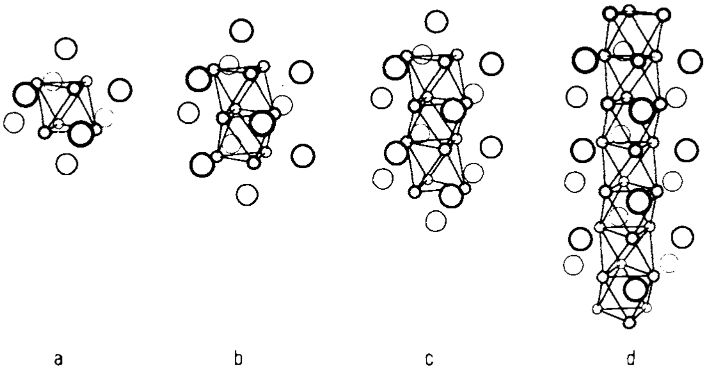

Fig. 11. Step by step condensation of a) $M_6X_8$ units *via* faces to b) double units $M_9X_{11}$, c) triple units $M_{12}X_{14}$ and d) to a one-dimensional infinite chain $M_3X_3$.

The $Fe_3Te_3$ chains are aligned parallel to each other in the structure of $TlFe_3Te_3$, as can be seen in Figure 12a; the $Tl^+$ ions occupy the channels formed by anions between the chains. The structure corresponds therefore to the "expanded" cluster structures[*], which have been treated before several times, and is closely related to a series of structures which can also be regarded as containing chains of face-sharing $M_6$ octahedra plus additional M atoms. The analogy with the $Mn_5Si_3$ structure type has already been referred to[154]. An extensive group of intermetallic phases crystallizes in this structure type[157]. Besides many silicides and germanides of transition metals and lanthanoids, the phosphide $Ti_5P_3$ should be mentioned too, as a representative of this structure

---

[*] The question arises as to why the basic MX structure without occupation of the voids does not occur, since the VEC in the cluster chain is not optimized by the additional M atoms.

type[158]. Figures 12a and 12b illustrate an extraordinary similarity between the structures of $TlFe_3Te_3$ and $Mn_5Si_3$. The second is derived from the first by substituting two Mn atoms for one Ti atom according to the formula $Mn_{6/2}Si_{6/2}Mn_2$. The topological changes involved are, however considerable. The $Fe_3Te_3$ chains are, in the presence of the large $Tl^+$ ions, separate structural units ($d_{Tl-Fe}=406$ pm) with almost undistorted $Fe_6$ octahedra ($d_{Fe-Fe}=260$ pm). In $Fe_5Si_3$ on the other hand, which forms a high temperature modification with the $Mn_5Si_3$ structure[159], strong interactions obviously exist between the Fe atoms belonging to the octahedron chain and those lying between the chains. The additional Fe atoms are 291 pm distant from the Fe atoms in the cluster chain and are extremely close together (236 pm). The $Fe_6$ octahedra themselves are expanded to 269 and 282 pm, the latter value holding for the distances in the chain direction.

The identical structural principle with *trans* face-linked $M_6X_8$ groups seems to be continued in the carbide $Mn_7C_3$[160,161]; the neighboring elements Cr and Fe form isostructural compounds[162,163]. The structure has not yet been solved quantitatively, but is similar to the structure of the boride $Ru_7B_3$ shown in Figure 12c[164], which corresponds to the formula $M_{6/2}X_{6/2}M_4$. All M atoms which are present in addition to the octahedron columns, form chains of $M_4$ tetrahedra. Further examples of this type will be briefly mentioned in Section 3.4.3. The special orientation of the octahedra and tetrahedra to each other, allows the X atoms in $Ru_7B_3$ to take up trigonal prismatic coordination once more.

One last example will show the extent of variation of possible structures on the basis of *trans* face-sharing $M_6X_8$ clusters. The MX chains of these clusters are as mentioned, sections of a hexagonal close-packing of spheres. Three-dimensional close-packing is obtained by linking the chains together *via* X atoms. The resulting composition, $M_{6/2}X_{6/6}=M_3X$, is realized in the compounds with the $Ni_3Sn$-type structure (Figure 12d), which appears in the low temperature modification of $Ni_3Sn$[165,166], as well as in a large number of other intermetallic compounds. The $Ni_3Sn$ structure is intimately related to the $Cu_3Au$ type; both are ordered $A_3B$ structures with hexagonal close-packing in the one case, and cubic close-packing[*] in the other. Thus, the same restrictions as were mentioned before when discussing the $U_3Si$ structure in terms of clusters hold for the $Ni_3Sn$ structure.

### 3.4. Linked Fragments of the $M_6X_8$ Cluster

Up to now, selected systems have been treated which can be discussed in terms of condensed octahedral $M_6$ clusters. This approach may give the false impression that the uniformity in the structures of metal-rich transition metal compounds is more pronounced than it really is. It was mentioned at the beginning that the variety of different $M_n$ clusters, which are known as isolated units, is retained in systems with condensed clusters. Some examples will be given in the following which can be derived by condensation of fragments ot the $M_6X_8$ cluster. Such "cluster fragments" occur frequently among the electron-rich d metals. A systematic treatment of the observed structures, as attempted for the $M_6$ cluster, cannot however be dealt with here.

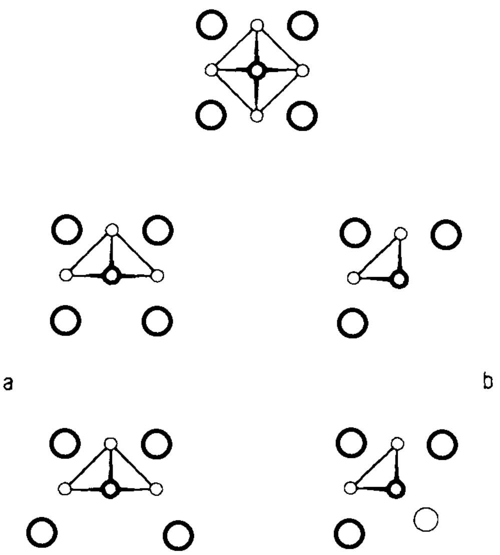

Fig. 13. Parts of the $M_6X_8$ cluster (*cf.* Fig. 3). a) The $M_5X_8$ grouping results from removal of one M atom. The atoms coordinated to the edges of the $M_5$ pyramid base ($X^{i'}$) can shift when the positions above the cluster vertex atoms ($X^a$) are not occupied. b) The cluster $M_4X_6$ results when two M and X atoms are removed in the indicated way. In the complex ion $Mo_4I_7^{2+}$, an additional I atom takes the place of the removed cluster fragment.

On removing one M atom from the $M_6X_8$ cluster, the $M_5X_8$ group remains, as shown in Figure 13a. This cluster has been prepared, as an isolated unit, in the compound $[(C_4H_9)_4N]_2Mo_5Cl_{13}$[47]. Cl atoms are bonded in several different ways in this unit; four atoms center the triangular faces of the square pyramid of M atoms ($X^i$), four lie above the edges of the pyramid base ($X^{i'}$) and five above the vertices ($X^a$). It may be imagined that the $X^{i'}$ atoms in the $Mo_5Cl_{13}^{2-}$ ion, in contrast to the $X^i$ atoms, are held in position by the $X^a$ atoms. In the case of unoccupied $X^a$ positions, an enlargement of the square formed by $X^{i'}$ atoms occurs in the way shown in Figure 13a.

There are two ways of removing two M atoms from an $M_6$ octahedron; the removal of two *trans* atoms leaves a square, the removal of two *cis* atoms a bent rhombus. Both groupings occur linked together in metal-rich compounds. The last named $M_4X_6$ cluster deserves mention as part of the $M_6X_8$ cluster since it was first identified as a linked structural unit in some transition metal compounds with elements of the 4th and 5th main groups, and was almost simultaneously synthesized as a discrete cluster in the compound $(C_4H_9)_4N_2Mo_4I_{11}$[48]. The cluster is coordinated by four additional I atoms in $X^a$ positions, and one further O atom above the centre of gravity of the bent rhombus. Some examples of condensed $M_5$ and $M_4$ clusters will now be given and discussed, followed by cases in which various cluster types occur together.

#### 3.4.1. $M_5$ Clusters

The linear structural element which results from the *trans* vertex-linkage of $M_5X_8$ clusters has the composition $M_{2/2}M_3X_{8/2}=M_4X_4$; it corresponds to the $M_5X_4$ chain formed from $M_6X_8$ clusters. This element stands out particu-

---

[*] It should be pointed out that $Fe_3Ge$ occurs in both forms [167, 168].

larly clearly in the structure of *o*-$Ni_4B_3$ (Fig. 14a)[169]. In this compound, discrete $M_4X_4$ chains are linked *via* $X^{i'}$ atoms, which are shifted considerably from their original positions in the isolated cluster. It is characteristic for this structure, as for all others with these chains, that the base of each $M_5$ pyramid is centered by an X atom. It may be assumed that the $Mo_5Cl_{13}^{2-}$ ion can bond additional ligands above the center of the pyramid base as well. The X atoms are surrounded by the M atoms in a trigonal prismatic manner. B—B bonds express themselves in the short distances (173 and 189 pm) between neighboring $X^{i'}$ atoms.

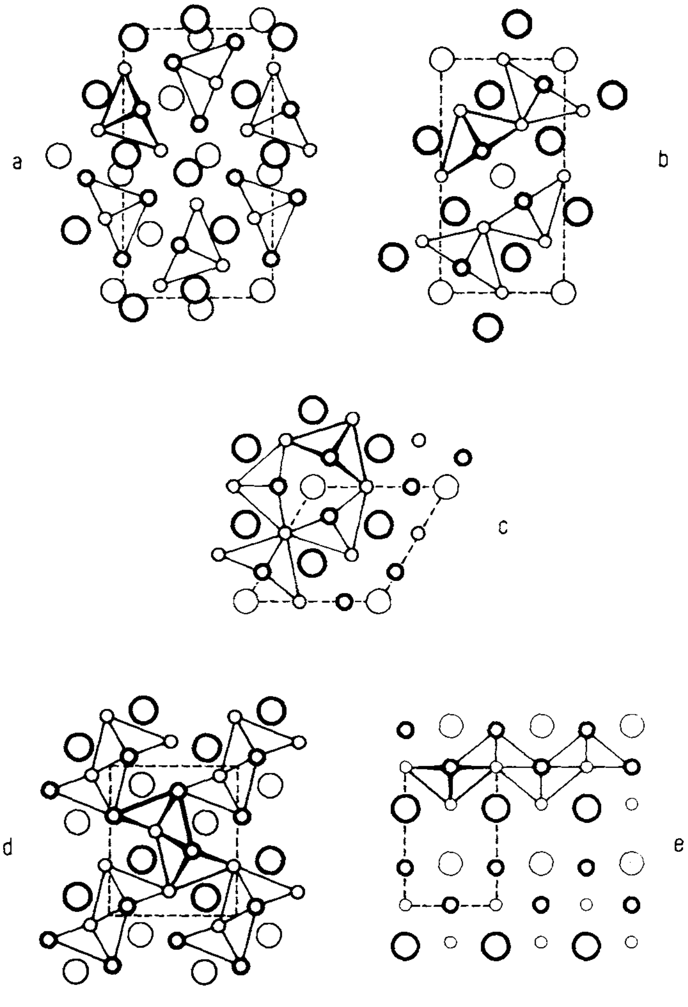

Fig. 14. Structures with condensed $M_5X_8$ clusters; a) *o*-$Ni_4B_3$; b) $Rh_5Ge_3$ and c) $Fe_2P$ with entirely vertex-linked $M_5$ clusters; d) $Co_2P$, whose structure contains (edge-linked) double chains of vertex-linked $M_5$ clusters and e) $Cu_2Sb$ with the corresponding two-dimensional infinite linkage.

The structure of $Rh_5Ge_3$ (Fig. 14b) offers an example of exclusive vertex-linkage between $M_5X_8$ clusters[170]. This structure constitutes an analogy to the $U_3Si$ type (Fig. 6b), but with the difference that the bases of the $M_5$ clusters are coordinated by additional X atoms. The structure corresponds to the formulation $M_{3/2}M_{2/2}X_{8/8}X_{1/2}$. $Cr_5As_3$ and the high temperature form of $V_5As_3$ crystallize in very similar structures[171].

The $M_5$ cluster plays a striking role in the $M_2X$ compounds of the electron-rich transition metals (in particular when X = Si, P, As). The structural principle extends from pure vertex-linkage to pure edge-linkage between the $M_4X_4$ chains formed by $M_5$ groups. In the $Fe_2P$ structure (Fig. 14c)[172], which is taken up by an extensive group of binary and ternary compounds, the chains are only bound *via* the free vertex atoms. The structure is described by the formula $M_{2/2}M_{3/3}X_{8/12}X_{1/3}$. By this is meant that the X atoms which surround every $M_5$ group occupy both $X^i$ and $X^{i'}$ positions in different clusters, and that additional X atoms coordinate the basal faces of neighboring $M_5$ groups (three in this case) as in the structure of $Rh_5Ge_3$. An interesting variant of the structure turns up for NiMoP (and other ternary compounds with the same composition)[173]. The atomic arrangement described in terms of trigonal $Ni_3$ and $Mo_3$ clusters, corresponds to the $Fe_2P$ structure; the Ni atoms taking the positions of the linking M atoms in the single $M_4X_4$ chain. $Co_2P$ crystallizes with the same structure at high temperature[174]; the structure of the low temperature form is shown in Figure 14d[175]. The atomic arrangement can be resolved into a single motif which contains two chains formed from $M_5$ clusters linked together *via* edges. As for the analogous double chain of $M_6X_8$ clusters in $Nb_2Se$ (*cf.* Fig. 8c), not all X positions are occupied. Double chains of this type are linked together *via* the free vertex atoms in the atomic arrangement of $Co_2P$ which is another important type of structure adopted by a number of binary and ternary compounds. The compound $V_2P$—in contrast to $Ta_2P$—also belongs to this type[176]. It is fascinating to compare the various compounds with structures related to $Co_2P$ (Fig. 14d) in the light of the present concept. The X coordination in the structure of $Co_2Si$[177] is considerably changed from that in $Co_2P$ but despite this the aggregation of M atoms can still be described as double chains of $M_5$ clusters. The disintegration of the cluster becomes recognizable in $Re_2P$[178]; the process is completed in the structure of $\theta$-$Ni_2Si$ ($Ni_2In$-type; *cf.* Fig. 15c)[179].

The first stage of the condensation of $M_4X_4$ chains *via* shared edges is completed in the $Co_2P$ structure. Continuing this type of condensation, a two-dimensional aggregate is obtained, and the final member of the series is reached with $Cu_2Sb$[180] whose structure is given in Figure 14e. Double layers of edge-linked $M_5$ groups are present. The X positions are (as for the edge-linked $M_6X_8$ cluster) partly occupied by the M atoms of adjacent clusters. Among many other compounds, $Mn_2As$ crystallizes with the $Cu_2Sb$ structure. The similarity to the structure of $Mn_3As$ is unmistakable; $Mn_3As$, $Cu_2Sb$ and $Ti_2Bi$ are in fact treated as stacking variants[181]. As for the structures with condensed $M_6$ clusters, there are a number of "expanded" structures with $M_5$ clusters, but these will not be dealt with here.

### 3.4.2. $M_4$ Clusters

If the $M_4X_6$ clusters shown in Figure 13b are linked together *via* the remote M atoms in the same way as the *trans* vertex-linkage of $M_6X_8$ clusters in the $M_5X_4$ chain, a linear unit with the composition $M_2M_{2/2}X_{6/2}$ results. Chains of this type, bound to each other by X atoms according to the formula $M_2M_{2/2}X_{2/2}X_{4/4}$, form the characteristic element in the structure of $Hf_3P_2$[182]. As shown in Figure 15a, this structure, which is also found for $Zr_3As_2$[183] consists entirely of such chains ordered parallel to each other. The structure of $Cr_3C_2$[184] is principally similar but the chains are oriented in a different way. $Sc_3P_2$ and $Sc_3As_2$ both have two modifica-

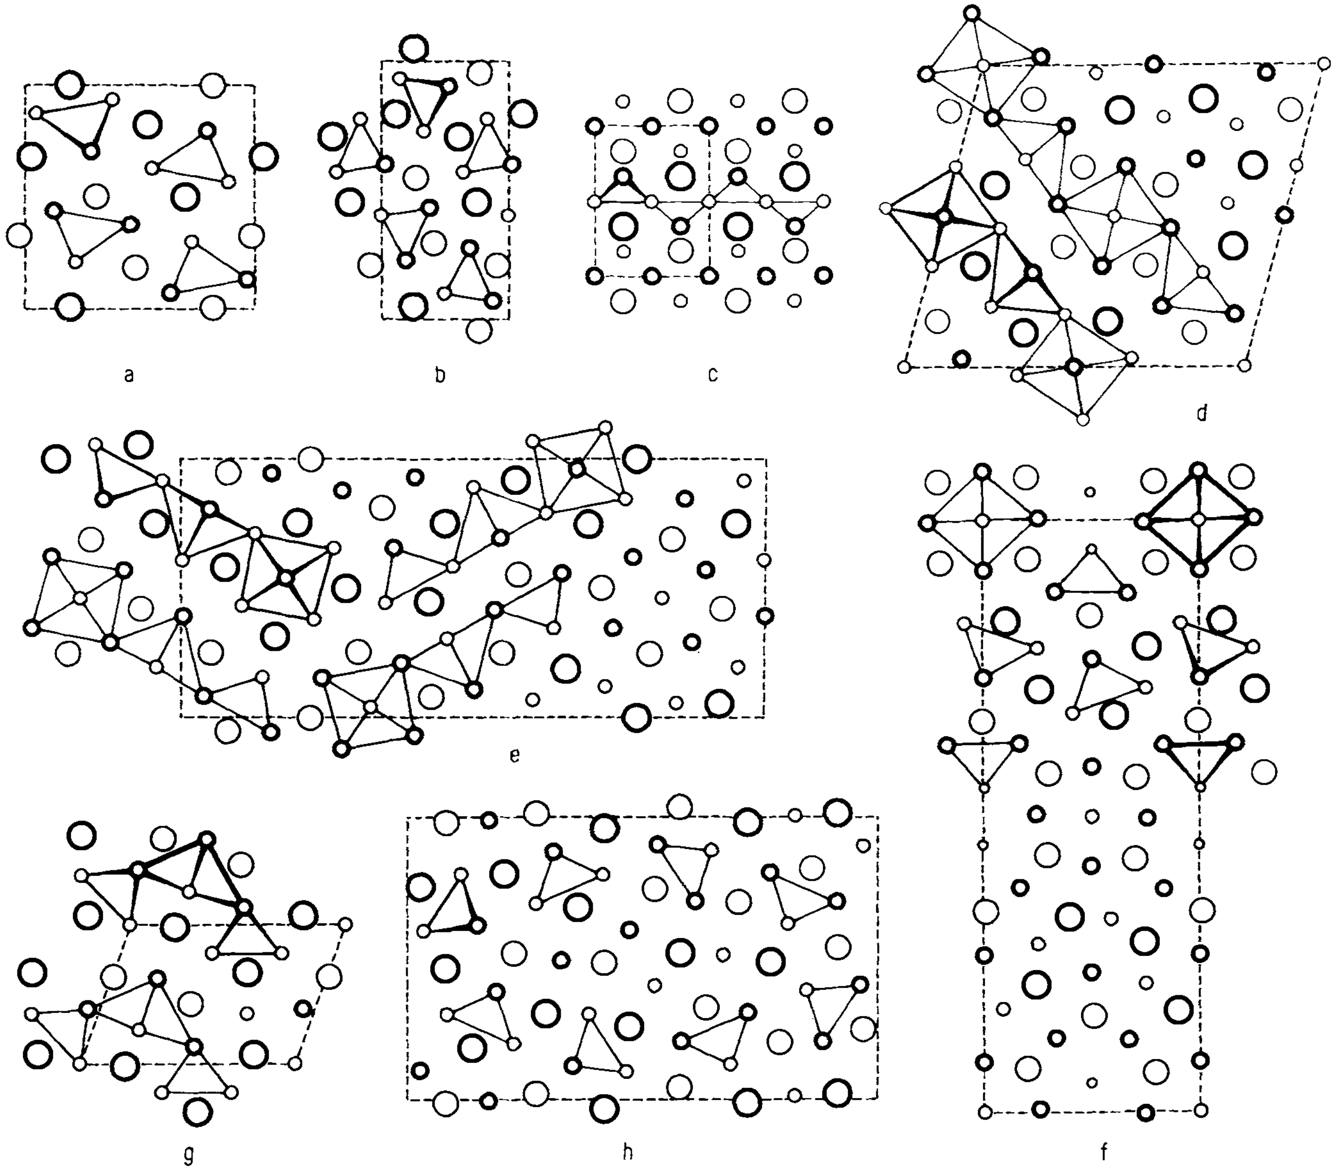

Fig. 15. Vertex-linked $M_4X_6$ clusters and structures which contain various types of condensed clusters together: a) $Hf_3P_2$ and b) $Cr_3C_2$ with isolated chains of vertex-linked $M_4X_6$ clusters; c) two-dimensional layers of vertex-linked $M_4X_6$ clusters in θ-$Ni_2Si$ (cf. $Co_2P$); projection of the structure onto the (110) plane; d) layer structure of alternating $M_5$ and $M_6$ clusters in $Nb_7P_4$ (cf. Fig. 5c); e) units of vertex-linked $M_6$, $M_5$ and $M_4$ clusters in $Nb_5P_3$; f) $Nb_8P_5$ contains isolated chains of vertex-linked $M_6$ and $M_4$ clusters; g) characteristic structural element of $Mo_8P_5$ built up from $M_5$ and $M_4$ clusters and h) structure of $Mo_4P_3$ formed of discrete chains of vertex-linked $M_4X_6$ units together with intermediate MX regions (cf. Fig. 5e).

tions with crystallize with the $Hf_3P_2$ and $Cr_3C_2$ structures[185]. Both the mixed-M carbide $Cr_2VC_2$[186] and the mixed-X boride-carbide and nitride-carbide, $Cr_3(BC)_2$ and $Cr_3(CN)_2$ respectively, exist with the $Cr_3C_2$-type arrangement[186, 187].

The $Hf_3P_2$ and $Cr_3C_2$ structures are crystallographically different but they are similar in that firstly, they both possess as characteristic elements the same chains formed from $M_4X_6$ clusters; secondly, the arrangement of the chains leads to directly comparable coordinations in which each $M_4$ group is surrounded by X atoms in much the same way as in the isolated $Mo_4I_7^{2+}$ cluster.

The structure of $Ni_2Si$ (θ-form) is shown in Figure 15c as an example of the three-dimensional linkage of the $M_4X_6$ cluster *via* vertex atoms[179]. This compound crystallizes with the $Ni_2In$ structure[188]. The layers of linked chains of $M_4X_6$ groups become evident in the chosen projection. The arrangement of the layers again leads to the characteristic coordination of each $M_4$ cluster by X atoms as in the isolated cluster $Mo_4I_7^{2+}$. The close relationship to the $Co_2P$ structure (Fig. 14d) has already been mentioned. In fact, the structure of θ-$Ni_2Si$ is converted into the $Co_2P$ structure by buckling the layers and simultaneously bringing them closer together. The bent $M_4$ rhombus seems to be an important structural unit in many further examples, some of which will be mentioned in the next section. Besides this arrangement of four M atoms, the square turns up frequently as an alternative octahedral fragment among metal-rich and intermetallic compounds of the elements under consideration. The many compounds which crystallize with the $W_5Si_3$- and $Al_2Cu$-type structures are possible examples[157, 189]. These will not be discussed in detail here, but for the sake of completeness one further $M_4$ cluster, which is well known as an isolated unit, must be mentioned; the tetrahedral $M_4$ cluster. One structure $Ru_7B_3$, which contains rows of such clusters has already been mentioned in Section 3.3. Further representatives exist in large numbers as "Tetraeder-Stern" structures[181]. One group of compounds with the composition $LnM_4B_4$, which has frequently been studied in recent times shows various possible modes in which tetrahedral $M_4$ clusters occur. In $YRu_4B_4$, isolated $Ru_4$ tetrahedra are present[190], whereas in $NdCo_4B_4$[191] and $LaRu_4B_4$[192] they are linked *via* edges to form one-dimensional chains. The present great interest in these compounds is related to their high superconducting transition temperatures[193] and, above all, to the discovery of competing superconductivity and ferromagnetism in $ErRh_4B_4$[194]. It may be noted in this context that the structures of the A15 phases, to which $Nb_3Ge$ belongs, with the highest superconducting transition temperature known, are also composed of networks of linked tetrahedra. Superconductivity and metal clusters may be related in a way that is not yet understood[195].

### 3.4.3. Structures with Several Types of Clusters

One example of the occurrence of various types of cluster in one compound ($M_6$, $M_3$) has already been given in Section 3.1 with the structure of $Nb_4As_3$. A few structures will now be discussed which can be completely resolved into mixed arrangements of linked $M_6$, $M_5$ and $M_4$ clusters. The niobium phosphides $Nb_7P_4$, $Nb_5P_3$ and $Nb_8P_5$, whose X/M ratios are very similar, are shown together, in Figures 15d, e, f. The structure of $Nb_7P_4$ has already been discussed in Section 3.1 as an "expanded" $M_5X_4$ variant according to the formula $M_5X_4 \cdot M_2$. It is interesting that the additional M atoms inserted between the $M_5X_4$ chains arrange themselves in such a way with the adjacent vertex atoms of the $M_5X_4$ chains that they form rows of linked $M_5$ clusters. This is indicated in Figure 15d. Thus, the $Nb_7P_4$ structure can also be regarded as a series of identical layers, each of which consists of alternating vertex-linked $M_6$ and $M_5$ cluster chains. A slight increase in the X/M ratio from 0.57 to 0.60 leads in $Nb_5P_3$[196] to a growth of the proportion of "partial-clusters". As indicated in Figure 15e, the entire atomic arrangement in this compound can be represented by linear units of vertex-linked parallel rows of $M_6$, $M_5$ and $M_4$ clusters. This type of structure was first found in $Hf_5As_3$[197]. A comparison with the $Hf_3P_2$ structure is interesting here since it shows that the atomic arrangements around the $M_4$ groups are to a large extent equivalent. Finally the structure of $Nb_8P_5$[198], which is also formed by $Zr_8As_5$[183], contains rows of vertex-linked $M_4$ clusters which surround single $M_5X_4$ chains. The Nb arsenides possess the same structures as the phosphides described above[91].

Interestingly enough, the compound $Mo_8P_5$[199] only contains structural elements formed from fragments of the $M_6X_8$ cluster even though it has the larger VEC. As illustrated in Figure 15g, each chain of $M_5$ clusters is linked *via* vertices to two chains of $M_4$ clusters. The structure is built up entirely by the repetition of such combined units. The arrangement of X atoms around each $M_4$ group is the same as in the isolated $Mo_4I_7^{2+}$ cluster. Around the $M_5$ group, neighboring M atoms occupy those positions, which are occupied by the Cl atoms in the isolated $Mo_5Cl_8^{3+}$ ion. In principle, the $M_4$ clusters can be completed in the structure of $Mo_8P_5$ to form distorted $M_5$ clusters by taking into account neighboring M atoms. In this way a network of such (vertex-sharing) clusters results. Close relationships can therefore be found to the structures treated in Section 3.4.1.

The phosphide $Mo_4P_3$[200] (Fig. 15h), which contains less Mo, provides another example of a compound whose structure demonstrates the possibility of an "expansion" of the cluster structure to a higher X content; additional M and X atoms are inserted in equal numbers between parallel chains of $M_4$ clusters, resulting in an overall composition $M_2M_{2/2}X_{2/2}X_{4/4} \cdot MK$. The situation corresponds to that in $Nb_4As_3$ and $V_4As_3$, which have already been mentioned and which can be described analogously as $M_4M_{2/2}X_{8/8} \cdot M_3X_2$. In $Nb_4As_3$ and the low temperature form of $V_4As_3$ however, the intermediate M atoms are arranged in trigonal $M_3$ groups with the X coordination as in $Nb_3Se_4$. The arrangement of the additional atoms in the high temperature form of $V_4As_3$ on the other hand, is very similar to that in $Mo_4P_3$.

### 3.5. Occupation of the Cluster Centers

One special aspect of the chemistry of metal clusters, which has increased in importance for molecular compounds should not be neglected. It was first demonstrated in the compounds $HNb_6I_{11}$[201] and $CRu_6(CO)_{17}$[202], in 1967, that the center of a transition metal cluster can be occupied by single atoms (H or C resp.). Since then an impressive number of comparable compounds with "interstitial" atoms has become known. These are of great interest because of their possible importance in catalytic processes, and have been summarized in several reviews[203-207].

It may be conjectured that the cluster centers can be occupied by single atoms in systems with condensed clusters as well. The first indication of the correctness of this supposition is given by the reversible $H_2$ absorption by the compounds ZrCl and ZrBr (*cf.* Section 3.2.2), which leads to the almost stoichiometric compounds ZrXH and $ZrXH_{0.5}$[208]; the position of the H atoms is still uncertain in these compounds. Apart from this, there are cases among the metal-rich transition metal compounds within the scope of this work, whose structures contain metal clusters, the centers of which are occupied by additional atoms. Such "filled" structures have already been mentioned in another context[209]. In conclusion, a few particularly striking examples of octahedral $M_6$ clusters will be discussed.

Three-dimensional vertex-linkage of $M_6X_8$ clusters leads to the structure of $U_3Si$ ($Cu_3Au$) (see Fig. 6b). If $M_6X_{12}$ clusters are linked in the same way, the NbO structure results (see Section 3.1). For the first arrangement, occupation of the octahedral centers leads to the perovskite structure. Indeed, many "perovskite" carbides and nitrides exist[210,211]; from these $Mn_3GeC$ and $Fe_3GeN$ may be cited here since they fall into the chosen range of element combinations. It is remarkable in this connection that the structure shows the same deviation as $U_3Si$ from cubic symmetry with increasing occupation of all centers. A fascinating example of the filled NbO structure is the nitride $W_3N_4$ ($N \cdot W_{6/2}N_{12/4}$)[212] whose structure however, still has to be verified; interestingly, NbO and $W_3N_4$ are isoelectronic!

The $Mn_5Si_3$ structure is particularly accommodating as far as the insertion of atoms into the octahedral centers is concerned[211,213,214]. Besides boron (*e.g.* $Nb_5Ge_3B$[215]), carbon above all is easily inserted, and the ferromagnetic compound $Mn_5Si_3C_x$[216] can be obtained by reaction of $Mn_5Si_3$ with C. For the compound $Ti_5P_3$, which has already been mentioned (Section 3.3), the composition $Ti_5P_3O_x$ is assumed[217,218]. The insertion of metal atoms is also possible, such as in the compound $Hf_5Sn_3Cu$[215]. Binary phases represent a special case. The complete occupation of all octahedral centers as for example in $Hf_5Sn_4$ ($=Sn{\cdot}Hf_5Sn_3$)[219], leads to the $Ti_5Ga_4$-type structure[220].

The ordered partial occupation of the centers of the $M_6$ octahedra is also known. For example, the structure of $Mn_{10}Ge_7$ corresponds to a half-filled $Mn_5Si_3$ structure[221]. In this case, it is interesting to see that the ordered semi-occupation resolves the *trans* face-linked octahedron chain into single $M_6X_8$ clusters, which are connected according to the formula $Mn_6Ge_6Ge_{2/2}$. This final example leads right back to the starting point of this work.

## 4. Final Remarks

The search for the smallest bonded units in the structures of metal-rich compounds of the transition metals and lanthanoids with p-elements leads to the following result—known for some time—that preferred coordination polyhedra occur for the non-metal atoms X. In addition the linkage of the polyhedra takes place in such a way that the M and X atoms often end up with an arrangement identical to that known from isolated metal clusters. The examples chosen for the present work (*cf.* Table 3) may provide convincing evidence for this idea; many more examples could be added. It should nevertheless be stressed that the "image-seeking" procedure illustrated with the aid of the examples shown here, is not yet always successful. Even in those cases where certain atomic arrangements can be interpreted in terms of condensed clusters, conclusions drawn from the crystal structure alone can be misleading. An example of this is the high pressure form of $Ag_2O$, which like $Ag_2F$ crystallizes in the anti-$CdI_2$ structure type[222] and therefore could be discussed as $Ag_{6/3}O_{2/2}$ within the concept of condensed clusters. In contrast to $Ag_2F$, the VEC is zero in the case of $Ag_2O$, and only van der Waals bonds exist between the $Ag^+$ ions. This example shows that further knowledge, above all about the VEC, is essential for the interpretation of structures of metal-rich compounds. It is well known that isostructural behaviour is no evidence for identical chemical bonding. Many of the metal-rich compounds under discussion possess structural antitypes (*e.g.* $Co_2P/PbCl_2$), for which the interatomic interactions postulated here are irrelevant. This is directly related to the question which arose for $U_3Si$ and $Ni_3Sn$ and which is particularly important for intermetallic phases. How far can the tendency to optimize space-filling (close-packing) be distinguished from the consequence of directional bonding? In particular, it may be very helpful that chemical bonding is

Table 3. Crystal data for the structures of compounds shown as projection, *cf.* footnotes on p. 4.

quantitatively related to the volumes of intermetallic phases within an isostructural family[223-225].

The objectives of further investigations have to be sought both in experimental work and in the more detailed analysis of structural data in the light of results obtained by other techniques. Our present knowledge of the existing metal-rich compounds and their structures appears in many respects fragmentary. The structural principles which have been recognized (for example, in the cases of the Ti sulphides and ternary metal-rich Mo compounds) allow us to be optimistic of finding many more compounds of this sort. One important area for further work is the correlation of information about composition, structure and VEC, which up to now has only been attempted for single cases in a preliminary way. Last but not least, the localized description of the often very complicated structures in terms of condensed clusters hopefully provides a guide for an appropriate quantitative description of electronic structure, and hence a detailed understanding of the chemical bonding in these compounds.

*Special thanks are due to my former co-worker Ch. Bauspieß, who assisted in the early stages of the development of the present concept, as well as K. Berroth, R. Eger, N. Holzer, Hj. Mattausch and E. Warkentin, who all helped to open up the chemistry of metal-rich lanthanoid halides. I had valuable discussions with my colleagues J. D. Corbett, R. E. McCarley and H. G. v. Schnering. I wish to thank Mrs. M. Raatz, K. Berroth and E. Warkentin for their help in producing the manuscript and the figures, also A. Griffiths for translating the text into English. Finally, I am indebted to the Verband der Chemischen Industrie—Fonds der Chemie—for their generous support of this work in the form of book donations.*

# Production of High Temperatures in the Chemical Laboratory: Examples of Application in Lanthanoid Oxo-Chemistry

## By Hanskarl Müller-Buschbaum[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

High-temperature reactions have always been a fascinating although difficult field of experimentation for the chemist. In the case of solid-state reactions the problems with apparatus increase exponentially with rising temperature, so that especially in this area of inorganic chemistry the modern techniques of producing high temperatures—from the solar furnace to the high-power $CO_2$ laser—have yielded new and interesting possibilities, particularly in the field of metastable high-temperature compounds.

## 1. Introduction

On account of limited preparational possibilities, research into lanthanoid oxo-compounds during the first half of this century was rather limited, as demonstrated clearly by the repeated investigations[1-3] of the phase diagram of the trivalent lanthanoid oxides in accordance with *Goldschmidt*[4] (Fig. 1); up to some 30 years ago, *i. e.* the dawn of modern high-temperature chemistry, the stability ranges of the three crystalline forms at high temperatures were unknown. In addition to the physical and thermodynamic data at high temperatures (for the definition of the term "high-temperature chemistry", see [5]), the formation of compounds, the phase diagrams, the reversibility or irreversibility of phase transformations, and above all accurate structural data are of interest.

As a result of the advent of new methods for the generation and application of high temperatures, the study of lanthanoid oxo-chemistry has undergone a burgeoning development in the last 30 years. Some of the most important fundamental studies in the field of high-temperature chemistry were carried out at the Institute of Inorganic Chemistry of the University of Münster under the direction of Professor *Klemm*. In the following review article the methods used for the production of high temperatures are considered, with selected examples of applications from the sphere of lanthanoid oxo-chemistry.

High temperatures can be produced by either chemical or physical methods. A number of such processes is presented in Table 1. Some processes affording very high final temperatures are nevertheless of little use in preparational solid-state chemistry, and these are consequently dealt with only briefly.

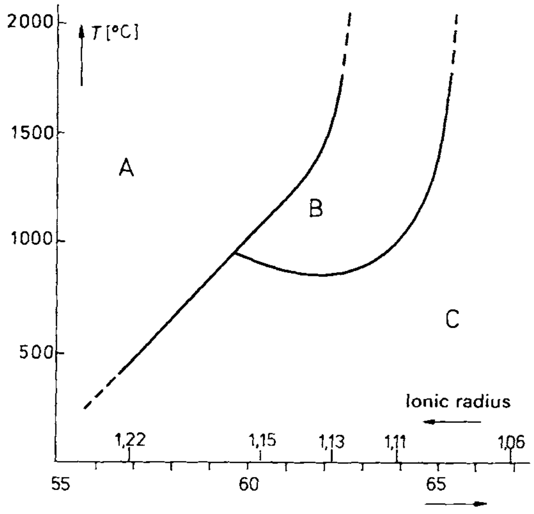

Fig. 1. Phase diagram for trivalent lanthanoid oxides, after *Goldschmidt*. For the A-, B-, and C-types, see text.

## 2. Methods of Limited Applicability for the Production of High Temperatures

### 2.1. Mechanical Techniques

The synthesis of new compounds by shock waves or a single adiabatic compression is the province of a few specialized teams. An explosive charge (*e. g.* hexogen) is set off and the

Table 1. Summary of the heat sources and heat production processes usable in chemical laboratories, and temperatures achievable in this way.

| *Mechanical processes* | | | *Thermochemical processes* | | *Natural heat sources* |
|---|---|---|---|---|---|
| Adiabatic compression ($>10^3$ °C) | | | Flames | Metallothermy | Solar furnaces |
| Adiabatic shock waves ($>10^4$ °C) | | | $2H_2+O_2$ (2660 °C) | Metal oxides, | ($\approx 3500$ °C) |
| | | | $C_2H_2+O_2$ (3100 °C) | sulphides, and halides | |
| | | | $C_2H_2+N_2O$ ($>3100$ °C) | +Al, Mg, Ca, Zr, *etc.* | |
| | | | Metal powder/$O_2$ flames | ($\approx 2000$—2500 °C) | |
| | | | "skating sun" | | |
| | | | ($\approx 2500$—4500 °C) | | |
| | | | *Electrical processes* | | |
| Resistance heating | | Electron-beam heating | Induction heating | Electric arc | Laser |
| Cr/Ni | (1100 °C) | Focal spot fusion | Inductive heating of electrically | Arc fusion | High-power $CO_2$ |
| SiC | (1500 °C) | Drip fusion ($>3000$ °C) | conducting substances | ($>3000$ °C) | laser ($>4000$ °C) |
| Pt/Rh | (1700 °C) | | Crucible-free fusion | Electric-arc plasma torch | |
| $MOSi_2$ | (1800 °C) | | Open plasma torch ($>10^4$ °C) | ($>10^4$ °C) | |
| $MO(H_2)$ | (2000 °C) | | Closed plasma torch | Arc-transport process | |
| C | (2500 °C) | | (thermal disequilibrium) | ($\approx 2000$—4000 °C) | |
| $ZrO_2$ | (2500 °C) | | ($\approx 10^3$—$10^4$ °C) | Artificial suns | |
| $MO_2+M_2O_3$ | (2000 °C) | | | ($\approx 2300$ °C) | |

shock front is passed through crystalline material; in addition to the pressure wave an equally steep temperature front is then formed, and the two together break the crystallites down to about 100 Å[7] to 10 Å[6], or about the order of magnitude of the elementary cells. This decomposition gives rise to a variety of structural disorders and lattice defects, raising the chemical reactivity to an extremely high level. The method has been used to synthesize ferrites[8,9], chromium[10] and tin[11] chalcogenides, and mixed tin dihalides ($SnCl_{0.5}Br_{1.5}$, SnClI, and SnBrI[12]). *Batsanow et al.*[13] found that the first few members of the lanthanoid oxide series $Ln_2O_3$ (Ln = La—Sm) react with water under the influence of shock waves to form $Ln(OH)_3$, whereas with $Eu_2O_3$ the product is the unexpected EuOH.

## 2.2. Thermochemical Techniques

The thermochemical methods are based on the principle of using the heat released in a chemical reaction for the production of the high temperatures. As far as manipulation is concerned, the most elegant examples of this type are hot flames, whose upper temperature is limited only by the chemical equilibrium of the combustion reaction, and in earlier years hot flames were in fact the only acceptable way for obtaining single crystals from the high-melting lanthanoid oxides. A disagreement between *Zachariasen*[14] and *Pauling*[15] on the structure of the hexagonal A-form of $La_2O_3$, a question that could not be decided definitively either way on microcrystalline powder preparations, was ultimately resolved by *Zachariasen*[16] on single crystals prepared by *Goldschmidt* with an oxyhydrogen flame. In 1956 *Tannenbaum* produced the first single crystals of the monoclinic B-form of $Sm_2O_3$ with an oxyacetylene flame. It was on this material that *Douglass* and *Staritzky*[17] were first able to determine the space group, the cell dimensions, and the optical properties, and *Cromer*[18] in 1957 was able to determine the crystal structure of the B-form of the lanthanoid oxides. This example illustrates the importance of high temperatures for the production of X-ray-perfect single crystals.

An obvious disadvantage of hot flames is that it is only possible to work with substances that can resist the oxidizing and reducing action of the flames at the high temperatures in question (Verneuil's process for the synthesis of rubies and sapphires). A particular difficulty is also presented by the extreme thermal expansion of the fuel gases as they heat up from room temperature to 2000—3000 °C: the strongly turbulent gases simply blast the molten samples out of the hot zone.

In metallothermic reactions (Al, Mg, Ca, Zr, *etc.* reacting with halides and oxides) the reacting metal intervenes to a far greater extent in the chemical process than the hot flames. For this reason the preparative applications are restricted to a few special examples, which will not be discussed in greater detail in the present review. The original method proposed by *Grosse* and *Conway*[19], of a metallic powder/$O_2$ flame, has also not been developed further. In one interesting variant, carrier materials coated with metals are combusted ("skating sun" phenomenon).

## 2.3. Electrical Techniques

### 2.3.1. Electron Beam Heating

The heating of metals by bombarding them with a beam of electrons, originated by *von Pirani*[20], was used by *Tiede*[21], *Tiede* and *Birnbräuer*[22], and *O'Bryan*[23] to melt metals, oxides, and carbides. In metallurgy, this technique, meanwhile perfected by the development of high-power electron guns (Fig. 2), has become a preferred method[24], since the melted material can be situated in a field-free space. Figure 2 shows *Stephan*'s 100 kVA apparatus[25]; the electron beam produced is focussed by magnetic lenses and emerges *via* a vacuum system into a field-free space likewise evacuated to about $10^{-3}$ mbar. The decisive advantages of this technique are protection of the cathode from evaporating material, suppression of perturbing glow discharge, and the simultaneous degassing and purification of the fused material. However, the use of the method is at the moment confined almost exclusively to metallic materials.

In this connection it is interesting to note that the heating of the extremely small samples in an electron microscope is identical with the older technique of preparation in the field. Thus, *Boulesteix et al.*[26] heated single crystals of the A-form of lanthanoid oxides to high temperatures (>2000 °C) by bombarding them with the electron beam of an electron microscope, to study the transition of the A-form into the Hand X-forms (high temperature modifications of $La_2O_3$) on the electron diffraction pattern (see Section 3.3).

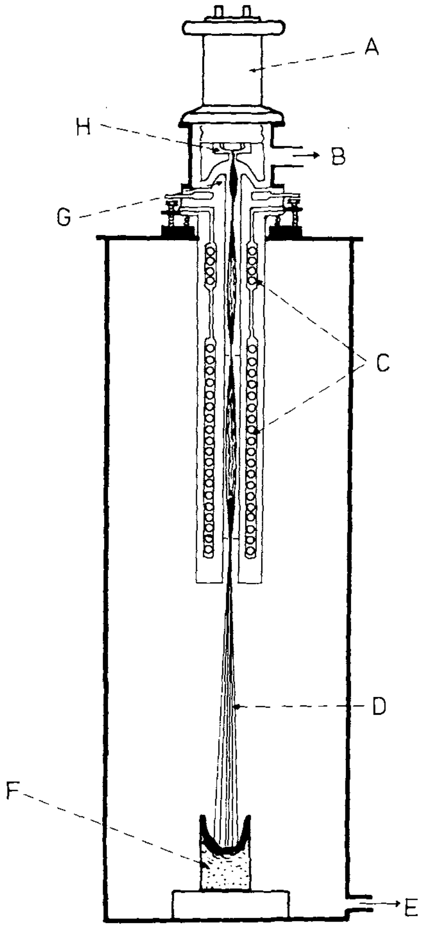

Fig. 2. Principle of an electron gun [25] for metal fusion in a field-free space. A: Insulator; B: pump for the electron gun; C: magnetic lenses; D: electron beam; E: pump for the preparation space; F: preparation; G: anode; H: cathode.

### 2.3.2. Electric Arc

Whereas the electric arc is used in a large number of ways for the production of high temperatures, in this section we shall consider only the direct application of arc fusion (heating in a d-c arc) and the original arc-transport process. The electric plasma-arc torches and electric arcs mentioned in Table 1 as artificial suns, are dealt with in Sections 3.4 and 3.3.

Direct heating in an electric arc resembles electron beam fusion, the principal differences being that

- in the electric arc the cathode drop is very small due to the low potential requirement ($\approx 10$ V),
- in the electric arc the power is produced by high currents,
- the substances to be heated are exposed to the material vaporizing in the arc (high-current arc).

In the high-intensity arc or the Beck arc temperatures of about 7000 °C are reached in long anode flames, *i. e.* temperatures much higher than are normally necessary for reactions in the solid state. Using a d-c arc, *Weir* and *Valkenburg*[27] reacted BeO with $Ga_2O_3$, $Y_2O_3$, and $La_2O_3$ and obtained, for example, the compound $BeY_2O_4$, whose structure—an $AB_2O_4$-type structure—was clarified later by *Harris* and *Yakel*[28]. *Miller* and *Daane*[29] prepared a number of lower-valence lanthanoid oxides ($LnO_{1.5-x}$) by the arc fusion of $Ln_2O_3$ with Ln (Ln = lanthanoid). As shown by density measurements, the deep-colored oxides $GdO_{1.495}$, $YO_{1.489}$, and $LuO_{1.485}$ obtained in this way contain a defect oxide lattice, which is also manifested in their formulas.

The arc-transport process described by *Drabble*[30], in which the material is transported by an electric arc, and which is particularly suitable for growing larger single crystals has so far received astonishingly little attention. A vertically burning arc between an electrode filled with a melt and a second electrode carrying the crystal is kept at a constant length by progressively raising the upper electrode (Fig. 3).

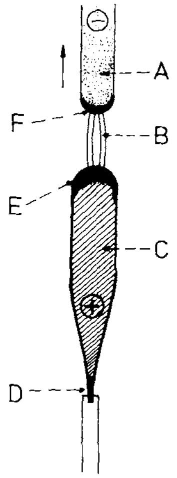

Fig. 3. Schematic representation of the arc transport process [30] for growing single crystals with transportation of the material in an arc. A: Feed electrode; B: arc; C: growing crystal; D: seed crystal; E: anode melt; F: cathode melt.

The fused oxides are transported by the arc from sintered $CeO_2$ or $La_2O_3$ electrodes to the opposite electrode, where they deposit and grow on the single crystal seed (the two electrodes can be tempered by additional heating). *Drabble*[30] investigated the dependence of the direction of transport on the chemical material, and found that both the material transport and its loss are a function of the length of the arc. However, careful maintenance of the constancy of the arc conditions is an extremely complicated experimental operation.

## 3. Universally Applicable Methods for the Production of High Temperatures

The conventional technique of resistance heating, long used in solid-state chemistry, the use of the sun as a natural source of heat, induction heating of electric conductors, and the various plasma torches are of differing practical significance, though all of them are more important than the methods outlined in the preceding section. The high-power $CO_2$ laser has been added in more recent times as an elegant and very promising energy source for solid-state chemistry. These techniques will now be discussed in chronological sequence.

### 3.1. Resistance Heating

Although few furnaces with resistance heating reach temperatures as high as 2000 °C, for many decades simple electric furnaces were the only usable heat sources and preparative chemists were forced to put up with their drawbacks. Many lanthanoid oxides were in fact prepared in such furnaces:

- Simple mixed crystals: $Ln_2O_3 \cdot Ln'_2O_3$ (Ln, Ln' = lanthanoid)
- Perovskites: $LnLn'O_3$
- Pyrochlore-type compounds: $M_2Ln_2O_7$ (M = tetravalent metals Zr, Th, *etc.*)
- Heterotype fluorite phases: $MO_2 + Ln_2O_3$ (M = Ce, Zr, Th, Hf, U, *etc.*)
- Compounds of the calcium ferrite-type: $MLn_2O_4$ (M = Ca, Sr, Ba, Eu, *etc.*)
- Compounds of the formula $Ln_2TiO_5$.

In addition to this there have been studies on binary systems, on the reversibility or irreversibility of the changes between allotropic modifications, and on higher and lower degrees of oxidation or phases and phase widths in lanthanoid-oxygen systems. Reviews of this work will be found in [31-35].

Lanthanoid oxo-compounds, for example the heterotype fluorite phases $MO_2 + Ln_2O_3$ (M = Zr, Th, Hf, Ce; Ln = lanthanoids and yttrium) showing oxygen-ionic conductivity can also themselves be used as resistance heating elements in high-temperature technology. Trivalent lanthanoid ions are incorporated at the lattice points of the tetravalent element in oxides such as $ThO_2$, $ZrO_2$, $HfO_2$, *etc.*, crystallizing in the fluorite lattice. The resulting oxygen-ionic conductors work particularly well in an oxidizing atmosphere. This is an advantage over heating elements that have to be protected against corrosive action of oxygen at high temperatures. Thus, a $ZrO_2$ resistance-heating furnace described by *Faucher, Dembinski* and *Anthony*[36] reached about 2500 °C both in inert and oxygen atmospheres. However, *Gorski* and *Dietzel*[37] showed that at such high temperatures contamination of the preparations by zirconia vapor is unavoidable. When an oxide furnace of this kind is started up the semiconducting material is preheated to 1000—1800 °C until, as a result of the fall in resistance, the size of the current increases constantly with rising temperature. An essential drawback of this fundamentally conventional technique is that because of the negative temperature coefficient of the resistance local hot zones appear in the heating conductors, leading eventually to destruction of the material through an accumulation of this effect[38,39].

Furnaces wound with molybdenum and tungsten resistance wires are not affected by these problems but are endangered by oxidation. This also applies to graphite (Tammann) heating conductors at temperatures above 1900 °C. Since even under a protective atmosphere or under vacuum significant quantities of carbon vapor are produced in the Tammann furnaces at temperatures above 2500 °C[40], it is preferable to reserve the use of these furnaces to reactions in which C and CO do not interfere; good examples of this are the experiments on the reduction of $Sm_2O_3$ with C or CO by *Smagina* and *Kutsev et al.*[41-43].

The main disadvantage of all heat conductor sources, however, is that the energy is invariably introduced into the sample from outside, through a boat or some other container. Since the sample is therefore somewhat colder than the vessel wall, there is always the risk of reaction with the crucible material.

### 3.2. Induction Heating

A high-frequency electric field induces eddy currents in conductors, and these can be utilized for the production of high temperatures. The temperatures achievable in this way are therefore limited only by the material, *i. e.* by the melting point of the inductively heated crucible material. The $LnO_{1.5-x}$ compounds mentioned in Section 2.3.2 were prepared by *Miller* and *Daane*[29] by this method. *Bedford* and *Catalano*[44] used induction furnaces with tungsten crucibles to investigate the systems Eu—$Eu_2O_3$, Sm—$Sm_2O_3$, and Yb—$Yb_2O_3$ between 1500 and 2300 °C. In 1977 *Greedan, Gibb,* and *Turner*[45] prepared $Eu_3TaO_6$ with divalent and trivalent europium using crucibles heated to 2200 °C by induction.

The use of high-frequency energy in induction furnaces is a relatively old technique, supplemented in the mid-sixties by inductively powered plasma torches (see Section 3.4.2).

### 3.3. Solar Furnaces and Artificial Suns

Solar furnaces, which have been used successfully both on the small scale as well as the large scale since 1960[51], represented a great step forward in high-temperature solid-state chemistry. A large-scale solar furnace plant has long been in operation on the technical scale at the Laboratoire des Ultra Réfractaires du Centre National de la Recherche Scientifique in Odeille/Fornt-Romeu.

Strictly speaking a solar furnace is not a furnace but an optical system by means of which sunlight is focussed onto a chemical preparation using parabolic mirrors and lenses (Fig. 4).

The mode of action of solar furnaces, *e.g.* the dependence of the flux density on the diameter of the focal spot, or that of the temperatures attained on the mirror aperture, has been described by *Noguchi*[46]. The precision with which a solar furnace can be operated for 1 h at about 2700 °C reaches the amazing value of ± 10 °C[47]. Solar furnaces can be designed in such a way that they allow heating of the samples under a protective atmosphere or under vacuum (*Laszlo*'s[48] and *Glaser*'s[49] construction, Fig. 5).

Special reference is made to the stripper inside the chamber, which mechanically removes evaporated material that would otherwise impair the transmission through the protective cap. *Noguchi et al.*[50] also describe solar furnaces for work under controlled gas atmospheres.

To eliminate the dependence of solar furnaces on the weather, and to preserve the elegant working technique of energy transfer by radiation, the next step was the development of "artificial suns", which make use of electric arcs, xenon high-pressure lamps, or high-frequency plasma torches as the energy sources in place of the sun. The principle of energy transfer by focussing with elliptical and parabolic mirrors is shown in Figure 6. To give an impression of the tech-

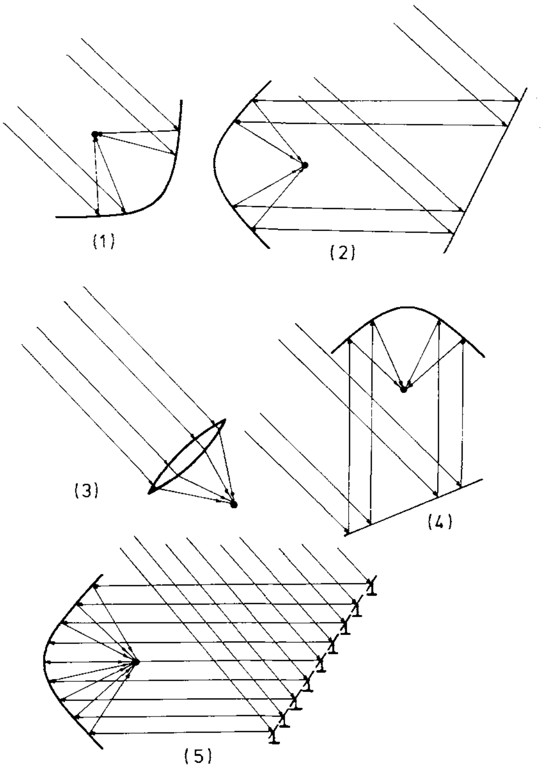

Fig. 4. Types of solar furnaces: (1) direct solar furnace; (2) horizontal heliostat; (3) type with a single lens; (4) vertical heliostat; (5) large-scale horizontal heliostat with illumination of the parabolic mirror by several plane mirrors.

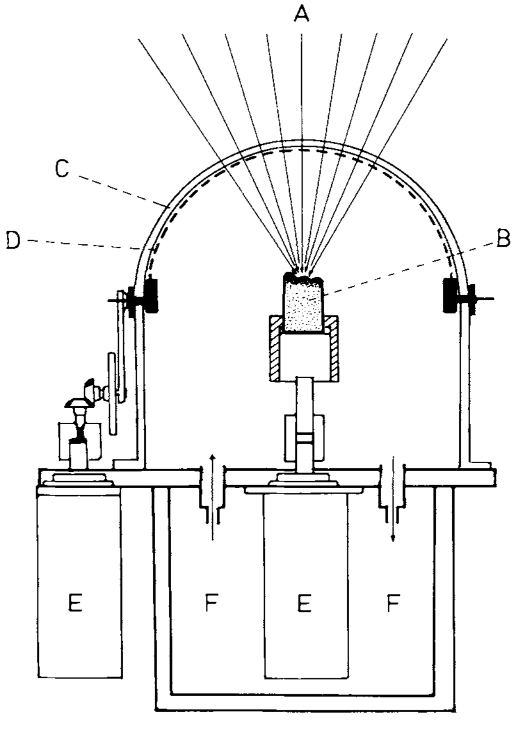

Fig. 5. Solid-state reaction, using a solar furnace and a specific gas atmosphere [48, 49] or vacuum. A: Sunlight; B: sample; C: quartz glass; D: stripper; E: motor; F: protective gas or vacuum.

nical embodiment of a radiation furnace of this kind, Figure 7 shows *Traverse*'s experimental construction[52], in which the preparation is again separated from the combustion space of the electric arc to prevent contamination by evaporating electrode material and to allow the performance of reactions under a special gas atmosphere.

Solar furnaces and artificial light optical systems have been responsible for a whirlwind advance of research into the high-temperature chemistry of the lanthanoid oxides.

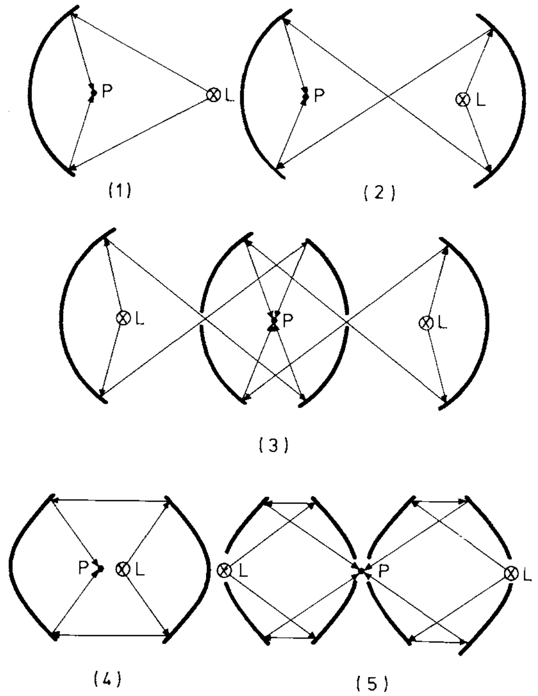

Fig. 6. Fundamental construction of optical heat sources (artificial suns). (1) Simple elliptical furnace; (2) double elliptical furnace; (3) multimirror system for two light sources with elliptical mirrors; (4) double mirror furnace with parabolic mirrors; (5) multimirror system for two light sources with parabolic mirrors (P = preparation; L = light source).

For example, *Foex*[53] and *Noguchi*[54] have determined the melting points of the trivalent oxides with a high degree of precision. *Trombe et al.*[55] used solar furnaces for zone melting, and *Kooy* and *Couruenberg*[56] and also *Collongues et al.*[57,58] for growing single crystals and for the purification of oxides. Using a solar furnace, *Segui* and *Trombe*[59] studied vaporization phenomena in the systems $La_2O_3$—$Nb_2O_3$/$TiO_2$/$Ta_2O_3$.

Numerous studies have been carried out on binary systems, *e.g.* $La_2O_3$—$Ln_2O_3$ (Ln = Sm, Ho, Yb, Y)[60], $ZrO_2$—$La_2O_3$[61], $ZrO_2$—$Nd_2O_3$[62], $ZrO_2$—$Sm_2O_3$/$Gd_2O_3$[63], and $ThO_2$—$La_2O_3$/$Sm_2O_3$[64-66]; the cooling curves[67] of the binary oxides $Ln_2O_3$ have been determined in the temperature range in which the Goldschmidt diagram (cf. Fig. 1) was still uncertain. In now already classical procedures, the phase diagram of the trivalent lanthanoid oxides (Fig. 8) has been conclusively elucidated, two new high-temperature forms (the H- and X-forms) having been found[68,69]. The allotropic conversions between the A-, B-, C-, H-, and X-forms[68,70] and the influence of alkaline earth metal oxides on the phase change between the C- and B-forms[71] have also been studied with solar furnaces. Since a low-valence oxide of europium EuO also exists, but cannot be readily obtained from $Eu_2O_3$, its isolation by *Achard*[96] by reduction of $Eu_2O_3$ under high vacuum with solar energy is noteworthy. In the early seventies, *Lopato* and *Kushewskii*[72] synthesized compounds of the composition $SrLn_2O_4$ (Ln = La—Lu) using solar furnaces at 2090 to 2240 °C.

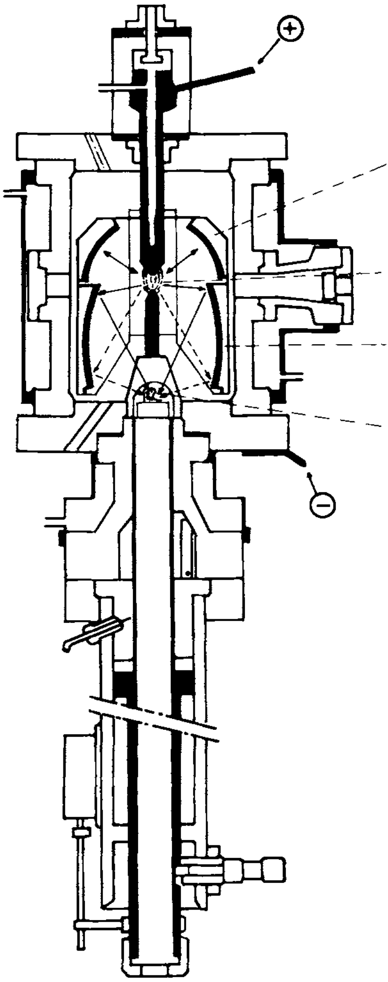

Fig. 7. Section through an electric arc furnace [52] for preparations under a specific gas atmosphere. A: Spherical mirror; B: electric arc; C: elliptical mirror; D: sample under a protective cap.

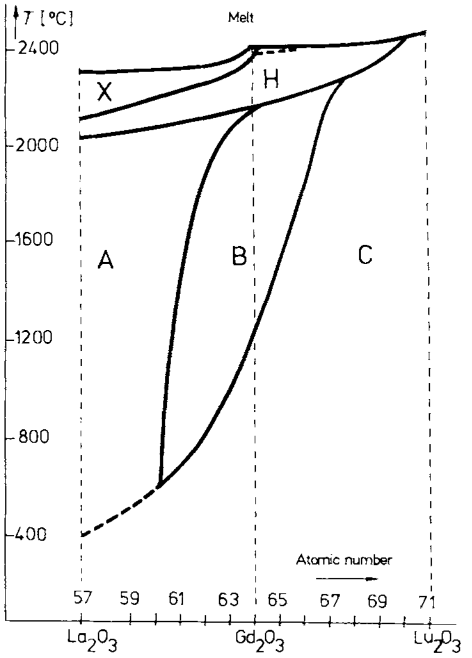

Fig. 8. Phase diagram for trivalent lanthanoid oxides [68, 69] with the new H- and X-high-temperature forms. For the A-, B- and C-types, see Section 1.

The essential problem in high-temperature chemistry is the prevention of wall reactions between the sample and its container. This is achieved by surface reactions on compressed finely divided material—the surface-acting solar furnaces are just as suitable for this as the $CO_2$ laser—or by a technique developed by *Trombe*[73], in which the molten material is processed in a centrifuge made of the same substance (Fig. 9). The advantage of this method, quite apart from the avoidance of wall reactions, is the utilization of the principle of a black body radiator for more accurate temperature measurement of the reaction mixture ("black body centrifuge"). For the problem of temperature measurement, see Section 3.5.

### 3.4. Plasma Torches

The modern plasma torches can be classified according to the manner of the plasma production:

1. Electric arc plasma torch
2. High-frequency plasma torch
   a) capacitative plasma torch
   b) inductive plasma torch
      α) open (normal-pressure) plasma torch
      β) closed (low-pressure) plasma torch

#### 3.4.1. The Electric Arc Plasma Torch

In the electric arc plasma torch the jet is produced by an electric arc (for a definition of plasma see [77]). The principle of *Wendler*'s[78] plasma torch for handling metal powders is presented in Figure 10. A high-density arc, traversed by a fuel gas (*e.g.* argon or nitrogen) which in this process is converted into the plasma state, is struck between a tungsten cathode and a copper anode. The fast gas flow prevents the arc from touching the cooled anode, *i.e.* the total electrical energy is essentially transferred into the plasma jet. The physical basis of all electric plasma-arc torches is thus the Gerdien arc[79], since the water-cooled anode causes a constriction of the plasma jet (thermal pinch effect), the current intensity and the temperature rising so dramatically that the high field intensities also produce a magnetic pinch effect.

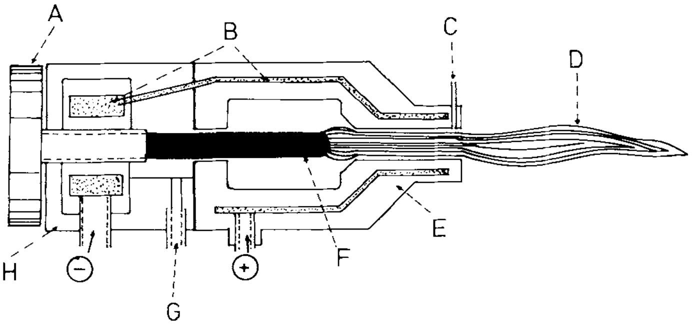

Fig. 10. Principle of an electric-arc plasma torch [78] for processing powdered materials. A: Adjustable electrode support; B: cooling; C: powder feed; D: plasma; E: anode; F: cathode; G: fuel gas supply; H: insulator.

The plasma jet can reach temperatures of 8000—50000 °C. Many descriptions of plasma torches and working techniques have been published[78,80-85], referring almost exclusively to material processing and treatment and to the synthesis of molecular compounds. Applications in the field of solid-state chemistry are hindered by the problems already mentioned in connection with hot flames (Section 2.2) and the extremely short residence time of the powdered samples within the plasma jet.

### 3.4.2. High-Frequency Plasma Torches

Of the two possibilities available for the transfer of high-frequency energy into plasma the method of inductive coupling is mainly preferred (for the use of capacitatively driven low-pressure plasma torches reference is made to *Veprek*'s work[86 91]). In inductive high-frequency plasma torches it is expedient to distinguish between the open and the closed variants.

*Open-high-frequency plasma torches:* open, inductively-coupled high-frequency plasma torches have been described by *Scholz*[92], *Reed*[93,94], and *Fricke*[95] (Fig. 11). Figure 11 shows two parallel quartz tubes surrounded by the induction coil of a conventional HF generator. At a working frequency of about 1—5 MHz a plasma torch, burning in the open air similarly to the electric plasma-arc torches against atmospheric pressure, is ignited by an electrode situated within the coil. However, the large thermal expansion of the fuel gas (ignition gas = argon, fuel gas = $N_2$, $O_2$, $H_2$, noble gases) causes an uncontrolled exhaustion of the plasma torch. To prevent this, *Reed*[93] designed a torch with a tangential feed of the fuel gas, producing a slight underpressure at the core of the jet. Because of this, charge carriers constantly flow back into the field of the induction coil. In this way it is even possible to carry finely divided material by the gas stream concentrically into the plasma jet, where it can react with the fuel gas[96] or can be fused and used for growing single crystals by the Verneuil process (cf. Fig. 11). *Reed*[97] grew centimeter-size single crystals of sapphires, $ZrO_2$ and metallic niobium in this way, since, given a suitable experimental setup, a fuel gas such as argon protects even extremely reactive substances such as niobium from the attack of $O_2$, $N_2$, $H_2O$, *etc.*

*Theta* and *Lejus*[98] obtained single crystals of $Nd_2O_3$ 2—3 cm in size by the Verneuil plasma torch process, which does not suffer from the disadvantages of an uncontrolled gaseous atmosphere of burning flames. The same authors also succeeded in making single crystals from oxide mixtures: CaO and $La_2O_3$ and also $Nd_2O_3$ and $La_2O_3$.

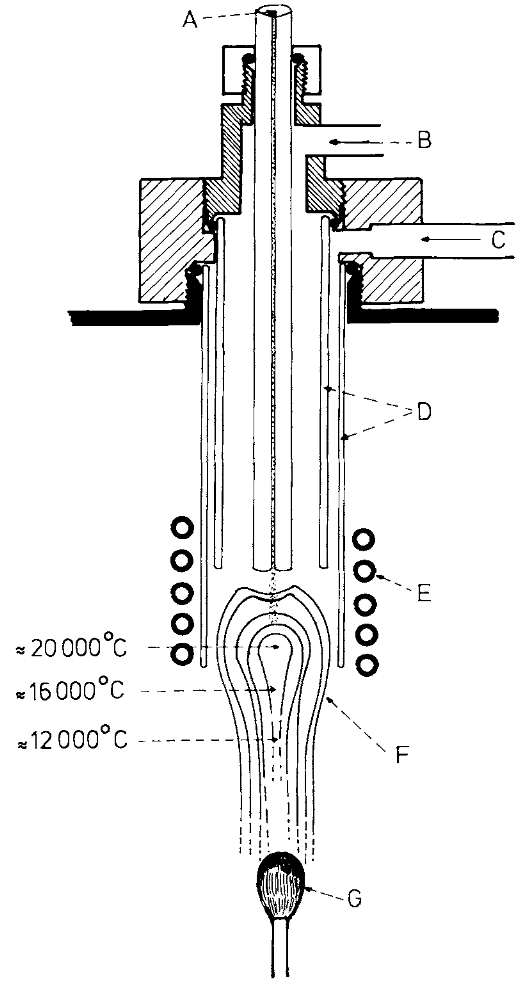

Fig. 11. Principle of an open (high-pressure) plasma torch [93, 94] with inductive coupling of the HF energy. A: Substance + carrier gas; B: plasma gas; C: cooling gas; D: quartz tube; E: induction coil; F: plasma torch; G: crystal.

Microwave plasma torches, whose operation has been described by *Scholz*[92], and which, depending on the frequency, lead to open point discharges, represent variants of the inductive high-frequency plasma torch shown in Figure 11. Figure 12 shows two designs, constructed as coaxial cavity resonators because of the high frequencies involved. The resonant cavity in Figure 12a is at the same time an anode oscillating circuit; by means of the capacitance $C_1$ a wavelength shortening is achieved, while $C_2$ allows adjustment to the transmitting tubes. Figure 12b shows a high frequency (2400 MHz) dipole coupling. The energy is taken by the electrode E from the cavity resonator, which serves as a transformer circuit, and conducted to the nozzle D. In both designs the plasma torch is stabilized by fuel gas escaping in the shape of a tubular envelope. For practical applications of microwave plasma torches reference may be made to a paper by *Seifert* and *Kappelt*[99], which deals with the growth of ferrite single crystals in a modification of the Verneuil process.

As against the above advantages of the open plasma torch, disadvantages arise in preparative solid-state chemistry, so that the applications in this field are restricted. Thus, the expansively burning flame—like chemical flames—makes it difficult to treat small quantities of the sample; powdered preparations can only be introduced into the jet in a stream, so that their residence time in the hot part of the plasma discharge is both short and uncontrolled. As a result of the steep temperature gradients of about 5000 °C inside the jet, it is almost impossible to carry out a homogeneous reaction combined with the establishment of a chemical equilibrium. For all these reasons the closed low-pressure plasma torch, developed in parallel with the open normal-pressure plasma torch, has proved more suitable for solid-state reactions.

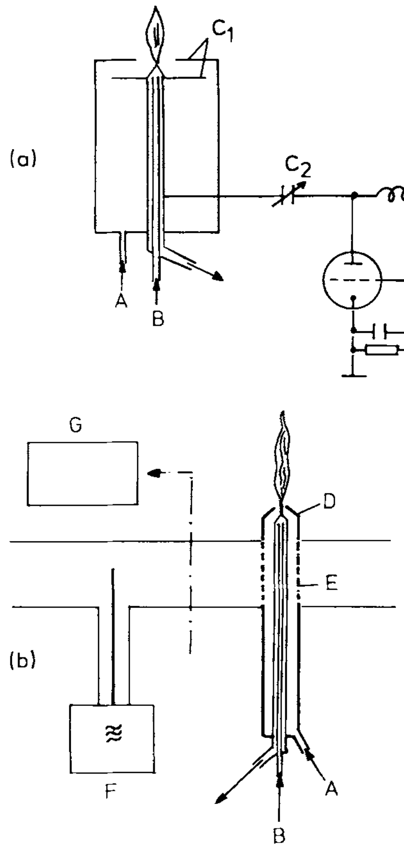

Fig. 12. Mode of operation of high frequency open plasma torches [92] (a) for several hundred MHz, (b) for 2400 MHz. A: Fuel gas; B: cooling; $C_1$, $C_2$: capacitators; D: nozzle; E: electrode; F: HF generator; G: cross section.

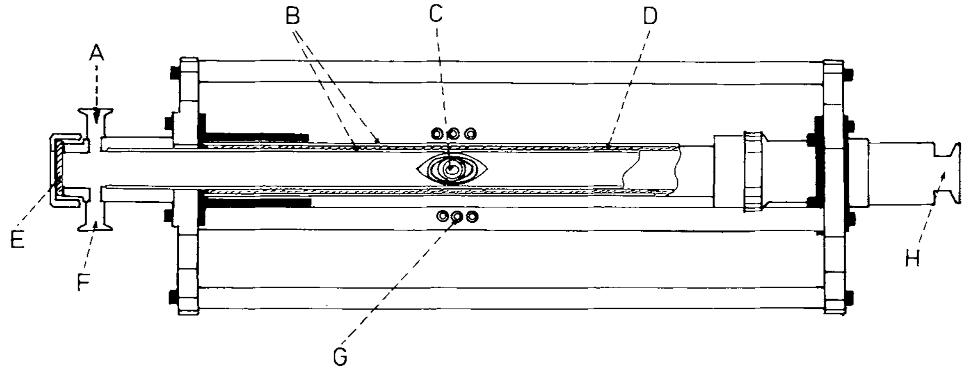

Fig. 13. Principle of a closed (low-pressure) plasma torch [100, 101] with inductive coupling of the HF energy. The torch can be displaced in a horizontal direction. The induction coil is fixed. A: Gas inlet (plasma gas); B: quartz tube; C: plasma; D: water cooling; E: window; F: pressure control; G: introduction coil; H: vacuum.

*Closed high-frequency plasma torches:* In contrast to the open, normal-pressure plasma torch, in the low-pressure variant there is a combustion chamber that can be evacuated (Fig. 13); the quartz tubes are cooled with water (tangential water cooling with a high pressure gradient).

If the inner tube is evacuated to 0.1—1 mbar, on inductive coupling of a high-frequency field (1—5 MHz) a steadily burning plasma jet is ignited at that point[100,101]. Samples pressed into pellets are situated in the cooled inner tube on a layer of MgO; rod-shaped pellets can be introduced coaxially into the plasma jet by moving the latter with a fixed induction coil. The sample temperature can be regulated sufficiently accurately *via* the HF power and the residual gas pressure. The energy is transferred from the plasma to the sample by collisions and radiation, by ionization and dissociation of primary species, by recombination of atoms to molecules, and in the case of a good intrinsic semiconductor by direct coupling of the heated sample to the high-frequency field. The advantages of the low-pressure plasma torch are the steadily burning and very hot plasma jet, the risk-free operation with hydrogen above temperatures of 3000 °C, and the introduction of energy as it were from within the tube onto the sample, so that, in contrast to conventional furnaces, the sample and not the furnace wall constitutes the hottest point in the entire system. The disadvantages of the closed plasma torch are the relatively low working pressure, which favors thermal decomposition of the reaction product, and the limitation of the available high-frequency power. Certain constructional prerequisites for water cooling of the quartz tube are already required at 12 kVA to prevent considerable delay in boiling. The fact that the low-pressure plasma torch works in a state of thermal disequilibrium, *i. e.* the electron and gas temperatures of the plasma torch can differ by $10^4$ °C, must be regarded as a drawback, but so far no perturbing influences have been observed in applications to solid-state reactions.

Originally only X-ray-perfect single crystals of lanthanoid oxides and their compounds were prepared with the closed plasma torch. Mention may be made at this point of the growing of $La_2O_3$ and $Nd_2O_3$ single crystals[102,103], whose structure proved to be more complicated than could be perceived in earlier works[14,16,104]. Stimulated by this result, which *Foex* and *Traverse* interpreted by the presence of a frozen metastable high-temperature modification, *Greis*[105] reinvestigated $La_2O_3$, heated to a relatively low temperature, by electron diffraction, while *Aldebert* and *Traverse*[106] studied the transitions between the A-, H-, and X-forms at high temperatures by neutron diffraction. Owing to the relatively low working pressure in the low-pressure plasma torch (0.1—10 mbar), $Tb_4O_7$ decomposes into $Tb_2O_3$[107] at high temperatures and dark-green to black single crystals are even obtained from the thermally stable $La_2O_3$[108], its color being due to a slight oxygen deficiency ($LaO_{1.5-x}$). Tempering of the black $La_2O_3$ single crystals in air regenerates the colorless form of $La_2O_3$.

The phase transformation between the monoclinic B-form and the hexagonal A-form in the $Sm_2O_3$—$La_2O_3$ system[109] has been studied by X-ray methods on single crystals from plasma torch reactions. Under appropriate experimental conditions, single crystals of $SrTb_2O_4$[110], $SrY_2O_4$[111], $LaYbO_3$[112], $LaErO_3$, $LaLuO_3$[113], $LaZr_2O_7$[114], and $Nd_2TiO_5$[115] have been obtained from oxide mixtures in low-pressure plasma torches to name but a few examples.

### 3.5. The $CO_2$ Laser

After it had become possible to raise the power of *Patel*'s[116] $CO_2$ laser by the admixture of nitrogen and helium[117–119] from the milliwatt range to 60—80 Watt per meter of discharge length, there was nothing left to hinder the development of high-power lasers into the kilowatt range. (For details of the energy transfer from the state of oscillation of the $N_2$ molecule to the laser level of the $CO_2$ molecule, the laser transfer into the $CO_2$ molecule, and the efficiency and power, see [120].) For preparative solid-state chemistry it is an important fact that the 10.6 μm radiation emitted by $CO_2$ lasers is absorbed and converted into heat by almost all substances. Thus, this working technique resembles those involving visible light, as already described in Section 3.3. For preparative purposes the laser radiation is generally focussed (KCl, $BaF_2$, or Ge lenses), the size of the focal spot influencing the power density; however, this can also be varied by continuous or pulsed energy output. Thus, according to our own experience[121], the size of the focal spot is limited only by the maximum laser power and the experimental conditions. Various working techniques for medium-power ($\approx 150$ W) and high-power ($\geq 450$ W) lasers have already been reported[121], so that here only the principle of a solid-state reaction with the $CO_2$ laser technique will be outlined. Figure 14 shows the way the focussed laser beam may be directed onto a sample, heating it to a high temperature in any desired atmosphere. The lenses and protective windows are made of KCl; a suitable gas flushing system should be used to ensure[121] that the windows do not become coated with vaporizing material, since even the thinnest film leads to absorption and hence destruction of the window. The sample can also be subjected to additional heating, by means of which the temperature gradient within it can be reduced from $\Delta_T \approx 2000\,°C$ to $\Delta_T \approx 500\,°C$.

The particular value of the laser technique lies in its possible applicability at high temperatures and pressures, *i. e.* conditions that frequently suppress the thermal decomposition of the reacting substances. High-temperature synthesis of lanthanoid oxometallates requires a high pressure of oxygen, which under these conditions is extremely reactive; so far only the laser autoclave technique[122] can prevent reaction of $O_2$ with the pressure vessel, in spite of the high sample temperatures. Figure 15 shows an autoclave with a window transparent to the laser radiation; the sample can be observed through a quartz side-port, using a television camera (for further details see [122]).

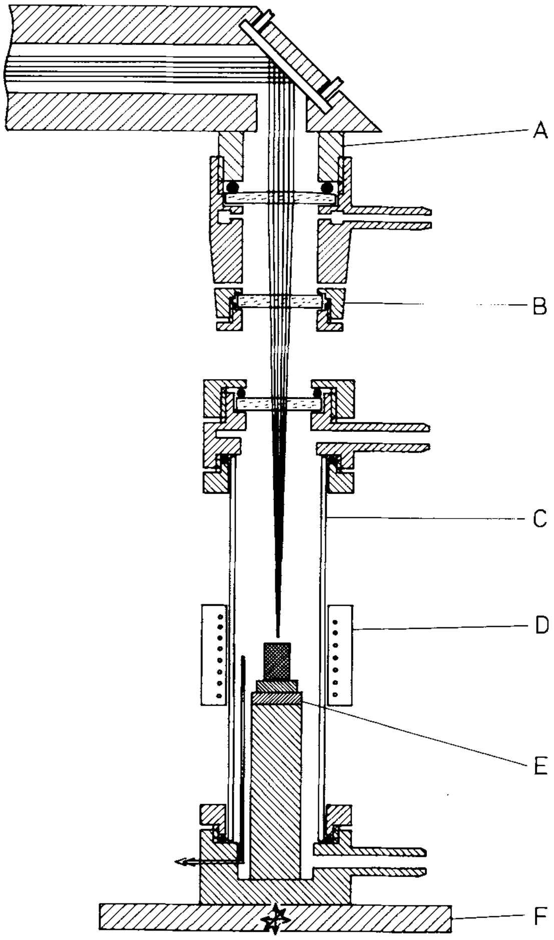

Fig. 14. Schematic representation of the performance of a high-temperature reaction with $CO_2$ laser energy under a specific atmosphere [121]. A: Collimator and focussing unit; B: protective window; C: sample space with the protective gas atmosphere; D: resistance heating; E: sample carrier; F: rotary, cross-slide and lifting stage.

The advantages and disadvantages of the laser technique have a decisive bearing on the course of a solid-state reaction. The advantageous features are, for example, high working temperatures kept constant over prolonged experimental periods, any desired gas atmosphere, and the very efficient transfer of energy to the sample. According to *Reed*[123-125], hot flames and laminar argon plasmas transfer 0.2 kW/cm$^2$ and a d-c arc transfers 16 kW/cm$^2$. The corresponding value for electron beams and lasers is $10^3$ kW/cm$^2$. A problem is that the energy absorbed in a thin surface layer is transported only poorly to the center of the sample, resulting in the build-up of an extremely steep temperature gradient. This gives rise to chemical disequilibria and in particular to the formation of metastable substances. This same disadvantage is of course the strength of the process when the aim is to prepare metastable high-temperature compounds. The metastable compounds $SrCa_2Sc_6O_{12}$[126], $SrCa_2Yb_{10}O_{18}$, and $SrCa_2Lu_{10}O_{18}$[127] have been synthesized by heating with plasma torches and quenching. *Foex*[70,71] as well as *Foex* and *Traverse*[67,69] describe impurity-stabilized modifications of lanthanoid oxides. Thus CaO, SrO *etc.* can, within wide limits (a few mol-% to molar concentrations) convert the cubic-C into the monoclinic B-form. The high-temperature reactions carried out with plasma torches and $CO_2$ lasers show that indeed small amounts of CaO "dissolve" in the lanthanoid oxides with stabilization of the monoclinic B-form; if the fraction of CaO *e.g.* in $Ho_2O_3$ exceeds 7%, a new, metastable compound $Ca_2Ho_2O_5$ is formed[128] with independent coordination polyhedra. Coincidentally, the positions of the metal atoms are identical with those in the monoclinic B-form; hence, the reason for the assumption in the cited papers of the presence of the monoclinic crystal form of the lanthanoid oxides on the basis of the X-ray powder diffraction patterns.

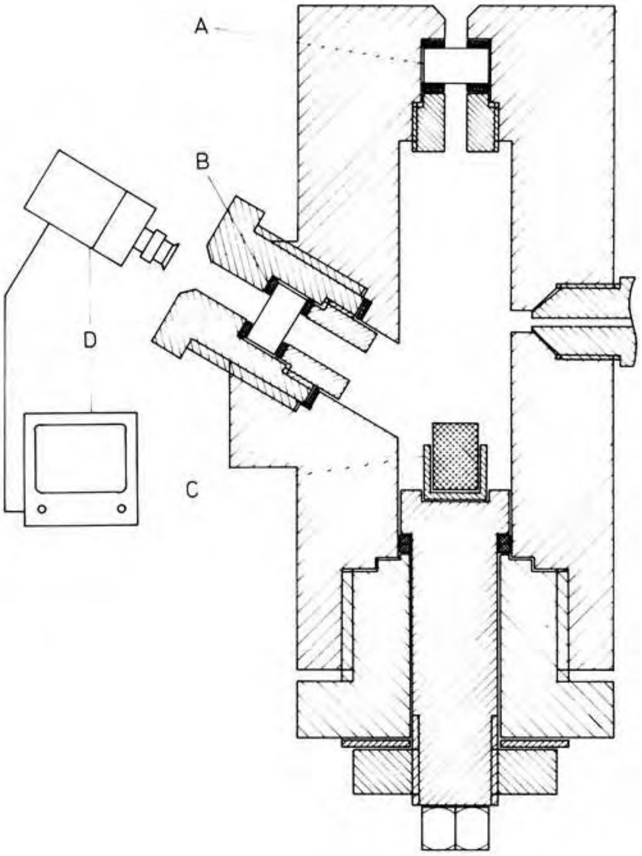

Fig. 15. Principle of a high-pressure autoclave for reactions with oxygen at high temperatures and pressures [122]. A: pressure-tight window permeable to the laser radiation; B: observation port; C: preparation support with solid preparation; D: TV camera with monitor.

A further interesting fact is that at high temperatures the calcium ferrite type ($MLn_2O_4$; M = Ca, Sr, Ba), normally stable in lanthanoid oxo-compounds, becomes unstable in the range of the light lanthanoids. The laser technique can be used to synthesize the metastable substances $Sr_3Nd_4O_9$[129] and $Sr_3La_4O_9$[130], in which $Sr^{2+}$ and $Nd^{3+}$ are distributed almost statistically, and $Sr^{2+}$ and $La^{3+}$ completely statistically, over the metal positions. Here a characteristic crystallochemical aspect of metastable lanthanoid compounds is recognizable.

The $CO_2$ laser technique allows risk-free operation with hydrogen atmospheres at temperatures in excess of 3000 °C, oxo-compounds of low oxidation state such as $La_2CoO_4$ and $Sm_2CoO_4$[131] being accessible with $Co^{2+}$ and $SrV_{10}O_{15}$ and $BaV_{10}O_{15}$[132,133] with a fraction of $V^{2+}$. By using high $O_2$ partial pressures above the reaction product single crystals of thermally unstable compounds can be synthesized at high temperatures[134], or higher oxidation states, such as $Ni^{3+}$ in $SrLaNiO_4$[135], can be stabilized.

Finally, let us consider briefly the problem of temperature measurement. With the exception of the laser and electron beam techniques, all other sources of heat emitting in the visible range (flames, furnaces, plasma torches, electric arcs, solar furnaces, *etc.*) give rise to considerable problems with accurate measurement of the surface temperature. The elegant pyrometric method requires a black-body radiator, *i.e.* the ratio of radiation emitted to that absorbed is equal to the intensity of the black-body radiator. This does not apply to the majority of substances having an absorption coefficient of less than one, so that elaborate calibration becomes necessary (cf. [52]). The $CO_2$ laser, however, emits in the infrared; as partially reflected radiation this is not recorded in the visible range in the pyrometric measurement, and the surface temperature of the sample can be obtained from its intrinsic emission.

## 4. Outlook

New methods for the generation and experimental application of high temperatures in the chemical laboratory have opened up new synthetic routes and facilitated the preparation of single crystals so important for structure determinations. Many compounds that cannot be synthesized at "lower" temperatures have now become accessible, the metastable substances being of special interest. Thus the metastable substances investigated so far are distinguished by daltonide compositions; however, considerable deviations are found in the micro region. Partial and total statistical occupation of point positions with metal ions of very different charge and electronic states are observed. In addition, under-population of certain regions of the metal lattice and stabilization effects of selected crystal structures by the incorporation of impurities are observed. These peculiarities of metastable oxometalates, observable in carefully performed structural investigations, lead to speculations about their possible physical properties. Thus, a mixture of metal ions with and without spin-orbit coupling having definite equivalent positions, *i.e.* in definite microsymmetry, could be interesting for magnetic studies. With metastable oxo-compounds a particularly small electronic work function can be expected within their range of stability and might provide stimulation to new investigations in the area of fluorescence phenomena of solids, extending beyond the investigation of doped pure substances. By skilful utilization of the thermal lability of various substances at sufficiently high temperatures it should be possible to obtain new nonstoichiometric compounds or phases. In particular, the possibility of working with atomic gases in plasma jets and the use of hydrogen at extremely hot sample surfaces (on bombardment with $CO_2$-laser jets) offer new ways to obtain low-valence compounds. Reaction of oxometalates with metals of low oxidation states beyond the first main- and sub-groups of the Periodic system can produce "anion-deficient" compounds which are distinguished by the extremely low coordination numbers of the metal ions. Compounds of this type constitute the scientifically fascinating transition to the metal-rich sub- and cluster compounds.

Finally, also of great interest to the high-temperature chemist is how methods which are already realizable shall one day find application in preparative chemistry. It is conceivable that nuclear energy and energy-rich particles could be employed, not as previously for radiative decomposition, but in combination with known methods for high-temperature radiative syntheses. For this reason many chemists are now eagerly awaiting future developments in the field of high-temperature chemistry, particularly with regard to the possible synthesis of new solid state compounds.

# Homoatomic Bonding of Main Group Elements

## By Hans Georg von Schnering[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Clusters of main group elements are not rare. On the contrary, it is becoming difficult to avoid the discovery of new substances of this type. Clusters are the natural intermediate stages between an element and its isolated atoms or ions. In the form of polycations and polyanions they offer models for the stepwise oxidation and reduction of an element and represent a bridge between the elements. The great majority of homonuclear bonded structures are already present in the solid phases of simple systems. Mobilization of these clusters as molecules represents a great challenge.

*"Then says little Max: that's easy!"*
[*Wilhelm Klemm*, lecture on inorganic chemistry, university of Münster 1951]

This, the birthday celebrants own, pithy introduction to the discussion of difficult factual material gives both courage and a warning that the greatest caution is needed. Even he who is advanced requires courage in order to apply himself, armed with insufficient knowledge and means, to that which is not yet really understood; but he will do it! The right and the duty to be sceptical lie with the reader; he should keep them alive.

## 1. Clusters: Aggregates of Things of the Same Kind

The term "cluster" was introduced as an attractive designation for the formation of $M_n$ groups of directly-bonded metal atoms M in metal compounds which are otherwise "normal"[1]. Such behavior is unexpected according to classical valence rules. There is no reason why this term should not be applied quite generally to emphasize regions of homonuclear bonding. Overlap with customary molecular descriptions, above all for compounds of the main group elements, are more useful than otherwise, since nothing disturbs the insight into the indivisibility of chemistry more than the staking of claims. Reference to the molecules $Na_2(g)$ and $F_2(g)$, which are in principle analogous, may be sufficient to illustrate this. Also, whether a cluster $E_n$ already counts as a cluster with $n=2$ or only when $n\geq 3$, whether polymers $E_\infty$ belong to the "claim" or not, whether electron deficiency is essential or not, these problems do not really exist. Let everyone use his own judgement and keep the boundaries open.

Today, cluster compounds are known of practically all elements. They occur as polycations, as polyanions and as neutral molecules. The selection given in Figure 1 shows that the size and stereochemistry of the cluster $E_n$ are variable within wide limits. In the solid state the clusters are often found linked *via* ligand bridges or directly condensed[2,3]. The consideration of the homonuclear bonded regions as quasi-isolated, "bare" units is, nevertheless extraordinarily helpful to a complete understanding.

Certain groups of elements form cluster compounds preferentially. These are: the heavy 5A, 6A and 7A elements, elements of the Fe group, the elements of the main groups 4B and 5B as well as, finally, boron. Since the atomic binding energies are highest for the above elements (Fig. 1), the con-

Heisenbergstrasse 1, D-7000 Stuttgart 90 (Germany)

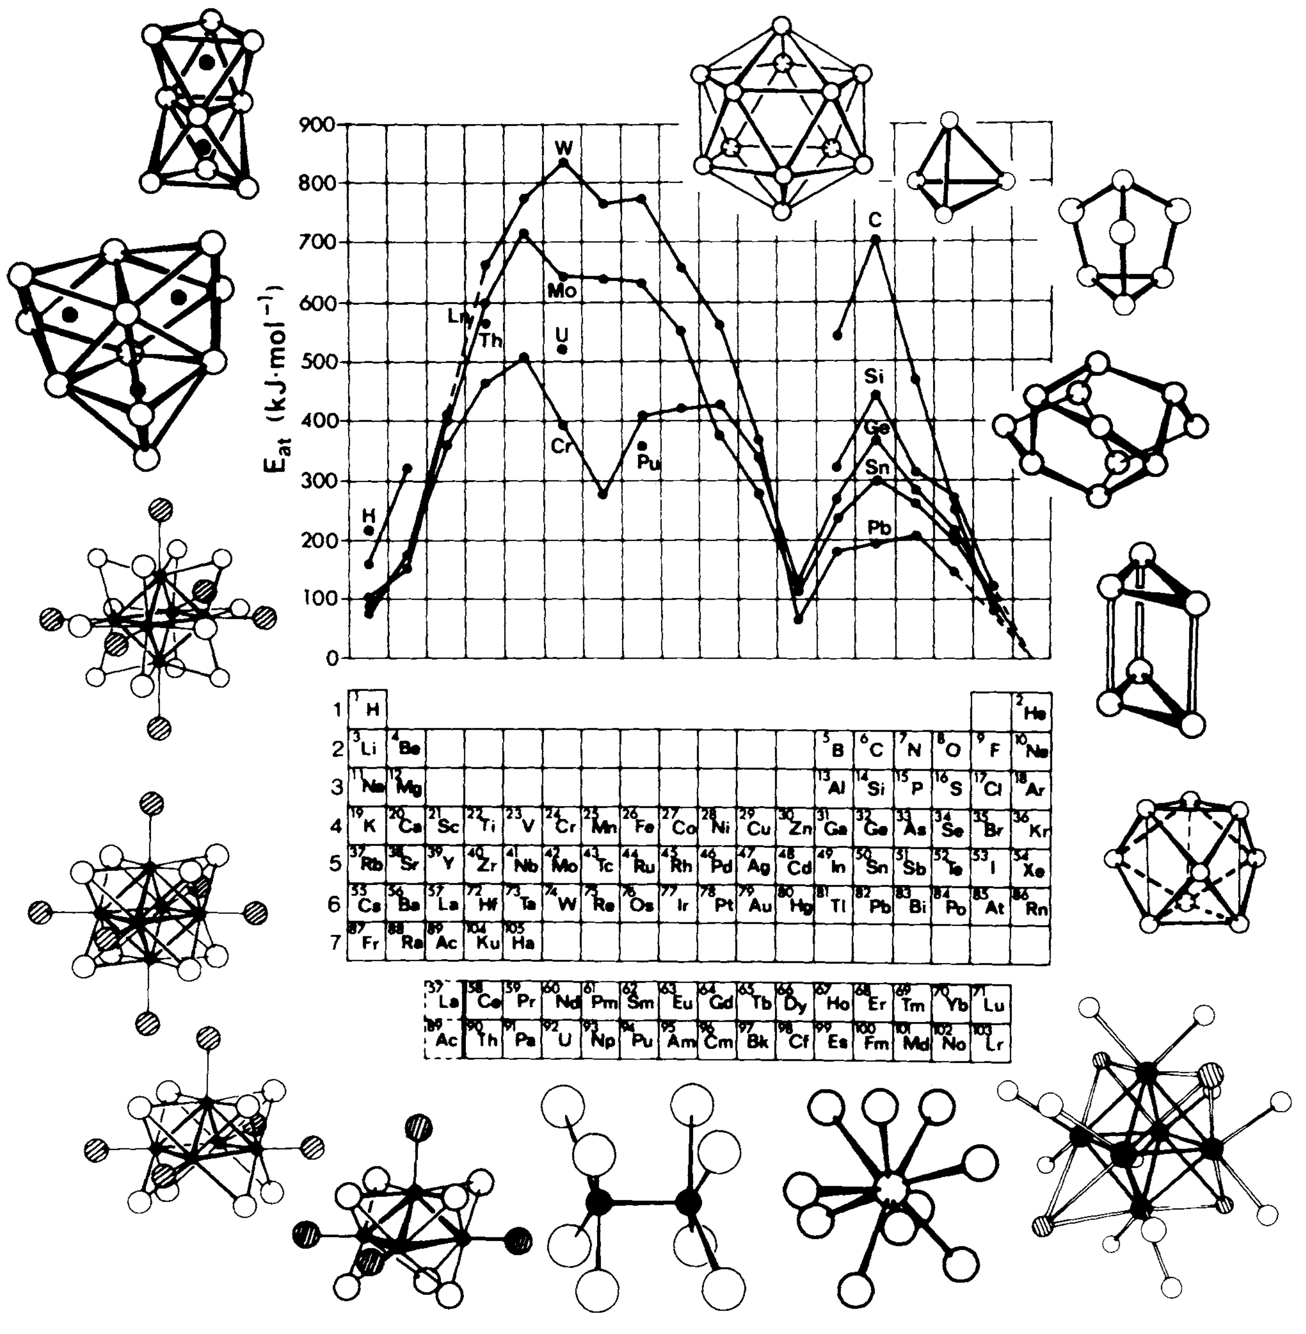

Fig. 1. Atomization energy $E_{at}$ of the elements [163]. Examples of clusters (clockwise) $B_{12}H_{12}^{2-}$, $P_4$, $P_7^{3-}$, $P_{11}^{3-}$, $Te_6^{4+}$, $Bi_9^{5+}$, $Rh_6(CO)_{16}$, $Au_{11}^{3+}$, $Re_2Cl_8^{2-}$, $Mo_4I_{11}^{2-}$ $Mo_5Cl_{13}^{2-}$, $Mo_6Cl_{14}^{2-}$, $Nb_6Cl_{18}^{4-}$, $Cs_{11}O_3^{5+}$, $Rb_9O_2^{5+}$.

nection between the occurrence of cluster compounds and the size of the homonuclear bond energy is obvious[2]. This energy, however, cannot be the only factor, as shown by the example of the $Hg^I$ compounds. After all, the homonuclear bond only has to be able to compete energetically with the heteronuclear bond.

The compounds with homonuclear linkages are often conspicuous because of their abnormal composition (as, for example, $Cs_{11}O_3$[4] or $Na_3P_{11}$[5]), which turns out to be normal in the sense of classical valence rules when one knows the structure and properties. A "normal" composition, however, does not rule out homonuclear bonds. ZnS, for example, is fully capable of building a tetrahedral structure as a Zn(I) disulfide with $Zn_2$ and $S_2$ pairs. The argument that this is a case of an oxidizing agent bound to a reducing agent without anything happening, is not serious, since there are many such examples, right up to charge transfer complexes. The clusters $E_n$ are in any case frozen-in redox steps between the element E and its electron-saturated formal cation or anion. The structural change which takes place parallel to these redox processes can be followed particularly well for the non-metals and meta-metals with predominantly localized bonds. The particular fascination of these compounds consists, therefore, not only in the occurrence of element-element bonds E—E, but also in the quasi-stepwise "break-up of element structures". Structural fragments are also formed in this process, of course, which are not formed as stable arrangements at all by the element; these correspond to excited states. The change in the electron balance often leads to structures which are typical for the neighboring elements. In this way, one crosses the periodic table step by step using "pseudo-elements" as a crutch. The cluster compounds lead finally to model structures, showing the first stages of reduction or oxidation of an element. The group $Cs_{11}O_3^{5+}$, the essential unit of the suboxide $Cs_7O$[4], shows that the oxidation of cesium leads to a localized elimination of oxygen while the rest of the metal remains intact. Oxygen is, therefore "precipitated" and not "dispersed". The structure of the cage compound $K_8Ge_{46}$[6]—corresponding to the gas hydrates $Xe_8(H_2O)_{46}$—with exclusively tetravalent Ge, shows that nothing happens to the germanium in the first stage of the reduction with potassium. The K atoms do not transfer their electrons to the Ge atoms, but form $K^+$ and give up the electrons to a conduction band without any appreciable Ge participation. A striking analogy to the solvation of electrons: germanium as "solvent" for $(K^+ + e^-)$!

The world of cluster compounds has found its place in the textbooks and the progress of recent years[7] has been described in detail in many articles[1–5,8]. The present article will concentrate on small regions of homonuclear linkage among main group elements.

## 2. On the Bonding

The bonding in clusters has been treated in various ways. The schemes for counting electrons developed by *Cotton et al.*[9], *Wade*[10] and *Lauher*[11] may be mentioned in this context. Each theory works well for particular types of cluster and leads in other cases to rather desperate efforts. A universal description of saturated and unsaturated systems does not seem to be easy to find. Apart from the boranes[12], the clusters of the main group elements can be treated extremely effectively using the comparatively simple valence rules of *Grimm* and *Sommerfeld*[13], of *Zintl*[14], of *Klemm* and *Busmann*[15,16] or of *Mooser, Pearson, Kjekshus* and *Hulliger*[17]. One should bear in mind, however, that the compounds are defenceless against our descriptions[18]. A description must be judged according to its effectiveness in relating stoichiometry, structure and properties.

The old (8-$N$) rule, generalized by *Mooser* and *Pearson*[17] uses a covalent model with collective counting of electrons. *Zintl*[4] and *Klemm*[15] examine local configurations in a setting of formal ions. Both descriptions are based on the assumption that the more electronegative partner B of a binary compound $A_mB_n$ obtains an octet configuration preferentially. With the first method, the sum of the valence electrons yields a universal statement on the number of homonuclear A—A and B—B bonds or on the number of nonbonding electrons. With the second method, one generates formal ions $A^{p+}$, $B^{q-}$, and ascribes to these, as pseudoelements E*, the homonuclear bonding of isoelectronic elements[5]. This yields for example, the well-known equivalence: $Si^{2-} \hat{=} P^{1-} \hat{=} S^0 \hat{=} Cl^{1+}$ for homonuclear bivalent units (2b)X. Finally, the Gillespie-Nyholm rules[19] are helpful in assembling the elements and pseudoelements together to form structures, or in analyzing structural principles. These electronic counting rhymes seem to be equivalent in many respects and can be summarized thus: (a) electron clouds repel each other.—(b) Isoelectronic units behave practically the same.—(c) The 8e rule and the 18e rule hold.—(d) Formal ions can be used with the bonding of isoelectronic elements or groups.—(e) for the same number of bonds various structural configurations are possible.—(f) Homonuclear bonds are supplemented by heteronuclear bonds in the sense of formal donor-acceptor interactions.

As mentioned above, the most important thing is to understand the relationship between stoichiometry ($\hat{=}$ number of valence electrons), structure ($\hat{=}$ electron distribution) and properties (color, conductivity, magnetism, reactivity *etc.*). Here are two examples of this: (1) The compound $K_8Ge_{46}$ (cf. Section 1) is a metallic conductor, since the K atoms have not given their electrons up to the Ge atoms (otherwise $(3b)Ge^-$ would be present and not $(4b)Ge^0$). If 8 Ge are substituted by 8 Ga, however, these fit into the structural framework as $(4b)Ga^-$. The conducting electrons are captured in the valence states and $K_8Ga_8Ge_{38}$ is a semi-conductor[20].–(2) $Sr_2As$ is described as a red compound, and must therefore be a semiconductor or insulator[21]. This is contradicted by the proposed structure, in which, besides "isolated" $As^{3-}$, only Sr atoms are supposed to exist with no indication of homonuclear interactions $(Sr^{2+} + e^-?)$. The electron balance, and therefore the formula, must be wrong. A new investigation shows that the compound is really $Sr_4As_2O$[22].

## 3. Structural Principles

Alone, the binary compounds which are formed between the electropositive metals and the non-metals and meta-metals are enough to constitute an overwhelming variety of substances, structures and properties. Figure 2 shows schematically which compounds have been identified up to the present time in one small region of the periodic table. The following compounds are formed, for example, between the alkali metals and phosphorus: $M_3P$, $MP_x$ $(x<1)$, MP, $M_4P_6$, $M_3P_7$, $M_3P_{11}$, $MP_5$, $MP_7$, $MP_{10.3}$, $MP_{11}$, $MP_{15}$. The substances are black up to the composition $M_4P_6$, and react immediatly with protic solvents. $M_3P_7$ and $M_3P_{11}$ are yellow or orange, but just as reactive. The remaining compounds are red or brown and, with increasing P content, more and more inert to mineral acids[5]. The remarkable variability in stoichiometry and properties is reflected in the structures, which indicate in multifarious ways the stepwise transition from the isolated $P^{3-}$ to elementary phosphorus. The structural variety can nevertheless be reduced to a few quasi-molecular building blocks, which are sections out of the various P modifications, or which could be structural parts of hypothetical forms of this element. Finally, all the structures can be built up from the atoms and pseudo-atoms $(3b)P^0$, $(2b)P^{1-}$, $(1b)P^{2-}$ and $(0b)P^{3-}$. A wide variety of structures is therefore based on relatively simple principles.

This holds in principle for all elements of groups 3B to 7B, even when the variety is not always so wide according to present knowledge. Silicon and phosphorus are developing visibly into "worthy" neighbors of boron and carbon, whose outstanding properties arise from a marked gregariousness. The structures which form are determined primarily by the number of valence electrons and are almost independent of the type of elements involved (Fig. 3). The decisive factor is the homonuclear bonding of the following: $(4b)Tl^{1-}$, $Si^0$, $P^{1+}$ or $(3b)Tl^{2-}$, $Si^{1-}$, $P^0$, $S^{1+}$ or $(2b)Si^{2-}$, $P^{1-}$, $S^0$ or

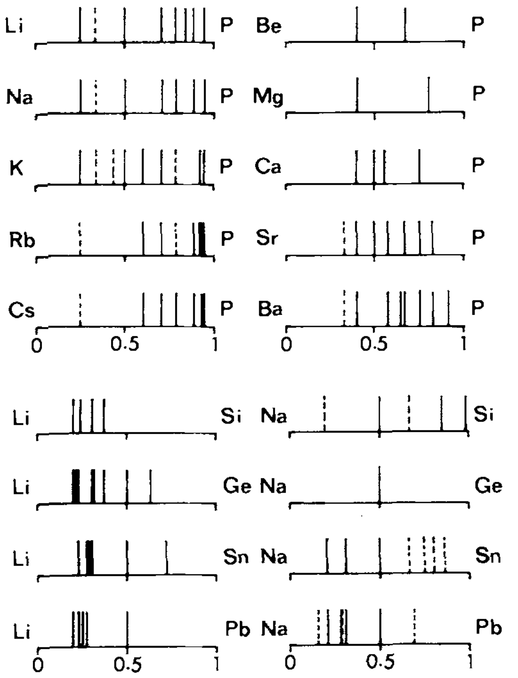

Fig. 2. Schematic representation of some binary systems. Compounds whose structures are certain are shown as continuous lines.

(1b)$Si^{3-}$, $P^{2-}$, $S^{1-}$, $Cl^0$, which lead to the formation of structures which are stereochemically identical or analogues. The great majority of homonuclear bonded groups are present in the solid state. They are, therefore, not "isolated", but bound to each other *via* heteronuclear interactions. In these intracollective interactions, the interatomic and intermolecular bonds between the pseudo-atoms E* and the pseudo-molecules M* (clusters), these units also behave just like the isoelectronic atoms and molecules. The heterobond can, as mentioned in Section 2, be treated independently of the intracluster bonding as an additional ionogenic bond or as a covalent donor-acceptor bond.

Some questions remain open despite the apparently closed picture (cf. Sections 2 and 6): in the treatment of degenerate bonds, in multicenter bonding, in the "assignment" of electrons used for external bonds. For example, the system $Si_4^0$[23], which has been proven to exist in an argon matrix, can be compared with $B_4Cl_4$. The tetrahedral cluster is—in contrast to $P_4$—formed by four three-center bonds, which in this manner provide each cluster atom with three shared electron pairs. The Si atoms in $Si_4^0$ complete their tetrahedral electron configuration (octet) by using free electron pairs, the B atoms in $B_4Cl_4$, on the other hand, by σ bonds to the Cl atoms. The equivalence can be described either by removing the "ligands" $[(B^+)_4 \triangleq (Si^{2+})_4]$ or by counting the electron pairs as part of the cluster $[(B^-)_4 \triangleq (Si^0)_4]$. This arbitrary method of cutting the outer bonds in different ways is capable of opening up interesting new aspects, *e.g.* a tetrahedral cation $(P^+)_4$.

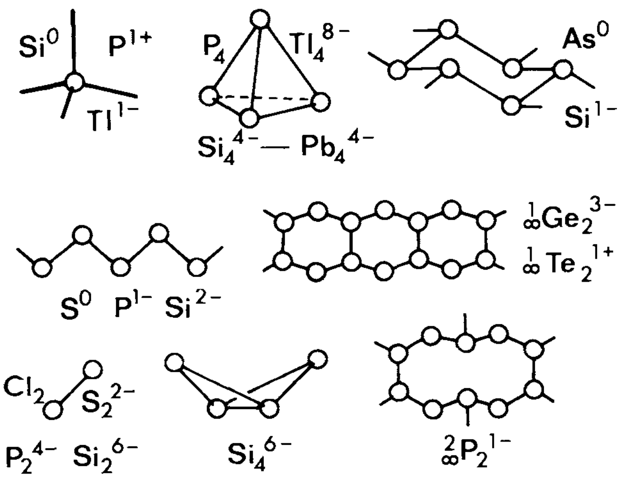

Fig. 3. Homonuclear bonds for isoelectronic elements E and pseudoelements E*.

## 4. Chain Structures

A series of compounds of the elements Zn, Cd, Hg and In are known which contain *polycations* of increasing chain length (Fig. 4). Examples are $In_2^{4+}$ and $In_3^{5+}$ in $In_6Se_7$ and $In_4Se_3$ respectively[24], $Zn_2^{2+}$ in the black $ZnP_2$, and $Cd_2^{2+}$ in the isostructural $CdP_2$[25]. In the case of mercury, the $Hg_2^{2+}$ groups are typical for $Hg^{I}$, and $Hg_3^{2+}$ and $Hg_4^{2+}$ have also been found in yellow and red salts respectively[26]. The final member of this condensation is also known: the metallic compound $Hg_{2.86}[AsF_6]$ contains the infinite, linear polycation $Hg_{2.86}^{1+}$ with the formal oxidation state $Hg^{0.35+}$[27]. In this way, an isolated metallic thread of mercury forms step by step from a molecular cation. A special feature of this compound is that the translational identity of the Hg atoms belonging to the "string" is incommensurate with that of the anions $[AsF_6]^-$; a strong indication of the autonomy of this string of pearls in its box.

The polyanions of phosphorus, arsenic and antimony in their compounds with the electropositive metals provide impressive examples of the configuration and conformation of homonuclear, two-bonded elements (2b)E or (2b)E*. The stepwise dismantling of 1-dimensional infinite chains can be studied using these structures. The *polyanion* $^1_\infty(X^{1-})$ is characteristic, not only for the alkali metal compounds MX, but also for the $MX_2$ compounds of the bivalent cations. There is a series of structure types, all of which possess the same helical construction, but which differ in the conformation of the helices and in their packing[28]. The diphosphides and the diarsenides of the lanthanoids form two structure types: the $LaP_2$ type[29] and the $CeP_2$ type[5,30], which are stable at high and low temperatures respectively. In the first structure type an $X_3^{5-}$ group occurs together with an $X_5^{7-}$ group, while the second structure type only contains $X_4^{6-}$ anions. In structures of the $Ca_2As_3$ type the groups $X_4^{6-}$ and $X_8^{10-}$ exist side by side[31], while the structures of $Eu_2Sb_3$[32] and $Sr_2Sb_3$[33] contain only $X_6^{8-}$ anions. The $Sr_3As_4$ structure, which is formed by almost all phosphides and arsenides of the divalent cations, is also characterized by $X_4^{6-}$ chains, although with a different conformation (torsional angle 90°)[34–36]. The adaptability of these polyhedra to external conditions, such as size and coordination of the cations, is shown in Figure 4 for the conformation of several $^1_\infty(2b)X^-$ chains. Each chain is labeled here by the sequence of the torsional angles γ and by the (analogous) conformational type: s ≙ staggered and e ≙ ecliptic.

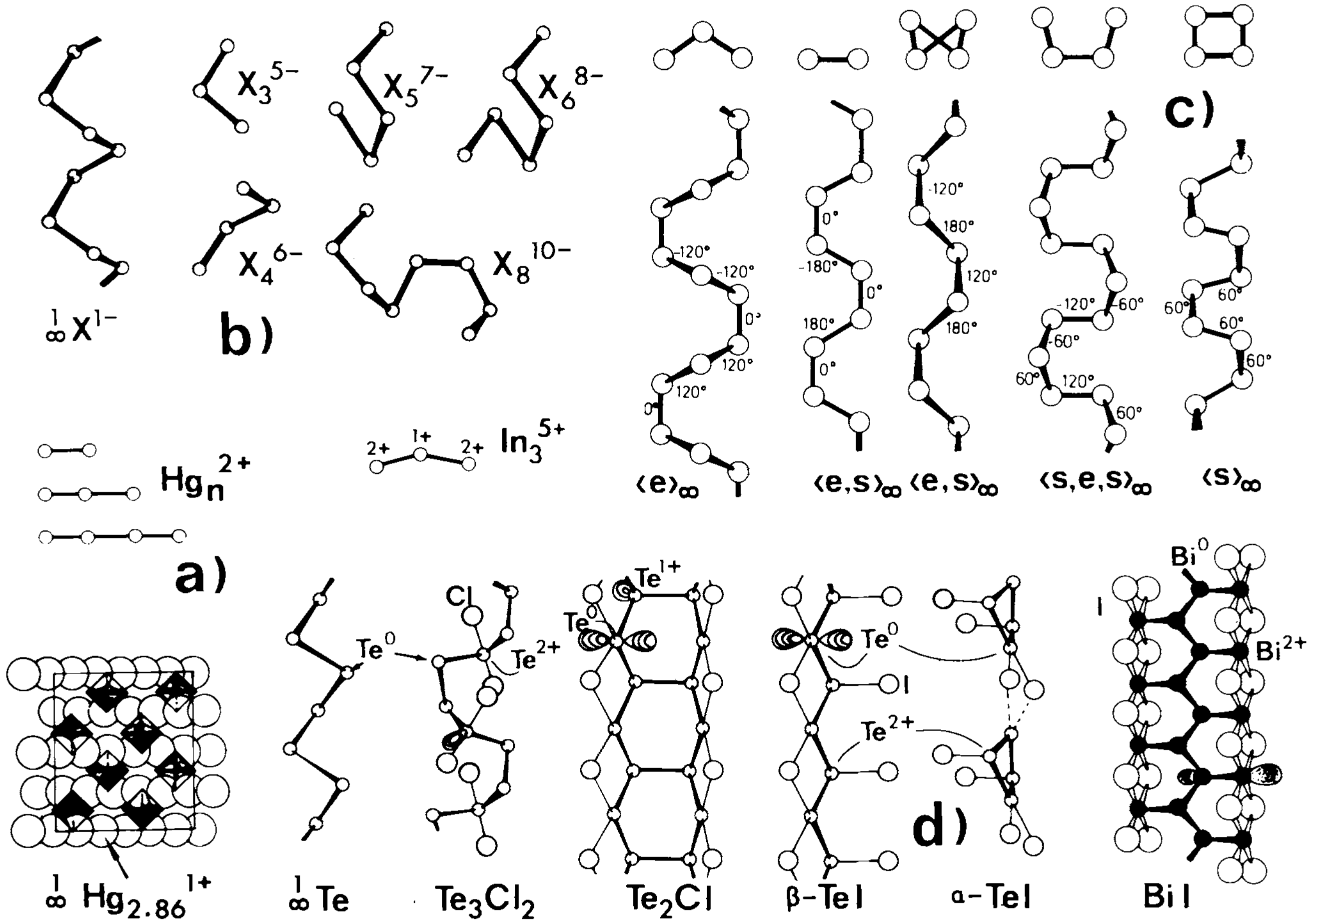

Fig. 4. Homonuclear chains. a) Polycations of Hg and In. b) Polyanions of P, As and Sb. c) Conformation of one-dimensional infinite polyanions in (from the left): BaAs$_2$ [94], GdPS [164], EuAs$_2$ [94], BaAs$_2$ and LiAs [105]: the projection in the chain direction (top), the dihedral angles and the conformation (s, e) are given. d) Linkage of Te and Bi in subhalides; the formal electron configuration is drawn for some atoms.

Several examples of polyanions with branched chains can be found among the subhalides of bismuth and tellurium: BiBr[37], BiI[38], Te$_3$Cl$_2$, TeCl and TeI[39]. The monohalides BiX possess several modifications, all, however, with the same structural principle (Fig. 4d). The branched one-dimensional infinite Bi chain can be regarded as a strip, which has been cut from the two-dimensional structure of condensed six-membered rings found in elementary bismuth. The Bi atoms are bonded in different ways. One half of them control three homonuclear bonds as (3b)Bi$^0$, the other half, in contrast, only one. Only these (1b)Bi$^{2+}$ possess Bi—X bonds so that these monohalides are mixed-valence Bi$^0$/Bi$^{2+}$ compounds of the type $\{$Bi$^0$[BiX$_2$]$\}$. In the subhalides of tellurium, modifications of the $^1_\infty$(2b)Te$^0$ chain can be found. Te$_3$Cl$_2$ still contains this chain, but every third Te atom is additionally bound to two Cl atoms (Cl$^-$ as donor). This Te atom has, therefore, a ψ-trigonal bipyramidal configuration, when the remaining free e$_2$ pair is included; a conceivable arrangement for Te$^{2+}$: $\{$Te$_2$[TeCl$_2$]$\}$. In the TeCl$_2$ structure, two Te chains are united to form a band of condensed six-membered rings. This Te$^{2+}$ band has the same structure as the Ge$_2^{3-}$ unit in the compound Sr$_3$Ge$_4$[8a] (Fig. 3). The three-bonded atoms behave like Sb atoms: (3b)Te$^+$. The others possess two additional Cl bonds (Cl$^-$ donor) as in Te$_3$Cl$_2$, but in a configuration which, according to *Gillespie*[19], corresponds to a ψ octahedral coordination: (2b)Te$^0$. At first glance, it appears strange that Te$^0$ is bound to Cl and not Te$^+$, but polar structures like $\{$Te$^+$[TeCl$_2$]$^-\}$ are not unusual. α-TeI and β-TeI are also mixed-valence compounds with, formally, ψ-tetrahedral (2b)Te$^{2+}$ and ψ-octahedral (2b)Te$^0$ (Fig. 4d). The Te$_4$ ring in α-TeI (as Te$_4^{4+}$) corresponds to the As$_4^{4-}$ anion in CoAs$_3$[40].

The polysulfides and polyiodides, which have been known for a long time, also belong to the group of compounds with homonuclear chains. They have been discussed in detail, for example, by *Steudel*[41] and *Tebbe*[42]. Sulfur linkages give examples of conformational variations which allow both cyclic and helical structures. For the iodides, on the other hand, gliding transitions between weak interactions I—I···I$^-$ and degenerate bonding states (I--I--I)$^-$ are typical, in which a local simulation of the non-metal→metal transition can be seen. One finds I$_\infty$ chains formed from regular or irregular series of I$^-$, I$_2$, I$_3^-$ and I$_4^{2-}$ units in compounds which possess rigid frameworks with suitable cavities. This is realized in various ways, *e.g.* with complex cations[43], with dextrins[44], in Tl$_3$I$_4$[42] or the variable iodides of the type M$_x$Tl$_6$I$_6$(I$_4$)[45]. I$_\infty^{z-}$ anions of this type are found to have incommensurable transitions, as for the (Hg$^{0.35+}$)$_\infty$ cations mentioned above. With regard to the non-metal→metal transition, the I chains represent the state below the critical temperature $T_c$ (partially localized bonds) and the Hg chains the state above $T_c$ (degenerate bonds).

## 5. Rings

Small homonuclear rings have been studied and described many times in detail, as for example, those in the silanes by *Hengge*[46] and those in the phosphanes by *Baudler*[47]. In particular, the latter investigation has recently led to the statement that the $P_3$ ring is apparently the most stable three-membered ring system[48]. Therefore, only a few structures will be treated here which can be discussed as π-systems, as well as some larger ring systems in polymeric structures.

The butterfly anion, $Si_4^{6-}$ in $Ba_3Si_4$[49] is, as a 22-electron system, the opened $Si_4^{4-}$ tetrahedrane[16,50,51]. It is also the monomeric structure of the polymeric ${}^1_\infty Ge_2^{3-}$ or ${}^1_\infty Te_2^{1+}$ (Fig. 3). At the same time, the $Si_4^{6-}$ butterfly, as a localized bonded system, can be equated to the isoelectronic groups $Bi_4^{2-}$[52] and $Te_4^{2+}$[53] with delocalized π bonds (Fig. 5).

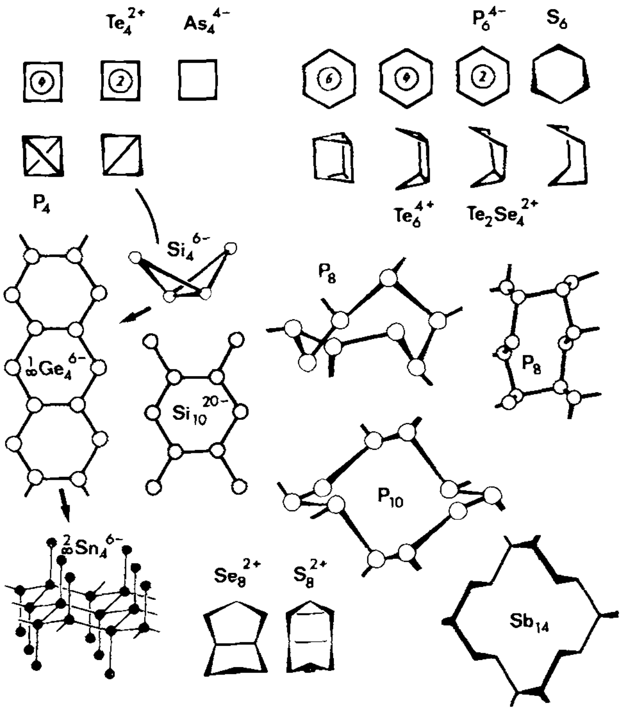

Fig. 5. Homonuclear ring systems (cf. text). On the lower right hand side are the condensed $P_8$ rings from $EuP_7$ [64] and $Th_2P_{11}$ [65], the $P_{10}$ ring from $EuP_7$ and the $X_{14}$ ring from the $MX_3$ compounds (M = Ca, Sr, Ba, Eu; X = P, As, Sb).

These systems behave, then, just like the cations $S_8^{2+}$ and $Se_8^{2+}$[54]. The heavy alkali metals form the compounds $M_4X_6$ with phosphorus and arsenic, in which strictly planar $X_6$ rings occur[55,56]. The bond distances P—P = 215 pm and As—As = 237 pm are noticeably shorter than the single bond lengths (221 and 245 pm, respectively). The formula $X_6^{4-}$ yields a "cyclohexene system" (here with a delocalized double bond). The existence of the isoelectronic $Te_6^{2+}$ is not yet certain, but for the cation $Te_6^{4+}$ a variant of the prismane series analogous to cyclohexadiene has actually been proven to exist[57] (Fig. 5).

The planar $Si_5$ rings and $Ge_5$ rings in the compounds $Li_{12}Si_7$[58] and $Li_{11}Ge_6$[59] must be mentioned as well. Higher bond-orders in the sense of cyclopentenes with delocalized double bonds can be argued for these compounds as well[58]. On the other hand, crystal fields can also stabilize excited molecular states. The first of the two SrSi modifications[60,61] contains normal ${}^1_\infty Si^{2-}$ chains with $(2b)Si^{2-}$. The other form possesses, however, the unusual planar ion $Si_{10}^{20-}$ (Fig. 5) with four $(3b)Si^-$, two $(2b)Si^{2-}$ and four $(1b)Si^{3-}$, that is, with three different states of charge. In this connection it is interesting to look at the polyanion ${}^2_\infty Sn_2^{3-}$ in $Li_5NaSn_4$[62]. It has the same structure as the isoelectronic carbon monofluoride $(CF)_n \mathrel{\hat{=}} (SnSn^{3-})_n$ (Fig. 5). With this ion, we have not only monomeric and polymeric variations of the homonuclear combinations $E_2E_2^*$ with $Bi_4^{2-}$, $Si_4^{6-}$, $Ge_4^{6-}$ or $Sn_4^{6-}$, but also all the limiting cases of formal charge distribution:

$$\{(2\tfrac{1}{2}b)Bi^{1.5-} + (2\tfrac{1}{2}b)Bi^{1.5-}\} \rightarrow \{(2b)Si^{2-} + (3b)Si^{1-}\} \rightarrow \{(1b)Sn^{3-} + (4b)Sn^{0}\}$$

Polymeric anions often contain large, linked ring systems, which are worthy of some interest because of their conformations. Examples are (Fig. 5): the $Ge_8$ ring of LiGe[63] with the $S_8$-crown conformation, the $P_8$ rings of $EuP_7$[64] and $Th_2P_{11}$[65], the $X_{14}$ rings of $CaP_3$[66], $SrAs_3$[67] and $BaSb_3$[68], and the $P_{12}$ rings of $LaP_5$[5,69] (cf. Section 11). Unfortunately, chemical methods are not yet available which can systematically separate and isolate such systems from the polymeric structures in solids.

## 6. Polycyclic Systems

The polycyclic polyhedra are particularly interesting for chemists, because they provide an immediate link between the structures of solid materials and known isolated molecules. In principle, the polyhedra span the surface of a sphere; their vertices are the atoms of a cluster. Two-center bonds correspond to the polyhedral edges, multicenter bonds the polyhedral faces. If one expects for the main group elements in the simplest case an electron octet with tetrahedral configuration, then those polyhedra are most interesting whose vertices are shared by three edges or three faces: *e.g.* tetrahedron $A_4$, trigonal prism $A_6$, cube $A_8$, pentagonal prism $A_{10}$, pentagonal dodecahedron $A_{20}$ and others. The faces correspond in chemical language to the rings of polycyclic systems, *e.g.* three-membered rings in the tetrahedron. The edges of the polyhedra can be bridged by additional atoms, which then represent "improper" two-bonded vertices (2b)A, without violating the Euler relationship between vertices, edges and faces of convex polyhedra[5,70]. The adamantane structure remains analogous to the tetrahedron despite the six two-bonded bridges. In such polyhedra, the missing bond functions will be directed outwards and be characterized by free electron pairs $e_2$ (donor), empty orbitals (acceptor) or ligands. Each atom which occupies a "proper" vertex of a cluster of this type with two-center bonds must contribute at least 5 electrons or 3 electrons and one ligand, while a bridging atom requires a configuration analogous to $>CH_2$. In this way, the elements of main group 5 (or isoelectronic pseudoelements E*) are the natural building bricks for polyhedra of this kind, as for all other "peripheral" structures. If the number of electrons per atom is less than five, only polycyclic groups with multicenter bonds remain, if one neglects for a moment the possibility of three-dimensional linkages. In clusters of this sort, more than three edges meet at a vertex (octahedron, icosahedron, among others) and polyhedra with triagonal faces seem to be preferred. The large family of the boranes was first described by *Lipscomb*[12] using a sophisticated system of two 2-center and three-center bonds, which span the surface of the polyhedra while including the H atoms. *Wade*[10], *Lauher*[11], *Williams*[71] and *Mingos*[72] have chosen MO treatments, which were also applied to clusters in general.

The real problem is actually the question: when is an arrangement with only one *exo*-bond per atom electronically saturated, and therefore particularly stable and, do the atoms involved strive for an 8e shell or an 18e shell? Playing with these electron counting rules[73] can be very stimulating (cf. the examples in Fig. 6).

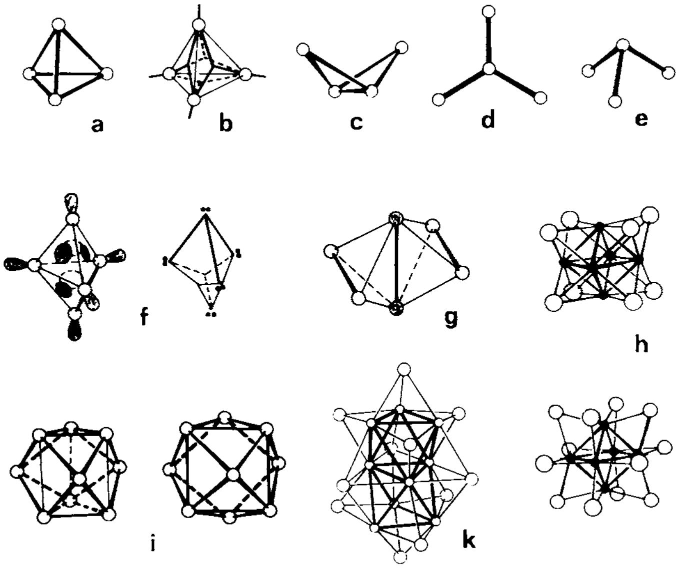

Fig. 6. Polycyclic systems I (cf. text): a) $P_4$, $Si_4^{4-}$ *etc.*; b) $B_4Cl_4$ or $Si_4$ with 3c-2e bonds; c) $Si_4^{6-}$; d) $Si_4$ star; e) $P_4^{6-}$; f) two views of $Bi_5^{3+}$; g) $Nb_2S_4^{4+}$ as double tetrahedron; h) $M_6X_8$ and $M_6X_{12}$; i) $Bi_9^{5+}$ or $Sn_9^{4-}$ as {3,3,3}-polyhedron and as {1,4,4}-polyhedron; k) $Mo_9S_{11}^{4-}$.

The stable configuration of a *closo*-$E_4$ tetrahedrane should be a 10e system according to *Wade*, if the *exo*-bonds are neglected. It could be described with one 4c-2e bond[*] and four 3c-2e bonds, which, however, together with the *exo*-bonding implies that the octets of the atoms are exceeded. Examples are not known. Instead, $B_4Cl_4$ and $Si_4$[23] exist with, in each case, 8 electrons in the skeleton, for which four 3c-2e bonds yield a tetrahedral configuration of the vertices. Since an additional electron pair cannot improve this configuration for any of the atoms involved, this is presumably the reason why a tetrahedral cluster is not stabilized with exactly 4+1 bonds. The same may be true for the other polyhedra whose vertices are shared by three faces. The saturated $P_4$ tetrahedrane is, as a 20e system, that is, with 12 electrons for skeletal bonds, without doubt the most stable configuration. Its isoelectronic relatives should be mentioned again (see Section 3): $As_4$, $Sb_4$, $Bi_4$, $Si_4^{4-}$, $Ge_4^{4-}$, $Sn_4^{4-}$, $Pb_4^{4-}$, $Tl_4^{8-}$ and, last but not least, the carbon compounds $C_4R_4$[74]. This is another case where a further electron pair is superfluous after the six 2c-2e bonds along the polyhedral edges have been built up into a formal tetrahedral electron configuration. The treatment of this cluster as a *nido*-$E_5$-polyhedron according to *Wade* conceals, however, a fascinating component. The $E_4$ tetrahedron would, in this sense, be a trigonal bipyramid with one missing vertex, which implies that we have a "tetrahedron" opened on one side—that is, a trigonal pyramid. Since this opening can take place in four different ways, the tetrahedral topology of $P_4$ would perhaps only result from a dynamic process. On the other hand, the tetrahedral cluster with exactly 20 electrons fits into the bonding scheme of *Lauher*[11], which requires 60 electrons in the stable configuration for 18e components. For the higher homologues one only has to add the electrons from the complete $d^{10}$ shell. For $P_4$ and $Si_4^{4-}$, we can imagine the empty 3d states as "reserving places" for 4 × 10 electrons, and in this strange way we come back to the participation of d orbitals in the bond scheme of these elements. But: "God is just!"[75], the carbon tetrahedrane is not satisfied with this description.

The uptake of two electrons certainly causes the tetrahedron to open up and form the butterfly cluster or its analogous forms with 22 electrons such as $Si_4^{6-}$ (see Section 5). With six electrons one of the three-membered rings is fully opened. This 26e system is isoelectronic with $SO_3^{2-}$ and is realized as a homonuclear unit in *e. g.* the trigonal pyramidal $P_4^{6-}$ anion of the polyphosphide $La_6Ni_6P_{17}$[76]. Meanwhile, the $Si_4$ cluster of the compound $Li_{12}Si_7$[58] sets us a real problem. The cluster forms a trigonal planar $Si_4$ star (Fig. 6d), a topology which is very appropriate for Stuttgart! $Li_{12}Si_7$ is a diamagnetic semiconductor, which removes all excuse for not treating it because it is an intermetallic phase. The compound $[Li_{24}Si_4(Si_5)_2]$ contains, besides the $Si_4$ star, two planar $Si_5$ rings. If these rings are described as saturated cyclopentanes $Si_5^{10-}$, then the 20e-system $Si_4^{4-}$ remains. This really should be a tetrahedron! Is this an excited state of the $P_4$ molecule, stabilized by the crystal field? This trigonal structure, on the other hand, reminds us directly of the $CO_3^{2-}$ anion, a 24e system. Using this description, with the units $Si_4^{8-}$ and $Si_5^{8-}$, the $Si_5$ rings would be left with the 28 electrons of a cyclopentene with a delocalized double bond. The bond lengths in both groups point at first glance against higher bond orders. They lie clearly in the range of single bonds with $d(Si—Si) = 236$ to 239 pm. This question will be discussed again in Section 13.

The trigonal bipyramidal 22e systems $Pb_5^{2-}$[77] and $Bi_5^{3-}$[78] are representatives of the $E_5$ cluster. Both *Lauher*'s rule (72e after adding 5 × 10 d electrons) and *Wade*'s rule (6 $e_2$ pairs for the skeleton) hold here. According to *Gillespie*[79], six 3c-2e bonds are present in these clusters (Fig. 6f). Here, the two apex atoms would have "tetrahedral", the three equatorial atoms "square pyramidal" electron configurations. If one chooses to describe the system as a mesomeric state between two limiting cases, with in each case three 3c-2e bonds and three 2c-2e bonds (Fig. 6f), all atoms would have, formally "tetrahedral" electron configurations. On homolytic separation one obtains the distribution of positive charge in $Bi_5^{3+}$ according to (a): $2 \times Bi^{+} + 3 \times Bi^{1/3+}$ or (b): $2 \times Bi^{1/2+} + 3 \times Bi^{2/3+}$. Model (b) yields, with 3c and 2c bonds, a more even distribution of charge on all atoms and, in fact, for both $Bi_5^{3+}$ and $Pb_5^{2-}$. Of course, only an exact analysis of the *exo*-contacts and, above all, a quantitative calculation, can show whether this is correct.

Octahedral $E_6$ clusters are typical for the transition metals. Among the main group elements only $B_6H_6^{2-}$ and the

---

[*] 4c-2e bond stands for a four-center two electron bond *etc.*

linked $B_6$ octahedra in the hexaborides of the type $CaB_6$ are known. In this case, the skeleton is formed from 14 electrons ($\hat{=}6+1e_2$). This agrees with the Wade rules. An 86e system (7 $e_2$ for the framework, 6 *exo*-$e_2$, 6 × 10 d electrons) is analogous for 18e components[11]. Unfortunately this method of counting is wrong, both for the well-known $Rh_6(CO)_{16}$ and for the apparently equally stable $M_6X_8$ and $M_6X_{12}$, clusters, which enrich the chemistry of the heavy transition metals in such an unusual way and are in addition the essential units for the concept of condensed clusters[80]. In any case, the MO treatment of *Cotton* and *Haas* of 1964[9] seems to me to be still topical. It describes the $M_6X_{12}$ cluster as a stable unsaturated unit with eight 3c-2e bonds (16 electrons in the skeleton) and the $M_6X_8$ cluster as a saturated unit with twelve 2c-2e bonds (24 electrons in the skeleton). The six M atoms obtain a complete 18e shell on including the 24 M—X bonds and the six potential bonds to outer ligands $:X^a$. The unsaturated state yields a 76e system, the saturated state of the $M_6$ cluster an 84e system (instead of 86e). *Lauher*'s description leads, however, to a quite unexpected aspect, which one should follow up in regard to cluster systems with formal similarities to spherical close-packing: the unit $M_6X_8$ possesses the structure of a face-centred cube. *Lauher* expects a stable system with 180e for this. In fact, if *all* M and X atoms are treated the same, then $Mo_6Cl_8^{4+}$, with the Mo atoms (6 × 6 electrons) and the Cl atoms ($8\times7+8\times10$ electrons), the six potential *exo*-electron pairs and the cationic charge, possesses exactly 180 electrons!

The 40e systems $Bi_9^{5+}$[81], $Sn_9^{4-}$[82] and $Ge_9^{4-}$[82,83] form one of the most beautiful clusters known. The existence of such large groups was derived by *Zintl et al.*[84] from the unusual behavior of the intermetallic phases $Na_4Sn_9$ and $Na_4Pb_9$. The structure however (Fig. 6i) was only determined a few years ago, and can be described in two ways, according to one's point of view; as a tricapped trigonal prism {3,3,3} or as a monocapped archimedean antiprism {1,4,4}. The two forms can easily be derived from each another, as is well known. The different points of view have theoretical foundations, and for this reason the original {3,3,3} polyhedron is gradually giving way to the {1,4,4}-polyhedron as the theory is consolidated. The latter polyhedron is, in fact, expected according to both *Wade* (*nido*-$E_{10}$ cluster) and *Lauher* (130e system including the d electrons). The assignment of bonding electrons to the edges and faces of the polyhedron is not possible, at least not in any simple way. According to *Gillespie*[79] all nine atoms possess a free electron pair and the remaining 11 electron pairs form eight 3c-2e bonds and three 4c-2e bonds, according to the faces of the {3,3,3} polyhedron. This would give $3\times Bi^{1/3-}$ and $6\times Bi^+$ (or $Sn^{4/3-}$ and $Sn^0$) with a sandwich-like charge distribution. The same result is obtained with two 3c-2e bonds and twelve 2c-2e bonds, but with only six *exo*-electron pairs on the prism atoms. The two clusters $Bi_9(e_2)_{11}^{5+}$ and $Mo_9Se_{11}^{4-}$[85] show a remarkable topological analogy to the "twins" $M_6X_{12}$ and $M_6X_8$, which can be derived from each other formally by exchanging the positions of electron pairs and X atoms. This may be useful for a better understanding. The $Ge_9^{2-}$ cluster, described by *Corbett et al.*[83] satisfies *Wade* ($E_9$ polyhedron) as well as *Lauher* (threefold capped trigonal prism, 128 e) and is also a hint for the remarkable valence behavior of this unit.

It will have become clear that the bonding in clusters can be viewed in quite different ways. At any rate, there is plenty of room for phantasy, and anomalous results mean, after all, that the next generation can still hope to find out something new. Above all, the unusual way in which main group elements fit into the 18e scheme as well, provides us with a striking insight. It has already been mentioned that the clusters $M_6X_8$ and $M_6X_{12}$ (Fig. 6h), of all things, do not fulfil *Lauher*'s rules (84e instead of 86e). But, to be fair, the rules do work for the group $[Nb_2(S_2)_2]^{4+}$, which one certainly would not look for, here (Fig. 6g). The remarkable orthogonal orientation of the two $S_2^{2-}$ anions to the $Nb_2$ pair in the structure of $NbS_2Cl_2$ has been referred to already[86]. If one counts 16 electrons for sulfur and takes the eight Nb—Cl bonds into account as *exo*-electron pairs, the group receives exactly 86 electrons. An 86e—$E_6$ cluster is, according to *Lauher*, not only stable as an octahedron, but also as an edge-sharing double tetrahedron—exactly the structure of $[Nb_2(S_2)_2]^{4+}$.

A series of fascinating polycyclic anions has been identified in recent years among the structures of the metal phosphides (Fig. 7), which at last allows well-founded statements to be made about the systematic structures of the lower Stock polyphosphanes[5]. A large number of phosphanes have been clearly identified from the homologous series $P_nH_{n-m}$ and $P_{m+n}H_n$ through the fundamental investigations made by *Baudler et al.*[87]. These should be derivatives of $P_2$ ($m=2$), of tetrahedrane $P_4$ ($m=4$), of prismane $P_6$ ($m=6$) and of cubane $P_8$ ($m=8$) with a considerable number of possible isomers[5]. The corresponding polyanions already show similarities to the structure of the molecular element in its real form ($P_2$ and $P_4$) as well as hypothetical forms ($P_6$ and $P_8$).

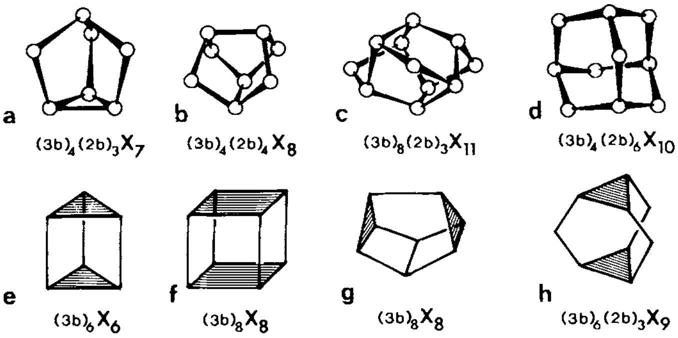

Fig. 7. Polycyclic systems II (cf. text): a) $P_7^{3-}$, $As_7^{3-}$, $Sb_7^{3-}$; b) $As_4S_4$, structural element in $P_{15}^-$; c) $P_{11}^{3-}$, $As_{11}^{3-}$; d) $P_{10}^{6-}$; e) prismane; f) cubane; g) cuneane; h) trigonal asterane as a possible structure for $P_9^{3-}$ or $P_9R_3$ [103].

The anion $P_7^{3-}$ is typical for the $M_3P_7$ compounds of the monovalent cations $M^+$, and for the $M_3P_{14}$ compounds of the divalent cations $M^{2+}$[5]. In accordance with the formula, it contains four $(3b)P^0$ and three $(2b)P^-$ and is isoelectronic with the well-known molecule $P_4S_3$. This nortricyclene system is a derivative of the $P_4$ tetrahedron; the bridging atoms over the three edges are improper vertices in the sense of the Euler polyhedra (Fig. 7a). The analogous nortricyclenes $As_7^{3-}$[88] and $Sb_7^{3-}$[89] are also known, and have been studied in detail. A comparison between the configurations of the $X_7^{3-}$ polyanions and those of $P_4S_3$ and the molecules $P_7(SiMe_3)_3$ and $P_4(SiMe_2)_3$[90] shows that the height of the anions is relatively small and that the distance between the two-bonded bridging atoms is relatively large. This is good evidence for the localization of finite formal charges on these two-bonded atoms[91]. It was recently possible to confirm this interpretation by the quantitative evaluation of the NMR spectra of $Li_3P_7$ in solution[92]. *Zintl* and *Klemm*'s concept of formal ions, which these days seems very crude, is, therefore, still capable of providing statements which are both sensible and far-reaching. The $P_7^{3-}$ anion is not only stable in suitable solvents[88,92]; it can also be found in melts at 720 K[5,93]. This explains the unusual thermal behavior of $K_3P_7$, for example. While the higher phosphides decompose by loss of P[94] and the lower phosphides by loss of K[95], the yellow $K_3P_7$ "sublimes"[94]. The equilibrium vapor contains, however, only K(g) and $P_4$(g); in other words, the sublimation corresponds somewhat to that of $NH_4Cl$. The considerable solubility of phosphorus in salt melts, above all in the presence of metals[5], can also be understood with the aid of these polyanions. The dynamic behavior of this system provides the final twist: according to *Baudler et al.*[92] this is the first inorganic "bullvalene" with valence tautomerism above 350 K, as suspected by *Bues et al.*[93]. The same structure was proposed for the corresponding heptaphosphane(3), $P_7H_3$[5]. This has also been proven recently by *Baudler et al.*[95].

The realgar molecule $As_4S_4$ has been known for a long time. Its structure is shared by the molecule $P_4S_4$[96], and very probably by the octaphosphane(4), $P_8H_4$, as well (Fig. 7b). This configuration is frequently found in polymeric form as a fourfold linked unit (4b)$P_8^0$, as, for example, in Hittorf's phosphorus[97] and in many polyphosphides[5] (cf. Section 8). Decaphospha-adamantane (Fig. 7d) is the last stage in the $P_4$ tetrahedrane derivatives with bridged edges. This system turns up as the anion $P_{10}^{6-}$ in the compound $Cu_4SnP_{10}$[98], which is otherwise characterized by a 4c-2e cluster $Cu_3Sn$. Unfortunately, it has not yet proven possible to obtain a neutral molecule from this polyanion (cf. Section 7).

The polyanion $P_{11}^{3-}$ is present, for example, in $Na_3P_{11}$[99] and $Cs_3P_{11}$[94,100]. It may be understood as a derivative of the much sought, but never found, octaphosphacubane $P_8$. This beautiful, chiral molecule with the symmetry $D_3$ is made up of eight (3b)$P^0$ and three (2b)$P^-$ atoms. By bridging three edges of cubane, six five-membered rings are obtained from the original six four-membered rings (Fig. 7c). Anyone who has rotated a model of this group about its threefold axis understands the name "UFOsane"[99] immediately. The undecaphosphane(3) $P_{11}H_3$ should also possess this structure, which has the highest symmetry of all conceivable isomers. Compounds with the $P_{11}^{3-}$ anion form under very similar conditions to those with the $P_7^{3-}$ group. It can be shown that the brilliant yellow $Na_3P_7$ and the orange $Na_3P_{11}$ can be readily (and reversibly) converted into each other, when in equilibrium with $P_4$(g)[101]. This transition can be well understood with the aid of the model[5]. In this connection, the occurrence of mixed crystals among the alkali metal phosphides is also important. These lead to phases containing both polyanions $P_7^{3-}$ and $P_{11}^{3-}$ (cf. Section 9). Important too, is the observation by *Bues* and *Somer*[102] that the $P_{11}^{3-}$ group remains intact in melts at 720 K, and can be identified spectroscopically. The analogous arsenic unit $As_{11}^{3-}$, recently described by *Belin*[156], shows impressively that surprising results could be expected in this region of chemistry.

The $P_{11}^{3-}$ cluster, as a derivative of cubane, certainly opens up new possibilities in the search for $P_8$ cubane, especially since the anions can be converted into neutral molecules (Section 7). The polymeric unit (4b)$P_8^0$ (see above) also shows that the great structural flexibility of phosphorus should enable the formation of cubane. The (4b)$P_8^0$ group can be understood as the polymerization product of an octaphosphacuneane (Fig. 7g), which is itself an isomer of cubane. Analogous statements can be made for a $P_6$ prismane. The structural units of the heptaphosphides $LiP_7$ or $RbP_7$[5] are not only derivatives of the $P_7^{3-}$ cluster, but can at the same time be considered to be derivatives of the polymeric $P_6$-prismane (Section 8).

## 7. Reactions at Polycyclic Anions

Obtaining molecules from metal salts is a familiar procedure—the preparation of acetylene from $CaC_2$ is one example. As far as the protolytic decomposition of the, in general very sensitive, phosphides, arsenides, silicides, germanides *etc.* is concerned, one has not got much further than the small hydrides, although (a) the existence of flexible polyanions such as $Sn_9^{4-}$ and $Sb_7^{3-}$ has already been proven by *Zintl*[84], (b) a whole series of higher hydrides were identified by *Baudler* among the insoluble *Stock*'s phosphanes, and finally (c) despite the fact that many research groups have worked on this problem. Refined chemical and physical methods have in recent years enabled the decisive first step to be made towards a systematic study of this class of substances. When one looks at the very simple methods, it seems puzzling today that this step was made so late and, partly, by chance. *Corbett* obtained crystalline salts of $Pb_5^{2-}$, $Sn_9^{5-}$, $Ge_9^{4-}$, $Ge_9^{2-}$ and $Sb_7^{3-}$ by using crown ethers[77,82,83,89]. *Kummer* obtained $Sn_9^{5-}$ and $Ge_9^{5-}$ from ethylenediamine in the form of solvated salts[82]. The last important step to substituted molecular clusters has not yet been made. If one thinks of the tetrahedral cluster $Si_4^{4-}$ or the $Si_4$ star (cf. Section 6), it should be worth every effort.

After the discovery of the polycyclic phosphides it was shown that they could yield $P_7H_3$, $P_{11}H_3$ and other phosphanes[5]. It also became clear that the yellow insoluble *Stock*'s phosphanes possess quite different characteristics according to the phosphide used [$(PH)_x$ from NaP with the $^1_\infty P^-$ chain; $P_7H_3$ from $Na_3P_7$ with the $P_7^{3-}$ group]. In 1979, *Baudler et al.* succeeded for the first time in obtaining the colorless $P_7H_3$ on a preparative scale by careful hydrolysis of $Li_3P_7$[95].

For the future, however, the synthesis of substituted clusters such as $P_7(SiMe_3)_3$ is of decisive importance. In 1975, *Fritz* and *Hölderich* succeeded in this synthesis, together with the preparation of Si-substituted groups such as $P_4(SiMe_2)_3$ in a one-pot process[90]. Soon afterwards, $P_{11}R_3$ and $As_7R_3$ were obtained and characterized[103] (Fig. 8). Their structures clearly prove that a description of this cluster system according to *Wade* (cf. *Belin*[156]) does not fit, because without doubt 14 electron pairs are reserved for the *exo*-cyclic bonds.

The synthesis is now fairly well optimized and gives high yields[104]. In this case, an old piece of chemical wisdom turned out once more to be true; that only microcrystalline ("amorphous") starting materials can be used for this heterogeneous reaction. Well-crystallized samples of $Na_3P_7$ and $Cs_3P_{11}$, for example, hardly react at all with $SiMe_3Cl$[104].

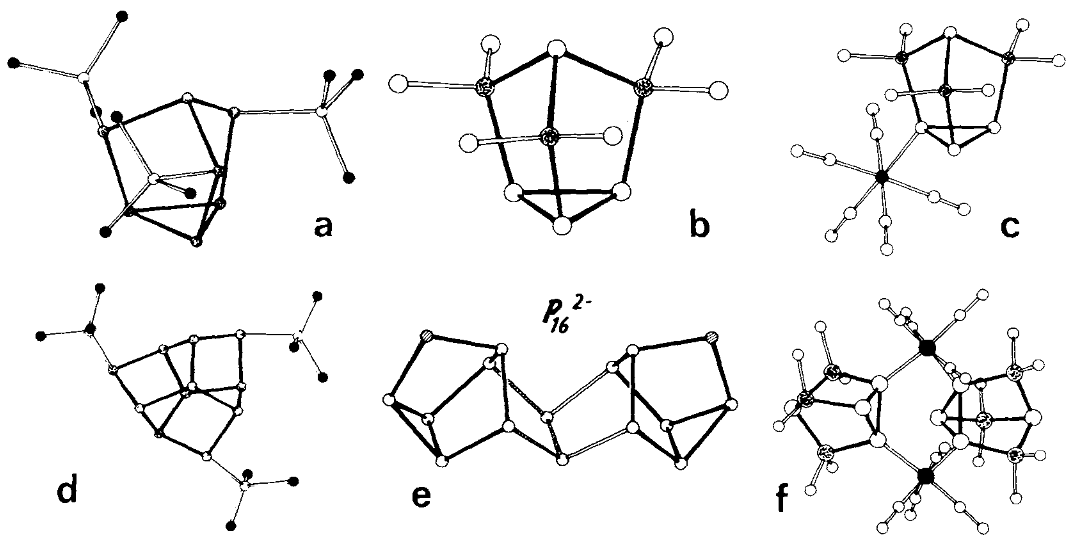

Fig. 8. Cluster molecules $P_7R_3$ and $As_7R_3$ (a), $P_4Si_3R_6$ (b) and $P_{11}R_3$ (d). Metal(0) complexes with $P_4Si_3R_6$ ligands (c, f) and the novel polyanion $P_{16}^{2-}$ (e) (cf. text).

The remarkable flexibility of the P—P bonds is not only reflected in the valence tautomerism of $P_7^{3-}$ and the abundance of different structures, but shows itself as well in the thermal decomposition and build-up of the phosphides, phosphanes, and substituted phosphanes. Molecules such as $P_9R_3$, $P_{14}R_4$ and $P_{16}R_2$ have already been discovered in mass spectra[90,103]. The anion $P_{16}^{2-}$ belonging to $P_{16}R_2$ (Fig. 8e)—the largest phosphide known—was only very recently trapped as a $Ph_4P^+$ salt[106]. The cluster $P_{16}^{2-}$ can be considered as a condensation product of $P_7^{3-}$ and $P_9^{3-}$. The salt is, by the way, the first polyphosphide without a metal cation and, because of its solvent properties, indicates a way of synthesizing polyanions at fairly low temperatures.

Some of the cluster molecules mentioned are excellent complexing agents for metal carbonyls[107-109] (cf. Fig. 8c, f). A lot more reactions are expected here. The chirality of $P_7R_3$ and $P_{11}R_3$ is also worthy of note; it could become useful for selective syntheses.

## 8. Condensed Polyanions

The condensation of chains to rings and finally to nets, as well as the condensation of polycyclic anions, lead with progressive oxidation successively to the structures of the elements. The richness in forms observed for phosphorus is reflected in the various structures of the condensed anions, which lead directly to *Hittorf*'s phosphorus, to black phosphorus, to gray arsenic and also to possible new forms of a three-bonded element[5].

It has already been shown for the one-dimensional infinite chains of two-bonded atoms and their fragments that, for the same number of homonuclear bonds and with constant bond angles, different types of structure can occur through changes in conformation, such as a torsional rotation. For higher condensed systems, the number of structural possibilities is still larger. Six-membered rings can occur in the chair or boat form and the additional linkages to tetrahedral or ψ-tetrahedral atoms can take place equatorially and axially (Fig. 9). The poly-phosphides, -arsenides and -antimonides, as well as silicides, germanides and stannides[7a,110] offer plenty of impressive examples.

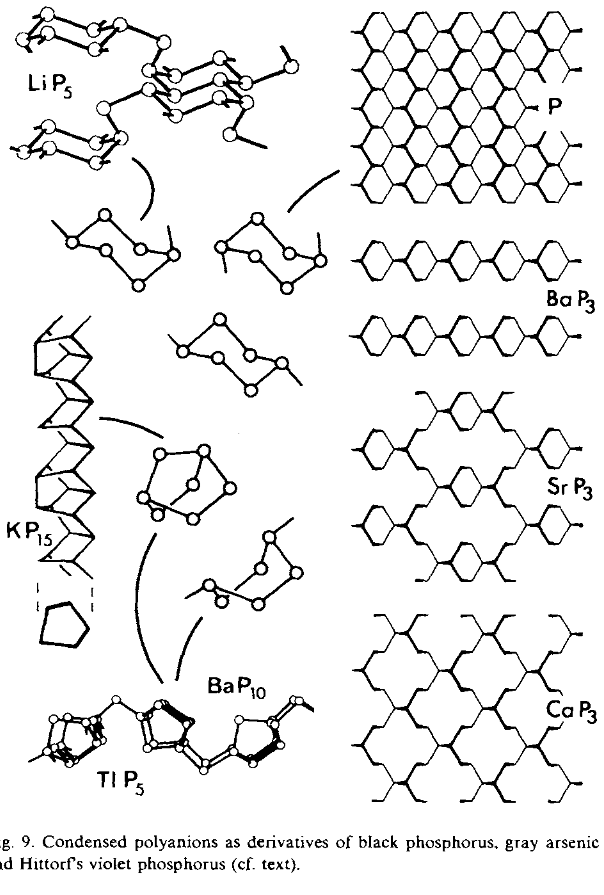

Fig. 9. Condensed polyanions as derivatives of black phosphorus, gray arsenic and Hittorf's violet phosphorus (cf. text).

The structures of orthorhombic black phosphorus and gray rhombohedral arsenic are known to differ solely in the

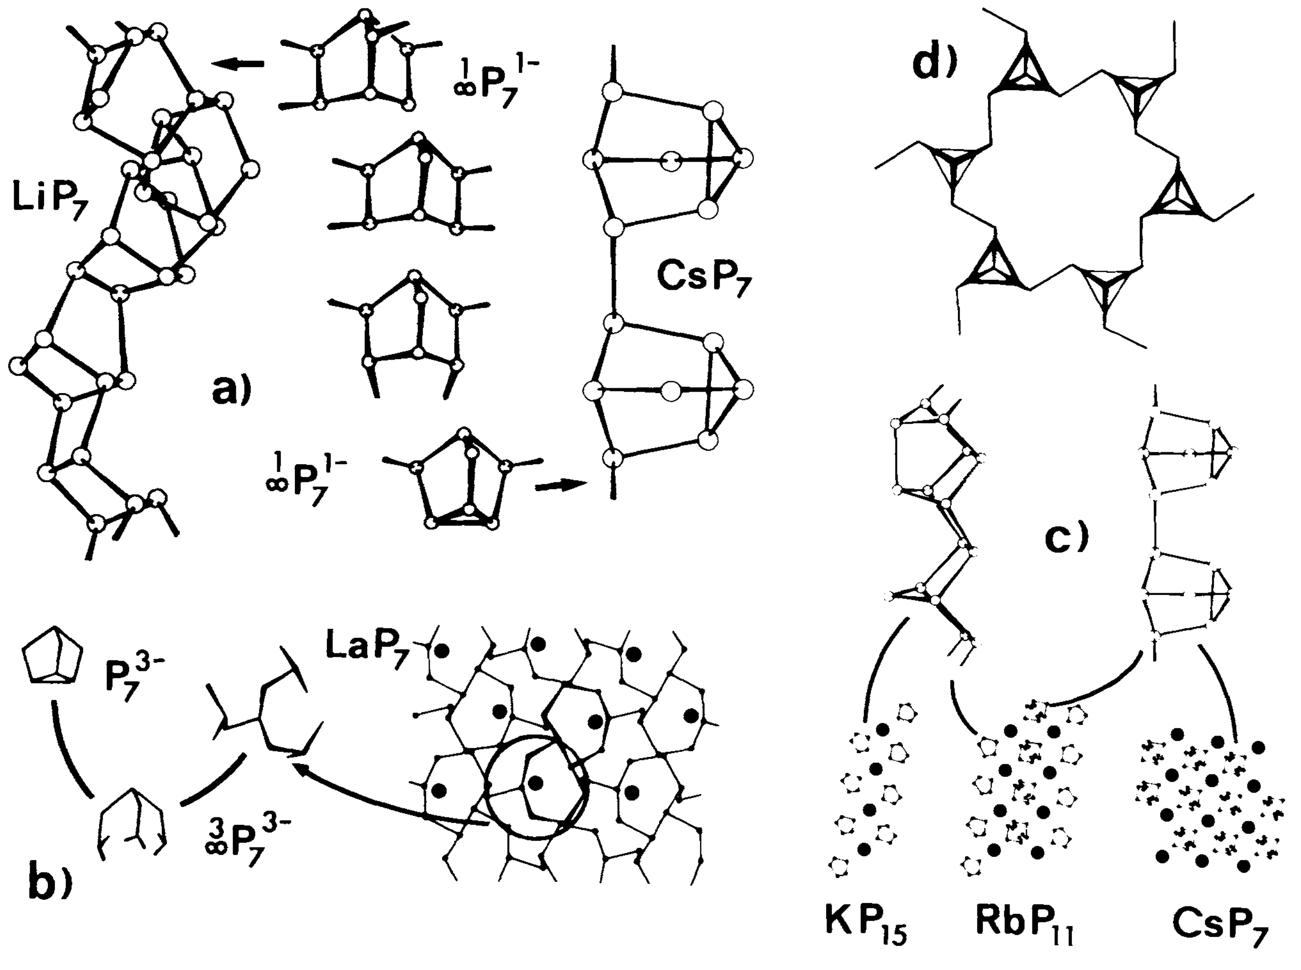

Fig. 10. Condensed polyanions from $P_7$ and $P_8$ clusters. a) Four sterical variants of $(3b)_6(2b)_1P_7^{1-}$; they lead to the helical LiP$_7$ structure and the linear CsP$_7$ structure, from which the monomeric $P_7^{1-}$ prismane derivative could be obtained by a further ring-closure. The two norbornane analogues (center) form the two-dimensional structure of $K_4IP_{21}$, for example. b) The nortricyclene $P_7^{3-}$ forms, after ring-opening, the three-dimensional polymeric LaP$_7$ structure. c) The combinations of the translationally commensurate units $P^1_{15}$ and $(P_7^{1-})_2$ leads to the RbP$_{11}$ structure. A peculiar feature of the $P^{1-}_{15}$ structure is the $P_8$ unit, which can be regarded as the polymeric form of an octaphosphacuneane. d) Six-membered ring of $P_7^-$ cluster, which with its chair conformation and its exocyclic bonds could built up a hypothetical "superphosphorus" of the gray arsenic type.

linkage of their condensed six-membered rings in the chair conformation, which in the case of arsenic is fully equatorial, for black phosphorus, however, partly axial. This leads in one case to a relatively slightly puckered structure, in the other case to a strong buckling of the layers. The phosphides, arsenides and antimonides $MX_3$ of the divalent metals modify the structure of black phosphorus in the sense that one quarter of the three-bonded atoms are removed from the two-dimensional framework. In this way, structures come into being which only contain one $(3b)X^0$ and two $(2b)X^-$, in accordance with the formulation. The overall picture remains of a structure with strongly buckled two-dimensional infinite polyanions[5]. The positions of the atoms which form the polyanion also remain almost unchanged from those in black phosphorus. The structures of CaP$_3$[66], SrP$_3$[111] and BaP$_3$[112] differ, however, in the arrangement of the vacancies, in that, in the first case, all the six-membered rings are broken up, in the second case only some of the six-membered rings exist, and in the third case one-dimensional infinite chains of linear condensed six-membered rings remain (Fig. 9).

The linkage of the six-membered rings is different in the structure of LiP$_5$[120]. Here, bands of condensed six-membered rings in the chair form are connected *via* two-bonded P atoms, which take up equatorial and axial positions in equal numbers. This structure is, in a sense, an intermediate stage between the structures of black phosphorus and gray arsenic.

If the six-membered rings are present in the boat form, there is a notable limitation: the possibility of an axial-equatorial linkage in the 1,4 position, as realized in LiP$_5$, is missing, since the boat is closed up to a norbornane structure as soon as one axial position is occupied (Fig. 9). The linkage of these $E_7$ units can take place in different ways. Important examples are KP$_{15}$, HgPbP$_{14}$, TlP$_5$ and BaP$_{10}$[114-117], in whose structures units of this type occur as sections of characteristic one-dimensional infinite tubes with a five-cornered cross-section. Also found in the structures are known elements such as the $As_4S_4$ molecule, which is present in KP$_{15}$ as a $P_8$ unit with four equatorial linkages in the *trans* position (Fig. 10c). The analogy between this unit and an (in this case polymeric) octaphosphacuneane has already been discussed in Section 6. The structures of TlP$_5$ and BaP$_{10}$ are completed by six-membered rings in the boat conformation with 1,4-equatorial linkages. This configuration leads in this case to linkage of the five-cornered tubes to two-dimensional infinite layers.

The linkage of the mentioned norbornane $E_7$ offers a series of possibilities which have been realized in its structural chemistry. If we assume that one of the 7 atoms is 2-bonding and the rest 3-bonding, then the 2-bonding atom is either, as the bridging atom across the six-membered ring, a member of both five-membered rings, or is just a member of the six-membered ring. Four atoms are in a position to form further bonds in both axial and equatorial directions (Fig. 10a). If the 2-bonded atom is in the bridge position, the linking bonds are in the equatorial direction and a linear structure results. If the linkages are both equatorial and axial, a two-dimensional aggregate results. These two elements govern the structure of $K_4IP_{21}$ and $Rb_4IP_{21}$[5,56,118].

If axial bonds in the 1,3 position saturate each other, a three-membered ring can form and give the above-mentioned nortricyclene system which is typical for $P_4S_3$ and the $X_7^{3-}$ anions. Here, however, the system is bonded at two extra positions, so that in the case of the polyphosphides the polyanion ${}^{1}_{\infty}P_7^{1-}$ forms. This structure is typical of the heptaphosphides of the large alkali metals $RbP_7$ and $CsP_7$[5,118]. The monomeric form of the anion ${}^{1}_{\infty}P_7^{1-}$, which is still hypothetical, can be obtained by a further ring-closure. The anion is particularly interesting as a prismane derivative. The linkage of the polymeric ${}^{1}_{\infty}P_7^{1-}$ chain can be broken by two electrons, giving the isolated anion $P_7^{3-}$. This unit does not have to be molecular, of course, it can polymerize as well by breaking the three-membered ring. In this form it builds the spatial network of the polyanion ${}^{3}_{\infty}P_7^{3-}$ in $LaP_7$ and $CeP_7$[5,119] (Fig. 10b).

If the two-bonded atom of the $X_7^{1-}$ unit is a member of the six-membered ring, then further linkage must lead to a helical structure. This is typical of the heptaphosphides of the small alkali metals $LiP_7$ and $NaP_7$[5,120]. It can be shown using the structures of the alkali metal heptaphosphides that K is too large for the $LiP_7$ structure and too small for the $RbP_7$ structure. In agreement with this, no "$KP_7$" has been prepared; instead, in the presence of iodine, only the "ersatz-$KP_7$", $KI \cdot 3KP_7 = K_4IP_{21}$ is formed[56].

The dimensions of the one-dimensional infinite linked $P_7^{1-}$ units in the $RbP_7$ structure agree exactly with the dimensions of the one-dimensional infinite five-cornered tubes of the $P_{15}^{1-}$ type, which are contained in the alkali metal compounds $MP_{15}$ (Fig. 10c). In fact, both units occur together in the compounds $RbP_{11}$ and $CsP_{11}$ and the geometrical commensurability allows us to expect the existence of further phases[5,118].

Not many chemical elements can, like phosphorus, claim to be produced and used in large quantities and simultaneously keep the secret of their structure so stubbornly. The latest investigations have done nothing to change this[121]. For red phosphorus one can say: Where nothing is known, one can speculate! *(K. Lorenz)*. The structural variety of the polyphosphides offers sufficient encouragement. A particularly colorful aspect is supplied by the $P_7^{3-}$ and $P_{11}^{3-}$ clusters, which, with the three 2-bonded P atoms polymerize exactly three times and form a "superphosphorus". A model consisting of condensed six-membered rings of pseudo-atoms (3b)[$P_7$] can at any rate be easily built and represents one of many possibilities (Fig. 10d). Also the condensation of these six-membered rings to a two-dimensional infinite structure can be easily realized by a model.

## 9. Mixed Phases and Phase Widths

Both terms are often used as an alibi for non-treatment. In textbooks and articles on cluster compounds, the "intermetallic compounds" which include much of what is discussed here, are often disposed of with the remark: they often possess large phase widths. In fact, this is only true for very few phases, since, more often than not, a series of closely-spaced stoichiometric compounds turns up. Genuine statistical distributions of various atoms over equivalent positions are, at most, preferred at high temperatures to the separation into suitably organized structures. The formation of clusters, whether strongly or weakly bound, is one of the possibilities for such suitably organized structures. Clusters, or analogous structural regions, take the place of the single atoms. The breakdown of a region of homogeneity into closely-spaced phases can be regarded as the formation of a series of compounds of "higher order". This kind of phenomena has not been studied enough up to now. The value of such studies will be briefly indicated with the following examples.

$Rb_3P_7$, $Rb_3P_{11}$, $Cs_3P_7$ and $Cs_3P_{11}$ possess practically the same structure; namely, a cubic $Li_3Bi$ arrangement in which the Bi atoms are replaced by the centers of $P_7^{3-}$ or $P_{11}^{3-}$ groups[122] (cf. Fig. 11a), as observed for $Na_3PO_4$, for example[123]. The orientation of the anions is random, as in plastic phases. There is good evidence for a continuous series of mixed crystals $M_3(P_7, P_{11})$ which is strange, since apart from the charge the anions have little in common. An interesting question is whether the reaction described above, $Na_3P_7 + P_4 \rightleftarrows Na_3P_{11}$, takes place here in the solid state, *e.g.*

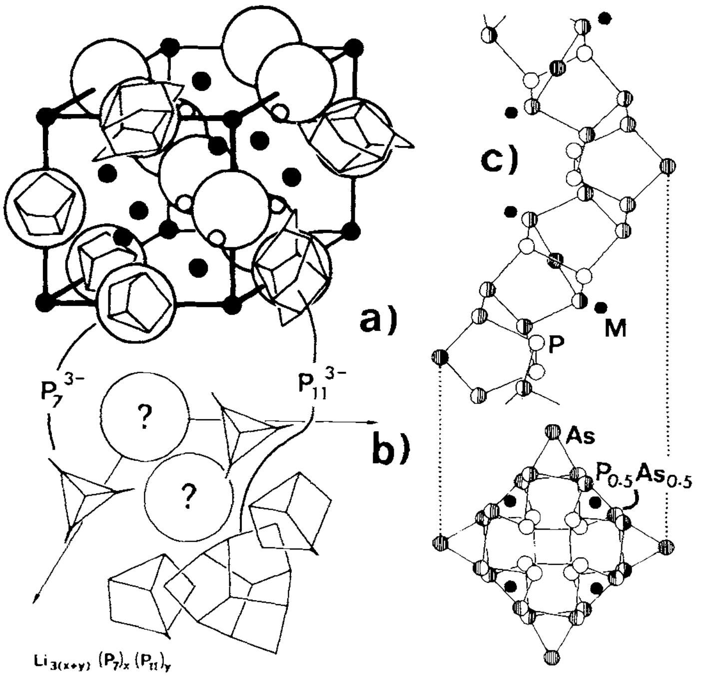

Fig. 11. Mixed crystals: a) $Li_3Bi$ as parent structure for $Cs_3P_7$, $Cs_3P_{11}$ and the mixed crystals $Cs_3$ ($P_7$, $P_{11}$) with statistical distribution and orientation of the cluster anions. b) Section of the hexagonal structure of the "red lithium phosphide" $LiP_x$ with partially ordered $P_7^{3-}$ and $P_{11}^{3-}$ as well as disordered (?) polyanions. c) Structure of the helical polyanions ${}^{1}_{\infty}X_7^{1-}$ in $LiX_7$ and $NaX_7$ with $X = P_{0.5}As_{0.5}$ (projections perpendicular to and along the fourfold helix). The As atoms occupy preferentially the peripheral positions, the P atoms the central part of the polyanion.

by $P_4$ diffusion. Mixed-order phases have not yet been observed here, but in the system Li/P, besides yellow $Li_3P_7$, a red phosphide $LiP_x$ exists with ordered $P_7^{3-}$ and $P_{11}^{3-}$ groups in the ratio 2:1, as well as a further orientation-disordered group[124]. The compounds $RbP_{11}$ and $CsP_{11}$ can also be treated as ordered phases in a mixed-crystal series between $MP_7$ and $MP_{15}$ (cf. Section 8). The marked tendency to twinning also indicates great mobility and perhaps also a variation in the stoichiometry at high temperatures (Fig. 11a, b).

Mixed crystals with different cluster-forming atoms can supply information on the function of the individual atomic positions. The peripheral positions of the ${}^1_\infty P_7^{1-}$ helix of $LiP_7$ and $NaP_7$ show a distinct preference for arsenic in $LiP_{3.5}As_{3.5}$[125] (Fig. 11c), while in $EuP_{3-3x}As_{3x}$ the preference of As for the $(2b)X^-$ position is weaker[126]. EuP forms the NaCl structure with $Eu^{III}$, but EuAs the $Na_2O_2$ structure with $Eu^{II}$. Mixed crystals with the EuAs structure go as far as 5 atom-% As; the rest possess the EuP structure[126]. Two important questions remain: (a) does the distribution of $P_2^{4-}$, $(PAs)^{4-}$ and $As_2^{4-}$ obey a mass-effect law? (b) How does the system behave at the boundary of the mixed series with respect to the redox reactions $2(Eu^{3+}+X^{3-}) \leftrightarrows 2Eu^{2+}+X_2^{4-}$?

## 10. Defect Structures

Several of the $MX_n$ compounds with homonuclear chains and rings (Sections 4 and 5) can be described as trigonal-prismatic defect structures. In these structures the metal atoms M form trigonal prisms in whose centers the X atoms lie. Two structure types with trigonal prisms which occur very frequently are $AlB_2$ and $\alpha$-$ThSi_2$ (Fig. 12). They differ in the relative orientation of the $M_6$ prisms, which, because of the three square faces of these polyhedra, can be varied in many different ways[127]. In the hexagonal $AlB_2$ type, all M prisms are oriented in the same way. The occupation of all centers by X atoms generates the well-known two-dimensional honeycomb structure of graphite. $Rb_4P_6$[55] and $Cs_4As_6$[56] are direct derivatives of this $Al_4B_8$ type, since, according to $M_4X_6\square_2$, a quarter of the X sites remain vacant in an ordered way and leave isolated planar $X_6$ rings. The defects and their order apparently depend on the valency.

If the prisms are rotated through 90° from one layer to the next, one obtains the $\alpha$-$ThSi_2$ type structure, which, on complete occupation of the prism centers, shows a characteristic three-dimensional network of three-bonded X atoms (Fig. 12). If the rotation takes place every second layer, an unknown tetragonal $MX_2$ type would result, containing a three-dimensional network of bands of $X_6$ rings rotated with respect to each other. The compounds $Eu_3P_4$[36], $Eu_3As_4$[35], $Sr_3As_4$[34], $Eu_2Sb_3$[32], $Ca_2As_3$[31] and $Sr_2Sb_3$[33] are defect structures of these two types with $M_3X_4\square_2$ or $M_4X_6\square_2$[128]. The ordering of the defects caused by the valency conditions can lead to chains of various lengths and conformations (Fig. 12). The pair of compounds $Ca_2As_3$ and $Sr_2Sb_3$ are noteworthy, since a chemical reaction, $X_4^{6-}+X_8^{10-} \leftrightarrows 2X_6^{8-}$, can take place simply by a reordering of the defects in the $M_6$ prisms. The search for such phase transitions would certainly be worthwhile.

While describing these structures as defect variants of $AlB_2$ and $\alpha$-$ThSi_2$ we were reminded that, in the case of the "disilicides" of the lanthanoids, compositions such as $MSi_{1.7}$ or $MSi_{1.4}$ are given, with very few exceptions[127]. Detailed studies have shown: (a) Only $EuSi_{2.0}$ possesses a completely occupied tetragonal $\alpha$-$ThSi_2$ structure, which fits into the picture of $Eu^{2+}$ and $(3b)Si^-$.—(b) The other silicides form the orthorhombic defect variant of $\alpha$-$ThSi_2$ ($\alpha$-$GdSi_2$) with $LnSi_{1.7}$ (Ln = lanthanoid) or the defect $AlB_2$ with $LnSi_{1.4}$ without noticeable phase widths.—(c) The vacancies in the defect $\alpha$-$GdSi_2$ structure can be filled with Ni, Cu, Ag, Au, Al, Ga. The structures are then, and only then, tetragonal. The occurrence of defects agrees with the model of finite $Si_x^{n-}$ chains, since the additional electrons from $Ln^{3+}$ should break Si—Si bonds. The length of the $Si_x^{n-}$ chains is, however, variable and their orientations are disordered[128].

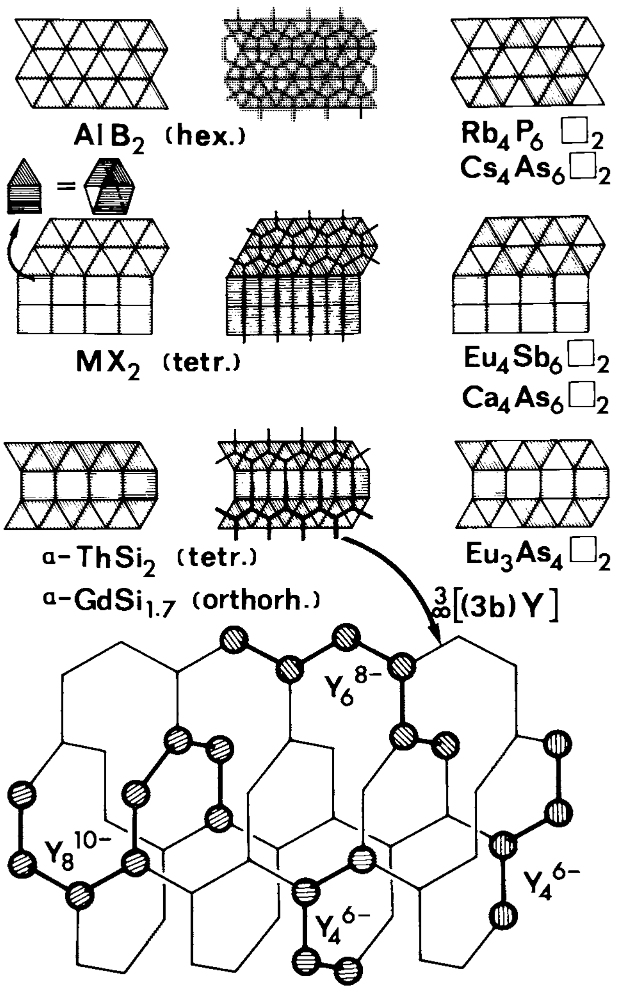

Fig. 12. Structures with metal prisms of the type $AlB_2$, $\alpha$-$ThSi_2$ and a hypothetical $MX_2$ compound with some defect variants. (above left: arrangement of the $M_6$ prisms; above center: prisms with the anion network; above right: order of defects; empty prisms are not shaded.) The ordering of the defects leads for $Rb_4P_6$ to isolated $P_6$ rings, but for the other structures to various anionic chains. In the lower part such chains are shown as sections of the Si sublattice of $\alpha$-$ThSi_2$.

A series of compounds apparently exists too, in whose structures the Si network of the $\alpha$-$ThSi_2$ type is broken up step by step. The final member of the series is the NbAs structure type with isolated $X^{n-}$ anions[127].

## 11. Real and Hypothetical Reactions in the Solid State

*Dunitz* and *Bürgi* have shown how one can obtain far-reaching information on chemical reaction paths from the details of static crystals structures[129]. Compounds with cluster anions can also be used for such studies. Firstly, the comparison between configurations and conformations of the polyanions on changing the cation allows statements to be made on the dynamics of the homonuclear structure. The various compounds can be regarded as frozen-in reaction steps and assigned to a reaction coordinate. Secondly, phase transitions are excellent subjects of study, above all when they go to higher order. Only a few investigations have been made in this area, and it would be of interest to mention some potential examples:

1. The phosphides $MP_{15}$ and $MP_{11}$ form, without exception, twinned crystals, the orientation of which stems from the ordering of the cations in channels of the structure. At high temperature, a mobility of the cations can be assumed which is accompanied by changes in the covalent bonds in the polyanion.

2. The possible reordering of the $X_n$ chains in derivatives of the $ThSi_2$ and $AlB_2$ structures has been referred to in Section 10. The diphosphides and diarsenides of the lanthanoids $LnX_2$ offer a similar example of a molecular reaction in the course of a phase transition. At low temperature, the $CeP_2$ type forms[5,30,130] with $X_4^{6-}$ and at high temperature the $LaP_2$ type[29] with $(X_3^{5-} + X_5^{7-})$ (cf. Fig. 13a).

3. $Th_2P_{11}$, the compound with the highest non-metal content known for a four-valent metal, is a particularly attractive example of a frozen-in ring-opening reaction with an $S_N2$ mechanism[65]. The polyanion sublattice forms bands of condensed $P_6$ rings (boat) and $P_8$ rings ($C_{2h}$ symmetry). Inserted between these are $P_6$ rings in the chair conformation and $P_3$ fragments of such rings. The $P_3$ fragments are all joined to the polyanion bands. A periodic modulation is present in the crystal resulting from a sequence of closed and opened $P_6$ rings. This modulation is, therefore, caused by a valency effect and is generated by the turning of a single P—P bond which opens the ring and joins the fragments to the polymeric anion with a simultaneous 1,4-charge transfer (Fig. 13b). At room temperature both of the boundary states are frozen in, giving the environment of the "mobile" P atom the configuration of the boundary states of an $S_N2$ reaction. The evidence suggests that at higher temperatures this process takes place in the crystal (perhaps with varying modulation wavelength).

4. The pentaphosphides of the trivalent lanthanoid cations, $LnP_5$, form a polyanion $^1_\infty(P_5^{3-})$ out of condensed $P_{12}$ rings. The structure can be derived from a hypothetical P modification with condensed six-membered rings in the boat form[5,69,131]. The polyanion adapts itself to the size of the

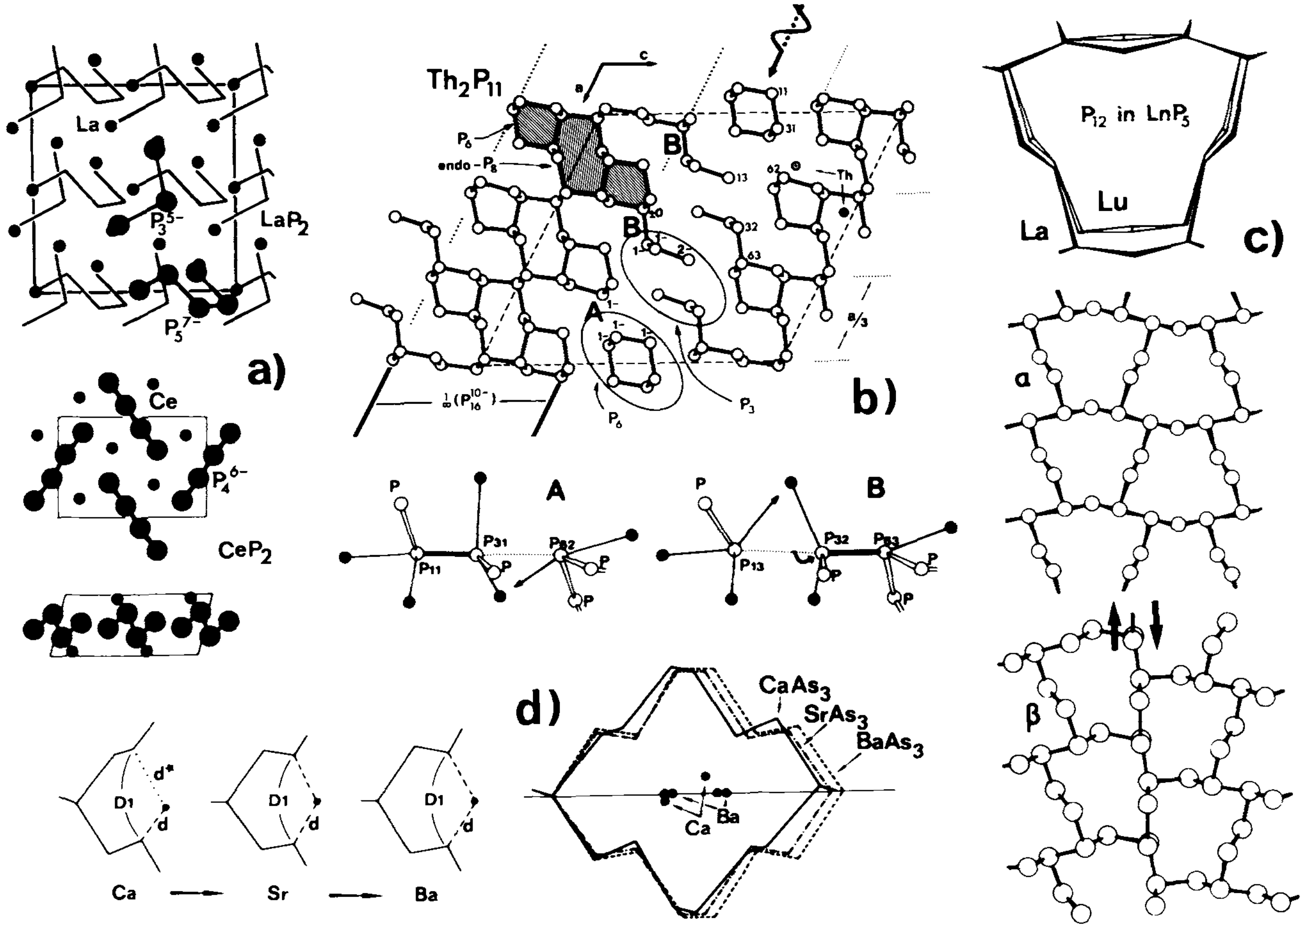

Fig. 13. Solid structures as models for reactions and reactions paths. a) High temperature and low temperature forms of $LnP_2$ and $LnAs_2$ with $X_4^{6-}$, and $X_3^{5-} + X_5^{7-}$, respectively. b) Part of the $Th_2P_{11}$ structure with the polyanionic band, built up from $P_6$ and $P_8$ together with the inserted $P_6$ rings and $P_3$ fragments. The modulation (arrow) along the *a*-axis results from a sequence of closed (A) and fragmented (B) $P_6$ rings. The configurations A and B exhibit the details of a frozen-in $S_N2$ reaction (center of the figure). Notice the formal charge transfer. c) Adaption of the $P_{12}$ ring to the sizes of the $Ln^{3+}$ ions in $LnP_5$ as a model for a reaction induced by pressure. The transition from α-$YbP_5$ to β-$YbP_5$ exhibits besides the volume contraction a shearing of the polyanion. d) Change in the conformation of the $As_{14}$ rings on substituting Ca by Sr and Ba as steps in a phase transition. The abnormal change in the conductivity goes hand-in-hand with the changes in non-bonding As—As distances D1.

cation in the series La–Lu by altering the P—P bond lengths and by conformational changes (Fig. 13c). β-$YbP_5$ forms a more closely-packed variant of the structure, which results formally from the first by a relative shift of the points where the condensation occurs at the twelve-membered rings. The structures of the $LnP_5$ series can be interpreted as stages of a reaction path brought about by application of pressure.

5. Triclinic $CaP_3$ passes at 990 K through a phase transition to give the monoclinic $SrAs_3$ structure. The induction period for this transition is very long[132]. The bonding in the polyanion remains unchanged; the only changes take place in the conformation. The details have not yet been investigated, but $T_c$ can, for example, be changed progressively in the isostructural mixed-crystal series $Ca_xEu_{1-x}As_3$[133]. The stages of the supposed reaction path are given by the series $CaAs_3$ (triclinic), $SrAs_3$ (monoclinic) and $BaAs_3$ (monoclinic). It is remarkable in this context that this series represents a transition from a semiconductor to a meta-metal and back to a semiconductor, which is connected with the change in a non-bonding distance in the polyanion $^2_\infty(As_3^{2-})$[134].

## 12. The Electrostatic Treatment of Cluster Compounds

Terms like ions or ionic bond elicit no more than a cynical smile from the colleagues of the ruling covalent clique. As always in times of an all-powerful doctrine, the dissenter has to knuckle under and recite his creed in secret, but anyone who wants to harvest in his lifetime cannot afford to wait for the *ab initio* theory of weather! Chemists are like farmers: they believe in rules, but are cunning enough to be able to interpret them as the occasion demands.

The compounds with homonuclear linkages which are discussed here actually have nothing to do with electrostatically balanced systems, since, in the formal ion model, equally-charged particles are close neighbors. *Kapustinskii*, however, has pointed out a remarkable phenomenon[135]: he showed that the enthalpy of formation of a solid can be calculated with sufficient accuracy from the Born-Haber cycle if one treats the transition $a\cdot M^{m+}(g) + b\cdot X^{n-}(g) \rightarrow M_aX_b(s)$—whatever its structure may be—with the expression $U_K = k\cdot A\cdot \nu\cdot z_1\cdot z_2\cdot R^{-1}$ ($k$ = constant; $A$ = Born repulsion; $\nu$ = sum of the ions $a+b$; $z_i$ = charge on ion "i", *e.g.* $m+$ and $n-$; $R$ = distance M—X, *e.g.* sum of the ionic radii). If $\nu z_1 z_2$ is replaced by $\sum z_i^2$, the relationship to the lattice potentials of the individual ions is obtained directly[136]. The decisive thing is that the constant $k$, apart from some conversion factors, contains *solely* the Madelung constant of the NaCl structure ($k \sim \frac{1}{2}\text{MF(NaCl)} = 0.8738$), *i.e.* with respect to the total energy: "Everything is rock salt!" in other words, nature does not do any more than it has to. Whatever the details of a real crystalline structure $\{M^{\delta+}X^{\delta-}\}_{\text{real}}$, however large the effective charges δ+ and δ− and the covalent part of the bond might be, it is energetically no more than if rigid particles with the picture-book charges $m+$ and $n-$ were joined together with the typical distance $R$ for condensed phases to a NaCl structure. The lattice energy $U_{BH}$ of a compound MX, which is inserted in the Born-Haber cycle, can therefore be written:

$$U_{BH}(\text{MX-real structure}, \delta+, \delta-) = U_K(\text{NaCl-structure}, 1+, 1-)$$

I would like to comment at this point that *Klemm* gave "effective Madelung constants" as early as 1931 for tetrahedral structures, for example, which made such structures energetically similar to NaCl[138]. The covalent age, which was then just beginning, prevented these ideas from being followed up.

The surprising example of niobium monoxide NbO has already been referred to [2]. This structure is, independent of the covalent Nb—O bonds, strongly characterized by the Nb—Nb bonds. Nevertheless, the experimental enthalpy of formation $\Delta H_f$ yields an "experimental" lattice energy $U_{ex}$ for the real structure, which is just as large as NbO would have with $Nb^{2+}$ and $O^{2-}$ in the NaCl structure.

On the other hand, if one calculates the electrostatic lattice energy of the real structure with the ideal charges 2+ and 2− (MAPLE after *Hoppe*[137]), the difference between $U_K$ and MAPLE is $\Delta E = 560\ \text{kJ}\cdot\text{mol}^{-1}$, which could certainly be the energy of the entire metal-metal bonding of an $Nb_6$ cluster

$$U_{BH} = U_K = \text{MAPLE} + \Delta E$$

with $\text{MAPLE} \mathrel{\hat{=}} U(\text{MX-real structure}, 2+, 2-)$ and $\Delta E \mathrel{\hat{=}}$ non-electrostatic part of the lattice energy.

The first problem is how to count up the energy of the individual bonds in an $M_6$ cluster of this type. This is different for the clusters of the main group elements. As shown above, these compounds largely follow the simple rules of bonding. For the following calculation, the binary MX compounds were used. These include, for example, NaS ($Na_2S_2$), NaP with $^1_\infty P^{1-}$, NaSi with $Si_4^{4-}$ and all the appropriate homologs. The formal ion $X^{1-}$ is common to all these compounds,

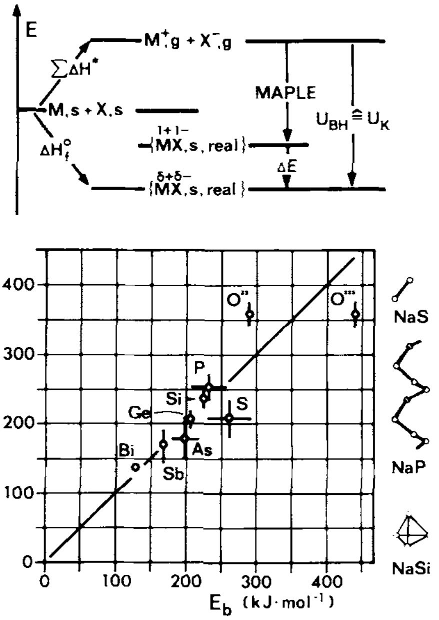

Fig. 14. Simplified Born-Haber cycle (top) with the enthalpy of formation $\Delta H_f$, the various terms of the excitation energy $\sum\Delta H^*$ and the lattice energy $U_{BH}$. According to *Kapustinskii* $U_K$ can be used as a good approximation for $U_{BH}$. $U_K$ should be composed of the Madelung part of the lattice energy MAPLE (calculated for the real structure with $z = \pm 1$) and the homonuclear bond energy $\Delta E$. Below: correlation of $\Delta E$ with the homonuclear bond energy $E_b$ [139] for representatives of the NaS, NaP and NaSi families. The deviations of $\Delta E$ result from various structures (cf. Table 1). The deviations in $E_b$ for some elements result from taking the repulsive electronic effects into account, *e.g.* O'' and O''' [139].

but it possesses different homonuclear X—X contacts (Fig. 14). The MAPLE lattice energy was calculated for the real structure $\{M^{1+}X^{1-}\}_{real}$, and subtracted from the $U_K$ calculated for a hypothetical NaCl structure according to *Kapustinskii*. For the calculation of $U_K$, $R$ was determined from the real molar volumes $V_m$, as the distance M—X in an NaCl structure with the volume 4 $V_m$. The differences $\Delta E$ agree surprisingly well with the usual homonuclear binding energies[139] (Fig. 14). The number of bonds was counted in the classical manner for the atoms in the polyanions; *e.g.* $Si_4^{4-}$ tetrahedrane contains six Si—Si bonds. The individual values for the various compounds do not show much scatter (Table 1), but have a certain trend $\Delta E \sim R$. This is related to the fact that, for constant homonuclear bond lengths, the cluster atoms get, *relatively,* closer together, as the elementary cell or the M—X distance becomes larger. Whether this really points to increasing $\Delta E$ values, or is compensated for by sinking effective charges, or is simply the result of incorrect methods, still has to be investigated. Whatever the answer, this electrostatic treatment of cluster compounds promises to provide, for the metal cluster too, a useful estimation of the binding energy for the homonuclear regions.

Table 1. Homonuclear bond energy $\Delta E$(X—X) from electrostatic calculations. See text and Figure 14 for the definitions of MAPLE and $U_K$. The Born repulsion was not taken into account. $R$ is the distance MX of an NaCl structure and a $CaF_2$ structure, respectively, with the same molar volume. The factor $m$ accounts for the number of X—X bonds per formula unit.

[a] $kJ \cdot mol^{-1}$. [b] $d_0(CaF_2)$; M(2+), X(1−).

The calculations yield an average value of $\Delta E = 361$ $kJ \cdot mol^{-1}$ for the O—O bond. This fits, in a qualitative way, the model that in the structures under study, the repulsive effect of free electron pairs is considerably reduced by the influence of the cations[139].

## 13. Again: The Bonding

*Schäfer, Eisenmann* and *Müller* discussed the Zintl phases some years ago in detail[8a], and contributed much more to this subject later[146]. They also dealt in depth with the question of those compounds for which the Zintl concept apparently fails, those which can be counted as belonging to metallic systems. Among these are above all the compounds of Li with the meta-metals[110], whose structures are variants of the body-centred cubic structure of metals. Clusters of metametal atoms $X_n$ are certainly found, but the valency sum often does not agree with the concept of formal ions. This effect has been explained by the agreement between the metallic radii of Li and X[147,148], that is, using the terminology of metallic phases. On the other hand, a significant relationship has been observed between the X—X distances and the electronegativity $\chi(M)$[8a], which, for example, leads to smaller distances $d_{XX}$ for lithium. This reduction in $d_{XX}$ can be traced back, not only to a reduction in the effective charge, but also to an increase in the classical Pauling bond order[149]. The two effects are interdependent. Lithium, the most electronegative of the alkali metals, also possesses the smallest cation and therefore the one with the largest polarizing influence. The reduction in the anion charge affects above all those states which are antibonding with regard to the X—X bonds, resulting in an increase in the bond order $n_{XX}$. Before these substances are pigeon-holed as intermetallic phases and removed in this way from simple valency considerations, one should remember that most of these phases are described as shiny metallic *and brittle.* Only a few are metallic and ductile. The decisive electrical properties have hardly been examined[150]. We recently established semiconductor behavior for some of these brittle Li phases. The violet $Li_{2.33}Si$ (formerly $Li_2Si$) belongs to these[151]. The diamagnetic phase contains $Si_2$ dumb-bells and, as $Li_{4.67}Si_2$, possesses a defect $M_5X_2$ structure *without* any sign of a significant phase width ($\rightarrow Li_{14}Si_6$).

With the help of several examples, it will now be shown that the bond-order concept leads to interesting results for the Zintl phases too. One obtains the bond order $n$ by comparing the bond lengths $d_n$ and $d_1$ according to *Pauling*[149] ($d_n = d_1 - k \log n$; $k = 60$—$71$ pm) or *Donnay-Allmann*[152] ($n = \{d_1/d_n\}^5$). The two expressions are equivalent, which can be shown by suitable transformation. We now turn to the Li-stannides[110] (Table 2). Using the simplified Mooser-Pearson relationship[17], the expected average bond orders for the anions X, $\bar{n}_{XX}$, can be calculated using the total number of electrons in the compound, $\sum e$, the number of "anions", $m_X$, and the average number of homonuclear bond lines observed in the structure, $\bar{b}_0$:

$$\bar{n}_{XX} = \bar{b}_c/\bar{b}_0, \quad \bar{b}_c = 8 - \sum e/m_X.$$

As shown in Table 2, $\bar{n}$ and the average distance $\bar{d}_{XX}$ agree with the Pauling formula $d_1(Sn^-) = 301$ pm. The values $\bar{n}_{XX}$ are apparently consistent with the variation in the distance $d_{XX}$. $d_1$ is, however, about 20 pm longer than the familiar single bond length $d_1(Sn) = 281$ pm. The same observation can be made for the polyanions of other elements. For example, $d_1(Sb^-) = 286$ pm, which is 12 pm longer than $d_1(Sb) = 274$ pm[140] and the same is true for other elements (*e.g.* $Li_2Sn_5$[8a], compared with β-Sn). An increase of 10—20 pm can be expected in the homonuclear bond lengths, if formal anions $X^-$ are directly bonded in place of neutral atoms $X^0$. If this is taken account of in the expected bond lengths $d_1(X^-)$ a clear indication of higher bond orders is obtained, which allows the Zintl phases to be treated as compounds with normal valency, even though this is forbidden according to the simple total number of topological linkages. The simple comparison between $d(X^-—X^-)$ and the distances in the element X is not very meaningful. Only if both near and far contacts are taken into account are the normal distances, $d_1(X) = 2r_{cov}$, obtained, as for example in the case of P, As, Sb, Bi with the condition $\sum n = 3$. For these elements, $n < 1$ holds for the shorter bonds too. This effect was used before by *Pauling* in deriving the metallic single bond radii.

Table 2. Effective bond order $\bar{n}_{XX}$, formal single bond lengths in polyanions $d_1(X\ \ )$ and the difference $\Delta d_1$ to the single bond lengths of neutral atoms $d_1(X)$ (cf. Text).

| | Ref. | $\bar{d}(X—X)$ [pm] | $\sum e$ | $\bar{b}_c$ | $\bar{b}_0$ | $\bar{n}_{XX}$ | $d_1(X\ \ )$ [a] [pm] | $\Delta d_1$ [pm] |
|---|---|---|---|---|---|---|---|---|
| $Li_7Sn_3$ | [110] | 294 | 19 | 1.67 | 1.33 | 1.25 | 301 | 20 |
| $Li_5Sn_2$ | [110] | 288 | 13 | 1.50 | 1.00 | 1.50 | 300 | 19 |
| $Li_{13}Sn_5$ | [110] | 286 | 33 | 1.40 | 0.80 | 1.75 | 303 | 22 |
| $Li_7Sn_2$ | [110] | 300 | 15 | 0.50 | 0.50 | 1.00 | 300 | 19 |
| $Li_{14}Si_6$ | [151] | 233 | 38 | 1.67 | 1.00 | 1.67 | 248 | 13 |
| $Li_{12}Si_7$ | [58] | 237 | 40 | 2.29 | 1.86 | 1.23 | 244 | 9 |

[a] $k = 70$ pm.

The above mentioned semiconductors, $Li_{14}Si_6$ ($Si_2$ pairs) and $Li_{12}Si_7$ ($Si_4$, $Si_5$) also turn out to be "normal" using this treatment. For the $Si_2$ pairs, the 233 pm distance, which is stretched by the charge, would correspond to the bond order $n = 1.67$. The $Si_4$ star with $\sum n = 3.7$ would be comparable to the carbonate anion and the $Si_5$ rings with $\sum n = 6.2$ would be comparable to cyclopentene[58].

Finally, a reference to $SiP_2$, a pyrite structure with short P—P distances (215 pm)[153,154]. The comparison with $PtP_2$ (P—P = 223 pm[155]) shows above all that the effective bonding state appears to lie between the limits ($Si^{4+} + P_2^{4-}$) with a P—P single bond and ($Si^{2+} + P_2^{2-}$) with a P=P double bond.

## 14. Plastic Phases

Crystals of plastic phases are soft and easily deformed. They form from the melt with a minimum thermal effect since the molecules or complex groups only lose their translatory degrees of freedom. The complex structural units often surround the positions of atoms in highly symmetrical simple structures and carry out free or only slightly hindered rotations. Sharp X-ray lines with rapidly falling intensity are typical for the plastic phases. Examples of these phases among the compounds discussed here are $Rb_3P_7$ and $Cs_3P_{11}$ (cf. Section 9) as well as white phosphorus and β-$P_4S_3$. While the two phosphides take up the structure of the intermetallic phase $Li_3Bi$ ($P_7$ and $P_{11}$ surround the Bi positions), it is interesting that $P_w$ and β-$P_4S_3$ do not follow simple metal structures. In crystalline white phosphorus, 58 $P_4$ tetrahedra surround the positions of the 58 Mn atoms in the unusually complex α-Mn structure[122,157], while the molecules in β-$P_4S_3$ envelope the positions of the 20 Mn atoms in the also complex β-Mn structure[122]. This behavior leads directly to the question of whether $P_4/P_4S_3$ mixed crystals can form, which has not yet been studied, but which could perhaps explain the strange behavior in the metastable part of the P/S system at around "$P_2S$". Four crystallographically different $P_4$ tetrahedra are present in crystalline white phosphorus. They are subjected to different crystal fields and differ from one other in their movement (Fig. 15). This difference is not observed in the NMR spectrum[158]. At 133 K only one of the $P_4$ tetrahedra is "frozen-in" (Fig. 15). A splitting in the NMR signals was attributed here to a lowering of the symmetry.

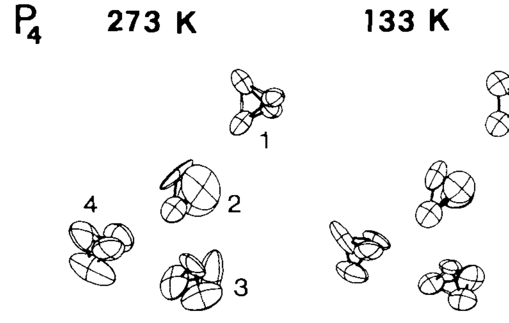

Fig. 15. The four independent $P_4$ tetrahedra in the structure of white phosphorus at 273 K and 133 K [122]. The hindered rotation is poorly described by the vibrational ellipsoids. The considerable changes on cooling to 133 K can, however, be recognized.

For β-$P_4S_3$, $Rb_3P_7$ and $Cs_3P_{11}$, the electron density in the region of the mobile clusters has not yet been analyzed in terms of preferred orientation. This has been done for white phosphorus, but the distances P—P = 195—200 pm are much too short. This effect is, however, typical, and results from the unsuitable algebraic treatment of the problem. The same is true for the P—P distances in the complex $[(np_3)Ni(P_4)]$[*] for example, which are also unreal[159].

## 15. Outlook

I had the impression a few years ago that there was not much more to learn about the cluster compounds of the main group elements. The astounding developments of recent years have taught me better. Apart from the work discussed here I would like to mention the studies made by my fellow-countrymen *Jeitschko*[160], *Schuster*[161] and *Schäfer*[146], who–representative of many colleagues in the world–by combining main group elements with transition elements, opened up new aspects of the problems of homonuclear linkages. The systematic investigation of simple classes of substances seems to promise a wealth of unforseeable experiences for the hunter and collector. Clear vision is, of course necessary, but, provided with the right pair of spectacles, one can even see cluster units in NaCl (Fig. 16).

Cluster compounds are sophisticated redox systems in the solid state, and simultaneously potential generators of interesting molecular compounds. The systematic investigation of physical properties and of chemical behavior are equally im-

---

[*] $np_3$ = tris[2-(diphenylphosphino)ethyl]amine.

portant. As always, we are just at the beginning. This was emphasized by *Klemm* as early as 1943, with a remark that is still topical today: in determining physical data one has to struggle less with the method than with the unyielding substance[162].

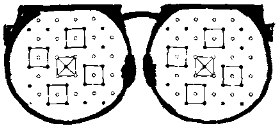

Fig. 16. The author's spectacles for discovering clusters in any structure.

One important aim is to bridge the unnatural gap between molecular chemists and solid state chemists, that is, between moleculists and collectivists. The clusters $P_7$, $As_7$, $Sb_7$, $P_{11}$, $As_{11}$, $Ge_9$, $Sn_9$, $Bi_9$, $Si_4$(I), $Si_4$(II) are impressive examples of the senselessness of all attempts by moleculists to ignore solid substances and by collectivists to let localized bonds in solids merge into bands. For a full understanding of the relationship stoichiometry-structure-properties one needs—after determining the facts—both, the fearless drawing of bond lines *and* the spreading of nets through packed structures. The elimination of language barriers between chemists of both faiths seems to me to be sometimes more difficult than between chemists and physicists. Stacked coordination polyhedra and condensed ring systems are often the same thing. Finally, young chemists have the right to learn at the beginning that, besides $SiCl_4$ and $SiRR'R''R'''$, NaSi exists as well and that "intermetallic phases" are not indecent. Otherwise they might think that elements can only be added from the right-hand side to the left-hand side.

*I wish to thank my wife Christa and my three daughters for putting up with me during the preparation of this work, also my co-workers for their active cooperation over many years. I am also indebted to Dr. W. Hönle, Dr. R. Nesper, Dr. M. Wittmann and Dr. W. Bensmann for their technical help, Mrs. C. Fowler for typing the manuscript, and Dr. A. Griffiths for translating the text into English. Our research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support over many years.*

Received: November 17, 1980 [A 347 IE]

# Ternary Sulfides: Model Compounds for the Correlation of Crystal Structure and Magnetic Properties

By Welf Bronger[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Relationships between crystal structure and magnetic properties enable an insight into the nature of the binding of atoms or ions in the solid state. Suitable as model substances are transition metal compounds in which the collective bonds that are generally present are directively degraded by incorporation of diamagnetic cations. This requirement of progressive degradation is met with in sulfides of the general composition $A_xM_yS_z$, where $A \triangleq$ alkali metal and $M \triangleq$ transition metal.

## 1. Introduction

Examination of the metal chalcogenides from the standpoint of the arrangement of the metals in the periodic system reveals a striking change in properties at the site of insertion of the transition metals. For example, the sulfides of the main group elements have considerable salt-like character, whereas those of the transition elements often have covalent-metallic character. Moreover, it is noteworthy that structures with distinct anisotropic atomic arrangements occur in the transition regions: thus, in the compounds MX of metals of the fourth period ($M \triangleq$ metal, $X \triangleq$ chalcogen) the CuS-type structure represents a transition to a layer structure, while the CuTe-type, which in the case of the iron chalcogenides also appears at the boundary to the salt-like manganese compounds, represents a real layer structure. These structural types form a transition to the NiAs-type, which is commonly met with in the transition-metal chalcogenides. In this type of structure the metal atoms occupy the octahedral sites of hexagonally packed layers of sulfur, selenium or tellurium, with relatively short metal-metal distances in the direction of the c-axis—a structure results which is obviously predestined for metallic bonding.

An analogous situation is found in the $MX_2$ compounds: The anisotropic structure type which here enables transitions from predominantly salt-like to predominantly covalent-metallic bonding, is realized only by the $CdI_2$ layer structure type. The dichalcogenides $TiS_2$, $TiSe_2$ and $TiTe_2$ crystallizing with this type of structure serve as typical examples.

These relationships between crystal structure and chemical bonding described for MX and $MX_2$ compounds of metals of the fourth period are also found in compounds of other stoichiometry as well as in the case of metals of higher periods. The anisotropic arrangements of the atoms occurring in the transition from extremely ionic to extremely covalent-metallic bonding, are always associated with characteristic electric and magnetic properties.

The variety of chalcogenides of the non-transition metals on the one hand and of chalcogenides of the transition metals on the other prompts the following question: what properties can be expected in the case of chalcogenides containing both a non-transition metal as well as a transition metal? In this context the most informative combination would be that of an alkali metal with a transition metal. This concept urged us to investigate compounds of the general composition $A_xM_yX_z$, where $A \triangleq$ alkali metal, $M \triangleq$ transition metal, and $X \triangleq$ chalcogen.

Regarding structural properties the prerequisites here are similar to those in the case of Zintl phases, in which the anisotropic crystal structures of the elements in the transition range between non-metals and metals can be copied and varied by combination of an electropositive metal with a semimetal. In the case of ternary chalcogenides appropriately containing an electropositive metal A and a transition metal M, one can similarly expect that the anisotropic arrangements of the atoms in the border region between ionic and metallic metal chalcogenides are copied and, moreover, so diversely modified that $[M_yS_z]$-framework structures are formed which resemble those of binary metal sulfides. In addition, as a result of incorporation of transition metals, the magnetic properties, in particular, might yield important information about the nature of the bonding and thus make a valuable contribution to the elucidation of chemical bonding in the solid state.

In the following paper, therefore, an account is given of the relationships between structure and magnetic properties in the case of the alkali metal-transition metal chalcogenides, with particular emphasis on the sulfides.

## 2. Synthesis of Ternary Alkali Metal—Transition Metal Sulfides

The first investigations on the existence of ternary sulfides of alkali metals and transition metals date back to about 1840 to 1875. Particularly worth noting are the works of *Völker*[1] and *Schneider*[2,3], from which it emerges that ternary sulfides such as $KFeS_2$, $NaCrS_2$ and $KCrS_2$ are formed on fusing together salts of the transition metals with sulfur and soda or potash. Some of these earlier findings were later confirmed around the turn of the century by *Milbauer*[4,5], who was able to synthesize ternary sulfides by reaction of KSCN with metal oxides at elevated temperatures. These older works then fell for a long time into oblivion, and it was not until the middle of the forties before new results were published by *Rüdorff et al.*[6-8], mainly on chromium and copper compounds. Analogies and interrelationship have now been recognized and are represented by a great number of new al-

kali metal-transition metal sulfides and selenides which have been characterized in recent times.

Based on earlier findings on the preparation of ternary sulfides, methods have been developed for the isolation of pure, above all oxygen-free, substances. For this purpose hydrides or the metals themselves are used as alkali metal components besides the carbonates, sulfides or polysulfides. The reaction partners are then transition metals in elemental form and sulfur or hydrogen sulfide. The reactions generally occur between 800 and 1300 °C in the melt, and on cooling under suitable conditions the ternary sulfides can be obtained as well formed, often beautifully colored crystals.

Parallel and as an extension to the fusion reactions ternary sulfides can be prepared by intercalation of alkali metals in the layer structures of metal chalcogenides. The disulfides and diselenides of transition metals of the 4th, 5th and 6th groups as well as those of rhenium and platinum usually serve as host structures. The reactions are generally carried out in liquid ammonia.

Table 1 contains a list of the ternary sulfides of alkali metals and transition metals which have so far been investigated in detail. The aforementioned intercalation compounds, which usually have wide ranges of homogeneity, are not listed. $AVS_2$ and $ACrS_2$ can still be regarded as borderline compositions for the incorporation of alkali metal A in the metastable disulfides $VS_2$ and $CrS_2$. Ternary sulfides for which accurate data on crystal structure and magnetic properties are not available are likewise not considered, or are regarded as a group with A $\triangleq$ alkali metal. In recent years some of the corresponding ternary selenides have also been synthesized. As far as known, their structural and magnetic properties are in all cases similar to those of the sulfides.

Table 1. Data on the crystal structure and magnetic properties of ternary alkali metal-transition metal sulfides.

| Compound | Structural characteristics | Shortest bond lengths M—M [pm] | Shortest bond lengths M—S [pm] | Magnetic properties | Ref. |
|---|---|---|---|---|---|
| $LiVS_2$ | Fully occupied $CdI_2$ type (cf. Fig. 1b) | 338.03(2) | 243(1) | Antiferromagnetic; still no three-dimensional arrangement of the moments at 4.2 K | [9]<br>[10] |
| $NaVS_2$ | Fully occupied $CdCl_2$ type (cf. Fig. 2b) | 357 | 246 [a] | Paramagnetic with delocalized moments corresponding to $V^{3+}$; antiferromagnetic arrangement below 50 K | [11]<br>[12] |
| $LiCrS_2$ | Corresponding to $LiVS_2$ | 346.37(3) | 240(1) | Antiferromagnetic arrangement of the moments at 4.2 K | [9]<br>[13] |
| $NaCrS_2$ | Corresponding to $NaVS_2$ | 355.44(2) | 243.4 | Paramagnetic with localized moments corresponding to $Cr^{3+}$; antiferromagnetic below 19 K ($NaCrS_2$) and 38 K ($KCrS_2$), resp. θ: 30 K ($NaCrS_2$); 112 K ($KCrS_2$) | [16]<br>[14]<br>[15] |
| $KCrS_2$ | Corresponding to $NaVS_2$ | 360.2(6) | 242.8 | | |
| $KCr_5S_8$ | Sulfur octahedra with central chromium atoms, linked *via* common edges and, in part, *via* common surfaces. The framework structure thus formed contains channels in which the alkali metal ions are arranged linearly | from 298(2)<br>to 366(1) | from 235(3)<br>to 251(2) | | [16] |
| $RbCr_5S_8$ | | from 296(1)<br>to 366(1) | from 235(1)<br>to 250(1) | | [16] |
| $CsCr_5S_8$ | | from 297(2)<br>to 363(1) | from 234(2)<br>to 252(2) | | [16] |
| $Rb_2Mn_3S_4$ | Sulfur tetrahedra linked *via* edges in which the manganese atoms are incorporated corresponding to $^2_\infty[Mn_{0.75}\square_{0.25}S]$. Separation by alkali metal atom layers (cf. Fig. 3b) | 296.7(1)<br>304.4(2) | 240.7(2)<br>242.4(3)<br>244.6(3) | Antiferromagnetic | [17]<br>[18]<br>[19] |
| $Cs_2Mn_3S_4$ | | 300.6(1)<br>310.3(1) | 241.9(2)<br>244.2(2)<br>246.0(2) | Antiferromagnetic | [17]<br>[18]<br>[19] |
| $Na_3FeS_3$ | Isolated $[Fe_2S_6]$-units (cf. Fig. 6) | 287.7(2) | 224.9(2)<br>225.2(2)<br>226.0(3)<br>229.8(2) | Antiferromagnetic coupling of the iron atoms in the binuclear complex | [20] |
| $Na_3Fe_2S_4$ | $^1_\infty[FeS_{4/2}]$-chains | 274.5(1)<br>274.9(1) | 228.4(1)<br>228.9(1)<br>229.8(2)<br>233.5(1) | | [21] |
| $KFeS_2$ | $^1_\infty[FeS_{4/2}]$-chains (cf. Fig. 4) | 270 | 218<br>229 | Linear antiferromagnetism; threedimensional arrangement of the moments below 250 K ($KFeS_2$), 188 K ($RbFeS_2$), and 66 K ($CsFeS_2$), resp. | [22]<br>[27]<br>[23] |
| $RbFeS_2$ | | 271 | 220<br>222 | | [24] |

## 3. Crystal Structures with Characteristic $[M_yS_z]$-Frameworks

The ternary sulfides presented in Table 1 do not show any, or only slight, phase widths. The combination of alkali metal and transition metal, moreover, leads to oxidation states of the transition metals which are typical for salt-like compounds. Phase widths and associated alloy-like properties are observed only on transition to intercalation compounds. The structures in this region also show a continuous transition. Thus the atomic arrangement in $LiVS_2$ or $LiCrS_2$ corresponds, on the one hand, to the nickel arsenide type with a layer distribution of the cations; on the other hand, it can also be described as a filled-up $VS_2$- or $CrS_2$-structure ($CdI_2$-type, cf. Fig. 1) and thus forms a direct transition to the lithium-deficient intercalation compounds, which crystallize with the same structure type with only partially occupied lithium positions. In the stoichiometrically analogous alkali metal compounds $NaVS_2$, $NaCrS_2$ and $KCrS_2$ the structure of the $MS_2$-framework does not correspond to the $CdI_2$-type, but to the $CdCl_2$-type. Here the sulfur layers are arranged in the sequence —ABCA— (Fig. 2a), so that the occupation of all octahedral sites with A and M atoms can be described in terms of the rock-salt structure with layerwise ordered cation distribution (cf. Fig. 2b). In the alkali-metal deficient $ACr_5S_8$ compounds which follow (in Table 1), the three-dimensional $[Cr_5S_8]$-framework is preserved. The linking of the sulfur octahedra is obviously directionally dependent, so that channels are formed in which alkali metal atoms with short A—A distances are incorporated.

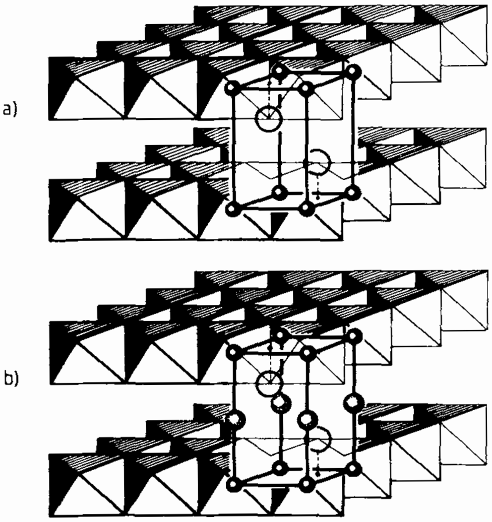

Fig. 1. a) $CdI_2$-type layer structure of many dichalcogenides $MX_2$. Open circles: X-, closed circles M-positions. b) Fully occupied $CdI_2$-structure ($LiCrS_2$-type). Dotted circles: alkali-metal positions. These symbols are also used in the following Figures.

In the alkali metal thiomanganates the structure of the $[Mn_3S_4]$-framework largely corresponds to the tetragonal CuTe layer structure-type (cf. Fig. 3a). The metal atoms occupy alternately every second layer of tetrahedral sites of a sequence of chalcogen atom layers. The only differences are that in the $[Mn_3S_4]$-framework, according to the stoichiometry, only three of four tetrahedral sites are occupied and that the layers, unlike in CuTe, are not arranged in the sequence —ABAB— but in the sequence —ABBA—. This enables the alkali metal atoms incorporated between layers of the same sequence to be coordinated by sulfur atoms in a cubic arrangement (cf. Fig. 3b).

The alkali metal thioferrates $AFeS_2$ crystallize in chain structure types. The $[FeS_2]$-framework corresponds to the $SiS_2$ structure: The iron atoms are coordinated tetrahedrally by sulfur atoms, while the sulfur tetrahedra are linked one-dimensionally *via* edges. The alkali metal atoms are incorporated between the chains, with differing coordination number according to size (cf. Fig. 4 and 5). The compound $Na_3Fe_2S_4$ also has an analogous framework structure. In the

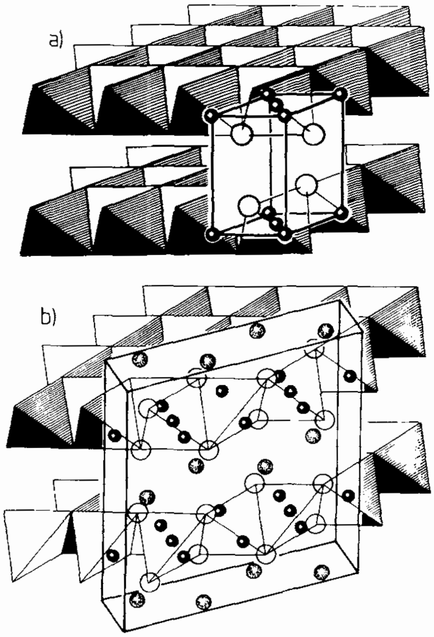

Fig. 3. a) CuTe structure. b) Fully occupied CuTe structure ($Cs_2Mn_3S_4$-type) with modified layer sequence.

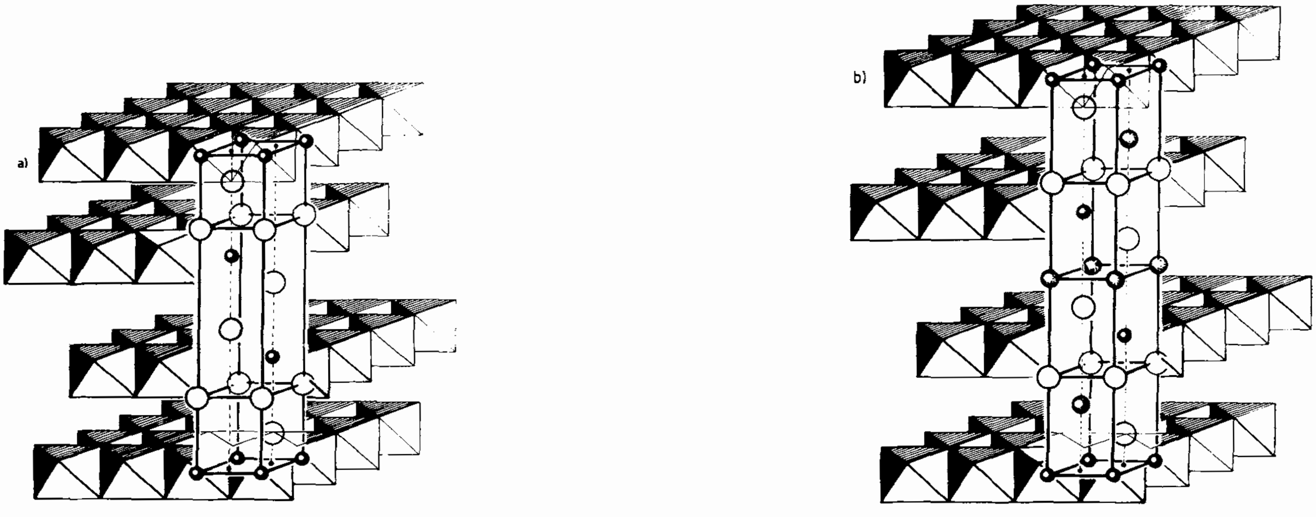

Fig. 2. a) $CdCl_2$-type, as layer structure previously not observed in metal dichalcogenides. b) Fully occupied $CdCl_2$ structure ($\alpha$-$NaFeO_2$ type). Characteristic atomic arrangement for many ternary sulfides of the composition $AMS_2$.

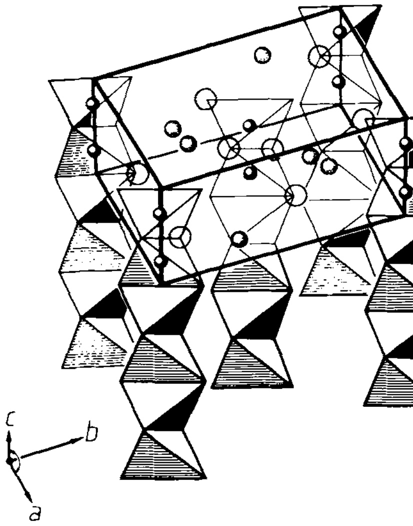

Fig. 4. $KFeS_2$-type structure.

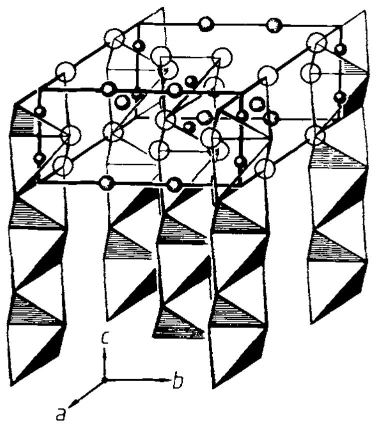

Fig. 5. $CsFeS_2$-type structure.

more sodium-rich compound $Na_3FeS_3$, however, even the one-dimensional framework is broken: only isolated $[Fe_2S_6]$ double tetrahedra are found which are arranged with the sodium atoms in a three-dimensional array (cf. Fig. 6).

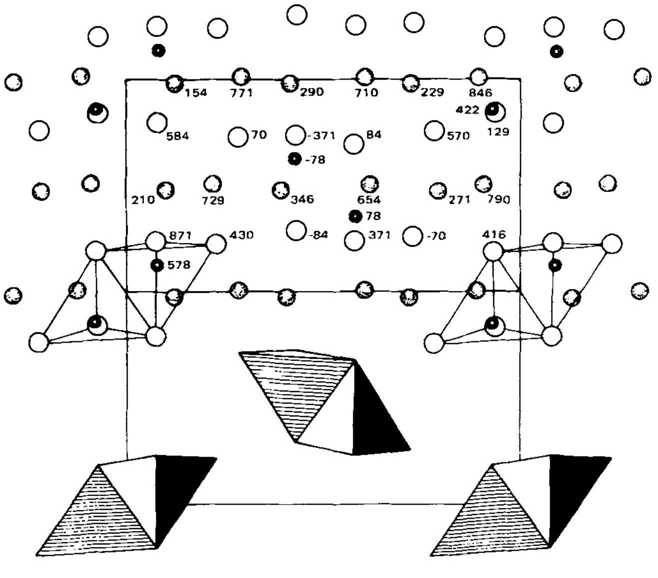

Fig. 6. $Na_3FeS_3$, atomic arrangement.

The ternary cobalt compound $Cs_2Co_3S_4$ is isotypic with the corresponding manganese compound (cf. Fig. 3). The nickel sulfides $A_2Ni_3S_4$, for which a detailed structure determination on single crystals is still lacking, have, on the other hand, a completely different structure. According to previous investigations they are isotypic with the analogous palladium and platinum compounds. The underlying constructional principle of these structures is illustrated in Figure 7 for the $Cs_2Pd_3S_4$-type as example: The palladium atoms are surrounded by a planar arrangement of sulfur atoms and the resulting rectangular arrays are linked with one another two-dimensionally *via* sides in a honeycomb-fashion. The sulfur-palladium-sulfur layer assemblies are finally separated from one another by double layers of alkali metal atoms. The observed planar coordination of transition metal atoms with $d^8$-configuration is in keeping with expectation; the layer structure of the $[Pd_3S_4]$-framework had hitherto not been observed in binary compounds. Moreover, ternary alkali metal thiopalladates and thioplatinates of the composition $A_2PdS_2$ and $A_2PtS_2$, respectively, could be synthesized. Their framework structure corresponds to that of $PdCl_2$: Here the arrangements with planar sulfur coordination are linked with one another one-dimensionally *via* sides. Figure 8 illustrates this with the $K_2PtS_2$-type as example. Finally, ternary platinum sulfides have been reported in which platinum atoms of oxidation states +4 and +2 are incorporated between sulfur layers with octahedral and planar coordination, respectively. The sulfur-platinum-sulfur layer assemblies are once again separated by alkali metal atoms. An accurate crystal structure investigation of $K_2Pt_4S_6$ is available.

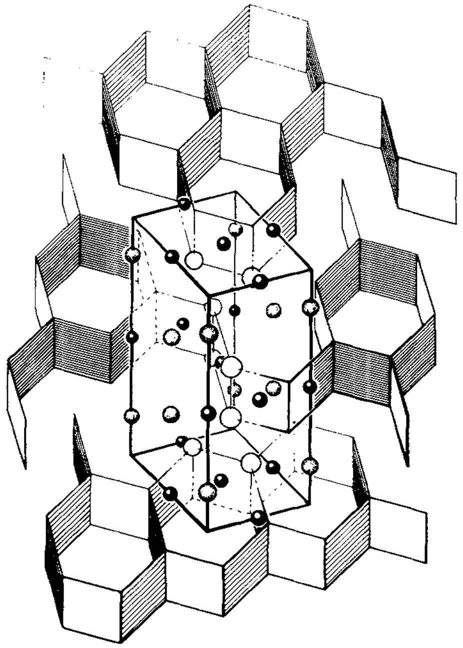

Fig. 7. $Cs_2Pd_3S_4$-type structure.

A number of ternary sulfides of alkali metals and copper have already been known for some time. The compositions (Table 1) indicate mixed valence compounds. Detailed structural investigations reveal, however, that a crystallographic differentiation between $Cu^{1+}$ and $Cu^{2+}$ is not possible. Thus, the copper atoms in the $KCu_4S_3$-type structure occupy equivalent positions. The atomic arrangement is once again

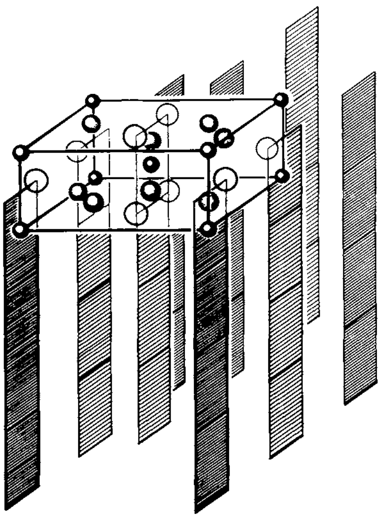

Fig. 8. $K_2PtS_2$-type structure.

describable as a layer structure, in which the copper atoms occupy double layers of tetrahedral sites built up by sulfur atoms and these arrays are separated by the alkali metal atom layers (cf. Fig. 9). A layer structure is also recognizable in the $K_3Cu_8S_6$-type structure. The copper atoms—here also a differentiation of oxidation numbers on the basis of coordination numbers and Cu—S distances is not possible—have approximately trigonal planar or distorted tetrahedral environments. Of the thiocuprates listed in Table 1, $Na_3Cu_4S_4$ is the most rich in alkali metal; it is typical, therefore, that the degree of cross-linking of the framework structure is further reduced. The copper-sulfur arrays form one-dimensional strands, in which the copper atoms have coordination number three. Besides the compounds listed here, there also exist some in which all copper atoms have completely filled d-levels, *i.e.* in which copper no longer functions as a transition metal. Corresponding diamagnetic compounds of silver are also known. Detailed information on alkali metal thioaurates is so far lacking.

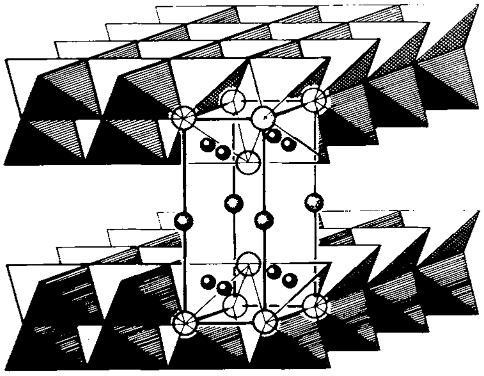

Fig. 9. $KCu_4S_3$-type structure.

In the case of 4d- and 5d-transition metals ternary chalcogenides of the general composition $A_xM_yX_z$ were unknown, apart from the aforementioned palladium and platinum compounds and intercalation phases in which alkali metals are intercalated in $MX_2$ layer structures. Only very recently molybdenum and rhenium compounds were discovered which contain isolated $[M_6S_8]$ clusters or, in the case of the alkali metal molybdenum sulfides, also condensed units of these clusters[41]. The structural data determined on single crystals of the rhenium compounds are given in Table 1; corresponding values for the molybdenum compounds are so far lacking. In the case of $Li_4Re_6S_{11}$ a framework structure was discovered which is already known for a binary system: linkage of the $[Re_6S_8]S^{4-}_{6/2}$ type is analogous to that in $Nb_6I_{11}$ ($\triangleq [Nb_6I_8]I_{6/2}$) (cf. Fig. 10).

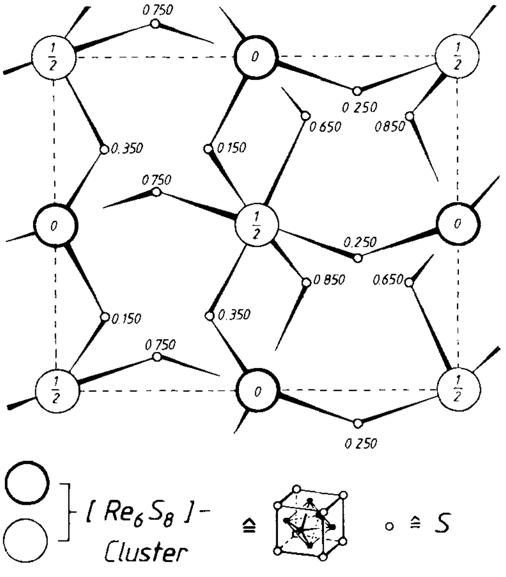

Fig. 10. $Li_4Re_6S_{11}$, structure of the $[Re_6S_8]S^{4-}_{6/2}$-framework.

Not to be overlooked are ternary sulfides which contain an f-element besides an alkali metal. For example, in the lanthanoid series (general symbol Ln) compounds of the composition $ALnS_2$ exist. At a radius ratio $r_{Ln^{3+}}/r_{A^+}$ above $\approx 0.9$ a random distribution of the cations can be found in the octahedral sites of cubic close packed layer sequences of the anions. At a smaller radius ratio an ordered distribution which deviates from the $CdCl_2$ framework structure becomes stable (cf. Fig. 2b).

At this juncture we might summarize as follows: The crystal structures of the ternary alkali metal-transition metal sulfides $A_xM_yS_z$ contain $[M_yS_z]$ frameworks which form three-, two- or one-dimensional arrays. Some of the atomic arrangements in these arrays were observed in binary compounds in which directed bonding entities lead to an anisotropic structure. Apparently, the Zintl-Klemm-Busmann principle[42] can be further extended beyond the explanation of the structure and bonding of Zintl phases, and as a matter of fact, quite generally, if ionic partners in a compound determine the makeup of covalent framework structures. Metallic properties can conceal the picture, but do not have to!

## 4. Magnetic Properties and their Correlation with Structure

In the ternary sulfides described here, magnetic properties can—in addition to the crystal structures—enable further insights into the bonding. Unfortunately, accurate data are still not available for all compounds (cf. Table 1). From the picture gained so far, however, it can be recognized that the covalent bonding moieties in the $[M_yS_z]$-framework structures can link *via* the direct interaction of neighboring M- and S-atoms to give ferro- or antiferromagnetic arrangements. Thereby direct exchange interactions of the paramagnetic centers might recede into the background compared to the indirect linkages *via* the sulfur ligands. These collective covalent bondings can now be correlated with each of the respective crystal structures *via* an analysis of the magnetic properties. Thus, *e.g.*, in the accurately investigated layer structures of the alkali metal thiovanadates and chromates (cf. Table 1) below the Néel temperatures one finds spin orders at which the coupling constants in the sulfur-transition metal-sulfur layer assemblies are markedly greater than between the layer assemblies. As a result of this anisotropy of the collective bonds furnished by the framework structure there can occur, *e.g.*, metamagnetic behavior, a phenomenon which makes itself manifest by the fact that at a critical field strength an external magnetic field perpendicular to the layers turns the antiferromagnetic arrangement of the spin moments between the layers into an energetically more favorable ferromagnetic arrangement. Since the strong ferromagnetic couplings in the layers thereby remain unaltered this spin flop mechanism makes itself significantly perceptible in the susceptibility values or in the neutron diffraction diagram. In a more accurate analysis a similar behavior might possibly be found in the layered tetrahedral framework structures of the alkali metal thiomanganates and thiocobaltates.

The chain structures of the sulfides $KFeS_2$, $RbFeS_2$, and $CsFeS_2$ behave like linear antiferromagnets at elevated temperatures. Here the couplings of the magnetic moments in the tetrahedral chains survive up to the decomposition temperatures. The antiferromagnetic interactions are correlated with remarkably short Fe—Fe and Fe—S distances of *ca.* 271 and 223 pm, respectively, within the chains (cf. Table 1). Corresponding distances in the thiomanganates(II), which are isoelectronic with regard to the M atoms, are longer; the resulting weaker collective bonds are also clearly recognized by the higher susceptibility values. In the ferrates it can also be observed that the anisotropy of the coupling phenomena increases on going from the potassium to the cesium compound, since the Néel points for the three-dimensional arrangements of the moments decrease on going from $KFeS_2$ to $CsFeS_2$—a clear demonstration that the atomic distances in the chains in the same sequence hardly change, in contrast to the distances between the chains. For the dinuclear complex $[Fe_2S_6]^{6-}$ in the atomic arrangement of the alkali-metal-rich compound $Na_3FeS_3$ the spin configurations of the individual atoms can be recognized directly *via* the temperature dependence of the magnetic susceptibilities (cf. Section 5.2).

Thioniccolates, thiopalladates and thioplatinates with planar ligand configurations of the transition metal atoms were found to be diamagnetic, thus indicating spin pairing of the $d^8$ system. The degree of diamagnetism corresponds, within the accuracy of measurement, to the values calculated from the increments. Of the copper compounds, only $KCu_4S_3$ has been investigated in detail. It is so far the only ternary alkali metal-transition metal sulfide which exhibits metallic conducting properties. The weak, almost temperature-independent paramagnetism of this compound might therefore be due to the conducting electrons.

In previous investigations the rhenium cluster compounds proved to be diamagnetic. This can also be expected from quantum mechanical calculations, for, with 24 valence electrons per $[Re_6]$-unit, all bonding orbitals are fully occupied. At the same time this implies that single bonds exist between the rhenium atoms in the almost regular $[Re_6]$-octahedra[43-45].

In the lanthanoid compounds $ALnS_2$ the expected magnetism of the trivalent ions was found at elevated temperatures. At very low temperatures Néel points can be observed. Accurate measurements of the magnetic susceptibilities have shown, moreover, that deviations from the linear $1/\chi - T$ law, *i.e.* from the Curie or Curie-Weiss behavior, occur far above the Néel temperatures. On the basis of quantum mechanical calculations there is the possibility of interpreting the measured behavior in terms of crystal field effects and exchange interactions and thus of gaining a deeper insight into the bonding[46,47]. This will be discussed in detail in Section 5.1 for the example of $NaCeS_2$.

It generally holds for the relationships between crystal structure and magnetic properties of the ternary sulfides presented here that the anisotropic $[M_yS_z]$-framework induced by incorporation of alkali metal ions is distinguished by strong covalent bonds. These bonds give collective couplings in non-spin-paired configurations of the M atoms and can be detected by anisotropic antiferromagnetic behavior. In spin-paired configurations of the M atoms, as enforced *e.g.* in ternary nickel(II), palladium(II) and platinum(II) sulfides by the M—S bonds of the planar oriented S ligands, diamagnetic behavior results. In this connection it should be mentioned that it is of importance for assessment of the magnetic behavior whether or not a compound has metallic properties. Conductivity measurements carried out so far[48] show that metallic properties occur exclusively in the mixed-valence compound $KCu_4S_3$.

## 5. Characterization of the Chemical Bond: Chemical Bonding and the Relationship between Structure and Magnetism

A further insight into the relationships between structure and magnetism is achieved if, as an extension to the analysis of the collective interactions, it is possible to measure the direct influence of the ligands on an individual central atom and to find a good fit of the measured values with model calculations. This will be discussed in the following Sections for two very different examples:

a) In $NaCeS_2$ the influence of the ligands on the cerium atom is relatively weak. An antiferromagnetic arrangement is first indicated at 4.8 K, so that above this temperature the influence of the crystal structure on the magnetic properties of the cerium atom can be observed directly[46,47].

b) In $CsFeS_2$ the influence of the ligand field is strong and, at the same time, collective couplings are present up to high temperatures. To gain information about the bonding from the magnetic properties, the antiferromagnetic interactions in the chains must be disturbed by the incorporation of diamagnetic ions. This has been successful in the series of mixed crystals $CsGa_{1-x}Fe_xS_2$[24].

### 5.1. First Example: $NaCeS_2$

$NaCeS_2$ crystallizes in the rock-salt structure. $Na^+$ and $Ce^{3+}$ ions are statistically distributed at the cation sites, their ionic radii, 116 and 115 pm, respectively, are practically equal. The sulfide, which has no phase width, can be obtained from the melt in very pure form as red crystals[49,50]. Figure 11 shows the $1/\chi_{mol}-T$ diagram[*]; the susceptibility

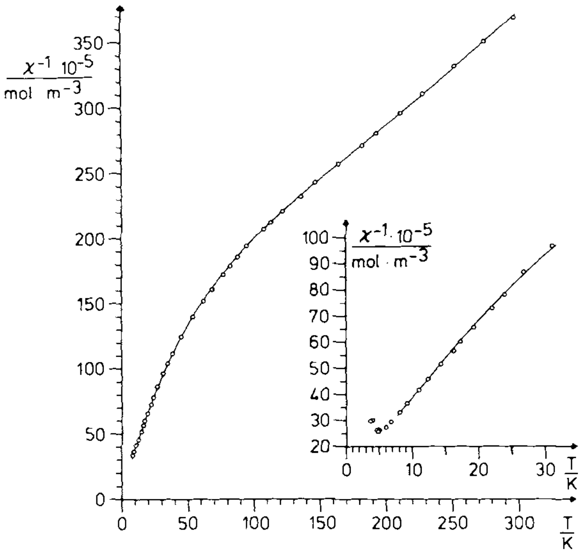

Fig. 11. $1/\chi_{mol}-T$ diagram of $NaCeS_2$: ○○○○ experimental values; —— calculated curves, using the susceptibility formula (4).

values were determined between 3.7 and 297 K by the Faraday method[46]. In the upper temperature range linear dependence is observed, below 4.8 K there exists an antiferromagnetic arrangement of the magnetic moments. The moment calculated from the linear region is in good agreement with the moment calculated for a free $Ce^{3+}$ ion. Below 150 K there are strong deviations from the Curie-Weiss law. This behavior has been successfully explained with the assumption of crystal field effects which could be taken into account by means of a point charge model, and by exchange interactions which were taken care of by a molecular field approximation. The parameters then obtained after a least squares fit to the experimentally determined susceptibility values provided information about the bonding of this sulfide.

The quantum mechanical calculations were performed using the perturbation method. The energy equation of the free $Ce^{3+}$ ion was assigned to the unperturbed system. In the case of compounds of the lanthanoids it is generally essential that the 4f electrons effecting the paramagnetism of the ions lie deep in the electronic sheath and hence are shielded by the outer 5s and 5p electrons. Thus, on incorporation into a crystal lattice not only are the spin moments essentially preserved but also the orbital moments. Moreover, the spin-orbital coupling is relatively strong, so that at room temperature generally only the lowest J-multiplet is occupied. The relevant ground state is given by Hund's rule. For the $Ce^{3+}$ ion it is more essential that expansion of the 4f orbitals in comparison to the ionic radius is greater than in the other lanthanoids and thus the influence of the ligands, promoted by the crystal structure, is distinctly more noticeable, and that quantum mechanical calculations for the $4f^1$-system with only one electron, necessary for calculation of these effects, are simpler than with other configurations.

The sixfold energy-degenerate $\psi$-functions, which correspond to the ground state of $Ce^{3+}$ with $J=5/2$ are suitable as basis functions for the calculations. The distance of the multiplet to the next term ($J=7/2$) is 2250 $cm^{-1}$. This was not taken into account in the calculations. The influence of the cubic crystal field leads to a splitting of the sixfold degenerated ground state into a doublet ($\Gamma_7$) and a quartet ($\Gamma_8$), whose energy difference $\Delta$ depends on the charge and the position of the atoms in the environs of the cerium atom under consideration[51]. A reduction in symmetry of the cubic crystal field caused by a non-homogeneous distribution of the cations in the outer coordination spheres of the cerium ions is of minor importance. The effect on the calculation of the susceptibility values is only slight, leading to a deviation of about 0.3%. Starting from the Van Vleck relation[52] for the calculation of the susceptibilities $\chi$

$$\chi = -\frac{N}{H}\,\frac{\sum\limits_i (\partial E_i/\partial H)\exp(-E_i/kT)}{\sum\limits_i \exp(-E_i/kT)} \tag{1}$$

in which $N$ is the Avogadro number and $-(\partial E_i/\partial H)=\mu_i$ the magnetic moment assigned to the energy state in the direction of the externally established field, a perturbation calculation with exclusive consideration of the influence of the crystal field gives

$$\chi_{KF} = \frac{5Ng^2\mu_B^2}{18kTZ}\,\{(5/2+16kT/\Delta)\exp(\Delta/kT)+13-16kT/\Delta\} \tag{2}$$

where $Z=2+\exp(\Delta/kT)$.

Exchange interactions can be taken into consideration by means of an additional perturbation calculation. In keeping with a Weiss formulation assuming a molecular field then gives for the magnetic susceptibility in the paramagnetic region

$$1/\chi = 1/\chi_{KF}-\lambda \tag{3}$$

with $\lambda$ as molecular field parameter. This effect requires a parallel shift in the $1/\chi-T$ curve, as is known for the linear case of the extension of the Curie law to the Curie-Weiss law. If anisotropic components besides the isotropic components are taken into account in the exchange interactions between the cerium atoms, which essentially occur *via* the sulfur atoms (superexchange), then the simple model must be extended so as to take into consideration the different influence of the exchange interactions on the crystal field states[53-55]. For calculation of the susceptibilities we finally arrive at the following relation:

$$\chi = \frac{(5/2+16kT/\Delta)\exp(\Delta/kT)+13-16kT/\Delta}{\dfrac{18kTZ}{5Ng^2\mu_B^2}-\left(\dfrac{5}{2}\lambda_1+\dfrac{16kT}{\Delta}\lambda_3\right)\exp\left(\dfrac{\Delta}{kT}\right)-13\lambda_2+\dfrac{16kT}{\Delta}\lambda_3} \tag{4}$$

---

[*] In order to facilitate a better comparison with values in the literature $\chi_{mol}$ is given in cgs units, the corresponding values in the SI system are obtained therefrom by multiplication with $4\pi\times10^{-6}$.

Here the molecular field parameters $\lambda_1$ and $\lambda_2$ give the exchange effects referred to the $\Gamma_7$ and $\Gamma_8$ functions, respectively; $\lambda_3$ describes to what extent the wave functions of the ground state are mixed with functions of the excited state by the molecular field (terms of the molecular field, which correspond to the 2nd order Zeemann effect).

Table 2. Parameters obtained from best fits using the susceptibility formulas (2), (3) and (4).

| Formula | $\Delta$ [cm$^{-1}$] | $\lambda_n \times 10^{-5}$ [m$^{-3}$ mol] $n=1$ | $n=2$ | $n=3$ | $R$-value [a] |
|---|---|---|---|---|---|
| (2) | 420 | 0 | 0 | 0 | 0.023 |
| (3) | 416 | −0.5 | − 0.5 | − 0.5 | 0.021 |
| (4) | 470 | −4 | −166 | 35 | 0.0075 |

[a] $R = \left[\sum_{i=1}^{n} |\chi_i(\text{obs.}) - \chi_i(\text{calc.})|\right] \Big/ \left[\sum_{i=1}^{n} \chi_i(\text{obs.})\right]$.

Table 2 lists the parameters determined from best fits using the susceptibility formulas (2), (3) and (4). The fit to the measured values was carried out by the method of least squares. The $R$ value can be regarded as a reliability factor. It is noteworthy that the $R$ value shows a decisively better fit on going from formula (3) to formula (4). If one considers the individual parameters obtained with the formula (4) in detail, it immediately follows from the positive sign of $\Delta$ that $\Gamma_7$ is the ground state. For $Ce^{3+}$, which is octahedrally surrounded by atoms with negative charges, this is to be expected. Figure 12 illustrates this result. Thus, the $\Gamma_8$ states have their maximum electron densities on the x, y and z axes if the $Ce^{3+}$ lies at the origin, *i. e.* in the direction of the negatively charged sulfur ligands, while the electron density maxima for the $\Gamma_7$ state lie along the cube diagonals. But it is also understandable that the $\Gamma_8$ state is decisive in the exchange interactions *via* the sulfur ligands, for only here is essential overlap of the orbitals of central atom and ligand to be expected. Thus the molecular field constant $\lambda_2$, which is assigned to the $\Gamma_8$ state, is also greater by a factor of 41.5 than the value of $\lambda_1$ assigned to the $\Gamma_7$ state. The negative signs of $\lambda_1$ and $\lambda_2$ correspond to antiferromagnetic interactions. These collective covalent bonds are also essentially consistent with the energy difference between the states $\Gamma_7$ and $\Gamma_8$ obtained from the fit with $\Delta = 470$ cm$^{-1}$, being about 57% greater than the value which can be calculated assuming purely ionic bonding (point charge model)[46].

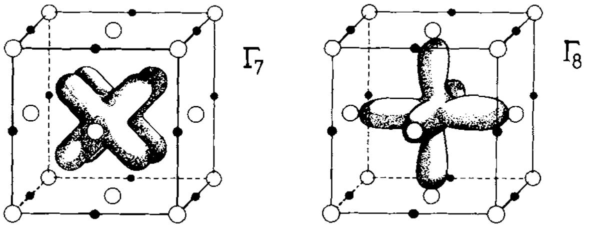

Fig. 12. Electron density distributions of the crystal field states $\Gamma_7$ and $\Gamma_8$. ○ ≙ $S^{2-}$, ● ≙ $Ce^{3+}/Na^+$.

Accordingly, from the change in magnetic susceptibilities of $NaCeS_2$ above the antiferromagnetic Néel temperature an insight can be gained into the chemical bonding: The purely electrostatic components enable an accurate reproduction of the experimental values *via* crystal field effects by point charge models and the covalent components *via* exchange interactions by a molecular field approximation.

### 5.2. Second Example: $CsFeS_2$

$CsFeS_2$ crystallizes in the structure already illustrated in Figure 5. The iron atoms are tetrahedrally surrounded by sulfur atoms, and the tetrahedra are linked one-dimensionally *via* edges to give chains. In the chains the Fe—Fe and, above all, Fe—S distances are markedly short (cf. Table 1); the chains themselves are relatively well separated from one another by the alkali metal atoms.

The magnetic properties of $CsFeS_2$ are closely related to the structural anomalies. Susceptibility measurements gave values which reveal antiferromagnetic interactions of the paramagnetic transition metal species; however, results of neutron diffraction experiments and Mössbauer spectra show that a three-dimensional arrangement of the magnetic moments occurs only below 55 K[24,27,56-58]. Above this Néel temperature $CsFeS_2$ exists as a linear antiferromagnet.

In order to measure the magnetic moment of an iron atom in the tetrahedral field of its sulfur ligands the collective bonds, recognizable by the antiferromagnetic behavior, must be broken. This possibility became feasible after the crystal structure determination of $CsGaS_2$ had shown a structure isotypic with $RbFeS_2$ (Fig. 4)[59], and thus the synthesis of a series of mixed crystals $CsGa_{1-x}Fe_xS_2$ with the two atomic arrangements shown in Figures 4 and 5 as terminal members appeared to be possible[24].

X-ray crystallographic investigations on the system $CsGa_{1-x}Fe_xS_2$ showed with reference to the phase sequences, that in the monoclinic $CsGaS_2$ structure gallium atoms can be replaced by iron atoms up to the approximate composition $CsGa_{0.75}Fe_{0.25}S_2$, that also a monoclinic phase with a small homogeneous region exists in which $x \approx 0.45$, and that the rhombic $CsFeS_2$ structure can take up only little gallium ($x \gtrsim 0.95$). The sequence of the lattice constants led to the following picture: On incorporation of iron atoms in the monoclinic $CsGaS_2$ structure the cell volume decreases with increasing $x$. The lattice constants $a$, $b$ and $\beta$ remain virtually constant with only slight variations, while $c$ decreases significantly. The $c$ axis represents the direction of the chains. Conversely, on incorporation of gallium atoms in the rhombic $CsFeS_2$ structure $c$ increases, while $a$ and $b$ once again scarcely alter. Structural investigations on single crystals confirm these results: The atomic distance of the cations in the chains significantly decreases with increasing $x$, *i.e.* with increasing iron content. Moreover, the distances to the four sulfur ligands in $CsFeS_2$ are also markedly smaller than in $CsGaS_2$ (Fe—Fe: 271.1 pm; Ga—Ga: 295.3 pm; Fe—S 231.1 pm; Ga—S: 227.4 pm). This finding is surprising, for the ionic radius of $Ga^{3+}$ (61 pm) is smaller than that of $Fe^{3+}$ (63 pm).

Here again it is clear that strong covalent bonding occurs in the iron-sulfur chains, *i. e.* the iron atoms are exposed to a strong ligand field of the tetrahedrally coordinating sulfur atoms.

The magnetic susceptibilities of some of the crystallographically investigated mixed crystals have been measured be-

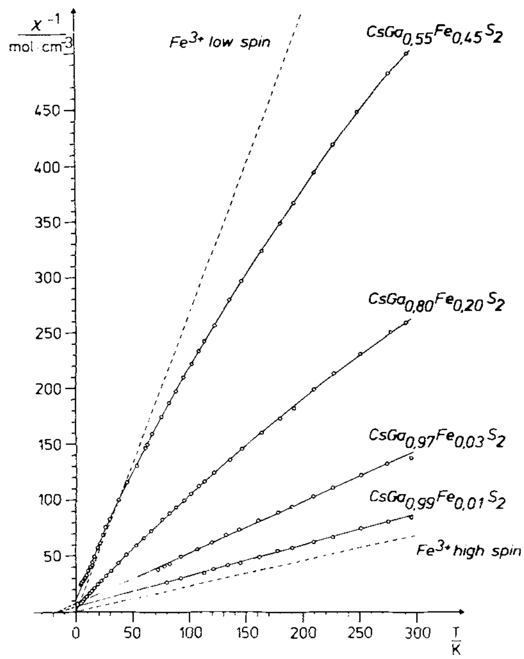

Fig. 13. $1/\chi_{mol}-T$ diagrams of a few mixed crystals $CsGa_{1-x}Fe_xS_2$: ○○○○ experimental values; —— curves calculated with the parameters from Table 3; ---- calculated curves for $Fe^{3+}$ low spin and $Fe^{3+}$ high spin.

Table 3. Calculation of $C$ ($\mu = 2.828\,C^{1/2}\,\mu_B$), $\theta$ and $\chi_0$ from the relation (5) for some mixed crystals of the series $CsGa_{1-x}Fe_xS_2$ (cf. Fig. 13)

| Composition | $\mu\,[\mu_B]$ | $\theta$ [K] | $\chi_0$ [$cm^3\,mol^{-1}$] |
|---|---|---|---|
| $CsGa_{0.99}Fe_{0.01}S_2$ | 5.39 | −15.5 | 0 |
| $CsGa_{0.97}Fe_{0.03}S_2$ | 4.21 | −17.4 | 0 |
| $CsGa_{0.80}Fe_{0.20}S_2$ | 2.66 | − 2.9 | $906\times10^{-6}$ |
| $CsGa_{0.55}Fe_{0.45}S_2$ | 1.81 | − 5.3 | $646\times10^{-6}$ |

tween 3.7 and 295 K using the Faraday method[24]. Figure 13 shows the $1/\chi_{mol}-T$ diagrams of some mixed crystals[*]. The curves obtained can be described by the relation (5)

$$\chi = C/(T-\theta)+\chi_0 \qquad (5)$$

where $\chi_0$ indicates a weak temperature-independent paramagnetism, which was set equal to zero for $x=0.03$ and $x=0.01$. The values of the parameters of eq. (5) determined by the method of least squares are collected in Table 3. For small values of $x$ the magnetic moments are close to that of $Fe^{3+}$ ions with $5.92\,\mu_B$, a value which corresponds to the high-spin state with five unpaired electrons in the 3d level ($S=5/2$). The magnetic moments become smaller with increasing ligand field strength and at $x=0.45$ reach a value which corresponds to a spin state with $S=1/2$.

Apparently a low-spin state is present with a tetrahedral ligand arrangement; this combination has so far never been observed. Figure 14 shows the corresponding electron configuration in a one-electron term system, which can be used here as an approximation assuming that the influence of the ligand field is strong compared to the electronic interactions.

An interpretation of the susceptibility curves (Fig. 13) assuming iron ions in the high-spin state and increasing antiferromagnetic coupling with increasing $x$ is not possible, since the susceptibility part from the coupling would then increase by a measurable amount with falling temperature—which cannot be expected for antiferromagnetic coupling. The concept of low-spin configuration in the tetrahedral field is also supported following investigations on the magnetic behavior of the recently discovered compound $Na_3FeS_3$ (cf. Fig. 6). The Fe—Fe and Fe—S atomic distances lie between those in $CsFeS_2$ and the corresponding ones in $CsGaS_2$. The susceptibility curves, however, still reveal a relatively strong ligand field, for apart from the high-spin state with $S=5/2$ one finds, with three shorter and one longer Fe—S distance (cf. Table 1), a spin state with $S=3/2$ for the two iron atoms of the dinuclear complex[60].

Measurements of the magnetic properties of $CsGa_{1-x}Fe_xS_2$ mixed crystals with $x\geq0.95$, which crystallize in the rhombic $CsFeS_2$-type structure, indicated strong perturbations of the antiferromagnetic interactions even at very low gallium contents. This observation prompted an attempt to mechanically perturbate the magnetic coupling in pure $CsFeS_2$. For this purpose crystals were carefully ground in a purified argon atmosphere. $1/\chi_{mol}-T$ diagrams of such samples are given in Figure 15. Curve I shows a plot of the susceptibility of pure coursely crystalline $CsFeS_2$. The X-ray

---

[*] See footnote on p. 59.

powder diagram of sample II already shows strong broadening of reflections. Associated with the perturbation of long-range order observed here, the susceptibility values change significantly. In the case of sample III the powder diagram shows only weak diffuse reflections. The extensive loss of long-range order yields a Curie-Weiss curve for the temperature-dependence of the susceptibility. With a $\theta$-value of $-66$ K the magnetic moment per iron ion is calculated as $1.7\,\mu_B$. This result is further confirmation of the assumption that in the substances investigated here the previously unobserved low-spin configuration of a transition metal atom is present in the tetrahedral field of its ligands. It should also be mentioned that the Mössbauer spectra of $CsFeS_2$ and $CsGa_{1-x}Fe_xS_2$ mixed crystals[61] are likewise consistent with an extensive spin-pairing in the iron atoms. From the results of neutron diffraction experiments, previously carried out on $RbFeS_2$ and $KFeS_2$, magnetic moments can be derived for the temperature range of the three-dimensional spin order which correspond to those expected for low-spin states[60].

Finally, it can be said that in the anisotropic structure of $CsFeS_2$ the iron atoms are strongly influenced by the sulfur atoms tetrahedrally coordinated to them—an influence, which is subsidized by the collective coupling of the sulfur tetrahedra to chains which then even changes the spin states of the iron atoms contrary to Hund's rule and which thus leads to the observed low-spin configuration.

## 6. Conclusion

The relationships outlined here between crystal structure and magnetism in ternary sulfides of alkali metals and transition metals should make a valuable contribution to our understanding of chemical bonding in the solid state and ought to stimulate further experiments in this sector. Our achievements so far in this area are certainly not only coupled with the compounds selected here; numerous transition metal compounds are already known whose magnetic and/or structural properties allow interesting conclusions to be drawn about the nature of chemical bonding. Having examined the ternary alkali metal-transition metal sulfides the next obvious candidates of interest are certainly the corresponding selenides and tellurides, followed by the phosphides or arsenides where one will find stronger transitions to metallic bonding. A similar and equally informative approach would be the replacement of the alkali metal components by less electropositive elements. In all cases, of course, it is important to synthesize pure substances and to determine both the crystal structure as well as the magnetic properties with high precision.

*I sincerely thank all my coworkers, present and past, who have valuably contributed to this work. We thank the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung in Nordrhein-Westfalen and the Fonds der Chemischen Industrie for financial support.*

# Recent Progress in Oxo- and Fluorometalate Chemistry

By Rudolf Hoppe[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

About a quarter of a century ago a review article having almost the same title appeared in this journal[1]. Since then many hundreds of new fluorides and oxides of metals have been synthesized, and repeatedly subjected to detailed investigation. Why, and to what end are such compounds still studied[2]? Has our knowledge been not only widened but also deepened? What advances have been made in synthetic chemistry in this sector? Have new ideas led to unforeseen results and have unexpected findings forced the revision of tested concepts? This area of research belongs to solid state chemistry, and in the meantime has become almost unsurveyable even for a committed researcher. In this paper, therefore, an attempt is made to outline any relevant advances that have been made and to present open questions and new aspects using selected examples, mainly from the chemistry of the *first row of the transition metal series.* Those not directly involved in this area may be surprised to find that even substances with a simple composition are also cited. They might ask whether such compounds mentioned in text books are not already understood. Although it is a widely-held view that such compounds are well known, this is incorrect: Probably no-one has ever prepared a sample of $CrF_2$ or $Na_2O$ whose composition "adequately" exactly corresponded to the quoted formula[3]. Typical examples which demonstrate the considerable effort necessary for finally proving what others long ago already assumed to know, can be taken from the area of inorganic chemistry (*e.g.*: $As_2O_5$[4]) as well as from organic chemistry (*e.g.* $C_4[C(CH_3)_3]_4$[5]).

## *Part A: Fluorometalates of the 3d-Metals*

In Kiel, November 1947, *W. Klemm* and *E. Huss* heated an intimate mixture of two chlorides ($2\,KCl + NiCl_2$, previously totally dried in a stream of HCl) in elemental fluorine. I watched, fascinated. It was not clear whether a *mixture* (*e.g.* $2\,KF + NiF_2$) or a *homogenous compound* (*e.g.* instead of $KNiF_3 + KF$: $K_2NiF_4$ or $K_2NiF_6$) would result. The intervening time was whiled away by discussion and prognostication of possible formulas and colors. My tip was: If $K_2NiF_6$, then red. When the sintered corundum boat was carefully drawn to the end of the reaction tube, the original *pale yellow* mixture of the chlorides was now *bright red*; $K_2NiF_6$ had been produced[6,7]. This, and another experiment carried out almost simultaneously, but independently, in Cambridge by *H. J. Emeléus* and *A. G. Sharp*[8], who by reaction of liquid $BrF_3$ on gold obtained $AuF_3$—already observed by *Moissan*[9]—pure for the first time as a *brown* powder, heralded the development of inorganic fluorine chemistry in the post-war era.

## 1. Characterization of Metal Fluorides

All fluorometalates are first obtained as powders in this "fluorination". On exposure to air many of them react, in some cases almost spontaneously, with the moisture of the atmosphere. Thereby hydrolysis often occurs, sometimes the formation of hydrates.

*"Fluorine-active"* substances in particular attack the surface (quartz, glass, metal) of the vessels in which they are contained, sometimes even in the cold and the dark. Most fluorometalates are insoluble in the usual solvents or react with decomposition.

After their preparation, only a few fluorides of the 3d-metals can be purified by sublimation (for example: lustrous *deep blue* crystals[10] of $TiF_3$). Recrystallization from the *melt* also usually meets with unprecedented difficulties. Added difficulties occur if on fluorination *volatile* metal fluorides (for example: $TiF_4$[11]) are formed.

For the above mentioned and other reasons, a compound obtained by fluorination generally cannot be *further purified*, as is otherwise usual.

The *analysis*, therefore, gives only the *over-all composition* of the compound. The accuracy of the *fluorine determination* is frequently unfavorably influenced by reactions which occur because of the reactivity of the samples during the necessary *solubilization*. This is also the case in the *iodometric* determination of *oxidation states*.

Problems are also met with in the *X-ray crystallographic characterization* of the powder samples. The lattice constants can be determined with certainty from the X-ray powder diagram only if an isotypic compound of known crystal structure exists, from which reliable indexing can be obtained. But even here care is required: Guinier-Simon patterns of $Pb_2RhF_7$[12] show an amazing similarity to those of $K_2[NbF_7]$[13] and can be correspondingly indexed. However, no $[RhF_7]$ groups are present having for $Rh^{3+}$, the "sensational" coordination number (C.N.) of *seven*. The structural elucidation performed on single crystals of $Pb_2RhF_7$ showed that indeed the same space group occurs and all particles occupy corresponding equivalent positions; however, the F-pa-

rameters are numerically so different that an *octahedral* $[RhF_6]^{2-}$ group and and *"isolated"* $F^-$ are present (see Fig. 1).

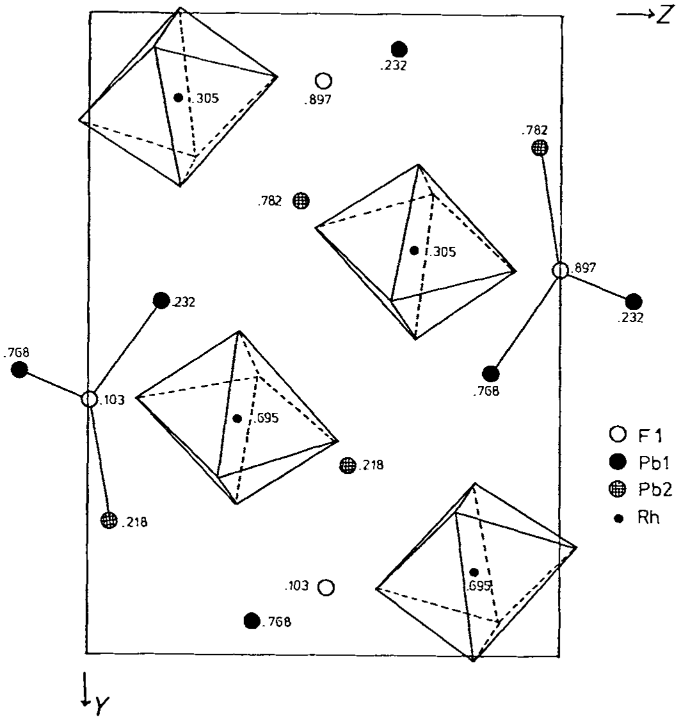

Fig. 1. Projection of the structure of $Pb_2RhF_7$ along [100].

It is especially difficult to prove the presence of impurities, and an exact determination of the *lattice constants* (even with substances crystallizing in the cubic system) is far less possible than one would suppose from the standard deviations.

The *growing* of sufficiently pure *single crystals* is tedious even for thermally stable fluorides, because of possible reactions with the surface of the container and above all with traces of moisture or $O_2$ (for example: $K_2NiF_4 \rightarrow K_2[Ni^{II}_{1-\delta}Ni^{III}_{\delta}F_{4-\delta}O_{\delta}]$[14]). It seemed hopeless ever to obtain single crystals of low-temperature forms (example: $\alpha$-$Ba_3Al_2F_{12}$, cf. Section 2.6) or of *thermally* less stable fluorides ($Li_2CrF_6$[15] disproportionates at room temperature, $Ba[MnF_6]$[16] decomposes on heating). *High-pressure fluorination* in Monel autoclaves [up to 4500 bar, $F_2$, $T = 600\,°C$] with the use of suitable *additives* (*e.g.* $O_2$, $BrF_5$, and also Ar), the choice of which requires much experience, opens up new possibilities for the first time[18] for growing single crystals, even in the case of especially *fluorine-active* compounds, apparently by making use of *chemical transport*[17].

An increasing number of physical measurements are being carried out on fluorides (even on those which are difficult to handle), *e.g.* magnetic measurements on $K_2Na[NiF_6]$[19] or $PdF_2$[20]. Considerable effort is often required to prove that special effects are not due to contaminants, but rather to the "pure" substance corresponding to the formula adopted.

## 2. New Results

A complete survey of new results would require space far in excess of that permitted here, while a summary (*e.g.* arranged according to oxidation states, formula types or crystal structures) might only be of interest to the specialist. Only *special features* have therefore been singled out. A glance at the corresponding fluorides of the 4d- and 5d-metals would seem most expedient.

### 2.1. New Oxidation States

*Tetravalent copper* was obtained for the first time in $Cs_2[CuF_6]$[21] and $Rb_2[CuF_6]$[22] by *high-pressure fluorination.* Both compounds are *orange,* as is $K_2CuF_6$[21], which, because of the even greater instability of the samples prepared so far, has not been characterized in detail.

The synthesis of these highly fluorine-active samples is critical. Only a slight deviation from optimum conditions (pressure of fluorine, time, temperature control) can lead to samples which are either incompletely fluorinated or have already undergone reaction with the crucible material with formation of black decomposition products.

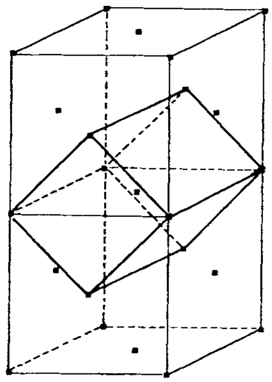

Fig. 2. Unit cell of $A_2[Cu^{IV}F_6]$ with A = Cs, Rb, derived from the $K_2[PtCl_6]$-type ($Cs_2CuF_6$: $a = 8.87_1$, $b/\sqrt{2} = 8.87_1$, $c/\sqrt{2} = 8.92_4$; $Rb_2CuF_6$: $a = 8.38_5$, $b/\sqrt{2} = 8.45_4$, $c/\sqrt{2} = 8.49_5$ Å; both are orange).

*Orthorhombic distortion of the $K_2PtCl_6$-type* (see Fig. 2) is slight. The *magnetic behavior* is here determined by the anomalously high value of the spin-orbital coupling constant ($\lambda_0 = -960\ cm^{-1}$)[23] and by the fact that the "mixing" of the first excited state ($^4T_{1g}$) with the ground state ($^2E_g$) does not necessarily lead to an increase in the magnetic moment in relation to the "spin-only" value ($\mu = 1.73\,\mu_B$).

We also obtained samples of *dark orange* "$Cs_2AgF_6$", about which we communicated only privately[24] because of incomplete characterization owing to its exceedingly easy decomposition. In the meantime, this fluoride has also been prepared by other workers[25] and has been formulated as $Cs_2Ag^{III}_{0.5}Ag^{V}_{0.5}F_6$[26]. Since ESR measurements on $Cs_2[CuF_6]$ clearly indicate the presence of $Cu^{4+}$ [21] (see Fig. 3) we are somewhat sceptical of this formulation.

The question of *tetravalent gold,* first raised some 30 years ago[27], is again of current interest: The *light-yellow* samples "$Cs_2AuF_6$" obtained at that time react with water (in contrast to $Cs[AuF_4]$[27], which likewise immediately decompose), but with vigorous *evolution of gas.* The state of development of X-ray crystallography at that time (only Debye-Scherrer patterns could be photographed on compounds sensitive to air) did not allow a detailed characterization. We now know that these compounds also contained *light-yellow*

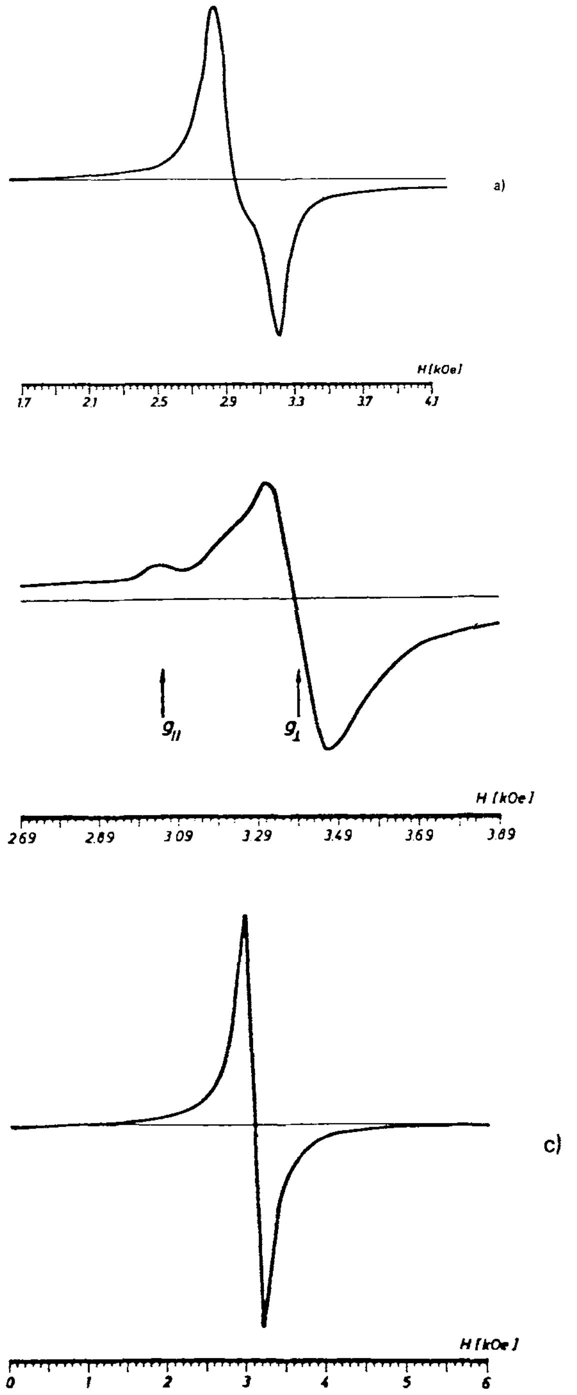

Fig. 3. ESR-spectra of a) Cs$_2$[Cu$^{IV}$F$_6$], b) Cu$^{II}$F$_2$, and c) Cs$_2$K[Cu$^{III}$F$_6$] at 297 K.

Cs[AuF$_6$][28], a fluoro complex of AuF$_5$[29]. New experiments using *high-pressure fluorination* of BaAuF$_5$ or SrAuF$_5$ have led to samples of the composition BaAuF$_7$ or SrAuF$_7$ respectively, while CaAuF$_5$ furnishes CaAuF$_6$; all the products are *light yellow*[30]. (NO)$_2^+$[Au$^{IV}$F$_6$]$^{2-}$ is also said to exist[31]. *Tetravalent cobalt* should also be mentioned here: Following the first report on "K$_3$CoF$_7$"[32], *P. Pfeiffer* doubted the existence of the coordination number 7, and in this he was right:

A detailed investigation showed that K$_3$[CoF$_6$] was responsible for the characteristic properties of the samples (*light blue*, paramagnetism with $\mu = 5.4\mu_B$ between 90 and 300 K). All the fluorides A$_3$[CoF$_6$] (A = Li to Cs) were then prepared as the pure compounds from the analogous, *colorless* (as macrocrystals *pale yellow*) cyanides A$_3$[Co(CN)$_6$][33,34]. These *sky-blue* fluorocobaltates(III) are the only known *high-spin complexes* of Co$^{3+}$. The confusion arose as a result of correct values in the F-analysis, but side-reactions of a mixture of 3KCl + CoCl$_2$ with HF residues in F$_2$ produced a mixture of 2K$_3$[CoF$_6$] + CoF$_3$ + 3KHF$_2$ instead of K$_3$CoF$_6$. However, the criticism stimulated further research: Cs$_2$[CoF$_6$][34] and its well-investigated analogues Rb$_2$[CoF$_6$] and K$_2$[CoF$_6$][35,36] are *brownish-yellow*. These cubic compounds (K$_2$[PtCl$_6$]-type) show a complicated magnetic behavior (on transitions between high-spin and low-spin behavior, *cf.* Section 2.12). Therefore, according to the Boltzmann-distribution, two states of different multiplicity ($^6A_{1g}$ and $^2F_{2g}$) are occupied (a "quasi-thermal" equilibrium between high-spin and low-spin states). Meanwhile, in the continued search for the *"genuine" K$_3$CoF$_7$*, numerous fluorides of the composition doubted by *Pfeiffer* have been obtained, *e.g. carmine red* Cs$_3$NiF$_7$ = Cs$_3$F[NiF$_6$] and the analogous, *bright yellow* Cs$_3$MnF$_7$[37] (*cf.* Section 2.7).

I am convinced that the continuing search for K$_3$F[CoF$_6$] will meet with success.

## 2.2. Fluorometalates with Unusual Coordination Numbers

Fluorocuprates(III) such as *green* K$_3$CuF$_6$[6,38] (see Table 1) closely follow the fluorides of the trivalent 3d-metals preceding copper in the periodic table; they are *paramagnetic*, the "central ion" Cu$^{3+}$ has C.N. 6. This is proved for the cubic elpasolite representatives such as K$_2$Na[CuF$_6$][38] by the structural type. A contrast to the known fluorides of trivalent silver and gold emerges here. These are all *yellow* and *diamagnetic* whether they are of the formula type Cs[AgF$_4$][39], BaAgF$_5$[40], K[AuF$_4$][27], BaAuF$_5$ or Ba[AuF$_4$]$_2$[40] (see Table 1). This striking difference is probably best explained in terms of the difference between 3d- and 4d- or 5d-orbitals.

In the meantime we have found an important connecting link—*intense red, paramagnetic* Cs$_2$K[AgF$_6$], a cubic elpasolite[41]. It follows, therefore that a much closer relationship should exist between the fluorides of the *coinage metals:* The long search (1951—1980) for a *tetrafluorocuprate(III)* finally

Table 1. Complex fluorides of the coinage metals (typical ecamples).

| | | | | | |
|---|---|---|---|---|---|
| K$_3$CuF$_6$<br>($a$ = 8.50 Å) | pale green<br>$\mu = 2.83\mu_B$<br>$\theta$ = 0 K | KAgF$_4$<br>$a$ = 5.90 Å<br>$c$ = 11.15 Å | yellow<br>diamagnetic | KAuF$_4$<br>$a$ = 5.99 Å<br>$c$ = 11.38 Å | yellow<br>diamagnetic |
| Rb$_3$CuF$_6$<br>($a$ = 8.91 Å) | brownish-green<br>$\mu = 2.82\mu_B$<br>$\theta$ = 0 K | RbAgF$_4$<br>($a$ = 6.0 Å)<br>($c$ = 11.8 Å) | yellow<br>diamagnetic | RbAuF$_4$<br>$a$ = 6.18 Å<br>$c$ = 11.85 Å | yellow<br>diamagnetic |
| Cs$_2$KCuF$_3$<br>$a$ = 8.92$_4$ Å | yellow-brown<br>$\mu = 2.83\mu_B$<br>$\theta$ = 0 K | Cs$_2$KAgF$_6$<br>$a$ = 9.17$_5$ Å | red<br>$\mu = 2.6\mu_B$ | — | |
| CsCuF$_4$<br>$a$ = 5.84$_7$ Å<br>$c$ = 12.03 Å | orange<br>diamagnetic | CsAgF$_4$<br>— | yellow<br>diamagnetic | CsAuF$_4$<br>— | yellow<br>diamagnetic |

led, on using high-pressure fluorination, to the preparation of *diamagnetic, orange* Cs[$CuF_4$], which, like Cs[$AgF_4$], crystallized as expected in the tetragonal K[$BrF_4$]-type structure; *i.e.* planar [$CuF_4$]-groups are present[42] (see Table 1). This stimulates continuation of the hitherto unsuccessful[43] search for *(probably) red, paramagnetic gold fluorides* such as $Cs_2K[AuF_6]$.

### 2.3. Fluorometalate or Double Fluoride?

According to *Werner*[44], a complex unit such as $[CuF_6]^{3-}$ or $[CuF_4]^-$ is a *fluorometalate* if it reacts in solution as an entity or is present in a crystal. In contrast, *double fluorides*[45] are those in which *structurally geometrically equivalent* positions (random or ordered) are occupied by *chemically different* entities (example: $MgMnF_6$[16], $ReO_3$-type = $Mg_{0.5}Mn_{0.5}F_3$; see Fig. 4). Compounds containing the same chemical entity in different oxidation states are also to be grouped under this heading. An example is *black* "$PdF_3$" = $Pd^{II}Pd^{IV}F_6$[46].

$LiYF_4$ would doubtlessly be formulated as "antischeelite" Y[$LiF_4$] because of its structural geometry; the $d$(Li—F) distances are substantially shorter than $d$(Y—F)[47]. This prompted the preparation of new scheelites with unusual oxidation states, *e.g.* $Pr^{IV}Cd^{II}[LiF_4]_2$[48], and therefore confirms that such different formulations for the same compound are more than "artificial" for systematic classification. But can bond lengths? Is the structure governed *only by the shortness of the bond lengths* as has been hitherto frequently supposed? With such a demarcation in the presuppositions, the fluorides cited in Table 2, which belong to the $ReO_3$-, $PdF_3$-, $VF_3$- or $LiSbF_6$-type, are double fluorides.

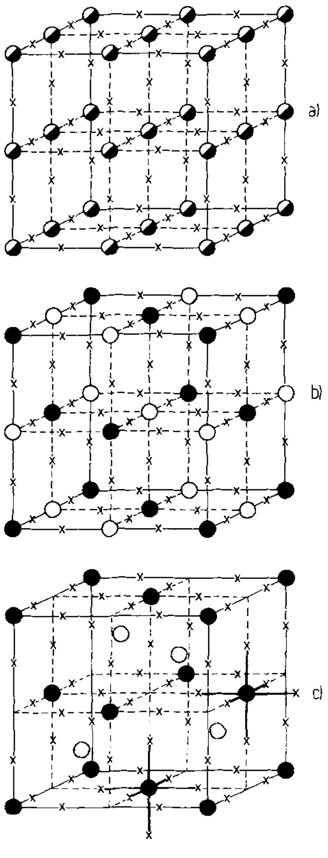

Fig. 4. a) $ReO_3$-type, example $A^{II}B^{IV}F_6$; ◑: $(1A^{II}+1B^{IV})/2$, ×: F.—b) Order variant with $A^{II}$ and $B^{IV}$ at structurally geometrically equivalent positions.—c) $A^{II}[M^{IV}F_6]$ with the anionic part of the crystal structure $M^{IV}\square F_6$ arranged corresponding to the $ReO_3$-type and $A^{II}$ at other positions.

Table 2. Compounds $A^{II}M^{IV}F_6$ and their colors.

| | | | |
|---|---|---|---|
| $VF_3$-Typ (Space group $R\bar{3}c$) | | | |
| $NiMnF_6$ | ocher-yellow | $NiTiF_6$ | pale yellow |
| $ZnMnF_6$ | orange-yellow | $ZnTiF_6$ | colorless |
| $MnTiF_6$ | colorless | $NiCrF_6$ | brown |
| $CoTiF_6$ | lilac | $ZnCrF_6$ | orange-yellow |
| $LiSbF_6$-Typ (Space group $R\bar{3}$) | | | |
| $HgMnF_6$ | orange | $CdCrF_6$ | pink |
| $CdMnF_6$ | yellow | $CaPtF_6$ | light-yellow |
| $CaMnF_6$ | yellow | $MgPtF_6$ | light-yellow |
| $MgMnF_6$ | yellow | $MnPtF_6$ | ocher |
| $CdTiF_6$ | colorless | $ZnPtF_6$ | light-yellow |
| $MgPdF_6$ | yellow | $CoPtF_6$ | light-brown |
| $ZnPdF_6$ | yellow | $NiPtF_6$ | egg-yellow |
| $CdPdF_6$ | yellow | $CaRhF_6$ | light-yellow |
| $CaPdF_6$ | yellow | $MgRhF_6$ | light-yellow |
| $CaCrF_6$ | pink | $ZnRhF_6$ | light-yellow |
| $MgCrF_6$ | pink | $CdRhF_6$ | light-yellow |
| $HgCrF_6$ | orange | $HgRhF_6$ | orange |
| | | $NiRhF_6$ | light-brown |
| $BaGeF_6$-Typ (Space group $R\bar{3}m$) | | | |
| $BaMnF_6$ | yellow | $PdPtF_6$ | green |
| $SrMnF_6$ | yellow | $PbPtF_6$ | light-yellow |
| $BaRhF_6$ | lemon-yellow | $BaCrF_6$ | yellow |
| $SrRhF_6$ | lemon-yellow | $SrCrF_6$ | yellow |
| $BaCrF_6$ | light-yellow | $BaTiF_6$ | colorless |
| $SrCrF_6$ | yellow | $SrTiF_6$ | colorless |
| $BaPtF_6$ | yellow | $SrNiF_6$ | carmine-red |
| $SrPtF_6$ | yellow | $BaNiF_6$ | carmine-red |

However, for those cited fluorides with *tetravalent chromium,* chemical arguments can be found for their classification as *double fluorides* or *fluorochromates*(IV): The cited *double fluorides disproportionate, e.g.,* during storage under inert gas at room temperature, into $CrF_5$ and fluorochromates(III). Compounds of the Ba[$SiF_6$]-type or the $K_2[PtCl_6]$-type and its "stacked variants" (*e.g.* of the $(NH_4)_2[GeF_6]$-type) are not *only fluorochromates(IV)* with respect to the geometrical aspects of the structure, but are also *stable for years* against disproportionation under the same conditions. Such classifications therefore should not be the subject of serious discussion as long as the "covalency" or "ionicity" of the chemical bond concerned has not been directly determined by experiment.

### 2.4. Thermochemistry of the Fluorometalates

There is little data available on the standard values of the *enthalpy of formation* of complex fluorides, and their accuracy is doubtful (see Table 3). More is known about ternary oxides[49]. Some characteristic values given in Table 3 show that in the series $K^+ > Na^+ > Ba^{2+} > Li^+ \simeq Sr^{2+} > Ca^{2+}$, the enthalpy of formation of comparable ternary oxides (from their binary components) markedly decreases under normal conditions, *i.e.* the energy of complex formation becomes smaller.

If one assumes that this general trend observed in the ternary metal oxides also applies in the case of fluorides, then it is understandable that in the mentioned series of *"counter cations"*, difficulties increase in trapping an "anomalously high" oxidation state of a 3d-metal. Table 4 lists as examples

Table 3. Standard values of the enthalpy of formation, $\Delta H^0_{298}$, of some metasilicates from the binary oxides, and of some fluoro complexes from the binary fluorides (all values in kcal/mol).

| | | |

the hexafluoroniccolates(IV): The formation of $K_2[NiF_6]$ with fluorine can hardly be avoided even under unfavorable conditions ($N_2$:$F_2$ = 10:1; 450 °C); $Na_2NiF_6$[50] can be obtained free from impurities only under $F_2$-pressure (150 bar). The synthesis of $Ba[NiF_6]$ and $Sr[NiF_6]$[52] was very difficult; we finally succeeded, after a 25 year search, by *high-pressure fluorination*. The resulting $BaNiF_6$ did not show the expected modification, which is isotypic with $BaSiF_6$, but a new monoclinic form previously unknown for fluorides $A^{II}M^{IV}F_6$ (A = Ba, Sr; M = 3d-metal) and which only transforms under high static pressure (50 kbar, 350 °C, 6 h) into the rhombohedral modification. This finding prompted the repreparation of *e.g.* $Ba[MnF_6]$[16] and $Ba[CrF_6]$[53] under analogous conditions, in order to observe the possible occurrence of a corresponding monoclinic form.

Thus, it is also understandable that all previous attempts to synthesize $CaNiF_6$ or $CdNiF_6$ remained unsuccessful. The examples of *carmine-red* $SrNiF_6$ and the still unknown (probably *red*) $Li_2NiF_6$ show that the formula type, and hence the crystal structure, also has a substantial influence on the producibility of such fluorides.

It is now clear why it is relatively easy to prepare samples of $Li_3[NiF_6]$[54] which are free of $Ni^{IV}$, and why $Cs_3[NiF_6]$[48] has so far not been obtained in pure form.

### 2.5. Fluorometalates with Different Coordination Numbers of the Same Central Atom

All known fluorides of bivalent nickel are *light green-yellow* as a powder; $Ni^{2+}$ has the C.N. 6 (macrocrystals [*e.g.* $BaNiF_4$[55]: diameter up to 3 cm] have also been described as red). The *composition* (examples: $KNiF_3 = K[NiF_{6/2}]$[56];

$K_2NiF_4 = K_2[NiF_{4/2}F_{2/1}]$[57]; $Ba_2NiF_6 = Ba_2F_2[NiF_{4/2}F_{2/1}]$[58]) has here *no influence* on the C.N. and color. The situation is different in the case of fluorides of bivalent palladium[59] (and silver[60]) (see Table 5): If there are *planar* $[PdF_4]^{2-}$ groups with *C.N. 4* present, then the compounds are *yellow* to *red* and *diamagnetic* ($Ag^{II}$-fluorides are naturally paramagnetic and of other colors). However, if the composition necessitates $Pd^{II}$ having *C.N. 6* and octahedral coordination, then the compounds are *blue* to *violet* and *paramagnetic*. Is it possible to prepare fluorides which exhibit both possible types of coordination for $Pd^{2+}$ at the same time? The first success is observed in recent attempts to resynthesize the scarcely known "$CsPdF_3$"[59]: As the X-ray structure analysis demonstrates[61] the *orange-brown* single crystals of $CsPd^{II}Pd^{II}F_5$ contain square and octahedrally coordinated $Pd^{II}$ in a ratio of 1:1.

We now know that $Cu^{III}$ in $Cs[CuF_4]$ also has a C.N. 4 with a planar arrangement of the four ligands. Would this not signal that renewed and more concerted effort to prepare such fluorides with "mixed" coordination, in which $Cu^{3+}$ is replaced by the isoelectronic $Ni^{2+}$ is warranted? "$PdF_3$" $= Pd^{II}Pd^{IV}F_6$[46] is a kind of counter-example, and demonstrates that clearly different oxidation states in a fluoride may lead to the *same* coordination.

## 2.6. Are there Oligo-Fluorometalates?

Arsenic and antimony form *binuclear* as well as the well-known *mononuclear* fluorocomplexes (example: colorless $K[AsF_6]$[62]); "salts" of the type $(XeF_3)^+[Sb_2F_{11}]^-$[63] are of special interest (*cf.* Section 2.13). Are there analogous fluorometalates of the d-metals?

Until recently, all compounds of the almost limitless number of multicomponent metal fluorides belonged to *one of only* two groups: a) with mononuclear units (*e.g. lime-green* $K_2Na[VF_6]$[64]), b) with "high-polymer" linked coordination polyhedra. These may be linked *one-dimensionally* (*e.g. deep-red* single crystals of $Sr[RhF_5] = Sr[RhF_{4/1}F_{2/2}]$[65]), *two-dimensionally* (*e.g. sky-blue* $K[CoF_4] = K[CoF_{2/1}F_{4/2}]$[66]) or *three-dimensionally* (*e.g. light-pink* $K[MnF_3] = K[MnF_{6/2}]$[67]).

Two new findings show that surprises must be reckoned with: *Colorless* $Cs_3[Fe_2F_9] = Cs_3[F_3FeF_3FeF_3]$[68] verifies that d-metals can also form *binuclear* fluorometalates. Moreover, there is here a linkage of two octahedra *via* a *common face*, previously regarded as unfavorable for electrostatic reasons. This was already known as a chain building unit from light yellow $Cs[NiF_3] = Cs[F_{3/2}NiF_{3/2}]$[69] (here in the form of infinite chains of octahedra connected by faces on both sides).—We detected the first *tetrameric fluoro-complex* in the low-temperature form of $Ba_3Al_2F_{12}$[70]. The analogy of this "ring" $[Al_4F_{20}]^{8-} = [F_{4/1}AlF_{2/2}]_4^{8-}$ (see Fig. 5) to pentafluorides such as $Ru_4F_{20}$[71] is surprising, and it refutes the theory that the ring formation takes place *via* the 4d- or 5d-orbitals[72] or, that it even requires d-orbitals.

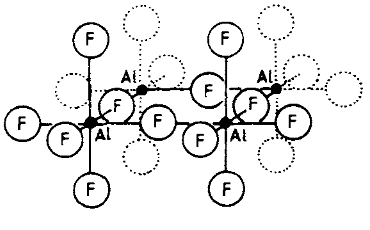

Fig. 5. The tetrameric $[Al_4F_{20}]^{8-}$ group in $Ba_3Al_2F_{12}$ (low temperature form).

The preparation of "mixed" fluorides such as $Ba_6Al_3FeF_{24}$ or $Ba_6AlFe_3F_{24}$ would therefore seem possible. $Na_5[F_6ZrFZrF_6]$[73] should also be mentioned. It contains two trigonal prisms (!) of $6F^-$, each "capped", the cap being bridging. Such fluorides are extremely important for the development of the theory of magnetic interactions between weakly paramagnetic ions (*cf.* Section 2.12).

## 2.7. Fluorometalates with "Single" and "Solitary" F-Atoms

The controversy surrounding $K_3CoF_7$ (*cf.* Section 2.1) stimulated the search for fluorides such as "$K_3NiF_7$" or "$K_3MnF_7$". For, in contrast to $K_2CoF_6$[36], which is difficult to obtain and very sensitive, compounds with $Ni^{4+}$ or $Mn^{4+}$ in place of Co such as *yellow* $K_2[MnF_6]$[74] are comparatively stable and are well-known. However, all experiments with these compounds as potential precursors remained unsuccessful. This was astonishing. The two *colorless* fluorosilicates $(NH_4)_3SiF_7 = (NH_4)_3[SiF_6]$ and $K_3F[SiF_6]$[75] have been known for some time, $(NH_4)_2TiF_7$ was found later[76]. Octahedral groups *e.g.* $[SiF_6]$ are present in their tetragonal crystal structure. Now, $Si^{4+}$ has, like $Ti^{4+}$, a "closed" electron configuration. Therefore, as suggested by *Klemm*[77], at least ions such as $Co^{4+}$ with "half-closed 3d-shells" should be able to form analogous fluorides. We decided to repeat some old experiments[78] and at once obtained a whole series of the desired fluorides $A_3MF_7$ (see Table 6). The use of a passivated Mg-metal boat instead of a sintered corundum one proved to be of vital importance in the success of our prepa-

Tabele 6. a) Tetragonal fluorides $A_3F[MF_6]$ of the $(NH_4)_3SiF_7$-type (above) and b) cubic fluorides $A_3[MF_7]$ of the $(NH_4)_3[ZrF_7]$-type below; $M^{IV}$ = Ce, Pr, Tb: colorless; $M^{IV}$ = Nd, Dy: orange).

| Compound | $a$ [Å] | $c$ [Å] | $c/a$ |
|---|---|---|---|
| $Cs_3SiF_7$ | 8.306 | 6.170 | 0.743 |

| $Cs_2RbCeF_7$ | $9.79_0$ | $CsRbKPrF_7$ | $9.52_1$ | $Rb_3TbF_7$ | $9.39_6$ |
| $Cs_3CeF_7$ | $9.94_9$ | $Cs_2KPrF_7$ | $9.65_9$ | $CsRbKTbF_7$ | $9.39_6$ |
| | | | | $Cs_2KTbF_7$ | $5.52_3$ |
| $Rb_2CsPrF_7$ | $9.63_9$ | $Cs_2KNdF_7$ | $9.60_5$ | $Rb_2CsTbF_7$ | $5.52_9$ |
| $Cs_2RbPrF_7$ | $9.77_6$ | $Cs_2RbNdF_7$ | $9.74_8$ | $Cs_2RbTbF_7$ | $9.69_7$ |
| $Cs_3PrF_7$ | $9.91_8$ | $Cs_3NdF_7$ | $9.87_3$ | $Cs_3TbF_7$ | $9.80_1$ |
| | | | | $Cs_2KDyF_7$ | $9.47_4$ |
| | | | | $Cs_2RbDyF_7$ | $9.63_0$ |
| | | | | $Cs_3DyF_7$ | $9.79_5$ |

ration (cf. Section 3.6). The existence of these substances shows that the "single $F^-$" is no "remarkable exception". The structural difference from the cubic fluorides of the $(NH_4)_3[ZrF_7]$-type with C.N. 7 is noteworthy (see Table 6).

The energetic reasons for the formation of the fluorides $A_3F[MF_6]$ ($M = Ti^{IV}$, $Cr^{IV}$, $Mn^{IV}$, $Ni^{IV}$) are still unclear, but such compounds are apparently thermodynamically stable as regards decomposition, *e.g.*, $Cs_3F[MnF_6]_{(solid)} \rightarrow Cs_2[MnF_6]_{(solid)} + CsF_{(solid)}$. *Colorless* $Ca_2F[AlF_6]$[80] should be mentioned as a fluoride of another formula-type with a "single $F^-$" (see Fig. 6).

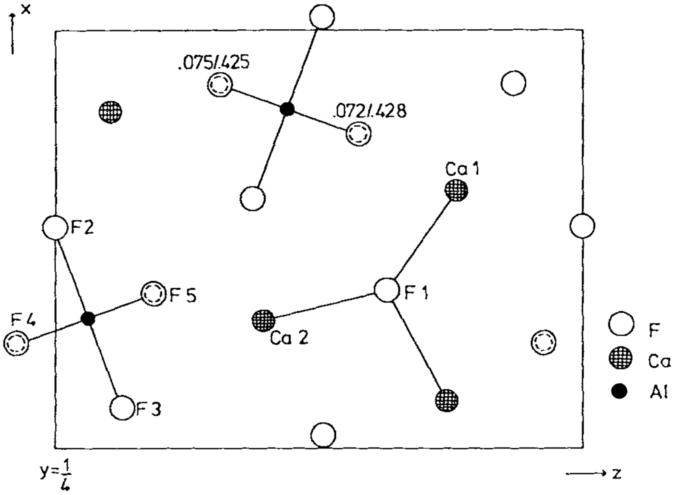

Fig. 6. Structure of $Ca_2AlF_7$ at $y = 1/4$. It can be seen that the $F1^-$ is surrounded by only $3Ca^{2+}$ as well as the $[AlF_6]^{3-}$ groups.

We speak here of a *"single $F^-$"*, because it is not directly coordinated in the classical sense within the "complex-building" moiety. The example of $Ca_2F[AlF_6]$ illustrates that such a $F^-$ coordinates to the "completing cations". Hence, the question immediately arises as to whether there is also a *"solitary $F^-$"* which does not coordinate either in one sense or another. Fluorides of thorium (and zirconium) would indicate that an examination of the d-metals is worthwhile. In the case of $KNaThF_6$[81], C.N. 6, as indicated by the composition, is not found, but C.N. 9, corresponding to $KNa[ThF_{3/1}F_{6/2}]$. Here, as with the analogous fluorides (*e.g.* also with $K_2[ZrF_6] = K_2[ZrF_{4/1}F_{4/2}]$[82]) the increase in C.N. by bridge formation was attributed to the *"size"* of the central ion. This is certainly incorrect. If it were so, C.N. 9 should be present all the more in fluorine-rich thorium compounds. This is not the case, however[83], because in $(NH_4)_4ThF_8$[84], even though the $Th^{4+}$ has C.N. 9 with respect to $F^-$, *one* of the $8F^-$ is a "single $F^-$" and, without any recognizable reason, is not coordinated to the $Th^{4+}$. In $K_5ThF_9$[85] there are sufficient $F^-$ for a C.N. 9, but $Th^{4+}$ again has C.N. 8, one of the $F^-$ remaining "single". Especially interesting, however, is the crystal structure of $K_7Th_6F_{31}$[85]; it is a compound comparable with $KNaThF_6$: Here *one of the 31 $F^-$* is not coordinatively attributed to either $Th^{4+}$ or $K^+$, rather one "solitary $F^-$" is present with only other $F^-$ in the *first sphere of coordination*[83].

## 2.8. Order/Disorder in Fluorometalates

Chemically very similar fluorides may differ markedly regarding the "arrangement" of the "cations": Thus *orange-yellow* $ZnCrF_6 = Zn_{0.5}Cr_{0.5}F_3$ and *brown* $NiCrF_6 = Ni_{0.5}Cr_{0.5}F_3$ have $VF_3$-type structure with random distribution of $M^{2+}$ and $Cr^{4+}$, and in *pink* $CdCrF_6$ and *orange-yellow* $HgCrF_6$ the cations are ordered[53] ($LiSbF_6$-type, see Table 2).

It is still unclear whether in such cases the "disorder" is simulated, *i. e.* there are micro-domains of *ordered* distribution which for their part are *disordered.*

Neither here nor in the case of the analogous fluorides, despite many attempts, has it been possible to prepare *both* types in the *same* substance, *e.g.* to prepare a modified form of $NiCrF_6$ with $LiSbF_6$-type structure. The $RbNiCrF_6$-type[68] (see Table 7) proved to be of special interest regarding the question of the disorder of cations. Here $M^{2+}$ and $M^{3+}$ are "statistically" distributed over the octahedral interstices, thereby decisively determining the magnetic behavior (*cf.* Section 2.12).

Table 7. Fluorides of the $RbNiCrF_6$-type.

| Compound | Color | *a* [Å] |
|---|---|---|
| $CsCuTiF_6$ | light-blue | 10.39 |
| $CsCuNiF_6$ | dark-brown | 10.14 |
| $CsMgFeF_6$ | colorless | 10.35 |
| $CsMgCoF_6$ | light-blue | 10.27 |
| $CsMgGaF_6$ | colorless | 10.23 |
| $CsMnGaF_6$ | pale pink | 10.42 |
| $CsMnFeF_6$ | pale green | 10.55 |
| $CsMnRhF_6$ | red-brown | 10.58 |
| $CsNiScF_6$ | light-yellow | 10.60 |
| $CsNiTlF_6$ | light-yellow | 10.60 |
| $CsNiRhF_6$ | light red-brown | 10.37 |
| $CsZnGaF_6$ | colorless | 10.29 |
| $CsZnInF_6$ | colorless | 10.58 |
| $CsNiInF_6$ | light-yellow | 10.64 |
| $CsZnTlF_6$ | colorless | 10.62 |
| $CsZnScF_6$ | colorless | 10.58 |
| $CsZnTiF_6$ | light-blue | 10.50 |
| $CsZnVF_6$ | light-green | 10.43 |
| $CsZnMnF_6$ | red-brown | 10.40 |
| $CsZnFeF_6$ | colorless | 10.42 |
| $CsZnCoF_6$ | light-blue | 10.34 |
| $CsZnNiF_6$ | dark-brown | 10.17 |
| $CsZnCuF_6$ | brown | 10.24 |
| $CsZnRhF_6$ | red-brown | 10.41 |

Calculations of the Madelung Part of the Lattice Energy (MAPLE)[87] show that an ordered distribution is usually so much more favorable, that under normal equilibrium conditions, disorder should not occur. In the case of the $RbNiCrF_6$-type structure, on the other hand, the situation is different, none of the possible ordered variants were, according to MAPLE, more favorable than the disordered $Rb(Ni_{0.5}Cr_{0.5})_2F_6$[88]. Such cases are rare.

However, new experimental investigations on single crystals established that ordered fluorides such as $CsAgFeF_6$[89] can be prepared (see Table 5); but, an *orthorhombic* unit cell is observed rather than the *cubic "aristo-type"*[90].

*Trirutiles* are derived from rutiles (see Fig. 7) with triplication of the *c*-axis (surprisingly, *"dirutiles"* have, as yet, not been described). Table 8 gives typical examples. It is remarkable that *ocker-colored* $Li_{1/3}Cd_{1/3}Co_{1/3}F_2$[91] is a genuine rutile, whereas according to magnetic measurements, *sky-blue* $LiZnCoF_6$ exists in a partially ordered form $(Li_{0.5}Zn_{0.5})_2CoF_6$ (cf. Fig. 7).

Table 8. Examples of mono- and trirutiles (fluorides).

| Compound | *c* [Å] | *c/a* (*c*/3*a*) | Color |
|---|---|---|---|
| $LiZnRhF_6$ | 9.235 | 0.660 | brown |
| $LiZnCrF_6$ | 9.10 | 0.655 | green |
| $LiNiVF_6$ | 9.142 | 0.656 | yellow-green |
| $LiMgGaF_6$ | 8.96 | 0.650 | light-gray |
| $LiZnCoF_6$ | $9.16_6$ | 0.661 | light-blue |
| $LiMgCoF_6$ | $9.05_4$ | 0.656 | light-blue |
| $LiNiCoF_6$ | $9.07_1$ | 0.656 | brown |
| $LiCuCoF_6$ | $3.10_5$ | 0.673 | ocher |
| $LiCuCrF_6$ | 3.035 | 0.662 | yellow-green |
| $MgF_2$ | 3.045 | 0.658 | white |
| $MgMgFeF_6$ | 3.130 | 0.673 | gray |
| $MgFeFeF_6$ | 3.120 | 0.665 | gray |
| $FeCoNiF_6$ | 3.175 | 0.678 | orange |

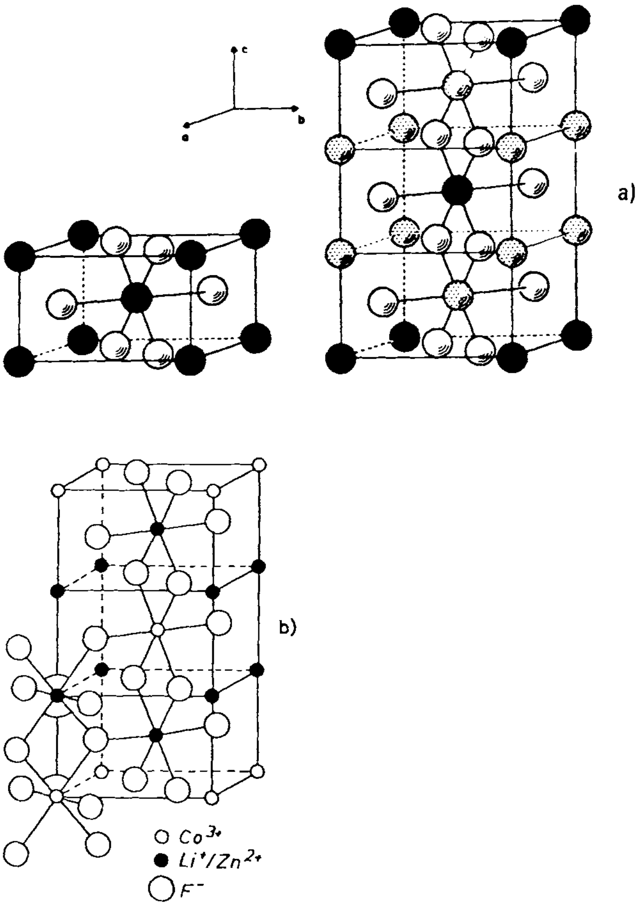

Fig. 7. a) The rutile-type structure and the unit cell of trirutiles which is derived from it. b) Trirutile $LiZnCoF_6$ with ordered distribution of $Co^{III}$ according to $(Li_{1/2}Zn_{1/2})_2Co^{III}F_6$.

*Ordered variants* for the same formula-type occur with larger differences in the ionic radii of the cations, namely the $LiCaAlF_6$-type[92] with *C.N. 6 for* $Li^+$ and $Ca^{2+}$ (*e.g.* $LiCaCoF_6$[91]) or the $LiBaCrF_6$-type[93] with *C.N. 4 for* $Li^+$ and *C.N. 12 for* $Ba^{2+}$ (*e.g.* $LiBaCoF_6$[91]). The *colorless* $LiSrFeF_6$[91] can be classified between them (Table 9), with *C.N. 6 for* $Li^+$ and *C.N. 8 for* $Sr^{2+}$.

Table 9. Motifs of mutual adjunction and coordination numbers in $LiCaAlF_6$, $LiSrFeF_6$ und $LiBaCrF_6$.

| C.N. | 4 | 4 | 4 | 3 | 4 | 3 | |

*Gutmann*[94] pointed out that the term *"order"* used in the crystallographic sense relates to the *arrangement* of particles.

## 2.9. The Madelung Part of the Lattice Energy (MAPLE) for Fluorometalates

If MAPLE is calculated for *fluoro-* or *oxometalates* then experience shows[87] that for well-determined crystal structures this value agrees with the sum of the MAPLE values of the binary components; the difference between them is lower than 1%, often lower than 0.5%. The MAPLE values given in Table 10 demonstrate how remarkable, on the whole this consistency is, if the individual differences in the contribution of the single components are considered.

We frequently use such MAPLE calculations in direct association with our preparative work. They show whether new structural suggestions are commensurable with those known, they indicate peculiarities and allow important structural parameters to be estimated independently from X-ray data, for those substances which have so far only been obtained as a powder. They can be consulted for an indication of the structural principles of still unknown binary metal fluorides.

Table 11 illustrates that a deviation in the MAPLE values may suggest a refinement of the structure, e.g. for *light-pink* $MnAlF_5$[95], and confirms the quality of the structure determination for $Cr^{II}Cr^{III}F_5$[96]. The example of $CaCrF_5$[97] underscores the limitations of the MAPLE concept: If the proposed structures are "adequately" good, then MAPLE cannot help to decide which space-group is present. If on the whole there is a good agreement, but very different single contributions for chemically and functionally equivalent particles appear, (for example: $BaFeF_5$[98]) then MAPLE warns not to trust the structural proposal too much (here: for the "sub-cell") and prompts a check. The "coordination numbers" of typical solid substances can be counted unambiguously only when it is known which one and to what distance a particle can be regarded as a "neighbor". Here, a new concept can be used, "Effective" Coordination Numbers (ECoN), so that such doubt on counting is removed[99]. Table 12 shows, that for *e.g.* $K_2[NiF_6]$, the value for the structure determining parameter $x_F$ derived from *calculations of ECoN* agrees well with that determined by *neutron diffraction*[100] on the powder. Table 13 shows that the analogously obtained values for powders of the mixed crystal series $Cs_2MnF_6$/$Rb_2MnF_6$/$K_2MnF_6$ are consistent; the pertinent MAPLE values give, by subtraction, practically consistent values for *ultramarine* $MnF_4$ whose structure is not yet known.

Table 10. The Madelung portion of the lattice energy (MAPLE) of two typical garnets (all values in kcal/mol).

Table 14 shows, for the example of yellow $K_2[MnF_6]$, how older ideas about the Mn—F distance can be revised and remain in agreement with the data obtained for cubic $K_2MnF_6$.

If it is assumed, as experience shows, that the theory of additivity of the MAPLE values of binary fluorides is valid in general for MAPLE values of ternary fluorides, then such

Table 14. MAPLE-values for the hexagonal modification of $K_2[MnF_6]$ with the newly determined lattice constants $a = 5.72_1$, $c = 9.32_4$ Å. From this it follows that $MAPLE(MnF_4) = 2460$ kcal/mol, which is in good agreement with the average $\overline{MAPLE}(MnF_4) = 2470$ kcal/mol (cf. Table 13).

| Ion | **Shortest distance [Å]** | MAPLE |

| | | $\sum = 2994$ |

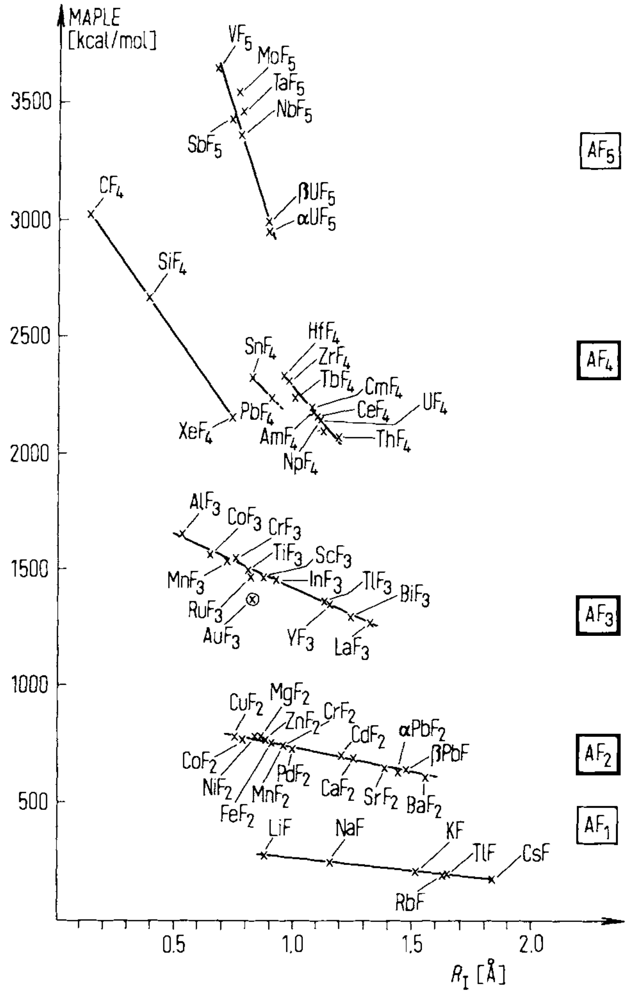

Fig. 8. MAPLE $(MF_n)$ as a function of the ionic radius of $M^{n+}$.

values can be calculated for still unknown fluorides. Figure 8 shows that conclusions can be made for the structural principles of binary fluorides still not investigated crystallographically.

## 2.10. Lattice Constants

Many may be surprised to learn that the lattice constants of even simple substances known for a long time—such as the fluorides LiF to CsF—are not all known with adequate certainty (example: $a$(CsF) = 6.002—6.05 Å[101]). The values for complex compounds vary so much, even in the case of "classic" examples with simple crystal structures ($K_2OsCl_6$: $a = 9.74_9$, $9.79_2$ or 9.82 Å; $K_2PtCl_6$: $a = 9.66$, 9.69, 9.73 or $9.75_5$ Å[101]), that the *"chemical quality"* of the sample must be questioned, even if the difference in precision of older (Debye-Scherrer patterns) and newer determinations (Guinier patterns) are taken into account. Moreover, it is unclear whether differences can be caused by varying content of $OH^-$ instead of $Cl^-$[102], with differing composition (*e.g.* $K_{1.96}[PtCl_{5.96}]$?) or by the orientation *e.g.* of the $[PtCl_6]$-groups not uniformly corresponding to the accepted structure.

Can the lattice constants be *theoretically calculated*? Not yed. Can they be *estimated from the ionic radii*? No, because there are no "rigid" ions. They can by estimated though, from fluorides of the same structural type, as shown in the case of the elpasolites[103].

However, they can be *compared*: Figure 9 shows that for the fluorides $Cs_2[MF_6]$ with M = Ti...Cu, which have the cubic $K_2PtCl_6$-type structure, the lattice constant $a$ decreases linearly with the atomic number. Since, in all known substances $M^{4+}$ has no $e_g$-electrons (with the exception of $Cu^{4+}$) no statement can be made about the still unknown $Cs_2[FeF_6]$ (with $t_{2g}^3e_{2g}^1$ for $Fe^{4+}$). From the values of $Cs_2[CuF_6]$ it is assumed that there could be non-cubic symmetry in the case of $Cs_2[FeF_6]$ too.

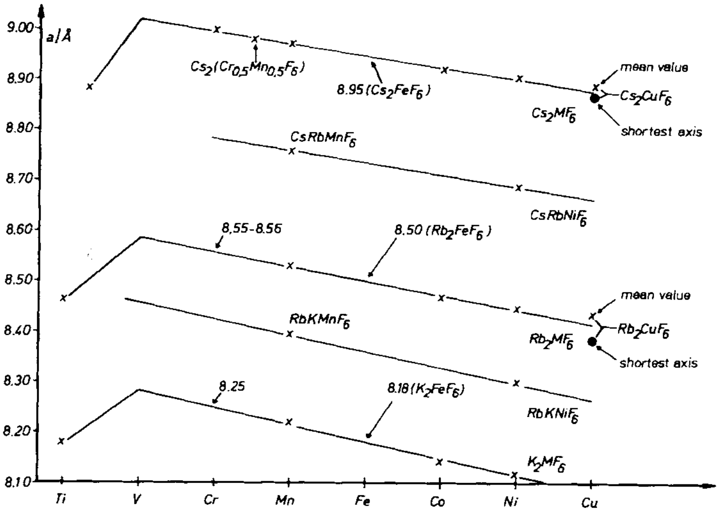

Fig. 9. Trend of the lattice constants of cubic fluorides of the $K_2PtCl_6$-type in the sequence $Ti^{IV}$—$Cu^{IV}$.

The situation is different for the cubic elpasolites $Cs_2K[ScF_6]$—$Cs_2K[CuF_6]$ (see Fig. 10). The lattice constant decreases regularly from the starting member of the series in spite of the addition of the $t_{2g}$-electrons. The jump to the sequence which begins with $Cs_2K[FeF_6]$ is related to the addition of the $e_{2g}$-electrons. Another jump is notable on going from $Cs_2K[NiF_6]$ to $Cs_2K[CuF_6]$; this may be caused by the addition of the second $e_{2g}$-electron.

Mixed crystals such as $CsRb[MnF_6]$ and $Cs_2[Cr_{0.5}Mn_{0.5}F_6]$[104] as well as $Cs_2[Ni_{0.5}Mn_{0.5}F_6]$[66] fit well into the series.

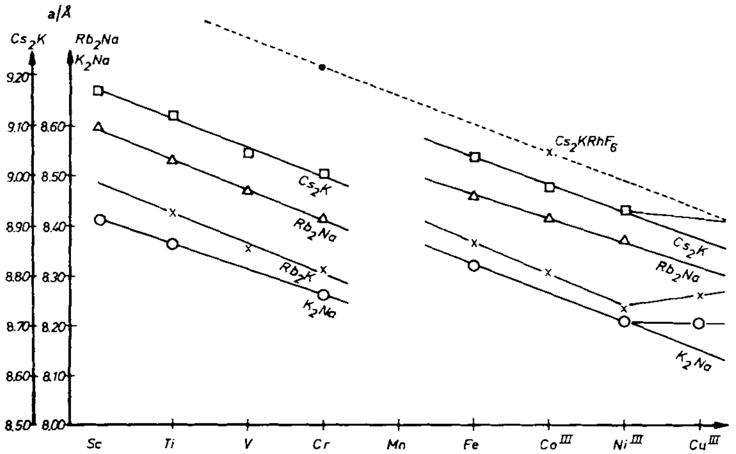

Fig. 10. Trend of the lattice constants of cubic fluorides of the elpasolite-type $A_2B[MF_6]$ in the sequence $Sc^{III}$—$Cu^{III}$.

Analogous linear relationships are found for the tetragonal fluorides of the $(NH_4)_3F[SiF_6]$-type (cf. Fig. 11), as also in the "real" heptafluorometalates of the $(NH_4)_3ZrF_7$-type (Fig. 12).

| $Cs_{1.6}Rb_{0.4}MnF_6$ | 8.891 | 8.888 | 0.208 |
| $Cs_{1.4}Rb_{0.6}MnF_6$ | 8.837 | 8.846 | 0.209 |
| $Cs_{1.2}Rb_{0.8}MnF_6$ | 8.815 | 8.804 | 0.210 |
| $CsRbMnF_6$ | 8.757 | 8.762 | 0.211 |
| $Rb_2MnF_6$ | 8.531 | 8.553 | 0.216 |
| $RbKMnF_6$ | 8.397 | 8.386 | 0.220 |
| $Rb_{0.8}K_{1.2}MnF_6$ | 8.360 | 8.353 | 0.221 |
| $Rb_{0.6}K_{1.4}MnF_6$ | 8.330 | 8.320 | 0.222 |
| $Rb_{0.4}K_{1.6}MnF_6$ | 8.270 | 8.286 | 0.223 |
| $Rb_{0.2}K_{1.8}MnF_6$ | 8.255 | 8.253 | 0.223 |
| $K_2MnF_6$ | 8.221 | 8.219 | 0.225 |

Table 15. Elpasolites $Cs_2NaLnF_6$: Agreement between the measured lattice constant and that calculated from a linear relationship between the lattice constant *a* and the mumber *n* of the 4f-electrons.

| Ln | $a_{calc}$ | $a_{abs}$ |
|---|---|---|
| Sm | $9.16_7$ | $9.17_3$ |
| Eu | $9.14_9$ | $9.15_4$ |
| Gd | $9.13_2$ | $9.13_6$ |
| Tb | $9.11_4$ | $9.09_9$ |
| Dy | $9.09_6$ | $9.09_4$ |
| Ho | $9.07_8$ | $9.07_5$ |
| Er | $9.06_0$ | $9.05_8$ |
| Tm | $9.04_2$ | $9.03_9$ |
| Yb | $9.02_5$ | $9.02_8$ |
| Lu | $9.00_7$ | $9.01_4$ |

Our experience shows that: *One* lattice constant is *no* lattice constant. Values obtained from various samples which have been prepared by different methods, and where possible from mixed crystals, should always be checked to see how well they fit together "within themselves". Figure 13 and Table 15 show that the actual precision of the determination in the case of cubic fluorometalates is clearly smaller than the usual standard deviation.

## 2.11. Chemical Properties of Fluorometalates

According to *Ruff*[105], colorless $HgF_2$ is extremely hygroscopic and should even withdraw water from moist $P_2O_5$ to form yellow-red products. Trifluoromercurates(II) such as colorless $Cs[HgF_{6/2}]$[106] are similarly sensitive to traces of moisture. However, sometimes $HgF_2$ is formed during their preparation and sublimes onto the cold end of the reaction tube where it forms *large* (diameter up to 5 mm), clear *colorless* single crystals[107], which are stable for days, even in moist air! This and other observations throw doubt on the frequently described special sensitivity of fluorometalates as a property of the "pure" substance. We assume that traces of HF (*e.g.* as $KHF_2$?) act here as an activator.

Yellow samples of $Cs_2[PdF_6]$[108] decompose quickly in the air to give black-brown hydrolysis products. If, after the actual fluorination of red $Cs_2[PdCl_6]$ (dil. $F_2$, 450 °C, 7d), the samples are annealed for a long time, then they are stable for hours in the air. If the samples are then re-annealed (200 bar $F_2$, 300 °C, 2d) they are again sensitive and decompose in a moment even under an inert gas (due to traces of moisture). Powder patterns show that the core of their black-brown crystallites is unaltered $Cs_2[PdF_6]$[109].

## 2.12. Magnetic Measurements of Fluorometalates

The Curie-Weiss law is valid in general for the complexes discussed here, if diamagnetic ligands "envelope" the paramagnetic central ion and "sufficient" magnetic dilution occurs (see Fig. 14). The occurrence of magnetic interactions in the collective *can* also be absent right to low temperature in linear chains (see Fig. 14).

$K_3[NiF_6]$ and $Cs_2K[NiF_6]$[110] are counter-examples (Fig. 15): Here, deviations occur although the mentioned criteria are fulfilled. They are caused by the influence of the ligand field which alters the energy term sequence of $Ni^{3+}$ from that of the ion in a vacuum; the ground state is now so close to the first excited state (of different multiplicity) that according to Boltzmann statistics, both are occupied. Roughly speaking it is as if there were a "thermal" equilibrium between two states of different multiplicity.

The influence of the ligand field can lead to strong deviations in the magnetic behavior expected according to classical ideas. *Light green* $Cs_2K[PrF_6]$ is *diamagnetic* at low temperatures (other than expected according to *Hund*: $\mu = 3.58\,\mu_B$). Non-diagonal elements in the *secular* determinant imply that there is, in addition, ***temperature independent "weak" paramagnetism***[111]; the ground state of $Pr^{3+}$ is here

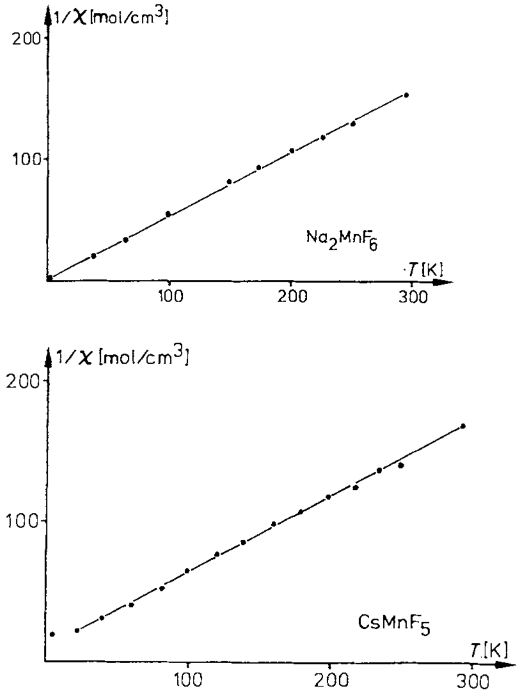

Fig. 14. Magnetic measurements of $Na_2MnF_6$ and $CsMnF_5$ in the range 3—300 K.

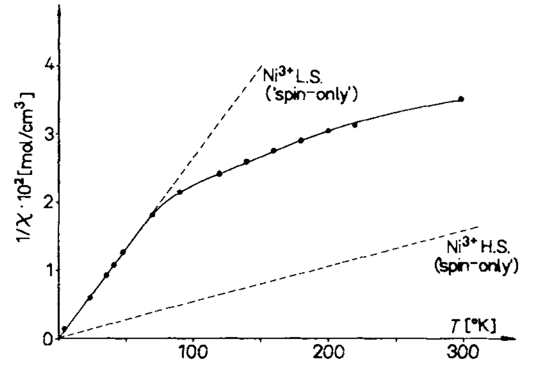

Fig. 15. Magnetic measurements of $Cs_2KNiF_6$ in the range 3—300 K.

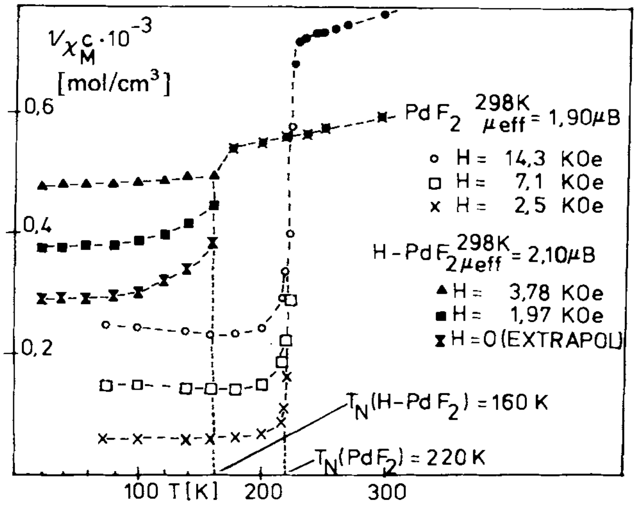

Fig. 16. Magnetic measurements of $PdF_2$.

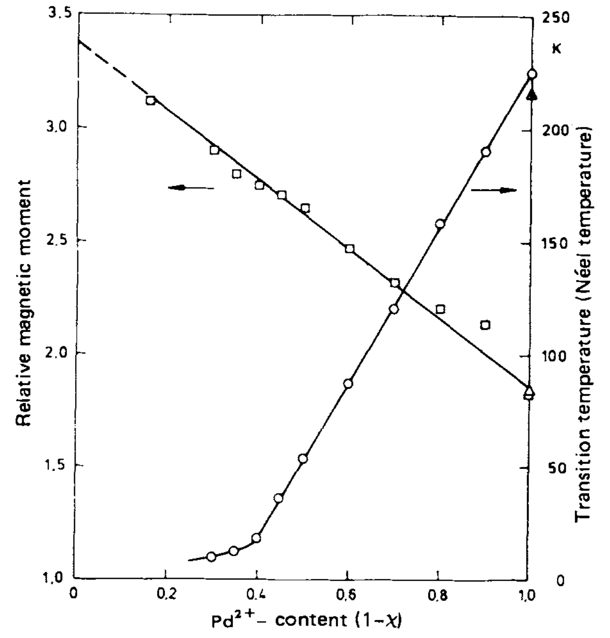

Fig. 17. Magnetic measurements of mixed crystals of $Pd_{1-x}Zn_xF_2$.

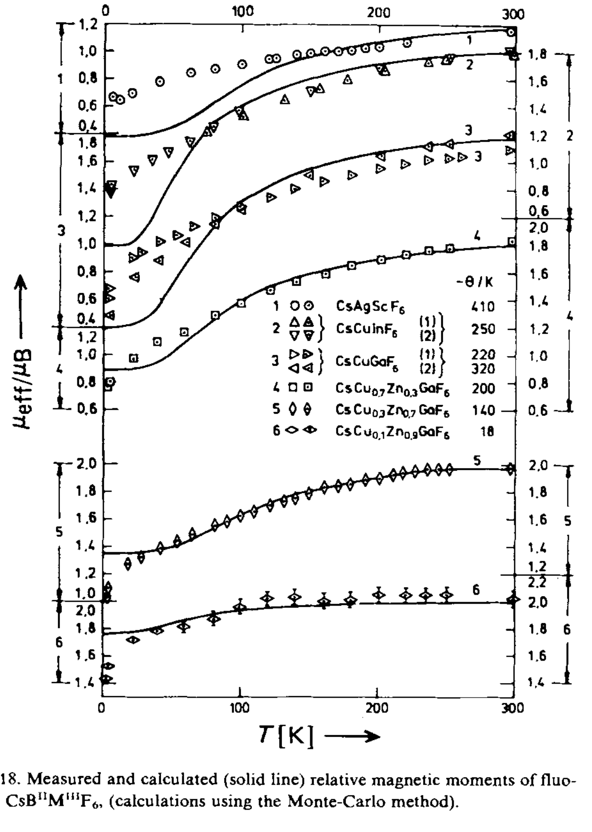

Fig. 18. Measured and calculated (solid line) relative magnetic moments of fluorides $CsB^{II}M^{III}F_6$, (calculations using the Monte-Carlo method).

$\Gamma_1$. $PdF_2$ should also be mentioned[112], it shows *antiferromagnetism* with *"weak" ferromagnetism* which is due to *"canted spins"* (see Fig. 16). Magnetic investigations on the mixed crystals $Pd_{1-x}Zn_xF_2$ gave additional information about the collective interactions[113] (see Fig. 17).

Paramagnetic $Cu^{2+}$ and diamagnetic $Ga^{3+}$ ions are randomly distributed in fluorides such as $CsCuGaF_6$[88], which belong to the $RbNiCrF_6$-type (*cf.* Section 2.8). The probability that mono-, bi- or *n*-nuclear "clusters" of $[CuF_6]$-groups are present, which have mutual bridge-building $F^-$, plays an important role in the interpretation of the magnetic measurements (Fig. 18). We have successfully used the Monte-Carlo method for this example[114].

The magnetic structure was determined for numerous fluorides with "normal" oxidation states (example: $Ba[NiF_4] = Ba[NiF_{4/2}F_{2/1}]$[115]) (see Fig. 19).

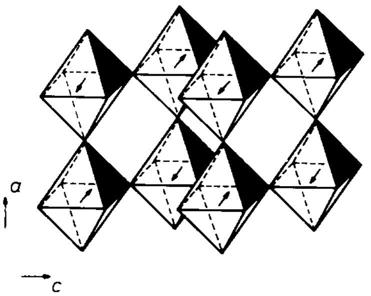

Fig. 19. Magnetic arrangement in $Ba[NiF_4]$ (schematic, only the $[NiF_{2/1}F_{4/2}]$ octahedra are shown).

### 2.13. Fluorometalates with Unusual Cations

The synthesis of xenon fluorides was initiated by two independent investigations: (a) Thermochemical estimations gave a value of *ca.* −30 kcal/mol for $\Delta H^0_{298}(XeF_2)$[116]. (b) Gaseous $PtF_6$ reacts with $O_2$ to form red $O_2^+[PtF_6]^-$[117], therefore the existence of "$XeF^+[PtF_6]^-$" seemed possible.

Since then, fluorides such as $O_2^+[SbF_6]^-$[118] *etc.* (see Table 16) have been prepared. The *bond length of the $O_2^+$-cation* (here 1.10 Å) was determined for the first time from the crystal structure of $O_2^+[Mn_2F_9]^-$[119] using X-rays (see Fig. 20).

Table 16. "Unusual cations" in fluorides of the type $A^+[MF_6]^-$.

$[A]^+ = O_2^+, Cl_2^+, Br_2^+, I_2^+$
$[KrF]^+, [Kr_2F_3]^+$
$[ClF_6]^+, [BrF_6]^+, [IF_6]^+$
$[ClOF_2]^+, [BrOF_2]^+, [NOF_2]^+$
$[XeF_5]^+, [XeF_3]^+, [XeF]^+, [XeOF_3]^+, [XeO_2F]^+$
$[MF_6]^- = [SbF_6]^-, [AuF_6]^-$
$[AsF_6]^-$

For some time it was thought that such "unusual" cations could be advantageously used to "stabilize" still unknown oxidation states of the 3d-metals. This is not the case: For the formation of *e.g.* $A^+[MnF_6]^-$ which contains *pentavalent manganese,* the deciding factor, according to the Born-Haber cycle, is the change of $\Delta H^0_{298}$ for the conversion of AF into $A^+_{gas}$ and $F^-_{gas}$. The following examples show that the "stabilizing" effect of both $O_2^+$ and $NO^+$, and also probably that of other cations such as $XeF_3^+$, presumably does not exceed that of $Cs^+$.

$$\begin{aligned}
&CsF_{solid} \rightarrow Cs^+_{gas} + F^-_{gas}; && \Delta H^0_{298} = +130.6\ \text{kcal/mol}\\
&LiF_{solid} \rightarrow Li^+_{gas} + F^-_{gas}; && \Delta H^0_{298} = +245.6\ \text{kcal/mol}\\
&NOF_{gas} \rightarrow NO^+_{gas} + F^-_{gas}; && \Delta H^0_{298} = +187.6\ \text{kcal/mol}\\
&\text{“}O_2F\text{”}_{gas} \rightarrow O^+_{2\,gas} + F^-_{gas}; && \Delta H^0_{298} = +216.8\ \text{kcal/mol} + \Delta H^0_{298}(O_2F
\end{aligned}$$

However, the addition of $O_2$ to $F_2$ in *high-pressure fluorination* plays an important role. Single crystals of *ultramarine* $MnF_4$[120] and *garnet-red* $MnF_3$[121] were thus obtained for the first time[18].

The formation of *dark red* and *water-clear* single crystals of $O_2^+[Mn_2F_9]^-$ and $(O_2^+)_2[Ti_7F_{30}]^{2-}$, respectively, show how the $O_2$ molecule acts in the "chemical transport" reaction.

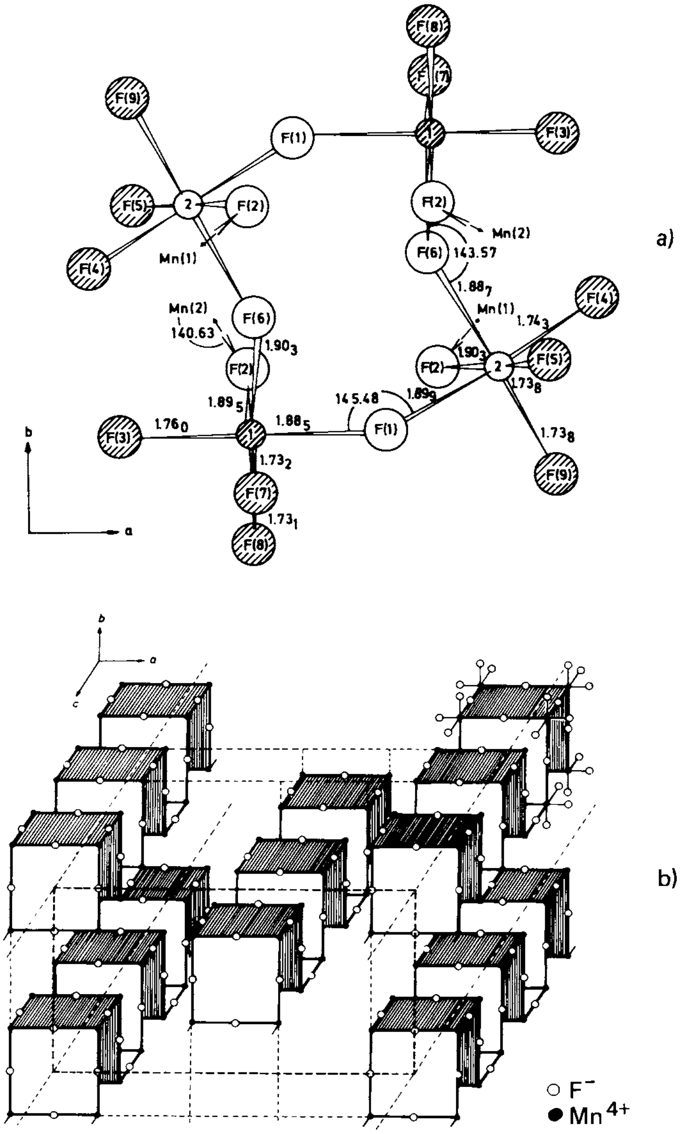

Fig. 20. a) Conformation and bond lengths of the $[Mn_4F_{18}]^{2-}$ group of $O_2^+[Mn_2F_9]^-$; b) Model of the meander-type arrangement of the linked $[Mn_4F_{18}]^{2-}$ groups.

In the first case a *meander-type* linkage of "four-membered ring" analogues of $Ru_4F_{20}$ (Fig. 20) gives a *"Zweier-Vierer" chain*[122], and in the second case[123] one of the few *genuine columnar structures*[124] is present (see Fig. 21).

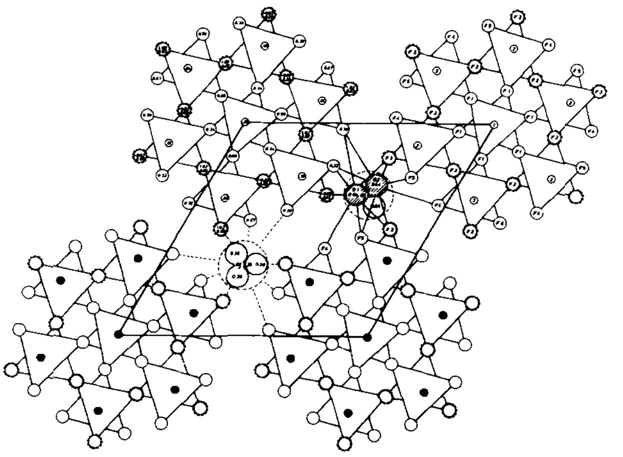

Fig. 21. $(O_2^+)_2[Ti_7F_{30}]^{2-}$ : Projection of the crystal structure along [00.1] (•: $Ti^{4+}$, ·: $F^-$, O: $O^{1/2+}$ at split-positions).

## 2.14. Reactions of Fluorides with Fluorometalates: "Exchange Reactions"

If a mixture of $K_2[MnF_6]+2CsF$ is heated in a welded gold tube, then $Cs_2[MnF_6]+2KF$ is formed smoothly[125]. $K_2[MnF_6]+2LiF$ is produced analogously under corresponding conditions from a mixture of $Li_2[MnF_6]+2KF$. The "exchange" of the "complementary cations" proceeds in accordance with the classical ideas about the complex-stabilizing effect of cations—here with differing ionic radius. In agreement with this, mixtures of $Cs_2[MnF_6]+2KF$ are unaltered by annealing[126]. However, these experiments were carried out under $F_2$ in corundum boats; they must be repeated using Mg-boats (*cf.* Section 2.7) in order to check whether or not $Cs_2KF[MnF_6]$ is formed.

Such exchange reactions proceed quite differently with oxometalates, and are mostly contradictory to classical ideas. Thus, a mixture of $2LiInO_2+Na_2O$ or *also* $2KInO_2+Na_2O$ gives $2NaInO_2$ in both cases as well as $Li_2O$ and $K_2O$, respectively. *Fluorometalates* can react with *oxometalates* to form only *binary* components. Thus, mild tempering (300 °C) of a mixture of $2Na_2[PbO_3]+Na_2[PbF_6]$ will give $6NaF+3$"$PbO_2$"[127]. The sharpness of the powder reflections of the binary component NaF (which has a relatively high melting point), is surprising under such mild conditions.

The frequently described fluorination reactions of organic compounds are also of industrial importance. Our attempts to get fluorometalates such as $Cs_2[NiF_6]$, $Rb_2[MnF_6]$, $K_2[CrF_6]$, $Ba[MnF_6]$, or $K[MnF_5]$ to react with *e.g.* $F_3C—CF{=}CF_2$ in the temperature range between 25 and 300 °C have always been unsuccessful if "pure" samples were used. Even, $AgF_2$ and $TlF_3$ did not detectably react when "dry" (reaction time in each case, 8 h).

## 2.15. Kinetic Influences in the Synthesis of Fluorides

*"Reaction with the surface of the vessel"* are difficult to suppress, especially if there are reactive end products. Sometimes it can be slowed down so that under otherwise optimum conditions, the reaction time is kept as short as possible.

We had to take other types of kinetic influences into account in the synthesis of oxygen-free *bright yellow* $MoF_3$[129] and new fluorides of tetravalent tungsten. If, *e.g.*, for the preparation of $K_2NaWF_7$ the mixture $2KF+NaF+W$ is heated in an autoclave with the stoichiometric amount of previously liquid fluorine, then the formation of *green* $K_2NaWF_7$ competes with that of volatile $WF_5$. The latter than reacts with the surface of the Monel autoclave, inspite of the inlay, to give gray reaction products. The conditions can be optimized by always using the same autoclave and controlling the experimental conditions exactly, especially the temperature control: So much tungsten [(instead of 1 W per 2 KF + 1 NaF, now $(1+\delta)$ W) and fluorine (instead of $2F_2$ per 1 W additional $(5\delta/2)F_2$)] is added so that practically quantitative "$K_2NaWF_7$" along with excess "$WF_5$" is formed within the reaction time. The samples so obtained are subsequently *homogenized* by annealing in a sealed Au-tube[130].

However, fluorides $TlAWF_7$ (A = Cs, Rb, K) are obtained from the mixtures $2TlF_3+AF+W$ by simply annealing in a Au-tube. The tube must be warmed with caution in order to avoid violent deflagration. The unavoidable intermediate formation of gaseous $WF_5$ would inevitably cause the Au-tubes to rupture; this can be prevented by counter-pressure (150 bar Ar) in an autoclave. The glittering *green* fluorides thus produced are cited in Table 17.

Table 17. Cubic fluorides of $(NH_4)_3[ZrF_7]$-type.

| Compound | Color | *a* [Å] |
|---|---|---|
| $Tl_2NaWF_7$ | green | $9.25_8$ |
| $Tl_2KWF_7$ | green | — |
| $K_2NaWF_7$ | gray-green | $8.81_6$ |
| $Rb_2KWF_7$ | green | $9.07_1$ |
| $Rb_2NaWF_7$ | green | $8.89_1$ |

## 2.16. Investigations of the Vibrational Spectra

The importance of the conclusions about structural details obtained from the reflection spectra of such fluorides is known. Only the examples $K_3[NiF_6]$[110] and $Cs_2K[VF_6]$[131] are referred to here.

Raman spectra are useful for the preparative chemist as a "finger-print method": According to Guinier patterns, lanthanoid fluorides such as *colorless* $Cs_3TbF_7$[132] belong to the cubic $(NH_4)_3ZrF_7$-type; the oxidation state of $Tb^{4+}$ has been proved and the Raman spectra are characteristically different (C.N. 7 for $Tb^{4+}$) from similar fluorides with C.N. 6, *e.g.* *colorless* $Cs_2Rb[TbF_6]$[132] (see Fig. 22).

The existence of analogous fluorides with tetravalent *neodymium* and *dysprosium* has been assumed for a long time[133], however, the characterization of the *yellow* samples (*e.g.* of $Cs_3NdF_7$ and $Cs_3DyF_7$) caused difficulties. New preparations of *orange-yellow* *e.g.* $Cs_2RbNdF_7$ and $Cs_2RbDyF_7$[134] produced by high pressure fluorination, exhibit characteristic peaks of $Cs_3CeF_7$ in the Raman spectra and thereby differentiate themselves from *light violet* $Cs_2RbNdF_6$ and *colorless* $Cs_2RbDyF_6$, the cubic elpasolites[135] which have a C.N. 6 for $Nd^{3+}$ and $Dy^{3+}$ as well.

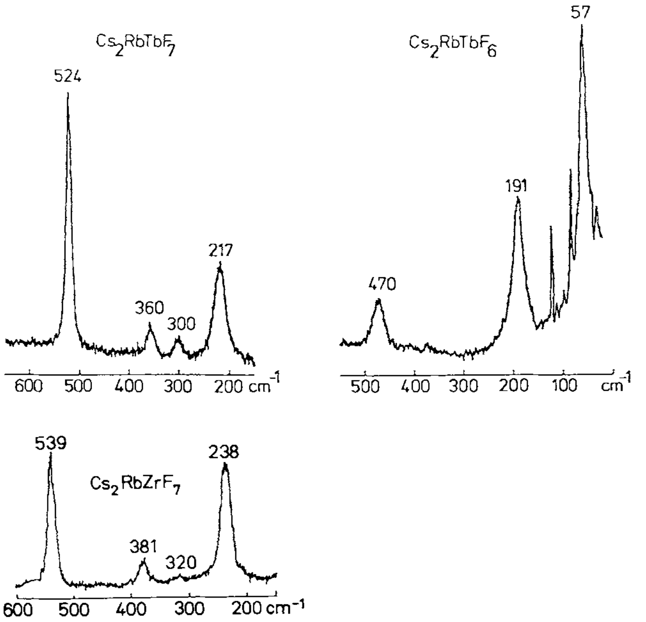

Fig. 22. Comparison of the Raman spectra of $M^{IV}$ fluorides with different coordination numbers.

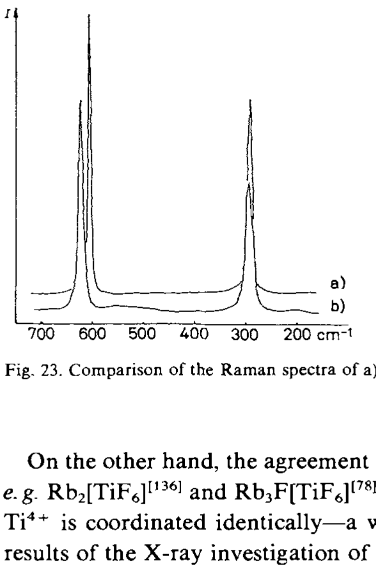

Fig. 23. Comparison of the Raman spectra of a) $Rb_2[TiF_6]$ and b) $Rb_3F[TiF_6]$.

On the other hand, the agreement of the Raman spectra of *e.g.* $Rb_2[TiF_6]$[136] and $Rb_3F[TiF_6]$[78] (see Fig. 23) shows that $Ti^{4+}$ is coordinated identically—a welcome support for the results of the X-ray investigation of the powder samples.

## 3. The Klemm Fluorination

For the preparation of other fluorides in an analogous way to $K_2[NiF_6]$, many factors play a deciding role, mostly only known to insiders. This is illustrated with some examples.

### 3.1. Purity of Fluorine

Fluorine electrolytically evolved on a nickel[137] or graphite[138] electrode—here called $F_2$(I) and $F_2$(II) respectively—always contains hydrogen fluoride and oxygen. Complete purification is difficult (oxygen is trapped *e.g.* as $O_2[SbF_6]$[139]) and for preparative purposes usually unnecessary. HF increases the reactivity. Thus *yellow* $Cs[AgF_4]$ is produced easily with $F_2$(I) but with difficulty using $F_2$(II), from mixtures of $2\,CsCl + Ag_2SO_4$. In contrast, colorless $Cs_2K[YF_6]$[140] is easily obtained with $F_2$(II) but difficult with $F_2$(I), because of the formation of $KHF_2$[*]. If corundum vessels are used for the reactions, then $F_2$(II) permits higher reaction temperatures.

### 3.2. What is Fluorinated?

If possible *compounds* should be fluorinated which already contain the "cations" in the desired ratio *e.g. colorless* $Li_3[Co(CN)_6]$[33] to $Li_3[CoF_6]$. Longer roundabout ways are also worthwhile. $BaPr^{IV}F_6$ and analogues $M^{II}LnF_6$ (M = Ba, Sr; Ln = Pr, Tb)[141] were hitherto only obtained by the following routes:

a) $6\,BaCO_3 + \text{“}Pr_6O_{11}\text{”} \xrightarrow[\text{reptd. evapn.}]{20\%\ HNO_3} 6\,\text{“}BaPr(NO_3)_5\,aq\text{”}$

b) $\text{“}BaPr(NO_3)_5\,aq\text{”} \xrightarrow[500\,^\circ C,\ 12\ h]{\text{HCl-stream}} \text{“}BaPrCl_5\text{”}$

c) $\text{“}BaPrCl_5\text{”} \xrightarrow[350\,^\circ C]{N_2/F_2\ (10:1)} \text{“}BaPrF_x\text{”}$ with $5 \leq x \leq 6$

d) $\text{“}BaPrF_x\text{”} \xrightarrow[500\,^\circ C,\ 12\ h]{F_2\,(500\,bar)} BaPrF_6$

The *molar volume* should decrease during fluorination: *e.g.* $CeF_4$[142] from $CeS_2$, not from $CeO_2$; $ZnF_2$[143] from ZnS or ZnSe, not from ZnO. Homogeneous samples of fluorometalates are only obtainable from *mixtures* if at least one component is "mobile".

### 3.3. How Does the Klemm Fluorination Proceed?

With ACl (A = K, Rb, Cs) as one of the components, the intermediate products are $A[ClF_4]$[144]; and probably $AHF_2$ as well, which leads to "full-fluorination". Little is known about other *intermediate products* of the reaction:

*Light yellow* $Ba[Ni(CN)_4]$ gives first[145] *green* $BaNi(CN)_4F_2$ (or $BaNi(CN)_4(HF)_2$[146]?) of unknown constitution. *Olive-green* "NiO" gives first a *velvet-black* product (NiOF, $NiO_{1+x}$?)[147] with $F_2$ at 300 °C. *Light-yellow* AuCl reacts with $F_2$ at 100 °C to give a *black* product, accompanied by a marked reduction in volume.

Mixtures of $BaCl_2 + NiCl_2$ yield $BaF_2 + NiF_2$ rather than $BaNiF_5$ which is easily produced from $Ba[Ni(CN)_4]$[145]. However, $2\,LiCl$ + "$MnO_2$" gives *bright yellow* $Li_2[MnF_6]$[148], because "volatile" $MnF_4$ is formed as an intermediate. $BaAgF_5$[149] can be produced not only from "$BaAgPO_4$"[150], but also from $BaCO_3 + AgF_2$, although $AgF_2$ (melting point 690 °C) is immobile; probably AgF and/or intermediate products such as *(orange-yellow?)* "$AgAgF_3$"[151] are formed first by partial *reduction in the fluorine stream*; these lower the melting point of $AgF_2$.

The reaction of oxides such as $Na_2PbO_3$[152] with $F_2$ was investigated in more detail: The *yellow* powder first becomes

---

[*] $3\,Cs_2K[YF_6] + 3\,HF = 2\,Cs_3[YF_6] + YF_3 + 3\,KHF_2$.

*black-brown* (200 °C, 2 h) and gives a *mixture* of $2NaF + "PbO_2"$, which also on annealing produces a mixture ($Na_2[PbF_6] + 2Na_2[PbO_3]$) in thermal equilibrium without $F_2$ being formed. Further heating with $F_2$ (300 °C) leads to $Pb_{12}O_{19}$ by reduction[127]. Only then is $Na_2[PbF_6]$ produced[153]. The sharpness of the NaF reflections of samples thus obtained is surprising. $LiInO_2$ and $NaInO_2$[154] analogously afford LiF and NaF, respectively, along with *yellow* $In_2O_3$; $NaTlO_2$ and $Li_2SnO_3$ behave correspondingly. Subsequently, $LiInF_4$, $NaInF_4$, $NaTlF_4$, and $Li_2SnF_6$ are formed[43].

### 3.4. How is Fluorination Carried out Today?

Whenever possible we fluorinate with "stationary" $F_2$ in order to reduce the influence of traces of HF. Local heating can be avoided by dilution (*e.g.* $N_2:F_2 = 10:1$) and lower temperatures at the beginning of the fluorination process.

*High-pressure fluorination* in Monel-autoclaves (up to 4500 bar, 600 °C [short-term], for up to 6 weeks and sealing after the Bridgman principle) offers certain advantages. The starting material must be carefully chosen in order to avoid violent explosions! Additives are necessary for the growth of single crystals, often Ar and $O_2$ are also favorable for still unknown reasons. The autoclave is filled with liquid fluorine, the end pressure can be adjusted *via* this amount (calibrated glass vessel).

### 3.5. Other Synthetic Routes

"Lower" fluorides are produced by annealing suitable mixtures (*e.g.* $2TlF_3 + V$) in a welded noble-metal tube. Redox reactions lead to otherwise inaccessible fluorides such as *deep-orange* $Tl_2VF_6$[155] or *straw-yellow* $Tl_2[MoF_6]$[129].

Oxide fluorides such as *e.g.* colorless $Pb[WO_3F_2]$, isotypic with $Sr[AlF_5]$[156], can be obtained by annealing the binary components. In the case of $Pb[WO_3F_2]$, gray samples are always produced in *new* welded tubes because partial reduction of $WO_3$ is unavoidable. However, if tubes which have already been used and then carefully cleaned are heated in $O_2$, then *colorless* samples are obtained. Probably hair-cracks allow some $O_2$ to penetrate the surface of the vessel and hinder the partial reduction of $WO_3$.

### 3.6. Choice of Vessel Material

The best material is still *sintered corundum.* Nevertheless, there are some fluorides, such as $Cs_3F[MnF_6]$ (cf. Section 2.7) which can only be produced in magnesium boats, previously passivated by $F_2$. Obviously the intermediate $CsHF_2$, formed from HF, reacts here with the corundum.

## *Part B: Oxometalates with d-Metals*

Are oxo- and fluorometalates comparable? Even *Scholder*[1] referred to the classical ideas of complex chemistry, according to which no principal difference in constitution exists between the two. In fact the different charge of $F^-$ and $O^{2-}$ leads to marked differences: For the *same oxidation state* (example: $Ba[MnF_6]$ and $Ba[MnO_3] = Ba[MnO_{6/2}]$[157]) the composition, and therefore the structure (*"isolated"* anions in the former, *3-dimensional giant anions* in the latter) is fundamentally different. For the *same composition* (example: $K[VO_3] = K[VO_{2/1}O_{2/2}]$[158] and $K[VF_3] = K[VF_{6/2}]$[159]) then, *non-commensurable* substances with different structures are present because of the different oxidation states. Tetrahedral groups with high oxidation state are well-known in oxometalates such as *e.g. colorless* $Cs_2[MoO_4]$[160] (isotypic with $\beta$-$K_2SO_4$). In the case of fluorometalates, so far only fluoroberylates such as $K_2[BeF_4]$[161] (related to olivine $Mg_2[SiO_4]$) are known. For $Cs[LiF_2] = Cs[LiF_{4/2}]$ and $RbLiF_2$[162] there is no analogy to silicates (here to "stuffed" framework structures of the $SiO_2$-type) but a characteristic *layer structure* determined by "double tetrahedra" *i.e.* $Cs^2_\infty[F_{2/2}LiF_2LiF_{2/2}]$ occurs.

*Remarkable differences* between both groups of compounds result from the fact that there are *"cation-rich" oxides* $A_2O$ (A = Li—Cs, Cu, Ag, Tl) which form numerous derivatives, however the fluoride analogs are missing; the unique sub-fluoride $Ag_2F$[163] is "without chemistry".

The plethora of the new investigations compels a limitation: Only *"genuine" oxometalates* with *"small" anions* of the d-metals are considered here.

## 1. What is an Oxometalate?

I do not know a generally applicable definition.

If a ternary metal oxide *e.g.* $KMnO_4$, dissolves in water without decomposing and thereby dissociates into ions, here $K^+$ and $[MnO_4]^-$, then an *oxometalate* is undoubtedly present. But the overwhelming majority of the compounds regarded as "oxometalates" are hydrolytically decomposed by water; in most cases other solvents are unknown. If *e.g.* $Na_6[ZnO_4]$[164] is dissolved in concentrated sodium hydroxide to give a clear solution, then nothing is known about the ions present in solution. If solid phases are formed *e.g.* $Na[Zn(OH)_3]$[165], then they crystallize as the phase with the lowest solubility under the reaction conditions. It is still not known to what extent they are involved in an equilibrium in solution.

The frequently used arguments derived from the geometry of the atomic positions are of doubtful value. I ask again: Does a shorter distance always represent also a stronger chemical bond?

An example might arouse further doubt: $Li_2SiO_3$ has been known for a long time. If, as in all previously known silicates, one assumes the C.N. 4 for $Si^{4+}$ relative to $O^{2-}$, then a structure of the type $[SiO_{2/1}O_{2/2}]$ must occur which contains $O^{2-}$-bridges. This means that it has either an *infinite chain* or a finite ring (found for the first time for alkali metal silicates with $K_6[O_{2/1}SiO_{2/2}]_3$[166], see Fig. 24) as a structural characteristic. But C.N. 4 is also to be expected for $Li^+$!

If we assume (in agreement with the known crystal structure of $Li_2SiO_3$[167]) that a (here: hexagonal) closest-packing of $O^{2-}$ is present and $Li^+$ and $Si^{4+}$ occupy tetrahedral inter-

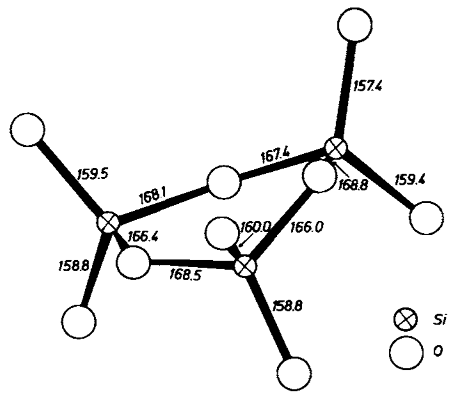

Fig. 24. $[Si_3O_9]^{6-}$ group of $K_6[Si_3O_9]$; bond lengths in pm.

stices in a regular fashion, then the cations are arranged themselves in a close-packed manner. Assuming that, for energetic reasons, the $Si^{4+}$ have the greatest possible distance from one another, then, according to Figure 25, there is only one possibility, to arrange $Li^+$ and $Si^{4+}$ electrostatically favorably within *each* layer. If these layers are stacked along [00.1] due to a closest packing, then $[O_{2/2}SiO_{2/2}]$ chains are automatically built in this direction; this is found in the case of $Li_2SiO_3$.

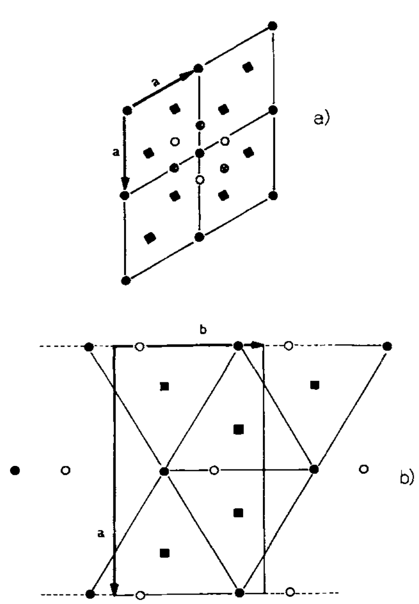

Fig. 25. a) $Li_2SiO_3$: ● $Si^{4+}$, ■ $Li^+$ within a layer; ○ and ⊗ possible positions of $Si^{4+}$ in the next layer (in projection). b) Arrangement of ● $Si^{4+}$, □ $Li^+$ in a layer, ○ $Si^{4+}$ in the neighboring layer.

Resumé: If $Li_2SiO_3$, according to $Li_{0.67}Si_{0.33}O$ is an *ordered variety* of the ZnO family, then the *composition* already determines the formation of $[SiO_{2/1}O_{2/2}]$ "chains". And if so can these then be regarded as "characteristic"?

## 2. Oxometalates with "Isolated" Anions

Thirty years ago one learnt for examinations that "isolated" oxo-complexes such as $[MnO_4]^-$ only exist if the oxidation state is "high", but also *e.g.* $[MnO_4]^{2-}$ in *green* $K_2MnO_4$[168] or the phosphate ion analog $[MnO_4]^{3-}$ in *blue* $Na_3[MnO_4]\cdot 10H_2O$[169] may be possible.

The new syntheses of numerous ternary and multi-component oxides containing metals in lower oxidation states confirmed this concept over many years: "Highly-polymeric" anions were found not only on typical double oxides *e.g.* the perovskites such as $CaTiO_3$, or the spinels of the $MgAl_2O_4$ type[170], but also in those compounds which correspond to *anhydrous* derivatives of amphoteric hydroxides (cf. Table 18).

Table 18. Order variants of the NaCl-type in oxides $AMO_2$.

| Compound | Type | Color | $a$ [Å] | $c$ [Å] | $c/a$ |
|---|---|---|---|---|---|
| $LiCrO_2$ | α-$NaFeO_2$ hex. $R\bar{3}m$ | olive-green | 289.9 | 1442 | 4.974 |
| $LiVO_2$ |  | black | 283.8 | 1480 | 5.215 |
| $NaAlO_2$ |  | colorless | 286.8 | 1588 | 5.54 |
| α-$NaFeO_2$ |  | black | 301.9 | 1593.4 | 5.28 |
| $NaYO_2$ |  | colorless | 338.6 | 1643 | 4.85 |
| $KInO_2$ |  | colorless | 329.6 | 1829 | 5.55 |
| $KTbO_2$ |  | colorless | 349 | 1860 | 5.33 |
| $KRhO_2$ |  | red | 317.5 | 1721 | 5.42 |
| $RbTlO_2$ |  | colorless | 345.3 | 1914.8 | 5.54 |
| $RbHoO_2$ |  | colorless | 346 | 1940 | 5.61 |
| $RbLuO_2$ |  | colorless | 340 | 1915 | 5.63 |
| $CsTlO_2$ |  | colorless | 338.8 | 2077 | 6.13 |
| α-$LiFeO_2$ | α-$LiFeO_2$ tetr. $I4_1/amd$ | black | 405.7 | 875.9 | 2.16 |
| $LiTmO_2$ |  | colorless | 440.5 | 1015 | 2.30 |

There are *"ordered variants"* of simple structural types here (NaCl, ZnS, also $Na_2O$ *etc.*). Surprisingly, "cation-rich" oxides also comply with this picture if the distances $d(A^I—O)$ and $d(M^{III}—O)$ are of about the same length *e.g. colorless* $Li_5AlO_4$[171] or *yellow* $Na_5TlO_4$[172]. Vacancies appear not only in the *cationic part* (*i.e.* $Li_5Al_2\square_1O_4 \triangleq Li_8O_4$), but also (though more rarely) in the *anionic part* (example: *red* $Na_4Mn_2O_5$[173] $= Na_4Mn_2O_5\square_1 \triangleq Na_6Cl_6$, derivative of the rock salt type) if cations and anions are not present in the same quantities.

In addition, even the crystal structure of $Na_3[AgO_2] \triangleq [Na_4O_2]$ (colorless single crystals) is a somewhat similar example[174]. In contrast to $K_2[HgO_2]$, the [O—Ag—O] dumbbells are not all arranged the same, but in two alternating directions (cf. Fig. 26).

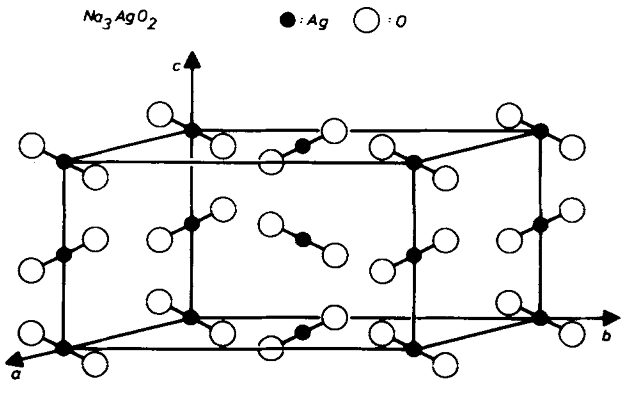

Fig. 26. Crystal structure of $Na_3[AgO_2]$, arrangement of the $[AgO_2]$ dumbbells in the unit cell.

There was a surprise with *colorless,* transparent single crystals of KAgO[175]. Because of the diagonal relationship of $Ag^+$ to $Hg^{2+}$ in the periodic table, a $[AgO_{2/2}]$ "chain" of ..O—Ag—O.. dumbbells, as with HgO[176], would be "normal". However, a "ring", *i.e.* an almost square planar unit of the type $K_4[(AgO_{2/2})_4]$[177] was observed. Would this point to the existence of further oxides with "small anions" having low oxidation states? Today we can answer this question with a Yes. Such "cation-rich" oxides are reported in the following Section.

## 3. Oxometalates with "Mononuclear" Groups

An unsolved, but current question concerning these metal oxides is whether groups with a single ligand exist, *i.e.* compounds of Cs[MO]-type, like Cs[ClO].

### 3.1. Mononuclear Groups with Only One Ligand

Three separate questions may be raised:

a) Intermediate phases appear in the system $Li_2O$/$Cs_2O$[43,178]. Would the "isolated" group [LiO] be capable of existence in (the still hypothetical) CsLiO, or would it polymerize according to $[LiO_{2/2}]$ or $[LiO_{4/4}]$?

b) Could a [:Tl—O]-type dumbbell with a *lone pair* as an "invisible" ligand occur in oxothallates(I) A[TlO], where $A^+$ is *extremely large,* larger than $Cs^+$!)?; colorless K[TlO] is, *e.g.* well known[179]).

c) Which structures do KAgO analogues have? Is the tetrameric "ring" (see Fig. 27) always formed? The structural elucidation of water-clear, *colorless* single crystals of recently obtained CsCuO[180] show that here, as in the case of *red* HgO[176], there is a chain built of *linear dumbbells* of OCuO (Cu—O—Cu angle = 89°). Contrary to our hopes, the *d*(Cu—O) distances within the dumbbell are of the same length.

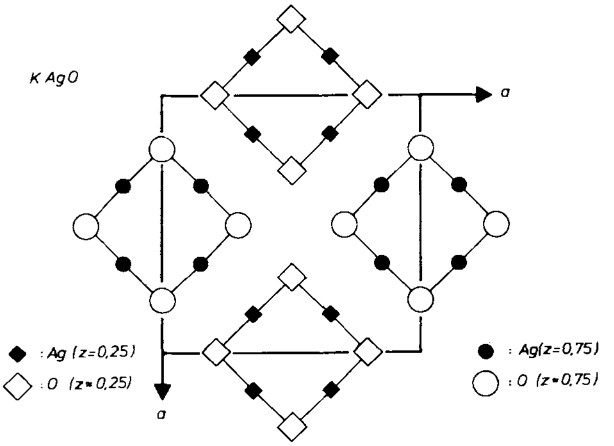

Fig. 27. Crystal structure of $K_4[Ag_4O_4]$, arrangement of the $[Ag_4O_4]$ rings in projection along [001].

Can oxides such as *e.g.* $(Ph_4As)[CuO]$ be prepared? Are perhaps the mentioned differences of the O...Cu—O distance present here?

*Yellow* CsAuO[182] follows $K_4[Ag_4O_4]$ corresponding to $Cs_4[Au_4O_4]$. It is the first defined oxoaurate(I) and was obtained by direct oxidation of *green* CsAu[183].

### 3.2. Mononuclear Groups with Two Ligands

These groups are very rare for metal oxides, two examples are known:

a) We had already obtained oxomercurates(II), such as $K_2[HgO_2]$[184], in the form of *colorless* single crystals. For this it was important that the reacting mixture (*e.g.* $K_2O + HgO$) was annealed in a sealed vessel. It has one of the rare *"stuffed" molecular structures* (see Fig. 28). The arrangement of the [O—Hg—O] dumbbells corresponds to the structure[185] of $XeF_2$[116].

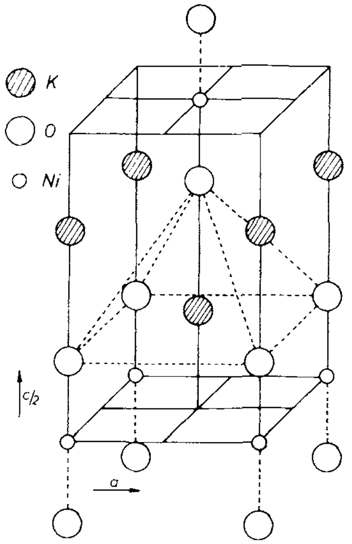

Fig. 28. The tetragonal $K_2[HgO_2]$-type, for example $K_2[NiO_2]$; only half of the unit cell is reproduced. The arrangement of the [ONiO] dumbbells corresponds to the $XeF_2$-type.

b) Little is known about the system K/Ni/O. For years many[186] experiments, including our own[187], remained unsuccessful. Finally we heated the mixture (*e.g.* $K_2O + NiO$) in a sealed Ni-tube and used the otherwise dreaded "reaction with the surface" in order to hinder the partial oxidation of $Ni^{II}$ to $Ni^{III}$, caused by unavoidable traces of $O_2$. This resulted in strongly dichroic (red/green), *lustrous dark red* single crystals of $K_2[NiO_2]$, which, like $Rb_2NiO_2$ and $Cs_2NiO_2$, is isotypic with the oxomercurates(II)[188].

It is fascinating that inspite of the unusually short $d(Ni—O) = 1.68$ Å distance in the linear dumbbells, the samples are paramagnetic and the Curie-Weiss law is obeyed with $\mu = 3.0\mu_B$, $\theta = -30$ K (as expected by *Klemm*[189]). Nothing is known about the bonding behavior.

### 3.3. Mononuclear Groups with Three Ligands

In contrast to oxides of non-metals ($BO_3^{3-}$, $CO_3^{2-}$, $NO_3^-$, $SO_3^{2-}$ *etc.*), these groups are rare in the case of metal oxides!

a) Although "FeO" is of great industrial importance and has been thoroughly investigated, oxoferrates(II) remained unknown for a long time, since unavoidable traces of $O_2$ effected oxidation of $Fe^{II}$ to $Fe^{III}$ when appropriate mixtures were annealed (*e.g.* BaO + FeO). Again, the "reaction with the vessel surface" (here: a Ni-bomb with Fe-lining) led for the first time to garnet-red single crystals of $Na_4[FeO_3]$[190] (see Fig. 29 and Table 19).

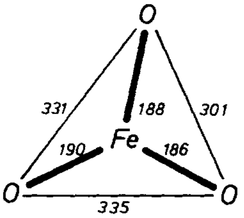

Fig. 29. The $[FeO_3]^{4-}$ group in $Na_4[FeO_3]$, distances in pm.

Table 19. Motifs of mutual adjunction in $Na_4FeO_3$; distances [pm] are given in addition to the Mo. A.

| | O1 | O2 | O3 | C.N. |
|---|---|---|---|---|
| Na 1 | 1/1<br>238 | 2/2<br>233 235 | 1/1<br>242 | 4 |
| Na 2 | 2/2<br>237 243 | 1/1<br>236 | 1/1<br>261 | 4 |
| Na 3 | 1/1<br>228 | 1/1<br>229 | 1/1<br>220 | 3 |
| Na 4 | 1/1<br>228 | 264 | 2/2<br>232 236 | 4 |
| Fe | 1/1<br>183 | 1/1<br>186 | 1/1<br>188 | |
| C.N. | 6 | 6 | 6 | |

*Carbonate-like*, almost planar $[FeO_3]^{4-}$ groups, exist. This finding confirms our concept, which had been developed to deal with the occurrence of such remarkable groups. The C.N. of the 3d-metal is so low here because of the numerous counter-cations which also have an affinity to coordinate to $O^{2-}$ and because of the tendency of $O^{2-}$ not to coordinate to more than a total of six cations.

This *experimental* finding obliged us to check the usual conceptions about "oxometalates". Contrary to all classical ideas, here the coordination number of the *ligand* has much more influence on the structure than does the nature of the central ion. In addition, there is the influence of the "ligands" on the crystal structure. Apparently, this latter mentioned influence (cf. [83]) is responsible for the individual components exhibiting unexpected coordination numbers in the structure of even "classical" examples of complex chemistry such as $K_2[PtCl_6]$ (here; 12 for $K^+$ with respect to $Cl^-$, instead of 6 as in KCl). The interplay of various influences which lead to the formation of this or that crystal structure is best surveyed if the "motifs of mutual adjunction" are considered (see *e.g.* Table 19).

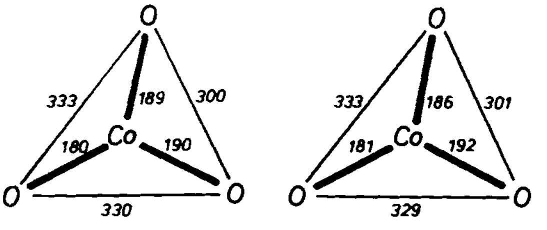

Fig. 30. The two crystallographically independent $[CoO_3]^{4-}$ groups in $Na_4[CoO_3]$, distances in pm.

b) From mixtures of $2Na_2O$ + "CoO" we obtained *deep red* single crystals of the analogous oxocobaltate(II) $Na_4[CoO_3]$[191]; it also contains carbonate-like groups (see Fig. 30).

c) In the search for the still unknown $K_4[NiO_3]$, we obtained *black* single crystals of $K_9[Ni^{II}O_3][Ni^{III}O_4]$[192], a *mixed valence* oxoniccolate(II,III) (see Fig. 31 and Table 20). In addition to the *paramagnetic* $[Ni^{III}O_4]^{5-}$ groups, there are *diamagnetic* planar $[NiO_3]^{4-}$ groups, like those occurring in the two previously cited oxides.

### 3.4. Mononuclear Groups with Four Ligands

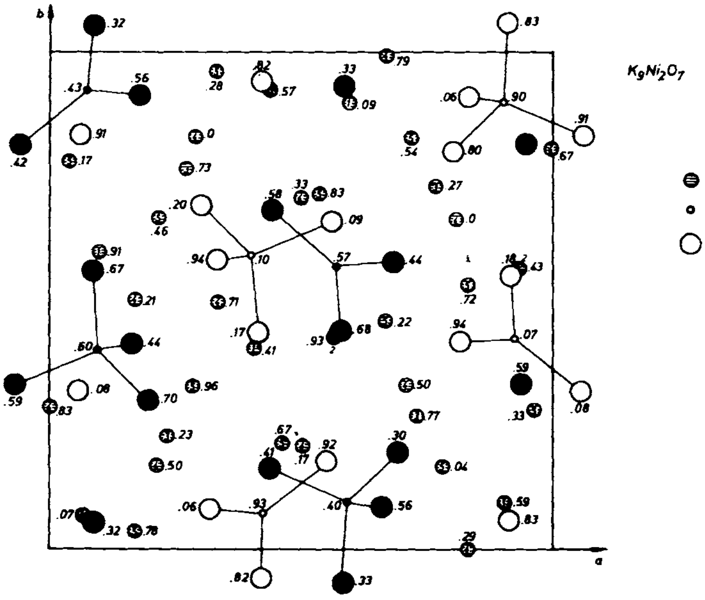

Fig. 31. Crystal structure of cubic $K_9[Ni^{II}O_3][Ni^{III}O_4]$, unit cells in projection along [001].

Table 20. Motifs of mutual adjunction in $K_9Ni_2O_7$; distances [pm] are given in addition to the Mo. A.

| | O1 | O2 | O3 | C.N. |
|---|---|---|---|---|
| K/1 | 3(1<br>268 | | | 3 |
| K 2 | 3/1<br>304 | 3/1<br>273 | | 6 |
| K 3 | 3/1<br>310 | 3/1<br>276 | | 6 |
| K 4 | 2/2<br>263<br>288 | 2/2<br>277<br>278 | 1/3<br>262 | 5 |
| K 5 | 2/2<br>284<br>285 | 2/2<br>286<br>293 | 1/3<br>307 | 5 |
| Ni 1 | 3/1<br>189 | | 1/1<br>196 | 4 |
| Ni 2 | | 3/1<br>180 | | 3 |
| C.N. | 8 | 7 | 7 | |

Such groups have only recently become known in lower oxidation state oxometalates. Sulfate-analogous groups were found to be present in the *colorless* oxides $Na_5[GaO_4]$, and $Na_6[ZnO_4]$[193]. In the meantime the oxomagnesate $K_6[MgO_4]$[194], which is isotypic with $Na_6[ZnO_4]$, has been obtained, so it would now seem that $Cs_7[LiO_4]$ should also be accessible. Single crystals of $Na_5[FeO_4]$[195] are *yellow*, those of $Na_5[CoO_4]$[196] are *violet*, and those of $Na_5[NiO_4]$[197] are *steel gray*; all are isotypic with colorless $Na_5[GaO_4]$. The recently prepared red-brown $Na_5[MnO_4]$ also belongs to this group.

*Oxometalates with "single" $O^{2-}$* are hardly known. To our surprise $Li_4[SiO_4]$ is not the Li-richest silicate, rather it reacts with excess $Li_2O$ to form $Li_8O_2[SiO_4] = (OLi_4)_2[SiO_4]$[198]. We obtained this silicate by a directed synthesis after we had successfully prepared *lustrous-red* single crystals of $Li_8O_2[CoO_4]$, the first compound of this type among the oxometalates of the d-metals[199] (see Fig. 32).

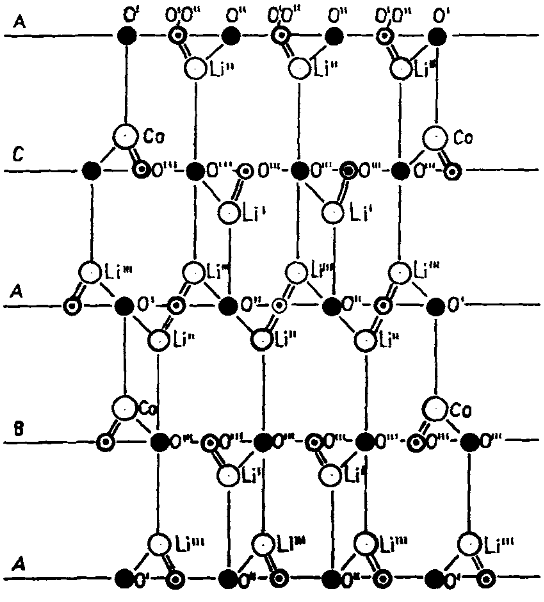

Fig. 32. Structural principle of $Li_8O_2[CoO_4]$, sequence of the layers of $O^{2-}$ along [00.1] with $Co^{2+}$ and $Li^+$ incorporated in the tetrahedral interstices.

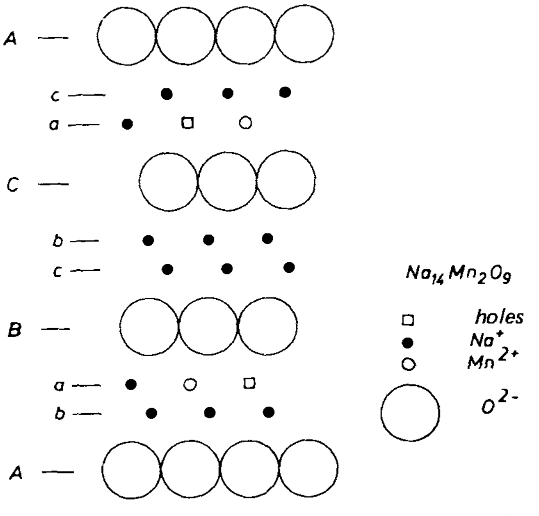

Fig. 33. Occupation of the tetrahedral interstices by $Na^+$ and $Mn^{2+}$ (with holes) in the cubic closed packing of $O^{2-}$ in $Na_{14}Mn_2O_9$; sequence stacking along [001].

The oxometalate $Na_{14}O[MnO_4]_2$, which shows the highest content of alkali oxide should be mentioned here. It is the first oxomanganate(II)[200] and forms *pale red* single crystals. The crystal structure is illustrated in Fig. 33.

*Oxometalates with "solitary" $O^{2-}$* (cf. Section *A* 2.7) are still unknown.

## 4. Oxometalates with Binuclear Groups

These groups, which have been known for a long time in oxochromates(VI) such as $K_2[Cr_2O_7]$, are present in only a few compounds of "cation-rich" metal oxides.

### 4.1. Binuclear Groups with a Total of Two Ligands

There are no examples known. A hypothetical example would be the $[:TlO_2Tl:]^{2-}$ group, in which the "lone pairs" act as "extra ligands" and could form bridges to the complementary cations, as has been found in *yellow* $K_4[Pb_2O_4]$[181] (*cf.* Fig. 34) and *orange-yellow* $K_2[Sn_2O_3]$[201].

Binuclear groups *with three ligands* are still unknown.

### 4.2. Binuclear Groups with Four Ligands

To date these are also unknown in the case of metal oxides of the d-metals; only two examples of such groups are known:

a) *light-yellow* $K_4[OPbO_2PbO]$ (see Fig. 34), in which each $Pb^{2+}$ has a "lone pair" as the fourth, invisible ligand[181].

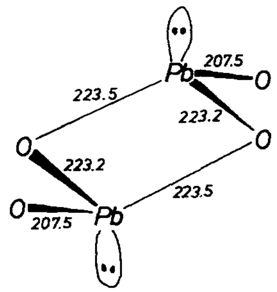

Fig. 34. $K_4[Pb_2O_4]$: The $[Pb_2O_4]$ group in perspective, bond lengths in pm.

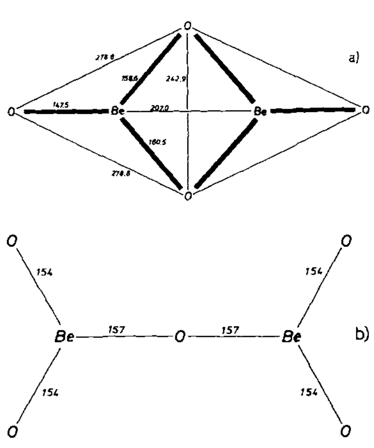

Fig. 35. a) Planar $[Be_2O_4]$ group in $K_4[Be_2O_4]$, distances in pm.—b) "butterfly" $[Be_2O_5]$ groups in $Na_6[Be_2O_5]$, distances in pm.

b) *colorless* $K_4[OBeO_2BeO]$[202] (see Fig. 35a), which contains two triangular groups linked *via* a common edge. The anion exhibits the *shortest Be—Be distance* known so far, *i. e.* *d*(Be—Be) = 2.07 å (in metallic Be: 2.23 Å). MAPLE, however, does not reveal any unusual energetic features.

### 4.3. Binuclear Groups with Five Ligands

There are no examples known for the d-metals, and only *one* such metal oxide has been prepared, namely $Na_6[O_2BeOBeO_2]$[203], which contains a "butterfly-like" anion (cf. Fig. 35b).

### 4.4. Binuclear Groups with Six Ligands

There are two examples; $K_6[Fe_2O_6]$ and $K_6[Mn_2O_6]$[204] (cf. Fig. 36). Unexpectedly, the groups contain edge-to-edge-linked tetrahedra. It is also unusual that the C.N. of part of the $O^{2-}$ exceeds the usual limiting value of 6. This grouping was recently found in $Na_6[Fe_2S_6]$ and $Rb_6[In_2S_6]$[205].

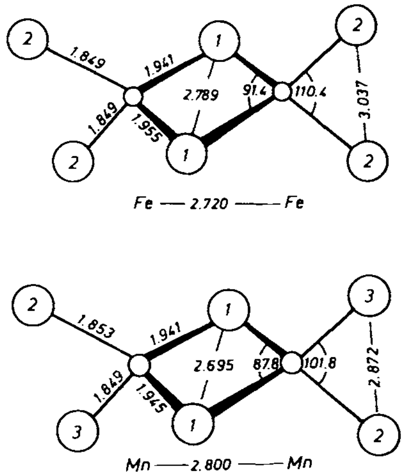

Fig. 36. $[M_2O_6]$ groups with M = Fe, Mn (double tetrahedra) of $K_6[M_2O_6]$; distances in Å.

In $Na_6[Au_2O_6]$[206], *pale-yellow* transparent single crystals, $Au^{3+}$ has a planar environment (cf. Fig. 37).

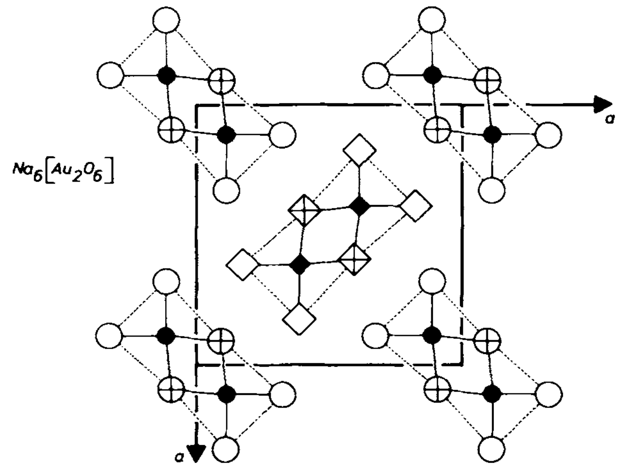

Fig. 37. $Na_6[Au_2O_6]$; arrangement of the planar $[Au_2O_6]$ group in the tetragonal unit cell, projection along [001].

### 4.5. Binuclear Groups with Seven Ligands

These are well known in oxometalates of higher oxidation states, such as *red* $Rb_2[Cr_2O_7]$[207] and its analogues. Generally, but by all means not always, all $[O_3M—O—MO_3]$ groups of such an oxide have the same conformation. However, in *red* $Sr[Cr_2O_7]$[208], two groups of different conformation are present in the ratio 1 : 1 (cf. Fig. 38).

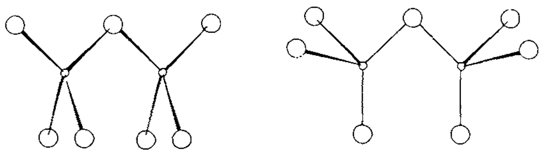

Fig. 38. Conformation of the two different $[Cr_2O_7]^{2-}$ groups in $Sr[Cr_2O_7]$.

In connection with the structure determination of *thortveitite* $Sc_2[Si_2O_7]$[209], the following questions arise. When does the valence angle M—O—M reach the value 180° within this group? When does the bridging $O^{2-}$ lie at a center of symmetry, and when not? Why does the bridging angle vary so much? Experimental findings are listed in Table 21.

Table 21. Bond angles M—O—M of some $Si_2O_7^{6-}$-groups.

| Compound | M—O—M [°] |
|---|---|
| $Sc_2Si_2O_7$ | 180 |
| $Y_2Si_2O_7$ | 134 |
| $Li_6Si_2O_7$ | 136 |
| $Rb_2Be_2Si_2O_7$ | 171 |

Only two examples are known for d-metals in *lower* oxidation states, and they are remarkably different: The *yellow, transparant* single crystals of $Na_8[Fe_2O_7]$[210] are isotypic with $Na_8[Ga_2O_7]$[211] and have the smallest M—O—M valence angle of 119.7° hitherto found in such $[M_2O_7]$ groups. Whereas with $K_6[Co_2O_7]$, which contains the *isoelectronic anion,* this angle widens to 180° and, moreover, the bridges are found at a center of symmetry! We obtained $K_6[Co_2O_7]$ in the form of *permanganate-colored* single crystals[212]. The enormous difference in the valence angle at the bridging $O^{2-}$ in the case of these two isoelectronic anions shows that attempts to interpret such differences of structure using ideas which are confined to the bonding situation inside the "closed" groups and perhaps include the "hybrid orbitals", are fundamentally insufficient. The influence of the "completing" cations is clearly seen; in one case eight smaller ($Na^+$) and in the other six larger ($K^+$) decidedly influence the *crystal structure* and with it the *configuration* of the anion.

## 5. Oxometalates with Tri- or Multinuclear Groups

Illustrative examples are known with d-metals in polyacids, above all of the elements of groups Va and VIa of the periodic table. While attempting to synthesize $Na_4[CoO_3]$—cf. Section *B* 3.3—we found *dark red* single crystals of $Na_{10}[Co_4O_9]$[213], the first example of an analogous *lower valence oxide* of the d-metals. The anion, which corresponds to the still unknown tetracarbonates such as $K_2[C_4O_9]$, has a conformation (see Fig. 39) which leads to *one* especially short Co—Co distance.

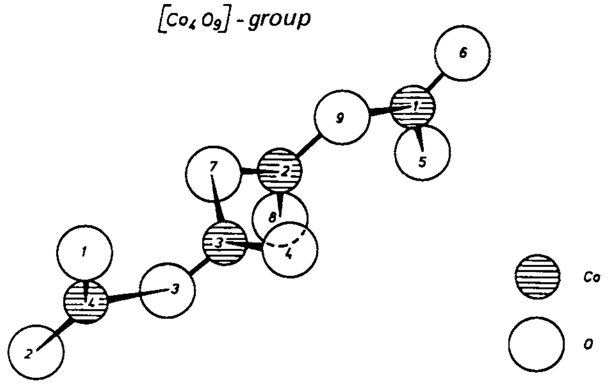

Fig. 39. $[Co_4O_9]$ group in $Na_{10}[Co_4O_9]$, conformation in perspective.

*Bright red* $Ag_{10}[Si_4O_{13}]$[214] was obtained as the first oxosilicate with a tetranuclear anion, and recently $Na_{14}[Al_4O_{13}]$[215] was obtained in the form of *clear, colorless* single crystals and is the first oligooxoaluminate.

## 6. On the Syntheses of New Oxides

When we started preparing "cation-rich" *oxoferrates(III)*, the system $Na_2O/Fe_2O_3$ was considered to have been essentially investigated. The crystal structures of the different forms of $NaFeO_2$ (ordered variety of the NaCl-type, and in the case of β-$NaFeO_2$ the ZnS-type) were known. Surprisingly, we then obtained $Na_5FeO_4$[216] and $Na_8[Fe_2O_7]$[210] with an *island structure,* $Na_{14}[Fe_6O_{16}]$[216] with a *chain structure* (see Fig. 40a), and $Na_4[Fe_2O_5]$[217] with a *sheet structure* (Fig. 40b). There is probably at least one further phase present in "$Na_3FeO_3$". It is assumed that these advances materialized because in each case mixtures of $Na_2O$ and "active" $Fe_2O_3$ were used, whereas previously $Na_2CO_3$ instead of $Na_2O$ was often used along with "normal" $Fe_2O_3$.

However, here, as with the syntheses of practically all other ternary or multicomponent metal oxides, the reactants are the *binary* components. We consider this type of reaction control to be improvable, even if especially "active" forms are introduced, and have already made some progress in this direction which will now be briefly reported here:

a) The *oxidation of intermetallic phases* has not been investigated in sufficient detail. The amount of moisture in the $O_2$ used proved to be important for the course of the reaction *e.g.* for NaTl. We obtained whisker-like, efflorescent single crystals of $LiSbO_3$ from the melt of LiSb under similar conditions.

b) Ternary oxides of the noble metals are obtained only with difficulty in the form of single crystals, since thermal decomposition usually occurs before the single crystals grow. We succeeded, however, in preparing glass clear, well formed single crystals of $Na_3[AgO_2]$[174], again by using the "reaction with the surface", and by exploiting a side reaction:
An oxide with a new type of formula results from the *exchange reaction* of $NaNiO_2$[218] and $K_2O$: $K_3[Ni^{II}Ni^{III}O_4]$[219] is formed by the partial reduction of $Ni^{III}$ to $Ni^{II}$, and in addition $Na_2O$. Apparently it is this "$Na_2O$" in *statu nascendi,* which with nascent $O_2$ enables the formation of single crystals *in situ* which cannot otherwise be prepared at temperatures as low as 300 °C.

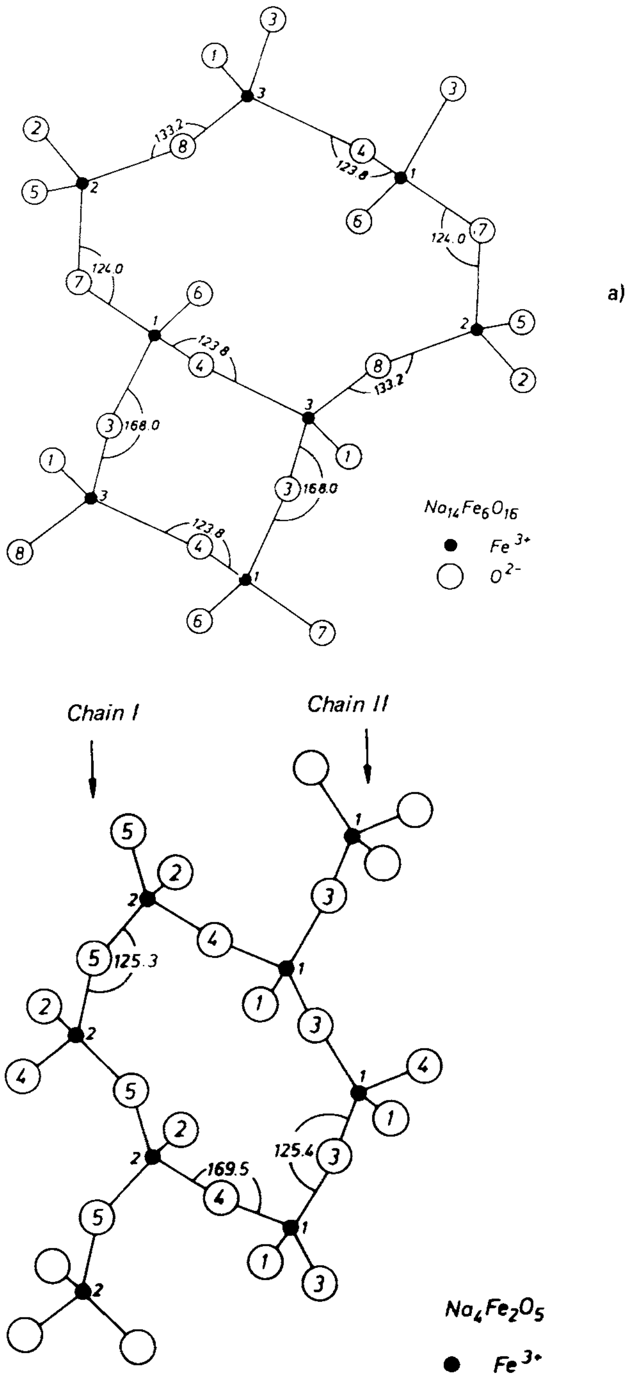

Fig. 40. a) Repeat unit of two rings in the "band structure" of $Na_{14}[Fe_6O_{16}]$.—b) Section from the $[Fe_4O_{10}]$ layer of $Na_4[Fe_2O_5]$.

c) From suitably chosen exchange reactions, *e.g.*

$$2\,LiInO_2 + Na_2O \rightarrow 2\,NaInO_2 + Li_2O$$
$$2\,KInO_2 + Na_2O \rightarrow 2\,NaInO_2 + K_2O$$

the change of $\Delta H^0_{298}$ is estimated to be only small (±2 kcal/mol). Such reactions are therefore especially sensitive to changes of $T$ because finally $\Delta G_T$ decides their fate.
Keeping this in mind, we have more closely investigated the reaction between *yellow* $K_2PbO_3$[220], an oxoplumbate which has the remarkable C.N. 5 for $Pb^{4+}$, and excess

$Li_2O$. We obtained *glass clear, colorless* single crystals of $K_2Li_{14}[Pb_3O_{14}]$[221], the first *oligooxoplumbate* with previously unobserved *triple-octahedra* groups (see Fig. 41).

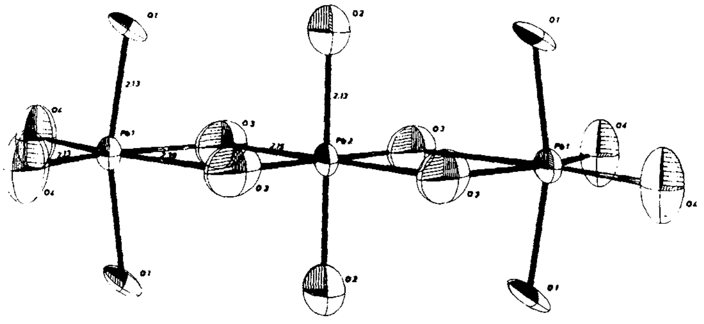

Fig. 41. The $[Pb_3O_{14}]$ triple octahedra of $K_2Li_{14}[Pb_3O_{14}]$ in perspective.

Further results of these investigations also reveal that other *lead oxides* for which similar unsuccessful searches had been made can also be grown at relatively low temperatures.

### *Part C: Synopsis*

From the plethora of new results which can hardly be surveyed by a single person, those chosen for this progress report originated from the investigations of *Wilhelm Klemm*, or were prompted by his questioning.

Our knowledge of the fluoro- and oxometalates has without doubt not only broadened, if the number of new substances and elucidated crystal structures can be called simply broadening, but also deepened, because:

- New synthetic routes have been discovered, of which the *high-pressure synthesis of novel fluorides and oxides* should be forcefully emphasized[222]. From known thermodynamic relationships it follows that even $F_2$- or $O_2$-pressures of 5 kbar do not open up a "new world of phenomena". Nevertheless, under such conditions substances whose existence was only hinted at or even overlooked in experiments performed under normal pressure, can be prepared in the form of well characterized compounds, and, if the conditions are chemically favorale, single crystals of *e.g.* "active fluorine" compounds can then be obtained.
- Exploitation of the "reaction with the surface" for the preparation of oxides (and fluorides?) which otherwise cannot be prepared or cannot be obtained as single crystals, undoubtedly constitutes a most invaluable extension to the normal preparative methods that are available.
- The "cation-rich" oxides, which (still) have no parallel in the fluorometalates, show a previously unexpected wealth of new compounds, some with "exotic" structures or component groups.
- Not only magnetic investigations and identification of "magnetic structures" by neutron diffraction, but also the interpretation of vibrational spectroscopic measurements, measurements of the electrical resistance or those made by electron spectroscopy, as have been carried out on *e.g.* suboxides of the alkali metals[233], promise to yield more detailed information about chemical bonding in the solid state.

But the new results not only help to broaden and deepen our knowledge, they also reveal even more clearly than before our inability to understand and interpret some of the profound peculiarities within the periodic table:

- What actually enables the *coinage metals* to break the normal rules of the periodic system of elements to such an extraordinary degree, and to form stable, "producible" compounds of the oxidation states +2, +3 and even +4 and +5?
- Has a yawning gap not developed after the synthesis of the noble gas fluorides, which brought a long and overdue harmoniously balanced confirmation of the periodic system? Does this gap extend up to the chemistry of the elements of the second sub-group zinc, cadmium and mercury, as many suppose and try to confirm through hitherto unsuccessful experiments?
- Are there possibly other still unknown gaps in the periodic system, which on critical and purposeful research would reveal further cracks in the trusted architecture of the system?

What is the situation in the field of solid state chemistry, where an abundance of metastable phases largely die latent in the shady gray of superficial knowledge? What revolutionary changes in our "solid" ideas would be brought about if new experimental techniques were to allow the growth of single crystals from metastable phases.

Why and to which end are the metal fluorides and oxides still being studied?

- If there are substances of simple composition, with "small" formulas and which can be regarded as being built up of ions, *i.e.* are accessible by simple calculations—they are to be found here.
- If the search for the *"vis vitalis"* fans out into a dendritic labyrinth of ever more complicated substances and reactions, and "progress" suggests we would understand the ocean of complications more and more, is it not necessary then to prove with such simple substances how difficult the interpretation of the known is, and how uncertain prophesies about the comparatively unknown remain? Is it not salutary to realize how hopeless it is, even with supposed elementary nature, to predict what could be captured by casting a line or net into the sea of the unknown?

We study them further in order to learn how difficult it is to acquire knowledge and how almost hopeless the perception of elementary nature is.

*My thanks go to my revered teacher Wilhelm Klemm who knows how to spice friendship with criticism and stimulating agreement. How little he, how little all those professors to whom I feel indebted—Otto Ruff, who answered all the schoolboy questions about the colors of metal fluorides, Walter Hückel who supplied "organic epistles" to he who had tried futilely for years to study; Werner Heisenberg, who activated Osenberg; Otto Diels, who even as a Nobel prize-winner could still become so wonderfully excited over the incomprehensible properties of oxalic acid; Hans Martin, to whom it was worth a night to discuss the fluorouranates(VI) of the alkali metals—how little they all resemble that caricature of the German professor—outlined as an object of ridicule by inadmissable generalization of some regrettable single cases, and which still dis-*

*turbs the human trust between the already experienced elder and the striving young student.*

*Without my co-workers only a fraction of the fruits of this research would have been harvested. I thank them for their more than enthusiastic assistance with the experiments.*

[124] Many "columnar structures" are actually "stacks", because the linkage forces within the stacked units is markedly stronger than between them. Here, as with $Cs_3[Al_3F_{12}]$ it is different; cf. *R. Lösch, C. Hebecker*, Z. Naturforsch. *B 34*, 131 (1979); *D. Babel, G. Knoke*, Z. Anorg. Allg. Chem. *442*, 151 (1978).

[125] Such "exchange reactions" have been investigated by us on other compounds: *R. Hoppe et al.*, unpublished.

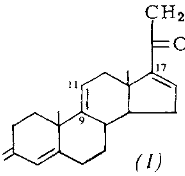
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

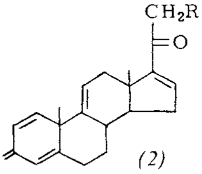
## A Novel Entry to Corticoids

By *Ulrich Kerb, Manfred Stahnke, Paul-Eberhard Schulze,* and *Rudolf Wiechert*[*]

Compounds of type *(1)* and *(2)* are key substances for the synthesis of highly active corticoids[1] such as dexamethasone, betamethasone and triamcinolone. The usual methods for their technical production are based on microbiological hydroxylation at $C_{11}$ and dehydration with cleavage of the 11- and 17$\alpha$-hydroxy groups.



*(1)*



*(2)*

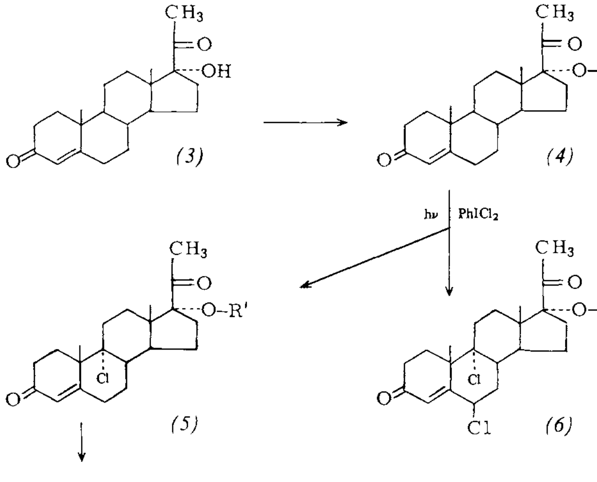
*(a)*, R = H; *(b)*, R = Acyl

A remarkable alternative to the enzymatic functionalizations at $C_{11}$—the radical relay chlorination was discovered by *Breslow et al.*[2]. They demonstrated, specifically on the example of 17-epitestosterone *m*-iodobenzoate, a regiospecific 9$\alpha$-chlorination.

We have investigated this reaction on numerous steroids and developed a technically useful method for the production of corticoid precursors. The esterification of the sterically hindered 17$\alpha$-hydroxy group on 17$\alpha$-hydroxyprogesterone *(3)* was accomplished in high yields with *m*-iodobenzoic anhydride and 4-(dimethylamino)pyridine[3].

The long-wave UV-light induced chlorination of the ester *(4)* with (dichloroiodo)benzene afforded the 9$\alpha$-chloro compound *(5)* as major product and the 6,9-dichloro compound *(6)* as by-product. By addition of the HCl-scavenger potassium acetate it was possible to completely suppress the allylchlorination to *(6)* and to isolate *(5)* in quantitative yield.

For the elimination of HCl and *m*-iodobenzoic acid a method was developed for thermolysis in high-boiling aromatic hydrocarbons. At 200—220 °C only HCl is cleaved off to give the 4,9(11)-diene; at 240—260 °C the desired triene *(1a)* is formed in very high yields. The tetraene *(2a)* was prepared in an analogous sequence.



*(1a)*

R' = $m$-$IC_6H_4$–CO

### Procedure

*(4):* A mixture of *(3)* (33.05 g, 100 mmol), 4-(dimethylamino)pyridine (48.87 g, 400 mmol) and *m*-iodobenzoic anhydride (95.6 g, 200 mmol) in toluene (300 cm$^3$) is stirred in a closed flask for 18 h at 50 °C (bath temperature). For workup the mixture is diluted with 800 cm$^3$ $CH_2Cl_2$ and successively washed with water, 1 N HCl, 5% $NaHCO_3$ solution, and once again with water. After drying over sodium sulfate and evaporating down in a vacuum, 57.4 g of crude product is obtained. Recrystallization from acetone affords 53.46 g (95%) pure *(4)*, m.p. 187—193 °C.

*(5):* A mixture of *(4)* (33.62 g, 60 mmol) and potassium acetate (60 g, previously dried over $P_2O_5$) in distilled $CH_2Cl_2$ (3.6 dm$^3$) is stirred under argon in a 4-liter Quickfit flask and after treatment with (dichloroiodo)benzene (19.8 g) is irradiated for 5 mins with a water-cooled Hanau TQ 150 immersion lamp. For workup the mixture is washed successively with 5% $NaHSO_3$ solution, 5% $NaHCO_3$ solution, and water and then evaporated down in a vacuum. The crude product is rubbed with pentane and filtered; yield 35.7 g *(5)*, m.p. 208—210 °C (dec.).

*(1a):* *(5)* (35.7 g) is added to preheated Dowtherm A (300 cm$^3$)[4] (oil-bath temperature 280 °C) and the mixture stirred for 25 min under argon at 250 °C internal temperature. After cooling in a stream of argon the mixture is diluted with $CH_2Cl_2$, washed with 5% $Na_2CO_3$ solution and water, evaporated down, and steam distilled. The residue after distillation is dried in a vacuum and recrystallized from methanol. 15.82 g of 4,9(11),16-pregnatriene-3,20-dione *(1a)* [m.p. 199.5—201 °C (199—201 °C[5]); $\lambda_{max} = 239$ nm ($\varepsilon = 25200$)] is obtained. Yield of the photochlorination and thermolysis 85%.

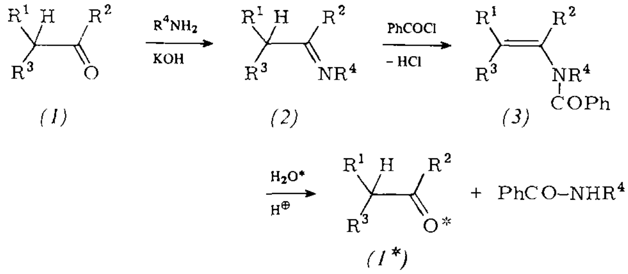
## Preparation of Labeled Aldehydes and Ketones from Enamides[**]

By *Bernard T. Golding* and *Ah Kee Wong*[*]

Full exploitation of $^{17}$O-NMR spectroscopy[1] in mechanistic organic chemistry requires efficient, simple methods for the synthesis of $^{17}$O-labeled compounds. The classical method for labeling aldehydes and ketones with $^{17}$O or $^{18}$O is based on their reversible hydration[2]. However, to obtain by this method aldehydes or ketones with the atom percentage of labeled oxygen approaching that of the water used, either a large excess of labeled water or repeated exchange is required. Several methods have been described in which an aldehyde or ketone is converted into a derivative which can be hydrolyzed with a stoichiometric amount of water. Suitable derivatives are acetals[3], dithioketals[4], and aminals[5].



| | R¹ | R² | R³ | R⁴ | Educt *(1)* |
|---|---|---|---|---|---|
| *a* | Pr | H | H | Et | pentanal |
| *b* | H | H | H | Et | acetaldehyde |
| *c* | —(CH$_2$)$_3$— | | H | Et | cyclopentanone |
| *d* | —(CH$_2$)$_4$— | | H | PhCH$_2$ | cyclohexanone |
| *e* [a] | Et | Me | H | PhCH$_2$ | 2-pentanone |
| | H | Pr | H | PhCH$_2$ | |

[a] *(3e)* is a mixture of *(3e')* top row and *(3e'')* (bottom row).

We have found a convenient, efficient method for preparing oxygen-labeled aldehydes and ketones based on the hydrolysis of enamides *(3)*. *N*-alkylideneethylamines (obtained by treating an aldehyde or ketone with EtNH$_2$/KOH)[6] or *N*-alkylidenebenzylamines *(2d), (2e)* (from ketone + benzylamine/3A sieves in CH$_2$Cl$_2$)[7] are allowed to react with benzoyl chloride/triethylamine[8] in ether *[(2a)—(2c)]* or haloalkanes[9] to give enamides *(3a)—(3e)*. These derivatives are quantitatively hydrolyzed to their parent aldehydes or ketones *(1)* and *N*-ethyl(or *N*-benzyl)benzamide by one equivalent of water in ether or haloalkane containing 0.05 mol-% HCl. The use of [$^{17}$O]- or [$^{18}$O]water in this procedure with *(1a)* and *(1c)* gives unlabeled *N*-ethylbenzamide (analysis by mass spectrometry) and labeled pentanal *(1a*)* or cyclopentanone *(1c*)*. The extent of labeling of the aldehyde or ketone was shown to be equivalent to that of the water used (IR spectroscopy as well as reduction with LiAlH$_4$ and derivatization with $\alpha$-C$_{10}$H$_7$NCO to an $\alpha$-naphthylurea that was examined by mass spectrometry).

The advantages of this method for synthesizing labeled aldehydes and ketones are that the precursor enamides *(3)* are easy to prepare[9] and can be stored (under N$_2$, $-20\,^{\circ}$C) until hydrolysis is effected; the by-product of hydrolysis, *N*-ethyl(or *N*-benzyl)benzamide, is easy to separate and does not catalyze further reactions of the aldehyde or ketone[10]; pure aldehyde or ketone is readily obtained in acceptable yield; if desired, oxygen-labeled alcohols (*e.g.* [$^{18}$O]-1-pentanol) can be obtained by addition of LiAlH$_4$ to the solution of *(1*)* in ether, after filtration of *N*-ethylbenzamide.

Benzaldehyde reacts with EtNH$_2$/KOH to give *N*-benzylidene-ethylamine, which with benzoyl chloride gives the adduct PhCHCl—N(Et)—COPH. This adduct was directly hydrolyzed with 1 equivalent [$^{18}$O]water (23 atom-% $^{18}$O) to benzaldehyde and *N*-ethylbenzamide. Extraction of benzaldehyde with ether and final purification by Kugelrohr distillation gave 23 atom-% [$^{18}$O]benzaldehyde (86%).

### *Procedure*

To *(3a)* in dry ether (2 cm$^3$/10$^{-3}$ mol) was added 1 mol equiv. 31 atom-% [$^{17}$O]water (BOC Ltd. Prochem) and 0.05 mol equiv. HCl (soln. in ether). The hydrolysis was followed by TLC and after 2 h/room temperature, diisopropylaminomethyl polystyrene (2 g/mmol HCl) was added. Filtration and partial evaporation caused crystallization of *N*-ethylbenzamide which was filtered off. The filtrate was concentrated and processed by preparative GLC (20% DEGS/chromosorb WHP, 130 °C) to give [$^{17}$O]pentanal *(1a*)* (52%); IR: $\nu = 1697$ (C=$^{18}$O), 1711 (C=O$^{17}$) and 1720 cm$^{-1}$ (rel. int. *ca.* 5:3:2); 54.24-MHz $^{17}$O-NMR (CDCl$_3$): $\delta = 582.9$ (relative to external 1:1 H$_2$O-D$_2$O).

[9] Formation of enamides *(3a)—(3c)* takes place rapidly on addition of benzoyl chloride in ether to a mixture of *(2a)—(2c)* + triethylamine in ice-cold ether. After filtration of triethylammonium chloride, the filtrate is concentrated and distilled to give *(3a)—(3c)* as colorless/pale yellow oils, which were characterized by their $^{1}$H-NMR spectra, mass spectra and by combustion analyses. The formation of *(3d)* and *(3e)* from *(2d)* and *(2e)* was followed in an NMR tube (solvent CDCl$_3$ or CCl$_4$).

[10] We have investigated the hydrolysis of *(2)* with 1 equivalent each of water and HCl as a route to labeled aldehydes and ketones. For aldehydes (*e.g.* pentanal) this method is unsatisfactory because of competing aldol condensation. However, the *N*-ethyliminium hydrochloride of camphor is a satisfactory precursor of oxygen-labeled camphors.—The *N*-ethylimine of camphor does not react with benzoyl chloride/$Et_3N$ in $CHCl_3$ at room temperature over several days.

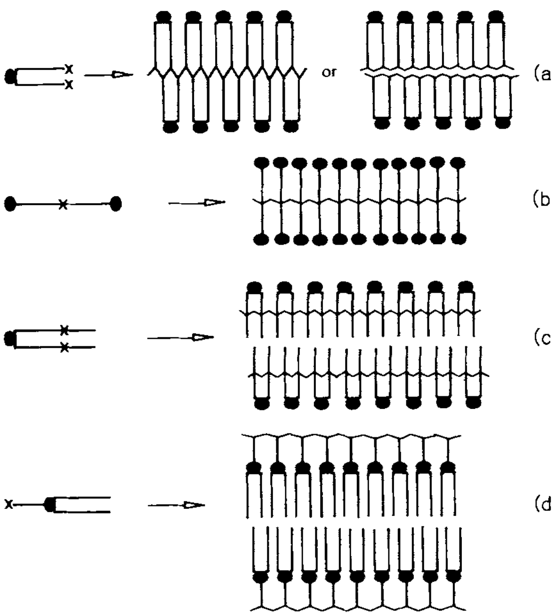
## Polymer Model Membranes[**]

By *Akira Akimoto, Klaus Dorn, Leo Gros,*
*Helmut Ringsdorf,* and *Hans Schupp*[*]

The synthesis of stable model membranes which can be used to study biological processes, for instance cell recognition or cell-cell-interaction, has been a scientific goal for a long time[1]. Especially liposomes—artificial, spherical particles with a bimolecular membrane and an aqueous interior—serve as models for biological membranes; however, they show a significantly decreased stability[2].

To stabilize synthetic double layers *Khorana et al.*[3] synthesized lipids carrying photoreactive groups and could prove a crosslinking of membrane components. Another method to stabilize model membranes providing an even broader scope of possible applications is the polymerization of lipid-analogous systems[4a] (Scheme 1).



Scheme 1. Possible preparation of polymer model membranes (x = polymerizable group). (a—c): polymerization preserving head-group properties; d: polymerization preserving chain mobility (Monomer examples, see Table 1).

All four possibilities in Scheme 1, however, alter the physical properties of the membrane: polymerization in the hydrophobic part of the monomers (examples a—c) especially influences the phase transition temperature, while polymerization in the hydrophilic moiety changes the headgroup properties. Nevertheless, in our opinion, the properties of biological membrane systems can be thoroughly achieved by making the right choice of polymerizable groups. Furthermore, by adding natural phospholipids the properties of biological membranes can be imitated to an even greater extent.

The different possibilities shown in Scheme 1 have all been realized. So far only a few contributions have appeared in the literature: acrylate and diacetylene systems have already been described by us[4b] and by *Regen et al.*[5a], *Chapman et al.*[5b], and *O'Brien*[5c]. Due to the conjugated double bonds of the polymer chain resulting in a rather rigid conformation in poly(diacetylene) compounds no phase transition temperature can be observed, in contrast to biological membranes[4b,5b]. New monomer systems for the polymerization according to Scheme 1 are collected in Table 1.

Table 1. Polymerizable and liposome forming lipid analogues Type (a)—(d), cf. Scheme 1. $R = CH_2{=}C(CH_3){-}CO$.

| | $n = 17,\ Y = R$ | *(11)* | 36-38 |
| | $n = 11,\ Y = (CH_2)_3{-}NH{-}R$ | *(12)* | – |
| | $n = 17,\ Y = (CH_2)_3{-}NH{-}R$ | *(13)* | 35-36 |
| | $H_3C{-}(CH_2)_{17}{-}O{-}CO$<br>$CH_2$<br>$^{*}CH{-}NH{-}Y$<br>$H_3C{-}(CH_2)_{17}{-}O{-}CO$ | | |
| | $Y = R$ | *(14)* | 64-68 |
| | $Y = CO{-}(CH_2)_5{-}NH{-}R$ | *(15)* | 78 |

The spreading and polymerization behavior of the monomers were investigated at the gas-water interface. The pressure-area diagrams of compounds *(3)* and *(4)* qualitatively resemble those of the corresponding diacetylene derivatives[6a]. However, they already show a liquid-analogous phase at substantially lower temperatures. The pressure-area diagram of *(5)* shows a solid-analogous phase at 2 °C, and a liquid-analogous film with transition to a solid phase at 25 °C (Fig. 1a).

In contrast to the diacetylenes, which react only topochemically[6b], the butadiene and acrylic derivatives can be polymerized by UV light at any temperature in the solid-analogous as well as in the liquid-analogous phase. The polymerization can be followed by measuring the contraction of the film. The pressure-area diagrams of the polymers show a steeper slope corresponding to the closer packing of the monomer units. This is shown for the butadiene derivative *(5)* (Fig. 1a) and the acrylic system *(13)* (Fig. 1b).

[**] Polyreactions in Oriented Systems, Part 23.—Part 22: *H. Koch, H. Ringsdorf,* Makromolek. Chem. Commun., in press.

These high packing densities together with the increased stability of the monolayers provide a basis for the use of these polymer systems as model membranes.

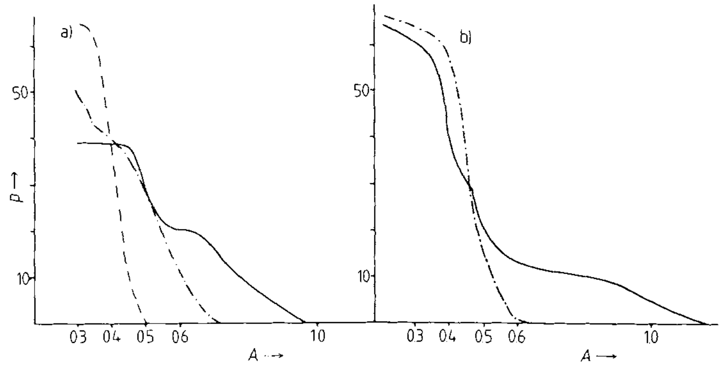

Fig. 1. a) Surface-pressure-area diagram of *(5)* at 2 °C (-----) and 25 °C (——) and of polymeric *(5)* at 25 °C (–·–·–). b) Surface-pressure-area diagram of *(13)* (——) and of polymeric *(13)* (–·–·–), each at 25 °C. $p$ = surface pressure (mN/m); $A$ = area (nm$^2$/molecule).

Liposomes, *i.e.* cell models with bimolecular membranes, were prepared by sonicating aqueous dispersions[2c] of the monomers at *ca.* 40 °C. On filtration through a 8-μm Millipore-filter, clear or slightly opaque solutions are obtained, which turn turbid after some days.

The polymerization of these monomer vesicles is carried out by UV-irradiation of the aqueous solutions. The polyreaction of the butadiene derivatives *(3)—(6)* in liposomes can be followed by the decreasing monomer absorption at 265 nm. The polymerization of the acryl derivatives *(7)—(9)* was proved by freeze-drying the aqueous solutions followed by gel-filtration. In contrast to the monomers the polymer vesicle solutions are stable for weeks.

It could be shown by electron microscopy that the vesicle structure is preserved during the polymerization. This is consistent with results obtained on polymerizing diacetylene vesicles[4b].

Compounds *(14)* and *(15)* were synthesized in order to study the influence of chiral membrane components on model reactions. In addition, mixed systems of polymerizable lipid analogues, natural phospholipids, and proteins are under current investigation. For investigations on cell recognition, monolayers and polymer liposomes consisting of glycolipids have been prepared (cf. [6c]).

### *Procedure*

*(1):* 11-(*N*-Methacryloylamino)undecanoic acid[7] is esterified with *N*-methyliminodiethanol in the presence of dicyclohexylcarbodiimide (DCC) and 4-(dimethylamino)pyridine and quaternized using methyl bromide[8].

*(3):* 2,4-Octadecadienoic acid[9] is esterified with *N*-methyliminodiethanol adding DCC/4-(dimethylamino)pyridine [8].

*(4):* Monomer *(3)* is allowed to react with methyl bromide in acetone.

*(5)* and *(6)* are synthesized *via* conventional lipid chemistry methods[10].

*(7)—(11), (14), (15):* The corresponding 1,2-diglycerine ester [*(7)*][11], 1,2-diglycerine ethers [*(8), (9)*][12], dialkylamines [*(10), (11)*] (Fluka, Eastman) or L-aspartic acid dioctadecyl esters [*(14), (15)*][13] are allowed to react with methacryloyl chloride or 6-(*N*-methacryloylamino)hexanoic acid [*(15)*] and DCC.

*(12), (13):* The corresponding dialkylamines are added to acrylonitrile, reduced with $LiAlH_4$[14], and then allowed to react with methacryloyl chloride.

## Liposomes from Polymerizable Glycolipids[**]

By *Hubert Bader, Helmut Ringsdorf,* and *Josef Skura*[*]

Polymerizable analogues of cell membrane components, *e.g.* phospholipids and lysophospholipids bearing acryl-, butadiene-, and diyne groups[1] in the hydrophobic parts of the molecules have already been synthesized and investigated in monolayers and liposomes[2].

In this connexion glycolipids are of particular interest, since they exhibit vital functions and properties in the natural cell membrane such as cell recognition, antigenicity, histocompatibility, and lectin affinity. Especially their properties as lectin receptors make glycolipids useful tools for studying specific interactions between lectins (sugar recognizing proteins) and saccharide bearing liposomes[3]. We report here on the first glycolipids with the diyne group [*(1)* and *(2)*], their behavior in monomolecular films, their poly-

[**] Polyreactions in Oriented Systems, Part 24.—Part 23: [1].

merization in monolayers and liposomes, as well as their interactions with the lectin Concanavalin A (Con A).

The glycolipids *(1)* and *(2)* (see Procedure) were spread as monomolecular layers at the gas-water interphase on a Langmuir film balance. Figure 1 shows the corresponding surface-pressure-area isotherms.

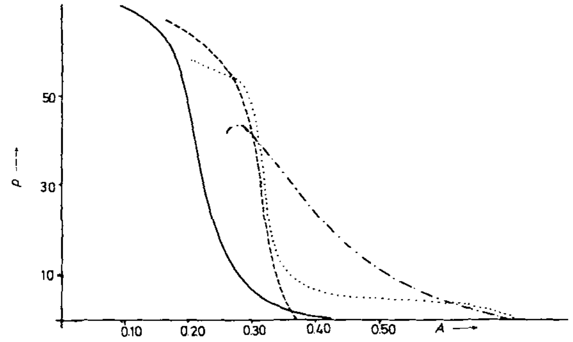

Fig. 1. Surface pressure-area isotherms of *(1)* at 20 °C (-·-·-) and 1 °C (·····), of *(2)* at 20 °C (——), and of polymer *(1)* at 1 °C (-----). $p$ = surface pressure (in mN/m), $A$ = area (in $nm^2$/molecule).

While *(1)* is only in a liquid expanded phase at 20 °C with a collapse point of 0.29 $nm^2$/molecule and 43 mN/m, at 1 °C it shows a liquid expanded phase up to about 0.45 $nm^2$/molecule and 8 mN/m followed by the solid-analogous phase with a collapse point of 0.31 $nm^2$/molecule and 51 mN/m. The high area value at the collapse point evidences the large area occupied by the glucopyranose ring bound directly to the diyne alcohol.

The glycolipid *(2)* has a solid phase in the whole temperature range investigated from 20 °C to 40 °C (collapse point 0.18 $nm^2$/molecule and 63 mN/m). The head-group of *(2)* occupies a smaller area than that of *(1)*; the reason for this is the hydrophilic spacer between galactopyranose and diynoic acid which permits a deeper penetration of the sugar moiety into the subphase.

When a monomolecular film of *(1)* is UV irradiated at 1 °C and a surface pressure higher than 10 mN/m, the typical polymerization of the diyne group takes place. The colorless monomer film turns blue and then red[4]. As expected the polymerized film does not exhibit a liquid expanded phase any more. The occupied area at the collapse point is only insignificantly smaller than in the monomer film.

The monomolecular film of *(2)* also yields a blue polymer film when irradiated at 20 °C and 35 mN/m, but does not show the color change to red caused by change of the polymer conformation even after 30 min of irradiation. As in the case of *(1)*, the contraction of the film during the polymerization is very small. When an aqueous suspension of *(1)* is sonicated for 15 min at 50 °C, a clear colorless solution is obtained, which is polymerized in a quartz cuvette at 0 °C by UV irradiation. As in monolayers, during the polyreaction the color change *via* blue to red takes place, as had already been observed in the case of different liposome forming diacetylene compounds[1]. In contrast, no liposomes are formed by *(2)* when sonicated for longer periods (up to 30 min) and at higher temperatures (up to 80 °C). Only a crystalline suspension is formed. Its filtrate turns faintly blue on irradiation. The strong tendency of the hydrazide linkages to form hydrogen bonds make glycolipid (2) excessively rigid and poorly dispersible in water, which is also confirmed by the missing liquid expanded phase in the monolayer.

The interaction of *(1)* with the lectin Con A was investigated in monolayers and with monomer and polymer liposomes. When a con A solution in phosphate buffer (pH 7.4) is injected under a monomolecular film of *(1)* on the same buffer at a constant surface pressure of 10 mN/m, a considerable expansion of the film can be observed due to strong interaction of the lectin with the monolayer.

Solutions of monomer and polymer liposomes of glycolipid *(1)* react with Con A solution by agglutination and precipitation within a short period of time. This effect could not be observed with different polymer liposomes not bearing saccharide moieties.

### *Procedure*

The glucose derivative *(1)* was obtained as a colorless solid (m.p. 73—75 °C)[6] when acetobromoglucose and 10,12-hexacosadiyne-1-ol in dry ether were allowed to react in the presence of silver 4-hydroxyvaleriate (Koenigs-Knorr reaction[5]), followed by the cleavage of the protective groups with sodium methoxide.

The lactobionic acid derivative *(2)* could be synthesized from lactobiono-1,5-lactone[7] *via* its hydrazide, followed by coupling with 10,12-hexacosadiynoic acid *via* its mixed anhydride with ethyl chloroformate (m.p. 114 °C)[6].

## Palladium-Catalyzed Reduction of Multiple Bonds with Mg/$CH_3OH$[**]

By *George A. Olah, G. K. Surya Prakash, Massoud Arvanaghi*, and *Mark R. Bruce*[*]

It has long been known that magnesium in methanol (or in ethyl or isopropyl alcohol) can been used for the reduction of carbon-heteroatom double bonds[1] and *N*-oxides[2]; more recently, the selective reduction of $\alpha$,$\beta$-unsaturated nitriles[3a] and aryl-substituted ethylenes has also been achieved in this way[3b]. In all these reactions, however, isolated, nonactivated double or triple bonds were found unaffected by the reducing system. We now wish to report that addition of catalytic palladium metal on carbon to the Mg/$CH_3OH$ reagent dramatically enhances its reactivity, thus allowing rapid

[a] All products were characterized by elemental analysis, and $^1H$-NMR and IR spectra. [b] Yield of isolated product. [c] Mixture of *exo* and *endo* derivatives. [d] Reduction with $CH_3O[^2H]$.

The present reducing system has distinct advantages over the conventional catalytic hydrogenation procedures[4]: cyclopropyl groups are not reduced by the system and also benzylic ethers and alcohols remain unaffected under the reaction conditions. On the other hand, the deuteration of multiple bonds is readily achieved in good yields with the use of $CH_3O[^2H]$. The system $Mg/CH_3OH/Pd—C$ thus serves as a useful convenient alternative procedure for catalytic hydrogenation or deuteration.

*Procedure:*

To the well stirred mixture of the corresponding unsaturated compound (10 mmol) and 50 mg of 10% Pd/C in methanol (30 cm$^3$) in a 250 ml round bottom flask at room temperature is added magnesium turnings (five equivalents of Mg per double bond). After a sluggish induction period the reaction starts with brisk evolution of hydrogen gas. After all the magnesium metal has dissolved, the mixture is poured with vigorous stirring into 30 cm$^3$ of an ice-cold 3 N HCl solution and extracted with ether (3 × 100 cm$^3$). The ethereal layer is washed twice with saturated brine solution (2 × 100 cm$^3$) and dried over $MgSO_4$. The solvent is removed by evaporation and the residue purified by distillation or recrystallization.—The reduction with $CH_3O[^2H]$ is carried out under a dry argon atmosphere.

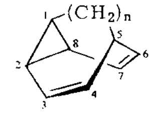
## 2,6-Barbaralane Dicarbonitrile: A Probe for Dewar-Hoffmann-Type Homoaromatic Molecules[**]

By *Helmut Quast, Yvonne Görlach,* and *Josef Stawitz*[*]

The originally postulated existence of neutral homoaromatic molecules through cyclic homoconjugative interaction of $(4n+2)$ $\pi$-electrons, which are located in *even* $\pi$-electron parts of the molecule, meets apparently unsurmountable energy barriers[1]. By extrapolating structural effects on the energy barrier of the degenerate Cope-rearrangement, *Dewar* and *Hoffmann* postulated a novel type of homoaromatic molecules, which is characterized by cyclic homoconjugative interaction of *uneven* $\pi$-electron parts of the molecule[2]. Indeed, by structural modifications, the energy barrier of the degenerate Cope-rearrangement may be drastically lowered, which leads to fluxional molecules, *e.g.* semibullvalene *(1a)* [$\Delta G^{\ddagger}_{133} = 23$ kJ/mol] and barbaralane *(1b)* [$\Delta G^{\ddagger}_{196} = 33$ kJ/mol][3]. Reducing the energy barrier further might result in stable molecules with a homoaromatic ground state. This has been predicted to be effected by azasubstitution at positions 2 and 6 or, alternatively, 3 and 7 of semibullvalene *(1a)* or by donor substituents at C-1 and C-5 and acceptor substituents at C-2, C-4, C-6, and C-8[2]. So far, no such compound is known. We now report a simple synthesis of 2,6-barbaralane dicarbonitrile *(6)*, which should allow an experimental investigation of the above predictions.



*(1a)*, n = 0
*(1b)*, n = 1

The readily available bicyclononanedione *(2)*[4] was converted quantitatively with trimethylsilyl cyanide and zinc iodide in dichloromethane[5] into the *O,O'*-bis(trimethylsilyl)biscyanohydrin (m.p. 97—99 °C), which apparently exists as one stereoisomer ($^1H$-NMR spectrum). By refluxing for 1.5 h in methanol and concentrated hydrochloric acid (1 : 1), the trimethylsilyl derivative was hydrolyzed to the biscyanohydrin. Without purification, this intermediate was allowed to react with 12 moles of trichlorophosphane oxide (per mol of biscyanohydrin) in boiling pyridine (2 h) and thereby converted in 53% yield [based on *(2)*] into the unsaturated dicarbonitrile *(3)*, which was sublimed at 110–125 °C/4 × $10^{-6}$ torr.

The bromination of *(3)* with *N*-bromosuccinimide in tetrachloromethane proceeds smoothly and completely diastereoselectively. However, even in other solvents, the bromination cannot be stopped at the stage of the bromodicarbonitrile *(4)*. Instead, with one mol of *N*-bromosuccinimide in boiling tetrachloromethane after 2 h, one obtains a mixture of 0.51 mol *(4)* and 0.22 mol dibromodicarbonitrile *(5)*, which can be easily separated by preparative layer chromato-

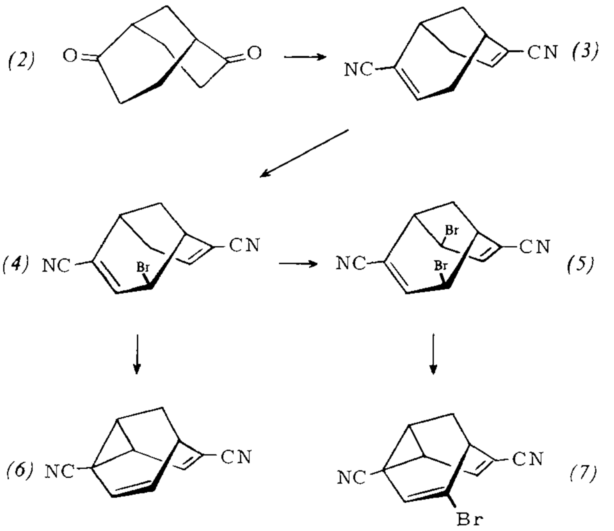
graphy (silica, ether/tetrachloromethane 1:1). According to the NMR spectra (Table 1), *(4)* and *(5)* form only one stereoisomer. Because of the C$_2$ symmetry of *(5)* its bromine atoms are homotopic.

The ring closure of the bicyclo[3.3.1]nonane to the barbaralane system has already been accomplished in different ways[6]. In the case of *(4)* and *(5)*, it is achieved extremely rapidly with alkoxides in alcohols. Thus, with sodium [D$_3$]methoxide in [D$_4$]methanol, immediate quantitative ring-closure occurs to give the (bromo-)barbaralane dicarbonitrile instead of H/D exchange. In preparative runs using 1.15 moles of sodium methoxide in methanol/benzene per mol of *(4)* and *(5)*, 77% *(6)* and 95% *(7)*, respectively, are obtained as crystalline products.



The assigned structures *(3)*—*(7)* are based on elemental analyses and IR, NMR, and mass spectra. X-ray structure determinations have been performed on *(3)*, *(4)*, *(5)*, and *(7)* which provide unequivocal proof of structure[7]. In particular, they establish the *exo* position of the bromine atoms of the bromodicarbonitriles *(4)* and *(5)* inferred already on the basis of steric arguments. The IR spectra of the bicyclononadiene dicarbonitriles *(3)*, *(4)*, and *(5)* show only one C$\equiv$N frequency arising from $\alpha,\beta$-unsaturated nitrile groups. In contrast, the IR spectra of the barbaralane dicarbonitriles *(6)* and *(7)* display two nitrile bands. An analogous situation is found for the C=C frequencies.

While the $^{13}$C-NMR spectra can be easily interpreted, long-range couplings complicate the 90-MHz $^1$H-NMR spectra in most cases (Table 1). The reported coupling constants were assigned with the aid of decoupling experiments under the simplifying assumption of first order spectra. The $^1$H-NMR data are in harmony with those of the parent hydrocarbons, *viz.* bicyclo[3.3.1]nona-2,6-diene[8] and barbaralane *(1b)*[9], respectively. Like barbaralane *(1b)*, *(6)* exhibits averaged NMR spectra at ambient temperature. In the 50-MHz $^{13}$C-NMR spectrum of *(6)* in [D$_2$]dichloromethane, the signal of C-2/C-6 as well as that of C-4/C-8 begins to broaden only at −60 °C[10]. That is, at −60 °C the degenerate Cope rearrangement of *(6)* still occurs rapidly on the $^{13}$C-NMR time scala; on the IR time scala, however, it is slow at +30 °C.

The $^1$H-NMR spectrum of the bromobarbaralane dicarbonitrile shows the signals of *two* vinyl protons and *two* cyclopropane protons. As anticipated, the compound prefers the structure *(7)* and hence may serve as a model for a static (non-fluxional) system.—Our approach offers a possible synthetic route to the hypothetical homoaromatic semibullvalenes of *Dewar* and *Hoffmann*[2].

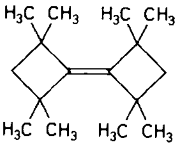
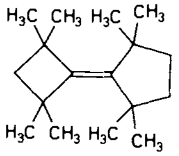
## Radical Cations of Sterically Hindered Bicycloalkylidenes: An Experimental Contribution Concerning the Planarity of the Ethylene Radical Cation[**]

By *Fabian Gerson, Javier Lopez, Adolf Krebs,*
and *Wolfgang Rüger*[*]

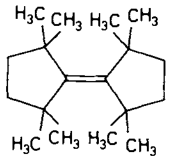
Experimentally derived information on the geometry of the ethylene radical cation is scarce[1]. Most semiempirical[2] and *ab initio* MO calculations[3] predict a planar arrangement of the atoms in this one-π-electron system, but the potential curve for the twisting of the $CH_2$-groups is expected to be extremely flat. Deviations from planarity should thus easily be brought about by bulky substituents. Investigations on the radical cations of 2,2,2′,2′,4,4,4′,4′-octamethylbicyclobutylidene *(1)*[4], 1,1,3,3-tetramethyl-2-(2,2,4,4-tetramethylcyclobutylidene)cyclopentane *(2)*[4] and 2,2,2′,2′,5,5,5′,5′-octamethylbicyclopentylidene *(3)*[5] ought to verify this statement.



*(1)*



*(2)*



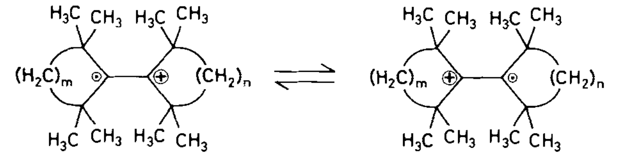
*(3)*

As shown by cyclic voltammetry[6], the first oxidation wave of the three compounds is reversible; in each case, one electron is released and taken up again. The relevant potential is substantially lower for *(3)* (+1.37 V *vs.* SCE) than for *(1)* (+1.81 V) and *(2)* (+1.65 V). Moreover, the dependence of the cyclic voltammograms on the scanning speed would point to the radical cation *(3)*$^{\cdot+}$ having a longer lifetime than *(1)*$^{\cdot+}$ and *(2)*$^{\cdot+}$.

The ease of formation of *(3)*$^{\cdot+}$ under a variety of conditions (reaction with $AlCl_3$ in $CH_2Cl_2$; electrolysis in $CH_2Cl_2$, $CH_2Cl_2/CF_3COOH/(CF_3CO)_2O$ or $CH_3CN$) and its remarkable stability (persistence) are consistent with these findings. Thus, the concentration of *(3)*$^{\cdot+}$ remains almost unchanged for weeks, when a solution of the radical cation is allowed to stand at room temperature with exclusion of air. Even upon the addition of water, the concentration decreases only gradually. In the temperature range 183—313 K, the ESR spectrum of *(3)*$^{\cdot+}$ exhibits the coupling constants $a(12\,H) = 0.203$ and $a(4\,H) = 0.028$ mT for the methyl and methylene protons, respectively, of *only one* cyclopentylidene moiety ($g = 2.0026$)[7].

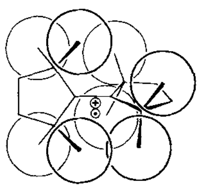
The radical cations *(1)*$^{\cdot+}$ and *(2)*$^{\cdot+}$ are less easily generated than *(3)*$^{\cdot+}$ and their persistence is substantially lower. Electrolytic oxidation of *(1)* and *(2)* in $CH_2Cl_2/CF_3COOH/(CF_3CO)_2O$ (volume ratio 10:1:1)[8] proved to be the best method of preparation of the corresponding radical cations. In the range 193—293 K, *(1)*$^{\cdot+}$ shows a hyperfine interaction with the methyl and methylene protons of *both* cyclobutylidene moieties: $a(24\,H) = 0.123$ and $a(4\,H) = 0.049$ mT, respectively ($g = 2.0027$). The ESR spectrum of *(2)*$^{\cdot+}$ recorded in the same solvent mixture ($g = 2.0026_5$) is strongly temperature dependent with strikingly varying line-widths of the individual hyperfine components. Computer simulations are consistent with the assumption that this behavior is due to electron exchange between the cyclobutylidene and cyclopentylidene moieties of *(2)*$^{\cdot+}$. An exact analysis is difficult, however, in the investigated temperature interval, whose lower (193 K) and upper (263 K) limits are determined by the freezing point of the solvent mixture and by the persistence of the radical cation, respectively. This is because neither the range of the "slow" nor that of the "fast" exchange is attained. The analysis is made all the more difficult by the fact that, in contrast to *(1)*$^{\cdot+}$ and *(3)*$^{\cdot+}$, the two cycloalkylidene moieties in *(2)*$^{\cdot+}$ are not equivalent.

From the ESR spectra of the three radical cations, it is possible to estimate the frequency of the electron exchange.



Whereas for *(2)*$^{\cdot+}$ ($m = 1$; $n = 2$) this frequency is evidently of the same order of magnitude as the hyperfine time-scale ($10^7$—$10^8$ $s^{-1}$), it must be substantially lower ($< 10^6$ $s^{-1}$) for *(3)*$^{\cdot+}$ ($m = n = 2$), and considerably higher ($> 10^9$ $s^{-1}$) for *(1)*$^{\cdot+}$ ($m = n = 1$).

The frequency of the electron exchange depends on the overlap between the $2p_z$ AO's at the two $sp^2$-hybridized carbon atoms and therefore on the extent of the coplanarity of the π-system. Hence, the experimental result implies that the energy required to approach coplanarity increases in the order *(1)*$^{\cdot+}$ < *(2)*$^{\cdot+}$ < *(3)*$^{\cdot+}$. This conclusion bears out the expectation that the planar arrangement is more difficult the larger the size of the cycloalkylidene moieties, because of the enhanced steric hindrance by the alkyl substituents. The same sequence should also hold for the trend of the moieties to twist about the central C—C bond. The high persistence of *(3)*$^{\cdot+}$ could then be rationalized by a nearly perpendicular arrangement of the five-membered rings, which offers an optimal protection of the radical and cationic centers by the methyl groups.



Finally, it should be mentioned that the structural parameters of the neutral molecules *(1)*, *(2)*, and *(3)* have not yet been determined. At present, merely results of calculations by the force-field method are available[9], according to which there should be no appreciable twist about the double bond, even in *(3)*. Presumably, the twist comes about only when the neutral two-π-electron system changes into the one-π-electron system of the radical cation.

## NMR Spectroscopic Investigation of Intercalation Compounds of Organic Molecules and Sheet Silicates—*p*-Xylene-Hectorite and Related Systems[*]

By *Colin A. Fyfe, John M. Thomas*, and
*James R. Lyerla*[*]

Many categories of sheet silicates are known to be capable of taking up, within their interlamellar spaces, a wide range of organic compounds[1,2a]. The majority of these "organic" intercalates break down upon heat-treatment simply to yield the separate parent materials, but it has of late become increasingly apparent that several, highly selective chemical conversions[1a,2-4] can be carried out through the agency of such intercalates. In elucidating the nature of the microenvironment to which the organic molecule is exposed in the interlamellar region little use has so far been made of NMR spectroscopy, even though this technique has already proved illuminating in probing the properties of clay:water systems[5], and also in clarifying the nature of adsorbed organic molecules at exterior surfaces (of ZnO for example[6a]), of organic clathrates[6b] and of small organic molecules, such as methanol, in zeolites and silica gel[5a].

We here report how, using a commercially available pulsed FT-NMR spectrometer, it is possible to assess (i) the degree of molecular freedom, (ii) the composition of mixtures and (iii) the keto-enol equilibrium of certain organic species retained in the interlamellar spaces of a synthetic hectorite—idealized formula $Na_{0.67}Si_8(Mg_{5.33}Li_{0.67})O_{20}(OH)_4$.

Experimental methods for preparing a range of room-temperature stable intercalates of hectorites (and of montmorillonites) are given elsewhere[7]. X-Ray diffractometry and TGA readily reveal the degree of uptake and extent of *c*-axis expansion that accompanies the formation of these intercalates. High-resolution $^1H$- and $^{13}C$-NMR spectra were obtained using a conventional Varian CFT-20 spectrometer at 80 MHz and 20 MHz, respectively. Both proton and carbon spectra were obtained using a spinning sample. The proton spectral widths were such that no extra proton decoupling power in addition to the 3 kHz available from the basic spectrometer was necessary to obtain $^{13}C$ spectra at ambient temperature.

Typical spectra of powdered specimens of the organic intercalates at 30 °C are shown in Figures 1 and 2. Although the proton peaks are rather broad they are much narrower than would be obtained from solid *p*-xylene or solid γ-butyrolactone, indicating that these organic molecules have considerable freedom of motion in the interlamellar region. The

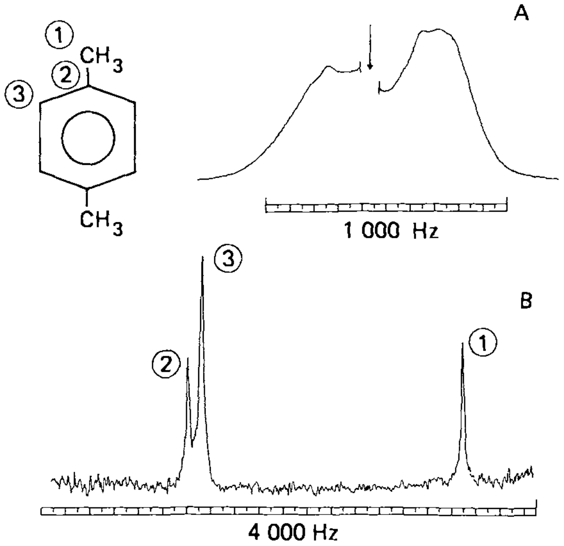

Fig. 1. A) $^1H$-NMR spectrum of the *p*-xylene-hectorite intercalate at 80 MHz (50 pulses). The vertical arrow indicates the position of a small, sharp peak arising from HOD impurity in the $D_2O$ lock reference which has been deleted for clarity (see also Fig. 2A). B) $^{13}C$-NMR spectrum of the same intercalate at 20 MHz (4000 pulses).

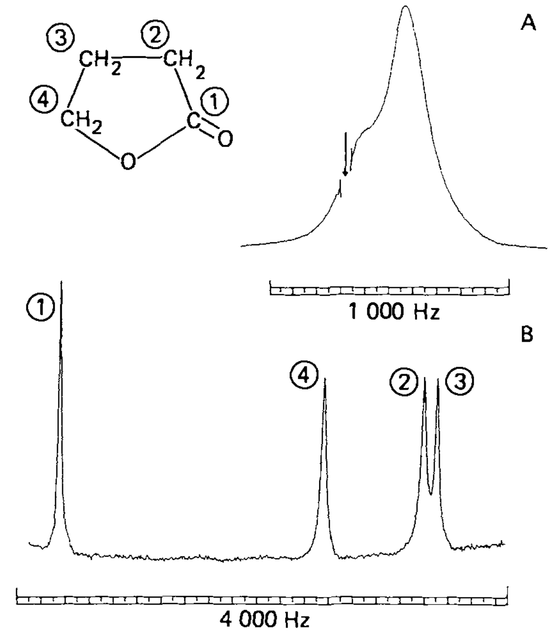

Fig. 2. A) $^1H$-NMR spectrum of the γ-butyrolactone intercalate of hectorite at 80 MHz (15 pulses). B) $^{13}C$-NMR spectrum of the same intercalate recorded at 20 MHz (16000 pulses).

[**] This work was initiated when two of us (*J. M. T.* and *C. A. F.*) were visiting scientists at IBM, San Jose. We are grateful to IBM and particularly to Dr. G. Castro for their hospitality and support, and also to the Science Research Council (U. K.) and the Natural Sciences and Engineering Research Council of Canada for their support.

two proton peaks for the xylene intercalate have relative intensities of 2:3 and the chemical shifts are very similar to the aromatic and methyl resonances in the high-resolution solution spectrum. The $^{13}C$-NMR spectrum shows separate sharp absorptions for each of the three different types of carbon in the molecule (linewidth *ca.* 25 Hz); and the relative chemical shifts [$\delta = 0.0$ ①, $-114.0$ ② and $-108.5$ ③] are identical to those of the pure liquid, again indicating that the molecules are motionally relatively free. The $^{13}C$-NMR spectrum of γ-butyrolactone (Fig. 2) shows four distinct peaks; and good quality, readily interpretable, NMR spectra are obtained from hectorite intercalates of several other organic molecules including tetrahydrofuran, ethylbenzene and 1,3-pentanedione.

The composition of ethylbenzene/*p*-xylene mixed intercalates could readily be deduced from the $^{13}C$-NMR spectra of the powdered solid. Moreover, the keto-enol equilibrium of 1,3-pentanedione in the interlamellar space is seen, by *in situ* NMR measurement, to be displaced in favor of the enol form.

It proved readily possible with these systems to measure, by standard methods, $^{13}C$ spin-lattice relaxation times. For the *p*-xylene intercalate the values are: (C1) 490, (C2) 430 and C3 480 ms, essentially indistinguishable from one another within the accuracy of the experiment. (Compare the corresponding values of 11.8, 13.5, and 44.7 s for the pure *p*-xylene as liquid.) These differences again point to the integration of the xylene guest into the sheet-silicate host. We have also shown, and shall describe more fully elsewhere, that magic-angle spinning, as expected[8], enhances the resolution of both the proton and the carbon spectra of these intercalates.

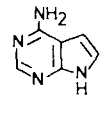
## Selective 7-Glycosylation of 4-Amino-7*H*-pyrrolo[2,3-*d*]pyrimidine to Ara-Tubercidin and Its α-Anomer

By *Frank Seela* and *Heinz-Dieter Winkeler*[*]

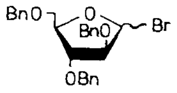
4-Amino-7-(β-D-arabinofuranosyl)pyrrolo[2,3-*d*]pyrimidine (ara-tubercidin) *(4b)*, like its aza analogue ara A[1], has antiviral properties; however, it is not deaminated by adenosine deaminase[2] and is therefore not deactivated.

Whereas ribonucleosides are only biologically accepted as β-anomers, the α-anomers of arabinonucleosides are also of interest since their 2′-hydroxy group is *trans* to the nucleobase and therefore several enzymes recognize α-D-arabinonucleosides like β-D-ribonucleosides[3].

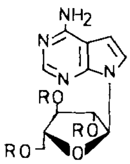
Ara-tubercidin *(4b)* can be obtained either semisynthetically from tubercidin[4] or by total synthesis *via* glycosylation of 4-chloro-2-methylthio-7*H*-pyrrolo[2,3-*d*]pyrimidine[2]. A selective 7-glycosylation of the aglycone *(1)* has hitherto not been described, since an exclusive activation of the pyrrole nitrogen avoiding the *N*-glycosylation of the pyrimidine nitrogens was not possible.



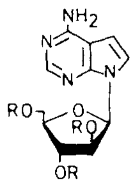
*(1)*



*(2)*



*(3a)*, R=Benzyl
*(3b)*, R=H



*(4a)*, R=Benzyl
*(4b)*, R=H

We were able to couple *(1)*[2,5] with the halogenose *(2)*[6] selectively at N-7 without protecting the 4-amino group under the conditions of phase-transfer catalysis[7]. A 1:1 mixture ($^{1}H$-NMR) of the anomers *(3a)* and *(4a)* is obtained in 57% yield, which, however, is difficult to separate on a preparative scale. Debenzylation of the mixture is accomplished by hydrogenation in the presence of palladium on charcoal and the reaction product is separated on an ionexchange column[8] yielding ara-tubercidin *(4b)*[2,4] and its α-anomer *(3b)*.

### *Procedure*

2,3,5-Tri-*O*-benzyl-1-*O*-*p*-nitrobenzoyl-D-arabinofuranose[6] (2.55 g, 4.4 mmol) is converted into the yellowish, viscous halogenose according to the procedure given in Ref. [7b] *(2)*. A suspension of pulverized *(1)* (0.5 g, 3.7 mmol)[2,5] in dichloromethane (10 cm$^3$) and dimethoxyethane (5 cm$^3$) is stirred with benzyltriethylammonium chloride (0.15 g, 0.55 mmol) and 50% aqueous NaOH (15 cm$^3$) for 5 min in a vibromixer.—The halo sugar is added dropwise to the emulsion and mixing of the layers is continued for a further 30 min. The organic layer is separated off, extracted with water, dried over sodium sulfate, filtered, and evaporated. The oily residue is dissolved in a small amount of chloroform/methanol (99:1) and chromatographed in the same solvent on silica gel (Lobar pre-packed column, size C, Merck). The main zone is separated and the solvent removed; 1.12 g (57%) of a yellowish, viscous mixture of the anomers *(3a)* and *(4a)* (1:1) is obtained. TLC ($CHCl_3/CH_3OH$ 98:2): $R_f = 0.3$; UV ($CH_3OH$): $\lambda_{max} = 270$ nm ($\varepsilon = 11\,400$).

The mixture *(3a)*/*(4a)* (1.0 g, 1.9 mmol) dissolved in methanol (100 cm$^3$) is hydrogenated at room temperature under normal pressure with 10% palladium on charcoal as catalyst. After filtration of the catalyst and evaporation of the solvent a colorless, oily crude product is obtained which is applied on a 2.5 × 30 cm ion-exchange column (Dowex 1 × 2, $OH^-$

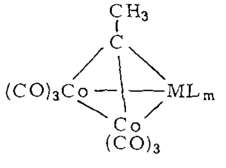
## Direct Metal Exchange in Carbonylcobalt Clusters[**]

By *Harald Beurich* and *Heinrich Vahrenkamp*[*]

Experience so far indicates that it should be extremely difficult to devise a directed synthesis of a tetrahedral framework structure consisting of heteroatoms, since each corner of the tetrahedron must be bonded to the remaining three corner units. It is therefore all the more astonishing that tetrahedral heteroatom clusters can be fromed indirectly in one-step[1] or in multi-step addition and substitution reactions by the systematic addition and incorporation of organometallic units[2,3]. We now wish to report that these types of organometallic expansion reactions can be performed by a still simpler direct metal exchange process. In this connection, carbonyl cobalt clusters were reacted with simple binuclear carbonyl (cyclopentadienyl) metallic compounds *(1)* which are present in equilibrium with their mononuclear radical moieties[4]. The latter species are able to attack the clusters and substitute the $Co(CO)_3$-units by organometallic groups. The binuclear complexes *(1)* and $CH_3CCo_3(CO)_9$ react to produce the hetero clusters *(2)*, of which we had already obtained *(2a)* and *(2b)* by the Co—As-elimination method. The reactions are accelarated by thermal and photochemical stimuli and proceed in low yield in the case of *(1c)* and in high yield with an excess of *(1d)*.

$L_nM{-}ML_n$

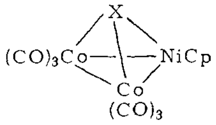


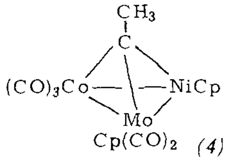
*(1a)*, $ML_n$ = $MoCp(CO)_3$
*(1b)*, $ML_n$ = $WCp(CO)_3$
*(1c)*, $ML_n$ = $FeCp(CO)_2$
*(1d)*, $ML_n$ = NiCpCO

*(2a)*, $ML_m$ = $MoCp(CO)_2$
*(2b)*, $ML_m$ = $WCp(CO)_2$
*(2c)*, $ML_m$ = FeCpCO
*(2d)*, $ML_m$ = NiCp

When *(1d)* was reacted with other cobalt clusters, similar products were obtained *e.g.* with $XCo_3(CO)_9$ (X = CF, $CC_6H_5$) the clusters *(3a)* and *(3b)* were formed, and the $NiCo_3$-cluster *(3c)* was formed from $Co_4(CO)_{12}$ and *(1d)* in at least twice the yield (50—90%) of the previously described process[5]. Table 1 gives the most important spectroscopic data of the new compounds.

*(3a)*, X = CF
*(3b)*, X = $CC_6H_5$
*(3c)*, X = $Co(CO)_3$





*(4)*

Table 1. Important spectroscopic data of the new hetero-cluster compounds. $^1H$-NMR in $C_6D_6$, TMS int. std., δ-values. IR in cyclohexane, ν(Co) [cm$^{-1}$].

| Cmpd. | $^1H$-NMR | IR |
|---|---|---|
| *(2c)* | 3.98, 3.76 | 2073 s, 2030 vs, 2020 vs, 1996 m, 1988 w, 1920 m |
| *(2d)* | 4.76, 3.43 | 2078 m, 2038 vs, 2020 vs, 2009 m, 1994 w |
| *(3a)* | 4.79 | 2085 s, 2048 vs, 2030 vs, 2021 m, 2011 w |
| *(3b)* | 4.78 | 2078 s, 2040 vs, 2020 vs, 2012 m, 1998 w |
| *(4)* | 4.84, 4.68, 3.70 | 2053 m, 2034 s, 2005 m, 1990 vs, 1976 s, 1968 st, 1947 vw, 1934 m, 1916 w, 1898 vw, 1870 vw |

The chiral trimetal cluster *(4)* was obtained from $CH_3CCo(CO)_9$ by a stepwise double metal exchange which proceeds *via (2a)* or *(2d)*. Compound *(4)* spontaneously forms optically active crystals, a structural analysis of which was carried out (Fig. 1)[6]; we have endeavored to obtain larger single crystals of *(4)* so that a separation of them into their enantiomers by manual selection can be carried out. Furthermore, since the cluster compound *(4)* can readily be prepared, it would be a suitable species with which to examine the process of optical induction in cluster catalysis reactions. This species should also provide definite proof that cluster compounds, viewed as a structural whole, can be catalytically active[7].

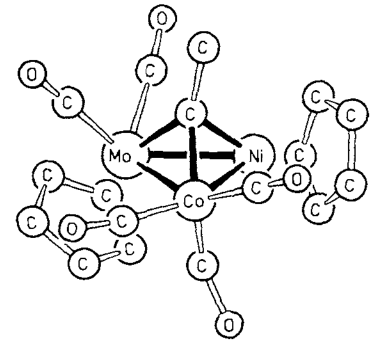


Fig. 1. Structure of *(4)*. The most important bond lengths are as follows; Co—Mo 265.1 (4), Mo—Ni 255.7 (3), Ni—Co 233.6 (4), Co—C 187 (2), Mo—C 208 (2), Ni—C 188 (2) pm [6].

### *Experimental*

A solution of *(2a)* (100 mg, 0.21 mmol) and *(1d)* (190 mg, 0.63 mmol) in 15 cm$^3$ benzene was stirred for 5 d at 60 °C. Chromatography on a silica gel column (3 × 30 cm) using a hexane/benzene eluent (9:1) produced firstly *(2a)* (green), secondly *(1d)* (red), and *(4)* (brown) as the third fraction. Recrystallization from hexane gave 20 mg (19%) of *(4)* as dark brown crystals (19%) (m.p. = 152 °C).

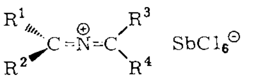
## Phenyl-Substituted Dimethyleneammonium Salts: 2-Aza-allenium Derivatives[**]

By *Ernst-Ulrich Würthwein*[*]

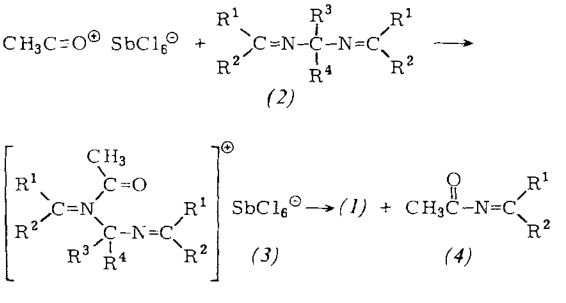
Dimethyleneammonium salts *(1)* have been postulated as intermediates[1a,b] and were observed in mass spectrometric fragmentations[1c], but little is known about their synthesis and reactivity[2]. These linear 2-aza-allenium salts, which have the topology and electronic structure of cumulenes, are of considerable theoretical interest. They are novel examples for the influence of positively charged, sp-hybridized nitrogen on charge distribution and structural preference. For organic synthesis the salts *(1)* can be used as highly reactive C—N—C synthons ("double" methyleneammonium or iminium salts), *e.g.* as electrophiles, dienophiles and as stable precursors for nitrile ylides[1b].



*(1a)*, $R^1, R^2, R^3, R^4$ = Ph
*(1b)*, $R^1, R^2, R^3$ = Ph; $R^4$ = H
*(1c)*, $R^1, R^3$ = Ph; $R^2, R^4$ = H

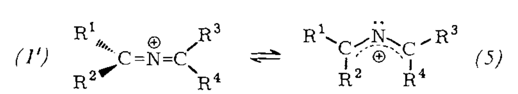
We report here a simple method for the synthesis of substituted dimethyleneammonium salts *(1)* which is applicable not only to the known tetraphenyl derivative *(1a)*[2a], but also to the tri- and diphenyl derivatives *(1b)*, *(1c)* and others. *(1c)* is the first chiral representative of this class of compounds.

Starting materials are the easily accessible *N,N'*-bisalkylidenediaminomethanes *(2)* ("iminals")[3], of which "hydrobenzamide" *(2c)*[3b] is the best known. Acylium salts, powerful acylation reagents[4], attack *(2)* at nitrogen and lead directly to *(1)*. The *N*-acyliminium salts *(3)* could not be detected as intermediates. *(1a)* and *(1c)* are isolated as crystalline solids when the reaction is performed in $CHCl_3$ or $CHCl_3/CCl_4$ (1:1), respectively, whereas *(1b)* is obtained as an oil, which does not crystallize easily from $CHCl_3/CCl_4$ (cf. *Procedure*).



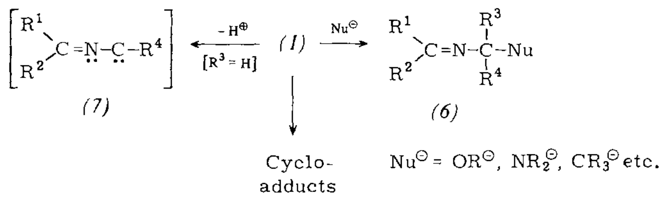
Apart from *(1)*, the cleavage of *(3)* yields the *N*-alkylideneacetamides *(4)*, which are of theoretical and synthetic interest as reactive dienes[5a] and 1,4-dipoles[5b]. The driving force which facilitates the formation of the highly reactive dimethyleneammonium salts *(1)* is the strong acyl-imine bonding in *(4)*[6].

The linear allene-like structure of *(1)* is especially evident from the very intense cumulene-stretching bands in the IR-spectrum, [$\nu=1870$ *(1a)*, 1890 *(1b)*, and 1910 $cm^{-1}$ *(1c)*] whose frequencies are similar to the corresponding absorptions in the allene spectrum. The planar, bent 2-azaallyl cation structure, *(5)*, can therefore be ruled out as a valence isomer of the cation *(1')* for *(1a)*, *(1b)* and *(1c)*. Compounds with amino-substituents in the 1- and 3-positions prefer the allyl form *(5)*, however, because of the formation of the electronically favorable amidinium fragments[7,8].



The ¹H-NMR signals for the cumulene protons in *(1b)* and *(1c)* occurs, as expected for methyleneammonium salts, at low field: $\delta=9.8$ *(1b)* and 9.4 *(1c)*. The $^{13}C$-NMR spectrum of *(1c)* ($CD_3NO_2$, 70 °C) exhibits a triplet at $\delta=145.3$ for C-1 and C-3 with an unusually large $^{13}C$-$^{14}N$ coupling constant ($^1J_{^{13}C\text{-}^{14}N}=16.3$ Hz); comparable methyleneammonium salts absorb at $\delta\approx170$ ppm, and the corresponding allenes at $\delta=80$—100.

Dimethyleneammonium salts *(1)* are valuable C—N—C synthons in organic synthesis; they react rapidly and under mild conditions with nucleophiles to give substituted *N*-methylimine derivatives *(6)*, which in turn can be subjected to a second, specific, nucleophilic attack at the imine group. The salts *(1)* can be used as ene-partner in cycloadditions; deprotonation of the derivatives *(1b)* and *(1c)* with strong, non-nucleophilic bases leads to the nitrile ylides *(7)*[9], which cannot be isolated, but give trapping products typical for this type of 1,3-dipole.



### *Experimental*

All operations were performed under a nitrogen atmosphere.

*(1c)*: A solution of *(2c)*[3b] (1.5 g, 5.0 mmol) in 20 $cm^3$ dry chloroform is treated with 0.4 g (5.0 mmol) acetyl chloride at room temperature with stirring. The reaction mixture is cooled to 0 °C and a solution of 1.5 g (5.0 mmol) antimony pentachloride in 20 ml $CHCl_3$ is added dropwise. When the addition is nearly complete a colorless precipitate forms. This solid is filtered off under nitrogen after 3 h stirring in the dark and is washed twice with 10 ml portions of $CHCl_3$. 2.0 g (76%) of the white, microcrystalline, extremely mois-

## Crystal Structure of $P_4O_7$[**]

By *Martin Jansen* and *Marlen Voss*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

$P_4O_6$ opens up several preparatively interesting possibilities, which, however, have hitherto remained largely unexploited. The reason for this appears to be coupled with the problematical isolation of pure $P_4O_6$[1] and the complexity of the $P_4O_6/P_4O_{10}$ system[2].

We report here on the reaction of $P_4O_6$ with alkali metal oxides $A_2O$ ($A = K$, Rb, Cs), which proves to be unexpectedly difficult: whereas no reaction occurs at low temperature (20—50 °C), increasing decomposition of $P_4O_6$ is observed with increasing temperature above 50 °C. In the temperature range 120—180 °C violent and uncontrolled reactions take place. On sublimation of the heterogeneous solid reaction products pure $P_4O_7$ separates in the form of translucent, strongly refracting crystals in the warm zone 120—130 °C of the temperature gradient (170→25 °C).

Owing to its extreme sensitivity towards moisture and oxidation the compound was prepared under argon for the X-ray crystallographic and vibration spectroscopic investigations. The structure determination[3] shows that $P_4O_7$ molecular units are present (cf. Fig. 1)[4]. The anisotropy of the temperature factors can be ascribed to librational motion of the rigid $P_4O_7$ groups (almost about the baricenter); the intramolecular distances quoted take into account this effect[5].

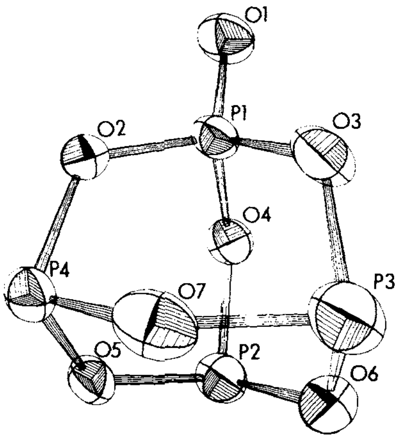

Fig. 1. Perspective representation of a $P_4O_7$ molecule. Bond lengths [pm] and angles [°] in $P_4O_7$ (maximum standard deviations: 0.7 pm and 0.3°, respectively): P1—O1 (O2; O3; O4) = 145.0 (159.7; 158.9; 159.5); P2—O4 (O5; O6) = 168.2 (164.2; 164.7); P3—O3 (O6; O7) = 168.9 (166.2; 164.4); P4—O2 (O5; O7) = 168.2 (164.2; 163.7); O1—P1—O2 (O3; O4) = 114.5 (115.3; 115.0); O3—P1—O2 (O4) = 103.8 (103.4); O2—P1—O4 = 103.2; O4—P2—O5 (O6) = 99.1 (97.9); O5—P2—O6 = 99.5; O3—P3—O6 (O7) = 97.1 (98.6); O6—P3—O7 = 100.3; O2—P4—O5 (O7) = 98.9 (98.1); O5—P4—O7 = 100.2; intermolecular: O3—O5 = 300.5; P2—O2 = 319.7.

Despite the low positional symmetry 1 in the crystalline state $P_4O_7$ has, within the limits of error of the structure determination, the $C_{3v}$ symmetry to be expected for the free molecule. One can clearly distinguish between pentavalent (P1) and trivalent (P2, P3, P4) phosphorus by virtue of the atomic environment (coordination number, P—O distances). However, the concept based on models that such molecules are made up of $P_4O_{10}$ and $P_4O_6$ moieties with retention of the P—O bond lengths is reconcilable only to a limited extent with the structural data found here. Thus, for example, the distance from P1 to the terminal O1 (145.0 pm) in $P_4O_7$ is significantly longer than the corresponding distances in $P_4O_{10}$ (139.0—142.9 pm)[6]. This observation points to a certain reduction in the "pentavalent character" of P1, which could be caused by a shift of electrons from the trivalent P2, P3 and P4 atoms linked by oxygen bridges. The marked difference in lengths of P—O bonds from P2, P3 and P4 undoubtedly follows from the stronger interaction of O2, O3 and O4 with P1. The shortest intermolecular contacts exist between bridging oxygen atoms and correspond exactly to the sum of the respective van der Waals radii.

Indications of a deviation from the ideal composition, as have been described in the case of $P_4O_{\approx 8}$[2b], have not been observed in the case of $P_4O_7$.

The possibility of a comparison is impaired by the fact that in the case of the dimensions of $P_4O_{10}$ determined by electron diffraction the influence of intermolecular interactions is practically missing and that the structure determinations on solid $P_4O_{10}$ are relatively inaccurate and have furnished controversial results.

## Electrochemical Processes in Supercritical Phases[**]

By *Giuseppe Silvestri, Salvatore Gambino, Giuseppe Filardo, Carmelo Cuccia'*, and *Enrico Guarino'*[*]

*Dedicated to the memory of Professor Raffaele Ercoli*

Substances in the supercritical state, *i. e.* at temperatures and pressures above their critical point, exhibit unusual solvent properties towards many organic and inorganic compounds[1]. The conductivity of supercritical steam containing various dissolved salts has been the object of considerable attention both for basic studies on the thermodynamic properties of such systems, and for the investigation of the corrosion processes taking place in power plants[2]. To our knowledge, nothing has been done to examine substances other than water as media for electrochemical processes in the supercritical state, although the combination of the solvent properties and fluid dynamic characteristics of such systems make them an interesting area to explore. In this communication we report our preliminary results concerning the use of carbon dioxide, bromotrifluoromethane, hydrogen chloride, and ammonia as supercritical solvents for electrochemical processes. Precise conductivity measurements were not the intention of this research, which was rather an initial evaluation of the synthetic possibilities opened by these systems[3].

Among the substances tested, a correlation between the conductivity of the liquid phase and that under supercritical conditions was observed *e. g.* a solution of tetrabutylammonium iodide in $CO_2$ was a poor conductor in the liquid, as well as in the supercritical state. Bromotrifluoromethane, in which electrolytes are practically insoluble, also proved to be a very poor conductor. $CO_2$ and $CF_3Br$ are consequently unsuitable as solvents for preparative electrolyses in the supercritical state, and were therefore not considered further.

Ammonia and hydrogen chloride, have high dielectric constants and also appreciable solvent properties even in supercritical conditions (see Table 1). In a series of preliminary experiments in sealed glass capillary tubes[3], it was observed that at 50 °C NaCl was relatively insoluble in $NH_3$ and that the meniscus disappeared at 129 °C; preparative scale electrolyses on this system with similar electrolyte concentration, were therefore performed at temperatures above 129 °C. The variation of the conductivity of the cell with temperature, for the system: Ag/$NH_3$, NaCl/Ag, is plotted in Fig. 1.

Table 1. Conductivity of electrochemical systems in supercritical condition [a].

| Solvent | *p* [bar] | | *T* [°C] | | *I* [mA] | *U* [V] |
|---|---|---|---|---|---|---|
| | exp. | crit. | exp. | crit. | | |
| $CO_2$ | 177 | 73.8 | 83 | 31 | 1.37 | 300 |
| $CF_3Br$ | 97.5 | 50.8 | 85 | 67 | 0.2 | 80 |
| HCl | 103.4 | 83.0 | 80 | 51.4 | 4.1 | 57 |
| $NH_3$ [b] | 171 | 113.8 | 155 | 132.5 | 25 | 47 |

[a] Conducting salt: $nBu_4NI$. [b] Conducting salt: NaCl.

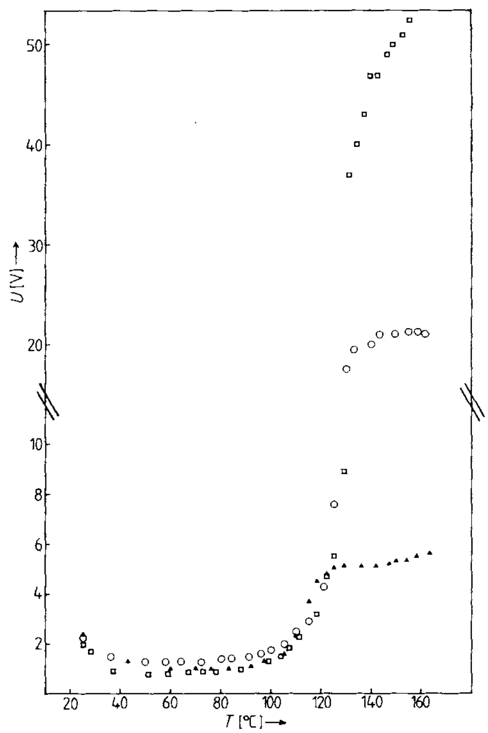

Fig. 1. The voltage of the $NH_3$/NaCl system at a constant current (5 mA) as a function of temperature. Measurements were carried out in a cylindrical stainless steel autoclave (206 $cm^3$). Silver foil (surface area of inner and outer cylinders 8.478 and 20.41 $cm^2$ resp.; electrode separation 0.8 cm) served as the electrodes which were held in Teflon frames and insulated from the autoclave jacket.

▲: 77.48 g/$NH_3$, 154 mg NaCl, $\rho$ = 387 g/$dm^3$

○: 64.5 g/$NH_3$, 154 mg NaCl, $\rho$ = 313 g/$dm^3$

□: 57.63 g/$NH_3$, 154 mg NaCl, $\rho$ = 280 g/$dm^3$

It was determinant, for the conductivity of the medium, that the supercritical system should have a high density (280—390 g/$dm^3$) ($\rho$ at the critical point 235 g/$dm^3$).

The curves show that the dependence of the conductivity with temperature beyond the critical point is approximately inversely proportional to the specific weight of the supercritical phase. Electrolyses were also performed over long periods of time, in which up to 4000 Coulombs were passed through the cell; it was observed that the conductivity of the system remains substantially unchanged during electrolysis. The data on electrolyses involving the above mentioned system, as well as the Fe/NaCl, $NH_3$/Fe system, are summarized in Table 2.

Table. 2. Preparative scale electrolyses in supercritical ammonia (Q = quantity of charge transported).

| Anode | *p* [bar] | *T* [°C] | $\rho$ [g/$dm^3$] | *Q* [C] | Anodic current efficiency [%] |
|---|---|---|---|---|---|
| Ag | 207 | 141 | 336.7 | 78.5 | 95 |
| Ag | 171 | 155 | 359.2 | 1177 | 82 |
| Fe | 161 | 146 | 368 | 4093 | 45 |

The anodic dissolution of silver takes place with very good current yields. Reduction of the silver ions at the cathode resulted in a deposit of fine silver powder on all the internal surfaces of the cell. In the case of iron, the anodic process of dissolution of the metal accounts for only 45% of the charge

---

[*] Prof. Dr. G. Silvestri, Dr. S. Gambino, Dr. G. Filardo, C. Cuccia, E. Guarino
Instituto di Ingegneria Chimica, Viale delle Sienze, Palermo (Italy)

[**] The content of this publication is part of a dissertation by C. C. and E. G.

passed, assuming that Fe(III) is produced at the anode. Hydrogen was also produced, in a quantity corresponding to 48% of the charge passed. The formation of hydrogen can be explained by assuming that, in addition to the oxidation of iron, the anodic reaction involves the well known oxidation of ammonia to nitrogen and ammonium ions: ($4NH_3 \rightarrow 1/2N_2 + 3NH_4^{\oplus} + 3e$), and the ammonium ions so formed are reduced at the cathode, producing molecular hydrogen. Electrochemical reactions in liquid ammonia behave in a similar way[4].

The use of hydrogen chloride as electrolytic medium is also of interest, but experiments with this solvent were difficult due to its high corrosive action. The experimental data obtained up to now confirm that hydrogen chloride containing dissolved potassium iodide gives rise to an increase in the cell resistance similar to that observed for the systems with ammonia. Electrolysis of the supercritical HCl/KI system produced elementary iodine at the anode.

The transition of a system from the liquid to the supercritical state results, as seen in these experiments, in an increase in resistance by one to two orders of magnitude (also Fig. 2). Looking at the possible use of these systems for synthetic purposes, the results obtained so far show that it is possible to obtain good conductivities when cells having a narrow gap between the electrodes are used with supercritical phases of high density.

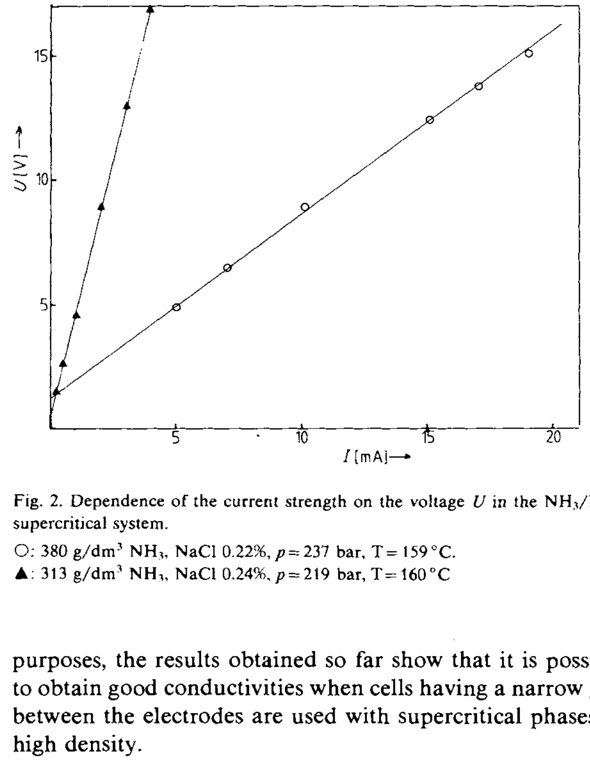

Fig. 2. Dependence of the current strength on the voltage $U$ in the $NH_3$/NaCl supercritical system.

○: 380 g/dm³ $NH_3$, NaCl 0.22%, $p$ = 237 bar, T = 159 °C.

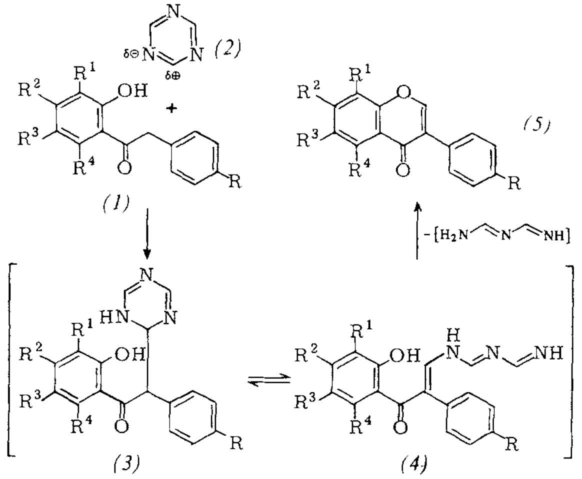
# Isoflavone Synthesis with 1,3,5-Triazine

By *Hem Chandra Jha, Fritz Zilliken*, and
*Eberhard Breitmaier*[*]

*Dedicated to Professor Rudolf Tschesche on the occasion of his 75th birthday*

The isoflavones *(5)*, which are of interest as antioxidants[1], fungicides[2] and anticontraceptives[3], are usually obtained by formylation of *o*-hydroxydeoxybenzoins *(1)* and subsequent cyclocondensation. Hitherto the systems formic acid and orthoformate/base[4a], zinc cyanide/hydrochloric acid[4b], dimethylformamide (DMF)/phosphorus oxide chloride[4c] and DMF/boron trifluoride/methanesulfonic acid[4d] have been used as formylating reagents. However, with exception of the latter method the yields are frequently poor and many by-products are obtained.



Since 1,3,5-triazine *(2)*, as a carbonyl-analogous electrophile, is attacked by CH-acidic compounds[5a] and is effective as a formylating agent[5b] we have tested it as a possible $C_1$-synthon in the synthesis of isoflavone. *(2)* reacts with *o*-hydroxydeoxybenzoins *(1)* in the presence of boron trifluoride ether in glacial acetic acid to give the corresponding isoflavones *(5)*. The advantages of this method are: good yields (up to 90%), short reaction times (2—3 h), mild conditions, and the simplicity of the technique and workup (Table 1).

The ring closure can be accomplished *via* the formyldeoxybenzoin formed from 1,3,5-triazine *(2)* and deoxybenzoin *(1)* in the sense of the Gattermann aldehyde synthesis[5b]. In analogy to earlier formylations[5a] the cyclization could also start with a nucleophilic addition of the acidic methylene group of *(1)* to the electrophilic carbon of *(2)*. The isoflavone *(5)* can be formed from the open-chain tautomer *(4)* of the primary adduct *(3)* with cleavage of the further reactive 1-amino-2,4-diaza-1,3-butadiene.

## *Procedure*

A solution of *(1)* (0.05 mmol) and *(2)* (0.1 mmol) in glacial acetic acid (1 cm³) is treated with 0.1 cm³ each of boron trifluoride ether (50% in diethyl ether) and acetic anhydride.

Table 1. Isoflavones from *o*-hydroxydeoxybenzoins *(1)* and 1,3,5-triazine *(2)*.

| Cpd. | R | $R^1$ | $R^2$ | $R^3$ | $R^4$ | Yield [%] | M.p. [°C] | Ref. |
|---|---|---|---|---|---|---|---|---|
| *(5a)* | $OCH_3$ | H | $OCH_3$ | $OCH_3$ | H | 95 | 174—175 | [6] |
| *(5b)* | $OCH_3$ | $OCH_3$ | $OCH_3$ | H | H | 92 | 151 | [7] |
| *(5c)* | OH | H | OH | H | H | 72 | 320—321 (dec.) | [8] |
| *(5d)* | $OCH_3$ | H | OH | H | H | 91 | 257—258 | [8] |
| *(5e)* | OH | H | OH | H | OH | 78 | 295—296 (dec.) | [8] |
| *(5f)* | $OCH_3$ | H | OH | H | OH | 81 | 212 | [8] |
| *(5g)* | OH | H | OH | OH | H | 58 | 320—321 (dec.) | [6] |
| *(5h)* | $OCH_3$ | H | OH | $OCH_3$ | H | 90 | 228—229 | [6] |
| *(5i)* | $OCH_3$ | H | OH | OH | H | 60 | 291—292 | [9] |

The mixture is boiled gently under reflux for 2—3 h, then cooled and poured into ice-water (20 $cm^3$). The precipitated isoflavone *(5)* is filtered off and purified by column chromatography (silica gel 60, particle size 0.063—0.200 mm; eluant benzene with increasing amounts of methanol) and recrystallization from methanol. The identities of the isoflavones thus obtained (Table 1) were confirmed by comparison with authentic samples (thin layer chromatography, melting points, IR and $^{13}C$-NMR spectra).

# $(NH_4)_4[P_4S_8]\cdot 2H_2O$, the Salt of a "Square" Phosphoric Acid[**]

By *Hans Falius, Werner Krause*, and *William S. Sheldrick*[*]

We have obtained a series of previously unknown phosphates upon oxidation of elemental phosphorus with polysulfidic sulfur[1]. Two of these, which were prepared from red phosphorus, display an identical composition, namely $M^IPS_2$ (without water of crystallization). They were shown to be *cyclo*-thiophosphates(III) with respective ring sizes of five and six members.

We have now succeeded in synthesizing a further thiophosphate with the same composition, in this case by the reaction of white phosphorus with polysulfides in a nonaqueous medium. This reaction is very rapid at room temperature and leads to a mixture of different thiophosphate anions, one of which, however, predominates proportionally. It could be isolated as the moderately soluble ammonium salt.

From the analytical and spectroscopic findings ($NH_4:P:S = 1:1:2$, oxidation number of phosphorus: +3, $^{31}P$-NMR: only one singlet) it was reasonable to assume that this salt was once again a cyclic thiophosphate(III). Furthermore, since the compound had been prepared from white phosphorus, it could be concluded that it contained a four-membered ring. This supposition was confirmed by the X-ray analysis[2] (Fig. 1).

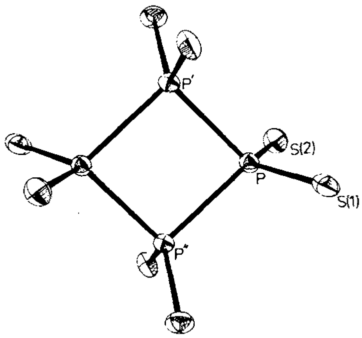

Fig. 1. Structure of the anion $[P_4S_8]^{4-}$. Bond lengths and angles: P—S1 197.6(1), P—S2 198.0(1), P—P' 228.0(1), P—P'' 228.7(1) pm; S1—P—S2 118.6(1), S1—P—P' 121.7(1), S1—P—P'' 111.8(1), S2—P—P' 119.7(1), S2—P—P'' 110.7(1)°.

The triethylammonium salt formed by the reaction (a) was converted into the sodium salt with sodium hydroxide, without having been first isolated. Addition of $NH_4NO_3$ to an aqueous solution of this readily soluble salt led to the crystallization of the less soluble ammonium octathiocyclotetraphosphate(III), $(NH_4)_4[P_4S_8]\cdot 2H_2O$ *(1)*. Similarly, use of a readily soluble potassium salt, such as potassium acetate, instead of $NH_4NO_3$, yielded a precipitate of the less soluble $K_4[P_4S_8]\cdot 2H_2O$ *(2)*.

$$P_4 + 4[Et_3NH]HS_{2.5} \rightarrow [Et_3NH]_4[P_4S_8] + 2H_2S \tag{a}$$

*(1)* forms shiny flaky platelets. Its $^{31}P$-NMR spectrum ($H_2O$) displays a singlet at $\delta = 121$ (85% $H_3PO_4$, external). The aqueous solution of this salt of a monobasic polyvalent acid has, as expected, a pH of 7; the anion is remarkably stable. Alkaline hydrolysis at boiling heat leads to thiomonophosphates(III): $[PHOS_2]^{2-}$ (high yield), $[PHO_2S]^{2-}$ (low yield), $[PHS_3]^{2-}$ (very low yield). On acid hydrolysis $[PO_4]^{3-}$ and $[PH_2O_2]^-$ are formed in addition to the previously mentioned phosphates(III). Precipitates are formed for the *cyclo*-thiophosphate with the following cations: $Pb^{II}$ (red-brown), $Sn^{II}$ (orange), Bi (brown-black), $Cu^{II}$ (yellow-brown), Cd (white), $Hg^{II}$ (bright yellow), Ag (yellow, slowly becoming brown and then black).

[**] This work was supported by the Fonds der Chemischen Industrie.

The anion of *(1)* is the first known homocycle consisting of four tetracoordinated phosphorus atoms. It represents, thereby, an ionic analogue to *cyclo*butane.

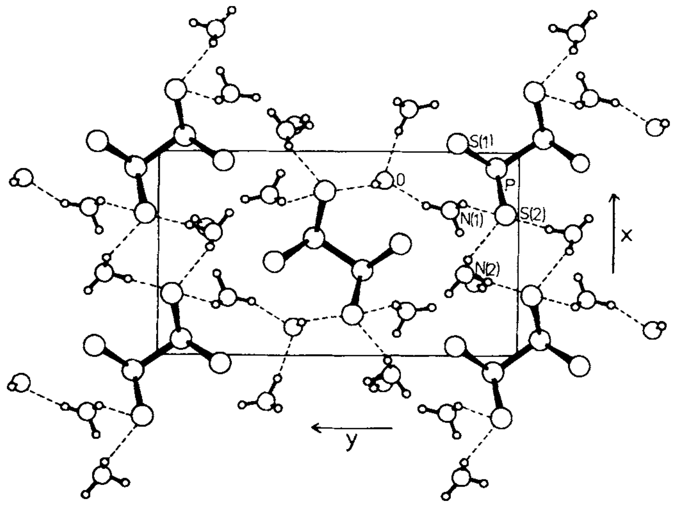

Fig. 2. Projection of the crystal lattice of *(1)* perpendicular to [001].

The crystal structure of *(1)* is stabilized by a network of N—H···S and O—H···S hydrogen bonds to S2, and N—H···O hydrogen bonds between N1 and the water of crystallization. N1 and the water oxygen lie in the mirror plane at z = 0.5, N2 in the mirror plane at z = 0. $[P_4S_8]^{4-}$ has crystallographic $C_{2h}$-symmetry, P′ being related by a $C_2$-axis and P″ by a mirror plane to P. The four-membered ring must, therefore, be exactly planar with angles of 90° at phosphorus. The P—P distances of respectively 228.0(1) and 228.7(1) pm are significantly longer than those which are normally observed (218—222 pm), independent of oxidation state and the nature of the substituents. Longer P—P bonds have been observed in caged phosphorus sulfides, namely 235 pm in $P_4S_7$[4] and 236 pm in α-$P_4S_4$[5].

*Experimental*

Solvents and $H_2S$ are dry. A mixture of $Et_3N$ (14 cm$^3$, 0.1 mol) and $CHCl_3$ (50 cm$^3$) is saturated with $H_2S$. 3.2 g (0.1 mol) of sulfur is added in portions, with stirring and further introduction of $H_2S$. After the sulfur has dissolved, the gas stream is strongly reduced and a solution of phosphorus (1.5 g, 0.05 mol) in $CS_2$ (5 cm$^3$) is added dropwise (water cooling). After stirring for a further hour the reaction mixture is shaken with 50 cm$^3$ of ice-cooled 10% NaOH. A mixture of sodium salts is exhaustively precipitated with ethanol from the upper aqueous phase. This is dissolved in 90 cm$^3$ of water and 10 cm$^3$ 25% $NH_3$ and $NH_4NO_3$ (15 g) are added with stirring. The *cyclo*-thiophosphate begins to crystallize during this addition. Yield 3 g (50%).—If recrystallization is necessary, *(1)* is dissolved in the required quantity of 10% NaOH and added to the described solution of water, 25% $NH_3$ and $NH_4NO_3$.

[1] *W. Krause*, Dissertation, Technische Universität Braunschweig 1978.

[2] *(1)* crystallizes orthorhombically (Pbam) with $a = 807.9(1)$, $b = 1433.7(4)$, $c = 868.1(1)$ pm, $Z = 2$, $\rho_{calc} = 1.61$, $\rho_{obs} = 1.58$ g·cm$^{-3}$. The structure was refined to $R = 0.037$, $R_w = 0.031$ for 1325 reflexions (Syntex $P2_1$-diffractometer, $\theta$'$2\theta$ mode, $2\theta \leqslant 60°$, $F^2 \geqslant 1.5\sigma(F^2)$, Mo-K$_\alpha$ radiation). A refinement in the non-centrosymmetric space group $Pba2_1$ did not lead to a significant improvement of the *R*-factor.

## Oxidation of Alcohols with Benzyl(triethyl)ammonium Permanganate

By *H.-Jürgen Schmidt* and *Hans J. Schäfer*[*]

Benzyl(triethyl)ammonium permanganate, which is safe to handle below 50 °C[1], can be used for the oxidation of hydrocarbons to alcohols or ketones[2a] and of ethers to esters[2b]. We report here on the oxidation of primary and secondary alcohols with this reagent (Table 1).

Table 1. Products of the oxidation of alcohols with benzyl(triethyl)ammonium permanganate.

| Alcohol [a] | Oxidation products (yield isolated [%]) |
|---|---|
| Benzyl alcohol | Methylene dibenzoate (62), chloromethyl benzoate (11), Benzoic acid (18) |
| 1-Heptanol | Methylene diheptanoate (70), chloromethyl heptanoate (9), heptanoic acid (15) [b] |
| 1-Decanol | Methylene didecanoate (71), chloromethyl decanoate (13), Decanoic acid (15) [c] |
| 2-Octanol | 2-Octanone (89), hexanoic acid (10) [d] |
| D,L-1-Phenylethanol | Acetophenone (78), benzoic acid (19) |
| Benzhydrol | Benzophenone (95), benzoic acid (3) |

[a] General reaction conditions: 5 mmol alcohol, 10 mmol benzyl(triethyl)ammonium permanganate in 75 cm$^3$ dichloromethane, 1—2 d at 5 to 40 °C. [b] Mixture of 94% $C_7$-, 5% $C_6$-, and 1% $C_5$-acids. [c] Mixture of 88% $C_{10}$, 7% $C_9$-, and 4% $C_8$-acids. [d] Mixture of 70% $C_6$-, 5% $C_7$-, and 20% $C_6$-acids.

The main products of the primary alcohols are the methylene diesters, which are presumably formed by nucleophilic attack of the carboxylates on the solvent dichloromethane[3]. While the carboxylic acids formed as byproducts contain shorter chain homologs—apparently by oxidative follow-up reactions—the diesters are uniform. Secondary alcohols furnish high yields of ketones, accompanied by the carboxylic acids formed by α-cleavage.

While benzyl alcohol and benzhydrol are oxidized with tetrabutylammonium permanganate in pyridine in yields of the same order[4], in the potassium permanganate-oxidation in water or glacial acetic acid the yields of the alcohol oxidation are distinctly lower[5]. In the oxidation of primary alcohols the title reagent is superior to solid carriers such as molecular sieves[6a], copper sulfate[6b] and aluminum oxide[6c] impregnated with potassium permanganate.

## Oxidation of Amines with Benzyl(triethyl)ammonium Permanganate

By *H.-Jürgen Schmidt* and *Hans J. Schäfer*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Tertiary amines can be heterogeneously oxidized with potassium permanganate only with difficulty, and even then to a mixture of products of little preparative use[1]. In contrast, the homogeneous oxidation with benzyl(triethyl)ammonium permanganate in dichloromethane affords an *N,N*-dialkylamide as single product in high yield. In the case of secondary and primary amines the oxidation is less selective (see Table 1).

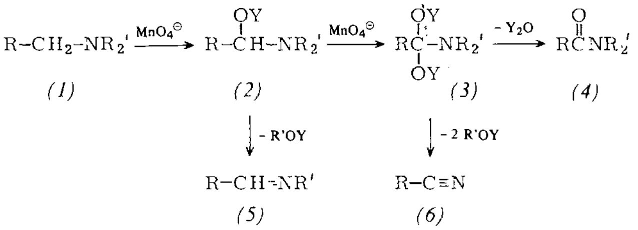
Table 1. Products of the oxidation of amines with benzyl(triethyl)ammonium permanganate.

| Amine [a] | Oxidation products (yield isolated [%]) |
|---|---|
| *n*-Decylamine [b] | Decanonitrile (11), decanamide (6), decanoic *N*-decylamide (35) |
| *n*-Decylamine [c] | Decanonitrile (54), decanamide (13), *N*-decylformamide (4), decanoic *N*-decylamide (15), decanoic acid (10) [d] |
| Di(*n*-butyl)amine | Butyric *N*-butylamide (44), methylene dibutyrate (14), butyric acid (30) [e] |
| Di(*n*-octyl)amine | Octanoic *N*-octylamide (49), methylene dioctanoate (11), octanoic acid (20) [f] |
| Dibenzylamine | *N*-Benzylbenzamide (36), dibenzamide (6), benzamide (20), benzaldehyde (7), benzoic acid (25) |
| *N*-Methylbenzylamine | *N*-Methylbenzamide (36), benzaldehyde (33), benzoic acid (27) |
| *N*-Methylaniline | *N*-Phenylformamide (<10) |
| *N*-Ethylaniline | *N*-Phenylacetamide (<10) |
| Tributylamine | *N,N*-Dibutylbutyramide (93), butyric acid (5) |
| *N,N*-Dimethylaniline | *N*-Methyl-*N*-phenylformamide (78) |
| *N,N*-Diethylaniline | *N*-Ethyl-*N*-phenylacetamide (63) |
| *N,N*-Dimethyldodecylamine | *N,N*-Dimethyldodecanoylamide (30), *N*-dodecyl-*N*-methylformamide (42) |
| *N*-Methyl-*N,N*-dioctylamine | *N*-Methyl-*N*-octyl-octanoylamide (51), *N,N*-dioctylformamide (21) |
| *N,N*-Dimethylbenzylamine | *N,N*-Dimethylbenzamide (70), *N*-benzyl-*N*-methylformamide (7), benzaldehyde (3), benzoic acid (14) |
| *N*-Ethylpiperidine | 1-Ethyl-2-piperidone (72), *N*-acetylpiperidine (13) |

[a] General reaction conditions: 5 mmol amine, 10 mmol benzyl(triethyl)ammonium permanganate in 75 cm$^3$ dichloromethane, 0.5 to 2 d at 0 to 40 °C; isolation of the product: HPLC separation. [b] At 20 °C and 1 equiv. benzyl(triethyl)ammonium permanganate. [c] At 40 °C and 2 equiv. benzyl(triethyl)ammonium permanganate. [d] Additional lower homologs. [e] Mixture of 80% $C_4$-, 20% $C_3$-acids. [f] Mixture of 75% $C_8$-, 20% $C_7$-, and 5% $C_6$-acids.

The formation of the products can be explained (in part analogously to [2]) according to Scheme 1.

The amine *(1)* is oxidized with permanganate to *(2)* or *(3)*. For example, *n*-decylamine reacts (i) *via (2)* to give the imine *(5)*, which with decylamine and after secondary oxidation yields decanoic *N*-decylamide, or (ii) *via (3)* to give the nitrile *(6)*; under milder reaction conditions the former pathway predominates, on more rapid oxidation the latter. Secondary amines furnish the amides *(4)* in yields between 35—50%. Side reactions are markedly reduced in comparison to the oxidation of primary amines; secondary amines give carboxylic acids and esters, presumably by oxidation of the imine *(5)*. Tertiary amines afford the amides *(4)* in 75—98% yield, practically without formation of byproducts. The different CH bonds react with about the following chemoselectivities: benzyl:$CH_2$:$CH_3$ = 24:2:1.



$$R{-}CH_2{-}NR_2' \xrightarrow{MnO_4^{\ominus}} R{-}\overset{OY}{\overset{|}{C}}H{-}NR_2' \xrightarrow{MnO_4^{\ominus}} R\underset{OY}{\overset{OY}{C}}{-}NR_2' \xrightarrow{-Y_2O} R\overset{O}{\overset{\|}{C}}NR_2'$$

$$R{-}CH{=}NR' \qquad R{-}C{\equiv}N$$

R = Phenyl, Alkyl; R' = H, Alkyl; Y = H, $MnO_3H^{\ominus}$

Scheme 1.

There are only few preparatively useful methods for the conversion of secondary and tertiary amines into amides. *N*-Methylamines form formamides on oxidation with oxygen on platinum[3]; *N*-methylanilines are oxidized with manganese dioxide to *N*-phenylformamides, while in anilines with longer-chain alkyl groups one residue is decomposed to formamide[4]. Other oxidizing agents such as benzoyl peroxide[5], bromine[6], *N*-bromosuccinimide[7] lead, similarly to aqueous permanganate solution[2], to aldehydes. Benzyl(triethyl)ammonium permanganate extends these possibilities, in particular, to the oxidation of tertiary amines.

## Topotactic Electron/Proton Transfer Reactions of Transition Metal Complexes with Columnar and Cluster Structures

By *Robert Schöllhorn, Klaus Wagner*, and *Hermann Jonke*[*]

Considerable work has been devoted in recent years to the investigation of reversible topotactic redox reactions, at ambient temperature, of electronically conducting solids with layer, chain and framework structures of the host lattice ma-

---

Gievenbecker Weg 9, D-4400 Münster (Germany)

trix[1]. There are no comparable reports, however, on this type of reaction in the case of molecular solids which is obviously a consequence of low electronic conductivities and of modest lattice energies which usually prevent topotactic processes. Favorable conditions should be expected in case of (*i*) extensive intermolecular delocalization of electrons, *e.g.* *via* charge transfer or metal d-orbital interaction, (*ii*) small guest ion size, *i.e.* minor steric perturbation of the host lattice, and (*iii*) appropriate intracrystalline transport pathways for guest ions with low activation energy. Since protons are the smallest guest ions available, we decided to start a systematic investigation on reversible topotactic electron/proton transfer reactions [eq. (1)] in molecular solids and report here on electrochemical and structural studies of transition metal complexes with metal/metal bonding.

$$xH^+ + xe + Z \rightleftarrows H_x^+[Z]^{x-} \quad (Z = \text{host lattice matrix}) \qquad (1)$$

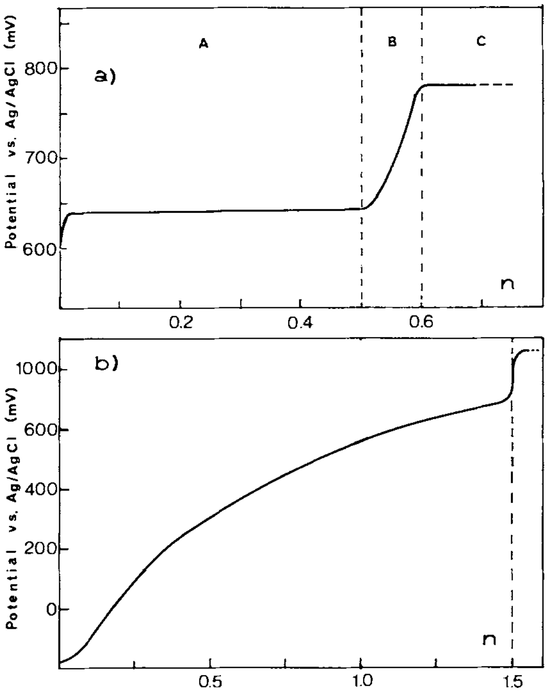

Fig. 1. Potential/charge transfer curve for anodic oxidation of (a) Magnus Green Salt $[Pt(NH_3)_4][PtCl_4]$ in 50% aqueous $H_2SO_4$ electrolyte, $n$ = e/formula unit; (b) $[Ta_6Cl_{14}](H_2O)_8$ in aqueous 1 M HCl/1 M NaCl electrolyte, $n$ = e/formula unit. Current density 100 μA cm$^{-2}$ (see text).

The heterogeneous oxidation of Magnus's Green Salt (MGS) $[Pt(NH_3)_4]^{2+}[PtCl_4]^{2-}$—whose structure is characterized by stacks of planar $PtX_4$ complex ions[2]—has been described by *Tschugajeff*[3]. The crystals obtained on $H_2SO_4/O_2$ oxidation behave as one-dimensional metallic conductors[4]; two different structure models have been proposed suggesting either Pt—Pt chains with coordinated $HSO_4$-ligands[5] or chlorine bridged ··X—Pt—X—Pt·· chain polymers[6]. We observed on galvanostatic anodic oxidation of single crystal or polycrystalline electrodes of MGS in aqueous $H_2SO_4$ electrolyte (40—70 wt-%; 300 K) quantitative oxidation with the formation of bright copper-red needles. The potential/charge transfer curve for this process is given in Fig. 1a. X-Ray studies and analytical investigations showed that the potential plateau of region A corresponds to a two phase region MGS/oxidized product. At low current densities the reaction in the two phase region is fully reversible and MGS is obtained quantitatively on cathodic reduction. The long axes of the crystal needles of the oxidized phase are oriented parallel to the original MGS crystals. Tetragonal symmetry was found with the lattice parameters $a = 946.4$, $c = 572.7$ pm. Charge transfer values, X-ray results and analytical data are consistent with the formula $[Pt(NH_3)_4PtCl_4]^{0.5+}[H_{1.5}SO_4]^{0.5-}(H_2O)_y$. The structure can be described as consisting of partially oxidized MGS type chains with metal/metal bonding and a Pt—Pt distance $d = c/2 = 286$ pm; the excess positive charge of the chain matrix is compensated by hydrated $HSO_4^-$ anions in the interchain space (Fig. 2). Further oxidation (region B, Fig. 1a) corresponds in agreement with the continuous rise in potential to a nonstoichiometric phase region and represents a reversible topotactic redox reaction by electron/proton transfer with very small changes in lattice parameters [eq. (2)]. Since the redox range

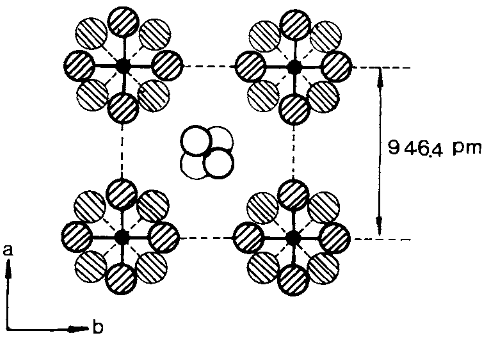

Fig. 2. Structure scheme of tetragonal $[Pt(NH_3)_4PtCl_4]^{0.5+}(H_{1.5}SO_4)^{0.5}(H_2O)_y$ with partially oxidized $PtX_4$ chains and hydrated interchain anions ($H_2O$ molecules not indicated). ● = Pt, ○ = O, ▨ = Cl, ▧ = $NH_3$.

$$\begin{aligned}&[Pt(NH_3)_4PtCl_4]^{0.5+}[H_{1.5}SO_4]^{0.5-}(H_2O)_y \rightleftarrows \\ &[Pt(NH_3)_4PtCl_4]^{(0.5+x)+}[H_{1.5-x}SO_4]^{(0.5+x)-}(H_2O)_y + xH^+ + xe\end{aligned} \qquad (2)$$

corresponds to $0 \leqslant x \leqslant 0.1$, the average oxidation state of Pt in the nonstoichiometric region varies between +2.25 and +2.3. The electron transport path is provided by the Pt metal chain, while hydrogen transport must proceed via the intracrystalline $HSO_4^-/H_2O$ electrolyte phase. A two phase range is found on further oxidation (region C, Fig. 1a), which is presently under investigation. On anodic oxidation of MGS in acid electrolytes with other tetrahedral anions, *e.g.* $HClO_4$, $H_3PO_4$, $HBF_4$, similar reactions and products are observed. The perchlorate compound is isomorphous with the sulfate and undergoes partial dehydration at 300 K/10$^{-3}$ torr; tetragonal lattice parameters of the dehydrated phase are $a = 747.5$, $c = 572.1$, $d$(Pt—Pt) = 286 pm. A series of platinum complexes related to MGS were found to exhibit analogous nonstoichiometric phase ranges on anodic oxidation, *e.g.* *cis*-$PtCl_2(NH_3)_2$ which yields reversibly a sulfate with columnar structure and an intrachain Pt—Pt distance of 295 pm.

Redox and exchange reactions of $M_6$-cluster halides (M *e.g.* Nb, Ta, Mo) are well known from studies in homogeneous solution[7]. We have now found that $Ta_6Cl_{14} \cdot 8H_2O$ is able to undergo reversible oxidation by topotactic electron/proton transfer in the solid state [eq. (3), Fig. 1b]. The structure of this cluster halide consists of $Ta_6Cl_{14} \cdot 4H_2O$ molecular units which are arranged in sheets *via* hydrogen bonding; the remaining four $H_2O$ are located between these layers[8]. The accessible redox range [eq. (3)] of $0 \leqslant x \leqslant 1.5$ is equivalent to a

$$[Ta_6Cl_{14}](H_2O)_8 \rightleftarrows [Ta_6Cl_{14}]^{x+}(OH^-)_x(H_2O)_{8-x} + xe + xH^+ \qquad (3)$$

change in Ta average oxidation state from +2.33 to +2.58. The hexagonal lattice parameters vary between $a=936.7$, $c=2600.5$ pm (reduced state, dark green) and $a=938.0$, $c=2589.6$ pm (fully oxidized state, dark brown). It is assumed for electrostatic reasons that the deprotonation takes place at $H_2O$ molecules coordinated directly to the $Ta_6$-cluster. $Nb_6Cl_{14}\cdot 8H_2O$ electrodes may be oxidized similarly; cathodic reduction is, however, kinetically hindered.

Electrochemical studies on quinoliniumtetracyanoquinodimethane $(QH^+)[(TCNQ)_2]^-$—which behaves as a one-dimensional electronic conductor[9]— revealed reversible electron/proton transfer according to eq. (4) (electrolyte 0.1 N $H_2SO_4/K_2SO_4$, two phase region at 150 mV *vs* Ag/AgCl with $x=2$). The protons are assumed to be bound to the —C≡N groups.

$$(QH^+)[(TCNQ)_2]^- + xH^+ + xe \rightleftarrows (QH^+)(H^+)_x[(TCNQ)_2]^{(1+x)-} \qquad (4)$$

The results presented demonstrate that under appropriate conditions reversible topotactic redox reactions may be observed readily also for molecular inorganic and organic solids which is of interest with respect to synthetic aspects (preparation of novel metastable phases), to the modification of physical properties of molecular solids and to potential technical use of these systems, *e.g.* as electrode materials in secondary batteries, nonemissive electrochromic devices, heterogeneous catalysts *etc.*

## Negative Ion Field Desorption Mass Spectrometry (NFD-MS) of Salts[**]

By *Karl H. Ott, Franz W. Röllgen, Jan J. Zwinselman, Roel H. Fokkens,* and *Nico M. M. Nibbering*[*]

The low field-strength required for field electron emission from metals and semiconductors and secondary effects such as cathode sputtering and gas discharges prevented in the past the development of field desorption mass spectrometry of negative ions (NFD-MS). However, more recently we were able to show that field desorption of negative ions is possible if the samples are admixed with polymers such as polyethylene oxides[1]. The viscous polymers reduce the field strength necessary to desolvate negative ions from the condensed phase below the threshold field strength for field electron emission.

With this method the compound to be investigated and polyethylene oxide 4000 (mixing ratio 1:1) is dissolved in water and deposited onto a 10-μm tungsten wire emitter. Thereafter the wire covered with the mixture is introduced into the FD source of a conventional mass spectrometer. After applying a voltage of −4 kV to the emitter, a mass spectrum of negative ions can be recorded in the usual way by heating the emitter wire.

[a] Very weak signal. [b] Potassium salt of penicillin V. [c] Metanil yellow orange. [d] Novalgin.

We have employed the new ionization method for the analysis of a number of inorganic and organic salts. A selection of the salts together with the characteristic ions observed in the NFD mass spectra are listed in Table 1. The spectra are very simple and do not exhibit fragment ions. The cluster ions which appear at higher salt concentrations and higher emitter temperatures allow the mass of the cation to be determined[2]. Doubly charged anions have not been detected so far. Additional ion signals resulting from fragmentation of the matrix have been observed with fluorides, hydroxides and strong oxidizing agents such as $KMnO_4$.

Comparing the widely used field desorption mass spectrometry of positive ions (FD-MS) with NFD-MS there are a

| $CH_3(CH_2)_{14}CO_2^-$ | 42 | $CH_3(CH_2)_8CO_2^-$ | 20 |
| $CH_3(CH_2)_{12}CO_2^-$ | 48 | $CH_3(CH_2)_6CO_2^-$ | 18 |

few points to be emphasized. 1. The detection sensitivity for anions of salts is significantly higher with NFD-MS; for the analytically important salts of sulfonic acids by at least one order of magnitude (with FD-MS information about the anion is provided by the cluster ions). 2. Without the exchange of cations no useful spectrum is obtained by FD-MS from salts such as $MgSO_4$, $CaCO_3$ and $Ca(CH_3CO_2)_2$. Particularly difficult to analyze are also salts of disulfonic acids such as *(6)*. 3. Anions of salts can selectively be detected from technical and biological mixtures without further preparation. In general this is not possible with FD-MS. As an example the mass spectrum obtained by NFD-MS of a soap containing potassium salts of fatty acids is listed in Table 2. For recording this spectrum it was not necessary to admix polyethylene oxide. The results demonstrate that NFD-MS opens up new possibilities for the analysis of salts.

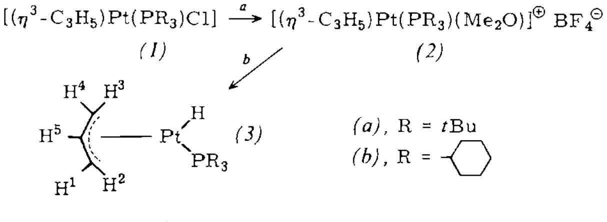
## $\eta^3$-Allyl(hydrido)phosphaneplatinum(II) Complexes

By *Giovanni Carturan, Alberto Scrivanti,* and *Franco Morandini*[*]

We recently reported that allylpalladium(II) complexes are effective catalysts in the selective hydrogenation of dienes to monoolefins[1]; the understanding of the mechanistic facets of this reaction were in part speculative because of the impossibility of detecting the intermediate active species. Within a $d^8$—$d^{10}$ metal system, the process accounting for selective hydrogenation might involve as a fundamental step the equilibrium between allyl (hydrido)-$d^8$ and olefin-$d^{10}$ species. Indeed, this equilibrium, although frequently invoked in a variety of homogeneously catalyzed reactions, has been recognized only for a limited number of organometallic complexes[2,3].

Our current interest prompted us to prepare novel allyl (hydrido)platinum(II) complexes *(3)* as outlined in Scheme 1. Complexes *(1)* react in dimethyl ether with $AgBF_4$ to give the solvated species *(2)*, which on treatment with $NaBH_4$ form complexes *(3)* at −70 °C in good yield. The new complexes have been fully characterized by their $^1H$- and $^{31}P$-NMR spectra (Table 1).



Scheme 1. Synthesis of complexes *(3)*. Reaction conditions: *a)* $AgBF_4$, −40 °C, 6 h, $Me_2O$; *b)* $NaBH_4$, −60 °C, 48 h, THF; after THF evaporation in *vacuo*, *(3)* was extracted with toluene and crystallized by addition of pentane at −70 °C.

In analogy to the allyl(hydro)nickel(II) complexes[2], but at variance with the usual allylplatinum(II) complexes[4], compounds *(3)* display a dynamic behavior in the $^1H$-NMR spectrum even at low temperature. The presence of the strongly electron perturbing action of the hydride ligand may account for this fact; indeed, for compounds *(3)*—as for the nickel complexes—a substantial reduction of the coupling constant $J_{Pt-P}$ (of about 500 Hz) and a general upfield shift of the allylic proton signals with respect to those of the parent chloro complexes *(1)* was observed[4].

Compounds *(3)* are very unstable and decompose above −30 °C with propene evolution, even in the solid state. This instability is expected, for the behavior of alkyl(hydrido)platinum(II) derivatives suggests that the reductive elimination of $CH_2{=}CH{-}CH_2{-}H$ should be favored in allyl(hydrido)platinum(II) complexes[5]. This elimination reaction leads, in the case of allyl(hydrido)-complexes of $d^8$-metals, to extremely labile 14 electron species, a fact upon which the versatility and the large catalytic application of these compounds is based[6].

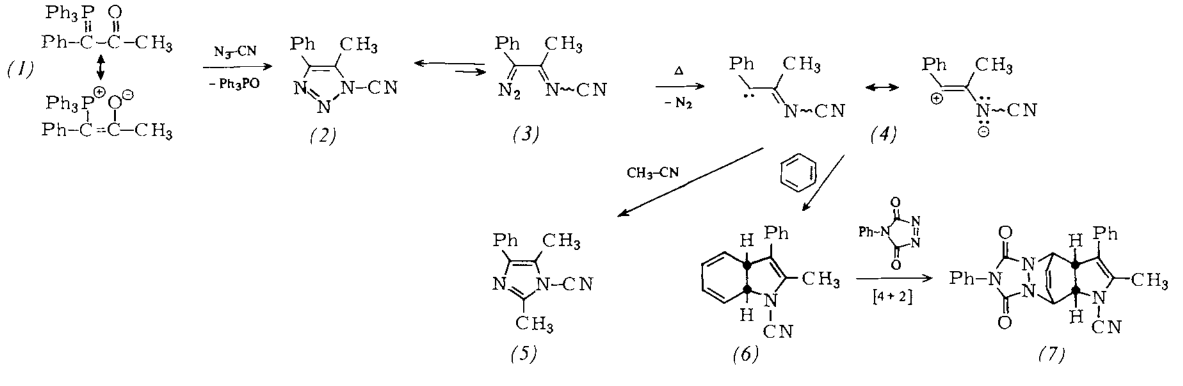
## Pronounced 1,3-Dipolar Cycloaddition Behavior of an α-Cyanimino Carbene[**]

By *Daniel Danion, Bernhard Arnold*, and *Manfred Regitz*[*]

Open-chain α-oxocarbenes such as benzoylmethyl or acetylmethyl carbene readily undergo Wolff rearrangement to ketenes, and only reluctantly undergo 1,3-dipolar cycloadditions—for instance, with acetonitrile—the yields of which are minimal and can be increased to a maximum of 17% only by addition of copper or copper compounds[1]. By way of contrast the α-cyanimino carbene *(4)* shows a pronounced readiness to undergo such cycloadditions.

A suitable starting material for the generation of *(4)* is the triazole-1-carbonitrile *(2)*, obtained in 90% yield by reaction of the methylenephosphorane *(1)* with cyanazide in dichloromethane/acetonitrile at 20 °C with concomitant formation of triphenylphosphane oxide [m.p. 140 °C; IR (KBr): $\nu_{C\equiv N} = 2260\ cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 2.65$ ($CH_3$)][2]. In spite of the pronounced tendency of 1,2,3-triazole-1-carbonitrile to undergo ring-opening[2], no α-diazoimine *(3)* can be detected alongside *(2)* in the equilibrium (no $C=N_2$ absorption in the IR spectrum ($CDCl_3$) at 20 °C); nevertheless, *(4)* is presumably formed under thermal conditions *via* a small equilibrium concentration of *(3)*.



When a solution of *(2)* in acetonitrile is heated under reflux for 10 h, 2,5-dimethyl-4-phenylimidazole-1-carbonitrile *(5)* is formed by [3+2]-cycloaddition of *(4)* to the solvent [yield 75%; m.p. 158 °C; IR (KBr): $\nu_{C\equiv N} = 2222\ cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 2.48, 2.58$ (each $CH_3$)]; the nitrile group in *(5)* can be readily cleaved by treatment with potassium hydroxide in ethanol[3]. *(4)* even adds to benzene (12 h reflux) with formation of 2-methyl-3-phenyl-3a,7a-dihydroindole-1-carbonitrile *(6)* as the sole reaction product [yield 80% m.p. 93 °C; IR (KBr): $\nu_{C\equiv N} = 2219$, $\nu_{C=C} = 1662\ cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 4.18$ (broad d, $^3J_{H\text{-}3a,H\text{-}7a} = 14.5$ Hz, H-7a), 4.90 (dd, $^3J_{H\text{-}3a,H\text{-}7a} = 14.5$ Hz, $^3J_{H\text{-}7,H\text{-}3a} = 4$ Hz, H-3a), 5.50, 6.18 (each m, H-4, H-7), 5.85 (m, H-5/H-6)][4].

As a 1,3-diene, *(6)* reacts with 1-phenyl-1,3,4-triazoline-2,5-dione (dichloromethane, 20 °C) in a [4+2]-cycloaddition to give *(7)* (m.p. 268 °C) in 86% yield. On heating with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in benzene *(6)* is dehydrogenated to 2-methyl-3-phenylindole-1-carbonitrile (yield 70%; 89 °C); $^1H$-NMR ($CDCl_3$): $\delta = 2.54$ ($CH_3$), 7.0—7.6 (aromatic H).

The ketenimine rearrangement of *(4)* involving a 1,2-methyl shift[5], which is observed alongside OH insertion (ratio 25:75) in the photochemical decomposition of *(2)* in methanol, does not occur in the presence of the dipolarophile.

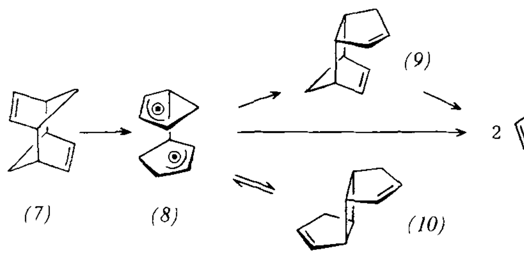
*(6)*, M.p. = 133 °C; $^1$H-NMR: $\delta = 5.94$ (s, 2H), 2.97 (s, 2H), 2.87 (m, 2H), 2.48 (m, 2H), 2.0—1.0 (m, 6H); MS: $m/e = 348$ ($M^+$), 216 ($C_6H_2Cl_4^+$), 132 ($C_{10}H_{12}^+$), 106 ($C_8H_{10}^+$), 91 ($C_7H_7^+$), 78 ($C_6H_6^+$), 66 ($C_5H_6^+$, 100%); UV (dioxane): $\lambda_{max} = 272$ ($\varepsilon = 2700$) sh, 287 (4000) sh, 297 (4800), 310 (4100) sh, 327 nm (1600) sh

*(7)*, M.p. = 135 °C in fused glass capilliary tube; $^1$H-NMR: $\delta = 6.08$ (s, 4H), 2.12 (m, 4H), 1.83 (AB, $\Delta\nu = 22.3$ Hz, $J = 9.0$ Hz, part B further split); $^{13}$C-NMR: $\delta = 134.81$ (C-3,4,7,8), 47.36 (C-9,10), 36.56 (C-1,2,5,6); MS: $m/e = 132$ ($M^+$, 3%), 66 ($C_5H_6^+$, 100%); UV (hexane): $\lambda_{max} = 211$ nm ($\varepsilon = 4500$); PE: 8.2, 9.8 eV

The *syn* alcohol *(1b)*, obtained by reduction of *(1a)* by diisobutylalane in dichloromethane, is transformed by treatment with methanesulfonyl chloride in ether/triethylamine into the ester *(1c)* (m.p. = 99 °C) in 82% yield; *(1c)* is then reduced to the hydrocarbon *(2)* (44%, for physical data see Table 1) by sodium in liquid $NH_3$/THF. Reaction of *(2)* with dichlorodicyano-*p*-benzoquinone in boiling $CCl_4$ gives *(3)* (55%), which in ether solution cyclizes to the four-membered ring compound *(4)* in 72% yield when photolyzed at 0 °C (Hanau Hg low-pressure lamp NK 6/20) through quartz. The assignment of the *exo* configuration to the photoproduct *(4)* follows from the absence of coupling between the aliphatic protons of the four-membered ring and the bridgehead protons, and from the small change in the chemical shift difference ($\Delta\delta = 1.06$ ppm) between the methylene protons of the norbornene part in going from *(3)* to *(4)*. The cyclobutene ring in *(4)* is degraded using the method of *Warrener et al.*[3], by first forming the cycloadduct *(5)* (74%)[4] with *o*-chloranil in $CCl_4$ (70 °C). Irradiation of a solution of *(5)* in dichloromethane with an incandescent lamp (Osram Bellaphot, 400 W) through Solidex gives the *bis* decarbonylated product *(6)* (69%). Compound *(6)* dissociates into a mixture of *anti*-tricyclo[4.2.1.1$^{2,5}$]deca-3,7-diene *(7)* and tetrachlorobenzene when photolyzed under similar conditions using a Hg high-pressure lamp (Philips HPK 125)[5]. The title compound *(7)* is separated from tetrachlorobenzene by column chromatography (silica gel, pentane) and from residual eluent by gas chromatography (10% DEGS, 0.5 m, 30 °C); it forms colorless crystals (38%) which have a high vapor pressure and a penetrating smell.

The PE spectrum of *(7)* is characterized by two broad bands of equal intensity at 8.2 and 9.8 eV; the large splitting ($\Delta IP = 1.6$ eV) of the vertical π-ionization potential is caused by the strong interaction between the double bonds and the central single bonds[6a]. This same electronic effect also manifests itself in the UV spectrum of *(7)*, the absorption maximum of which occurs at $\lambda = 211$ nm ($\varepsilon = 4500$); an unusually long wavelength for an unconjugated diene[6b].

The [4+4]-dicyclopentadiene *(7)* dissociates to the monomer at 180 °C by a [4+4]retrocyclization, which according to the rules of conservation of orbital symmetry[7] must proceed *via* the diradical *(8)*. Its intermediary is indeed indicated by small amounts of *endo*-[2+4]-dicyclopentadiene *(9)* and *anti-cis*-[2+2]-dicyclopentadiene *(10)*, products of recyclization, which under the reaction conditions also dissociate to the monomer[9,10].



The thermal behaviour of *anti*-[4+4]-dicyclopentadiene differs significantly from that of the *syn* stereoisomer[1], which at 58 °C forms *syn-cis*-[2+2]-dicyclopentadiene *via* a synchronous Cope rearrangement without giving the products of a radical process.

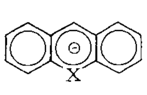
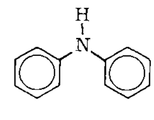
## Generation and NMR Spectroscopic Investigation of Diheteroanthracenide Ions: Stable 4nπ Systems[**]

By *A. G. Anastassiou, H. S. Kasmai,* and *M. R. Saadein*[*]

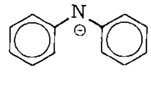
The three potentially antiaromatic 4*n*π systems *(1a)*—*(1c)* were recently prepared and analyzed (NMR) in our laboratories[1] to reveal, at least in the case of the first-row variants *(1a)*[1a] and *(1b)*[1b], the presence of well-developed molecular paratropicity. In an effort to assess the possible effect that increased π-frame electronegativity may have on the magnitude and/or nature of this ring current effect we next focussed our attention on a group of direct diheteroatomic relatives of *(1)*, namely the amide ions *(5)* and wish to briefly elaborate on our findings in the area.



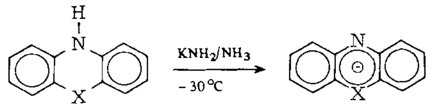
*(1)*



*(2)*



*(3)*



*(4)* → *(5)*

*(a)*, X = NMe
*(b)*, X = O
*(c)*, X = S

The desired diheteroanthracenide ions *(5a)*—*(5c)* were prepared as deeply colored, thermally stable solutions[2] by deprotonation of the amines *(4a)*—*(4c)* with $KNH_2$ in $NH_3$ at *ca.* −30 °C. For purposes of direct comparison the $^1$H-NMR spectra of the *N*-methyl-5,10-dihydrophenazine anion *(5a)* and phenooxazine anion *(5b)* are reproduced in Figure 1. As expected, the $^1$H-NMR spectrum of the phenothiazine anion *(5c)* is similarly patterned [δ = 5.7—6.2 (m, 6 H), 6.41 (dt, 2 H)], while that of the diphenylamide ion *(3)* is markedly different [δ = 6.0—6.4 (m, 2 H) and 6.7—7.1 (m, 8 H)]. The $^{13}$C-NMR data of the compounds described are collected in Table 1.

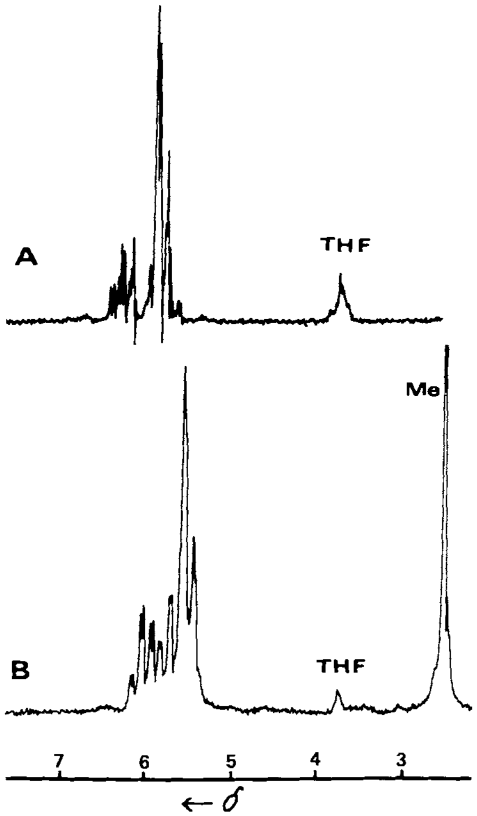


Fig. 1. 60-MHz $^1$H-NMR spectrum (A) of the phenoxazene anion *(5b)* and (B) of the N-methyl-9,10-dihydrophenazine anion *(5a)* in liquid ammonia (THF as internal standard) at *ca.* 34 °C.

Table 1. $^{13}$C-NMR data [a] of compounds *(2)*, *(3)*, *(4b)*, *(4c)*, *(5a)*—*(5c)*. The instability of 5,10-dihydrophenazine *(4a)* in liquid ammonia precludes the recording of a $^{13}$C-NMR spectrum.

| Cpd. | Chemical Shift [b]<br>tert. C-atoms | <br>quat. C-atoms |
|---|---|---|
| *(5a)* [c] | 40.51, 45.15, 45.74, 55.25 | 72.99, 86.62 [d] |
| *(5b)* | 44.02, 44.99, 48.31, 57.09 | 80.28, 82.72 [d] |
| *(5c)* | 47.00, 50.55, 57.74, 60.35 | 49.27, 89.05 [d] |
| *(4b)* | 46.49, 48.47, 53.48, 57.04 | 76.86, 66.64 |
| *(4c)* | 46.77, 54.20, 58.92, 59.96 | 49.75, 75.66 |
| *(2)* | 50.63, 53.11, 62.46 | 77.78 |
| *(3)* | 43.57, 50.86, 62.00 | 91.62 |

[a] The spectra were recorded at 60 MHz and *ca.* 30 °C in liquid ammonia containing *ca.* $10^{-1}$ cm$^3$ [D$_8$]tetrahydrofuran as standard. [b] δ values, referred to the central signal of the low-field multiplet of [D$_8$]THF ($\delta_{TMS} = -67.9$). [c] δ = −36.33 ($CH_3$). [d] C-9a.

Direct comparison of the $^1$H-NMR data of the anions *(5)* with those of the conjugate acids *(4)*, all of which exhibit bands in a region (δ = 6.5—7.0) normally reserved for mesomerically enriched benzenoid moieties, clearly reveals the "4*n*"-π diheteroanions *(5)* to be endowed with elements of molecular paratropicity. Additionally, internal comparison along these lines between *(5a)*, *(5b)*, and *(5c)* appears to establish the magnitude of the induced ring current to be largest in the former and smallest in the latter[3]. Interestingly, this interpretation gains credence from an analysis of the $^{13}$C-NMR data (Table 1) which appears to also offer a reasonable explanation as to why sulfur is less effective than either oxygen or nitrogen (NMe) in contributing its lone pair to the development of π delocalization in *(5)*. Specifically, one notes that whereas the signals of the tertiary carbons of

*(5)* appear at increasingly high field on passing from *(5c)* to *(5b)* to *(5a)*, as required for increased $\pi$ participation of the system's two heteroatomic lone pairs, the degree of *overall* delocalization of the nitrogen-centered negative charge as assessed by the increasingly *downfield* shift of the directly adjacent quaternary carbon unit, *i. e.*, C-9a[4], is seen to implicate the existence of an alternate sequence namely *(5b)* ($\delta = 82.72$) < *(5a)* ($\delta = 86.62$) < *(5c)* ($\delta = 89.05$)!

We are thus faced with an interesting situation whereby the effectiveness of X in mobilizing the nitrogen-centered negative charge increases in the order S < O < NMe for extended delocalization into the benzenoid moieties and in the order O < NMe < S for *overall* but spacially limited participation. This apparent discrepancy, which was recently also shown to obtain in the case of the related monoheterocarbanions *(1)*[1], is best reasoned by the second-row nature of sulfur and its consequent ability to stabilize an adjacent negative charge be it inductively or *via* direct expansion of its "octet".

Finally, it is notable that whereas the data presented in this report relating to the "benzenoid" chemical shifts of *(5)* clearly implicate, at least in the case of the diaza derivative *(5a)*, the presence of a substantially delocalized distinctly paratropic molecular periphery, the effect does not appear to be as extensive as was recently observed with the monohetero carbanionic relatives *(1)*[1]. For obvious reasons the increased electronegativity of the negatively charged center on passing from *(1)* to *(5)* is believed to account for much of the observed differences.

[2] The sample remained qualitatively and quantitatively unchanged (NMR) after 10 h exposure to ambient temperature.

[3] The centers of both major and minor absorption manifolds consistently undergo 0.2 to 0.25 ppm upfield shifts on passing from *(5c)* to *(5b)* to *(5a)*.

[4] An increase in the degree of amide ion delocalization ought to enhance the double bond character of the link connecting $-\overset{\ominus}{N}-$ to C-9a with consequent deshielding of the carbon center. Hence one's expectation that increased amide ion delocalization should lead to a downfield shift of the C-9a resonance.

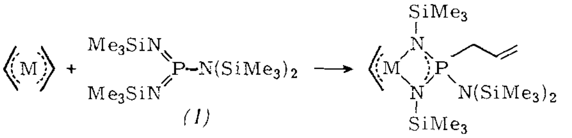
## Novel Nickel- and Palladium-Complexes with Aminobis(imino)phosphorane Ligands for the Polymerization of Ethylene[**]

By *Wilhelm Keim, Rolf Appel, Arnold Storeck, Carl Krüger*, and *Richard Goddard*[*]

Few investigations have been carried out on the influence of chelate ligands in homogeneous catalysis with transition metal compounds. As we discovered earlier, remarkable stereoselective effects can be achieved with bidentate ligands[1]. We report here on novel nickel- and palladium-complexes containing an aminobis(imino)phosphorane as chelate ligand.

The *in-situ* reaction of bis(1,5-cyclooctadiene)nickel or bis($\eta^3$-allyl)nickel with the aminobis(imino)phosphorane *(1)* in toluene yields a catalyst which polymerizes ethylene to polyethylene at 70 °C and 50 bar. Activities of 1000 mol ethylene per mol of nickel are achieved. The physical properties of the short-chain branched polymer lie between those of high-pressure polyethylene and "EPDM". Catalysts of this type are of interest because of their potential for the production of high-pressure polyethylenes.

In the stoichiometric reaction of bis($\eta^3$-allyl)nickel with *(1)* we isolated the complex *(2)*, whose structure followed from spectroscopic data ($^1$H-, $^{13}$C-, and $^{31}$P-NMR, IR), the mass spectrum ($M^+$ with the expected isotopic ratio) and the comparison of these data with those of the analogous palladium compound *(3)*. The formation of *(2)* proceeds *via* an unexpected allyl rearrangement, which leads to a P-bonded $\sigma$-allyl group.



*(2)*, M = Ni; *(3)*, M = Pd

The complex *(2)* contains a four-membered ring made up of two nitrogen atoms, the nickel atom, and the phosphorus atom. Four-membered rings of aminobis(imino)phosphoranes are well known[2], but so far not in combination with transition metals. With respect to electron distribution and bonding there exist resemblances to the phosphoniobis(methanide) derivatives described by *Schmidbaur*[3]. A sulfur analog of *(1)* could recently be complexed as "P=S side-on" ligand to platinum[4].

In analogy to the synthesis of *(2)* we also reacted bis($\eta^3$-allyl)palladium with *(1)* to give the remarkably stable complex

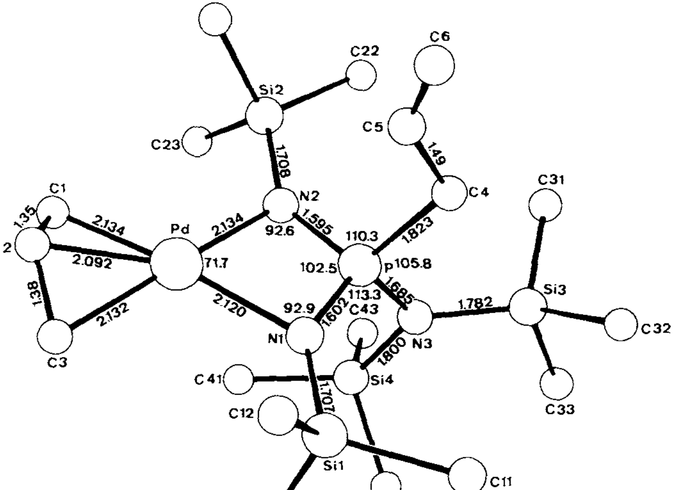


Fig. 1 Molecular structure of complex *(3)* in the crystal. Cell data: $a = 9.174$ (1), $b = 17.745$ (2), $c = 18.900$ (2) Å, $\beta = 104.610$ (7)°, space group $P2_1/c$, $Z = 4$ with $\rho_{calc} = 1.24$ gcm$^{-3}$, $R = 0.037$, $R_w = 0.04$.

*(3)*. The $^1H$-, $^{13}C$-, and $^{31}P$-NMR spectra as well as the IR spectrum corresponded to those of *(2)*. The mass spectrum shows the molecular ion with the expected ratio of isotopes.

A crystal structure analysis was carried out on *(3)* (Fig. 1). The primary skeleton of the molecule is characterized by its near $C_s$(m) symmetry, the mirror plane running through N3, P, Pd and C2 perpendicular to a planar ($\pm 0.03$ Å) four-membered ring formed from Pd, P, N1 and N2. Only the arrangement of the trimethylsilyl groups at N1 and N2 do not correspond to this symmetry. The terminal atom C6 of the allyl group is disordered. The phosphorus atom has approximate tetrahedral configuration. Like the Si—N bonds the P—N bonds are of varying length. Thus, in the strained four-membered ring[5] we find on average P—N = 1.598 Å, and thus high multibonding character. The length of the exocyclic P—N bond (1.685 Å) in comparison with the sum of the covalent radii of the two atoms (1.84 Å) is likewise indicative of multibonding character, albeit to a lesser extent. As complex ligand the R—N—$PR_2$—N—R group, like the isoelectronic phosphoniobis(methide) group ($H_2C$—$PR_2$—$CH_2$)[6], is to be regarded as a three-electron donor with analogous geometry and bonding. Thus a 15-electron configuration is present at the central palladium, like in the educt bis($\eta^3$-allyl)palladium.

The palladium complex *(3)* cannot catalyze the polymerization of ethylene. Dry *(3)* is air-stable for several days at room temperature, but decomposes within hours at 50 °C.

### *Procedure*

All operations must be carried out under argon.

*(2)*: A solution of *(1)*[8] (6.8 g, 0.019 mol) in toluene (15 $cm^3$) was added dropwise within 30 min at −78 °C to a stirred suspension of bis($\eta^3$-allyl)nickel[7] (2.5 g, 0.018 mol) in toluene (10 $cm^3$). A reddish brown solution was formed. After standing for several days at −78 °C, red-brown crystals separated out (1.17 g); on concentration of the mother-liquor and addition of a small amount of dichloromethane a further 3.1 g could be isolated. Total yield 4.27 g (47%) of *(2)*, m.p. 135 °C (dec.).

*(3)*: *(1)* (5.5 g, 0.015 mol) was added dropwise within 3 min at −20 °C into a solution of bis($\eta^3$-allyl)palladium[9] (2.8 g, 0.015 ml) in toluene (20 $cm^3$). After *ca.* 12 hours' stirring at room temperature the solvent was removed in an oil-pump vacuum and the residue taken up in 10 ml dichloromethane: Yellowish-green crystals precipitated at −15 °C. Yield: 3.53 g (43%) *(3)*, m.p. 95—96 °C (dec.).

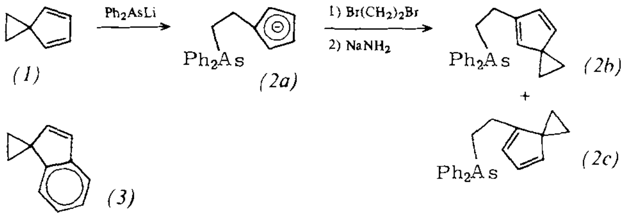
## Synthesis of Multielectron Ligands for Transition Metals *via* Spiro[cyclopropane-1,1′-indene][**]

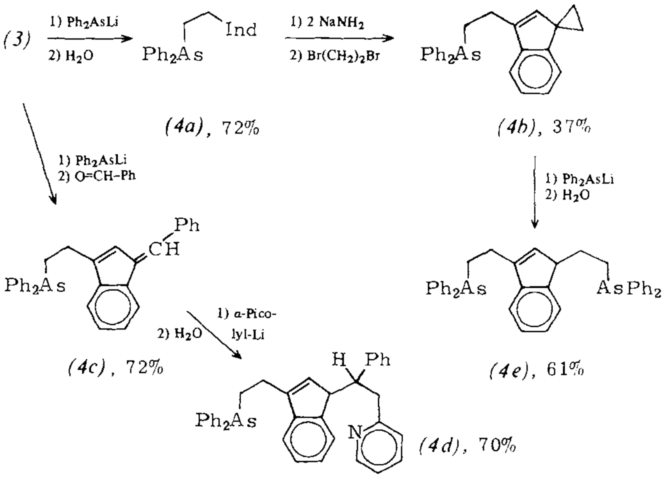
By *Karlheinz Berghus, Angelika Hamsen, Alfons Rensing, Annegret Woltermann* and *Thomas Kauffmann*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

We have recently shown that spiro[2.4]hepta-4,6-diene *(1)* is highly suitable for the synthesis of multielectron ligands for transition metals[1]. As anticipated, analogous ligands *e.g.* *(4a)*, *(5a)*, *(6a)*, and *(6b)* (Ind = 3-indenyl) can be prepared from spiro[cyclopropane-1,1′-indene] *(3)* by similar transformations[2].



Attempts to extend the donor capability of the compounds obtained by addition of a cyclopentadienyl- or indenyl group as five-electron donor[3] demonstrated the expected superiority of indene derivatives for this purpose. Thus, while the reaction of *(2a)*[1] with 1,2-dibromoethane and sodamide led to an (as yet) inseparable mixture of the isomers *(2b)* and *(2c)*, the corresponding reaction of the indene derivative *(4a)*→*(4b)* and the comparable reactions *(3)*→*(4c)* and *(5a)*→*(5b)* gave single products.



*(4b)* and *(4c)* were coupled with a further 2-electron donor group and by this means the potential 9-electron ligands *(4e)* and *(4d)*[4] respectively, were obtained.

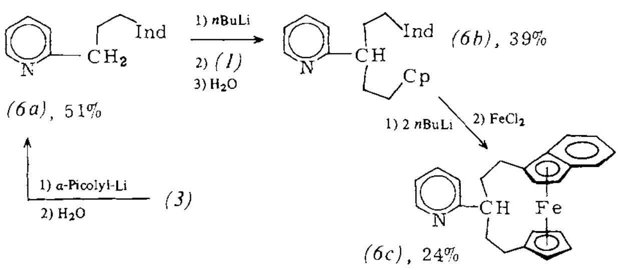
| *(6c)* | $n_D^{20}$ = 1.6434 | in C$_6$D$_6$: 2.0—2.7 (m; 8 H, CH$_2$—CH$_2$), 2.95 (m; 2 H [Cp]), 3.7 (mc; 1 H [Cp]), 3.98 (d; 1 H [Ind]), 4.4 (mc; 1 H [Cp]), 4.5—4.8 (m; 1 H, CH—), 4.85 (d; 1 H [Ind]), 6.65—7.6 (m; 7 H, aromatic H), 8.6 (m; 1 H, N—CH) | 381 (47%, *M*$^+$), 276 (14), 142 (6), 115 (11), 106 (9), 84 (100) |

The ligands with the indenyl group have the distinctive feature, not shown by the cyclopentadienyl analogues, that they endow their transition metal complexes with chirality; the stable iron complex *(6c)*[4] was prepared by us and illustrates this capability. This feature could be useful in the development of asymmetric homogeneous catalysts.



The structures of the products have been determined by mass- and NMR-spectroscopy and elemental analysis (see Table 1).

[2] In the absence of synthetic details [*S. W. Staley, M. A. Fox, T. K. Hirzel,* J. Am. Chem. Soc. *98*, 3910 (1976)] we obtained a 58% yield by reacting a solution of indene in THF with 2 equivalents NaNH$_2$ and 1 equivalent 1,2-dibromoethane.

[3] Conventional count of electrons in donor ligand with transition metals.

[4] The position of the CC double bond in the five-membered ring of the indene residue of *(4d)* is not clear. The compound *(6b)* consists of a mixture of the isomers with Cp = 1,3- or 1,4-cyclopentadienyl respectively. It should be possible to separate *(6c)* into two diastereomers, but to date this has been unsuccessful.

## Crown Arsanes; Air-Stable Multielectron Ligands for Transition Metals[**]

By *Johann Ennen* and *Thomas Kauffmann*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Many of the transition metal reagents and catalysts used in organic synthesis contain ligands which do not participate directly in the reaction ("passive ligands"[2]) and which are often not optimal (low stability of bonding to the metal, easily attacked by nucleophiles, or toxic ligands such as CO or NO). We have therefore synthesized polydentate multi, electron ligands[1,2] and now wish to describe macrocyclic polyarsanes. These "crown arsanes" are air stable and are therefore considerably easier to handle and store than the highly air sensitive macrocyclic polyphosphanes[3]. Both types of compounds suffer from the disadvantage however that the isolation of pure chiral products is difficult. To our knowledge crown arsanes were not known[4], although open chain polyarsanes have already frequently been used to complex with transition metal elements.

The starting materials *(1)*, *(2)*, *(3)*, and *(4)*, which are not described in the literature, were synthesized (reactions were

carried out in THF at 20 °C unless otherwise stated)[5]. Of these, only the electrophiles *(1)* and *(3)* were isolated [*(3)*; yield 25% relative to *(1)*]. In this connection it was advantageous that the arsane group reacted with alkyl halides much less readily than the phosphane group.

Using the principle of dilution (all reactions carried out at 20 °C in THF) oily fractions of the crown arsanes *(5)—(7)*[6] were obtained from the starting materials and were cleaned by passing through a chromatographic column (SiO$_2$: diethylether/pet. ether 1:20) and isolated by chromatography. Stereoisomeric mixtures were obtained; this also applied to *(3)*.

## Alkyl(dicyclopentadienyl)lutetium Complexes: Monomeric Alkyllanthanoid Derivatives[**]

By *Herbert Schumann, Wolfgang Genthe*, and
*Norbert Bruncks*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Alkyl derivatives of lanthanoids of low coordination number are very unstable. Hitherto, the isolation of such derivatives at room temperature could be accomplished only with sterically very demanding alkyl groups, with possible association *via* basic ligands or with formation of multinuclear electron-deficient compounds[1]. According to X-ray structure analysis the cyclopentadienyl(methyl)lanthanoid derivatives[2] first described in 1975 are dimeric with CH$_3$ bridges between two lanthanoid atoms[3].

We have now found that dicyclopentadienyllutetium chloride reacts with organolithium compounds in tetrahydrofuran at −78 °C to give monomeric alkyl(dicyclopentadienyl)lutetium derivatives, some of which are remarkably thermostable. Whereas the methyl, ethyl and *n*-butyl derivatives can be detected only NMR spectroscopically in benzene at room temperature as 1:1 complexes with tetrahydrofuran (THF) we have been able to isolate corresponding compounds with larger alkyl or aryl ligands as colorless to pale yellow needles which are stable up to 100 °C (Table 1).

$$(C_5H_5)_2LuCl + LiR \xrightarrow[-78\,^\circ C]{THF} (C_5H_5)_2LuR \cdot THF + LiCl$$

*(1a)—(1h)*

The X-ray structure analysis of the trimethylsilylmethyl derivative *(1f)* (Fig. 1) shows that the lutetium is surrounded by a distorted tetrahedral array of the methylene carbon C1, the oxygen of the THF, and the centers of the two cyclopentadienyl ligands. The distance between lutetium and C1 is only about 11 pm shorter than the Yb—C distance in dimeric dicyclopentadienyl(methyl)ytterbium, in which the methyl group bridges two ytterbium atoms[3]. The surprisingly large bond angle of 131 °C at C1 is determined by the spatial requirement of the trimethylsilyl group bound to the same C-atom, and the cyclopentadienyl and THF ligands around the lutetium.

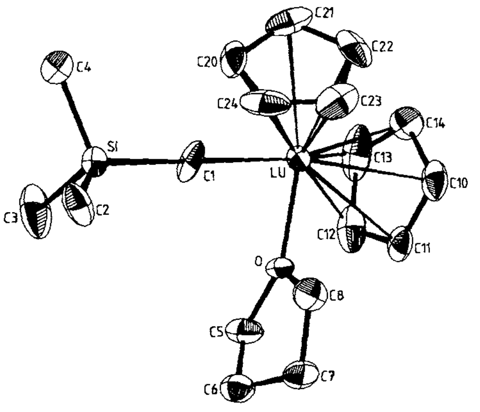

Fig. 1. Structure of $(C_5H_5)_2LuCH_2Si(CH_3)_3 \cdot THF$ *(1f)*; orthorhombic, space group $P2_12_12_1$, $Z = 4$, $a = 1738.1(8)$, $b = 1226.8(3)$, $c = 917.0(3)$ pm, $V = 1.955 \times 10^9$ pm$^3$, $\rho_c = 1.58$ g/cm$^3$; 2735 independent reflections; Syntex $P2_1$ four-circle diffractometer $R = 0.058$. Important bond lengths and angles: Lu—C1 238, Lu—O 229, Lu—RingI 235, Lu—RingII 234, Si—C1 183 pm; Lu—C1—Si 131, C1—Lu—O 96, O—Lu—RingI 106, RingI—Lu—RingII 130, RingII—Lu—C1 111, O—Lu—RingII 104, RingI—Lu—C1 105°.

The new compounds *(1a)—(1h)* are extremely sensitive towards moisture and oxygen. On hydrolysis all the ligands are removed from the lutetium with formation of $Lu(OH)_3$. *(1f)* forms stoichiometric amounts of cyclopentadiene, tetramethylsilane and THF. With $I_2$, on the other hand, only the alkyl moiety is removed; reaction of *(1f)* and $I_2$ leads to $(C_5H_5)_2LuI \cdot THF$ and $(CH_3)_3SiCH_2I$. In the thermolysis of *(1e)* and *(1f)*, which commences at 100 °C, THF is first removed and then at 130 °C [*(1e)*] or 180 °C [*(1f)*] the alkyl residue; *(1e)* yields, *via* β-elimination, isobutane and isobutylene in equimolar amounts, whereas tetramethylsilane is formed from *(1f)*. Above 300 °C the remaining $(C_5H_5)_2Lu$ fragments comproportionate with formation of $(C_5H_5)_3Lu$ which sublimes at this temperature.

### *Procedure*

A solution of $LuCl_3$ (3.3 g, 11.8 mmol) in THF (50 cm$^3$) is treated at room temperature with 9.5 cm$^3$ of a 2.58 M solution of $NaC_5H_5$ in THF and the mixture stirred for 1 h. After cooling to −78 °C, 16 cm$^3$ of a 0.756 M solution of $LiCH_2Si(CH_3)_3$ in pentane is added dropwise and the reaction mixture stirred for 2 h at −78 °C and 6 h at 25 °C. The solvent is removed and the residue dried at room temperature and extracted with toluene (3 × 200 cm$^3$). The residue is dissolved in pentane/diethyl ether (20:1) and cooled within 2 days to −30 °C; yield 4.4 g (81%) yellow needles.

[**] Organometallic Compounds of the Lanthanoids, Part 9. This work was supported by the Fonds der Chemischen Industrie and by the Senator für Wirtschaft des Landes Berlin (ERP grant, Project 2327).—Part 8: [5].

thesizing peralkylated lanthanoid complexes[1]. However, the extreme sensitivity of the isolated permethylated erbium and lutetium complexes *(1)* and *(2)*, and the fact that interpretable $^1$H-NMR spectra could only be obtained for the diamagnetic lutetium compound, have so far precluded concrete data on the structure being obtained.

We report here on the X-ray structure analysis of the title compound *(1)*. Single crystals were obtained by slowly cooling a solution of *(1)* in diethyl ether to −30 °C under argon.

The structure analysis shows that lanthanoids can form organometallic compounds in which all coordination sites on the metal are occupied by carbon atoms of *monohapto*-bonded alkyl groups. In the crystal the erbium is surrounded by the 6 methyl groups in a slightly distorted octahedral arrangement. All the Er—C bonds are of equal length, and the methyl groups are bridged pairwise by lithium atoms, resulting in a slight widening of the corresponding Me—Er—Me angles to 93°. The lithium atoms are each located at the centers of tetrahedra made up of two methyl groups and the two nitrogen atoms of a tmen ligand. Thus, an octahedron results that is coupled *via* three corners, which are not linked with each other, to three tetrahedra (Fig. 1). Since both N atoms of a tmen group are coordinated to a lithium atom, *(1)* is monomeric in the crystal. By way of contrast the bidentate dioxane ligands in $[Li(dioxane)]_3[Cr(CH_3)_6]$ function as bridges between two hexamethylchromium units[2].

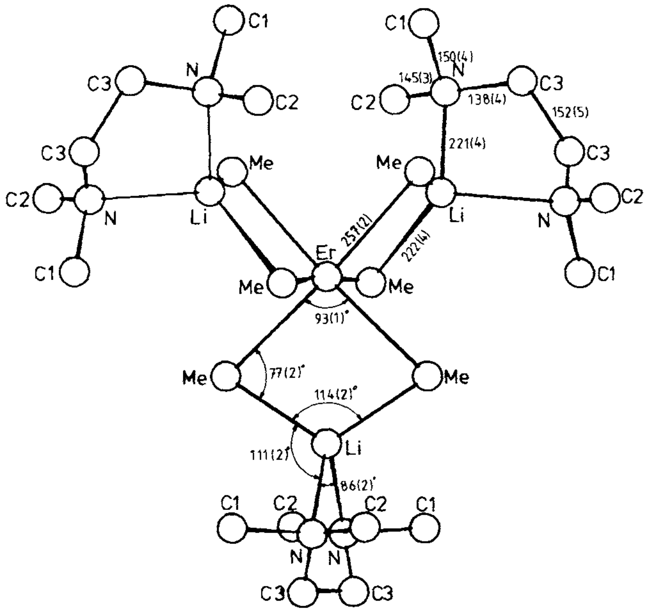

Fig. 1. Structure of $[Li(CH_3)_2NCH_2CH_2N(CH_3)_2]_3[Er(CH_3)_6]$ *(1)*; rhombohedral, space group $R\bar{3}c$, $Z=2$, $a=1309(2)$ pm, $\alpha=79.39(10)°$, $V=2.139\times10^9$ pm$^3$, $\rho_c=0.97$ g/cm$^3$, $l_{pykn}=0.91$ g/cm$^3$; $R=0.085$. Syntex-P2$_1$ four-circle diffractometer; bond lengths in pm.

The bond angles at the lanthanoid as well as the Er—C bond lengths in *(1)*, the first electron-deficient compound with methyl bridges between lithium and a lanthanoid, are comparable with those in electron-deficient compounds with other metal atoms. Thus, the dimeric $[(\eta^5\text{-}C_5H_5)_2YbCH_3]_2$, which contains a $Yb_2(CH_3)_2$ four-membered ring, also possesses an angle of 93° at the ytterbium atom[3]. The bond lengths $d(Yb—C)=254$ pm in $[(\eta^5\text{-}C_5H_5)_2YbCH_3]_2$[3] and $d(Yb—C)=253$ pm in $(\eta^5\text{-}C_5H_5)_2Yb(CH_3)_2Al(CH_3)_2$[4], two further lanthanoid derivatives with electron deficient bonds, correspond to the Er—C bond length of 257 pm. In contrast, the lanthanoid-C distance is shortened if the alkyl group has no bridging function: in $(\eta^5\text{-}C_5H_5)_2LuCH_2Si(CH_3)_3\cdot THF$[5], $d(Lu—C)=238$ pm.

In order to test the validity of this structural principle in the series of the hexamethyl complexes of the lanthanoids, we prepared the complexes *(3)*—*(7)* in the same way as *(1)* and *(2)*.

$$MCl_3 + 6\,LiCH_3 + 3\,tmen \xrightarrow[-78\,°C]{Et_2O} \underset{(1)—(7)}{[Li(tmen)]_3[M(CH_3)_6]} + 3\,LiCl$$

$tmen = (CH_3)_2NCH_2CH_2N(CH_3)_2$

| Cpd. | M | Color | Thermal behavior | |
|---|---|---|---|---|
| *(3)* | Pr | green | dec. pt. | 59—62 °C |
| *(4)* | Nd | blue | dec. pt. | 78—83 °C |
| *(5)* | Sm | yellow | dec. pt. | 85—88 °C |
| *(1)* [1] | Er | pink | m.p. | 138—139 °C |
| *(6)* | Tm | white | m.p. | 109—114 °C |
| *(7)* | Yb | white | m.p. | 141—142 °C |
| *(2)* [1] | Lu | white | m.p. | 141—142 °C |

The compounds *(1)*—*(7)*, which have been completely characterized by elemental analyses, are extremely sensitive towards moisture and atmospheric oxygen; some of them even ignite spontaneously. A notable feature is the enhanced thermal stability of the complexes with increasing atomic weight of the lanthanoid.

## Structure of the Antibiotic Moenomycin A[**]

By *Peter Welzel, Franz-Josef Witteler, Dietrich Müller*, and *Werner Riemer*[*]

Moenomycin A is a major component of flavomycin®, which is employed in animal nutrition[1]. It inhibits the transglycosylation step[2] in the biosynthesis of murein, the rigid component of the bacterial cell wall. For moenomycin A we propose structure *(1)*.

It was known from degradation studies that moenomycin A is built up of parts A-B-C and D-E-F-G-H-I[3]. Thus, the sugar chain in *(1)* could be cleaved quite selectively at the glycosidic bonds of the two *N*-acetylated amino sugars with

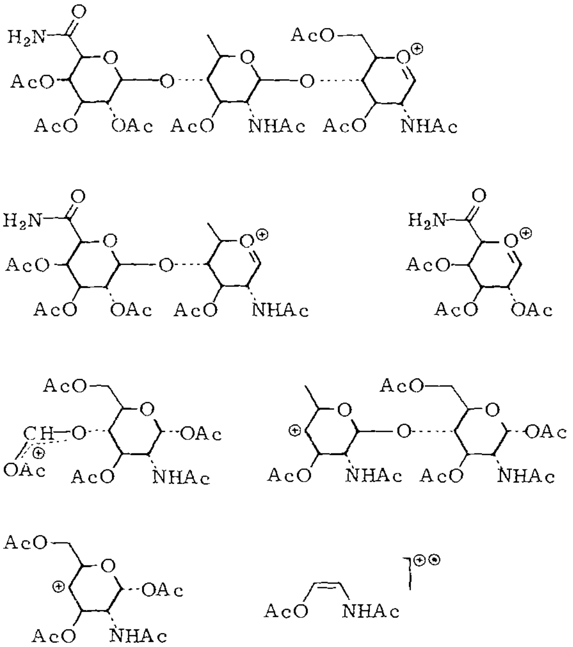
(1)

(2)

trifluoroacetic acid[4]. In order to determine how the two partial structures are connected to each other we have exploited the observation that glycosides of *free* amino sugars are particularly stable towards hydrolysis[5]. It was to be expected that, after cleavage of the *N*-acetyl groups, the glycosidic bond of the quinovosamine unit (C) could be preserved on acid hydrolysis, not, however, the linkage between the glucosamine (E) and the moenuronic acid unit (F), since moenuronic acid is known to decompose with loss of $CO_2$ and water on acid treatment[3,6]. After cleavage of the amide bonds in *(1)* (1 N NaOH), acid hydrolysis (2 N HCl), reaction of the cleavage products with methanolic HCl and methanolic $NH_3$ (to convert the galacturonic unit into the uronamide), acetylation and chromatographic separations, the trisaccharide derivative *(2)* was obtained with the glycosidic linkage of the quinovosamine unit (C) intact. Total hydrolysis of *(2)* with 2 N HCl or 1.5 N methanolic HCl yielded quinovosamine, glucosamine, and galacturonic acid[7].



Scheme 1. Fragments in the mass spectrum of *(2)* that are important for the structure elucidation.

The sequence of the monosaccharide units in *(2)* follows quite clearly from the fragments of the high resolution mass spectrum shown in Scheme 1. Whether the quinovosamine unit is (1→3) or (1→4) linked to the glucosamine could be elucidated only on the basis of the 250-MHz $^1H$-NMR spectrum, which was completely analyzed by double resonance experiments (Table 1). From the large coupling constants $J_{2',3'}$, $J_{3',4'}$, $J_{4',5'}$ it can be deduced that the quinovosamine unit is present in the $^4C_1$ conformation; $J_{1',2'} = 8.6$ Hz then proves the β-glycosidic linkage of the quinovosamine and glucosamine units. The (1→4) link of the two sugars follows from the chemical shifts of 4-H (ether proton) and 3-H (proton next to an ester group).

Table 1. $^1H$-NMR data of *(2)* (270 MHz, $CDCl_3$).

δ = 6.08 (d, 1-H), 4.40 (m, 2-H), 5.19 (dd, 3-H), 3.70 (dd, 4-H), 3.90 (m, 5-H), 4.14 (dd, 6a-H), 4.50 (dd, 6b-H), 5.80 (d, NH), 4.31 (d, 1′-H), 3.99 (m, 2′-H), 5.04 (dd, 3′-H), 3.51 (dd, 4′-H), 3.4 (m, 5′-H), 1.31 (d, $CH_3$-6′), 4.70 (d, 1″-H), 5.10 (m, 2″-H, 3″-H), 5.78 (narrow, not resolved m ($W_{1/2}$ *ca.* 4 Hz), 4″-H), 4.25 (br. s ($W_{1/2}$ *ca.* 3.4 Hz) 5″-H), 5.88 and 6.59 ($N''H_2$), 1.94, 1.98, 1.98, 2.06, 2.07, 2.07, 2.08, 2.15, 2.19 (Ac), $J_{1,2} = 3.7$, $J_{2,3} = 11.0$, $J_{3,4} = 8.8$, $J_{4,5} = 10.0$, $J_{5,6a} = 1.4$, $J_{5,6b} = 3.5$, $J_{6a,6b} = 12.9$, $J_{2,NH} = 10.0$, $J_{1',2'} = 8.6$, $J_{2',3'} = 10.4$, $J_{3',4'} = 9.2$, $J_{4',5'} = 9.2$, $J_{2',N'H} = 9.6$, $J_{1'',2''} = 7.7$ Hz

In the region F-G-H-I, compound *(1)* exhibits structural analogies with the intermediate consisting of a substituted disaccharide and a polyprenol diphosphate found in the murein biosynthesis, whose use for the synthesis of the polysaccharide chains is inhibited by *(1)* (see [1]).

## *Procedure*

A solution of *(1)* (2.0 g) in 1 N NaOH (16 $cm^3$) is heated under reflux in an argon atmosphere for 24 h; subsequently, the solution is neutralized and lyophilized. The residue dissolved in 10 $cm^3$ of 2 N HCl is heated under reflux for 1 h. After neutralization, the solution is diluted with water and extracted several times with chloroform. The aqueous layer is lyophilized and freed from inorganic salts by chromatography on 50 g of silica gel (2-propanol/conc. $NH_3$ 65:35). The eluate is lyophilized, the residue stirred in 100 $cm^3$ of 1.5% methanolic HCl for 22 h at room temperature, evaporated to dryness, taken up in 80 $cm^3$ of methanol, treated with 30 $cm^3$ of saturated methanolic $NH_3$-solution, stirred for 15 h at 0 °C, and evaporated. The residue is dried in a high vacuum and then acetylated for 3 d at room temperature in 28 $cm^3$ of pyridine and 14 $cm^3$ of acetic acid anhydride in the presence of catalytic amounts of 4-(dimethylamino)pyridine. After dilution with dichloromethane, washing with water, drying, and evaporating, the residue is chromatographed, firstly on 250 g of silica gel (petroleum ether/chloroform/ethanol 4:2:1) and then on a Lobar column (60 g silica gel; toluene/

0570-0833/81/0101-0122 $ 02.50/0

chloroform/ethanol 2:1:1); yield 36 mg *(2)*, m.p. 309—310 °C (from ethanol/petroleum ether).

## Tri-*tert*-butylcyclotriarsane[**]

By *Marianne Baudler* and *Paul Bachmann*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

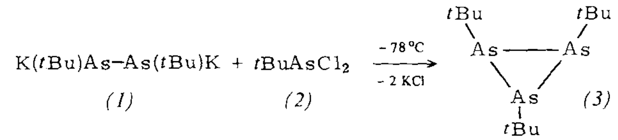
Numerous homo- and heterocyclic phosphorus three-membered ring compounds have become preparatively accessible in recent years[1]. Following the synthesis of the diphosphaarsirane $(t\mathrm{BuP})_2(t\mathrm{BuAs})$[1,2] and the phosphadiarsirane $(i\mathrm{PrP})(t\mathrm{BuAs})_2$[3] the question arose whether also monocyclic triarsanes $(\mathrm{RAs})_3$ are capable of existence and can be isolated. Hitherto, only compounds were known in which the arsenic three-membered ring is stabilized by bracketing in a polycycle [$\mathrm{As_4}$[4a], $\mathrm{As_4S_3}$[4b], $\mathrm{CH_3C(CH_2As)_3}$[4c], $\mathrm{As_7^{3-}}$[4d]] or by complexation [$\mathrm{As_3Co(CO)_3}$[5a], $[(\mathrm{triphos})\mathrm{M}(\mathrm{As_3})\mathrm{M}(\mathrm{triphos})]^{2+}$ (M = Co, Ni)[5b]]. A previously reported triphenylcyclotriarsane[6a] has so far not been confirmed[6b].

We report here on the synthesis of the tri-*tert*-butylcyclotriarsane *(3)*, the first monocyclic homonuclear three-membered ring compound of an element of the 4th period.

Problems were to be expected through oligomerization to higher-membered cycloarsanes $(\mathrm{RAs})_n$ $(n>3)$; owing to the lower bonding energy of the As—As bond compared to that of the P—P bond, such reactions should proceed even more rapidly than in the case of the cyclotriphosphanes[7]. A certain kinetic stabilization of the three-membered ring moiety could, however, be expected by steric shielding with *tert*-butyl substituents.

The simplest method for the synthesis of tri-*tert*-butylcyclotriphosphane[8] cannot be employed for the synthesis of the arsenic compound *(3)*: on dehalogenation of dichloro(*tert*-butyl)arsane with metals we obtained always the cyclotetraarsane $(t\mathrm{BuAs})_4$[9a] as main product; in addition $(t\mathrm{BuAs})_5$ and polycyclic arsanes could be detected by $^1$H-NMR spectroscopy. The thermal stability and tendency of formation of *(3)* are obviously less than in the case of the corresponding cyclotriphosphane.

*(3)* can, however, be obtained as main product by directed [2+1]-cyclocondensation of 1,2-dipotassium 1,2-di-*tert*-butyldiarsenide *(1)* with dichloro(*tert*-butyl)arsane *(2)* in apolar solvents at low temperature.



$(t\mathrm{BuAs})_4$ and small amounts of unidentified compounds are also formed. The product pattern depends on the molar ratio of the reactants, on the concentration of the $t\mathrm{BuAsCl_2}$ solution, the reaction time and the quantities used; the yield of *(3)* which can be isolated pure by low-temperature crystallization and sublimation was optimized by $^1$H-NMR spectroscopy.

The cyclotriarsane *(3)* forms colorless, tabloid shaped crystals (m.p. 41 °C (dec.), sealed tube), which are stable in the dark and in the absence of air at −30 °C. They are readily soluble in benzene or *n*-pentane. On exposure to air they spontaneously ignite, on exposure to light they turn yellow within a few hours, and at room temperature oligomerization gradually takes place to $(t\mathrm{BuAs})_4$. The composition of *(3)* is confirmed by elemental analysis (As, C, H), cryoscopic molecular weight determination (in cyclohexane), and the mass spectrum (field ionization, $M^+$: $m/e = 396$, 100%). The $^1$H-NMR spectrum (benzene) shows two singlets at $\delta = 1.16$ and 1.41 in the ratio 1:2. It follows then that the *tert*-butyl substituents are arranged on both sides of the ring plane; the *all-cis* isomer was not detectable. In agreement with these findings the $^{13}$C{$^1$H}-NMR spectrum (benzene) shows two singlets each for the primary and tertiary C-atoms at 34.48, 32.41 and 35.88, 29.55, respectively of which each high-field signal corresponds to the *trans* substituents. The IR and Raman spectra of *(3)* exhibit characteristic differences from the spectra of $(t\mathrm{BuAs})_4$ in the lower wave number region (cf. Table 1).

Table 1. IR- and Raman frequencies ($<700$ cm$^{-1}$) of $(t\mathrm{BuAs})_3$ *(3)* and $(t\mathrm{BuAs})_4$.

| Cpd. | IR (KI disk) [cm$^{-1}$] | Raman (krypton) [cm$^{-1}$] |
|---|---|---|
| $(t\mathrm{BuAs})_3$ *(3)* | 685 (m), 558 (m), 535 (vw, sh), 515 (vw, sh), 490 (vw, sh), 395 (m), 388 (w, sh), 348 (w), 293 (w), 278 (w) | 540 (w, sh), 513 (m), 398 (vw), 328 (m), 298 (w), 284 (w), 250 (vw), 221 (m), 197 (m), 182 (s), 139 (m), 116 (m), 107 (m, sh) |
| $(t\mathrm{BuAs})_4$ | 699 (w), 565 (vw), 519 (w), 386 (w), 288 (m) | 522 (s), 391 (vw), 308 (m), 294 (m), 292 (m, sh), 217 (s), 158 (s), 123 (m), 112 (s) |

### *Procedure*

A solution of *(2)* (8.4 g, 41.4 mmol, substoichiometric amount) in *n*-pentane (40 cm$^3$) is added dropwise within 30 min at −78 °C to a vigorously stirred suspension of *(1)*[9b] (15.5 g, 45.3 mmol) in pentane (100 cm$^3$). The mixture is stirred for a further 30 min; thereafter the proportion of *(3)* amounts to about 60 mol-% ($^1$H-NMR). The precipitate is rapidly filtered off in the cold and the filtrate which is collected in a precooled vessel is concentrated to about 60 cm$^3$ at −78 °C. After 5 days storage in the cold the solution is siphoned off from any precipitate which has settled out (mainly $(t\mathrm{BuAs})_4$) and concentrated to *ca.* 50 cm$^3$; removal of precipitate is repeated again after 3 days. The workup is monitored by $^1$H-NMR inspection of all fractions. The solution is then concentrated to *ca.* 30 cm$^3$ at −78 °C and the yellowish

[**] Contributions to the Chemistry of Arsenic, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 2: *M. Baudler, H.-J. Stassen,* Z. Anorg. Allg. Chem. *345*, 182 (1966).

crude product which has precipitated out after 3 d is separated off. Dissolution in a little pentane at room temperature and cooling to −78 °C yields 3.4 g (21%) of pale yellow *(3)*, purity 90—95% (rest $(t\mathrm{BuAs})_4$, $^1$H-NMR). Molecular sublimation (2 cm) at room temperature and $10^{-4}$ torr, during which partial rearrangement to $(t\mathrm{BuAs})_4$ already takes place, however, affords 1.2 g (7.3%) of colorless, finely crystalline *(3)* as middle fraction; purity 100%.

## *cyclo*-Leu$^5$-Enkephalin[1]

By *Horst Kessler* and *Günter Hölzemann*[*]

The discovery, isolation and elucidation of the composition and structure of the enkephalins

H-Tyr$^1$-Gly$^2$-Gly$^3$-Phe$^4$-Xxx$^5$-OH
*(1)*, Xxx = Leu, Leu$^5$-enkephalin;
*(2)*, Xxx-Met, Met$^5$-enkephalin

as endogenous ligands for the opiate receptor aroused considerable attention. Although detailed studies on the conformation of these pentapeptides have indicated a preferred conformation with a β-loop between the amino acids 5→2[2], the backbone and the side chains are very flexible and permit the participation of many conformations at equilibrium in solution[2,3]. Therefore, conclusions on the receptor geometry and comparisons with the steric structure of rigid morphine are problematical. Our findings on cyclic pentapeptides[1,4,5] would lead one to expect considerably restricted mobility in the case of *cyclo*-enkephalins. We report here the synthesis of, and first conformational studies on, cyclo-Leu$^5$-enkephalin *(c1)*[6].

For the synthesis of *(c1)* we did not cyclize a peptide having a natural sequence, but the linear peptide H-Gly-Phe-Leu-Tyr-Gly-X using the azide method. The region Gly$^2$-Gly$^3$ was chosen to ensure minimal steric hindrance during the cyclization, to avoid racemization and to circumvent problems in the hydrazinolysis[7] of the Boc-pentapeptide methyl ester. The ester was obtained from the fragments Boc-Gly-Phe-Leu-OCH$_3$ and H-Tyr-Gly-OCH$_3$, which had been prepared by usual methods of peptide synthesis.

Table 1. 270-MHz $^1$H-NMR data of *cyclo*-Leu$^5$-enkephalin *(c1)* in [D$_6$]-DMSO at 25 °C. δ values, *J* [Hz].

| *(c1)* | Tyr$^1$ [a] | Gly$^2$ | Gly$^3$ | Phe$^4$ [b] | Leu$^5$ |
|---|---|---|---|---|---|
| NH | 8.29 | 8.62 | 7.75 | 8.09 | 7.96 |

[a] Aromatic protons A 6.94, B 6.64; OH 9.22. [b] Aromatic protons around 7.2. [c] Temperature-dependence of the NH-proton signals between 20 and 100 °C (ppb).

The 270-MHz $^1$H-NMR spectrum of *(c1)* in [D$_6$]-dimethyl sulfoxide ([D$_6$]-DMSO) (see Table 1) is very similar to that of

*cyclo*(Phe$^3$-Gly$^4$-Gly$^5$-Phe$^1$-Phe$^2$)[4,8] *(3)*

The assignment of the Gly$^2$- and Gly$^3$-signals, which suggests itself by way of analogy with *(c1)* and *(3)*, and the differentiation of the Tyr$^1$- and Phe$^4$-signals was confirmed by NOE measurements. Irradiation of the NH frequency produced a more or less significant effect on the α-H atom of the amino acid preceding the peptide sequence[9]. The temperature gradients of the NH signals in *(c1)* and *(3)* and the spectra obtained on titration of the DMSO solution with CDCl$_3$ are also very similar. Such a spectral similarity can only be expected if the conformations of the two peptides resemble each other. Hence, exchange of the amino acids Phe$^3$→Tyr$^1$ and Phe$^2$→Leu$^5$ in the transition from *(3)* to *(c1)* has no effect on the conformation. Arguments regarding the dominating conformation of *(c1)* in solution correspond to those in the case of *(3)*[4]: the internal orientation of the leucine-NH

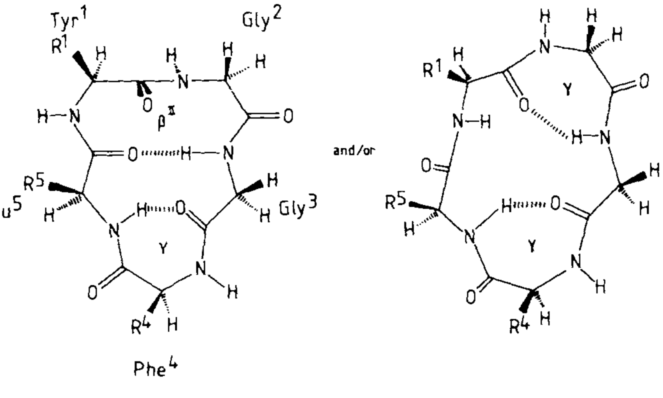

Fig. 1 Conformation of *cyclo*-Leu$^5$-enkephalin *(c1)* in DMSO. R$^1$ = *p*-CH$_2$C$_6$H$_4$OH; R$^4$ = CH$_2$C$_6$H$_5$; R$^5$ = CH$_2$CH(CH$_3$)$_2$. Left: βγ-, right: γγ-conformation.

(small temperature coefficient, see Table 1) can only be brought about by a γ-loop of the amino acids 5→3, while the NH proton of $Gly^3$ can form a β-loop to the $Leu^5$-CO or a γ-loop to the $Tyr^1$-CO (Fig.1). We do not as yet wish to stipulate a particular conformation, though the sizes of the NH—$C_\alpha$H coupling constants would appear best explained in terms of a γγ-conformation. The poor solubility of *(c1)* in water thwarts a check on the biological activity.

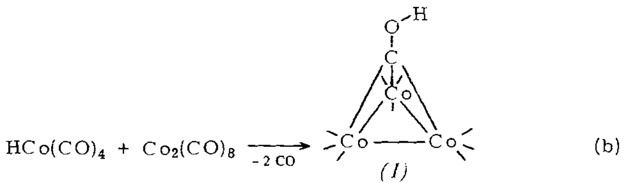
## Crystal and Molecular Structure of $Co_3(CO)_9COH$, A Possible Intermediate in the Reduction of CO by Molecular Hydrogen[**]

By *Hans-Norbert Adams, Giuseppe Fachinetti,* and *Joachim Strähle*[*]

$Co_3(CO)_9C$—OH *(1)* can be obtained in solution by acidification of the $[Co_3(CO)_{10}]^-$ anion[1a]. *(1)* has the property of being quantitatively converted into $HCo(CO)_4$ and $Co_4(CO)_{12}$ (or $Co_2(CO)_8$, depending on the CO partial pressure), thus demonstrating the first conversion of an O-bonded hydrogen to a metal-bonded hydrogen[1a]. Moreover, $HCo(CO)_4$ was converted into the trinuclear cluster $Co_3(CO)_9C$—OH *(1)* on reaction with $Co_2(CO)_8$ in the presence of $NEt_3$, thus showing for the first time that the previously mentioned hydrogen migration can be reverted[1b]. In view of the already established[2] reaction (a) these findings were believed to represent an unprecedented example of a cluster-formation assisted four-electron one-step reduction of CO by molecular hydrogen.

$$H_2 + Co_2(CO)_8 \rightleftharpoons 2\ HCo(CO)_4 \qquad \text{(a)}$$



$$HCo(CO)_4 + Co_2(CO)_8 \xrightarrow[-2\,CO]{} \qquad \text{(b)}$$

*(1)*

The IR and $^1$H-NMR spectra (in solution)[1a] suggested the basic structure shown in equation (b) for *(1)*. However, it was important to verify whether the molecular parameters of *(1)* were in agreement with a substantial reduction of the apical CO group. For the X-ray structure analysis solvent-free *(1)* was prepared by acidification of $LiCo_3(CO)_{10}$.[3] with anhydrous HCl in a hydrocarbon solvent at low temperature (see Procedure).

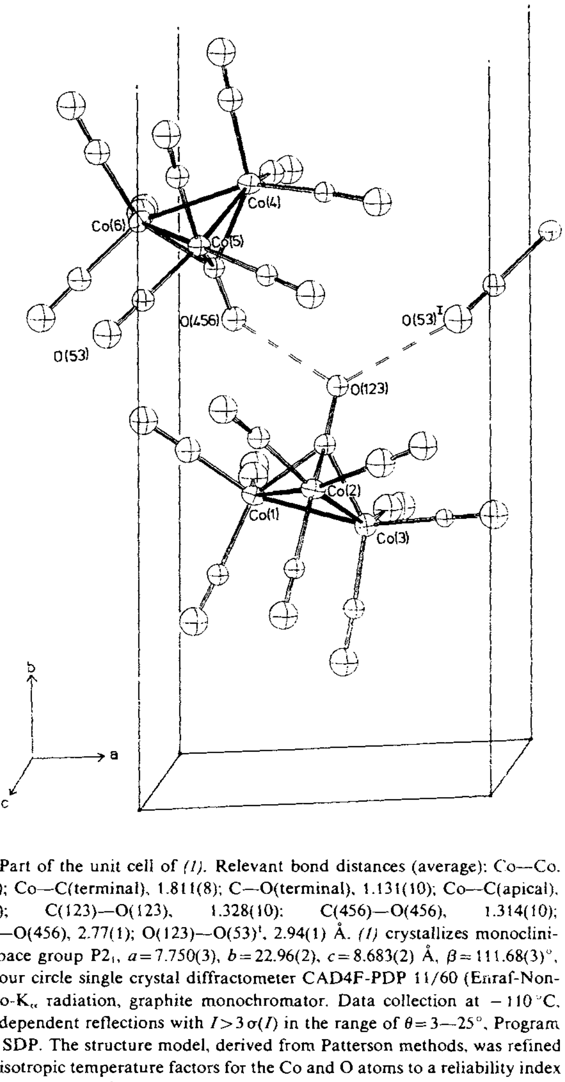


Fig. 1. Part of the unit cell of *(1)*. Relevant bond distances (average): Co—Co, 2.478(5); Co—C(terminal), 1.811(8); C—O(terminal), 1.131(10); Co—C(apical), 1.928(8); C(123)—O(123), 1.328(10); C(456)—O(456), 1.314(10); O(123)—O(456), 2.77(1); O(123)—O(53)$^I$, 2.94(1) Å. *(1)* crystallizes monoclinically, space group $P2_1$, $a$=7.750(3), $b$=22.96(2), $c$=8.683(2) Å, $\beta$=111.68(3)°, $Z$=4, four circle single crystal diffractometer CAD4F-PDP 11/60 (Enraf-Nonius), Mo-$K_\alpha$ radiation, graphite monochromator. Data collection at −110 °C, 1632 independent reflections with $I > 3\sigma(I)$ in the range of $\theta$=3—25°, Program System SDP. The structure model, derived from Patterson methods, was refined with anisotropic temperature factors for the Co and O atoms to a reliability index $R$=0.051. A final difference Fourier map did not show any significant electron density for the H atoms.

In the $Co_3(CO)_{10}$ clusters (Fig. 1) each Co atom is bonded to three terminal CO groups. The three Co atoms form a regular triangle which is completed to a tetrahedron by an apical CO group. The Co—C and C—O distances in the terminal CO groups as well as the Co—Co distances are of the same magnitude as observed in $LiCo_3(CO)_{10} \cdot i Pr_2O$[4]. The position of the hydrogen atom could not be determined with certainty. However, the C—O bond length of the apical CO group was found to be 1.33(1) Å, which clearly indicates that

[+] Author to whom correspondence should be addressed.

the H atom is bonded to the oxygen atom of the apical CO group. In addition, short intermolecular O—O distances are found between the apical O atoms of two neighboring clusters as well as between O(123) and O(53)$^1$ of a third cluster, thus supporting the assumption of intermolecular hydrogen bridges.

1.33 Å is the longest CO distance found for metal-coordinated CO, thus showing a considerable reduction of CO bond order (the average terminal C—O distance is 1.15 Å; the C—O distance in methanol is 1.43 Å). For comparison: in $[HFe_4(CO)_{13}]^-$[5], which is presented as a model[6a,b] of CO scission to hydrocarbons, the CO distance is 1.26(3) Å.

We suggest *(1)* as a model for hydrogenation of CO to methanol in homogeneous phase. We believe that *(1)* behaves in solution as a discrete molecule with no important intermolecular contacts, as evidenced by its high solubility in hydrocarbons. On the other hand, the multisite interactions in the solid state, similar to those already found[4] in the lithium derivative $LiCo_3(CO)_{10}\cdot i Pr_2O$ qualify *(1)* as a possible model also for the hydrogenation of CO in the heterogeneous phase.

*(1)* could possibly be a real intermediate in the homogeneous phase hydrogenation of CO to methanol[7]; high $H_2$—CO-partial pressures and high temperature are necessary for $HCo(CO)_4$-assisted low-nuclearity endothermic[8] cluster formation. The thermal[6c] and photochemical[9] hydrogenation of $Co_3(CO)_9C$—R to hydrocarbons provides further experimental evidence for this claim.

### *Procedure*

Ether-free $LiCo_3(CO)_{10}$: A suspension of $LiCo_3(CO)_{10}\cdot Et_2O$ (10 g) in diphenyl ether (50 cm$^3$) stirred at 28.5 °C/*ca.* $5\times10^{-2}$ torr for 12 h under argon. The resulting green pyrophoric solid is filtered after addition of toluene (50 cm$^3$), washed with toluene and dried *in vacuo*. The yield is almost quantitative. The IR spectrum of the product in dibutyl ether is superimposable on that of $LiCo_3(CO)_{10}\cdot i Pr_2O$[4] and $LiCo_3(CO)_{10}\cdot Et_2O$[3] in the same solvent.

Solvent-free *(1)*: A suspension of $LiCo_3(CO)_{10}$ (2.8 g) in toluene (10 cm$^3$) and hexane (30 cm$^3$) is acidified, under an Ar atmosphere, at −80 °C with the stoichiometric amount of anhydrous HCl; after 5 minutes' stirring at about −17 °C the mixture is filtered at this temperature. The solution is cooled to −65 °C under a CO atmosphere and allowed to stand overnight; the crystals which separate are finally filtered off and dried *in vacuo* (25% yield). During all of these operations the temperature should not exceed −10 °C. The brick-red compound *(1)* is unstable thermally and must be kept under a CO or an Ar atmosphere at liquid nitrogen temperature.

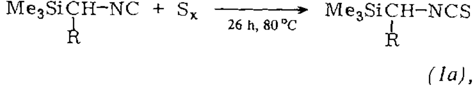
## Trimethylsilylmethyl Isothiocyanate, An Isothiocyanatomethanide Equivalent[**]

By *Toshikazu Hirao, Atsushi Yamada, Yoshiki Ohshiro,*
and *Toshio Agawa*[*]

Functionalized isothiocyanates[1a] are useful reagents for heterocycle synthesis[1b], particularly when a carbanion center can be generated in the α-position relative to nitrogen. The metalation of activated isothiocyanate was reported by *Hoppe*[2], but this method is unsatisfactory in the case of methyl isothiocyanate. The well known fluoride ion-induced liberation of carbanions from silyl compounds[3] would indicate that trimethylsilylmethyl isothiocyanate *(1a)* is a suitable precursor for isothiocyanatomethanide *(2)*.

*(1)* was prepared by the addition of sulfur[4] to trimethylsilylmethyl isocyanide[5] in 76% yield. It is a stable liquid at room temperature and can be stored for some time under nitrogen ($\nu_{NCS}=2180$ and 2080 cm$^{-1}$). Compound *(1b)* was prepared analogously (80% yield).



$$Me_3Si\underset{R}{\underset{|}{C}}H{-}NC + S_x \xrightarrow[26\ h,\ 80\,°C]{C_6H_6} Me_3Si\underset{R}{\underset{|}{C}}H{-}NCS$$

*(1a)*, R = H
*(1b)*, R = $SiMe_3$

The isothiocyanate *(1a)* was allowed to react with carbonyl compounds in the presence of a catalytic amount of tetra-*n*-butylammonium fluoride[3a] to produce the oxazolidine-2-thiones *(3)* (Table 1). The reaction proceeds smoothly at room temperature. Potassium fluoride with triethylbenzylammonium chloride (TEBA·Cl) or [18]crown-6 is also effective as a catalyst (Table 1).

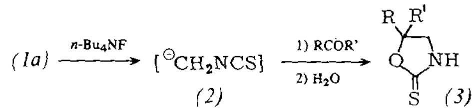


Table 1. Synthesis of oxazolidine-2-thiones *(3)*. Catalyst: $n$-$Bu_4NF$ (0.1 equivalent).

| | | RCOR′ | | *t* | Yield [%] | M.p. [°C] |
|---|---|---|---|---|---|---|
| | | R | R′ | [h] | [a] | [b] |
| *(a)* | | Ph | H | 8 | 74 | 130—131 |
| | [c] | Ph | H | 2 | 74 | |
| | [d] | Ph | H | 5 | 65 | |
| *(b)* | | Et | H | 5 | 63 | 87—89 |
| *(c)* | | *i*Pr | H | 10 | 67 | 101—102 |
| *(d)* | | Ph | Ph | 40 | 25 | 186—188 |
| *(e)* | | Ph | Me | 23 | 35 | 201—203 |

[a] Isolated yield. [b] Uncorrected. [c] Catalyst: KF(1.0) + TEBA·Cl (0.1 equiv.). [d] Catalyst: KF(1.0) + [18]crown-6 (0.1 equiv.). [e] Together with 17% 5-methyl-3-(*N*-methylthiocarbamoyl)-5-phenyloxazolidine-2-thione as a by product.

When bis(trimethylsilyl)methyl isothiocyanate *(1b)* was used in the reaction with benzaldehyde under similar conditions, β-styryl isothiocyanate *(7)*[6] was obtained as a major product along with 5-phenyl-4-(trimethylsilyl)oxazolidine-2-

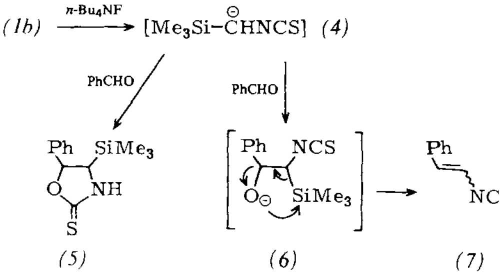
thione *(5)*[6] in 31 and 6% yields, respectively. Nucleophilic attack of the carbanion *(4)* on benzaldehyde leads to the β-trimethylsilyl alkoxide intermediate *(6)*, which fragments *(7)*. The formation of *(5)* can be explained in terms of a ring closure of a rotamer of *(6)*.



It could also be shown that the fluoride-catalyzed reactions of *(1a)* and *(1b)* offer a facile and mild generation of the carbanions *(2)* and *(4)*, respectively.

*Experimental*

*(3a):* A solution of 0.430 g (3.0 mmol) of trimethylsilylmethyl isothiocyanate *(1a)* in THF (2 cm$^3$) was added dropwise at 20 °C to a solution of 78 mg (0.3 mmol) of tetra-*n*-butylammonium fluoride and 0.640 g (6.0 mmol) of benzaldehyde in THF (3 cm$^3$). The resultant mixture was stirred at 20 °C for 8 h, poured into 60 cm$^3$ of water, and extracted with chloroform. The combined organic layer was dried over $Na_2SO_4$ and concentrated *in vacuo*. The residue was chromatographed on silica gel; yield 0.40 g (74%) *(3a)*.

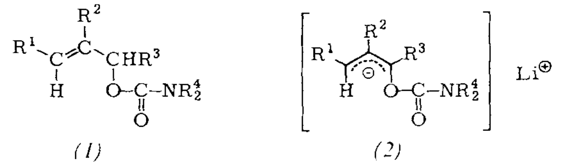
# Dilithiated Allyl *N*-Alkyl- or *N*-Phenylcarbamates, Readily Accessible Propionaldehyde-d$^3$ Equivalents[**]

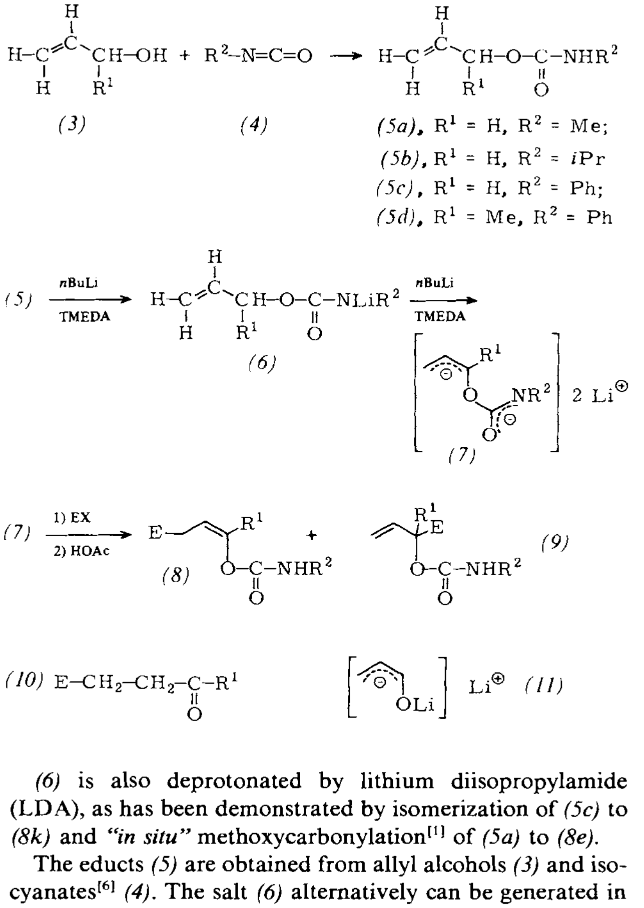
By *Rudolf Hanko* and *Dieter Hoppe*[*]

We recently reported[1] on the deprotonation of allyl *N,N*-dialkylcarbamates *(1)* to (carbamoyloxy)allyllithium compounds *(2)* and their use as "carbonyl-d$^3$ reagents"[2]. On comparing these lithium compounds with other homoenolate equivalents[3] a remarkable feature is their substituent compatibility; even lithium compounds of 1,2,3-trialkyl-substituted 1-oxyallyl anions *(2)* have been obtained[4].



For generation of persistent solutions of *(2)*, their carbonyl function must be protected against nucleophilic attack. This can be achieved by shielding the carbonyl group with sterically demanding *N*-alkyl moieties[5] or—as reported here—by reducing the electrophilicity of the carbonyl group ("electronic protection"). Deprotonation of the allyl *N*-alkyl- or *N*-phenylcarbamates *(5)* provides lithium salts *(6)*, hence even strongly nucleophilic alkyllithium compounds can be used for the metalation.

Double deprotonation of the carbamates *(5)* with 2.1 equivalents of a hexane solution of *n*-butyllithium (*n*BuLi) in tetrahydrofuran (THF)/*N,N,N',N'*-tetramethylethylenediamine (TMEDA) at −78 °C to −50 °C yields stable solutions of dilithiated esters *(7)*. In their reaction with electrophiles (EX) predominantly *Z*-configurated γ-adducts *(8)* are formed, along with small amounts of the allyl esters *(9)* (cf. Table 1). The enol esters *(8)* are hydrolyzable under acidic conditions to yield β-substituted carbonyl compounds *(10)*[4].



*(5a)*, R$^1$ = H, R$^2$ = Me;
*(5b)*, R$^1$ = H, R$^2$ = *i*Pr
*(5c)*, R$^1$ = H, R$^2$ = Ph;
*(5d)*, R$^1$ = Me, R$^2$ = Ph

*(6)* is also deprotonated by lithium diisopropylamide (LDA), as has been demonstrated by isomerization of *(5c)* to *(8k)* and *"in situ"* methoxycarbonylation[1] of *(5a)* to *(8e)*.

The educts *(5)* are obtained from allyl alcohols *(3)* and isocyanates[6] *(4)*. The salt *(6)* alternatively can be generated in a one-pot process by reaction of *(4)* with metalated *(3)*

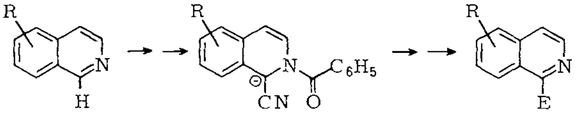
# Lithiated *N*-pivaloyl-tetrahydroisoquinoline—a Supernucleophile

By *Jean-Jacques Lohmann, Dieter Seebach, Max A. Syfrig*, and *Masaaki Yoshifuji*[*]

The Reissert reaction[1] [equation (a)], an umpolung of the $a^1$ reactivity[2] of isoquinolines, leads to electrophilic substitution at C-1 of the heterocycle; this approach is considered as the method of choice for this transformation. Its limitations, amongst others, are the poor nucleophilicity of the intermediate benzyl-, cyano-, and amide-stabilized carbanions; to our knowledge no alkylation reactions with secondary alkyl halides are known. Furthermore, no 1,1-dialkylated isoquinoline derivatives can be prepared.



(a)

Investigations of the acidity of secondary amines such as *(1)* indicated that as expected, the benzyl site of the corresponding nitrosamines (X = NO) and triphenylacetamides ($X=COC(C_6H_5)_3$) as well as the urea derivative *(4)*, could be readily deprotonated[3]. The nucleophilicity of the lithium compounds obtained however left much to be desired. It is therefore all the more surprising that the pivalylamide *(6)*[4a,b] reacts quantitatively within 5 min with *tert*-butyllithium/tetramethylethylenediamine (*t*BuLi/TMEDA) to produce an orange red solution of the lithium derivative, which at low temperature can be "titrated" against most electrophiles. Products of type *(6)* (Table 1) are produced even when the electrophile is a primary alkyl *chloride*, a *secondary* alkyl iodide[5] or an easily deprotonated ketone. The adducts formed from propionaldehyde and benzaldehyde are separable mixtures of the corresponding hydroxypivalamides *(6h)* or *(6i)*, and the aminoalkyl pivalates *(8)* or *(9)*, each compound being diastereoisomerically pure according to NMR spectroscopy. Dimerization with iodine produced only one isolable product *(10)*, of unknown configuration[6]. The abstraction of the tertiary benzylic proton from *(6a)* ($E=CH_3$) using the conditions described above was also facile, as shown by the formation of the dimethyl derivative *(11)*.

The conversion of the amide *(6)* into the amine *(5)* could best be performed[7] by reaction with exactly one equivalent of the aluminate *(12)*[8] in benzene at 20—80 °C (see example in Table 1). The hydroxyalkylated compounds *(6)* $E=C(OH)R^1R^2$, rapidly rearrange in trifluoroacetic acid to pivalates of type *(8)* or *(9)*[9].

As seen in Table 1, the α-hydroxy-isobutyramide *(3)*[4c] is also a candidate for the alkylation of the tetrahydroisoquinoline system. It may be lithiated by two equivalents *t*BuLi/HMPT and the products cleaved in boiling methanolic potassium hydroxide. We have however been unable to find

[9] The diastereomerically pure amides *(6)*, E = CH(OH)R are unfortunately converted into mixtures of diastereoismers *(8)* or *(9)*. This type of rearrangement has also been observed in peptides having hydroxyalkyl side chains, see e.g. *A. Rüegger, M. Kuhn, H. Lichti, H.-R. Loosly, R. Huguenin, Ch. Quiquerez, A. von Wartburg*, Helv. Chem. Acta *59*, 1075 (1976).

## Radical Complexes of Molybdenum as Reactive Intermediates

By *Dieter Fenske* and *Anestis Christidis*[*]

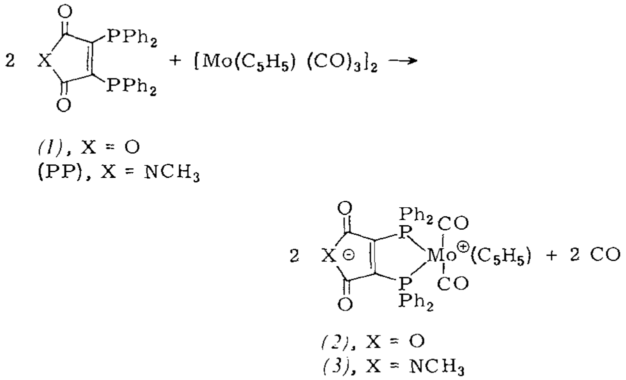
*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

In ligand exchange reactions of metal(0) complexes such as $Co_2(CO)_8$ or $Pd(PPh_3)_4$ with ditertiary phosphanes such as

---

[*] Priv.-Doz. Dr. D. Fenske, A. Christidis
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

bis(diphenylphosphino)maleic anhydride *(1)* and -*N*-methylimide (PP) we observed the formation of paramagnetic complexes in which the coordination of the bidentate ligand to the metal is accompanied by an electron transfer from the metal into a $\pi^*$ orbital of the ligand[1,2]. The ligand is converted into a complex bonded radical anion ($PP^-$), as illustrated by the formulas $Co^+(CO)_3(PP^-)$ and $Pd^{2+}(PP^-)_2$. Such complexes are in part extremely reactive, so they only occur as non-isolable intermediates, *e.g.* in the reaction of $Ni(C_5H_5)_2$ with *(1)*[1]. We have now observed a further secondary reaction to the deep-brown radical complexes *(2)* and *(3)* which are obtainable from $[Mo(C_5H_5)(CO)_3]_2$ and *(1)* or (PP), respectively.



*(1)*, X = O
(PP), X = NCH$_3$

*(2)*, X = O
*(3)*, X = NCH$_3$

The reaction of $[Fe(C_5H_5(CO)_2]_2$ with (PP) or *(1)* analogously leads to paramagnetic complexes of the type $Fe^+(PP^-)(C_5H_5)(CO)$. However, we restricted our studies to *(3)* and its secondary reactions.

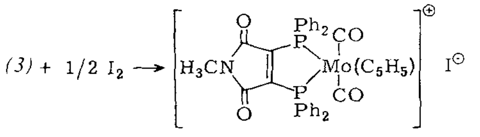
The following findings show that in the formation of *(3)* an unpaired electron is transferred from molybdenum into a $\pi^*$ orbital of the complex bonded ligand.

1. The magnetic moment of *(3)* is obtained from the susceptibility $\mu_{eff}$, which follows the Curie law, $\mu_{eff}=1.72\ \mu_B$ (at 295 K). Accordingly, an unpaired electron is present.

2. The ESR spectrum of *(3)* in tetrahydrofuran consists of a triplet of three groups of signals in the intensity ratio 1:2:1. The triplet structure is due to coupling between unpaired electron and P nucleus, the fine structure of each triplet component to corresponding coupling with the N and H nuclei of the NCH$_3$ group ($a_P=9.28$, $a_N=1.84$, $a_H=0.68$ gauss)[3].

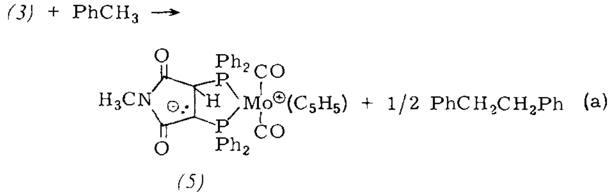
3. In the IR spectrum the $\nu$CO bonds of the ligand PP on complexation to *(3)* are lowered by about 80—100 cm$^{-1}$, as we have previously always observed when such ligands are transformed into radical anions[1,2].

4. Oxidation of *(3)* with $I_2$ in $CH_2Cl_2$ leads to the iodide *(4)* of the cation formed by withdrawal of electrons from *(3)*. *(4)* is diamagnetic and the $\nu$CO bands of the ligand PP occur in the same region as the free ligand. A crystal structure analysis confirms the presence of the complex cation and the anionic nature of the iodine outside of the coordination shell.



*(4)*

The yield of *(3)* is satisfactory only when the synthesis is carried out in a relatively short reaction time; a secondary reaction occurs on prolonged reaction in boiling toluene. On heating a solution of *(3)* in toluene for several days we obtained yellow crystalline *(5)*, which, in contrast to *(3)*, is diamagnetic. According to the IR spectrum, *(5)* contains CO ligands; the ligand PP has somewhat modified IR bands. The phosphorus atoms are no longer symmetry equivalent ($^{31}$P-NMR: $\delta=-26.5$ and $-72.9$, referred to 85% $H_3PO_4$; $J_{P,P}=10$ Hz[4]. A crystal structure determination[5] enabled *(5)* to be characterized and, at the same time, provided an explanation of the secondary reaction that takes place on prolonged heating in boiling toluene [eq. (a)]. The formation of 1,2-diphenylethane could be demonstrated.



*(5)*

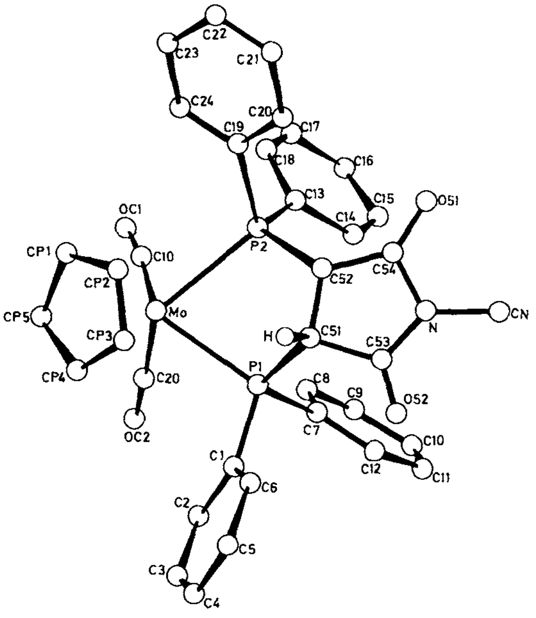


Fig. 1. Molecular structure of the molybdenum complex *(5)* in the crystal [5].

*(5)* crystallizes from toluene as a 1:1 solvate with the solvent. Figure 1 shows the molecular structure, in which the H atoms except that on C51 added during the formation of *(5)* from *(3)* have been omitted; it was unequivocally located in a difference Fourier synthesis. The formation of a CH bond at C51, which previously belonged to the C=C bond in the maleimide system of *(3)*, follows from the sum of the angles of the bonds from C51 to P1, C52 and C53 (332°). The atoms C52, C53, C54 and N in the five-membered ring, on the other hand are planar coordinated.

By addition of the H-atom, C51 becomes a center of chirality, and is probably formed by participation of the previously unpaired electron in the PP radical of *(3)*. The electrons of the original C=C bond are shifted to C52. The strong influence of the new bond system on the bond lengths in the Mo(H—PP$^-$) part of the molecule of *(5)* follows from the following data (in pm):

| | | |
|---|---|---|
| Mo—P1 = 250(0.1) | Mo—P2 = 256(0.1) | |
| P1—C51 = 184(1) | P2—C52 = 175(1) | |
| C51—C52 = 151(1) | C51—C53 = 153(1) | C52—C54 = 140(1) |
| N—C53 = 134(1) | N—C54 = 145(1) | |
| O52—C53 = 123(1) | O51—C54 = 123(1) | |

These distances indicate considerable mesomeric interaction of the free electron pair on C52 with the $>C{=}O$ groups, with the free electron pair on the imide nitrogen, and with the phosphorus atoms.

The cyclopentadiene ring in *(5)* is *pentahapto* bonded to molybdenum. The bond lengths in the $Mo(CO)_2(C_5H_5)$ part of the molecule are normal (in pm):

Mo—CP = 230—236    CP—CP = 139—142
Mo—C10 = 199(1)    Mo—C20 = 196(1)
C10—OC1 = 114(1)    C20—OC2 = 115(1)

A further proof for the constitution of *(5)* is its smooth oxidation to *(4)* [eq. (b)]:

$$(5) + I_2 \rightarrow (4) + HI \qquad \text{(b)}$$

*Procedure*

A solution of $[Mo(C_5H_5)(CO)_3]_2$ (1.2 g, 2.45 mmol) and (PP) (2.36 g, 4.91 mmol) in boiling toluene is stirred until evolution of CO is complete. Brown *(3)* crystallizes from the dark-brown solution; yield 95%.—The iodide *(4)* is prepared by oxidation of *(3)* (2.38 g, 3.41 mmol) with iodine (0.435 g, 3.42 mmol) in ether/1,2-dichloroethane (1:1) at °C; dark-red crystals, yield 80%.—When *(3)* is heated for several days at 80 °C in toluene, *(5)* is obtained as large, yellow crystals; yield 40—60%.

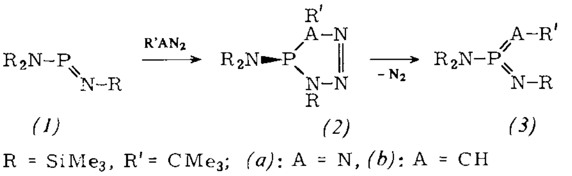
## $N_2$-Elimination from a [3+2]-Cycloadduct of Diazoalkane and Amino(methylene)phosphane to give a $\lambda^3$-Phosphirane[**]

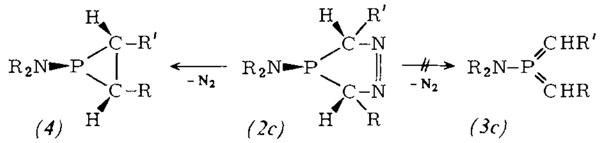
By *Edgar Niecke, Wolfgang W. Schoeller,* and *Dirk-Andreas Wildbredt*[*]

Kinetically stable phosphorus ylides such as *(3a)* and *(3b)* can be obtained by $N_2$-elimination from the thermolabile[1] [3+2]-cycloadducts *(2a)* and *(2b)*, respectively, of the iminophosphane *(1)* and the heteroallenes $R'AN_2$[2].

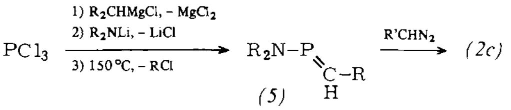


R = SiMe$_3$, R' = CMe$_3$; *(a)*: A = N, *(b)*: A = CH

In an attempt to generate the still unknown bis(methylene)phosphorane *(3c)* in a similar way from the analogue 1,2,4$\lambda^3$-diazaphospholine *(2c)* of *(2b)*, we obtained the $\lambda^3$-phosphirane *(4)* isomeric to the phosphorus ylide *(3c)*.



The highly electrophilic [bis(trimethylsilyl)amino](trimethylsilylmethylene)phosphane *(5)*, which is isoelectronic to *(1)*, proved to be a suitable precursor for the synthesis of *(2c)*. *(5)* can be readily obtained in a one-pot reaction and can be smoothly converted into the desired [3+2]-cycloadduct *(2c)* by reaction with 1-diazo-2,2-dimethylpropane.



The composition and constitution of *(5)*, *(2c)* and *(4)* are confirmed by elemental analysis, mass spectra, NMR data (Table 1) and, in the case of *(5)*, also by the IR spectrum. A noticeable feature on comparison of *(5)* with the known methylene phosphanes[3] is the downfield shift of the $^{31}P$-NMR signal ($\delta=308.7$) and the upfield shift of the $^{13}C$-NMR signal ($\delta=147.9$); this would indicate considerable changes in the polarity of the P=C bond and explain the high reactivity of *(5)* towards dipolar and oxidative addition[4]. The high value for $^2J_{SiCP}$ (40.5 Hz) would suggest existence of the sterically favorable Z-form, which has been demonstrated for the corresponding imine derivative *(1)*[5]. The P=C valence vibrations ($\nu_{P\ CH}=1120$, $\nu_{P\ CD}=1085$ cm$^{-1}$) can be identified by comparison of the very similar IR spectra of *(5)* and *(1)*[6] and of the derivative of *(5)* deuterated at the methylene carbon.

In the [3+2]-cycloaddition product *(2c)* the $^{31}P$-nucleus is drastically shielded ($\Delta\delta=300$ ppm), as is also observed in the transition from *(1)* to *(2a)*. The symmetry of *(2c)*—and thus

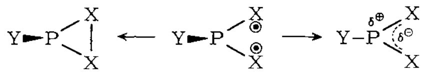
the *trans*-position of the methylene protons to the lone pair at the phosphorus atom—follows from the low absolute contribution of the P—C—H coupling constants.

The geometry in the HC—P—CH fragment of the $\lambda^3$-phosphirane *(4)* is the same; the *cis* relationship of the methylene protons is additionally indicated by the large value of the H—C—C—H coupling constant. A further indication of the special bonding in the phosphirane *(4)* is the marked upfield shift of the $^{31}$P-NMR signal.

An explanation of the findings described in the first paragraph is possible in terms of the Bell-Evans-Polanyi principle[7]. If the diradical *(A)* occurs as hypothetical intermediate in the $N_2$-elimination from the cyclic azo compounds *(2)* then it essentially depends upon two factors as to whether the ylide *(B)* or the three-membered ring *(B')* is formed:

a) on the magnitude of the resonance stabilization, which leads to a preference of the singlet *(B)* over the triplet state *(A)*;

b) on the stability of the X—X bond, whose contribution favors a ring closure to *(B')*.



(B')  (A)  (B)

The formation of the three-membered ring *(4)* in the reaction of *(2c)* would indicate that the gain in energy by cyclization already overcompensates that gained by resonance stabilization. Consistent with this conclusion are the MINDO/3 calculations[8] on this system, which show the ylide form to be the energetically less favorable and give a relatively high energy barrier for a valence isomerization *(B')*$\rightleftharpoons$*(B)* (Fig. 1).

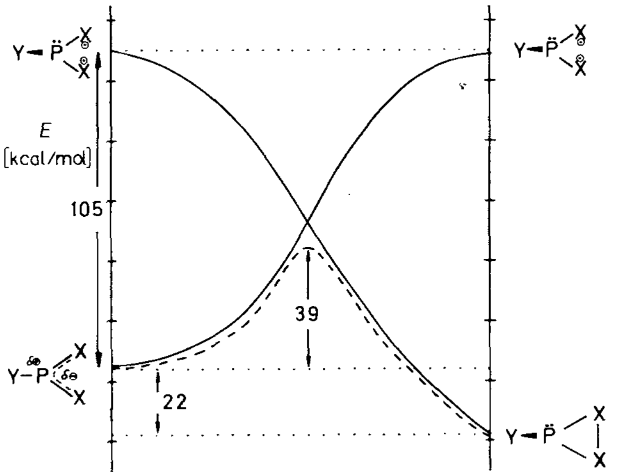


Fig. 1. The Bell-Evans-Polanyi principle for the equilibrium *(B)*$\rightleftharpoons$*(B')*. Dotted line: energy surface for the valence isomerization with $X = CH_2$, $Y = NH_2$ calculated according to the MINDO/3 method [8].

*Procedure*

*(5)*: Bis(trimethylsilyl)chloromethane (18 g, 92 mmol) is allowed to react with Mg (92 mmol) in tetrahydrofuran (THF) (50 cm$^3$) to give the Grignard compound, which is added dropwise into a solution of $PCl_3$ (12.6 g, 92 mmol) in THF (20 cm$^3$) cooled with an ice/salt mixture at such a rate that the temperature does not exceed 10 °C. The mixture is then heated to boiling and treated dropwise with a solution of lithium bis(trimethylsilyl)amide (15.3 g, 92 mmol) in THF (50 cm$^3$). After 1 hours' heating under reflux the solvent is removed and the residue pyrolized in a vacuum at 150 °C. *(5)* distils over as a bright yellow liquid; b.p. 57—59 °C/0.1 torr, yield 13.7 g (54%).

*(2c)*: A stirred solution of *(5)* (5.5 g, 20 mmol) in ether (20 cm$^3$) is treated at 0 °C with an excess of 1-diazo-2,2-dimethylpropane in THF. After 1 hours' stirring at room temperature the solvent is removed and the residue recrystallized from *n*-pentane; yield 4.1 g (55%) *(2c)*, white needles of m.p. 94-96 °C (dec.).

*(4)*: *(2c)* (2.0 g, 5 mmol) is pyrolyzed in a vacuum by heating from 80 to 120 °C. *(4)* distils over as a colorless liquid; b.p. 93—95 °C/0.1 torr; yield 1.4 g (76%).

## Preparative Separation of Lanthanoids by High-Pressure Liquid Chromatography (HPLC)[**]

By *Werner Weuster* and *Hermann Specker*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

All lanthanoids can be analytically separated in μg amounts by thin layer chromatography and HPLC[1]. It has also proven possible to separate all lanthanoids in ores, industrial products and irradiated fuel elements by HPLC and to determine them with a high degree of accuracy[2].

We have now attempted the isolation of individual lanthanoids in pure form, at first in mg amounts. In a preliminary experiment a mixture containing an overall weight of 4.64 mg of Sm, Gd, Eu and Tb was chromatographed, the technique adopted being based on analytical experience (Fig. 1). Diisopropyl ether/tetrahydrofuran/nitric acid (100:44:3) was used as eluent. The eluate was collected in separate fractions at 0.3 min intervals and the peak areas determined and printed out at the same intervals *via* an in-built integrator, thus enabling a direct determination of the content of each fraction. It can already be seen from Figure 1 that Sm and Tb are present in pure form, while Gd and Eu overlap in two fractions, as was also demonstrated thin-layer chromatographically. As a check, 1% of the neighboring element Eu was

[**] We thank Dr. *F. Eisenbeiss*, Merck, for providing us with the HPLC column.

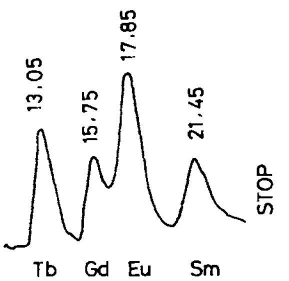

Fig. 1. HPLC separation of the elements Tb, Gd, Eu, and Sm with retention times (min). Column: Merck Si 40 (250 × 7 mm); Apparatus: Hewlett-Packard HPLC 1084B; fluorescence detector, Schoeffel Instruments. Detection: Fluorescence quenching on breakthrough of the lanthanoids without addition of reagent.

added to pure Sm, 1% Gd to the Tb; these additions could be detected very accurately by thin layer chromatography. Thus the purity of Sm and Tb is with certainty >99%. Further investigations with the difficultly separable pair Gd-Eu in different concentration ratios (up to 10:1) give in the case of 17 fractions an overlapping of two fractions, eight fractions of the Gd contained less than 1% Eu; seven fractions of the Eu less than 1% Gd.

As a practical application we have preparatively separated a monazite sand. The quoted amount of lanthanoids in the sample was 5.2 mg. La, Ce, Pr, Nd, Sm, Gd, Y and Er could be detected by HPLC analysis (Fig. 2). Of the total 85 fractions 4 contained pure Er, 2 pure Y, 6 pure Gd, 5 pure Sm, 10 pure Nd, 4 pure Pr, 12 pure Ce and 18 pure La, whereby

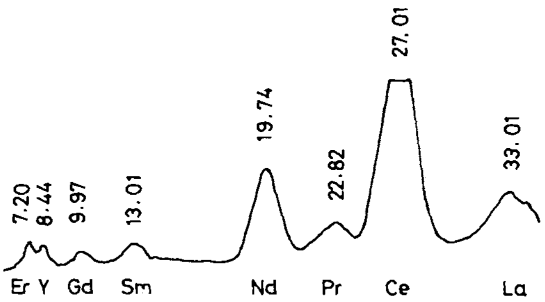

Fig. 2. HPLC separation of a monazite sand with retention times (min). Column, apparatus and detection, see caption to Fig. 1.

the purity is ≧99%, as was confirmed thin layer chromatographically by the addition method. These separations require a total of 35 minutes.

We used columns having a capacity of 5 mg. It is expected that larger columns with the same retention times and considerably higher flow will allow separations on the g scale.

## BOOK REVIEWS

**Pyrolytic Methods in Organic Chemistry. Application of Flow and Flash Vacuum Pyrolytic Techniques.** By *R. F. C. Brown.* Academic Press, New York 1980. xii, 347 pp., bound $ 38.50.

This is the first book since *Hurd*'s 1929 treatise on "The Pyrolysis of Carbon Compounds" to be devoted to this subject. Written by one of the pioneers of flash vacuum pyrolysis, the book gives a fairly broad account of all pyrolytic methods used in organic chemistry. Although a book of this wide scope cannot possibly be fully comprehensive, all the more important reactions are treated, and a very good selection of references is given. By specifying the scope of each chapter and citing review articles on specialized topics (*e.g.* ester pyrolysis which is not dealt with in detail because an extensive review literature exists) a considerable degree of completeness is achieved, and further study by the interested reader is greatly facilitated. The literature covers the period up till the end of 1977, with a few references from 1978 being included.

After a short introductory chapter, the second chapter deals with apparatus and methods and is very useful for the novice in the field, giving designs and/or photographs of apparatus used by various groups.

The remaining seven chapters review the literature on pyrolysis reactions arranged according to compound type, reaction type, or the nature of the reactive intermediates generated by pyrolysis (free radicals, arynes, and cyclobutadienes; elimination reactions; carbenes and nitrenes; fragmentation of cyclic structures; fragmentation of acyclic structures; cleavage of carbocyclic and heterocyclic systems; rearrangement without fragmentation). Obviously, a uniform arrangement of the material was not intended, and this is largely due to the enormous diversity of reactions covered. It is altogether extremely difficult to classify such extensive material in a consistent manner, and therefore similar reactions are often found in several different chapters (*e.g.* arynes in Chapters 3, 5, and 6; derivatives of *Meldrum*'s acid in Chapters 5, 6, 8, and 9). Such cases are, however, always cross-referenced, so that the reader can easily trace the occurrence of related intermediates in different types of reactions throughout the book.

In some of the chapters detailed mechanistic discussion is limited, and many reaction mechanisms are taken from the original literature without further comment. In keeping with the rather factual presentation of the material, theoretical treatments of important aspects of the chemical reactivity of intermediates otherwise presented in the book are lacking or only briefly mentioned (*e.g.* diradicals, cyclobutadiene, benzynes). Comparisons with photochemical reactions are seldom made, but mass spectrometric analogies are frequently mentioned.

There are several less serious printing mistakes in the formulas, but few in the text, and the references are admirably precise. The layout is excellent and the book is easy to read.

All in all, the book can be strongly recommended to anybody who wishes to use or learn about pyrolysis reactions. Also the active researcher in the field will undoubtedly find it a most welcome reference volume.

*Curt Wentrup* [NB 523 IE]

# Toxication of Foreign Substances by Conjugation Reactions

By Dieter Reichert[*]

Elucidation of the metabolic pathways of foreign compounds in mammalian organisms contributes substantially to the understanding of toxic effects and is therefore a basic component of every risk analysis. The abundance of chemical reactions which take part in metabolic transformations allows one to speculate that we, with our present state of knowledge, are just at the beginning of a development which will help explain the interplay between chemical structure, biochemical transformation and toxic effects. This applies in particular to the conjugation of foreign compounds with structures and molecules endogenous to the body. Until recently it was thought that these conjugation reactions lead to chemically and biologically inert products, which could be easily eliminated by the organism. Using new biological testing procedures and sensitive methods of analysis, this assumption has been refuted. The fact is, that highly toxic, mutagenic and carcinogenic products can result from the chemical interactions of foreign substances with endogenous substrates.

## 1. Introduction

Nowadays we are exposed to a constantly increasing number of xenobiotics, *i.e.* substances foreign to the organism; examples of these are pesticides, solvents, occupationally used compounds, drugs and food additives such as olfactory and taste substances, stabilizers, antioxidants and many others. These xenobiotics have entirely different types of chemical structures. Some are subsequently eliminated unaltered, in urine, feces or exhaled air. These substances often do not cause any effect in the body; they are biologically inactive. Usually, however, foreign compounds are chemically changed in the organism by endogenous, nonspecific enzymes, the so-called "drug-metabolizing enzymes". These metabolic alterations often influence only the toxicological or pharmacological profile of the foreign substance. The products which are formed vary according to the type of metabolic transformation and to the chemical structure of the xenobiotic, and can be either nontoxic and easily eliminated, or be biologically reactive, causing acute toxic damage in organs, as well as mutagenic and carcinogenic effects[1,2].

In the risk assessment of xenobiotics, consideration of chemical reactivity and metabolic studies are the first steps in the investigation. Thereby it is most essential to delineate the reaction pathways and to test the detected metabolites for their potential biological reactivity. The rapid progress in this field is evident from the identification of constantly increasing numbers of metabolic pathways and new types of metabolites[3].

The complexity of the biochemical alterations leading ultimately to toxication or detoxication will be elucidated using the example of conjugation reactions in which endogenous molecules are transferred to functional groups of foreign compounds to form a conjugate.

## 2. Metabolic Fate of Xenobiotics in the Organism

Metabolic changes or biotransformations generally take place in two phases (Fig. 1). In Phase I, functional groups are introduced into a lipophilic substance *via* oxidation, reduction or hydrolysis. These reactions are catalyzed by various monooxygenases, reductases or hydrolases. Phase II, which can run either subsequent or parallel to Phase I, is a conjugation reaction. Here an endogenous substance, for example glucuronic acid, is conjugated *via* a transferase to a functional group of a foreign molecule. The result is that the compound becomes more polar, can be more easily eliminated and generally is less toxic. The reaction sequence is illustrated in Figure 2; following the introduction of a functional group into an aromatic or aliphatic molecule *via* oxidation, the endogenous substance is bound to this group[3-5].

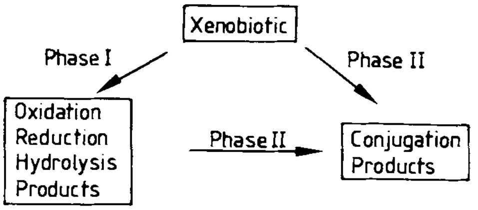

Fig. 1. Scheme of the biotransformation of compounds foreign to the body.

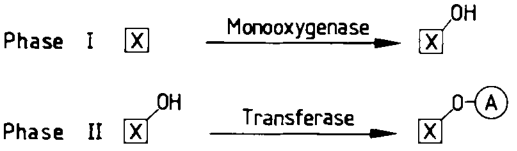

Fig. 2. Scheme of a "functionalization reaction" with subsequent conjugation.

Activation (toxication) of xenobiotics by metabolic conversion was first shown in some oxidation reactions, *i.e.* with benzo[a]pyrene, dimethylnitrosamine or, more recently, with vinyl chloride; only the oxidation products of these compounds are mutagenic and carcinogenic[6]. The oxidation products of the widely used analgesic paracetamol or of the diuretic furosemide are held responsible for liver necrosis[7]. The Phase II reactions known to date, however, often diminish toxic or pharmacologic effects by decreasing the concentration of the biologically active molecule. From this fact the assumption has developed that conjugation reactions are detoxifying reactions, as contrasted with oxidative processes. Nowadays this supposition is no longer valid without qualification, since investigations show that the conjugation products formed are not always as innocuous as had been originally assumed. This fact was recognized essentially after the introduction of biological testing methods which led to new, unexpected findings regarding the significance of conjugation reactions for the detoxication and toxication of compounds foreign to the body.

## 3. Detection of Toxic Metabolites

Metabolic studies can be useful in clarifying the mechanisms of toxicity of xenobiotics. In this respect, one of the greatest difficulties is the unequivocal identification of the respective reactive, and thereby assumedly toxic, metabolites. The proof is often only indirectly attainable on account of the high degree of reactivity and the short half-life of the intermediates. In the meantime, a series of *in vitro* testing methods has been developed; these tests are based principally on the proof of DNA damage in bacterial or mammalian cells. In this review, only the essential tests will be briefly characterized.

### 3.1. Covalent Binding to Macromolecules

The presence of reactive products can be established by the detection of covalent binding to tissue macromolecules such as proteins, DNA or RNA[1,8]. The evidence of covalently bound radiolabel after administration of a radiolabeled xenobiotic in an *in vitro* procedure is a primary testing method for reactive metabolites. By varying the labeling of the molecule it is possible to ascertain which part is covalently bound. The incubation of the assay with the appropriate transferases and cosubstrate provides additional indications of the structural characteristics of the reactive product.

### 3.2. Mutagenicity Tests

In order to determine their mutagenic potential, xenobiotics (or their metabolites) are tested as to whether they induce mutations in genes or chromosomes. Gene mutation tests are carried out on microbial systems; chromosomal damages can be investigated additionally with human cell cultures or with cultured mammalian cells[9-11]

#### 3.2.1. Microbial Tests

The microbial testing system which is currently most often used for the detection of mutagens and/or carcinogens was developed by *Ames et al.*[12]. This procedure employs bacterial strains of *Salmonella typhimurium,* which are incapable due to a point-mutation, of synthesizing the amino acid histidine. The introduction of a mutagen gives rise to back-mutants, which can again produce histidine. They are able to form colonies on nutrient media which do not contain histidine. The colonies are macroscopically visible; their number is an indication of the quantity of back-mutants and allows one to estimate the intensity of a mutagenic effect. One advantage of the Ames-Test is that it enables a differentiation between xenobiotics which cause base-pair substitution mutations and those which induce frame-shift mutations[*]. In the first case, they are generally alkylating compounds of low molecular weight and in the second case they are mostly aromatic substances with two or more rings. An additional attribute of this test is that it enables examination of the mutagenic characteristics of a xenobiotic with enzymes from different species and tissues. Transferases and cosubstrate, along with the foreign compound, are added to the Salmonella strains and incubated. Many reactive, potentially carcinogenic metabolites of xenobiotics have been identified using this effective testing procedure[13].

---

[*] Frame-shift mutations are characterized by deletion or insertion of a nucleotide in the DNA sequence, which results in a shift from the normal in each subsequent group of three nucleotides.

### 3.2.2. Cell Transformation Tests

Cell transformation tests have proven particularly successful—in addition to the Ames Test—for the detection of chemical carcinogens. In this method, mammalian cells (*i. e.* human fibroblasts, liver cells, lymphocytes or hamster embryo cells) are isolated and exposed to the test substance in a culture medium. The cells can then be fixed for cytogenetic studies and microscopic evaluation (chromosome and genome mutations), or they can be added to a culture medium in which only the transformed cells can continue growing[9, 10]. The number of colonies is a measure of a mutagenic effect. As with the Ames Test, microsomal enzymes or transferase activity can also be added with the test substance in order to detect metabolically reactive products as well.

The host-mediated assay, along with a number of additional test systems, is particularly valuable; bacterial or mammalian cells are implanted (generally intraperitoneally) into animals, and the latter treated with the test chemical. The administered cells and their mutants are subsequently recovered and counted. The advantage of this system is primarily that the formation and transformation of the reactive intermediates take place in the host organism itself[14].

## 4. Important Conjugation Reactions

The conjugation reactions which are important in man are listed in Table 1. Quantitatively, the most significant reaction is the glucuronidation of xenobiotics; this is mediated by glucuronyl transferases, which transfer glucuronic acid to numerous substrates. Other transferases transfer sulfate-, acetyl-, glutathione-, glycine- or methyl-residues. The various enzymes are either membrane-bound or dissolved in the cell cytosol (Table 1). Conjugation reactions generally require the expenditure of metabolic energy. One exception is the conjugation with glutathione; when catalyzed by glutathione transferases, glutathione is not only able to bind to substrates but can also react directly with sufficiently electrophilic partners. A decrease in the glutathione content and the appearance of mercapturic acids (*S*-substituted, *N*-acetyl derivatives of cysteine) in urine are proofs of glutathione conjugation and also provide strong evidence for the occurrence of electrophilic, toxic metabolites[15].

Table 1. Important conjugation reactions in humans.

| Conjugation | Enzymes | Subcellular Localization | Functional Groups |
|---|---|---|---|
| Glucuronidation | Glucuronyl transferases | Endoplasmic reticulum | —OH, —COOH, —$NH_2$, NH, —SH |
| Sulfation | Sulfotransferases | Cytosol | —OH, Aryl—$NH_2$ |
| Acetylation | Acetyltransferases | Cytosol | —$NH_2$ |
| Glutathione conjugation | Glutathione transferases | Cytosol | —Halogen, Epoxides, —$NO_2$ |
| Glycine conjugation | Acyltransferases | Mitochondria | —COOH |
| | Glycine transferases | Mitochondria + Cytosol | —COOH |
| Methylation | Methyltransferases | Endoplasmic reticulum + Cytosol | Aryl-OH, —$NH_2$, NH, —N, —SH |

The cyanide-thiocyanate detoxication is not specifically elaborated in Table 1. In this reaction, the toxic cyanide is converted into thiocyanate by the enzyme rhodanese. Thiosulfate serves as the sulfur donor. This reaction has long been employed therapeutically in the administration of thiosulfate in cases of hydrocyanic acid poisoning.

Binding to colamine (2-aminoethanol) is a novel conjugation reaction recently detected in man and animals. Here strongly electrophilic intermediates can react with phosphatidylethanolamine with (enzymic) splitting of phosphatidyl residues. *N*-substituted colamine has been found as a metabolite in the metabolism of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) and 1,1-dichloroethylene, as well as in blood and urine[16, 17]. In essence, this reaction can be viewed as an inactivation step. The reaction leads, however, to membrane damages, since phosphatidylethanolamine occurs primarily in the organism as a bound component of cell membranes; this is the current explanation for the hepatotoxicity of 1,1-dichloroethylene [17]. The metabolism of this carcinogenic compound is shown in Figure 3.

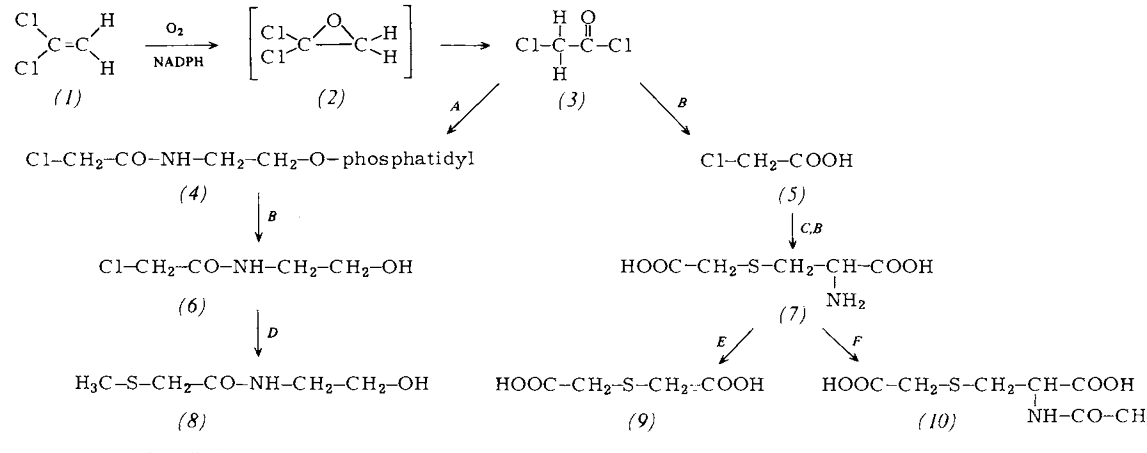

Fig. 3. Metabolism of 1,1-dichloroethylene *(1)*. The metabolites identified were *(5)* as well as *(8)—(10)*. A: reaction with phosphatidylethanolamine, B: hydrolysis, C: reaction with glutathione, D: reaction with methionine, E: deamination and decarboxylation, F: acetylation.

The conjugation reactions cited above also occur in most mammalian organisms. However there are noteworthy qualitative and quantitative differences among some animal species[18,19]. For example, cats have a strongly diminished ability to glucuronidize xenobiotics; guinea pigs do not form mercapturic acids, as the *N*-acetylation of the *S*-substituted cysteines cannot be accomplished: dogs cannot acetylate aromatic amines and hydrazines. Non-human primates resemble man most closely in terms of enzymic makeup.

### 4.1. Activation by Glucuronidation and Sulfation

In the human organism, glucuronidations are carried out on endogenous substances (steroids, thyroxine, bilirubin or serotonin and some amino acids) as well as on xenobiotic substances. In this way the glucuronyl residue can be enzymatically conjugated with a wide spectrum of chemically different compounds (Table 1).

The mechanisms for the formation of glucuronyl- and sulfate compounds are well known[4]. The first step in the biosynthesis of "activated" glucuronic acid is catalyzed by the UDPG-pyrophosphorylase enzyme (UDP = uridine-5′-diphosphate, PP = diphosphate):

$$\text{Glucose-1-phosphate} + \text{UTP} \rightarrow \text{UDP-glucose} + \text{PP}$$

UDP-glucuronic acid is formed by dehydrogenation of UDP-glucose:

$$\text{UDP-glucose} + 2\,\text{NAD}^{\oplus} \rightarrow \text{UDP-glucuronic acid} + 2\,\text{NADH} + 2\,\text{H}^{\oplus}$$

The transfer of UDP-glucuronic acid to the different functional groups (XH) is accomplished by UDP-glucuronyl transferases

$$\text{UDP-glucuronic acid} + \text{R—XH} \rightarrow \text{R—X—}\beta\text{-glucuronide} + \text{UDP}$$

Sulfotransferases transfer the sulfate residue to the hydroxyl and amino groups (Table 1). The sulfation of xenobiotics requires considerable energy. The following reactions make this clear; the sulfate donor is 3′-phosphoadenosine-5′-phosphosulfate (PAPS), which is formed from adenosine-5′-phosphosulfate (APS).

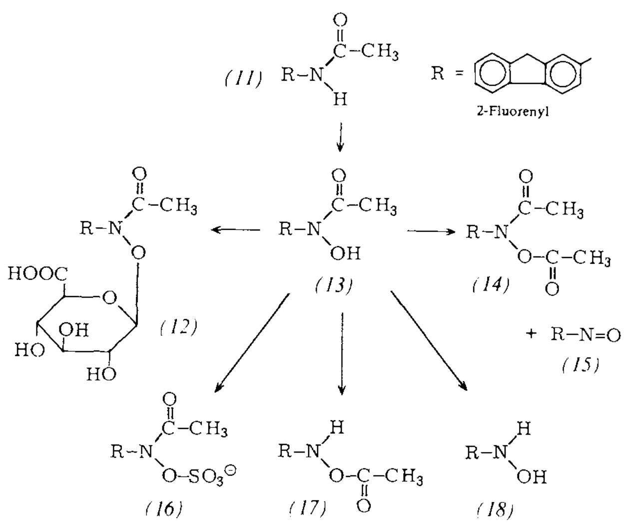
$$\text{APS} + \text{ATP} \rightarrow \text{PAPS} + \text{ADP}$$

APS in turn is formed from sulfate ions and ATP:

$$\text{SO}_4^{2\ominus} + \text{ATP} \rightleftharpoons \text{APS} + \text{PP}$$

Finally, the sulfotransferases transfer the high energy sulfate residue to a functional group (usually —OH) of a xenobiotic:

$$\text{R—OH} + \text{PAPS} \rightarrow \text{R—O—SO}_3^{\ominus} + \text{PAP} + \text{H}^{\oplus}$$



The fact that conjugation reactions can also lead to the toxication of absorbed substances was first established in the case of glucuronidation and sulfation[6,20,21]. *N*-(2-Fluorenyl)acetamide, (2-(*N*-acetylamino-fluorene)) (AAF) *(11)* served as the model compound. This substance is carcinogenic for some animal species and noncarcinogenic for others. There were indications that neither AAF *(11)* nor the oxidation product *N*-hydroxy-AAF *(13)* could be the ultimate cancer causing compound. Both, for example, do not bind to DNA in appropriate test systems. However if one incubates this system with sulfotransferase and glucuronyl transferase, reactive products which can bind to DNA are formed[23]. An intermediate product of these reactions, the *N*-bound sulfate *(16)*, is currently regarded as the ultimate carcinogen in this reaction sequence. This assumption is supported by the highly electrophilic nature of this ester, by a direct correlation of sulfotransferase activity with the formation of hepatic tumors in various rat strains and by a lowered rate of tumor formation if the sulfate concentration in the rat is experimentally reduced[24]. This compound's high biological activity is also demonstrated by a high mutagenic potential[25].

In spite of the apparent key role of the ester of sulfuric acid *(16)* in the origin of hepatic tumors, it was possible to prove that further reaction pathways of *N*-hydroxy-AAF *(13)* to electrophilic products exist. A major metabolite of *N*-hydroxy-AAF *(13)* arises through conjugation with glucuronic acid. This metabolite, AAF-*O*-glucuronide *(12)*, is formed in the liver and can easily reach other tissues *via* the bloodstream. As the ultimate carcinogen, it is held responsible for the formation of extrahepatic tumors, *i.e.* of the mammary glands and of the auditory canal. Similarly, *N*-acetoxy-AF *(17)* and *N*-acetoxy-AAF *(14)* are discussed as ultimate carcinogens, in particular for the extrahepatic tissues named above, for which no measurable sulfotransferase activities have been detected. It is assumed that the cited esters *(14)*, *(16)*, and *(17)* are precursors of the reactive nitrenium ion, which is ultimately responsible for the covalent binding to proteins, RNA or DNA.

This example from experimental cancer research shows how difficult it can be to discover the ultimate carcinogen or the actual toxic agent, particularly if several possible reactive products are identified by metabolic studies.

Other compounds having a hydroxylamine-group exhibit similar properties, in that they form reactive *N*-glucuronides or *N*-sulfates *in vivo* and *in vitro*. Further examples are the glucuronides of *N*-(*p*-biphenyl)hydroxylamine, benzidine, 2-naphthylamine and 1-naphthylamine. Their conjugation products are held responsible for urinary bladder carcinomas[20,22]. Here the glucuronic acid can be bound either as a 1-desoxy derivative or as *N*-glucuronide (Fig. 4).

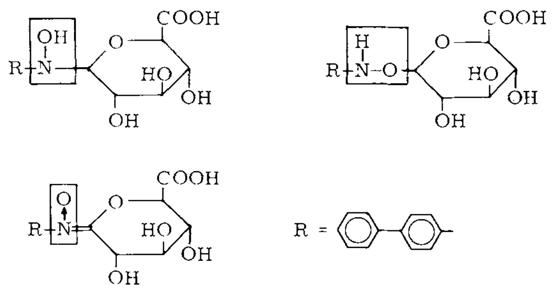


Fig. 4. Carcinogenic glucuronic acid conjugation products of *N*-(*p*-biphenyl)hydroxylamine.

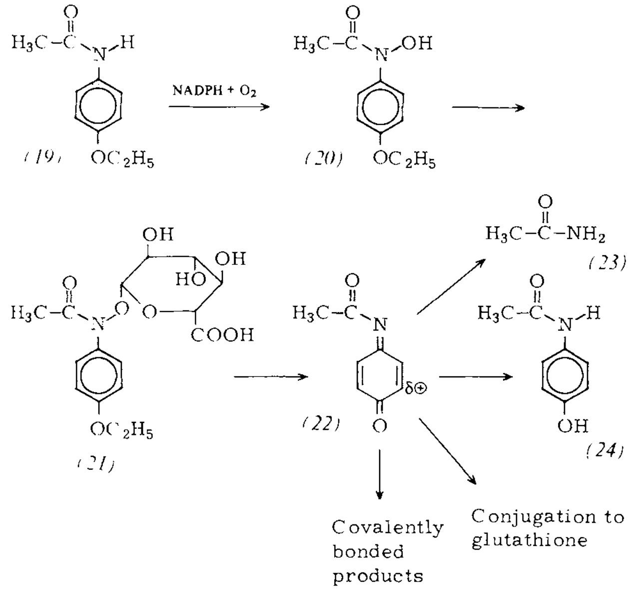
A further example of a *N*-hydroxylation with subsequent glucuronidation is provided by phenacetin, which is widely known as an analgesic. Phenacetin *(19)* is first *N*-hydroxylated to *(20)* and then glucuronidized to *(21)*[26]. In the metabolism of this compound, the formation of a reactive intermediate (*N*-acetyl-imidoquinone) *(22)*, which can bind covalently to proteins, is achieved only *via* the glucuronide or the sulfate. The formation of paracetamol *(24)* *via* a glucuronide is regarded as certain, even if other alternative pathways to that shown are conceivable. The glucuronide is formed in the liver, but it can be transported to other organs, *i. e.* to the kidneys where it can be concentrated in the collecting tubules. It is conceivable that a reactive intermediate could also be formed there, possibly additionally accelerated by the low pH. This could explain the papillary necroses observed with phenacetin abuse[26]; another consequence of such abuse is a high incidence of renal pelvis tumors[27,28]. In this case, the conjugation with glutathione is regarded as an inactivation step, *i. e.* detoxication.



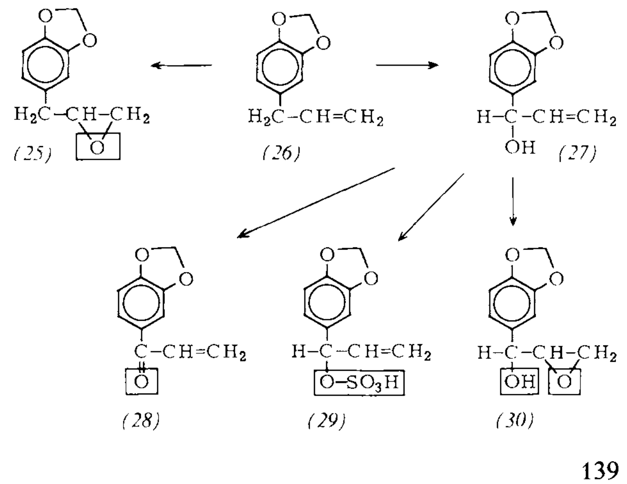
These examples show that *N*-hydroxy compounds such as the hydroxylamines tend to form reactive *N*-bonded sulfates or *O*-glucuronides[29]. Both conjugation products are better suited to bind to nucleic acids than the respective hydroxylamines. The reason for this is that the sulfate- and glucuronide-residues are better leaving groups than the hydroxyl groups and therefore more readily form the electrophilic arylnitrenium ions.

Many aromatic amines are not only used as drugs, as cited above, but are widely dispersed in general in the environment and are, to some extent, known carcinogens. Therefore the incidence of these compounds, as well as the formation of such conjugation products are judged to be toxicologically critical for man. For animal species which are not capable of *N*-hydroxylating amines, these compounds are not carcinogenic, as has been shown by the example of AAF *(11)* (Table 2).

Table 2. *N*-hydroxylation of *N*-(2-fluorenyl)acetamide (AAF) *(11)* in different animal species correlated with carcinogenic activity [30].

| Species | *N*-hydroxylation [% of dose] | Carcinogenic Effect |
|---|---|---|
| Rabbit | 13—20 | + |
| Rat | 0.3—15 | + |
| Man | 4—14 | ? |
| Dog | 5.2 | + |
| Hamster | 5.0 | + |
| Mouse | 1.8—2.3 | + |
| Cat | 1.5 | + |
| Steppe lemming | Traces | − |
| Guinea pig | 0 | − |
| Rainbow trout | 0 | − |

There are a number of other compounds and structures, besides the *N*-hydroxy compounds, which are activated by glucuronidation or sulfation. Safrole *(26)* (4-allyl-1,2-methylenedioxybenzene) is a naturally occurring component of oil of sassafras, certain spices and essential oils. It has also been used as a flavoring component in soft drinks. This substance is hepatotoxic for man and animal[31,32] and produces adenomas and carcinomas of the liver in mice and rats[31,33]. This substance therefore has been prohibited as a food constituent in the USA since 1960. Safrole *(26)* is activated *via* two different metabolic steps in the mammalian organism. The first step in the metabolism of this substance is the oxidation to the proximate carcinogen 1′-hydroxysafrole *(27)*[34]. By means of this "functionalization reaction", the transmittance of endogenous substrates by transferases is made possible. The sulfate *(29)* and the glucuronide can be identified as electrophilic esters; both are regarded as candidate ultimate carcinogenic metabolites and therefore are held responsible



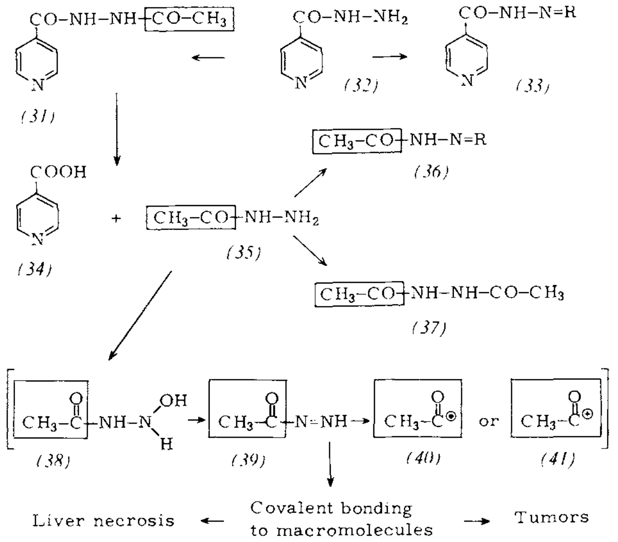
for the formation of liver carcinomas[35]. In addition to these conjugation reactions, the double bond is oxidized to an epoxide [see *(25)* and *(30)*]. Epoxides themselves can often bind covalently to macromolecules. Obviously, not all of the covalently binding structures occurring in the metabolism of safrole *(26)* have yet been clarified.

Numerous other allylic and propenylic allenes, which closely resemble safrole *(26)* in structure, are components of natural foodstuffs or can be used as food additives. One of these representative compounds is estragole (1-allyl-4-methoxybenzene), which is an additive to vinegar and a component of many essential oils and spices, *i. e.* anise, star anise, fennel and tarragon. Even low doses of this substance induce hepatocellular carcinomas in mice[36]. In this case as well, there is first an oxidation to a hydroxy-compound; the formation of an ester of 1′-hydroxyestragole leads to an electrophilic derivative, which is held responsible for the carcinogenic effect of estragole.

### 4.2. Activation by Acetylation

Acetylations take place preferably on substances which have an amino group. The high energy molecule in this case is acetyl coenzyme A, which is formed by numerous intermediary metabolic reactions. *N*-acetylation is a primary inactivation route for numerous drugs of medical interest such as procainamide, hydrazine, sulfamethazine and various other compounds with sulfonamide structures Furthermore, *N*-acetylation is a main pathway in the metabolism of carcinogenic arylamines such as 2-fluorenylamine and 2-naphthylamine[4,37].

An example of a toxication through acetylation is provided by the compound isonicotinic acid hydrazide or isoniazid (INH) *(32)*, which is the most potent tuberculostat currently at our disposal. Following the acetylation on the free amino group of the hydrazide moiety producing *(31)*, hydrolytic cleavage to isonicotinic acid *(34)* and acetylhydrazine *(35)* occurs. Acetylhydrazine *(35)* is regarded as causing liver damage. The molecular basis for this damage is postulated to be the oxidation of acetylhydrazine, which occurs on the endoplasmic reticulum, to a highly reactive acylating and alkylating intermediate. Covalent binding on macromolecules goes along with cell necrosis and possible formation of tumors[38]. These findings explain the high incidence of liver damages by isoniazid *(32)* and the chemically related iproniazid [*(32)*, —NH-*i*Pr instead of —$NH_2$], and at the same time remind one of restraint in the use or in the therapeutic administration of monosubstituted hydrazines. Products *(33)* and *(36)* arise by oxidation with α-oxocarbonic acids.



Inter-individual differences, together with the cited species variations play an important role in conjugation reactions. This is especially true for acetylations, with the genetically determined varying activities of *N*-acetyltransferases. The metabolism of INH *(32)* serves here as an example. Individuals, who are capable of acetylating rapidly, form more acetylhydrazine *(35)*. This genetic polymorphism has important pharmacological and toxicological consequences; the use of normal dosages can cause a rapid decrease in the therapeutically effective serum level of INH *(32)*. The assumption that such rapid acetylators tend more towards liver damage, due to increased formation of acetylhydrazine, has however not been experimentally proven. Persons having a slow acetylator phenotype seem more likely to be threatened by parenchymatous damage, since INH *(32)* can impede the formation—which may be regarded as an inactivation reaction—of diacetylhydrazine *(37)*. In these cases the formation of a hydroxylamine derivative, by oxidation of the amino group, is favored and this leads to further reactive intermediates *(39)* and *(40)* or *(41)*[39].

The polymorphism of acetylation is observed with other substances as well. The individually different enzyme content is possibly also responsible for differing susceptibility to carcinogenic arylamines and their metabolites. Only a few examples are known, such as *p*-aminobenzoic acid, whereby apparently equal rates of acetylation were measured[40].

In some cases, acetylated compounds are less water soluble than their precursors. Examples of such are the pharmacologically employed sulfonamides; sulfapyrazine, sulfathiazole, sulfadiazine or sulfamethazine. In using these drugs, one must expect renal damage, as they can precipitate as crystals due to the acid pH of the urine and the favorable concentrating conditions in the renal tubuli. They then lead to obstruction of the renal tubuli and renal pelvis. Therefore, it is always necessary to assure sufficient fluid intake when sulfonamides are administered[4,5].

### 4.3. Activation by Conjugation with Glutathione

Glutathione (L-γ-glutamyl-L-cysteinylglycine) is dissolved in the cytosol of animal and plant cells. Particularly high concentrations are measured in the liver, in erythrocytes and in the crystalline lens (of the eye) of mammals. Glutathione is synthesized in the cell *via* six enzyme catalyzed reactions in the so-called γ-glutamyl cycle, and then again decomposed into individual amino acids[41].

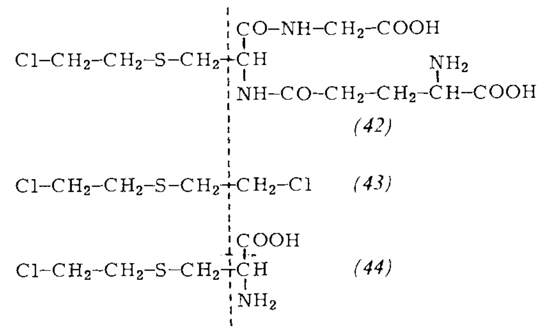
Glutathione has an integral role for a great number of biological functions[41] such as, a) protection of the cell membrane by preservation of essential thiol groups of proteins and other molecules, b) decomposition of hydrogen peroxide or free radicals, c) transport of amino acids, amines or small peptides through cell membranes, and d) detoxication of electrophilic xenobiotics and/or their metabolites *via* conjugation and subsequent elimination of the product as mercapturic acid, whereby glutamate and glycine first split off and then the amino group is acetylated. The reaction sequence is presented in Figure 3, using the metabolism of 1,1-dichloroethylene *(1)* as an example. Numerous mercapturic acids have been isolated[42].

In its reduced form, glutathione is a strong nucleophile. Therefore conjugations can occur either by a direct $S_N2$ reaction of the thiol group with sufficiently electrophilic substrates, or by an enzymic reaction catalyzed by glutathione-*S*-transferases. Up to now, seven of these enzymes from the cytosol of human and animal liver cells have been isolated and purified[43,44]. Glutathione transferases are highly specific in their requirement for glutathione, but multifunctional when involved in the catalysis of reactions with glutathione[45].

Formerly only detoxifying functions were ascribed to conjugations with glutathione. Numerous examples, such as those of paracetamol *(24)* or halogenated aliphatic and aromatic hydrocarbons confirm the protecting action of glutathione against the toxic effects of these foreign substances. It was first shown for paracetamol that a direct correlation exists between the glutathione concentration in the cell and the incidence of covalent bonds with essential nucleophilic cell components[7]. If the glutathione concentration decreases to less than about 30% of the normal value, the protecting capacity is no longer sufficient and the number of covalent bonds increases exponentially, ultimately leading to cell necrosis and parenchymal destruction.

These biochemical correlations are used therapeutically to treat poisonings with mercapturic acid precursors, whereby one attempts to raise the cellular concentration of reactive thiol groups. This is successful with compounds having better bioavailability than glutathione (*i.e.* *N*-acetylcysteine or cysteamine). Severe paracetamol poisonings have been successfully treated using this specific therapy[46,47].

Recently, however, participation of glutathione has also been proven in the activation of xenobiotics to mutagenic and potentially carcinogenic electrophiles. 1,2-Dichloroethane—having an annual worldwide production of almost two million tons[48] and being by far the most highly produced chlorinated aliphatic hydrocarbon—is mutagenic in the Ames Test[49,50]. The activation to a mutagen is observed if a postmitochondrial liver cell fraction[*] is added to the bacteria. The addition of a pure microsomal fraction on the other hand does not lead to an activation. Therefore an activation pathway other than that of oxidation by microsomal mixed-function oxygenases must be involved. Further investigations with pure enzyme preparations and the system of the isolated perfused liver preparation confirmed that the mutagenic effects of 1,2-dichloroethane only increase in the presence of glutathione and the glutathione transferases[50,51]. The prerequisite therefore is enzymic conjugation with glutathione. This reaction leads *via* the substitution of a chlorine atom with glutathione to a β-halogen thioether *(42)*, which is responsible for the mutagenic[50] and carcinogenic[52] effect of 1,2-dichloroethane. Such compounds are highly reactive and have been recognized for a long time for their mutagenic and carcinogenic effects, as is shown for example by the chemical warfare agent mustard gas *(43)*, which carries the same leaving group (Fig. 5). The analogous nitrogen-mustard gas type derivatives are used in chemotherapy for carcinomas. These compounds (for example *N*-oxide-mustard gas or cyclophosphamide) are also carcinogenic in animal experiments.



$$Cl{-}CH_2{-}CH_2{-}S{-}CH_2{-}\overset{CO-NH-CH_2-COOH}{\underset{NH-CO-CH_2-CH_2-\overset{NH_2}{C}H-COOH}{CH}}\quad (42)$$

$$Cl{-}CH_2{-}CH_2{-}S{-}CH_2{-}CH_2{-}Cl\quad (43)$$

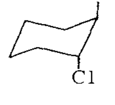
$$Cl{-}CH_2{-}CH_2{-}S{-}CH_2{-}\overset{COOH}{\underset{NH_2}{CH}}\quad (44)$$

Fig. 5. Mutagenic and carcinogenic β-halogen thioethers with the same leaving group; conjugation products of 1,2-dichloroethane with glutathione *(42)*; mustard gas *(43)*; *S*-(2-chloroethyl)-L-cysteine *(44)*.

1,2-Dibromoethane, which is frequently employed as a pesticide and as a gasoline additive, is activated by conjugation with glutathione in the same manner as with 1,2-dichloroethane. The conjugation product, here as well, has strong alkylating properties and can account on a molecular basis for the pronounced mutagenic and carcinogenic effects[52,53] of 1,2-dibromoethane. The above-mentioned β-halogen thioethers *(42)* and *(44)* are subject to further metabolic changes *in vivo* and *in vitro:* 1) oxidative dehalogenation to *S*-(2-hydroxyethyl)-L-cysteine (or *S*-(2-hydroxyethyl)-L-glutathione); 2) conjugation with a further glutathione molecule to form a dithioether. Both metabolic products are biologically inactive. Thus, in metabolism, glutathione conjugation leads initially to a toxication and then later assists in a detoxication of one and the same substance.

Compounds having good leaving groups substituted on vicinal carbon atoms are generally transformed through glutathione conjugation into potential mutagens[54]. The strength of the mutagenic effect is dependent on both the nature and arrangement of the substituents. The more electrophilic the substituent is, the stronger the mutagenic effect. Furthermore, stereochemical factors influence the biological efficacy[50]. Thus, the conjugation product of *cis*-1,2-dichlorocyclohexane *(45)* and glutathione is mutagenic while that of the *trans*-isomer *(46)* is nonmutagenic.

*(45)*



*(46)*

It was surprising to note that these types of structure-effect relationships were ascertained as early as 20 years ago. *S*-(2-chloroethyl)-L-cysteine *(44)* (Fig. 5) was already recognized in 1960 as a highly reactive alkylating compound and was investigated thoroughly as a model substance for a powerful mutagen[55]. This fact should lead to re-examination of the risk analysis process used for exogenous substances. The first

---

[*] *i.e.*, the 9000 g supernatant (S-9) of a liver homogenate.

step in a risk analysis must be the elucidation of the chemical reactivity of the foreign compound which is then correlated to model substances whose toxic potential and pattern of metabolites are known; only then should the microbial tests and metabolic studies be carried out. Had this procedure been used earlier, xenobiotics which were produced for decades in great quantities (as 1,2-dichloroethane or vinyl chloride) would have been recognized sooner as posing a carcinogenic risk.

## 5. Outlook

The examples of toxication by conjugation of compounds foreign to the body with endogenous substances set forth here, make clear the dual function of transferases. In most cases, the pharmacological efficacy is raised by conjugation, and the conjugation products are also usually less toxic. Nevertheless, it could be shown by means of some examples that the transfer of endogenous substrates can also be tied to an activation, *i.e.* toxication of the foreign compound. Risk analysis of compounds foreign to the body is thereby made substantially more difficult. On the one hand, a multitude of metabolic intermediate and end products can be regarded as the ultimate damaging agents; on the other, conjugation reactions are subject to enormous qualitative and quantitative differences among species. Since conditions which are the same as those in man with regard to the metabolism of xenobiotics are not found in any other animal species, each case must be treated separately and the animal species which most closely resembles the circumstances in man, with respect to a specific substance, selected.

Before a total concept of the biological activity of a compound foreign to the body can be developed, all structural changes to which such exogenous compounds in the organism are subject must be examined. Each new metabolite of the foreign compound or biotransformation pathway which is detected could be toxicologically relevant. The examination of even some reactions which had been known for some time and which had been regarded as toxicologically harmless, has indeed demonstrated the complexity of metabolic transformation with the appearance of unexpected, highly toxic products. The great number of endogenous molecules with which foreign compounds can react, allows one to anticipate a multitude of new reaction products and makes the conjugation reaction particularly interesting.

With the introduction of new *in vitro* test systems and sensitive analytical procedures in the risk assessment of xenobiotics, we are at the beginning of a development which acknowledges the full significance of the conjugation reaction for the toxication and detoxication of compounds foreign to the body. The classical assignment of the conjugation reactions to the category of detoxication reactions must finally be abandoned.

# Protein Differentiation: Emergence of Novel Proteins during Evolution

By Georg E. Schulz[*]

The almost limitless number of proteins can be reduced to approximately 200 basic structures, *i. e.* geometries of polypeptide chains; these form the set from which the tracable protein differentiation started. Protein differentiation begins with a gene duplication. One of the gene products is conserved since it must continue to fulfill the original function. The other gene product is conserved as soon as it has taken over a new function. Comparing amino acid sequences of equivalent proteins in two species yields the evolutionary distance between these species, which allows dating of their common ancestor ("molecular palaeontology"). These comparisons are now applied to the geometries of nonequivalent proteins, elucidating the pathways of protein differentiation.

## 1. Introduction

In today's terrestrial world there exist approximately $10^{11}$ distinct proteins. When all differences between proteins performing corresponding functions in non-identical species are neglected, this number is reduced to about $10^5$. Since such an array is still very large, further reduction is profitable. This is achieved by neglecting all differences in protein functions and concentrating on basic protein structure, *i. e.* the geometries of polypeptide chains. At this level of geometrical comparison, the number of different proteins is merely of the order of $10^2$; such a number corresponds approximately to the number of paintings one would view in an art exhibition. By virtue of this suggested simplification, the protein world becomes as comprehensible as an art gallery.

Both reductions of complexity, from $10^{11}$ to $10^5$, and from $10^5$ to $10^2$, correspond to historical biological processes which ran in the opposite direction; from limited to vast diversity. The first reduction step corresponds to the well-known process of evolution of species whereas the second step reflects the evolution of proteins, or "protein differentiation". The term "differentiation" was chosen[1] because the evolution of proteins resembles the differentiation process of tissue cells; the individual proteins are duplicated like cells (but on a secular time scale). Subsequently, the two copies evolve separately and serve different functions in the organism.

Proteins have to be well characterized if they are to be distinguished from one another. For this purpose, global characteristics such as molecular weight, sedimentation velocity, amino acid composition, *etc.*, do not suffice. The following discussion requires an exact structural description; either knowledge of the total sequence of all amino acid residues along the polypeptide chain (the "protein sequence"), or knowledge of the path of the polypeptide chain in three dimensions (the "protein geometry"). Knowing both sequence and geometry, and therefore the spatial arrangement of all atoms (the "protein structure") is an even better starting point for further investigations[2]. About $10^3$ sequences and $10^2$ geometries and structures are known today[3,4]; this data base is large enough not only to reveal the pathways of protein variations accompanying the evolution of species but also to elucidate the evolutionary pathways of protein differentiation.

## 2. Variations Accompanying Species Evolution

Soon after the first successful sequence analysis it became clear that homologous proteins in different species are not identical in all amino acid residue positions. The copies of the antibacterial protein lysozyme present in man and baboon for example, are not identical in 14 of the 131 positions. Accordingly, one has to accept that 14 amino acid changes occurred during the separate evolution of baboon and man; presumably 7 in each branch. As a general rule, the earlier the branching point the more exchanges have to be expected. Comparing the lysozymes of man and duck, for example, one detects as many as 53 nonidentical amino acid residues.

In order to comprehend these species-specific changes, it is worthwhile to assess the role of macromolecules in the biological system (Fig. 1). The genetic information laid down as a sequence of nucleotides in the DNA, primarily defines the amino acid sequence; given a sequence, the corresponding protein structure is assumed automatically by the sponta-

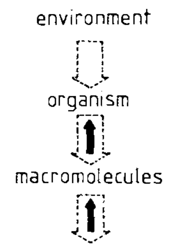

Fig. 1. Position of macromolecules in the biological system. The genetic information laid down in DNA exactly defines the structure of macromolecules; these are for the most part proteins but also include some RNA molecules. The macromolecules in turn exactly define the organism to which they belong. In the time scale of evolution however, the causality is reversed by the effects of mutation and selection. Eventually, the ecological conditions determine the genetic information of an organism.

neous folding process. The structures of RNA molecules, for example ribosomal RNA, are determined in a similar manner. At the next level, each organism is defined by its set of macromolecules. Every variation starts at the DNA level as a mutation of the genetic information, which subsequently is expressed at the macromolecular level and therefore at the level of organisms.

Screening experiments, in which haemoglobins were analyzed, showed that the frequency of spontaneous mutations in man amounts to $10^{-3}$ *per* protein *per* person[5]. If all these mutations were accepted and passed on to the descendants, the $10^5$ generations separating man from the gorilla should have given rise to completely different macromolecules. The α- and β-chains of the haemoglobins of gorilla and man, however, differ by only one amino acid each. Such a limited acceptance of the vast number of spontaneous mutations offered, demonstrates that at the macromolecular level the organisms and environment can select from a virtually unlimited number of mutations in the DNA. As a consequence, in the evolutionary time scale, the information flows in the opposite direction (from top to bottom in Fig. 1).

An example for the acceptance of a mutation, which is understood in detail, is the sickle cell gene of the β-chain of haemoglobin, which in areas subject to malaria is observed with frequencies up to 40%[6]. As shown in Figure 2, the sickle cell gene differs from the normal one by exchange of a glutamic acid for a valine at the protein surface. Through this exchange a linear aggregation of the haemoglobin molecules becomes energetically favored. The arising fibers, stretch the erythrocytes to a sickle-like shape. Since sickle cells tend to break up when passing through the capillaries, the mutation eventually causing anaemic conditions and possibly early death. In spite of the unfavorable consequences for the organism, this mutation has been accepted, because fiber formation impedes the invasion of plasmodia in erythrocytes and thus protects the person carrying the sickle cell-gene to a certain extend against malaria. In this example evolution follows a passage between Scylla and Charybdis; on one side death by malaria, on the other death by anaemia.

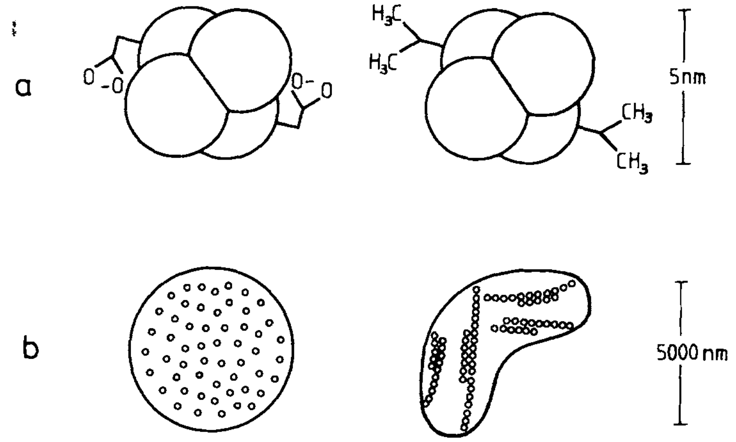

Fig. 2. Sickle cell gene of haemoglobin. a) The difference between sickle cell and normal haemoglobin is the change from glutamic acid to valine in position 6 of the β-chain. b) In erythrocytes, normal haemoglobin occurs monodisperse, in spite of the high concentration of 300 mg/ml, whereas sickle cell haemoglobin aggregates to fibers.

In the case of sickle cell haemoglobin, the environment represented by malaria parasites has forced the acceptance of a mutation that is otherwise deleterious to the organism (Fig. 1). At the macromolecular level the exchange is neutral, because it does not hinder the individual molecule in performing its function; namely transporting $O_2$. This example demonstrates how much a sequence difference observed today depends on details of the environment in the past. Consequently, it seems very unlikely that we can ever completely understand the presently observed protein differences completely. Nevertheless, these differences may still be analyzed statistically in order to elucidate general rules governing protein variations.

If all amino acid exchanges are considered equivalent, a very simple measure of the difference between two sequences arises; the number of residue changes, or in normalized form, the number of residue changes per residue position. In addition, if the frequency of exchange in a given protein can be taken as constant during evolution, this provides a time scale allowing the conversion of a sequence difference into an evolutionary distance, or, into a measure of the time of the branching from a common ancestor. On this basis a "molecular palaeontology" becomes feasible. Let us consider a protein with a given function, for instance lysozyme. If lysozyme sequences of N species are known, one may derive $N\cdot(N-1)/2$ evolutionary distances between these species. These data suffice for arranging the respective species into a phylogenetic tree[3].

As a rule, the molecular palaeontology extends into appreciably earlier times than its conventional counterpart. Using the sequences of cytochrome c-like proteins, for example, allows one to relate bacteria to each other which presumably separated as long ago as about $3\cdot10^9$ years[7]. From the existing $10^5$ proteins which perform a particular function it should be eventually possible to establish $10^5$ phylogenetic trees and to combine them. Drawing from such an extensive data base should render molecular palaeontology a highly accurate method.

Comparative sequence analyses showed that the frequency of change in a given protein depends critically on its interactions with the surrounding material. Histones, for example, are deeply buried in chromatin and form numerous contacts with neighboring molecules. Moreover, as a constituent part of chromatin, histones are required for functions as central to an organism as mitosis and meiosis. Accordingly, they only vary with a rate of 0.1 changes *per* position *per* $10^{10}$ years. Compared to histones the "easy-going" fibrinopeptides, which cover the surface of fibrin preventing spontaneous blood coagulation, change their amino acids a thousand times faster. Fibrinopeptides of species which separated only ten million years ago contain about 20% sequence differences today.

This rule not only applies for structural proteins like histones and fibrinopeptides but also for enzymes. In enzymes, however, the contacts to the surrounding material are of minor importance in relation to their catalytic reactions. Here, one expects that the amino acid residues in the catalytic center would change reluctantly. Exactly this situation has been observed in all known enzymic structures; the catalytic center is strongly conserved. Conversely, the catalytic center of several enzymes was recognized by means of the amino acids conserved. Both rules; conservation of contacts and conservation of chemical reactions, reflect the selectioning influence of organisms (Fig. 1) on the variation of macromolecules.

Amino acid exchanges may destroy proteins if they decrease protein stability. Such exchanges are, however, already discriminated against at the macromolecular level (Fig. 1). This process can be traced in the observed sequences. If the mutation rates in the chain positions at the protein surface are compared with those in the protein interior, it becomes clear that the surface is altered appreciably faster than the interior. This gradient can be explained, because proteins are packed together as tightly as crystals of small molecules, *i. e.* the contacts between different parts of the polypeptide chain are optimised[4]. In contrast to exchanges at the surface, those in the interior invariably disrupt this packing and decrease protein stability; internal changes are therefore rarely accepted.

Up to this point only changes of amino acid residues have been discussed, *i. e.* variations of side chains which conserve the main chain. No reason exists, however, for leaving the main chain untouched during evolution. Main chain modifications, *i. e.* insertions and deletions of amino acid residues, are considerably rarer. In general they appear only after about half the side chains have been altered; at 30% and 15% of remaining sequence identity, the fraction of insertions and deletions increases to 10% and 30%, respectively. After correction for multiple changes at each position, these values indicate that main chain links vary about ten times slower than side chains.

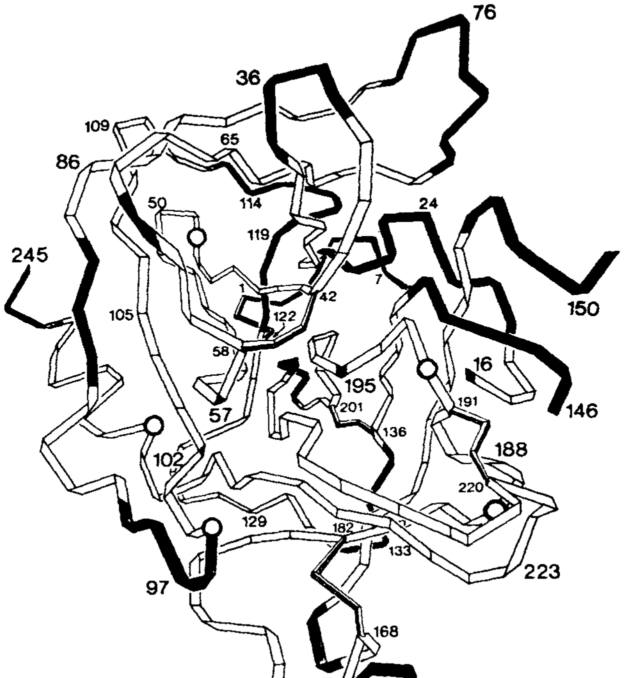

Fig. 3. Overlay of the polypeptide chains of chymotrypsin and protease-B of *Streptomyces griseus*. The chain fold and the numbering scheme of chymotrypsin is used [8]. The dark stretches of the chain are missing in protease-B (cf. chymotrypsin); circles denote the insertions in protease-B. Since both sequences agree in merely 12% of the positions, they could only be aligned after overlaying the chain folds [9]. The topology of the chain between residues 25 and 115 is identical to that between residues 135 and 225.

The two proteins depicted in Figure 3 exhibit 38% insertions and deletions; a sequence alignment becomes virtually impossible with so many main chain modifications. Alignment of such sequences can only be achieved if both protein structures are known. Overlaying the structures than reveals all insertions and deletions and permits the determination of the number of amino acid exchanges. Figure 3 shows in addition that main chain modifications occur exclusively at the protein surface. In the protein interior such modifications would undermine stability even more strongly than amino acid changes, and reduce their chance of being accepted.

Since main chain modifications usually enlarge or shorten chain loops at the surface, they do not affect the general path of the polypeptide chain in three dimensions; the so-called "chain topology". As a consequence, the chain topology is the best conserved property of proteins. It is retained even after all sequence identities have vanished. To date, no example of a protein change occurring during species evolution which altered the chain topology is known.

## 3. Functional Variations

In the course of structural analyses not only similarities between proteins performing identical functions in different species were discovered, but also similarities between proteins performing different functions in the same organism. As an example, the sequences of the digestive enzyme elastase and of the plasma enzyme thrombin have been aligned in Figure 4. The polypeptide chains correspond with each other in as many as 30% of the amino acids, raising the question whether they have a common origin. This question implies that there exists an evolution of proteins, which alters protein function and therefore exceeds the protein variations accompanying the evolution of species.

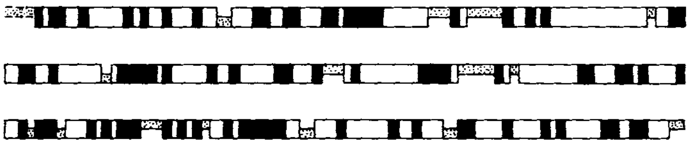

Fig. 4. Comparison of the amino acid sequences of elastase [10] and thrombin [11]. The dark and light regions denote identical and differing amino acid residues, respectively. Dotted regions are insertions in thrombin (upper) and elastase (lower). The compared chain length is 266 residues, 79 of which are identical. Among the $266-79=187$ differences there are 33 insertions and deletions. These numbers amount to $79/266=30\%$ sequence identity and $33/266=12\%$ changes of the main chain.

To answer this question, we estimate the probability of finding the observed sequence identity by chance. Assuming equal probabilities for all 380 possible amino acid exchanges, and that all insertions and deletions have been positively located (Fig. 4), the probability of random coincidence amounts to

$$\left(\frac{1}{20}\right)^{79}\cdot\left(\frac{10}{20}\right)^{187}\cdot\frac{266!}{79!\cdot 187!}\approx 10^{-38}.$$

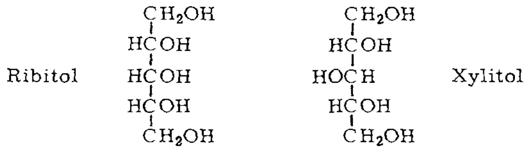
(Numbers stem from the legend to Fig. 4; 20 stands for the 20 standard amino acids)

Without the simplifying assumptions, this value increases by several orders of magnitude. However, the resulting probability remains small enough to exclude, for all practical purposes, coincidence occuring by chance. There must therefore be a reason underlying the discovered sequence identity; either the calculation is completely wrong, because the number of sequences which allow stable proteins is very limited, or, elastase and thrombin are connected by an historical development.

Since numerous stable proteins containing totally different sequences are known, the calculation is approximately correct. As a consequence, an historical connection between these two proteins has to be assumed. Elastase and thrombin originated from a common ancestor, or stated reversely, after separation the proteins have acquired different functions in the organism. At the cellular level such a process is called "differentiation". Transferring this term to the level of macromolecules[1] we refer to "protein differentiation".

An assumption as basic to biology as protein differentiation should be founded on evidence which is more direct than approximately calculated probabilities. Such evidence is available because changes of protein function can be followed directly. It is well known to physicians, that parasites become resistent to an effective drug and that this resistance is hereditary. Most probably, mutations have changed the functions of one or more parasite proteins in such a way that the parasite can resist the drug.

Even more direct evidence was obtained from evolution experiments on *Klebsiella aerogenes*[12]. This organism accepts ribitol as an energy and carbon source, whereas the epimer xylitol can scarcely be used. Both, ribitol and xylitol, are picked up and prepared for further use by the enzyme ribitol dehydrogenase; ribitol is, however, converted 100 times faster than xylitol. This system permits the application of evolutionary pressure to modify the enzyme specificity by offering xylitol exclusively as the carbon and energy source. As a first adjustment to this pressure the bacteria did not alter the specificity of ribitol dehydrogenase, but its concentration by means of gene multiplication; a costly method for balancing low enzymatic activity. However, mutations giving rise to amino acid changes in ribitol dehydrogenase, which improved the conversion of xylitol, emerged at later stages of the experiment. The results show that gene multiplication can occur, and that a change of enzymatic specificity and thus enzyme function is quite possible.



Gene multiplication and functional variation can therefore be observed. As sketched in Figure 5, protein differentiation starts by duplicating or multiplying a gene; during the ensuing development at least one copy of the gene is preserved to fulfill the original function. The additional copies are like children on a playground. Since their gene product is not vital, they experience no pressure from "above" (Fig. 1), and can change freely until they are capable of performing a new function. As soon as the new function becomes vital for the organism however, the gene has come of age and its liberty ends.

Isoenzymes provide examples for early stages of protein differentiation. These groups of enzymes are coded on separate genes, occur in parallel in the same organism, and their functional and structural difference is relatively small. Well-known isoenzymes are the skeletal and heart muscle variants of lactate dehydrogenase, which are in concordance in three quarters of their amino acid residues[13,14]. In comparison, the differences between the three isoenzymes of adenylate kinase are much larger[15]. These isoenzymes are specialized for the cytosol, the intermembrane space of mitochondria, and the matrix of mitochondria, respectively. A clear case of protein differentiation is also observed with the enzyme couple lysozyme and lactalbumin. At the time when mammals appeared, the lysozyme gene was duplicated; one copy retained its antibacterial capability whereas the second copy became an important part of the mammalian milk and thus satisfied newly arising needs. The historical relationship between these two enzymes is beyond doubt, because they show as much as 38% sequence identity. It is worth mentioning that both enzymes operate on saccharides; this aspect of their function has been conserved.

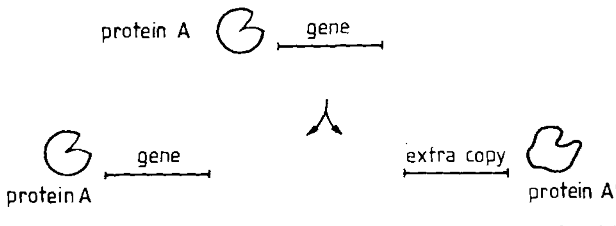


Fig. 5. Schematic representation of gene duplication. After duplicating the original gene, one of the copies produced still fulfills the original function of the protein; it is therefore well conserved. The other product can change quite freely. In cases where gene duplication is only a means for increasing the production, all gene copies are conserved because they are all needed. In the tandem gene duplications listed in Table 1 both products are joined, forming a single chain.

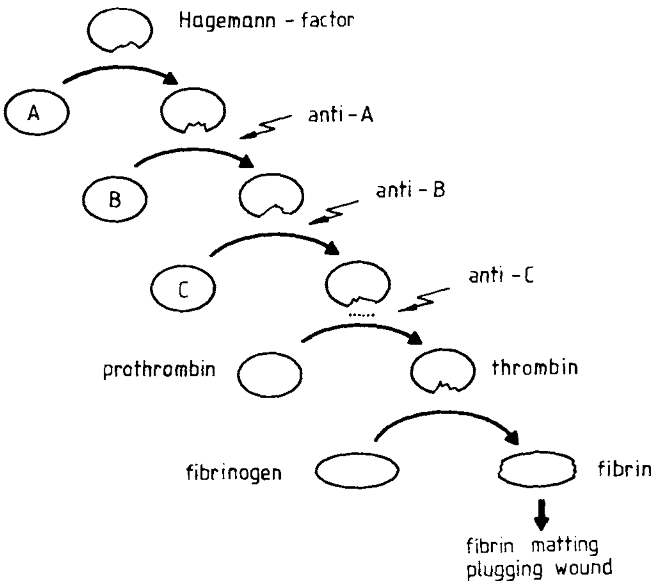

Fig. 6. Simplified scheme of the enzyme cascade for blood coagulation [16]. The Hagemann-factor activates enzyme A, this in turn activates enzyme B, *etc.*, until fibrin matting plugs the wound. At each level, the respective enzyme is specifically inhibited and since several very specific recognition processes are involved, the regulation is extremely exact.

A characteristic example of protein differentiation is found with the blood coagulation cascade sketched in Figure 6. When blood circulation was "invented", a repairing system became necessary to prevent leakage of all fluid after the slightest damage. A feasible method would be to plug the wound by coagulation. However, although this is easy to accomplish, it is most important to plug wounds exclusively and not the circulatory system itself. To achieve this distinction exact control is required. The problem was solved by developing a team of enzymes, ordered strictly hierarchically. On damage, the initial enzyme (Hagemann-factor) is released, and starts activating its subordinates (Fig. 6). At each level, effectors regulate the cascade precisely; each enzyme being extremely specific for its substrate.

Sequence analyses disclosed that the enzymes of this cascade are related to each other. Since thrombin belongs to this group, they are furthermore related to elastase (Fig. 4) and to the digestive enzymes trypsin and chymotrypsin as well as to some structurally known bacterial proteases (Fig. 3). Since blood clotting arose later in evolution than digestion, one can safely assume that the cascade is made up of (highly specialized) descendants of (comparatively primitive) digestive enzymes. Whereas the cascade proteins work in a very well defined manner, on only one substrate, the digestive enzymes "cut" all proteins they encounter to small pieces. Presumably, the cascade proteins did not appear simultaneously but evolved one by one from a single ancestor, proceeding from the bottom to the top of Figure 6. Accordingly, the organism started with an effective but badly regulated repair system which became more and more precisely controlled during evolution. Higher precision and more complexity was attained using proteins created by the differentiation process. A similar cascade is the complement system of the immune response[17] which it is also based on trypsin-like proteins.

The evolution to higher animal forms is also reflected in the differentiation process involving globins. When blood circulation was established, haemoglobin separated from myoglobin; haemoglobin became the far-travelling $O_2$-carrier in the blood, whereas myoglobin stayed in the cell as a local $O_2$-carrier and storage device. With the "invention" of the placenta, an $O_2$-transfer from mother to embryo was needed. For this purpose the $\gamma$-, $\varepsilon$- and $\zeta$-chains of haemoglobin were created, the $O_2$-binding characteristics of which differ from those of $\alpha$- and $\beta$-chains. $\gamma$-, $\varepsilon$- and $\zeta$-chains are produced at early stages of the ontological development; after birth they are superseded by the adult $\alpha$- and $\beta$-forms.

A further relationship was found between the immunoglobulines and HL-A-proteins[18], which label the tissue individually and thus appreciably complicate transplantations from one person to another appreciably. The muscle proteins parvalbumin, troponin-C, the light chains of myosin, and the Ca-dependent regulator protein[19] also have a common ancestor. Furthermore, it is known that historical connections exist between several protease inhibitors and a nerve growth factor[3], as well as connections between the hormones insulin, relaxin, and two tissue growth factors[20].

With a few exceptions, all these differentiated proteins have retained some functional similarity. One has to keep in mind, however, that all examples mentioned above are based on sequence comparisons, which can only reveal initial stages of separate developments. Using structural comparisons, as in Figure 3, or purely geometric comparisons, it should be possible to recognize much more distant relatives.

## 4. Evidence for Distant Relationships

In the course of X-ray structure analyses, pairs of proteins were discovered, which showed no sequence similarity and no functional similarity but resembled one another in their main chain geometries; such a pair is azurin[21] and superoxide dismutase[22]. In both proteins, the chain forms the $\beta$-pleated sheet sketched in Figure 7. The topologies of the $\beta$-sheets are identical. If each of these two proteins consisted of only a single $\alpha$-helix or a simply connected $\beta$-sheet, an explanation for the coincidence would be at hand: such structures are perferred by the chain because they are energetically favored. The observed complexity of the chain geometry, or "chain fold", is a clear indication however, that the coincidence is neither a random nor an energetic phenomenon. Consequently, one has to assume that a relationship between the proteins exists, which is so distant, that in the time course of separate evolution all sequence similarity has been erased, but the strongly conserved chain fold has been retained.

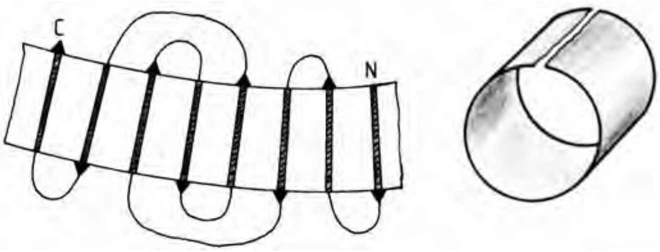

Fig. 7. Concordance of the topologies of the polypeptide chains of azurin [21] and superoxide dismutase [22]. The strands of the antiparallel $\beta$-pleated sheet are drawn as arrows. As indicated, the $\beta$-sheet rolls up forming a barrel.

Table 1. Structural repeats within one chain.

| Protein | Number of repeats |
|---|---|
| Ferredoxin [27] | 2 |
| Parvalbumin [28] | 3 |
| Wheat germ agglutinin [29] | 4 |
| Acid proteases [30, 31] | 4 |
| Hexokinase [32] | 2 |
| Dehydrogenases [33] | 2 |
| Serine proteases [8] | 2 |
| Immunoglobulines [34] | 4 |
| Arabinose-binding protein [35] | 2 |
| Glutathione reductase [36] | 2 |
| Rhodanese [37] | 2 |

In a number of other proteins, similar chain folds showing no sequence similarity are repeated two or more times along a single polypeptide chain. The known examples are listed in Table 1. A very significant similarity is observed in the enzyme rhodanese, in which a complicated chain fold of 140 residues is precisely repeated. Obviously, rhodanese results from a gene duplication with subsequent splicing of the two duplicates, a so called "tandem gene duplication". Since ample evidence for such duplications exists from sequence comparisons in proteins like serum albumin[23,24], haptoglobin[25], and protein-A of *Staphylococcus aureus*[26], they will not be discussed here. In addition to these similarities within one chain, chain fold similarities between parts of different proteins have been found; they will be considered in Section 5.

Although there seems to be no doubt that the observed chain fold similarities indicate historical relationships, the proof is more intuitive and is not as quantitative as for example the probabilities derived above from sequence identities. In order to prove such distant relationships, one has to establish a measure for the similarity of chain folds; furthermore, one has to transpose this measure to a probability. A convenient measure of similarity is the average distance between two chains. This is the distance which remains after both chain folds have been optimally overlayed by computer as sketched in Figure 8a.

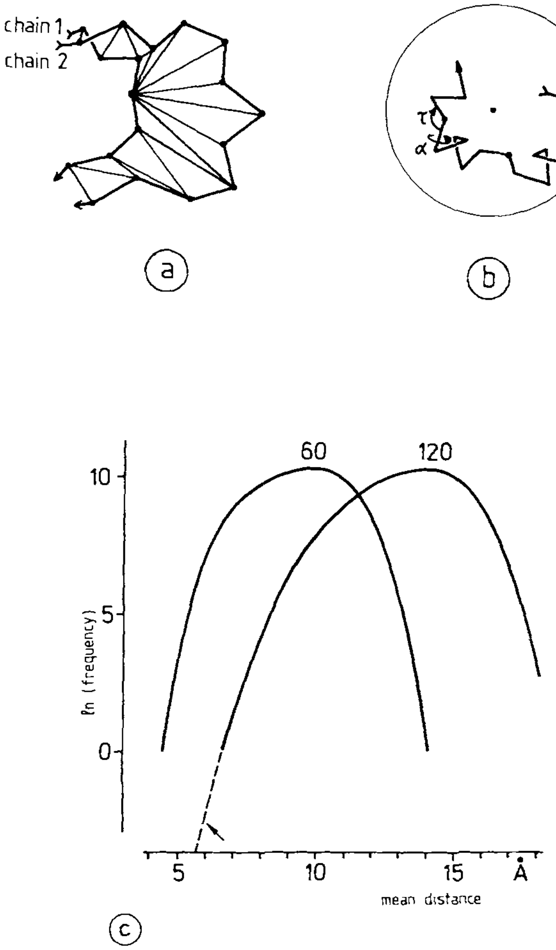

Fig. 8. Distribution of mean distances between two polypeptide chains [38]. a) After optimal relative rotation and translation there remains a residual difference between the two chain geometries. The mean distance between two polypeptide chains is determined by averaging the distances between corresponding $C_\alpha$-atoms. b) The simulation of random geometries is undertaken using conditions as natural as possible. Frequencies of the virtual bond angles τ and dihedral angles α between $C_\alpha$-atoms are adjusted to the observed values. Moreover, the chain simulation accounts for the observed fraction of α-helices, protein globularity, as well as protein density. c) Logarithmic representation of the mean distance distributions for chains with 60 and 120 links, based on about 1 million chain fold comparisons. In order to read the probability for the relationship between the two domains of glutathione reductase (arrow), the respective distribution had to be extrapolated.

This measure of similarity does not solve the problem of relationship *per se*. It only becomes useful if one knows the probability of this similarity occurring by chance. Such a probability can be obtained from the distribution of this measure obtained from comparisons of randomly chosen structures; this distribution has therefore to be calculated. Since, on average, short chains have smaller distances from each other than large chains, not only one but several distributions have to be calculated; one for each given chain length.

In principle one should derive these distributions from comparisons between known protein geometries; the number of known protein geometries is, however, rather small. Moreover, these proteins are distributed over quite a range of different chain lengths. Thus, the number of available comparisons for a given chain length, does not permit a useful distribution curve to be established. Even more seriously, however, the undetected relationships between the structurally known proteins, renders such a distribution meaningless in the most interesting region of small distances: no relationship can be derived from a distribution containing related proteins.

The only solution is to generate chain folds, as naturally as possible, by computer and to compare these simulated chain folds with each other. A chain fold generation method is given in Figure 8b. The resulting folds are globular, their densities correspond to those of proteins, and the dihedral angles between chain links fit the natural distribution. Thousands of such chains were generated and millions of geometric comparisons were carried out, yielding the distributions shown in Figure 8c. Using these, it is now possible to convert any distance between two chain folds (Fig. 8a) into a probability. For this purpose the distribution is integrated from the left side up to the observed distance value, and this integral is then divided by the integral over the total distribution[38].

Applying this method to the similar chain folds of the enzyme glutathione reductase (Table 1), one derives a mean distance of about 6 Å at a (mean) chain length of 120 residues, and therefore a probability for random coincidence of $2\cdot10^{-7}$. A comparison of the two similar chain folds within serine proteases (Table 1) yields a mean distance of about 5 Å at a (mean) chain length of 90 residues, giving rise to a probability for random coincidence of $5\cdot10^{-7}$. These values are so small that a relationship can safely be assumed. In conclusion, the calibration curves of Figure 8c allow one to convert all geometric comparisons between globular proteins into probabilities. On this basis, one can quantify relationships which are too distant to have left any detectable trace in the sequence.

## 5. The Number of Original Protein Structures

As soon as relationships can be quantified, one may ask the question whether all proteins are eventually related to each other, having been descended from a common ancestor with the original protein geometry. With the help of Figure 9 the answer can be easily given. The two protein geometries depicted have absolutely nothing in common; prealbumin consists throughout of an antiparallel β-pleated sheet[39], whereas adenylate kinase[40] contains numerous α-helices and a parallel β-pleated sheet. If these proteins ever had a common ancestor, there is no hope whatsoever of deriving this from the presently existing proteins. Using the similarity analyses described, today's proteins can only be traced back to a rather large group of original structures.

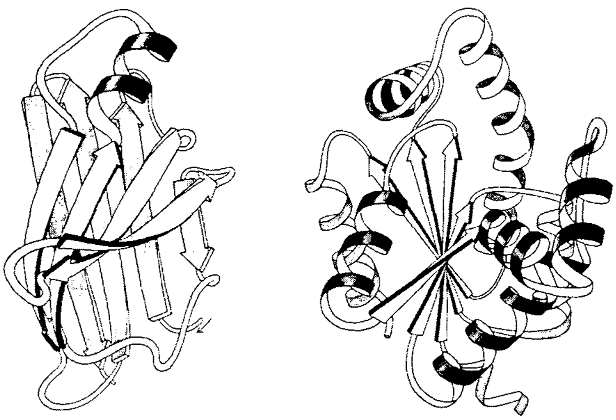

Fig. 9. Topologies of the polypeptide chains of prealbumin (left) and adenylate kinase (right). (Countesy of Dr. *Jane S. Richardson*, Little River Institute, Box 92B, Rt. 1, Bahama, N.C. 27503 (USA).

How large is this group? It has been mentioned above that about $10^5$ proteins with different functions exist. In the course of sequence analyses about $G = 150$ sequences of such proteins have been established, and about $Z = 50$ unexpected relationships have been discovered. According to Poisson statistics the rate of coincidences Z/G, equals the average occupation G/M, where M is the total number of unrelated proteins[41]. Therefore, the number of classes M, into which the $10^5$ functionally different proteins (or the $10^{11}$ distinct proteins) can be arranged, relying on sequence data, is about 500[3]. An analogous estimate can be made for the 70 known chain folds of proteins with different functions. Assuming that a relationship exists as soon as the probability for random coincidence (Fig. 8) drops below 1%, the coincidence rate (between domains, see Section 6) is about 0.3. Using this method it turns out that there are approximately 200 original chain folds, to which all proteins can be traced back.

The chain fold is the most strongly conserved property of a protein and therefore the most useful trait known for distinguishing between original proteins. As a consequence, the chain fold is an efficient criterion for protein classification.

## 6. Domains as Building Blocks

In Section 5, proteins were classified into groups, each of which most probably descended from a single ancestor. This raises the question whether these ancestral proteins were smaller, larger, or equal sized when compared with today's proteins. In cases like cytochromes[7], where evolution can be traced back to very early times, no indication can be detected that early proteins have sizes different from late ones. Proteins do not grow or shrink but merely undergo random fluctuations; the insertions and deletions in the polypeptide chain mentioned above. Presumably, the cytochromes arose with approximately their present size.

This hypothesis is corroborated, in particular, by the frequently encountered domains: these are regions of the chain which form many internal contacts but few contacts with other parts of the chain[4]. All proteins with molecular weights above 20000 are subdivided into at least 2 domains. Very obvious examples are the domains of trypsin-like proteins[8] and of glutathione reductase[36], the geometries of which were compared to each other in Section 4. In the spontaneous folding process after (or during) chain synthesis on the ribosome, the domains most probably assume their final geometries separately and independently from each other.

Domain sizes vary between 50 and 150 amino acids. The lower limit presumably reflects the requirement that proteins—and hence domains—have to be stable and rigid for executing specific functions. Chains with less than 50 links have a rather large surface even if they are globular. Below 50 residues, the fraction of surface residues, and thus the fraction of energetically favorable contacts between water and polar groups of the chain (in particular the peptide bonds), increases to such an extend that these contacts spread the chain. Although no reason for the upper limit is known, it is presumed that the folding of a larger, and therefore more complicated domain becomes geometrically too difficult.

Thus, proteins consist of (one or) several structurally self-supporting parts of defined size, which can be considered as building blocks. Changes of protein size during evolution are for the most part changes in the number of building blocks assembled. In this respect, changes of the sizes of the building blocks themselves play only a minor role. The group classification of Section 5 refers to domains and not to proteins consisting of several domains.

A number of structural analyses showed that identical, or more exactly, similar domains (see Section 4) are encountered in different proteins. This indicates that larger proteins have been assembled using a modular system based on domains as building blocks. The domain module A of Figure 10 is known from Figure 7. It appears singly in superoxide dismutase and azurin, doubly in the light, and four times in the heavy chains of the immunoglobulins. All examples in Table 1 are proteins like the immunoglobulins; they contain

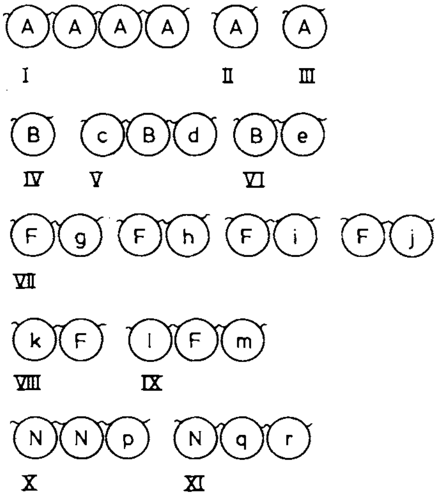

Fig. 10. Domain composition of some proteins. Domains recurring with identical (or more exactly, similar) geometry are labelled with capital letters. I: heavy chains of immunoglobulins [34], II: azurin [21], III: superoxide dismutase [22], IV: triose-phosphate-isomerase [42], V: pyruvate kinase [43], VI: glycolate oxidase [44], VII: lactate-, malate-, glyceraldehyde-3-phosphate dehydrogenases [45], and phosphoglycerate kinase [46, 47], VIII: alcohol dehydrogenase [45], IX: phosphorylase [48], X: glutathione reductase [36], XI: *p*-hydroxy benzoate hydroxylase [49].

structural repeats within one chain, which one can designate as domains.

Domain B of Figure 10 reveals another aspect of the modular system. This domain has been discovered in three different proteins. It not only appears singly in triose-phosphate-isomerase, but is also the central domain along the chain of pyruvate kinase, and finally it is part of glycolate oxidase. In this latter case, the same module is not repeated along a single chain but is combined with different modules to form new composite chains. The same applies for domains F and N of the remaining proteins of Figure 10. As an alternative to the suggested domain combinations, it could be envisaged that the structures result from a separate evolution in which domains B, F, N were particularly strongly conserved. This alternative is rather unlikely, however, because the remaining domains have totally different structures, and furthermore the repeated domains are positioned at completely different parts of the polypeptide chains; domain F appears at the beginning, in the middle, and at the end of the respective polypeptide chains.

Domains F and N indicate another property of the modular system. In all proteins shown, domain F binds the dinucleotide NAD at identical positions of its chain fold. The same applies for domain N, except that it binds two different dinucleotides; FAD at the first domain of glutathione reductase and *p*-hydroxybenzoate-hydroxylase, and NADPH at the second domain of glutathione reductase. With these properties, domains F and N can be considered as carriers of partial functions.

The functional aspect is particularly clear in glutathione reductase, where FAD works as a bridge in the transfer of reduction equivalents from NADPH to oxidized glutathione. Here, three partners join in the catalytic reaction, and each partner binds its specific domain; FAD and NADPH at the first and second domain, respectively, and glutathione at the third[36]. From this observation one may suggest the hypothesis that during evolution, the capability for complicated chemical reactions is acquired by combination of domains carrying the necessary partial functions; the selection of modules is directed by the required reaction. This hypothesis assumes that on the time scale of evolution, genes corresponding to the domains can be freely transferred and fused on the genome. Since gene transfer and fusion processes are known to occur during the differentiation of antibody producing cells in the development of individual organisms[50], this assumption does not pose any serious problem.

## 7. Conclusions

During evolution, the proteins vary as continuously as the species. The observed changes yield important insights into protein structures and above all they permit the distinction between essential and non-essential traits to be made. Newly arising tasks will be accomplished by novel proteins, which are produced by gene duplication of existing proteins and subsequent changes. In this process, the original proteins retain their old functions; the process is called protein differentiation. Quantitative data for the evolutionary distance between two proteins cannot only be derived from sequence comparisons, but also from geometric comparisons. Since geometries are most strongly conserved, such comparisons lead to the recognition of very distant relatives. It is most unlikely that all proteins have descended from a single ancestral structure; rather, one has to assume that there exist about $10^2$ original structures, or more exactly, original domain geometries. Proteins do not grow or shrink unidirectionally during evolution; the encountered changes of size arise from combination of domains. These are gene duplications followed by (gene transfer) and gene fusion. Large proteins are most likely assembled using a modular system, where modules with the required partial functions are selected and assembled. In the light of the gradually emerging order in the protein world, complete comprehension of all protein structures is no longer a utopian dream.

# Alkylsulfamoyl Chlorides as Key Units in the Synthesis of Novel Biologically Active Compounds for Crop Protection

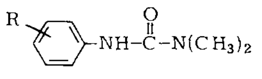
## By Gerhard Hamprecht, Karl-Heinz König, and Gerd Stubenrauch[*]

*Dedicated to Professor Dr. Matthias Seefelder on the occasion of his 60th birthday*

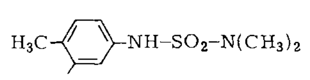
Due to their bifunctional character, alkylsulfamoyl chlorides are versatile units for the synthesis of heterocycles, polar sulfamates, and sulfonamides. In the last decade, synthetic methods of general preparative use have been developed, by means of which amine hydrochlorides, isocyanates, aziridines or tertiary alcohols can be reacted with suitable sulfuric acid derivatives to give novel, variously substituted alkylsulfamoyl chlorides. These compounds can subsequently be converted either to previously unobtainable *N*-alkoxyalkyl-*N*-alkylsulfamoyl chlorides or to novel heterocycles of the type 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxide, 2*H*-1,2,6-thiadiazin-3-one-1,1-dioxide and 2*H*-1,2,4,6-thiatriazin-5-one-1,1-dioxide; these compounds are examples of interesting models which illustrate the relation between the structure and the action of the compound, and in some cases lead to highly selective, ecologically unobjectionable herbicides. On the other hand, the alkylsulfamoyl chlorides themselves can be *N*-acylated to give further 3- to 5-atom bifunctional synthesis units, with which novel heterocyclic syntheses can be carried out. Further uses of the alkylsulfamoyl chlorides include the preparation of biologically active sulfamates, and cycloaddition reactions of *N*-sulfonylamines prepared *in situ.*

## 1. Introduction

In present-day chemical crop protection, carbonic acid derivatives occupy an important place; products derived for example, from isocyanates, such as the *N*-alkyl-*N'*-phenylureas *(1)* are selective herbicidal compounds[2a], which are used today on a worldwide scale in bulk crops such as sugar cane and cotton, to ensure that the increasing demand for foodstuffs and raw fibers will be met.



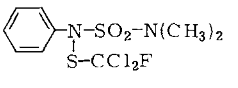
*(1a)*, R = 3-Cl, 4-CH$_3$: Dicuran®
*(1b)*, R = 3-CF$_3$: Cotoran®



*(2)*

In contrast, sulfonic acid derivatives have hitherto found little use. First, the use of monoalkylsulfamoyl chlorides as starting materials, was unknown, and secondly the first investigations of the relation between structure and action, including for example, the replacement of the dimethylcarbamoyl group in *(1)* by the dimethylsulfamoyl group, gave sulfamides *(2)* having only a slight herbicidal action.

Only in the fungicide sector was a sulfonic acid derivative Euparen® *(3)*, prepared from dimethylamidosulfonyl chloride (see Section 2.7) able to acquire practical importance, namely in the control of Botrytis in strawberries[2b].



*(3)*

In contrast, as recently as the 1960's, monoalkylsulfamoyl chlorides were considered to be a class of compounds incapable of existence[3]. Evidently by analogy with carbamyl chlorides, which on heating undergo a reversible cleavage reaction to give isocyanates and hydrogen chloride, it was as-

$$\mathrm{RNH{-}COCl} \rightleftharpoons \mathrm{RN{=}C{=}O} + \mathrm{HCl}$$

$$\underset{(4)}{\mathrm{RNH{-}SO_2Cl}} \xrightarrow{?} [\mathrm{RN{=}SO_2}] + \mathrm{HCl}$$

---

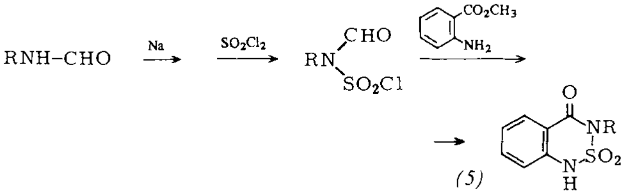
sumed that the corresponding sulfamyl compounds would show irreversible formation of sulfenes; such compounds were in fact only detected later, by *Burgess et al.*[4], at low temperatures in the presence of bases.

## 2. Syntheses of alkylsulphamoyl chlorides and related intermediates

### 2.1. Synthesis of alkylsulfamoyl chlorides from amine derivatives

*Teufel* succeeded in preparing the first *N*-alkyl-*N*-formylsulfamoyl chlorides with unbranched alkyl groups, by reacting the sodium salts of *N*-alkylformamides with sulfonyl chloride. These were then converted to 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides *(5)* and collected in this form.



*(5)*

However the low yields resulting from the drastic reaction conditions proved an obstacle to a broader use of the reaction.

Free alkylsulfamoyl chlorides *(4)* were first obtained by *Weiss* and *Schulze* by cleavage of sulfamides with sulfonyl

$$\text{RNH-SO}_2\text{-NHR} \xrightarrow{\text{SO}_2\text{Cl}_2} 2\ \text{RNH-SO}_2\text{Cl}\quad \textit{(4)}$$

chloride in an autoclave[6a] and later by heating amine hydrochlorides with sulfonyl chloride in acetonitrile[6b].

$$\text{RNH}_2\cdot\text{HCl} \xrightarrow{\text{SO}_2\text{Cl}_2} \text{RNH-SO}_2\text{Cl}\quad \textit{(4)}$$

The limiting factors were respectively the use of difficultly obtainable sulfamides in a pressure reaction, and solvent losses as a result of partial chlorination to trichloroacetonitrile. The latter compound can for example trimerize exothermally[7] to 2,4,6-tris(trichloromethyl)-1,3,5-triazine in the distillation residue, so that the reaction can only be recommended for use on a laboratory scale.

The direct sulfochlorination of amines required very long reaction times, of the order of 24 hours, and its investigation in other solvents proved unsuccessful. In spite of certain limitations, the above reaction nevertheless dispelled a long held prejudice and opened the way to the use of sulfamyl chlorides in some initial laboratory syntheses of biologically active compounds; in particular, the bifunctional character of the novel two-atom units provided a stimulus to carry out novel heterocyclic syntheses.

### 2.2. Synthesis of alkylsulfamoyl chlorides from isocyanates

In the period which followed, the *N*-alkylsulfamic acids *(6)* (*N*-alkylamido sulfuric acids)[8], prepared from the corresponding isocyanates and sulfuric acid in chlorohydrocarbon solvents, proved to have very diverse uses for the synthesis of α-branched and higher homologues; the acids can be converted to their halides *(4)* in a one-pot process, using a variety of halogenating agents[9].

$$\text{RN=C=O} \xrightarrow[-\text{CO}_2]{\text{H}_2\text{SO}_4} \underset{\textit{(6)}}{\text{RNH-SO}_3\text{H}} \longrightarrow \underset{\textit{(4)}}{\text{RNH-SO}_2\text{Cl}}$$

A selection of these recently prepared intermediates is shown in Table 1.

Table 1. *N*-Alkylsulfamic acids of type *(6)*.

RNH—$SO_3H$ *(6)*

| | R— | M.p. [°C] | Yield [%] |
|---|---|---|---|
| *(6a)* | $(CH_3)_2CH—CH(CH_3)—$ | 152—154 | 93 |
| *(6b)* | $(CH_3)_2CH—CH(C_2H_5)—$ | 102—108 | 90 |
| *(6c)* | $(CH_3)_2CH—CH_2—CH(CH_3)—$ | viscous | 94 |
| *(6d)* | $(CH_3)_2—CH(CH_3)—$ | 184—188 (decomp.) | 93 |
| *(6e)* | Cyclohexyl-$CH(CH_3)—$ | 75—80 | 98 |
| *(6f)* | 1-Norbornyl-$CH(CH_3)—$ | 98—100 | 91 |

Suitable halogenating agents include sulfinyl chloride and phosphorus halides[10], the latter especially in the case of the sparingly soluble *N*-alkylsulfamic acids *(6)*; depending on the chain length of the sulfamic acid moiety, and hence on the ease with which the halides *(4)* may be distilled, yields of 40—85% are achieved. In contrast, phosgenation, in the presence of conventional catalysts, such as tertiary bases or dimethylformamide, proved to give unsatisfactory results, since in some cases the very reactive sulfamoyl chlorides react fur-

$$\underset{\textit{(4)}}{\text{RNH-SO}_2\text{Cl}} \xrightarrow{\text{OHC-N(CH}_3)_2} \text{RNH-SO}_3^{\ominus}\ (\text{CH}_3)_2\overset{\oplus}{\text{N}}\text{=CH-N(CH}_3)_2$$

[a] Oil bath of a rotary evaporator, [b] *(4f)* ≡ *(8c)*, Table 3. [c] 100 MHz.

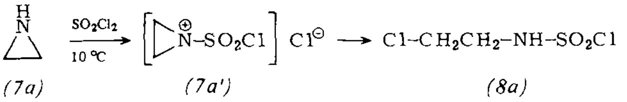
ther, for example with dimethylformamide (DMF), to give amidinium sulfamates, a type of reaction which is known in the case of arylsulfonyl chlorides[11].

"Stable" catalysts for this reaction have proved to be dichloromethyleneammonium compounds[12], which give better phosgenation yields. Table 2 shows a selection of recently prepared alkylsulfamoyl chlorides *(4)*.

These compounds are very reactive and, for example, undergo vigorous exothermic hydrolysis with water. Where the compounds *(4)* distil at temperatures above 125 °C, it is advantageous to employ a thin layer evaporator, since slow decomposition occurs at higher temperatures, evidently with sulfene formation.

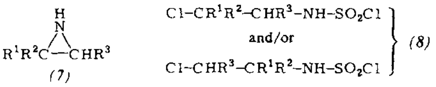
## 2.3. Synthesis of β-(haloalkyl)sulfamoyl halides from substituted aziridines

Specific β-(haloalkyl)sulfamoyl halides *(8)* were synthesized since their potentially cleavable groups permitted unsaturated derivatives, or derivatives with a variety of nucleophilic substituents to be prepared. The ring opening of aziridines *(7)* with sulfonyl halides[13] proved to be a useful method of synthesis; the reaction takes place under extremely mild conditions.



The yield of the reaction depends largely on the solvent employed; we first used carbon tetrachloride, but only obtained about 5% *(8a)*, while with the polar solvent acetonitrile the yield was 65% *(8b)*, so that the actual ring opening step appears to proceed *via* a strongly polar ionic complex intermediate *(7a')*. Whether ring opening occurs in the 2- or 3-position depends on the particular substituents on the ring. Table 3 gives a survey of branched (β-chloroalkyl)sulfamoyl chlorides *(8)*.

Table 3. (β-Chloroalkyl)sulfamoyl chlorides of type *(8)*, from aziridines *(7)*.

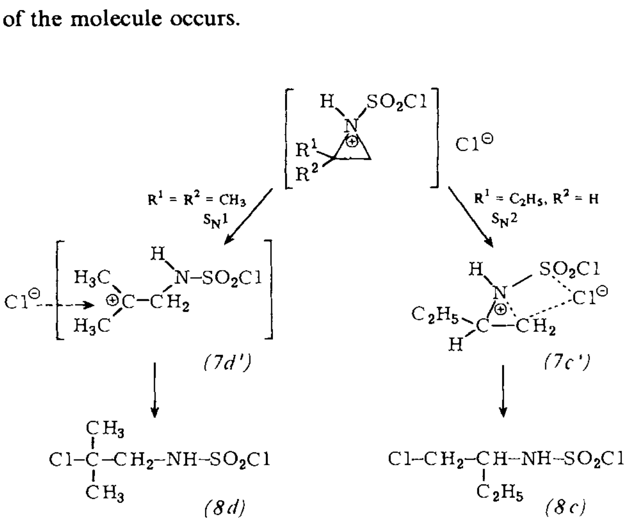


| | Part structure in *(7)* | in *(8)* | | | $n_D^{25}$ | Yield [%] | ¹H-NMR (CDCl₃), TMS as internal standard, 60 MHz), δ-values [a]. |
|---|---|---|---|---|---|---|---|
| *(7b)* | $CH(CH_3)—CH_2$ | *(8b)* | (22%) | $Cl—CH(CH_3)—CH_2—$ | 1.4959 | 55 | 1.53—1.63 (d; $CH_3$) |
| | | *(8b')* | (78%) | $Cl—CH_2—CH(CH_3)—$ | | | 1.41—1.51 (d; $CH_3$), 3.62—3.82 (m; $Cl—CH_2$), 6.0—6.45 (d; NH), |
| *(7c)* | $CH(C_2H_5)—CH_2$ | *(8c)* | [b] | $Cl—CH_2—CH(C_2H_5)—$ | 1.4860 | 52 | *cf.* Table 2m *(4f)* |
| *(7d)* | $C(CH_3)_2—CH_2$ | *(8d)* | | $Cl—C(CH_3)_2—CH_2—$ | 1.4852 | 43 | 1.68 (s; $CH_3$), 3.4—3.55 (d; $CH_2$), 6.2—6.7 (t; NH) |
| *(7e)* | $CH(CH_3)—CH(CH_3)$ | *(8e)* | | $Cl—CH(CH_3)—CH(CH_3)$ | 1.4878 | 44 | 1.38—1.45 (d; $N—C—CH_3$), 1.52—1.59 (d; $Cl—C—CH_3$), 3.7—4.1 (m; N—CH), 4.28—4.55 (m; Cl—CH) |

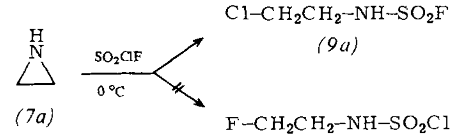
[a] 3.6—3.82 (m; $CH_2$), 6.2—6.6 (NH). [b] *(8c)* ≡ *(4f)*, Table 2.

While *(7b)* gives a mixture of *(8b)* and *(8b')*, ring opening of *(7c)* only gives the α-branched product *(8c)*. The geminally substituted *(7d)*, on the other hand, only gives the β-branched product *(8d)*.

The results described, indicate a competition between two mechanisms. If ring cleavage occurs *via* a carbenium ion ($S_N1$ reaction), then it would be expected, as in *(7d')*, to preferentially occur at the more highly substituted carbon atom rather than formation of a primary carbenium ion. Conversely, the sterically less bulky *(7c')* *a priori* offers less of an obstacle to a bimolecular mechanism, so that here a $S_N2$ reaction, with ring opening and substitution on the same side of the molecule occurs.



In the reaction of aziridines with sulfonyl chloride fluoride, the more reactive chloride always migrates, so that (β-chloroalkyl)sulfamoyl fluorides such as *(9a)* ($n_D^{25}=1.4363$) are obtained.



Fluorine-substituted alkylsulfamoyl halides—whose synthesis appeared particularly desirable because of the "bioisosteric properties" of fluorine and hydrogen—were obtained by reaction with sulfonyl fluoride. Because of the low boiling point of the halogenating agent (−50 °C), the reaction had to be carried out at lower temperatures, required longer reaction times (6—8 h) and gave yields of only up to 40% (Table 4).

In the reaction with sulfonyl fluoride, the $S_N1$ mechanism is again more important, as substantiated by the higher pro-

Table 4. (β-Fluoroalkyl)sulfamoyl fluorides of type *(10)* from azidiridenes *(7)*.

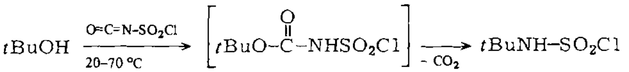
portion of *(10b)* and *(10c)* formed. The reasons may be the lower reaction temperature, the use of catalytic amounts of Lewis acids, and the smaller size of the fluoride ion.

## 2.4. Synthesis of *tert*-alkylsulfamoyl chlorides

The preparation of *tert*-butylsulfamoyl chloride *via* the sulfamic acid[9] or sulfonyl chloride[14] gives only moderate space-time yields. The reaction of *tert*-butanol with chlorosulfonyl isocyanate in nonpolar solvents proceeds more rapidly, *via* decarboxylation of an intermediate chlorosulfonylurethane *(11a)*, to give a high yield of *tert*-butylsulfamoyl chloride *(12a)*[15].



$$t\text{BuOH} \xrightarrow[20\text{–}70\,^\circ\text{C}]{\text{O=C=N–SO}_2\text{Cl}} \left[t\text{BuO–}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{–NHSO}_2\text{Cl}\right] \xrightarrow[-\,\text{CO}_2]{} t\text{BuNH–SO}_2\text{Cl}$$

*(11a)* *(12a)*

The transformation resembles the reaction of carboxylic acids with chlorosulfonyl isocyanate to give acylaminosulfonyl chlorides[16], and is particularly suitable for use with tertiary alcohols (Table 5).

Table 5. *tert*-Alkylsulfamoyl chlorides of type *(12)*.

$RNH—SO_2Cl$ *(12)*

[a] Thin layer evaporator.

Compounds of type *(12)* can be directly further converted in solution; for distillative purification of sizable batches, it is advisable to use a thin layer evaporator, since for example, compound *(12a)* starts to dealkylate above 140 °C [cf. also the heterocyclic compound *(5e)* derived therefrom].

$$\underset{(12a)}{(CH_3)_3CNH\text{–}SO_2Cl} \xrightarrow[-\,(CH_3)_2C=CH_2]{>140\,^\circ C} \underset{(13)}{NH_2SO_2Cl}$$

## 2.5. Synthesis of *N*-(alkoxy)sulfamoyl chlorides

Because of the sensitivity of the N—O bond, for example of *N*-(triphenylmethyl)-*O*-methylhydroxylamine, in acid medium[17], it initially seemed doubtful whether *N*-(alkoxy)sulfamoyl chlorides *(15)* could be prepared. However, under certain special conditions, namely reaction of the salts *(14)* with phosphorus pentachloride, 60—70% yields proved obtainable (Table 6)[18].

$$(14)\quad RONH—SO_3Na \xrightarrow{PCl_5} RONH—SO_2Cl \quad (15)$$

Table 6. *N*-(Alkoxy)sulfamoyl chlorides of type *(15)*.

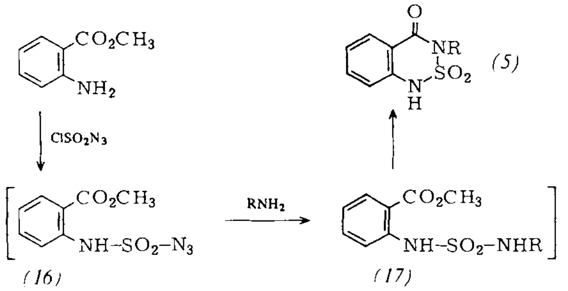
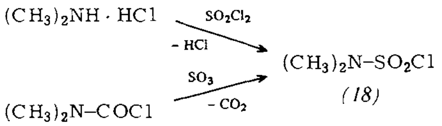
## 2.6. Synthesis of sulfamoyl pseudohalides to circumvent the synthesis of sulfamoyl acid chlorides containing sensitive substituents

To prepare specifically substituted, 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides *(5)*, whose sulfamoyl chloride intermediates were difficult to obtain, the method of *Matier* and *Comer*[14] was modified so that the sulfamoyl azide intermediate *(16)* was only handled in solution and the product *(17)* was purified, before alkaline cyclization, by washing with dilute acid. "Sensitive" substituents, R, in this context are *e.g.* cyclopropyl, phenyl and allyl (see Table 13, Section 3.1).

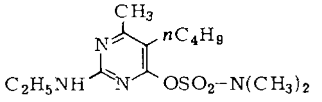


## 2.7. Conversion of monoalkylsulfamoyl chlorides to novel substituted dialkylsulfamoyl chlorides

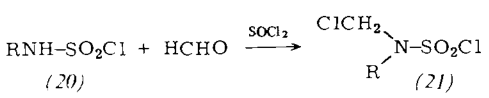
In contrast to the monoalkylsulfamoyl chlorides the corresponding dialkyl derivatives *(18)* were obtained no less than a century ago by *Behrend,* who heated dimethylamine hydrochloride with sulfonyl chloride[19]. This has remained the method of preparation ever since (although polar solvents have been substituted), apart for the method involving sulfonation of carbamyl chlorides[20].



However, the drastic reaction conditions involved in sulfochlorination and sulfonation prevent the controlled introduction of heterosubstituents, such as halogen atoms or alkoxy groups, so that until now only commercial products derived from *N,N*-dialkylsulfamoyl chlorides were known; *e.g.* Euparen *(3)*[2b], mentioned at the outset, or the fungicide Bupirimate *(19)*[21].



(19)



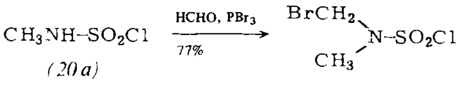
$$\mathrm{RNH{-}SO_2Cl + HCHO \xrightarrow{SOCl_2} (ClCH_2)(R)N{-}SO_2Cl}$$

(20) (21)

The starting point for an alkylating synthesis appeared to be the *N*-monosubstituted sulfamoyl chloride. On addition of sulfinyl chloride to a mixture of *(20)* and formaldehyde, rapid evolution of gas commenced and after brief heating, high yields of novel *N*-alkyl-*N*-(chloromethyl)sulfamoyl chlorides *(21)* were obtained in high yield (Table 7)[22].

The use of phosphorus tribromide, instead of sulfinyl chloride, gives the corresponding *N*-(bromomethyl) compounds, *e.g.* the analogue of *(21a)* (b.p. = 84—92 °C/0.2 mbar).

With paraldehyde and sulfinyl chloride, a mixture of *(22)* and its dehydrohalogenation product *(23)* was obtained[23].



$$\mathrm{CH_3NH{-}SO_2Cl \xrightarrow[77\%]{HCHO,\ PBr_3} (BrCH_2)(CH_3)N{-}SO_2Cl}$$

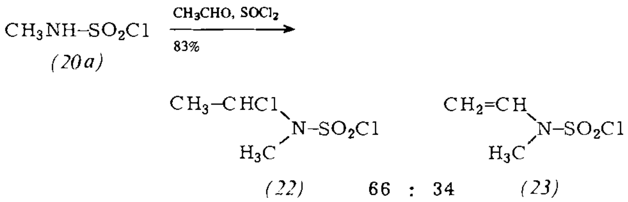
(20a)

Table 7. *N*-Alkyl-*N*-(chloromethyl)sulfamoyl chlorides of type *(21)*.

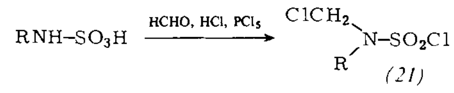
$ClCH_2NR{-}SO_2Cl$ *(21)*

| | R | B.p. [°C/mbar] | $^1$H-NMR ($CDCl_3$, TMS as internal standard, 60 MHz), δ-values |
|---|---|---|---|
| *(21a)* | $CH_3$ | 54—60/0.1 | 3.12 (s; $CH_3$), 5.3 (s; $CH_2$) |
| *(21b)* | $C_2H_5$ | 61—65/0.01 | 1.24—1.49 (t; $CH_3$), 3.38—3.73 (m; C—$CH_2$—N), 5.38 (s; Cl—$CH_2$—N) |
| *(21c)* | $iC_3H_7$ | 75—83/0.2 | 1.35—1.45 (d; $CH_3$), 3.95—4.5 (m; CH), 5.26 (s; $CH_2$) |
| *(21d)* | $nC_6H_{13}$ | 130/0.01 | 0.86—0.97 (t; $CH_3$), 1.2—1.85 (m; $(CH_2)_4$), 3.42—3.6 (t; C—$CH_2$—N), 5.42 (s; Cl—$CH_2$—N) [100 MHz] |

Treating the reaction mixture with hydrogen chloride gas, and concentrating it below 50 °C, gave the pure α-(chloroethyl) compound *(22)*. [*(22)*, b.p. 73-79 °C/0.6 mbar; $^1$H-NMR ($CDCl_3$, TMS int., 60 MHz); δ = 1.71-1.83 (d; $CH_3$—C), 3.03 (s; $CH_3$—N), 6.02-6.32 (m; CH)].



In addition to the sulfamoyl chlorides, the sulfamic acids from which they were derived could also be converted into *(21)*, using somewhat more drastic reaction conditions, *i.e.* prior treatment with hydrogen chloride gas, and use of phosphorus pentachloride; the yield being 50—70% depending on the chain length[22].

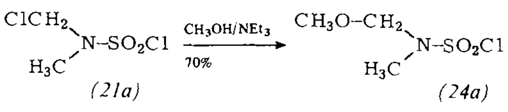


$$\mathrm{RNH{-}SO_3H \xrightarrow{HCHO,\ HCl,\ PCl_5} (ClCH_2)(R)N{-}SO_2Cl}$$

(21)

However, because of the formation of traces of toxic α-haloethers, the batches have to be distilled carefully, and the volatile fractions hydrolyzed with water. The acute oral toxicity of *(21)* in rats[24] is of the same order of magnitude of that found with conventional corrosive acid halides: *(21a)*, 1000 mg/kg; *(21)*, R = $nC_3H_7$, 2210 mg/kg.

The bifunctional character of the novel derivatives *(21)* makes additional reactions possible. Surprisingly, the α-halogen atom in *(21a)* could be replaced by reaction with sodium methoxide, or better still with excess alcohol in the presence of stoichiometric amounts of base, without a reaction occurring at the acid chloride group:



$$\mathrm{(ClCH_2)(H_3C)N{-}SO_2Cl \xrightarrow[70\%]{CH_3OH/NEt_3} (CH_3O{-}CH_2)(H_3C)N{-}SO_2Cl}$$

(21a) (24a)

Higher and unsaturated alcohols reacted similarly (see Table 8)[25].

*König* had described a similar selective alkoxylation of *N*-(chloromethyl)-*N*-methylcarbamoyl chloride; there, in spite of the aminal structure of the compound, *N*-(alkoxymethyl)-

Table 8. *N*-(Alkoxymethyl)-*N*-alkylsulfamoyl chlorides of type *(24)*.

$R^1O—CH_2N(R^2)—SO_2Cl$ *(24)*

| | $R^1$ | $R^2$ | B.p. [°C/mbar] | $^1$H-NMR ($CDCl_3$, TMS as internal standard, 60 MHz), δ-values |
|---|---|---|---|---|

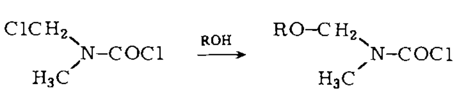
| *(24b)* | $CH_3$ | $C_2H_5$ | 102—106/ 0.01 | 1.23—1.44 (t; C—$CH_3$), 3.34—3.69 (m; C—$CH_2$), 3.39 (s; O—$CH_3$), 4.72 (s; O—$CH_2$) |
| *(24c)* | $CH_3$ | cyclo-hexyl | 102—106/ 0.01 | 1.1—2.2 (m; Cyclohexyl), 3.35 (s; O—$CH_3$), 4.79 (s; O—$CH_2$) |
| *(24d)* | $CH_2$=CH—$CH_2$ | $CH_3$ | 60—63/ 0.01 | 3.01 (s; $CH_3$), 4.0—4.09 (d; C—$CH_2$—O), 4.7 (s; O—$CH_2$—N), 5.02—6.1 (m; $CH_2$=CH) |

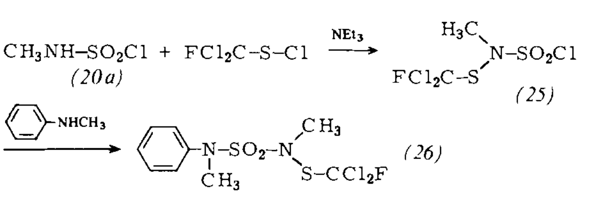
*N*-methylcarbamoyl chlorides were obtained in good yields[26].



From the point of view of their reactivity, the sulfamoyl chlorides *(24)* are comparable with the dialkylsulfamoyl chlorides without additional functional groups; biologically active sulfamate esters derived from them also showed a comparable alkylating action[27].

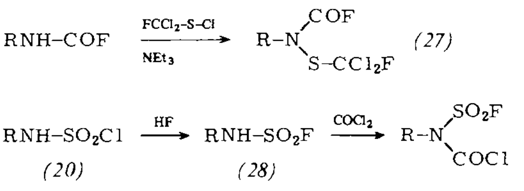
## 2.8. Acylation of monoalkylsulfamoyl chlorides, to novel polyatomic synthetic units

As early as the 1960's, *Schulze* and *Weiss* had prepared fungicidal sulfamides of type *(26)*[28] derived from an *N*-(alkylsulfenyl)-*N*-methylsulfamoyl chloride, the acyl derivative having been prepared *in situ* from sulfamoyl chloride and sulfenyl chloride.

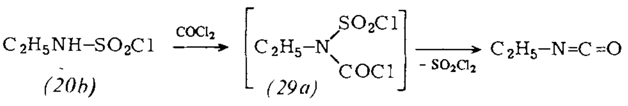


Similar intermediates *(25)* were subsequently isolated (by analogy with carbamoyl halides, which only react in the form of their fluorides)[29], by first synthesizing the corresponding *N*-alkylsulfamoyl fluorides *(27)* and then reacting these with an acyl halide[30].

*Bartholomew* and *Kay* subsequently applied the reaction with phosgene directly to two sulfamoyl chlorides *(20)* [or *(4)* or *(8)*], but found that a special kieselguhr filter aid was necessary if substantial amounts were to be isolated[31].



We have found that *N*-alkyl-*N*-(chlorocarbonyl)sulfamoyl chlorides *(29)* are very sensitive to impurities, which catalyze their decomposition; for example, when *(20b)* was reacted with phosgene without a filtration aid, we isolated ethyl isocyanate as a volatile decomposition product, instead of *(29a)*.



We subsequently found that preparative synthesis by this reaction benefited from a two-phase washing process with water (the products being surprisingly stable to water), and in this way it proved possible to isolate good yields of the compounds *(29)*, which constitute triatomic bifunctional units for synthesis (Table 9)[32].

Table 9. *N*-Alkyl-*N*-chlorocarbonylsulfamoyl acid chlorides of type *(29)*.

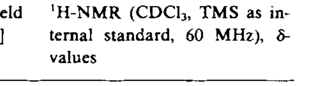
$R{-}N(SO_2Cl)(COCl)$

*(29)*

| | R | B.p. [°C/mbar] | Yield [%] | $^1$H-NMR ($CDCl_3$, TMS as internal standard), δ-values |
|---|---|---|---|---|
| *(29a)* | $C_2H_5$ | 57/0.12 | 85 | 1.46—1.49 (t; $CH_3$), 4.19—4.28 (m; $CH_2$) [270 MHz] |
| *(29b)* | $nC_3H_7$ | 67—72/ 0.12 | 78 | 0.81—1.1 (t; $CH_3$), 1.5—2.1 (m; C—$CH_2$), 3.8—4.08 (t; N—$CH_2$) [60 MHz] |
| *(29c)* | $nC_4H_9$ | 70—76/ 0.12 | 68 | 0.85—1.03 (t; $CH_3$), 1.28—1.81 (m; $CH_2$—$CH_2$—C), 3.45—3.59 (t; N—$CH_2$) [100 MHz] |
| *(29d)* | Cyclo-hexyl | 100—105/ 0.12 | 68 | IR: νC=O 1755 cm$^{-1}$ |

In the same way, reaction of sulfamoyl chlorides *(20)* [or *(4)* or *(8)*] with chloroformic acid esters gave yields of up to 91% of *N*-(alkoxycarbonyl)-*N*-alkylsulfamoyl chlorides *(30)*, which serve as triatomic synthesis units of graded reactivity (Table 10)[32].

Table 10. *N*-(Methoxycarbonyl)-*N*-alkylsulfamoyl chlorides of type *(30)*.



| | R | B.p. [°C/mbar] | Yield [%] | $^1$H-NMR ($CDCl_3$, TMS as internal standard, 60 MHz), δ-values |

The acylated bifunctional *N*-alkylsulfamoyl chlorides *(29)*—*(34)* are attractive intermediates for the preparation of five- and six-membered heterocycles. Their use in synthesizing biologically active compounds will be dealt with in Section 3.8.

## 3. The route from the intermediate to novel reference structures of biologically active compounds

Whilst in the early 1960's world-wide chemical crop protection research still resulted in the annual appearance of about 25 biologically active compounds on the market, this number has dropped in the interim to about 15[34]. The lower rate of innovation is less a reflection of a decline in intensive research than of the high degree of development achieved in technology. The enormous rise in development costs as a result of toxicological and metabolic investigations, and extensive clearance procedures, which may vary from country to country, makes the market launch of a novel biologically active compound a high-risk decision nowadays, in view of already existing solutions to various problems and intensive competition.

This makes it all the more important, not least for economic reasons, to investigate novel intermediates by broad and systematic variation, involving a number of reference structures, and to achieve new insight into the relationship between structure and activity.

### 3.1. 3-Substituted 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides

An example of the use of intermediate products to be found in BASF research, is provided by the quinazolinediones, which have been known for some time.

In conjunction with the observation that 3,1-benzoxazin-4-ones *(35)*, derived from anthranilic acid, exhibited selectivity in Indian corn and grain[35], anthranilic acid was first combined with the known urea structure. While the resulting open-chain compounds *(36)* proved to have only a low herbicidal activity, their cyclization gave active quinazoline-2,4-diones *(37)*[36] which, especially on subsequent hydrogenation and *N*-acylation, to give compound *(38)* R = $iC_3H_7$, exhibited selectivity in potatoes and Indian corn[37]. At the same time, they are structurally related to the herbicidal uracils *(39)* and *(40)* developed by Du Pont[38,39], with which they ultimately share a common prototype in nature, uracil *(41)*.

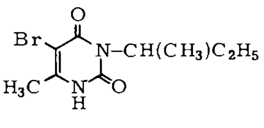
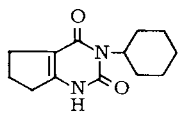
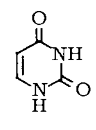
*(38)*, BAS 3490 H



*(39)*, Bromacil

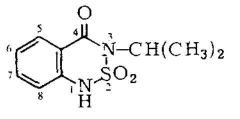


*(40)*, Lenacil



*(41)*, Uracil

To broaden the selectivity of *(37)*, the next modification of the molecule was to replace a carbonyl by a sulfonyl group, using alkylsulfamoyl chlorides; in this way, *Zeidler* and *Fischer* discovered the highly active herbicides, 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides, such as Basagran® *(5a)*[40] (biologically active compound: bentazone).



*(5a)*, Basagran®

Basagran® *(5a)* is nowadays employed extensively as a selective, postemergence herbicide in numerous crops such as soybean, rice, Indian corn, grain and groundnuts, and is distinguished by a high degree of tolerance by crop plants, and low toxicity ($LD_{50}$ for oral administration to rats; 2063 mg/kg). In view of its favorable—viewed also on the long term—ecotoxicology, it is nowadays one of the modern, crop treatment agents.

*(5a)* is at the same time an example of the "bioisosteric" replacement of the carbonyl group by a sulfur dioxide group, which has similar electronic properties; in both cases, the acid amide proton is acidic. According to X-ray structural analysis (Fig. 1)[41], the two nitrogen atoms lie in the plane of the benzene ring; the sulfur atom, on the other hand, is splayed out sufficiently far that one of the associated oxygen atoms lies in the plane of the benzene ring, whilst the other is almost at right angles to this. A striking feature is the difference between the two N—S bonds; the shorter bond length, 1.60 Å, in the case of the aryl-(N—S) bond is intermediate between that of a single bond (1.74 Å) and double bond (1.54 Å)[42] and indicates a considerable (d-p)π overlap and conjugation with the aromatic structure. This is largely absent in the isopropyl nitrogen (N—S = 1.67 Å), so that here the single-bond character predominates.

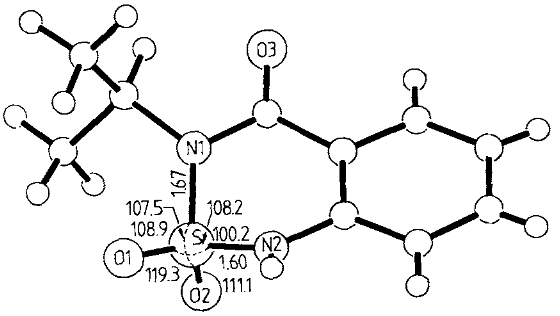


Abb. 1. Bond lengths [Å] and bond angles [°] of *(5a)* in the crystal [41].

Bentazone *(5a)*, acts by inhibiting photosynthesis; this inhibition can be measured in a Hill reaction on isolated chloroplasts[43] (see Section 3.2). Tolerant plants overcome the observed reduction in $CO_2$ assimilation relatively rapidly, after application of the biologically active compound, while with controllable weeds any such assimilation is checked.

The biologically active compound[44] is metabolized *via* a hydroxylation of the arene in positions 6 and 8, followed—depending on the species of plant—by conjugation to monosaccharides and oligosaccharides (in soybean) or ultimately by further degradation, to natural aminoacids (rice). Neither residues of the intact biologically active compound, nor residues of its hydroxy-metabolites, are detectable in the seeds of the plants.

In the soil, the half-life is 2—5 weeks; analogous hydroxy-metabolites are incorporated, in insoluble form, into humic acids in the soil.

In parallel to the biological development, the process chemistry had to be advanced. The difficulties observed in the preparation of the biologically active compound directed our interest first of all to known heterocyclic reactions. *Inter alia*, we carried out alkylation experiments on the 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxide described by *Cohen et al.*[45], but these always led only to the isomeric 1-alkyl-1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides instead of the desired 3-alkyl derivatives[46].

A breakthrough, both with respect to the preparation of the compounds and in the fine selection of biological properties, was only achieved through the systematic development of novel sulfamoyl chloride syntheses (see Sections 2.2—2.6). Thus variously substituted 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides *(5)* became obtainable in high yields *via* methyl anthranilate and alkaline cyclization[47] or *via* anthranilic acid and cyclization under acid conditions[48]. Table 13 shows a selection of these derivatives, which previously could not be prepared.

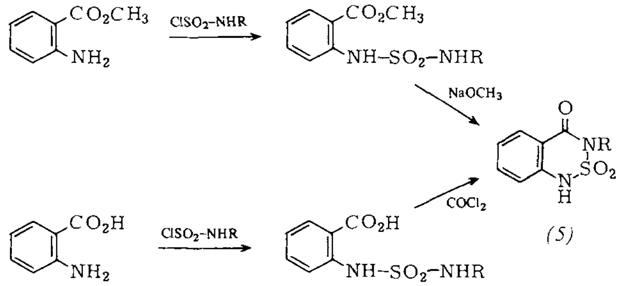

Table 13. Substituted 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides [49] of type *(5)*.

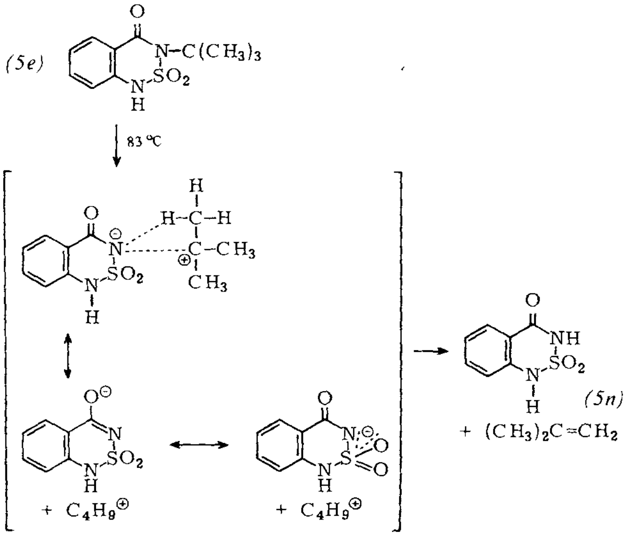
| | R— | M.p. [°C] | | R | M.p. [°C] |
|---|---|---|---|---|---|
| *(5a)* | $(CH_3)_2CH—$ | 135-137 | *(5h)* | $Cl—CH_2CH_2—$ | 165—167 |
| *(5b)* | $C_2H_5—CH(CH_3)$ | 112—114 | *(5i)* | $F—CH_2CH_2—$ | 162—164 |
| *(5c)* | $(C_2H_5)_2CH—$ | 128—132 | *(5j)* | $C_6H_5—$ | 192—195 |
| *(5d)* | $(CH_3)_2CH—CH(CH_3)—$ | 118—122 | *(5k)* | $CH_3O—CH_2—CH(CH_3)—$ | 95—96 |
| *(5e)* | $(CH_3)_3C—$ | 83 (decomp.) | *(5l)* | $Cl^{\ominus}(CH_3)_3N^{\oplus}—CH_2CH_2—$ | 252 |
| *(5f)* | Cyclopropyl | 168—170 | *(5m)* |  | 234 (decomp.) |
| *(5g)* | $CH_2{=}CH—CH_2—$ | 154—158 | | | |

The biologically active compounds *(5)* are freed from the auxiliary base by stirring the mixture in water and acidification, or by alkaline extraction followed by acidification. However to avoid hydrolysis, the alkaline cyclization can also be carried out with aqueous alkali followed by rapid acidification.

Only *(5a)* required special synthetic conditions; because of its screened sulfonamide proton, alkaline cyclization only proved possible with lithium methoxide in DMSO as the solvent. Surprisingly *(5e)* decomposes above 83 °C, with elimination of isobutene, giving compound *(5n)*.



The ease with which *(5e)* thermolyzes, indicates the intermediate formation of the 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxide anion, stabilized by the carbonyl and the sulfur dioxide group, as "leaving group". The reaction has a parallel in the dealkylation of tertiary *N,N'*-dialkylsulfamides, which, in the presence of trifluoroacetic acid, decompose into monoalkylsulfamides and *tert*-butyl trifluoroacetate[50].

*(5l)* and *(5m)* are derived from *(5h)* by a substitution reaction with tertiary base, effected by heating for 8 hours at 80 °C in dioxane; however, in contrast to Cycocel® (2-chloroethyl-(trimethyl)ammonium chloride), which is a growth regulator, compound *(5l)* shows only slight activity.

With respect to their herbicidal action, the α-branched derivatives (Table 13) are distinctly superior to the non-branched derivatives. For example, compounds *(5b)* to *(5d)*, show very good toleration in rice, Indian corn, soybean and wheat, even at 4 kg/ha, while having the same action on weeds as the isopropyl compound *(5a)*; furthermore, they show slight activity against barnyard grass and annual bluegrass.

### 3.2. Application of the Hill reaction to the systematic design of biologically active compounds

In spite of the high selectivity and activity of whatever structure of biologically active compound has proved best in screening tests, the chemist can ultimately not be sure whether any additional substituents might not lead to an improvement in these properties. Thus, the simple α-branching in the 3-position, and the non-substitution of positions 1 and 5—8 were in the first place suggested by the prototype compounds *(37)* and *(40)*, but were also chosen for economic reasons. Simple considerations however show that even monosubstitution by 10 different substituents in the aromatic ring, and in positions 1 and 3 of an alkyl residue having up to four atoms, would require the synthesis of 1.76 million different compounds to cover each permutation.

To permit sensible use of available capacity for synthesizing compounds, it is advantageous to employ biological testing models which permit a deeper insight into plant-physiological phenomena, for example through measurements of the Hill reaction[51]. For such measurements, plant leaves—mustard leaves are commonly used—are homogenized in a high frequency disperser, and the material then separated in an ultracentrifuge. *Hill* was the first to discover that isolated chloroplasts in the presence of Fe(III)-salts, develop oxygen continuously when exposed to light. This so-called "Hill reaction", entails cleavage of a water molecule in a primary photochemical reaction, into oxygen, protons and electrons. Instead of the natural electron acceptor NADP, synthetic acceptors, for example potassium hexacyanoferrate, which on reduction undergo an easily measureable change in absorption, are generally added. The quantitative determination of the amount of $Fe^{2+}$ formed per unit time is carried out photometrically at 510 nm, after addition of phenanthroline. For herbicides, which inhibit the Hill reaction, the concentration of the inhibitor (in %) is plotted against the logarithm of the herbicide concentration. The $pI_{50}$ (the negative logarithm of the concentration required for 50% inhibition) can then easily be read off the graph. In experiments with series of chemical compounds, a semiquantitative method is in most cases considered adequate; in this, the inhibition is measured first at a biologically active compound concentration of $10^{-5}$ mol/dm$^3$ and additionally at a lower concentration ($10^{-6}$ or $10^{-7}$ mol/dm$^3$). The determination of the absolute $pI_{50}$ is relatively involved, since the value also depends on the manner in which the chloroplasts have been prepared, their concentration and the membrane integrity[52].

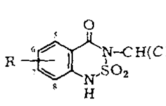
To the synthetic chemist, the value of the $pI_{50}$ measurement is that the actual herbicidal action is separated from other factors (albeit these are vital in practical use) such as stability, metabolism, and uptake and transportation of the biologically active compound by the leaves or roots, and thus provides him with guidance for optimization to achieve maximum activity (for examples of $pI_{50}$ values, see Table 14).

### 3.3. Synthesis of aryl-substituted 3-alkyl-1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides

Using the methods of synthesis described in this article, and employing substituted 2-aminobenzoic acid, we prepared a range of very diverse aryl-substituted 3-alkyl-1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides, of which a selection is shown in Table 14, alongside their corresponding $pI_{50}$ values.

It also proved possible to prepare certain derivatives directly, by halogenating or nitrating compound *(5a)* under mild conditions, without ring cleavage; in such reactions, it is the 6-position which is predominantly attacked first, after

Table 14. Aryl-substituted 3-alkyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides of type *(42)*.



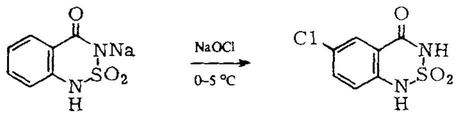
*(42)*

| | R | M.p. [°C] | $pI_{50}$ [a] |
|---|---|---|---|
| *(42a)* | 5-Cl | 175—177 | 3.38 |
| *(42b)* | 6-Cl | 190—194 | 4.06 |
| *(42c)* | 7-Cl | 155—159 | 4.36 |
| *(42d)* | 8-Cl [53] | 84—88 | 4.92 |
| *(42e)* | 6,8-$Cl_2$ | 158—161 | 4.92 |
| *(42f)* | 8-$CH_3$ [54] | 125—126 | 4.17 |
| *(42g)* | 6-$NO_2$ | 205—208 | 3.91 |
| *(42h)* | 6,8-$(NO_2)_2$ | 202—205 (decomp.) | — |
| *(42i)* | 8-Br | 105—109 | — |
| *(42j)* | 6-SCN | 170—173 | 3.93 |

[a] See Section 3.2. High $pI_{50}$ values indicate good herbicidal properties.

which excess electrophilic agent attacks the 8-position. As an example *(5a)* reacts with $SO_2Cl_2$ at 70 °C to give *(42b)* and *(42d)* in a 4:1 ratio when treated with $HNO_3$ at 30 °C, compound *(5a)* only gives the 6-nitro derivative *(42g)*.

*(43)*

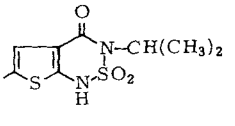


*(44)*

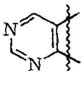
Even under the very mild reaction conditions which were actually investigated for the synthesis of specific $N$-substituted derivatives, for example the reaction of the sodium salt of *(5a)* with chlorine thiocyanate at 15—20 °C to *(42j)* or of *(43)* with sodium hypohalite, substitution took place exclusively in the 6-position possibly *via* a rearrangement, to *(44)* (m.p. = 228—230 °C, decomp.).

As shown by the photosynthesis inhibition values ($pI_{50}$) in Table 14, the herbicidal activity increases, in the case of chlorine-substitution, from the 5-position to the 8-position; a similar relation was also found for methyl-substitution. In fact, both *(42d)* and *(42f)* proved to have strong herbicidal properties, the latter furthermore being selective in cotton cultures. Additional 1-substitution as in *e.g.* *(53c)* however makes the use of these compounds even more interesting to the biologist, because of the *safety of the effect*, and accordingly this pattern of substitution has been developed further (see Table 16). It must however be stated that combining the synthetic work with $pI_{50}$ measurements allowed the number of laboratory experiments to be effectively reduced, and at the same time allowed identification of that part of the molecule responsible for biological activity.

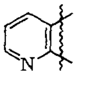
Among the numerous derivatives with heterocyclic substituents which we prepared, only the pyridine derivative[55] *(47)* and its salts exhibit powerful herbicidal action. In particular, the excellent postemergence action against dead nettle and dog's mercury, when using 1 kg/ha, deserves mention. The compound exhibits good selectivity towards rice, Indian corn and barley cultures.



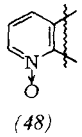
*(45)*



*(46)*



*(47)*



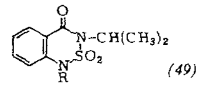
*(48)*

The $N$-oxidation of *(47)* to *(48)* is accompanied by a complete loss of activity.

### 3.4. Synthesis of 1,3- and 1,3,8-substituted 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides

The free NH-group in the 1-position of *(5a)* has acidic character and may therefore be expected to undergo a range of alkylation reactions[45]. For example, alkylation using lower dialkyl sulfates in an aqueous alkaline medium, and the reaction of previously formed salts with alkyl halides or arylsulfonates under anhydrous conditions both proceed smoothly; Table 15 shows a small selection of the compounds prepared.

Table 15. 1-Substituted 3-isopropyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides of type *(49)* [56], *(50)* and *(51)*.



*(49)*-*(51)*

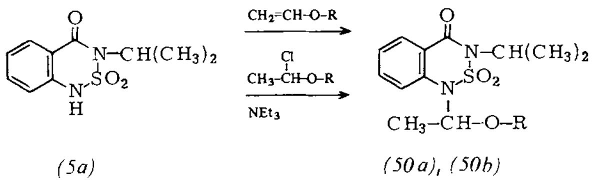
| | R | M.p. [°C] |
|---|---|---|
| *(49a)* | $CH_3$ | 54—55 |
| *(49b)* | $C_2H_5$ | 56—58 |
| *(49c)* | $CH_2$—C—CH | 108—112 |
| *(49d)* | $CH_2$—CN | 119—121 |
| *(49e)* | $CH_2$—SCN | 124—126 |
| *(49f)* | $CH_2$—$N_3$ | 83 |
| *(50a)* | $CH(CH_3)$—$OCH_3$ | [a] |
| *(50b)* | $CH(CH_3)$—$OC_2H_5$ | [b] |
| *(50c)* | $CH(CH_2Cl)$—$OCH_3$ | 109—111 |
| *(50d)* |  | 116—118 |
| *(51a)* | $CH_2OH$ | 95 (decomp.) |
| *(51b)* | $CH_2Cl$ | 116—122 |
| *(51c)* | $CH_2O$—2,4,6-$Cl_3C_6H_2$ | 198—203 |
| *(51d)* | $CH_2SCH_3$ | 84—87 |
| *(51e)* | $CH_2OCHO$ | 99—104 |
| *(51f)* | $CH_2NH$—1-Br—4,6-$(NO_2)_2C_6H_2$ | 131—137 |
| *(51g)* | $CH_2OCH_3$ | [c] |

[a] $n_D^{25} = 1.5240$. [b] $n_D^{25} = 1.5235$. [c] $n_D^{25} = 1.5420$.

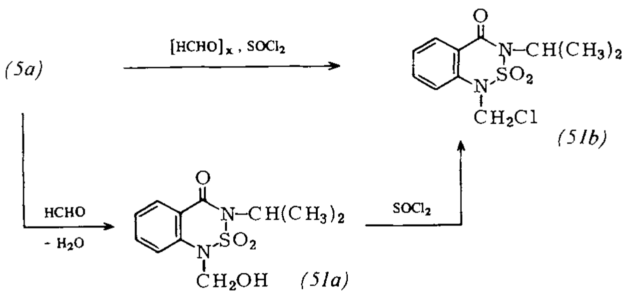
It also proved possible to carry out acylations using a range of organic and inorganic acid halides and anhydrides, again under anhydrous conditions, with or without the aid of an organic base[57]. Similar experiments on the synthesis of arylsubstituted derivatives have also been carried out by others[58].

While amines do not react with vinyl ethers, *(5a)* and other 3-alkyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides *(5)* react with vinyl ethers, in the presence of a catalytic amount of an acid, to give a high yield of the corresponding 1-(α-alkoxyalkyl) derivatives *(50)* (Table 15)[59]. As a result of the acidifying influence of the sulfonyl group, the aniline group acquires an activity comparable to that of phenols with respect to adduct formation with the vinyl ether. As may be expected, the resulting group can be removed again in acid media. The formation of the adduct directly, avoids handling α-haloethers, which also react smoothly.

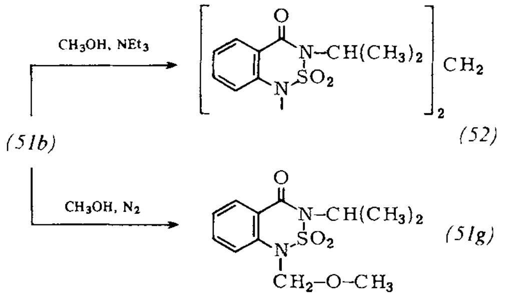
Substituted 1-chloromethyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides such as *(51b)* can be obtained in virtually quantitative yield by reacting *(5a)* with paraformaldehyde



and sulfinyl chloride in an inert solvent. If aqueous formaldehyde is used and the water is removed, it is also possible to isolate *(51a)* and react it analogously with a halogenating agent to give *(51b)*. If *(51b)* is to be isolated, the latter procedure is preferred, in order to avoid formation of α-halo-ethers.



In general, *(51b)* can be washed with water, but it is more advantageous to carry out a one-pot reaction with the nucleophilic agent, followed by extraction with alkali to hydrolyze traces of haloether. Compound *(51b)* is very reactive, *i. e.* it reacts with a wide range of nucleophilic agents, such as phenols, thiols, carboxylic acids or amines, in the presence of a base (Table 15)[60]. Under the same reaction conditions, alcohols or alcohoxides gave only the dimer *(52)* (m.p. = 182—186 °C), in addition to starting material.

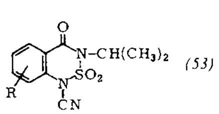


Only if the base was omitted and hydrogen chloride flushed out of the refluxing reaction mixture by means of an inert gas was it possible to isolate high yields of compound *(51g)* and higher analogues[61].

A further group of biologically interesting 3-alkyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides are the 1-carbonitriles *(53)*[62]. Compound *(53a)* is formed on reaction of *(5a)* with cyanogen bromide and compounds *(53b)* to *(53e)* are obtained from the corresponding precursors of type *(42)*, (Table 16).

The herbicidal action of 1-substituted 3-alkyl-1$H$-2,1,3-benzothiadiazin-4-one-2,2-dioxides is markedly substituent dependent. Thus, for example, *(49a)* and *(49b)* (Table 15) are substantially less active than their analogues *(49c)* to *(49f)* with larger substituents. The advantage of these relative to the standard compound is due to their high compatibility with crop plants such as potato, onion and sunflower.

Table 16. 3-Isopropyl-4-oxo-3,4-dihydro-1$H$-2,1,3-benzothiadiazin-1-carbonitrile-2,2-dioxides of type *(53)*.



| | R | M.p. [°C] | | R | M.p. [°C] |
|---|---|---|---|---|---|
| *(53a)* | H | 100—101 | *(53c)* | 8-Cl | 123—124 |
| *(53b)* | 8-CH₃ | 103—104 | *(53d)* | 8-Br | 136—140 |
| | | | *(53e)* | 7-Cl | 146—147 |

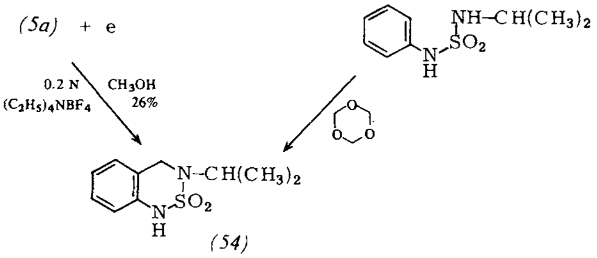
The 1-acyl-substituted derivatives, and the vinyl ether adducts *(50)* (Table 15), on the other hand, more closely resemble the standard *(5a)* with respect to selectivity and action. In some cases, however, they are more effective against charlock, chamomile and goosefoot.

A noteworthy feature of derivatives with substituted 1-methyl groups (Table 15) is the emergence of a new crop plant compatibility, for example in the use of *(51b)* or *(51g)* with cotton, with a certain reduction in the spectrum action.

The same effect was also observed with *(42f)*[54] and *(53b)*; the latter being further characterized by greater activity against chickweed and cleavers. In addition *(53c)* proved useful in controlling deadnettle and dog's mercury.

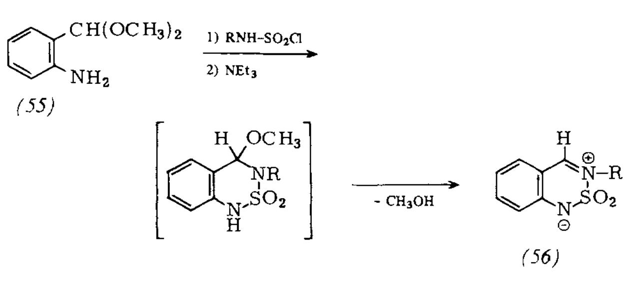
### 3.5. 3-Alkyl-3,4-dihydro-1$H$-2,1,3-benzothiadiazin-2,2-dioxides and Related Compounds

The carbonyl group in compound *(5a)* can be reduced electrolytically, so that 3,4-dihydro-3-isopropyl-1$H$-2,1,3-benzothiadiazin-2,2-dioxide *(54)* is obtained.

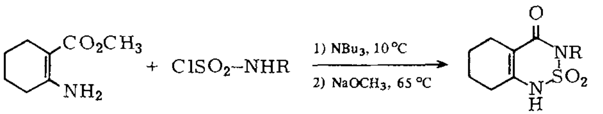


The same heterocyclic compound was later also prepared by *Pews*[63], who cyclized $N$-isopropyl $N'$-phenylsulfamide with trioxane.

Other compounds in which the carbonyl group has been converted to a derivative are meso-ionic 2,1,3-benzothiadiazin-2,2-dioxides of type *(56)* which are obtained directly on reaction of 2-aminobenzyldehyde-acetals such as *(55)* with alkylsulfamoyl chlorides[64].



Aryl-hydrogenated 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides are difficult to obtain by catalytic hydrogenation of the corresponding benzo-heterocyclic compound. A better method employs β-enaminocarboxylic acid esters, for example methyl 2-aminocyclohex-1-ene-1-carboxylate *(57)*, which is converted directly into the 5,6,7,8-tetrahydro-derivative *(58)* (m.p. = 196—198 °C decomp.) in a one-pot process, by reaction with *N*-isopropylsulfonyl chloride *(20c)* followed by heating the mixture with sodium methoxide.

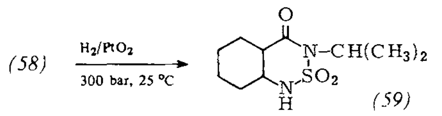


*(57)* *(20c)* *(58)*

R = $CH(CH_3)_2$

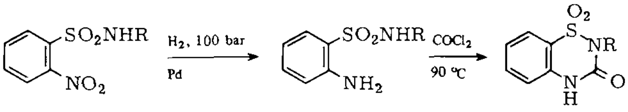
*Kloek* and *Leschinsky* had developed a multi-step synthesis of the same compound[65].

Finally, *(58)* was transformed into *(59)* (*cis*:*trans* mixture, m.p. = 95—110 °C) by catalytic reduction.



Surprisingly, all the hydrogenated analogs described in this Section proved only to have a low herbicidal activity in spite of their structural similarity to the commercial product Basagran® *(5a)* or the uracil derivative lenacil *(40)*.

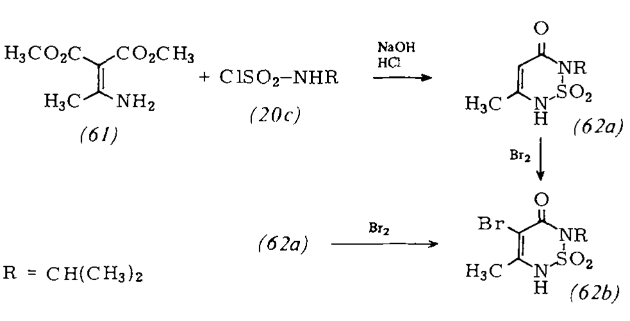
In conclusion, it may be noted that the 2-alkyl-2*H*-1,2,4-thiadiazin-3-one-1,1-dioxides *(60)*, which are inversely isomeric to *(5a)* and are derived from *o*-nitrobenzenesulfonamides by reduction and phosgene cyclization, prove to be weaker herbicides than the corresponding compounds of type (5) *(42)*[66].



*(60)*

### 3.6. 2*H*-1,2,6-Thiadiazin-3-one-1,1-dioxides

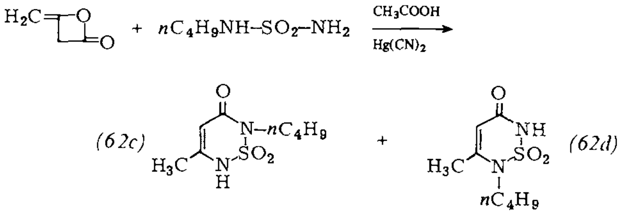
The concept of this class of compounds again arose from a natural substance, namely uracil *(41)*, mentioned at the outset. Reaction of (1-aminoethylidene)malonic acid derivatives such as *(61)* with alkylsulfamoyl chlorides such as *(20c)*, led to cyclization giving *(62a)*; subsequent halogenation gave novel derivatives such as *(62b)*[67].



*(61)* *(20c)* *(62a)*

R = $CH(CH_3)_2$ *(62b)*

Compared to the earlier condensation reaction of diketene with sulfamides, sulfamoyl chlorides are more selective, since sulfamides had always led to an isomeric mixture; here of *(62c)* and *(62d)*[69].

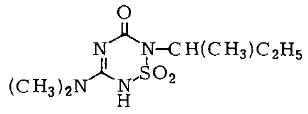


*(62c)* *(62d)*

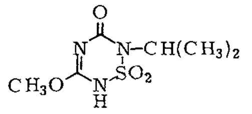
Although compound *(62b)* is isosteric with branched bromacil derivatives *(39)*, it does not have a herbicidal action; the reason appears to be that bromine is more easily eliminated from *(62b)*[69].

### 3.7. 2*H*-1,2,4,6-Thiatriazin-5-one-1,1-dioxides

The synthesis of these compounds has been pursued by two industrial laboratories. Following on its own development work leading to the fungicide Bupirimate® *(19)*[21], ICI produced 3-dimethylamino derivatives *(63)*[70], which can be used to control mildew and rust, and also have a herbicidal action in rice.



*(63)*

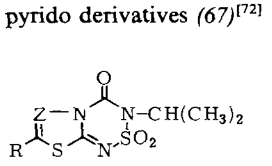


*(64)*

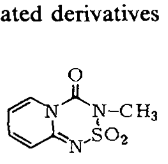
In BASF, it was principally the search for further fields of use of sulfamoyl chlorides as heterocyclic synthesis units, which led to the herbicidal 3-alkoxy derivative of type *(64)*[71]. These compounds are particularly suitable for the selective control of cyperaceae in rice, but, in contrast to *(63)*, have only a slight fungicidal action.

### 3.8. Five- and Six-membered ring heterocycles from acylated alkylsulfamoyl chlorides

With the object of investigating the biological action of 1,2,4,6-thiatriazin-5-one-1,1-dioxides fused to a heterocyclic structure, substituted [1,3,4]thiadiazolo[3,2-*c*][1,2,4,6]thiatriazinone dioxides *(65)* and analogous thiazolo derivatives *(66)*, pyrido derivatives *(67)*[72] and other related derivatives

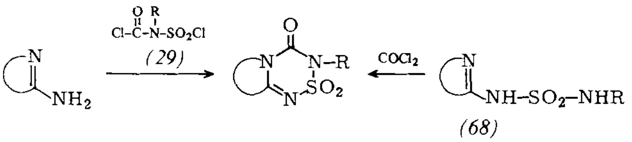


*(65)*, Z = N, R = $(CH_3)_3C$
*(66)*, Z = CH, R = H



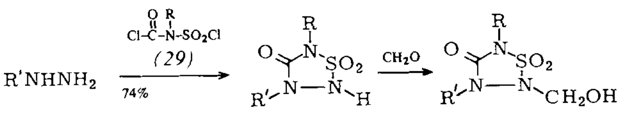
*(67)*

were prepared, but proved only to have a low herbicidal activity[73]. A suitable method of synthesis is direct condensation of a 2-amino-azaheterocyclic compound with the acylated sulfamoyl chloride *(29)*; however, the yields obtained by this method are mostly lower than in the case of stepwise synthesis by phosgenation of the sulfamides *(68)* (*cf.* [72]).



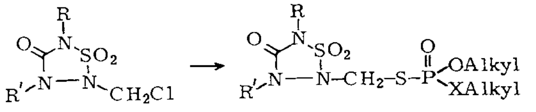
(29) (68)

In contrast, alkylhydrazines react very smoothly with *(29)* to give 3,5-dialkyl-1,2,3,5-thiatriazolidin-4-one-1,1-dioxides *(69a)*[72]. These can next be hydroxymethylated with formaldehyde, similarly to compound *(51b)*, to give *(69b)*.



(29) (69a) (69b)

The latter can then be converted, with sulfinyl chloride, to the very reactive 2-chloromethyl derivatives *(69c)*. Their subsequent reaction with phosphate salts gives novel heterocyclic phosphoric acid derivatives of type *(70)*, which can be used in plant protection, hygiene and storage protection areas[74].

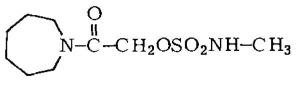


(69c) (70)

## 4. Future Prospects

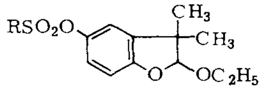
Work on 1*H*-2,1,3-benzothiadiazin-4-one-2,2-dioxides as modern crop protection agents has led, *via* alkylsulfamoyl chlorides which could be produced industrially, to a range of new heterocyclic synthesis reactions which have had repercussions in additional fields of use.

As an example of a sulfamoyl ester, we may mention sulfglycapin *(71)*[75] which, when used in rice crops, selectively controls species of cyperaceae and of barnyardgrass and, in particular, weeds such as *Leptochloa fascicularis* and *Leersia oryzoides*, which hitherto have been difficult to destroy.



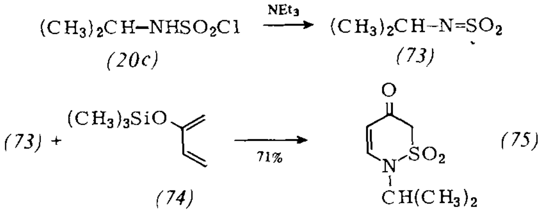
(71)

As regards herbicidal sulfamoyl aryl esters, *Rohr* and *Fischer* showed, in the case of compound *(72b)*, which is analogous to ethofumesate *(72a)*[76] (a selective herbicide in beet), that herbicidal receptors in the plants cannot differentiate biologically between the two types of sulfonic acid derivatives[77].



*(72a)*, R = $CH_3$ : Ethofumesate
*(72b)*, R = $CH_3NH$

The ability to use the sulfamoyl chlorides to synthesize a new category of double bond rich material, the *N*-sulfonylamines[4], has only very recently been employed in adduct formation with activated dienes. Thus, *(73)* smoothly undergoes adduct formation with *(74)*, to form 1,2-thiazin-5(6*H*)-one-1,1-dioxides such as *(75)*[78]; these constitute a novel heterocyclic six-membered ring system, which is evidently formed *via* a two-stage mechanism.



(20c) (73) (74) (75)

A century after the discovery of dimethylsulfamoyl chloride, the chemistry of monoalkylsulfamoyl chlorides has essentially been advanced by industrial laboratories. The fact that these compounds have now become industrially readily available, together with their reactivity and bifunctional character, may be expected to stimulate the broader use of these synthesis units, which show many interesting aspects with respect to preparative possibilities and biological properties.

*The late Dr. A. Fischer deserves great credit in connection with the discovery of the first biologically active 1H-2,1,3-benzothiadiazin-4-one-2,2-dioxides. We particularly want to thank Dr. B. Würzer and co-workers for the broad biological testing, which further stimulated the progress of our research. In addition to those whose names appear in the literature references, we would also like to thank the following colleagues, at this point, for their kind collaboration; Dr. G. Retzlaff for measuring and interpreting photosynthesis inhibition values, Dr. W. Bremser for the spectroscopic aspects of our work and Dr. H. Pütter for electrochemical experiments.*

# Irritant and Defense Substances of Higher Plants—A Chemical Herbarium[**]

**By Hermann Schildknecht[*]**

*Dedicated to Professor Karl Freudenberg on the occasion of his 95th birthday*

All living organisms respond to stimulation, reacting more or less sensitively and more or less typically to a wide variety of energy forms such as light, heat, gravity, pressure (sound), electricity—and chemicals. A living organism responds to an irritation by releasing irritants which—as potential defense substances—are directed against the attacker or assist the organism endogenously in an intrinsic defence reaction. Often very small energy changes perceived by the plant are enough to induce a series of physiological processes ultimately manifested as a glandular reaction or even movement. The irritants involved in these processes act on membranes as defense substances in the presence of an attacker, or as endogenous factors in their own cellular environment. These chemically very diverse low-molecular active principles have been found in many parts of plants and in many plant families. For this reason alone we could speak of a chemical herbarium, but the case is even stronger because, in this botanical documentation, not only the individual chemicals are considered in context but also whole sets of interacting substances, since it is only in these sets that optimal activity is found (just as one considers not only the parts of a plant but also the whole plant in botany).

## 1. Introduction

A hundred years ago, in 1880, the "Power of Movement in Plants"[1] appeared as one of the later Volumes of the collected works of *Charles Darwin.* In this book, some 500 pages long, *Darwin* described a fascinating behavior pattern according to which all rootlets, shoots, petioles, and leaves perform elliptical to circular motion. Why did *Darwin* begin, at the age of 71 and not in the best of health, 5 years before his death in 1882, a series of painstakingly planned experiments with about a dozen genera from completely different plant families on the circumnutation induced by light and gravity?

[**] Plant Defense Substances, Part 14.—Part 13: [185].

His own discovery of the principle of evolution compelled him to do so, for according to this it was impossible that the climbing plants should have developed into many groups if all plants did not possess some small capacity for movement of this kind[2]. As he then went on to include plant sleep, the so-called nyctitropic movement, in his considerations, *Darwin* was on the verge of a purely phenomenological contemplation that "it is hardly possible to doubt that plants must derive some great advantage from these remarkable powers of movement"[1].

Likewise a hundred years ago, the physiological foundations of plant defense behavior were discussed by *Wilhelm Pfeffer* in his general considerations "On the Nature of Stimulation Processes"[3]. *Pfeffer*'s approach was that of a man of exact natural science, although it was not particularly substance-oriented; to him stimulation processes were at first only excitation processes and "accordingly, specifically for example, the sudden stimulation reactions (such as the closing of the leaves of the sensitive plant) are not of such general significance as the host of the slow and constantly occurring reactions and regulations"[4]. However, even in Volume II of *Pfeffer*'s Plant Physiology[5] one can read, that "it is presumably precise chemical stimuli that play a prominent role in the autoregulatory guidance of inner activity and thus also of autonomous movement."

Here unequivocal reference is made to chemistry, the material basis of all stimulation processes, which at every turn, including the domain of plant defense mechanisms, confronts the natural-products chemist with ever new perspectives. It is a stimulating but sometimes also a demanding task for analytical chemists to correlate observations with chemical structures, revealing that *Martin Lindauer* had hit the nail right on the head in his book "The Biological Clock"[6] when he said that the basic requirement for all life is having the right substance in the right quantity, at the right place, and at the right time.

To the chemist the right substance means knowing the correct structure of an active principle, which is only optimally effective when, as per *Paracelsus*, the dose is also correct. The right place for a plant defense substance is, for example, the stinging hair or the cuticular tissue, and in the case of a movement factor the cell membrane, where it must be present at the right time when the plant is about to fold its leaves to sleep. The aim of the following considerations is to present the biological phenomenon of plant defense, with these aspects as the guiding motif.

## 2. Irritant and Defense Substances from Glandular Hairs

### 2.1. The Defense Substances of *Urtica dioica*, *Laportea moroides*, and *Jatropha urens*

#### 2.1.1. The Organs of Defense

The chemical interaction between life-forms—their chemical ecology—can be illustrated particularly well with the example of defense substances as used by the stinging nettle. Here a mechanical defense and a chemical defense are combined.

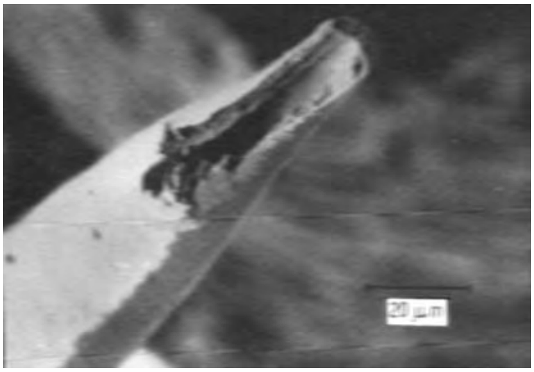

Fig. 1. Stinging nettle *(Urtica dioica)* trichome with a broken-off stinging hair tip, taken with a Kontron scanning electron microscope.

The hairs of the stinging nettle (Fig. 1) are poison reservoirs with siliculated tips at the upper end. The tips break off easily making each hair into a sharp-pointed cannula through which some 0.003 $mm^3$ of the total quantity of 0.008 $mm^3$ of liquid poison flows into the injured skin. This results in the familiar stinging from which the whole plant takes its name. *Laportea moroides*, another member of the *Urticaceae* family, is markedly more toxic; one prick may easily give rise to long-lasting pain, the injured skin area remaining sensitive to pressure, cold, and moisture for days and even weeks (Fig. 2). *Laportea* has yet another form of defense:

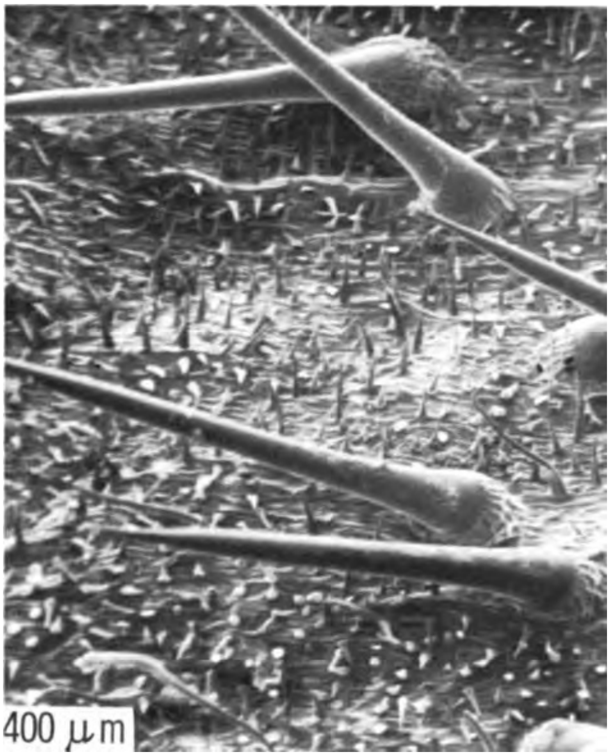

Fig. 2. Stinging hairs of *Laportea moroides*, taken with a Kontron scanning electron microscope.

when its leaves are picked in a greenhouse, a keen sensation of irritation to the mucous membranes of the nose and the eyes is experienced, which can only be prevented by the use of a gas mask. The initial pain is attributed to the same compounds as in the stinging hairs, and the long-term effect to a higher-molecular, nondialyzable substance whose action may possibly be based on the release of endogenous histamine.

The *L. moroides* bush grows in the wild in eastern Australia, but, of course, in Europe it must be kept in a greenhouse. Propagation from seed, which can be gathered at all times of the year, presents no problems.

The up to 1-cm long stinging hairs of *Jatropha urens*, a member of the *Euphorbiaceae*, are particularly distinctive. Like other plants with stinging hairs, in its homeland in Central and South America it is a troublesome weed. When touched, the tip of the *Jatropha urens* stinging hair breaks off and the poison, a strong irritant, drips out (Fig. 3). One can well imagine that the fruits important for continuation of the species, protected with stinging hairs (Fig. 4), are effectively defended in this way.

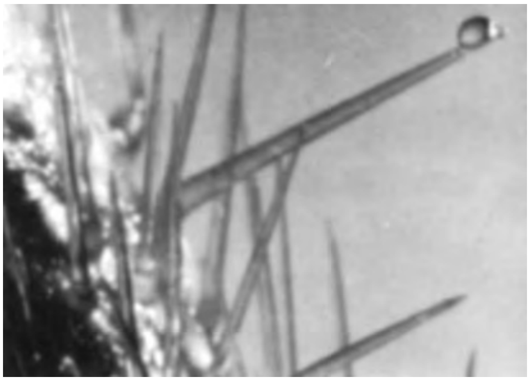

Fig. 3. Stinging hairs (8 mm long) of *Jatropha urens* (macro-photograph), after the poison has emerged from the broken-off tip.

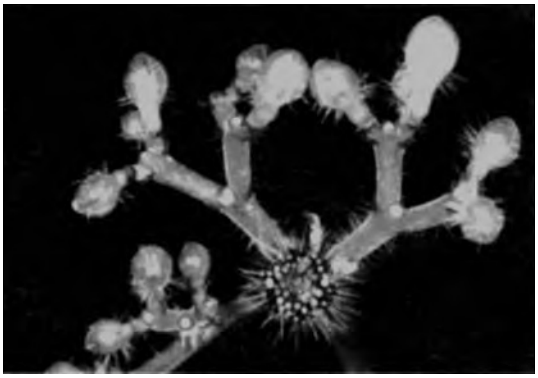

Fig. 4. Fruit of *Jatropha urens* surrounded by many stinging hairs (diameter 15 mm).

While the defense substances of the above plants have often been studied in the past, it is only in the last few years that a satisfactory understanding has been achieved.

### 2.1.2. History of the Active Principles in Stinging Hairs

Since the suggestion put forward by *Gorup Besanez*[7] in 1849 formic acid has time and again been held responsible for the easily demonstrable action of nettles[8], although *Haberlandt*[9] questioned this as early as 1886 and suspected a dissolved, albumin-like substance, or perhaps even an enzyme; on this point see Table 1. *Flury*[10] suggested a nonvolatile, nitrogen-free acid as the toxic principle, while *Nestler*[11] attributed the stinging primarily to the mechanical stimulus, but conceded that an enzyme might also be involved. However, these findings were unable to explain the

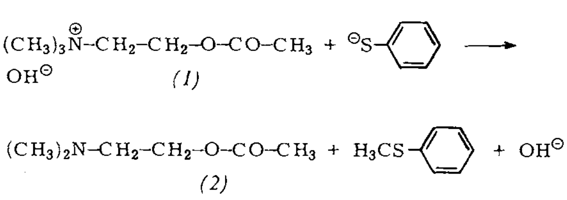
action of the stinging-nettle poison. In 1947, *Emmelin* and *Feldberg*[12] were the first to detect a histamine- and acetylcholine-like action on guinea-pig intestine, a finding supplemented in 1956 by *Collier* and *Chesher* with a muscle-contracting toxic component[13].

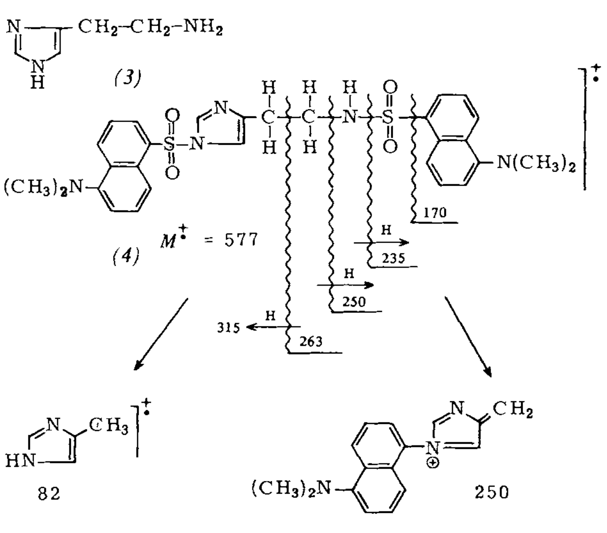
A more detailed chemical identification of the physiologically active constituents of stinging-nettle secretion commenced in 1960[14], when biogenic amines became detectable by paper- and thin-layer chromatography and later fluorimetrically as well[15]. Reliable identification of the stinging-hair poisons began with a clean isolation of the hairs by shaving, with the aid of an electrostatic air separation[14] of the hairs and the leaves, or by separating the hairs from deep-frozen leaves[16]. Even when the pure defense organs have been obtained (2 g of stinging hairs from 2 kg plant), the detection of the biogenic amines still remains problematic, since these biologically very active substances are present only in small quantities and moreover are very unstable.

### 2.1.3. Mass Spectrometry of the Biogenic Amines

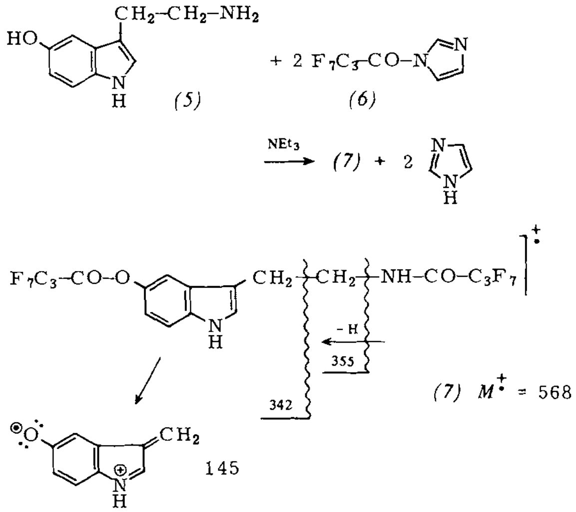
According to *Jenden et al.*[18], for the detection of acetylcholine *(1)*, the latter is demethylated with thiophenolate in butanone at 80 °C to dimethylaminoethyl acetate *(2)*, which can be readily detected by gas chromatography on an 8%-SP-1000 separation column combined with mass-spectrometry through the characteristic base peak with $m/e = 58$.



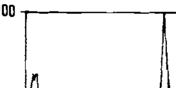
Histamine *(3)* can be reliably identified only after derivatization with dimethylaminonaphthalenesulfonyl chloride (DANS)[19,29]. The dansyl product *(4)* is strongly fluorescent and can be detected even in very small quantities, after preparative TLC, by mass spectrometry on the basis of its clear fragmentation pattern, as shown in the scheme below, the masses $m/e = 577$ and 82 being particularly informative.



Serotonin *(5)* can only be isolated sufficiently for an analysis when the stinging hairs have been extracted with acetone and the biogenic amine *(5)* has been made highly volatile for gas chromatography. A mild but effective method is derivatization with heptafluorobutyrylimidazole (HFBI) *(6)* in the dark at room temperature, with triethylamine as a catalyst, in dry ethyl acetate[21].



On a packed 3% OV 101 separation column the reaction products obtained give a complex gas chromatogram so that the desired serotonin derivative *(7)* from the stinging hairs of *Urtica dioica* and *Laportea moroides* had to be detected by mass-fragmentography with a combination of GC and MS by monitoring the characteristic $m/e$ values 355, 342, and 145 (Fig. 5). The detection of serotonin in the stinging hairs of *Urtica dioica* in this way remains problematic on account of the small quantity present, in contrast to *Laportea moroides*. The same is true of the biogenic amines 2-amino-1-phenylethanol *(8)* and tyramine *(9)*, which can be found



*(8)*

*(9)*

amongst the *Urtica* defense substances only by using mass-spectrometry. The thin-layer chromatogram reveals other amines as well, but these could not be identified.

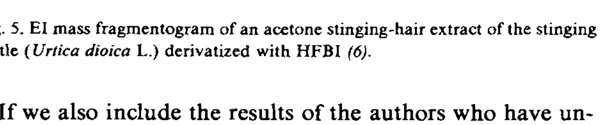


Fig. 5. EI mass fragmentogram of an acetone stinging-hair extract of the stinging nettle (*Urtica dioica* L.) derivatized with HFBI *(6)*.

If we also include the results of the authors who have undertaken comparative physiological experiments[12-14], we arrive at the following synopsis of concentrations of the active principles in the stinging hairs of these *Urtica, Laportea,* and *Jatropha* species; cf. Table 2.

Table 2. Comparison of the concentrations of the three most important stinging-hair amines acetylcholine *(1)*, histamine *(3)* and serotonin *(5)*.

| Stinging hairs of | Stinging hair content [mm³] | *(3)* [μg] | *(5)* [μg] | *(1)* [μg] |
|---|---|---|---|---|
| *Urtica dioica* | 0.008 | 0.01 | 0.004 | 0.04 |
| *Laportea moroides* | 0.07 | 0.025–0.05 | 0.001 | 0.01–0.025 |
| *Jatropha urens* | 1 | 1–2 | 0.5–1 | — |

The histamine and serotonin contents of the stinging hairs of *J. urens* can be determined from the size of the spots in the thin-layer chromatogram[16,23]. The high content of biogenic amines in *J. urens* accords well with the experience on handling this plant, but an unquantifiable toxic action persists even after the use of suitable antagonists[22,12]. In addition, it is difficult to determine how much secretion is active in the skin after one prick, this being a function of the size of the stinging hair.

### 2.1.4. The Function of Biogenic Amines

The three biogenic amines *(5)*, *(3)* and *(1)* which are also the most important ones according to *Guggenheim*[24], have thus been reliably detected in the glandular hairs of the poisonous plants under discussion. Their pharmacological properties and their occurrence in animals' defense organs clearly demonstrate the defensive function of these plant toxins.

Histamine *(3)* and serotonin *(5)* are stored as tissue hormones in mast cells, basophilic leucocytes, and thrombocytes, from which they can be released by certain stimuli. Acetylcholine *(1)* is a neurotransmitter formed in cholinergic nerve cells, and is responsible for the transmission of nerve impulses.

Many animal defense secretions contain histamine and serotonin[25]. These are found in coelenterate venoms and in the venom of ***Phoneutria nigriventer*** from the family of South American comb spiders. Histamine is present in the venom apparatus of bees and histamine and serotonin in that of wasps. This mixture is supplemented in hornet venom by a strikingly large quantity of acetylcholine (5% of dry matter), which is responsible almost exclusively for the action of hornet stings on the heart. *(3)* has an acute effect on the circulation, and all three biogenic amines cause the initial pain after the sting. The round stingray *(Urolophus halleri)* is also actively venomous; its venom contains two highly-toxic protein fractions as well as serotonin.

The simple biogenic amines are found everywhere in the defense secretions of the skin glands of amphibians. Serotonin occurs in practically all tree frogs *(Hylidae)* and in the coral-finger tree-frog *(Hyla caerula)* it is also accompanied by histamine and the decapeptide caerulein. The skin secretion of the orange-speckled toad *(Bombina variëgata variëgata)* has a characteristic smell inducing violent sneezing and catarrh-like symptoms in man, and contains 5-hydroxytryptamine (serotonin) in an amount of 10% of the dry weight; another typical feature is that free amino acids are present, as well as low-molecular peptides.

### 2.1.5. Further Investigations

*Hemolysins:* In addition to the large stinging hairs of *Laportea moroides,* Figure 2 shows a large number of smaller gland cells which may be the source of a sneeze-promoting secretion, like the toad secretion just mentioned. The catarrhal symptoms also persist for three hours without abatement after picking *Laportea* stems, before gradually subsiding.

Whereas unfortunately it has proved impossible to detect and isolate the relevant components of the active principle *via* the vapor phase, it was found that the toxic effect is accompanied by a hemolyzing component of the secretion from the pure stinging hairs. Shaved stems of *L. moroides* are inactive (Table 3; for preparation of the extract see Table 4).

Table 3. Hemolytic indices of extracts from various parts of the *L. moroides* plant; $HU_{50}$ gives the quantity of hemolysin (in grams) necessary to release 5 g of hemoglobin from an erythrocyte suspension with potentially 10 g of hemoglobin.

| Sample | $HU_{50}$ |
|---|---|
| Pure stinging hairs | 1.19 |

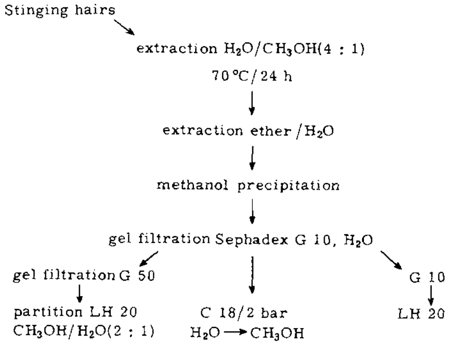
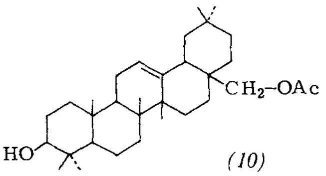
Table 4. Preparation of an extract of the stinging hairs of *L. moroides*.



In comparison, the hemolytic index of Merck's "Saponin weiss" is 0.156. This comparison is permissible, insofar as after careful chromatographic separation on molecular sieves a *Laportea* hemolysin was isolated from the active-principle mixture, whose aglycone according to high-resolution mass-spectrometry could be a pentacyclic triterpene. *(10)* would be a possible compound from the oleanane series.



*(10)*

The proposed structure may be regarded as a useful working model, since the field of the active principles under discussion is like a jungle, in which any aid to orientation can only lead forward. The main aim here is to correlate ostensibly unconnected findings in such a way that generally valid principles will emerge. The membrane activity of saponins is manifested here in the case of the *Laportea* hemolysin, as it is in the case of leaf movement factor 1 from *Albizzia lophanta* (cf. Section 8.3).

The *Jatropha* hemolysin is not detectable in 3.7 mg of dried secretion from 2000 stinging hairs. However, it has an

$HU_{50}$ of 1.266 when the secretion is dripped directly into an erythrocyte suspension. It is very probable that a protein is present[26, 16].

*Free Sugars and Amino Acids:* Whereas on the basis of dialysis experiments and enzymatic tests *Robertson* and *MacFarlane* 1957[22] only suspected an oligosaccharide with a molecular weight of 1000, glucose, fructose, and sucrose have now been detected in the poison secretion of *L. moroides* by GC-MS after persilylation[16]. The same sugars are found in the sweet-tasting secretion of *J. urens* (cf. Fig. 6).

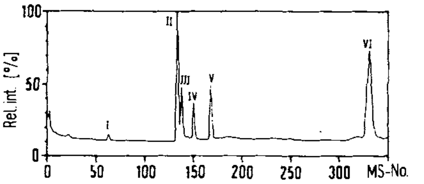


Fig. 6. Reconstructed gas chromatogram of silylated stinging hair fluid of *J. urens* on 3% OV 101, glass column, 2 m, 1/4" temperature conditions: column 140 °C isothermically, from spectrum 21 heated to 240 °C at 4 °C/min; injector 240 °C (III to VI, see Table 5).

A comparison of the retention times of fractions III to VI and of reference substances is given in Table 5. The assignment of the retention times is confirmed by corresponding mass spectra and high-pressure liquid chromatograms. Table 6 shows that sugars are present in the stinging hairs of *J. urens* in quantities comparable to those of the physiologically active amines histamine *(3)* and serotonin *(5)*.

Table 5. Retention times of fractions III to VI (see Fig. 6) and the corresponding reference substances (TMS = trimethylsilyl).

| Fraction/Reference | Retention time [min] |
|---|---|
| III | 14.3 |
| IV | 15.74 |
| V | 17.74 |
| VI | 30.3 |
| TMS-D-Fructofuranose | 14.34 |
| TMS-α-D-Glucopyranose | 15.86 |
| TMS-β-D-Glucopyranose | 17.72 |
| TMS-Sucrose | 30.24 |

Table 6. Sugar and amine content of the stinging hairs of *J. urens*.

| Sugar | μg/hair | Amine | μg/hair |
|---|---|---|---|
| Fructose | 0.8 | Histamine | 1–2 |
| Glucose | 0.68 | Serotonin | 0.5–1 |
| Sucrose | 0.56 | | |

The determination of the free amino acids in the stinging fluid of *J. urens* is sensible if only because this is a pure secretion, free from other cell constituents. In addition, it is suspected that the free amino acids form part of a whole complex of active principles, as is the case with many amphibian poisons and biogenic amines. As can be deduced from the elution diagrams (Fig. 7), the 18 amino acids detected include the most important ones; glutamic acid is particularly well represented (17.5 wt-%), as is aspartic acid (10.3 wt-%). The presence of the sugars and of the free amino acids could raise the activity.

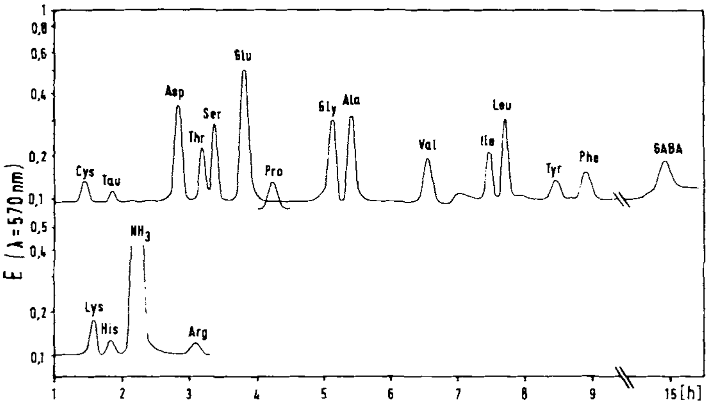

Fig. 7. Elution diagram of the amino acids from the stinging fluid of *J. urens*; taken with the Labotron amino-acid analyzer. GABA = γ-aminobutyramide.

## 2.2. The Primrose Defense Substances

### 2.2.1. The Defense Organ

*Primula obconica,* the Japanese primrose, is a pretty and unassuming but poisonous plant, known also as pot or poison primrose. The poison, contained in glandular hairs growing all over the plant (cf. Fig. 8), is apparently secreted constantly and for allergic people can pollute the atmosphere. However, the glandular hairs differ markedly from the trichomes of the previously mentioned *Urticaceae* and *Euphorbiaceae.*

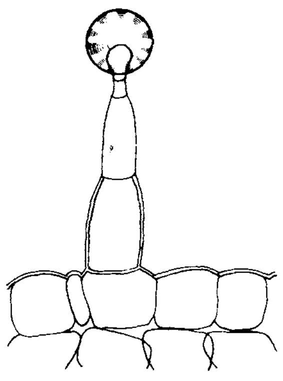

Fig. 8. Glandular hair of poison primroses with droplet of poison, schematic.

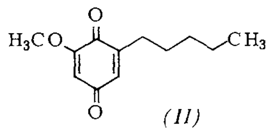
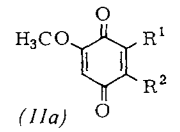
Thus, with the aid of the scanning electron microscope the tips of the stinging hairs of *L. moroides* were found to contain silicon and potassium, and in addition calcium was found at the tip break-points, its content increasing toward the base[191]. None of these elements are found in the stinging hairs of *J. urens*, where instead after the tip has been broken off a sharp-pointed cannula forms at the tapered site (see Fig. 1). This too is absent in the primroses covered with glandular hairs, so that the defense substances become active under the skin not mechanically but only on account of their special molecular structure.

### 2.2.2. Chemistry and Toxicology of Primrose Defense Substances

Around the turn of the century, when many varieties of primrose were already grown commercially, alarming articles appeared in leading medical publications describing the irritant action of primroses on the skin and almost resulting in a ban on their cultivation. *Nestler*[27] found that the action is due to yellow crystals appearing in the secretion, and *Bloch* and *Karrer*[28] that the isolated compound (primin) is in fact highly toxic to the skin of people especially sensitive to primroses. The yellow primin can be sublimed, is steam-volatile, forms a dark-colored product with hydroquinone and a precipitate with 2,4-dinitrophenylhydrazine, and quite generally speaking tends to exhibit the reactions of a quinone rather than of a lactone as suspected by *Bloch* and *Karrer*[28]. On the basis of an electron-pyrolysis analysis and of IR and NMR data, primin was finally identified as 2-methoxy-6-*n*-pentyl-*p*-benzoquinone *(11)*[29]. The fact that this quinone is the sought-for allergen could be demonstrated by *Hjorth* and *Fregert*[30] in Lund, Sweden on patients clinically sensitive to the plant. A comparison with synthetic variants of primin (methoxyquinones with longer or shorter side chains) was very informative: only the primin was strongly active even in patients with a low sensitivity (cf. Table 7). Most of the patients reacted to the 6-methyl and the 6-ethyl derivative only when administered in highly concentrated solutions. An allergic effect was sometimes also observed with methoxyquinones substituted at C-5 of the quinone nucleus, but only in very sensitive subjects. The optimal length and position of the side chain can be regarded as an immunological factor, but it can also correspond to increased skin permeability. Apparently the quinone allergens form antigens freely, only when the stereochemistry of the molecule permits a protein to interact with it easily. On the other hand, quinones with short side chains are too soluble in water and those with long side chains are too lipophilic.



*(11)*



*(11a)*

Table 7. Test reactions of 20 patients to primin *(11)*, as well as some variants and isomers *(11a)*. $c=0.48$ mmol/dm$^3$.

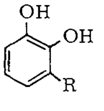
| 20 | − | − | − | − | − | − | − | + | − | | − | | − |

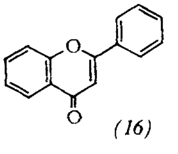
[a] Concentration: $c/4$.

The fact that *p*-benzoquinone and toluquinone provoke no reaction whatever also shows the importance of the methoxy group in the physiologico-chemical action. Here we are dealing with an especially impressive example of a structure-action relationship of a phytotoxin. Similar considerations were borne in mind by *Baer et al.*[31] when they attempted to interpret the extreme contact dermatitis caused by urushiol, the toxic irritant principles of poison ivy *Rhus toxicodendron L.*; in this case a mixture of catechols *(12)*, *(13)*, *(14)*, and *(15)* is present.

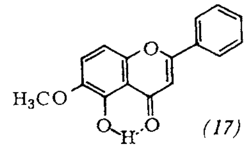


*(12)*, R = $(CH_2)_{14}$–$CH_3$
*(13)*, R = $(CH_2)_7$–CH=CH–$(CH_2)_5$–$CH_3$
*(14)*, R = $(CH_2)_7$–CH=CH–$CH_2$–CH=CH–$(CH_2)_2$–$CH_3$
*(15)*, R = $(CH_2)_7$–CH=CH–$CH_2$–CH=CH–$CH_2$–CH=$CH_2$

Thus, it is only necessary to synthesize the appropriate chemical variants to be able to draw conclusions about evolutionary analogies. However, urushiol leads us beyond its own plant family and back to the *Primulaceae*, since here too phenols are found as potential contact allergens. Particularly in the primroses dusted as though with flour we find, as a first line of defense, pure flavone *(16)* and 5-hydroxy-6-methoxyflavone *(17)*[32]. Neither *(16)* nor *(17)* is by nature allergenic[32], but they can become allergenic after repeated contact, as happened to *Nestler* in the course of his work[33].



*(16)*



*(17)*

In the quinones of the *Primulaceae* at least, we find true defense substances, if only because the compounds are produced and stored in special defense organs. This is also indicated by the occurrence of quinones in the defense glands of ground beetles[34], earwigs[35], and diplopods[36], where the defense function of the quinones is undisputed[37]. The pygidial defense glands of the dytiscids, predacious aquatic beetles, contain above all aromatic hydroxycarboxylic acids, with which these insects protect themselves from life-threatening attack by fungi[38].

Quinones and phenols are also the active principles that play an essential part in the competition between different higher plants and between higher plants and microorganisms. In botanical literature references of this nature are found under the term allelopathy[39]. However, before we embark upon this field of defense chemistry, mention should be made of the analysis and the toxicology of the defense substances, directed—as in the case of the *Urticaceae, Euphorbiaceae,* and *Primulaceae*—against our own main defense organs, the mucous membranes; the term "skin-to-skin effect" would be appropriate in this context.

## 3. Irritants and Defense Substances from the Bast and the Berries of the Thymelaeaceae

The bast of a bush (Fig. 9), which in early spring could represent welcome fresh food for famished wild animals such as the deer and the rabbit, is protected from them by a toxin which, by inducing an extremely severe mucosal irritation, would spoil once and for all even the most voracious appetite. The recurring description of the striking efficacy of daphne poison, upon which man as researcher and healer has lavished special attention through the ages, is enough to support this theory[40].

Fig. 9. *Daphne mezereum*, the spurge laurel.

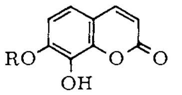
*Johann Friedrich Gmelin,* the father of the author of "Gmelin's Handbook of Inorganic Chemistry", gives a description in his general history of plant toxins[41] which is illuminating for our theme of the defense substances of plants insofar as it clearly portrays the associated physiological effects and gives a list of vivid names by which the plant is known:

"Mezereum, lousewort, spurge laurel, devil-in-the-bush, virgin's bower, mountain pepper, spurge olive, *Daphne Mezereum* Linn. All parts of this plant, the roots, the bark, leaves, and above all the berries have a quite extraordinary pungency and when rubbed on the skin produce reddening and blistering, but if swallowed they result in a fearful and sustained burning in the mouth and the throat often in real inflammation of these parts, in an unslakable thirst, the most violent vomiting, persistent and dreadful diarrhea, stomach pains that endure long after, sleepless nights, a raging fever, indescribable physical weakness, and peeling of skin all over the body. Death is not uncommon. The mere effluvia of the flowers can cause fainting in unventilated rooms. Even the smoke of the wood in which they were smoking their meat proved fatal to some soldiers in Corsica after convulsions and a sensation of being choked. In cattle the berries give rise to bloody stools, and to wolves and dogs they are deadly. The flowers are carefully avoided by bees."

It should be noted that the daphne toxin, mezerein[42], occurs in particularly high concentrations in the fruits, important for preservation of the species[43], just as the strongest nonprotein poison, tetrodotoxin, occurs predominantly in the ovaries and testicles of the globefish[25]. However, the mezerein in the fruits (Fig. 10) could also be there to help in wide dispersal of the seeds for propagation of the species because of its strongly purgative action[44].

Fig. 10. The shiny red berries of *Daphne mezereum.*

Rather fewer physiologically active compounds now regarded as defense substances had been classified before the actual defense substance of the spurge laurel, *i.e.* the resinous inflammatory principle[45], was isolated in pure form. *Zwenger*[46] established the structure of daphnin *(18)* and found umbelliferone *(19)* by dry distillation of the bark. As early as 1870 *Casselmann*[47] described a volatile "coccognin", which may well have been the sublimable daphnetin *(20)* discovered in 1879 by *Stünkel*[48]. In 1963 *Tschesche et al.*[49] reported a dicoumarin, daphnoretin *(21)*, and its glycoside daphnorin *(22)*. Guided by an inflammation test in experiments on themselves, *Schildknecht* and *Edelmann* (1967)[50] isolated 400 mg of crystalline mezerein from 1 kg of dried seed, whose inflammation threshold was 0.2 μg/mouse ear and whose median inflammatory dose (see Table 8)[51] was 0.023 : 1.27 μg/mouse ear[52]. Mezerein is considerably cocarcinogenic[53]. The inflammatory power and the cocarci-



*(18)*, R = Glucosyl

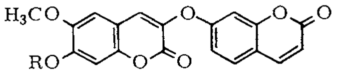
*(19)*



*(21)*, R = H
*(22)*, R = Glucosyl

nogenic action, although weaker than those found by *Hecker et al.*[54] for the most active phorbol ester, are nonetheless of comparable magnitude. That was reason enough to determine the structure of mezerein, which has the empirical formula $C_{38}H_{38}O_{10}$ (Table 8). In the absence of equipment for X-ray structural analysis, mainly spectroscopic methods were used[55] leading, surprisingly, to the discovery of an orthobenzoic acid ester and a cinnamalacetic acid residue. However, the basic structure, the hydrocarbon daphnane, can be compared with phorbol ester type structures from the *Euphorbiaceae.* In this way a structure was found for mezerein that resembled the structure established by *Stout et al.* for daphnetoxin *(23)* using X-ray structure analysis[56] and, after slight revision, was confirmed at the same time by *Ronlan* and *Wickberg*[57].

All *Thymelaeae* species are poisonous[58] and are avoided by cattle even in coastal regions where nothing else grows than, for example, the salt-tolerant *Thymelaea hirsuta*[59] (cf. Fig. 11 and 12). In their natural surroundings only two plant families, one of them the *Thymelaeaceae,* are poisonous to camels[60], and we now know that this is due to skin-irritant compounds very closely related to mezerein *(23)* in their chemical composition[61]. The name thymelein *(25)* has been suggested for the skin-irritant defense substance of *T. hirsuta* which was isolated and whose structure was clarified in 1974. The skin-irritant compounds from *Daphne gnidium*, which is probably the most poisonous plant in the Mediterranean region (cf. Fig. 13), is painstakingly avoided by herds of goats in the carique (wild fig) and maquis (scrub) areas in southern France even in times of severe food shortages[62], have a very similar structure.

Fig. 11. Branches of *Thymelaea hirsuta.*

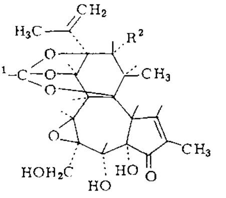
Fig. 12. Leaves and flowers of *Thymelaea hirsuta.*

Fig. 13. A *Daphne gnidium* bush.

The irritants are also present in the bast and the berries, and even in the leaves, and again they are chemically related to the mezerein from *D. mezereum*[63].

The already mentioned daphnetoxin *(23)* was the first of these compounds to be isolated; it was followed by a substantially stronger skin-irritant compound, the cinnamic ester *(27)* of 12-hydroxydaphnetoxin, whose alkaline saponification yields cinnamic acid and mezerenol *(26)*, the hydrolysis alcohol of mezerein. This defense substance was isolated as an antileukemic compound from *Gnidia lamprantha Gilg* and called gnidicin *(27)*[64]. Another active component of the skin-irritant mixture from *D. gnidium* proved to be similar in structure to huratoxin *(28)*, except that it was the ortho-ester of *trans*-2,4-decadienoic acid *(29)* (Table 8).

Table 8. Irritant defense substances from plants of the order *Thymelaeales* [65] (after [55, 61, 63]).



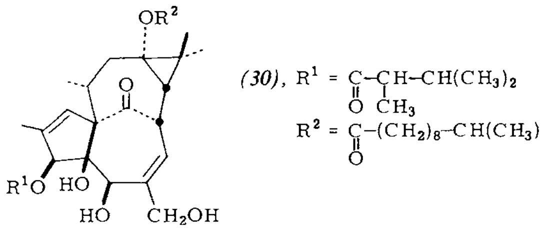
*(23)-(29)*

| No. | Name | $R^1$ | $R^2$ |
|---|---|---|---|
| *(23)* | Daphnetoxin, | $C_6H_5$ | H |
| *(24)* | Mezerein | $C_6H_5$ | $OCO—(CH{=}CH)_2—C_6H_5$ |
| *(25)* | Thymeleine | $(CH{=}CH)_2—(CH_2)_4—CH_3$ | $OCO—C_6H_5$ |
| *(26)* | Mezerenol | $C_6H_5$ | OH |
| *(27)* | Gnidicin | $C_6H_5$ | $OCO—CH{=}CH—C_6H_5$ |
| *(28)* | Huratoxin | $(CH{=}CH)_2—(CH_2)_8—CH_3$ | H |
| *(29)* | | $(CH{=}CH)_2—(CH_2)_4—CH_3$ | H |

Euphorbias protect themselves in a number of ways by the production of a milky latex. This allows wound closure after damage to the plant, but the fluid is also a strong skin irritant and accordingly has the same defensive function as the toxin in bast plants of the Thymelaeales group just described. Alongside the thorny opuntias, the Canary Island euphorbia *(E. canariensis)*, the leafless bush euphorbia *(Euphorbia aphylla)*, and the *Euphorbia regis-ubae* are the most widespread in mountain regions (cf. Fig. 14)[66]. The strongly skin-irritant active principles are esters of phorbol, *e.g.* 12-*O*-tetradecanoylphorbol 13-acetate (TPA)[67] from purging croton *(Croton tiglium)*, a member of the *Euphorbiaceae*.

Fig. 14. Euphorbias growing alongside opuntias, avoided by grazing cattle.

Whether it grows in meadows or pastures, cattle avoid the cypress spurge *(Euphorbia cyparissias)* with the strongly irritant active principles in its sap. From the parts of the plant growing above the soil and from the root *Hecker* and *Ott*[68] extracted *inter alia* 14 more or less irritant diterpene esters of the polyfunctional alcohols 13-hydroxyingenol and 13,19-dihydroxyingenol, *e.g.* 3-*O*-(2,3-dimethylbutyryl)-13-*O*-isododecanoyl-13-hydroxyingenol *(30)*.

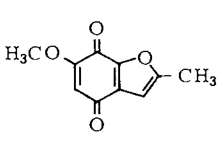


*(30)*, $R^1 = \overset{\displaystyle O}{\overset{\|}{C}}—\underset{\displaystyle CH_3}{CH}—CH(CH_3)_2$ (O below C)

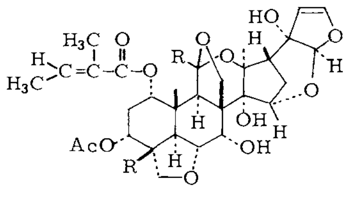
$R^2 = C(=O)—(CH_2)_8—CH(CH_3)_2$

## 4. Defense Against Insects

Many plants are not eaten by insects only because they offer no incitement to them. The ultimate eating signal is a chemical one. The silk worm is lured to the plant on which it feeds by terpenes—sterols induce the creature to bite at it, and only when cellulose and sugar are present is the food swallowed[69]. If one of these chemical reflex-triggers is lacking, the plant will not be damaged. There are, however, a number of substances, *e.g.* alkaloids, that serve as active deterrents and as it were "poison" the plant. The wild potato is "soured" for the larva of the Colorado beetle by an alkaloid; in the *Nicotiana* species, of which tobacco is a member, it is the nicotine, located in the tips of the glandular hairs, that performs this function. It thus becomes an insecticide, since aphids are not only prevented from sucking the plant but are actually paralyzed and destroyed. If we consider the fundamentals of this phenomenon of plant self-defense it soon becomes clear that many so-called secondary plant constituents must be mentioned at this point, *e.g.* acameline *(31)*, which *Schmalle* and *Hausen* isolated from the blackwood *Acacia melanoxylon* of the *Mimosaceae* family and identified as *(31)*[70].



*(31)*

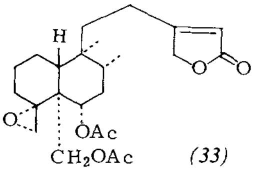


*(32)*, R = $C(=O)—OCH_3$

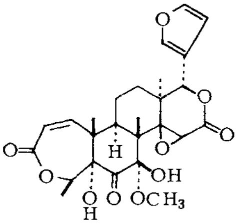
### 4.1. Defense Substances as Protection Against Predators

The deterrent substances described most often are those directed against the African armyworm, *Spodoptera esempta* and *S. littoralis*[71]. The active principle azadirachtin *(32)* has also been isolated from the Indian neem tree *(Azadirachta indica)* and from the closely related species *Melia azedarah*, together with meliantril, the substance that inhibits destruction by locusts.

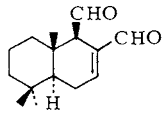
From the leaves of the bugle *Ajuga remota (Labiatae)*, which are not attacked by the African armyworm, the eating-inhibitor ajugarine *(33)* has been isolated, a subtance also effective on locusts[71]. How complicated the structure of active principles of this kind can be is demonstrated by the formula of harrisonin *(34)* from the African bush *Harrisonia abyssinica* Oliv, a *Simarubaceae.* 650 g of root bark yielded 70 mg of the crystalline harrisonin *(34)*[71]. The structure was determined almost exclusively by $^{13}$C-NMR spectra. Harrisonin acts as an antibiotic against *Bacillus subtilis* and is also cytotoxic. From the bark of an East African *Canellaceae, Warburgia stuhlmannij,* the eating-inhibitor polygodial *(35)* was isolated and its structure was elucidated[72]. This sesquiterpene still acts as a very efficient armyworm deterrent in a concentration of 0.1 ppm.



*(33)*



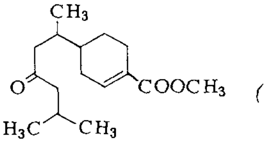
*(34)*



*(35)*

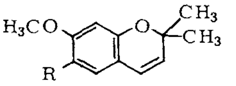
### 4.2. Defense Substances as Development Inhibitors

Maturation is a hormone-regulated process even when we are talking about the development of an insect larva into the imago. The fact that the host plants of the phytophages "know" this is a still unsolved puzzle of co-evolution, in the course of which all organisms have adjusted to one another.



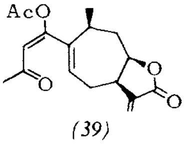
*(36)*

Juvabione *(36)*, a third-generation insecticide, is a juvenile-hormone analogue with a development-inhibiting action, extracted from the wood of the balsam fir. Juvenile-hormone antagonists can also inhibit the development of insects. *Bowers*[73] isolated active principles of this type from the leaves of the familiar ornamental plant *Ageratum houstoneanum* and called the antijuvenile hormones 7-methoxy- *(37)* and 6,7-dimethoxy-2,2-dimethylchromene *(38)* precocenes.

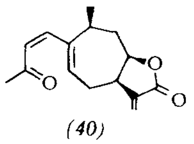


*(37)*, R = H
*(38)*, R = $CH_3O$

From the leaves of the clover *Xanthium canadense Mill.*, an annual weed, *K. Kawazu et al.*[74] isolated a remarkably effective insect-development inhibitor. The compounds responsible for the larval growth inhibition, santhumin *(39)* and 8-*epi*-xanthine *(40)*, were isolated by means of liquid-liquid extraction and chromatography[74].



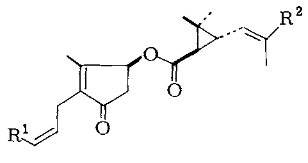
*(39)*



*(40)*

### 4.3. Defense Substances as Insecticides

When we refer to the antijuvenile hormones discovered by *Bowers*[73] as 4th generation insecticides we are in fact neglecting the natural insecticidal substances of *Chrysanthemum cinerariaefolium.* The action of this plant was discovered simply by observing that veritable mountains of dead insects of various kinds were often found in places where it grows. The insecticides of pyrethrum, which are obtained from the flower heads, namely pyrethrin I *(41)* and II *(42)*, cinerin I *(43)* and II *(44)*, and jasmolin I *(45)* and II *(46)*, are cyclopentenyl esters of chrysanthemumic acid[75]. Along with nicotine, pyrethrum is the strongest insecticidal plant-defense substance known.



| | $R^1$ | $R^2$ |

| *(44)* | $CH_3$ | $CO_2CH_3$ |
| *(45)* | $C_2H_5$ | $CH_3$ |
| *(46)* | $C_2H_5$ | $CO_2CH_3$ |

## 5. Phytonicides and Wound Gases

The higher plants live mainly on carbon dioxide and water. Unlike many creatures, they do not go in search of their food but need light to synthesize it, and therefore have large assimilating external surfaces. Because of this they are easy prey, and only by producing solid, liquid, and above all gaseous defense substances can a plant, rooted as it is to the spot, procure living space for itself and protect it. *Tokin*[76] called these bactericidal, protozoacidal, and fungicidal substances "which are related to the protective and healing powers of plant organisms" phytonicides.

*Tokin* discovered the action of the phytonicides in 1928 and 1929, when he vainly attempted to convince himself of the validity of *Gurwitsch*'s theory of mitogenetic rays. What *Gurwitsch et al.*[77] regarded as the action of invisible radiation could in *Tokin*'s opinion be explained much better by the presence of volatile active principles.

### 5.1. The Phytonicide Test and the Isolation of Volatile Microbicidal Defense Substances

Defense substances are mainly emitted by a plant from damaged parts such as leaves. They are primarily protozoacidal and fungicidal, and according to *Tokin*[76] can easily be detected with a protozoa test (cf. Fig. 15). The time needed to destroy ciliates is observed, as is the behavior in the killing of protozoa on the basis of differential phytonicidal action.

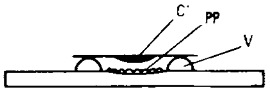

Fig. 15. *Tokin*'s test arrangement for the aerial phytonicides of a plant pulp PP, C = ciliates from a hay infusion in a drop of water, V = vaseline sealing ring.

For their elucidation the volatile active principles are isolated *via* the vapor phase by headspace analysis, *i. e.* by adsorption or by passing the gases and vapors into water or freon 11[78-80]. The active principles are then obtained by ice zone melting[81], normal freezing[82], or by extraction of the aqueous solution with freon 11[83]. The substances isolated by adsorption on a Tenax column of an environmental gas chromatograph are desorbed by heating the column and analyzed by GC-MS.

## 5.2. The Chemical Nature of the "Aerial Phytonicides" of Foliage Plants

The volatile defense substances from the leaves, buds, and bark of the bird-cherry *Prunus padus* are benzaldehyde *(47)* and hydrocyanic acid *(48)*. It is indicative of the defensive function of the aerial phytonicides that they are about ten times as active from the buds as from the leaves. It has likewise been proved that hydrocyanic acid is given off by the leaf pulp of the mountain ash *Sorbus aucuparia*, quickly destroying gnats when they land on the pulp. Although many plants are able to give off enzymatically released hydrocyanic acid, according to *Paris*[84] we cannot conclude from this that cyanogenic glycosides must be the precursors. The defense function of hydrocyanic acid is also indicated by the fact that arthropods use it as a poison gas[85,86].

*(47)*

HCN *(48)*

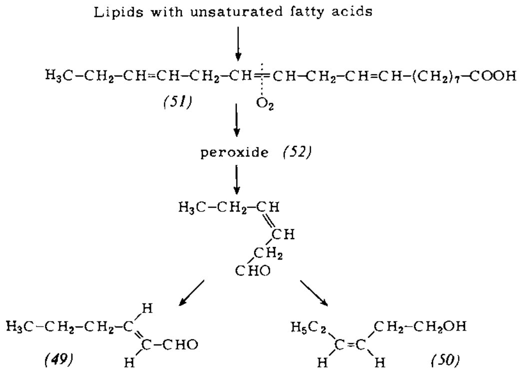
The most widespread aerial phytonicide of foliage plants is *trans*-2-hexenal *(49)*, which was detected as early as 1912 by *Curtius* and *Franzen* as a leaf aldehyde in the steam distillate of hornbeam leaves. However, the intact trees of *Robinia pseudoacacia* also constantly give off small quantities (3 $\mu g/m^3$ air) of *trans*-2-hexenal *(49)* into their surroundings. *(49)* has also been shown to be a leaf phytonicide of the common oak *(Quercus pedunculata)*, alder *(Alnus glutinosa)*, blackcurrant *(Ribes nigrum)*, lupin *(Lupinus angustifolius)*, bilberry *(Vaccinium myrtyllus)*, red whortleberry *(Vaccinium vitis-idaea)*, privet *(Fraxinus ligustrum)*, and grass. *(49)* as well as *cis*-3-hexen-1-ol *(50)* also occurs in the scent of the flowers[79]. It is therefore not surprising that the defense substances of pentatomid bugs *(Pentatomidae)* are in the main *(49)* besides octenal and decenal. Since bedbugs also store *(49)* in addition to *n*-octenal in their defense glands, it may be assumed that the leaf bugs do not take up the *trans*-2-hexenal from the leaves but synthesize it themselves[88,89].

## 5.3. "Phytons" as Wound Gases

*Trans*-2-hexenal *(49)* not only enables the higher plants to surround themselves with a zone of defense but also to protect themselves when damaged against microorganism infestation and in the event of more severe damage even to regenerate. Thus, at low concentrations *(49)* stimulates callus formation, while at higher concentrations it promotes sprouting. In primary suberization and callus formation the action of *(49)* by far surpasses that of the wound hormone traumatic acid[87]. It is therefore understandable that small ground shrubs such as the bilberry and the red whortleberry give off more *trans*-2-hexenal when damaged than *e. g.* locust trees[88].

After mechanical damage, physiological and chemical changes take place in the damaged plant cells and cell compartments[90], which lead to the production of the wound gases *(49)* and *(50)*[91]. It is assumed that the precursor of these hexene derivatives is linolenic acid *(51)*, which on penetration of oxygen into the wound is split into two 6-carbon fragments by an enzyme bound to the thylacoid structure of the plastids, the decomposition proceeding *via* an intermediate peroxide *(52)* (Table 9).

Table 9. Biosynthesis of the leaf aldehyde *(49)* and leaf alcohol *(50)* (after [90]).



This is a general mechanism of biosynthesis, so that the different activities in the leaves of different plants are merely due to different hexenal doses and not, as *Tokin* thought, to structurally different phytonicides.

The above growth-promoting properties of *trans*-2-hexenal are the exact counterpart of what must be understood by the term "phytonicidal". For this reason, the term "phyton"[87] should be adopted instead to denote all substances given off by higher plants for their protection, both when they are protozoacidal, bactericidal and fungicidal and when they act as growth-promoting substances like the wound gases *trans*-2-hexenal *(49)* and ethylene. In this way misunderstandings would be avoided, and since the same root is used we would be reminded of the term "phytonicides". It is incomprehensible how *Tokin*'s work could be forgotten, so that for example *Gross*[92] regarded the fungitoxic plant constituents, which *Stoessl*[93] called preinfectional defense substances, as phytoalexins (cf. Section 7).

We can therefore speak of phytons whenever excretory active principles, and not only those of phytonicidal nature, exert their effect. Substances of this type are given off into their surroundings not only by the assimilating plant organs. The flowers of higher plants are a special source of phytons with an action spectrum whose significance is perhaps still unrecognized.

### 5.4. Flower Phytons as Irritants in Flower Ecology

The flower is almost invariably the most beautiful part of a plant, and its chemistry is also as a rule particularly attractive because of the sweet-smelling substances involved. However, flowers are sometimes protected by ugly, though useful, thorns and poisonous spines (see Fig. 4). Should unpleasant flower scents be included in the same category? Scent may well have several functions to perform, even though one should not, like *Müller*[94,95], under the influence of Darwin's theory of natural selection, ascribe a function to each flower characteristic. We know that flower scents have a short-range rather than a long-range action, but our knowledge of them is still very scant[96], particularly as regards their composition. Only recently has it become possible to formulate a more or less satisfactory picture of a bouquet, as can be seen from the analytical results obtained with extremely delicate instrumental techniques.

The blossoms of the sweet chestnut emit a stink rather than a fragrance—at least for the human nose. Yet they lure many beetles, and in particular ladybugs *(Coccinella septempunctata)*, especially since these blossoms also secrete a little nectar. The scent was analyzed by GC-MS after a special headspace extraction of catkins still on the tree[83]. The gas chromatogram gives a glimpse of "untouched nature", for only a few of the many peaks have been ascribed to known substances. However, these few compounds already indicate how many functions are encoded in a flower's fragrance (Fig. 16).

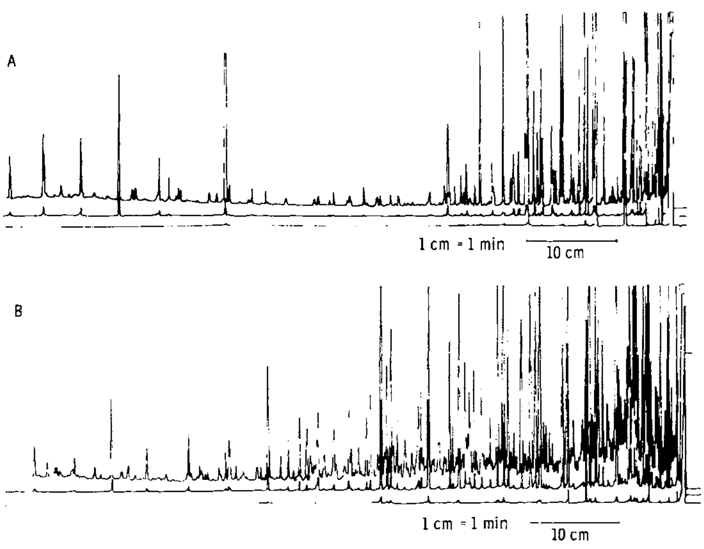


Fig. 16. Gas chromatogram of the fragrance of living chestnut blossoms (A) and chestnut honey (B) (GC-MS system, Finnigan, Model 3200 F-003).

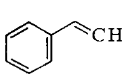
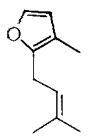
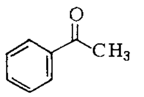
The main peaks appearing after the peaks for the solvents (chloroform, 1,2-dichloroethane, and toluene) correspond to styrene *(53)*, rosefuran *(54)*, acetophenone *(55)*, and 3-phenyl-1-propanol *(56)*. These compounds are also found in honey scent when a headspace analysis is performed on honey that has been collected fresh and undiluted from the honeycombs of beehives in a chestnut wood. The gas chromatogram from the headspace analysis (Fig. 16) shows that the substances determining the fragrance of sweet-chestnut honey are styrene *(53)* and a rosefuran that has not been precisely identified, as has also been shown by a "sniff test"[97]. The flower fragrance also includes ethyl butyrate, diethyl carbonate, isopentanol, limonene, *trans*-2-hexenal *(49)*, ethyl benzene, ethyl carbonate, α-pinene, acetoin, *cis*-hexenyl acetate, 2-methyl-4-octanone, *cis/trans*-3-hexen-1-ol, diacetonyl alcohol, *cis*-linalool oxide, *o,m,p*-tolylaldehyde, 1-phenylpent-en-4-one, naphthalene, ethyldihydronaphthalene, 1-phenylethanol, and benzyl alcohol.



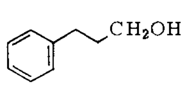
*(53)*



*(54)*



*(55)*



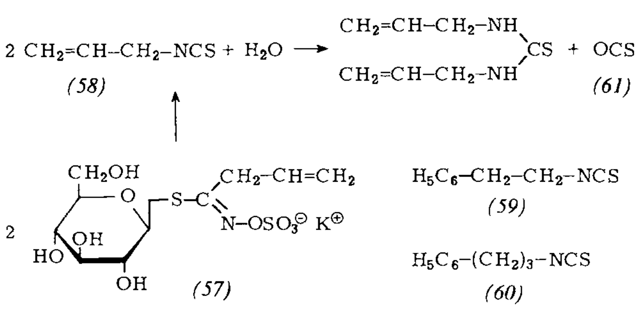
*(56)*

The real purpose behind this still incompletely determined mixture of substances is unknown. It certainly contains defense substances acting as eating-inhibitors or having a microbicidal effect. The significance of this combination of active principles will only be recognized when chemists and biologists join forces to obtain a solution.

### 5.5. Defense Substances in the Roots

*Virtanen*[98] has identified the lacrimatory substances in the onion, which according to *Tokin*[76] have a particularly high phytonicidal activity.

The volatile phytonicides of the horseradish *Cochlearia armoracia* are to be sought primarily among isothiocyanate esters. Thus, on comminution of this root allyl isothiocyanate *(58)* is produced by enzymatic hydrolysis of sinigrin *(57)*, in addition to phenylethyl isothiocyanate *(59)* and phenylpropyl isothiocyanate *(60)*. By an enzymatic process the ester *(58)* gives rise to carbon oxysulfide *(61)*, identified by its melting point, molecular weight, and IR spectrum[99]. On comminution of 5 kg of horseradishes 60 mg of OCS is obtained, which exerts an antibiotic action on gram-positive bacteria and explains why the bactericidal action of finely comminuted horseradish is far greater than that of the corresponding quantity of allyl isothiocyanate[100].

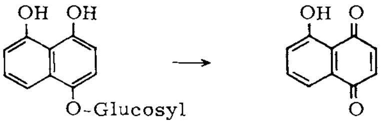


## 6. The Defense Substances of Allelopathy

Many of the hundreds of substances emitted day and night above and below ground by the higher plants into their biotope are defense substances by means of which the individuals of a given natural community protect their living space and strive for dominance, often becoming weeds in this way. Strong chemical interaction between the higher plants is thus set up, a "chemical ecology", or interaction between higher plants and microorganisms. This phenomenon, by which plants assert themselves chemically over other forms of life, has been called allelopathy by *Molisch*[101], and in 1969—1970 *Müller* discussed in detail the biochemical parameters inherent in this concept[102-104].

### 6.1. Allelopathic Defense Substances from the Foliage of Leaf Plants

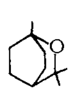
Partly for historical reasons, a discussion of typical allelopathic active principles should start with a naphthoquinone known as juglone *(63)*, which can poison the whole area overshadowed by a walnut tree, a phenomenon already reported by *Pliny the Elder*[105]. The precursor *(62)*[106], which can be found in the leaves, fruits, and roots of all walnut species *(Juglandaceae)*, is carried by rainwater into the soil, where it is quickly oxidized to *(63)* and inhibits, *inter alia*, the growth of grasses *(Gramineae)*, tomato plants, potatoes, and apple trees. The vegetation under a walnut tree is thus severely depopulated. Juglone *(63)* is highly toxic, a 10-ppm aqueous solution inhibiting the growth of tomato seedlings by 50% and a 100-ppm solution destroying them completely[107].



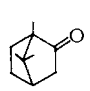
*(62)* *(63)*

Storage of the compound in the form of a hydroquinone which has to be activated by oxidation to the corresponding quinone *(63)*, is reminiscent of the defense chemistry of the bombardier beetle, which stores hydroquinone in its defense bladder until it has been disturbed; the hydroquinone is then oxidized explosively to *p*-benzoquinone in a catalytic process occurring in a kind of combustion chamber[108,109].

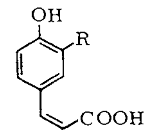
Some particularly volatile terpenes play a significant part in the interspecific interaction of plant communities (allelochemical effect[110]). In the chaparral of southern California on many loamy soils, grasses can only encroach one or two meters upon *Salvia leucophylla*, a sage, and *Artemisia california*, a mugwort. According to *Muller* and *Chou*[111], the cause of this warding-off of competitors is not shade, aridity, nutrients, or any animal influence but the gas-chromatographically detectable monoterpenes 1,8-cineol *(64)* and camphor *(65)*; the main phytotoxins given off, in vapor form, by *S. leucophylla* are *(64)* and *(65)*; these are again washed by rain into the ground, where, bound in a soil colloid, they exert a germination-inhibiting effect on grass seed. Another ubiquitous and dominant shrub of the southern Californian chaparral, adenostoma, excretes some defense substances which are carried by rainwater and dew into the soil, from where they can easily be extracted[111]. Both in the aqueous extract of adenostoma branches and in the alkaline ethanol extract ferulic acid *(66)*, *p*-coumaric acid *(67)*, syringic acid *(68)*, vanillic acid *(69)*, and *p*-hydroxybenzoic acid *(70)* have been identified. All these phenols, and also the phenols detected in adenostoma leaves, namely arbutin *(71)*, hydroquinone *(72)*, and umbelliferone *(73)*, proved in a bioassay on the growth of the seeds of *Lactuca sativa* to be strongly toxic[112].



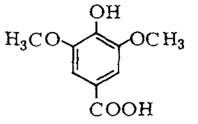
*(64)*



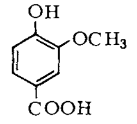
*(65)*



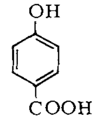
*(66)*, R = OCH$_3$
*(67)*, R = H



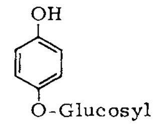
*(68)*



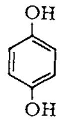
*(69)*



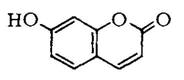
*(70)*



*(71)*



*(72)*



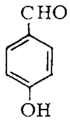
*(73)*

Of the eight compounds named above, the five *(66)—(70)* found in the soil are not necessarily responsible for the growth-inhibiting allelochemical effect, since this is also observed in the absence of phenols. The allelopathic effect traceable back directly to the roots should therefore be given much more consideration in future ecological studies.

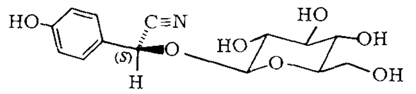
### 6.2. Allelopathic Defense Substances of the Rhizosphere

*Remmert*[39] reports a particularly impressive case of competition between trees and Scotch heather *(Calluna vulgaris)*. The latter asserts itself against its far larger competitors by damaging the mycorrhiza necessary for the trees' sustenance. Once the heather has asserted itself with the aid of these allelopathic defense substances, as *e.g.* in the northwestern Spanish province of Galicia, reforestation with oak, a species basically indigenous to the region, is possible only to a moderate degree. *Ballester et al.*[113] were completely successful in demonstrating, in germination experiments, the allelopathic action of ten phenols, among them again vanillic acid *(69)* from besom heath *(Erica scoparia)*.

The couch grass *(Agropyron repens)*, one of the six most widespread weeds of Central Europe, is suspected of excreting from its creeping rhizomes a phytotoxin having an adverse effect on the germination and growth of cultivated plants. According to *Tauscher et al.*[115], the inhibitor is not the acetylenic hydrocarbon agropyrene mentioned in this connection[114], but a phytotoxin with a molecular weight of less than 1000. The rhizome exudates of Johnson grass *(Sorghum halepense)*, familiar as a troublesome weed on cultivated land almost everywhere in the world, influence especially the germination and growth of all competitor plants. *Rice et al.*[116] have demonstrated that this root-allelopathic effect is due to hydrocyanic acid *(48)* and *p*-hydroxybenzaldehyde *(74)* from the phytotoxin dhurrin *(75)*, whose steric configuration was established by *Towers* on the basis of $^1$H-NMR measurements[117,118].

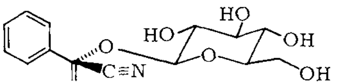


*(74)*

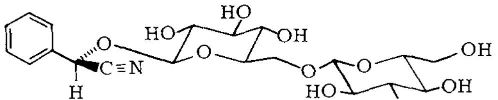


*(75)*

*(75)* is a cyanogenic glycoside, which thus belongs to a class of compounds already named as precursors of the aerial phytonicides of *Rinaceae* mentioned in Section 5.2, namely benzaldehyde *(47)* and hydrocyanic acid *(48)*. Cyanogenesis, the ability of certain plants to liberate hydrogen cyanide, has been known for centuries. More than 800 plant species from up to 80 plant families can produce HCN[119], the general rule being that both these defense substances, *e.g. (47), (48)*, and their precursors prunasin *(76)* and *(77)*, are nontoxic to their producers. On the other hand, HCN also has an inhibiting action on the respiration of the isolated roots of peach trees[120]. This implies autointoxication by the tree's own defense substance, but on balance the substance is beneficial, insofar as the living space is not populated more and more densely with its descendants but rather tends to spread out. The chemical interactions involved in the formation of plant populations, and the mechanisms on which they are based, are still largely virgin territory awaiting the attention of ecologists, biologists, and chemists.



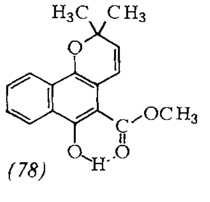
*(76)*



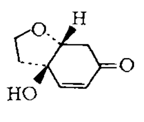
*(77)*

### 6.3. Further Studies

The rhizosphere often contains, in the truest sense of the word, the root upon which the thriving of many higher plants is based in a sometimes inhospitable biotope. The substances acting here have just been discussed. However, we must not forget all the secondary plant constituents for which the correct bioassay has not yet been found, but which on the basis of their organ-specific location in the plant, and also on the basis of the time of their occurrence, should be included in the group of allelopathically active substances. In the roots of the common catchweed *(Galium mollugo)* we find, particularly in the fall, a yellow compound called mollugin with the structure *(78)*[121]. Further work is needed to establish whether the particularly resistant meadow weed *(G. mollugo L.)* establishes itself in a species-rich biotope by means of this methyl 6-hydroxy-2,2-dimethyl-2*H*-naphthol[1,2-*b*]pyran-5-carboxylate *(78)*. The same applies to the (3a*R*,7a*R*)-3a-hydroxy-3,3a-7,7a-tetrahydro-1-benzofuran-6(2*H*)-one *(79)*, described as a constituent of the growing tips of the foxglove *(Digitalis purpurea)* by *Raymakers* and *Compernolle*[122]; the structure assigned has now been corrected[123].



*(78)*



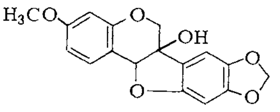
*(79)*

## 7. Phytoalexins, the Defense Substances Responsible for Plant Resistance[124-127]

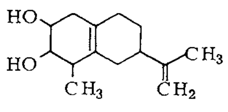
*Ward*[128] in England and *Bernard*[129] in France were the first to observe that pathogenic fungi often grow more slowly in plant tissue because the plant reacts defensively to the attack. It is even possible for resistance to develop. Thirty years later *Müller* and *Börger*, in the Arbeitsberichte der Biologischen Reichsanstalt für Land- und Forstwirtschaft in Berlin-Dahlem, published their phytoalexin theory of the resistance of plants to disease[130], according to which the resistance phenomenon in the plant kingdom is based on a chemical defense mechanism as well as on organ-specific structural barriers and other resistance factors against pathogenic microorganisms. The fungitoxic antibiotics formed endogeneously after an infection in a so-called "defense necrosis" can comprise isoflavanoids, terpenoids, polyacetylenic compounds, and dihydrophenanthrenes, and thus belong to the chemically already known substance classes of secondary constituents. The host plants can be found amongst the *Leguminosae, Solanaceae, Malvaceae, Convolvulaceae, Umbelliferae, Gramineae, Rosaceae,* and *Compositae, i.e.* practically throughout botany. To include here all the phytoalexins known so far would be a case of obscuring the wood by the trees, especially as it is still a subject of controversy whether phytoalexins can really be regarded as the defense substances of higher plants without any reservations[123]. On the other hand, in a consideration of defense substances, no environment may be ignored, be it in the macro or in the micro sphere, outside, or even inside the living plant organism.

### 7.1. Structure and Occurrence of Phytoalexins

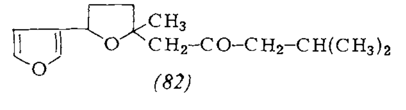
The weakly antibiotically active pisatin *(80)* from garden peas *Pisum sativum* L. *(Leguminosae)*[131], rishitin *(81)* from the potato *Solanum tuberosum* L. *(Solanaceae)*[132], and the ipomeamarone *(82)* from the sweet potato *Ipomoea batatas* Lam. *(Convolvulaceae)*[133] were the first phytoalexins to be isolated from infected plant tissue, characterized, and identified chemically[134].



*(80)*

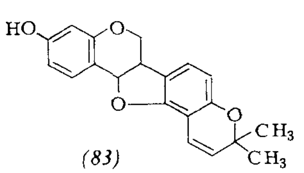


*(81)*

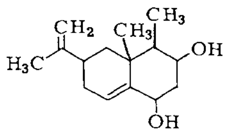


*(82)*

*Leguminosae* in general form isoflavanoids as pterocarpanoid phytoalexins; these have been encountered at all times in the healthy tissue of many plant species. An example is phaseolin *(83)*, which is very probably produced by a combination of the shikimate and acetate-malonate routes of biosynthesis. The *Solanaceae* phytoalexins belong to the group of terpenoids, as do the above-mentioned rishitin *(81)* and the sesquiterpene capsidiol *(84)* isolated from the fruit of the sweet pepper after the latter had been infected with a number of fungi[135-137]. The acetylenic phytoalexins *trans,trans*-3,11-tridecadiene-5,7,9-triyne-1,2-diol *(85)* and *trans*-11-tridecen-3,5,7,9-tetrayne-1,2-diol *(86)*, obtained from the infected hypocotyls of safflower *(Carthamus tinctorius)*, are also not unusual components for the *Compositae*. Dihydrophenanthrenes can be expected in orchids, *e.g.* orchinol *(87)*.



*(83)*

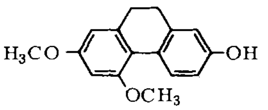


*(84)*

$CH_3CH{=}CH{-}(C{\equiv}C)_3{-}CH{=}CH{-}CHOH{-}CH_2OH$ *(85)*

$CH_3CH{=}CH{-}(C{\equiv}C)_4{-}CHOH{-}CH_2OH$ *(86)*

It has been observed that tissue fragments of the military orchis *(Orchis militaris)* form the phytoalexin *(87)* 36 h after infection, the maximum concentration occurring only 8 days later.

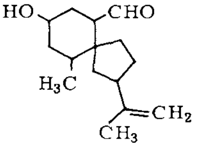


*(87)*

### 7.2. Phytoalexins—the Chemical Response to a Stimulus

Early on in phytoalexin research it was discovered that even cell-free extracts of sprouting conidia or of fungal cultures can trigger the formation of phytoalexins in tissue treated with them[138-140], but the isolation and demonstration of the biologically active eliciting substances in pure form presented major problems. To begin with it was only known that macromolecules are involved in the induction of phytoalexins. *Metlitskii et al.*[141] demonstrated that the maximum activity of an extract of sprouting zoospores of potato blight *P. infestans* in the formation of the phytoalexins *(81)* and of lubimin *(88)* in potato tissue is closely connected with a protein fraction.

In the context of the irritant and defense substances of higher plants, forming the subject of this review, it is important that phytoalexins are "stress compounds"[142] formed in response to many stimuli, *e.g.* cold[143] or UV light[144,145]. Even the toxic heavy metals are possible phytoalexin inductors[146-149], above all mercury and copper.



*(88)*

The response to an abiotic elicitor such as $CuCl_2$ is less specific[127], but it may be that we have yet to recognize the prevailing guiding principle, which may not be structural in nature at all but perhaps physiological, for plants react specifically in certain host-parasite combinations[127]. In the following section we shall see that this can also lead to a chemical selectivity of endogenously active defense substances.

## 8. Leaf Movement Factors as Endogenously Active Defense Substances of Sleeping and Sensitive Plants

In the discussion of the phenomenon that even purely physical stimuli induce the formation of phytoalexins we must admit that no corresponding selectively active biochemical mechanism has yet been discovered. It may well be that chemists dare not think heuristically and use a guide to trace back the route taken by nature in the evolution of the defense mechanisms mentioned at the beginning of this article. Thus, as a working hypothesis one could take membrane activity as the principle of endogenously acting "tamed defense poisons". Experimentally, these substances are indicated by a bioassay with the sensitive plant *Mimosa pudica* L., the prime example of plants exhibiting external movements in response to irritation.

### 8.1. Bioassay for Movement Factors

Wherever a movement factor is suspected, its aqueous extract is prepared and tests are performed on it as such or after separation into its components, making use of the rapid reactivity of *Mimosa pudica* L. (Fig. 17). This test is carried out in a climatic chamber with a leaf of *M. pudica* placed in a solution of the supposed active principles. The movement factors are drawn up and cause each pair of pinnules to fold up neatly one behind the other. For the evaluation of the amount of the movement factor it is important to remember that the correlation between the time of response and the concentration of the test solution is not linear but is better described by a hyperbola[151].

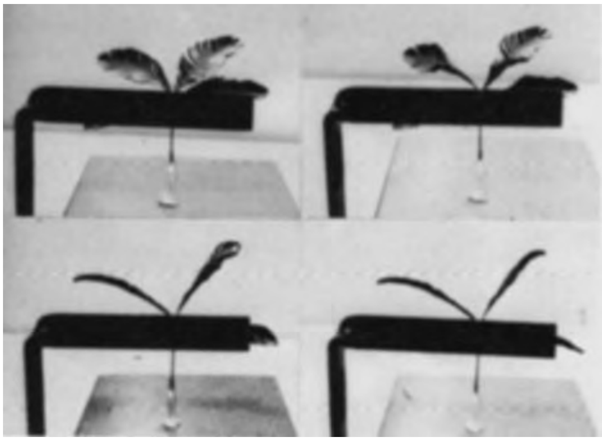


Fig. 17. Bioassay for the detection of leaf movement factors. The supposed active principle is placed in a small glass vase and is drawn up by the rachis of *M. pudica*. After a short time the plant reacts by folding up its pinnules [150].

Some very active and less active substances can be characterized by the Fitting-Hesse-Schildknecht test[150]. According to *Fitting*[152], they are very diverse in nature but always membrane-active; the cause of the visible movement is loss of semipermeability and thus ultimately a) a change in submicroscopic structures in the boundary plasma layers and b) the resulting intercellular escape of tissue sap from the vacuoles of the joints. Membrane processes of this kind are always associated with changes in electric potential, the cell becoming depolarized. An action potential is triggered, which is used in an electrophysiological test for the evaluation of an irritant. The visual test is better suited to the movements discussed here, because it yields detailed information on the nature of the chemonastic compounds[153].

### 8.2. Plants with Chemonastic and Nyctinastic Substances

The term "nastic movement" denotes a movement in plants which is determined anatomically and occurs independently of the direction of stimulation. When the stimulus is chemical, the movement is said to be chemonastic[5]. In certain insectivorous plants the bending movement is induced externally by certain substances, for example by proteins, ammonia, or phosphate, similarly to the case of a tactile stimulus. Stimulants can, however, also be formed and become active within the plant (endogenous chemonasty). An endogenous chemonastic action must be assumed above all for the compounds that give rise to sudden water movements in the vascular bundles in *M. Pudica* L., without the aid of physiological reactions, as the stimulus is conducted[154] even through dead cells and in dead stems and leaf fragments[5,155]. They are found everywhere in plants of the *Leguminosae* family, but especially when the green parts of the plants are extracted, which react seismonastically and nyctinastically, *i.e.* which perform a bending movement as a result of vibration impact, or a pull or periodically, dependent on the time of day[156,157]. The *Leguminosae* listed in Table 10 have been investigated preferentially[158-168], although plants from the *Oxalidaceae* family also exhibit nyctinasty (Fig. 18) and thus contain demonstrable leaf movement factors[169].

Fig. 18. Common yellow oxalis *(Oxalis stricta* L.) [169] in the early morning (left) and "sleeping" at 2 a.m. (right).

Table 10. Plants whose extracts are „active" in the bioassay [170].

| Plant | *t* [s] | Location |
|---|---|---|
| *Mimosa pudica* | 25 | Heidelberg |
| *Robinia pseudacacia* | 60 | Heidelberg |
| *Acacia karroo* | 30 | Heidelberg |
| *Acacia dealbata* | 40 | Southern France |
| *Acacia melanoxylon* | | Heidelberg |
| Phyllodes | 110 | |
| Pinnae | 50 | |
| *Albizzia lophanta* | 50 | Heidelberg |
| *Gleditsia triacanthos* | 60 | Heidelberg |
| *Delonix regia* | 50 | Teneriffe |
| *Glycine max.* | 120 | Heidelberg |

### 8.3. Leaf Movement Factors (LMF) of *Albizzia lophanta*[171]

The periodic leaf movements during the day—called sleep movements by *Linnaeus* and nyctinasty by *Pfeffer*—of *Albizzia lophanta* and *A. Julibrissin* are based on turgidity changes in the pulvini, cushionlike enlargements at the base of the petioles[172]. They are closely related to endogenous factors of the physiological clock[173], whose internal stimulation makes the pinnae fold up and thus screen the plant from external irritation. The challenge to the chemist is to discover the chemical basis of this fascinating physiological process (Fig. 19).

Fig. 19. *Albizzia lophanta* by night. Research plot at Hainsbachweg, Heidelberg (Germany).

Using high-pressure liquid chromatography *Hein*[165] isolated from a chemonastically active extract of *A. lophanta* a chemonastically active fraction having all the known properties of saponins. The fraction was so strongly hemolytic that for this reason alone a membrane-active substance could be suspected. The aglycone of this first LMF from an *Albizzia* species, called A-LMF 1, is according to a mass-spectrometric analysis most similar to the acacic acid lactone found in many African *Albizzias*. At least here the defense substances of the *Leguminosae* can be compared with the phytoalexins, which are after all often found among already known secondary plant constituents.

### 8.4. Leaf Movement Factors (LMF) of *Acacia karroo*

*Acacia karroo* is not sensitive, but it too folds up its pinnae at night, when it looks like a stimulated mimosa (Fig. 20).

Fig. 20. *Acacia karroo (Acacieae)*, photographed by day (left) and by night in the greenhouse of the Institute of Organic Chemistry, University of Heidelberg (Germany) [161].

For 10 years now it has been the object of many investigations on leaf movement factors, K-LMF, responsible for the nyctinasty illustrated in Figure 20[160, 161]. Probably the most important result, and one in many respects guiding further work, was that K-LMF 1 must be very similar to the LMF 1 of *Mimosa pudica*[160]. *Lang*[161] was then able to establish the identity of K-LMF 1 with M-LMF 1 by means of $^{13}$C-NMR spectroscopy (Fig. 21).

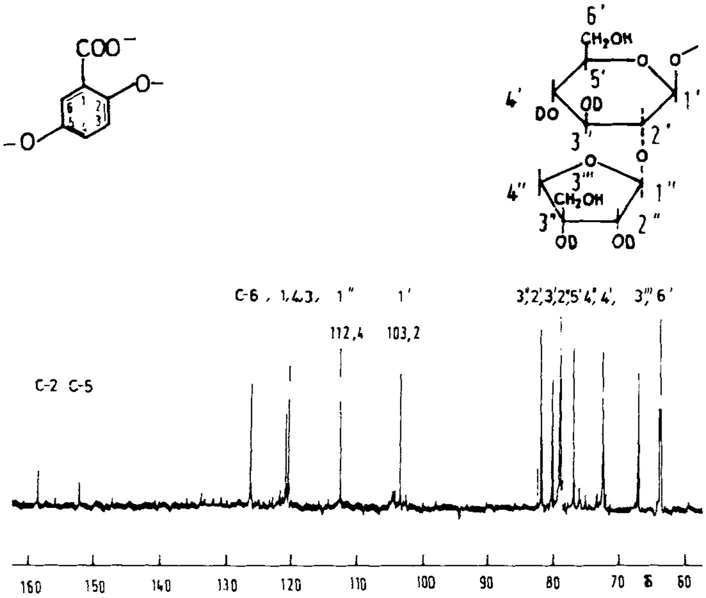

Fig. 21. 75.46 MHz $^{13}$C-NMR spectrum of K-LMF 1 in $D_2O$. Technique: Broadband decoupling. Reference signal: C-3 of gentisic acid maltoside [175] (after [189]).

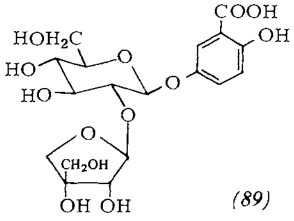
According to this, the K-LMF 1 and M-LMF 1 from the chemonastically active fraction of *A. karroo* and *M. pudica* is the gentisic acid derivative *(89)*, the first factor to be isolated from the active mixture in pure form. It has already been found that for optimal activity still other glycosides of aromatic hydroxyacids must be present. For example, *Schumacher*[162] suspected a derivative of gallic acid, which may even be present as a sugar sulfate.



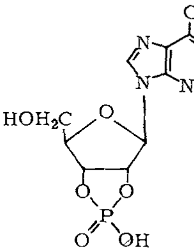
*(89)*

### 8.5. The Leaf Movement Factors of *Mimosa pudica* L. (M-LMF)

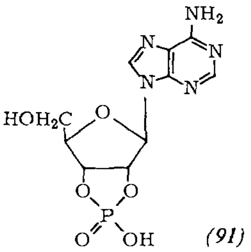
Sensitive plants were much discussed by philosophers even in the pre-Christian era, various theories being advanced to account for the rapid mimosa reaction. However, only recently were investigators courageous enough to see a clear defense reaction in the fact that at the slightest touch the pairs of pinnules fold together, first the pinnae and then the whole leaf pressing close to the stem, and the whole plant pressing itself to the ground like a hen threatened by a hawk (Fig. 22). We agree with *Hassenstein*[190] that this behavior represents a beautiful example of plant mimicry.

Fig. 22. Young plants of *M. pudica* in the greenhouse of the Institute of Organic Chemistry, University of Heidelberg (Germany); top: undisturbed; bottom: blown upon.

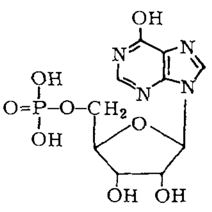
In 1916 *Ricca* first postulated that this fascinating behavior pattern, as *Darwin* had called it[1], must be due to a stimulant substance[176], which was subsequently characterized by *Fitting* (1936)[177], *Soltys et al.* (1936)[178, 179], and a little later by *Hesse*[180] as a hydroxycarboxylic acid with a molecular weight of between 350 and 450. This was confirmed by *Banarjee et al.*[181] in 1946. A reductone was still suspected in 1957[182]. The fact that the long sought leaf movement factor from *M. pudica* is the gentisic acid glucoapioside *(89)* was first fully recognized in 1978[185], and the last structure problems were solved by co-analytical investigation[161,162]. Already then there were some indications that M-LMF 1 cannot be the only cause of the movement mechanism. The scatter of the response times was greater than could be explained on statistical grounds. The active principle found is but one factor in a stimulation chain that definitely also comprises amino acids[183] and possibly even an inhibitor, D-pinitol[187]. In any event, it seemed appropriate to look for further members of this chain, and such were found in a highly enriched active principle fraction[184]. Of the maximum of five further components, one was obtained in the pure state by making use of solubility differences and with the aid of UV, IR, and $^1$H-NMR spectroscopy identified as 2′,3′-guanosine cyclomonophosphate *(90)*. Besides this M-LMF 2, an M-LMF 3 has also been identified, 2′,3′-adenosine cyclomonophosphate *(91)*, on the basis of its similar structure. Although *(90)* and *(91)* are inactive in pure form in the above-described bioassay, they are definitely also important components of the whole active principle complex. One could almost suppose that these LMF are stimulus-potentiating factors, just as the 6-hydroxypurine-5′-mononucleotide *(92)* was identified as a long-sought flavor potentiator[186].



*(90)*



*(91)*



*(92)*

This comparison is pertinent, if only because both processes are membrane-bound. However, the search must continue for the missing LMF, which include a gallic acid derivative with an as yet unknown structure, as in the case of *Acacia karroo.*

## 9. Epilogue

Anyone who has succeeded in finding his way through *Darwin*'s ideas will also have the courage to extend *Darwin*'s tendency to generalize[2] to the defense substances of higher plants, arriving ultimately at the concept of plant behavior. For according to the Darwinian principle of evolution, defense movements must also make use of defense chemicals, which were perhaps at first intended only for protection with glandular hairs. Whether indeed the defense substances are considered on their own, for example as gland secretions, or whether they are seen in the context of an endogenous defense mechanism, *e.g.* as phytoalexins or leaf movement factors, their function can be recognized only in terms of a struggle of the higher plants for existence.

Such trains of thought are supported by considerations on the coevolution of plant enemies, which not only have a resistance towards plant defense substances but even use the latter for their own defense. A specialist of this sort is, *e.g.*, the larva of the ichneumonidae *Neodiprion sertifer*, which, in a coevolutionary sense, does not only not respect the terpenoid defense substances of pine trees but even makes use of them as a defense substance for itself.

In explaining the numerous possibilities of the defense of higher plants against actual and potential parasites a natural scientist does not look for a generalizing model but rather attempts to link together the many findings. For a natural products chemist this approach forms a sound basis for the discovery of new active principles.

*I wish to express my sincere thanks to numerous colleagues, both past and present, who have contributed so much to the work cited in this paper and to the development of this area of chemistry. I thank Herr W. Schmitt for his help with the horticultural work, Herr H. Spiess for taking the photographs, and Frau G. Büchler for typing the manuscript. Many of the investigations mentioned here would not have been possible without generous support by BASF AG and especially by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.*

# COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## Lewis Acid Catalyzed Alkylations of CC-Multiple Bonds; Rules for Selective Enlargements of Carbon Skeletons[**]

By *Herbert Mayr*[*]

Lewis acid catalyzed addition reactions of alkyl halides to olefins (eq. I) are usually not considered for CC—bond formations[1a,b], since reactions of this type frequently do not terminate at the 1:1-stage but provide polymeric products (eq. II).

$$\mathrm{AX} + \mathrm{>C{=}C<} \xrightarrow{\text{Lewis acid}} \mathrm{A{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}X} \quad (=\mathrm{BX}) \qquad (\mathrm{I})$$

$$\mathrm{AX} + n\,\mathrm{>C{=}C<} \xrightarrow{\text{Lewis acid}} \mathrm{A{-}(\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-})_nX} \qquad (\mathrm{II})$$

In this communication a simple rule is presented, which demonstrates that with definite pairs of olefins and alkyl halides the selective formation of 1:1-products can be achieved.

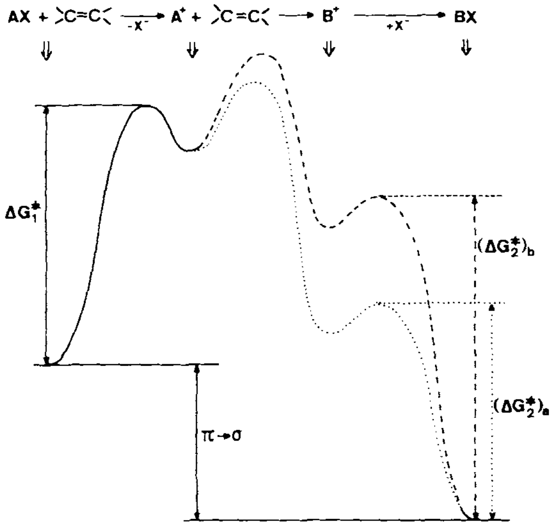

Fig. 1. Energy profile of the addition of an alkyl halide AX to olefins. Case a) (·····): $\Delta G^{\dagger} > \Delta G^{\ddagger}_2$; case (b) (– – – –): $\Delta G^{\dagger} < \Delta G^{\ddagger}_2$ (see text).

In Figure 1 the overall reaction is split into three independent steps: 1) dissociation of AX and formation of carbenium ion $A^+$; 2) addition of $A^+$ to the CC-multiple bond, and formation of the new carbenium ion $B^+$; 3) ion combination. Two cases for different magnitudes of $\Delta G^{\dagger}$ and $\Delta G^{\ddagger}_2$ are treated in Figure 1:

a) A carbenium ion $B^+$, which is more stabilized than $A^+$, forms in the addition step *i.e.* $(\Delta G^{\ddagger}_2)_a < \Delta G^{\dagger}$[2] (dotted line). After a small degree of conversion AX, BX and unreacted olefins are present in the reaction mixture. Since $(\Delta G^{\ddagger}_2)_a < \Delta G^{\dagger}$, BX is ionized more rapidly by the Lewis

Henkestrasse 42, D-8520 Erlangen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

acid than AX, and $B^+$ reacts with further olefin. This process is repeated; the olefin polymerizes whereas AX does not react further. b) Now, carbenium ion $B^+$ is less stable than $A^+$, *i.e.* $(\Delta G^{\ddagger}_{2}) > \Delta G^{\ddagger}_{1}$[2]. Figure 1 (broken line) shows that the addition step may also be exothermic in this case, since energy is gained from the conversion of a $\pi$-into a $\sigma$-bond[3]. Now AX dissociates faster than BX and adds to the olefin while the concentration of BX increases.

From these considerations it is concluded that *Lewis acid catalyzed additions of alkyl halides to CC-multiple bonds can only lead to 1:1-products if the educts dissociate more rapidly than the products. In other words, polymerization can only be inhibited if the initial carbenium ion $A^+$ is better stabilized than $B^+$*. Of course formation of BX is also impossible, if $B^+$ is a highly unstable intermediate; the condition $\Delta G^{\ddagger}_{1} < \Delta G^{\ddagger}_{2}$ therefore is a necessary but not a sufficient criterion for formation of 1:1-addition products.

These conclusions are based on the assumption that the rates of addition reactions are roughly proportional to the dissociation rates of the corresponding alkyl halides. This condition is fulfilled in the absence of large steric effects, since $\Delta G^{\ddagger}$ for the addition reactions of carbenium ions $A^+_1, A^+_2, \ldots A^+_n$ to a standard olefin decreases with increasing stability of $A^+_n$ (Leffler-Hammond postulate[4]).

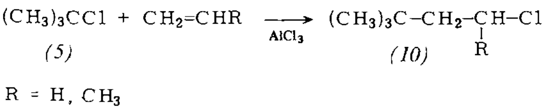
Since most information about carbenium ion stability comes from solvolysis studies, we used the solvolysis constants determined in 80% ethanol (Table 1) for the approximate determination of the relative magnitudes of $\Delta G^{\ddagger}_{1}$ and $\Delta G^{\ddagger}_{2}$. Although this procedure is certainly subject to error, the following examples show that the data are transferable. The formation of 1:1-adducts, as shown in eq. I, is only observed if the structural type of the product BX is located above that of educt AX in Table 1.

Table 1. Solvolysis constants of alkyl chlorides in 80% aqueous ethanol at 25 °C.

| | RX | $10^6 k_1$ [$s^{-1}$] | Lit. |
|---|---|---|---|
| *(1)* | $CH_2{=}CPhCl$ | $\approx 10^{-10}$ | [a] |
| *(2)* | $(CH_3)_2CHCl$ | $2 \times 10^{-3}$ | [5a] |
| *(3)* | $CH_2{=}CH{-}CH(CH_3)Cl$ | $5 \times 10^{-1}$ | [5b] |
| *(4)* | $CH_3{-}CH{=}CH{-}CH_2Cl$ | $\approx$ 1 | [b] |
| *(5)* | $(CH_3)_3CCl$ | 9 | [5b, c] |
| *(6)* | $C_6H_5{-}CH(CH_3)Cl$ | $1 \times 10^{1}$ | [5d] |
| *(7)* | $(CH_3)_2C{=}CH{-}CH_2Cl$ | $\approx 4 \times 10^{2}$ | [b] |
| *(8)* | $(C_6H_5)_2CHCl$ | $2 \times 10^{3}$ | [5b] |
| *(9)* | $CH_3O{-}CH_2Cl$ | $\approx 1.5 \times 10^{7}$ | [5e] |

[a] Estimated from the activation parameters of the solvolysis of α-bromostyrene [5f]. [b] Calculated from $k_1$ [3] and the reaction rate ratio at 44.6 °C in 80% ethanol, which was obtained from the data in [5g] using the Winstein-Grunwald relationship [5b, c].

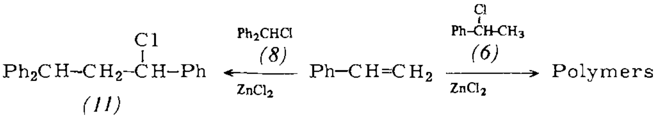
*Examples: Schmerling* reported the predominant formation of the 1:1-product *(10)* in the aluminum chloride catalyzed reaction of *tert*-butyl chloride *(5)* with ethene and propene[6]; in both cases slowly ionizing alkyl halides (primary and secondary respectively) are formed from the more reactive substrate *(5)*. Additions to *iso*-butene were not reported.



$$\underset{(5)}{(CH_3)_3CCl} + CH_2{=}CHR \xrightarrow[AlCl_3]{} \underset{(10)}{(CH_3)_3C{-}CH_2{-}\underset{R}{\underset{|}{C}}H{-}Cl}$$

R = H, $CH_3$

While the zinc chloride catalyzed addition of benzhydryl chloride *(8)* to styrene resulted in a 54% yield of the addition product *(11)*[7], the reaction of 1-phenylethyl chloride *(6)* and styrene only produced polymeric material under the same reaction conditions. In the first case the reaction terminates at the 1:1-product stage since the rapidly dissociating alkyl halide *(8)* yields *(11)*, a product of type *(6)*, which dissociates more slowly than *(8)* (Table 1). In the second case both educt and product are of the same structural type.



$$\underset{(11)}{Ph_2CH{-}CH_2{-}\overset{Cl}{\overset{|}{C}}H{-}Ph} \xleftarrow[ZnCl_2]{\underset{(8)}{Ph_2CHCl}} Ph{-}CH{=}CH_2 \xrightarrow[ZnCl_2]{\underset{(6)}{Ph{-}\overset{Cl}{\overset{|}{C}}H{-}CH_3}} \text{Polymers}$$

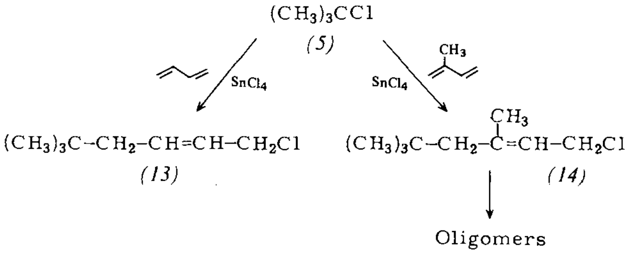
The high yields of 1:1-products observed in the Lewis acid catalyzed additions of RX to alkynes[8] can also be attributed to the slow solvolysis rates of vinyl halides.

$$R^1{-}Cl + R^2{-}C{\equiv}C{-}R^3 \xrightarrow{ZnCl_2} R^1R^2C{=}CR^3Cl$$

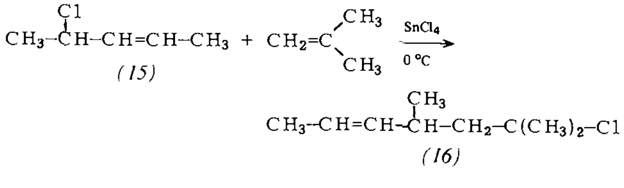
$$(E)\text{-}(12) + (Z)\text{-}(12)$$

$R^1$ = $t$Bu, $PhCH_2$, $Ph_2CH$; $R^2$ = H, Alkyl; $R^3$ = Alkyl, Aryl

The $SnCl_4$ catalyzed reaction of *tert*-butyl chloride with butadiene yields the allyl chloride *(13)*[9]; in contrast only oligomers resulted when *(5)* was reacted with isoprene. *Petrov* and *Leets* accounted for the latter observation, suggesting that isoprene reacted more rapidly with *(14)* than with *(5)*; Table 1 permits a quantitative explanation. Compound *(4)*, the model for *(13)*, dissociates more slowly, whereas *(7)*, the model for *(14)*, dissociates faster than *(5)*.

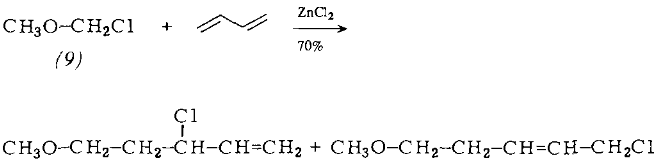


Consequently, the dialkylallyl chloride *(15)*, with a similar solvolysis constant to *(7)*[5g, 10] gives the 1:1-product *(1b)* with *iso*-butene[11].



$$\underset{(15)}{CH_3{-}\overset{Cl}{\overset{|}{C}}H{-}CH{=}CH{-}CH_3} + CH_2{=}C(CH_3)_2 \xrightarrow[0\,^\circ C]{SnCl_4} \underset{(16)}{CH_3{-}CH{=}CH{-}\overset{CH_3}{\overset{|}{C}}H{-}CH_2{-}C(CH_3)_2{-}Cl}$$

In the presence of $ZnCl_2$ or $HgCl_2$, chlorodimethylether *(9)* can be added to a series of olefins *e.g. iso*-butene, 2-methyl-2-butene, 1,3-butadiene and 1,3-cyclohexadiene[12]. Again, the high dissociation rate of the educt *(9)* (Table 1) accounts for the exclusive formation of 1:1-products. According to a qualitative analysis, the synthetically important



Lewis acid catalyzed additions of acetals and ketals to enol ethers[1c], as well as the ionic additions of haloalkanes to haloalkenes. (Prins reaction)[1a] are also in agreement with this rule. The lack of appropriate solvolysis data precludes a quantitative treatment however.

*Scope and limitations.* This rule has been deduced for addition reactions in which low equilibrium concentrations of carbenium ions are involved. Therefore it cannot be applied if educts and products are markedly ionized under reaction conditions, or if generation and trapping of carbenium ions are irreversible processes, a situation which is encountered in cationic additions initiated by silver trifluoroacetate[13]. Furthermore, this rule is not applicable to substitution reactions in which the addition step is followed by rapid elimination; electrophilic aromatic substitutions and the reactions of siloxyalkenes with alkyl- and acyl halides fall into this category[14]. The influence of steric effects is currently being investigated.

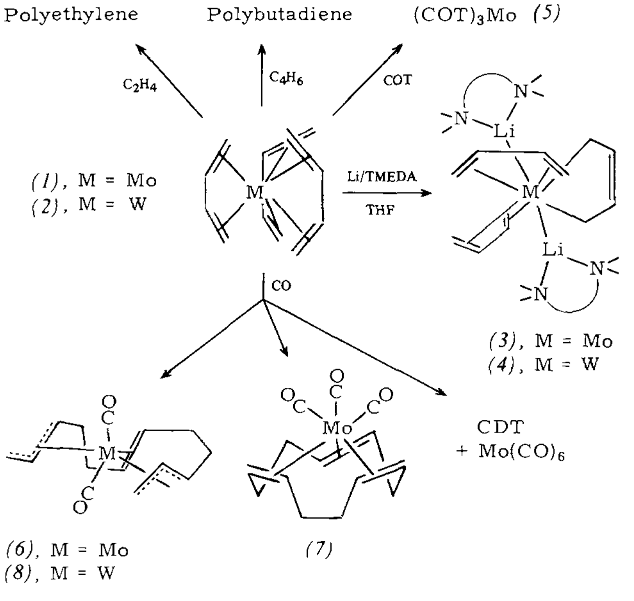
## Reductive Synthesis and Reactivity of Tris(butadiene)molybdenum and -tungsten

By *Wolfgang Gausing* and *Günther Wilke*[*]

*Dedicated to Professor Karl Freudenberg on the occasion of his 95th birthday*

Tris(butadiene)-molybdenum *(1)* and -tungsten *(2)* were first obtained in small amounts by *Skell et al.*[1a] by co-condensation of the metals with butadiene. The X-ray structure analysis of *(1)*[1b] shows the $\eta^4$-complexed butadiene molecules to have an *s-cis* conformation and a trigonal-prismatic arrangement. As far as the reactivity of *(1)* and *(2)* is concerned only the stability of the two substances towards air has so far been mentioned. *(1)* and *(2)* would now appear to be interesting starting compounds for studying the chemistry of olefin-molybdenum and -tungsten complexes, all the more so as they are attractive sources for "naked" molybdenum or tungsten[2]. We report here the synthesis of such complexes *via* a conventional route and discuss a few of their reactions.



---

[*] Prof. Dr. G. Wilke, Dr. W. Gausing
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

Molybdenum and tungsten chlorides ($MoCl_5$, $MoCl_4 \cdot 2THF$, $MoCl_3 \cdot 3THF$, $WCl_6$, $WCl_4 \cdot 2THF$) can be converted into *(1)* and *(2)* by reduction with magnesium in a tetrahydrofuran (THF)/butadiene mixture at low temperatures. The NMR and IR spectra of the two complexes are very similar, so that *(2)* probably has the same structure as *(1)*. Detailed $^1H$-NMR investigations reveal that in *(2)* an exchange process for the methylene hydrogen atoms, presumably involving formation of an intermediary metallacyclopentene[3] is occurring. Consistent with this hypothesis, *(1)* and *(2)* react at low temperatures with lithium in the presence of tetramethylethylenediamine (TMEDA) to give the adducts *(3)* and *(4)*, respectively, which have been shown by IR and NMR spectroscopy to contain an $\eta^2$-bonded besides two $\eta^4$-bonded $C_4H_6$ ligands. By analogy to the olefin-$Li_2Ni$ complexes[4], we suggest structures with dilithium-transition metal groupings for *(3)* and *(4)*.

At elevated pressures and temperatures *(1)* and *(2)* induce the polymerization of both butadiene as well as ethylene; in the reaction of *(2)* with ethylene, oligomers are also formed. On reaction with cyclooctatetraene (COT), and with carbon monoxide, it is clear that butadiene is more firmly complexed in *(2)* than in *(1)*. Thus, reaction of *(1)* with COT yields labile $(COT)_3Mo$ *(5)*; compound *(2)*, on the other hand, does not undergo any well defined reaction with COT, even at elevated temperatures. Solutions of *(1)* react with CO under normal pressure at 50–60 °C to give $Mo(CO)_6$ and a mixture of isomeric 1,5,9-cyclododecatrienes (CDT) (*ttt*:*ttc*:*tcc* = 1:13.6:15.7), whereas *(2)* reacts only under drastic conditions to give $W(CO)_6$ without any noticeable amounts of CDT being liberated. The compounds *(6)* and *(7)* have been previously isolated and are possible intermediates of the stoichiometric synthesis of CDT on molybdenum. From the reaction of *(2)* with carbon monoxide, we were able to isolate *(8)*. According to NMR and IR spectra *(7)* contains a *trans,cis,cis*-1,5,9-cyclododecatriene (*tcc*-CDT) complexed to molybdenum, while *(6)* and *(8)* contain $C_{12}H_{18}$ chains with a complexed *trans* double bond and *trans,syn*-substituted $\eta^3$-allyl groups[5]. The reaction sequence $(1) \rightarrow (6) \rightarrow (7) \rightarrow \mathrm{CDT} + Mo(CO)_6$ serves as a model for the catalytic synthesis of CDT on transition metals[2].

The isomerization of an $\eta^4$-bonded butadiene to an $\eta^2$-bonded ligand (*vide supra*) is reminiscent of the exhaustively investigated reactions of the allyl-transition metal compounds[7]. $\eta^3$-$\eta^1$-Isomerizations of allyl complexes are discussed, in particular, as a reaction step preceding C—C coupling in catalytic cyclooligomerizations of 1,3-dienes[6]. By analogy, one can assume that coupling of an $\eta^4$-bonded butadiene ligand with suitable substrates—*e.g.* with further butadiene in the stoichiometric synthesis of CDT on molybdenum—is preceded by isomerization to an $\eta^2$-bonded butadiene. Further evidence of this being the case is furnished by investigations on (COT)Zr- and (COT)Hf-butadiene complexes[8].

### *Procedure*

A suspension of magnesium sand (12 g, 0.494 mol; activated by heating with $I_2$ *in vacuo* and etching with $C_2H_5I$) in *ca.* 1.7 dm$^3$ THF was treated at −20 °C with 180 cm$^3$ liquid butadiene and 74.5 g (197.4 mmol) $MoCl_4 \cdot 2THF$[9]. After 48 hours' stirring at −20 to −15 °C a greenish-brown solution was formed. After concentration by evaporation at −10 °C the resulting residue was dried at room temperature in an oil-pump vacuum and then extracted with toluene. The brown toluene solution after removal of solvent by distillation *in vacuo* gave a tacky residue, which was extracted with *ca.* 3.5 dm$^3$ pentane. The brown crude product obtained after cooling the extract in a vacuum was dissolved in a little warm THF (50 °C) and the solution stored for 24 h at −20 °C. After dilution with *ca.* 150 cm$^3$ cold ether the crystalline precipitate was recovered by filtration at −20 °C, washed with ether, and dried in an oil-pump vacuum. Yield: 14.5 g (56.2 mmol $\hat{=}$ 29%) $(C_4H_6)_3Mo$ *(1)*. The NMR, IR and MS data agree, within the accuracy of measurement, with the data quoted by *Skell et al.*[1].

## Synthesis, Isolation, and Identification of Translationally Isomeric [3]Catenanes[**]

By *Gottfried Schill, Klaus Rissler, Hans Fritz,* and *Walter Vetter*[*]

In connection with our studies on the synthesis and physico-chemical properties of [3]catenanes containing a central macrocarbocycle[1] we have cyclized the diamine *(2)*, obtained from the dinitro compound *(1)*[2] by catalytic reduction with Raney nickel in 2-pentanol[3], in the presence of $Na_2CO_3$ and NaI under high dilution conditions. Three monomeric cyclization products were isolated in yields of 21, 7.7 and 0.9% by chromatography. It follows from spectroscopic data that the main product has the structure *(3)*[4].

(7a), $R^1$ = $CH_3$, $R^2$ = $OCH_3$, $R^3$ = H
(7b), $R^1$ = $CH_3$, $R^2$ = H, $R^3$ = $OCH_3$

The mass spectrum of *(3)* shows the molecular ion as base peak at *m/e* = 1550 and only slight fragmentation, characteristic for doubly bridged compounds of the type *(3)*[5]. Consistent with the $C_{2v}$ symmetry required for *(3)*, the $^{13}$C-NMR spectrum (90.5 MHz) contains one set of signals for each of the C-atoms of the benzene rings, of the four $(CH_2)_{12}$-bridges over the benzene rings, and each of the two diastereotopic $(CH_2)_{22}$-bridges. Also in agreement with the symmetry in *(3)*, the 360-MHz $^1$H-NMR spectrum shows only one signal for each of the aromatic protons and the diastereotopic protons of the four N—$CH_2$ groups, but two signals for the benzylic $CH_2$-groups of the $(CH_2)_{22}$ bridges.

As in earlier procedures[6] the chemical bonds between the benzene rings and the double-bridge systems were cleaved in two steps. The dipyrocatechol obtained by acid-catalyzed hydrolysis of the two acetal groups was dehydrogenated with iron(III) sulfate to the corresponding 4-amino-1,2-benzoquinone. Its hydrolysis in the acidic reaction medium yielded a compound containing 2-hydroxy-1,4-benzoquinone structural units. Reductive acetylation with zinc/acetic anhydride/sodium acetate afforded a mixture of products which could be separated by preparative layer chromatography on silica gel with ethyl acetate into two fractions ($R_f$ = 0.30 and 0.21). The more rapidly eluted compound is assigned the constitution *(4)*, the more slowly eluted fraction consists of a mixture of hitherto inseparable *(5a)* and *(5b)*.

The assignment of the structures *(4)* and *(5a, b)* to the two fractions is based on the assumption that the chromatographic differences between *(5a)* and *(5b)* should be less than that between *(5a)* or *(5b)* and *(4)*. The $^{13}$C-NMR spectrum of *(4)* shows only one set of signals for the C-atoms of the aromatic rings and of the three different *O*-acetyl groups. On the other hand, since the two macrocycles in *(4)* are heterotopic, two signals each are observed at 210.66 and 210.62 and 42.86 and 42.81, respectively, for the C-atoms of the keto-carbonyl groups and the α-$CH_2$ groups. The signals of the other heterotopic C-atoms of the macrocycles overlap.

The $^{13}$C-NMR spectrum of the mixture of *(5a)* and *(5b)* shows signals with very similar chemical shifts to those of *(4)*. Two signals differing by less than 0.5 ppm are observed for each of the C-atoms of the aromatic rings and for the *O*-acetyl groups. Consequently, a maximum of only two signals is observed for the C-atoms of the now enantiotopic macroheterocycles, *e.g.* at δ = 210.28 and 210.19 for the keto-carbonyl C-atoms and at 42.79 and 42.74 for the C-atoms of the α-$CH_2$-group.

The $^1$H-NMR spectrum (360 MHz) of *(4)* shows a singlet at δ = 6.96 for the aromatic proton. Correspondingly, in the case of the mixture of *(5a)* and *(5b)* two signals are observed at δ = 6.96 and 6.95.

In the compounds *(4)*, *(5a)* and *(5b)* a new form of isomerism is present, for which we propose the term *translational isomerism* because such isomers are only interconvertible by translation of the 26-membered macroheterocycles across a high steric barrier. This isomerization is so strongly hindered by bulky aromatic components in these compounds that isolation of the isomers is possible. When heated to 200 °C, *(6)* or *(7a)* and *(7b)* slowly decompose; mutual isomerization is not observed.

In the two phase system benzene/30% aqueous solution of sodium hydroxide both *(4)* as well as *(5a)* and *(5b)* can be hydrolyzed and converted into the hexamethyl ethers *(6)* and *(7a,b)*, respectively, with tetrabutylammonium sulfate as catalyst and dimethyl sulfate, without isolation of intermediate products, and converted into the hexamethyl ethers *(6)* and *(7a, b)*, respectively. Remarkably, the translational isomers do not interconvert, even at the reaction temperature of 80 °C. Signal patterns corresponding to those in the acetyl derivatives are observed in the $^1$H- and $^{13}$C-NMR spectra of *(6)* and the $^1$H-NMR spectrum of the mixture of *(7a)* and *(7b)*.

It cannot be established with certainty whether *(6)* differs from *(7a)* and *(7b)* mass spectrometrically. During the recording of the mass spectra (MS 9, 70 eV) it was not possible to accurately reproduce all peak intensities, even under identical conditions of sample introduction and evaporation (*ca.* 300 °C). Consequently, the following intensity data hold both for *(6)* as well as for *(7a)* and *(7b)*. The molecular ion shows an intense peak at $m/e=1790$ (25%[7] of the base peak at $m/e=55$). The peak of the ionized [2]catenane is observed at $m/e=1369$ (50%). If a thermal decomposition of the catenane structure is excluded then formation of this ion from the doubly charged molecular ion of the [3]catenane must be assumed. The molecular ion of the macrocarbocycle appears at $m/e=948$ (50%). The peaks at $m/e=895$ (30%), 684.5 (3%) and 474 (10%) represent the same structures again, but this time as doubly charged ions. The complete fragmentation patterns of the two macrocyclic components are found in the low mass range in addition to the protonated molecular ion of the macroheterocycle at $m/e=422$ (50%)[8]. Surprisingly, besides this ion yet another ion occurs at $m/e=436$ (25%), presumably formed by transfer of a methyl group from a methoxy group of the macrocarbocycle to the amide group of a macroheterocycle.

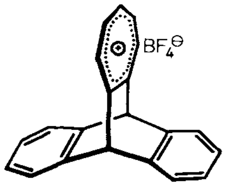
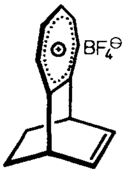
## 1,4-Dihydro-1,4-ethenobenzotropylium Tetrafluoroborate; Synthesis and Intramolecular Charge-Transfer Interaction[**]

By *Tomoo Nakazawa, Keiji Kubo,* and *Ichiro Murata*[*]

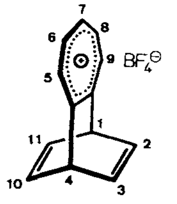
We have already reported the syntheses of the bridged tropylium ions *(1)*[1] and *(2)*[2], the model compounds for intramolecular charge-transfer (CT) interaction between the tropylium ion and remote π-systems which are not in parallel planes. As part of our program to design a simplified molecule capable of retaining intramolecular CT interaction between nonparallel donors and acceptors, we wish to draw attention to some of the novel structural features of compound *(3)*; a molecule constructed of amalgamated tropylium ion and barrelene (bicyclo[2.2.2]octatriene) frameworks. Studies on *(3)* provide useful information not only on the intramolecular CT interaction between donor and acceptor, with rigid spatial arrangement, but also on the π-π interaction between two ethylene π-systems incorporated into a bicyclo[2.2.2]octane framework.



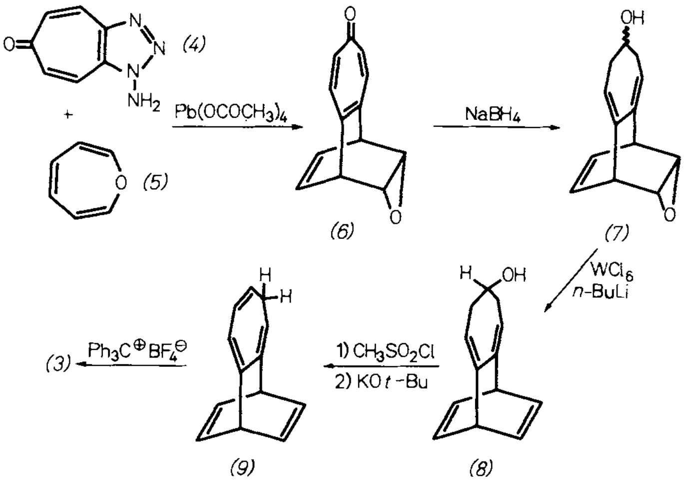
*(1)*



*(2)*



*(3)*



The synthetic route to *(3)* is shown in Scheme 1. The bridged tropone derivative *(6)* [pale yellow needles, m.p. = 166.5 °C, dec. (benzene)][3] was obtained in 95% yield by a procedure developed by us recently[4], which consists of treatment of a mixture of 1-amino-1*H*-cycloheptatriazol-6-one *(4)*[5] and 2 equivalents of oxepin *(5)*[6] with 1 equivalent of lead tetraacetate. Reduction of *(6)* with sodium borohydride (in 98% methanol, room temp., 2 h) gave the epimeric mixture of the alcohols *(7)* [colorless needles, m.p. = 98—104 °C, yield 79%][3]. Transformation of *(7)* into the tetraenol *(8)* [colorless needles, m.p. = 127—129 °C (hexane and benzene), yield 45%][3], which was unsuccessful when attempted with the usual deoxygenating reagents, was effected by using lower valent tungsten chloride prepared *in situ* from tungsten hexachloride and 2 equivalents of *n*-butyllithium in tetrahydrofuran[7]. The tetraenol *(8)* could be converted quantitatively into its mesylate ($CH_3SO_2Cl/Et_3N$ in dichloromethane, 0 °C, 10 min), which, without purification, afforded the cycloheptatriene derivative *(9)* [colorless liq., yield 50% referred to *(8)*][3], on treatment with 2.5 equivalents of potassium *tert*-butoxide (THF, −45 °C, 1.5 h). Conversion of *(9)* into the desired cation *(3)* was accomplished by use of trityl

tetrafluoroborate in dichloromethane at −74 °C. The tetrafluoroborate of cation *(3)*, which was obtained in 47% yield as greenish yellow needles, decomposed at 204—207 °C (acetonitrile or ethyl acetate)[3], but is very stable under ambient conditions. Assignment of structure is supported by its $^1$H- and $^{13}$C-NMR spectra shown in Table 1.

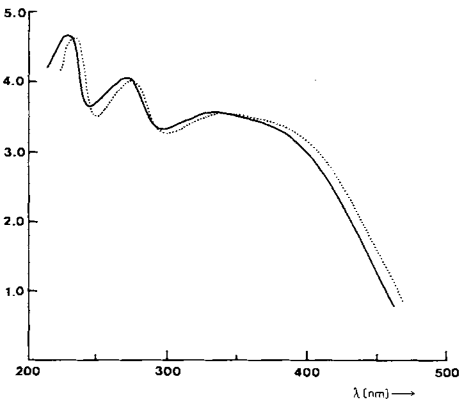

Fig. 1. UV/VIS spectrum of *(3)* in $CH_3CN$ (——) and in $CH_2Cl_2$ (······).

The UV/VIS spectrum of *(3)* (Fig. 1) exhibits a broad and intense CT absorption in the 300 to 450 nm region which is solvent dependent, and shows a bathochromic shift in the less polar dichloromethane. The broad shape of this CT absorption suggests that the band consists of two or more electronic transitions. This is confirmed by the curve resolution (331 and 387 nm) and by the MCD spectrum of *(3)* which shows a positive peak with its maximum at 333 nm and a negative trough at 387 nm in the CT region[8]. Since the interaction between the two non-conjugated ethylene π-orbitals in *(3)* gives rise to two occupied π-orbitals, the two observed CT bands at 387 and 333 nm are assigned to the electronic transitions from the HOMO and the next HOMO of the two interacting ethylene π-orbitals, to the LUMO of the tropylium π-orbital, respectively. In fact, the energy difference of these two CT transitions (0.52 eV) is roughly equal to the orbital energy gap of bicyclo[2.2.2]octadiene, $\varepsilon(b_2(\pi)) - \varepsilon(a_1(\pi)) = 0.58$ eV, measured by PE spectroscopy[9].

The thermodynamic stability of *(3)* was evaluated by means of its $pK_{R^+}$ value, which is found to be $7.0 \pm 0.2$ in 20% aqueous acetonitrile. It is evident that the stability of the tropylium ion is markedly diminished in *(3)* compared with *(2)* ($pK_{R^+} = 8.4_7$)[2] and its dihydro analog ($pK_{R^+} = 8.8_2$)[2]. This trend observed on successive introduction of the double bond in the ethano-bridge system can be attributed to the decrease in the electron-donating inductive effect of the bridged alkyl group[2].

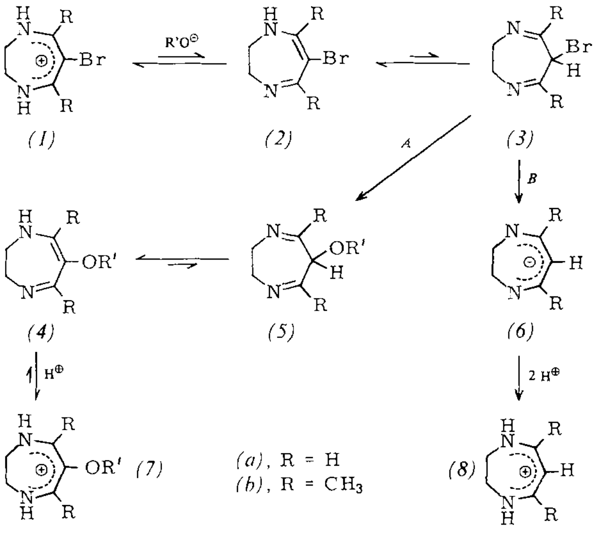
## An Onium Anion

By *Douglas Lloyd, Raymond K. Mackie, Glynis Richardson,* and *Donald R. Marshall*[*]

When 6-bromodihydrodiazepinium salts *(1)* react with alkoxides they may undergo either nucleophilic substitution to give 6-alkoxy-derivatives (route A) *(7)*, or protodebromination to give the products *(8)* (route B)[1]. It has been suggested that both of these reactions involve initial formation of the dihydrodiazepine base *(2)*, which can tautomerize to provide a bisimine species *(3)* very susceptible to nucleophilic attack[1]. The type of product which results seems to be determined largely by steric factors[1].



The tautomerization of *(2)* to *(3)* involves the loss of a considerable amount of resonance energy[1b], but there is some energetic compensation in the loss of vicinal crowding between the 5-, 6- and 7-substituents[1c].

Evidence in favor of this mechanism is provided by the following facts: (a) the bromine atom of *(1a)* is immune to attack by alkoxide ion (save for conversion into the corre-

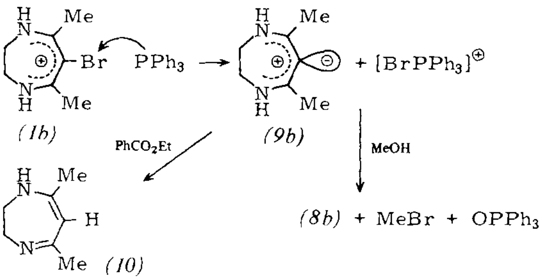
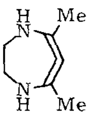
[+] Author to whom correspondence should be addressed.

sponding dihydrodiazepine base), presumably because in *(2a)* there is minimal crowding between the 5-, 6- and 7-positions in the conjugated form of the base and hence no steric factor to assist change to the bisimine form[1c]; (b) *N,N'*-disubstituted 6-bromodihydrodiazepinium salts such as *(13)* do not undergo reactions of types *A* or *B*[1a].

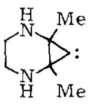
When the salt *(1b)* is heated with a molar equivalent of triphenylphosphane in methanol, the product *(8b)* is formed in high yield. The $pK_a$ for the acid-base equilibrium involving *(1b)* is 11.8[2]. It seems very unlikely, therefore, that in the presence of triphenylphosphine in methanol there could be sufficient base form present to sustain the protodebromination reaction proceeding *via* this base as intermediate. An alternative mechanism, in keeping with the known reactivity of triphenylphosphane towards bromine[3a], could involve the following sequence of reactions[3].



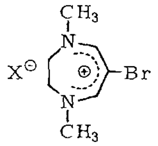
The postulated intermediate species *(9b)* is remarkable in that it is at the same time an onium ion and a carbanion. Alternative forms which might be considered for this species, but which would involve substantial distortion of the geometry of the ring[4] are the allene *(11)* (by analogy with structures considered for cycloheptatrienylidene[5]) or the carbene *(12)*. However contributions from either of these structures would involve considerable increase in geometric strain in the molecule, coupled with loss of the delocalization energy (*ca.* 20 $\mathrm{kcal \cdot mol^{-1}}$ [1b]) of the vinamidinium system[6].



*(11)*



*(12)*



*(13)*

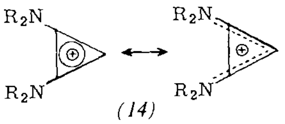
In the onium ion *(9b)* the anionic lone-pair is orthogonal to the delocalized system, which adds further complication by being an electron-rich cation[7].

A variety of evidence is available in support of this mechanism, and, consequently, of the postulate of this *onium anion (9b)*.

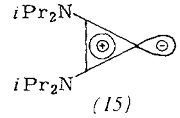
- If perdeuteriomethanol is used as solvent a 6-deuteriodihydrodiazepinium salt is formed.
- The cation *(1a)*, which will not undergo protodebromination with alkoxides[1c], is protodebrominated by triphenylphosphane, although a higher boiling solvent, 1-pentanol, is required to promote the reaction.
- The salt *(13)*, which cannot form a dihydrodiazepine base, also undergoes protodebromination when heated with triphenylphosphane in 1-pentanol.
- Protodebromination of *(1b)* in 1-propanol provided the other expected products, triphenylphosphane oxide and 1-bromopropane, which were isolated and characterized.
- The higher temperatures required for *(1a)* and *(13)* may be associated with the diminished crowding between the 5-, 6- and 7-positions in these molecules, making the C—Br bond slightly stronger and/or raising the energy of the transition state because of diminished steric assistance. The 6-chloro-analogue of *(1b)* likewise undergoes protodechlorination in refluxing 1-propanol but not in refluxing methanol. The higher temperature required is similarly reasonable.

It seemed possible that in an aprotic solvent such an onium anion *(9)* might gain a proton at the 6-position by transfer from a nitrogen atom.

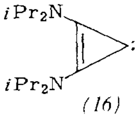
The *N,N'*-disubstituted dihydrodiazepinium species *(13)* could not provide a proton in this way. In accord with this proposition, *(1b)* underwent protodebromination when heated in dry ethyl benzoate but similar treatment of *(13)* only produced polymeric material, presumably resulting from alternative reactions of the intermediate species.



*(14)*

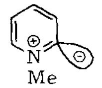


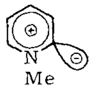
*(15)*



*(16)*

*(17)*





*(18)*

There is other evidence for the formation of onium anions in the literature even although they have not been formulated as such.

Bisaminocyclopropenium salts *(14)* and the vinamidinium system in *(1)*[6], are electronically similar and reactivity in keeping with this has been reported[8a]. It has been postulated that the onium ion *(15)* is formed as an intermediate in a number of reactions[8b,c], but it has been described as a carbene *(16)*, which can be another contributing form.

Also the ready decarboxylation of 2-pyridine carboxylic acids has for some time been attributed to the formation of the intermediate pyridinium ylid *(17)*[9]. If the pyridinium cation is regarded as a delocalized system, this species *(17)* provides another example of an onium anion *(18)*.

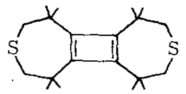
# The Electronic Triplet State of a Peralkylated Cyclobutadiene[**]

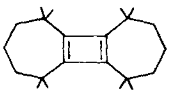
By *Jakob Wirz, Adolf Krebs, Hermann Schmalstieg* and *Herbert Angliker*[*]

In accordance with the results of *ab initio* calculations, recent experiments have established that the ground state of cyclobutadiene *(1)* is a singlet ($S_0$) and that its geometry is probably rectangular[1]. In contrast, the energy level and geometry of the triplet state ($T_1$) have not yet been determined. All efforts to detect ($^3$*1*) existing in thermal equilibrium with *(1)* have been unsuccessful. Even the use of derivative *(2)*, stabilized by sterically demanding substituents, produced no ESR signal in solution or solid state studies at temperatures up to +100 °C[2]. It is therefore probable that the triplet excitation energy of *(2)* exceeds 40 kJ/mol.

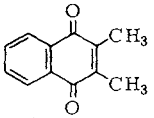
*(1)*



*(2)*



*(3)*



*(4)*

We report here that we have generated and observed the triplet state of the isolable, alkyl-substituted cyclobutadiene *(3)*[3] using the technique of flash photolysis (Nd laser at 353 or 530 nm, pulse duration 20 ns, kinetic measuring configuration). The direct excitation of *(3)* produced no short or long term changes in its absorption spectrum in the range 250 to 820 nm. This was anticipated, since we had found earlier[4a] that electronically excited [4n]annulenes undergo very rapid radiationless decay, so that fluorescence emission or intersystem crossing to the $T_1$ state is effectively prevented. We therefore determined the bimolecular rate constants $k_{et}$ for the quenching of several excited triplet sensitizers ($^3S$) by *(3)* in degassed benzene (25 °C). For this purpose we used polycyclic arenes which have characteristic triplet absorption bands[5a] and the triplet energies of which are known[5b-e].

The decay kinetics of the ($^3S$) state in the absence of *(3)* in a time range >10 μs was dominated by ($^3S$)—($^3S$) annihilation. For this reason the concentration (0.001 to 0.1 M)[6] of the quenching agent *(3)* was chosen such that the lifetime of the ($^3S$) state was reduced to about 0.5 μs. The decay then followed pseudo first-order kinetics, and hence the observed decay rate of ($^3S$), $k_{obs}$, could be equated to the rate of the quenching process, $k_{et}$ [*(3)*].

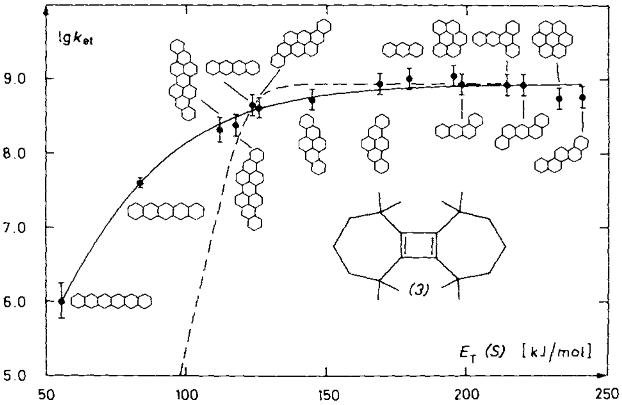


Fig. 1. Logarithmic plot of the rate constants $k_{et}$ for triplet energy transfer from several sensitizers *(S)* to the cyclobutadiene derivative *(3)*, against the triplet energy $E_T$ of the sensitizers *(S)*. For the sake of clarity, only the carbon framework of the benzene rings is shown.

Figure 1 shows $k_{et}$ plotted logarithmically against the triplet energy $E_T$ of the sensitizers *(S)*. The hypothesis that the quenching of ($^3S$) by *(3)* can be assigned to a triplet energy transfer process is decisive for the interpretation of the results. Since the sensitizers ([*(S)*] ≈ $10^{-4}$ to $10^{-5}$ M) were not consumed, even upon prolonged irradiation, the process of quenching must regenerate the starting materials. A reversible electron transfer (*via* a triplet exciplex) is improbable on energetic grounds. Furthermore, all solutions immediately returned to their original absorbance in the visible region after the absorption of ($^3S$) was quenched; if ion-pair intermediates of the type $^3(S^{\dot{+}}\cdots 3^{\dot{-}})$ or $^3(S^{\dot{-}}\cdots 3^{\dot{+}})$ having $\tau \gtrsim 20$ ns had been involved, they would have produced a strong transient absorption in the visible region. On the basis of semiempirical calculations on cyclobutadiene *(1)*[7], we anticipated that ($^3$*3*) would exhibit a relatively weak, broad (*Franck-Condon*-forbidden) absorption band in the near UV. In most cases, measurements could not be made in this spectral region due to the strong background absorption of the parent solutions. A suitable sensitizer, by means of which the UV region became accessible, proved to be 2,3-dimethyl-1,4-naphthoquinone *(4)*. Its absorption maximum lay close to the laser wavelength of 353 nm and because *(4)* had a very high rate of quenching, $k_{et} = 7 \times 10^9$ $\mathrm{M}^{-1}\,\mathrm{s}^{-1}$, a concentration of [*(3)*] = 0.01 M was sufficient to quench ($^3$*4*) within *ca.* 20 ns. Under these conditions we were able to observe a short-lived product ($\tau = 240$ ns, 1st order decay) of the quenching process which exhibited a weak absorption band increasing gently in intensity from 400 to 300 nm. The spectrum of this sequential product corresponds qualitatively to that expected for ($^3$*3*), but is not consistent with the assignment $^3(3^{\dot{+}}\cdots 4^{\dot{-}})$.

A section through the energy surfaces of $S_0$ *(3)* and $T_1$ *(3)* is shown in Figure 2; the diagram displays the consistent results of numerous *ab initio* calculations on *(1)*[1], and qualitatively takes account of the asymmetric steric interaction arising from the α-methyl groups of *(3)*. The equilibrium geometries shown for $S_0$ *(3)* and $T_1$ *(3)* differ considerably; accordingly the vertical excitation energy $E_T^{\mathrm{v}}$ is much larger than

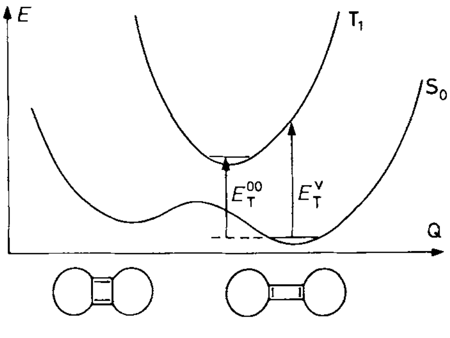

Fig. 2. Qualitative energy diagram for the double bond isomerization process in *(3)* (Q is reaction coordinate). The X-ray structural analysis of *(3)* [8] has yielded a planar 4-membered ring having bond lengths 133.9 (C=C) and 159.7 pm (C—C), corresponding to the right hand structural formula.

the "adiabatic" or "nonvertical" value $E_T^{00}$. In fact the smooth descent of the quenching curve for $E_T$ *(S)* values <120 kJ/mol is characteristic of a "nonvertical" energy transfer process[9]. For example, for $E_T^v = E_T^{00} = 120$ kJ/mol the dashed curve in Figure 1 would be expected. Moreover, it is striking that the plateau region of quenching rates for energy-rich sensitizers is reached at $k_{et} \cong 10^9$ M$^{-1}$ s$^{-1}$, which is approximately an order of magnitude less than the normally observed diffusion controlled limit. This presumably arises from the steric screening of the π-system by the alkyl substituents in *(3)*, since an exchange mechanism for the transfer of triplet energy[10] requires the chromophores to overlap. It should be noted that fluorenone and 2,3-dimethylnaphthoquinone *(4)* ($E_T = 213$ and 220 kJ/mol, resp.; $\pi\pi^*$) are quenched by *(3)* at a rate close to the diffusion controlled limit ($k_{et} = 9\times10^9$ and $7\times10^9$ M$^{-1}$ s$^{-1}$, resp.). This may be a consequence of the increased electron affinity[10b] and/or the modest spacial requirements of the carbonyl groups.

Based on a semi-classical model for the triplet energy transfer process in solution, *Balzani et al.*[9] recently suggested a general relationship between $k_{et}$ and $E_T^{00}$ *(S)* which makes use of several spectroscopic, kinetic and thermodynamic parameters and which satisfactorily describes both "vertical" and "nonvertical" quenching processes. *Balzani's* function (equation 29 in [9]) was fitted to the measured values of $k_{et}$[11] by application of the method of least squares[12]. The solid line shown in Figure 1 was obtained with the following values for the adjustable[13] parameters; $E_T^{00}$ *(3)* = 50±5 kJ/mol, $k_{en}^0 = (1.1\pm0.1)\times10^9$ s$^{-1}$ (rate constant for the energy-transfer in an activated encounter complex) and $\Delta G^{+}(0) = 1700\pm300$ cm$^{-1}$ [free energy of activation for a thermoneutral energy transfer from ($^3S$) to *(3)*]. From $\Delta G^{+}(0)$ and $E_T^{00}$ *(3)*, a lower limit of 120 kJ/mol for $E_T^v$ *(3)* can be estimated. A decrease in the energy transfer rates of the high-energy sensitizers is barely observable (picene and coronene, Fig. 1), although the energy of the $T_2$-state of *(3)* is very high (*ca.* 300 kJ/mol above $T_1$)[7]. An "inverted region", in the sense of the *Marcus* theory (equation 10 in [9]), accordingly does not appear even in this rather sensitive case.

*Conclusions:* Using flash spectroscopic sensitization of the cyclobutadiene derivative *(3)*, we were able to observe a short-lived (240 ns) intermediate which absorbed at wavelengths less than 400 nm. This species was assigned to the lowest triplet state of *(3)*. From the observed relation between the rate constant $k_{et}$ and the triplet energy $E_T^{00}$ *(S)* of the sensitizers used, the following estimates for the adiabatic and vertical triplet energies of *(3)* have been obtained: $E_T^{00} = 50\pm5$ kJ/mol, $E_T^v \geq 120$ kJ/mol.

[13] The following parameters have been determined elsewhere [9] and were not varied: $k_d = 10^{10}$ M$^{-1}$s$^{-1}$ (benzene, 25 °C), $k_d = 1.2\times10^{10}$ s$^{-1}$, $\Delta G^{+}_{(S)}(0) = 500$ cm$^{-1}$ (polycyclic arenes).

## Addition of Carbenes to Reactive Metal-Metal Bonds — A Simple Synthetic Method for μ-Methylene Complexes[**]

By *Wolfgang A. Herrmann, Christine Bauer, Johann Plank, Willibald Kalcher, Dieter Speth,* and *Manfred L. Ziegler*[*]

Following the synthesis of the first μ-methylene complex[1a], this class of compounds was rapidly extended, for which purpose diazoalkanes[1] and dihaloalkanes[2] were recognized as the most efficient carbene transfer reagents[3]. Apart from their well-documented synthetic use in organometallic chemistry, μ-methylene complexes are evidently also of interest for mechanistic studies concerning the *Fischer-Tropsch* process, not least because of their high reactivity with small molecules such as hydrogen and carbon monoxide[2b].

[**] Transition Metal Methylene Complexes, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Degussa Hanau, BASF AG, and Hoechst AG. Part 15: *W. A. Herrmann, J. Plank, M. L. Ziegler, P. Wülknitz*, Chem. Ber., *114*, 716 (1981).

Subsequent to our work on dimetallacyclopropanes[1,4] we have found a further simple, generally applicable synthetic method which implies clean carbene addition to reactive metal-metal bonds. For example, the diazoalkanes *(2a)—(2g)* react with solutions of the binuclear rhodium compound *(1)*[5] in tetrahydrofuran (THF) to give near quantitative yields of the novel, easily crystallizable, nitrogen-free μ-methylene complexes *(4a)—(4e)* or *(5f)* and *(5g)*, respectively, which are air-stable in the solid state (Table 1). The extremely high reactivity of the starting compound *(1)*[6] even with the most stable diazoalkanes is evidenced by immediate [*(2a)—(2e)*] or smooth nitrogen elimination [*(2f)* and *(2g)*] at $-80\,^{\circ}C$ from these and many other diazo precursors. Carbene addition to the metal-metal bond (possibly *via* [2+3]-cycloaddition between *(1)* and *(2)*) first gives the triply bridged μ-methylene complexes of type *(3)* which, under certain steric conditions, can be isolated and characterized at room temperature as stable intermediates; the compounds resulting from tetrabromo-diazocyclopentadiene and 9-diazofluorene[7] may be quoted as well-characterized examples of this general observation. In boiling THF, however, the primary products *(3)* rapidly undergo CO-elimination, with the final compounds *(5)* being formed in practically quantitative yields.

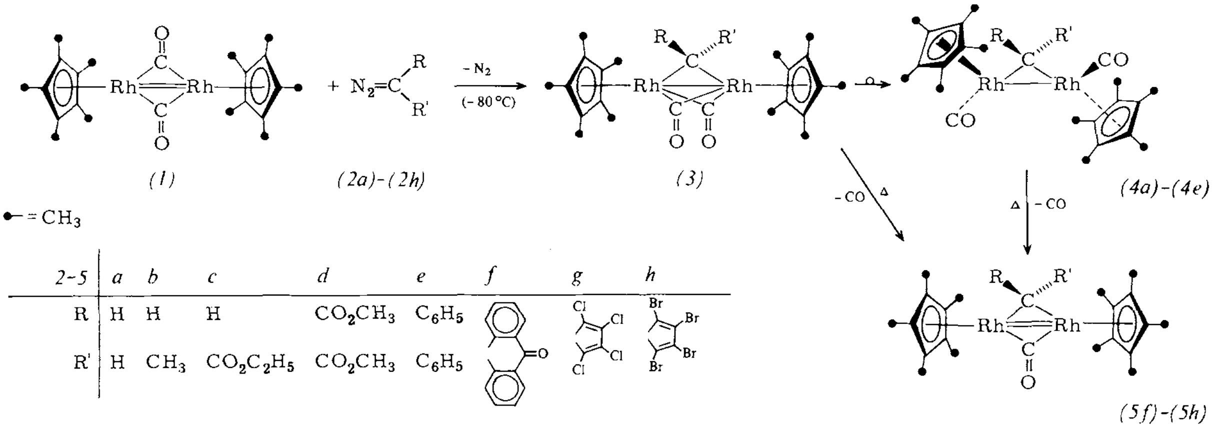

Table 1. Selected spectroscopic and physical data of the novel μ-methylene rhodium complexes *(4a)—(4e)*, *(5f)* and *(5g)*. Composition and constitution were verified by total elemental analysis, IR, $^1H$-NMR, $^{13}C$-NMR, mass spectroscopy (EI or FD); in addition, molecular weights were determined by osmometry.

[a] Beckmann 4240: Reproducibility. ±1 $cm^{-1}$. [b] The $C_5(CH_3)_5$ signals appear as pseudo-singlets: the Rh—H couplings (<0.5 Hz) were only determined in a few cases. [c] After re-crystallization from *n*-pentane, *(4a)—(4e)*, or $CH_2Cl_2$/ether, *(5f)* and *(5g)*. [d] $^{13}C$-{$^1H$} NMR data ($CDCl_3$; int. TMS; 32 °C; ≈10% $^{13}CO$ enrichment): $\delta = 196.64$ [t: CO, $^1J_{Rh,C} = 44$ Hz], $\delta = 111.36$ [t; $CH_2$, $^1J_{Rh,C} = 29$ Hz], $\delta = 100.06$ [s, $C_5Me_5$], $\delta = 10.60$ [s, $CH_3$]. The multiplicity of the CO resonance proves that, in contrast to the $C_5H_5$ compounds [9b], rapid intramolecular CO exchange occurs on the NMR time scale (racemization of the chiral metal centers); at $-40\,^{\circ}C$ ($CD_2Cl_2$) only a doublet appears ($^1J_{Rh,C} = 89.7$ Hz).

Apart from CO-elimination, the carbene addition products *(3)* also provide the possibility of intramolecular carbonyl bridge opening. The isomers *(4a)—(4d)* thus accessible, resist decarbonylation under both thermal and photochemical conditions (THF, 66 °C, 5 h). By way of contrast, the μ-diphenylmethylene derivative *(4e)* is slowly converted to *(5e)* in the dark (THF, 25 °C). The complexes *(5f)* and *(5g)*, formed through consecutive carbene addition[8] and CO-elimination, exhibit the structural characteristics of *(1)*; comparison of *(1)* and *(5)* once again emphasizes the close electronic[9a] and structural[9b] analogies between carbonyl and methylene bridges.

The above-mentioned striking dependence of the product pattern upon the constitution of the diazo substrates predominantly arises from steric factors. The isomers of type *(4)* cannot be formed if sterically demanding cyclic carbenes are present in the immediate precursors *(3)* (*e.g.*, 9-fluorenylidene, 10-oxo-9,10-dihydro-9-anthrylidene, or cyclopentadienylidenes flanked by halogen substituents, *etc.*) since there is no way of further approaching the bulky pentamethylcyclopentadienyl groups. The molecular structures of the typical examples *(4d)* and *(3h)* nicely amplify on this statement (Fig. 1 and Table 2). While on the one hand, the small steric requirements of the methoxycarbonyl substituents in *(4d)* can tolerate consid-

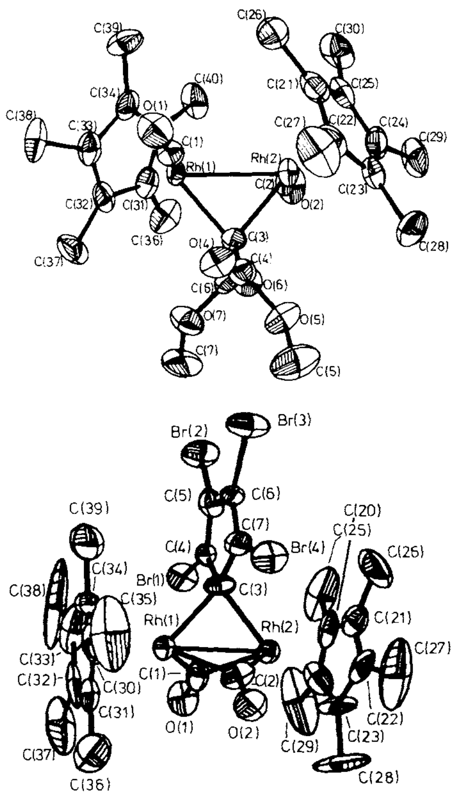

Fig. 1. ORTEP-Drawing of the μ-bis(methoxycarbonyl)methylene complex *(4d)* (above) as well as the μ-tetrabromocyclopentadienylidene complex *(3h)* (below). Scale models show that the planar, rigid α-bromo substituted five membered ring in *(3h)* cannot accept the structure type *(4)* because of considerable steric interaction with the $CH_3$ groups. *(4d)*: triclinic (from *n*-pentane/ether), space group $C_i^1$-$P\bar{1}$, $a=939.4(5)$, $b=1000.3(3)$, $c=1678.0(4)$ pm: $\alpha=76.67(2)$, $\beta=76.86$ *(3)*, $\gamma=68.80(3)°$, $Z=2$; 3815 non-zero reflections ($I>3\sigma(I)$; LP and absorption correction: $2\leq 2\theta\leq 60°$; $R_w=0.039$. *(3h)*: triclinic (from $CH_2Cl_2$/ether), space group $C_i^1$-$P\bar{1}$, $a=893.1(4)$, $b=1093.8(3)$, $c=1689.3(3)$ pm; $\alpha=76.37(2)$, $\beta=78.25(3)$, $\gamma=67.08(3)°$, $Z=2$; 2377 non-zero reflections ($I>3\sigma(I)$); $R_w=0.042$. Both structures were determined conventionally using a computer-controlled Syntex single crystal diffractometer and the SHELXTL program (P3, Data General Nova 3 System). — The structures of *(4a)* and *(4b)* show the same general features as found for *(4d)* (W. A. Herrmann, M. L. Ziegler, et al., unpublished results).

erable tilting of the $C_5Me_5$-rings towards the plane of the dimetallacyclopropane system and thus permit terminal coordination of the carbonyl functionalities, the strictly planar tetrabromo-cyclopentadienylidene bridge in *(3h)* forces the CO ligands into bridging positions, because it repels the two parallel $C_5Me_5$ rings towards each other. The unsubstituted $C_5H_5$ ligand, as a result of its far smaller size, still accepts the structure type *(4)*[10], even with extended planar cyclic carbene ligands present in such molecules. Both the synthetic routes and the structural influence of the methylene ligands described in this paper also hold for the nitrosyl complex $[(\eta^5\text{-}C_5H_5)Fe(\mu\text{-}NO)]_2$ which is a congener of the rhodium dimer *(1)*[11].

## *Procedure*

All operations were carried out under $O_2$ and $H_2O$ free conditions (Schlenk technique).

*(4a)*: A solution of *(1)* (532 mg, 1.0 mmol) in 80 $cm^3$ THF is treated with 10 $cm^3$ of a 0.2 M solution of $CH_2N_2$ in diethyl ether at −80 °C. Nitrogen is evolved and the deep blue solution becomes red within 1-2 min. The mixture is then allowed to warm up to room temperature, the solvent removed using an oil pump and the product recrystallized from the brick-red residue using *n*-pentane (−25 °/−80 °C); yield 514 mg (94%). The compound *(4a)*, which is stable in air, is very soluble in all common organic solvents.

Table 2. Selected bonding parameters of the μ-methylene complexes *(4d)* and *(3h)*.

| | *(4d)* | *(3h)* |
|---|---|---|
| Bond lengths [pm] | | |
| Rh(1)—Rh(2) | 266.3(1) | 261.2(2) |
| Rh(1)—C(3) | 208.3(6) | 210.3(15) |
| Rh(2)—C(3) | 207.6(6) | 211.8(11) |
| Rh(1)—C(1) | 183.3(9) | 203.4(18) |
| Rh(2)—C(1) | — | 205.5(14) |
| Rh(1)—C(2) | — | 202.3(14) |
| Rh(2)—C(2) | 183.7(10) | 201.1(20) |
| C(1)—O(1) | 115.5(12) | 117.7(9) |
| C(2)—O(2) | 115.1(13) | 116.8(21) |
| Bond angles [°] | | |
| Rh(1),C(1),O(1) | 166.6(6) | 138.5(9) |
| Rh(1),C(3),Rh(2) | 79.6(2) | 76.5(4) |
| Rh(1),C(2),Rh(2) | — | 80.7(7) |
| Rh(1),C(1),Rh(2) | — | 80.1(4) |
| C(4),C(3),C(7) | — | 101.6(9) |
| C(4),C(3),C(6) | 108.2(5) | — |
| Interplanar angles [°] [a] | | |
| Cp(C20—24)/Cp(C30—34) | 47.6 | 7.2 |
| Cp(C30—34)/$CR_2$ | 129.4 | 6.6 |
| Cp(C20—24)/$CR_2$ | 129.9 | 0.7 |
| Cp/Rh(1),Rh(2),C(3) | 55.9 | 90.3 |
| Cp′/Rh(1),Rh(2),C(3) | 55.8 | 90.3 |
| Rh(1),Rh(2),C(3)/$CR_2$ | 82.1 | 90.6 |

[a] The interplanar angles are calculated from the best planes of the $C_5Me_5$ ligands, the methylene bridges $CR_2$ [*(4d)*: C(3), C(4), C(6); *(3h)*: C(3—7), Br (1—4)] and from the Rh(1), C(3), Rh(2) plane. The strictly planar tetrabromocyclopentadienylidene ligand of *(3h)* exhibits alternating C—C bond lengths typical of a 1,3-diene system. The $C_6Me_5$ rings form angles of 41.2 and 89.6° resp., with the Rh(1), Rh(2)-vector.

*(5f)*: A solution of *(1)* (266 mg, 0.5 mmol) in 60 $cm^3$ THF at −80 °C, is treated dropwise with a solution of 10-diazoanthrone (110 mg, 0.5 mmol) in 15 $cm^3$ THF. $CO/N_2$ are evolved and the color changes from deep blue to blue-green. Finally the solution is stirred for 30 mins at 25 °C, concentrated using a water aspirator and the residue chromatographed on Florisil (10 × 1 cm column, water-cooled jacket). Using *n*-pentane/benzene (5:1) and benzene as eluents, small amounts of $[\eta^5\text{-}C_5(CH_3)_5]Rh(CO)_2$ or *(1)*, respectively, are eluted. *(5f)* appears in a deep blue band (benzene/diethyl ether 5:2). The eluent is removed *in vacuo*. The residue is recrystallized from $CH_2Cl_2$/diethylether (−80 °C). Yield 334 mg (96%); very soluble in $CH_2Cl_2$, moderately soluble in ether, practically insoluble in *n*-hexane.

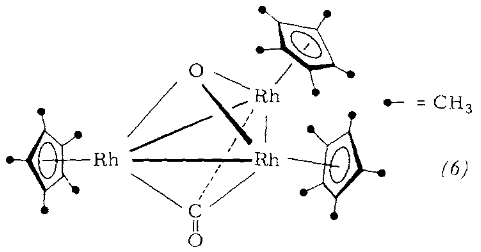
[5] The synthesis of *(1)* on a 6g-scale can be carried out by reaction of $[\eta^5\text{-}C_5(CH_3)_5]Rh(CO)_2$ [5b] with $(CH_3)_3NO\cdot 2H_2O$ [boiling acetone, 3h; yield 80-90%]. Column chromatography of the crude material on $SiO_2$ also resulted in the isolation of the novel, trinuclear $\mu_3$-oxo-complex *(6)* in 7–10%



*(6)*

yield. This compound forms deep purple, air-stable crystals (from $CH_2Cl_2$/ether), which are thermally stable up to temperatures >265 °C (sealed capillary); very soluble in THF, methanol and dimethylformamide, moderately soluble in acetonitrile and diethylether, practically insoluble in *n*-pentane. IR: 1661 vs, 1654 vs, 1648 s (sh) $cm^{-1}$ [$\nu$CO, KBr]; 1655 vs, 1649 vs, 1643 vs (sh) $cm^{-1}$ [$\nu$CO, $CH_2Cl_2$]; $^1$H-NMR: (90 MHz, $CDCl_3$, 33 °C, int. TMS) $\delta = 1.81$; field desorption mass spectrum (from acetone): $m/e = 758$ ($M^+$); correct elemental analysis. b) *J. W. Kang, P. M. Maitlis*, J. Organomet. Chem. *26*, 393 (1971).

[6] The application of the EAN-rule to *(1)* leads to the formulation of a Rh=Rh double bond [cf. *A. Nutton, P. M. Maitlis*, J. Organomet. Chem. *166*, C21 (1979)] which suggests an analogy between carbene-addition and the cyclopropanation of alkenes. However, since considerable uncertainties exist over metal-metal multiple bonds and since bond orders are rarely well defined, we stress caution in over-evaluation of such formalisms [cf. *e.g.* *I. Bernal, J. D. Korp, M. G. Reisner, W. A. Herrmann*, *ibid.* *130*, 321 (1977)].

[7] This compound (yield 100%), forms black, completely air-stable needles which have a metallic luster (M. p. 179 °C, decomp.). IR($\nu$CO): 1842 vs, 1788 vs [KBr]; 1846 s, 1792 vs [THF]. $^1$H-NMR ($CDCl_3$, int. TMS, 33 °C): $\delta = 1.36$ ["s", 30H], $\delta = 7.0$–7.8 [m, 8H].

[8] We have also observed smooth additions with $CH_2$-analogous molecules. For example, *(1)* gives the deep red, air-stable complex $(\mu\text{-}SO_2)[\{\eta^5\text{-}C_5(CH_3)_5\}Rh(CO)]_2$ in 98% yield, when treated with $SO_2$. IR ($\nu$CO): 1980 vs [KBr]; 1985 vs [THF]. $^1$H-NMR ($CDCl_3$, int. TMS, 29 °C): $\delta = 2.00$ ["s"]; FD mass spectrum (from acetone): $m/e = 596$ ($M^+$).

## Tetrafluoroboric Acid-Methanol (1/2), Cyclic Molecules by Hydrogen Bonds between Ions[**]

By *Dietrich Mootz* and *Michael Steffen*[*]

We have been able to characterize the phase $HBF_4\cdot 2CH_3OH$[1] which melts congruently at −41 °C in the system $HBF_4\cdot CH_3OH$—$CH_3OH$ by its crystal structure analysis as an oxonium salt $[(CH_3OH)_2H]BF_4$ with molecular structure.

Samples of corresponding composition have been prepared by passage of boron trifluoride[2] into a mixture of hydrogen fluoride and methanol in the ratio 1:2. Growth of a single crystal on a diffractometer in a teflon tube sealed at both ends was achieved by slow cooling in a stream of cold gas at −50 °C. The X-ray measurements were also carried out at this temperature. They showed[3] the monoclinic space group $P2_1/c$, the lattice constants $a = 5.197$, $b = 14.458$, $c = 9.318$ Å and $\beta = 94.61°$, four formula units per unit cell, and the atomic arrangement shown in Figure 1[4].

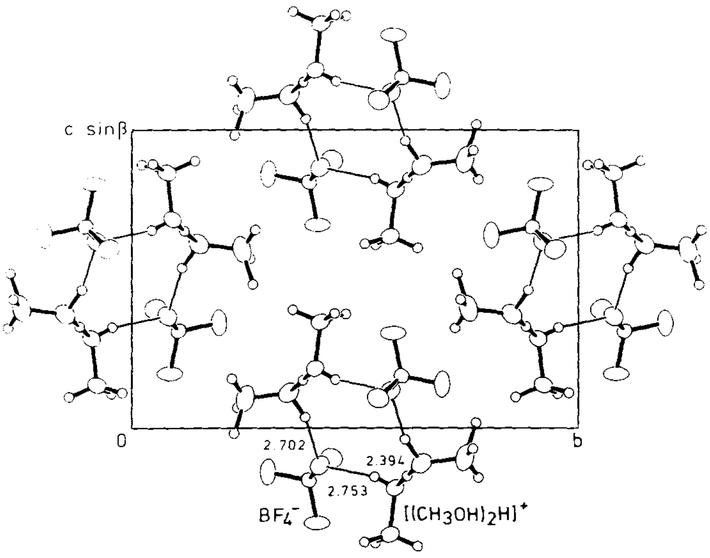

Fig. 1. Crystal structure of $C_2H_9O_2BF_4$. Projection down the *a*-axis, with O...O and O...F distances of the hydrogen bonds in Å.

The acid proton links two methanol molecules by a very short hydrogen bond (O....O distance 2.394 Å) to give a bis(methanol)hydrogen cation $[(CH_3OH)_2H]^+$, which can also be regarded as a methyl-substituted $H_5O_2^+$ ion, and which to our knowledge has hitherto not been observed in a crystal structure. Its two terminal OH protons are oriented *cis* to each other. Cations of this type and $BF_4^-$ anions are coupled by hydrogen bonds O—H···F with O....F distances of 2.702 and 2.753 Å to give molecular cyclic dimers of the formula unit with centrosymmetric $O_4F_2$ six-membered rings planar within 0.13 Å. Both independent hydrogen bonds involve the same F atom of the four independent ones; its B—F distance of 1.407 Å is markedly longer than those of the other three between 1.356 and 1.365 Å.

We have also been able to obtain single crystals of the "parent compound" (without methyl-substitution) $H_5O_2BF_4$ (m.p. −34 °C) and to determine its structure. The O....O distance in the $H_5O_2^+$ ion is 2.412 Å; owing to the greater number of protons capable of forming hydrogen bonds, the cations and anions are cross-linked in a three-dimensional network. The structure is not an isotype of $H_5O_2ClO_4$[5].

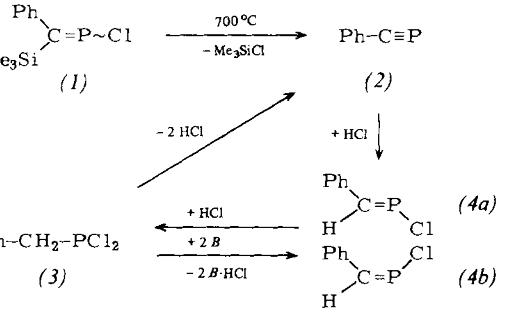
## Elimination and Addition at the Phosphorus-Carbon pπ-pπ Bond[**]

By *Rolf Appel, Günther Maier, Hans Peter Reisenauer,*
and *Axel Westerhaus*[*]

The existence of three phosphaalkynes has so far been reported: Besides the parent compound, phosphaacetylene HCP, which was first obtained as long ago as 1961 on passage of $PH_3$ through an electric arc generated between graphite electrodes[1a,b], the fluoro- and the methyl-derivative (1-phosphapropyne) could later also be prepared and characterized, in particular by microwave and photoelectron spectroscopy[1c]. In both cases the method employed for the synthesis was the elimination of hydrogen halide, from trifluoromethylphosphane and dichloro(ethyl)phosphane, respectively. The pyrolysis of dichloro(ethyl)phosphane, however, does not proceed uniformly; ethylene, $PCl_3$, ethane and acetylene are formed as well as HCl, and the 1-phosphapropyne obtained in only low yield is contaminated with difficultly separable byproducts.

We have now found that when chloro[phenyl(trimethylsilyl)methylene]phosphane *(1)*[2] is heated to 700 °C under vacuum (Hg-diffusion pump), chlorotrimethylsilane is selectively cleaved and phenylmethylidynephosphane (2-phenylphosphaacetylene) *(2)* is formed in almost quantitative yield. The elimination process was optimized by means of a mass spectrometer coupled directly to the pyrolysis apparatus and *(2)* was collected in a cold trap cooled to −196 °C.



The P≡C triple-bond structural element in *(2)* is detectable by the characteristic $^{13}C$- and $^{31}P$-NMR data[3] and is confirmed by stepwise HCl-addition; initially the phosphaalkene *(4a)* is formed, which reacts with a second equivalent of HCl to give the benzyldichlorophoshane *(3)*. It can be shown by $^{31}P$-NMR spectroscopic measurements that *(3)* can also be dehydrochlorinated with tertiary amines *(B)*, with reversal of this formation reaction[2]. However, the *Z*-isomer *(4b)* is formed concomitantly besides *(4a)*. Owing to a stereospecific *cis*-addition at the triple bond, *(4b)* is not obtained on addition of HCl to *(2)*.

In contrast to the halosilane-elimination, direct vacuum pyrolysis of *(3)* affords numerous unidentified by-products and only very small amounts of *(2)*.

*(2)* exists in the monomeric state only at low temperatures; slow decomposition sets in above −50 °C. According to $^{31}P$-NMR spectroscopic measurements its half-life at 0 °C is 7 min. The silyl compound $Me_3SiCP$[4] is much more stable.

### *Experimental*

A quartz tube (25 mm diameter) packed with quartz wool in the hot zone is preheated in a controllable 10 cm-long ring oven at 750 °C. Approximately 0.5 g of an excess supply of *(1)* (room temperature) is thermolyzed under vacuum (Hg-diffusion pump) for 12 h and the condensate collected in cold-trap at −196 °C. The condensate is taken up in a small amount of $CD_2Cl_2$ and rapidly filtered at −78 °C; the filtrate contains only $(CH_3)$ SiCl and *(2)*.

*(3)* is thermolyzed analogously at 800 °C. According to $^{31}P$-NMR measurements the condensate consists mainly of unreacted *(3)* together with small amounts of *(2)* and a series of unidentified by-products.

## $Ba_4SiAs_4$ and $Ba_4GeAs_4$, Zintl Phases with Isolated $SiAs_4^{8-}$ and $GeAs_4^{8-}$ anions[**]

By *Brigitte Eisenmann, Hanna Jordan,*
and *Herbert Schäfer*[*]

Zintl phases are intermetallic compounds which display a pronounced heteropolar bonding contribution and whose anionic partial lattices, in agreement with an ionic formulation, obey the $(8-N)$ rule. A classification according to this Zintl-Klemm concept[1] embraces the majority of compounds of the alkali and alkaline-earth metals which contain, in particular, the semimetals of the 4th and 5th main group as anionic partners. Only such compounds have so far been systematically characterized whose anionic partial lattice is made up of merely one element. No comprehensive investigations have been carried out on compounds with binary anions which may also be interpreted as Zintl phases and which represent bridging members between ternary intermetallic compounds and salts with complex anions.

Particularly impressive examples for such an extension of the Zintl-Klemm concept are the isotypic compounds $Ba_4SiAs_4$ and $Ba_4GeAs_4$ reported here for the first time, which contain "isolated" $SiAs_4$- and $GeAs_4$-tetrahedra, *i.e.*

surrounded only by Ba counterions. The atomic arrangement determined by complete X-ray structure analyses[2] is perspectively reproduced in Figure 1. The Si—As and Ge—As distances of 239.3 and 240.7 pm and of 246.4 and 248.1 pm, respectively, are in very good agreement with the sums of the radii of the elements of 240.1 (Si—As) and 248.3 pm (Ge—As).

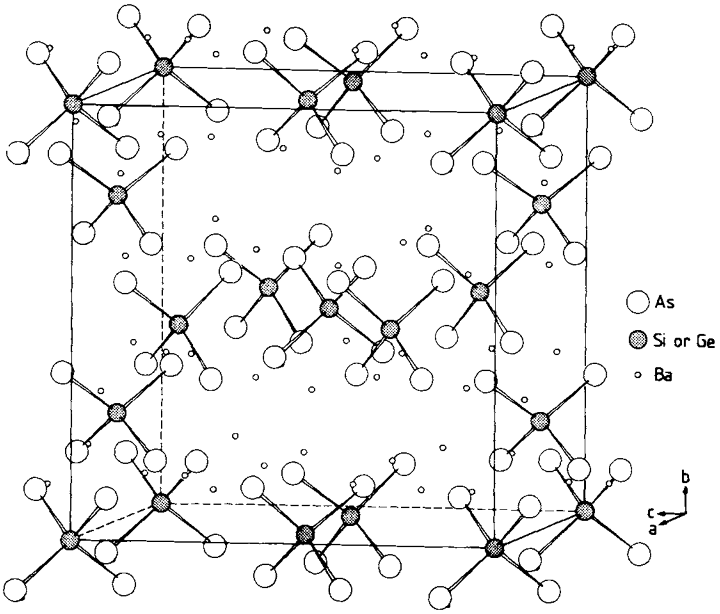

Fig. 1. Unit cell of $Ba_4SiAs_4$ and $Ba_4GeAs_4$.

Corresponding to the observed bonds between the electronegative elements (Si and Ge with four bonds $\hat{=}$ formal charge 0. As with one bond $\hat{=}$ formal charge 2—[1]), $Ba_4SiAs_4$ and $Ba_4GeAs_4$ can be ionically formulated according to $4\,Ba^{2+} + SiAs_4^{8-}$ or $GeAs_4^{8-}$. Hence, the principle already found for the previously described[3] compounds containing polyanions is preserved. That is the semimetal of lower electronegativity is saturated by covalent bonds and the charges provided by the alkaline-earth metal are to be ascribed to the more electronegative partner.

## *Experimental*

Stoichiometric amounts of the elements were heated under argon in a quartz ampoule within 8 h to 1000 °C, kept at this temperature for 1.5 h, and then slowly cooled to 600 °C. The product is annealed at this temperature for 12 h and the furnace then switched off.—Both compounds form lustrous, dark metallic, cubic shaped crystals which become covered with dark decomposition products of unknown composition on exposure to a moist atmosphere.

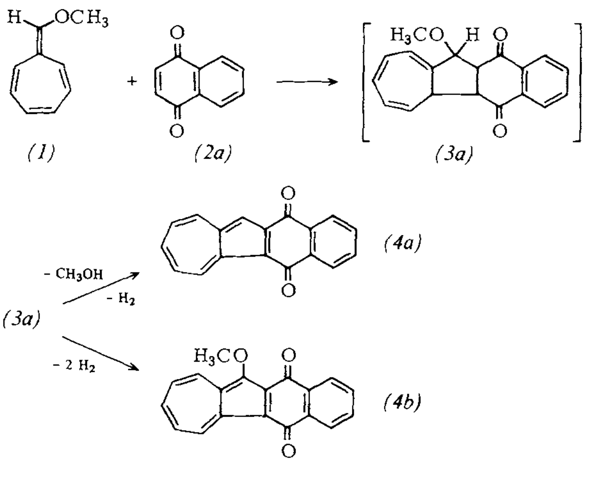
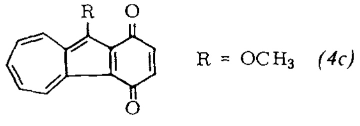
# Acenazulenediones: Synthesis, Spectroscopy, Electrochemical Detection of a Double Redox Cycle[**]

By *Margarete Baier, Jörg Daub, Adelheid Hasenhündl, Andreas Merz,* and *Knut M. Rapp*[*]

8-Methoxyheptafulvene *(1)* adds compounds containing electron-deficient multiple bonds with formation of hydroazulenes[1]. Hence, reaction with *p*-quinones *(2)* should lead, *via* hydroacenazulenediones *(3)* to diones *(4)*.



Reaction of *(1)* with 1,4-naphthoquinone *(2a)* in the molar ratio 1:2 affords naphth[2,3-*a*]azulene-5,12-dione *(4a)* and the methoxy compound *(4b)* in a ratio of 65:35 in 67% overall yield. If the reaction is carried out in a ratio of 1:1 the proportion of *(4a)* increases to >95% with a total yield of *(4)* of 34%. This is consistent with favored cleavage of $CH_3OH$ from the non-isolable intermediate *(3a)* at small quinone concentration. *(4a)* and *(4b)* were separated by column chromatography (low-pressure, Merck pre-packed column, silica gel, dichloromethane). Reaction of 1,4-benzoquinone with *(1)* affords 10-methoxybenz[*a*]azulene-1,4-dione *(4c)* in only 9% yield; a product with R = H was not found. The low yield of *(4c)* is attributed to polymerization of *(1)*.



The spectra of *(4)* show characteristic features of the individual structural moieties (Table 1). Typical for the azulene moiety is the longest-wave band in the electronic spectrum

[**] Fulvenes with Inverse Ring Polarization, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF.—Part 4: [1].

[*(4a)*: $\lambda_{max} = 655$ nm]; the hydrocarbon naphth[2,3-*a*]azulene absorbs in the same region ($\lambda_{max} = 647$ nm)[2]. A pronounced solvatochromism is determinable for the long-wave bands of *(4)* [*(4a)*: $\lambda_{max}(CH_3CN)$: 655 nm, $\lambda_{max}$(benzene): 672 nm]. The quinones *(4)* can thus be compared with merocyanines in which the quinone moiety has acceptor properties and the cycloheptatriene moiety has donor properties.

Table 1. Some physical data of acenazulendiones *(4)*.

*(4a)*: M.p. = 279—280 °C; IR (KBr): 1668 (CO), 1634 (CO), 740, 710 $cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 7.5$—8.0 (m, 5H), 8.1—8.35 (m, 2H), 8.6 (d, $J = 9.5$ Hz, H-6), 9.9 (d, m, $J = 9.5$ Hz, H-10); UV-VIS ($CH_3CN$): $\lambda_{max}$ ($\log\varepsilon$) = 248 (4.1), 308 (4.3), 415 (3.6), 585 (2.8), 610 (2.9), 655 nm (2.7); MS (70 eV): $m/e = 258$ ($M^+$, 100%), 230 (20), 202 (31), 176 (4), 129 ($M^{2+}$); redox potentials in $CH_3CN$: reduction −0.69 V, −1.39 V; oxidation +1.28 V (irrev.)

*(4b)*: M.p. = 217—220 °C; IR (KBr): 1665 (CO), 1625 (CO), 730, 705 $cm^{-1}$. $^1H$-NMR($CDCl_3$): $\delta = 4.3$ (s, $OCH_3$), 7.2—8.3 (m, H-1,2,3,4,7,8,9), 8.6 (d, t, $J = 9.8$ Hz, H-6), 9.9 (d, m, $J = 10$ Hz, H-10); UV-VIS ($CH_3CN$): $\lambda_{max}$ ($\log\varepsilon$) = 253 (3.9), 312 (4.0), 454 (3.5), 678 nm (2.6); MS (70 eV): $m/e = 288$ ($M^+$, 87%), 273 (100), 260 (11), 245 (20), 144 ($M^{2+}$, 4), 136.5 (<2); redox potentials in $CH_3CN$: reduction −0.69, −1.39 V, oxidation +1.11, +1.50 V (irrev.)

*(4c)*: M.p. = 191 °C (dec.); IR (KBr): 1650 (CO), 1622 (CO), 850, 735 $cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 4.2$ (s, $OCH_3$), 6.75, 6.83 (d, AB-part, $^3J = 4.4$ Hz, H-2, H-3), 7.42—7.82 (m, H-6,7,8), 8.65, 9.63 (d,d, $J = 10.2$ Hz, H-5, H-9); UV-VIS ($CH_3CN$): $\lambda_{max}$ ($\lg\varepsilon$) = 265 (4.3), 315 (4.3), 472 (3.8), 690 nm (3.2); MS (70 eV): $m/e = 238$ ($M^+$, 82%), 223 (100), 210 (5); redox potentials in $CH_3CN$: reduction −0.62, −1.32 V; oxidation +1.15, +1.55 V (irrev.)

The unusual electrochemical behavior of the quinones *(4a)* and *(4b)* in aprotic medium ($CH_3CN$ or dimethylformamide (DMF), 0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$) is demonstrated in the following by example of the cyclic voltammetry of *(4a)* (Fig. 1a): The reversibility of the one-electron reduction to the radical anion *(4a⁻̇)* (signals I and I′) is curtailed by an homogeneous secondary reaction (complete reversibility at $v \geq 5$ $Vs^{-1}$). Consequently, an additional redox pair of peaks III and III′ occurs besides the signals for the formation of the dianion ($4a^{2\ominus}$) (II and II′) as well as an additional signal IV for the irreversible oxidation, which is not observed, for example, in the case of anthraquinone. In the direct current polarogram, only the reduction steps quoted in Table 1 are observed at the mercury dropping electrode[3]. The complete reduction (1F/mol) at −0.8 V leads to a deep-red solution ($\lambda_{max}(CH_3CN) = 470$ nm, broad band), whose cyclic voltammogram now only shows the peaks III/III′ and IV (Fig. 1b). The red species is re-converted into the educt *(4a)* both by the electrolysis at +1.0 V as well as by oxidation with atmospheric oxygen.

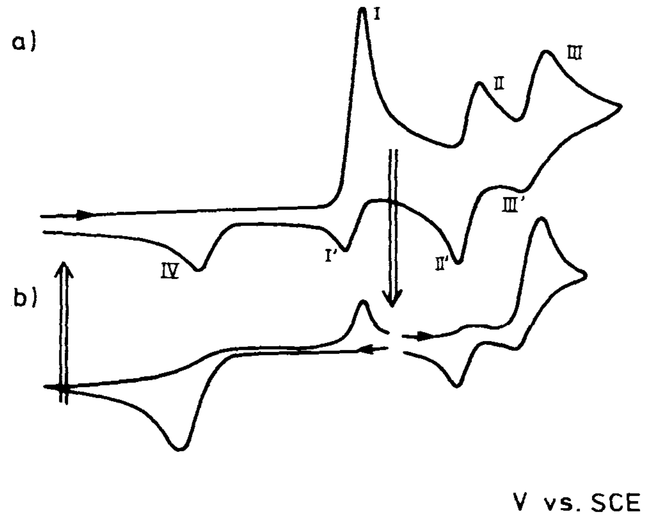

Fig. 1. Cyclic voltammograms of naphth[2,3-*a*]azulene-5,12-dione *(4a)* (in $CH_3CN$/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$, Pt-disk electrode, scanning rate $v = 0.1$ $Vs^{-1}$). a) $2 \times 10^{-3}$ M *(4a)*; b) after complete reduction of this solution at −0.8 V. I,I′,II,II′,III,III′,IV, see text and Scheme 1.

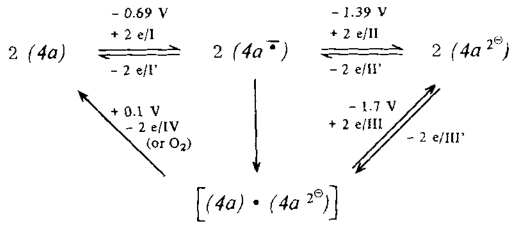
We interpret this behavior in terms of an association of the radical anions *(4⁻̇)* formed in the primary step to give quinhydrone-like EDA complexes [quinone × quinone$^{2\ominus}$]. These complexes are more difficult to reduce as well as more difficult to oxidize than the radical ions *(4⁻̇)* (Scheme 1).



Scheme 1. Redox cycle on uptake of electrons by *(4a)*. I,I′,II,II′,III,III′,IV, see Fig. 1.

In acid medium (0.05 M $HClO_4$ in 95% aqueous DMF, glassy-carbon electrode) the quinones show the usual reversible two-electron reduction, even though marked deviations of the cyclovoltammogram from the ideal shape here also indicate the participation of association.

The behavior in the redox process is consistent with the concept of "heptafulvenes with normal and inverse electron distribution"[4]. The quinones *(4)* correspond to heptafulvenes *(5)* with normal electron distribution (*i.e.* X and Y are acceptors—the system is stable). The monoanions *(4⁻̇)* and dianions ($4^{2\ominus}$) formed in the reduction correspond to the heptafulvenes *(5)* with inverse electron distribution (*i.e.* X and Y are donors—the system is destabilized. ($4^{2\ominus}$) can be stabilized as the EDA complex [*(4)*·*($4^{2\ominus}$)*].

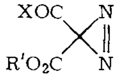
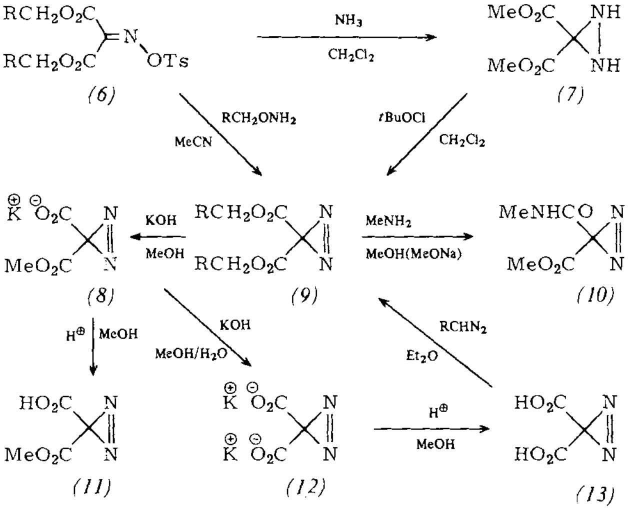
*(4)*



*(5)*, X = RO, $R_2N$

All attempts to photocyclize diesters and amidoesters of diazomalonic acid have been unsuccessful due to the spontaneous isomerization of the diazirines *(5)* to the educts. This has been attributed to the steric effects of the two carbonyl substituents[2]. Indeed, within a few weeks, *(4)* undergoes spontaneous isomerization at room temperature to the diazo compound[4]. This fact, the low thermal stability of the spiranes *(1)* $n=4$[1] and *(3)*[3], and the lability of *(1)* in acidic media[1] may be attributed to the favorable interaction (pseudoconjugation[3]) between the diazirine ring and the $C{=}O$ group in the five and six membered rings. (cf. spiro-activation[5]). We therefore believed that a study of the synthesis of diazirines *(5)*, with conformationally mobile $C{=}O$ groups, would provide a route to their stable derivatives.

We have found that the 3,3-diazirinedicarboxylates *(9)* are readily accessible by reaction of the tosyloximes *(6)* with *O*-alkylhydroxylamines[6] or by oxidation of the 3,3-diaziridinedicarboxylic dimethyl ester *(7)* with *tert*-butylhypochlorite[7]. The esters *(9)*, thus obtained, are colorless and stable at 0 °C; after being stored for a month at 20 °C, crystals of *(9a)* were unchanged and a solution of *(9a)* in trifluoroacetic acid was unchanged after 2 hours ($^1$H-NMR investigation). Mild amidation and alkaline hydrolysis of *(9a)* (0 to −5 °C) yielded the monamide *(10)*, which was stable at 0 °C, and the salts *(8)* and *(12)* respectively. While crystals of the dipotassium salt *(12)* were also unchanged after storage for two months at 20 °C, the monopotassium salt *(8)* decomposed within a few hours at 0 °C. Both salts exploded when triturated!



*(a)*, R = H; *(b)*, R = Me

The monoacid *(11)* and diacid *(13)* are colorless stable crystalline substances at 0 °C; the structure of *(13)* was confirmed by conversion to the diesters *(9)*. The UV-spectra of all the diazirine products obtained displayed a shoulder around the 240–250 nm region and a band at 286–300 nm (see Table 1). We have assigned this band to a $\pi\rightarrow\pi^*$ transition[8], since its position was almost identical in the esters *(9)*, amide *(10)*, and acids *(11)* and *(13)*. Furthermore when methanol was substituted for heptane as solvent, and when $HClO_4$ was added to a solution of *(9a)* in methanol, no hypsochromatic shift was observed.

Table 1. Yields and some characteristic physical data of compounds *(8)*, *(9a)*, *(9b)*, *(10)*, *(11)*, *(12)*, and *(13)*.

| Comp. [a] | Yield [%] | M.p. [°C] | IR $\nu_{C=O}$ [cm$^{-1}$] | $^1$H-NMR (δ values, $C_6D_6$) | UV (π−π*) $\lambda_{max}$ [nm] (lg ε) | Solvent |

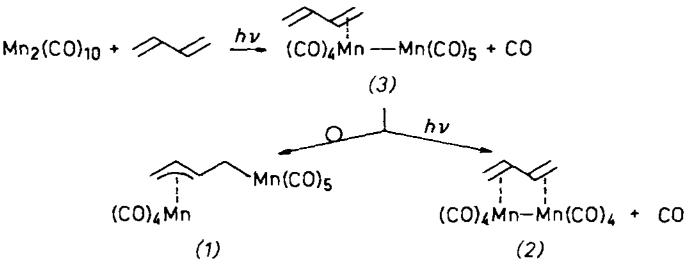
## Cleavage of a Metal-Metal Bond by 1,3-Butadiene under Photochemical Conditions[**]

By *Cornelius G. Kreiter* and *Wolfgang Lipps*[*]

Carbonyl-transition metal compounds usually react with olefins on irradiation with cleavage of carbon monoxide to give olefin complexes[1]. Application of this reaction principle to a carbonyl complex containing a metal-metal single bond, such as $Mn_2(CO)_{10}$, and 1,3-butadiene leads within 10 minutes irradiation to formation of the complexes $Mn_2(CO)_9C_4H_6$ *(1)* and $Mn_2(CO)_8C_4H_6$ *(2)* as main products, which can be separated from each other by HPLC. The complex *(2)* is the already well-known μ-(η-1,3-butadiene)octacarbonyldimanganese(0), in which the *trans*-1,3-butadiene ligand on both manganese atoms of $Mn_2(CO)_{10}$ replaces an equatorial CO ligand[2]. Complex *(1)*, however, is not the expected precursor *(3)*; the IR and NMR spectroscopic data would rather indicate cleavage of the Mn—Mn bond and formation of a 2—4-η$^3$-1-σ-2-butenylene bridge between two separated $Mn(CO)_5$- and $Mn(CO)_4$-moieties.

*(1)* and *(2)* could be formed *via* a common precursor, the aforementioned $Mn_2(CO)_9C_4H_6$ *(3)*. This complex, however, cannot be detected directly: the IR spectrum of the reaction solution contains the νCO bands of $Mn_2(CO)_{10}$, *(1)* and *(2)*, but no intense bands that would be expected for *(3)*. *(1)* is formed from the postulated *(3)* with cleavage of the Mn—Mn bond by the η$^2$-1,3-butadiene ligand, while *(2)* is formed from *(3)* by photochemical displacement of a second CO ligand.



In the $^{13}$C-NMR spectrum of *(1)* (Table 1) the $C_4H_6$ ligand gives rise to two methine and two methylene signals. Their upfield shift compared to the signals of free 1,3-butadiene[3]

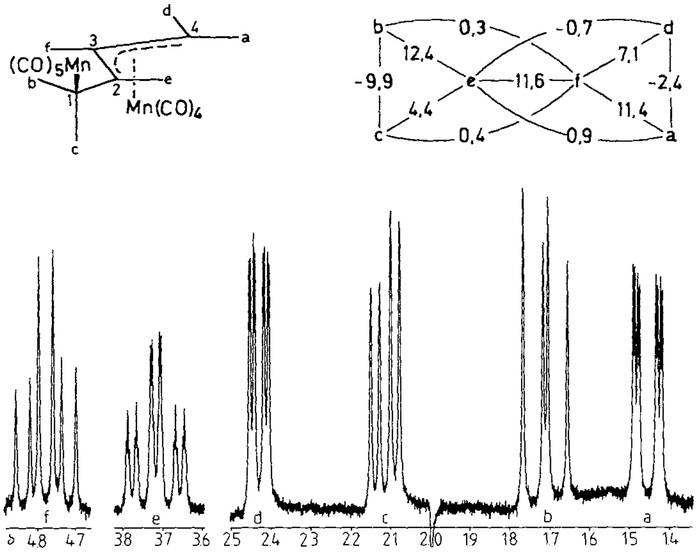


Fig. 1. $^1$H-NMR spectrum and δ-*J* diagram of *(1)* in $CD_2Cl_2$.

and the $^{1}J_{^{13}C,\,^{1}H}$-coupling constants indicate $sp^2$ character[4] of the methine groups and one of the methylene groups and their π-bonding to manganese. The $^{1}J_{^{13}C,\,^{1}H}$-coupling indicates an $sp^3$ hybridization for the second methylene group.

Four (a, d, e, f) of six $^{1}$H-NMR multiplets (Fig. 1) of *(1)* are typical for an $\eta^3$-enyl ligand with a methylene group in *E* position[5]. Since formally three electrons to a $Mn(CO)_4$ group and one electron to a $Mn(CO)_5$ group are lacking for the 18-electron occupation, $Mn(CO)_4$ must be bound to an enyl system, $Mn(CO)_5$ to the $sp^2$ methylene group. Complexes with unsymmetrical enyl ligands are chiral, as follows from the signal splitting of the diastereotopic protons (b, c) of the *E*-$sp^3$ methylene group. The magnitude of the splitting and the extremely different vicinal coupling constants suggest preferred orientation in the complex *(1)* with maximum separation of the carbonylmanganese groups. This might best be explained in terms of spatial requirements.

### *Experimental*[7]

All operations were carried out under an inert gas ($N_2$, He). 1,3-Butadiene (25 $cm^3$) is allowed to condense into a solution of $Mn_2(CO)_{10}$ (750 mg, 1.92 mmol) in *n*-hexane (225 $cm^3$) and the mixture is irradiated for 10 min at 253 K. After filtration of the solution through filter flocs the solvent is removed by evaporation; the residue is taken up in *n*-hexane (20 $cm^3$) and separated into 2 $cm^3$-fractions by HPLC with *n*-hexane. Zone 1: $Mn_2(CO)_{10}$ (50%); Zone 2: *(1)*; Zone 3: $Mn_2(CO)_8(C_4H_6)_2$, rejected; Zone 4: *(2)*. After removal of solvent, *(1)* is recrystallized from *n*-hexane, *(2)* from ether at 240 K; *(1)*, yellow platelets, yield 240 mg (30%), m.p. 104 °C (dec.); IR: $Mn(CO)_4$: 2060, 1989, 1972, 1958; $Mn(CO)_5$: 2105, 2011, 1998 $cm^{-1}$. *(2)*, fine, orange crystals, yield 55 mg (7.4%), m.p. 146 °C (dec.).

## 9,9′-Bianthryl-10,10′-dicarbonitrile, An Aromatic π-System with Six One-electron Redox Steps[**]

By *Jürgen Heinze*[*]

The chemical and physical properties of electrochemically generated radical ions of aromatic hydrocarbons have long been investigated in detail[1]; studies on electrochemically stable di- and trications or anions on the other hand, are limited to but a few examples[2]. Aromatic systems, which exhibit more than four reversible one-electron redox steps have hitherto not been described in the literature[3]. The difficulties encountered in the electrochemical generation of multiply-charged organic ions are often due to the reactivity of impurities which remain in the solvent during usual work-up of the sample[4] or stem from competing reactions of the solvent-electrolyte system, whereby the electroactive species is trapped by electrophilic or nucleophilic addition reactions[5].

In the group of arenes, we have observed for the first time *six* reversible one-electron redox steps; namely, in 9,9′-bianthryl-10,10′-dicarbonitrile, whose ions are adequately stabilized by the two cyanide groups. The success of the experiment rested on a special working technique which enabled total exclusion of water and other protic impurities[6]. The measurements were carried out in propionitrile with tetrabutylammonium hexafluorophosphate ($TBAPF_6$, 0.1 M) as supporting electrolyte. A platinum disk electrode fused in soft glass served as working electrode. The electrochemical behavior of the compound was investigated by cyclic voltammetry (CV) (see Fig. 1 and Table 1).

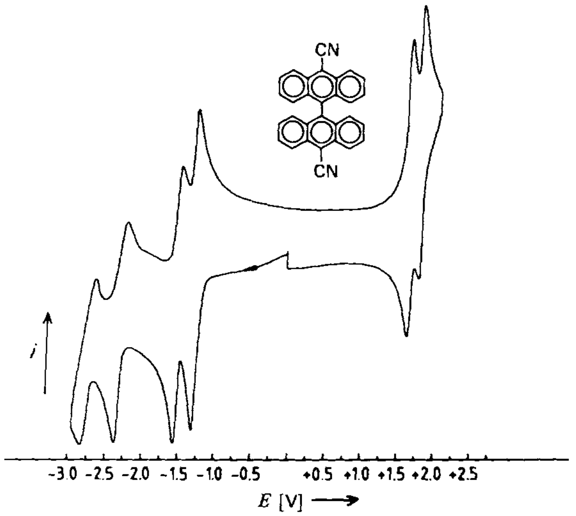

Fig. 1. Cyclovoltammogram of 9,9′-bianthryl-10,10′-dicarbonitrile in super-pure propionitrile/0.1 M $TBAPF_6$ at a Pt-disk electrode *vs.* Ag/AgCl, $v = 300$ mV/s.

Table 1. Standard potentials and heterogeneous rate constants $k_s$ of the cathodic and anodic redox steps of 9,9′-bianthryl-10,10′-dicarbonitrile in propionitrile/0.1 M $TBAPF_6$ *vs.* Ag/AgCl.

| Redox steps | $E^0$ [mV] | $\Delta E_n$ [mV] [a] | $k_s$ [cm/s] |
|---|---|---|---|
| 1 red | −1270 | — | 0.25 |
| 2 red | −1538 | 268 | 0.10 |
| 3 red | −2328 | — | 0.039 |
| 4 red | −2712 | 384 | 0.015 |
| 1 ox | 1702 | — | 0.044 |
| 2 ox | 1878 | 176 | 0.027 |
| 3 ox | (2700) | — | — |

[a] $\Delta E_n = E^0_{2n} - E^0_{2n-1}$ $(n = 1, 2)$.

The molecule (A) can be reduced in four successive one-electron transfer reactions up to the tetraanion [eq. (a)]. Surprisingly, in the anodic direction successive reversible oxidation takes place up to the dication. Above +2.7 Volt a further wave becomes visible, indicating transition to the trication. Since the electrode is passivated in this region, and,

Institut für Physikalische Chemie der Universität
Albertsstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

$$\begin{array}{ccccccccccccccc} (A^{3\oplus}) & \overset{-e}{\leftrightarrows} & A^{2\oplus} & \overset{-e}{\leftrightarrows} & A^{\oplus} & \overset{-e}{\leftrightarrows} & A & \overset{+e}{\rightleftarrows} & A^{\ominus} & \overset{+e}{\rightleftarrows} & A^{2\ominus} & \overset{+e}{\rightleftarrows} & A^{3\ominus} & \overset{+e}{\rightleftarrows} & A^{4\ominus} \\ & (E^0_{3\,\mathrm{ox}}) & & E^0_{2\,\mathrm{ox}} & & E^0_{1\,\mathrm{ox}} & & E^0_{1\,\mathrm{red}} & & E^0_{2\,\mathrm{red}} & & E^0_{3\,\mathrm{red}} & & E^0_{4\,\mathrm{red}} & \end{array} \qquad (a)$$

moreover, the solvent attacks the trication *via* a CE mechanism, this wave was not investigated. All six steps are stable in the time-scale of the electrochemical experiment. In the case of the tetraanion and the dication, however, with longer measuring times ($v < 200$ mV/s) secondary products appear, as a result of reaction with the solvent-electrolyte system.

Since the molecule is made up of two equal moieties, between which weak interactions occur, the redox potentials of the two mono- and di-ions and of the tri- and tetraanions lie relatively close to one another[7]. From the different intervals $\Delta E_{2\,\mathrm{red}} > \Delta E_{1\,\mathrm{red}} > \Delta E_{1\,\mathrm{ox}}$ a decrease in the Coulomb interaction between the centers with equal charge can be observed along the series tetraanion, dianion, and dication. On transition from the monocation to the dication the redox potential separation is only 176 mV—a finding indicative of a strong mutual twisting of the two halves of the molecule.

9,9′-Bianthryl-10,10′-dicarbonitrile is an excellent model system for the study of solvation effects in organic molecules. CV measurements in the temperature range between 20 and −60 °C showed that the $\Delta E$ value markedly diminishes with decreasing temperature. In agreement with the Born model, this supports the assumption of an enhanced solvation of the species in the higher charged states[8]. The changes in $k_s$ (Table 1), whose values are significantly smaller in the formation of the di-, tri- and tetraion, point in the same direction.

## Novel Method for the Phase-Transfer Catalyzed Sulfodechlorination of 1-Chloro-2,4-dinitrobenzene[**]

By *Markus Gisler* and *Heinrich Zollinger*[*]

*Dedicated to Professor Robert Schwyzer on the occasion of his 60th birthday*

The replacement of chlorine by a sulfonic acid residue in arenes activated by -M-substituents is an important industrial reaction. Sulfite serves as nucleophilic reagent. If the arene derivative is insoluble in water then sulfodehalogenation takes place as a two-phase reaction only at the phase boundary between the arene, usually employed as melt, and an aqueous solution of $Na_2SO_3$. The reactions are consequently slow and require seemingly drastic conditions; undesirable side reactions, *e.g.* reduction of nitro groups by sulfite, lower the yield. The yields can be improved by carrying out the reactions in boiling aqueous alcohol; thus, *Lunt*[2] achieved yields of 81% in the sulfodechlorination of 1-chloro-2,4-dinitrobenzene.

Under the usual phase-transfer conditions (reagents: tetra-*n*-butylammonium sulfate and $K_2SO_3$; $CH_2Cl_2/H_2O$ two-phase system) we did not obtain higher yields than when using the conventional method[2-4].

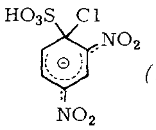
We report here on the use of protonated *tertiary* amines as phase-transfer catalysts for the sulfodechlorination. In some representative cases of one series of tri-*n*-alkylamines considerably better yields and higher purity of product were obtained on reaction of 1-chloro-2,4-dinitrobenzene with potassium disulfite ($K_2S_2O_5$) (Table 1).

Table 1. Yield and purity of 2,4-dinitrobenzenesulfonic acid in the phase-transfer catalyzed sulfodechlorination of 1-chloro-2,4-dinitrobenzene with potassium disulfite in the presence of tertiary amines (3 h, 0–8 °C).

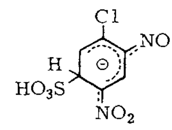
| Amine | Yield [%] [a] | Purity [%] [a] |
|---|---|---|
| Tri-*n*-propylamine | 81 | 96 |
| Tri-*n*-butylamine | 97 | 96 |
| Tri-*n*-pentylamine | 95 | 99 |
| Tri-*n*-hexylamine | 85 | 78 |
| Tri-*n*-octylamine | 76 | 87 |

[a] Yield and purity were determined UV spectroscopically.

A further series of tertiary amines proved ineffective[5]. Apparently the lipophilicity of the tertiary amines concerned plays an important role: In the case of tri-*n*-butylamine and tri-*n*-pentylamine it is apparently optimal under the reaction conditions employed. Tri-*n*-butylamine has the additional advantage that it can be readily regenerated by liquid/liquid extraction. Tri-*n*-hexylamine and tri-*n*-octylamine molecules are too large for the sulfodechlorination of 1-chloro-2,4-dinitrobenzene; the yield decreases with increasing length of the alkyl chain of the amine, and the purity of the product is reduced by irremovable amine. The organic phase turns red-violet in color during the reaction. This coloration also occurs on using quaternary ammonium compounds or crown ethers as phase-transfer catalysts. This coloration, as we have been able to establish by $^1$H-NMR spectroscopy, is caused by the Meisenheimer complex *(1)* or *(2)*[5].



*(1)*



*(2)*

*Procedure*

A solution of $K_2S_2O_5$ (2.27 g, 0.01 mol) in cold water (10 cm$^3$) is treated with $CH_2Cl_2$ (10 cm$^3$) and tri-*n*-butylamine (4.9 cm$^3$, 0.02 mol) and the mixture cooled to 0 °C. A freshly prepared solution of 1-chloro-2,4-dinitrobenzene (2.03 g, 0.01 mol) in $CH_2Cl_2$ is then added at 0 °C and the final mixture stirred for 3 h. The organic phase momentarily turns wine-red to red-violet in color and then pale yellowish-orange. After removal of the cooling-bath the reaction mixture is treated with 25 cm$^3$ of 0.8 M KOH. The precipitated product is filtered off, washed with $CH_2Cl_2$ (25 cm$^3$) and

## Trinuclear Clusters from $HCo(CO)_4$ Solutions[**]

By *Giuseppe Fachinetti*, *Laura Balocchi*, *Fernando Secco*, and *Marcella Venturini*[*]

Since its discovery by *Hieber et al.*[1a], $HCo(CO)_4$ *(1)* has been the subject of very extensive spectroscopic[1b], catalytic[1c] and kinetic studies[1d].

Surprisingly, it has now been found that, by carefully removing the gas evolved at the appropriate temperature (see *Experimental*), the trinuclear electronically unsaturated hydrido cluster $HCo_3(CO)_9$ *(3)* is the product of the thermal decomposition of *(1)* in pentane solution, together with the expected $Co_2(CO)_8$ *(2)*[1d] [eq. (a) and (b)].

$$\underset{(1)}{HCo(CO)_4} \rightarrow 1/2\,H_2 + 1/2\,\underset{(2)}{Co_2(CO)_8} \tag{a}$$

$$\underset{(1)}{HCo(CO)_4} + \underset{(2)}{Co_2(CO)_8} \rightleftarrows \underset{(3)}{HCo_3(CO)_9} + 3\,CO \tag{b}$$

This finding, and the earlier observation[2,4a] that *(3)* reacts rapidly and quantitatively with CO to give equimolar quantities of *(1)* and *(2)* (or $Co_4(CO)_{12}$ *(7)*, depending on the CO partial pressure) bring us to the important conclusion that the carbonyl species of equation (b) are in equilibrium.

*(3)* is the first hydrido-carbonyl cluster of cobalt to be *isolated* from *(1)*. The isolation of $HCo_3(CO)_9$ *(3)* may be interpreted in terms of the thermodynamically less unfavorable[3] 18e→46e transformation of *(1)* into *(3)*, as compared with the 18e→16e conversion of *(1)* into $HCo(CO)_3$. Since *(3)* can also be obtained from $Co_3(CO)_9C{-}OH$ *(4)* [eq. (c)][4a] it was suggested, by analogy with the recently demonstrated[4b] "redox condensation"[5] with $LiCo(CO)_4$ *(5)* [eq. (d)], to assume *(4)* as an intermediate in the formation *(3)* from *(1)* [eq. (e)].

Several experiments carried out between 0 and 40 °C at different concentrations of *(1)* and CO pressures between 0 and 1 bar failed to yield the thermally unstable *(4)* in observable concentrations; under these conditions *(3)* was obtained, and at higher temperatures *(7)* was the sole reaction product.

$$\underset{(4)}{Co_3(CO)_9C{-}OH} \longrightarrow CO + \underset{(3)}{HCo_3(CO)_9} \tag{c}$$

$$\underset{(5)}{LiCo(CO)_4} + \underset{(2)}{Co_2(CO)_8} \rightleftarrows \underset{(6)}{LiCo_3(CO)_{10}} + 2\,CO \tag{d}$$

$$\begin{tikzcd} \underset{(1)}{HCo(CO)_4} + \underset{(2)}{Co_2(CO)_8} \arrow[r, "-2\,CO"'] & \underset{(4)}{Co_3(CO)_9C{-}OH} \arrow[dl, "-CO"] \\ \underset{(3)}{HCo_3(CO)_9} \arrow[u, "+3\,CO"] \arrow[r, "Ar", "20\,^{\circ}C"'] & H_2 + \underset{(7)}{Co_4(CO)_{12}} \end{tikzcd} \tag{e}$$

In order to gather experimental evidence about the validity of the mechanism suggested in eq. (e), *(1)* was allowed to react with one equivalent of triethylamine and an excess of *(2)* [toluene, 40 min, 10 °C, vacuum]; the triethylamine-adduct *(8)* was formed as main product, which could also be obtained independently from *(4)* and $NEt_3$ [eq. (f) and (g)].

$$\underset{(4)}{Co_3(CO)_9C{-}OH} + NEt_3 \rightarrow \underset{(8)}{Co_3(CO)_9C{-}OH \cdot NEt_3} \tag{f}$$

$$\underset{(9)}{NEt_3 \cdot HCo(CO)_4} + \underset{(2)}{Co_2(CO)_8} \rightarrow \underset{(8)}{Co_3(CO)_9C{-}OH \cdot NEt_3} + 2\,CO \tag{g}$$

According to an X-ray structure analysis *(4)* contains an approximately sp$^3$-hybridized apical carbon atom carrying the alcoholic OH-group[6]. The reaction described in equation (g) is the first example of an amine-assisted transformation of a metal-bonded hydridic hydrogen atom into an *O*-bonded hydrogen atom. Moreover, the O-atom of a terminal CO ligand becomes an alcoholic O-atom.

To conclude: (*i*) solutions of *(1)* yield trinuclear clusters—presumably *via* attack of the proton of *(1)* at a CO-group in *(2)*[7]. It is plausible that other conditions could permit low-nuclearity clusters to exist as intermediate species in homogeneous processes such as hydroformylation or the reduction of CO to methanol[1c]. (*ii*) Reaction (d) corresponds to a cluster-assisted four-electron reduction of carbon. On a model system we have therefore observed some of the stoichiometric steps required for the reduction of CO to methanol. (*iii*) *(1)* can function as a proton- or hydride-donor[8], depending on the solvent and reaction partners. In solvents of low polarity, such as the ones used in this study, tertiary amines and edge-bridging CO-groups are believed to enhance the proton activity of *(1)*.

### *Experimental*

Unless otherwise stated, all the operations reported in this study were carried out under an atmosphere of purified argon.

*(5):* The reagent was obtained by stirring a tetrahydrofuran solution of *(2)* with anhydrous LiOH at room temperature under an atmosphere of CO for several (1—4) days until a colorless solution was obtained. After filtration, the solvent was evaporated under reduced pressure and the residue was heated to 140 °C for 1 h at *ca.* 0.05 torr. The solid residue was dissolved in ether (CAUTION: strongly exothermic reaction!), the solvent evaporated, and the residue heated again under the conditions specified above. Dissolution in a toluene/ether mixture yielded a colorless solution which was filtered. Evaporation to dryness, heating of the solid residue at 130° *in vacuo*, and washing with toluene afforded the ivory-colored, microcrystalline, pyrophoric *(5)* (70% yield; correct elemental analysis).

*(1)*: As stable 0.04 M solution in pentane: Solvent-free *(5)* was treated with the stoichiometric amount of dry HCl. Afterwards, pentane was added.

*(3)*: A 0.04 M pentane solution of *(1)* was maintained at 20 °C and intermittently connected to a vacuum line in order to evacuate the gaseous reaction products. After about 45 min the solution was cooled to −78 °C and the resulting green-maroon solid filtered off. Sublimation at 18°/0.05 torr afforded *(2)* and a green residue, which was identified by IR comparison with an authentic sample as *(3)* ($\nu_{CO}$: 2054, 2037, 1879 cm$^{-1}$ in hexane).

*(8)*: This was prepared in essentially quantitative yields from *(4)*[6] and the stoichiometric amount of $NEt_3$ at *ca.* −30° in a hexane/toluene mixture. The adduct is a dark violet solid, stable at 0 °C under an Ar atmosphere, and is extremely sensitive to moisture and air. Its IR spectrum ($\nu_{CO}$: 2063 w, 2000 vs, 1990 s, 1985 sh cm$^{-1}$, toluene solution) is similar to that of *(4)* ($\nu_{CO}$: 2095 w, 2038 vs, 2022 s, 2005 sh cm$^{-1}$ in the same solvent), except for the shift to lower wavenumbers. *(8)* gave a correct elemental analysis for cobalt. Its thermal decomposition at room temperature in toluene gave *(7)* and *(9)* according to *(8)* → 1/2 *(7)* + *(9)*.

*(9)*: Reaction of stoichiometric amounts of *(1)* and $NEt_3$ in hexane at −80 °C gave *(9)* as a colorless solid soluble in aromatic solvents. IR (toluene): $\nu_{CO}$ = 2005 w, 1950 s, 1890 vs cm$^{-1}$; $^1$H-NMR ($C_6D_6$): δ = −8.1 (s, 1 H), −2.0 (q, 6 H); −0.5 (t, 9 H).

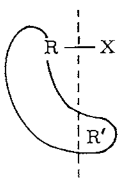
# Functional Groups at Concave Sites: Asymmetric Diels-Alder Synthesis with Almost Complete (Lewis-Acid Catalyzed) or High (Uncatalyzed) Stereoselectivity[**]

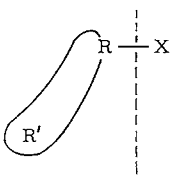
By *Günter Helmchen* and *Roland Schmierer*[*]

*Dedicated to Professor Gerhard Pfleiderer on the occasion of his 60th birthday*

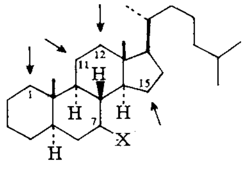
The terms concave/convex have been used casually for the characterization of molecular morphological aspects of intermolecular interactions[1]. They also enable a useful description of intramolecular spatial relationships, *e.g.* of a substituent X relative to the rest of the molecule or a further group R′ in the molecule. As illustrated by the two-dimensional "molecules" *(1)* and *(2)*, X is at a concave/convex site relative to the rest of the molecule or to R′ when X and one or more atoms ≠ H of the rest of the molecule or of R′ lie in the same half-space/different half-spaces defined by[2] the plane (– – –) dividing the X—R bond at its midpoi[3].



*(1)*



*(2)*



*(3a)*, X = α-OH
*(3b)*, X = β-OH

We have taken this classification, unambiguous for rigid and conformationally established structures, as a basis for the development of new alcohol reagents (R—X···C—OH) for diastereoface-differentiating asymmetric syntheses[4] with esters (X = planar prochiral acyloxy group); we assumed that alcohols of type *(1)* are better suited for this purpose than are those of type *(2)* (*e.g.* menthol, borneol, 2-octanol) which have generally been used so far. Thus, of a large number of chiral alcohols used in the atrolactic acid synthesis according to the McKenzie-Prelog method[5] (assignment of configuration) only in a few cases were enantiomeric yields (e.e.[4]) of >50% achieved[6]; these were unequivocally, or potentially (in the case of several possible conformers), compounds of type *(1)*. This is particularly clear in the case of the epimeric 7-cholestanols *(3)*, of which *(3a)*, e.e. = 13%, belongs to the type *(2)*, and *(3b)*, e.e. = 69%, to the type *(1)* (R′ = $C^{15}H_2$). Analogous conditions should exist for X at the positions of the steroid moiety marked by arrows[7].

The alcohols *(4)* and *(5)* are presented here as new reagents of type *(1)*. They are distinguished, apart from by their

*(4)*

[*] Priv.-Doz. Dr. G. Helmchen, Dr. R. Schmierer
Institut für Organische Chemie, Biochemie und Isotopenforschung
der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by Thomae, Biberach (Germany).

morphology, by the following properties: a) The group R can be readily varied. b) Their diastereomeric esters can usually be separated by liquid chromatography (LC). This enables a precise analysis and preparative purification of mixtures of the diastereomers. c) The alcohols are readily accessible as pure enantiomers from (+)-camphor[8]. d) Although *(4)* and *(5)* are constitutional isomers they yield inversely configurated products, since the "convex" methyl group at C-1 exerts only a small effect.

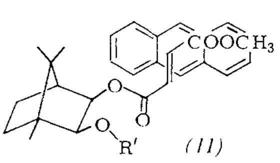
We report here[9] on the cycloaddition of the methyl fumarates *(6)* and *(7)* obtained from *(4)* and *(5)*, and (comparison with results quoted in the literature) of the menthyl ester *(8)* with anthracene (for reaction conditions, see Tables 1 and 2)[10]. The configuration of products *(9)* was determined *via* the optical rotation of the diols *(10)*[11a], prepared by reduction with $LiAlH_4$ and purified *only by LC*. In this way[11b], or still better by HPLC or $^1$H-NMR analysis (signal of the $COOCH_3$ group) of the crude product *(9)*, the diastereoselectivity was determined.

Table 1. Uncatalyzed asymmetric cycloaddition of *(6)*, *(7)* and *(8)* to anthracene [toluene, 110 °C, 5d, *c* (anthracene) = 0.1 mol/dm$^3$, *c* (dienophile) = 0.05 mol/dm$^3$, *c* (hydroquinone) = 0.005 mol/dm$^3$]. d.e. = diastereomeric yields (definition analogous to e.e. [4]).

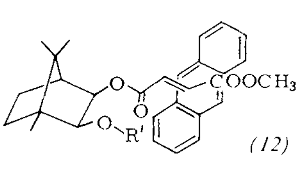
| Dienophile | Yield [%] *(9)* [a] | α [b] | d.e. [%] $^1$H-NMR/HPLC |
|---|---|---|---|
| *(8)* | 47 | 1.08 (98:2) | /<10 |
| *(6a)* | 30 | [c] (98:2) | <10/ |
| *(6b)* | 68 | 1.6 (95:5) | <10/<10 |
| *(6c)* | 90 | 1.4 (9:1) | 60/58 [d] |
| *(7c)* | 68 | 1.07 (9:1) | 34/ [e] |

[a] The products were isolated by medium-pressure chromatography: For apparatus see *G. Helmchen, G. Nill, D. Flockerzi, W. Schühle, M. S. K. Youssef*, Angew. Chem. *91*, 64 (1979); Angew. Chem. Int. Ed. Engl. *18*, 62 (1979). [b] α = chromatographic separation factor, determined by HPLC (apparatus, see [a]); eluent: petroleum ether/low boiling ethyl acetate in the ratio given in brackets. [c] No separation of the diastereomers. [d] Absolute configuration of the preferred diastereomer: 11*S*, 12*S*. [e] Absolute configuration of the preferred diastereomer: 11*R* 12*R*.

With one exception[12a], e.e. = 39%, only a small e.e. has so for been achieved (normal pressure: <13%; high pressure: <21%)[5, 12b] in the uncatalyzed Diels-Alder reaction. This is also true (Table 1) for *(6a)* and *(6b)* and, as expected, for *(8)*. Thus, anthracene is not an atypical diene. It would seem significant that in the case of *(6c)*, high diastereoselectivity is accompanied by increased reactivity. Assuming transition states with the topography *(11)* (preferred) and *(12)*[13] this points both to effective diastereoface-differentiated[4] shielding as well as to electronic and conformational influence of the enone system by the *N*-phenylcarbamoyl group (for an analogous observation see[7a]). As expected, with *(7c)* the inversely configurated product is obtained, but in poorer yields and with lower diastereoselectivity.



*(11)*



*(12)*

The Lewis acid-catalyzed reaction of fumarates and acrylates with butadiene or cyclopentadiene is already fairly stereoselective, d.e. ≅ 50–80%[5], in the case of menthyl esters, so that here too the reaction of *(8)* with anthracene (Table 2) is typical. With *(6a)* and *(6c)*, complete or almost complete asymmetric induction, respectively, is achieved[14]; once again, *(6c)* is particularly reactive. Temperature-dependence of the diastereomeric yields[4] observed here—it is greater at −30 °C or at −78 °C than at 0 °C [the small variation in the case of *(6a)* is significant]—has hitherto not been reported. The configurational relationships are the same for the uncatalyzed and the catalyzed reaction.

Table 2. Lewis acid-catalyzed cycloaddition of *(6)*, *(7)* and *(8)* to anthracene [$CH_2Cl_2$, 1d, 1 equivalent $AlCl_3$ (with respect to the dienophile); for concentrations see Table 1]: absolute configuration of the preferred diastereomer: 11*S*, 12*S*.

| Dienophile | *T* [°C] | Yield [%] *(9)* [b] | d.e. [%] $^1$H-NMR/HPLC/o.p. [c] |
|---|---|---|---|
| *(6a)* | 0 | 74 | 98/—/— |
| | −30 | 96 | >99/—/97 |
| | −78 | 58 | 98/—/— |
| | −78 [a] | [d] | |
| *(6b)* | 0 | [d] | |
| *(6c)* | 0 | 0 | |
| | 0 [a] | 100 | 86/86/— |
| | −30 [a] | 100 | 99/—/— |
| | −78 [a] | 96 | 66/—/— |
| *(7c)* | 0 | 0 | |
| | 0 [a] | 100 | 92/—/94 [e] |
| | −30 [a] | <10 | |
| *(8)* | +25 | 92 | —/—/62 |
| | 0 | 90 | —/76/82 |
| | −30 | 21 | —/—/76 |

[a] 2 equivalents $AlCl_3$. [b] See footnote [a] in Table 1. [c] d.e. of *(9)* = optical purity (o.p.) [4] of the diol *(10)* obtained by reduction of the unseparated diastereomers *(9)*. This value is less accurate than the other two, since the optical rotation of *(10)* is relatively small [11b]. [d] Reaction products: *(9)*, R′ = H. [e] Absolute configuration of the preferred diastereomer: 11*R*, 12*R*.

Ethanol [11a] is not a suitable solvent, since (±)-*(10)* is considerably less soluble than (+)-*(10)*.

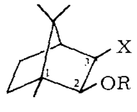
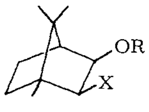
## Functional Groups at Concave Sites: Asymmetric Alkylation of Esters with Very High Stereoselectivity and Reversal of Configuration by Change of Solvent[**]

By *Roland Schmierer, Gregor Grotemeier, Günter Helmchen*, and *Adel Selim*[*]

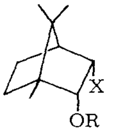
A new concept for the development of reagents for asymmetric syntheses first proved successful in the case of Diels-Alder reactions[1]. We report here on experiments with reagents *(1)*—*(3)*, which are closely related to those quoted in[1], in the α-alkylation of the esters *(4)*—*(6)* to products *(7)*—*(9)* *via* lithium enolates. An asymmetric induction in this important C—C coupling was previously achieved in enantiomeric yields (e.e.) of 7 to 50%[2] only for the very special case of esters *(10)*.



*(1)*, R = H
*(4)*, R = $COCH_2R^1$
*(7)*, R = $COCHR^1R^2$



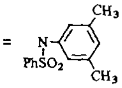
*(2)*, R = H
*(5)*, R = $COCH_2R^1$
*(8)*, R = $COCHR^1R^2$

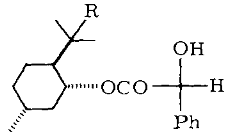


*(3)*, R = H
*(6)*, R = $COCH_2R^1$
*(9)*, R = $COCHR^1R^2$

*(a)*, X =
$OC(=O)-N(CH_3)Ph$

*(b)*, X =





*(10a)*, R = H
*(10b)*, R = Ph

The esters *(4)*—*(6)*[3] were metalated with lithium cyclohexylisopropylamide (LiCHIPA) at −78 °C in tetrahydrofuran (THF) or THF/hexamethylphosphoric triamide (HMPT) 4:1[4]. In all cases, clear, colorless or lemon-yellow colored (sulfonamides) solutions were formed. These were allowed to react with alkylating agents $R^2$—X′ (X′ = Br or I, addition of 1 equivalent of HMPT) by warming to −40 °C and maintaining the mixture at this temperature (TLC control). The products *(7)*—*(9)* were isolated by extraction and analyzed by HPLC and/or $^1$H-NMR. Despite only moderate separation factors (α ≅ 1.1—1.3)[5], esters *(7)*—*(9)* could by obtained pure on a gram scale by preparative medium-pressure liquid chromatography because of initially high enrichment. On reduction [$Ca(BH_4)_2$[6a] or $LiAlH_4$[6b]] they gave enantiomerically pure alcohols $R^1R^2CH—CH_2OH$[7], which are valuable chiral synthons, particularly for the synthesis of natural products[8].

The α-alkylation proceeds in very good yields and with excellent diastereoselectivities (Table 1). In THF as solvent a diastereoselectivity of ≥ 90:10 is achieved with the urethanes *(4a)*, independent of the nature of groups $R^1$ and $R^2$. Other than in the case of the Diels-Alder reactions[1], a greater selectivity is achieved in these alkylations with the 2- than with the 3-acyloxybornanes.

Table 1. Reaction of the lithium enolates of the esters *(4)*—*(6)* with alkylating reagents $R^2$—X′ to give esters *(7)*—*(9)*; solvent: THF (A) or THF-HMPT 4:1 (B) [a].

| No. | Educt $R^1$ | $R^2X'$ | Solvent | Diastereoselectivity HPLC/ $^1$H-NMR | Configuration [b] | Yield [c] [%] |

[a] The solvent contained *ca.* 5% hexane. [b] Absolute configuration of the chirality center of the acyl group of *(7)*—*(9)* determined *via* the optical rotation of the alcohols $R^1R^2CH—CH_2OH$ obtained by reduction; No. 1—9, 12—6: [3a]; No. 10, 11, 17, 18: [8]; No. 19—22: Assumption of same absolute configuration for 2-methyl-1-octadecanol and -hexadecanol of the same sign of rotation. [c] Total yield of pure, chromatographically isolated esters *(7)*—*(9)*. Values in brackets: yields corrected with respect to recovered educt. [d] Determined *via* the optical rotation of 2-methyl-3-phenyl-1-propanol obtained by reduction: $[\alpha]_D^{22} = +9.9°$ ($c = 3.7$, $CHCl_3$); the reference sample was prepared by reduction of (+)-2-benzylpropionic acid [5b] with $LiAlH_4$: $[\alpha]_D^{22} = -10.0°$ ($c = 4.1$, $CHCl_3$).

The sulfonamides *(4b)* and *(6b)* show particularly remarkable properties (cf. Table 1, Nos 19—22): *In THF and in THF-HMPT (4:1) as solvent, products with inverse configuration are obtained, with almost complete asymmetric induction in each case.* Thus, it was possible, to our knowledge for the first time in this way, to prepare both enantiomers from one compound. The same solvent effect also occurs, albeit to a lesser extent, in the case of the urethanes *(4a)* and *(5a)* (Table 1). Corresponding experiments have already been carried out with chiral oxazolines[9a] and hydrazones[9b]; addition of HMPT led to considerable reduction in the selectivity, and only in one case to reversal of configuration; however, the diastereoselectivity (58:42) was not significant[9b].

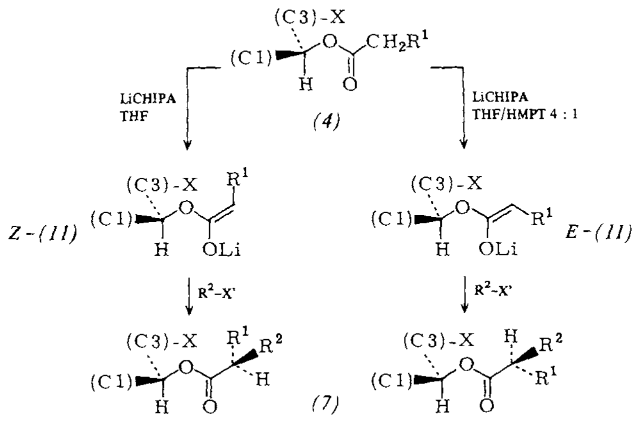
We thank Frl. Dipl.-Chem. *G. Heiligenmann* for the examples No. 10, 11, 17, 18 (Table 1). Part of this work was presented in lectures at the Universities of Göttingen (June 2, 1980), Freiburg (June 9, 1980), and München (July 25, 1980).



Scheme 1. Configurations of educt, intermediates and products in the asymmetric alkylation of the esters *(4)*.

The configurational relationships can all be explained on the basis of the following *hypotheses* (cf. Scheme 1):

1) According to *Ireland* and *Willard* the esters Alkyl-$CH_2$—COOR are deprotonated with lithium amides in THF preferably to *Z*-, in THF-HMPT (4:1) preferably to *E*-enolates (selectivity in each case$\geq$4:1)[10]; thus, *Z*- or *E-(11)* can be generated selectively from *(4)*.

2) The conformation of the H—C—O—C—OLi group parallels that of the corresponding H—C—O—C=O group of esters[11] (torsional angle about the bold bonds $\cong 0°$).

3) Attack of the electrophile $R^2$—X at the enolate is blocked by the group X; that is in the case of *(11)* it takes place from the front side. Under otherwise equal conditions, therefore, *Z*- and *E*-enolates are alkylated to inversely configurated products.

4) The esters *(4)* and *(5)* as well as *(4)* and *(6)* are heterochiral[12] with respect to the X—C—$\overset{\bullet}{C}$H—O group ($\overset{\bullet}{C}$ = C-2 or C-3), and therefore under the same conditions give products with inverse configuration of the acyl group.

5) Inversely configurated products are also formed in the reactions of *(4)*—*(6)*with $R^2$—X′ when $R^1 = R^a$, $R^2 = R^b$ and $R^1 = R^b$, $R^2 = R^a$ (cf. references cited in[9a]).

Other than in the case of the systems described in[9], complexation of the lithium by X in *(4)*—*(6)* does not seem to play an important role. This is supported by results obtained with esters of 2-aminoalcohols [*(1)*, X = *N*(alkyl)aryl; *N*-alkylephedrine] and 1,2-diols and their derivatives [*(1)*, *(2)*, X = *O*-alkyl and $O(CH_2)_2OCH_3$, 2,2′-binaphthol, *trans*-1,2-cyclohexandiol][13].

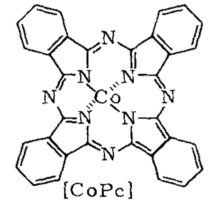
# Selective Reduction of the Nitro to the Amino Functional Group by means of the Phthalocyaninecobalt (I) Anion; Synthesis of N-Heterocycles and Alkaloids

By *Heiner Eckert*[*]

The directed transformation of functional groups, while other functionalties with similar reaction specifity are retained intact, is one of the most frequently encountered problems in synthetic organic chemistry. The reduction of nitro to amino groups is the best route to the important aromatic amine class of compounds; it is however well known[1a] that this is often accompanied by reactions of other functional groups (C=C, >C=O, —C≡N, aryl halides)[1]. Under basic reaction conditions rearrangement products and products arising from *N*-coupling are often produced in considerable amounts[1a,2]. The reduction of unsaturated compounds in the presence of metallic macrocycles of the vitamin $B_{12}$ structure type, although not with stable phthalocyaninemetal anions, has already been described[3].

Aromatic and aliphatic nitro compounds *(1)* can be reduced to primary amines *(2)* at room temperature using weakly basic conditions in protic solvents *e.g.* alcohols, in the presence of the phthalocyaninecobalt (I) anion$[Co^IPc]^{\ominus}$. The reaction proceeds cleanly and selectively: the following functional groups do not react; arenes and aryl halides, C=C double bonds even when activated, cyanides and isocyanides, aldehydes and ketones, carboxylic acid esters and am-

$$\underset{(1)}{O_2N{-}R{-}X} \xrightarrow[\text{MeOH}]{6\,[Co^IPc]^{\ominus}} \underset{(2)}{H_2N{-}R{-}X}$$



[CoPc]

ides (see Table 1). The high yields, in particular with *(1g)* and *(1i)* which have a strong tendency to form side products, indicate the extremely high selectivity[4a] of the stable phthalocyaninecobalt (I) anion. Apart from its role in reduction reactions $[Co^IPc]^\ominus$ only participates in substitution reactions[4a] with alkyl[4b] or acyl halides[4a]. Control experiments indicated that even at long reaction times, hexanedinitrile *(3)* and ethyl cinnamate *(4)* were not attacked by $[Co^IPc]^\ominus$; only the transesterification of *(4)* was observed. Both the characteristic selectivity and reactivity parameter "supernucleophilicity relative to alkyl halides" ($n_{CH_3I} = 10.8$)[5a] and low reduction potential (−0.37 V)[5b] of the phthalocyaninecobalt(I)anion, have been determined in preliminary investigations of its mechanism of action[6] and for reduction processes.

Table 1. Selective reduction of nitro compounds *(1)*, which contain other reactive functional groups, to amines *(2)* by means of $[Co^IPc]^\ominus$ at 20–25 °C in methanol.

| | R | X | t [h] | Yield [%] |

[a] EtOH as Solvent.

As a result of its high selectivity and mild conditions of reaction, this reduction method is highly suitable for use in the synthesis of *N*-heterocycles by the Friedländer reaction[7]. The nitroaldehydes *(1i)* or *(1k)* were reduced in this way in a one-pot reaction and, without being isolated, the sensitive aldehydes produced were condensed with the ketones *(5)*; it was therefore unnecessary to protect the reactive functional groups in the intermediates (Table 2). The synthesis of the alkaloid comptothecine *(9)* and its derivatives[8], which are powerful antitumor agents, was successfully carried out by condensing *(1i)* or *(1k)* with *(7)* to give the tetracyclic systems *(8a)* or *(8b)* respectively (A-B-C-D) with yields of 62 and 51% respectively; it is particularly noteworthy that *(7)* contains groups which can be further reduced. The classic, base catalyzed Friedländer reaction using freshly prepared *(2i)* and *(7)* proceeds in only 20% yield and leads to the formation of side products which are difficult to separate[8a].

*(9)*

### *Procedure*

*(2)*: Under a nitrogen atmosphere, Li[CoPc]·4.5 tetrahydrofuran (THF)[9] (17–18 g, 19–20 mmol) is dissolved in 100 cm³ $N_2$-saturated methanol. The deep green solution is treated with 3.0 mmol *(1)* and stirred at 20–25 °C (Table 1). 10 cm³ $H_2O$ is then poured into the reaction mixture, $CO_2$ and air passed in for 5 min and the mixture centrifuged to separate the deep blue precipitate (5 min; 3000 rpm) which is then washed twice with methanol. The combined centrifugates are then concentrated and the residue distributed between ether and water. The organic phase is dried over $Na_2SO_4$ and the solvent evaporated; compound *(2)* remains. For compound *(2a)* the mixture is not treated with $H_2O$, but with 50 cm³ of 1 N hydrochloric acid and centrifuged. The centrifugate is then made alkaline with NaOH and extracted with ether. The ether phase is extracted with 10 cm³ of 1 N hydrochloric acid and water and the combined aqueous extracts concentrated, by means of which *(2a)*·HCl remains.

*(6)*: Under a $N_2$ atmosphere, Li[CoPc]·4.5 THF[9] (12–13 g, 13–14 mmol) is dissolved in 70 cm³ $N_2$-saturated methanol. The deep green solution is treated with an excess of *(6)* (*ca.* 50 mmol), 2.0 mmol *(1i)* or *(1k)* and stirred at 20–25 °C (see Table 2). Following this, 5 cm³ of $H_2O$ is added to the green reaction mixture, $CO_2$ and air passed into the mixture for 5 min, before being centrifuged (5 min; 3000 rpm) from the deep blue precipitate, which is then washed once with ethanol and twice with ether. The combined centrifugates are concentrated, the still damp residue distributed between 0.5 N hydrochloric acid and hexane, and the hexane phase extracted twice with water. The combined aqueous phases are washed with hexane, neutralized with 5 N NaOH and extracted with ether. The ether extract is dried over KOH and concentrated; *(6)* remains behind.

*(8a)*: Under a nitrogen atmosphere, Li[CoPc]·4.5 THF[9] (11.9 g, 13.2 mmol) is dissolved in 70 cm³ methanol which had been saturated with $N_2$. The deep green solution is treated with *(1i)* (302 mg, 2.0 mmol) and *(7)* (376 mg, 2.0 mmol)[8a] and stirred at 20–22 °C for 260 h. Following this, 5 cm³ $H_2O$ is added to the reaction mixture, $CO_2$ and air passed in for 5 mins and the mixture then centrifuged (5 min, 3000 rpm) from the deep blue precipitate; the latter is washed with warm (50 °C) nitrobenzene (5 × 40 cm³). Further washing with methanol (3 × 40 cm³) and ether (2 × 40 cm³) and drying at 60 °C yields $Co^{II}Pc$ (7.35 g, 98%). Solvent is removed from the combined nitrobenzene centrifugates and the residue triturated in methanol and filtered. Yield 340 mg (62%) *(8a)*. M.p. = 340 °C (decomp.).

## "Magnetochemical Series" for Lanthanoid Compounds[**]

By *Werner Urland*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

*Klemm* was the first to make use of magnetic measurements to determine the "valence" of rare earth elements in compounds where this was not immediately apparent from their composition (*e.g.* $Ce^{IV}O_2$, $Ce^{III}S_2$)[1]. In this article it will be shown that magnetochemistry also enables statements to be made about the chemical bonding in lanthanoid compounds.

Powdered samples of NT-$CsTmO_2$[2a] (NT ≙ low temperature form), NT-$CsYbO_2$[2b], $CsAPrF_6$ (A = K, Rb)[2c], $Cs_2AHoF_6$ (A = Na,K, Rb)[2d], $Cs_2LiTmX_6$ (X = Cl, Br, I)[2e], $Cs_2NaTmI_6$[2e], $Cs_2KTmX_6$ (X = Cl, Br)[2f], $CsATmF_6$ (A = Na, K, Rb)[2f], $Cs_2AYbF_6$ (A = Na, K, Rb)[2g] and $Cs_2NaYbBr_6$[2g] were studied over the temperature range of 3–250 K using the Faraday method. Their magnetic behaviour could be explained applying a model of paramagnetism[3a] in which the influence of the crystal field was treated by the Angular Overlap (AO) model[3b]. The conventional crystal field parameters can be expressed in terms of the AO parameters, $e_\sigma(R)$ and $e_\pi(R)$, which are directly related to the $\sigma$- and $\pi$-covalent contribution to the chemical bonding and should be proportional to the square of the respective overlap integral[3b]. If it is assumed, on the basis of earlier investigations[4], that the value of the ratio, $e_\sigma(R)/e_\pi(R)$, lies between 2 and 6 for all the compounds considered here, then the values of $e_\sigma(R)$ for the alkali metal thulium halides can be determined unequivocally from measurements of the magnetic susceptibility. From these considerations, a ligand "magnetochemical series" can be drawn up. Table 1 shows values of $e_\sigma(R)$ compared with those of the overlap integrals $S_\sigma^2(R)$. The values of $S_\sigma^2(R)$ for the quaternary sodium compounds[2e,f] were calculated from[5] using the 4f-$Er^{3+}$ and 4f-$Yb^{3+}$ functions[6a] respectively, and the corresponding np-ligand function of $X^-$ [6b] (for NT-$CsTmO_2$ of $O^{2-}$, 2p solution function for the +2 potential well[6c]) for the respective $Tm^{3+}$-ligand ion distance $R$. Then the average value was formed. Since the Hartree-Fock 5p-function for $I^-$ could not be found in the literature, the calculation of the respective overlap integrals was not performed in this case.

Table 1. AO parameters $e_\sigma(R)$, overlap integrals $S_\sigma^2(R)$ and $Tm^{3+}$ ligand ion distances $R$, for NT-$CsTmO_2$ and $Cs_2NaTmX_6$ (X = F, Cl, Br, I).

| Compound | $e_\sigma(R)$ [$cm^{-1}$] | $S_\sigma^2(R) \cdot 10^4$ | $R$ [pm] | Ref. |
|---|---|---|---|---|
| NT-$CsTmO_2$ | 450 [a] | 2.47 | 219.8 | [2a] |
| $Cs_2NaTmF_6$ | 450 ± 10 | 2.36 | 217 [b] | [2f] |
| $Cs_2NaTmCl_6$ | 215 ± 10 [c] | 0.81 | 269 [d] | [2e,f] |
| $Cs_2NaTmBr_6$ | 145 ± 8 [c] | 0.60 | 284 [d] | [2e,f] |
| $Cs_2NaTmI_6$ | 125 ± 5 | — | 308 [d] | [2e] |

[a] Without determination of the errors involved. [b] cf. [7]. [c] Average value, including the values for lithium and potassium compounds. [d] Sum of the ionic radii of $Tm^{3+}$ and ligand ion for the coordination number 6: *R. D. Shannon*, Acta Crystallogr. *A 32*, 751 (1976).

With the exception of NT-$CsYbO_2$[2b] the unequivocal determination of $e_\sigma(R)$ from magnetic studies of this type did not prove possible for the remaining compounds. As an approximation a value of $e_\sigma(R)/e_\pi(R) = 3$ can be used for the halides[4a]. The values of $e_\sigma(R)$ for the ratio $e_\sigma(R)/e_\pi(R) = 3$ also allow the ligands to be arranged in a "magnetochemical series" (Table 2).

Table 2. AO parameters $e_\sigma(R)$ for $e_\sigma(R)/e_\pi(R) = 3$, overlap integrals $S_\sigma^2(R)$, and $Yb^{3+}$-ligand ion distances $R$ for NT-$CsYbO_2$ and $Cs_2NaYbX_6$ (X = F, Cl, Br).

| Compound | $e_\sigma(R)$ [$cm^{-1}$] | $S_\sigma^2(R) \cdot 10^4$ | $R$ [pm] | Ref. |
|---|---|---|---|---|
| NT-$CsYbO_2$ | 360 ± 30 | 2.18 | 219 | [2b] |
| $Cs_2NaYbF_6$ | 360 ± 30 | 2.11 | 216 | [2g] |
| $Cs_2NaYbCl_6$ | 252 [a] | 0.72 | 267 [b] | [2g,8] |
| $Cs_2NaYbBr_6$ | 160 ± 10 | 0.59 | 278 | [2g] |

[a] For $e_\sigma(R)/e_\pi(R) = 1.62$. [b] *G. Meyer*, personal communication.

When the ligands are ordered according to increasing $e_\sigma(R)$ values, (cf. Tables 1 and 2), the following "magnetochemical series" arises:

$$I^- < Br^- < Cl^- < F^- \approx O^{2-}$$

Table 3. AO parameters $e_\sigma(R)$ for $e_\sigma(R)/e_\pi(R) = 3$, overlap integrals $S_\sigma^2(R)$ and $M^{3+}$—$F^-$ distances $R$ for $Cs_2AMF_6$ (A = K, Rb; M = Pr, Ho, Tm, Yb).

| Compound | $e_\sigma(R)$ [$cm^{-1}$] | $S_\sigma^2(R) \cdot 10^4$ | $R$ [pm] | Ref. |
|---|---|---|---|---|
| $Cs_2KPrF_6$ | 720 ± 30 | 6.90 | 227 [a] | [2c] |
| $Cs_2RbPrF_6$ | 690 ± 30 | | | |
| $Cs_2KHoF_6$ | 420 ± 30 | 2.88 [b] | 219 | [2d] |
| $Cs_2RbHoF_6$ | | | | |
| $Cs_2KTmF_6$ | 420 ± 10 | 2.36 | 217 [a] | [2f] |
| $Cs_2RbTmF_6$ | 390 ± 10 | | | |
| $Cs_2KYbF_6$ | 360 ± 30 | 2.11 | 216 [a] | [2g] |
| $Cs_2RbYbF_6$ | | | | |

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

From Table 3 it can be seen that the values of $e_\sigma(R)$ decrease with increasing atomic number of the lanthanoid element, and in this way a similar "magnetochemical series" for the central ions also follows, which corresponds to the pattern of the "lanthanoid contraction".

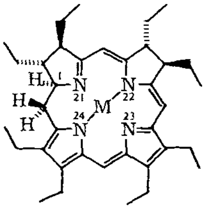
## Conformational Coupling between Ring A and Ring B in Isobacteriochlorins[**]

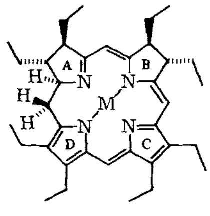
By *Christoph Kratky, Christof Angst,* and *Jon Eigill Johansen*[*]

Of the 16 possible isomers of nickel(II)octaethyl-1,2,3,7,8,20-hexahydroporphyrinate *(1),* almost exclusively the diastereomers *tttt-(1)* and *ttct-(1)* were obtained from complexation and tautomerization reactions[1a]. Their crystal structures revealed a conformational coupling between rings A and B: The ethyl substituents on both ring A, as well as on ring B, have diequatorial conformation in the *ttct*-isomer, whereas in *tttt-(1)* the substituents on ring A are diequatorial, those on ring B diaxal. At first we assumed that the conformational coupling is a result of the perturbation in the planarity of the porphyrin system (due to $sp^3$-hybridization of C-1 in ring A), which propagates *via* the coordinated nickel(II) ion to ring B.

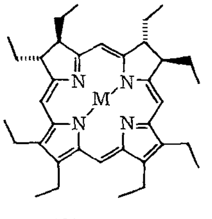
At the tetrahydro stage predominantly isobacteriochlorins and nickel(II) isobacteriochlorinates also having *trans* oriented vicinal ethyl groups on rings A and B were observed[1]. Octaethylisobacteriochlorin *(2)* and its metal complexes, *e.g. (3),* have been proposed as synthetically convenient models for the natural product sirohydrochlorin[2], with previous experiments being restricted to mixtures of the *ttt*- and *tct*-isomers[3]. In the case of the nickel complexes *(3),* the separation of the mixture was achieved by HPLC[1a]. We have now been able to separate the (HPL chromatographically inseparable) mixture of the free ligands *(2)* by fractional crystallization[4].



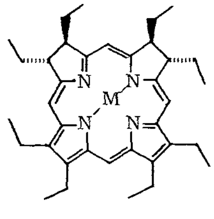
*tttt-(1),* M = Ni



*ttct-(1),* M = Ni



*ttt-(2),* M = 2 H
*ttt-(3),* M = Ni



*tct-(2),* M = 2 H
*tct-(3),* M = Ni

Remarkably, the crystal structures of the nickel complexes *ttt-(3)* and *tct-(3)* show the substituents on rings A and B (Fig. 1) in a surprisingly similar conformation to *tttt-(1)* and *ttct(1),* respectively. In the free ligands *ttt-(2)* and *tct-(2)* (Fig. 1), *trans* vicinal ethyl groups always have diaxial conformation and thus, in contrast to *(3),* show no conformational coupling.

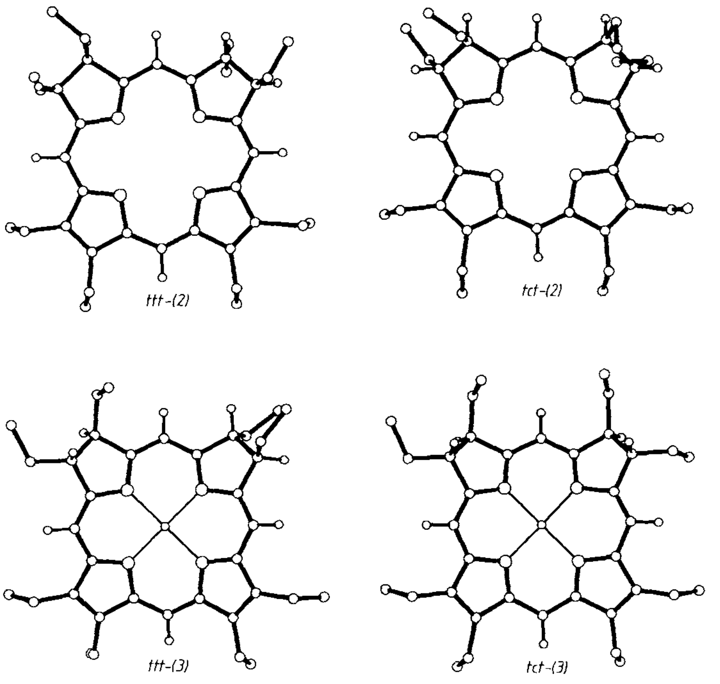


Fig. 1. Crystal structures of some isobacteriochlorins. Projection into the plane of the atoms N-21—N-22—N-23. *ttt-(2):* from ether/methanol, monoclinic, $P2_1/c$, $a=16.43$, $b=8.16$, $c=24.67$ Å, $\beta=97.68°$, $Z=4$, $\varrho_x=1.10$ g cm$^{-3}$, 4564 reflections refined (1001 with $I>2.5\sigma(I)$), $R=0.14$; *tct-(2):* from ether/methanol, orthorhombic, Pbca, $a=12.38$, $b=22.14$, $c=24.69$ Å, $Z=8$, $\varrho_x=1.06$ g cm$^{-3}$, 5310 reflections refined (1213 with $I>2.5\sigma(I)$), $R=0.13$; *ttt-(3):* from ether/hexane, triclinic, $P\bar{1}$, $a=8.73$, $b=13.12$, $c=15.27$ Å, $\alpha=105.79$, $\beta=102.52$, $\gamma=101.31°$, $Z=2$, $\varrho_x=1.26$ g cm$^{-3}$, 5578 reflections refined (4481 with $I>2.5\sigma(I)$), $R=0.05$. *tct-(3):* from ethyl acetate, monoclinic, $P2_1/c$, $a=9.66$, $b=20.89$, $c=15.92$ Å, $\beta=99.97°$, $Z=4$, $\varrho_x=1.26$ g cm$^{-3}$, 5765 reflections refined (1019 with $I>2.5\sigma(I)$), $R=0.10$ (see [5]).

[**] This work was supported by the Österreichische Fonds zur Förderung der wissenschaftlichen Forschung (Project No. 3763), the Österreichische Akademie der Wissenschaften, the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung, and the Norwegian Research Council of Science and Technology (Travelling scholarship for *J. E. J.*). We thank Prof. *A. Eschenmoser* for stimulating advice and support of this work.

On incorporation of nickel(II) into the isobacteriochlorin ligand system the macrocycle collapses into a strongly contracted conformation. The "closing up" of the four nitrogen atoms, enforced by the coordinative requirements of the small nickel(II) central atom, effects considerable deformation of the entire porphyrin ring: Oppositely situated five-membered rings are mutually twisted by *ca.* 50° with respect to an axis through their nitrogen atoms[5], leading to the formation of a strongly puckered macrocycle with approximate $D_{2d}$ symmetry (Fig. 2). The conformational coupling between rings A and B observed in the nickel complexes *(1)* and *(3)* is an immediate manifestation of this $D_{2d}$-deformation, which is not observed [*ttt-(2)*] or, if so, only to a very slight extent [*tct-(2)*] in the free ligands[5].

This $D_{2d}$-type deformation with small central atoms[6] (nickel(II)[7], low spin cobalt[8a] and iron[8b]) was occasionally observed, though without such far-reaching stereochemical consequences, in unhydrogenated metal porphyrinates.

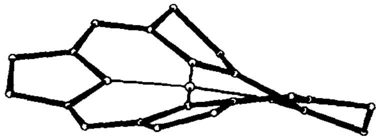

Fig. 2. Conformation of the hydroporphyrin system in the crystal structure of *ttt-(3)*.

The crystal structures[1a] (Fig. 1) suggest that a *diequatorial* conformation of *trans* vicinal ethyl groups is energetically preferred over a diaxial conformation in the (contracted) nickel complexes *(1)* and *(3)*, since the maximum number of diequatorial pairs of ethyl substituents consistent with the overall conformation of the macrocycle is always found. This is in excellent agreement with the observed relative thermodynamic stabilities: *tttt-(1)* and *ttt-(3)* can epimerize to over 50% into *ttct-(1)*[1a] and *tct-(3)*, respectively, whereas *ttct-(1)* and *tct-(3)* are hardly converted under the same conditions[9]. In the conformationally unfixed[10] free ligands *(2)*, on the other hand, the vicinal ethyl groups always have *diaxial* conformation. This could explain the difficulties encountered on attempting a separation of *ttt-(2)* and *tct-(2)* by HPLC.

## Chalcogenide Iodides of Arsenic[**]

By *Rüdiger Kniep* and *Horst Dieter Reski*[*]

*Dedicated to Professor Wilhelm Klemm on the occasion of his 85th birthday*

Investigations in ternary systems As-(S,Se,Te)-I have hitherto been decided, in particular, by the interest attached to relatively stable semiconducting chalcogenide iodide *glasses;* data on the composition and structure of *crystalline* phases are sparse and by no means free of inconsistencies[1]. It seemed worthwhile to us to narrow this "gap" regarding the well-documented and still topical class of compounds comprising the Sb- and Bi-chalcogenide halides of the SbSI-type[2a] (ferro- and photoelectric properties[2b]).

According to our thermoanalytical and X-ray crystallographic findings (cf. Table 1) the quasibinary sections $As_2Te_3$-$AsI_3$ and $As_2Se_3$-$AsI_3$ of the respective ternary systems contain the thermodynamically stable phases: $As_4Te_5I_2$ (m.p. incongruent 303 °C), α-AsTeI[3a] (m.p. incongruent 281 °C), and α-AsSeI (m.p. incongruent 221 °C); in addition, the metastable phases β-AsTeI and β-AsSeI could also be isolated. The existence of the stable phase AsSI[3b] is confirmed by us.

The growth of single crystals of the above mentioned arsenic chalcogenide iodides is rendered difficult by the tendency of such systems to form relatively stable glasses; success was achieved as follows: α-AsTeI, black metallic, monoclinic-prismatic crystals; hydrothermally[4a] (HI 67%, 65% packing, 155 → 145 °C, 42d)[4b]. β-AsTeI, black metallic, compact crystals; primary crystallizate on cooling from melts ("$As_8Te_7I_5$") from *ca.* 330 °C (4d); shortest possible post-annealing phase, since β-AsTeI is already completely transformed into α-AsTeI after, 18 h at *e.g.*, 180 °C. $As_4Te_5I_2$, metallic (somewhat like $As_2Te_3$), platelike crystals with prominent laminar cleavage; on cooling of melts (60 mol-% $As_2Te_3$/40 mol-% $AsI_3$) from *ca.* 320 °C (7d). α-AsSeI, in transmitted light dark-red, in reflected light metallic, needle-shaped with pronounced fibrillar cleavage; after cooling (7—8d) of AsSeI melts (320 °C), incorporated in a wax-like ma-

[a] Crystal structure analysis: MoKα, Syntex $P2_1$, ω-scan, $F_0 > 3.92\sigma_F$, E-XTL program system *α-AsTeI:* 2563 symmetry independent reflections, 1219 significant, $2\theta_{max} = 80°$, $R = 8.7\%$ (with empirical absorption corrections); *β-AsTeI:* 40 symmetry independent reflections, 39 significant $2\theta_{max} = 75°$, $R = 8.9\%$ (without absorption corrections); *α-AsSeI:* 1474 symmetry independent reflections, 865 significant, $2\theta_{max} = 65°$, $R = 6.8\%$ (with empirical absorption corrections). [b] Photographic investigations on single crystals. [c] Lattice constants from X-ray powder data (isotypic relation with α-AsSeI).

The crystal structures of α-AsTeI, β-AsTeI and α-AsSeI were determined (cf. Table 1). Figure 1 shows the macromolecular (1/∞) structural units of α-AsTeI and α-AsSeI. α-AsTeI shows the same double chain structure as is found in SbSI[2a] and corresponding isotypic 5B-6B-7B-compounds[1]. The $[As_2Te_2I_2]_\infty$ double chain in α-AsSeI is degenerated to an AsSe spiral with $2_1$ symmetry and still only terminal iodine atoms; the coordination and bond geometries change on (formal) transition from the α-AsTeI to the α-AsSeI structural unit as follows (cf. also caption to Fig. 1): chalcogen (C.N.3, trig. pyr) → (C.N.2, angular[6]); arsenic (C.N. 5, tetrag. pyr.) → (C.N. 3, trig. pyr.); iodine (CN. 2, bridging) → (C.N. 1, terminal). Figure 2 shows the projections of the structural assemblies of α-AsTeI and α-AsSeI in the direction of view of the (1/∞) structural units in comparison with the corresponding projection on the SbSI structure[2a]. SbSI and α-AsTeI show different packing of the same macromolecular structural units in the structural assemblies, while α-AsTeI and α-AsSeI show a comparable packing of different (modified) structural units; in general the crystal structures of α-AsTeI and α-AsSeI can thus be regarded as "variations of the SbSI type".

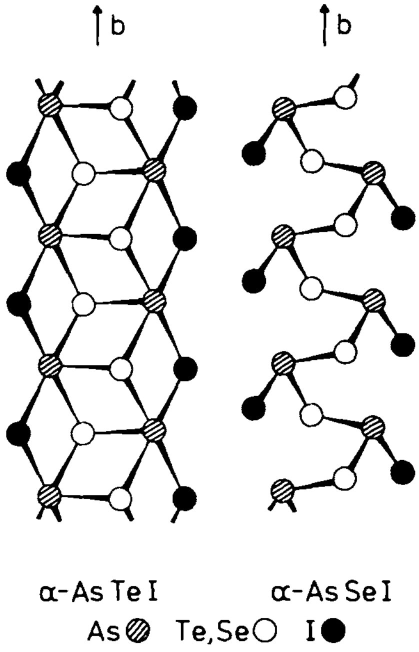

Fig. 1. Macromolecular structural units of α-AsTeI (left) and α-AsSeI (right). Bond lengths and angles (averaged values: standard deviations 0.01 Å and 0.4°, respectively): *α-AsTeI:* As—I 3.089, As—Te 2.741 Å; AsIAs 81.8, AsTeAs 91.5, IAsI 81.8, IAsTe 92.2, TeAsTe 90.5°. *α-AsSeI:* As—I 2.680 [8]; As—Se 2.430 Å; AsSeAs 97.4, IAsSe 97.1, SeAsSe 96.2°. Intramolecular interactions take place between As atoms and each of the neighboring Se and I atoms in the b direction (lying above in the figure): 3.079 and 3.518 Å (sum of the corresponding van-der-Waals radii: As...Se 4.00, As...I 4.15 Å [9]).

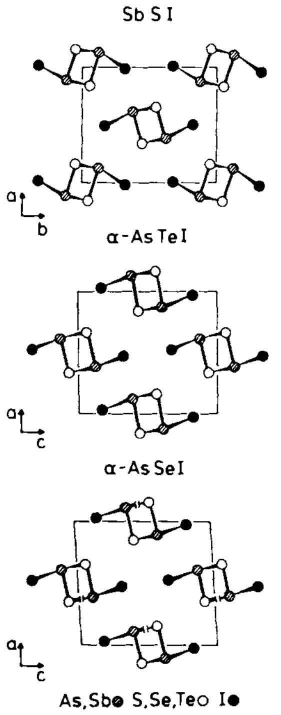

Fig. 2. Arrangement of the structural units of SbSI [2a], α-AsTeI and α-AsSeI in the structural assemblies. Projections in the direction of the macromolecular structural units. In α-AsTeI and α-AsSeI the shortest intermolecular interactions in each case are between As atoms of a structural unit and the bridging or terminal I atoms of the neighboring structural unit in the (101) direction (average value: 3.777 and 3.668 Å, respectively; standard deviations, see caption to Fig. 1).

*0570-0833/81/0202-0213 $ 02.50/0*

On crystallization of arsenic chalcogenide iodide glasses, particular importance attaches to the metastable ternary β-phases (Table 1). Thus, *e.g.*, in each case the ternary crystalline phase initially formed during the ordering processes on thermal treatment of glasses of the $As_2Te_3$-$AsI_3$ section is the cubic (metastable) β-AsTeI[7]. In this crystal structure (AB-type, fcc) tellurium and iodine are randomly distributed at positions of a partial lattice, while the As partial lattice—likewise random—is only 50% occupied. In the course of further ordering (annealing; β-AsTeI → α-AsTeI) the randomly semi-occupied As positions separate into ordered vacancies and fully-occupied lattice sites parallel to the (111) faces of the cubic system and thus contribute to approximation to the structural assembly of the monoclinic thermodynamically stable α-AsTeI. The As—(Te,I) distance of 2.895 Å in β-AsTeI is of the same order of magnitude as the averaged value 2.915 Å for all As—(Te,I) bond lengths of the macromolecular (ordered) structural element of α-AsTeI. Similar structural and phase relationships can be expected for α-AsSeI and β-AsSeI[10]; a metastable AsSI phase has not been observed by us.

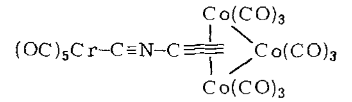
## Permetalated Methyl Isocyanide[**]

By *Wolf Peter Fehlhammer, Fritz Degel,*
and *Heribert Stolzenberg*[*]

α-Metalated isocyanides such as M—CX(H)—NC (X = H, $CO_2R$, $SO_2$aryl; M = Li,Na,Cu) have recently become important as versatile synthons in preparative organic chemistry[1]. Except for the silylated species $H_{3-n}(SiR_3)_nCNC$[2], however, these main group metal-organic isocyanides in general are poorly characterized, occurring only at low temperatures and in low concentrations, respectively.

We now present a stable transition metal derivative *(1)*, in which the CNC-skeleton functions as a $\mu_4$-bridge between a chromium atom and three cobalt atoms.

Compound *(1)*, which can be synthesized in 24% yield from $Cr(CO)_5CNCCl_3$[3] and $Co_2(CO)_8$ (molar ratio 4:9) is of interest for at least two reasons: *(i)* as the first functional isocyanide with an α-acetylenic C-atom, and *(ii)* as the first nonacarbonyltricobalt cluster containing a *functional* nitrogen-grouping on the methylidyne C-atom[4].



$$(OC)_5Cr{-}C{\equiv}N{-}C\begin{array}{l}Co(CO)_3\\Co(CO)_3\\Co(CO)_3\end{array}$$

*(1)*

As expected, the IR spectrum of *(1)* consists of the ν(CO) pattern of the $Co_3(CO)_9$ and $Cr(CO)_5$ moieties (cyclohexane: 2110 vw, 2062 s, 2044 m, 1980 s, 1969 vs, 1945 vs $cm^{-1}$) which presumably masks the weak intensity ν(CN) band. In the mass spectrum of *(1)* the molecular ion and all CO-deficient molecular fragments down to the base peak of CO-free $[CrCNCCo_3]^+$ appear as 15 equidistant groups of lines.

According to X-ray structure analysis[5], the molecule in the solid state has a crystallographic plane of symmetry which contains 13 of the total of 35 atoms (Fig. 1). The structural dimensions in the $CCo_3(CO)_9$ cluster compare well with those reported for other representatives of this cluster family[6]. In the $Cr(CO)_5$ moiety, the *trans* CO ligand with $d(Cr{-}C11) = 1.860(4)$ and $d(C11{-}O11) = 1.159(6)$ Å as against $\bar{d}(Cr{-}C_{cis}) = 1.892(9)$ and $\bar{d}(C{-}O)_{cis} = 1.140(6)$ Å reflects the *trans*-influence of a typical *C*-isocyanide, having a linear structure (CNC angle = 176.0(3), CrCN = 177.7(3)°).

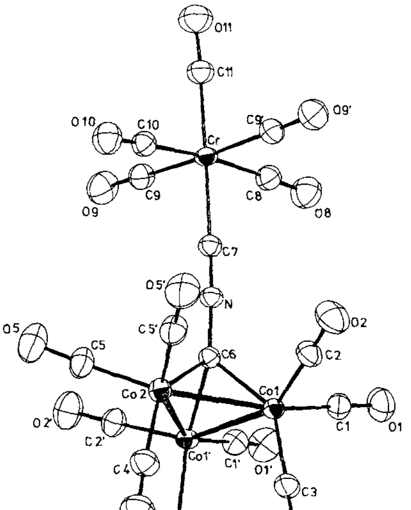


Fig. 1. ORTEP diagram of $(CO)_5CrCNCCo_3(CO)_9$ *(1)* showing 30% probability ellipsoids [5].

A normal C≡N bond length (1.160(5) Å) coupled with a markedly short N—C6 bond (1.354(5) Å), however, clearly demonstrates the sp character of the methylidyne C-atom.

Particular attention has been paid to the X-ray structural assessment of the *isocyanide* nature of *(1)*, since we had observed isocyanide → cyanide isomerization in a number of

[**] Metal Complexes of Functional Isocyanides, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Bayer AG for supplying the isocyanide dichloride.—Part 4: [7a].

cases, even under very mild conditions[7]. Least-squares refinement calculations on the isocyanide and cyanide isomers and a comparison of their thermal parameters, however, left no doubt as to the correctness of the assignment.

The perchlorinated trichloromethyl isocyanide dichloride *(2)*[8a] would appear to provide a direct entry to metal-rich, CNC-bridged systems such as *(1)*. Indeed, it reacts with excess $Co_2(CO)_8$ immediately and cleanly to give *(3a)*, but there is no further reaction. The much higher reactivity of the chlorine atoms in the α-position with respect to the isocyanide dichloride function thus is also established for reactions with organometallic nucleophiles[8]. Attempted dehalogenation by conventional methods[9] of *(3a)* to give the parent isocyanide has so far failed. "Oxidative three-fragment addition" of *(3a)* to $Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2$ under very mild conditions yields a second permetalated methyl isocyanide species *(4)* exhibiting a weak IR absorption at 2170 $cm^{-1}$ [$\nu(CN)$][10]. On reaction with $Pt(PPh_3)_3$, on the other hand, *(3a)* only undergoes substitution to give *(3b)*.

$Cl_3C{-}N{=}CCl_2$

*(2)*

$L(CO)_8Co_3{\equiv}C{-}N{=}CCl_2$

*(3a)*, L = CO
*(3b)*, L = PPh₃

$(CO)_9Co_3{\equiv}C{-}N{\equiv}C{-}Pt(Cl_2)PPh_3$

*(4)*

$Cl_2C{=}N{-}CCl_2CCl_2{-}N{=}CCl_2$

*(5)*

Interestingly, reaction of *(2)* with $Fe_2(CO)_9$ (molar ratio 1:1, tetrahydrofuran) proceeds by a completely different route: at room temperature, C—C coupling takes place with formation of metal-free *(5)*, which is also accessible by high-temperature chlorination of tetramethylethylenediamine or dimethylformamide[8a].

## BOOK REVIEWS

**Reaction Rates of Isotopic Molecules.** By *L. Melander* and *H. W. Saunders, Jr.*, Wiley, New York 1980. xiv, 391 pp., bound, £ 16.30.

This is a completely new and extended edition of *Melander's* "Isotope Effects on Reaction Rates" (Ronald, New York 1960). A short introduction is followed in turn by the mathematical foundations for the description and calculation of isotope effects from molecular data, an explanation of the measurement techniques, and the evaluation of experimental data. The special section deals with the measurements of primary and secondary kinetic hydrogen isotope effects and also solvent isotope effects and their interpretations. After a description of the isotope effects of carbon and other nonmetals, the book concludes with a discussion of the techniques for, and results from, measurements of the isotope effects in complex reaction systems, including enzymatic reactions. A three-part appendix provides instructions for calculations and tables.

Particular stress is placed on detailed mathematical treatment of the isotope effect, which is used to derive reaction-kinetic interpretations and mechanistic applications. The examples given have been chosen as a means of explaining the theory. The arrangement and presentation are clear, making it easy for the less initiated. The consistent and complete treatment of the entire field distinguishes this book from its competitors, which all too often concentrate on individual aspects. Since much of the relevant work is nowadays taking place in biochemistry, we might have expected a rather greater emphasis on this area, *e.g.* a description of some relevant procedures and concepts (equilibrium perturbation method, partitioning factor). All in all, this is currently the most authoritative book for anyone concerned with the theory, application, and interpretation of kinetic isotope effects.

*F. J. Winkler* [NB 534 IE]

# Target Directed Drug Synthesis: The Aminoacyl-tRNA Synthetases as Possible Targets

**By Friedrich von der Haar, Hans-Joachim Gabius and Friedrich Cramer**[*]

*Dedicated to Prof. Dr. Hans Herloff Inhoffen on the occasion of his 75th birthday*

The "tailor-made" pharmaceutical has been an old dream ever since *Paracelsus'* days. His saying *"Dosis sola facit venenum"* is still valid. The ideal pharmacon should inhibit the pathological process or the parasitical organism to a maximum while causing as little harm as possible to the human organism. In order to achieve this goal one must try to make use of metabolic differences between the metabolism of the pathological organism and normal human metabolism in a rational way. With today's improved knowledge of enzymatic processes this seems to be a possible and highly promising approach. The pharmaceutical should act upon a process of central importance, such as the process of protein biosynthesis, where the required highly accurate construction of the macromolecules is achieved by a "proofreading" process. It is shown that this "proofreading" mechanism exhibits specific difference in different species.

## 1. Introduction: Is Target Directed Drug Synthesis Feasible?

"... here one is dealing with the problem of curing an organism which is infected by certain parasites by killing these parasites within the organism. That is to say: the organism must be sterilized with the aid of substances that have been produced in the retort of the chemist[1]".

"If one wants to study this question experimentally one must look for substances which firstly in the test tube act in an inhibitory manner or by killing the bacteria, which secondly are virtually undangerous for the organism, which thirdly preserve the disinfecting action even within the organism[2]".

This was written by *Paul Ehrlich* 75 years ago, in the same year when *H. H. Inhoffen,* to whom this article is dedicated, was born. *Ehrlich* postulates, at that time highly advanced, have only been fulfilled to a very limited extent to date. The pharmaceutical industry has created a vast number of highly efficient drugs, in a rather non-rational approach, however. Most pharmaceuticals have been discovered by vast screening programs involving thousands of compounds, or owe their discovery to the "trial and error" method[3]. Furthermore, the mode of action of many active drugs was initially unknown, a situation which continues even today. A good example of this is "Aspirin" (acetylsalicylic acid), by far the most widely used drug. While aspirin was registered in 1899, its mode of action, the inhibition of the synthesis of prostaglandins or of the prostaglandin cyclooxygenase, was only explained in 1971 and 1975, respectively[4,5].

Biochemical and molecular biological research in recent years has been able to clarify essential pathways in cells and organisms and thereby has opened possibilities for the more rational synthesis of pharmaceuticals. In spite of this, however, satisfactory drugs exist for only one third of all diseases, as *König* has demonstrated[3,6].

When the mode of action for a specific drug has been elucidated in a model organism or an experimental animal, one

can expect that the mode and the intensity of action will vary in different organisms. Thus, for example, it is known that pyrimethamine, trimethoprim and methotrexate are inhibitors of the essential enzyme dihydrofolate reductase. It has been observed that pyrimethamine is 3600 times more effective against this enzyme from plasmodia than against the enzyme from human tissue. Pyrimethamine can therefore be used as an antimalarial drug against plasmodia. Trimethoprim is 60000 times more effective against dihydrofolate reductase from bacteria in comparison with the human enzyme and is therefore an antibacterial drug. Methotrexate also has a strong general activity against dihydrofolate reductase from human tissue and can therefore be used as an antineoplastic drug[7]. If the precise inhibition kinetics of these three substances with regard to the different enzymes had been known, the specific mode of action of pyrimethamine, trimethoprim and methotreaxate could in principle have been predicted. In theory, a target directed drug synthesis would have been possible if biochemical studies of the *in vitro* situation had resulted in complete understanding of the mode of action of the enzymes involved. The structure of a drug fulfilling *Ehrlich's* postulate, that drugs should be "strongly inhibitory for parasites in the test tube, but practically harmless towards the organism" could in principle be predicted from an understanding of the enzymatic properties of the parasite and the host *in vitro*. Without doubt such differences exist which will be more effective when the enzymes involved occupy a key position in metabolism. Here an important task for the biochemist in the pharmaceutical industry can be identified: to elucidate differences in the mechanisms of key enzymes so that preferential inhibition can be achieved by the synthesis of specific antimetabolites. This approach has been recently proposed in a highly interesting article by *Cohen*, who termed this "target directed drug synthesis"[8].

## 2. Aminoacyl-tRNA Synthetases as Target Enzymes

With infectious diseases, an invading pathogen has to be affected without harming the host. A potential target enzyme must play such a crucial role in the life-cycle of the pathogen, that perturbation of its action is sufficient to inhibit growth of the pathogen to such an extent that the self-defense mechanism of the host can control the infection. One possible way of achieving this is to administer an enzyme inhibitor for a key enzyme involved in metabolism. Perhaps a more efficient technique would be the use of substrate analogs, which are processed by the enzyme into erroneous products. In an ideal case these erroneous products should be of importance in additional processes thus resulting, independent of the action of the target enzyme itself, in perturbing the metabolism in many places. It is this latter aspect which led us to consider aminoacyl-tRNA synthetases as potential candidates for target directed drug design.

Aminoacyl-tRNA synthetases are a group of at least 20 enzymes corresponding to the 20 amino acids commonly found in proteins. Each enzyme selects its amino acid from the cellular pool, activates it by consumption of an equivalent adenosine triphosphate (ATP), and esterifies it to the 3'-terminal adenosine of its corresponding transfer ribonucleic acid (tRNA). The aminoacylated tRNA is complexed with an elongation factor and channeled into the ribosomal system where peptidization takes place (Fig. 1, upper part). Since the specific position of a particular amino acid within the growing protein chain is determined solely according to the well known codon-anticodon interaction between mRNA and tRNA, aminoacyl-tRNA synthetases must verify that a particular amino acid is linked exclusively to the tRNA with the corresponding anticodon. This is not a trivial problem, since in several cases amino acids have very similar structure (e.g. tyrosine and phenylalanine or isoleucine and valine).

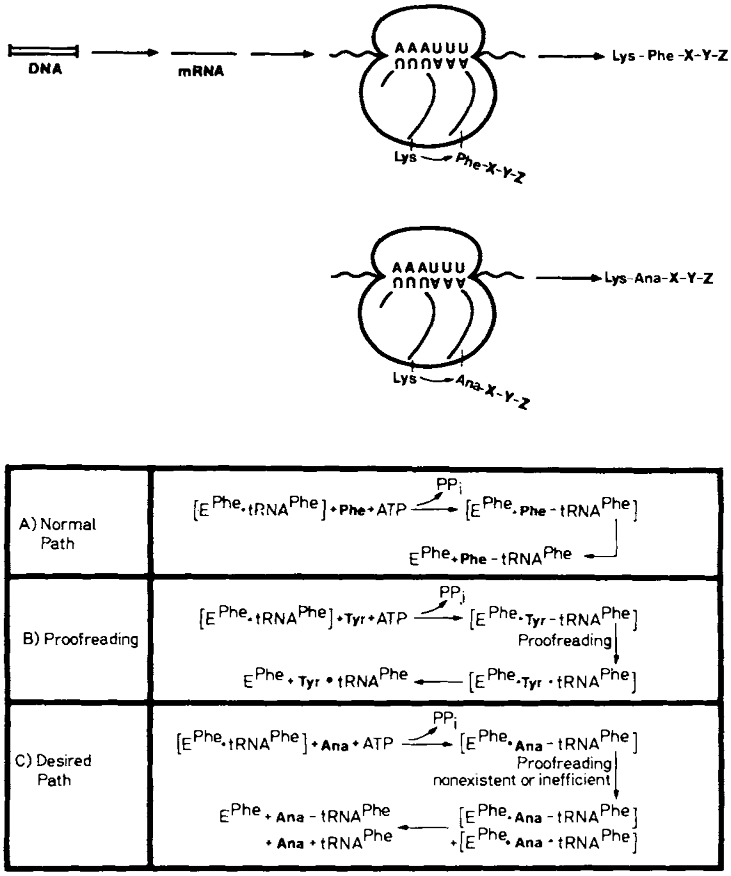

Fig. 1. Schematic representation of phenylalanine activation and incorporation into a growing protein chain. A) Normally, phenylalanine is esterified to $tRNA^{Phe}$—C—C—A. The Phe—$tRNA^{Phe}$—C—C—A is transferred into the ribosomal machinery and phenylalanine is incorporated into any position determined by the codon UUU due to interaction with the anticodon AAA (or AAG) of $tRNA^{Phe}$. B) To prevent misincorporation of misactivated amino acids such as Tyr, the proofreading was developed. C) If an analog (Ana) of Phe escapes the proofreading pathway it is incorporated into a growing peptide chain. In the example given above, a peptide ...Lys—Ana—X—Y—Z—$NH_2$ instead of ...Lys—Phe—X—Y—Z—$NH_2$ would be built up. ($NH_2$-groups have not been shown in order to improve clarity. E = phenylalanyl-tRNA synthetase, $PP_i$ = diphosphate; for other abbreviations see text.)

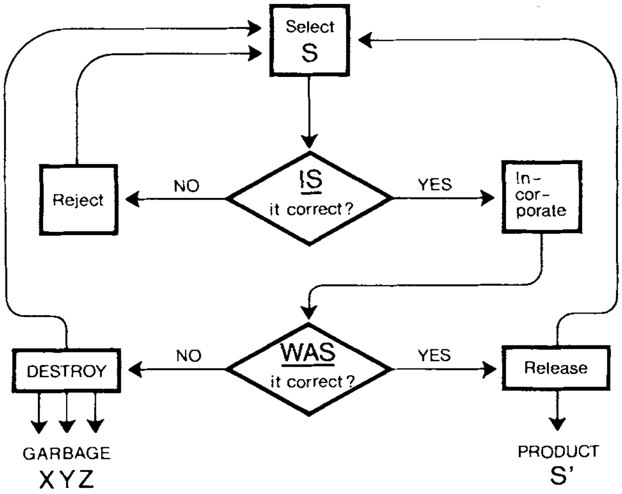
Research in our laboratory during recent years has provided information which indicates that the required accuracy is a result of a two-step mechanism consisting firstly of transfer of the amino acid to the tRNA and secondly a "proofreading" step[9,10] as exemplified for phenylalanyl-tRNA synthetase in Figure 1.

Phenylalanyl-tRNA synthetase from yeast normally binds phenylalanine, activates it by consuming one equivalent of ATP, and transfers it to the phenylalanine tRNA ($tRNA^{Phe}$). Subsequently, the product, Phe—$tRNA^{Phe}$, is released (Fig. 1, pathway A).

Occasionally the enzyme binds and activates tyrosine, and in this case, tyrosine is also transferred to the tRNA$^{Phe}$. However, this erroneous product Tyr—tRNA$^{Phe}$ is not released from the enzyme. In a control step, phenylalanyl-tRNA synthetase from yeast hydrolyzes the ester linkage between tyrosine and tRNA$^{Phe}$ and releases both substrates[11]. This correction step which we phrased "chemical proofreading"[12] prevents the misincorporation of a tyrosine in place of a phenylalanine in a growing peptide chain (Fig. 1, pathway B).

The essentials of this selection process are presented in a more generalized way in Scheme 1. Interacting with the 20 amino acids from the pool, the enzyme in each case asks: "Is this particular amino acid the right one?". If the answer is "no" the amino acid is rejected, if the answer is "yes" the amino acid will be processed further. The error rate of this first selection step is considerably reduced in the subsequent step. The enzyme now asks: "Was the first discrimination correct?". When the answer is "yes" the product is released, otherwise, the ester bond is hydrolyzed. For each amino acid incorrectly activated, the cell consumes one ATP molecule.



Scheme 1. Flow diagram for a two-step selection process. High specificity is obtained by an energy consuming proofreading process.

The mechanistic details of this correction step are still not known for the case of incorrect selection of tyrosine rather than phenylalanine by phenylalanyl-tRNA synthetase. In a further example, the misactivation of valine by isoleucyl-tRNA synthetase, we attempted to fit all experimental details into a mechanistic scheme[12] (Fig. 2). Valine (Val) differs from isoleucine (Ile) by the absence of one methyl group. Val—tRNA$^{Ile}$ becomes isosteric with Ile—tRNA$^{Ile}$ if in place of the missing methyl group a water molecule appears. Our results indicate that this water molecule is activated by the enzyme and used to split the ester bond in Val—tRNA$^{Ile}$[12]. Specificity in this case is due to self-protection of the correct product against hydrolysis, which can occur in the incorrect product. Since the difference is in chemical reactivity, we termed this mechanism "chemical proofreading"[12].

For an E$^{Phe}$ directed drug synthesis, it is desirable for the enzymes of the host and pathogen to differ to such an extent, that design of a phenylalanine analog, which is proofread by the host but not by the pathogen, is possible. In this ideal case the analog would be incorporated statistically into a number of enzymes in place of phenylalanine (Fig. 1, pathway C) leading to malfunctioning enzyme proteins. Due to the accuracy normally observed in protein synthesis[13,14], one would tend to extrapolate that even a relatively small number of misincorporated analogs would result in serious interference with the metabolism of the pathogen. This proposal applies not only for phenylalanyl-tRNA synthetase but for any aminoacyl-tRNA synthetase which follows an analog pathway, for instance isoleucyl- or valyl tRNA synthetase[12].

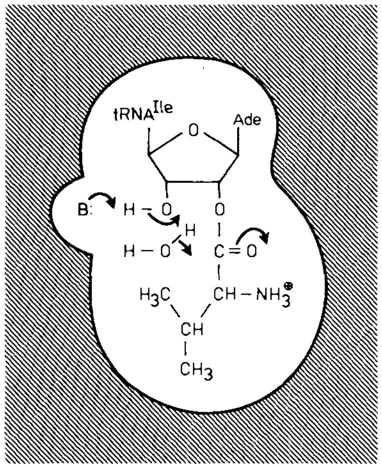


Fig. 2. Mechanism of proofreading Val—tRNA$^{Ile}$ by isoleucyl-tRNA synthetase from yeast.

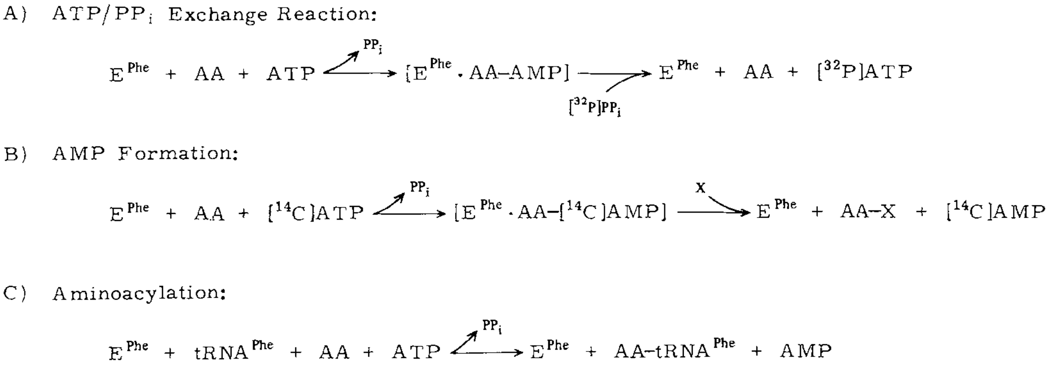
## 3. Comparison of Proofreading Mechanisms of Phenylalanyl-tRNA Synthetases in Different Organisms

In order to examine differences in the proofreading mechanisms in a variety of enzyme sources, phenylalanyl-tRNA synthetases from *Escherichia coli*, *Saccharomyces cerevisiae* (bakers' yeast), *Neurospora crassa* and turkey liver were purified to homogeneity[15]. Subsequently, the interaction of these enzymes with eight different phenylalanine analogs was studied. Additionally, tyrosine, leucine and methionine, the natural amino acids known to be misactivated by the enzyme from bakers' yeast[11], were investigated. Prior to discussion of these results in summarized form, the methodology used to obtain them will be outlined.

Three different types of assay were used (Scheme 2). The so called ATP/PP$_i$ exchange assay (Scheme 2, reaction A) is based on the fact, that the amino acid is intermediately activated by splitting ATP into AMP and PP$_i$. If [$^{32}$P]PP$_i$ is added externally it will be incorporated into ATP due to the reversibility of the activation. If this test, which is independent of tRNA, is positive, an analog is undoubtedly a substrate.

The fate of the activated substrate can be followed by measuring the consumption of ATP or the formation of adenosine monophosphate (AMP) (Scheme 2, path B). This test is again based on the intermediate activation; every amino acid processed by an aminoacyl-tRNA synthetase involves the consumption of one equivalent of ATP, irrespective of subsequent reactions of the activated amino acid. Catalytic formation of AMP from ATP will be observed, if the activated amino acid is immediately hydrolyzed or if it is transferred to a tRNA and subjected to proofreading. With this reaction the influence of tRNA can be followed, even if no stable aminoacylated tRNA is formed. Pathway B in Figure 1 shows that no Tyr-tRNA$^{Phe}$ is released from the enzyme, but that one equivalent of AMP is formed, for every equivalent of Tyr—tRNA$^{Phe}$ formed intermediately. Thus, aminoacylation can be followed indirectly[12].



A) ATP/PP$_i$ Exchange Reaction:

$$E^{Phe} + AA + ATP \xrightarrow{PP_i} [E^{Phe} \cdot AA\text{–}AMP] \xrightarrow[{[^{32}P]PP_i}]{} E^{Phe} + AA + [^{32}P]ATP$$

B) AMP Formation:

$$E^{Phe} + AA + [^{14}C]ATP \xrightarrow{PP_i} [E^{Phe} \cdot AA\text{–}[^{14}C]AMP] \xrightarrow{X} E^{Phe} + AA\text{–}X + [^{14}C]AMP$$

C) Aminoacylation:

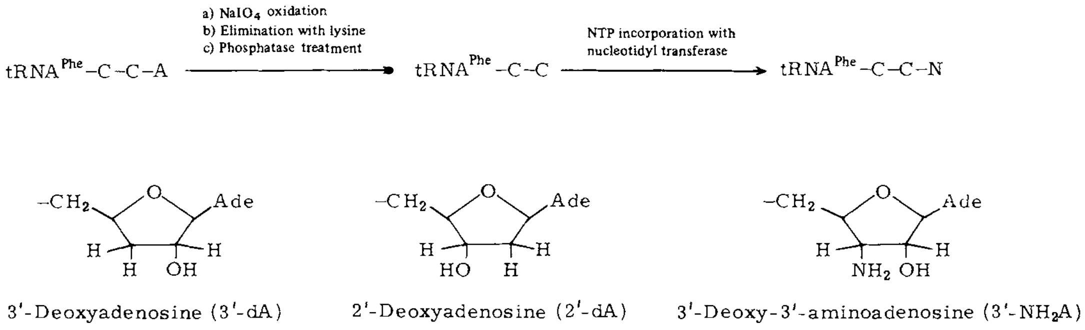
$$E^{Phe} + tRNA^{Phe} + AA + ATP \xrightarrow{PP_i} E^{Phe} + AA\text{–}tRNA^{Phe} + AMP$$

Scheme 2. Assays for substrate properties of phenylalanine and its analogs (AA = amino acid; X = tRNA$^{Phe}$ or other nucleophile).

Finally the transfer of a substrate to tRNA$^{Phe}$ can be measured, if a stable product is released from the enzyme (Scheme 2, path C). If a radioactively labeled substrate is available, its incorporation can be followed directly. Alternatively, unlabeled substrate can be incorporated into the tRNA and the amount of free tRNA$^{Phe}$ remaining after a certain reaction time back-titrated with [$^{14}$C] phenylalanine (see also Table 1).

Table 1: tRNA$^{Phe}$—C—C—N dependent [$^{14}$C]AMP formation *via* phenylalanyl-tRNA synthetase from turkey liver and *bakers'* yeast, $k_{cat}$ [min$^{-1}$].

| Enzyme | Source | Leu | Met | Tyr |
|---|---|---|---|---|
| $E^{Phe}$ | baker's yeast | <0.05 | <0.05 | <0.05 |
| | turkey liver | 0.75 | 1.35 | <0.1 |
| [$E^{Phe} \cdot$ tRNA$^{Phe}$—C—C] | baker's yeast | <0.05 | <0.05 | <0.05 |
| | turkey liver | 0.80 | 1.60 | <0.1 |
| [$E^{Phe} \cdot$ tRNA$^{Phe}$—C—C—3'-dA] | baker's yeast | <0.1 | <0.1 | <0.1 |
| | turkey liver | 0.64 | 1.13 | <0.1 |
| [$E^{Phe} \cdot$ tRNA$^{Phe}$—C—C—A] | baker's yeast | 0.64 | 2.03 | 6.80 |
| | turkey liver | 2.93 | 3.62 | 0.31 |
| [$E^{Phe} \cdot$ tRNA$^{Phe}$—C—C—2'-dA] | baker's yeast | <0.05 | <0.05 | <0.05 |
| | turkey liver | 2.50 | 3.57 | 0.27 |



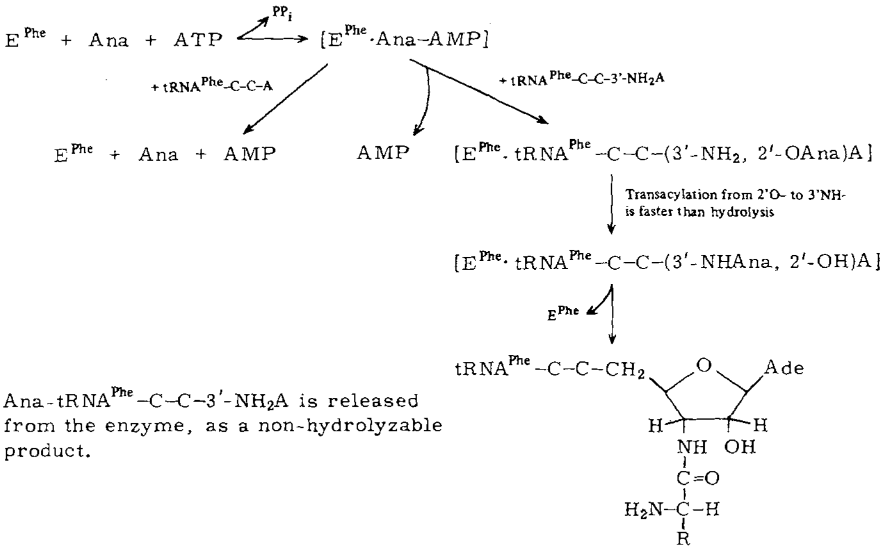
Scheme 3. Modification of the 3'-end of tRNA$^{Phe}$ (tRNA$^{Phe}$—C—C—3'dA and tRNA$^{Phe}$—C—C—3'NH$_2$A are substrates: tRNA$^{Phe}$—C—C—2'dA and tRNA-$^{Phe}$—C—C are not substrates).

In order to increase the information obtained from these tests we developed the following methodology. Normally the 3'-terminus of tRNA$^{Phe}$ consists of an adenosine, whose 2'-hydroxyl group is the acceptor for the activated phenylalanine. To study this transfer reaction in more detail, we removed the 3'-terminal adenosine and replaced it by adenosine analogs using the enzyme nucleotidyl transferase, which has a low specificity for the substrate adenosine triphosphate *in vitro*[16]. The analogs used for this investigation are given in Scheme 3. The prerequisite for the present investigation was the ability to modify tRNA$^{Phe}$ in such a way, that it was not longer susceptible to proofreading after esterification with misactivated phenylalanine analogs. In this respect the tRNA$^{Phe}$—C—C—3'NH$_2$A was of special importance. With this 3'-NH$_2$A group, phenylalanine or any misactivated analog is transferred to the 2'-OH. Subsequent nucleophilic attack of the 3'-NH$_2$ on the 2'-hydroxyl group ester bond and formation of a 3'-amide is more rapid than hydrolysis by proofreading. The stable amide cannot be hydrolyzed further by phenylalanyl-tRNA synthetase[9,14] (Scheme 4).

Using this methodology we obtained the results summarized as follows:

a) Phenylalanyl-tRNA synthetase from *E. coli*, bakers' yeast and *N. crassa* behave qualitatively the same. They activate all the phenylalanine analogs investigated.

b) The misactivated analogs are transferred to tRNA$^{Phe}$—C—C—3′NH$_2$A albeit that the efficiency is somewhat different for the respective analogs.



Scheme 4. Properties of tRNA$^{Phe}$—C—C—3′NH$_2$A upon transfer of phenylalanine analogs.

c) With natural tRNA$^{Phe}$—C—C—A the amino acid analogs were intermediately transferred to the tRNA$^{Phe}$ and, with one exception described below, subsequently hydrolyzed from the tRNA$^{Phe}$—C—C—A prior to release of erroneous product.

d) Only moderate quantitative differences were observed with respect to the extent with which these analogs could substitute for phenylalanine in the enzymatic reactions studied. These differences allow speculations regarding the nature of the binding site to be made[15].

The phenylalanyl-tRNA synthetase from turkey liver behaved markedly differently:

a) In the ATP/PP$_i$ exchange assay, all the phenylalanine analogs were active as well as the natural amino acids leucine, methionine and tyrosine. However, tyrosine was observed to be a very poor substrate for the turkey liver enzyme in contrast to *E. coli*, bakers' yeast and *N. crassa*[15].

b) In contrast to the enzymes from *E. coli*, bakers' yeast and *N. crassa*, none of the misactivated analogs could be esterified to a measureable extent to tRNA$^{Phe}$—C—C—3′NH$_2$A by the enzyme from turkey liver. Since, however, a tRNA$^{Phe}$-dependent AMP formation was observed with this enzyme, the analogs must have been processed by the phenylalanyl-tRNA synthetase from turkey liver.

This latter results suggests that with the enzyme from turkey liver, a proofreading mechanism operates without intermediary transfer of misactivated analog to tRNA$^{Phe}$—C—C—A. That this pathway does exist, can be observed from the tRNA$^{Phe}$—C—C—N-dependent AMP formation described in Table 1, in which enzymes from bakers' yeast and turkey liver are compared. For the free enzyme and the [E$^{Phe}$·tRNA$^{Phe}$—C—C] complex, the misactivated intermediates have significant stability in the presence of enzyme from bakers' yeast, whereas they are unstable in the presence of enzyme from turkey liver.

With the complex E$^{Phe}$·tRNA$^{Phe}$—C—C—3′dA we observe the same high rate of AMP formation as in the case of free enzyme. However, it must be restated that this modified tRNA$^{Phe}$—C—C—3′dA, in the presence of a phenylalanine analog, is a substrate for the yeast enzyme but not for the turkey liver enzyme. With this modified tRNA$^{Phe}$ proofreading in the yeast system does not occur owing to the absence of the 3′-hydroxyl group which is essential for this process[14], while with the turkey liver enzyme transfer of the amino acid does not appear to occur.

As expected, enhanced AMP production as a result of proofreading takes place with the [E$^{Phe}$·tRNA$^{Phe}$—C—C—A] complex with enzymes from both organisms. An unexpected result was observed using the [E$^{Phe}$·tRNA$^{Phe}$—C—C—2′dA] complex: the complexed tRNA$^{Phe}$—C—C—2′dA is neither a substrate for phenylalanylation in the yeast nor turkey liver systems, and does not result in proofreading with the yeast enzyme. However, a very efficient proofreading reaction takes place with the turkey liver enzyme, which is specific for misactivated amino acids. In the presence of phenylalanine, increased stability of the activated intermediate was observed[15].

The most likely explanation for this data is that with the turkey liver enzyme, a proofreading reaction takes place without transfer of the misactivated amino acid to the tRNA$^{Phe}$. The 3′-terminal adenosine, and in particular the non-accepting 3′-OH of this adenosine, plays an important role in this step in accordance with our suggestions regarding "reactive site triggering"[17].

A proofreading mechanism preventing transfer of the misactivated amino acid to the tRNA$^{Phe}$ is obviously safer than one operating after transfer. Without transfer to the tRNA, an incorrectly activated amino acid has no chance of being incorporated within a protein. In this instance, incorrectly activated amino acids can only inhibit an aminoacyl-tRNA synthetase and, unless this inhibition is very severe, should result in little harm to the cell. Whatever the implications of these mechanistic differences may mean to cell biology, it is only important for the present discussion that such differences exist, and that they are a prerequisite for target directed drug design. Finally the question arises as to whether or not these differences can be utilized.

## 4. *N*-Benzyl-L-phenylalanine

*N*-Benzyl-D,L-amphetamine has been shown to be a very potent inhibitor for the phenylalanyl-tRNA synthetase of *E. coli* but not for the rat liver enzyme in the ATP/PP$_i$ exchange assay[18]. Despite the close structural relationship, neither enantiomer of *N*-benzylphenylalanine is reported to be an inhibitor for the enzyme from *E. coli*[19]. This discrepancy suggests that the phenylalanine analog is a substrate; although previous authors[18,19] did not appear to take this into consideration, we have subsequently observed it to be the case[15].

Whereas *N*-benzyl-D,L-amphetamine shows a dramatic difference in inhibitory power for the *E. coli* and rat liver systems[18], the Michaelis-Menten ($K_m$) values for *N*-benzyl-L-phenylalanine in the ATP/PP$_i$ exchange assay are very similar in *E. coli*, bakers' yeast and turkey liver systems (Table 2). In accordance with the results described in the preceding section, the analog can be esterified to tRNA$^{Phe}$—C—C—3'NH$_2$A only by the *E. coli* and yeast enzyme but not by the turkey liver enzyme. The value of $K_m$ in this transfer reaction is about 17 fold higher for the *E. coli* enzyme and 38 fold higher for the yeast enzyme relative to the respective $K_m$ in the ATP/PP$_i$ exchange assay. A much higher value of $K_m$ in reactions involving tRNA complexed to the enzyme, as compared with reaction of free enzyme, is observed with all our analogs tested[15], and this observation substantiates earlier discussions regarding the influence of the tRNA on enzyme conformation[14,17]. It however puts question marks against interpretations which attempt to extrapolate results obtained from ATP/PP$_i$ exchange with free enzymes to reactions with enzyme·tRNA complexes[19].

Table 2: *N*-benzyl-L-phenylalanine as substrate for several phenylalanyl-tRNA-synthetases.

| | Source of enzyme: | | |
|---|---|---|---|
| | *E. coli* | Bakers' yeast | Turkey liver |
| $K_m$ in the ATP/PP exchange reaction [μM] | 85 | 157 | 205 |
| Esterification to tRNA$^{Phe}$—C—C—3'-NH$_2$A [%] [a] | 64 | 50 | 0 |
| $K_m$ for esterification to tRNA$^{Phe}$—C—C—3'-NH$_2$A [μM] | 1500 | 6000 | — |
| Esterification to tRNA$^{Phe}$—C—C—A [%] [b] | 6 | 0 | 0 |

[a] Determined by the method of back-titration: Enzyme, tRNA$^{Phe}$—C—C—3'-NH$_2$A, ATP and unlabeled analogs are incubated for 30 min. Then excess ATP, [$^{14}$C]phenylalanine and additional enzyme are added in order to determine the account of nonacylated tRNA$^{Phe}$. Amount of tRNA acylated with analog is the difference between the nonacylated tRNA and total tRNA present. [b] Determined by the method of back-titration as well as by direct incorporation of [$^{14}$C]*N*-benzyl-L-phenylalanine and subsequent product analysis.

The most important result in the context of our present discussion is, however, that *N*-benzyl-L-phenylalanine, to a low but measurable extent, escapes the proofreading process with the *E. coli* enzyme and stable *N*-benzyl-L-phenylalanyl-tRNA$^{Phe}$—C—C—A is released (Table 2). This fact was unequivocally confirmed as follows: [$^{14}$C]*N*-benzyl-L-phenylalanine was synthesized and incorporated into tRNA$^{Phe}$—C—C—A. The [$^{14}$C]*N*-benzyl-L-phenylalanyl-tRNA$^{Phe}$—C—C—A was isolated by column chromatography, subjected to hydrolysis with alkali and the only radioactive compound liberated shown to be *N*-benzyl-L-phenylalanine by thin layer chromatography[15].

## 5. Conclusions

In this article we have not described or proposed a new pharmaceutical, we have rather tried to demonstrate a principle by using an example: The principle of the target directed drug synthesis with the example of the proofreading in the protein biosynthesis as target.

The various branches of evolution have adopted, improved and diversified the biochemical pathways. Even such a central and universal process as protein biosynthesis, which is directed by the universal genetic code and which uses the same 20 amino acids in all organisms, exhibits important species-specific differences. These can be observed in the degree of fidelity of amino acid recognition. These differences might be used pharmacologically. Depending on their place in the tree of evolution, organisms should behave differently with respect to incorporation of incorrect amino acids. In support of this suggestion we have given experimental proof using the phenylalanyl-tRNA synthetase system. Amino acid analogs are antimetabolites, the mode of action of which is largely unknown. In addition to phenylalanyl-tRNA synthetase, there are at least 19 further aminoacyl-tRNA synthetases — a wide open field for future research.

*The authors are grateful to Prof. Dr. E. Holler, Regensburg, for a sample of partially purified phenylalanyl-tRNA synthetase from E. coli and to Fritz Benseler, Erika Graeser and Jörg Schischkoff for skilfull cooperation upon isolation of the enzyme from Neurospora crassa as well as with the synthesis of N-benzyl-L-phenylalanine.*

# Advances in Organophosphorus Chemistry Based on Dichloro(methyl)phosphane

**By Klaus Weissermel, Hanns-Jerg Kleiner, Manfred Finke, and Utz-Hellmuth Felcht**[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

Besides phosphorus trichloride and phosphane, dichloro(methyl)phosphane is gaining importance as a starting material for the synthesis of organophosphorus compounds. It provides ready access to phosphonic, phosphinic and phosphonous acid derivatives, as well as their secondary products. The synthetic and application potential of organophosphorus compounds—based on industrially produced dichloro(methyl)phosphane—is illustrated by means of numerous examples.

## 1. Introduction

To comply with the definition of organophosphorus chemistry, at least one phosphorus-carbon bond must be present in a compound. There are several possibilities of achieving this. The reaction of methane with phosphorus trichloride has been realized on the industrial scale. At about 600 °C in the gas phase at short residence times it leads, smoothly to dichloro(methyl)phosphane *(1)*[1]

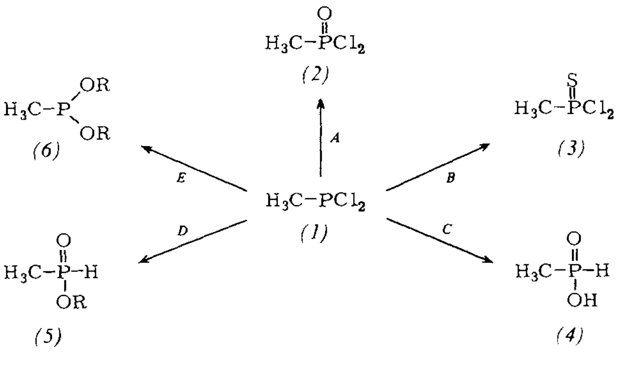
$$CH_4 + PCl_3 \longrightarrow \underset{(1)}{H_3C{-}PCl_2} + HCl$$

*(1)* is a colourless liquid which can be distilled without decomposition, but is extremely sensitive to moisture and is highly reactive. Many reactions of this simple "building block" have been investigated, and are described in a number of selected examples.

## 2. Reactions of Dichloro(methyl)phosphane *(1)* and its Most Important Secondary Products

Under optimized reaction conditions the simple reactions provide high yields.

The most important reactions of *(1)*[2,3] are shown schematically in Figure 1. Oxidation of *(1)* leads directly to methylphosphonic dichloride *(2)*[1]. Atmospheric oxygen, dinitrogen tetroxide[4] and chlorosulfuric acid[5] can be used as oxidizing agents, the latter method yielding especially pure products. With aluminum chloride catalysis, *(1)* reacts with elemental sulfur to form methylthiophosphonic dichloride *(3)*[1,6]. In the presence of excess water *(1)* reacts to form methylphosphinic acid *(4)*.



R = Alkyl

Fig. 1. Important reactions of dichloro(methyl)phosphane *(1)*. *A* Oxidation; *B* Sulfurization; *C* Hydrolysis; *D* Alcoholysis; *E* Alcoholysis in the presence of base.

Reaction of *(1)* with an excess of alcohols in the absence of bases, leads to the methylphosphinic esters *(5)*. For example, the isobutyl ester *(5)*, $R = iC_4H_9$[1] is obtained in good yield. In order to prevent acidolysis from *(5)* → *(4)*, hydrogen chloride liberated during the reaction *(1)* → *(5)* has to be removed in a current of nitrogen[7].

In contrast to the phosphinic esters *(5)*, the phosphonous diesters *(6)* can normally be produced only by alcoholysis in the presence of bases or other acid binders. Reaction of *(1)*

---

[*] Prof. K. Weissermel, Dr. H.-J. Kleiner, Dr. M. Finke, Dr. U.-H. Felcht

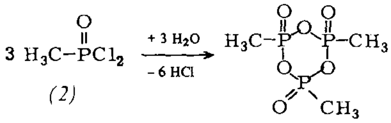
Postfach 800320, D-6230 Frankfurt am Main 80 (Germany)

with alcohols at −40 °C and subsequent neutralization of the hydrogen chloride formed in the process by ammonia has proved to be the simplest method[8]. A particularly suitable procedure for the preparation of the frequently used methylphosphonous diethyl ester *(6)*, $R = C_2H_5$, consists of reacting *(1)* with ethanol in the presence of dimethylaniline at 0 °C in *n*-pentane, and isolating the reaction product under mild conditions[9].

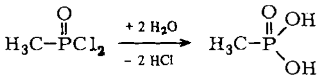
### 2.1. Reactions of Methylphosphonic Dichloride *(2)*

Methylphosphonic dichloride *(2)*, an important intermediate for the preparation of other derivatives of this acid, is only accessible, apart from the method starting from *(1)*, *via* multiple-step syntheses. *(2)*, for example, reacts with water in the molar ratio 1:1 to form methylphosphonic anhydride *(7)*[10] that is presumably present as the trimer.



(2) (7)

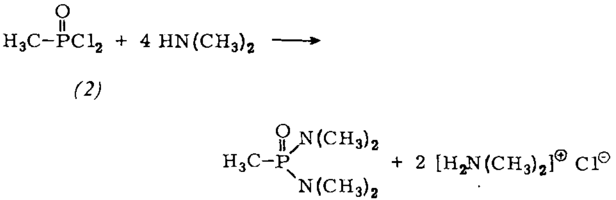
*(7)* can be stored without undergoing decomposition and is readily soluble in aprotic solvents. It is suitable, for example, as a condensation agent for peptide syntheses[11]. *(2)* also reacts readily with hydrogen sulfide to give the corresponding trimeric methylthiophosphonic anhydride[12]. As expected, complete hydrolysis of *(2)* leads to methylphosphonic acid *(8)*.



(2) (8)

$$H_3C{-}\overset{O}{\overset{\|}{P}}Cl_2 \xrightarrow[-2\,HCl]{+2\,H_2O} H_3C{-}\overset{O}{\overset{\|}{P}}(OH)_2$$

In addition, the bis(dialkylamides) of methylphosphonic acid are readily accessible from *(2)*; of these the tetramethyl derivative *(9)* is of interest as an aprotic solvent. In its possible applications it is similar to dimethyl sulfoxide and hexamethylphosphoric triamide. Because of its relatively good stability towards alkali metals and alkaline earth metals and its high basicity, *(9)* is especially suitable as a solvent for reactions with nucleophilic compounds[13].



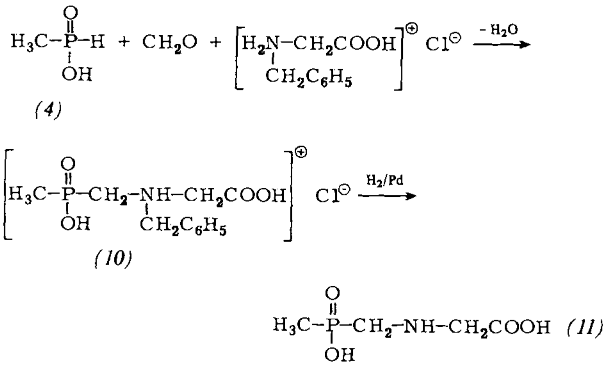
(2) (9)

$$H_3C{-}\overset{O}{\overset{\|}{P}}Cl_2 + 4\,HN(CH_3)_2 \longrightarrow H_3C{-}\overset{O}{\overset{\|}{P}}[N(CH_3)_2]_2 + 2\,[H_2N(CH_3)_2]^{\oplus}\,Cl^{\ominus}$$

Among other reactions of *(2)*, the reaction with aromatic Grignard compounds to form diaryl(methyl)phosphane oxides should be mentioned[14].

### 2.2. Reactions of Methylphosphinic Acid *(4)*

The acid *(4)* has so far only found limited preparative use; however, it serves as an intermediate.



(4) (10) (11)

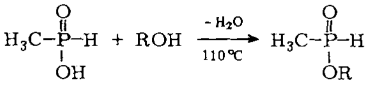
$$H_3C{-}\underset{OH}{\overset{O}{\overset{\|}{P}}}{-}H + CH_2O + \left[\underset{CH_2C_6H_5}{H_2N}{-}CH_2COOH\right]^{\oplus} Cl^{\ominus} \xrightarrow{-H_2O}$$

$$\left[H_3C{-}\underset{OH}{\overset{O}{\overset{\|}{P}}}{-}CH_2{-}\underset{CH_2C_6H_5}{NH}{-}CH_2COOH\right]^{\oplus} Cl^{\ominus} \xrightarrow{H_2/Pd} H_3C{-}\underset{OH}{\overset{O}{\overset{\|}{P}}}{-}CH_2{-}NH{-}CH_2COOH$$

Thus, in crude aqueous solutions, such as formed in the hydrolysis of *(1)*, *(4)* condenses with *N*-benzylglycine hydrochloride and formaldehyde, in the presence of concentrated hydrochloric acid, to the phosphinic acid derivative *(10)*[15].

*(10)* can be hydrogenated in 50% ethanol with palladium/activated charcoal to *N*-[hydroxy(methyl)phosphorylmethyl]glycine *(11)*[15].

Furthermore, with longer-chain alcohols, using toluene as a water entraining agent, the acid *(4)* can be converted without marked decomposition into the methylphosphinic esters *(5)*, $R \geqq C_4$[16].

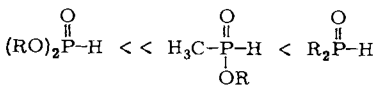


(4) (5), R = Alkyl ≧ C₄

$$H_3C{-}\underset{OH}{\overset{O}{\overset{\|}{P}}}{-}H + ROH \xrightarrow[110\,°C]{-H_2O} H_3C{-}\underset{OR}{\overset{O}{\overset{\|}{P}}}{-}H$$

### 2.3. Reactions of Methylphosphinic Esters *(5)*

Because of their reactive P—H bond, the esters *(5)* are of paramount importance as intermediates. Their reactivity exceeds that of phosphonic dialkylesters and approaches that of secondary dialkylphosphane oxides.

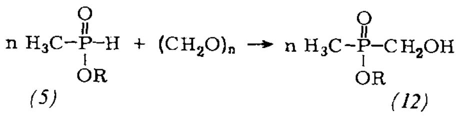


(5)

$$(RO)_2\overset{O}{\overset{\|}{P}}{-}H \ll H_3C{-}\underset{OR}{\overset{O}{\overset{\|}{P}}}{-}H < R_2\overset{O}{\overset{\|}{P}}{-}H$$

2.3.1. Addition of Methylphosphinic Esters *(5)* to Formaldehyde

In the simplest case the esters *(5)* can be added, without catalysis, to paraformaldehyde at 80–90 °C, to give hydroxymethyl(methyl)phosphinic esters *(12)*[17].

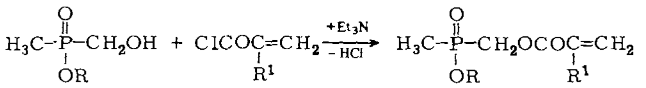


(5) (12)

R = Alkyl

$$n\,H_3C{-}\underset{OR}{\overset{O}{\overset{\|}{P}}}{-}H + (CH_2O)_n \rightarrow n\,H_3C{-}\underset{OR}{\overset{O}{\overset{\|}{P}}}{-}CH_2OH$$

Water-soluble phosphoryl-substituted acrylates *(13)*[18] which are suitable as comonomers, are obtained from *(12)* and either acryloyl or methacryloyl chloride.

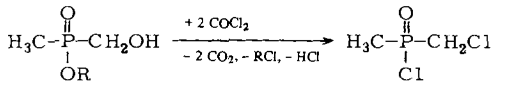


$$H_3C\text{-}P(O)(OR)\text{-}CH_2OH + ClCOC(R^1){=}CH_2 \xrightarrow[-HCl]{+Et_3N} H_3C\text{-}P(O)(OR)\text{-}CH_2OCOC(R^1){=}CH_2$$

*(12)* *(13)*

R = Alkyl; $R^1$ = H, $CH_3$

Reaction of *(12)* with phosgene at room temperature leads to chloromethyl(methyl)phosphinic chloride *(14)*[1,19] (see also Section 2.6.).



$$H_3C\text{-}P(O)(OR)\text{-}CH_2OH \xrightarrow[-2\,CO_2,\,-RCl,\,-HCl]{+2\,COCl_2} H_3C\text{-}P(O)(Cl)\text{-}CH_2Cl$$

*(12)* *(14)*

R = Alkyl

### 2.3.2. Addition of the Methylphosphinic Esters *(5)* to Compounds with Nonactivated Multiple Bonds

*(5)* can add to molecules which contain nonactivated double or triple bonds. A few typical examples are shown schematically in Figure 2.

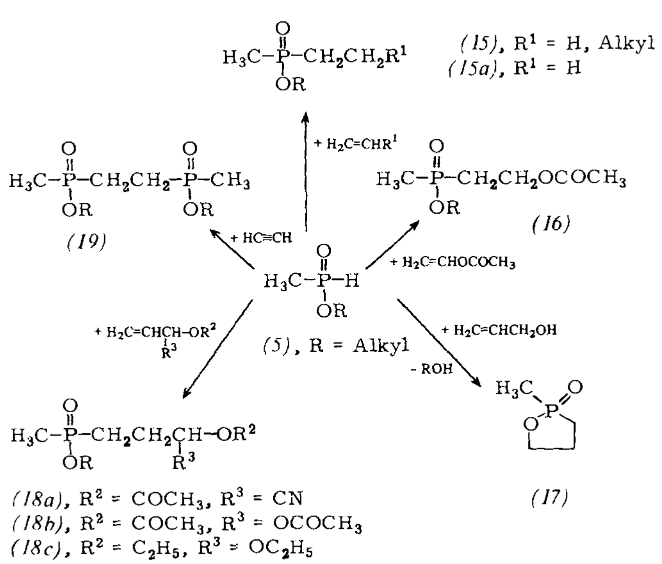


Fig. 2. Addition of *(5)* to compounds with nonactivated multiple bonds.

In the presence of peroxide-based catalysts the esters *(5)* react smoothly at about 150–170 °C with α-olefins to give alkyl(methyl)phosphinic esters *(15)*; the reaction is also catalyzed by UV-irradiation[20].

The addition of *(5)* to vinyl acetate in the presence of peroxides, particularly if an excess of *(5)* is used—leads to 2-acetoxyethyl(methyl)phosphinic esters *(16)*[21] in high yields.

The reaction with allyl alcohol proceeds analogously; 2-methyl-1,2-oxyphospholane 2-oxide *(17)* ("phostone") is formed directly *via* intramolecular alcohol cleavage[22]. Polycondensates formed simultaneously can to a large extent be cracked to monomeric phostone at high temperature *in vacuo*.

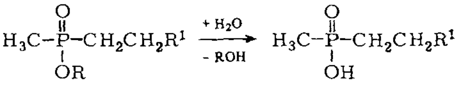
The addition compound *(18a)* is an important intermediate which is obtained from *(5)* and 1-cyanoallyl acetate (acroleincyanohydrin acetate)[23]. *(5)* also adds to the corresponding diacetate or diethyl acetal, the products *(18b)* or *(18c)*[24,25] being formed in high yields.

In the radical additions of *(5)* mentioned here, the phosphorus atom is almost exclusively linked to the carbon atom of the double bond which has the greater portion of hydrogen substituents.

The addition of *(5)* to acetylene at atmospheric pressure leads to the *P,P'*-ethylenebis(methylphosphinic) esters *(19)*[26].

#### *Alkyl(methyl)phosphinic Esters (15) and Secondary Products*

Hydrolysis of the phosphinic esters *(15)* at 160—200 °C leads to the phosphinic acids *(20)*[27].

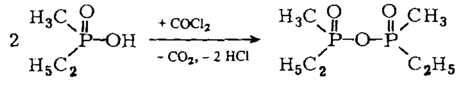


$$H_3C\text{-}P(O)(OR)\text{-}CH_2CH_2R^1 \xrightarrow[-ROH]{+H_2O} H_3C\text{-}P(O)(OH)\text{-}CH_2CH_2R^1$$

*(15)* *(20)*

R = Alkyl, $R^1$ = H, Alkyl

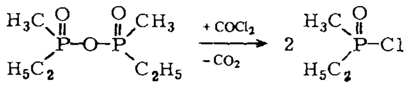
In the simplest case, ethyl(methyl)phosphinic acid *(20a)*[1] is obtained from *(15a)*; with phosgene in the molar ratio 2:1, phosphinic anhydride *(21)* is obtained almost quantitatively



$$2\,(H_3C)(H_5C_2)P(O)OH \xrightarrow[-CO_2,\,-2\,HCl]{+COCl_2} (H_3C)(H_5C_2)P(O)\text{-}O\text{-}P(O)(CH_3)(C_2H_5)$$

*(20a)* *(21)*

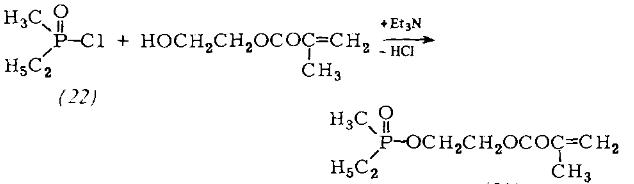
from *(20a)*[1,28]. Ethyl(methyl)phosphinic chloride *(22)*[1] is also readily accessible from the anhydride *(21)* by reaction with phosgene.



$$(H_3C)(H_5C_2)P(O)\text{-}O\text{-}P(O)(CH_3)(C_2H_5) \xrightarrow[-CO_2]{+COCl_2} 2\,(H_3C)(H_5C_2)P(O)Cl$$

*(21)* *(22)*

Alkyl(methyl)phosphinic chlorides, as monofunctional phosphoryl chlorides, are valuable intermediates. Thus from *(22)* and (2-hydroxyethyl)methacrylate the methacrylate *(23)* is obtained, the properties of which resemble those of the phosphorus containing acrylate *(13)*.

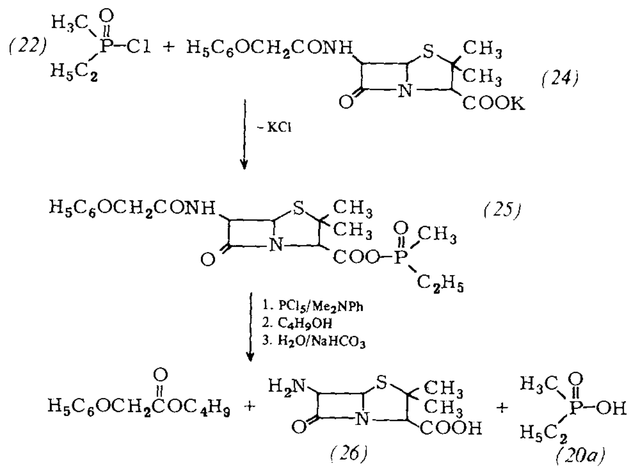


$$(H_3C)(H_5C_2)P(O)Cl + HOCH_2CH_2OCOC(CH_3){=}CH_2 \xrightarrow[-HCl]{+Et_3N} (H_3C)(H_5C_2)P(O)\text{-}OCH_2CH_2OCOC(CH_3){=}CH_2$$

*(22)* *(23)*

In addition, the alkyl(methyl)phosphinic chlorides enlarge the arsenal of protective group reagents. This may be illustrated by an example: from *(22)* and penicillin V, in the form of potassium salt *(24)* it is possible to prepare the mixed anhydride *(25)*.

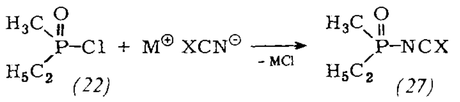
The carboxyamide group of the side chain is subsequently converted into the imide chloride by phosphorus pentachloride at about 0 °C, the anhydride function being preserved. By addition of butanol the imino ester is formed, which can



be smoothly hydrolyzed to 6-aminopenicillic acid *(26)*, an important intermediate for the synthesis of antibiotics.

Phosphinic chlorides can be used also for the synthesis of cephalosporin derivatives[30].

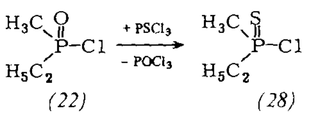
Among numerous further reactions, the reaction of *(22)* with cyanates and thiocyanates is of interest. It leads to the highly reactive phosphinic acid derivatives *(27)*[31], which have been used also to synthesize and modify natural products[32].



$$\underset{(22)}{\mathrm{H_3C(H_5C_2)P(=O)\!-\!Cl}} + M^{\oplus}\,XCN^{\ominus} \xrightarrow[-\,MCl]{} \underset{(27)}{\mathrm{H_3C(H_5C_2)P(=O)\!-\!NCX}}$$

M = Ag, Na, $NH_4$; X = O, S

Ethyl(methyl)thiophosphinic chloride *(28)* is formed by reaction of *(22)* with thiophosphoryl chloride at about 160 °C[33].

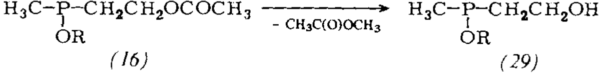


$$\underset{(22)}{\mathrm{H_3C(H_5C_2)P(=O)\!-\!Cl}} \xrightarrow[-\,POCl_3]{+\,PSCl_3} \underset{(28)}{\mathrm{H_3C(H_5C_2)P(=S)\!-\!Cl}}$$

Methylthiophosphinic chlorides are suitable educts for the preparation of methyldithiophosphinic acids, which form readily crystallizable metal complexes, some being intensely colored and many exhibiting extraordinary thermal stability[34].

### *2-Acetoxyethyl(methyl)phosphinic Esters (16) and Secondary Products*

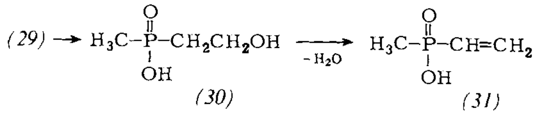
Transesterification of *(16)* with alcohols, preferably in the presence of bases, leads to formation of 2-hydroxyethyl-(methyl)phosphinic esters *(29)*; the yields being virtually quantitative[35].



$$\underset{(16)}{\mathrm{H_3C\!-\!P(=O)(OR)\!-\!CH_2CH_2OCOCH_3}} \xrightarrow[-\,CH_3C(O)OCH_3]{+\,CH_3OH/OH^{\ominus}} \underset{(29)}{\mathrm{H_3C\!-\!P(=O)(OR)\!-\!CH_2CH_2OH}}$$

R = Alkyl

The alcohols *(29)* provide the simplest access to methyl(vinyl)phosphinic acid *(31)*: hydrolysis to 2-hydroxyethyl(methyl)phosphinic acid *(30)* and subsequent dehydration of the latter *in vacuo*[36].



$$(29) \rightarrow \underset{(30)}{\mathrm{H_3C\!-\!P(=O)(OH)\!-\!CH_2CH_2OH}} \xrightarrow[-\,H_2O]{} \underset{(31)}{\mathrm{H_3C\!-\!P(=O)(OH)\!-\!CH\!=\!CH_2}}$$

### *Phostone (17) and Secondary Products*

As the "lactone" of 3-hydroxypropyl(methyl)phosphinic acid, phostone *(17)* is suitable for numerous reactions. Figure 3 shows several examples.

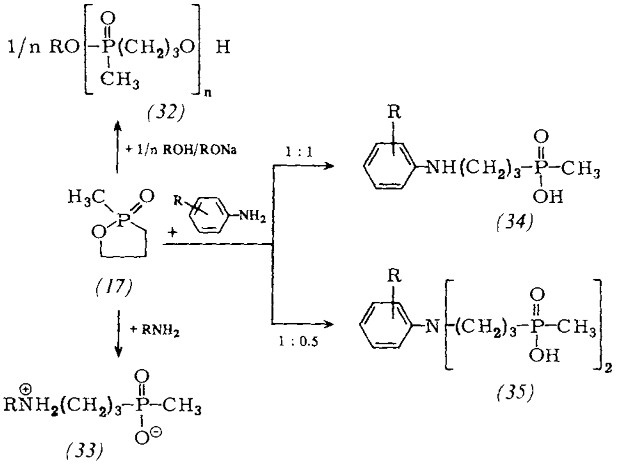


Fig. 3. Reactions of phostone *(17)*.

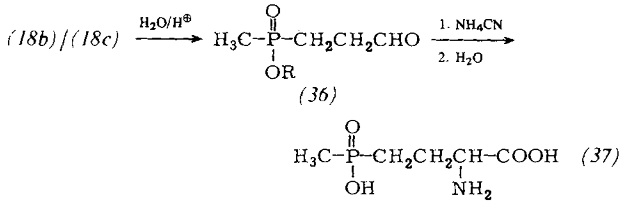
In the presence of catalytic quantities of the corresponding alcoholates, *(17)* reacts by oligoaddition to the adducts *(32)*[37]. Aliphatic amines form the internal salts *(33)* with *(17)*[38]. Depending on the molar ratio, either 3-anilinopropyl(methyl)phosphinic acids *(34)* or the corresponding *N,N*-disubstituted compounds *(35)* can be prepared from *(17)* and anilines, the yields being high[39].

### *2-Formylethyl(methyl)phosphinic Esters (36) and Secondary Products*

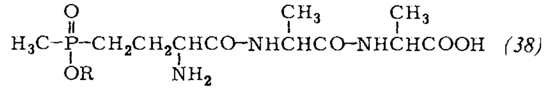
The esters *(18b)* and *(18c)* can be hydrolyzed in acidic media to 2-formylethyl(methyl)phosphinic esters *(36)*[24,25]. By means of a Strecker synthesis and subsequent hydrolysis, 2-amino-4-[hydroxy(methyl)phosphoryl]butyric acid *(37)* is obtained from *(36)*[25].



$$(18b)/(18c) \xrightarrow{H_2O/H^{\oplus}} \underset{(36)}{\mathrm{H_3C\!-\!P(=O)(OR)\!-\!CH_2CH_2CHO}} \xrightarrow[2.\ H_2O]{1.\ NH_4CN} \underset{(37)}{\mathrm{H_3C\!-\!P(=O)(OH)\!-\!CH_2CH_2CH(NH_2)\!-\!COOH}}$$

The amino acid *(37)*, also termed "phosphinothricin", was the first phosphinic acid derivative discovered in nature; it was isolated as the tripeptide *(38)* by *Bayer et al.*[40] in culture filtrates of *Streptomyces*[41].

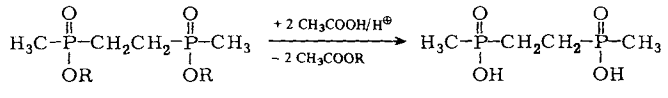
The route *via* cyanohydrin *(18a)* is the method of choice for the synthesis of phosphinothricin *(37)*.



$H_3C-P(=O)(OR)-CH_2CH_2CH(NH_2)CO-NHCH(CH_3)CO-NHCH(CH_3)COOH$ *(38)*

### *P,P'-Ethylenebis(methylphosphinic) Ester (19) and Secondary Products*

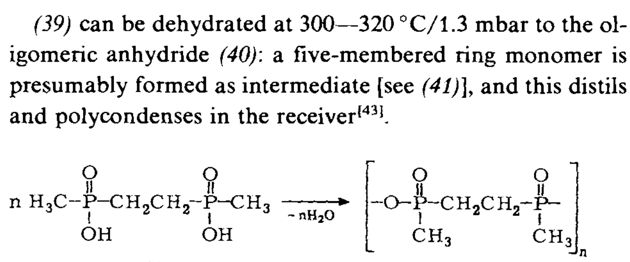
Cleavage of the ester *(19)* with acetic acid at about 140 °C in the presence of acid catalysts, preferably sulfuric acid, leads smoothly to *P,P'*-ethylenebis(methylphosphinic) acid *(39)*, m.p. = 190—191 °C[42]. This procedure is generally suitable for the preparation of high melting phosphinic acids which are readily soluble in hot and sparingly soluble in cold glacial acetic acid.



$H_3C-P(=O)(OR)-CH_2CH_2-P(=O)(OR)-CH_3 \xrightarrow[-2\,CH_3COOR]{+2\,CH_3COOH/H^{\oplus}} H_3C-P(=O)(OH)-CH_2CH_2-P(=O)(OH)-CH_3$

*(19)*, R = Alkyl *(39)*

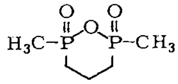
*(39)* can be dehydrated at 300—320 °C/1.3 mbar to the oligomeric anhydride *(40)*: a five-membered ring monomer is presumably formed as intermediate [see *(41)*], and this distils and polycondenses in the receiver[43].



$n\ H_3C-P(=O)(OH)-CH_2CH_2-P(=O)(OH)-CH_3 \xrightarrow{-nH_2O} [-O-P(=O)(CH_3)-CH_2CH_2-P(=O)(CH_3)-]_n$

*(39)* *(40)*

However, the anhydride *(41)*, which can be prepared in the same way at 250 °C from *P,P'*-trimethylenebis(methylphosphinic) acid is a six-membered ring compound (b.p. = 163 °C/0.3 torr, m.p. = 122—130 °C[43].



*(41)*

### 2.3.3. Addition of Methylphosphinic Acid Esters *(5)* to Compounds with Activated Double Bonds

The ester *(5)* adds to compounds with activated double bonds; in the presence of bases, derivatives of phosphinic acid esters are formed. Suitable unsaturated compounds, among others, are esters[44,45], amides[46] or α,β-unsaturated carbonitriles. A few selected reactions are compiled in Figure 4.

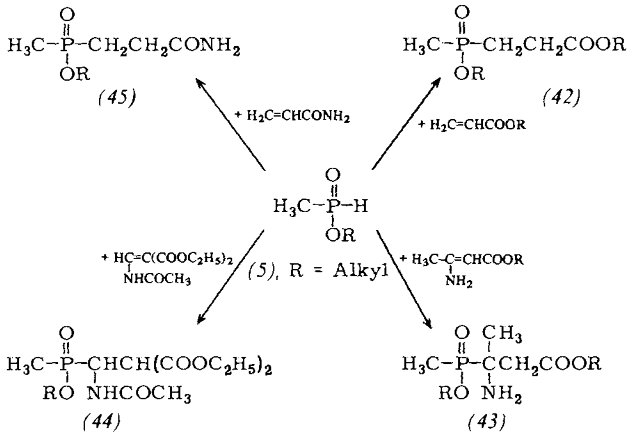


Fig. 4. Addition of *(5)* to compounds with activated double bonds.

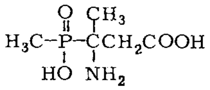
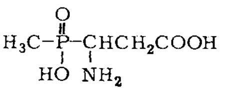
The amino acids *(46)* or *(47)* are formed by hydrolysis of *(43)*[44] or hydrolysis and decarboxylation of *(44)*[45].



*(46)* $H_3C-P(=O)(HO)-C(CH_3)(NH_2)CH_2COOH$



$H_3C-P(=O)(HO)-CH(NH_2)CH_2COOH$ *(47)*

## 2.4. Reactions of the Methylphosphonous Diesters *(6)*

### 2.4.1. Arbusov reactions with Methylphosphonous Diesters *(6)*

In Arbusov reactions the diesters *(6)* are more reactive than trialkyl phosphites. A few selected reactions are given in Figure 5.

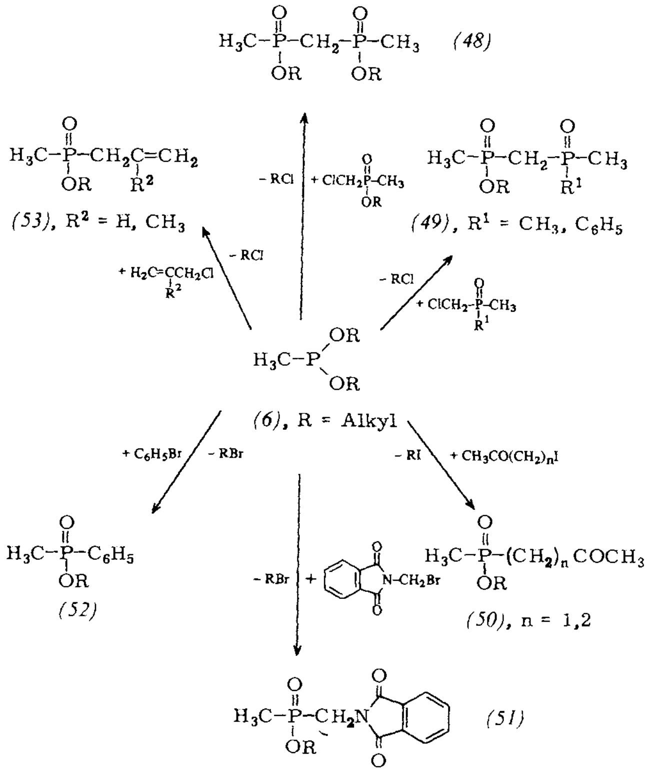


Fig. 5. Arbusov reactions of the methylphosphonous acid diesters *(6)*.

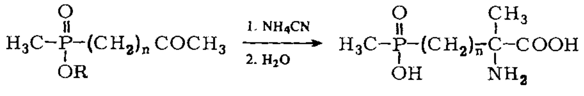
The *P,P'*-methylenebis(methylphosphinic) ester *(48)*, formed at 170—180 °C in almost quantitative yield, can be hydrolyzed to bisphosphinic acid, and the latter converted to polymeric titanyl complexes[47]. The phosphinic acids obtainable by hydrolysis of *(49)* form metal chelates having good thermal stability[48].

The phosphorus-containing amino acids *(54)* can, like *(37)*, be prepared by the Strecker synthesis[44].

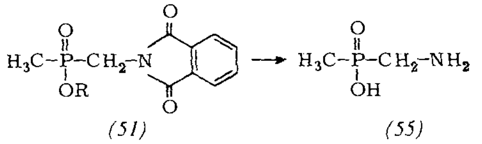


$H_3C-P(=O)(OR)-(CH_2)_nCOCH_3 \xrightarrow[2.\ H_2O]{1.\ NH_4CN} H_3C-P(=O)(OH)-(CH_2)_n-C(CH_3)(NH_2)-COOH$

*(50)* *(54)*

R = Alkyl, n = 1, 2

Aminomethyl(methyl)phosphinic acid *(55)* is accessible from *(51)* by hydrolysis[49]. In the presence of nickel halide catalysts *(6)* reacts with aryl halides, for example, bromobenzene, to give *(52)*[50]. Such catalysts, especially Raney nickel, have also been used for reactions of methallyl and allyl chloride with *(6)* to obtain the unsaturated phosphinic esters *(53)*[51].

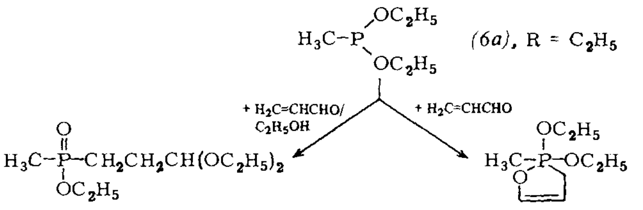


*(51)* *(55)*

R = Alkyl

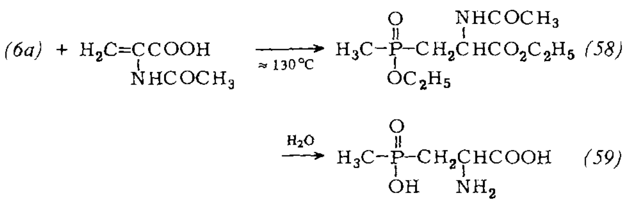
### 2.4.2. Addition of the Methylphosphonous Diesters *(6)* to Compounds with Activated Double Bonds

In contrast to the esters *(5)*, the diester *(6a)* in excess ethanol, adds smoothly to acrolein, to give diethylacetal *(56)*[52]. In the absence of ethanol, *(6a)* reacts with acrolein to give the pentacoordinate phosphorus compound *(57)*[53].



*(56)* *(57)*

The phosphonic ester *(58)* is obtained from *(6a)* and 2-acetamidoacrylic acid at about 130 °C; *(58)* can be hydrolyzed to a phosphorus-containing analogue of aspartic acid *(59)*.

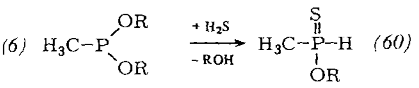


$$(6a) + H_2C{=}C(NHCOCH_3)COOH \xrightarrow[\approx 130\,^\circ C]{} H_3C{-}P(O)(OC_2H_5){-}CH_2CH(NHCOCH_3)CO_2C_2H_5 \quad (58)$$

$$\xrightarrow{H_2O} H_3C{-}P(O)(OH){-}CH_2CH(NH_2)COOH \quad (59)$$

### 2.4.3. Reaction of Methylphosphonous Diesters *(6)* with Hydrogen Sulfide

Of value in preparative chemistry is a procedure for the preparation of methylthiophosphinic ester *(60)*, in which the esters *(6)* are reacted with hydrogen sulfide at 50 °C under pressure in the presence of weakly basic amines, *e.g.* diethylaniline[54].



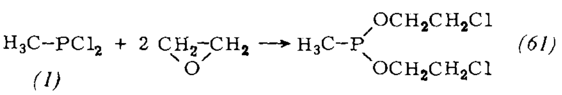
$$(6)\ H_3C{-}P(OR)_2 \xrightarrow[-\,ROH]{+\,H_2S} H_3C{-}P(S)(H)(OR) \quad (60)$$

R = Alkyl

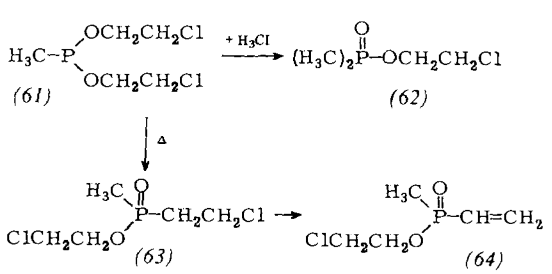
Methylthiophosphinic esters *(60)* have so far only rarely been used as synthetic building blocks. In the presence of radical initiators, compounds such as *(5)* can add smoothly to olefins; thus *via* addition to vinyl acetate, the 2-acetoxyethyl(methyl)thiophosphinic esters are obtained. The P=S group does not interfere with the radical addition.

### 2.5. Reaction of Dichloro(methyl)phosphane *(1)* with Ethylene Oxide

Reaction of *(1)* with ethylene oxide in the molar ratio 1:2 leads to methylphosphonous bis(2-chloroethyl) ester *(61)*, which occupies a special position among diesters of type *(6)*[55].



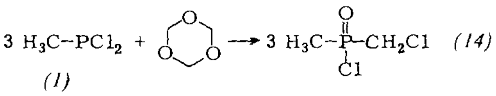
*(61)* reacts with methyl iodide, even at 30 °C, to form dimethylphosphinic 2-chloroethyl ester *(62)* and thus provides access to dimethylphosphoryloxy compounds[55].



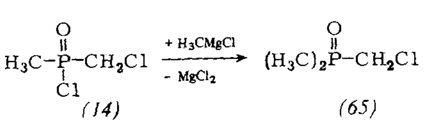
At 160 °C *(61)* reacts to form the phosphinic ester *(63)*, which eliminates HCl at 80 °C in the presence of triethylamine (molar ratio 1:1), the methyl(vinyl)phosphinic ester *(64)* being formed[55,56].

### 2.6. Reaction of Dichloro(methyl)phosphane *(1)* with Trioxane

The well known reaction of *(1)* with paraformaldehyde leads to chloromethyl(methyl)phosphinic chloride *(14)* in 70% yield[57]. *(14)* can also be obtained in almost quantitative yield from *(1)* and trioxane in the presence of Lewis acid catalysts in a current of hydrogen chloride at 130—150 °C[58] (see also Section 2.3.1.).



The phosphinic chloride *(14)* can be converted by Grignard reaction with methylmagnesium chloride to chloromethyl(dimethyl)phosphane oxide *(65)*[1,59].



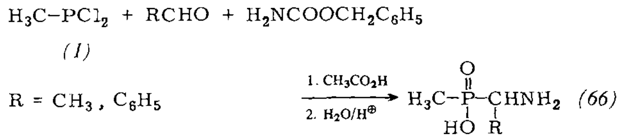
$$H_3C{-}P(O)(Cl){-}CH_2Cl \xrightarrow[-\,MgCl_2]{+\,H_3CMgCl} (H_3C)_2P(O){-}CH_2Cl$$

*(14)* *(65)*

Introduction of the tertiary phosphane oxide group into strongly hydrophobic compounds *via (65)* can considerably increase their water-solubility.

## 2.7. Reaction of Dichloro(methyl)phosphane *(1)* with Aldehydes and Carbamates or with Schiff's Bases

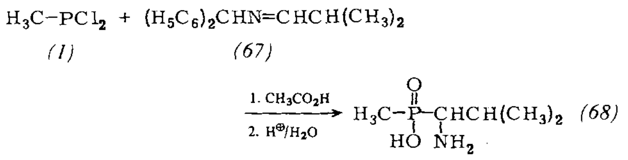
The direct preparation of 1-aminoalkyl(methyl)phosphinic acid is possible by condensation of *(1)* with aldehydes in the presence of carbamates. For example, if a mixture of *(1)*, benzylcarbamate and acetaldehyde or benzaldehyde is heated in glacial acetic acid and subsequently hydrolyzed with aqueous hydrochloric acid, 1-aminoalkyl(methyl)phosphinic acid *(66)* is obtained in 50—60% yield[60].



$$H_3C{-}PCl_2 + RCHO + H_2NCOOCH_2C_6H_5 \quad (1)$$

$$R = CH_3,\ C_6H_5 \quad \xrightarrow[2.\ H_2O/H^{\oplus}]{1.\ CH_3CO_2H} \quad H_3C{-}\underset{HO}{\overset{\overset{O}{\|}}{P}}{-}\underset{R}{C}HNH_2 \quad (66)$$

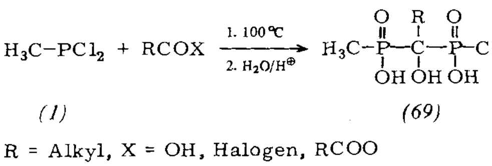
Phosphinic acids of this type are also obtained by reaction of *(1)* with Schiff's bases in glacial acetic acid and subsequent hydrolysis. Thus reaction of *(1)* with *(67)* and subsequent acidolysis, produces 1-amino-2-methylpropyl(methyl)phosphinic acid *(68)*[61].



$$\underset{(1)}{H_3C{-}PCl_2} + \underset{(67)}{(H_5C_6)_2CHN{=}CHCH(CH_3)_2} \quad \xrightarrow[2.\ H^{\oplus}/H_2O]{1.\ CH_3CO_2H} \quad H_3C{-}\underset{HO}{\overset{\overset{O}{\|}}{P}}{-}\underset{NH_2}{C}HCH(CH_3)_2 \quad (68)$$

## 2.8. Reaction of Dichloro(methyl)phosphane *(1)* with Aliphatic Carboxylic Acids

Dichloro(methyl)phosphane *(1)* reacts with aliphatic carboxylic acids — in the simplest case with glacial acetic acid — and also with their anhydrides and chlorides; hydrolysis of the primary products leads to derivatives of *P,P'*-(α-hydroxyalkylidene)bis(methylphosphinic) acid *(69)*[62].

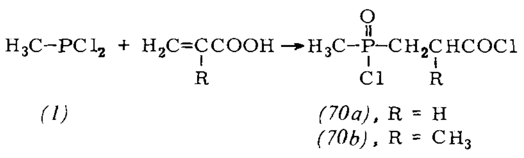


$$\underset{(1)}{H_3C{-}PCl_2} + RCOX \xrightarrow[2.\ H_2O/H^{\oplus}]{1.\ 100\,^{\circ}C} \underset{(69)}{H_3C{-}\underset{OH}{\overset{\overset{O}{\|}}{P}}{-}\underset{OH}{\overset{R}{C}}{-}\underset{OH}{\overset{\overset{O}{\|}}{P}}{-}CH_3}$$

R = Alkyl, X = OH, Halogen, RCOO

In contrast to the corresponding biphosphonic acids, compounds of type *(69)* do not exhibit any notable sequestering properties in aqueous systems.

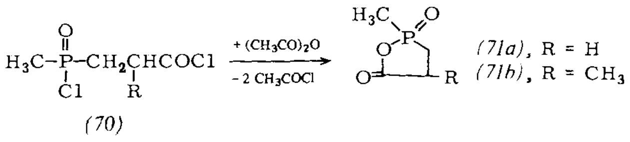
Acrylic acid reacts with *(1)* in a strongly exothermic reaction to form 3-[chloro(methyl)phosphoryl]propionyl chloride *(70a)*[63,64]. The reaction with methacrylic acid proceeds analogously to form *(70b)*.



$$\underset{(1)}{H_3C{-}PCl_2} + H_2C{=}\underset{R}{C}COOH \longrightarrow H_3C{-}\underset{Cl}{\overset{\overset{O}{\|}}{P}}{-}CH_2\underset{R}{C}HCOCl$$

*(70a)*, R = H
*(70b)*, R = $CH_3$

If the reaction is carried out continuously at 50—60 °C, the dichlorides *(70)* are obtained in almost quantitative yield[65]. They are smoothly cyclized by acetic anhydride to the 1,2-oxaphospholane-5-one 2-oxides *(71)*[1,63,64].



Numerous reactions of the phospholanes *(71)* (Fig. 6) proceed *via* ring opening. Thus the phosphinic acids are formed with water *(72)* and the phosphinic esters *(73)* are formed with alcohols such as ethanol. The reaction of *(71)* with aliphatic and aromatic amines leads to carboxamides, *e.g.* *(74)*[64], or with L-proline esters, after suitable isolation, to the compounds *(75)*[66].

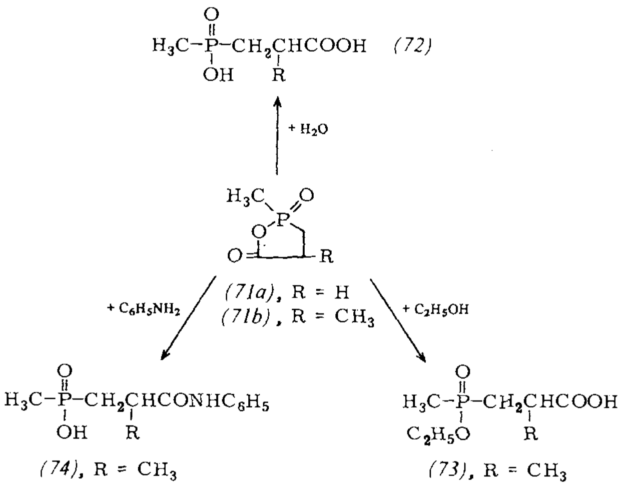


Fig. 6. Reactions of phospholanes *(71)*.

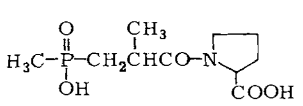
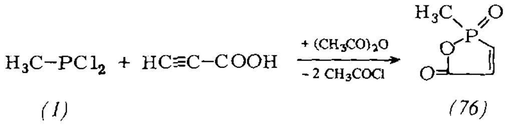


*(75)*

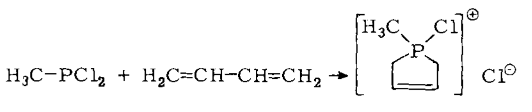
In a violent reaction with propiolic acid, *(1)* forms a phosphinic acid derivative which cyclizes when treated with acetic anhydride to form 2-methyl-Δ³-1,2-oxaphospholene-5-one 2-oxide *(76)*[64].



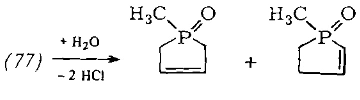
Reaction of *(1)* with *cis*-3-chloroacrylic acid[67], or preferably with 2-chloroacrylic acid[68], also leads to *(76)* using the same work-up procedure.

## 2.9. Reaction of Dichloro(methyl)phosphane *(1)* with 1,3-Dienes

[1+4]-Cycloaddition of *(1)* to 1,3-dienes, *e.g.* butadiene, leads to the phosphonium salt *(77)* which is readily converted by water into a mixture of the 1-methylphospholene oxides *(78)* and *(79)*[69,74].



(1) (77)

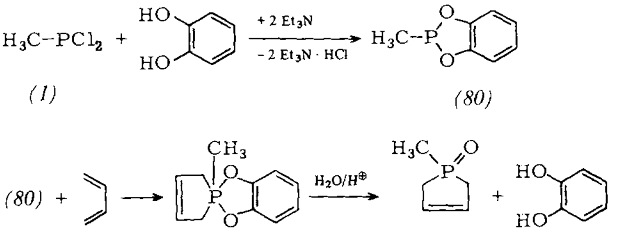


(77) (78) (79)

0.5 : 0.5

The extremely long reaction times can be shortened with the aid of solvents such as nitrobenzene, acyl chlorides and particularly phosphoryl chloride[75-78].

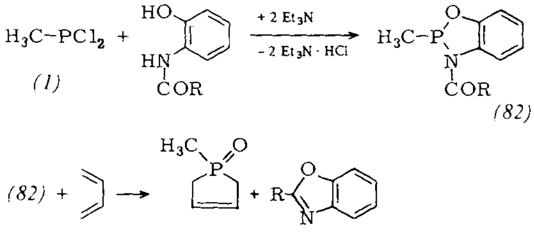
Two further syntheses of *(78)* proceed *via* benzoxaphospholenes. Benzodioxaphospholene *(80)*, obtainable from *(1)* and pyrocatechol cyclizes to the spiro compound *(81)* with butadiene and is hydrolyzed only very slowly to *(78)*[79].



(1) (80)

(80) + ... (81) (78)

Reaction of *(1)* with 2-(acylamino)phenols produces the isolable benzoxazaphospholenes *(82)*[80] in almost quantitative yield. The latter compounds react smoothly with butadiene to form *(78)* and 1,3-benzoxazoles *(83)*[81]. These compounds *(83)* can be readily split again into the 2-(acylamino)phenols. In both syntheses *(78)* is formed virtually free of isomers.

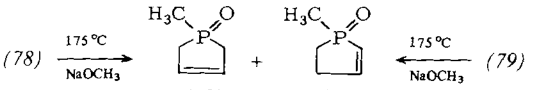


(1) (82)

(82) + (78) (83)

R = H, $CH_3$

Directed isomerization of *(78)* or *(79)* is possible above 150 °C in the presence of catalytic amounts of alkali metal alcoholates. The ratio 45:55 of *(78)* to *(79)* is always attained, regardless of whether *(78)* or *(79)* is used as starting material.



(78) (78) (79) (79)

0.45 : 0.55

## 2.9.1. Reactions of 1-Methyl-2-phospholene 1-Oxide *(78)*

Not only *(78)*, but also *(79)*, can react with a large number of compounds. Reactions of *(78)* are compiled in Figure 7.

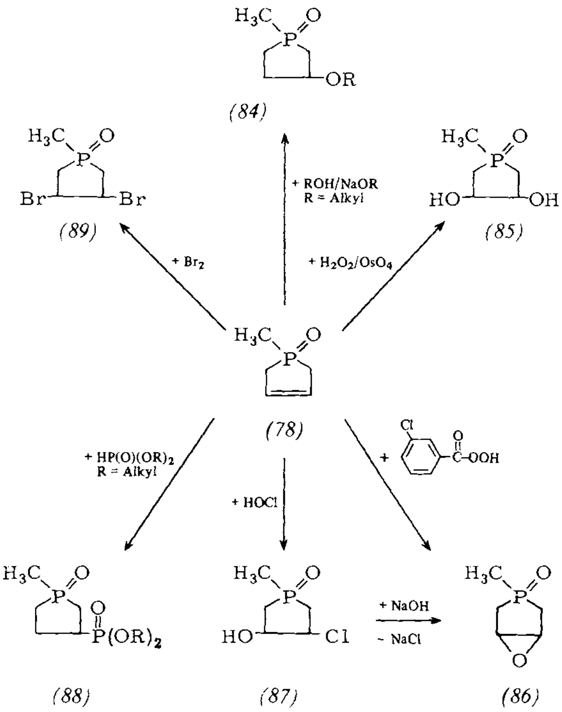


Fig. 7. Reactions of 1-methyl-phospholene 1-oxide *(78)*.

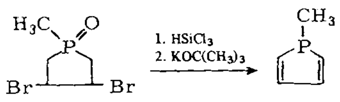
The addition of alcohols leads to 3-alkoxyphospholane 1-oxides *(84)*, good yields only being obtainable if alkali metal alcoholate (molar ratio approximately 1:1) is added[82].

In the presence of osmium tetroxide, *(78)* reacts with hydrogen peroxide to form 1-methyl-3,4-phospholanediol 1-oxide *(85)*[83].

The epoxide *(86)* is accessible either by reaction of *(78)* with *m*-chloroperbenzoic acid or—more advantageously—*via* the isolable 3-chloro-1-methyl-4-phospholanol 1-oxide *(87)*[84].

In the presence of radical initiators, the phosphonic diesters add to the double bond of *(78)* or *(79)*; the esters *(88)* being formed[85].

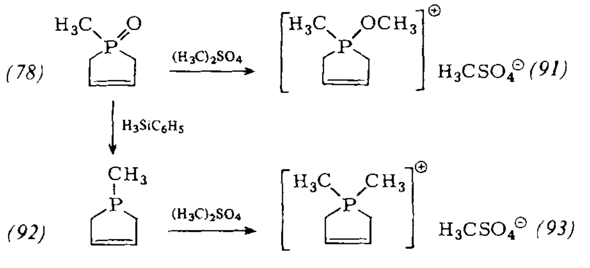
It is possible to brominate *(78)* to 3,4-dibromo-1-methylphospholane 1-oxide *(89)*, the reduction of which with trichlorosilane and subsequent dehydrobromination with potassium-*tert*-butoxide leads to 1-methylphosphole *(90)*. The spectroscopic data and reactivity of *(90)* are an indication of its aromatic character[86].



(89) (90)

*(78)* and *(79)* are readily quaternized by alkylation agents; thus the phosphonium salt *(91)* is obtained by reaction with dimethyl sulfate. The phospholene oxides *(78)* and *(79)* can

be reduced by organosilicon compounds to the phospholene *(92)*, which can be quaternized to the phosphonium salt *(93)*[87].



## 3. Fields of Application

### 3.1. Biocidal Compounds

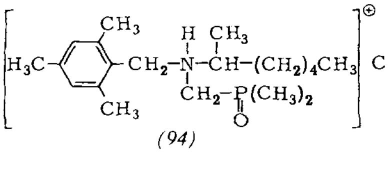
Because of their phosphorylating properties, methylphosphonic dichloride *(2)* and, in particular, methylthiophosphonic dichloride *(3)* are valuable starting materials for the synthesis of crop protection chemicals with biocidal properties[88-90]. The versatile synthetic potential of these acid dichlorides is supplemented by the alkyl(methyl)phosphinic chlorides and their thio-analogues, for example, ethyl(methyl)- *(22)* and chloromethyl(methyl)phosphinic chloride *(14)* or also ethyl(methyl)thiophosphinic chloride *(28)*[91].

Some derivatives of phosphinic acid exhibit biocidal properties. For example not only phosphinothricin *(37)*, but also its tripeptides *(38)* are suitable for use as herbicides[92,93]. Condensation products of the α-aminoalkyl(methyl)phosphinic acids *(55)*, *(66)* and *(68)* with one or more alanine residues exhibit herbicidal effects and plant growth regulating activity[61].

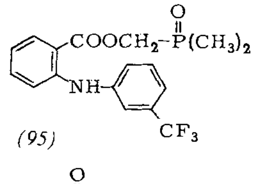
### 3.2. Pharmacologically Active Compounds

Starting from chloromethyl(dimethyl)phosphane oxide *(65)*, phosphane oxides having pharmacological activity can be obtained. Introduction of the phosphane oxide group into known active systems frequently improves solubility, while retaining the pharmacological activity. *(94)* is an antihistamine[94,95], *(95)* is of importance as an analgesic[96], and the phosphane oxides *(96)* are suitable as anti-hypertensives[97].

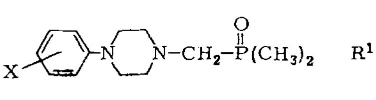
The benzodiazepines *(97)* are effective soporifics and have tranquilizing properties[98]; other 1,4-benzodiazepines with dimethylphosphoryl groups have been investigated in this connection[99]. The excellent water-solubility of the phosphane oxides *(97)* should be specially mentioned; the other benzodiazepine derivatives are far less soluble in water. The phosphinic acid derivative *(75)* has been found to be an active agent with hypotensive properties[6].



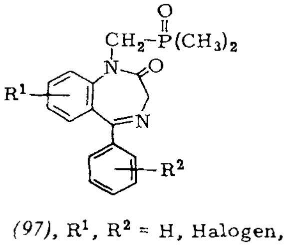
*(94)*



*(95)*



*(96)*, X = H, Cl, Alkyl



*(97)*, $R^1$, $R^2$ = H, Halogen, $CF_3$

### 3.3. Compounds Having Flame Retardant Activity

The well-known efficiency of numerous organophosphorus compounds as flame-retarding agents also extends to phosphinic acid derivatives and tertiary phosphane oxides. While derivatives of phosphonic acid are especially suitable for flame-retardant finishes of cellulosic fabrics, these same phosphorus compounds have also proved highly suitable, in this context, for polymers and polycondensates. They can be used in different ways:

a) *Introduction into the polymer chain:* by condensation of the oxaphospholane derivative *(71a)* into polyethyleneglycol terephthalates, polyesters are obtained which exhibit good permanent flame retardancy and can be made into flame-retardant fibers and filaments[100-102]. The phosphoryl acrylates *(13)* and *(23)* are monomers which, for example, can be used for terpolymerization with vinylidene chloride and acrylonitrile. Flame-retardant fibers having high luster and good lightfastness can be produced from the acrylonitrile polymers modified in this way[103-104].

b) *Use as additives:* because of their stability to hydrolysis and heat, phosphinic acids and their salts, as well as tertiary phosphane oxides, are particularly suitable as polymer additives. Thus, the alkali metal salts of the simple phosphinic acids *(20a)* or *(39)* can be used as additives for the production of flame-retardant polyamide molding compounds[105].

c) *Use as flame retardant textile auxiliaries:* textiles made from synthetic material can be rendered flame retardant by impregnation with phosphorus-containing compounds. Very high demands are made on these flame-retardant finishes; they should not adversely affect the properties of the textile material such as the "handle". Water-soluble products suitable for this purpose—*e.g.* the oligoadduct *(32)*, n = 11, ROH = glycerin[37]—are obtained by reacting phostone *(17)* with alcohols. Furthermore, polyadducts with similar properties *(71)* can also be obtained by reaction of the oxaphospholane derivatives with polyhydric alcohols and subsequent ethoxylation[106]. After cross-linking with "methylol-melamine esters", the products obtained with the aid of these—technically easy procedures—provide a washfast, flame-retardant finish on synthetic fibers.

A further possibility of achieving this consists of treating the textile material with a mixture of the water-soluble phosphoryl acrylates *(13)* or *(23)* and *N*-(hydroxymethyl)acrylamide in the presence of radical initiators. In this case the "methylol-melamine esters" can be completely dispensed with[107].

### 3.4. Metal Extraction Agents

Water-insoluble phosphinic esters *(15)*, for example, methyl(octyl)phosphinic acid isobutyl ester, are metal extraction agents. It has been suggested, for example, that they be used for the separation of zinc ions from aqueous $ZnCl_2$/$CdCl_2$ solutions[108] and also as additives in uranium(VI) extraction processes[109].

### 3.5. Further Uses

The phospholene oxides *(78)* and *(79)* can be used as catalysts for the preparation of flame-retardant polyurethane foams[110—114].

In alkaline media, hexyl(methyl)phosphinic and methyl(octyl)phosphinic acids exhibit outstanding wetting properties; consequently, they are suitable for the preparation of mercerizing solutions[115].

As an additive, *P,P'*-ethylenebis(methylphosphinic) acid *(39)* improves the heat and light stability of polyolefins[116].

## 4. Prospects

Owing to the intensive work being done in the field of organophosphorus compounds, and on their production on an industrial scale, it can be expected that they will find increasing use in many areas of application. Organophosphorus compounds can be both important starting materials and intermediates, as well as end products. The extraordinary multiplicity of reactions in which they can participate is due to a large number of intrinsic properties and the capacity of phosphorus to exist in several oxidation states. To utilize this possibility more than in the past in organic chemistry, is both an incentive and a challenge.

# Darwin and Molecular Biology[**]

## By Manfred Eigen[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

*Darwin*'s "idea of the century", the principle of selection, is as important in the age of molecular biology as it was a hundred years ago. As a natural law it is open to rigorous physical proof, if certain prerequisites are met, and to quantitative experimental test—*in vitro* and *in vivo*—under defined laboratory conditions.

If we, living in the second half of the twentieth century, ask ourselves whose work has furthered our understanding of the phenomenon of "life" to the greatest extent, then the name *Darwin* springs at once to mind.

"If you ask whether we shall call this the century of iron, or of steam, or of electricity, then I can answer at once with complete conviction: it will be called the century of the mechanistic understanding of Nature—the century of Darwin", wrote his contemporary, *Ludwig Boltzmann,* in 1886[1].

It is scarcely possible that the founder of statistical physics, writing these lines, was referring to *Darwin* the observer, the botanist, the zoologist. It was *Darwin*'s perception to which he was paying tribute. Today, with the improved methods and profound insights of molecular biology, *Darwin*'s gigantic empirical opus has become a matter of historical interest only, an outstanding achievement of the last century—not out-of-date, but out of the front line of modern science. *Darwin*'s true legacy is an insight, which is as relevant in the twentieth century as in the nineteenth, even if today the emphasis is placed rather differently.

**The story** of this epoch-making idea began in 1831, when the twenty-two-year-old *Charles Robert Darwin* boarded the British Admiralty surveying ship H. M. S. Beagle. A graduate in theology, he was thoroughly convinced of the truth of the doctrine of creation. But he was also possessed by an unremitting desire to discover the natural world. He was open-minded and prepared to draw conclusions from what he saw. Returning five years later from his journey around the world, he still hesitated to unveil to the public the crux of his experiences and observations. *Darwin*'s diaries make it clear that he had already arrived at the basic concept of his principle of selection in 1838, when he first became acquainted with *Thomas Robert Malthus*' "Essay on the Principles of Population"[2], a work which had appeared in 1798 and provoked much discussion. It is uncertain when this idea took final form in *Darwin*'s mind. For twenty years he worked on, endeavouring to broaden the empirical basis of his work. It took the news that a fellow countryman, *Alfred Russel Wallace,* had independently come to similar conclusions and the receipt of a copy of an essay[3] from *Wallace,* to jolt him into putting his theory into the form of a book—planned initially to appear in several volumes. The findings of these two scientists were publicly presented at the memorable meeting of the Linnean Society of London on July 1st, 1858. *Darwin*'s fundamental work "The Origin of Species"[4] finally appeared on November 24th, 1859, put to press by the well-known London publisher *John Murray.* Here at least the

principle of selection, borne out by a mass of observations, was developed clearly as the basis of evolution.

It has recently been put forward by *Brackman*[5] that *Darwin* was only able to formulate his concept of selection and evolution after reading *Wallace*'s manuscript. This suggestion is refuted not only by entries in *Darwin*'s diary but also by a plan sketched out in 1842 and 1844, known today as the "Foundations of the Origins of Species"[6]. *Wallace* never challenged *Darwin*'s priority—just as *Darwin* never denied his debt to *Wallace.*

The presentation by *Wallace* is simple and straightforward—*Darwin*'s texts are harder to read. Although both reached the same conclusions, *Darwin*'s reasoning is more convincing. For *Wallace,* the form of the growth law of a population plays only a secondary role, because—as he states explicitly—the population is in any case constant, and because even minor differences in succeeding generations should suffice to cause weaker and less well-organized forms to die out.

This is a correct observation, but still not an explanation. For *Darwin,* selection arises only from the "enormous geometric power of increase" of organisms. He records this in 1842 and makes reference to *Malthus.*

**Growth** alone is indeed not sufficient to explain selection[7].

In Figure 1a, growth curves for three growing species are shown. It is assumed that each one reproduces itself at a linear rate in time, that is, new members are produced at constant speed. If we now impose competition upon the system by limiting the total population—this is done by making the rate of removal (*e. g.,* by death) of each species proportional to its population size—the result is a stable coexistence of all these species, in which the selective advantage of a particular one results solely in its population becoming greater than those of the other two (see Fig. 1b). It is immaterial whether this advantage is due to a higher birth rate, a lower death rate, or both.

Genuine selection does not appear until we assume exponential growth, a condition simulated in Figure 2a. If the population is again restricted by removal of total excess production - for each species proportional to its fraction of individuals - only the species with optimal birth and death rates survives. Selection is determined solely by the inherent properties of the species and not by its population size (which the chemist would call "concentration" or "mass action"). If a mutant individual with an evolutionary advantage arises some time after the others, its progeny can outgrow them, even though it starts with a numerical disadvantage (Fig. 2b). Again, "advantage" means higher rate parameters for growth (reproduction), lower rate parameters for decay (death), or both. The effect of "mass action" cancels out, as removal is also proportional to each particular population size.

"Mass-action" appears in selection when growth accelerates at a rate faster than exponential. The examples in Figures 3, based upon hyperbolic growth laws (quadratic dependence for population growth, linear for decay) show sharp and unambiguous selection as a consequence of competition. However, in this case, the result of selection is a once-and-for-all decision. This may at first seem surprising, since the hyperbolic growth curve approximates very well to an exponential in any restricted time interval below the singularity. Such a form, however, then depends upon the population size at any given moment ($e^{k'Nt}$ instead of $e^{kt}$). It is therefore not enough for a mutant to have a sufficiently high rate parameter $k'$, since it would still be at a disadvantage by a factor $N$—the number of individuals already present. Such a factor is extremely difficult to overcome in real situations by favourable kinetic properties.

Populations obeying all these three growth laws—linear, exponential and hyperbolic—may be found in the biological world. For example, if two species obtain nourishment from two independent but restricted sources, the result is a con-

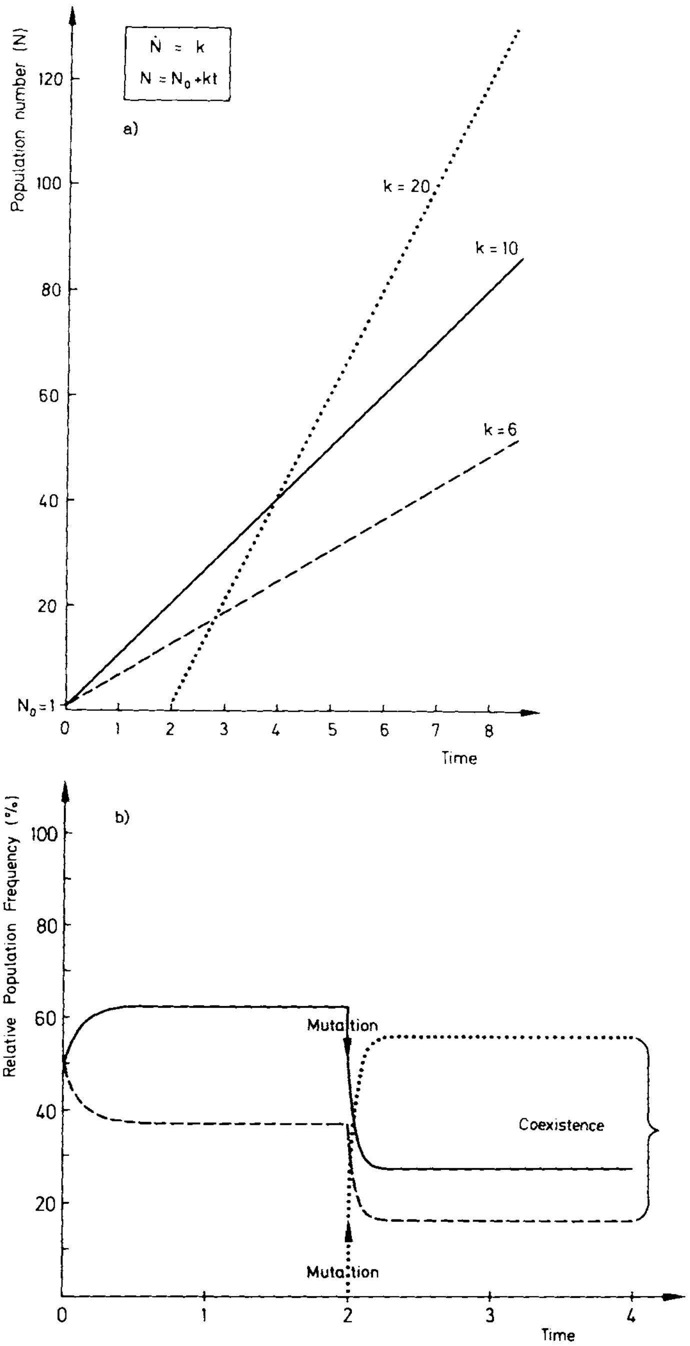

Fig. 1. a) A system with a constant rate of growth shows a linear growth law. b) Restriction of growth due to a first-order decay process results in coexistence of the competing species. The time required to reach a steady state depends on the number of individuals. The curves in this Figure and in Figures 2b and 3b are calculated on the basis of a total population $N = 10$.

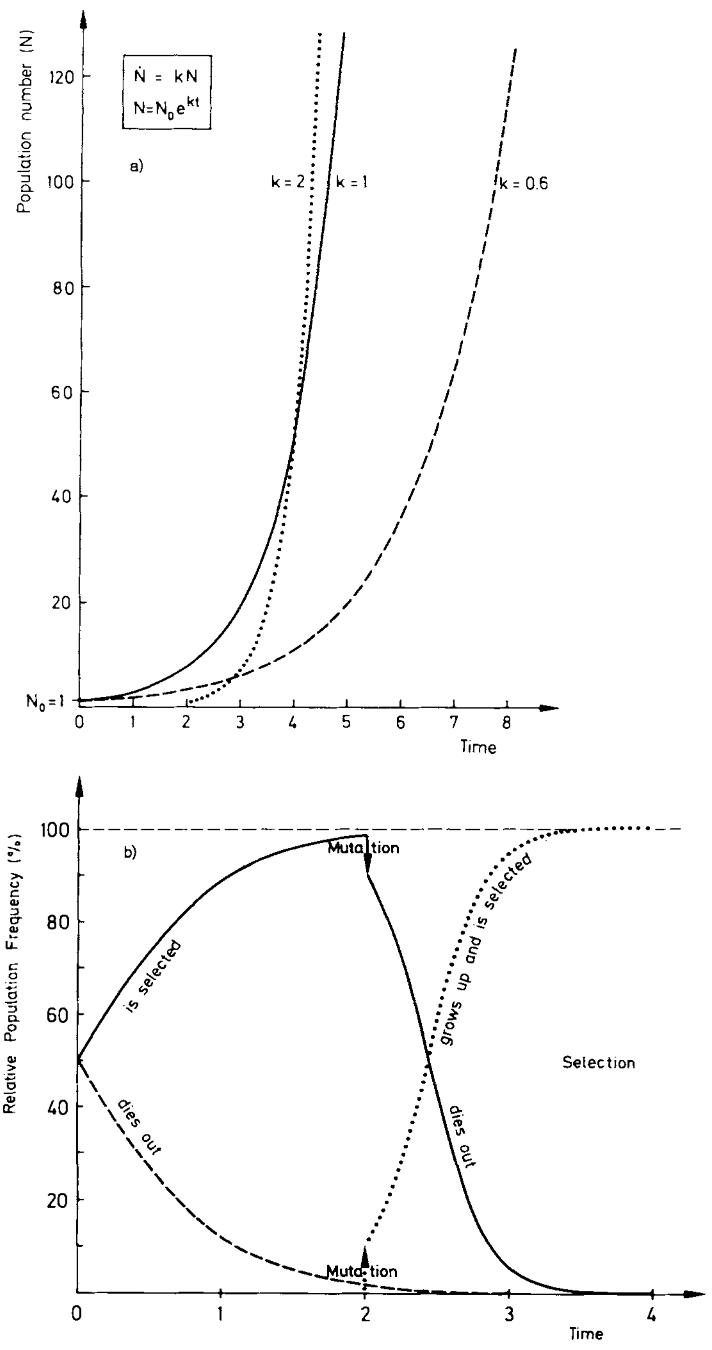

Fig. 2. a) A system with a linear autocatalytic rate term shows an exponential growth law. b) Limitation to a constant total population results in selection of the species with the highest effective growth rate. Mutants arising later grow successfully if they bear a selective advantage.

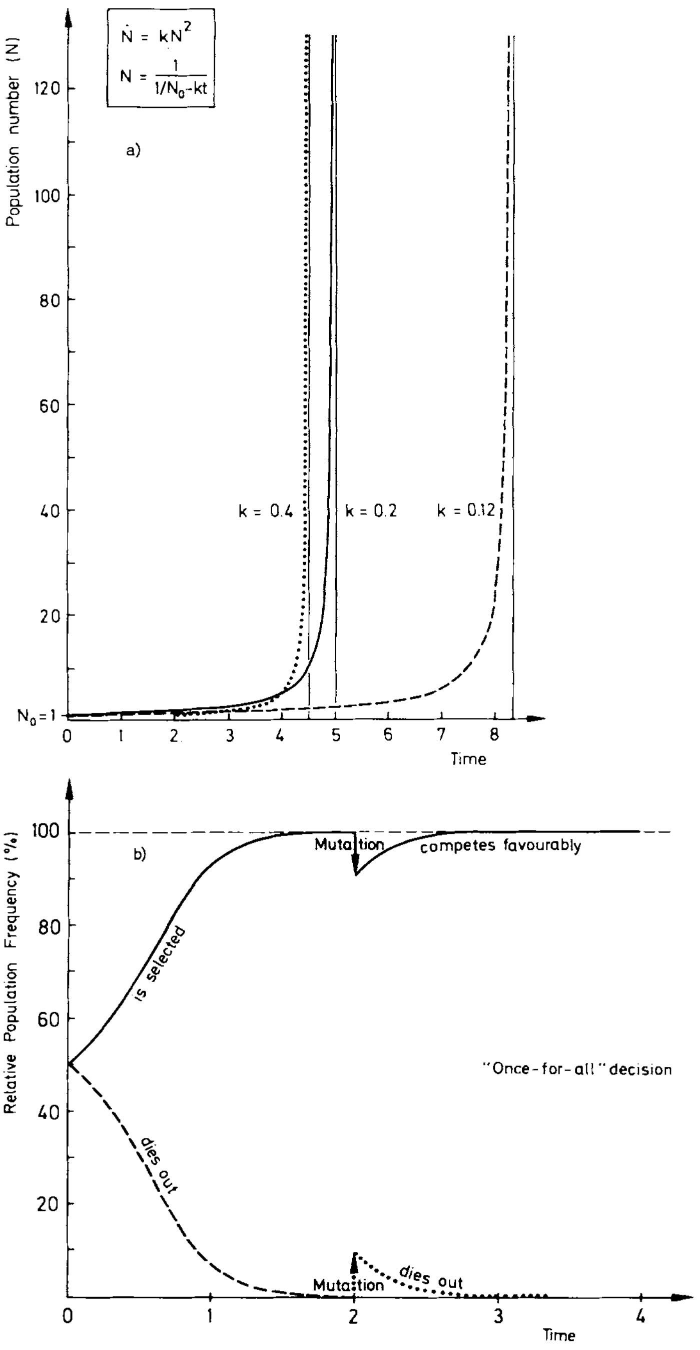

Fig. 3. a) Autocatalytic systems with a higher-order rate law show a hyperbolic growth law. b) Limitation of hyperbolic growth leads to selection with a "mass-action effect", which makes a once-and-for-all decision. The sharpness of selection in the course of time depends strongly upon the total population, *N*.

stant growth rate and thus a linear increase in population leading to coexistence of both species. Biologists call this niche formation. Selection then only takes place within each distribution of mutants. Niche formation has resulted in the coexistence of a great variety of species. However, these originally arose by selection on the basis of exponential growth laws. Hyperbolic growth limits the variety of species in an "all-or-none" way. Even the molecular self-organisation of life—as will be shown below—has passed through a phase of "co-operative" enhancement, in which the molecular machinery and a universal code for all posterity was laid down in a once-and-for-all decision.

It is futile to ask whether *Darwin* envisaged all this; however, his repeated reference to *Malthus* makes it clear that he was well aware of the significance of the form of the growth law.

Later, *Darwin* was to refine his ideas continually and to reexamine many details. His original work of 1859[4] was followed by five further editions during his lifetime, amid newer works on alterations to plants and animals caused by domestication, on the descent of Man, on the expressions of emotions, on geology and above all on botany.

What is the **essence of the principle of selection?** Both *Darwin* and *Wallace* treated the phenomenon of life for the first time as an object of scientific research, by assuming natural causes for its origin and its evolution, by setting up hypotheses which could be tested objectively, and, in *Darwin*'s case in particular, by showing many times over how such a test can be carried out using the methods of scrupulous observation. The palaeontologist *George Gaylord Simpson*[8] regarded this as the "most important accomplishment" of *Darwin*'s work, which "would have been revolutionary even if *Darwin* had been quite mistaken in the specific theories that he advanced" (*Simpson* adds: "As a matter of fact, he was not").

*Darwin* expended great effort on the minute analysis of all the facts which spoke for or against the assumption of an evolutionary development of living things. This assumption was by no means new; it was familiar to every natural scientist of the time. *Darwin* took the hypothesis from the work of *Jean Baptiste de Lamarck*[9], who had propounded it at the beginning of the nineteeth century. It seems, however, that *Darwin* begrudged *Lamarck* the credit for this. Although he described *Lamarck* as a "justly celebrated naturalist", he cannot resist mentioning[8] that his grandfather, Dr. *Erasmus Darwin,* had anticipated *Lamarck*'s opinions and "their erroneous grounds", and that in addition *Etienne Geoffroy Saint-Hilaire* in France and *Johann Wolfgang von Goethe* in Germany had already expressed similar opinions. *Goethe*'s works on morphology made a considerable contribution indeed to the doctrine of evolution, even though they were concerned with demonstrating its effects rather than postulating its causes.

Departing from *Lamarck, Darwin* postulated the descent of *all* living beings from a common ancestor, in agreement with *Goethe* and *Geoffroy Saint-Hilaire,* who took it that "what we call species are various degenerations of the same type". But only *Darwin,* dissatisfied with conjecture, assembled his evidence piece by piece. When in the end the burden of proof became crushing, and even mankind had to be included in his theory, *Darwin* became—and in some circles he still is today—an object of censure. In fact earlier research, such as *Goethe*'s discovery of the human intermaxillary jawbone, had already pointed towards this conclusion, for which *Darwin* simply had to provide the explanation. Modern molecular biology and the quantitative comparison of genetic information in different organisms has long since decided the issue in *Darwin*'s favour. Even when one can still read, "The theory of man's descent by natural selection from closely allied, preexisting species has never been proven, and probably never will be"[5], there is nonetheless no alternative "theory of man's descent" which can explain the phylogenetic family trees resulting from sequence homologies between individual RNA and protein molecules. Examples of these are shown in Figures 4 and 5 and in Table 1.

The stroke of genius consisted in tracing the process of evolution back to its natural cause. Reality is complex, but its principles are simple. *Darwin* had discovered a simple truth.

In the sixth edition of the "Origin of Species", which *Darwin* himself edited and which he saw as the final version, to be bequeathed to posterity, he wrote: "This preservation of favourable individual differences and variations, and the destruction of those which are injurious, I have called Natural Selection, or the Survival of the Fittest." *Darwin* uses several

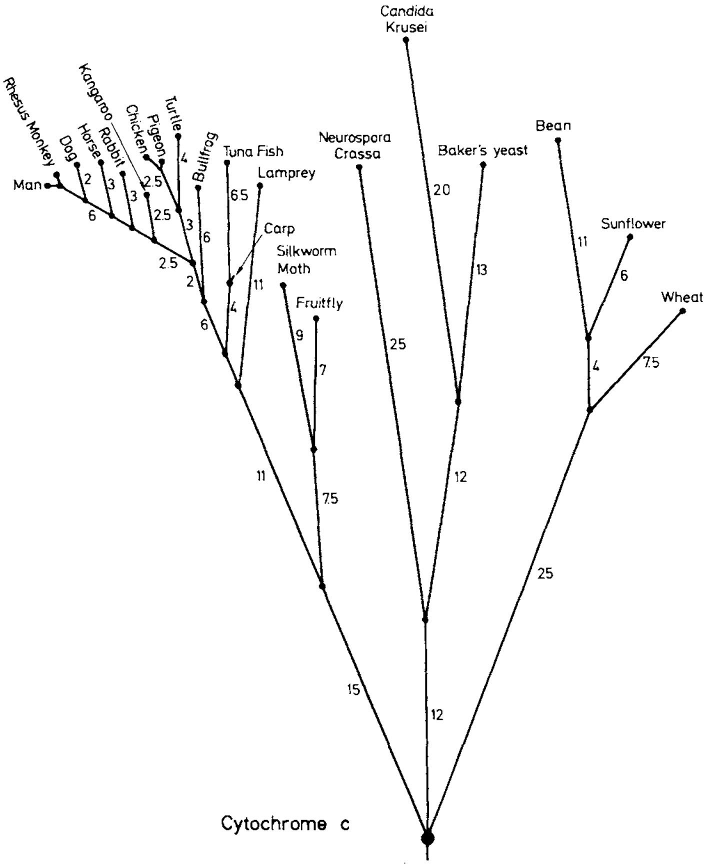

Fig. 4. Phylogenetic tree resulting from a sequence comparison of cytochrome c [10]. The distance reflects clearly the development of eucaryotes. Subtle branching effects among primates are more easily recognised in the haemoglobin sequences (Table 1).

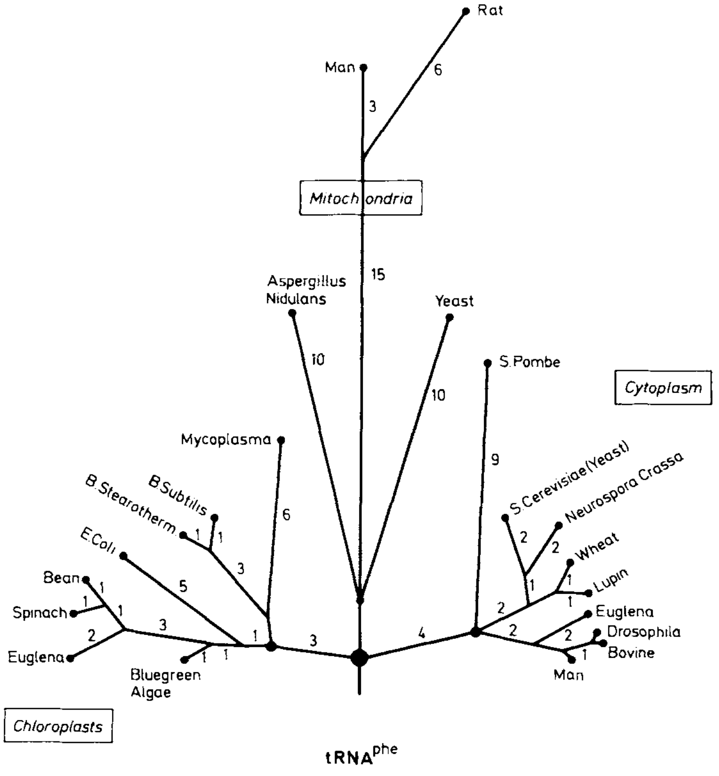

Fig. 5. Phylogenetic tree resulting from a comparison of transfer-RNA (isoacceptor for phenylalanine with the anticodon GAA) [11]. The conservative nature of this molecule conveys particularly clearly the effect of nearness of kin: division into pro- and eucaryotes, branching-off of mitochondria and chloroplasts, fanning-out among the procaryotes. Finer detail is on the other hand hardly visible for nearer kinship (*e.g.* difference from drosophila to man: one base pair).

expressions which he had taken from *Herbert Spencer*, such as "destruction", "struggle for existence" *etc.*, which today are somewhat misleading: they fail to express the passive nature of much of the competition, which indeed Darwin himself did not wish to deny. This is clear in his rejection of *Karl Marx*, who attempted to base his terminology on *Darwin*'s.

Table 1. Percentage differences between haemoglobin β-chains of various primates. Data from "Atlas of Protein Sequence and Structure" [10].

| | Man | Chimpanzee | Gorilla | Gibbon | Baboon | Spider Monkey | Tamarin | Squirrel Monkey | Rhesus Monkey | Japanese Macaque |
|---|---|---|---|---|---|---|---|---|---|---|
| Man | 0 | 0 | 1 | 1 | 5 | 4 | 5 | 6 | 5 | 5 |
| Chimpanzee | 0 | 0 | 1 | 1 | 5 | 4 | 5 | 6 | 5 | 5 |
| Gorilla | 1 | 1 | 0 | 2 | 5 | 5 | 6 | 7 | 5 | 4 |
| Gibbon | 1 | 1 | 2 | 0 | 5 | 3 | 4 | 5 | 4 | 3 |

| Japanese Macaque | 5 | 5 | 4 | 3 | 8 | 5 | 5 | 7 | 1 | 0 |

*Darwin*'s view was that the total number of individuals in a population alters only very slowly in comparison with the rate at which new individuals are produced. This means that, on average, the number of deaths and the number of births are approximately equal. On account of the considerable inherited variation (which *Darwin* under- rather than overestimated), the individuals which are best suited to their environment ("fittest") will have the greatest probability of survival and will produce descendents with better genetic equipment than will the less fit. What the advantage—considered to be purely genetic in origin—consists of, whether it results in an active "struggle for existence" or a passive thinning-out of the less fit individuals, caused by differences in fertility and lifespan, is more or less immaterial. *Darwin* also left open the question of whether evolution takes place exclusively by a natural process of selection, and he was right to do so. Not because he thus left open a back door for purpose-directed evolution in the Lamarckian sense, but simply because he felt that a principle can only ever express a single aspect of reality and not reality *in toto.*

The laying of a quantitative foundation for *Darwin*'s theses had to wait for the population genetics of this century, represented by such names as *John B. S. Haldane*[12], *Ronald A. Fisher*[13] and *Sewall Wright*[14]. This science showed:

1. that natural selection may be derived rigorously—*i. e.*, mathematically—from the properties of populations of living individuals,
2. that various real situations can be described by alternative models which, while not disagreeing with the selection principle, have to take account of further factors, and
3. that the laws of sexual heredity, discovered by *Gregor Mendel*, can be integrated into the theory, but are then of decisive influence, above all in the question of genetic variation.

It is clear that Nature produces apparent deviations from strict "Darwinian" behaviour. An example of this is provided by the so-called neutral mutations. These are alterations in the genetic equipment which result in no advantage or disadvantage for the progeny, and so are selectively "neutral". The Japanese geneticist *Motoo Kimura*[15] has set up a theory of fluctuations, from which it emerges that neutral mutations of this kind can spread through a population and thus cause evolutionary drift which has no selective advantage. He came to the remarkable conclusion that in view of the complexity of the hereditary material of higher organisms the greater part of any alteration is to be attributed to a genetic drift of this kind. There has been controversy over the quantitative importance of this effect—an issue which could be decided by experimental test. Modern genetics has the means to do this. This kind of selection, which is not guided by a selective advantage, is sometimes referred to as "non-Darwinian"[16]. This could leave the impression that *Darwin* regarded his principle as a dogma. Let us read what he himself had to say about it: "Variations neither useful nor injurious would not be affected by natural selection, and would be left either a fluctuating element, as perhaps we see in certain polymorphic species, or would ultimately become fixed, owing to the nature of the organism and the nature of the conditions." This is precisely what the theory of neutral mutations lays down. *Darwin,* unacquainted with the mechanism of sexual recombination of chromosomes, could naturally never have guessed the extent of this process.

We now come to the central question: What **new perception** of Nature was encapsulated in the principle of selection? We do not mean here the actual biological process, with all its complicated superstructure—we want to understand the principle itself. What is it? An axiom, an underivable, fundamental law, to which all living matter is subject, which we simply have to observe and accept? Or is it a heuristic device, which simply describes a pattern of observations, but whose seeming regularity disappears when it is rigorously analysed?

It is neither the one nor the other. The principle of selection turns out to be a law which is rigorously derivable from physical premises.

To illustrate this, let us examine a physico-chemical law with which we are all familiar—the law of mass-action. It governs the distribution of chemical reactants in equilibrium. In thermodynamics, "equilibrium" is characterised by an extremum principle, which in this case means that in a system at constant temperature and pressure, which does not exchange matter with its surroundings (a "closed" system), the Gibbs' free energy tends towards a minimum, and the system is in equilibrium when this minimum is reached. At this point the distribution of reactants and product is determined, exclusively and therefore reproducibly, by the mass-action constant.

The selection principle may be approached in a very similar way. We are interested in the selection of a particular genotype which on the basis of its phenotypic properties may be summed up as "the fittest". The genotype, the genetic information of an organism, is represented by an enormous molecular chain, in which each monomeric subunit (nucleotide) corresponds to a "letter" of the genetic message. Even in the simplest, single-celled organisms, such as the *Coli* bacterium, this message consists of four million nucleotides, corresponding in letters to a 1000-page book. The human genome has three thousand million nucleotides—a respectable "library"! When a genetic message is reproduced, some letters are "read off" wrongly; we call these "mutations". They are the origin of evolutionary progress. Selection thus means two things:

1. The information representing the fittest phenotype has to be chosen, copied many times over, and made into the starting-point for further development.
2. The information for the fittest phenotype has to be stable enough to remain intact until a better mutant arises. In other words, mistakes must not accumulate but must remain below a critical threshold level.

One might formulate the physical problem which is to be solved by way of selection as follows:
What **mechanism** could guarantee the necessary but spontaneous origin of information?

The complexity of living organisms rules out any solution for this problem such as is offered by the law of chemical mass-action. Even a single gene, which encodes one of many thousand functions, has an inconceivably large number of possible arrangements of its elements, even if the total length and overall composition are known. Accumulation of errors could lead from a given sequence to any other one, and if thermodynamic equilibrium were to be reached all possible sequences would appear, with various probabilities. It is easy to estimate that if each possible sequence were represented by one molecule then the volume of the universe would not be sufficient for more than a tiny fraction of the material necessary.

Only selection can circumvent this dilemma. An essential prerequisite for this is the prevention of equilibrium, and this is only possible by continually supplying free energy to the system. In organisms this requirement is met by metabolism.

Natural selection rests on two further prerequisites: self-reproduction and variability. The self-reproduction of molecules in turn presupposes particular structural properties, which are fulfilled, for example, by the nucleic acids. It is these which endow all organisms with the ability to reproduce themselves. Variability is simply a consequence of "blurred" self-reproduction.

These three prerequisites suffice for the deduction of a governing **extremum principle,** valid for "open", self-reproducing systems and leading to selection as a regular feature of the behaviour of matter, appearing under defined conditions[17,18].

Let us define a population (or concentration) variable belonging to a reproductive unit "*i*" ("*i*" can be for example a DNA or RNA molecule, a cell, an organism, *etc.*) as $c_i$, and its proportion in a total population containing n species as $x_i$ $(=c_i/\sum_{k=1}^{n} c_k)$. The rate of variation in time of this component $(\dot{x} \equiv dx/dt)$ is then given by the differential equations

$$\dot{x}_i = (w_{ii} - \bar{E}(t))\,x_i + \sum_{l \neq i} w_{il}\,x_l \tag{1}$$

$$\sum_{k=1}^{n} \dot{c}_k = \bar{E}(t) \sum_{k=1}^{n} c_k - \phi \tag{2}$$

The individual terms have the following meanings:

Diagonal terms: $w_{ii}x_i$ (or $\sum_{k=1}^{n} w_{kk}x_k$) = first-order autocatalytic self-reproduction

Off-diagonal terms: $w_{ij}x_j$ (or $\sum_{l \neq i} w_{il}x_l$) = mutations; i arises through the incorrect reproduction of j or l

Sum term: $\bar{E}(t) = \sum_{k=1}^{n} w_{kk}x_k + \sum_{k=1}^{n} \sum_{l \neq k} w_{kl}x_l$ = average production rate

Flux term $\phi$: this describes regulable fluxes of dilution and wastage

This system of equations for the **"relative"** population variables applies to all possible time-dependent and -independent (stationary) conditions, with or without the imposition of fluxes, as long as the concentrations of the nutrients are kept constant (buffered).

The non-linear system of equations can be transformed into a diagonal form[19,20] and emerges as

$$\dot{y}_i = (\lambda_i - \bar{\lambda}(t))\,y_i \tag{3}$$

where $y_i$ is a composite population variable and $\lambda_i$ its corresponding eigenvalue. The transformation preserves the non-linear term $\bar{E}(t) = \bar{\lambda}(t)$, which can further be represented as the average of all the separate eigenvalues.

Thus the extremum principle emerges directly from the system of differential equations (3). All the population variables $y_s$ for which $\lambda_s < \bar{\lambda}(t)$ have a negative $\dot{y}_s$ value and thus die out, while all $y_g$ with $\lambda_g > \bar{\lambda}(t)$ increase. This however results in a continual displacement of $\bar{\lambda}(t)$, so that fewer and fewer eigenvalues can fulfil the threshold requirement. Finally $\bar{\lambda}(t)$ becomes equal to the highest eigenvalue $\lambda_{max}$.

The extremum principle thus runs:

$$\bar{E}(t) \equiv \bar{\lambda}(t) \rightarrow \lambda_m \tag{4}$$

$$y_m \rightarrow \sum_{k=1}^{n} x_k \tag{5}$$

This results in a self-organisation of the system, in which only that part of the population distribution with the highest $\lambda_m$ value survives. We call this a quasi-species. Second-order perturbation theory shows that the quasi-species selected will be dominated by one or several degenerate "master-types", which possess the highest diagonal term $w_{mm}$ within the distribution. Its proportion in the distribution may be relatively small, and can be calculated to be

$$\frac{x_m}{\sum_{k=1}^{n} x_k} = \frac{Q_m - \sigma_m^{-1}}{1 - \sigma_m^{-1}} \tag{6}$$

Here $Q_m$ is the quality of reproduction ($1 - Q_m$ is the error rate per replicative unit) and $\sigma_m$ the superiority of the master-type, which gives the factor by which the master-type is more efficiently reproduced than its mutational distribution.

In biology we refer to the master-type which is most suited to normal conditions as the wild-type. The target of selection is, however, not the wild-type alone, but a stationary distribution of mutants around it, whose relative frequencies are given by the off-diagonal terms $w_{im}$, divided by the differences between diagonal terms, $w_{mm} - w_{ii}$

$$\frac{x_i}{x_m} = \frac{w_{im}}{w_{mm} - w_{ii}} \tag{7}$$

The concentration ratios are reached independently of whether the system as a whole is growing or is in a stationary state.

The fact that this extremum principle is valid for Darwinian systems leads to the following **consequences:**

1) Selection of a distribution of mutants dominated by the best-fitted variant. This is stable as long (and only as long) as the conditions $\sigma_m > 1$ and $Q_m > \sigma_m^{-1}$ are fulfilled.
2) Evolution by selection of newly-appearing mutants which on account of a selective advantage violate the condition for stability $\sigma_m > 1$ and thus make the previous distribution unstable.
3) The second (and stronger) condition for stability, $Q_m > \sigma_m^{-1}$, can only be fulfilled by limiting the information content. If the master-type *m* is composed of $\nu_m$ units of information (*e.g.* nucleotides in a master sequence) and the average quality of reproduction is $\bar{q}_m$ ($1 - \bar{q}_m$ = average error rate per symbol), than the overall quality of a reproductive unit with $\nu_m$ symbols is given by $Q_m = \bar{q}_m^{\nu_m}$, where $Q_m$ is the probability that the entire unit will be copied correctly. For $1 - \bar{q}_m \ll 1$, since $Q_m > \sigma_m^{-1}$, we can write

$$\nu_m \leq \frac{\ln \sigma_m}{1 - \bar{q}_m} \tag{8}$$

The error thresholds applicable to biological evolution can be measured experimentally and are summarised in Table 2.

Table 2. Experimentally determined information thresholds of biological evolution.

| Process | Measured on | with Error rate | Upper limit of number of symbols (nucleotides) | Comparable linguistic unit |
|---|---|---|---|---|
| Base pairing (enzyme-free) | AU-polymers | 1:10 | 10 | syllable - word |
| | GC-polymers | 1:100 | 100 | word - sentence |
| Enzymic RNA replication | RNA viruses | 1:10000 | 10000 | essay |
| Enzymic DNA replication | procaryotes | 1:10000000 | 10000000 | book |
| Recombinative Reproduction | eucaryotes | 1:3000000000 | 3000000000 | library (containing ~ 10000 volumes) |

The two processes: selection as the stabilisation of a particular distrubution and evolution as the establishment of one new distribution after another (destabilisation of old and stabilisation of new distributions) are results of an "inner propensity", just as is the attainment of chemical equilibrium in a closed system. They can therefore be reproduced and quantitatively tested in the laboratory. The results of such experiments, using distributions of RNA molecules[21,22] or of viruses[23,24] in experiments *in vivo* and *in vitro*, yield information about the composition of the distribution of mutants, about the proportion of the "fittest" individual components and about the available storage capacity for information.

Thus we have the physical content of *Darwin*'s principle, a principle which shows how complex structures, with properties adapted to their environment, arise in a seemingly goal-directed way—although the goal is only defined by means of the process of evolution. This is equally true for organisms, for cells and for replicating molecules—and even finds its use in technology. *Rechenberg*[25] has invented a procedure for building complex structures suited to particular tasks. It emerges (and can also be shown mathematically) that for complex systems involving many parameters a succession of mutation and selection of the best-suited structure reaches the target more quickly than systematic, goal-directed optimisation.

Although *Darwin* cannot have foreseen such detailed extensions of his concept of selection and evolution, there is no doubt that he recognised its general implications. Thus he writes to *Nathaniel Wallich* in 1881:

"You expressed quite correctly my views where you said that I had intentionally left the question of the Origin of Life uncanvassed as being altogether *ultra vires* in the present state of our knowledge, and that I dealt only with the manner of succession. I have met with no evidence that seems in the least trustworthy, in favour of so-called Spontaneous Generation. I believe that I have somewhere said (but cannot find the passage) that the principle of continuity renders it probable that the principle of life will hereafter be shown to be a part, or consequence, of some general law."

It is clear that selection and evolution on a molecular scale, based on the self-reproduction of nucleic acids, is a **necessary** condition for the genesis of life. Does this further provide a **sufficient** explanation for the molecular organisation of the living cell, of which we now know so much?

The answer is: no.

The Darwinian principle contains the definition of its own limitation, which appears in the error threshold in equation (8). The reproduction of the original sequences was limited in its accuracy by the molecular forces of base-pairing. Even in the case of the stable G-C pair the length of a reproducible sequence is less than 100 nucleotides. This has been confirmed by measurements on model systems (cf. Table 2)[26,27]. Such an "information crisis" could only be overcome by the evolution of a mechanism of enzymic reproduction. Evolution requires the storage of information in reproducible sequences. To make the information available, a process of decoding is necessary. However, the simplest decoding equipment requires much more information than could ever have been accommodated in one of the primordial sequences[28]. Thus a further necessary condition was the functional integration of various replicative units. The various carriers of information could indeed all have emerged from a single, selected distribution of mutants, but they then had to adapt to their various functions. *Darwin*'s principle is not sufficient to account for this, for the following conditions must all have been fulfilled simultaneously:

1) Each replicative unit within the functionally integrated system must remain in continuous competition with its own mutants, and therefore work so well that no information is lost from one generation to another.
2) Competition between the replicative units (master sequences) belonging to the functional system must be abolished and replaced by a mutual regulation of concentration.
3) The functional unit must as a whole be able to compete successfully with alternative units.

Theory[18] tells us that a circular, closed network of coupled reactions—we call it a hypercycle—is the only system capable of fulfilling these three conditions simultaneously and thus of overcoming the **information crisis.**

A further problem arises in connection with the evolution of a translation apparatus. Let us call it the **Genotype-Phenotype-Dichotomy.** The information, which is later selected, resides in the genotype. However, its selection is based on the phenotypic properties displayed by the products of its translation. These must interact selectively with their "own" genotype, or otherwise the evolution of phenotypic properties will not be possible.

As an example, let us consider what happens when a bacterial cell is infected by RNA phage. In order to assure preferential reproduction of its genome, the virus codes for a protein which combines with proteins of the host cell to produce an RNA replicase; this recognises and reproduces the viral genome but not any of the RNA sequences of the host cell. Here again we encounter the hyperbolic growth law mentioned at the beginning. The rate of reproduction is on the one hand proportional to the number of templates (copies of the viral genome) and on the other to the number of functioning replicase units, which is itself proportional to the number of copies of the viral genome, since the replicase is a decoding product of the genome. The resulting quadratic, self-catalytic rate law gives rise to hyperbolic growth.

The origin of the translation apparatus poses problems of this kind, soluble only by postulating both hypercyclic organisation and compartmentation of the functionally integrated system[29]. The growth laws resulting from these necessitated a once-and-for-all decision on the organisation of the translation apparatus and the structure of the genetic code. The result of this decision has been binding on all living beings ever since.

If on the one hand *Darwin*'s principle is insufficient to account for the origin of life, it is on the other hand an essential premise for consequences whose importance reaches far **beyond the borders of biology.** Wherever there is natural selection, the result is self-organisation into sharply-differentiated, discrete states instead of the broad Gaussian distribution to which we are used in stochastic systems at thermodynamic equilibrium. The principle of natural selection could thus explain why sharply-defined states occur at all, instead of continua: why there is "something" and not "everything". It would be interesting to look for such applications in elementary-particle physics[30], neurobiology[31,32] or sociobiology; this means looking for the prerequisites of such behaviour in each case.

To end with, a comment on the many **misinterpretations** to which the Darwinian principle has time and again fallen victim. Physical principles indeed lie behind real processes, but reality, overspread by a myriad of extraneous influences, cannot be "reduced" to a single principle. Inattention to the difference between Principle and Reality is the sole cause of the fruitless wrangling between the so-called Holists and Reductionists.

Consider the wonderfully logical, self-consistent edifice of equilibrium thermodynamics. Its principles were developed in connection with a theory of the efficiency of the steam engine. None the less, one cannot even build a steam engine with their help, to say nothing of setting it in motion. To do this one has first to take the machine well away from a state of equilibrium.

History testifies to the misuses which have been made of *Darwin*'s doctrine outside of biological science. In biology, in any case, the idea of "Darwinism" is inappropriate. A law of Nature is not a *Weltanschauung*. If the requirements are fulfilled, the consequences will take place—predictably and inevitably. It is after all not customary to call an astronomer a "Newtonist".

Finally, the question **"Creation or Evolution?".** A believer in creation cannot evade including the natural laws in the creature. A God who contradicted His own laws would be contradicting Himself. So evolution, for the believer, is the mechanism of creation. God has not forbidden us to consider and to fathom His works. *Darwin* doing this, conquered a fresh summit of discovery.

*I am particularly grateful to Ruthild Winkler-Oswatitsch for her assistance in the drafting of the manuscript and the illustrations, and to Paul Woolley for his excellent translation of my paper into English.*

# Biliproteins

## By Hugo Scheer[*]

*Dedicated to Professor Hans-Herloff Inhoffen on the occasion of his 75th birthday*

Biliproteins, covalently bonded complexes of proteins and bile pigments, serve as light-harvesting pigments in photosynthesis and light-sensory pigments of photosynthetic organisms. Recent developments in the biochemistry and biophysics of these pigments are reviewed and an attempt is made to describe their functions of light-harvesting and of information transduction on a molecular level.

## 1. Introduction

Cyanobacteria, red algae, and cryptophytes contain large quantities of blue and red pigments, which essentially determine the color of these organisms and may amount to 40% of the protein[1]. *Engelmann*[2] was the first to relate these pigments to photosynthesis; *Haxo*[3], *Emerson*[4], and *Gantt*[5], among others, recognized their function as light-harvesting pigments, mainly of photosystem II. In 1928, *Lemberg*[6] demonstrated that they contain bile-pigment chromophores; in accord with their origin and composition, these chromoproteins are thus called *phycobiliproteins.*

Pigments of this structure, but having completely different functions, exist in many other organisms. The most important compound of this group is *phytochrome.* This sensory pigment of green plants was discovered in 1945 by action-spectroscopy[7]. Owing to its instability and low concentration, it was first enriched and characterized by absorption spectroscopy as late as 1959[8]. Phytochrome is a photoreversibly-photochromic pigment. The position of the equilibrium between its two forms (R- and FR-form), the total concentration, and other factors are fundamental in regulating the development of plants[9]. Another group of photoreversibly-photochromic pigments, the phycochromes, were isolated from various cyanobacteria[10], and at least one phycochrome was also related to developmental processes like chromatic adaption[1,11,12].

These three groups of pigments are referred to as biliproteins (Table 1). This contribution deals with recent developments in their biochemistry and biophysics. Since the last comprehensive survey in this field[13a] several different aspects have been reviewed[1,5,9,13-25,310]. It should be mentioned that besides these genuine biliproteins, there also exist bile pigment-protein aggregates lacking a covalent bond between both component parts. These include the physiologically important complex of bilirubin, which is only sparingly soluble in water, with serum albumin[26], and an increasing number of invertebrate pigments[13,27-30]. A selection of them is included in Table 1.

Table 1. Natural occurrence and functions of biliproteins. The first three groups of pigments are the subject of this report.

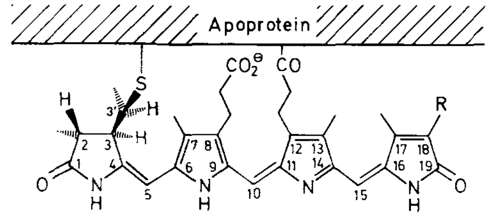
| Pigment | Occurrence | Function | Chromophore structure | Ref. |
|---|---|---|---|---|
| Phycobiliproteins (*e.g.* phycocyanin (PC) allophycocyanin (APC) phycoerythrin (PE)) | Cyanobacteria<br>Red algae<br>Cryptophytes | Antenna pigments of photosynthesis | Phycocyanobilin *(1a)*, phycoerythrobilin *(2) etc.* | see Text |
| Phytochrome | Higher green plants, certain algae, fungi (?), mosses, red algae (?) | Reaction-center pigments of photomorphogenesis | *(1b)*, *(3)* [a] | see Text |
| Phycochromes | Cyanobacteria, red algae | Possibly reaction center pigments of photomorphogenesis and chromatic adaption ("adaptachromes") | *(1a)* (?) | [1, 10–12] |
| Bilirubin-serum-albumin complexes | Vertebrates | Water-soluble transport form of bilirubin | — | [26] |
| Aplysioviolin | *Aplysia* (sea hare) | Defense excretion | Monoester of *(5)* | [29] |
| Turboverdin | *Turbo cornutus* (mussel) | Protective coloration (?) | [18-Ethyl]-[3-(2-hydroxyethyl)]-*(19)*, R=H | [30] |
| Pterobilin | Lepidoptera | Protective coloration (?) | IXγ-Isomer of *(19)*, R=H | [27] |
| Phorcabilins | Lepidoptera | Protective coloration (?) | Extended derivatives of pterobilin, similar to *(31)* | [27] |

[a] The substituents R, R′ und R″ in *(3)* suggest that the double bond between C-4 and C-5 present in $P_r$ is no longer noticeable in the absorption spectrum (see Section 2.3).

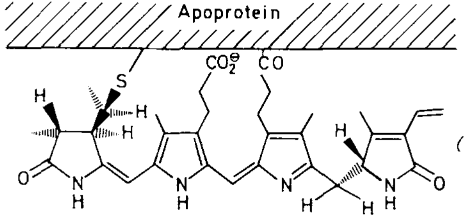
## 2. Structure of Chromophores

The two major chromophores of phycobiliproteins are *(1a)* (phycocyanobilin) and *(2)* (phycoerythrobilin)[*]. (In the formulas the bond to the protein is indicated.) *(1a)* is the blue chromophore of phycocyanins and allophycocyanins, *(2)* is the red chromophore of phycoerythrins. One or the other of them exists in each of the known phycobiliproteins, while R-phycocyanin (R-PC)[**] contains both. In addition, there occur several other chromophores with hitherto unknown structures, *e.g.* a phycourobilin in the γ-chain of B-phycoerythrin (B-PE)[**][31], the red chromophore in the α-chain of phycoerythrocyanin[32], the third chromophore ($P_{590}$) of PC from a *Hemiselmis species*[33] and the blue chromophore of PC from *Chroomonas*[34].

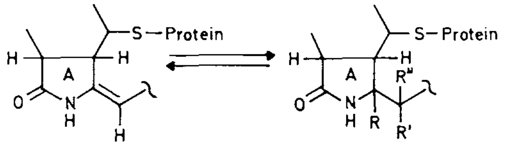
Strictly speaking, the structures *(1a)* and *(2)* have so far been unequivocally determined on only a few phycobiliproteins. Generally, they are identified by chromatographic comparison of the cleaved chromophores and spectroscopic investigations on denaturated biliproteins (see Section 2.3).



*(1a)*, R = $C_2H_5$ *(1b)*, R = $C_2H_3$



*(2)*



*(1b)* *(3)*

The chromophore *(1b)* of the R-form of phytochrome ($P_r$) is very similar to phycocyanobilin *(1a)*[35–38]. Instead of the ethyl-group it contains a vinyl-group at C-18[37,38], but the absolute configurations at C-2, C-3 and C-3′ are identical[39]. The structure of the $P_{fr}$-chromophore is still unclear; however, it is known that it contains a shorter conjugation-system than the $P_r$ chromophore[35] but the same β-pyrrolic substituents[37]. Comparative investigations on free bile pigments have currently led to two models which would account for the properties of the $P_{fr}$-chromophore. It could be a geometrical (*Z,E*)-isomer[40] or a substitution product of the $P_r$-chromophore[41] (see Section 2.4).

### 2.1. Cleavage of Chromophores

For a long time elucidation of the structures of biliprotein-chromophores was complicated by their covalent bonds to

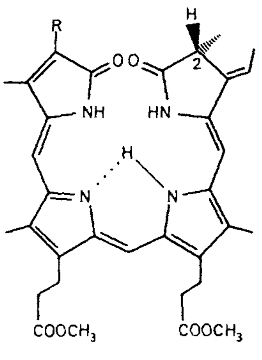
---

[*] The nomenclature of the bile-pigments has been modified several times in recent years. Four systems were and are used concomitantly. Trivial names and the numbering system of *H. Fischer*, which correlates the bile pigments with the porphyrins, are mainly used in the older literature [for example *(19)* = biliverdin IXα]. The numbering system, still used today and shown in formulas *(1)* and *(23)*, results from the first attempt of a rational nomenclature. It allows no direct correlation between the C-atoms of macrocyclic tetrapyrroles, and the linear tetrapyrroles derived therefrom. Apart from using a certain number of trivial-names, it is based on the completely saturated "bilan". An exchange-nomenclature is possible for both systems: A new substituent replacing the original one of a parent compound is placed in square brackets [*viz.* [*(18)*-vinyl]-*(1a)* = *(1b)*]. The nomenclature used in this article corresponds to the VIth Memorandum of the IUPAC Nomenclature Commission. Aside from a limited number of trivial-names [*e.g.* *(19)* = biliverdin] it is based on bilin which, ***in natural bile pigments***, contains the maximum number of non-cumulated double bonds [cf. *R. Bonnett*, in [24a], Vol. 1, 1978, p. 1; example: *(23)* = 2,3,7,8,12,13,17,18-octaethyl-2,3-dihydro-1,19[21*H*,24*H*]-bilindione]. The nomenclature recently proposed by the IUPAC (Pure Appl. Chem. *51*, 2251 (1979)) is similar.

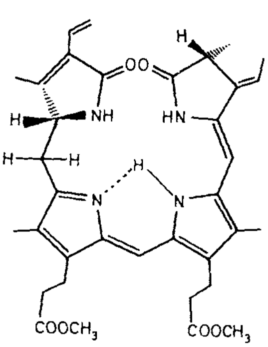
[**] Abbreviations: PC = phycocyanin, APC = allophycocyanin, PE = phycoerythrin, $P_r$, $P_{fr}$ = phytochrome in the R- or FR-form (see Sections 4.3 and 5.2). Prefixes indicate the parent organisms: C = cyanobacteria, R = red alga, B = *Bangiales* (an order of red alga), K = cryptophytes.

the proteins, which preclude a cleavage without chemical modification. Depending on the conditions of cleavage, different phycobilins result from one and the same pigment, so that the nomenclature became very complex (cf. [13,22,24]).

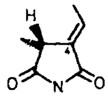
The best characterized products are the ethylidenebilins *(4a)* and *(5)*, which are formed as main products on treatment of the corresponding biliproteins with the chromophores *(1a)* and *(2)*, respectively, in refluxing methanol[42] or long chain alcohols[43], as well as by treatment with HBr/trifluoroacetic acid (TFA)[44]. The cleavage proceeds by stereoselective elimination of the C-3-thio ether[45]; in *(2)* and/or *(5)* the asymmetric C-16 can epimerize at the same time[46,47]. The structures, suggested originally from $^1$H-NMR and MS data[48-51] and from chromic acid degradation[13,52,53], have been confirmed by total syntheses[46,54].



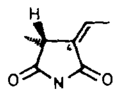
*(4a)*, R = $C_2H_5$
*(4b)*, R = $C_2H_3$



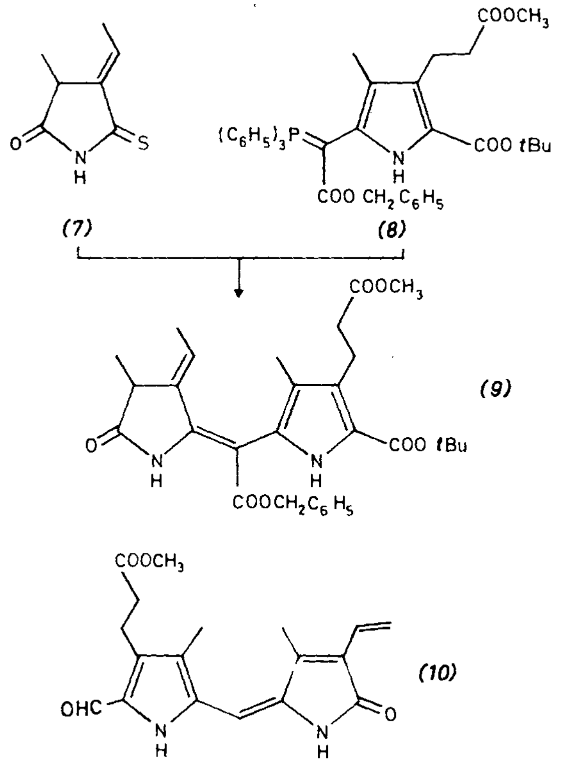
*(5)*



*(6a)*



*(6b)*

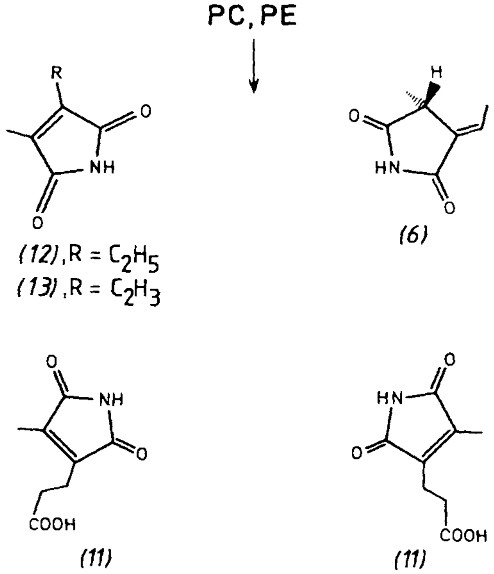


Scheme 1.

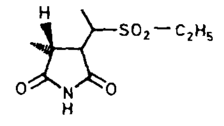
The key reaction in the synthesis is the regioselective coupling of rings A and B, which is possible in good yields by condensation of the monothioimide *(7)* with the pyrrole ylide *(8)*; condensation of the product *(9)* with the CD-fragment *(10)* yields *(4b)* (Scheme 1). For thermolabile substituents[54], sulfur-contraction[54a] can be used instead. By the first procedure the 18-vinylbilindione *(4b)* (= "P$_r$-bilin") was obtained[38]. It could be correlated with *(1b)* by treatment of the latter with HBr/TFA[55]. The stereochemistry of *(4a)* and *(5)* at C-2 was established by chromic acid degradation to the imide *(6)* with known absolute (4*R*)-configuration[56], while that of *(5)* at C-16 was established by asymmetric synthesis and correlation with (4*R*,16*R*)-urobilin[46,57].

## 2.2. Degradation Reactions of Biliproteins

On oxidation with chromic acid, tetrapyrroles are degraded to cyclic imides possessing (at least in principle) the same β-pyrrolic substituents. This method, originally introduced by *H. Fischer*, has in the meantime been improved several times and standardized, and has especially been applied to biliproteins by *Rüdiger et al.*[13,53]. The "hydrolytic" chromic acid degradation of phycocyanin (PC) at 100 °C yields the three imides *(6)*, *(11)* and *(12)*, while that of phycoerythrin (PE) and P$_r$[37] affords the imides *(6)*, *(11)* and *(13)*, the latter of which readily decomposes under the reaction conditions. On oxidation at ambient temperatures, no *(6)* is formed, and *(11)* can only be extracted in about 50% yield, thus indicating protein bonding to the respective rings[13].



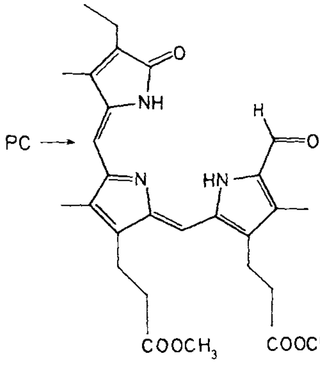
Under these conditions, the degradation of the tetrapyrrole is accompanied by oxidation of the thio ether to sulfone *(14)*, which eliminates —SO$_2$—C$_2$H$_5$ to give *(6)*[58] in the presence of aqueous ammonia. This reaction sequence not only demonstrates the protein-bond of ring A, it is also ste-



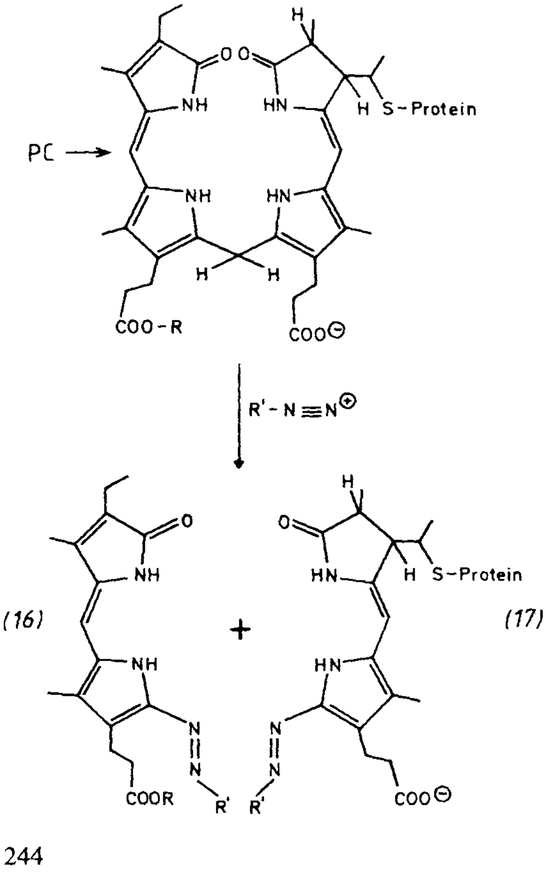
*(14)*

reoselective[45,58,59] and leads, with the well-known *4R,E*-configuration of the imide *(6a)*[56], to the *2R,3R;3'R*-configuration of *(1a)*, *(1b)*, *(2)* and *(3)*. A possible second binding site[13] is still controversial[22,60-65].

During chromic acid degradation the information concerning α-pyrrolic and methine-substituents is lost and, *e.g.*, hydrolysis of the β-pyrrolic substituents cannot be excluded. The milder degradation procedure with chromate yields imides of the terminal rings, whereas the inner ones yield pyrroledicarbaldehydes[13,53]. Thus, it is possible to differentiate, *e.g.*, between isomeric biliverdins, and to assign the IXα-type substitution to *(1)*-*(5)*. A recently developed milder method of oxidation enables regioselective cleavage of biliprotein chromophores like *(1a)* at the methine bridge next to ring A, to give formyltripyrrinones. The method is specific for A-dihydrobilindiones[66,67]. Thus, tripyrrinone *(15)* was obtained in this way from PC. Another selective cleavage reaction, in this case however between rings B and C, is the diazo reaction[68]. This reaction, important in the medical analysis of bilirubin[69], can be applied to the higher oxidized bilindiones present in the biliproteins, only after a pretreatment[70]. The protein first has to be unfolded by addition of urea, and then the central methine bridge of the chromophores has to be reduced by $NaBH_4$. The complete reaction sequence can be carried out under very mild conditions (4 °C, pH = 7). The fragments *(16)* and *(17)* were obtained from PC. *(17)* confirms again the binding of ring A to the protein; both of the last mentioned reactions also indicate the existence of a second bond at ring C, at least in PC of *Spirulina Platensis*, used in these studies. The proportion of free, extractable *(16)* is increased after hydrolytical pre-treatment; *(15)* is only obtainable in this way.



*(15)*

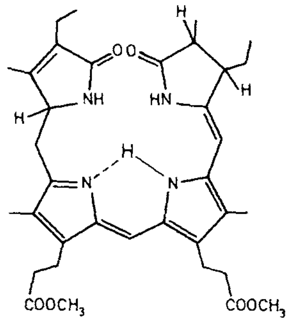


*(16)*

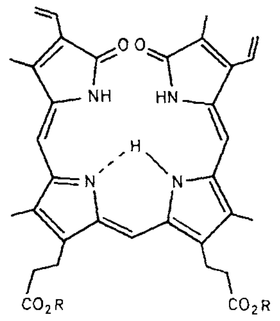
*(17)*

## 2.3. Spectroscopy of Denatured Pigments

A sensitive, non-destructive method for the analysis of biliprotein chromophores is UV-VIS absorption spectroscopy. In the native pigments the spectral properties are strongly dependent on the protein environment (see Section 3), but the non-covalent interactions responsible for these effects are decoupled by complete unfolding using urea, guanidinium chloride, or heat. Although still covalently bound to the protein, the chromophores can be correlated with free bile pigments of known structure. The identification is improved by measuring the free bases as well as the cations, anions, and metal-complexes; for an exact characterization the most suitable are cations and zinc-complexes[35,36,61,71,72]. The method has also been successfully applied for the quantitative determination of the number of chromophores (Table 3)[61,72]; and by acid-base titration the pK-values of protonation and deprotonation are available as additional important parameters[35,36].



*(18)*



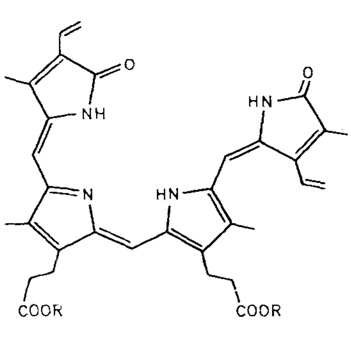
*(19)*

Denaturated PE is spectroscopically very similar to *(18)*; it contains the rhodin-chromophore *(2)*[71]. Denaturated PC and $P_r$ absorb at longer wavelengths than *(18)*, but at shorter wavelengths than bilindiones such as *(19)*. The spectroscopic similarities to *(23)* indicate the 2,3-dihydrobilindione conjugation system for the chromophores of both pigments. The 18-vinyl group of *(1b)* leads to a small red-shift of the absorption as compared to pigments containing *(1a)*[35]. At pH ≤ 5.2 denaturated $P_{fr}$ has an absorption maximum at 610 nm; thus, in contrast to native phytochrome the denaturated $P_{fr}$ absorbs at *shorter wavelengths* than denaturated $P_r$ under the same conditions ($\lambda_{max}^{cation}$ = 660 nm). Therefore, $P_{fr}$ has a shorter conjugation system than $P_r$[35]. Analogous results have been obtained when proteolytic digestion is used instead for the uncoupling of the chromophore[55]. The A-dihydrobilindione structure of the chromophores *(1a)* and *(1b)* and the thioether-bond have recently been proved, too, by NMR spectroscopy of the respective bilipeptides[38,65]. This method also afforded independent proof of the presence of the 18-vinyl group in *(1b)*[38].

### 2.4. Reactivity of Chromophores

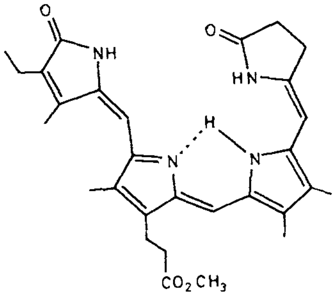
The different spectra of both forms of denaturated phytochrome ($P_{fr}$ and $P_r$) demonstrate that the chromophores have different molecular structures. Conformational[73] changes, protonation-deprotonation[74] and the like, can thus be excluded as the *sole* reactions during phytochrome-transformation, and photochemical reactions gain a special interest. The primary reaction of the phytochrome system is the photochemical transformation of $P_r$ into $P_{fr}$, or *vice versa.* The reaction has several spectroscopically well defined intermediates, which are different for the forward and back reactions, respectively. The structures of the intermediates are still unknown, but the results of flash[75-78] and of low-temperature spectroscopy[77,79-82] as well as of dehydration experiments[82-84] have shown, that only the first step(s) are photochemical one(s), followed by dark-reactions (cf. [18]). Owing to the formal analogy with the reactions of rhodopsin[85], an analogous nomenclature[84] has been used.

In the context of these results, photochemical reactions of free bile pigments[86] and especially of bilindiones related to the $P_r$-chromophore *(1b)* were investigated. From the criteria, determined by the natural system, it should be possible to obtain some evidence regarding the structure of $P_{fr}$, the reaction pathway, and the primary signal of the phytochrome system. There exist two well known photochemical reactions for the conversion $P_r \rightarrow P_{fr}$ which meet most criteria: 1. geometrical isomerization at the double-bond between C-4 and C-5 or C-15 and C-16; 2. oxidative substitution at the C-5 methine bridge. It has been known for some time that dipyrromethenones form stable geometric (*Z*,*E*)-isomers which are in photochemical equilibrium[87,88]. Photochemical studies on pterobilin ("biliverdin IXγ") gave first indications, that corresponding isomers also exist in the case of bilindiones[27]. The isomerization reactions have been investigated systematically by *Falk et al.* with partial structures and integral bile pigments. They could show that bilindiones isomerize at one or at both terminal methine bridges and they have isolated and characterized the resulting products, like *(20)*[40,88,89]. Starting with an *E*-configurated formylpyrromethenone *Gossauer et al.*[90] recently also achieved the total synthesis of (*E*,*Z*,*Z*)-bilindiones. In comparison to the (*Z*,*Z*,*Z*)-educts, the absorption maxima are displaced to shorter wavelengths, *e.g.* to regions expected for a $P_{fr}$-chromophore model. This shift has been rationalized in terms of a simultaneous change of the configuration at the double bond between C-4 and C-5 in *(20)* and of the conformation of the neighboring single bond between C-5 and C-6. By this mechanism the *E*-configurated double bond is partially uncoupled from the remaining π-system[91]. For the thermal reisomerization $\Delta G^0 = -20$ kJ/mol and $\Delta H^{\neq} = 105$ kJ/mol were determined[92]. Non-symmetrically substituted bilindiones yield two (*E*,*Z*,*Z*)-isomers[40]. A regioselective isomerization is observed with less symmetrical educts[93].

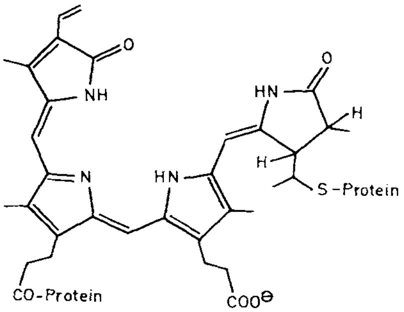


*(20)*

As a consequence of the hydrated ring A—and additionally of the 18-vinyl group in the case of $P_r$ [*(1b)*]—the chromophores of biliproteins are perturbed from symmetry. Ramachandran calculations indicate a preferred isomerization of the $\Delta^4$-bond next to the hydrogenated ring for steric reasons, thus products of the violin spectral type are expected[94]. This assumption has recently been confirmed experimentally[90b]. $\Delta^{15}$-*E*, but not $\Delta^4$-*E*-configurated 2,3 dihydrobilindiones are accessible by total synthesis, the former having a rhodin-type spectrum due to uncoupling of ring D[90b]. A violin-type spectrum is then expected for the hypothetical, less stable $\Delta^4$-*E*-isomer.

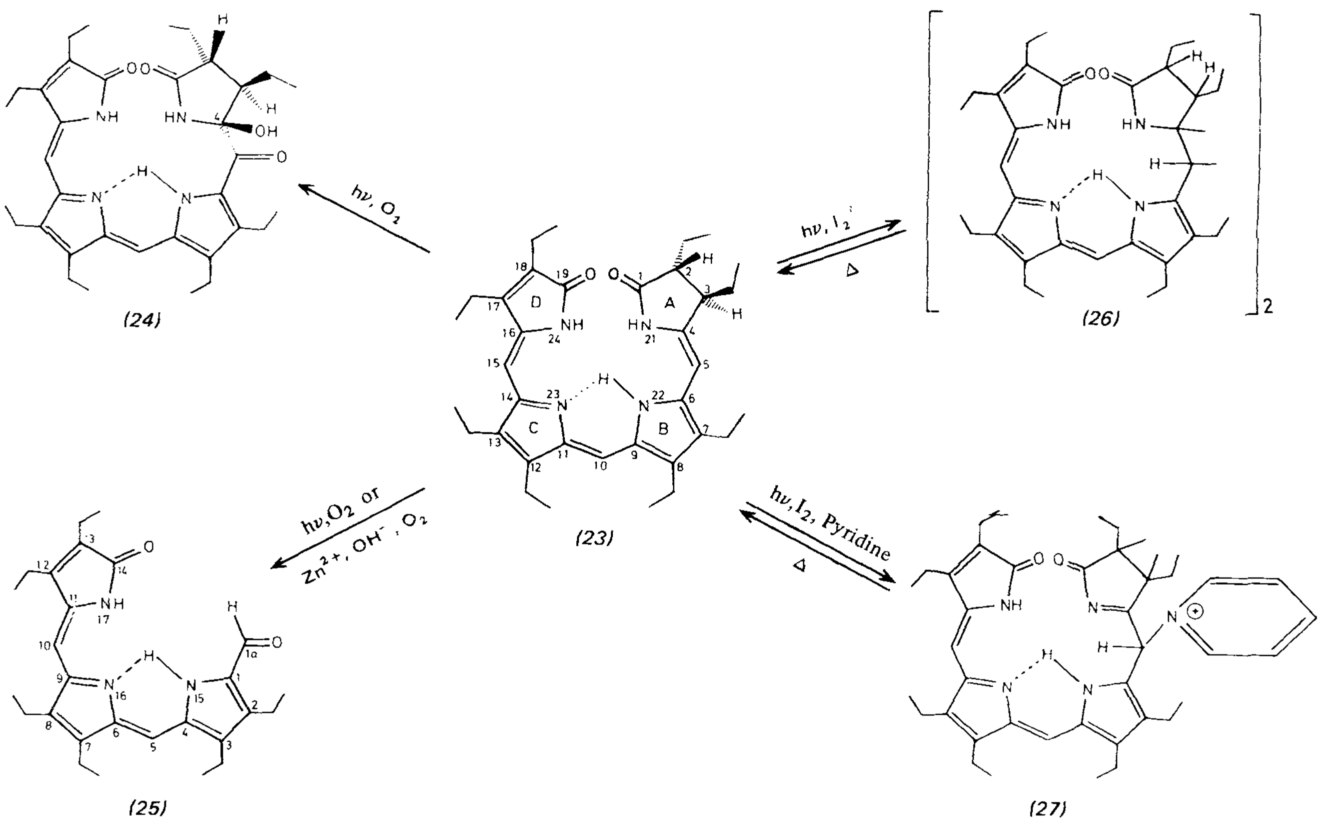


*(21)*



*(22)*

The hypothetical (*E*,*Z*,*Z*)-isomer of *(1b)* [cf. *(22)*] would be spectroscopically comparable with the $P_{fr}$-chromophore. The reaction mechanism is as yet only difficultly reconcilable with the properties of phytochrome. The photoisomerization of bilindiones does not proceed directly, but rather *via* intermediate rubinoid products formed in a dark reaction. Due to their low electron density at C-10[95], the bilindiones reversibly add nucleophiles[89b,96-99] and the yellow pigments thus formed are the substrates proper for isomerization[89b]. In accord with their absorption maximum at 450 nm, blue light is especially effective for isomerization[89b], whereas the action-spectrum of the $P_r \rightarrow P_{fr}$ transformation has its maximum at 660 nm in the red spectral region, the absorption-



Scheme 2.

maximum of the $P_r$-chromophore. The mechanism of reaction is, however, very dependent on the substrate structure, and direct photochemical reactions basically seem to be possible in all cases in which the geometry of the tetrapyrrole skeleton differs from the flat uniform helix. Examples are *N*-alkylated bilindiones[93] and non-(*Z,Z,Z*)-isomers[92]. It still remains open, how the asymmetry of the natural chromophores and their protein environment can affect the course of reaction.

The second model reaction for the $P_r \rightarrow P_{fr}$ transformation is a photochemical oxidation of the $P_r$-chromophore *(1b)*. Denaturated $P_r$ is oxidized by strong oxidizing agents ($Fe^{III}$, $Ce^{IV}$) to products, spectroscopically similar to denaturated $P_{fr}$[35]. The phytochrome transformation had already been correlated with redox-reactions[100-102]; and the spectra indicate a photochemical oxidation of the chromophore during $P_{fr}$-formation. This possibility was studied using *(23)* as a model for $P_r$. Comparison of *(23)* and *(19)* allows one to further analyze, whether a hydrogenated ring has similarly pronounced effects on the reactivity of bile pigments, as it has in the cyclic tetrapyrroles (cf. *e.g.* [103]). The products of photooxidation of *(23)* are summarized in Scheme 2. In presence of oxygen, the purpurins *(24)* and *(25)* are formed in a regioselective, self-sensitized singlet-$O_2$ reaction[66].

*(25)* is likewise accessible by a smooth dark-reaction[19], which is also suitable as a degradation reaction for biliproteins[67]. Spectroscopically similar products were observed during the dark reaction of *(19)* with singlet-$O_2$[104]; the typical spectrum with two bands[66], however, makes the proposed endoperoxide structure[104] unlikely and rather suggests the formation of purpurins as well. The influence of the hydrogenated ring on these reactions is very pronounced. *(23)* reacts much more rapidly than the fully unsaturated analogue and other bilindiones, and the reaction is regioselective at C-5. Although the spectroscopic characteristics of *(24)* and *(25)* correspond to denaturated $P_{fr}$, like other purpurins[109] they regenerate *(23)* in only small yields and under drastic conditions.

With regard to the reversion, especially the products *(26)* and *(27)*, derived from anaerobic photooxidation, seem attractive, because they correspond in their spectroscopic characteristics to denatured $P_{fr}$ and because they can regenerate *(23)*, at least thermally. These reactions, too, are specific for the A-dihydrobilindione *(23)* and are regioselective at the C-5 methine bridge; corresponding reactions at C-15 or with fully unsaturated bilindiones were only observed as rare exceptions[106]. The dimerization of *(23)* to *(26)* is reminescent of the reversible photodimerization of pyrimidines in nucleic acids (cf. *e.g.* [107]). In phytochrome, the presence of two chromophores would be a precondition, which seems unlikely from the known data[14,18,21,55]. The formation of the pyridiniobilindione *(27)* demonstrates, however, that in principle other partners may take place in the reaction besides a second bilindione[41]. Probably, the reaction proceeds in two steps. The educt is first oxidized in one or two one-electron steps. Such a series of oxidations has been established electrochemically with bilindiones[108] and is supported by observation of long-lived cation radicals during oxidation of Zn-*(23)*[109]. In the second step, the nucleophilic addition of pyridine at C-5 takes place. Obviously, the reactivity of the intermediates is reversed. The *(27)* that is formed, formally possesses the conjugation system of the educt *(23)*; but its absorption spectrum is shifted to shorter wavelengths, because the $\Delta^5$-bonding is twisted by the steric hindrance between the rings A, B and the bulky C-5 substituent[41,110].

Regarding the latter as a model reaction would require $P_r$ to contain both an oxidant and a nucleophile. According to present day knowledge, amino acid residues are the only candidates, because phytochrome is transformed in solution and contains only carbohydrates[111] besides the chromophore. For oxidation, cystine residues are possible candidates, for addition tryptophan, tyrosine, serine, cysteine and the like. There do in fact exist certain indications to this effect; thus, $P_{fr}$ contains one to two accessible SH-residues more than $P_r$[112,113], and *(23)* reacts with *e.g.* derivatives of tryptophan to give violins[106]; but here again a decision is not yet possible.

## 3. Chromophore-Protein Interactions

### 3.1. Molecular Ecology

The chromophores of native and denaturated biliproteins differ so conspicuously in their properties (Table 2) that a relationship between the two may seem unlikely. Phycobiliproteins can be denaturated reversibly and in excellent yields with urea or guanidinium chloride[22]. Since the covalent bonds between chromophore and protein are retained, the different properties of the chromophores in native and denatured pigments, respectively, are exclusively due to non-covalent interactions with the native protein. These interactions are essential in optimizing the chromophores for their function of photoreception. This includes (a) an increase in the extinction-coefficient by nearly one order of magnitude, leading to an increased light-absorption, (b) the suppression of radiationless deactivation to diminish energy losses in favor of fluorescence (phycobiliproteins) or of photochemical reactions (phytochrome), and (c) the chemical stabilization of chromophores (Table 2). In addition, also the positions of the absorption maxima of certain chromophores are variable between remarkable limits [*e.g.* 80 nm for *(1a)*] and thus permit a "fine tuning" of the energy transfer. The question as to the origin of these optimizations, which may be paraphrased under the heading "molecular ecology", is essential for an understanding of the function of biliproteins. Geometrical transformations, protonation-deprotonation, and a restricted flexibility of chromophores seem to be some of the essential factors.

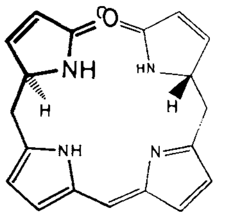
Table 2. Molecular ecology of the biliproteins. Comparison of the properties of native bilindiones, with those of denatured pigments and free bilindiones of similar structures.

| | Free bilindiones or denatured biliproteins | Native biliproteins |
|---|---|---|
| UV/VIS absorption spectra (see Fig. 1) | Broad bands, intense ($\varepsilon \approx 35000$) [a] in the near UV, weak ($\varepsilon \approx 15000$) [a] in the visible range | Narrow bands, weak ($\varepsilon \approx 15000$) [a] in the near UV, intense ($\varepsilon \approx 100000$) [a] in the visible range |
| Photochemistry | Mainly radiationless deactivation, low quantum yields ($\leq 10^{-3}$) for fluorescence or photochemical reactions | High quantum yields for fluourescence ($\geq 0.6$ in phycobiliproteins) or photochemical reactions ($\approx 0.15$ in phytochrome) |
| Chemical stability | Poor; ready formation of metal complexes, facile nucleophilic addition or reduction at C-10, sensitive towards photooxidation | Good; little to no reaction with these reagents |

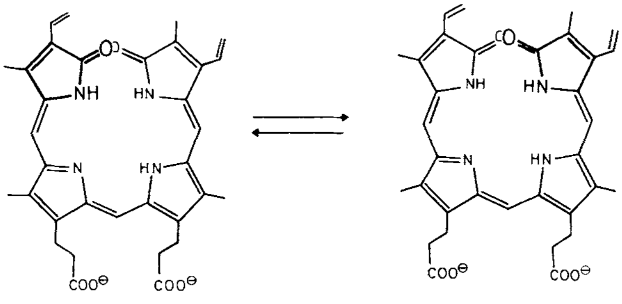
[a] All extinction coefficients are given with respect to one chromophore. They have to be multiplied by the number of chromophores (Table 3) to obtain the extinction coefficients of the respective biliprotein. Somewhat varying $\varepsilon$-values are cited in the literature, due to different methods of determination.

### 3.2. Geometry of Chromophores

The first detailed analysis of the geometry of free bile pigments stems from *Moscowitz et al.*[114], postulating a cyclohelical porphyrin-like structure in solution for urobilins [*(28)*; for sake of clarity, the substituents have been omitted], with the sign of the twist determined by the absolute configuration of the α-pyrrolic centers C-4 and C-16. Cyclohelical structures have also been established for bilindiones, like *(19)*, both by X-ray analysis[115,116] as well as by $^1$H-NMR[117,118] measurements and measurements of solvent-induced circular dichroism (SICD)[117,119] in solution. In the formally achiral bilindiones of the biliverdin type, this results in a uniform population of two enantiomeric conformations *(29a)* and *(29b)* which differ in their sign of rotation and are in equilibrium with each other ($\Delta H_0^{\ddagger} = 42$ kJ/mol for a derivative of *(19)*[120]). The equilibrium may be shifted sufficiently by dissolution in chiral solvents[117] or by adsorption to the chiral biopolymer serum-albumin[121] to allow the observation of typical Cotton effects of inherently dissymmetric chromophores. In support of this, purpurins like *(25)* containing planar chromophores[122] give no SICD-effect[123].



*(28)*

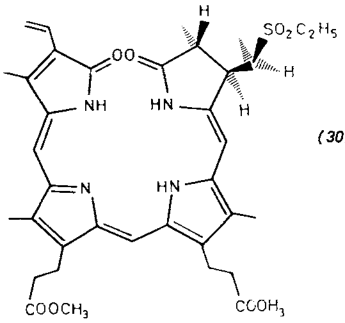


*(29a)* *(29b)*

The *E,Z,Z*-isomeric bilindiones are SICD-negative[90], too, thus supporting the suggested *anti-,syn-,syn*-conformation [Formula *(20)*][91].

The state of equilibrium between the two helical forms may also be shifted by asymmetric centers within the molecule. The high rotational values of optically active urobilins are due to the asymmetric centers C-4 and C-16 having the same absolute configuration by which one form is preferentially populated for steric reasons[114]. Since the absolute configuration of the helix can be derived from the sign of rotation of helical chromophores, the absolute configuration of the assymmetric centers is thus also indirectly accessible[46,57,94b,114].

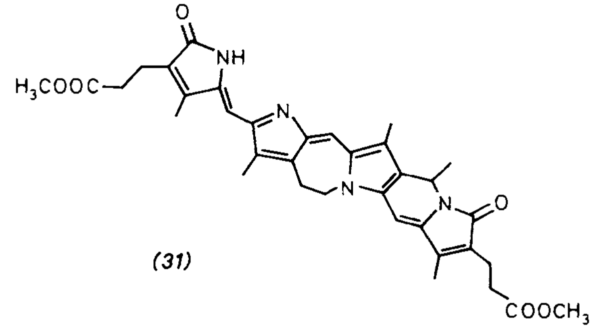
In the biliprotein-chromophores *(1)—(3)*, ring A has at least three asymmetric centers. The different steric hindrance of the two forms has been estimated by Ramachandran calculations on *(30)* as a model of denaturated PC and $P_r$ to result in an energy difference of $\Delta G^0 = 4$—8 kJ/mol[94]. Accordingly, denaturated PC exhibits a rather strong optical activity ($\Theta_{605} = 133000$[124]). In the chromophore *(2)* of PE, the influence of the asymmetric centers of ring A is opposite to the influence of the asymmetric C-16; accordingly the optical activity of denaturated PE is much lower[144].



*(30)*

The hitherto described effects can only be rationalized in terms of a preferential cyclohelical conformation of free bile pigments of the biliverdin type. This conformation is, however, not rigid but rather flexible, and it also exists in equilibrium with more extended conformations. The broad absorption bands, which are unstructured even at low temperatures[19,125], refer to this situation, as well as the exceptions in planar pigments like *(25)*[66]. Recently, the problem was investigated in detail by the Mülheim group. It was possible, by fluorescence spectroscopy, to differentiate at least two conformer populations in biliverdin[119]. The form fluorescing at longer wavelengths was identified as a cyclic conformation, since only this one showed an SICD effect; the form emitting at shorter wavelengths was associated with a more extended conformation because of its higher ratio of absorption of the visible and near UV-band, $Q_{uv}^{vis}$ *(vide infra)*. The equilibrium between both forms is dependent on temperature and solvent; the open form is preferred in viscous H-donor solvents[126], especially in lipid-vesicles[127]. Strong intramolecular H-bridges similar to those of bilirubin[128] were also implicated as the origin of the formation of isomers in biliprotein cleavage products. These H-bridges were only observed in the case of the free acids[43].

The denaturated biliproteins are so similar in their properties to free bile pigments of corresponding structure [*(18)* for PE, *(23)* for $P_r$ and PC], that they also are expected to assume preferentially cyclohelical conformations. The modified spectroscopic properties of native biliproteins (*e.g.* PC, Fig. 1) originate mainly from their chromophores being rigidly fixed by the protein in an extended conformation[19,125]. The intensity ratio $Q_{uv}^{vis}$ of the visible with respect to the near UV-band is mainly determined by the geometry of the chromophore. In the case of cyclohelical conformations $Q_{uv}^{vis}$ is small and thus similar to that for a porphyrin, whereas in extended conformations it is large and thus similar to that for a polyene. This is one essentially consistent result obtained from MO-calculations by several groups[80,91,121,131,134] and is confirmed by the spectral data of free bilins of known conformation. $Q_{uv}^{vis} = 0.25$ in cyclohelical *(19) (vide supra)*, but is increased to 6.4 in isophorcabilin *(31)*, which by reason of its additional intramolecular bridges can only assume extended conformations[27b].



*(31)*

A value of $Q_{uv}^{vis} = 0.15$ was measured recently for a 21,24-methanobilindione, which necessarily possesses the *all-syn,Z*-conformation[321]. The variation in the $Q_{uv}^{vis}$ of bilindiones due to formation of cations, anions and Zn-complexes is comparatively small, and the absorption in the near UV, in particular, remains essentially unchanged[36].

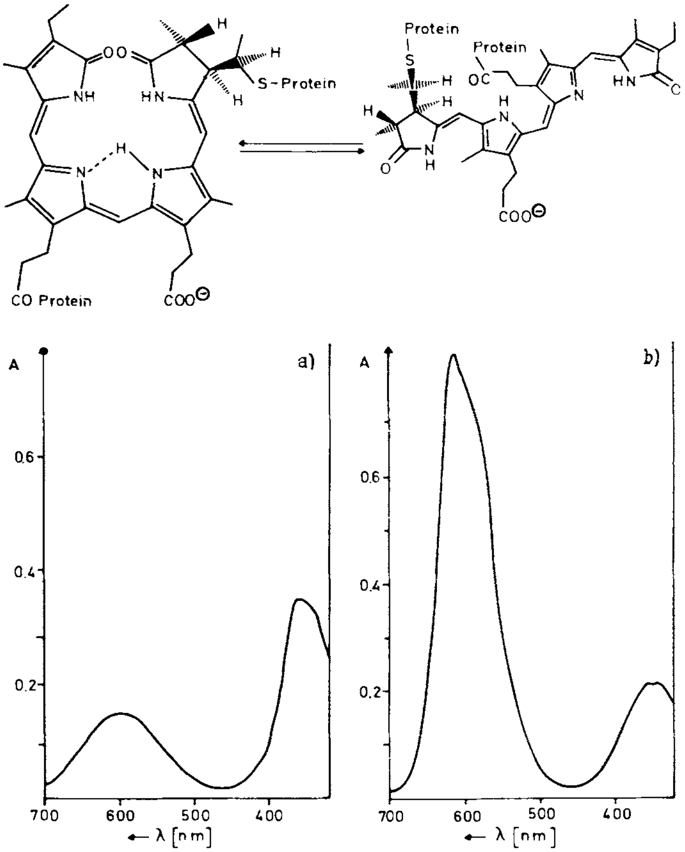


Fig. 1. Spectrum of denatured (a) and native phycocyanin (b) from *Spirulina platensis* (same concentrations in (a) and (b)). The denaturation by urea (8 M) is reversible; similar changes are observed upon thermal denaturation. The formulas depict the type of conformation for the two forms: cyclohelical for (a) and extended (in a sterically unhindered conformation) for (b).

In denaturated PC at pH 7.5, $Q_{uv}^{vis}=0.43$; it is increased to 4.1 in native PC, with both bands changing their intensity in opposite directions (see Fig. 1)[125]. Similar effects are observed with $P_r$[55]. Thus, the chromophores of both native pigments are present in an extended conformation. There is an interesting aspect of these findings: the extended conformations of bilindiones are higher in energy than the cyclic ones[92,94] and the necessary energy has to be provided by the protein. The energies of folding of several phycocyanins are indeed much lower than in other proteins of comparable size[135], *i.e.* the difference is possibly due to the strained chromophores[129]. In native PE, $Q_{uv}^{vis}$ increases to a comparable extent as found in PC, as compared with the denaturated pigment[139,144]. To our knowledge, the relation between the absorption and geometry of chromophores of PE has only once been studied theoretically[144a], and extended pigments corresponding to bilindione *(31)* possessing the tetrahydro-conjugation system of rhodin *(18)* have so far not been reported. On the basis of calculations, however, it is likely that $Q_{uv}^{vis}$ is also a certain indicator of the geometry of molecules, which would suggest extended chromophores for native PE, too.

The high ellipticities of the long-wavelength CD-bands of native PC as well as of PE would indicate an inherently dissymmetric chromophore, and therefore a more or less uniform twist of the extended chromophore. Generally, the bands have a positive sign. $P_r$ is a remarkable exception in having a negative CD-band despite it presumably[37] having the same absolute configuration of the asymmetric centers as $P_{fr}$ at ring A[135a]. At least in this case, an exciton-coupling would seem to be unlikely since phytochrome carries only one chromophore.

The picture is more complex with $P_{fr}$, the active form of phytochrome. On the one hand, $Q_{uv}^{vis}$ of native $P_{fr}$ is only half that in native $P_r$ (see *e.g.* [18]) and, on the other, the absorption maximum of the native pigment is extremely red-shifted. Denaturated $P_{fr}$ absorbs in its protonated form (pH = 2) at 610 nm[35], corresponding to a maximum for the free base at about 570 nm[35,71]. The absorption maximum of native $P_{fr}$ ($\lambda_{max}=730$ nm) is shifted to the red by more than 160 nm ($\hat{=}3850\ cm^{-1}$). While the lower value of $Q_{uv}^{vis}$ is still compatible with a rather extended conformation, the pronounced red-shift cannot be explained by a conformational change alone. Since the deprotonation of bilindiones leads to red-shifts of the same magnitude [*e.g.* 3800 cm$^{-1}$ in *(23)*][36] this effect was rationalized as a deprotonation of the $P_{fr}$-chromophore[35] in the native pigment. Recent MO-calculations on chromophores with the conjugation system of *(3)* support this interpretation[133].

### 3.3. Charge and Chromophore-Chromophore Interactions

In addition to geometrical transformations, electric charges in the vicinity of the chromophore are possibly important factors for the functionally important fine-tuning (see Section 5.1) of the absorption maxima of phycobiliproteins. Phycobiliproteins contain up to four chromophores on one subunit and up to six within the (αβ)-monomer (Table 3). Although they frequently have the same molecular structure [*e.g.* *(2)* in C-PE] and by and large the same geometries,

Table 3. Classification and properties of biliproteins.

| Type [a] | $\lambda_{max}$ [nm] (VIS) | Chromophore α- | β- chain | γ- | Protein structure Monomer | Aggregation | Mol.wt. [k] α- | β- chain | γ- | Occurrence | Ref. |

[a] The prefixes are derived from the parent organisms: C = Cyanobacteria, R = red algae, B = *Bangiales* (on order of red algae), K = cryptophytes, b and B refer to different quaternary structure. [b] Phycoerythrocyanin. [c] R-PE is possibly a glycochromoprotein [25, 226]. [d] Phytochrome is probably a glycochromophosphoprotein [111, 201]. [e] Special form, possibly aggregate [147, 182]. [f] Shoulder, resolved below 77 K [125, 137, 138, 151a]. [g] Shoulder due to phycourobilin chromophores [i]. [h] Chromophore of unknown structure $\lambda_{max,\ pH=3.0}^{denatured}=600$ nm. [i] Additional chromophors of unknown structure: $\lambda_{max,\ pH=2.0}^{denatured}=690$ nm [33, 34, 189]. [j] Phycourobilin chromophore, detailed structure unknown: $\lambda_{max,\ 0.1\ M\ HCl}^{denatured}=498$ nm [22]. [k] Approximate value $10^{-3}$. [l] A pigment similar to B-PE has also been reported for a marine cyanobacterium [204].

too, they differ spectroscopically, chemically and functionally, due to the different environments of their chromophores (see Section 3.4) and their correspondingly different chromophore-protein interactions. For example, APC-B absorbs at 670 nm[148b], the s-chromophore of C-PC at 590 nm[36,140–142]; in spite of their absorption difference of 80 nm ($\hat{=}$2020 $cm^{-1}$), however, they possess the identical chromophore *(1a)*. Chemical differences are evidenced, *e.g.*, by a different stability towards reduction[129] or unfolding[125], spectroscopically several absorption bands can be resolved, especially at low temperatures[125,136–139], in the fluorescence[139–143] and CD-spectra[144–147]. These differential effects are physiologically essential (see Section 5.1) for an optimal energy-transfer and they were investigated for the first time in some detail by fluorescence-measurements[140]. The site-specific chromophore interactions are obviously already fixed in the sub-units, since the CD- and absorption spectra are unchanged during aggregation to the (αβ)-monomers. In a C-PE the spectrum was identical with the sum of the subunit spectra[144]. In contrast, further aggregation of the monomers causes shifts to longer wavelengths of the visible bands. An additional long-wavelength band appears in the difference[148–154], low-temperature[136,137] and CD-spectra[145–147,152]. Its displacement is small in PC and PE (10—15 nm $\hat{=}$ 250—450 $cm^{-1}$), but rather pronounced in APC. Monomeric APC absorbs at 620 nm, the trimer at 650—670 nm, at the same time the absorption is almost doubled[149].

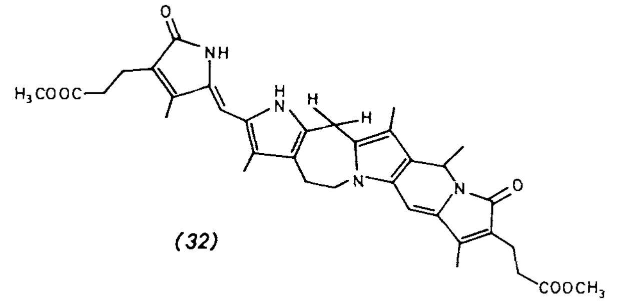
Recently, evidence has also accumulated for chromophore-chromophore interactions which have been related to displacements of absorption maxima. S-shaped CD-bands were observed in C-PE[144], B-PE[31], K-PC[34] and an allophycocyanin[152]. This type of band may be caused by exciton splitting, but a decision is difficult if several chromophores are present. The long-wavelength shift of the absorption-band[147] of the trimeric APC $(\alpha\beta)_3$[149] was recently interpreted as a chromophore-chromophore interaction of "intermediate strength" (= CD-inactive) between different monomers in the aggregate[150].

### 3.4. Increased Fluorescence and Chemical Stability

The second conspicuous feature of native biliproteins is their photochemical behavior. Phycobiliproteins fluoresce with quantum yields near to one (see [142]), phytochrome has quantum yields of 0.13 and 0.17 for the photoreversible transformation between the two forms[17]. Free bilindiones and denaturated biliproteins show only a very low fluorescence[96,119,130,132,155–157] and phosphorescence[156,158]; the "natural" *all-syn,Z*-bilindiones[66,105,159–162] and even the distinctly more reactive A-dihydrobilindiones[66,105] are also photochemically rather inert. The major pathway of deexcitation of free bile pigments or denaturated biliproteins is therefore radiationless deactivation. Two mechanisms are plausible: vibration-induced deactivation[163] and proton-transfer or even only perturbations of hydrogen-bond potential-curves[164]. Both are able to cooperate in a complex manner, since, *e.g.*, an intramolecular hydrogen bond is able to hinder torsional movements, but at the same time can open a new channel of radiationless deactivation (see [163,164]).

Both mechanisms have been investigated on partial-structures[159] and—hitherto less systematically—on integral bile pigments[96,155–157]. Both were recognized as essential, but a quantitative estimation is difficult, since chemical manipulations will generally influence both factors. Thus, *e.g.*, the *N*-methylation of a dipyrromethenone will inhibit intermolecular proton transfer by suppression of dimerization in unpolar solvents[156], but will at the same time restrict the conformative mobility. Similar reasoning applies to *N*-protonation[96,155]. The influence of viscosity which essentially decreases vibrational relaxations has hitherto mainly[158] been investigated at lower temperatures[96,132,155]. Bilindiones[96,132,155] and especially conformatively more rigid pigments like isophorcabilin *(31)* show a moderate fluorescence at 77 K[155c].

In this respect, the rather strong fluorescence of isophorcarubin *(32)* is noteworthy[165]. The ring-A,B fragment of *(32)* is identical to that of a common 10,23-dihydrobilindione ("bilirubin"), and its fluorescence should therefore only be weak[86,166]. The C,D-fragment is rather rigid, however, and is incapable of allowing intramolecular H-transfer, so the fluorescence has thus been related to the latter[165]. Hitherto, no direct approach has been tested to quantitatively separate the contributions of proton-transfer processes; one possibility would be a systematic investigation of $^2H$-isotope effects[167].



*(32)*

In biliproteins the radiationless deactivation is strongly decreased. The vibrational relaxation can be effectively decreased by a rigid fixation of the chromophores. Indications of this are the decreased bandwidths of the absorption spectra[66,125] which is also evident in the fluorescence-excitation-spectra[139–143], the large negative temperature coefficient of the fluorescence[17,139], and the small phonon-coupling to the protein[138].

An effective instrument for repressing proton-transfer-reactions would be the transfer of chromophores into a hydrophobic environment, *e.g.* into the interior of proteins. An extended conformation of the molecule would further inhibit intramolecular transfer. The lack of typical reactions of bilindiones, *e.g.* the formation of Zn-complexes[168] in biliproteins, could be evidence of this[22,169] as well as the quenching of fluorescence with benzoquinone[170,322].

On the other hand, there are several recent results which put the chromophores into a hydrophilic or at least water accessible position near the surface of the biliproteins: Thus there are reports of redox-reactions of chromophores at electrode-surfaces[171], in solution[99,100,129,172] and at membranes[173], of the reversible addition of thioles and dithionite (or rather sulfoxylate[174]) to the central methine bridge[129,172], of chromophore-chromophore interactions during the aggregation of APC[151], of low-temperature photochemistry related to proton transfer[138] and of an $H_2{}^{18}O$-exchange of *both* lactam oxygens at C-1 and C-19[175]. In the case of the reaction of PC, APC and PE with dithionite, it could be demonstrated that this reagent is in thermodynamic equilibrium with the chromophores. At least in this case, the decreased reactivity of the chromophores in the native pigment is thus determined thermodynamically and not kinetically[129]. Possibly, the conformational changes are one direct cause of the increased stability.

Perhaps the quantum yield of fluorescence is the most sensitive parameter of the state of phycobiliproteins. During controlled protein unfolding it already clearly decreases before the absorption- or CD-spectra noticeably change[144,176]. Under partial denaturating conditions, the photochemical behavior of phycobiliproteins changes in a complementary fashion. In presence of allylthiourea[178], the photochemical stability of PC is decreased[177]. In presence of 0.5 M guanidinium chloride[179] or on diminution of the pH-value to 3.8[180], solutions of PC and APC become photoreversibly-photochromic. The latter result is especially of interest with regard to the phycochromes[10-12] and possibly to phytochrome, too, because they show similar difference-spectra.

## 4. Proteins

Phycobiliproteins represent a period of evolution of about 3.5 billion years and they exist in procaryotes as well as in eucaryotes, in very different biotopes. They are thus of interest for comparative investigations which currently culminate in a complete sequencing of two PC-molecules[62,63]. The most important data of biliproteins that have been characterized spectroscopically and by their origin, are summarized in Table 3. The phycobiliproteins are globular and soluble in water, those isolated from red algae and cyanobacteria show pronounced aggregation. Analysis of the N-terminal sequences, immunochemical investigations and hybridization experiments indicate a common phylogenetic tree for these pigments (Fig. 2). The closest relationship exists between corresponding subunits of one type of protein from different organisms; a more distant relationship exists between corresponding subunits of different types of pigments and between the different subunits of the same pigment. Also the pigments of red algae and cyanobacteria seem to be more closely related with each other than than with the pigments of cryptophytes.

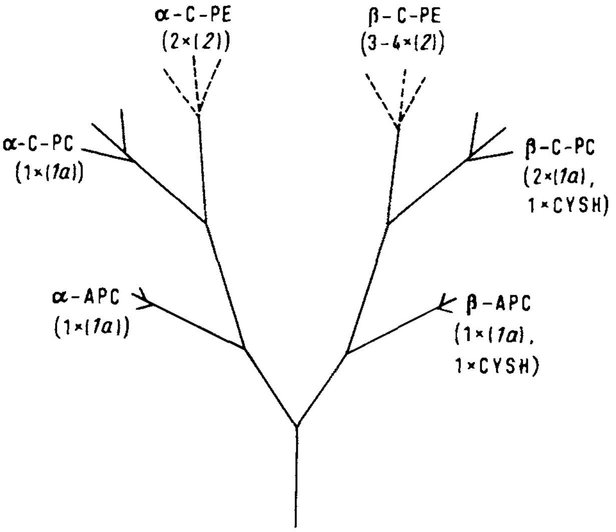


Fig. 2. Phylogenetic tree of biliproteins and their α- and β-subunits from cyanobacteria. C-PC = Phycocyanin, C-PE = phycoerythrin, APC = allophycocyanin (after [205]).

The protein moiety of phytochrome is distinctly different from that of the phycobiliproteins. It is considerably larger, it probably possesses a dumbbell-shaped structure, and $P_{fr}$ in particular has a tendency to associate with membranes. Immunochemical and spectroscopical investigations demonstrate the distinct similarity of phytochrome(s) from different organisms. So far there is no direct indication of a phylogenetic relationship with the phycobiliproteins. The similar structure of the chromophores, their similar binding to the apoprotein, comparable non-covalent interactions, and finally the occurrence of phycochromes are indirect indications thereof, but they don't exclude a converging development.

### 4.1. Phycobiliproteins: Monomers

The most data available on primary structures are those for phycocyanins. Aside from the determination of N-terminal sequences (see[15,205,206]) and of chromophore binding regions[62-65,207-211] of several organisms, the sequences of PC isolated from *Mastigocladus laminosus*[62], a thermophilic cyanobacterium, and from *Cyanidium caldarium*[63], a monocellular thermoacidophilic red alga, have recently been established. The complete analyses of the β-chain of PC isolated from *Synechococcus spec.* 6301 (formerly called *Anacystis nidulans*)[64], a monocellular mesophilic cyanobacterium, and of the β-chain of APC from *M. laminosus* have also been carried out[205]. The homologies of the respective α- or β-chains of the two complete structures are remarkable (80 or 78%) considering the different taxonomic positions and biotopes of the organisms.

However both are thermophilic organisms and the sequence, known up to 80%, of the marine cyanobacterium *Agmenellum quadruplicatum* shows only a homology of about 30% (*L. Fox,* private communication). A high homology is also found on comparing the PC β-chains with that of *S. spec.* The α- and β-chains of PC from each of the two organisms show much lower homologies (25% in PC from *M. laminosus*)[205]. The relationship between the same subunits of pigments of a different spectral-type is also obvious in the primary structures. Thus, the β-chains of PC and APC of *M. laminosus* are homologous to 25%, and the relationship becomes even more distinct on comparing the secondary structures (as calculated by the method of *Chou* and *Fassman*)[205].

The homology is not uniform, but particularly high in the chromophore regions. An earlier survey indicated a very high homology of the N-terminal regions within the corresponding subunits of pigments of different origin and of different spectral-type[15]. The low homology of these regions of PC and APC of *M. laminosus* found by the "Zürich-group", is, however, the first example of an exception to this rule, or it indicates an exceptional position of APC. The homology of the chromophore binding regions is supported by comparison of sequences of chromopeptides isolated from different phycoerythrins[209] and cyanins[62-65,207,210,211]. Thus, five different amino acid sequences have been identified in the region of the binding cysteins in PE from *Pseudanabaena* W1173, containing five chromophores. PE from *Phormidium persicum,* containing six chromophores, possesses six different binding regions, five of which correspond unequivocally to the five regions of the first named pigment[209]. The sequences of peptides characteristic of the individual chromophores can be correlated with the spectra of the chromophores in these pigments[139]. Hitherto, little was known about the phylogenetic origin of the increasing number of chromophores on the individual peptide chains on going from APC to PC to PE. Interestingly, however, a comparison of PC and APC from *M. laminosus* shows that the additional chromophore binding site on the $\beta$-chain of PC is formed by insertion of a short peptide in the APC sequence[205].

Studies on the protein moieties of the biliproteins complement the data on the chromophore binding mode as derived from investigations of chromophores (see Section 2). With only one exception[213] all of the known "chromopeptides" contain cysteine[35,62–65,205–216]. The early proposition[212], that this amino acid takes part in chromophore binding was first verified for a B-PE peptide from *Porphyridium cruentum*[208], and it was later recognized that cysteine functions as the binding amino acid for *all* chromophores in several C-phycocyanins and phycoerythrins[62–63,209,211,216]. These results are supported by a comparison of the number of bonded cysteines and the number of chromophores in pigments of several red algae and cyanobacteria[217]. It follows, together with the proof of the thioether bond to ring A of the chromophores [Section 2.2, formulas *(1), (2)*], that the blue *(1a)* and red *(2)* chromophores are bound to the protein *via* cysteine residues. The yellow urobilinoid chromophores of B-PE and R-PE are supposed to have even a second cysteine-chromophore bond to ring D[22,217].

Pigments of cryptophytes have hitherto been the subject of fewer investigations; the finding of a single, free cysteine-SH in one chromopeptide is indicative of a special binding position[215].

There is less agreement on other and possibly additional chromophore protein bonds. In particular, the linking of serine with one of the propionic acid side chains is plausible[22,209,213,215]. There are no such indications from the sequenced phycocyanins and allophycocyanins, but such a connection is discussed as being the only binding site of a K-PC[215] and of a R-PE[22], and it was identified in addition to the cysteine bond in one C-PE chromophore[209]. The problem is complicated by the possibility of both artifactual hydrolysis of esters and the formation of new bonds during protein degradation (see [22]). *Crespi* and *Smith*[214] postulated a lactim-ester binding to aspartate to account for the easy splitting of the thioether bond, but investigations of models show that this activation is not necessary[54c,58,218]. Also, a binding to glutamate is reported for a cryptophytan chromopeptide[215].

Only little is known so far about the secondary- and tertiary structures. Although PC and PE in particular can be readily isolated and crystallize well, there exists as yet no high-resolution X-ray analyses[32,193,194,219,220]. This may be explained by an unfavorable packing, leading to partial obliteration of reflexes due to interference from neighboring molecules[221]. The amino acid sequences and the solubilities are typical for globular proteins, with APC containing a higher proportion of hydrophobic amino acids than PC and PE. The crystal packing[32,193,194] and the investigations in solution[222] show an oblong shape (2.5—3.5 nm diameter, 5—6 nm in length) of the ($\alpha\beta$)-monomer of PC; a size which has also been deduced for other biliproteins[223–225] from electron-microscopical measurements. According to circular dichroism measurements on several pigments, the $\alpha$-helix content is about 60% in the $\alpha$- and 40% in the $\beta$-chain[144,147]. The secondary structure of PC and APC of *M. laminosus* has been estimated from the sequence. Here, too, the $\alpha$- and $\beta$-chains show differences, and there are indications of a different flexibility of the peptide backbone in the environment of the different chromophores[205].

As the second essential method, the immunochemistry confirms the relationships between the phycobiliproteins. The pigments of the same spectroscopic type, APC[148b,149,187,227–229] or PC[32,72,148b,149,187,227–229] or PE[198,227,228,230,231] are closely related immunochemically irrespective of their origin from the procaryotic cyanobacteria and the eucaryotic red algae. In contrast, the pigments of the different spectroscopic types do not undergo cross reactions, even if they are produced from the same organism. On this basis, R-PC[72] and phycoerythrocyanin[32,230], which contain blue chromophores *(1a)* as well as red chromophores *(2)*, were classified as phycocyanins, and APC-B as a true allophycocyanin[148b]. The subunits of individual C-PE[231] and also those of APC[149]—which are difficult to differentiate by other methods—are immunochemically not related, in contrast to the close relationship of corresponding subunits of pigments from other different organisms.

The cryptophytan-pigments, too, assume an immunochemically special position. First investigations[227] revealed no relationship with pigments from cyanobacteria and red algae; this has been supported for PC[228], whereas PC as well as PE from two different cryptophytes cross-react with PE from the red alga *Prophyridium cruentum,* but not with C-PE[198]. Accordingly, both pigments of cryptophytes seem to be related to PE from red algae.

Until now no defined immunological determinants are known. The missing cross-reaction of APC and PC has been taken as an indication of the chromophore not being a determinant, since both contain *(1a)*[231]. The different spectra of PC and APC, however, point to different states of this chromophore in the native pigments which may lead to significant differences in immunochemically relevant criteria, *e.g.* conformation and charge. There are also indications of the chromophore being accessible from the outside (Section 3.4). Immunochemical methods are principally suitable for a numeric taxonomy. With C-PE, isolated from seven different types of cyanobacteria, it could be demonstrated by a quantitative study that there are determinants specific of the species, as well as determinants specific of the spectral type, and that the results depend upon the method used (phage test or precipitation test)[230].

### 4.2. Phycobiliproteins: Quaternary Structure

The quaternary structure and higher aggregates have been investigated more thoroughly than the secondary and tertiary structures. They are decisive for the biological function of the phycobiliproteins. Most of the pigments possess an

$(\alpha,\beta)_n$-structure, with $n$-varying between one and higher than 12 depending on their state of aggregation and their origin *(vide infra)* (Table 3). In some pigments, yet a third subunit has been found, as in B-PE and R-PE ($\alpha_6\beta_6\gamma$)[153,193,194], in APC I ($\alpha_3\beta_3\gamma$)[182] and in PC from *Chroomonas spec.* with an $\alpha\alpha'\beta_2$ structure[189].

The molecular weights vary between 9200[189] and 20500[232] for the $\alpha$-subunits and between 16000 and 23500 for the $\beta$-chain, with the $\alpha$-subunits of the cryptophytan biliproteins at the lower limits. The $\gamma$-chains are considerably heavier. The subunits are classified by definition according to their molecular weights ($\alpha < \beta$). In the case of a different number of chromophores, the $\beta$-subunit always contains more than the $\alpha$-subunit. An alternative classification is possible immunochemically. It has been proven especially useful with APC[149], which has subunits carrying one chromophore each and which may have very similar molecular weights[1].

The subunits can be separated preparatively by ion-exchange chromatography, after being partially[139,196] or completely[62-64,147,149,223,234] unfolded. The separately renaturated subunits preferentially aggregate to dimers. In a mixture, the native pigments $(\alpha\beta)_n$ can be reconstituted in good yields. Smooth hybridization in 40—60% yield has been found[233] with complementary C-PC subunits isolated from monocellular and filamentous cyanobacteria, respectively; and there are even APC hybrids from the subunits of cyanobacteria and the red alga, *Cyanidium caldarium*[149]. A limiting factor for the yields is certainly the sensitivity of the chromophore in the denaturated pigments.

The controlled denaturation of monomer pigments has been investigated in the case of PC[125] and PE[144]. In each case sequential effects could be observed. The fluorescence decreases first[144,176], followed by absorption changes of the chromophores (in C-PC in a stepwise fashion[125]), and finally the protein structure (observed by CD) melts[144].

Corresponding to the strong coupling between chromophore and protein the quantum yield of fluorescence and the absorption spectra are the most sensitive indicators of the state of the protein (see Sections 3.3 and 3.4), *e.g.* partial proteolysis or denaturation.

The thermodynamics of the unfolding of proteins has been investigated on phycocyanins from several biotopes. Starting with undefined aggregates, $\Delta G^{0'}$ for pigments from meso-, psychro- and halophilic organisms is in the range of 10—22 kJ/mol[135] for complete unfolding by 8 M urea. These values are considerably lower than for globular proteins of similar size and free of disulfide bonds[235,236]. Comparable values have been found only for pigments of thermophilic organisms[135]. A possible factor is the energy necessary for "stretching" the chromophores of the native pigments[129] (see Section 3.2). The refolding kinetics of PC from *Spirulina platensis* is multiphasic, with a rapid first phase ($\tau_{1/2} = 110$ msec) accessible by fluorescence as well as by absorption measurements[237].

Phycobiliproteins from cyanobacteria and red algae show (with exception of the already complex-monomers APC-I, B-PE and R-PE (Table 3)) a distinct aggregation, which was mainly investigated systematically by *Berns et al.*[23] on C-PC. Starting from monomers, preferentially tri- and hexamers are formed[238]. These are the basic building blocks both for the crystalline pigments[32,194,219] as well as for phycobilisomes[223-225], as the light harvesting superstructures of these organisms[5]. Dependent on the conditions of isolation, higher aggregates[23,239] and hetero aggregates[223,224,240] have also been found, which represent more or less intact fragments of phycobilisomes[5] and even aggregates thereof[225]. Electron microscopic investigations by *Mörschel et al.*[248] revealed that the hexamers of PC are made up of two torus-shaped $(\alpha,\beta)_3$-trimers, one on top of the other, and that in B-PE the $\gamma$-chain occupies the central cavity of the cylinder that is formed.

In the pH range close to the isoelectric point ($\approx 5.3$) the equilibrium is mainly shifted in favor of the hexamer. In dilute solutions at $pH = 6$ to $pH = 5.4$, an equilibrium between monomer and hexamer has been established for several phycocyanins with an equilibrium constant of about $10^{30}$, in favor of the hexamer[239,241].

Also, trimer-hexamer equilibria[242] and—at higher pH values—monomer-tetramer[243] and monomer-dimer[244] equilibria have been studied by ultracentrifugation. At low concentrations, C-PE exists in a monomer-dimer equilibrium[139]. The aggregation is favored at elevated temperatures[238], at higher ionic strengths[245], by arenes[246], and by low concentrations of guanidinium chloride[247]; it is decreased by chaotropic salts[245] and H/D exchange[239,249]. These results, which indicate a high degree of hydrophobic interactions in aggregate formation, have been compared with the formation of detergent micelles[238]. The role of ordered water structures was recently studied in association experiments with tetraalkylammonium salts[250]. Since cyanobacteria also occur in extreme biotopes, the phycobiliproteins are suitable objects for the study of such adaptations. C-PC from a psychrophilic organism[251] possesses similar aggregation properties as the pigments from mesophilic organisms, whereas phycocyanins from halophilic[252] and thermophilic[253] organisms are clearly different. The molecular causes of these adaptions have also been investigated by calorimetric measurements of the protein folding[135] and sequencing studies[62].

In contrast to the pigments of the red algae and of the cyanobacteria, cryptophytan biliproteins show no significant aggregation. This is reflected in the absence of phycobilisomes in cryptophytes.

### 4.3. Phytochrome

Although ubiquitous in green plants, phytochrome has been purified from only a few species sufficiently enough to allow the chemical characterization of the protein.

Monomeric phytochrome from oats and rye has a molecular weight of about 120000[200,201] and it probably has a dumbbell shape[203,204] (for reviews see [1,14,18,21]). The hitherto best characterized pigment from oats is readily cleaved by endogenous proteases (at the incision?), to yield a still photochemically active fragment with a molecular weight of 60000[255-257]. This fragment is generally referred to as "small" phytochrome; for some time it was regarded as the native monomer. This partial degradation changes the absorption spectra, the photochemical quantum yield[262], the energy transfer from tryptophan to the chromophore[263], and the immunological properties[264]. "Large" phytochrome forms aggregates, whose dimeric structure is confirmed by gel-filtration[203,256,258], sedimentation[201,254,255], and electron microscopy[254]. Additional forms of $P_{fr}$ of even higher molecular weight have been reported, whose nature is still unknown[256]. Phytochrome contains about 35% hydrophobic amino acids and about 27 cysteines[201,203] including the chromophore-binding one. In addition, 4% sugar has been found in "small" phytochrome[111]; the "large" pigment contains one phosphate group[201,202].

There are conflicting results regarding the symmetry of the "large" phytochrome. Dimeric "large" phytochrome appears in the electron microscope as "tetramer" (9 × 9 nm)[254]. The molecular weight[255–257] of "small" phytochrome would also indicate two domains of roughly the same size to be present in "large" phytochrome. Two research groups have compared the peptides of the trypsin digests of "large" and "small" pytochrome from oats. *Stoker et al.*[259,260] have concluded a high degree of symmetry from the similar peptide maps, whereas *Kidd et al.*[261] arrived at the opposite conclusion on the basis of significant differences when using a different labeling technique. The available data also point to an asymmetric chromophore distribution, *i. e.* only one half contains a chromophore (see [14,18,21]). Antiserum against "large" phytochrome produces spurs with "small" phytochrome but not *vice versa,* which also indicates an asymmetry of the determinant regions[264].

The phytochromes from different sources are spectroscopically indistiguishable. Immunochemical experiments, too, reveal a close relationship between the hitherto investigated phytochromes from oat, rye, corn, barley, pea[203,258,264]. The amino acid analyses as well as the N-terminal sequences are different for "large" phytochrome from rye and oats, but this is possibly due to the purification procedures used[201,203].

For a better understanding of the function (see Section 5.3), protein-chemical differences between the two forms are essential. Following the works of *Tobin* and *Briggs*[191], who in 1973 questioned a greater part of the formerly reported differences, greatly improved isolation methods[200,265–267] and new analytical techniques led to more promising results. Thus, indications of a preferential interaction between $P_{fr}$ and cholesterol[268] were obtained, and *Smith* discovered a preferential assoziation of $P_{fr}$ with dextran blue[269] which may also be useful for the purification of phytochrome by sorption in the $P_{fr}$-form on dextran blue-agarose and subsequent desorption after irradiation with far-red light[269a]. $P_{fr}$ isolated after *in vivo* transformation, contains a larger fraction of high molecular weight components ($\geq$400000)[256]. In presence of bivalent ions, it binds relatively unspecifically to particulate fractions ("pelletability", see [270,271]). $P_r$ and $P_{fr}$ are immunochemically indistinguishable[272], and isoelectric focussing also gives identical results[113]. Significant differences were found, however, on titration of readily accessible amino acids[113]. $P_{fr}$ contains one accessible cysteine and one histidine more than $P_r$, and the modification of two tyrosines inhibits the photochemical reactions.

### 4.4. Phycochromes

Originally, the term phycochromes was coined—in analogy to phytochrome—for the light sensory pigments in cyanobacteria (for a recent survey see [10]). Today, however, all potentially photoreversibly-photochromic pigments of these organisms are called phycochromes, irrespective of any known function (see [10]). To characterize the function of these photoreceptors, which in no case is as yet certain, *Bogorad*[1] proposed the term adaptochromes, in accord with the most important and obvious effect of light-regulation, the chromatic adaption (see Section 5.3). Already at an early stage, phycochromes were related to phycobiliproteins. *Scheibe*[273] succeeded for the first time in the enrichment of a fraction having photoreversibly-photochromic properties. Subsequently, the *Björns* characterized four such pigments as fractions of phycobiliproteins from different algae[274,275] which were called phycochromes a, b, c and d. Of these, phycochrome c is of particular interest, as its light-induced difference spectrum is similar to the action spectra of chromatic adaption of several cyanobacteria and to the photomorphogenesis of *Nostoc.* The phycochromes have been enriched by isoelectric focussing; in the case of phycochrome b an almost complete separation was possible from the photochemically inactive light-harvesting phycobiliproteins present in large excess. So far, only one of the proteins has been characterized in detail. It is suggested to be identical with the α-subunit of phycoerythrocyanin[275a].

A fascinating aspect was revealed by two research groups during recent investigations on partially denaturated "common" biliproteins. Treatment of PC and APC from *Tolipothrix tenuis* with 0.5 M guanidinium chloride[179] gave them photoreversibly-photochromic properties characteristic of phycochrome a or c[174], and likewise APC from *Fremyella diplosiphon* obtained the photochromic properties of phycochrome c, on lowering the pH to 3.8[180]. By this treatment the chromophores seem to be sufficiently decoupled from the protein such that the fluorescence is already decreased, but the radiationless deactivation is not yet prominent. The quantum yields of the photoreactions (about 10%) are comparable to those of phytochrome. Independent of the proof of the biological relevance of phycochromes these results throw new light on the physicochemical interactions between chromophore and protein, and on the possible phylogenetic relations between phycobiliproteins and phytochrome.

## 5. Biological Functions

### 5.1. Phycobiliproteins

Phycobiliproteins are antenna or light-harvesting pigments of cyanobacteria, red algae, and cryptophytes. The absorption bands of the most abundant pigments of this group, the phycoerythrins (PE) and phycocyanins (PC), are found in the green to orange spectral range. The light-harvesting pigments of green plants, chlorophyll a and b, absorb only slightly in this range, thus guaranteeing biliprotein producing organisms an ecological advantage in deep water and under a canopy of green plant.

The organization of biliproteins and the mechanism of energy transfer is very similar in cyanobacteria and red algae, but the cryptophytes differ considerably. In the former, the phycobiliproteins are localized in particles visible by electron microscopy, called phycobilisomes, which are located at the outer surface of the thylacoid membranes[5,224,276]. The phycobilisomes of different species have distinctly different sizes and fine-structures, the ones most thoroughly investigated to date being those from the two red algae, *Porphyridium cruentum*[5,279] and *Rhodella violacea*[223,224] (see Fig. 3), and from the cyanobacterium *Synechococcus sp.* 6301 *(Anacystis nidulans)*[278]. Besides the light-harvesting pigments proper, *e.g.* PC and PE, they contain small amounts of several different allophycocyanins[148b,182], which are essential for the transfer of energy to chlorophyll. In addition, small amounts of colorless proteins have been described which are possibly important for the organization of phycobilisomes[223,278,280].

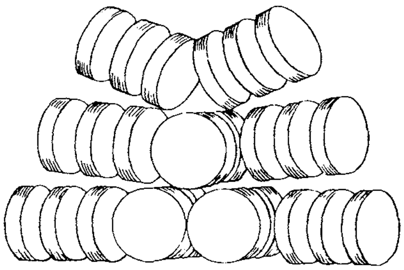

Fig. 3. Model of a phycobilisome of the monocellular red algae, *Rhodella violacea.* The "core" is made up from three APC hexamers, the rods fixed to it ("tripartite units") consist of one PC hexamer and two B-PE monomers, in this order when looking from the core (after *E. Mörschel, W. Wehrmeyer,* Ber. Dtsch. Bot. Ges. *92,* 393 (1979)).

Within the phycobilisomes the different pigments are densely packed in such order, that the absorption maximum increases from the "outside" to the "interior" of the phycobilisome. *Gantt et al.*[5] developed a model for phycobilisomes from *Porphyridium cruentum,* which reminds one of an onion cut in half: layers composed of PE surround inner layers of PC, which surrounds an APC-core. This arrangement was derived from dissociation experiments in buffers of low ionic strength, whereby the pigments were released sequentially[5]. It was convincingly proved by fluorescence spectroscopy[281] and immuno-electron-microscopy[281,282]. Using the latter method, APC could be shown to be localized on that side of the phycobilisome facing towards the membrane[282].

The architecture of phycobilisomes of the monocellular red alga *Rhodella violacea* (see Fig. 3) is basically similar but perhaps even more impressive, due to their flatness[223,224]. Six conspicuous rod-shaped stacks are attached to the APC-core[224]. These rods can be isolated by careful dissociation[223]. By electron-microscopic inspection, they appear as stacks of three small double-disks ("tripartite units"). The double-disks have the dimensions and fine structure of hexameric C-PC $(\alpha\beta)_6$ or of the fundamentally similar B-PE $(\alpha_6\beta_6\gamma)$. The former are supposed to be identical with the C-PC-hexamers which have been observed during the *in-vitro* association or during the crystallization (homoaggregates, see Section 4.3). A further dissociation of the rods and an analysis of the fragments revealed that two adjacent double-disks consist of PE, the final one of PC, *i.e.* they form a heteroaggregate of two different biliproteins[223]. Such heteroaggregates of PC and PE were recently also isolated from *P. cruentum*-phycobilisomes and from cyanobacteria[240,283a,284]. They show an excellent energy-transfer from PE to PC (reversible dissociation, see [283a]). A reconstitution of phycobilisomes starting with the isolated biliproteins is not (yet) possible. Perhaps the aforementioned colorless proteins are necessary as structural elements[280]. In support of this, phycobilisomes partially dissociated into a crude APC fraction and a PC-PE-complex can be reconstituted[283b]. Since the tripartite units of *R. violacea* contain no colorless proteins, these rather seem to take part in the APC-PC-coupling or in the membrane-binding[223]. A first experimental indication of this is the recent identification of a heavy, colorless protein (molecular weight about 80000), in both isolated phycobilisomes and thylacoid membranes freed of biliproteins[283b].

Comparatively less is known about phycobilisomes of cyanobacteria, but the results indicate similar structural principles as in those of *R. violacea.* By electron microscopy, *Wildman* and *Bowen*[277] have identified phycobilisomes in all of the 27 tested cyanobacteria, in some of them with excellent resolution, but until recently the isolation was more difficult than in red algae. A complete separation from other pigments was achieved by immunochromatography, but the elution of the phycobilisomes purified in this manner was only possible under dissociating conditions[280]. Phycobilisomes have been isolated from *Nostoc* species[151a,284] from *Synechococcus spec.* 6031 *("Anacystis nidulans")*[278] and from other species[285,286]. The phycobilisomes of *S. spec.* 6301 appear in the electron microscope as aggregates of rods similar to those of *R. violacea* (Fig. 3). Here, too, APC seems to be located at the coupling position, since the energy transfer from PC to APC is interrupted by the dissociation[278]. Recently, the electron-microscopic characterization of phycobilisomes of two other cyanobacteria was achieved by using zwitterionic detergents which are reported to inhibit the aggregation during purification[225]. These investigations confirm the general structural principle of Figure 3, with variations in the number of the central APC-disks, the number and the length of the "branches"[278], and also by their arrangement in two (Fig. 3) or three dimensions (*P. cruentum*[279,282]). The phycobilisomes of chromatically adapting cyanobacteria show small but distinct differences in size and arrangement[287], as well as in the pattern of the colorless proteins[280]. The "branches" of *Tolypothrix tenuis* increase in length in green light[288]. In this process, not only additional PE-units seem to be added, but also part of the PC is removed.

Phycobilisomes are extraordinary efficient antennas which absorb light by a high effective cross-section, and transfer the excitation energy to the reaction-centers. This energy transfer has quantum yields up to 100%[142,143,289,290] and is only decoupled under starving conditions (light[201], N[292]). The transfer mainly occurs to photosystem II (PS II), as was originally concluded from the bichromatic action-spectra[3,4]. Heterocysts contain no PS II and have been regarded as being free of phycobilisomes[293] (see, however, [323]). Recently, *Katoh* and *Gantt*[294] isolated photosynthetic vesicles with the phycobilisomes still bound, showing PS II activity. This activity decreases in parallel with the dissociation of the phycobilisomes (induced by a decrease in ionic strength). The coupling between the phycobilisomes and the reaction centers is variable and depends on the physiological conditions[295]. For *Anabaena variabilis,* grown heterotrophically in darkness, however, an energy transfer to PS I was reported, and recently in PS I samples from *Chlorogloea fritschii*[296], fluorescence-spectroscopic evidence was obtained for the occurrence of APC. APC fluoresces similarly to certain chlorophylls[294], but direct support comes from the results cited in ref. [323].

One reason for the efficient energy transfer is the organization of the phycobilisomes. This ensures that the energetically favored "downhill" transport of excitation-energy from the "high-energy PE" to the "low-energy APC" is directed at the same time from the PE periphery to the APC-core of the phycobilisome. Possibly, a recently described "foot structure"[279] serves for further transfer into the membrane and for the fixation of the phycobilisomes[279]. A second factor is the intense absorptions of the biliproteins ($\approx 10^5$ $cm^2 \times mol^{-1}$) which cover almost the entire spectral region from about 500 to 670 nm (cf. [5]), combined with a high degree of fluorescence (= low radiationless deactivation) of the chromophores[142] and distances of 3.5—6 nm between the chromophores[139,142,297]. These distances are optimal in a disordered structure for the energy transfer between suitable chromophores by the Förster-mechanism, because they are below the critical radius. As has recently been described for C-PE, the quantum yield of fluorescence increases by aggregation of isolated subunits to the monomer[139]. It increases even more during aggregation of the monomers to tri- and hexamers[141], or to the quasi-hexamer B-PE[142]. At the same time the fluorescence-polarization[139,142,297] and the time constant of the energy transfer decreases[297].

Due to the rapid migration of energy and the greater probability of a "downhill"-transport of energy, the fluorescence in each aggregate[139] is emitted almost exclusively from the chromophores, absorbing at the longest wavelengths, which were thus classified as "f"-chromophores[140]. The "s"-chromophores absorbing at shorter wavelengths act as sensitizers, and only exceptionally show a detectable fluorescence[139]. During the gradual association of phycobilisomes, this transfer chain is extended successively to yield "Förster-cascades". Due to their architecture, each pair of neighboring pigments provides for an optimal overlap of the emission band of the donor and the absorption band of the acceptor (Table 4). This process was demonstrated for biliproteins with different chromophores[140,142,297], of heteroaggregates[223,253], and of whole phycobilisomes[143,289,290]. In the intact phycobilisome, the result of this process is such, that the chromophores of APC, the biliprotein present in least amount, are the only ones to fluoresce, and all the remaining chromophores serve as sensitizers, with a transfer-probability of "at least 99%" in phycobilisomes of *P. cruentum*[290].

Table 4. Schematic representation of energy transfer within a phycobilisome like the one shown in Fig. 3 (only one tripartite unit and one APC are considered), and of the absorption and emission spectra of the phycobiliproteins (averaged absorption maxima, the emission maxima of "s"-chromophores have been estimated from the absorption maxima by assuming a Stokes-shift of 15 nm).

| Pigment | Chromophore | Absorption [nm] | Fluorescence [nm] |

[a] PUB = phycourobilin chromophore.

Cryptophytes possess biliproteins as antenna-pigments, too, but they are distinct from those of cyanobacteria and red algae (for a recent review, see [298]). Cryptophytan biliproteins are localized on the inner side of the thylacoid membrane[299]. Hitherto, the search for phycobilisomes has met without success, although *Wehrmeyer et al.*[300] recently obtained electron-microscopic evidence of particulate structures which may contain biliproteins. The energy transfer in cryptophytes must also be different, since no APC has so far been detected, and generally they only contain either PC *or* PE. As in the biliproteins of cyanobacteria and of red algae[34,297,300], only the chromophore lowest in energy fluoresces. In accord with the exciton-coupling between the chromophores postulated by *Jung et al.*[34], *Kobayashi et al.*[297] reported an extremely fast transient (energy-transfer) ($\leq 8$ ps) in PC of *Chroomonas*. The transfer from K-PC to chlorophyll a by the Förster-mechanism appears unproblematical, especially in pigments like PC-645 from *Chroomonas*[34,189,300] and PC-641 from *Hemiselmis virescens*[33], absorbing and emitting at rather long wave-lengths. In contrast, the emission-band of PE is located in a region of minimal absorption of chlorophyll a, so that either only incomplete energy-transfer is possible, or another pigment has to be positioned between them[301]. Indeed, cryptophytes contain possible candidates, *e.g.* chlorophyll *c*.

According to the data summarized above, the morphology of the antennas and the structure of the biliproteins would seem to be closely related. Each biliprotein of the cyanobacteria covers only a comparably small portion of the spectrum. Only APC has properties favorable for energy transfer to chlorophyll; an energy transfer of PE to chlorophyll requires the aggregation of several pigments. This disadvantage is compensated for by the flawless architecture of the phycobilisomes, which enables a vectorial energy flux direct to the reaction-center of PS II. In the cryptophytan phycocyanins, such energy transfer-chains are already realized within the individual biliproteins. *Chroomonas*-PC, for example, contains chromophores absorbing in the region from 573 to 652 nm[32,189], so a higher degree of organization would seem unnecessary. Finally, in the red algae both strategies are combined. They contain phycobilisomes, as well as the pigments R-PC, R-PE and B-PE, each of which contain different chromophores already joined to an energy transfer-chain of moderate length.

In addition to the well documented light-harvesting functions, other functions of phycobiliproteins are discussed. Under conditions of deficient N[1] and S[302], phycobiliproteins are degraded as protein-reserves (?). In cyanobacteria in particular they constitute a considerable fraction of the total protein, and basically they are of less importance for photosynthesis than the reaction centers. They also may have functions in light protection, since mutants free of biliproteins are more sensitive to light than the wild-types.

Finally, there is substantial evidence for phycobiliproteins, also having or having had functions in the electron transfer[303,304]. A corresponding function *in vivo* has as yet not been detected, and may have been lost during evolution.

Electrodes covered with biliproteins show photopotentials[171,305]; moreover, PC catalyzes electron-transfer through synthetic lipid-membranes[173,304]. In both cases the action spectra and absorption spectra are similar. PC undergoes specific interactions with $Fe^{3+}$, but not with $Fe^{2+}$, and it shows an asymmetric effect on the electron transfer of charged synthetic membranes loaded asymmetrically with that pigment[306]. The redox potentials of free bile pigments have been calculated theoretically[95,307], and the chromophores of native biliproteins have been shown to be much more stable towards redox reagents than those of the denaturated pigments[35,129].

### 5.2. Phytochrome

The function of phytochrome is that of a light-sensory pigment of green plants. In the transformation from heterotrophic etiolated growth in higher plants, *e.g.* in seedlings below the surface, to autotrophic, photosynthetic growth, phytochrome mainly functions as a sensor of light as such, in the "high-energy reactions" phytochrome functions as a sensor of light-intensity, and finally due to the $P_r$ and $P_{fr}$ equilibrium being dependent on the spectral distribution of the light especially within the photosynthetically important red spectral region, it renders possible a "color-vision" in green plants. Whereas a large variety of physiological and some structural aspects of phytochrome have been investigated in considerable detail[9,14,16 18], knowledge of the mechanism of information-transfer and -transduction is as yet only fragmentary. The models are difficult to evaluate in this context and shall only be outlined here. For further information, the reader is referred to recent reviews[9,14,16b,17,18,21,303,309].

Phytochrome is synthesized in its physiologically inactive form, $P_r$; the beginning of each physiological reaction sequence is the photochemical transformation into $P_{fr}$. The formation of $P_{fr}$ is fundamentally and nearly completely reversible by light ≥740 nm; this is not true, however, for all steps of the subsequent reaction-sequence. The *in vivo* decomposition of $P_{fr}$ or $P_r$-receptor complexes is a simple example (cf. *e.g.* [14,18]). Depending on the duration of the reaction ($\tau_{rev}$) until an irreversible step is reached, the physiological answer is reversible (or annulled) only for a certain time. Since the time ($\tau_{rev}$) of escape from reversibility varies among the diverse physiological answers by several orders of magnitude, the phytochrome answers have been classified into modulation (large $\tau_{rev}$-value = "reversible") and differentiation processes (small $\tau_{rev}$-value = "irreversible") (for recent discussions, see [18,308]). A variety of biochemical and physiological results critically summarized by *Marmé*[309] have indicated, at least for the modulation reactions, reversible changes of membrane properties to be operative.

Based on the hitherto known differences between $P_r$ and $P_{fr}$ (see Section 4.4) and on the photochemistry of model-systems (see Section 3.3), several hypotheses have been proposed for the primary reactions. *Song et al.*[263] postulated a light-induced photoisomerization[40] by proton-transfer, by which a receptor site formerly covered by the chromophore becomes accessible. *Hunt* and *Pratt*[113] argue, that chemical modifications of amino acids newly accessible by this transformation should interfere with the photoreversibility. As this is not the case[113], they regard this result as support of the conformational change of the protein, discussed by *Smith*[9a] as a primary signal. Finally, a third hypothesis postulates a reversible redox-reaction between protein and chromophore with the formation of a new chromophore-protein bond[106]. Each of these hypotheses is able to explain modification of membrane-properties, directly by redox and/or protonation-deprotonation processes, and indirectly by conformational changes by uncovering receptor binding sites, but a differentiation is not yet possible.

### 5.3. Phycochromes and Phycobiliprotein Biosynthesis

The biosynthesis of the phycobiliprotein-chromophores follows fundamentally similar pathways as does the formation of the more thoroughly investigated mammalian bile pigments. δ-Aminolevulinic acid is condensed to a cyclic tetrapyrrole, most probably protoporphyrin, which is subsequently opened oxidatively resulting in formation of a bile pigment with loss of the former C-5 as carbon monoxide[311 313]. The ring-opening process is formally and mechanistically similar[314] to the heme-oxygenation[315], but chemical evidence would indicate that the ring-opening of a Mg-porphyrin *via* 7,8-dihydroporphinatomagnesium may also be possible[161]. It is also not clear, whether the apoprotein is bound to the chromophore after (and not before) the ring-opening, and whether it adds to the 3-ethylidene group of bilindione *(4)* (and not to the vinyl-groups of a precursor). A hint as to the alternatives, not put in brackets here, is the finding[312] that *Cyanidium caldarium* excretes *(4)* as well as addition-product(s) of *(4)* in the dark[54c,316]. Another indirect indication is the facile and reversible addition of nucleophiles to *(4)* and *(6)*[54c,58,59], and very recently *Troxler et al.* (private communication, 1980) have demonstrated the uptake of heme and its conversion into phycocyanin in cyanobacterial protoplasts.

The biliprotein-synthesis in most of the cyanobacteria and at least in some red algae is regulated by light. It is of special interest that the antenna-pigments adjust to the quality of light available ("chromatic adaption"). In prevailing red light, especially the blue phycocyanins are formed, whereas in green light, *e.g.* under a canopy of leaves or in deeper waters, the red phycoerythrins are preferentially formed[1,11,287,317]. This effect has been investigated mainly with *Tolypothrix tenuis*[12,318] and with *Freymella displosiphon*[319,320]. Based on the action spectra, the chromatic adaption has been explained in terms of photochromic receptor pigment-systems, functionally termed adaptochromes, or chromes. There are also photomorphogenetic effects in cyanobacteria and red algae which are connected with such receptors. Little is known about receptor pigments (see Section 4.4), and virtually nothing about their mechanism of action.

## 6. Concluding Remarks

For a long time phycobiliproteins have been the victims of "mammalian chauvism" and, owing to their covalent protein bonds, have been much less investigated than the other tetrapyrrolic pigments of photosynthesis, the chlorophylls. In contrast to the latter, however, the phycobiliproteins have the great advantage of not being integrated into membranes. This property and the discovery of the central function of another biliprotein, phytochrome, during the development of plants, recently led to a boom in biliprotein research. No other photosynthetic light-harvesting system is as well investigated as the phycobilisomes, and—with the exception of rhodopsin—no light-sensory pigment is as well characterized as phytochrome.

In this report an attempt has been made to correlate the properties of the isolated chromophores with the function of the pigments *in vivo*. The correlation is somewhat subjective and partly fragmentary, but has been borne out for the most part in recent years. Some of the obvious gaps in the case of phytochrome are the structure of $P_{fr}$ and the closely related questions regarding the nature of the primary signal and the role of specific interactions between phytochrome and certain receptor membranes and organelles. An advancement in this area should certainly stimulate further investigation of the related phycochromes as well.

Many of the numerous questions arising from the functionally and morphologically impressive model of the phycobilisomes will only be possible to answer by the collaboration of biophysicists and biochemists. Details on the chromophore-protein interactions and the interrelationships between the biliprotein-chromophores and the chlorophylls within the photosynthetic membrane are essential for an understanding of the energy transfer on a molecular basis. The increasing complexity of the phycobilisome structures raises questions as to their elements of organization, their biogenesis and its regulation. The answers will not only be of interest to the inquisitive, but may perhaps also contribute to our understanding of light-harvesting and information-transduction in general.

# COMMUNICATIONS

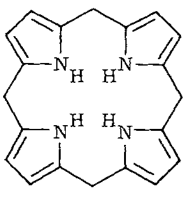
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

## Interconversion of the Chromophore Systems of Porphyrinogen and 2,3,7,8,12,13-Hexahydroporphyrin[**]

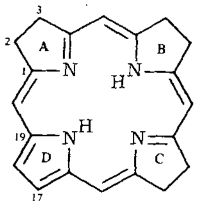
By *Jon Eigill Johansen, Virginia Piermattie, Christof Angst, Eva Diener, Christoph Kratky*, and *Albert Eschenmoser*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

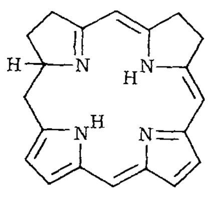
Our search for a non-oxidative isomerization of porphyrinogens *(1)* to the corphinoid ligand system of 2,3,7,8,12,13-hexahydroporphyrin *(2)* led at first to structures of type *(3)*[1a,b], in which the cyclic conjugation of the chromophore double bonds is broken, and not to *(2)*. We have now been able to convert a porphyrinogen into the ligand system *(2)*, about which only little is known so far[2]. This structure is of interest in relation to the problem of the origin of the corrin structure[1b], and also to problems of contemporary corrin biosynthesis[3].



*(1)*



*(2)*



*(3)*

The tautomerization of octaethylporphyrinogen *(4)* under strict exclusion of oxygen produces nickel complexes of type *(3)*, as described earlier[1a]. This transformation proceeds faster, and gives different products, if instead of triethylamine the guanidine derivative 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD)[4] is used as the base for tautomerization. Under the conditions shown in Scheme 1, *(4)* forms a mixture of nickel complexes, which apart from didehydrogenated components[5a] consists mainly of the diastereomers *(5)* (see Table 1). After anaerobic column chromatography on silica gel, a total of seven diastereomers were discernible by high pressure liquid chromatography (HPLC); three of them could be separated preparatively by HPLC on silica gel and crystallized, the major components being *tctcc-(5)*[5b] and *tctct-(5)*[5c]. The assignment of configuration for *tctct-(5)* followed from the molecular symmetry evident in the $^1$H-NMR spectrum, as well as from the spontaneous didehydrogenation in air to the known[1a,d] Ni$^{2+}$-isobacteriochlorinate *tct-(6)* and a Ni$^{2+}$-bacteriochlorinate (*ttc-(7)*, Table 1). The corresponding didehydrogenation of *tctcc-(5)* gives as the main product *tct-(6)*[6] and a new (therefore not the *ttt*-configuration[1a,d]) isobacteriochlorinate, which must have the configuration *tcc-(6)*. X-ray structure analysis of *tctcc-(5)* (Fig. 1) again reveals the specific macro-ring deformation, which was previously

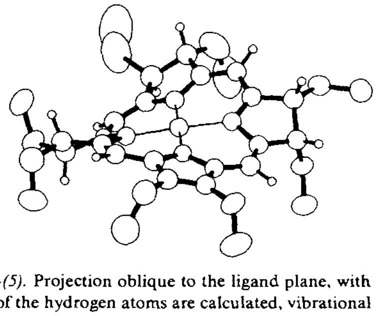


Fig. 1. Crystal structure of *tctcc-(5)*. Projection oblique to the ligand plane, with ring D in foreground. Positions of the hydrogen atoms are calculated, vibrational ellipsoids of non-hydrogen atoms with 50% probability (cf. also Table 1 and [1c], Fig. 3).

Fig. 3).—MS: $m/e=540$ (100%, $M^+$).—$^1$H-NMR (360 MHz, $C_6D_6$): $\delta=0.77/0.79/0.84/0.85$ (4t/each $J=7$ Hz/4$CH_3$), 1.02 (t/$J=7$ Hz/2$CH_3$), 1.3—2.0 (many peaks/6$CH_2$) superimposed at 1.54 (t/$J=7$ Hz/2$CH_3$), 2.85—3.05 (many peaks/2$CH_2$), 3.1—3.4 (many peaks/6CH), 5.99/6.05 (2s/2H/H-5, 10), 6.47/6.86 (2s, br/2NH), 7.11 (s/2H/H-15, 20).—$^{13}$C-NMR ($C_6D_6$): $\delta=11.86/11.99$ (2q/2$CH_3$), 12.43/13.05/18.11 (3q/each 2$CH_3$), 18.77 (t/2$CH_2$), 21.34 (t/4$CH_2$), 20.25/20.45 (2t/2$CH_2$), 47.23/47.51/52.30 (3d/each 2CH), 91.00/91.60 (2d/2CH), 99.70 (d/C-15, 20), 125.29/127.87 (2s/each 2C), 151.17/151.56 (2s/2C), 153.45/171.90 (2s/each 2C).—Structure determination at −170 °C: monoclinic $P2_1/c$, $a=15.086(4)$, $b=12.419(3)$, $c=20.086(5)$ Å, $\beta=123.23(3)°$, $Z=4$, $\rho_x=1.146$ g cm$^{-3}$. 5252 refined reflections, $R=0.076$ (362 parameters) (cf. Fig. 2)

[a] Presumably also containing absorption from isobacteriochlorinate components.

found in isomers of type *(3)* in the hexaporphyrinate series[1a], as well as in the series of $Ni^{2+}$-isobacteriochlorinates[1d]. This deformation[7] indicates that the inner coordination cavity of the hexa- and tetrahydroporphinoid ligand systems tends to be too large for ions such as $Ni^{2+}$.

Using the reaction conditions which resulted in high yields of nickel complexes of type *(3)*[1a] from *(4)* (triethylamine/acetic acid (4:1), 140 °C in xylene), the mixture of diastereomers *(5)* did not isomerize to complexes of type *(3)*.

The porphyrinogen → corphin tautomerization is not only—as was originally assumed—mediated by transition metal ions such as $Ni^{2+}$, but by $Mg^{2+}$ as well. This allows the preparation of metal-free hexahydroporphyrins of type *(2)* [≙ *(9)*]. In this way, the transformation of *(4)* in the presence of bromomagnesium-TBD/TBD under rigorous exclusion of oxygen, leads to the almost exclusive formation (UV/VIS!) of compounds of type *(8)* which, however, could not be isolated because of their extremely high air-sensitivity (didehydrogenation within seconds to $Mg^{II}$-isobacterio- and bacteriochlorinates; UV/VIS). By decomplexation of the reaction mixture with acetic acid and separation by anaerobic column chromatography, a fraction consisting of 16 diastereomers of type *(9)* (identified by HPLC and UV/VIS) was obtained in over 70% yield. These metal-free ligands are distinctly less air-sensitive than the corresponding magnesium complexes and three individual diastereomers could be isolated by preparative HPLC and crystallization. X-ray structure analysis (Fig. 2) revealed the major component[8] to be the diastereomer *ccctc-(9)* (which probably is not the thermodynamically most stable isomer). Figure 3 shows the UV/VIS spectrum (see Table 1).

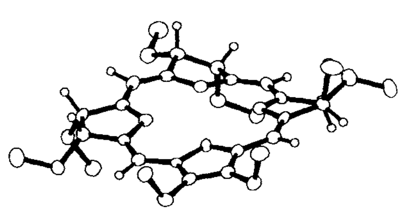

Fig. 2. Crystal structure of *ccctc-(9)* (cf. legend to Fig. 1).

Equilibration of *ccctc-(9)* [or the total fraction of diastereomers *(9)*] by tautomerization in pyridine-acetic acid under rigorous exclusion of oxygen (cf. Scheme 1) led to re-formation of octaethylporphyrinogen *(4)* as the major product (74% in crystalline form[9]); by-products were small amounts of isobacterio- and bacteriochlorins (UV/VIS) formed by dehydrogenation. Pure *(4)* remained unaffected by similar reaction conditions. This result answers one of the questions which had led to the present investigation[1a,b]: *Hexahydroporphinoid ligand systems prefer corrin-like arrangements of the chromophore double bonds in the presence of suitable metal ions; in their metal-free and neutral forms, however, these systems exist preferentially as tetrapyrrolic porphyrinogens*[10]. What should be remembered in this context is the coronoid array of peripheral methyl groups in the structure of natural corrinoids.

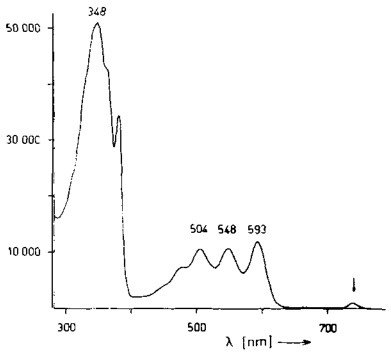

Fig. 3. UV/VIS spectrum of *ccctc-(9)* in benzene, $c = 17.3 \times 10^{-6}$ mol/dm$^3$ (cf. also Table 1). The absorption in the vicinity of 720 nm (arrow) originates from a trace (< 1%) of didehydrogenation product (bacteriochlorin).

Within the family of hydroporphyrins, the corphinoid[11a] ligand system *(2)* [$\triangleq$ *(9)*] occupies a central position; it presents itself as a direct preparative link between porphyrinogens and the chromophore systems of sirohydrochlorin and bacteriochlorophyll[11b]. We suspect that reaction conditions exist that will allow a transition of *(2)* to the corrin structure.

# Cyclization of a Seco-porphyrinogen to Nickel(II) C,D-Tetradehydrocorrinates[**]

By *Christof Angst, Christoph Kratky,* and *Albert Eschenmoser*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

Among the hexahydroporphinoid ligand systems isomeric to porphyrinogen, structures of type *(1)* are formed with conspicuous ease[1a-c]. The interrupted conjugation of the double bond system at position C-1 is reminiscent of the corrin ligand. In the corrin series, the exact analogue of *(1)* is the ligand system of C,D-tetradehydrocorrin *(2)*. We report here experiments in which we obtained members of this previously unknown class of compounds[2].

We had attempted to apply the process of tautomerization/complexation found for (octaethyl-)porphyrino-

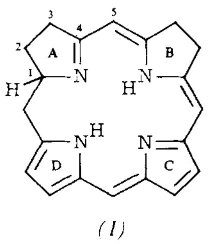
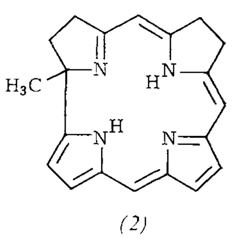
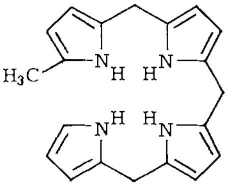
gens[1a,b,d] to the non-macrocyclic analogues, *i. e.* to seco-porphyrinogens of type *(3)* (1-methylbilinogens), aiming at a direct formation of complexes of the isomeric D-didehydrocorrin *(4)*. At the same time, this implied the question as to whether the oxidative dihydrobilin → octadehydrocorrinate (A→D) ring closure of *A. W. Johnson et al.*[3] would also operate non-oxidatively at the lower oxidation level of hexahydrobilins or didehydrocorrins[4].



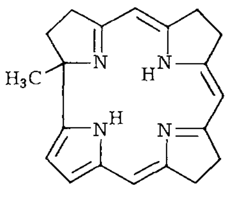
*(1)*



*(2)*

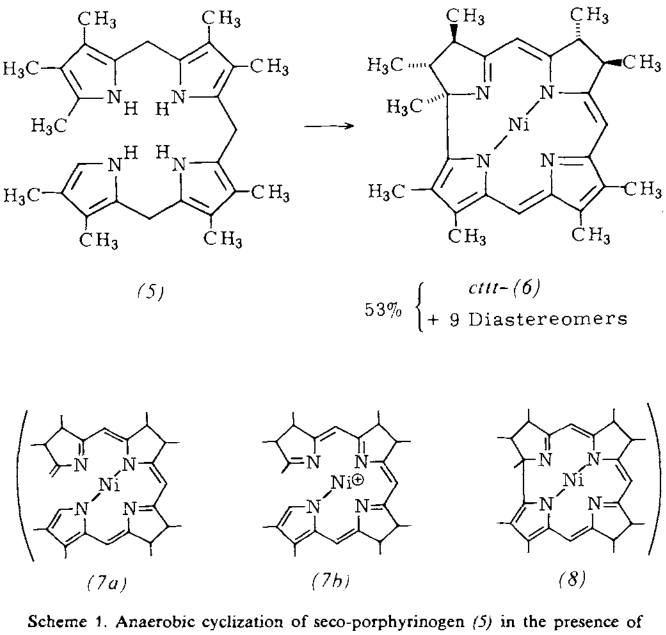


*(3)*



*(4)*

Under the conditions shown in Scheme 1, a mixture of diastereomeric *rac*-$Ni^{2+}$-1,2,3,7,8,12,13,17,18-nonamethyl-12,13,18,19-tetradehydro-[24H]corrinates *(6)* was formed in respectable yield from nonamethylbilinogen *(5)*[5] by tautomerization, complexation, cyclization and, unexpectedly, didehydrogenation. After anaerobic column chromatography of the deep-green reaction product on silica gel (hexane/ether (5:1)), ten from a total of 16 detected components of the product fraction were identified as diastereomeric C,D-tetradehydrocorrinates *(6)* by HPLC and UV/VIS spectroscopy (yield 53%). Eight of the ten diastereomers were isolated by chromatography[6a] and crystallized. X-ray analysis (cf. Fig. 1) showed the major component[6b] to possess, probably the thermodynamically most stable, *cttt (6)*-configuration (see Table 1). The constitution of five of the six by-product fractions from HPLC (cf. above) was assigned by UV/VIS spectroscopy as follows: $Ni^{II}$-A,B,C,D-octadehydrocorrinate *(9)* (*ca.* 2% of the product mixture, one fraction)[7], B,C,D-hexahydro type *(10)* (*ca.* 4%, two fractions)[8a], and A,C,D-hexadehydrocorrinate *(11)* (*ca.* 12%, two fractions)[8b]. The D-didehydro chromophore *(8)*[1e] was not found.



Scheme 1. Anaerobic cyclization of seco-porphyrinogen *(5)* in the presence of 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD) and $Ni^{2+}$ ions. 12 TBD/AcOH (4:1), 0.9 $Ni(OAc)_2 \cdot 4H_2O$, *p*-xylene, 140 °C, 16 h, starting material molarity $1.2 \times 10^{-2}$ M.

Table 1. Spectroscopic and crystallographic data ($\lambda_{max}$ [nm]; $\delta$-value, $\delta$ (TMS) = 0; experimental details cf. [1c]).

*cttt-(6)*: dark green needles from ether/hexane. UV/VIS ($CH_2Cl_2$): $\lambda_{max} = 379$ (lg $\varepsilon = 4.40$), 423 (3.94), 489 (3.79), 600 sh (3.93), 641 (4.19).—MS: $m/e = 484$ (89%, $M^+$, $^{58}Ni$) + isotope peaks, 469 (100%, $M^+ - CH_3$, $^{58}Ni$), *etc.*—$^1$H-NMR ($CDCl_3$): $\delta = 1.19$ (s/$CH_3$), 1.21/1.38/1.40/1.47 (4d/each $J = 7$ Hz/4$CH_3$), 2.03 (m/CH), 2.17/2.23/2.26/2.31 (4s/4$CH_3$), 2.69 (m/CH), 2.85 (m/2CH), 5.28 (s/H-5), 5.99 (s/H-10), 7.04 (s/H-15).—$^{13}$C-NMR ($CDCl_3$): $\delta = 9.7$ (2q/2$CH_3$), 10.1/11.3/13.6/15.8/17.3/17.5/21.8 (7q/7$CH_3$), 45.3/46.8/49.3/50.1 (4d/4CH), 79.5 (s/C-1), 86.7 (d/C-5), 91.2 (d/C-10), 113.2 (d/C-15), 114.8/126.0/127.3/127.5/136.5/137.0/152.1/155.6/158.1/167.7/168.7 (11s/11C).—Structure determinations: triclinic $P\bar{1}$, $a = 8.248(3)$, $b = -1.855(3)$, $c = 14.700(8)$ Å, $\alpha = 90.42(1)$, $\beta = 103.77(1)$, $\gamma = 93.60(1)^\circ$, $Z = 2$, $\rho_x = 1.159$ g cm$^{-3}$. 4906 refined reflections, $R = 0.097$ (298 parameters) (cf. Fig. 1 and 2)

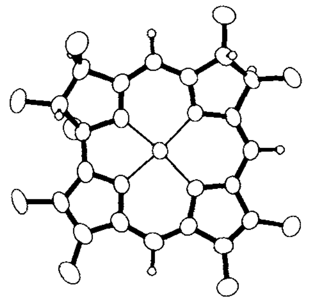


Fig. 1. Crystal structure of *cttt-(6)*. Projection in the plane of atoms N-21, N-22 and N-23; vibrational ellipsoids of the non-hydrogen atoms with 50% probability; hydrogen atom positions calculated (cf. also Table 1).

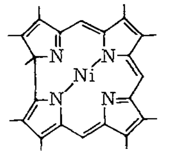
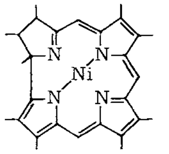
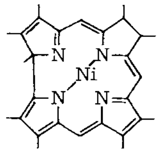
The use of 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD)[9a] as buffer-partner was imperative for the transformation *(5)*→*(6)*; other organic bases led to mixtures which either did not contain *(6)* at all (triethylamine, cf. [1a,b]) or only in small and non-reproducible amounts (diazabicycloundecene). Substitution of TBD by *N*-methyl-TBD[9b] led—*ceteris paribus*—to lower yields of *(6)*. Therefore, it is not the high basicity alone which makes TBD so suitable for the reaction. A series of over thirty experiments[1c] revealed that the nature of the product depends to an unusually high degree on details of the reaction conditions[10].



*(9)*



*(10)*



*(11)*

In all probability, there is more than one reaction path from *(5)* to *(6)*. A probable route is a tautomerization/complexation of the seco-porphyrinogen *(5)* to seco-corphinoid intermediates of type *(7)*; from there, various pathways to D-didehydrocorrinates *(8)* exist (cf. [1d] as well as the facile (A→D) cyclization of an nickel-seco-corrinate analogous to

*(7a)*[1e]). The conjugative stabilization accompanying the formation of the pyrromethenic partial structure in the C,D-ring region presumably promotes an eventual didehydrogenation step[11] to *(6)*. The same partial structure also occurs in the hexahydroporphinoid ligand system *(1)*.

The transformation *(5)*→*(6)* is another experimental variant of *Johnson*'s synthesis of corrinoid structures from tetrapyrrolic precursors[3].

Fig. 2. Crystal structure of *cttt-(6)*. Projection at right angles to the plane of atoms N-21, N-22 and N-23; ring-D in foreground (ligand system without substituents).

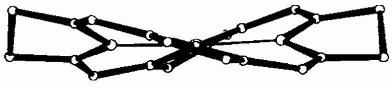


Fig. 3. Crystal structure of *tctcc*-Ni$^{II}$-2,3,7,8,12,13,17,18-octaethyl-2,3,7,8,12,13-hexahydroporphyrinate (cf. *tctcc-(5)* in [1d]). Same projection and scale as Fig. 2.

Figure 2 shows the molecule *cttt-(6)* (cf. Fig. 1) in side view. The four coordination centres and the metal ion have essentially a coplanar arrangement; the characteristic macroring deformation observed in the nickel(II) complexes of the tetrahydro-[12] and hexahydroporphyrin[1a,d] series is absent (for comparison see Fig. 3). This observation corroborates our contention that the coordination cavity of corrinoid ligand systems is closer to the spatial coordination optimum of transition metal ions such as $Ni^{2+}$ than the cavity of hydroporphinoid ligand systems.

## Electrophilic Reactions of Aryl- and Heteroaryl(trimethyl)silanes with a Remarkable Nucleophilic Catalysis[**]

By *Franz Effenberger* and *Wolfgang Spiegler*[*]

*Dedicated to Professor Gerhard Pfleiderer on the occasion of his 60th birthday*

*Eaborn et al.*[1] have shown that the facile displacement of the trimethylsilyl moiety by electrophiles is a decisive factor in the protodesilylation of aryl(trimethyl)silanes; on the basis of kinetic data, they have proposed a mechanism for this reaction analogous to that for electrophilic aromatic substitution. The very high *ipso* rate factors for a series of electrophilic desilylation processes[2] gave rise to the expectation that aryl(trimethyl)silanes[3] might also be successfully employed for synthetic purposes; this was confirmed by a regiospecific route to polysubstituted benzenes *via* aryl(trimethyl)silanes reported recently[4].

Our own investigations of the acylation of aryl(trimethyl)silanes[5], and reports in the literature on reactions of aldehydes with trimethylsilyl(pentahalo)benzenes[6a] and heteroaryl(trimethyl)silanes[6b], have led us to the assumption that a mechanism different from that formulated by *Eaborn*[1] might be operative in these cases. For this pathway, the breaking of the aryl-silyl bond—with at least partial evolution of aryl anions—would be rate-limiting; substituents which stabilize negative charges should therefore enhance the reactivity of aryl(trimethyl)silanes towards electrophiles.

But 2-nitrophenyl(trimethyl)silane *(1a)* does not react with benzaldehyde even upon heating to 100 °C in dimethylformamide (DMF) for three days. If, however, potassium *tert*-butanolate is added in catalytic amounts, electrophilic

substitution proceeds smoothly even at $-60\,^\circ C$, *(2a)* being formed within 1 h in 92% yield. Analogously, from a series of substituted phenyl(trimethyl)silanes *(1a)*—*(1h)* and benzaldehyde, the benzhydrylsilyl ethers *(2a)*—*(2h)* or, after hydrolysis, the benzhydrols *(3)* were obtained (Table 1).

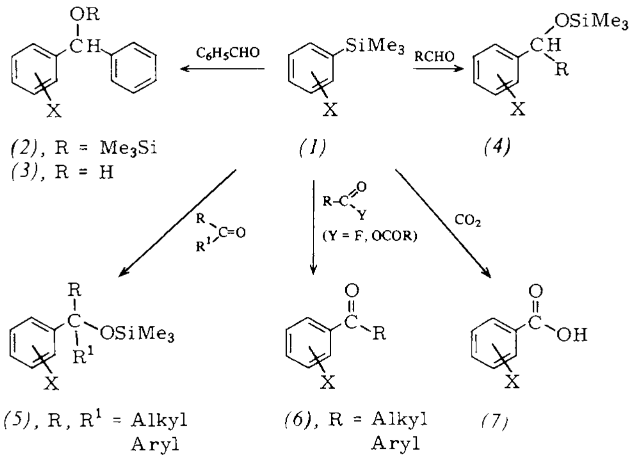

Table 1. Benzhydrylsilyl ethers *(2)* and benzhydrols *(3)* from mono-substituted phenyl(trimethyl)silanes *(1)* and benzaldehyde.

[a] Determined by gas chromatography. [b] Isolated. [c] Hexamethylphosphoric triamide. [d] Determined by gas chromatography after acid hydrolysis.

For the nitro- and chlorophenyl(trimethyl)silanes, the relative reactivity correlates well with the $\sigma^I$-substituent constants[7a], but diverges significantly from the order of stabilization of the phenyl anions which would be essential intermediates for a nucleophilic desilylation[7b]. The $\sigma^I$ correlation holds also for the other arylsilyl substrates *(1c)*—*(1f)* in Table 1; the remarkable increase in reactivity from *(1d)* to *(1f)* is similarly mirrored in the substituent constants. This clearly indicates that the electrophile participates significantly in the rate-limiting step of the reactions reported here—in contrast to normal nucleophilic desilylation[7b]. Since "hard" bases have proven especially effective nucleophilic catalysts ($KOC(CH_3)_3$, KF, CsF, tetraalkylammonium fluoride, KOAc)[8], one must assume that interaction of the catalyst with the silicon is the decisive factor for the reaction.

We have also extended the reaction to substituted benzaldehydes and aliphatic aldehydes, to ketones, acyl fluorides and carboxylic acid anhydrides as well as to carbon dioxide; the respective products, secondary *(4)* and tertiary benzyl alcohols *(5)*, aryl ketones *(6)* and substituted benzoic acids *(7)*, are obtained, at least in part, in excellent yields.

The scope of the procedure can be further widened by variation of the arylsilyl substrate. From 2-trimethylsilylbenzthiazole and benzaldehyde, for instance, the substitution product is formed in 78% yield, only after heating to $160\,^\circ C$ for 40 h[6b]; in the presence of 1 mol-% of potassium *tert*-butanolate, 91% of the product is obtained after 15 min at $-60\,^\circ C$. Since the heteroaryl(trimethyl)silanes are readily accessible *via* cycloaddition reactions[3], this method allows the introduction of substituents into heterocyclic substrates with high regioselectivity[9].

The reaction will be of special preparative advantage in those cases where organometallic derivatives cannot be employed because of the presence of reactive functional groups in the molecule (nitro or carbonyl compounds) or because of secondary reactions, *e.g.* formation of dehydroarenes from halogen compounds or isomerization to more stable anions.

### *Experimental:*

*(2a)*: Potassium *tert*-butanolate (83 mg, 0.74 mmol) is added to a constantly stirred mixture of *(1a)*[10] (3.91 g, 20 mmol) and benzaldehyde (2.12 g, 20 mmol) in 25 $cm^3$ DMF at room temperature. The solutions warms slightly and turns red; as indicated by GLC, the reaction is complete after 1 h. The catalyst is filtered off, and the DMF distilled off. Upon fractional distillation, the oily residue yields 4.81 g (80%) *(2a)*, b.p. 136—138 °C/0.1 torr. $^1H$-NMR ($CDCl_3$): $\delta = 0.07$ (s, 9H), 6.57 (s, H), 7.20—8.00 (m, 9H).

## Nucleophilic Catalysis of Reactions of Tricarbonyl(trimethylsilylarene)chromium Complexes with Electrophiles[**]

By *Franz Effenberger* and *Klaus Schöllkopf*[*]

*Dedicated to Professor Gerhard Pfleiderer on the occasion of his 60th birthday*

Electrophilic substitution of aryl(trimethyl)silanes having electron-donating substituents, *e.g.* alkyl- or aminophenyl(trimethyl)silanes, is not amenable to nucleophilic catalysis[1]; Friedel-Crafts catalysts, on the other hand, specially facilitate reactions of such substrates with electrophiles. In this case, however, the directing influence of the substituents often overrides the tendency of the trimethylsilyl moiety to *ipso*-substitution, and regular H-substitution results[2]. Recent investigations have established the electron-withdrawing effect

---

[*] Prof. Dr. F. Effenberger, Dipl.-Chem. K. Schöllkopf
Institut für Organische Chemie der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Herr *Steegmüller* for experimental assistance; NATO research grant No. 1602 is gratefully acknowledged. Electrophilic aromatic substitution, Part 21.—Part 20: [1].

of the tricarbonylchromium group in arene(tricarbonyl)-chromium complexes and given many examples for their preparative application[3a]. Both the facile metalation of these complexes[3b] and the dissociation constants of the respective complexed benzoic acids[3c] clearly demonstrate the high inductive aryl anion stabilization potential of the $Cr(CO)_3$ group; thus, an electrophilic desilylation under nucleophilic catalysis[1] seems feasible.

Tricarbonylchromium complexes of mono- and bis(trimethylsilyl)benzenes [*(2)*, R = H, $Me_3Si$], which are readily obtainable in good yield from the respective benzene derivatives *(1)* by heating with hexacarbonylchromium[4], do not react with aldehydes and ketones even at elevated temperatures. Upon addition of nucleophilic catalysts such as potassium *tert*-butanolate or cesium fluoride, however, formation of *(3)* takes place, even at room temperature (Table 1).

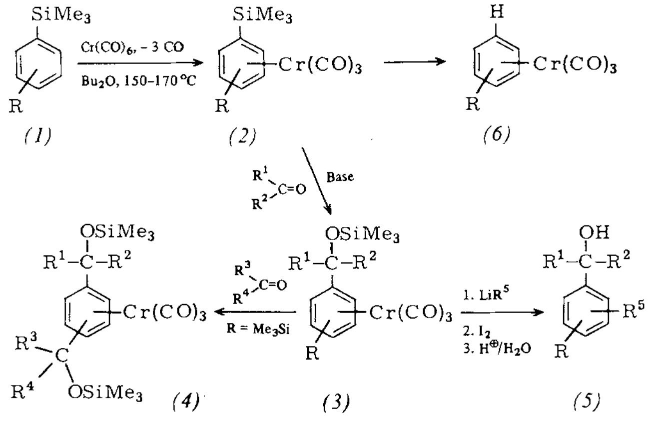

Table 1. Reaction of tricarbonyl(trimethylsilylarene)chromium complexes *(2)* with electrophiles in dimethylformamide (DMF) with addition of 10 mol-% CsF.

| Educt | R | R¹ | R² | *t* [h] | Product | Yield [%] |

| *(2a)* | *o*-$CH_3$ | H | $C_6H_5$ | 0.25 | *(3a)* | 81 |
| *(2b)* | *m*-$CH_3$ | H | $C_6H_5$ | 0.5 | *(3b)* | 83 |
| *(2c)* | *p*-$CH_3$ | H | $C_6H_5$ | 2.5 | *(3c)* | 81 |
| *(2d)* | *o*-Cl | H | $C_6H_5$ | 0.75 | *(3d)* | 83 |
| *(2e)* | *m*-Cl | H | $C_6H_5$ | 0.3 | *(3e)* | 70 |
| *(2f)* | *p*-Cl | H | $C_6H_5$ | 2.0 | *(3f)* | 57 |
| *(2g)* | H | H | $C_6H_5$ | 5.0 | *(3g)* | 88 |
| *(2g)* | H | H | $CH_3$ | 5.0 | *(3h)* | 30 [a] |
| *(2g)* | H | H | $C_3H_7$ | 6.0 | *(3i)* | 43 [b] |
| *(2g)* | H | $CH_3$ | $CH_3$ | 10.0 | *(3k)* | 50 [c] |
| *(2g)* | H | $CH_3$ | $C_6H_5$ | 7.0 | *(3l)* | 29 [d] |
| *(2g)* | H | $C_6H_5$ | $C_6H_5$ | 40.0 | *(3m)* | 75 |

[a] 32% *(6g)*. [b] 38% *(6g)*. [c] 28% *(6g)*. [d] 55% *(6g)*.

The position of R relative to the trimethylsilyl group does not greatly influence the rate of formation of *(3)* from *(2)*, as is to be expected from the dissociation constants of the substituted (tricarbonylchromium)benzoic acid complexes[3c]. This is in sharp contrast, though, to the nucleophilic catalysis of electrophilic substitutions where the rate is enhanced by electron-withdrawing groups in the substrate[1]. With enolizable carbonyl reagents, partial protodesilylation of the complexes *(2)* to *(6)* is unavoidable.

Products which still bear a trimethylsilyl group are susceptible to secondary reactions with another carbonyl compound to give *(4)*. Since the activating $Cr(CO)_3$ group is retained in formation of *(3)* or *(4)*, the respective benzene derivatives *(5)* can be obtained by subsequent addition of nucleophiles[3a] and oxidative work-up.

The introduction of many different types of substituents into easily accessible benzene derivatives *(1)*, can therefore be carried out using this method. Compared to the transformations *(2)*→*(3)* or *(3)*→*(4)* *via* organometallic derivatives, the procedure offers a much wider range of substituent variation[1]; at the same time, undesirable metalation processes, *e.g.* benzyl anion formation from alkylbenzenes[3b], are avoided.

*Experimental:*

*(3g)*: Benzaldehyde (2.13 g, 20 mmol) is added dropwise to a stirred solution of *(2g)*[5] (5.73 g, 20 mmol) and CsF (0.30 g, 2 mmol) in 15 $cm^3$ DMF under an inert gas atmosphere. The completion of the reaction is monitored by GC. The reaction mixture is diluted with 150 $cm^3$ ether, the precipitated salt filtered off, and the ethereal phase washed with water and dried over sodium sulfate. The solvent is stripped off, and the residue recrystallized from *n*-hexane. Yield: 6.9 g (88%) *(3g)*, m.p. 90—91 °C.

## Synthesis and ESR Characterization of the Triplet Species $\mu$-($\eta^6$:$\eta^6$-Biphenyl)-bis[($\eta^6$-benzene)vanadium][**]

By *Christoph Elschenbroich* and *Jürgen Heck*[*]

While the individual electrons of the two radical centers in a real diradical are neither paired nor unpaired, but independent of each other so that no distinction can be made between a mono- and a diradical by ESR spectroscopy, a triplet radical can be recognized by its zero field splitting and by a characteristic hyperfine structure[1]. The transition between diradical and triplet radical is, however, gradual and it is therefore important to study the extent of spin-spin interaction as a function of the nature, separation, and charge of the radical centers. Such investigations have been carried out on coupled pairs of triphenylmethyl radicals *(1)*[2] and, *inter alia*, on bisnitroxides *(2)*[3].

Our interest focusses on paramagnetic intersandwich compounds of the type *(3)*[4]. We report here on the preparation and properties of the neutral complex $\mu$-($\eta^6$:$\eta^6$-biphenyl)-bis[($\eta^6$-benzene)vanadium(0)] *(5)*$^{\cdot\cdot}$, which is isoelectronic with the dication {$\mu$-($\eta^6$:$\eta^6$-biphenyl)-bis[($\eta^6$-benbenzene)chromium(I)]}$^{+\,+}$ *(4)*$^{+\,+}$[4b]. We obtained the novel in-

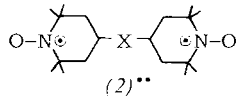
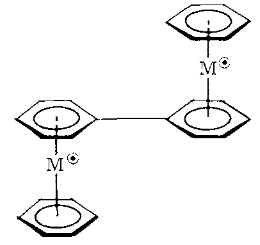
*(1)*$^{\bullet\bullet}$

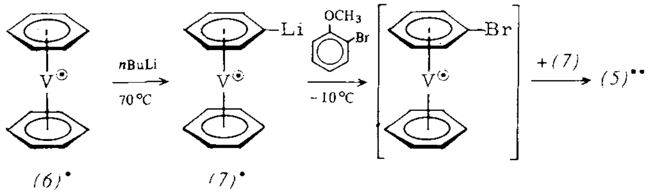


*(2)*$^{\bullet\bullet}$



*(3)*
*(4)*$^{\dot{+}\dot{+}}$, M = Cr$^{\oplus}$
*(5)*$^{\bullet\bullet}$, M = V

tersandwich compounds *(5)*$^{\bullet\bullet}$ by metalation of *(6)*$^{\bullet}$ with *n*-butyllithium (during which not only *(7)*$^{\bullet}$ but also higher metalated products are formed), and subsequent coupling as shiny black, very air-sensitive crystals. They are moderately soluble in toluene and almost insoluble in ethers. *(5)*$^{\bullet\bullet}$ can be sublimed ($>180\,^{\circ}C/<10^{-4}$ torr; decomp. 285 °C). The composition of *(5)*$^{\bullet\bullet}$ follows from elemental analysis and from the high-resolution mass spectrum[5].



*(6)*$^{\bullet}$ *(7)*$^{\bullet}$

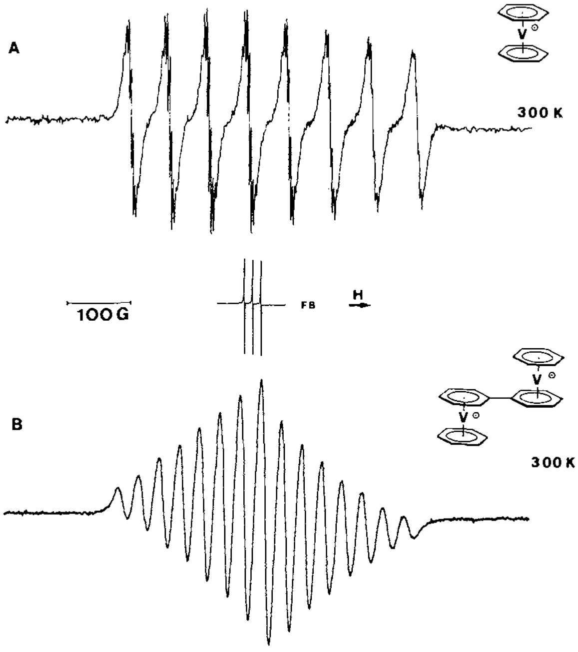


Fig. 1. X-band ESR spectra of the mononuclear complex *(6)*$^{\bullet}$ (A) and of the dinuclear complex *(5)*$^{\bullet\bullet}$ (B) at room temperature in liquid solution (toluene). FS = Fremy's salt, $g = 2.0056$.

In contrast to *(4)*$^{\dot{+}\dot{+}}$, *(5)*$^{\bullet\bullet}$ displays a well resolved ESR spectrum ($g = 1.988 \pm 0.001$) in liquid solution at room temperature; this is shown in Figure 1 together with the spectrum of the mononuclear complex *(6)*$^{\bullet}$. The hyperfine structure of *(6)*$^{\bullet}$ is governed by the vanadium coupling $a(1\ ^{51}V) = 63.8 \pm 0.3$ G[6] ($I\ ^{51}V = 7/2$) and by the small proton coupling $a(12\ ^{1}H) = 4.0 \pm 0.10$ G[6], whereas the spectrum of the dinuclear complex *(5)*$^{\bullet\bullet}$ comprises 15 lines in the intensity ratio 1:2:3:4:5:6:7:8:7.... with a separation of $31.0 \pm 0.5$ G between adjacent lines. Hence, the unpaired electrons in *(5)*$^{\bullet\bullet}$ couple with *both* $^{51}V$ nuclei, and there is rapid exchange, *i.e.* the exchange interaction $J$ is substantially greater than the hyperfine interaction $a(^{51}V)$.

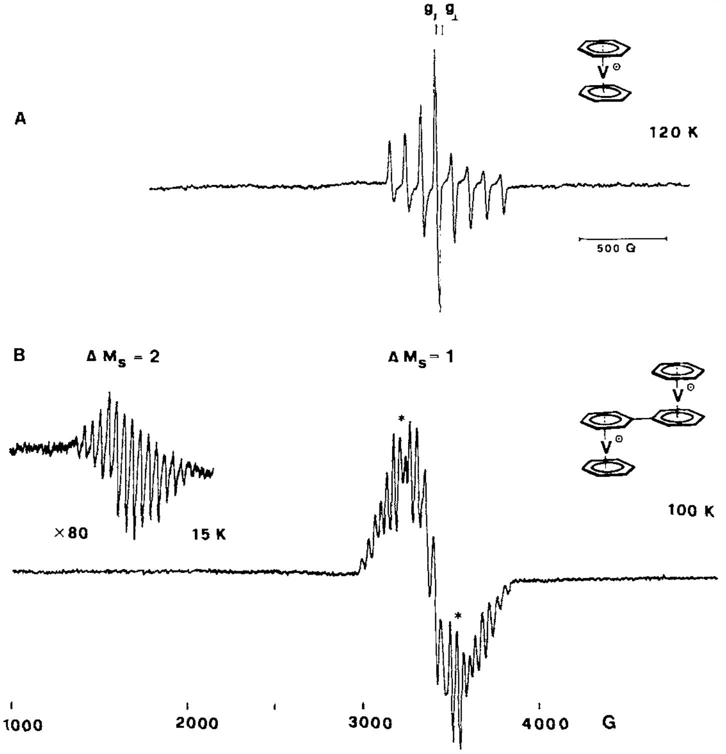

Fig. 2. X-band ESR spectra of the complexes *(6)*$^{\bullet}$ (A) and *(5)*$^{\bullet\bullet}$ (B) in rigid glassy solution (toluene). The $g \approx 4$ region was recorded with 80-fold amplification. Lines marked with asterisks: centers of the two outer $^{51}V$ multiplets at separation $2D$.

The triplet character of the intersandwich complex *(5)*$^{\bullet\bullet}$ is supported by its ESR spectrum in rigid glassy solution (Fig. 2), which shows a structure with more lines than the mononuclear complex *(6)*$^{\bullet}$ in the region $g \approx 2$ and a half-field signal ($\Delta M_S = 2$) in the region $g \approx 4$. From the overall extension of the spectrum of *(5)*$^{\bullet\bullet}$, and taking into account the $^{51}V$-hyperfine structure, a zero field parameter $D = 0.0154$ cm$^{-1}$ can be deduced[8] which in the point-dipole approximation corresponds to an average distance of the two unpaired electrons[7] of $R_{ESR} \approx 540$ pm and thus a *trans*-conformation of the two sandwich complex moieties ($R_{model} = 550$ pm). Other than in the case of the isoelectronic complex *(4)*$^{\dot{+}\dot{+}}$ the half-field signal for *(5)*$^{\bullet\bullet}$ is only observable at high amplification. This is consistent with the fact that the zero field splitting for *(5)*$^{\bullet\bullet}$[9] is smaller than for *(4)*$^{\dot{+}\dot{+}}$ ($D = 0.0257$ cm$^{-1}$[4b]). Further, the total intensity of the $\Delta M_S = 2$ signal in the case of *(5)*$^{\bullet\bullet}$ is spread over 15 hyperfine components [$a(2\ ^{51}V) = 43 \pm 1$ G], whereas only one component appears for *(4)*$^{\dot{+}\dot{+}}$ owing to the preponderance of the non-magnetic nuclei $^{52}Cr$ (90.5%).

The smaller magnitude of the parameter $D$ for *(5)*$^{\bullet\bullet}$, as compared to *(4)*$^{\dot{+}\dot{+}}$, might contribute to the fact that *(5)*$^{\bullet\bullet}$, in contrast to *(4)*$^{\dot{+}\dot{+}}$, affords a well resolved ESR spectrum in liquid solution. Furthermore, an averaging of the zero field splitting in the case of *(5)*$^{\bullet\bullet}$ is promoted by a shorter correlation time of the molecular motion, since *(5)*$^{\bullet\bullet}$ should have a smaller effective radius than the solvated dication *(4)*$^{\dot{+}\dot{+}}$.

*Procedure*

All operations were carried out under $N_2$ with anhydrous and $O_2$-free solvents.—*(6)* (5.4 g, 26 mmol) is metalated in methylcyclohexane (300 $cm^3$) for 4 h at +90 °C with *n*-butyllithium (27.3 ml, 54.6 mmol) (5% excess) and tetramethylethylenediamine (8.4 ml, 54.6 mmol). The mixture is then cooled to −10 °C, treated dropwise with a solution of *o*-bromoanisole (1.6 ml, 13 mmol) in methylcyclohexane (50 $cm^3$), stirred for 7 h at −10 °C and 9 h at room temperature, hydrolyzed with 1 $cm^3$ $H_2O$, stirred for a further 1 h, and evaporated to dryness. The blackish brown residue is taken up in 200 $cm^3$ toluene and filtered through a column (silanated silica gel, length 25 cm, ∅ 2 cm). After extraction with toluene (3 × 200 $cm^3$) the combined filtrates are evaporated to dryness. On sublimation ($<10^{-4}$ torr) of the black-brown residue, two fractions were obtained: 1) $T = 120$ °C: 4.14 g *(6)*; 2) $180 \leq T \leq 210$ °C: 150 mg $(5)^{\cdot-}$, yield 13%, based on the amount of $(6)^{\cdot}$ used. $(5)^{\cdot-}$ crystallizes from toluene/petroleum ether (40:60) as black, shiny platelets.

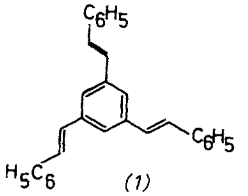
[8] In our analysis we have assumed, that the distance between the two lines marked with asterisks in Fig. 2 corresponds to the parameter $2D$. These positions were obtained by counting eight lines from the low field and high field ends of the spectrum towards its center. The analysis of the spectrum was affirmed by computer simulation.

[9] The intensity of the formally forbidden ($\Delta M_S = 2$)-transitions increases with decreasing distance between the unpaired electrons, *i.e.* with increasing dipole-dipole interaction *D*.

## A Simple Route to a New Type of Cyclophane[**]

By *Juri Juriew, Tatjana Skorochodowa, Jewgeni Merkuschew, Werner Winter,* and *Herbert Meier*[*]

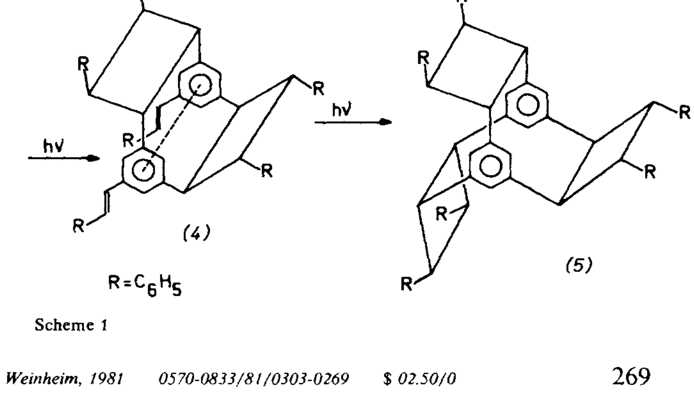
Although the first synthesis of a cyclophane was reported as long ago as 1899[1], this class of compounds has only relatively recently become the subject of extensive studies[2]. The stepwise synthesis of several bridges between two aromatic ring systems is preparatively laborious. Consequently, methods in which several bridges are formed in a single step have proven particularly attractive[2]. In order to check whether this is possible by photochemical cycloaddition we have investigated the *(E,E,E)*-1,3,5-tristyrylbenzene *(1)*, which is directly accessible by various methods[3,4] from 1,3,5-trimethylbenzene.



*(1)*

The UV spectrum of *(1)* [$\lambda_{max} = 317$ nm ($\log\varepsilon = 4.96$)] shows the characteristic $\pi,\pi^*$-transition of the *trans*-stilbene; there is only slight interaction between the three styryl groups[5]. On irradiation at this wavelength one can observe, as well as the fluorescence ($\lambda_{max} = 410$ nm), a photoreaction. The olefinic double bonds disappear and the $^1H$-NMR spectrum shows groups of signals of saturated aliphatic protons. It may be assumed that dimers with one, two, and finally three four-membered rings are formed by $[2\pi + 2\pi]$-cycloaddition with preservation of the *E*-configurations (Scheme 1). The formation of head-to-head and head-to-tail adducts is possible. The fact that *e.g.* two head-substituents can be arranged *cis* or *trans* to each other results in a number of stereochemical possibilities. However, the successive formation of four-membered rings considerably limits these possibilities.

The reaction, involving the loose singlet excimers *(2)*, which guarantee an efficient stereochemically controlled photoreaction, proceeds *via (3)* and *(4)* to *(5)*. After irradiation of *(1)* in *ca.* 0.02 M benzene solution a compound of m.p. 280 °C can be isolated as main product in 25—30% yield. The FD-MS spectrum indicates formation of a dimer, and according to the UV spectrum the product does not contain any stilbene groups. The $^1H$-NMR spectrum reveals the presence of three four-membered rings with 12 protons (sharp signal at $\delta = 4.45$). Only two signals ($\delta = 56.2$ and 43.0)



Scheme 1

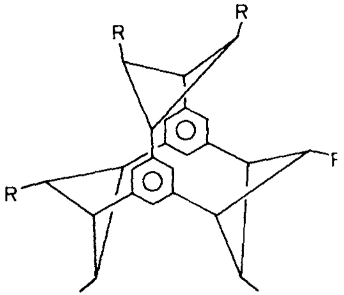
appear in the upfield part of the $^{13}$C-NMR spectrum ($CD_2Cl_2$); under "off-resonance conditions" each of them splits into a doublet. Both *(5)* ($C_{3h}$ symmetry) and *(5a)* ($D_{3h}$ symmetry) are compatable with these results; *(5a)* would be formed on threefold stereospecific head-to-tail cycloaddition. Both *(5)* and *(5a)* represent a new type of cyclophane in which both benzene nuclei are bridged by rings.



*(5a)*

All attempts to reach a decision between *(5)* and *(5a)* by spectroscopic methods failed. An X-ray structure analysis[6] (Fig. 1) finally confirmed the "lateral" coupling of the cyclobutane rings, *i.e.* the structure *(5)*.

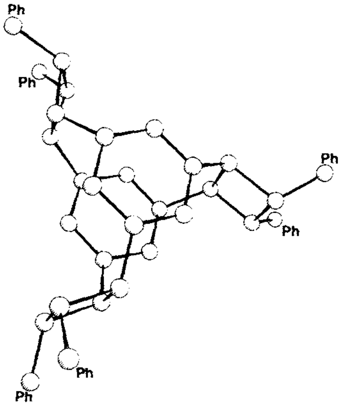


Fig. 1. Structure of the cyclophane *(5)* in the crystal. For sake of clarity only the central cyclophane moiety is shown.

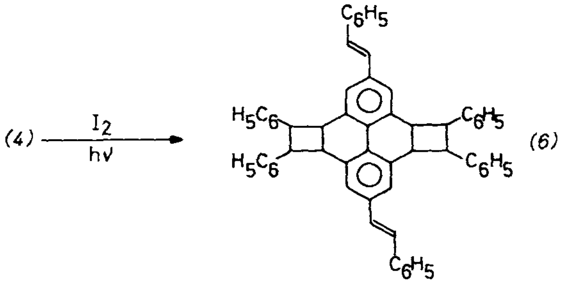
The packing in the crystal in this "paddle wheel" molecule leads to a symmetry distortion[7]. "Levorotatory" and "dextrorotatory" systems are formed which effect a complicated disorder within the unit cell[8]. The average distance between the two central benzene rings in *(5)* is 2.85 ± 0.06 Å. Due to strain the cyclobutane bonds in the three bridges of the [$2_3$]cyclophane are stretched to 1.64(2) Å. The [$3_3$]cyclophane *(5a)* ought to exhibit considerably less strain. We ascribe the regio- and stereoselective formation of *(5)* to the above-mentioned excimer formation.

The photoreaction is blocked by iodine at *(4)*, since dehydration at this stage gives the pyrene derivative *(6)* (m.p. 312—314 °C).



Thus the dimerization of di- and tristyrylbenzenes[9] in preference to dehydrogenating cyclization to polycyclic arenes takes place in $10^{-2}$ M solutions, even in the presence of iodine. Only the third ring-closure, which leads to the strained cyclophane *(5)*, is hindered by iodine.

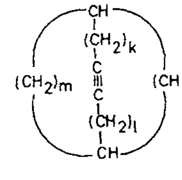
# Isolation of a Highly Strained Bicyclic Alkyne[**]

By *Herbert Meier, Cornelius Schulz-Popitz*,
and *Hermann Petersen*[*]

With the exception of norbornyne ($k=l=0$, $m=1$, $n=2$)[1], strained bicyclic hydrocarbons *(1)* containing a triple bond, have so far not been reported in the literature. Higher bicycloalkynes[2] without geometrical ring strain[3], however, have already been described on a number of occasions. For the preparation of highly strained and reactive cycloalkynes, the fragmentation of 1,2,3-selenadiazolene has proved especially useful[4].



*(1)* (k, l, m, n = 0,1,2...)

We report here on the synthesis of bicyclo[6.1.0]non-2-yne *(1a)* ($k=0$, $l=4$, $m=0$, $n=1$) and bicyclo[5.1.0]oct-2-yne *(1b)* ($k=0$, $l=3$, $m=0$, $n=1$). Starting from cyclooctene *(2)* the bicyclic ketone *(6)*[7] was obtained *via (3)*[5], *(4)*[6], and *(5)*. The ketone *(6)* can be transformed *via* the semicarbazone *(7)* into the selenadiazole *(8)*, thermolysis of which affords *(1a)*, which is distilled directly into a cold trap. The *in-situ* prepa-

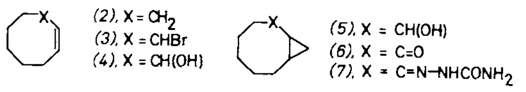
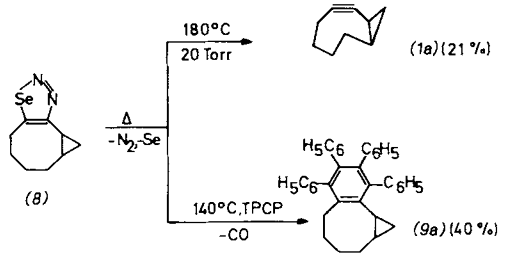
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

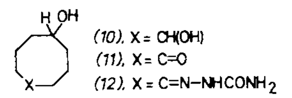
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

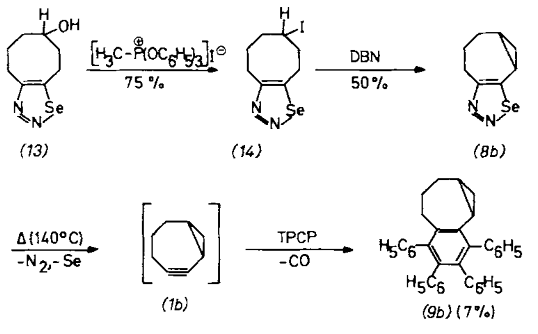
ration in boiling xylene proceeds in high yields, as shown by the trapping reaction with tetraphenylcyclopentadienone (TPCP), which yields *(9a)* (m.p. 231 °C) in 40% yield.





Pure *(1a)* is moderately stable at room temperature and is characterized by its Raman spectrum ($CDCl_3$, $\nu_{C\equiv C}=2204$, 2220 $cm^{-1}$) and especially by its $^{13}C$-NMR spectrum. The acetylenic C-atoms C-2 and C-3 absorb at $\delta=98.4$ and 89.0 respectively, the three-membered ring C-atoms at 5.8 (C-1), 14.1 (C-9) and 22.5 (C-8). C-4 gives a signal at $\delta=19.9$. The signals for C-5, C-6 and C-7 ($\delta=36.5$, 31.6 and 22.7) were not assigned. The ring strain in cycloalkynes leads—most markedly in the case of the acetylenic C-atoms—to a downfield shift of the $^{13}C$-absorptions[4a]; the δ-values found for *(1a)* indicate a high degree of geometrical ring strain.





The next lower homologue *(1b)* is prepared from 1,5-cyclooctadiene *via (10), (11), (12)* and the selenadiazole *(13)*. Conversion into the iodide *(14)* and 1,3-elimination of HI[8], during which regioselective deprotonation takes place with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN), leads to *(8b)*. Thermolysis of *(8b)* affords *(1b)*, which however cannot be isolated. The enormous strain, and thus short lifetime, manifest themselves in the trapping reaction with TPCP, in which *(9b)* (m.p. 217 °C) is formed in only 7% yield. (Cycloheptyne can be trapped in 29% yield by this method, cyclohexyne in 6% yield[9]). *(1a)* is thus the first bicyclic alkyne to be isolated, despite high geometric ring strain.

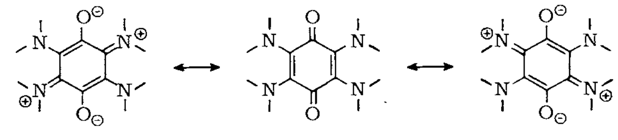
## Polymethinic Ring Compounds and the Polymethinic Carbonyl Group

By *Siegfried Kulpe*[*]

The name "stellaquinones" had been proposed by *Wallenfels* and *Draber*[1] for the deep-colored and stable tetraaminoquinones. In these compounds a bonding system with hexagonal symmetry and capable of resonance was concluded from the mesomerism of the resonance structures *(1a)*—*(1c)*.



*(1a)* *(1b)* *(1c)*

The same authors, however, later tried to explain the physicochemical properties of the di- and triaminobenzoquinones in terms of steric effects in pure quininoid (polyenic) electronic structures. The sole reason for revocation of their original hypothesis was the unexpectedly small red shift of such important C=O stretching vibrations shown by all investigated diaminoquinones ($\nu_{C=O}$ between 1653 and 1667 $cm^{-1}$) and tetraaminoquinones ($\nu_{C=O}$ between 1620 and 1639 $cm^{-1}$) in comparison to the carbonyl frequency in *p*-benzoquinone ($\nu_{C=O}=1681$ $cm^{-1}$). The C=O bond length in *p*-benzoquinone (1.222(24) Å[3]) is ideal for an unsaturated six-membered carbon ring. This particular type of symmetric oxygen substitution at the benzene ring permits conversion from the aromatic into the quininoid (polyenic) electronic structure. According to the mesomeric resonance structures *(1a)*—*(1c)* the carbonyl bond must be drastically extended. This should lead to a large red shift of its valence vibration frequencies, which however is not observed.

Essential for this hypothesis for the di- and tetraaminoquinones, which is contrary to experimental findings, was that only mesomerism between the three structural units *(2a)*—*(2c)*[10] was assumed[1,2].

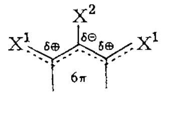
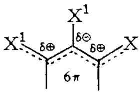
In spite of this, *Wallenfels* and *Draber* were working in the right direction: The tetra- and diaminoquinones are a *non-quininoid* class of compounds. Their properties are understandable if one regards them as *coupled polymethinic* electron systems[4].

If tetraaminoquinones are likewise assumed to have a *polymethinic* electron structure, then apart from their general properties the behavior of their carbonyl group is also plausible. Tetraaminoquinones can be regarded a cross-conjugated, non-alternating polymethines. Formally, the two non-alternating substituted trimethine structural units *(3a)* and *(3b)* (Scheme 1) can be regarded as polymethine units which superpose and ramify in the six-membered ring.

*(3a)*





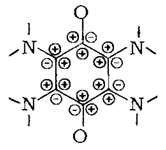
*(3b)*

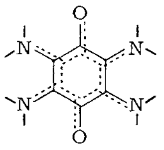
Scheme 1. $X^1 = N$, $X^2 = O$, small π-electron density at the methine C-atom corresponding to a partial positive charge δ⊕, and large π-electron density to a partial negative charge δ⊖.

The superposition of the structural units *(3a)* and *(3b)* follows the rules given in Ref. [5]. According to the sign of the π-electron charge they give *(4a)*, according to the π-electron distribution *(4b)*; that is, there is a high π-electron delocalization over all non-hydrogen atoms of polymethine character, which is responsible for the deep color of the compounds.

Without accurate X-ray structure analyses it is difficult to quote more accurate charge distributions in such cross-decoupled, non-alternating systems such as *(4)*. It is suggested that the C-atoms in the six-membered ring are partially positively charged, the O-atoms partially negatively charged. It is more difficult to comment on the N-atoms[6].

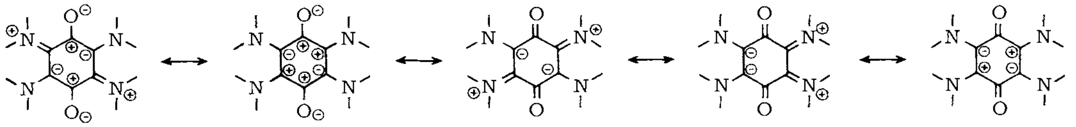
*(4a)*





*(4b)*

For an explanation of these polymethinic electron structures in terms of resonance theory many polar resonance structures must be taken into consideration, *e.g.* *(5a)*—*(5e)*. As a rule, polymethinic atoms are not electrically neutral (π-charge alternation!).



*(5a)* *(5b)* *(5c)* *(5d)* *(5e)*

Carbonyl groups in polymethinic structures with mesomeric participation of resonance structures such as *(5a)* and *(5b)* contain the well known dipolar structural unit *(6)*.

*(6)*

*(7)*

The heteropolarity of this bond effects elongation as would have to exist according to *(2b)* and *(2c)*. We refer to such a C=O group as a *polymethinic carbonyl group*[7] and exemplify it by *(7)*.

This description expresses the MO concept far better and corresponds to a mesomerism of the four resonance structures *(2a)*—*(2c)* and *(6)* in the VB concept.

The *polymethinic carbonyl group* has the following properties: 1) its C=O bond is not drastically stretched; 2) its valence vibration frequency is not drastically shifted bathochromically; 3) nevertheless, it acts as an electron acceptor, is resonance stabilizing, and acts as member of a polymethinic base chromophore, which results in longwave and especially intense light-absorption, as is observed for the di- and tetraaminoquinones.

In the case of highly symmetric polymethines (*e.g.* open-chain, unsubstituted "oxonoles"[*]) there can be a significant widening of the carbonyl bond, which however is not so drastic as would be the case on neglection of its ionic character according to *(6)* and *(7)*.

An inappropriate assignment of the C=O valence vibration always arises when the *polymethinic* character of the carbonyl group is overlooked[8]. Such *polymethinic carbonyl groups* can occur on any desirable ring as well as open-chain systems. In our opinion they can be distinguished from *polyenic carbonyl groups,* which are essentially described by *(2a)*, are not ionic, not conjugated with stretched electron systems, and consequently have other properties. Both kinds of carbonyl groups are not easy to differentiate in their bond lengths and IR spectra. However, they are distinguishable by an accurate X-ray structure analysis.

Drastic expansion of bonding due to homopolarity of polymethinic bond partners has already been described[4b,9]. This phenomenon is closely connected with the problem discussed above.

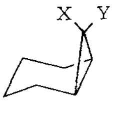
# Stereochemistry of Substitution at the Cyclopropane Ring in 7-Aminonorcaranes[**]

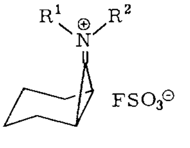
By *Elmar Vilsmaier, Wolfgang Tröger,*
and *Michael Gewehr*[*]

In nucleophilic substitutions on norcarane derivatives *(1)*, X, Y$\neq$NR$_2$, a substituent in the *endo* position is a better leaving group than in the *exo* position[1a–d]. In these cases a *cis*-cycloheptenyl-[1a,c] or a partially opened cyclopropyl-cation[1b,e] is formed as an intermediate. The different rates of formation of these cations cause the discrimination between *endo* and *exo* leaving groups.

On the other hand, 7-aminobicyclo[4.1.0]heptane derivatives, are capable of forming a cation with an unopened three-membered ring, *e.g.* *(2a)*[2]. We report here on differences in the reactivity of *exo* and *endo* leaving groups in norcarane derivatives from which a cation of type *(2)* can be formed.



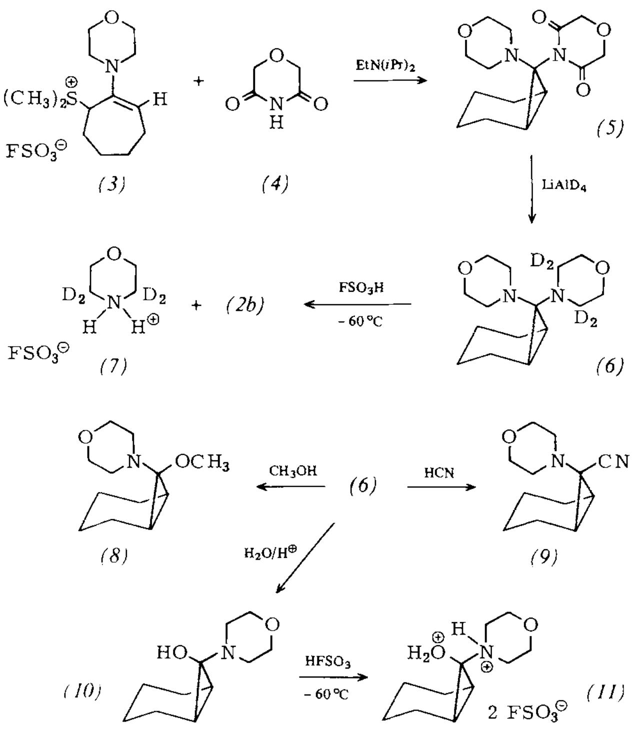
*(1)*



*(2a)*, R$^1$ = R$^2$ = CH$_3$
*(2b)*, R$^1$, R$^2$ = –(CH$_2$)$_2$–O–(CH$_2$)$_2$–

Since the morpholino moiety in the bicyclo[4.1.0]heptane system is a simple "stereoindicator"[3], we have chosen the dimorpholine derivative *(6)* for our investigations; deuterium-labeling enables the differentiation between *exo*- and *endo*-substituents.

For the synthesis of *(6)*, the enaminosulfonium salt *(3)* was reacted with the imide *(4)* to give the bicycle *(5)*, whose $^1$H-NMR spectrum shows the typical ABXY system of an *endo*-morpholino moiety. Reduction of *(5)* with LiAlD$_4$ affords the tetradeuterioaminal *(6)* in 48% yield.



An ABXY system for the eight morpholino H-atoms[3] shows that the *endo*-morpholino moiety is undeuterated. The *exo*-morpholino H-atoms appear as a singlet at $\delta = 3.62$ (C$_6$D$_6$); *exo*-NC*H*$_2$-signals (cf. [3]) are absent. The $^{13}$C-NMR spectrum in each case shows exclusively a triplet ($\delta = 50.2$), $^1J_{^1H^{13}C} = 133$ Hz) for the NCH$_2$-atoms and a quintet $\delta = 51.0$, $^1J_{^2H\text{-}^{13}C} = 20$ Hz) for the NCD$_2$ atoms.

Reaction of *(6)* with HFSO$_3$ at $-60\,^\circ$C leads to formation of an iminium ion, which can be characterized by $^{13}$C-NMR spectroscopy. A singlet shifted to very low field ($\delta = 204$) and a doublet in the alkane region ($\delta = 21$) (Table 1) establish the cyclopropylideneammonium structure of *(2b)*[4]. In the case of a partially[1e] or completely[5] opened cyclopropyl cation, the doublet would appear at $\delta = 150$—180. The cyclopropylidenemorpholinium salt *(2b)* differs markedly from the morpholinium salt *(7)*, which gives only a broad signal for NCD$_2$. No triplet splitting and hence no NCH$_2$ group can be detected for *(7)* ($^1J_{^1H\text{-}^{13}C} = 140$ Hz) within a limit of error of 5%. It thus follows that the *exo*-substituent is cleaved with a selectivity of $\geq 95\%$ on generation of *(2b)* from *(6)*.

The different substitutability of the two morpholino moieties in *(6)* can also be established by solvolysis. Methanolysis[3] of *(6)* leads to formation of *(8)*, acid hydrolysis[3] to *(10)*, and reaction with HCN (cf. [6]) to *(9)*, in each case with the given configurations. The $^2$H$_4$-morpholine content can be determined by mass spectroscopy; in the case of *(8)* it is 0.1%, in *(10)* 1%, and in *(9)* 8%[7]. The same result is also obtained, though less accurately, from the $^1$H-NMR spectra by integration of the OC*H*$_2$- and NC*H*$_2$-signals. This means that at least 99% of the *exo*-morpholino moiety is replaced on reaction of *(6)* with methanol or H$_2$O/H$^\oplus$.

The lower selectivity in the reaction of *(6)* with HCN is ascribed to an isomerization of the educt (longer reaction time). In CH$_3$CN the acidity of *(7)* is sufficient for this. Owing to concomitant formation of *(7)*, attempts to prepare *(6)* from *(3)* and 3,3,5,5-tetradeuteriomorpholine[8] (analogously to [3]) led only to a mixture of isomers of *(6)*. According to the mass spectrum (molecular peaks for $^2$H$_0$, $^2$H$_4$ and $^2$H$_8$-aminal), the *exo-endo* isomerization also takes place intermolecularly.

Table 1. $^{13}$C-NMR signals of the cations studied; $\delta$ values, HFSO$_3$ solvent, $-60\,^\circ$C, TMS as external standard.

| | Morpholine | | Bicyclic system | | |
|---|---|---|---|---|---|
| | OCH$_2$ (t) | NCH$_2$ (t) | C-7 (s) | C-1,6 (d) ($^1J_{^1H\text{-}^{13}C}$ [Hz]) | C-2,5, C-3,4 (t) |
| *(2b)* | 71.1 | 54.3 | 204 | 21.0 (173) | 19.8, 18.4 |
| *(11)* | 67.8 | 47.4 | 81.1 | 19.3 (163) | 19.6, 16.0 |
| *(13)* | 66.6 | 48.8 | 81.5 | 21.9, 19.2 [a], | 15.8 |
| *(7)* | 69.3 | 43.8 [b] | | | |

[a] Unequivocal assignment not possible owing to the low intensity. [b] Unresolved signal (halfwidth 50 Hz).

In HFSO$_3$ at $-60\,^\circ$C the hemiaminal *(10)* is not converted into the expected compound *(2b)*, but into an ammonium salt *(11)*, which is presumably diprotonated. In contrast to *(2b)*, which undergoes ring-opening even at $-20\,^\circ$C in HFSO$_3$, *(11)* is stable for several hours, even at $+20\,^\circ$C. However, addition of *(12)*[3], an isomer of *(10)*, to HFSO$_3$ at $-60\,^\circ$C leads to formation of the iminium salt *(2b)*. Low-intensity $^{13}$C-NMR signals [corresponding to *ca.* 20% of *(2b)*] are observed (Table 1) which, on comparison with the spectrum of *(11)*, can be assigned to the salt *(13)*[10].

Both the reactions of *(6)*, *(10)* and *(12)* in HFSO$_3$, as well as the solvolyses, clearly show that the *exo*-substituent is the preferred leaving group in a 7-aminonorcarane derivative. Other than in the case of the solvolyses, equilibrium reactions can be ignored with HFSO$_3$ as solvent. Hence, the find-

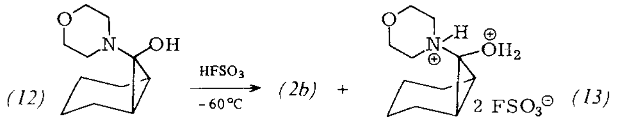
Paul-Ehrlich-Strasse, D-6750 Kaiserslautern (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.



ings in HFSO$_3$ can be interpreted in terms of a sterically determined, more rapid protonation of the *exo*-substituents. Since a non-protonated amino group is necessary for the generation of *(2b)* only *exo*-protonated *(6)* and *(12)*, but not *(10)*, lead to *(2b)*.

### *Procedure*

*(5)*: A mixture of *(3)* (6.8 g), *(4)* (2.3 g) and ethyldiisopropylamine (2.6 g) (20 mmol of each) in anhydrous acetonitrile (20 cm$^3$) is heated to 70 °C for 1.5 h and worked up as described in Ref. [10]. Yield of *(5)*: 5.2 g (88%); m.p. 160 °C.

*(6)*: A mixture of *(5)* (4.4 g, 15 mmol) and LiAlD$_4$ (1.3 g, 30 mmol) in anhydrous tetrahydrofuran (THF) is heated under reflux for 70 h. After removal of THF by distillation, the residue is extracted five times with 50 cm$^3$ of pentane. Removal of the pentane affords 1.9 g (48%) of pure *(6)*; m.p. 75 °C.

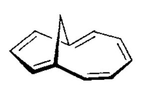
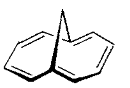
## A Convenient Synthesis of “Homoazulene” (1,5-Methano[10]annulene)[**]

By *Lawrence T. Scott, William R. Brunsvold, Mark A. Kirms* and *Ihsan Erden*[*]

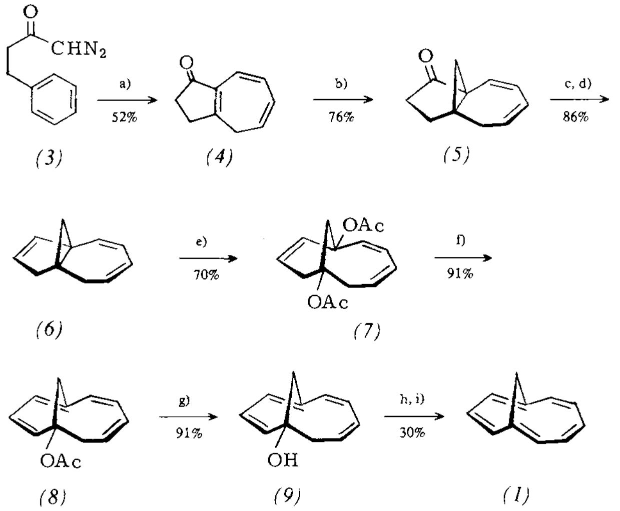
The beautiful annulene chemistry developed by *Vogel et al.* during the past two decades has contributed enormously to current thinking about cyclic conjugation in nonbenzenoid systems[1]. Throughout this work, formidable challenges in organic synthesis have time and again been masterfully met in a fashion rarely rivaled outside natural product chemistry. Exciting new advances continue to be made as the family of bridged annulenes and related ions grows ever larger. In this regard, the elegant synthesis of 1,5-methano[10]annulene *(1)* by *Masamune* and *Brooks* in 1977 must be recognized as a major step forward[2]. A long-missing member of the bridged annulene family, this pivotal compound bears an isomeric relationship to the parent hydrocarbon of *Vogel et al. (2)*. Herein we wish to describe an alternative synthesis of *(1)* which is suitable for the preparation of material in sufficient quantity to permit extensive physical and chemical studies[3] (Scheme 1).

*(1)*





*(2)*



Scheme 1. Synthesis of *(1)*. a) CuCl, C$_6$H$_5$Br, 80 °C; b) CH$_2$SO(CH$_3$)$_2$, CH$_3$SOCH$_3$, 75 °C; c) TsNHNH$_2$, CH$_3$OH, 25 °C; d) CH$_3$Li, Et$_2$O, 25 °C; e) Pb(OAc)$_4$, C$_6$H$_6$/HOAc (4:1), 0 °C; f) catalytic amounts of Pd(OAc)$_2$, (C$_6$H$_5$)$_3$P, Na$_2$CO$_3$, *n*C$_7$H$_{16}$, 85 °C; g) CH$_3$Li, Et$_2$O, 0 °C; h) CH$_3$SO$_2$Cl, Et$_3$N, CH$_2$Cl$_2$, 0 °C; i) *t*BuOK, *t*BuOH/25 °C.

Diazoketone *(3)*, available in essentially quantitative yield from hydrocinnamic acid, has previously been shown to give the excellently functionalized bicyclic trienone *(4)* by way of an intramolecular carbene addition[4]. Nucleophilic cyclopropanation[5] then completes the carbon framework of *(1)*. Conversion of dienone *(5)* to triene *(6)*, *via* the tosylhydrazone[6], followed by cleavage of the undesired propellane bond with lead tetraacetate[7] in benzene produces the nicely crystalline diacetate *(7)* (m.p. 90—92 °C) in good yield. Subsequent elimination of one acetoxy group, *via* a transient $\pi$-allyl palladium intermediate[8], affords the tetraene acetate *(8)* which can be carried through to 1,5-methano[10]annulene *(1)* by classical methods. Spectral properties of the orange hydrocarbon thus obtained agree with those in the literature[2].

Although still in the early stages, our program to thoroughly explore the physical and chemical properties of *(1)* and its derivatives has already yielded evidence that the $10\pi$-system of this novel hydrocarbon bears a conspicuous resemblance to that of azulene[9]. Accordingly, we advocate the trivial name “homoazulene” for *(1)* rather than the alternative “1,5-methano[10]annulene” which suggests only perimeter conjugation.

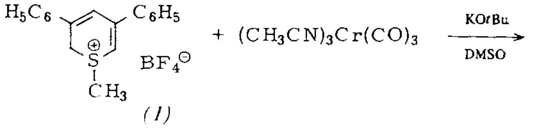
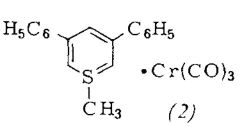
## Tricarbonyl(1-methyl-3,5-diphenyl-$\lambda^4$-thiabenzene)chromium(0)[**]

By *Lothar Weber*[*]

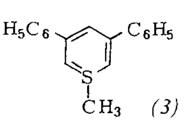
$\lambda^4$-Thiabenzenes merit interest in being examples of six-membered ring systems with 6π-electrons. Some derivatives, *e.g.* *(3)*, have been previously generated and studied in solution by means of $^1$H-NMR spectroscopy, but their inherent thermolability precluded their isolation and complete characterization[1]. We have, for the first time, been successful in stabilizing a thiabenzene derivative as a ligand in a transition metal complex: the title compound *(2)*.



*(1)*



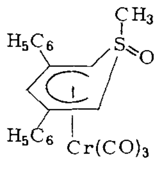
*(2)*



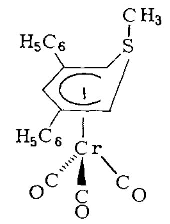
*(3)*

Complex *(2)* is formed by reaction of the thiinium salt *(1)*[1] with potassium *tert*-butanolate and triacetonitrile(tricarbonyl)chromium(0) in dimethylsulfoxide (DMSO) as a dark red crystalline, air stable solid; yield 75%[2].

In addition to the molecular ion, the mass spectrum of *(2)* contains readily characterizable fragments formed by ligand cleavage. IR- and NMR-spectroscopic data of *(2)* are consistent with coordination of the heterocycle to the metal (Table 1). The highest wave number CO band of *(2)* is shifted to lower wave numbers by 18 $cm^{-1}$, relative to the analogous thiabenzene oxide complex *(4)*[3].



*(4)*



*(2)*

Table 1. Selected data of complex *(2)* and its analogous 1-ethyl-complex.

*(2)*, MS: $m/e$=400 ($M^+$), 372 $(M-CO)^+$, 344 $(M-2CO)^+$, 316 $(M-3CO)^+$, 300 $(M-3CO, -CH_3, -H)^+$, 269 $(C_5H_3(C_6H_5)_2Cr)^+$, 217 $(C_5H_3(C_6H_5)_2)^+$; IR ($CH_2Cl_2$): 1952 vs, 1888 s, 1851 s $cm^{-1}$ (ν(CO); $^1$H-NMR ([$D_6$]acetone, TMS): δ=2.21 (s, $CH_3$), 3.39 (d, 2-, 6-H, $J$=1.5 Hz), 6.74 (t, 4-H, $J$=1.5 Hz), 7.33—7.89 (m, $C_6H_5$); $^{13}$C-NMR ([$D_6$]acetone, δ(CO)=206.0): δ=27.88 (C-2, -6), 41.48 ($CH_3$), 90.54 (C-4), 106.28 (C-3, -5), 128.89, 129.32, 129.59 and 141.64 ($C_6H_5$), 237.60 (CO).

Analogue: IR ($CH_2Cl_2$): 1951 vs, 1886 s, 1850 s $cm^{-1}$ (ν(CO)); $^1$H-NMR ([$D_6$]acetone, TMS): δ=1.06 (t, $CH_3$, $J$=8 Hz), 2.49 (q, $CH_2$, $J$=8 Hz), 3.39 (d, 2-, 6-H, $J$=1 Hz), 6.72 (t, 4-H, $J$=1 Hz), 7.36—7.78 (m, $C_6H_5$)

The enhanced donor capacity of the ligand *(3)* in complex *(2)* relative to the thiabenzene oxide ligand in complex *(4)* is revealed by a downfield shift of the $^{13}$CO resonance of 2.12 ppm.

The X-ray structure analysis of *(2)* clearly establishes that the chromium atom is $\eta^5$-bonded to the five carbon atoms of the heterocycle, which lie in a planar arrangement. The sulfur atom is located 0.76 Å above this plane and does not interact with the metal: $d$(Cr—S)=2.88 Å[4]. Thus the properties of thiabenzene *(3)* as a ligand can best be described in terms of an ylide and not as an arene.

The reaction of *(1)* with tricarbonyl(cycloheptatriene)molybdenum(0) or with tricarbonyl(cycloheptatriene)tungsten(0) affords a molybdenum (42% yield, m.p.=169 °C, decomp.) or tungsten analogue (47% yield, m.p.=132 °C, de-

[**] Transition Metal Sulfur Ylide Complexes, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft. The X-ray structure analysis of *(2)* was carried out by Dr. *R. Boese*. I am grateful to Prof. Dr. *G. Schmid* for helpful discussions. Part 9: *L. Weber*, Chem. Ber. *114*, 1 (1981).

comp.) respectively. The spectroscopic properties of these purple air stable, diamagnetic solids correspond to those of *(2)*, indicating analogous structures.

Preliminary studies have shown, that the novel complexes of type *(2)* undergo alkylation at the methyl group. Thus, the lithiation of *(2)* in tetrahydrofuran at −70 °C with the equivalent amount of *tert*-butyllithium and subsequent addition of excess methyl iodide produces reddish-brown tricarbonyl(1-ethyl-3,5-diphenyl-$\lambda^4$-thiabenzene)chromium(0) in 63% yield (m.p. = 156—158 °C, decomp., see Table 1).

### *Procedure*

30 cm$^3$ of anhydrous DMSO is added to a mixture of $(CH_3CN)_3Cr(CO)_3$ (1.011 g, 3.9 mmol), *(1)* (1.057 g, 3.0 mmol)[1], and potassium *tert*-butanolate (0.337 g, 3.0 mmol) under nitrogen at room temperature. The resulting dark red solution is stirred for 1.5 h at room temperature. After evaporation of the solvent and volatile components *in vacuo*, the residual red oil is taken up in $CH_2Cl_2$ (20 cm$^3$). The solution is filtered through a G4-frit, and 5 cm$^3$ of methylcyclohexane added to the filtrate, which is then slowly evaporated *in vacuo* until a dark red oil separates. The supernatant liquid is decanted, and the oil washed with light petroleum (4 × 10 cm$^3$). The residue is recrystallized twice from $CH_2Cl_2$/light petroleum and after drying *in vacuo* yields dark red *(2)*; yield 0.897 g (75%), m.p. = 152—154 °C.

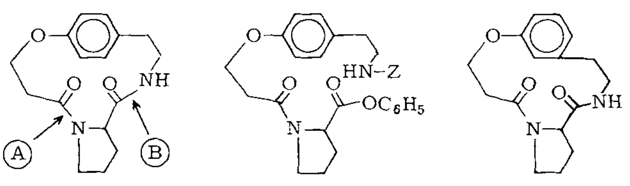
## A Novel Method for Preparation of Ansapeptides; Synthesis of Model Peptide Alkaloids

By *Ulrich Schmidt, Helmut Griesser,*
*Albrecht Lieberknecht,* and *Jörg Talbiersky*[*]

In the course of experiments directed towards the synthesis of peptide alkaloids[1] we have developed a novel ring closure method for formation of these 13- and 14-membered ansa peptides. We investigated the cyclization using the model compound *(1)*, which differs principally from the natural product by substitution of a β-phenoxyamino acid by β-phenoxypropionic acid. *Rapoport et al.*[2] had previously prepared *(1)* by ring closure at Ⓐ using the nitrophenyl ester method[3a]. For synthesis of the natural product[3b], however, it appeared to us that ring closure at the unhindered primary amino group, positionⒷ, would be more favorable.



*(1)* *(2)* *(3)*

$Z = C_6H_5CH_2OCO$

For the ring closure, a dioxane solution of the pentafluorophenyl ester *(2)*[4] was added dropwise to a rapidly stirred suspension of Pd/charcoal in dioxane at 95 °C into which hydrogen was passed. The solution contained 1 mol 4-pyrrolidinopyridine[5] per mol *(2)* as catalyst and 2% alcohol (with respect to the solvent). The benzyloxycarbonyl group is first removed by hydrogenolysis, and ring closure apparently occurs on the ω-amino ester which is still adsorbed on the catalyst[9].

Using conditions of dilution, 50% of *(1)* was formed (determined gas chromatographically). The yields drop dramatically if alcohol is not added or its concentration exceeds 5%, if the reaction temperature is lower than 70 °C and if other, or no bases are used as catalysts (*e.g.* pyridine, *N*-methylimidazole). Under these conditions dimeric cyclopeptide is only obtained in small amounts, whereas it becomes the major product (yield 45%) if the reaction is carried out in ethyl acetate at 75 °C.

The smallest bridge in *para*-ansa compounds, which can be formed by ring closure of a *para*-substituted aromatic compound in satisfactory yields, contains ten members. In the model compound *(1)*, which has a ten-membered bridge, the formation of the bridge is made all the more difficult by the *s-trans*-conformation of both amide groups.

We obtained the 13-membered ring compound *(3)*, which has a 10-membered *meta*-bridge, in 80% yield[6]; *(3)* is therefore considerably more easily formed than *(1)*. Up till now, the shortest *meta*-bridge to a benzene ring, formed by ring closure in satisfactory yield, is nine-membered (resorcinol heptamethylene ether)[7].

The method described here leads to formation of difficultly accessible compounds of this type in up to three or four times better yield than the nitrophenyl ester route[2]. A further advantage is the considerably easier work-up, since the reaction solution does not contain any trifluoroacetic acid (for deblocking the Boc-group) or high boiling solvent (dimethylacetamide).

### *Procedure*

A solution of *(2)*[4] (165 mg) in 20 cm$^3$ dioxane is uniformly injected over 18 h[9] to a rapidly stirred suspension of Pd/activated charcoal (600 mg, 5%) in 350 cm$^3$ pure dioxane at 90 °C (temp. in flask), which contains 7 cm$^3$ ethanol and 40 mg 4-pyrrolidinopyridine. At the same time, hydrogen is passed through the solution. The solution is filtered, concentrated, and the product isolated using medium pressure chromatography on silica gel (dichloromethane/methanol 98:2); (yield 39 mg, 50%) of *(1)*. The chromatographically pure product ($[\alpha]_{546}^{20} = -27.3$ ($c = 1.15$, ethanol)) is dissolved in 20 cm$^3$ water-free ether and after a few hours *ca.* 2 mg racemate[8] precipitates (M.p. = 202—205 °C). Concentrating the mother liquor yields the *S*-enantiomer as an oil ($[\alpha]_{546}^{20} = -28.1$ ($c = 0.56$, ethanol)). The racemate and *S*-en-

[2] *J. Clark Lagarias, R. A. Houghten, H. Rapport*, J. Am. Chem. Soc. *100*, 8202 (1978).

[3] a) After cleavage of the Boc-group, a solution of the trifluoroacetate salt of the ω-amino carboxylic acid nitrophenyl ester in dimethylacetamide is added over 50 h to a solution of pyridine at 90 °C. The yield of *(1)* as an oil amounts to 24% according to [2]; the rotational value is not specified. Upon repetition, we determined the yield to be 12% by gas chromatography. b) See *U. Schmidt, A. Lieberknecht, H. Griesser, J. Häusler*, Angew. Chem. *93*, 272 (1981); Angew. Chem. Int. Ed. Engl. *20*, 281 (1981).

[4] Synthesis of *(2)*: Addition of *p*-hydroxyphenylacetonitrile to methyl acrylate, saponification of the ester group, coupling with L-prolinebenzyl ester (DCCD process), catalytic hydrogenation of the nitrile group, cleavage of the benzyl ester group by hydrogenolysis, acylation of the primary amino group by benzyl chloroformate (Z—Cl) and formation of the pentafluorophenyl ester (DCCD process).

[5] The catalytic effect is absent if the amide is formed *via* the nitrophenyl ester (*D. Hollitzer, W. Steglich*, unpublished results; cited in *G. Höfle, W. Steglich, H. Vorbrücken*, Angew. Chem. *90*, 602 (1978); Angew. Chem. Int. Ed. Engl. *17*, 569 (1978)).

[6] The starting material was prepared analogously to *(2)* [4]. After crystallization, the product was separated by medium pressure chromatography. M.p. = 165—168 °C (partial decomp.); $[\alpha]_{546}^{20} = -5.5$ ($c = 0.42$, ethanol); $[\alpha]_{364}^{20} = -50.7$ ($c = 0.42$, ethanol).

[7] *A. Lüttringhaus*, Justus Liebigs Ann. Chem. *528*, 181 (1936).

[8] *(1)* Crystallized in space group $P2_1/C$; from its centre of symmetry this must be the racemate ($a = 11.28$, $b = 14.70$, $c = 12.60$ Å; $\beta = 134.1°$, $Z = 4$) (determined by Dr. *J. J. Stezowski*).

[9] Note added in proof (1. 3. 81): We assume that ring closure is accomplished on the surface of the catalyst; consequently the reaction time (and with that the dilution) can be diminished drastically: the ring closure giving rise to *(1)* and *(3)* was accomplished in 5 h and 0.5 h respectively.

## Synthesis of Dihydrozizyphin G[**]

By *Ulrich Schmidt, Albrecht Lieberknecht, Helmut Griesser*, and *Johannes Häusler*[*]

*Dedicated to Professor Gerhard Pfleiderer on the occasion of his 60th birthday*

Peptide alkaloids typically have a 13-, 14- or 15-membered ansa structure, the bridge of which contains a dipeptide unit. Approximately 80 alkaloids having this structural element have been isolated over the past 15 years, principally from *Rhamnaceae*, and their structures determined. Many of these alkaloids have antibiotic activity against lower funghi and gram positive bacteria[1]. Until now, no synthetic route to these species was known: we describe here, however, the synthesis of dihydrozizyphin G *(1)* (zizyphin G: *(2)*[2]).

Racemic *trans*-3-(*p*-cyanomethylphenoxy)proline was obtained using a method previously described for the preparation of *trans*-3-phenoxyproline[3]: The ester of 3-bromodehydroproline was treated with sodium *p*-cyanomethylphenolate, the product saponified and reduced with dimethylaminoborane/acetic acid. (Yield 25% relative to bromodehydroproline ester). The corresponding Boc-compound (yield 95%) couples with *S*-prolinebenzyl ester. Both diastereomers, *(3a)* and *(3b)* were easy to isolate using medium pressure chromatography on silica gel (petroleum ether/ethyl acetate 1:1). Hydrogenolysis of the ester group (Pd/carbon in dioxane), catalytic hydrogenation of the nitrile group ($Rh/Al_2O_3$, 10% $NH_3$ in ethanol, 3 bar $H_2$), and acylation with benzyl chloroformate (Z—Cl) leads to *(4a)* and *(4b)* respectively [yields 88 and 84% relative to *(3a)* and *(3b)* respectively], which were converted into the active esters *(5a)* and *(5b)* (yields 88 and 83% respectively) using pentafluorophenol and DCCD (dicyclohexylcarbodiimide). The diastereomeric series designated *a* and *b* could not be assigned until dihydrozizyphin G had been synthesized.

*b*, *R*, *R*, *S*
*(7)*, Y = –OH; *(8)*, Y = $-OC_6F_5$
Z = $COOCH_2C_6H_5$

Using a method which we had developed[4], and reaction conditions of 50 h at 95 °C, the cyclopeptide *(6a)* was obtained from the "correct" diastereoisomer *(5a)*, by ring closure at position Ⓑ, in 35% yield. Although "tight" cyclopeptides are frequently more easily prepared if one of the amino acids of the ring belongs to the *R*-series, the "incorrect" diastereoisomer *(6b)* was formed from *(5b)* in lower yield (10%). Apart from the monomeric cycles *(6a)* and *(6b)*, the corresponding dimers were formed in approximately equal amounts. The monomers and dimers could be separated chromatographically on silica gel using ethyl acetate as eluent. *(6a)* and *(6b)*—in contrast to the dimeric compounds—could be sublimed without decomposition at 120 °C in high vacuum. Ring closure at position Ⓐ was more favorable, and resulted in the formation of *(6a)* from *(8)* in 67% yield. For this purpose, Boc-*trans*-3-(*p*-cyanomethylphenoxy)proline was hydrogenated to the *p*-aminomethyl compound and acylated with the benzyloxycarbonyl protected *S*-prolinehydroxysuccinimide ester to the diastereomeric dipeptides *(7a)* and *(7b)* (yield 100%, relative to the Boc-compound). The diastereomers could not be separated

by chromatography, either at this stage or as the pentafluorophenyl esters *(8a)* and *(8b)*. We therefore used the diastereomeric mixture, *(8a)* + *(8b)*, [yield 80% relative to *(7a)* + *(7b)*] for the ring closure reaction. The "correct" cyclopeptide *(6a)* was also formed more easily here (yield 67%) than its diastereomer *(6b)* (yield 30%). The diastereomers *(1c)* and *(1d)*, which are easily separable by chromatography were coupled with Boc-isoleucine using the DCCD-procedure after removal of the Boc-group. Cleavage of the Boc-group (trifluoroacetic acid, resorcinol dimethyl ether, 3 h, 20 °C) resulted in formation of dihydrozizyphin G *(1a)*, for the *a*-series, and isomer *(1b)* for the *b*-series.

Table 1. Selected physical data of the compounds synthesized.

| Compd. | Yield [%] | Educt | $R_f$ [c] | $[\alpha]_D^{20}$ (Methanol) | MS (20 eV), *m/e* [d] |
|---|---|---|---|---|---|
| *(6a)* | 35<br>67 | *(5a)*<br>*(8a)* + *(8b)* | 0.29 | −95.5 ($c=0.78$) | 429 ($M^+$, 100%), 329 ($M^+$ − Boc, 83) |

| $^1$H-NMR (90 MHz, 300 K, $CDCl_3$, TMS int.), *(1a)*: $\delta = 4.11$ (d/$J$ = 14.0 Hz/4 H, 4.23 (d/$J$ = 14.0 Hz/4 H), 7.43 (m/20 H); *(2a)*: $\delta = 4.09$ (s/4 H), 4.23 (d/$J$ = 14.7 Hz/2 H), 4.51 (d/$J$ = 14.7 Hz/2 H), 7.42 (m/20 H); *(3a)*: $\delta = 4.33$ (s/8 H), 7.38 (m/20 H); *(1b)*: $\delta = 1.24$ (t/$J$ = 7.3 Hz/12 H), 3.07 (dq/$J$ = 14.0 Hz and $J$ = 7.3 Hz/4 H), 3.29 (dq/$J$ = 14.0 Hz and $J$ = 7.3 Hz/4 H); *(2b)*: $\delta = 1.22$ (t/$J$ = 7.3 Hz/6 H), 1.23 (t/$J$ = 7.3 Hz/6 H), 2.97 (dq/$J$ = 13.8 Hz and $J$ = 7.3 Hz/2 H), 3.29 (dq/$J$ = 13.8 Hz and $J$ = 7.3 Hz/2 H), 3.25 (dq/$J$ = 13.5 Hz and $J$ = 7.3 Hz/2 H), 3.54 (dq/$J$ = 13.5 Hz and $J$ = 7.3 Hz/2 H); *(3b)*: $\delta = 1.22$ (t/$J$ = 7.3 Hz/12 H); 3.14 (dq/$J$ = 13.5 and $J$ = 7.3 Hz/4 H), 3.46 (dq/$J$ = 13.5 Hz and $J$ = 7.3 Hz/4 H)<br>Coalescence temperatures [a, b] ([$D_7$]-DMF), *(1a)*: $T_c = 385$ K; *(1b)*: $T_c = 409$ K, $\Delta G^{\neq} = 86$ kJ/mol; *(3b)*: $T_c = 370$ K, $\Delta G^{\neq} = 77$ kJ/mol; *(2a)* and *(2b)* decompose before the onset of coalescence. |

[a] $\Delta G^{\neq}$ was not calculated for *(1a)*, since the method of approximation is not applicable; *D. Kost, E. H. Raban, E. H. Carlson*, Chem. Commun. *1971*, 656; *D. Kost, A. Zeichner*, Tetrahedron Lett. *1974*, 4533. [b] Above the coalescence temperature, the diastereotopic protons from *(1a)* gave a singlet, and those from *(1b)* and *(3b)* resp. a quartet.

The configurational stability of complexes *(1)*—*(3)* at 27 °C is indicated by their $^1$H-NMR spectra in solution (Fig. 1, Table 1): while only an AB- and $ABX_3$-system is found for the eight equivalent diastereotopic methylene protons in *(1a)* and *(1b)* respectively, an AB-system and in addition a somewhat broad singlet, which can be interpreted as an AB-system with small $\Delta\nu/J$ ratio, is found for *(2a)*. Two $ABX_3$-systems are obtained for *(2b)*. In *(3a)* and *(3b)* all diastereotopic methylene protons are again equivalent: a broad singlet is observed for *(3a)* and an $ABX_3$-system for *(3b)*.

At higher temperatures, coalescence of the methylene proton signals of *(1a)*, *(1b)* and *(3b)* is observed. Since the "free" lone-pair of electrons on the hydroxylamine N-atom form a bond to molybdenum, and are therefore sterically fixed, simple nitrogen inversion[4] as in the free ligands cannot occur[5,6]. We therefore suggest that the configurational isomerization stem from a rapid rotation-inversion at nitrogen[5,6] with concomitant reformation of the Mo—N bond, the rate

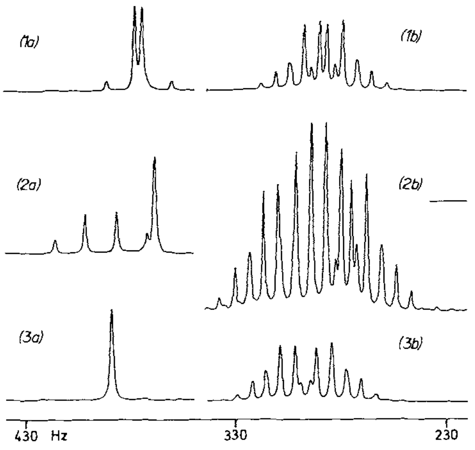

Fig. 1. $^1H$-NMR spectra of the diastereotopic protons of complexes *(1)*—*(3)* at 27 °C.

determining step being the dissociation of the Mo—N bonds at a rate which is rapid on the NMR time scale. The values of $\Delta G^{\neq}$ for *(1b)* and *(3b)* could be determined from the coalescence temperatures by simultaneous decoupling of the methyl protons (Table 1). The values obtained support the suggested mechanism; they are clearly higher than those of the noncomplex bonded ligands[7].

Finally, it is interesting that substitution of both oxo-oxygen atoms in *(1b)* by two sulfur atoms in *(3b)* lowers the dissociation barrier of the Mo—N bond. An increase in the electron density at the molybdenum(VI)-centre weakens the Mo—N bond.

### *Procedure*

$H_2S$ is passed for 30 mins into a stirred solution of *(1a)*[2] (3 g, 5.4 mmol) and *(1b)*[8] (3 g, 10 mmol) respectively, in 150 cm³ benzene over 10 g dry $Na_2SO_4$. The mixture is stirred for 12 h in a closed flask, the deep red solution filtered off and the solvent removed. One half of the residue is dissolved in 20 cm³ benzene and chromatographed at 20 °C on 150 g aluminum oxide 90 (activity grade II—III); the other half is dissolved in 20 cm³ $CHCl_3$ and chromatographed on 100 g silica gel 60. The red-violet *cis*-dithio compounds *(3a)*$\cdot C_6H_6$ (yield 15%) and *(3b)*$\cdot 0.33\ C_6H_6$ (13%) are obtained from the first half. The faster eluting violet fraction from the chromatographed chloroform solution is rejected: solvent is removed from the succeeding yellow fraction until crystallization just begins. Yellow crystals of *(2a)* (yield 10%) and *(2b)* (8%) respectively are filtered off and air-dried.

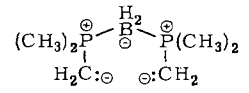
# Synthesis of a Borato(phosphoniomethanide)(phosphoniooxide)-Ligand and Its Organoberyllium Complex[**]

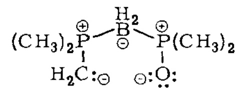
By *Hubert Schmidbaur* and *Erwin Weiss*[*]

Incorporation of onium centers into organoelement ligands effects a drastic change in the complexation properties, as occurs, *e.g.*, in numerous coordination compounds of the phosphorus ylides[1]. The strong σ-donor effect, in the absence of effective back-bonding, leads to particularly high electron densities at the central atom. These effects are also discernable in the boratobis(phosphoniomethanide) ligand *(A)* with its continuously alternating charges[2,3]. Interest therefore attaches to a related chelate system in which one of the two $CH_2$-functions is replaced by a strongly electronegative donor atom. We now report on the synthesis of the bidenate ligand *(B)*, its precursors, and a typical complex.



$$\begin{array}{c}(CH_3)_2\overset{\oplus}{P}-\underset{\ominus}{\overset{H_2}{B}}-\overset{\oplus}{P}(CH_3)_2\\ H_2C{:}^{\ominus}\qquad {}^{\ominus}{:}CH_2\end{array}$$

*(A)*

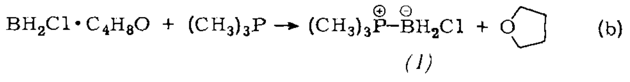


$$\begin{array}{c}(CH_3)_2\overset{\oplus}{P}-\underset{\ominus}{\overset{H_2}{B}}-\overset{\oplus}{P}(CH_3)_2\\ H_2C{:}^{\ominus}\qquad {}^{\ominus}{:}\ddot{\underset{..}{O}}{:}\end{array}$$

*(B)*

Trimethylphosphanechloroborane *(1)*[4] is readily accessible *via* the route outlined by steps (a) and (b) (cf. Procedure); yield 96%; m.p. 73 °C; $\nu(BH_2) = 2395$ and $2420\ cm^{-1}$; $\delta(P) = -11.1$, q, $J(PB) = 81$ Hz.

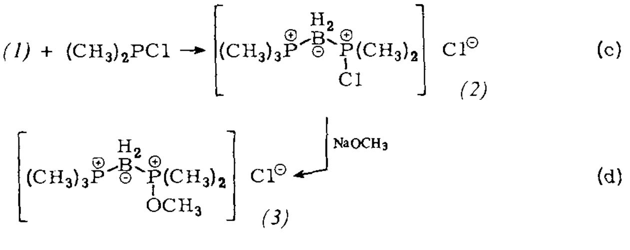
$$BH_3\cdot C_4H_8O + HCl \rightarrow BH_2Cl\cdot C_4H_8O + H_2 \qquad (a)$$



$$BH_2Cl\cdot C_4H_8O + (CH_3)_3P \rightarrow (CH_3)_3\overset{\oplus}{P}-\overset{\ominus}{B}H_2Cl + \qquad (b)$$

*(1)*

Reaction of *(1)* and chlorodimethylphosphane at 70 °C, in the absence of solvent, affords the boratobis(phosphonium) salt *(2)*; yield 71%; m.p. 84 °C; $\nu(BH_2) = 2400$ and $2440\ cm^{-1}$; $\delta(PC_3) = -9.05$, $^1J(PB) = 89$ Hz, $\delta(PC_2Cl) = 90.0$, $^1J(PB) = 98$ Hz. The P—Cl function of *(2)* reacts with sodium methoxide [step (d)] to give the derivative *(3)*; yield 90%; m.p. 130 °C (dec.); $\nu(BH_2) = 2380$ and $2420\ cm^{-1}$; $\delta(PC_3) = -7.96$, $^1J(PB) = 79$ Hz; $\delta(PC_2O) = 104.17$, $^1J(PB) = 101$ Hz.



$$(1) + (CH_3)_2PCl \rightarrow \left[(CH_3)_3\overset{\oplus}{P}-\underset{\ominus}{\overset{H_2}{B}}-\underset{Cl}{\overset{\oplus}{P}}(CH_3)_2\right]Cl^{\ominus} \qquad (c)$$

*(2)*

$$\left[(CH_3)_3\overset{\oplus}{P}-\underset{\ominus}{\overset{H_2}{B}}-\underset{OCH_3}{\overset{\oplus}{P}}(CH_3)_2\right]Cl^{\ominus} \xleftarrow{NaOCH_3} \qquad (d)$$

*(3)*

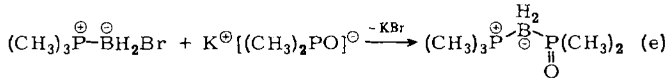
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and by Hoechst AG.

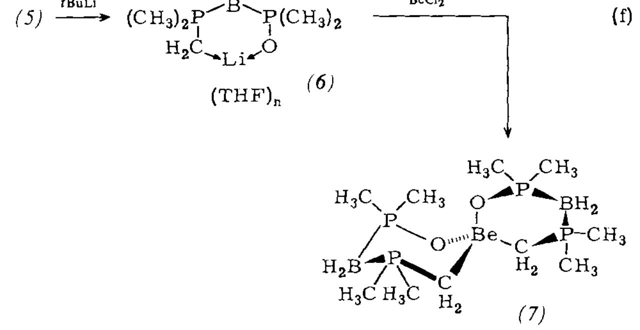
Hydrolysis of *(2)* or *(3)* with water or alkali hydroxide affords only small amounts of an oxide *(5)*, whereas reaction (e) of the readily accessible[5] bromine analog of *(1)* with the potassium salt of dimethylphosphinous acid leads directly to the neutral oxide *(5)*; yield 82%; m.p. 79 °C; $\nu(BH_2) = 2360$—2395, $\nu(P{=}O) = 1120\ cm^{-1}$; $\delta(PC_3) = -5.45$, $^1J(PB) = 79$ Hz, $\delta(PC_2O) = 50.22$, $^1J(PB) = 123$ Hz; $m/e = 166$ ($M^+$).



$$(CH_3)_3\overset{\oplus}{P}-\overset{\ominus}{B}H_2Br + K^{\oplus}[(CH_3)_2PO]^{\ominus} \xrightarrow{-KBr} (CH_3)_3\overset{\oplus}{P}-\overset{H_2}{\underset{\ominus}{B}}-\underset{O}{\underset{\|}{P}}(CH_3)_2 \quad (e)$$

*(4)* *(5)*

*(5)* can be metalated with *tert*-butyllithium at −78 °C in tetrahydrofuran (THF)/pentane; loss of alkane takes place with formation of the lithium complex *(6)*, which does not have to be isolated free of solvent but can be reacted further, *in situ*, with metal halides. Thus, *e.g.* with $BeCl_2$ the spirocyclic beryllium complex *(7)*, m.p. 59 °C, subl. at 60—100 °C/$10^{-4}$ torr, is obtained. The colorless, slightly air- and moisture-sensitive crystals are soluble in polar aprotic solvents.



In the mass spectrum the molecular ion appears as base peak ($m/e = 339$, $2\times{}^{11}B$). In the IR spectrum $\nu(P{=}O)$ is reduced to 1065 cm$^{-1}$ owing to metal coordination. As expected the phosphorus atoms are pairwise non-equivalent: $\delta(PC_3) = -5.07$, qd, $^1J(PB) = 95$, $^2J(PP) = 15$ Hz; $\delta(PC_2O) = 63.62$, qd, $^1J(PB) = 107$, $^2J(PP) = 15$ Hz. The $^1H$- and $^{13}C$-NMR spectra show the sets of doublet signals derivable from the symmetry. The $^{13}C$-NMR spectrum, in particular, demonstrates the non-equivalence of the two $CH_3$ groups on each P-atom, also recognizable on models. In the solid state *(7)* undergoes oligomerization on storage at room temperature, so that aged samples are no longer volatile.

The ligands (B) of complex *(7)* thus correspond to the isoelectronic[2,3,7] chelate type *(A)*, but they favor complexation with highly charged, small, and difficultly polarizable ("hard") metal centers. Beryllium is one of the most favorable candidates for this purpose.

### *Procedure*

Combination of equimolar amounts of $BH_3\cdot THF$ in excess THF and ethereal HCl at −20 °C leads, with evolution of $H_2$, to a clear solution of $H_2BCl\cdot THF$, which is allowed to react at 0 °C with one equivalent $(CH_3)_3P$ to give *(1)* quantitatively. The product crystallizes from ether/pentane. Addition of $(CH_3)_2PCl$ (6.32 g) to *(1)* (8.2 g) (66 mmol of each) and heating to 70 °C (without solvent) leads to formation of the salt *(2)*, which for purification is taken up in $CH_2Cl_2$, filtered, and crystallized at −30 °C by addition of ether (yield 11.2 g; 71%). Reaction of *(2)* (1.97 g) with $NaOCH_3$ (0.48 g) (8.92 mmol of each) in THF at 0—20 °C yields the methoxy derivative *(3)*, which after 16 h is crystallizeable by removal of solvent, dissolution in $CH_2Cl_2$, filtration and addition of ether to the filtrate at −30 °C (1.74 g; 90%).

$(CH_3)_3P$—$BH_3$ is transformed into $(CH_3)_3P$—$BH_2Br$ in the usual way[5], and 10.3 g (61.2 mmol) of the product *(4)* allowed to react at 0 °C in THF with K $[(CH_3)_2PO]$—freshly prepared from $(CH_3)_2POH$[6] (4.78 g) and KH (2.46 g) (61.24 mmol of each) in 100 ml of THF at 0 °C, but not isolated. After filtration from KBr, *(5)* can be crystallized at −30 °C from ether/pentane (8.3 g; 82%).

A solution of *(5)* (0.96 g, 5.78 mmol) in THF (10 ml) is treated at −78 °C with an equivalent of *t*BuLi (in pentane) and, after 1 hours' stirring, $BeCl_2$ (0.23 g), 2.89 mmol) is added to the mixture. Stirring is continued for 16 h, the mixture allowed to warm to room temperature, the solvent removed and replaced by toluene, the resulting solution filtered, and the residue finally obtained from the filtrate is sublimed (0.11 g; 11%).

All the compounds gave correct elemental analyses and characteristic $^1H$-, $^{13}C$-, $^{31}P$-NMR and mass spectra.

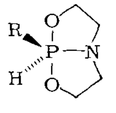
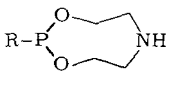
thermore, evidence for the presence of a sodium phosphoranide in an equilibrium mixture in solution has recently been obtained[3]. We report here the isolation and crystal structure of a molybdenum adduct, which is the first transition metal complex with a phosphoranide ion as ligand.

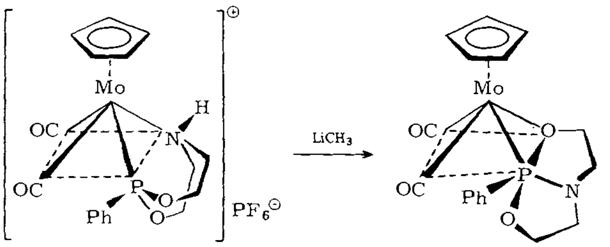
Bicyclic phosphoranes of type *(1a)* react with a variety of transition metal carbonyl complexes to give coordination adducts of their normally undetected tautomeric form *(1b)*. Coordination occurs either *via* P alone or *via* P and N[4]. The reaction of *(1a)* with $C_5H_5(CO)_3MoCl$ can be directed towards substitution of either two carbonyl groups or of one carbonyl and the chloride. In the latter case it yields the cationic species *(2)*[4b]. We selected *(2)* as a substrate on which to attempt the abstraction of the nitrogen bonded proton.



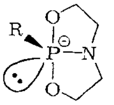
*(1a)*



*(1b)*



*(2)* *(3)*



*(4)*, R = $C_6H_5$

The action of methyllithium on *(2)* in THF at 60 °C yielded the neutral complex *(3)*, in which the pentacoordinated bipyramidal phosphorus atom is bonded to molybdenum and acts as an anionic phosphoranide ligand *(4)*. The two additional electrons needed by the metal to achieve an 18-electron configuration are provided by one of the oxygen atoms, giving the hitherto unknown MoPO three-membered ring. It is noteworthy that this structural arrangement, rather than one in which the nitrogen acts as the additional donor, avoids the unfavorable location of the oxygen atoms in equatorial positions and the phenyl group in an apical position, which would have resulted had this structural alternative been adopted.

All spectroscopic and analytical data of the red-orange crystalline material, isolated in 21% yield, are in accord with structure *(3)*. It exhibits two $\nu$(CO) vibrations at 1925 and 1835 cm$^{-1}$; the $\nu$(N—H) vibration of the educt *(2)* has disappeared. The $^1$H-NMR spectral data exclude the possibility of addition of $CH_3^\ominus$. The only sharp signal observed is that of the $\delta(C_5H_5) = 5.32$ (in $CDCl_3$); the signal integrations are also consistent with the abstraction of a proton. $^{31}P\{^1H\}$-NMR spectra of *(3)* show a singlet at an unusual location ($\delta = +23.8$) relative to the free phosphorane *(1a)*: $-44.3$ and to the metal complexes of the tautomer *(1b)*: $+185$ to $+200$[4b].

The structure of *(3)* was further established by X-ray crystal structure analysis[5] and is shown in Fig. 1.

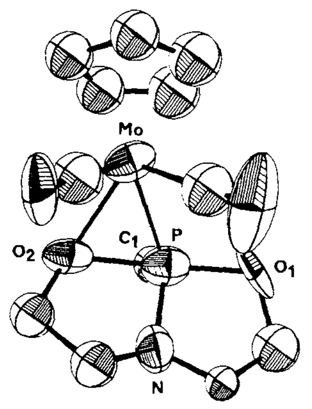


Fig. 1. Molecular structure of complex *(3)* in the crystal; of the phenyl group bonded to phosphorus only C-1 is reproduced (ellipsoids with 50% probability).

The bicyclic phosphoranide ligand whose N-bridgehead is close to planar (sum of angles 345 ± 5°), is almost perpendicularly orientated with respect to the $C_5H_5$ ring. The P—N bond length (1.69(5) Å) is in the range expected when N is equatorially bound to a bipyramidal pentacoordinated P atom[6]. The P—O2 distance in the coordinated five-membered ring (1.893(4) Å) is 0.24 Å longer than P—O1 in the uncoordinated ring. The P—Mo distance 2.375(2) Å) is 0.07—0.14 Å shorter than in complexes having the $C_5H_5MoPR_3$ pattern ($R = OCH_3, C_6H_5$)[7]; this may simply result from the contraction of the radii normally observed when going from a tri- to a pentacoordinated phosphorus atom.

### *Procedure*

An equimolar mixture of the $PF_6$ salt *(2)* (630 mg, 1.1 mmol) and $CH_3Li$ (0.7 cm$^3$ of 1.6 M solution in diethyl ether) in THF (50 cm$^3$) is stirred for 60 min at 60 °C. After evaporation of THF the oily residue is dissolved in ether (20 cm$^3$) and filtered. The concentrated filtrate is chromatographed on $SiO_2$ (column 20 × 2 cm), the product eluted with ether as an orange band (yield 100 mg, 21%), and recrystallized from ether/pentane (2:1) to give *(3)* as red-orange crystals (decomp. 86 °C)[8].

*(4c)*, R = H, X = H, $Y = OSi(CH_3)_2C(CH_3)_3$
*(3d)*, R = H, X and Y = H and OH

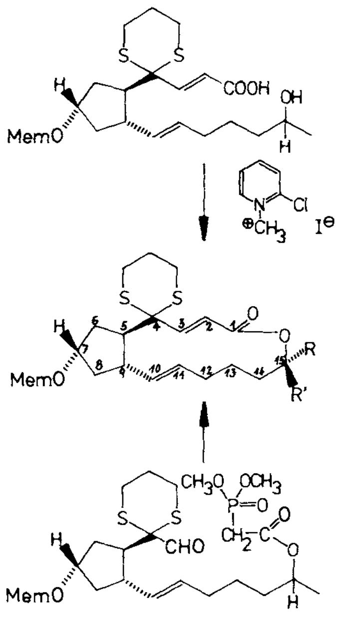
They can be obtained most easily, and with excellent stereoselectivity, from the readily preparable cyclopentenone derivative *(1)*[2] by vinyl cuprate addition of the intact silyl-protected side chains to C-9 and a subsequent reduction-inversion sequence[1].

If this sequence is carried out with the corresponding Mem esters *(4)* the ability of this special ester group[3] in *(3b)* and *(4b)* to form complexes enables direct reduction to the mixture of aldehydes *(3c)/(4c)*. Wittig chain-expansion, hydrolysis, and cleavage of silyl ether afford the seco-acids *(5)* as a mixture of epimers (C-15).

Although the lactonization reaction of the corresponding 4-Mem ethers is said to be highly stereospecific, with distinct preference for the natural configuration at C-15[4], *(5)* shows no stereospecificity whatsoever on lactone formation according to the method of *Mukaiyama, i. e.* the two C-15 epimeric lactones *(6a)* and *(6b)* are formed in exactly equal amounts.

Since many Wittig or Wittig-Horner cyclizations have recently been successfully employed for the synthesis of medium-sized and large rings[5] we have examined the possible use of these cyclizations for the synthesis of the 13-membered ring system brefeldin A.

The silyl ether in *(3c)/(4c)* was cleaved off and the phosphonate *(7)* generated by the DCCD technique; *(7)* was then deprotonated as the C-15 epimeric mixture with sodium hydride, resulting in cyclization (Table 1). After 8 h at room temperature a lactone is isolated which, according to the NMR data, corresponds with high selectivity (10:1) to the epimer *(6b)* (Table 1). The sequence already described by us: thioketal cleavage, reduction, Mem-ether cleavage, leads indeed to 4-epi-15-epi-brefeldin A. Owing to the higher polarity of the phosphonate, the non-cyclized portion can be separated, hydrolyzed and protected at the hydroxyl group as the silyl ether. The enriched aldehyde *(3c)* thus obtained can be subjected to chain-expansion in the above-mentioned way, and on lactonization affords brefeldin A.



*(5)*

*(6a)*, R = H; R' = $CH_3$

*(6b)*, R = $CH_3$; R' = H

*(7)*

Table 1. Some physical data of the compounds *(6)* and *(5b)*.

*(6)*, IR ($CCl_4$): 1735, 1720, 1200, 910 $cm^{-1}$; $^1$H-NMR ($CDCl_3$, 90 MHz): $\delta = 1.23$ (3H, d, $J = 6.5$ Hz), 1.31 (6H, t, $J = 7$ Hz), 1.45—2.75 (18H, m), 2.95 (2H, d, $J = 21$ Hz), 3.41 (3H, s), 3.62 (4H, m), 4.18 (4H, q), 4.18 (1H, m), 4.71 (2H, s), 4.9 (1H, m), 5.3 (2H, m), 8.87 (1H, s); MS (250 °C): $M^{\oplus}$ absent, 582 ($M^{\oplus} - 28$, 5%), 505 (15.5), 492 (14), 473 (19.5), 434 (15), 309 (17.5), 279 (12.5), 198 (54.5), 187 (64.5), 179 (39), 151 (26.5), 123 (31), 89 (25), 59 (100); high resolution calc. 582.2449, obs. 582.2449 ($M^{\oplus} - 28$)

*(5b)*, IR ($CCl_4$): 1715, 1630 $cm^{-1}$; $^1$H-NMR ($CDCl_3$, 90 MHz): $\delta = 1.24$ (3H, d, $J = 6.5$ Hz), H-15, 1.25—2.5 (14H, m), 2.5—3.25 (4H, m, thioketal), 3.34 (3H, s, Mem ether, O—$CH_3$), 3.65 (4H, m, Mem ether, O—$CH_2$—$CH_2$—O), 4.13 (1H, m, H-7), 4.71 (2H, s, Mem ether, O—$CH_2$—O), 4.95 (1H, m), 5.2 (2H, m, inactive olefin), 6.13 (1H, d, $J = 15.5$ Hz), 6.70 (1H, d, $J = 15.5$ Hz, active olefin); MS (70 °C): 455 ($M^{\oplus} - 1$, 9.5%), 427 (2), 380 (5), 350 (195), 274 (12), 149 (45.5), 89 (100), 59 (86); high resolution calc. 455.1926, obs. 455.1924 ($M^{+} - 1$)

This constitutes a case of a kinetic separation of the epimers of the stereoisomeric C-15 alcohols, and it is noteworthy that the phosphonate with natural configuration at C-15 leads to cyclization products only after several days at room temperature. Attempts to accelerate this process by increasing the temperature lead to considerable resinification. Hence, in the phosphonate cyclization there is a dependence on the configuration at C-15—interestingly, however, in the reverse sense to that in the Corey cyclization.

## *Procedure*

*(7)*: A solution of *(3d)* (740 mg, 1.72 mmol) in anhydrous dichloromethane (20 $cm^3$) is treated with dimethoxyphosphorylacetic acid (320 mg, 1.9 mmol), dicyclohexylcarbodiimide (395 mg, 1.9 mmol) and 4-(dimethylamino)pyridine (40 mg) and the mixture stirred for 3 h at room temperature. The urea is filtered off. The filtrate is taken up in $CH_2Cl_2$, washed with water, dried, and evaporated down. The residue is chromatographed on silica gel (eluent: ether + 5% $CH_3OH$); yield 905 mg (86%).

*(6b)*: Under an $N_2$ atmosphere a solution of *(7)* (100 mg, 0.16 mmol) in anhydrous dimethoxyethane (5 $cm^3$) is added dropwise within 8 h to a suspension of NaH (30 mg) in anhydrous dimethoxyethane (25 $cm^3$). After one hours' stirring at

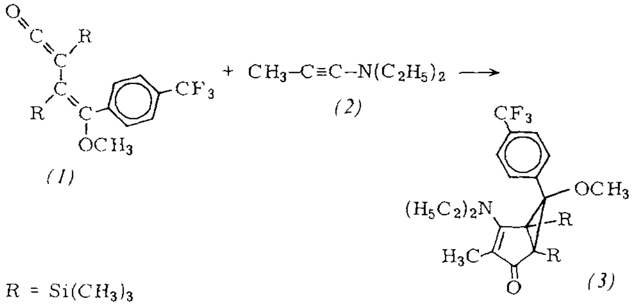
## Addition of Ynamines to Vinylketenes[**]

By *Karl Heinz Dötz, Barbara Trenkle,*
and *Ulrich Schubert*[*]

Ketenes can add ynamines at the C=C- or at the C=O-bond[1]. The recently discovered entry to stable vinylketenes[2] also provides the possibility of investigating the virtually unresearched cycloaddition behavior[3] of this class of compounds.

On reaction of 4-methoxy-4-(4-trifluoromethylphenyl)-2,3-bis(trimethylsilyl)-1,3-butadien-1-one *(1)* with 1-diethylamino-1-propyne *(2)* in hexane at room temperature the bicyclo[3.1.0]hex-3-en-2-one derivative *(3)* is obtained instead of the expected four-membered ring derivative. Of the possible *endo-exo* isomers only the *endo*-aryl form is obtained. Such bicycles are already accessible by photolysis of cyclohexadienones: for example, *o*-quinol acetates give exclusively the *endo*-aryl compounds, while *p*-quinol derivatives afford predominantly *exo*-isomers[4].



*(1)*

*(2)*

*(3)*

R = $Si(CH_3)_3$

The IR spectrum[5] of *(3)* shows a $\nu$(C=C) absorption shifted to extremely long wavelength at 1585 cm$^{-1}$, indicating a considerable charge transfer from the amino group to the carbonyl group. This is confirmed by the X-ray structure analysis[6] (Fig. 1), which shows a shortening of the C4—N (137.9 pm) and C2—C3 (141.5 pm) bond lengths and a lengthening of the C2—O2 (125.2 pm) bond in the aminoenone grouping of the five-membered ring compared to those in analogous bicycles not containing an amino function. The two *cis* trimethylsilyl substituents may be responsible for the lenthening of the C1—C5 bond (156.6 pm) and widening of the C5(C6)—C1—Si1 (136.7°, 124.1°) and C1(C6)—C5—Si2 (124.8°, 129.2°) angles.

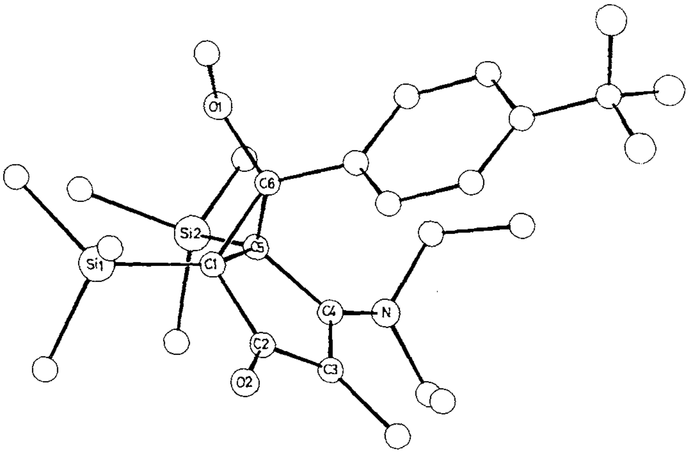


Fig. 1. Molecular structure of *(3)* [6].

The formation of the bicycle *(3)* can be explained in terms of an initial [2+2]-cycloaddition of the ynamine to the vinylketene to give cyclobutenone, followed by ring opening to an homologized dienylketene. Such compounds have already been detected as precursors of bicyclohexenones in the photoisomerization of cyclohexadienones[7].

*Procedure*

A mixture of *(1)* (1.08 g, 2.7 mmol) in hexane (15 cm$^3$) and *(2)* (0.84 cm$^3$, 6.0 mmol) is stirred for 3 h at room temperature. After removal of solvent the residue is chromatographed on silica gel (Merck, Act. 2—3). Elution of the yellow main zone with dichloromethane/pentane (1:1) and subsequent recrystallization from pentane affords *(3)* as colorless crystals; m.p. 122 °C, yield 0.51 g (38%).

## Intramolecular Nucleophilic Addition in a Thiolato-bridged "Crown-like" Iridium Complex

By *Jean Devillers, Dominique de Montauzon,*
and *René Poilblanc*

The oxidative addition of alkynes to Ir(I) atoms of binuclear complexes has recently been described[1]. Starting from

---

$[Ir(\mu\text{-}S\text{—}tBu)(CO)_2]_2$, a trinuclear complex with Ir(II)—Ir(II) bonding was obtained.

$Ir_3(\mu\text{-}S\text{—}tBu)_3(\mu\text{-}C_4F_6)(CO)_6$ *(1)*

We now report on the reaction of *(1)* with excess hexafluoro-2-butyne, which leads to formation of a complex whose chemical and spectroscopic data[2] are consistent with formula *(2)*

$Ir_3(S\text{—}tBu)_3(CO)_5(C_4F_6)_2$ *(2)*

The infrared spectra[2] show five CO bands, and two groups of C=C bands. The band at 1621 $cm^{-1}$ can be assigned to a σ-bonded alkyne, as in complex *(1)*[3]. The two other bands at 1830 and 1802 $cm^{-1}$ are attributed to a π-bonded alkyne[4]. The $^{19}F$-NMR spectrum[2] confirms the existence of these two modes of coordination of the alkyne ligands. Furthermore the $^1H$-NMR spectrum[2] shows that the three *tert*-butylthiolato groups are nonequivalent.

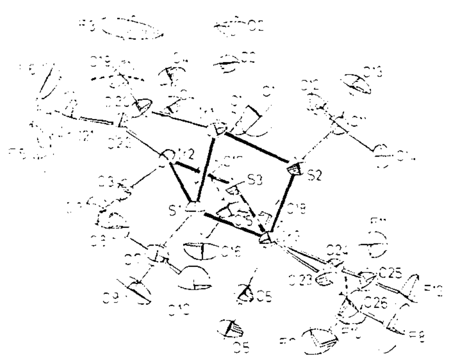

Fig. 1. ORTEP-drawing of complex *(2)* in the crystal [5]; atoms F1, F2 and F9 are not shown. Most important bond lengths and angles: Ir1—Ir2 = 2.707(1), Ir1—Ir3 = 3.730(1), Ir2—Ir3 = 3.717(1), Ir1—S1 = 2.342(2), Ir2—S1 = 2.339(3), Ir3—S1 = 2.467(2), Ir3—S2 = 2.453(2), Ir3—S3 = 2.431(3), Ir1—C1 = 1.940(13), C1—O1 = 1.115(13), Ir1—C20 = 2.085(10), Ir3—C24 = 2.036(10), S1—C7 = 1.889(10), C20—C22 = 1.291(15), C23—C24 = 1.244(14) Å; Ir1—S1—Ir2 = 70.7, Ir2—S3—Ir3 = 99.7, S1—Ir1—S2 = 78.7, S1—Ir2—S3 = 80.7, S1—Ir3—C5 = 97.2, C24—Ir3—S2 = 93.3, S2—Ir3—C5 = 170.8, Ir1—S1—C7 = 124.3, C1—Ir1—C2 = 98.2°.

Figure 1 shows the results of the X-ray structure analysis. The geometry around the $Ir^{II}$ atoms (Ir1 and Ir2) is almost the same as in *(1)*. The similarity of the Ir1—Ir2 distances in *(1)* and *(2)* (2.71 and 2.69 Å respectively), strongly suggests the existence of a metal-metal bond in *(2)*. Substitution of a CO group by a π-bonded $C_4F_6$ group at $Ir^I$-atom (Ir 3) leads to significant changes in the geometry of the remaining part of the complex. The chair conformation of the ring formed by Ir1—S1—Ir2—S3—Ir3—S2 in *(1)* is transformed into a "boat" conformation in *(2)*. The rotation of Ir3 around the S3—S2 axis is probably correlated with inversion of configuration at the S3 atom as well as with the formation of the S1—Ir3 bond. The Ir3—S1, Ir3—S3 and Ir3—S2 bond lengths are similar (Fig. 1). As a consequence, the S1 atom is linked to all three Ir atoms and is thus tetracoordinated. For the same reason, the coordination number of the Ir3 atom, which was four in *(1)*, increases to five in *(2)*. The geometry around Ir3 can be described as a distorted trigonal bipyramid with S1, S3 and the center of C23—C24 bond in the equatorial plane. The formation of the S1—Ir3 bond and the related modifications of the structure are attributed to the electron-withdrawing effect of the fluoroalkyne group bonded to Ir3.

*Procedure*

*(1)* (0.587 g, *ca.* 0.5 mmol) was transferred to a thick-walled glass reaction vessel fitted with a Teflon stopcock. After evacuation and cooling to −196 °C, pentane (*ca.* 30 $cm^3$) and 1.0 g hexafluorobut-2-yne (excess) were condensed into the flask. The reaction mixture was then allowed to warm-up slowly to room temperature and stirred for three days. The solution was then evaporated under reduced pressure, and lemon yellow crystals obtained at −20 °C from 3 $cm^3$ pentane. These were vacuum dried: yield 72%.

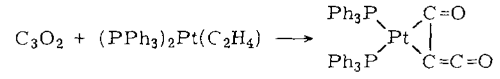
## Reactions of Carbon Suboxide with Platinum(0) Complexes[**]

By *Gastone Paiaro* and *Luciano Pandolfo*[*]

Until now, no systematic study of the properties of carbon suboxide *(1)*[1] as a ligand in transition metal complexes has been reported. *(1)* has been regarded as an activated olefin in reactions with transition metals. On the one hand, by analogy with $C_3S_2$[2], it reacts with C=O and C=C groups, but on the other it can for example form diphenylketene-carbene complexes by dissociating into CO and $C_2O$ moieties[4].

We report here on the reactions of *(1)* with the complexes $(PPh_3)_2Pt(C_2H_4)$ *(2)* and $(PPh_3)_2Pt(O_2)$ *(4)*. Reaction of *(2)*



$$C_3O_2 + (PPh_3)_2Pt(C_2H_4) \longrightarrow (Ph_3P)_2Pt\begin{matrix} C{=}O \\ | \\ C{=}C{=}O \end{matrix}$$

*(1)* *(2)* *(3)*

with *(1)* affords the complex *(3)*, whose IR spectrum exhibits a strong ketene band ($\nu = 2080$ $cm^{-1}$) and a carbonyl band ($\nu = 1765$ $cm^{-1}$). Cyclic voltammetric measurements performed in DMSO using a mercury-covered spherical gold electrode indicate that *(3)* undergoes irreversible reduction at a potential of −1.8 V (*vs.* SCE). Furthermore, potentiostatic coulometry carried out at a mercury electrode indicate that two electrons are involved in the overall cathodic process. These results suggest that a metallocyclopropane structure[5] is probable for *(3)*, formed by formal oxidative addition of *(1)* to *(2)*.

Reaction of *(1)* with *(4)* *via* 1,2-addition of the dioxygen moiety across the C=C bond results in formation of a product whose elemental analysis and spectroscopic parameters

---

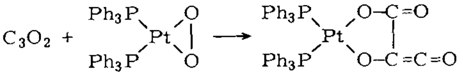
Istituto di Chimica Analitica, Università di Padova
Via F. Marzolo 1, I-35100 Padova (Italy)

[**] This work was supported by C.N.R. (Roma).

are consistent with the structure *(5)*[6]. The IR spectrum of *(5)* exhibits strong ketene and carbonyl bands ($\nu = 2080$ and $1625\ cm^{-1}$ resp.): a peroxide O—O bond could not be observed either by IR-spectroscopy (no band at $825\ cm^{-1}$) or by an iodine test[7]. *(5)* isomerizes in solution giving a known compound $[(PPh_3)_2Pt(O)_2]C_3O_2$ having an intense band at $\nu = 1685\ cm^{-1}$[8].



*(1)* *(4)* *(5)*

These types of reactions of carbon suboxide *(1)* with compounds *(2)* and *(4)* are of interest because they lead to complexes in which there is a "free" ketene group and indicate that the dioxygen ligand in *(4)* attacks $C_3O_2$ directly.

*Procedure*

All solvents were degassed and manipulations carried out under an argon atmosphere. *(1)* was prepared by dehydration of malonic acid with $P_4H_{10}$.

*(3)*: *(1)* (0.25 mmol) is passed into a solution of *(2)* (0.19 mmol) in 10 cm$^3$ ether at $-20\,^\circ C$; white microcrystalline *(3)* is filtered off. Yield 37%, m.p. = 128—129 °C (decomp.).

*(5)*: *(1)* (2.8 mmol) is passed into a solution of *(4)* (2.1 g, 2.8 mmol) in 30 cm$^3$ $CH_2Cl_2$; white microcrystalline *(5)* is filtered off and washed with cold $CH_2Cl_2$. Yield 41%, m.p. = 130—132 °C (decomp.). Elemental analysis corresponded to *(5)*·$CH_2Cl_2$.

## Reactions of Carbon Suboxide with Rhodium(I) Complexes[**]

By *Gastone Paiaro* and *Luciano Pandolfo*[*]

As part of our studies on the coordinating properties of carbon suboxide *(1)* with transition metals[1], we examined the reaction of rhodium(I) complexes with *(1)*.

Reaction of $(PPh_3)_3RhCl$ *(2)* with *(1)* in benzene gives *trans*-$(PPh_3)_2(CO)RhCl$ *(3)* in addition to polymers derived from $C_2O$[2].

$$\underset{(1)}{C_3O_2} + \underset{(2)}{(PPh_3)_3RhCl} \rightarrow \underset{(3)}{(PPh_3)_2(CO)RhCl} + PPh_3 + 1/n\,(C_2O)_n$$

The course of the reaction in $CH_2Cl_2$ has been followed by IR spectroscopy: an intense band at $2080\ cm^{-1}$ ($\nu_{ketene}$) soon appears but decreases in intensity and eventually disappears while a band at $1970\ cm^{-1}$ ($\nu_{CO}$) increases. Another band at $2210\ cm^{-1}$ reaches its maximum intensity after 1 h and completely disappears after 24 h. These results suggest that the reaction proceeds *via* nucleophilic attack of a tricoordinated rhodium species on the electrophilic C-1 of *(1)*. In this way *(1)* is cleaved into CO and $C_2O$, producing the thermodynamically stable carbonyl rhodium complex *(3)*[3].

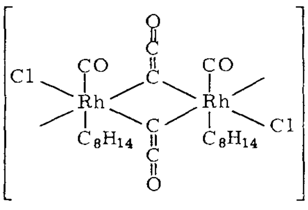
The binuclear $[(C_8H_{14})_2RhCl]_2$ *(4)* reacts with *(1)* in toluene to give the brick-red complex *(5)*.

$$\underset{(1)}{C_3O_2} + \underset{(4)}{[(C_8H_{14})_2RhCl]_2} \rightarrow \underset{(5)}{1/n\,[C_8H_{14})(CO)Rh(C_2O)Cl]_n} + C_8H_{14}$$

Compound *(5)* is stable and insoluble in most organic solvents; only chloro-bridge splitting reagents such as pyridine "dissolve" it.

$$(5) + n\text{py} \rightarrow \frac{n}{2}\,[(C_8H_{14})(CO)(py)Rh(C_2O)Cl]_2 \quad (6)$$

The IR spectrum of *(5)* contains bands which can be assigned to a terminal carbonyl group ($\nu = 2010\ cm^{-1}$), an Rh—Cl bridge ($\nu = 303\ cm^{-1}$), a ketene ($\nu = 2080\ cm^{-1}$) and cyclooctene ligand ($\nu = 2935$, $2800\ cm^{-1}$); these assignments were confirmed by $^1H$-NMR spectroscopy ($[D_6]$-dimethylsulfoxide; $\delta = 5.51$ (2H), 2.51 (4H), 1.43 (8H)). Potentiostatic coulometry ($-1.75$ V *vs.* SCE) carried out at a platinum electrode, indicates that three electrons are involved in the overall cathodic reaction of *(5)*. On the basis of these results the structure of *(5)* must consist of a polymeric rhodium(III) complex having chlorine and carbene bridges as shown in *(5a)*[4].



*(5a)*

Carbon suboxide *(1)* does not react with $[(C_8H_{12})RhCl]_2$ or $[(C_2H_4)_2Rh(C_5H_5)]$ in $CH_2Cl_2$ solution. The type of reaction described here is of particular interest in relation to catalytic decarbonylation[5].

*Procedure*

All reactions were carried out under an atmosphere of argon. *(1)* was prepared by dehydration of malonic acid with $P_4O_{10}$.

*(3)*: *(1)* (2.3 mmol) is passed into a solution of *(2)* (2.27 mmol) in 100 cm$^3$ benzene at room temperature. A red solid precipitates and is filtered off and crystallized from acetone. Yellow crystals[3], m.p. = 195 °C.

*(5)*: *(1)* (1.45 mmol) is passed into a solution of *(4)* (1.28 mmol) in 50 cm$^3$ toluene at 0 °C; the solution becomes red. After 24 h the solution is colorless and a red solid is formed. After elemental analysis this corresponds to *(5)*·$C_7H_8$; yield 77%.

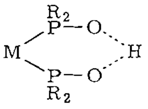
## Reaction of Platinum(II) *N*,*N*-Dialkyldithiocarbamates with Diphenylphosphane Sulfide[**]

By *David M. Anderson, E. A. V. Ebsworth, T. Anthony Stephenson*, and *Malcolm D. Walkinshaw*[*]

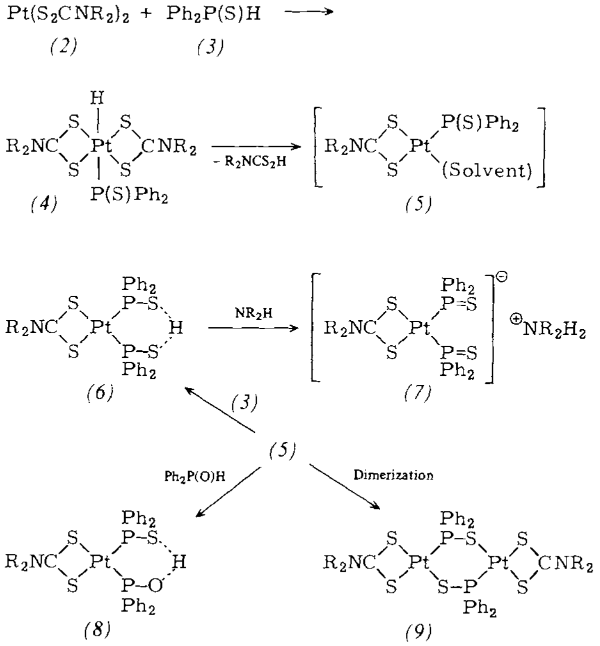
A variety of transition metal complexes containing the six membered ring *(1)* has been isolated in recent years. They were produced either by addition of phosphinous acids or their salts to suitable metal complexes or by solvolysis of coordinated P—X bonds (X = halogen, OR *etc.*)[1]. Replacement of the proton in *(1)* by Lewis acids or transition metal ions is also well established[1].



*(1)*, R = Ph, OMe, OEt

In contrast, no evidence has been found for the thio-analogues of *(1)*. In an attempt to remedy this deficiency, we reacted [Pt($S_2CNR_2$)$_2$] *(2)* with diphenylphosphane sulfide *(3)* in alcohols and found a variety of products (Scheme 1), depending both on the amount of sulfide and water present in the reaction mixture (cf. related studies on the reaction of *(2)* with $Ph_2P(O)H$ in which the well-known [Pt($S_2CNR_2$)($Ph_2PO$)$_2$H][2] is the only product isolated).

Thus, refluxing a mixture of *(2)* with an excess of *(3)* in *dry* ethanol for 24 h gives, as the major product, the novel anions [Pt($S_2CNR_2$)($Ph_2PS$)$_2$]$^-$ *(7)*, isolated as their dialkylammonium salts. Evidence for this formulation is based on elemental analyses, conductivity measurements in methanol, $^1$H- and $^{31}$P{$^1$H}-NMR studies[3] and verification of the structure of *(7a)* by X-ray structural analysis (Fig. 1). This shows the platinum atom to be coordinated in square planar fashion by two sulfur and two phosphorus atoms. Each $NEt_2H_2^{\oplus}$ ions lies close to one [Pt($S_2CNEt_2$)($Ph_2PS$)$_2$]$^{\ominus}$ ion, making contacts N2...Pt 3.65 Å, N2...S4 3.18 Å and N2...S3 3.27 Å. All atoms on other neighbouring anions are more than 4 Å from N2. The P1, P2, S3, S4 plane is tilted 70° from the coordination plane and the sulfur atoms are 4.7 Å apart (cf. [Pd($S_2PMe_2$)($Ph_2PO$)$_2$H] where the PPOO-plane is tilted 26.1° from the metal coordination plane and the O—H—O distance is 2.41 Å[2]).



Scheme 1. Possible mode of formation of compounds *(7)*, *(8)* and *(9)* from *(2)* and *(3)*. *(a)*, R = $C_2H_5$, *(b)*, R = $iC_3H_7$.

However, if the reactions are carried out in *wet* solvents, the major products are the unique, neutral, mixed chalcogenide complexes *(8)*[3].

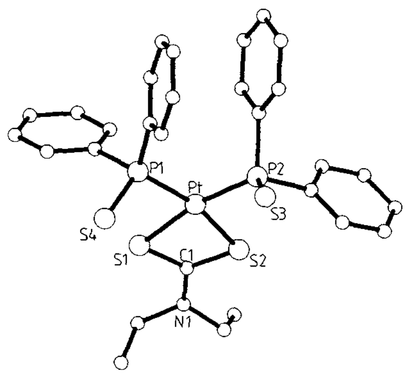


Fig. 1. Molecular structure of diethylammonium salt *(7a)* [4].

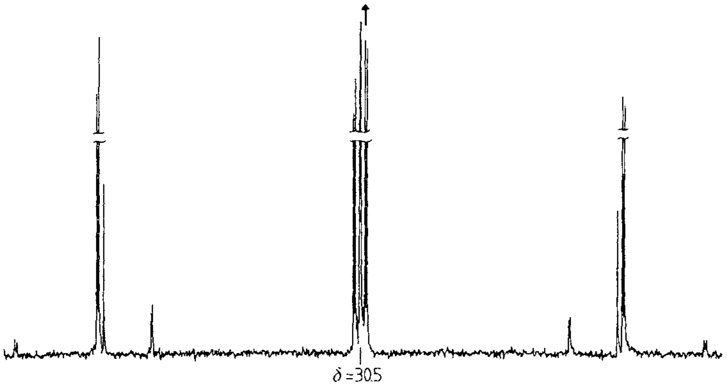

Fig. 2. $^{31}$P-{$^1$H}-NMR spectrum of *(9a)* in $CDCl_3$ at 301 K. $^1J_{PtP}$ = 3656.4, $^2J_{PtP}$ = 80.5, $^3J_{PP}$ = 13.6, $^3J_{PtPt}$ = 940 Hz.

[**] We thank the Science Research Council for a research studentship (to *D. M. A.* and Johnson Matthey Ltd. for loans of potassium tetrachloroplatinate(II).

In contrast, refluxing *(2)* and *(3)* (1:1 molar ratio) in dry ethanol gives the *binuclear* complex $[\{Pt(S_2CNEt_2)(Ph_2PS)\}_2]$ which on the basis of detailed $^{31}P\{^1H\}$-NMR studies (Fig. 2) is assigned structure *(9)*. Related complexes of platinum(I) of type $[Pt(PR_3)R_2PS]_2$ have recently been synthesized from $[Pt(PPh_3)_4]$ either by reaction with *(3)*[5] or $[R_2PS]_2$[6].

A possible rationalization of the mode of formation of compounds *(7)*, *(8)* and *(9)*, involving oxidative addition of *(3)* to *(2)* and subsequent reductive elimination of $R_2NCS_2H$ (which readily decomposes to $R_2NH$ and $CS_2$[7]), is outlined in Scheme 1.

Finally, preliminary studies show that analogous complexes can be formed starting from *(2)* and $PF_2(S)H$ and also, as for compounds of type *(1)*, their thio-analogues *(7)* and *(8)* will react with both Lewis acids and transition metal ions.

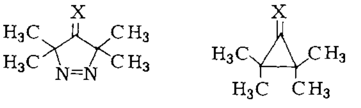
# Tetramethylcyclopropanone and Isopropylidene(dimethyl)thiirane *via* Photolysis of Reluctant 3,3,5,5-Tetramethyl-1-pyrazolines; Influence of Solvent and Temperature on the Competition between [3+2]- and [4+1]-Photocycloelimination[**]

By *Helmut Quast* and *Andreas Fuss*[*]

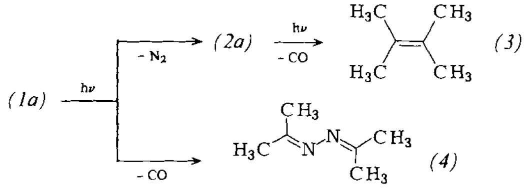
*Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday*

Photolysis of 1-pyrazolines of type *(1)* having an exocyclic double bond at C-4, still holds many surprises[1]. For example, on photolysis of the pyrazolinimine *(1b)* we recently obtained cyclopropanimine *(2b)*, but only at 90 °C[2]. This unexpected temperature dependence of the $N_2$ photoextrusion from *(1b)* encouraged reinvestigation of the long-standing problem[3a] concerning the surprising thermal *and* photochemical reluctance of 1-pyrazolinone *(1a)* [$\Phi_{313}=0.012$ in benzene at 25 °C[3b]] to lose molecular nitrogen. Furthermore, in the case of the 1-pyrazolinethione *(1d)* photolysis at *low* temperature might provide an opportunity to generate the hitherto unknown cyclopropanethione *(2d)*. So far, the *thermal* generation of reactive $C_3H_4S$-species from other precursors has inevitably led to methylenethiiranes[4], which a should be about 30 kJ/mole more stable than cyclopropanethiones[4d].



*(1)* *(2)*

*(a)*, X = O
*(b)*, X = N–CH$_2$–C(CH$_3$)$_3$
*(c)*, X = N–NH$_2$
*(d)*, X = S
*(e)*, X = SO



In view of the low quantum yield of the 313 nm photolysis of *(1a)* and the fact that the n,π* absorptions of *(1a)*[1] and cyclopropanone[5] occur in the same spectral region, a selective irradiation of *(1a)*, without excitation of the cyclopropanone product, is difficult. Therefore, *(1a)* was irradiated using an intense light source *without* a filter[6a,b]. We obtained 2,3-dimethylbutene *(3)* and acetone azine *(4)* (Table 1), and, in [D$_3$] acetonitrile, also 1—3% of the pyrazolidinone *(6)* *via* photoreduction of *(1a)* ($^1$H-NMR, GC, IR).

Table 1. $^1$H-NMR determined conversion and relative product ratio *(3)*:*(4)* in the photolysis [6a, b] of 1-pyrazolinone *(1a)*.

| Solvent | *T* [°C] | *t* [min] | Conversion [%] | Ratio *(3)* : *(4)* |
|---|---|---|---|---|
| [D$_{12}$]Cyclohexane | 10 | 60 | 52 | 63 : 37 |
| | 90 | 30 | 67 | 57 : 43 |
| [D$_6$]Benzene | 10 | 60 | 37 | 78 : 22 |
| | 90 | 30 | 63 | 64 : 36 |
| [D$_3$]Acetonitrile | 10 | 60 | 27 | 83 : 17 |
| | 90 | 30 | 55 | 68 : 32 |

2,3-Dimethylbutene *(3)* could have been formed *via* photodecarbonylation of *(2a)*. In order to trap *(2a)*, *(1a)* was irradiated in [D$_4$]methanol[6a,c,d], and after 1—6 h at 5 °C (14—97% conversion) we obtained only 1% *(3)*, 4—5% *(4)*, and 6—11% of the expected secondary product *(5)* of *(2a)*; the major products were 30—37% *(6)*, 23—27% *(8)*, and 26—29% *(9)*. Since cyclopropanols, especially alkylated derivatives, are very readily cleaved by *homolysis*[7], *(5)* reacts with triplet-state benzophenone to afford 1,1,2,2-tetraphenyl-1,2-ethanediol and the esters *(8)* and *(9)* in virtually quantitative yield. The latter arise from disproportionation of the radical *(7)*[7a]. Therefore, formation of *(6)*, *(8)* and *(9)* in approximately equal amounts suggests the existence of a relatively long-lived excited state of *(1a)*, most probably $T_1$*(1a)*, which can abstract hydrogen from the photostable[7a] hemiacetal *(5)*. An interaction between azo and carbonyl orbitals, as deduced from the photoelectron spectrum of *(1a)*, has been invoked to account for the accelerated intersystem crossing $S_1$*(1a)*$\rightarrow$$T_1$*(1a)* and hence the reluctance of *(1a)*[1].

Table 1 shows the influence of solvent and temperature on the remarkable competition between the photoextrusion of $N_2$ and CO from *(1a)*. At 5 °C in methanol, the ratio of [3+2]- versus [4+1]-cycloelimination is (92±1):(8±1). Thus, loss of nitrogen is favored by polar solvents and lower temperatures.

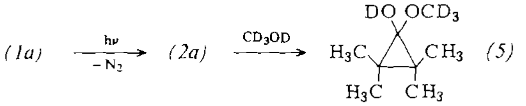
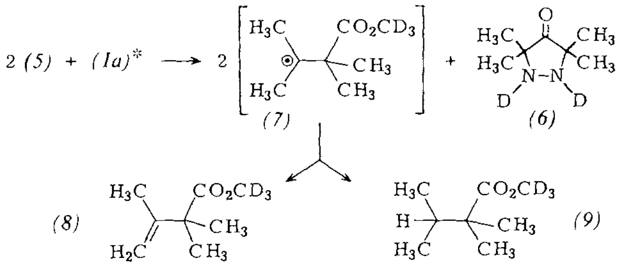
[**] Photochemical formation of methylenecyclopropane analogues. Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results are part of the prospective Dissertation of *A. F.* — Part 3: [2].

The much more efficient $[\Phi_{185}=0.63\pm0.05]$ 185 nm photolysis of *(1a)* in pentane yields only 29% *(3)* and 15% *(4)*, but 49% of 2,4-dimethylpenten-3-one, an isomer of *(2a)*[8]. After almost two decades, we have eventually succeeded in completing the final step of *Mock*'s elegant strategy for the generation of *(2a)*[3a].





The thione *(1d)* was prepared conveniently from dichlorodisulfane[9] and the hydrazone *(1c)*[10]. Both n,π* absorptions of the C=S- and N=N-chromophores of *(1d)* exhibit the expected low intensity [$\lambda_{max}$(log ε, in hexane): 234.5 (3.947), 302.5 (2.117), 342 (2.362), 529 (1.102)]. When *(1c)* was irradiated at 5 °C in [$D_{14}$]methylcyclohexane ($\lambda=350$ nm)[6a,c,e], up to 50% conversion, only one compound was formed in 74% yield (in benzene: 65% yield at 29% conversion). NMR spectra (in [$D_6$]benzene: $\delta_H=1.55$ (s, 2CH$_3$), 1.69 and 1.79 (q, $J=0.6$ Hz, CH$_3$); $\delta(^{13}C)=21.1$, 21.3 (CH$_3$), 28.3 (2CH$_3$), 46.5 (quart. C), 114.4, 130.9 (C=C)) and comparison with an authentic sample of *(10)*[4b] established the isopropylidenethiirane structure *(10)* as the photoproduct. On prolonged irradiation of *(1d)*, unidentified products emerged. In contrast to *(1a)* and *(1b)*[2], the photolysis temperature (−60 to +90 °C) had no significant influence. At −195 °C in [$D_{14}$]methylcyclohexane, however, *(1d)* was photostable. The photolysis of *(1d)* using light of wavelengths >330 nm produced a single product only up to 26% conversion. Moreover, on irradiation of 1-pyrazolinethione-*S*-oxides of type *(1e)* at 0 °C in benzene, the corresponding isopropylidenethiirane-*S*-oxides were obtained in 13—17% yields[11].

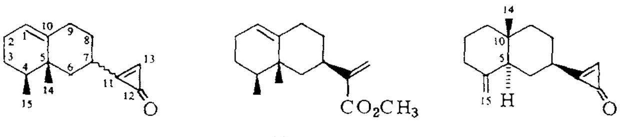
## Naturally Occurring Cyclopropenone Derivatives[**]

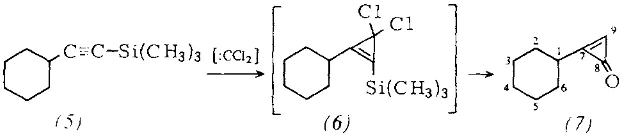
By *Ferdinand Bohlmann, Jasmin Jakupovic, Lutz Müller,* and *Angelika Schuster*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

The overground part of *Telekia speciosa* (Schreb.) Baumg. (Compositae, Tribus Innulae) contains, besides numerous sesquiterpene derivatives[1], two difficultly separable, relatively polar compounds of empirical formula $C_{15}H_{20}O$ which, according to the IR spectrum, however, are not alcohols. The main component reacts with methanol in the presence of 4-pyrrolidinopyridine[2] to give the well known methyl ester *(3)*[3]. IR ($\nu$=1840 and 1588 cm$^{-1}$) and $^1$H-NMR spectroscopic data ($\delta$=8.46, d, $J$=1.5 Hz) indicate presence of the cyclopropenone derivative *(1)*. The $^1$H-NMR signals of *(1)* can be completely assigned by spin-decoupling. The $^{13}$C-NMR spectrum is also consistent with structure *(1)*.



*(1)*, 7α-H *(2)*, 7β-H *(3)* *(4)*



Since no data were available for monosubstituted cyclopropenones, we prepared cyclohexylpropenone *(7)* by addition of dichlorocarbene to *(5)*. The dichloro compound *(6)* probably occurring as an intermediate hydrolyzes even during work-up, giving moderate yields of *(7)*, whose $^1$H- and $^{13}$C-NMR spectroscopic data correspond very well with those of the natural product (Table 1). The stereochemistry at 7-H in *(1)* follows from the coupling constants and the stereochemistry of *(3)*. Noteworthy is the extreme downfield shift of the $^{13}$C-NMR signals of C-11 in the case of *(1)* and of C-7 in the case of *(7)*, which may be due, *inter alia*, to the dis-

*(4)*, IR ($CCl_4$): $\nu = 1835, 1600\ cm^{-1}$; MS: $m/e = 216.151$ ($M^+$, 3%), 201 (11), 188 (21), 173 (45), 91 (100); $[\alpha]^{24} = +22$ ($\lambda = 589$ nm), $+24$ (578), $+25$ (546), $+34$ (436) ($c = 0.1$, $CHCl_3$)

[a] Coupling constants *J* [Hz]: *(1)*: 1,2α = 1,9 = 2; 1,2β = 5; 2,9 = 2; 4,15 = 6.2; 6α,6β = 14; 6α,7 = 6; 6β,7 = 2.5; 6β,8β = 2.5; 7,8α = 4.5; 7,8β = 8β,9α = 8β,9β = 2.4; 7,13 = 1.5; 8α,9α = 4.5; 8α,9β = 8α,8β = 13; 9α,9β = 14; *(2)*: 1,2 = 5; 4,15 = 6.5; 6α,6β = 13.5; 6α,7 = 11; 6β,7 = 3.5; 6β,8β = 2; 7,8α = 13; 7,8β ≈ 1; 8α,8β = 8α,9β = 13; 8α,9α = 4; 9α,9β = 15; *(4)*: 3,15 = 5,15 = 15,15′ ≈ 1,5; 5,6β = 12.5; 6α,7 = 7,8α = 4; 6β,7 = 7,8β = 12.5; *(7)*: 1,2α = 1,6α = 3.5; 1,2β = 1,6β = 9.5. [b] RDA = Retro-Diels-Alder cleavage.

According to the $^1$H-NMR data (Table 1) the second component is undoubtedly the eudesmane derivative *(4)*. Although, only few signals are interpretable by 1st order rules the spectrum is, nevertheless, very similar to that of the corresponding eudesmane. The allyic coupling for 13-H is missing; however, the chemical shift of 13-H is almost the same as that in the case of *(1)*.

We have also isolated *(1)* from *Lychnophora passerina* Gardn. (Compositae, Tribus Vernonieae), as well as an isomeric cyclopropenone which may have the structure *(2)*. The altered couplings for 7-H show that the cyclopropenone moiety in *(2)* must be arranged equatorially. The $^1$H-NMR data of *(2)* (Table 1) are similar to those of *(1)*. Only the chemical shifts of 6-H and 8-H are somewhat different from those of *(1)*, since the deshielding effects operate differently owing to the changed stereochemistry, as can be deduced from Dreiding models. *(1)*, *(2)* and *(4)*, are the first naturally occurring cyclopropenone derivatives.

*Experimental*

The overground parts of the plants were extracted with ether/petroleum ether and the extracts worked up by column chromatography and by TLC ($SiO_2$). 1.5 kg of overground parts of *Telekia speciosa* gave 25 mg of *(1)* and 3 mg of *(4)* [TLC: ether/petroleum ether (1:1)], 650 g of overground parts of *Lychnophora passerina* gave 10 mg of *(1)* and 6 mg of *(2)*, while 8 mg of *(1)* and 6 mg of *(2)* were isolated from 100 g of roots. *(1)* and *(2)* are colorless oils.

*(7)*: To a solution of 100 mg of *(5)* (prepared by reaction of 1,1-dibromo-2-cyclohexylethylene with *n*-butyllithium at −78 °C and subsequent treatment with chlorotrimethylsilane) in 5 $cm^3$ $CHCl_3$ is added 15 mg of benzyl(triethyl)ammonium chloride and the stirred mixture treated dropwise at 20 °C with 5 $cm^3$ 50% NaOH solution. After 2 h the mixture is poured into 100 $cm^3$ of $H_2O$, taken up in ether, and the residue obtained on evaporation purified by TLC (ether); yield: 60 mg *(5)* and 8 mg *(7)*.

## Biosynthesis of Natural Porphyrins: Studies with Isomeric Hydroxymethylbilanes on the Specificity and Action of Cosynthetase[**]

By *Alan R. Battersby*, *Christopher J. R. Fookes*, *George W. J. Matcham* and *Pramod S. Pandey*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

Uroporphyrinogen-III *(4)* is the precursor of the natural porphyrins, chlorins and corrins and its biosynthesis from porphobilinogen *(1)* requires the enzymes deaminase and cosynthetase[1]. The biosynthesis involves the building of an unrearranged tetrapyrrole, the bilane derivative[3,4] *(2)*, followed by a single *intramolecular* rearrangement[2,3]. An enzymic replacement of the amino function of *(2)*, $X = \overset{+}{N}H_3$ and of *(1)* by another nucleophile [shown as X in *(2)*] before the final cyclization with rearrangement is discussed *e.g.* in[3]. With deaminase acting alone on porphobilinogen *(1)*, the product released is the unrearranged hydroxymethylbilane[5,6,7] *(3)*. Natural and synthetic[5] *(3)* were identical substrates for cosynthetase and the product was uroporphyrinogen-III *(4)*.

The foregoing knowledge and synthetic methodology made it possible to probe the action of cosynthetase by syn-

thesizing hydroxymethylbilanes, which are isomeric with the natural substrate. Four bilanes were constructed: the reversed ring-B *(6)*, reversed ring-C *(7)*, reversed ring-D *(8)* and *(9)*, in which rings A, B and C have been reversed relative to the natural, unrearranged hydroxymethylbilane *(3)*. Similar synthetic routes were used for all four and the approach for the reversed ring-D bilane *(8)* is illustrated. The five formyl bilane esters as *(10)*, were shown to be isomerically pure by HPLC and were characterized by mass spectrometry and NMR.

The freshly prepared, derived bilanes *(3)* and *(6)*—*(9)* were then incubated separately (pH = 8.25) with cosynthetase, free from deaminase, which had been isolated from *Euglena gracilis;* non-enzymic ("chemical") ring-closure of each bilane was carried out at the same pH. The unrearranged hydroxymethylbilane *(3)* was included in the set of experiments as a standard.

It was found that the natural unrearranged hydroxymethylbilane *(3)* was by far the best substrate for cosynthetase but interestingly, the cyclizations of reversed-C *(7)* and reversed-D *(8)* bilanes were also enzymically accelerated. In contrast, the reversed-B *(6)* and reversed A, B, C *(9)* bilanes did not

act as substrates (see Table 1). The products from the action of cosynthetase on bilanes *(3)*, *(7)* and *(8)*, and also from chemical ring-closure at pH 8.25, were analyzed by HPLC[5]. The results (see Table 1) showed in each case that chemical ring-closure occurred with essentially no rearrangement. Importantly, *ca.* one third of the enzymic product from the reversed ring-D bilane *(8)* was uroporphyrinogen-I *(5)* arising from enzymic inversion of the terminal ring-D. Knowing the isomeric composition of the product and also the chemical and enzymic rates of ring-closure, it can be calculated that *ca.* 45% of bilane *(8)*, ring-closed by cosynthetase, undergoes ring-D reversal to produce uroporphyrinogen-I *(5)*. Although the reversed ring-C bilane *(7)* is a relatively poor substrate for cosynthetase, similar calculations show that in this case, the ring-closure promoted by cosynthetase, nevertheless, occurs with efficient formation (>95%) of uroporphyrinogen-IV *(11)*, presumably from inversion of the terminal ring[8].

These results interlock with those obtained earlier[9], in which deaminase and cosynthetase acted together on members of a set of isomeric aminomethylbilanes (*2*, $X{=}\overset{+}{N}H_3$ and isomers). Interpretation of these early experiments was complicated by the fact that two enzymic steps were involved; thus, conversion of any of the aminomethyl into hydroxymethyl bilanes by deaminase[4] would enhance the rate of uroporphyrinogen formation, even when cosynthetase is not involved, as is the case for the reversed ring-B bilane *(6)*. The present work focuses attention on cosynthetase alone and shows the following: (a) Cosynthetase is not an absolutely specific enzyme, but all the studied modifications of pyrrole rings produced a substantial adverse effect on affinity, rate of reaction and/or efficiency of the inversion process. (b) Cosynthetase has evolved to invert the terminal ring during ring-closure of the natural hydroxymethylbilane *(3)* and will do a similar inversion when an isomeric hydroxymethylbilane acts as a substrate *e.g.* it does so efficiently (but slowly) with bilane *(7)* as substrate. (c) Cosynthetase will even partially turn back the terminal ring of bilane *(8)* in which ring-D had already been inverted by synthesis. This result excludes the possibility that formation of uroporphyrinogen-III *(4)* from the regular hydroxymethylbilane *(3)* involves rearrangement of *(3)* into *(8)* as a first step.

[7] The intermediate released by deaminase was also observed independently in Texas and the natural material was shown to be a substrate for cosynthetase (see *G. Burton, P. E. Fagerness, S. Hosozawa, P. M. Jordan, A. I. Scott*, J. Chem. Soc. Chem. Commun. *1979*, 202) but it was wrongly concluded that its structure is an *N*-alkylpyrrole macrocyclic system (see *G. Burton, H. Nordlöv, S. Hosozawa, H. Matsumoto, P. M. Jordan, P. E. Fagerness, L. M. Pryde, A. I. Scott*, J. Am. Chem. Soc. *101*, 3114 (1979).

[8] In principle, uroporphyrinogen-IV could also be formed from bilane *(7)* by inversion of ring-B but the sum of evidence points to this being highly unlikely.

## "Chemical Mutation" by Amino Acid Exchange in the Reactive Site of a Proteinase Inhibitor and Alteration of Its Inhibitor Specifity[**]

By *Herbert R. Wenzel* and *Harald Tschesche*[*]

*Dedicated to Professor Gerhard Pfleiderer on the occasion of his 60th birthday*

Low-molecular weight protein proteinase inhibitors inhibit serine-proteinases by reversible, substrate-analogous association at the active center of the enzyme[2]. The specificity of an inhibitor is determined by the geometry of the amino acid residues at the contact surface and in most cases dominated by the amino acid $P_1$[3a,3b] in its reactive center. This is supported by comparison of the sequences of homologous inhibitors[4a] and in two cases by semisynthetic amino acid replacements[4b]: thus, by enzymatic reactions $P_1 = Arg$ could be replaced by Lys in the soybean inhibitor (Kunitz) and $P_1 = Lys$ by Arg in the inhibitor from bovine organs. The anti-tryptic activity of both proteins was preserved. Replacement of the basic amino acids by Trp converted the two inhibitors with primary specificity against trypsin into inhibitors with primary specificity against chymotrypsin. The "enzymatic mutation" has so far only been used with success in the case of basic and aromatic amino acids, since no suitable enzyme system could be found for other amino acids.

We describe here a method which enables insertion of almost every amino acid in the position $P_1$ of the inhibitor (Kunitz) from bovine organs by a peptide-chemical method. The natural inhibitor ($P_1 = Lys^{15}$) inhibits trypsin extremely strongly, chymotrypsin strongly, leukocytic elastase scarcely, and pancreatic elastase not at all. (A projection of the α-carbon atoms of the inhibitor is shown in[5].)

The $Lys^{15}$—$Ala^{16}$ peptide bond in the reactive site of the native inhibitor is hydrolyzed according to previously described methods; with carboxypeptidase B one then obtains the inactive modified des-$Lys^{15}$ inhibitor[6]. Water-soluble carbodiimides enable coupling of Val—OMe with the free carboxyl group of $Cys^{14}$[7] (Scheme 1).

The product is an excellent inhibitor for elastase from human leukocytes. The maximum inhibition is only reached after several minutes; obviously the complex between elastase and $Val^{15}$-inhibitor is formed relatively slowly. If this complex is dissociated by drastic lowering of the pH (kinetically controlled dissociation), an inhibitor is obtained which immediately inhibits elastase to the maximum. This finding suggests resynthesis of the peptide bond $Val^{15}$—$Ala^{16}$ by the proteinase during the complex formation[8].

The semisynthesis has so far also been carried out according to the same procedure with the methyl esters of Arg, Phe, Met, Leu, Ala and Gly. According to the amino-acid analysis of the crude material about 2.2 to 4.1 amino acids were inserted per inhibitor molecule, up to 0.3 thereof in the decisive position $P_1$, *i.e.* 30% yield. The other part was coupled to the five carboxy groups ($Asp^3$, $Glu^7$, $Glu^{49}$, $Asp^{50}$, $Ala^{58}$) already present in the unmodified inhibitor. These are so far removed from the reactive site, that their derivatization has hardly any influence on the inhibitor activity.

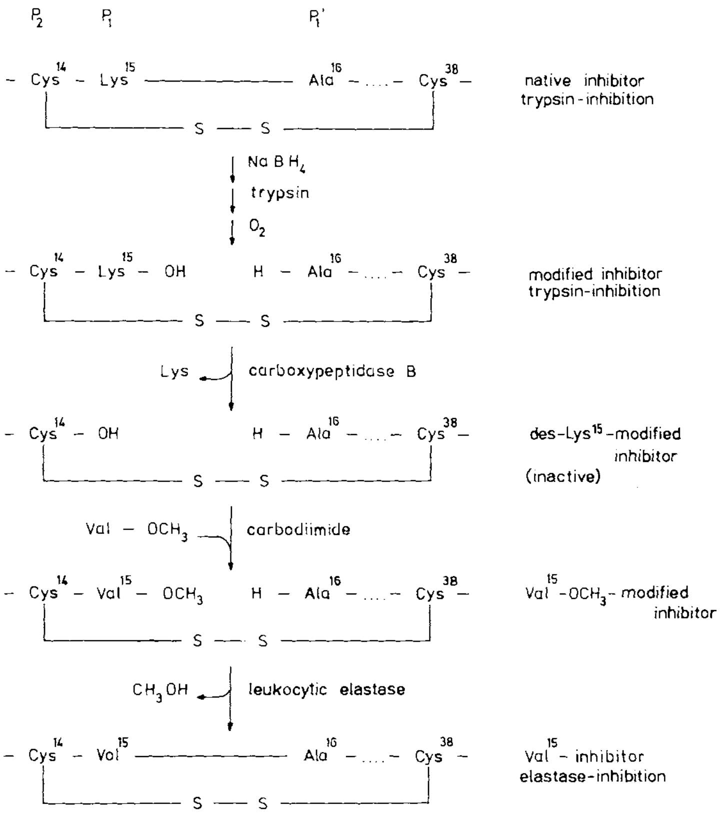
Fakultät für Chemie, Lehrstuhl Biochemie der Universität
Postfach 8640, 4800 Bielefeld 1 (Germany)

[**] Delivered in part in a lecture at the Spring Conference of the Gesellschaft für Biologische Chemie, Münster, March 1980 [1]. This work was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Fonds der Chemischen Industrie. We thank Bayer AG for supplying us with Trasylol® [Trypsin-Kallikrein® inhibitor (Kunitz) from bovine lung].



Scheme 1. Replacement of Lys$^{15}$ by Val in the position P$_1$ of the inhibitor (Kunitz) from bovine organs.

The inhibitor specificity of the new semisynthetic inhibitors can be largely predicted from the residue P$_1$ and from the known cleavage specificity of the individual proteinases: The insertion of Arg restores the original anti-tryptic activity. Introduction of Phe or Met leads to strong chymotrypsin inhibitors which also still weakly inhibit trypsin. Moreover the Met$^{15}$ inhibitor also weakly inhibits the elastases from porcine pancreas and human leukocytes. A strong inhibitor against both elastases and chymotrypsin is obtained by insertion of Leu, trypsin is then only weakly inhibited. The Val$^{15}$-inhibitor appears to be more specific; it shows strong activity against human leukocyte-elastase and weak activity against trypsin, chymotrypsin, and porcine pancreas-elastase. All four enzymes are only weakly inhibited by the Ala$^{15}$ inhibitor. Surprisingly the Gly$^{15}$ inhibitor shows no elastase-, but good chymotrypsin-, and excellent trypsin-inhibition.

The peptide-chemical method represents an important extension to the methods for the semisynthesis of proteinase inhibitors, and allows further detailed investigation of the relationship between sequence and reactivity of these proteins.

### *Procedure*

A solution of 100 mg of modified des-Lys$^{15}$ inhibitor (Kunitz) from bovine organs[6], 20 mmol amino acid methyl ester hydrochloride, 200 mg *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride, and 400 mg *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide-methyl *p*-toluenesulfonate in 20 cm$^3$ water is allowed to react with stirring in an autotitrator at constant pH = 4.75 (addition of 0.5 M HCl)[7]. After cessation of reaction the inhibitor is separated by gel filtration on Sephadex G-25 fine (eluting reagent 0.1 M acetic acid) from low-molecular substances and high-molecular protein aggregates.

## Novel 4-Amino-2-azabutadienes and 1-Aminobutadienes; Syntheses of Pyridines, Benzenes, and Azoles[**]

By *Rudolf Gompper* and *Ulrich Heinemann*[*]

2-Aza-1,3-butadienes have been prepared for a variety of purposes during the past ten years; only very few 1-amino-[1] and 1-alkoxy-2-azabutadienes[2] have so far been used for the preparation of pyridines by Diels-Alder reactions. On the other hand, numerous interesting [4+2]-cycloadditions of donor-substituted 1,3-dienes are known (cf. [3]). Further methods for the preparation of donor-substituted 2-azabutadienes would therefore seem desirable.

In connection with our studies on the reactions of 1-acceptor-substituted vinamidinium salts[4] we have found that the azomethines *(1)*[5] can be converted into 4-amino-2-azabutadienes *(2)* by heating with dimethylformamide diethylacetal (Tables 1 and 2).

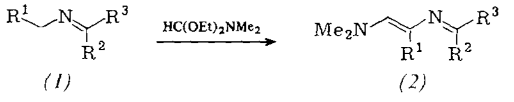

Table 1. Synthesized 4-amino-2-azabutadienes *(2)*.

| *(2)* | R$^1$ | R$^2$ | R$^3$ | Yield [%] | M.p. [°C] |
|---|---|---|---|---|---|
| *a* | $CO_2Me$ | H | $C_6H_5$ | 83 | 99—100 |
| *b* | $CO_2Me$ | H | $p$-$ClC_6H_4$ | 70 | 112—114 |
| *c* | $CO_2Me$ | H | $p$-$MeC_6H_4$ | 82 | 86—88 |
| *d* | $CO_2Me$ | H | $p$-$Me_2NC_6H_4$ | 58 | 138—139 |

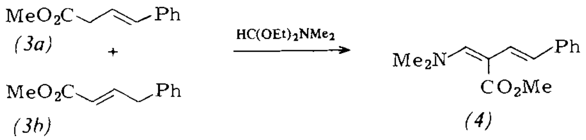
[a] *(2g)* could only be obtained with $[Me_2NCHCl]^+Cl^-$ in presence of $NEt_3$ [8].
[b] B.p. 140 °C/10$^{-2}$ mbar (Kugelrohr).

By the same method a mixture of the esters *(3a)* and *(3b)*[6] affords the 1-aminobutadiene *(4)*. Preliminary experiments

---

[*] Prof. Dr. R. Gompper, Dr. U. Heinemann
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.



have also shown that other orthocarboxylic acids and orthocarboxylic acid derivatives as well as carbenium salts derived therefrom can be condensed with *(1)* and related compounds.

The novel 4-amino-2-azabutadienes *(2)* and the aminobutadiene *(4)* are suitable as starting materials for the preparation of heteroarenes and arenes, respectively. On reaction with acetylenedicarboxylate, *(2a, b, c)* afford the 6-aryl-2,4,5-pyridinetricarboxylates *(5a, b, c)*, while *(4)* affords the 2,3,5-biphenyltricarboxylate *(6)*, which on treatment with conc. sulfuric acid furnishes the anhydride *(7)* (Table 2).

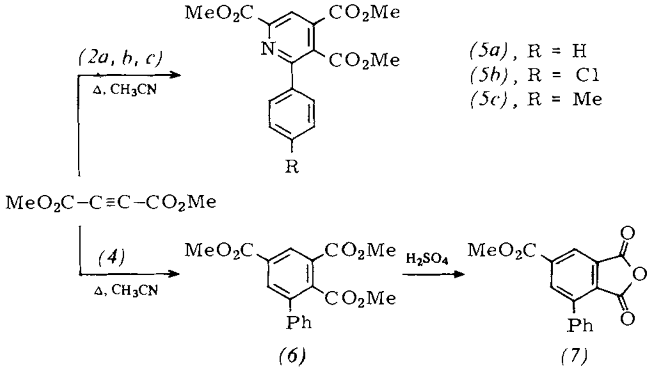


Table 2. Some data of the compounds of type *(2)* and *(4)* to *(10)*.

*(5b)*: yield 38%; m.p. = 96—98 °C

*(5c)*: yield 15%; m.p. = 88—90 °C

*(6)*: yield 35%; m.p. = 79—80 °C

*(7)*: yield 96%; m.p. = 189—191 °C; $^1H$-NMR ($CDCl_3$): $\delta = 4.07$ (s, 3 H, $OCH_3$), 7.61 (s, 5 H), 8.56 (d, $J = 1$ Hz; 1 H), 8.66 (d, $J = 1$ Hz, 1 H)

*(8)*: yield 86%; m.p. = 90—91 °C; IR (KBr): 1720 $cm^{-1}$; $^1H$-NMR ($CDCl_3$): $\delta = 2.74$ (s, 3 H, $SCH_3$), 3.96 (s, 3 H, $OCH_3$), 8.25 (s, 1 H)

*(9)*: yield 85%; m.p. = 88—89 °C

*(10a)*: yield 22%; m.p. = 128—129 °C

*(10b)*: yield 38%; m.p. = 72—74 °C

The azabutadienes *(2f, g)* can also be used for the synthesis of azoles. For example, if the solution of *(2f)* in tetrahydrofuran is treated with dil. hydrochloric acid and the mixture heated to boiling the methyl 2-methylthio-4-oxazolecarboxylate *(8)* is obtained. The thiazole derivative *(9)*[7] is formed in the same way in high yields when hydrogen chloride is passed into the solution of *(2f)* in tetrahydrofuran at room temperature followed by hydrogen sulfide at elevated temperature. Finally, the imidazoles *(10a)* and *(10b)*, respectively, are obtained on heating *(2f)* with the respective amine hydrochlorides in dioxane-dimethylformamide or dimethylformamide.

## Aminopyridines, Aminpyrimidines, and Tris(dimethylamino)benzene from (Aza)Vinamidinium and (Aza)Pentamethinium Salts[**]

By *Rudolf Gompper* and *Ulrich Heinemann*[*]

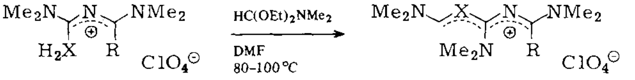
Pentamethinium salts, which can be prepared, *inter alia*, by reaction of 1-methylvinamidinium salts with dimethylformamide-diethylacetal[1a], can be converted by ammonium chloride into pyridines[1]. According to this synthetic principle, pyrimidines should be obtainable *via* 2-azapentamethinium salts *(2)* if 1-methyl-2-azavinamidinium salts *(1)*[2] are used as starting materials. 1-Methylvinamidinium salts and the corresponding 2-aza-derivatives, on the other hand,

---

[*] Prof. Dr. R. Gompper, Dipl.-Chem. U. Heinemann
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

should also react directly *via* intermediary (2-aza)hexatrienes to give benzene- and pyridine-derivatives, respectively. This would provide a simple method for the synthesis of electron-rich six membered (hetero)arenes.



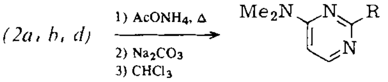
*(1)*, X = CH
*(3)*, X = N
*(2)*, X = CH
*(4)*, X = N

Table 1. Synthesized azamethinium salts *(2)* and *(4)*.

| | R | M.p. [°C] | UV (CH$_2$Cl$_2$) $\lambda_{max}$ [nm] (lg $\varepsilon$) | Yield [%] |
|---|---|---|---|---|
| *(2a)* | H | 125—126 | 278 (4.17), 319 (4.56) | 84 |
| *(2b)* | Ph | 148—149 | 283 (4.04), 325 (4.51) | 74 |
| *(2c)* | Me | 95—97 | 320 (4.55) | 83 |
| *(2d)* | NMe$_2$ | 99 | 268 (4.11), 319 (4.42) | 89 |
| *(4)* | H | 107—108 | 269 (4.55) | 90 |

Reaction of the 1-methyl-2-azavinamidinium salts *(1)* with dimethylformamide diethylacetal affords the 2-azapentamethinium salts *(2)* in good yields. In an analogous way the 1-amino-2-azavinamidinium salt *(3)*[3] affords the 2,4-diazapentamethinium salt *(4)* (Table 1).

On heating with ammonium acetate the salts *(2a, b, d)* are converted into the pyrimidines *(5)* (Table 2).



*(5a)*, R = H
*(5b)*, R = Ph
*(5c)*, R = NMe$_2$

Table 2. Some data of the compounds of type *(5)*—*(7)*.

*(5a)*: yield 56%, b.p. 60 °C/0.1 mbar ([4a] 131—132 °C/67 mbar)

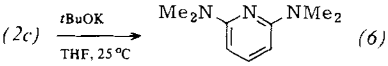
*(5b)*: yield 70%, m.p. 71—72 °C ([4b] 70 °C)

*(5c)*: yield 43%, m.p. 54—55 °C ([4c] 47—49 °C)

*(6)*: yield 57%, b.p. 140 °C/0.01 mbar, m.p. 33—34 °C

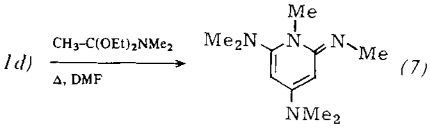
*(7)*: yield 66%, m.p. 90—93 °C (dec.); IR (KBr): 1588, 1563 cm$^{-1}$; $^1$H-NMR (CDCl$_3$): $\delta$ = 2.96 (s) and 3.06 (s) (18 H), 5.22 (s, 1 H), 5.73 (s, 1 H)

The last ring member required for the cyclization of *(2)* to a six-membered ring—introduced by ammonia in the case of *(2a, b, d)*—is already contained in the molecule as methyl group in the case of *(2c)*. Accordingly, treatment of *(2c)* with potassium *tert*-butoxide in tetrahydrofuran leads, presumably *via* an azahexatriene as intermediate[5], to the (no physical data given[6]) 2,6-bis(dimethylamino)pyridine *(6)* (Table 2).



The reaction of *(2c)* to give *(6)* has a parallel in the formation of 3-chloroanisole along with 2,4-dichlorobenzaldehyde from 4-methoxy-3-penten-2-one and dimethylformamide-phosphorus oxide chloride[7], when, however, no intermediates were isolated.

A modification of the method for the preparation of *(6)* and related compounds consists, *e.g.* in heating *(1d)* with *N,N*-dimethylacetamide diethylacetal instead of with dimethylformamide acetal. Reaction *via* azapentamethinium and azahexatriene intermediates, however, does not lead to the expected 2,4,6-tris(dimethylamino)pyridine, but to 4,6-bis(dimethylamino)-1-methyl-2-methylimino-1,2-dihydropyridine *(7)* (Table 2).



This method can also be used for the formation of a pyridine ring according to the [4+2]-scheme, and for preparation of benzene derivatives. On heating the vinamidinium salt *(8)*—prepared in analogy to the method described in ref. [8] from 1,1-bis(dimethylamino)ethylene and *N,N*-dimethylacetamide- dimethyl sulfate in dichloromethane (yield 70%, m.p. 104—105 °C)—with an excess of *N,N*-dimethylacetamide diethylacetal in dimethylformamide, the 1,3,5-tris(dimethylamino)benzene *(9)*, first synthesized by *Effenberger* and *Niess*[9], is obtained in quantitative yield. The process can also be carried out as a "one-pot" reaction by heating the *N,N*-dimethylacetamide-dimethyl sulfate adduct with an excess of 1,1-bis(dimethylamino)ethylene and *N,N*-dimethylacetamide diethylacetal in dimethylformamide; *(9)* is formed in 77% yield. *(9)* is even obtained, though so far only in a yield of 15%, on heating *N,N*-dimethylacetamide diethylacetal with a catalytic amount of boron trifluoride-ether.

## σ-Framework Radical Cations — A Novel Type of Reactive Intermediates[**]

By *Peter Gölitz* and *Armin de Meijere*[*]

*Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 75th birthday*

In polycyclic systems containing both a carbenium ion and a radical center at two bridgehead positions, an interaction

---

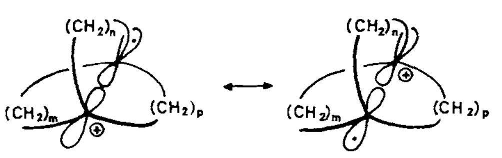
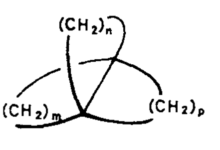
0570-0833/81/0303-0298 $ 02.50/0

between these could lead to a delocalization of the unpaired electron. Such radical cations *(1)* would then correspond to propellanes *(2)*, whose molecular orbital responsible for the central bond is occupied by only one electron.



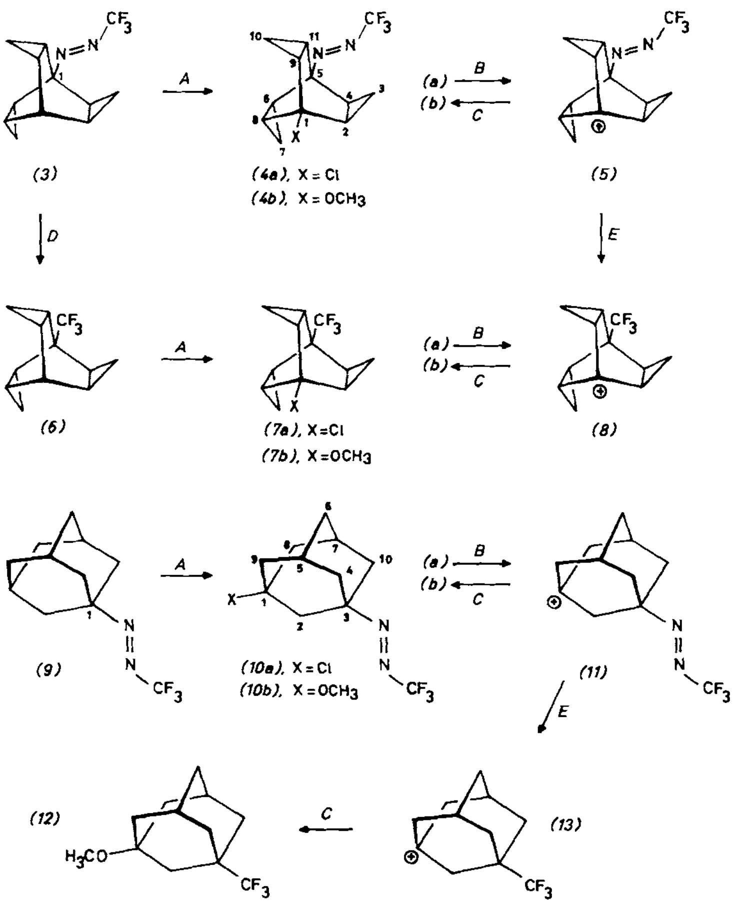
*(1)*



*(2)*

Although numerous propellanes[1], bridgehead carbenium ions[2] and also bridgehead radicals[3] have been generated and investigated, no example of type *(1)* has yet been described in the literature; so far only semiempirical quantum chemical calculations for such a system have been mentioned[4].

This is a report on a novel general method by which radical cations of hydrocarbons with a pure $\sigma$-bond framework can be generated. Possible precursors for such species are polycyclic molecules which contain a "nucleofugic" and a "radicofugic" leaving group on two bridgehead positions. The trifluoromethylazo group is particularly well suited as a radicofugic leaving group. Thus, because of their relatively high photostability, the trifluoromethylazo-derivatives[5] of trishomobarrelene *(3)* and adamantane *(9)* can readily be photochlorinated with *tert*-butyl hypochlorite to their difunctional derivatives *(4a)* (59% yield) and *(10a)* (25%), respectively (Scheme 1)[6]. In the reaction of *(4a)* and *(10a)* with antimony pentafluoride in sulfonyl chloride fluoride[7] the trifluoromethylazo group shows excellent stability towards Lewis acids; at −100 to −80 °C, solutions of the bridgehead carbenium ions *(5)* and *(11)*, respectively, were obtained with intact $CF_3N_2$ groups, which were characterized by their $^1$H- and $^{13}$C-NMR spectra (see Table 1). The solution of *(5)*—but not of *(11)*—could be kept at −10 °C for 1 h without any observable decomposition, yet another confirmation of the unusual stability of bridgehead carbenium ions with the trishomobarrelene skeleton[8]. Reactions of *(5)* and *(11)* with sodium methoxide/methanol solution at −70 °C afforded only the unrearranged methoxy(trifluoromethylazo) derivatives *(4b)* and *(10b)*, respectively.



Solutions of the carbenium ions *(5)* and *(11)* were each irradiated at −80 °C for 18 h with a 500-W mercury high-pressure lamp[9]. Although a considerable amount of polymeric products was formed in both cases, the newly recorded $^{13}$C-NMR spectrum of the solution of *(5)* showed all the signals doubled except that for the substituted bridgehead C-atom. The $^{13}$C-NMR spectrum of the 5-trifluoromethyltrishomobarrelenyl cation *(8)* independently generated from *(6)*[5] *via (7b)* proved that the new signals in the spectrum of the irradiated solution of *(5)* belonged to *(8)*. Upon quenching, this solution yielded 1-methoxy-5-trifluoromethyltrishomobarrelene *(7b)* (7%) besides *(4b)* (15%). The irradiated solution of the adamantyl cation *(11)* was treated analogously, but, due to a large proportion of polymeric substances, no $^{13}$C-NMR spectrum could be recorded. The reaction with sodium methanolate/methanol, however, afforded both *(10b)* (14%) as well as the methyl ether *(12)* (12%).

The formation of trifluoromethyl radical-recombination products *(8)* and *(13)* during photolytic cleavage of the $CF_3N_2$-substituted carbenium ions *(5)* and *(11)*, is a clear indication of the intermediary cage radical cations *(14a)* and *(15a)*. So far, nothing is known about the lifetime of these

Table 1. $^1$H- and $^{13}$C-NMR spectroscopic data ($\delta$ values, TMS int.) and melting points of the novel trishomobarrelene and adamantane derivatives. All the new compounds gave correct elemental analyses and IR spectra.

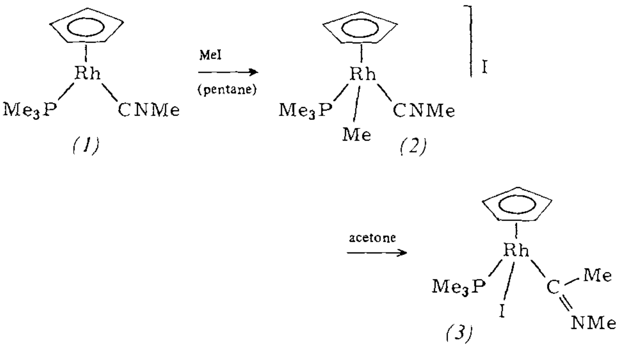
## Cobaltaheterocycles by [3+2]-Cycloaddition of an Acetimidoylcobalt Complex with Acetone and Acetonitrile[1]

By *Helmut Werner, Bernd Heiser*, and *Alfred Kühn*[*]

*Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday*

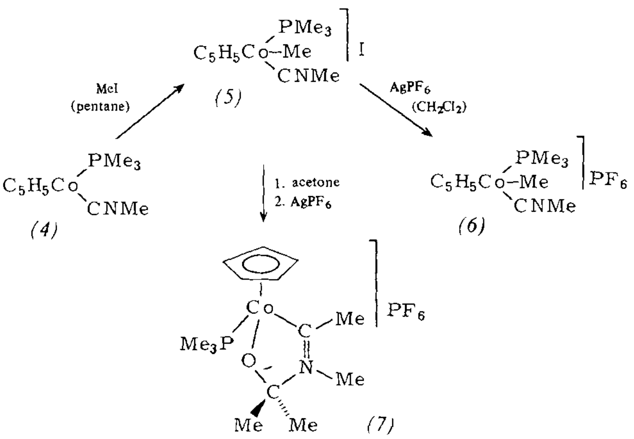
The series of Lewis-base half-sandwich compounds of the type $C_5H_5Co(PMe_3)L$ ($L = PMe_3$, $PPh_3$, $P(OR)_3$[2], CO, CS[3]) was recently extended by the synthesis of the isocyanide complexes $C_5H_5M(PMe_3)CNR$ (M = Co, Rh; R = Me, *t*Bu, Ph)[1]. Since the donor-acceptor properties of isocyanides and CO are similar[4], we expected that the reactions of $C_5H_5M(PMe_3)CNR$, *e.g.* with iodomethane, would proceed analogously to those of the carbonyl complexes $C_5H_5M(PMe_3)CO$ (M = Co[3a], Rh[5]).

This expectation is fulfilled in the case of the methyl isocyanide-rhodium complex *(1)*. Reaction with iodomethane in pentane initially yields initially the salt-like compound *(2)*, which on stirring in acetone (4 h, 50 °C) is transformed, with migration of the methyl group from the metal to the isocyanide carbon, into the acetimidoyl complex *(3)*.



(1) (2) (3)

The first step in the reaction of the methyl isocyanide-cobalt complex *(4)* with iodomethane probably proceeds analogously to that of *(1)*. A yellow solid is obtained whose IR spectrum [$\nu(CN) = 2203\ cm^{-1}$, in nujol] is consistent with the composition *(5)*. The complex *(5)* is unstable in solvents such as $CH_3NO_2$ or $CH_2Cl_2$, but can be converted into the



(4) (5) (6) (7)

Table 1. Spectroscopic data of the reaction products ($^1$H-NMR: $\delta$ values, TMS int., $J$ in Hz; IR nujol, values in $cm^{-1}$).

| Complex | $^1$H-NMR Solvent | $C_5H_5$ | $P(CH_3)_3$ | $NCH_3$ [a] | $XCH_3$ | IR $\nu$(CN) |
|---|---|---|---|---|---|---|
| *(2)* | $(CD_3)_2CO$ | 5.80 "t"<br>$J_{RhH} = J_{PH} = 0.6$ | 1.85 d × d<br>$J_{RhH} = 1.0$<br>$J_{PH} = 11.7$ | 3.75 | 0.83 d × d (X = Rh)<br>$J_{RhH} = 1.1$<br>$J_{PH} = 2.5$ | 2200 |
| *(3)* | $(CD_3)_2CO$ | 5.43 d × d<br>$J_{RhH} = 0.6$<br>$J_{PH} = 1.6$ | 1.78 d × d<br>$J_{RhH} = 0.9$<br>$J_{PH} = 11.5$ | 3.20 | 2.87 (br) (X = C) | |
| *(6)* | $CD_3NO_2$ | 5.17 d<br>$J_{PH} = 0.5$ | 1.57 d<br>$J_{PH} = 11.1$ | 3.47 | 0.73 d (X = Co)<br>$J_{PH} = 3.0$ | 2203 |
| *(7)* | $CD_3NO_2$ | 5.30 d<br>$J_{PH} = 0.5$ | 1.55 d<br>$J_{PH} = 11.8$ | 3.03 | 3.33 (br) [b]<br>1.37 s<br>1.30 s | 1560 |
| *(9)* [c] | $(CD_3)_2CO$ | 5.19 d<br>$J_{PH} = 0.4$ | 1.44 d<br>$J_{PH} = 11.5$ | 3.14 s | 2.20 s (X = C) | [d] |

[a] Relative to broad signal, except in the case of *(9)*. [b] Signal of the methyl group on the C-atom $\alpha$ to cobalt. [c] Protons of the exocyclic $CH_2$-group give rise to two doublets of doublets at $\delta = 5.01$ ($J_{PH} = 4.4$, $J_{HH} = 2.5$ Hz) and 4.59 ($J_{PH} = 3.2$, $J_{HH} = 2.5$). [d] Three bands for $\nu$(CN) and $\nu$(CC) at 1610, 1570, and 1520 $cm^{-1}$.

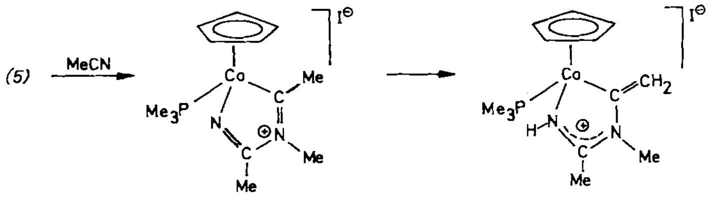
Am Hubland, D-8700 Würzburg (Germany)

yellow, air-stable salt *(6)* with $AgPF_6$ (in $CH_2Cl_2$). Treatment of *(5)* with acetone leads to precipitation of a brown, microcrystalline powder which, according to elemental analysis, is formally a 1 : 1 adduct of acetone and *(5)*. On the basis of $^1$H-NMR data (Table 1) we ascribe the hexafluorophosphate formed on reprecipitation with $AgPF_6$ the structure *(7)*.

The compound *(5)* also reacts with acetonitrile in the same fashion as with acetone. Possibly the initial product formed in the reaction is the compound *(8)*, analogous to *(7)*, which very rapidly forms the tautomeric complex *(9)*. The corresponding $PF_6$ salt is obtained on reaction with $AgPF_6$ (in $CH_3NO_2$) or on addition of acetonitrile to *(7)*.



*(8)*  *(9)*

The structure of the cation of *(9)* is shown in Figure 1. The cobalt-containing heterocycle is completely planar (maximum deviation of the atoms from the ring plane 1 pm), and the C-atoms C11, C12 and C13 also lie in the ring plane. The presence of the exocyclic double bond is confirmed by the length of the C10—C13 bond (134 pm). On the basis of the relatively small difference in the C9—N1 and C9—N2 bond lengths the positive charge in the NCN fragment of the ring should be delocalized.

Acetone and acetonitrile have only slightly activated multiple bonds and are therefore generally not capable of undergoing [3+2]-cycloadditions[7]. The observation that the acetimidoylcobalt group formed by the electrophilic attack of MeI at the Co—CNMe bond of *(4)* rapidly reacts both with $Me_2C{=}O$ as well as with $MeC{\equiv}N$ points to a high nucleophilicity of the acetimidoyl N-atom, probably owing to the electron supply of the electron-rich $C_5H_5(PMe_3)Co$ fragment.

# BOOK REVIEWS

**The Biosynthesis of Mycotoxins.** Ed. by *P. S. Steyn.* Academic Press, New York 1980. x, 432 pp., bound, $ 44.00.

A clear distinction must always be drawn between primary and secondary metabolism. Primary metabolism is absolutely essential, while secondary is not. In secondary metabolism a very wide range of compounds is synthesized (without aim or purpose?) and we can regard this area as a "playground for evolution". From a consideration of their mode of action, the secondary metabolic products which are synthesized by microorganisms and which inhibit or kill microorganisms are known as antibiotics. To them has recently been added the large group of mycotoxins, the toxic secondary metabolites of fungi. The particular interest in this group of substances started at the beginning of the sixties with the discovery of aflatoxin, a metabolic product of *Aspergillus flavus* and *Aspergillus parasiticus* that turned out to be a highly active carcinogen. It is not surprising that since then the analysis of this class of substances has been worked out very thoroughly and a firm recommendation has been made to destroy all moldy food.

The present work is an excellent survey of the latest stage of research into the biosynthesis of mycotoxins. The first paper, by *Bu'Lock*, gives an introduction to the field that is well worth reading. The summary reports are written by authoritative experts: *Floss* reports on the biosynthesis of the ergot alkaloids, *Tamm* on the biosynthesis of trichothecin mycotoxins and cytochalasines; *Steyn, Vleggaar* and *Wessels* provide an important contribution on aflatoxins, *B. Franck* reports on the biosynthesis of ergochrome, and *Yamazaki* on neurotropic mycotoxins; *Lolita Zamir* on patulin and penicillic acid; *Kirby* and *Robins* write a contribution on gliotoxin and related epipolythiodioxopiperazines; *Holzapfel* reports on the biosynthesis of cyclopiazonic acid and related compounds, *Sankawa* on mycotoxins of the anthraquinone series, and *Vleggaar* and *Steyn* conclude with a study of those mycotoxins that up to now have been considered to be of smaller importance.

The mycotoxins are of chemical interest both from the analytical and the synthetic point of view, since they are generally complex molecules belonging to diverse classes. The present book will be of use to chemists, biochemists, food chemists, biologists, toxicologists, and pharmacists.

*Franz Lingens* [NB 532 IE]

**Biotransformation von Arzneimitteln** (Biotransformation of Pharmaceuticals). By *S. Pfeifer*. Vol. 3. Verlag Chemie, Weinheim 1979, 560 pp., bound, DM 118.—.

The third volume of this series of monographs[*] deals with the metabolism of 311 compounds, particular attention being paid to members of the following groups: antiallergics, antibiotics, bronchodilators, diuretics, local anaesthetics, sweetening agents, and cytostatics. The literature is covered up to the beginning of 1978; supplements to the literature in volumes 1 and 2 update these to the same point in time.

A total of 851 substances is described in this three-volume work, including not only drugs in general usage but also pharmaceuticals no longer used in therapy and substances still at the stage of clinical trials. The nomenclature is not completely uniform. In general the Latin versions of the international short names are used (for example acidum etacrynicum). This may be the usual nomenclature in the German and European pharmacopeias, but it sounds very strange to those who are not pharmacists. For unambiguous identifications the reader is referred to reference works.

The telegraphic style and the extensive use of abbreviations and symbols result in compressed descriptions not always easy to follow. Each monograph has a similar structure. A set of formulas is presented (the metabolites are generally given as partial formulas), with no differentiation between the main and the subsidiary biotransformation reactions. This is followed by data on separation techniques, species, and analysis. In the next section, "Comments", information in keyword form is given on the pharmacokinetics, together with supplementary data on the metabolites. No claims are made to completeness. The literature references used are given (without titles) at the end, in alphabetical order by authors.

These monographs should not be regarded as critical summaries presenting the metabolic behavior of the individual pharmaceuticals. However, they could be useful as a preliminary source of information for the nonspecialist, for some essential information appears with equal validity side by side with unverified data. The work does, however, constitute a very comprehensive compilation of the literature on the substances in question, with some general explanations and additional comments, which is what the reader might expect in a study of the literature cited. The author and his associates have thus made a very important contribution to this specialist field, particularly when we consider the effort still required in making a literature search in the field of biotransformation of pharmaceuticals, even with all the aids of modern technology.

The collection as a whole forms a very useful reference work, and should be welcomed by all concerned with the biotransformation of drugs. The authors should be encouraged in their intention of keeping this work as up-to-date as possible by literature supplements. If at a later date a new edition is brought out, it might be possible to make it appeal to a wider circle of readers, especially if the format could be modified.

# Macromolecular Chemistry Today—Aging Roots, Sprouting Branches

By Hermann F. Mark[*]

In the early twenties, I did research in a small team (together with *R. Brill, I. R. Katz, M. Polanyi* and *R. Weissenberg*) at the Kaiser-Wilhelm-Institut für Faserstoffchemie (Chemistry of Fibers) in Berlin-Dahlem, in *R. O. Herzog*'s group. We investigated the structures of industrial textile fibers (cotton, wool, silk, hemp) and of other natural products such as starch, rubber, leather and wood. In those days, each of these important products was the subject of a large, separate research field—both in science and engineering. There were textbooks on cellulose, on proteins, on rubber, on starch; each of the fields had its own journals and there were special societies and conferences for chemists working on starch, rubber, proteins and cellulose. Similarities were not considered—even if they were obvious; each of the different areas was a world of its own, and little if any overlap existed, which might have led to mutual stimulation.

This situation suddenly changed when *Hermann Staudinger* established the concept of *macromolecules,* setting his face against strong and broad opposition. It now became clear that all the many products were structurally similar: they consisted of *long chain* molecules. Chain length itself was initially not considered to be so important—there ought to be more than eight or ten, perhaps there were more than one hundred repeating units. But what was the structural basis for the vast range of properties and behavior of these natural products? The *microstructure* of the main chains and the type of *substituents* linked to them! The latter could be hydrophilic or hydrophobic, small or large, basic or acidic; one was back again in the well-known field of classical organic chemistry. A new, unifying principle had emerged which made things marvelously clear and easy. Half a century before, the confusing manifoldness of thousands of synthetic dyes had become explicable by the unifying principle of chromophoric groups, and all colors of the spectrum could be prepared by simply adding auxochromic moieties to the molecules. Now again, a unifying principle—the concept of long main chains (hydrocarbons, polyethers, polyesters, polyamides) and the presence of different side chains and substituents—explained the confusing variety in the behavior of many important natural products. From the chemist's point of view, the difference between rubber and wool had become basically as small as the difference between a yellow and a blue dye.

A unifying principle, once accepted, creates order where confusion reigned and understanding where uncertainty prevailed: consider how the work of *Lavoisier* and *Mendeleev* influenced chemistry!

A few years later, I worked in *K. H. Meyer*'s group in Ludwigshafen in the central laboratories of IG Farben together with *M. Dunkel, H. Fikentscher, E. Dorrer* and *C. Wulff.* Trying to make synthetic polymers, we all realized the enormous advantage the macromolecular model had for our way of thinking and for the design of new experiments: so did innumerable chemists in other laboratories. A boom began no one had dreamt of—a boom in the understanding, production and manifold applications of macromolecular products of all kinds. New ideas and methods kept progress in motion.

If today, 60 years later, we look back at this development of chemical science and industry, the question arises: has it lost momentum, or can we notice new impulses?

One answer to this question is given by the reports on recent advances published in the current issue of this journal. Many macromolecular substances and classes of compounds have already been highly developed; their further develop-

0570-0833/81/0404-0303 $ 02.50/0

ment will be slow and lead mainly to more elaborate and cheaper products. Other fields exist, however, in which the as yet unattainable is sought.

The article "Half a Century of Polystyrene—a Survey of the Chemistry and Physics of a Pioneering Product" by *A. Echte et al.,* goes back to work carried out in the middle of the twenties for which two patents were granted to *C. Wulff* and myself and to *E. Dorrer* and *C. Wulff.* The original "Sumpfphasen" ("swamp phase")-polymerization had already been remarkably stimulated by the concept of long chain molecules and yielded a product which at the time was commercially highly successful. During the next five decades, the regularity and reproducibility of molecular weights were constantly improved. Later, copolymerization and polymer blending were used (together with many new methods in synthesis and processing) to expand the range of applications, in order to compete with other polymeric products. From the three or four prototypes of the early years, a vast variety of more than a hundred useful products has emerged; one can hardly imagine doing without them in the household, electrical industries (telephone, radio, television) and for the interior equipment of all kinds of vehicles. Polystyrene will continue to flourish, further improvements will be necessary, but one can handly expect striking innovations.

In contrast, the articles by *H. Ringsdorf et al.* and *U. Zimmermann et al.* report on the breaking of new ground. Some 40 years ago, *I. Langmuir* considered the structural analysis of proteins and the synthesis of one of these compounds to be an important long-term objective in chemistry. Much has happened since, and even the macromolecular structure of complicated proteins like hemoglobin has been largely explained. As a next long-term objective in macromolecular biochemistry, "synthesis" of a cell was aspired. Before there is a chance to synthesize, one has to become familiar with the target structure by *e.g.* deliberately altering it and studying the resulting effects. Such investigations have been started in Mainz *(H. Ringsdorf),* London *(D. Chapman)* and Jülich *(U. Zimmermann).* In order to stabilize cell membranes *Ringsdorf* tries to introduce polymerizable molecules, which due to their structure are compatible with membrane constituents. Their polymerizable groups can be activated whenever desired. In this way, ***stabilized cell models*** are available which may serve as models for studies of membrane properties and membrane transport or even as antitumor agents. The solution of this problem requires exceptional skill in the synthesis of new, complicated monomers which consist of *e.g.* a sugar- and a lipid-moiety covalently bound to a polymerizable group (diacetylene, butadiene). *Zimmermann*'s method of fusing cells and incorporating different substances into them requires knowledge of electronics and electrical engineering. Synthetic work and the application of biophysical methods can, however, only be successful if the cooperating cell biologists and membrane physiologists give the right "instructions": there is a "multilingual" borderland, beyond which only a well established interdisciplinary team can expect to progress. This cooperation may give rise to an entirely new discipline which survives the old ones. "Material science" thus originated from metallurgy, ceramics and plastics technology. What about "Life Science"? Can polymer chemistry, cell biology and medicine overlap and strive together for new goals?

Similar pioneering work with quite different objectives is reported by *G. Wegner* in his contribution on "Polymers with Metal-like Conductivity—A Review of their Synthesis, Structure and Properties". The production and application of macromolecular substances has so far tried to achieve certain thermal and mechanical properties—high melting points, resistance to solvents, elasticity, toughness—because these are essential for fibers, films, molded shapes *etc.* A polymer scientist would say they are consequences of the movement of chain segments and atoms. The phenomena discussed by *Wegner,* however, are based on the movement of *electrons* in organic solids—especially in macromolecular systems. In contrast to metallic solids, which contain many mobile electrons and are therefore conductors or semiconductors, organic solids, like cellulose, rubber, polystyrene or nylon have no mobile charges; they are typical insulators and have long been used successfully as insulating materials. Nevertheless it seems worthwhile to try to produce conducting or semiconducting organic polymers: easy processing, low specific weight and resistance to corrosion are appealing advantages. Indeed, in recent years, it has been discovered that by loosening binding electrons or by creating additional charges (doping) remarkable degrees of conductivity can be realized. In *Wegner's* article, remarkable thoughts and experiments are presented which are situated between two established disciplines: physics of metals and chemistry of macromolecules. Only well-organized team-work will be successful in this new and eminently promising field.

To sum up, these contributions (written in the year of *Hermann Staudinger*'s 100th birthday) clearly show that macromolecular chemistry has become a huge tree with new branches still sprouting.

# Polymeric Antitumor Agents on a Molecular and on a Cellular Level?

By Leo Gros, Helmut Ringsdorf, and Hans Schupp[*]

"Chemistry has become a mature science, with all the advantages and handicaps of maturity: harvest is abundant, but many people think future and adventure are to be found elsewhere"[1a]. This holds true—in 1981, the year of *Hermann Staudinger*'s 100th birthday—for macromolecular chemistry, too. Where can the polymer chemists seek adventures? Unsolved problems in neighboring fields like medicine and molecular biology attract his zeal. Cancer chemotherapy is such a field. Can the polymer chemist help to solve its problems?

Polymers may be pharmacologically active as such. If used as carriers, they may, due to their intrinsic properties, influence body distribution, excretion or cell uptake of the pharmaca they carry. Hence, there is a chance for new ways in therapy, including affinity chemotherapy using synthetic macromolecules.

Our own body has a perfect biological system for affinity therapy: immune response to infection selectively attacks foreign cells. It is fascinating to observe what the immune system does to a tumor cell which could not escape immune surveillance (cf. Fig. 14). Can these specific cell-cell interactions be mimicked? What do we have to learn for an experimental approach to this adventure? Stable membrane and cell models can be synthesized, a first step towards this goal.

Macromolecular chemistry is far from being able to offer satisfying solutions for a specific tumor therapy; striving for it, polymer chemists can learn lots of things. In order to do so, they will have to enter neighboring fields and they will have to be willing and able to cooperate.

*Irrtümer haben ihren Wert;*
*Jedoch nur hie und da.*
*Nicht jeder, der nach Indien fährt,*
*Entdeckt Amerika.*[**]
*(Erich Kästner)*

## 1. Introduction

Interdisciplinary thinking is no longer regarded as poaching in other people's territory; a modern scientist must enter neighboring fields. When doing so, he may need the help of model concepts, which, far from being perfect definitions, can serve as sign posts in the thicket of facts. This is what the authors have in mind when they talk about antitumor agents on a molecular and on a cellular level, trying to characterize different modes of action of these drugs.

Most of the antitumor agents presently used may be regarded as drugs acting on a molecular level: Let us imagine a cell-killing drug which enters a cell and for example cross-links DNA or inhibits a key enzyme. Cell metabolism is thus disturbed on a molecular level; the internal medium of the cell is damaged causing a series of events. "Death", *i.e.* destruction of the cell is the final result of this series of chemical reactions. Drugs of this type may be called drugs acting on a *molecular level.*

Mother Nature, however, often combats tumor cells in a different way: the immune system recognizes degenerate cells; antibodies together with a protein complex (complement system) or, alternatively, killer cells interact with and destroy the tumor cell membrane. Membrane destruction, although perhaps induced chemically (*e.g.* by membrane destabilizing agents), is ultimately a physical phenomenon: the internal medium of the cell can no longer exist because the crucial compartment-forming structure (the cell membrane), which separated the cell from its environment, is destroyed (cf. Fig. 14). Systems which in this manner destroy a cell as a whole may be called antitumor agents acting on a *cellular level.*

In recent years, chemists have tried to develop not only low molecular, but also polymeric antitumor agents. The present survey attempts to review current activity and to discuss possible developments in the field of polymeric antitumor agents on a molecular and on a cellular level from a polymer chemist's point of view.

After a short description of guidelines in the design of antitumor agents and of chances in the "tailoring" of such drugs (Section 2), we will discuss in Section 3 why and how polymeric antitumor agents on a molecular level have been developed. Section 4 deals with possible starting points for a different approach; the question is whether one can design polymeric antitumor agents on a cellular level, imitating the final step of natural immune response.

## 2. Tailor-Made Antitumor Agents?

Surgical and radiation treatments are the most common tumor therapies. Their effect is optimal only when the tumor

is localized. If the tumor cells are spread over the body, a therapy is needed which can reach them wherever they may be situated. This is (at least in theory) the domain of cancer chemotherapy[1b]. Although in recent years, considerable progress has been achieved in this field, the main problem of chemical treatment of tumors remains largely unsolved: most antitumor drugs are not selective, they are highly toxic for both cancer and normal cells.

Chemists who set about developing antitumor active substances may either isolate natural products or synthesize new compounds and then test their activity on cell cultures and animal models. This procedure, however, does not satisfy the scientist searching for causal relationships, and is in any case extremely expensive. Nevertheless, this screening plays an important role: at the National Cancer Institute (USA), 30800 new compounds were screened in 1972[2].

At the beginning of this century, *Paul Ehrlich* proposed targeting to affected tissues[*] by means of appropriate receptors[3]. Interest in tackling the tumor problem in this way, *i. e.* immunologically, has constantly grown, due to the increasing knowledge of high specifities of cell-cell-recognition and immune response. Thus, in the past years a large number of investigations have been carried out with the goal of replacing unspecific antitumor agents (toxic to all cells) by tailor-made, specific drugs which act selectively on tumor cells.

"Drug design"[4]—*i. e.* tailoring of pharmaca—presupposes "taking the target's measurements". A thorough knowledge of structure-activity relationships and a detailed understanding of biochemical and morphological characteristics of the target cell are required. Here we encounter a crucial problem: Despite the fact that innumerable investigations have been done in the field, we are still far from a true understanding of the origin and spread of tumors. The possibilities of "rational drug design" should not be overestimated[5]. Nevertheless, the idea of investigating the differences between tumor and normal cells in order to develop a therapeutic potential remains a suitable guideline[1,6].

It must be considered, however, that there is no such thing as "the tumor cell". The about 100 human tumors known are significantly different from each other. Even in any one tumor there are several different cell-subpopulations (phenotypes) which themselves can change during tumor development[7]. Table 1 shows several differences between normal and malignant cells of a given tissue. Not all of these characteristics, however, apply to all tumor types[8].

This survey of typical tumor cell properties may seem impressive; yet one has to note that although these differences may be used diagnostically, they provide only a narrow basis for selective chemotherapy.

Among these, the high mitotic activity of many tumors must be emphasized. Most antitumor agents used clinically act upon metabolic pathways related to cell growth. Rapidly dividing tumor cells are therefore effectively attacked by cytostatic agents and radiation therapy, but normal tissues which divide rapidly, too—*e. g.* liver, lymph system *etc.*—are equally damaged.

Table 1. Characteristics of tumor cells as compared with normal cells.

| Properties | Ref. |
|---|---|
| *Cellular metabolism and intracellular environment* | |
| 1. increased content of methylated nucleosides | [9] |
| 2. different enzyme patterns | [10] |
| – increased activity of DNA-synthesizing and decreased activity of DNA-catabolizing enzymes | [10] |
| – lack of asparagine-synthetase (several types of leukemia) | [11] |
| – increased activity of proteolytic lysosomal enzymes | [12] |
| – strongly decreased activity of $Mn^{2+}$-superoxide dismutase | [13] |
| 3. higher need for exogenous $Zn^{2+}$ | [14] |
| 4. lower $Ca^{2+}$ and higher $K^{+}$-concentrations | [15] |
| 5. lower pH of cytoplasm (after injection of glucose) | [16] |
| *Membrane structure and properties* | [17] |
| 6. higher rate of endocytosis | [18] |
| 7. altered phospholipid contents | [17d] |
| 8. different glycoproteins (lectin receptors) of the membrane | [7, 19] |
| 9. tumor associated surface antigens | [20] |
| *Cell growth and behavior of cells in tissues* | |
| 10. impaired cell proliferation | [21] |
| 11. lower cohesion in tissues | [22] |
| 12. lower contact inhibition | [22] |
| 13. metastasizing activity | [23] |
| 14. "invasiveness" = active penetration into other tissues | [22] |

It is out of the question that a tumor cell-specific chemotherapy has not been achieved so far. Nevertheless, besides high mitotic activity, some of the differences between normal and tumor cells mentioned in Table 1 have proved to be helpful in "rational drug design". We will come back to endocytotic activity (point 6 in Table 1) and tumor-associated antigens (point 9 in Table 1) later and just mention the exploitation of different enzyme patterns (point 2 in Table 1). An enzyme therapy with asparaginase has already been used in the treatment of certain leukaemias[11,24]: These leukaemic cells are unable to produce asparagine and need an extracellular asparagine supply. Asparaginase used as a therapeutic agent degrades asparagine and thus deprives the cells of a substance which is essential for protein biosynthesis.

This example of a relatively high degree of specificity is an exception. Many attempts have therefore been made[2,6,25] to obtain antitumor agents of a high selectivity:

1) Isolation or synthesis of new active compounds, *e. g.* hormones, plant products, interferones, antimetabolites.
2) Further development of known antitumor agents with the aim to improve selectivity, *e. g.* by fixation to tissue-specific substances (like hormones[26]) or applying the transport form—active form concept[27].
3) Use of carrier systems designed to more selectively carry the antitumor agent to the target (the tumor)[28]. In particular, the following carriers have been proposed:
    - polymers (cf. Section 3)
    - liposomes[29]
    - cells[30]

During the last decade many scientists have placed their hopes in the carrier approach, the increasing number of papers and reviews[28-30] speaks for itself. In the following, we would like to discuss some essential aspects of one of these carriers, namely polymers.

---

[*] Much earlier, in the 14th century, drug targeting was familiar to physicians. In the preface to his collection of tales, *Don Juan Manuel* (El Conde de Lucanor, Editorial Castalia, Madrid 1976) tells us why he teaches practical philosophy through pleasant stories: "I did as physicians do when they, in order to make a medicament for the benefit of the liver, add sugar, honey or some other sweet stuff, because the liver likes sweet things. And due to this preference for the sweet, the liver attracts the sweet and the medicament with it. The same is done with every organ which needs a medicament: the drug is mixed with something the organ naturally is inclined to".

## 3. Polymeric Antitumor Agents on a Molecular Level

### 3.1. Polymeric Antitumor Agents—Why?

The investigation of polymers in medicine[31] (biomaterials) is one of the new and fascinating areas in polymer science. One of the interesting topics is the investigation of pharmacologically active polymers, *i. e.* macromolecules which are pharmacologically active by themselves or which can be used as carriers for low molecular weight pharmaca.

Although polymers have been widely used in medicine, *e. g.* as materials for artificial organs and implants[32], pharmacologically active polymers are still subject to considerable scepticism. Nevertheless, much has been achieved, and a growing number of papers and review articles on the subject have been published[33-43]. Many of these publications deal with the development of polymeric antitumor agents[28,44,53]. Why? *Harris Busch* gives quite a simple answer: "Everybody wants to contribute to the cancer problem..."[45]—and so do polymer chemists!

One of the first considerations leading to the development of pharmacologically active polymers was the hope that one might achieve depot effects due to high molecular weights[46]. This hope had been cherished by experience with synthetic polymeric plasma expanders[47]. But taking into account that there is a great variety of possible interactions between polymers and biological systems, the depot effect is just one of many promising applications of pharmacologically active polymers.

As discussed before, specificity of antitumor drugs is a crucial problem in tumor chemotherapy[48]. One approach to the synthesis of specific low molecular weight antitumor agents—the use of tumor cell-specific transport moieties attached to the drug—often meets with substantial difficulties. The following example will illustrate this and show why macromolecular science might be able to contribute to a solution of this problem.

*Connors et al.*[49] investigated the influence of substituents on the cell-specific uptake of sulfadiazines by tumor tissue in rats.

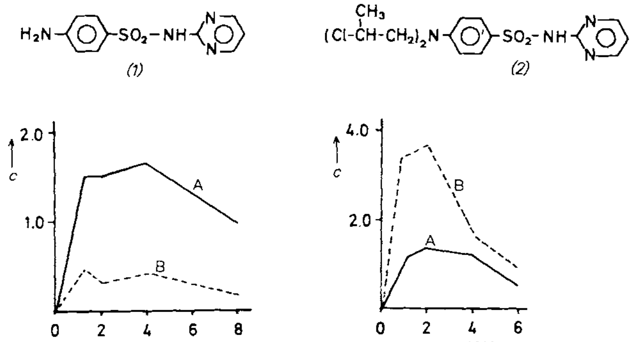

Fig. 1. Different cell uptake of sulfadiazines *(1)* and *(2)* by liver and tumor cells (Walker tumor in rats) [49]. *c*: μg of compound per mg tissue, *t*: time after intraperitoneal injection (i.p.), A: tumor cells, B: liver cells.

Figure 1 shows that the sulfadiazine derivative *(1)* is preferentially taken up by Walker tumor tissue compared to liver tissue (left). *Connors et al.* concluded that linkage of this tissue-specific compound to the cytotoxic Lost-system might result in a combined tumor-specific and cytotoxic activity and thus synthesized the sulfadiazine-Lost conjugate *(2)*. This substance is indeed an antitumor agent. However, instead of being taken up into tumor tissue, it was found to be enriched in the liver (Fig. 1, right).

This means that, in this particular case, chemical linkage of two structural units in a small molecule (the properties of which are highly dependent on its structure) does *not* result in a combination of the desired functions[50]. This problem does not always occur[51], but is found very often[52]. Nature achieves high specifities by, for example, building up high molecular weight compounds with different functional units (which are very often localized seperately). Structural complexity affords functional specificity.

As an approach, one might try to achieve a combination of desired properties (*e.g.* cell toxicity, solubility, tumor cell specificity) by linking the appropriate structural units to different domains along a polymer chain. Figure 2 shows a model[36,53] of such a compound.

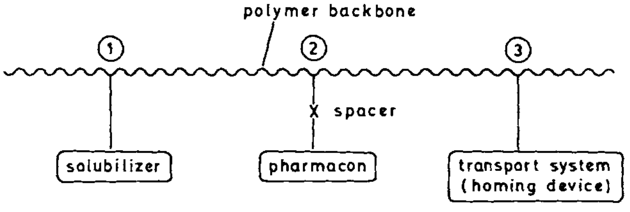

Fig. 2. Model of a pharmacologically active polymer [36, 53].

One domain within the model macromolecule ① contains units which may influence *solubility* (lipophilicity, hydrophilicity), body distribution and acute toxicity of the whole molecule. In a second domain ②, the *drug* is linked to the polymer chain by a *bond*, which may be cleaved or may be stable under *in vivo* conditions. A *spacer group* may be necessary to separate the drug from the main chain in order to make it accessible to enzymes or receptors. Finally, a unit which assures preferential uptake into a target tissue *("homing device")* may be conceived.

Function and biological activity of pharmacologically active polymers are especially influenced by polymer specific structural parameters:

- Molar mass and molar mass distribution influence body distribution of polymeric pharmaca[54]. High molecular weight compounds for example cannot enter the brain (blood-brain barrier[55]) and generally are not resorbed after oral administration. Renal clearing depends on molar mass[56]. As a result, high molecular weight compounds in particular are excreted slowly and stored, especially in the cells of the reticuloendothelial system (RES)[57].
- Stereochemistry of polymers may influence their biological properties. Isotactic poly(acrylic acid) shows a higher antiviral activity than the heterotactic compound[58]. Poly(D-lysine) is not degraded, poly(L-lysine) is degraded inside the cell[59].
- Copolymerization allows systematic variation of the distribution of active units along a polymer chain. Moreover, copolymers can be tailor-made in order to vary hydrophilicity or lipophilicity of the entire molecule and of single domains (block systems). Properties of the microenviron-

ment in a polymer coil can differ drastically from those of the bulk solution and are strongly influenced by comonomer composition[60]. Thus, time of release of polymer-fixed drugs can be varied.

- Incorporation of labile groups into the main chain renders hydrolytic or enzymatic degradation possible, and hence leads to a slow release of polymer-fixed or incorporated drugs (chronomers)[61].
- Careful selection of appropriate spacer length and structure allows a wide variation of cleavability[62].
- Toxicity of low molecular weight compounds can be masked by fixing them to a polymer chain[62b,63].
- Binding of haptens (low molecular weight molecules which, when attached to certain macromolecular carriers, elicit an immune response) to synthetic polymers leads in almost every case to substantially reduced[62b] immune response or even blocks it totally[64].
- Moreover, one can consider macromolecules to show pharmacological (*e.g.* antitumor) activity as such, without a drug (*e.g.* antitumor agent) fixed to it. This is indeed the case, as will be shown in Section 3.3.1.

In contrast to the advantages of polymer specific properties mentioned so far, there are important disadvantages, objections and problems[62c].

- Biocompatibility of water soluble polymers has so far only been tested in a few isolated cases. We still lack overall experience with hemolytic activity, pyrogenicity, osmotic properties, and interaction with plasma constituents under *in vivo* conditions.
- Non-degradable synthetic polymers can be used in order to obtain depot-effects. A long-lasting systemic storage of high molecular weight compounds can however not be accepted from pharmacological and toxicological points of-view. Therefore, the development of bio-degradable polymers is becoming more and more important[66]; oligomers or polymers of low molecular weight which can be excreted may be also used.
- There have been few systematic investigations on the body-distribution of polymers and its change with time[54].
- Little attention has been paid to immunological reactions against pharmacologically active polymers[64b].
- Synthetic polymers investigated so far are not resorbed from the gastrointestinal tract; a fact which decisively limits the choice of appropriate drug formulations.

Nothing at all could be said in favor of polymeric pharmaca if they were just "me-too drugs"[4]—drugs which can do a job that low molecular weight pharmaca can do just as well. Therefore it is reasonable to concentrate efforts on the development of pharmacologically active polymers in such areas where low molecular weight drugs have failed or have given only insufficient therapeutic results. One such area is the chemotherapy of cancer. There is no doubt that the use of polymeric antitumor agents has only been moderately successful up to now. Investigations carried out so far, however, give clear-cut evidence that these drugs open up new possibilities which could not be realized by the use of low molecular weight drugs.

### 3.2. How Do Macromolecules Enter Cells?

Besides diffusion and active transport, there is one other way in which cells take up material: endocytosis[67] (phagocytosis, pinocytosis). Cell uptake of polymers is normally limited to this mechanism[68], which resembles the ingestion of material by amoebae:

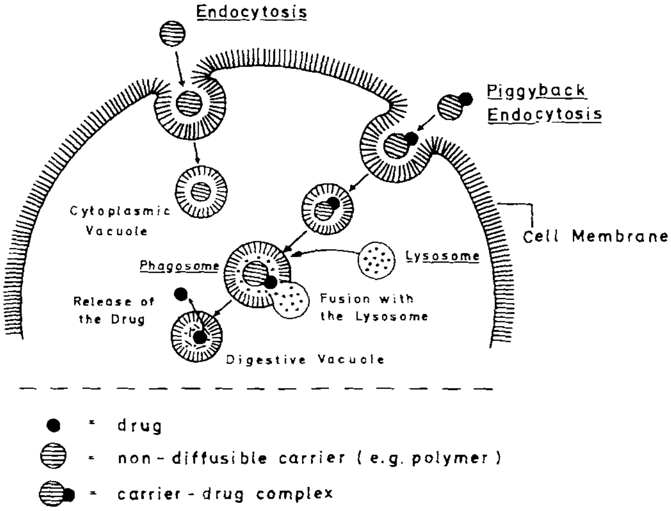

Fig. 3. Schematic representation of cell-uptake of polymers by endocytosis and piggyback-endocytosis.

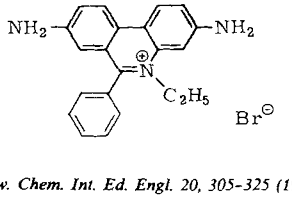
The endocytosis of polymers is normally initiated at the cell membrane. Subsequently, membrane invaginations are formed which are then separated from the membrane. The vacuoles thus formed can fuse intracellularly with a lysosome. The about 40 lytic lysosomal enzymes will then attack the endocytosed macromolecule. Many investigators have studied the influence of charge, hydrophobicity and molecular weight on endocytotic uptake and have obtained contradictory results[69].

A special case of endocytosis is called piggyback-endocytosis[70] (Fig. 3): a pharmacon is attached to a macromolecule which can be taken up by endocytosis. This, on the one hand, prevents diffusion of the drug through the membrane and therefore leads to a first degree in cell specificity (because the drug-carrier-complex will only be taken up by cells having endocytotic activity). As tumor cells in general have a higher rate of endocytosis than the corresponding normal cells (see Table 1), it was expected that the use of polymeric carriers might lead to a certain tumor cell specificity. On the other hand, antitumor agents which cannot enter the cell through the membrane can be transported into the cell *via* endocytosis when linked to a polymer (cf. Section 3.3.3).

*A. Trouet et al.*[71] presented an interesting example for therapeutic usefulness of piggyback endocytosis. They studied the effect of ethidium bromide *(3)* on *Trypanosoma Cruzi*. If added to a cell culture *(in vitro)* of this parasite, *(3)*, is highly toxic for *T. cruzi* cells. However, when administered *in vivo* to a mouse infected by *T. cruzi*, the drug has hardly any



*(3)*

effect at all. Figure 4 shows why the parasite can escape the toxic drug *in vivo* and how, by means of piggyback endocytosis, it can be attacked effectively: *T. cruzi* is taken up by endocytosis and thus ultimately resides inside the lysosomes. Due to a special cell wall structure, it there resists the lytic enzymes (Figure 4).

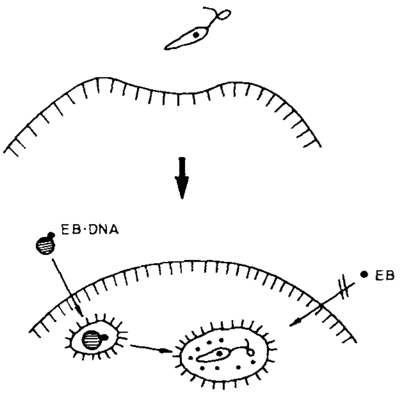


Fig. 4. Schematic representation of cell-uptake of the parasite *Trypanosoma cruzi* *via* endocytosis; effect of the ethidium bromide-DNA complex (EB-DNA) on a cell attacked by the parasite (cf. [71]).

While free ethidium bromide *(3)* cannot enter the cell, it is taken up as a complex with DNA, probably *via* piggyback endocytosis. After fusion of the ethidium bromide-loaded vacuole with a lysosome inhabited by a parasite, the DNA carrier will be degraded by lysosomal enzymes and the drug can attack the parasite.

Experimental results shown in Figure 5[71] show that mice infected with *T. cruzi* have much better chances of survival when *(3)* is not administered in a free form but rather as a complex with the carrier molecule DNA.

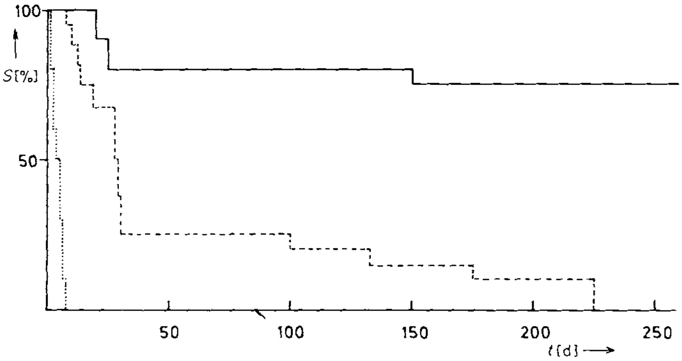

Fig. 5. Survival of mice infected by *Trypanosoma cruzi* [71]. Treatment: 3 injections (on days 2, 3, 4). (······) control animals, no treatment; (– – – – – –) 3 × 0.5 mg ethidium bromide *(3)*; (———) 3 × 0.5 mg ethidium bromide-DNA complex; $S$ = percent surviving animals; $t$ = time after i.p. injection of *T. cruzi*.

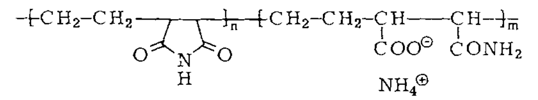
Systems of this type which can be targeted to lysosomes *via* endocytosis are called "lysosomotropic" and discussed as carriers for pharmaca by *de Duve et al.*[72].

## 3.3. Polymeric Antitumor Agents on a Molecular Level—Selected Examples

After having briefly discussed the special mode of uptake of polymeric molecules into cells, we shall now select a few of the numerous examples of polymeric antitumor agents; though far from being exhaustive, these will serve to illustrate the relevant possibilities and problems.

### 3.3.1. Synthetic Polymers Themselves Are Active Against Tumors

As pointed out previously (Section 3.1), it was found that synthetic polymers as such act upon cells and organisms without any low molecular weight drugs linked to them. Poly(acrylic acid), for example, shows antiviral activity, which is highly dependent on both molecular weight and tacticity[58]. DIVEMA, a copolymer of maleic anhydride and divinyl ether[73], stimulates the immune system and is discussed as a possible interferon inducer[74]. Recently, a comprehensive treatise on anionic polymeric drugs has been published[75]. Some cationic drugs show antitumor activity, too[76]. Recently, a random copolymer of low molecular weight *(4)* attracted special attention. It consists of ethylene and modified maleic acid units[77].



*(4)*

When tested against a methylcholanthrene-induced bladder carcinoma of rats, *(4)* caused an increased lifespan and almost totally inhibited the formation of the lung metastases found in untreated control animals. When *(4)* was administered after operative removal of the tumor, animals not only were free of metastases but also showed no recurrence of the tumor, when the polymer was administered repeatedly every 6 weeks (Fig. 6)[77].

The authors could show that *(4)* enhances immune response of the animals and that this effect is due to a stimulation of the antibody-producing B-cells. *(4)* is not toxic, nor immunogenic. First clinical trials[78] on patients with gastrointestinal tumors show that *(4)* is also non-toxic in humans. The results published so far suggest an increase in lifespan. Another copolymer which shows antitumor activity without being cytotoxic itself has been published recently[79].

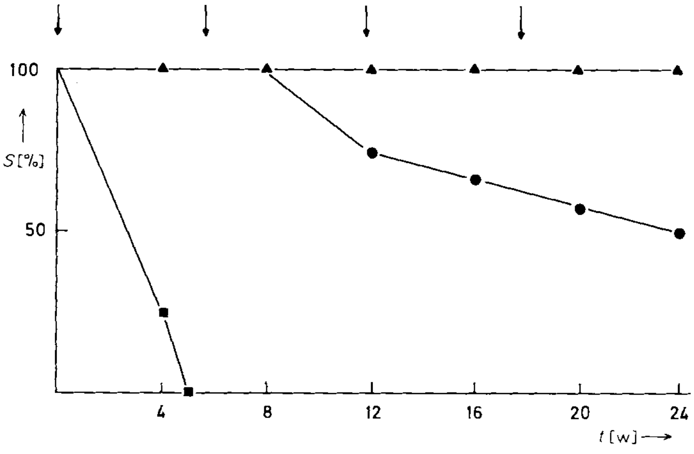


Fig. 6. Survival of rats after surgical removal of a primary carcinoma of the bladder and subsequent treatment with copolymer *(4)*. (■—■) untreated controls, death caused by lung metastases; (●—●) single dose of *(4)* (day 1): recurrence of local tumor; (▲—▲) four doses of *(4)* at 6 week intervals (see arrows); $S$ = percent survivors; $t$ = time after excision of primary tumor.

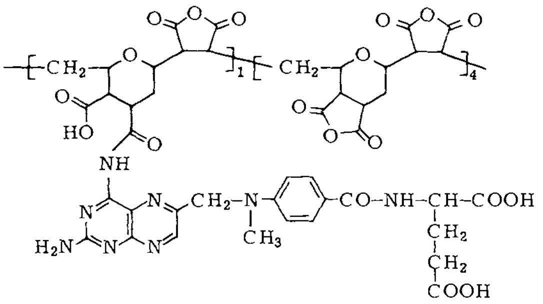
Thus, the idea of enhancing the body's own immune response with suitable immune-stimulating polymers has found more experimental support.

### 3.3.2. Fixation of Methotrexate to an Immune-Stimulating Carrier Polymer

The immune-modulating effect (*e.g.* activation of macrophages) of the cyclo-copolymer of divinylether and maleic anhydride (DIVEMA) stimulated the idea of using this polymer as a carrier for the folic acid antagonist methotrexate (MTX). MTX is an antitumor agent used clinically; its immunosuppressive properties often give rise to therapeutic problems.



*(5)*

Polymer DIVEMA-MTX *(5)* was synthesized by covalent binding of the pteridinyl group of MTX to DIVEMA[80]. The effect of *(5)* on the macrophage system (macrophages are immune cells which literally eat up foreign material) was tested. It showed a stimulating effect which was, however, slightly inferior to that of DIVEMA itself[81].

In spite of the lability of the linkage of MTX to DIVEMA, copolymer *(5)* showed higher antitumor activity (as tested against L1210 leukaemia in mice). This may be due to sustained release and longer systemic circulation of MTX (Fig. 7)[82].

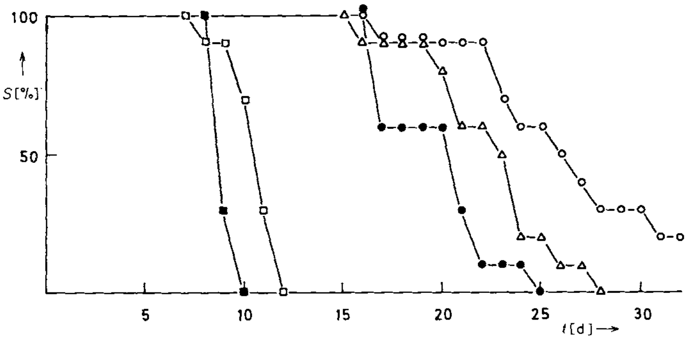


Fig. 7. Survival of CDF$_1$-mice (male) after i.p. injection of $10^5$ L1210-tumor cells and subsequent treatment with polymer-fixed methotrexate *(5)* on days 1,5,9,13,17 [82]. (■—■) untreated controls; (□—□) treatment with DIVEMA (80 mg/kg body weight); (●—●) treatment with DIVEMA + MTX (29 + 10 mg/kg body weight); (△—△) treatment with MTX (20 mg/kg body weight, optimum dose); (○—○) treatment with DIVEMA-MTX *(5)* (31 mg/kg body weight) ≙ 8 mg MTX/kg body weight); S = percent survivors; *t* = time after tumor inoculation.

One undesired effect of polymer fixation is a marked increase in toxicity of DIVEMA-MTX in a therapeutic dose range. This is probably due to uptake of the polymer into the macrophages, where MTX is cleaved from the carrier and exhibits toxic effects. Moreover, the *in vitro* inhibition of tetrahydrofolic acid dehydrogenase by *(5)* was evaluated (Murine L5178 Y-tumor cells being used as model system)[83]. The results suggest that MTX is cleaved rapidly from the carrier polymer.

### 3.3.3. Combination of MTX with a Lysosomotropic Carrier

Besides being immuno-suppressive, MTX shows one more disadvantage: some tumor cells are resistant against the drug.

This is probably due to the lack of the appropriate transmembrane transport system for MTX[84]. *Ryser* and *Shen*[84] showed that MTX linked covalently to poly-(D-lysine) and poly-(L-lysine) is taken up equally well by resistant and nonresistant cells. MTX linked to a polymer of molecular weight 60000—70000 is taken up 200 times better than free MTX. Cell growth is, however, only inhibited if a poly-(L-lysine) carrier is used (Fig. 8)[84].

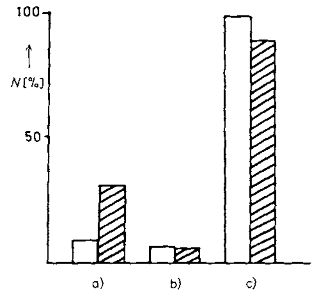

Fig. 8. Growth inhibition of Chinese hamster ovary (CHO) cells after application of $10^{-6}$ moles of MTX [84]: a) low molecular weight MTX; b) poly(L-lysine)-MTX, MW 70000; c) poly-(D-lysine)-MTX, MW 60000; unshaded: non-resistant cell line; shaded: MTX-resistant cell line; $N$ = number of residual cells after 4 days (% of cells in untreated control culture).

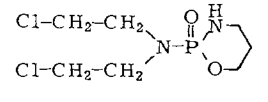
The authors showed that only this polymer and not the poly-D-isomer, is degraded intracellularly. Polymer-bound MTX being only a weak inhibitor of dihydrofolic acid reductase, enzymatic degradation of the polymer is essential for an inhibiting effect. The MTX-poly-(L-lysine) conjugate is a lysosomotropic system (cf. Section 3.2.) which is only activated in the secondary lysosomes (phagosomes). Thus, MTX-resistance of tumor cells can be overcome. Moreover it seems that, due to higher activities of proteolytic enzymes in some solid tumors (see Table 1), a certain tumor cell specificity can be obtained. These investigations show that stereochemistry of the polymer main chain may play an important role in antitumor activity.

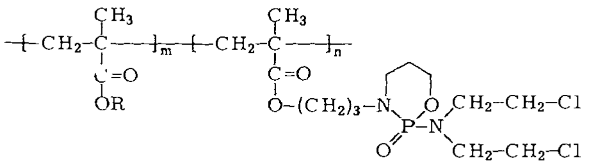
### 3.3.4. A Way Out of an Impasse

2-[Bis-(2-chloroethyl)amino]-1,3,2-oxazaphosphorinane 2-oxide (cyclophosphamide, cytoxane) *(6)* is a well known antitumor agent[85] and can be regarded as a non-toxic pro-drug of the ultimately active *N,N*-bis(2-chloroethyl)phosphoric diamide (Friedman acid) *(10)*[27].



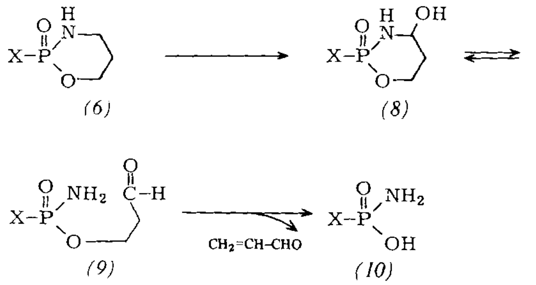
*(6)*

According to the model discussed above (Fig. 2), polymeric derivatives of cyclophosphamide (CP) of the type *(7)* were synthesized[86].



(7a), $R = -(CH_2)_2-SO-CH_3$; (7b), $R = -(CH_2)_2-\overset{\oplus}{N}(CH_3)_3\ Cl^{\ominus}$

These compounds turned out to be only weakly active in animal tests. In order to understand why this is the case, we have to consider the metabolism of CP *(6)* (Fig. 9).



$X = (Cl-CH_2-CH_2)_2N$

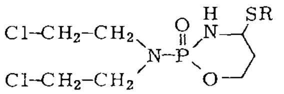
Fig. 9. Metabolic activation of cyclophosphamide *(6)* in the organism by hydroxylation and release of acrolein.

Investigations concerning the metabolism of transport form and active form of CP by *Hohorst* and *Brock*[87] as well as by *Connors et al.*[88] showed that *(6)* is hydroxylated preferentially by liver enzymes whereupon acrolein is spontaneously released, yielding Friedman acid *(10)*.

While *(6)* is inactive *in vitro* (due to the lack of hydroxylating enzymes), it shows high cell toxicity *in vivo* after oxidation to the labile 4-OH-CP *(8)*. Accordingly, the primary metabolite *(8)* is not only active *in vivo* but also in cell cultures.

Polymers *(7)* contain CP in a covalently fixed form which, even if it is cleaved from the polymer after transport to a tumor cell, is inactive: it has to go to the liver for hydroxylation. So polymers *(7)* are almost inactive.

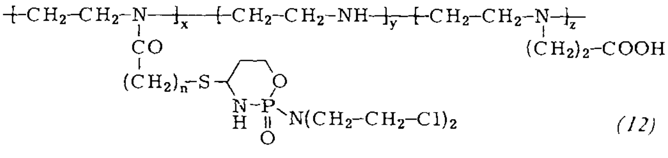
What can be learned from this impasse? A covalent fixation of an antitumor agent to a polymeric carrier has to be achieved in such a way that a directly active species can be cleaved off. After *Takamizawa et al.*[89] had found a way to synthesize the active labile metabolite *(8)*, *Hohorst et al.*[90] were able to prepare stabilized derivatives *(11)* which can be hydrolytically cleaved to yield *(8)*.



*(11)*

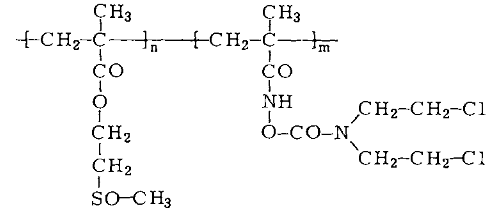
Now it was possible to fix the active metabolite in its stable form *via* derivatives with reactive groups R ($R = -(CH_2)_n-OH$ and $-(CH_2)_n-COOH$)[91] to a polymer carrier, *e.g.* modified poly(ethylenimine).

Polymers *(12)* can, after transport to tumor cells and cleavage of the active metabolite *(8)* from the carrier, directly act cytotoxically. The antitumor activity of low molecular weight derivatives of type *(11)* is comparable to the activity of CP itself[91c]. When DIVEMA is used as a carrier polymer, activity decreases[91c]. Polymers *(12)* are currently being tested.



*(12)*

Similar considerations governed fixation of bis(2-chloroethyl)amine (N-Lost) to polymers. If fixed as an amide, this highly cytotoxic compound is inactive. Therefore, polymer fixation was carried out using labile bonds (*O*-acyl-hydroxamic acids, urethanes), *e.g.* *(13)*[92].



*(13)*

First investigations show that compounds *(13)* are active *in vitro*[92].

These two examples suggest that cleavability of the polymer-pharmacon bond[62] and bio-availability of cytotoxic units play a decisive role in the use of polymeric carrier systems.

### 3.3.5. Affinity Chemotherapy—
### An Attempt at Targeting Antitumor Agents

As a last example for antitumor agents on a molecular level, we will describe a system which includes a homing device (as discussed in the model, Fig. 2).

Animal cells contain specific surface proteins (surface antigens), which are involved in many biological processes (cell-cell recognition, immune response, cell differentiation). If we are able to produce antibodies against a certain target tissue (*i.e.* against surface antigens of cells of this tissue), the antibodies should be able to recognize the target tissue specifically. Such an antibody might be loaded with antitumor agent and serve as a specific transport vehicle to target cells which bear the corresponding antigen on their surface. This is the principle of affinity chemotherapy which was proposed by *Paul Ehrlich* as early as 1906[3] and was developed, *inter alia*, by *Wilchek et al.*[93]. It is shown schematically in Figure 10.

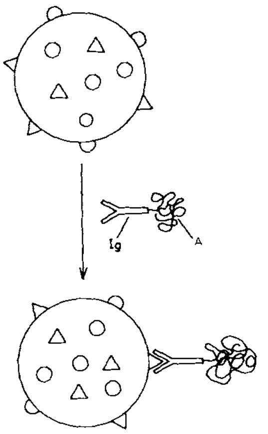


Fig. 10. Schematic representation of affinity chemotherapy of a *tumor cell*. A: polymeric antitumor agent; Ig: Immunoglobulin; △: tumor associated antigens; ○: antigens of a normal cell.

Apart from problems with preparation and isolation of pure, tumor-specific antibodies, one main difficulty is to find the optimum concentration of antitumor agent fixed to the antibody. If the amount of antitumor agent is too low, the tumor cell may be recognized, but antitumor activity will be insufficient. If it is too high, as shown schematically in Figure 11a, the combining site of the antibody may be blocked and recognition of the antigen becomes impossible.

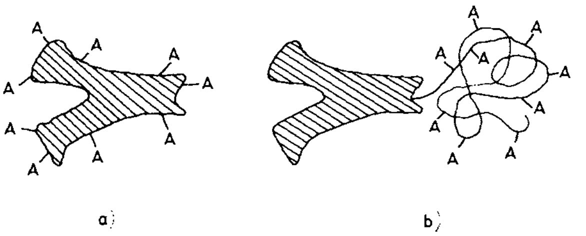

Fig. 11. Schematic representation of the binding of an antitumor agent (A) to an antibody. a) Direct fixation of antitumor agents to immunoglobulins; b) fixation of a polymer loaded with antitumor agent to an immunoglobulin.

One might avoid the difficulties described above by binding the antitumor agent to a polymer which (as discussed in the model, Fig. 2) itself is linked to an antibody serving as homing device (Fig. 11b) and which does not interfere with the combining site of the antibody. Such a polymer has *e.g.* been synthesized by *Rowland, O'Neill* and *Davies* (Fig. 12)[94].

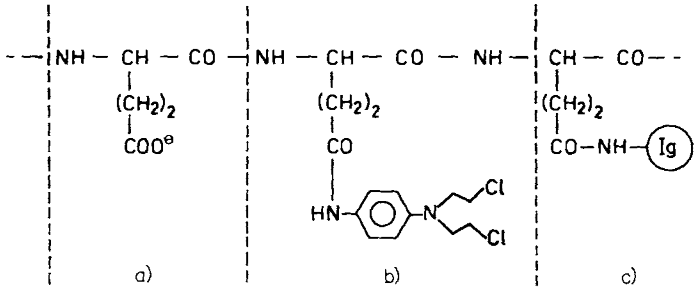

Fig. 12. Polymeric, tumor cell-specific alkylating antitumor agent (cf. Fig. 2 and 13). a) Solubilizer, poly(glutamic acid) (PGA); b) pharmacon, *p*-phenylenediamine-lost (PDM); c) homing device, immunoglobulin (Ig).

Poly(glutamic acid) (PGA) serves as a macromolecular carrier. The carboxylate groups of glutamic acid (a) may be regarded as the solubilizer described in the model (Fig. 2). *p*-Phenylenediamine-lost (PDM) fixed as an amide to the polymer chain is the antitumor agent (b). As a homing device (c) a protein (Ig) was used which had been isolated from the serum of rabbits "vaccinated" with lymphoma tumor cells. (These rabbits should have produced tumor specific antibodies.) When tested *in vivo* against EL-4 lymphoma of mice, this system was superior to the corresponding control systems. None of the animals treated with the terpolymer died within 60 days after inoculation of tumors (Fig. 13).

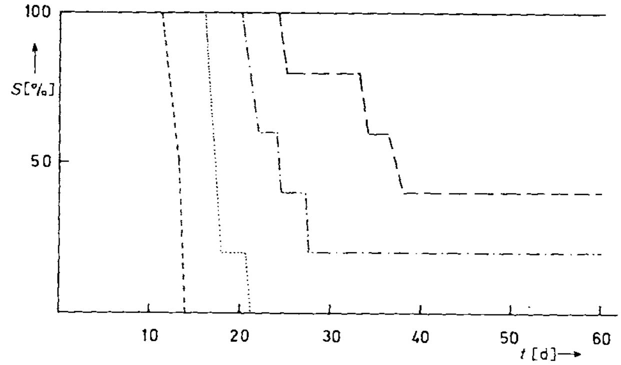

Fig. 13. Survival of mice bearing an EL-4-lymphoma after treatment with polymeric antitumor agents (cf. Fig. 12) [94]. (– – – – – – – –) untreated controls; (·········) 4 mg Ig; (–·–·–·–·) 750 μg PGA-PDM; (— — — —) 4 mg Ig + 750 μg PGA-PDM; (————) PGA-PDM-Ig (≙4 mg Ig and 750 μg PGA-PDM; *S* = percent survivors; *t* = time after tumor inoculation.

On the basis of control experiments, the authors conclude that the effect is due to the carrier and is not merely a synergistic effect (*i.e.* an effect which can just as well be obtained by administration of a mixture of free immunoglobulin (Ig) and lost-polymer). Later, *Rowland* reported similar experiments with dextran as carrier system and could not completely exclude synergistic effects in this case[95]. The concept of affinity chemotherapy is likely to bring about useful results in the development of antitumor agents[20,96]. The first positive results obtained in animal tests justify further research in the area of targeting of antitumor agents using a homing device.

### 3.4. From Research Lab to Clinic?

An unprejudiced reader may conclude from the five examples given in Section 3.3 that polymeric antitumor agents on a molecular level will soon be or are already used clinically in chemotherapy. This is, however, not the case; some of the relevant problems have already been mentioned in Section 3.1. What has been achieved so far? Concepts for pharmacologically active polymers have been developed. Numerous substances have been synthesized. Model considerations and a broad spectrum of molecular structures have opened a vast field which has to be investigated more systematically and in close interdisciplinary team-work.

Same old story: there is an idea, one can show that it works "in principle", and then the tedious and laborsome phase of optimization and adaption towards a biological target system begins. Accordingly, our knowledge of tumor cells and of interactions between an organism and pharmacologically active polymers must be substantially improved. Great care has to be taken in the transfer of results from animal tests to clinical trials[97]: many of the drugs active in animal models turned out to be inactive in humans. Regarding the nice graphs showing increase in lifespan (Fig. 13), one should not forget that affinity chemotherapy in human patients requires detection and isolation of human tumor-specific antibodies—a problem not yet solved. Recent progress in membrane biology, immunology, and gene technology (isolation of monoclonal antibodies) raises hopes for further advancements.

## 4. Polymeric Antitumor Agents on a Cellular Level?

### 4.1. Can the Immune Response to Tumor Cells Be Mimicked?

Of all parts of a cell which change during the transition from a normal to a malignant cell (carcinogenesis), the biomembrane is affected to a great extent (cf. Table 1). Many signals controlling cell growth, mitosis and cell uptake originate in the membrane. It is therefore not surprising that minor changes in the cell surface have major consequences for cell behavior. In this context, the cell membrane with its associated antigens[98] plays a key role as a starting point for considerations to solve the tumor problem by mimicking parts of the immunological process.

### 4.1.1. Death of a Tumor Cell

Although tumor cells can normally escape the immune system, it is very impressive to see what happens, if they fail to circumvent the immune defense of the body. Figure 14[99] demonstrates this and shows the death of a tumor cell, a process which takes place on a cellular level and which may teach us how to develop antitumor agents on this cellular level.

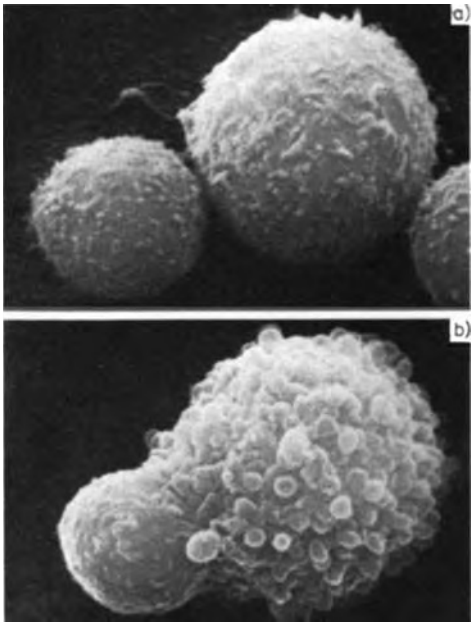

Fig. 14. Electron microscopic picture showing a T-lymphocyte attacking a tumor cell [99]. a) The tumor cell (right) has antigens on its surface which are recognized selectively by the activated lymphocyte (*i.e.* by the antibodies in the lymphocyte membrane). b) Death of a tumor cell. Destruction by the lymphocyte occurs by membrane destabilization—"bubbles" are formed.

These two pictures (Fig. 14) show the sequence of an attack of a T-lymphocyte on a malignant cell. The tumor-associated antigens are recognized by the attacking lymphocyte. This corresponds to the principle of affinity chemotherapy described in Section 3.3.5, but in this case on a cellular level. The subsequent destruction of the tumor cell is not a molecular process (as defined in Section 1), but is the consequence of the membrane destruction (formation of bubbles) after contact of the T-lymphocyte with the tumor cell. This mechanism of destruction by a membrane destabilization is not well understood in all details; three possibilities at least are discussed: a locally high concentration of lysophospholipids[100], release of toxic (*i.e.* membrane destructive) substances by the lymphocyte[101] or spontaneous membrane destabilization by a change of protein conformation[102].

The basis of all hypotheses is destruction on a purely physical level. Although there is not yet any exact proof, there are a number of hints supporting this assumption: a mere adsorption of liposomes, *i.e.* closed spherical structures, to a cell can destabilize both membranes to an extent that allows a penetration of low molecular substances into the cell[103]. A cell fusion, which can take place only after a strong destabilization of the membranes, can be induced in several ways, for example biologically (by means of the Sendai virus[104]), chemically (by the presence of calcium ions[105] or by incorporation of lysophospholipids[100] into a membrane), or physically (by applying an electric field[106]).

Bearing in mind the picture of the death of a tumor cell, one wonders whether antitumor agents on a cellular level can be conceived and whether they would be able successfully to mimic such a process.

A possible starting point for solving this problem could be the interaction of a tumor cell with a synthetic vesicle, which would have to fulfill the following criteria:

1. Possibility of cell-specific recognition.
2. Ability to destabilize the tumor cell membrane.
3. Similar or higher stability than the tumor cell membrane.

All three points are largely unsolved problems in the investigation of the use of liposomes in medicine described in the literature. Attempts to mimic the above-described interaction of a lymphocyte with liposomes from natural or synthetic phospholipids will lead to the destruction of the liposome rather than of the malignant cell: the liposome is fused, undergoes endocytosis, or its membrane is destabilized[107]. This is of course not what one expects from an antitumor agent on a cellular level. Even less is known about the problems of cell specific recognition (cf. Section 4.3.3.) and of destabilization of the tumor cell membrane (cf. Section 4.3.4.). Membrane-destroying compounds would also destroy the liposomes. It is essential, therefore, to increase the stability of synthetic liposomes. Among the three problems mentioned, this particular one seems to have the best chance of being realized. In addition, stabilized cell models are of interest *per se*, *e.g.* for the investigation of cell recognition[108], cell-cell interaction[109] *etc.* The problem of stability is also essential for the use of liposomes as drug carrier systems. Liposomes used so far, exhibit a relatively high permeability for entrapped drugs when exposed to blood, since they are destabilized by adsorption of proteins and destroyed by the action of lipase[110]. In the following Section we will describe current considerations on, and experiments designed for, the creation of models of biomembranes and cells with high and variable stability.

### 4.1.2. Mother Nature Forms Stable Membranes. Can a Chemist Reach Her Standards?

The well-known membrane model of *Singer* and *Nicolson* (Fig. 15) pictures a double layer formed by a lipid matrix and proteins, *e.g.* enzymes as informational and functional units "floating" in this lipid matrix[111].

However, this intuitive representation is oversimplified: Vesicles from natural phospholipids have the same lipid matrix, but are rather unstable; some biomembranes contain only 25% of lipids[112]. Obviously Nature finds additional means for creating membranes of high stability. Let us look at two of these in more detail:

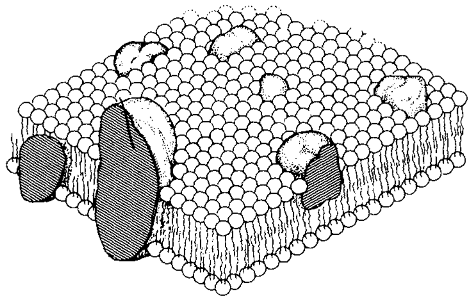

Fig. 15. Fluid mosaic model of biological membranes after *Singer* and *Nicolson* [111].

1. Besides the so-called "integral" membrane proteins (which are embedded in the hydrophobic part of the membrane), there are peripheral proteins, only found in the hydrophilic part of the membrane. Some of these peripheral proteins act as a support, because they are associated with several integral proteins. A well-known example is spectrin situated at the inside of the erythrocyte membrane[113].
2. As an example of an enveloped vesicle we have the so-called "coated vesicles"[114]. Here a phospholipid vesicle within a cell is coated by a polypeptide and resembles a football in a basket. A comparable form of membrane coating is found in the cell walls of bacteria[115]. Here too, macromolecules provide an envelope similar to a basket, but they consist of polysaccharides cross-linked by oligopeptides. It is remarkable that this extreme stabilization by an exogeneous support is found in bacteria, which (as parasites in foreign tissues) have to be especially resistant.

How can a stabilization of biomembranes be achieved synthetically? The attempt to mimic a support similar to the spectrins seems unlikely, for very little is known, as yet, about the interactions between peripheral and integral proteins. An increase of stability *via* polymer coating, as in the case of a bacterial membrane, sounds more realistic and is in fact used to immobilize living cells. This coating however prevents contact and hence interaction of different cells[116].

The most convenient and realistic attempt seems to be a method which uses membrane lipids for stabilization. One experiment of this type (though having a different purpose) has been described by *Khorana et al.*[117]. These authors incorporated lipids carrying photoreactive groups into a membrane and could (by irradiation) covalently fix proteins to these lipids. Another method with much greater potential uses polyreactions of lipids carrying polymerizable groups.

Before we report on investigations of such systems in the next Section, we will introduce models used to study membrane properties.

### 4.1.3. Membrane Models

A knowledge of the bulk properties of lipids and surfactants is not sufficient to gauge their ability to form membranes. The interaction with an aqueous phase results in totally different properties, which can be described by terms like amphiphilic behavior, micelle and liposome formation, and formation of lyotropic phases[118]. For thermodynamic reasons lipids undergo self-organization to membrane-like structures when brought into an aqueous medium. Several methods have been developed in recent years for investigations on those structures. The most common membrane models, namely monolayers[119], black lipid or bilayer membranes (BLM)[120], and liposomes[121], are shown schematically in Figure 16[122].

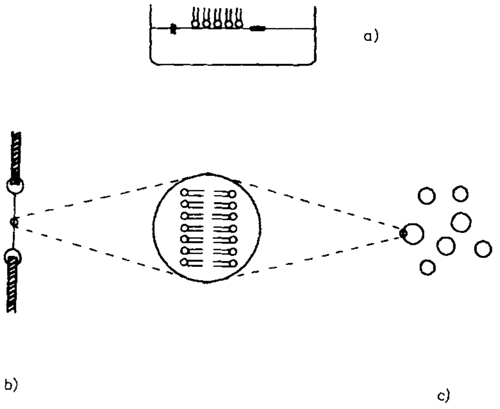

Fig. 16. Orientation of amphiphilic compounds in model membranes: a) monolayer; b) bimolecular lipid membrane (BLM); c) liposome. Between b) and c) a cross-section through the BLM or liposome wall is shown.

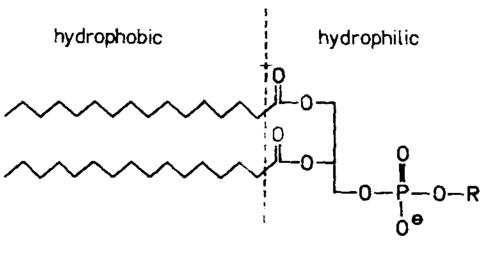
In all three cases amphiphilic lipids orient spontaneously to form a structure which resembles the phospholipid structure in a biomembrane. These membrane models permit investigations of physical properties of oriented systems in a variety which cannot be performed with complex natural membranes. A comparison and discussion of these models is given by *Noell*[122].

## 4.2. Polymeric Membrane Models

### 4.2.1. Polymerizable Lipids

The main component of lipids in a membrane consists of phospholipids. The structure of typical representatives of these amphiphilic systems (with hydrophobic alkyl chains and a hydrophilic head group) is shown in Figure 17.



Lecithin $R = -(CH_2)_2-\overset{\oplus}{N}(CH_3)_3$

Cephalin $R = -(CH_2)_2-\overset{\oplus}{N}H_3$

Phosphatidylserine $R = -CH_2-\underset{\oplus NH_3}{CH}-COO^{\ominus}$

Fig. 17. Structures of the most common biomembrane phospholipids.

If one intends to synthesize polymerizable lipids to build up membranes of high stability, the polymerizable group can be introduced into different parts of the lipid molecules, *i.e.*

into the hydrophilic head group or into the hydrophobic alkyl chain (Fig. 18)[123].

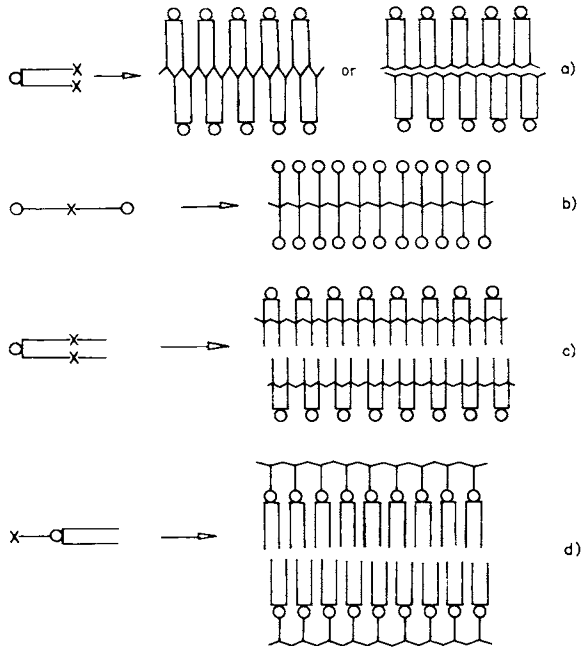


Fig. 18. Possible ways to synthesize polymeric model membranes [123] (x = polymerizable group). a)—c) Polymerization with preservation of head group properties; d) polymerization with preservation of chain mobility. For examples of appropriate monomers, see Table 2.

All four principles in Figure 18 result in systems which have properties differing from those of cell membranes. Methods a—c have no influence on the head groups and hence preserve physical properties (such as charge, charge density, *etc.*) but change the fluidity of the hydrophobic chains. In case d the fluidity is not affected, but there is no free choice of the head groups. All polymeric lipid systems will show an increase in viscosity and a decrease in the lateral mobility of the molecules.

All four possibilities shown in Figure 18 for the formation of polymerizable lipids have been realized synthetically[123]. To choose the proper lipid to start with, "one need not attempt to reproduce Mother Nature slavishly" *(Fendler)*[124]. *Kunitake* (1977)[125] was able to show that simple molecules like dialkylphosphates or dialkyldimethylammonium salts can form liposomes. *Fuhrhop*[126] and *Kunitake*[127] could realize liposome formation with molecules consisting of one chain with two hydrophilic head groups (cf. Table 2, type b). Acrylic and methacrylic groups (type a and d in Table 2) as well as diacetylene and diene groups (type b and c) have been used as polymerizable groups. Some of the synthesized polymerizable lipids are listed in Table 2.

The compounds shown in Table 2 have been investigated regarding their ability to undergo polymerization in a membrane-like orientation. The formation of monolayers at the gas-water interface is the oldest and most simple of the membrane models in Figure 16. A monolayer permits a variety of investigations and is especially suited for studying polymerizations. This method will therefore be described in more detail.

Table 2. Several examples of polymerizable, liposome-forming lipid analogues (cf. Fig. 18).

| Type | Compound | | Ref. |
|---|---|---|---|

### 4.2.2. Investigations of Polymerizable Amphiphiles in Monolayers

The earliest reports on the behavior of oil on water were given by the Babylonians. They spread oil droplets on a water surface and used the behavior of the films for soothsaying on health, war or wealth[135]. (The progress of science is obvious: Today lipids are spread on water and one attempts soothsaying—on the lipids.)

As early as 1917 *Irving Langmuir* recognized that amphiphilic substances can form a film on a water surface with a thickness of exactly one molecular layer[136]. Such a monomolecular film forms a two-dimensional system, which by variation of surface pressure, area and temperature permits the measurement of phase diagrams. The most common form of recording diagrams is the so-called pressure-area diagram measured with a Langmuir film balance (Fig. 19)[119].

Different states can be seen in the monolayer by analogy to pV-diagrams of three-dimensional systems: At to pressures

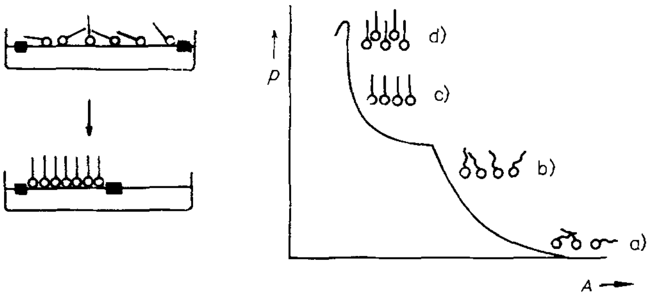

Fig. 19. Left: Langmuir film balance, schematic; right: representation of surface pressure area diagram of a monolayer at the gas-water interface [a)—d), explained in the text]. $p$ = surface pressure, $A$ = area.

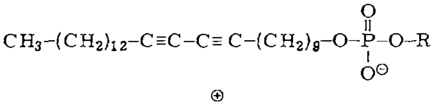
a gas-analogous phase (a) is formed, which obeys a two-dimensional gas law. Compression leads to an expanded or liquid-analogous state (b) with a contact of head groups, but a high mobility of the hydrophobic chains. Further compression results in a condensed or solid-like phase with head-packing (c) or chain-packing (d). The smallest area of a solid film is in the order of 0.18 nm$^2$ per alkyl chain and corresponds to the occupied area of a paraffin chain in a crystal. A further decrease in the area of the film results in a collapse of the monolayer; beyond this collapse-point there is no well-defined system and the molecules lose their high degree of orientation.

The measurement of surface pressure-area diagrams provides a method for studying the influence of variables like temperature, head group, alkyl chain length and pH on membrane properties (*e.g.* stability). This can be demonstrated by amphiphilic compounds *(27)—(29)* with different biological headgroups (lysophospholipid analogues)[137] (Fig. 20):



$$CH_3{-}(CH_2)_{12}{-}C{\equiv}C{-}C{\equiv}C{-}(CH_2)_8{-}O{-}\underset{O^{\ominus}}{\underset{|}{\overset{O}{\overset{\|}{P}}}}{-}O{-}R$$

*(27)*, R = $CH_2{-}CH_2{-}\overset{\oplus}{N}(CH_3)_3$
*(28)*, R = $CH_2{-}CH_2{-}NH_3^{\oplus}$
*(29)*, R = H

A decrease in the occupied area of the head group results in an increase in the packing density of the molecules: *(27)* exhibits only an expanded film; *(28)* forms a liquid-analogous as well as a solid-like phase. *(29)* exhibits only a condensed phase.—Monolayer properties of many natural phospholipids and synthetic lipids are described in the literature[138,144].

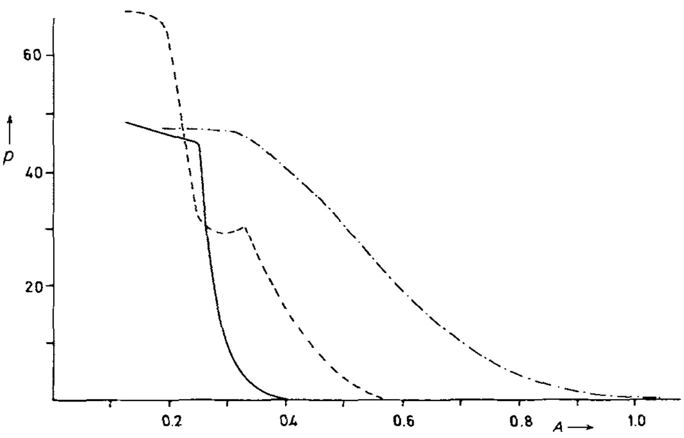


Fig. 20. Influence of the head group of lysophospholipid analogues *(27)—(29)* on their properties in monolayers [137]. Surface pressure-area diagram of *(27)* (–·–·–); *(28)* (– – –), and *(29)* (——). $p$ = surface pressure (in mN/m); $A$ = area (in nm$^2$/molecule).

Apart from the characterization of lipids in a monolayer, several other examples of the versatility of this method have been described. *Gorter* and *Grendel* postulated the existence of a double layer in biomembranes from the occupied area of membrane extracts in monolayers[139]. Many membrane reactions can be monitored in monolayers, for example adsorption of proteins at a monolayer and insertion into the lipid matrix[140]. Another example is the investigation of the activity of the enzyme lipase as a function of the surface pressure[141]. The investigation of the miscibility of different phospholipids and the characterization of phospholipid-cholesterol mixtures provides a method for the interpretation of their action in biomembranes[142]. Interactions of local anesthetics with membranes have been studied in monolayers as a model[143].

The correlation of monolayer properties and spherical membranes (liposomes, cells) has been discussed by *Blume*[144].

### 4.2.3. Polymerization in Monomolecular Layers

Since the orientation and packing density of the monomers in monomolecular layers can be varied, this method allows the investigation of a polyreaction in such systems, as is shown schematically in Figure 21[145].

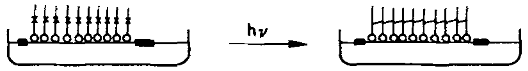

Fig. 21. Schematic representation of the synthesis of polymeric monolayers by UV-irradiation, orientation of the molecules being preserved (x = polymerizable groups).

The orientation of the monomer units remains unchanged; the reaction results in a highly oriented stable polymer film with a degree of orientation not realizable by other methods, *e.g.* the spreading of the same substance after polymerization in solution[146]. UV-initiated monolayer polymerization has been studied intensively in recent years[145-148]. Normally the reactions involve contraction of the film; the surface pressure-area diagrams of the polymers exhibit a smaller occupied area, a steeper slope, and a higher collapse pressure[146]. Hence the polyreaction can be followed by measuring the film contraction versus time at constant pressure. This can be shown in the case of the diacetylene lipid *(21)* (Fig. 22)[132].

In recent years another method has been developed for monitoring the polymerization kinetics by measuring the UV absorption in monolayers[148]. A special Langmuir film balance was constructed to fit a commercial UV spectrometer. This polyreaction can be easily monitored by the new device (Fig. 27), since the polydiacetylenes exhibit a high extinction coefficient in the visible region. The polymerization of diacetylenes in the solid state has long been known[149]. The polyreaction is topochemically controlled; *i.e.* the structure of the monomer crystal determines the reactivity and structure of the polymer. The color of the polymer (blue/red, cf. Fig. 26) with conjugated double and triple bonds depends on the conformation of the polymer backbone in the solid state[150] and in solution[151].

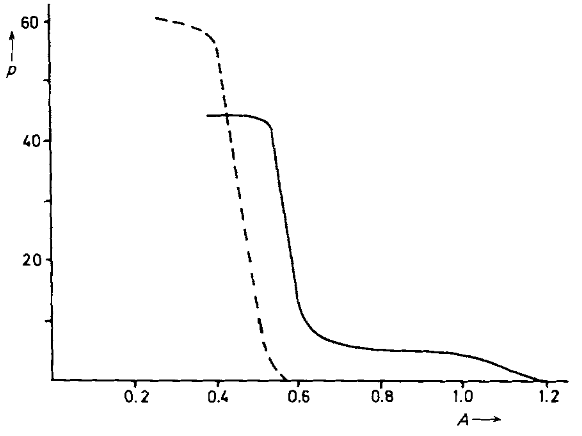

Fig. 22. Surface pressure-area diagram of monomeric and polymeric ammonium lipid *(21)* [132] (Table 2). (————) monomer; (--------) polymer; $p$ = surface pressure (in mN/m); $A$ = area (in nm$^2$/molecule).

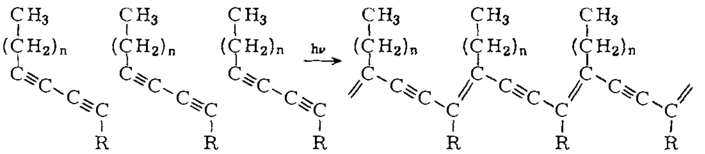
The spectroscopic investigation of the polymerization of diacetylene surfactants and lipids in monolayers shows that it is comparable to the polyreaction of these systems in a crystal[148]. The blue ($\lambda_{max}$ = 620 nm) as well as the red ($\lambda_{max}$ = 540 nm) form of the polymer can be detected, depending on irradiation time. The polymerizability of the diacetylene lipid *(21)* proves that the required packing density for a topochemical reaction is realizable in monolayers. It can be shown that a polyreaction is only possible in a solid-analogous monomer film, *i. e.* in our example at surface pressures above 10 mN/m[132, 134, 148]. Irradiation of a liquid-analogous film ($p$ < 10 mN/m) does not lead to a polymer.



In contrast to the topochemically polymerizable diacetylenes, the methacrylic and diene derivatives of lipids and surfactants are polymerizable not only in the solid-like but also in the liquid-like state[123, 130]. Figure 23 shows the contraction behavior of the diene lecithin *(20)* during irradiation in the liquid-analogous state ($p$ = 7 mN/m)[130].

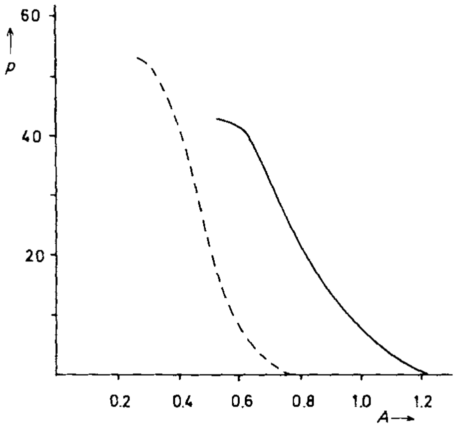


Fig. 23. Surface pressure-area diagram of monomeric and polymeric lecithin derivative *(20)* [130] (Table 2). (———) monomer; (------) polymer; $p$ = surface pressure (in mN/m); $A$ = area (in nm$^2$/molecule).

Compared to the diacetylenes, the methacrylic and diene systems exhibit a higher mobility of the non-conjugated polymer chains and are therefore more suitable for the formation of flexible membranes.

For all investigated systems, the surface pressure-area diagrams of the polymer exhibit a higher packing density and a higher collapse pressure than those of the corresponding monomers, thus supporting the concept of a higher film stability of the polymerized membranes. This is demonstrated in Figure 24:

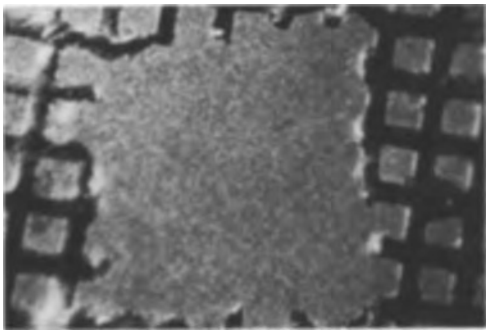

Fig. 24. Bilayer of a polymerized diacetylenecarboxylic acid deposited on an electron microscope grid. The stable bilayer spans an area of about 0.25 mm$^2$.

A double layer of a poly(diacetylenecarboxylic acid) spans a width of 0.5 mm in diameter in an electron microscope grid. This bilayer membrane remains stable for weeks in air or in water[147d].

So far these investigations show that a polyreaction in oriented planar systems is possible and leads to highly oriented and very stable model membranes. It remains to be seen whether polymerization is possible in spherical bilayers such as liposomes and whether the vesicles thus formed exhibit a higher stability than the low molecular systems.

## 4.3. Polymeric Liposomes as Cell Models

### 3.2.1. Structure and Formation of Liposomes

Liposomes are the nearest approach to biomembranes; they are closed, spherical structures having an aqueous interior and one or several lipid double layers[152].

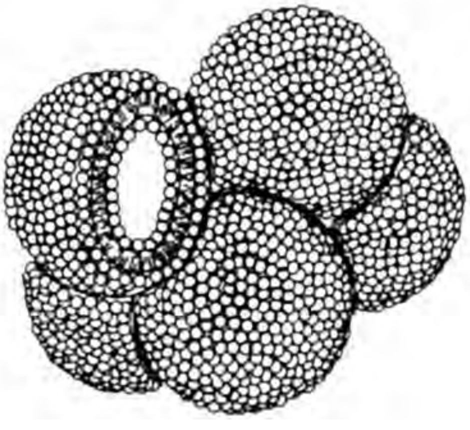

Fig. 25. Schematic representation of unilamellar liposomes (*i. e.* consisting of one bilayer).

Such vesicles can be formed from synthetic amphiphiles and membrane extracts; reconstituted membranes, *i. e.* liposomes of cell membrane constituents, contain nearly all components of cell membranes (lipids, proteins, glycolipids *etc.*). Erythrocyte ghost-cells formed by osmotic shock constitute one further example[153].

Vesicles of synthetic lipids or lipid analogues have a much simpler composition and, depending on the method of formation, one obtains double- or multilayered vesicles of different sizes[121].

The most common methods to prepare liposomes[121]—which are not discussed in detail here—are the ultrasonication of lipid suspensions in water, the injection of methanolic or ethereal solutions of lipid into water, the dialysis of surfactant-lipid mixtures and the shaking (by hand) of lipid films on glass surfaces in water.

The polymerizable lipids and lipid analogues *(14)*—*(25)* (Table 2) described in Section 4.2.1. have been transformed into liposomal solutions by ultrasonication of their crystal suspensions[123,154b]. Long chain diacetylenecarboxylic acids and their derivatives could be transformed into liposomes[154b], by analogy to the investigations of *Gebicki* and *Hicks*[155], with unsaturated surfactants. Small and relatively homogeneous vesicles with a single bilayer are formed after long sonication times. On filtration through a Millipore filter, clear or slightly opaque solutions are obtained. The monomeric liposomes are relatively unstable: like vesicles from normal lipids their solutions turn turbid after some days.

### 4.3.2. Polymerization in Liposomal Systems

The clear monomeric vesicle solutions of methacrylic, diene and diacetylene lipids and surfactants can be polymerized by UV-irradiation. In the case of diacetylene lipids, the transition from monomeric to polymeric liposomes can be observed visually and spectroscopically by the color change mentioned above (Fig. 26). As with the monolayer polymerization, deep-colored polymer solutions are obtained[154b].

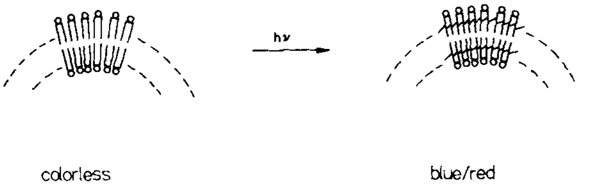

Fig. 26. Polymerization of liposomes of the diacetylene lipid *(21)* (Table 2, cf. Fig. 27). The colorless monomer solution is converted into deep-blue or brilliant red polymer solutions.

The color change from blue to red (Fig. 26) occurs on prolonged irradiation or at high temperatures. The visible spectra of the red form in monolayers and liposomes are identical with regard to the wavelengths, as can be seen in Figure 27.

Electron microscopy can provide direct evidence that the polymers are still liposomal structures. Figure 28 shows a solution of the monomeric vesicle of the ammonium lipid *(21)*[154b].

The structure remains unchanged during polymerization, as can be seen by a comparison with the corresponding polymer solutions. This is consistent with the investigations of *Regen et al.*[128] for the case of the polymethacrylic lipid *(15)*.

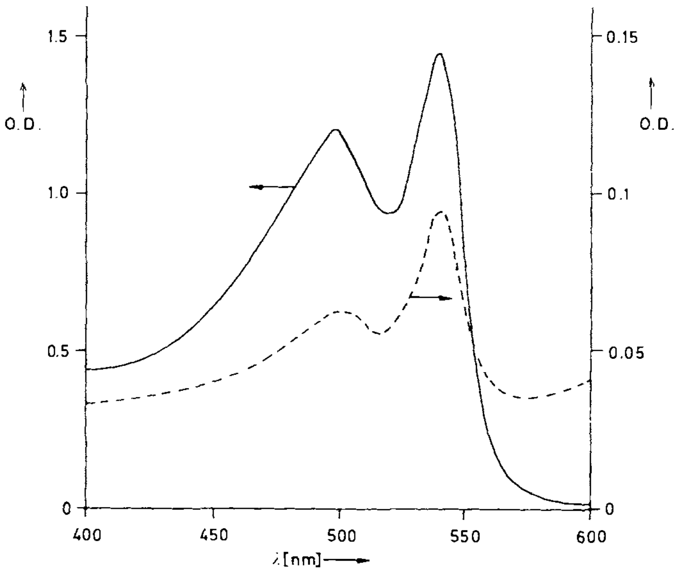

Fig. 27. Visible spectra of the red species of a polymerized monolayer and polymerized liposomes of diacetylene lipid *(21)* [154b]. (----) spectrum of monolayer (cf. Fig. 22); (——) spectrum of liposome solution (cf. Fig. 26); O.D. = optical density.

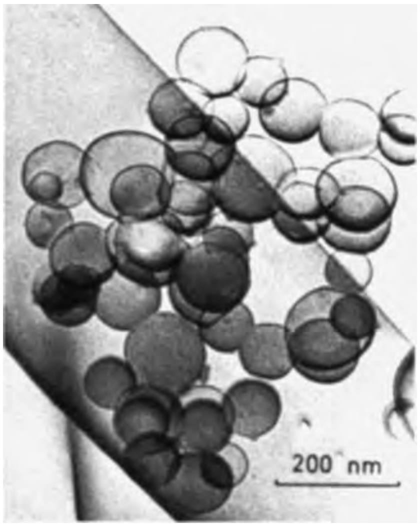

Fig. 28. Electron microscopic picture of small, unilamellar monomer liposomes formed by the diacetylene lipid *(21)* after ultrasonication. Negative stain (uranyl acetate) [154b].

The size distribution of monomeric and polymeric vesicles is essentially the same, as shown for liposomes of the diene lipid *(20)* by GPC measurements[156].

Polymerization of liposomes affects the stability. In contrast to monomeric liposomes, the polymers remain stable for weeks. Entrapped substances are released to a much smaller extent from polymeric liposomes than from monomeric ones. This has been studied in the case of the diene lipid *(20)*: Entrapped 6-carboxyfluorescein (6-CF), in high concentration, exhibits self-quenching; release into the surrounding aqueous medium results in a strong fluorescence due to the dilution[154a]. Below the phase transition temperature, liposomes made from dipalmitoylphosphatidylcholine exhibit an 8% release after 40 hours. Liposomes made of monomeric *(20)* are in the liquid state and release the dye much more rapidly. Polymeric liposomes, however, showed no significant release after 40 hours (Fig. 28a)[156].

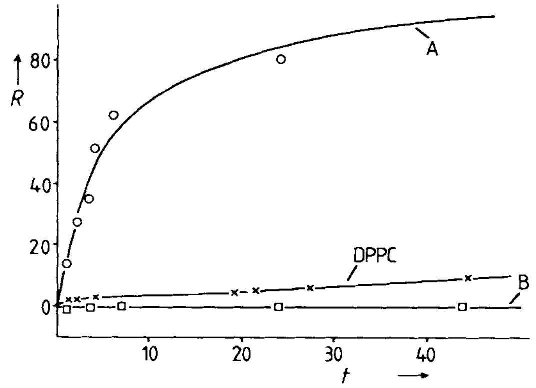

Fig. 28a. Release of entrapped 6-carboxyfluorescein from liposomes of monomeric and polymeric *(20)*. For comparison: DPPC (dipalmitoylphosphatidylcholine). R = % relase: t = time in h

Vesicle solutions can be diluted with ethanol without precipitation[154b]. The solutions of polymeric liposomes of *(21)* and *(14)* are stable in 80% ethanol for weeks. This could also be shown by *Regen* for the case of the polymerized methacrylic lipid *(15)* (Fig. 29)[129].

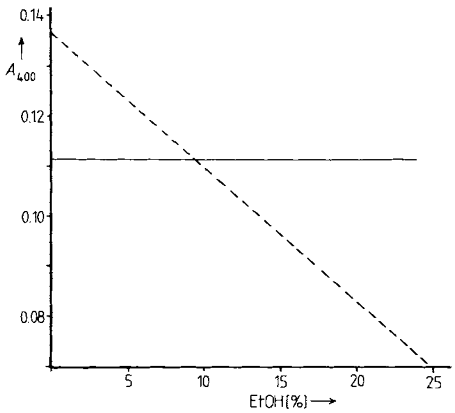

Fig. 29. Comparison of the stability of monomeric (-----) and polymeric (———) liposomes of the methacryloyllipid *(15)* after addition of ethanol [128]; $A_{400}$ = absorption at 400 nm.

A precipitation can be achieved by addition of salts, *e.g.* KCl. Here, too, the polymeric liposomes are not destroyed osmotically. Electron micrographs of the precipitate still show spherical vesicles[154b].

Another indication of the high stability of polymeric liposomes is obtained by scanning electron microscopy (Fig. 30). While monomeric vesicles are destroyed due to the drastic preparation conditions (high vacuum), pictures of polymeric liposomes showing spherical structures can be obtained[154b].

Among the different possibilities for model membrane investigations described in Section 4.1.3., up to now polymerization in monolayers and liposomes have been realized and discussed. Polymerization of surfactants and lipids in a bimolecular lipid membrane (BLM) has not yet been described in the literature. It could be shown, however, that polymerizable surfactants and lipids form BLM's comparable to phospholipids[157]. Mixtures of polymerizable lipids with phospholipids could also be realized. In the case of a methacrylic lipid a polymerization has already been achieved[157].

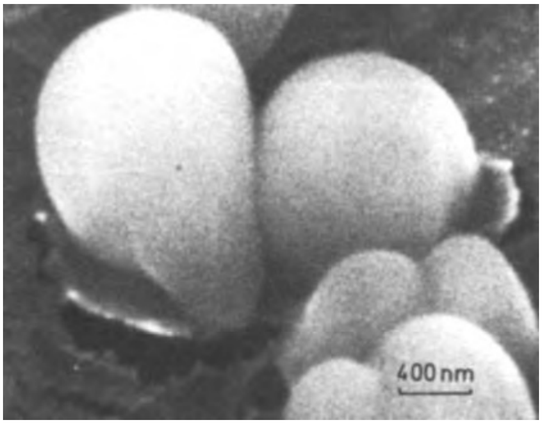

Fig. 30. Scanning electron microscope picture of large multilamellar polymer vesicles from the diacetylenelipid *(21)* [154].

4.3.3. Surface Recognition Experiments with Polymeric Liposomes

In Section 4.1.1. three criteria have been laid down for an hypothetical polymeric antitumor agent on a cellular level. High stability—the most simple condition— has been realized.

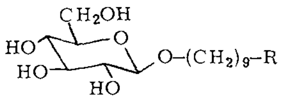
The next problem, namely the specific recognition, has been investigated in the case of low molecular liposomes in numerous experiments.

The structural composition of liposomes already influences the *in vivo* behavior. Size, charge and lipid composition influence the clearing time from biological systems and the ability for the uptake into certain organs[158]. However, a specific targeting cannot be achieved by variation of these parameters.

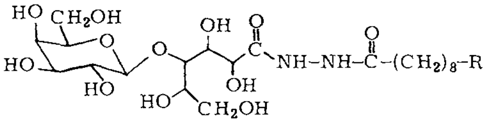
In recent years attempts to achieve a more specific transport of liposomes have been described. *Cohen et al.* coated liposomes with aggregated immunoglobulin[159]. The uptake into phagocytes could be increased by a factor of 60 compared to uncoated liposomes. *Gregoriadis* and *Neerunjun* achieved a "homing" of antibodies with cell cultures[160]. The uptake of liposomes by the corresponding cells showed a 25-fold increase if the liposomes carried the antibodies. Similar attempts had been made using lipid-fixed antibodies[161]. In spite of these encouraging attempts a direct targeting has not yet been achieved. Liposomes are mainly accumulated in liver and spleen and are cleared from the blood too rapidly.

With polymeric liposomes, only simple model reactions have been carried out so far. The interactions of membrane-bound sugars and lectins offered a promising perspective to study the feasability of specific recognition: in the biological membrane, sugar residues located at the outside fulfill many important functions[162]. Some sugar molecules can be recognized and bound specifically by various plant proteins, the so-called lectins[163]. The binding of lectins to glycoproteins and glycolipids incorporated into normal liposomes and the agglutination of the lectin-liposome complex have been intensively investigated[164]. The lectin most widely used is Concanavalin A (Con A), which at pH 7 forms a tetramer and has four binding sites for sugars such as D-mannopyranose and D-glucose[163].

The amphiphilic monomers *(30)* and *(31)* with gluco- and glycopyranose ring, respectively, as head group have been synthesized and investigated in order to achieve a model reaction with Con A[129,165]:



*(30)*



*(31)*

R = $C{\equiv}C{-}C{\equiv}C{-}(CH_2)_{12}{-}CH_3$

*(30)* could be transformed into liposomes by ultrasonication and subsequently polymerized, yielding the typical blue and red solutions. On addition of Con A to monomeric and polymeric liposomes, agglutination and precipitation of the liposomes takes place within a few seconds. This effect did not occur with polymerized vesicles not containing sugars at their surface[129,165].

The incorporation of non-polymerizable glycolipids into polymeric liposomes has been realized, too[129]. These liposomes bearing sugar molecules at the membrane surface are recognized and precipitated by the lectin. It is remarkable that by addition of the corresponding free sugar the lectin-liposome complex can be dissociated and the red precipitate dissolved. This means that the sugar bearing polymeric liposomes are not destroyed during the recognition and precipitation processes. These experiments demonstrate that glycolipids can be specifically recognized even in polymeric liposomes. At present, investigations are being carried out with polymeric liposomes carrying only a small amount of sugar moieties and attempts are under way to incorporate lectins into polymeric vesicles. In this context, the question of the use of mixed systems is interesting, and in the next Section possibilities are discussed for achieving a more biomembrane-like behavior of synthetic polymeric liposomes by using mixtures of natural phospholipids, polymerizable phospholipids, and proteins.

### 4.3.4. On the Way to Cell Models?

Polymeric antitumor agents on a cellular level? The question remains.

We have mentioned three important requirements such systems would have to meet: stability, ability to recognize and to destroy cells. Synthesis of sufficiently *stable* liposomes from amphiphilic monomers has been achieved. An example for a specific *recognition* of these polymeric liposomes could be shown (lectin-sugar interaction). Although one has to admit that it is still a long way to real "targeting", considering the successful incorporation of monoclonal antibodies[166a] into low molecular weight liposomes[166b], one can be hopeful.

As far as the third requirement *(cell-destroying principle)* is concerned, we can only speculate on the basis of biochemical knowledge: one could incorporate lysophospholipid-producing enzymes (*e.g.* phospholipase A) into a stable vesicle which itself resists enzymatic attack; one could also prepare mixed liposomes with high lysophospholipid content, because the polymeric membrane components should not be affected by lysis. Attempts to destroy tumor cells selectively by synthetic alkyl-lysophospholipids have been reported[167]. One more possibility is the transport of polymeric surfactants to a tumor cell membrane, using carrier liposomes which are resistant to polysoaps. The latter example resembles that which is called "humoral immune answer"[168].

In order to acheive release of entrapped material from polymeric liposomes, these stable liposomes must have areas which can be destabilized or "opened"—just like a bottle is uncorked (see Scheme in Figure 31).

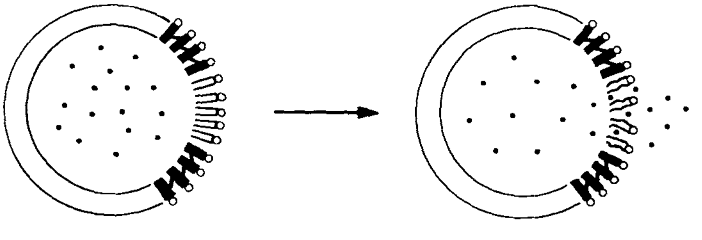


Fig. 31. Destabilization of labile parts in polymerized liposomes (schematic); liposome contents are released (mechanisms of destabilization are explained in the text).

One can think about different mechanisms which allow opening (increase in permeability, uncorking) of stable, polymeric liposomes:

- photochemical membrane destabilization[169]
- pH-dependent opening under acidic conditions[170]
- temperature-dependent opening by exceeding phase transition temperatures (hyperthermia)[171]
- enzymatic procedures

The corresponding investigations on low molecular weight liposomes have been published[169-171].

Thus, the increased stability of polymerized liposomes is only a first, though crucial, step on the way towards the hypothetical antitumor agents on a cellular level.

Apart from the special goals discussed in this report, polymerized vesicles open new applications wherever stable compartments are required. The use of microenvironments[60,172] and microcompartments is one major principle of life. Biomimetic[173] application of the compartment principle meets with ever-increasing interest and has already been successful in a number of cases, *e.g.* solar energy conversion[174,124], synthesis of enzyme models[175] and use of liposomes as drug carriers[29a-c] and in clinical analysis. Not all possible avenues have been explored so far. Compartmentation is a useful principle for microencapsulation[176] and optimization of catalytic processes. *Stabilization* of such compartments (*e.g.* liposomes, micelles) by polymerization may considerably extend the scope of applications. On polymerized liposomes, one can carry out reactions which selectively occur at the outer membrane layer and thus produce different inner and outer membrane structures[126b] without destruction of the liposome. More complex systems are however required in order to move from simple compartments to specifically active vesicles.

Membranes consisting of polymerizable units, areas which can be destabilized, proteins, and recognition units allow the "formation" of liposomes which may be regarded as single cell models.

Model discussions have in general proved to be very useful in modern cell membrane research[177]. Current membrane models—though perhaps oversimplified—are of high potential value for an understanding of important biological processes[178], *e. g.* intercellular communication, cell uptake of extracellular material, and transformation of external impulses into intracellular effects. Figure 32 shows four possible paths to cell models with polymerizable units.

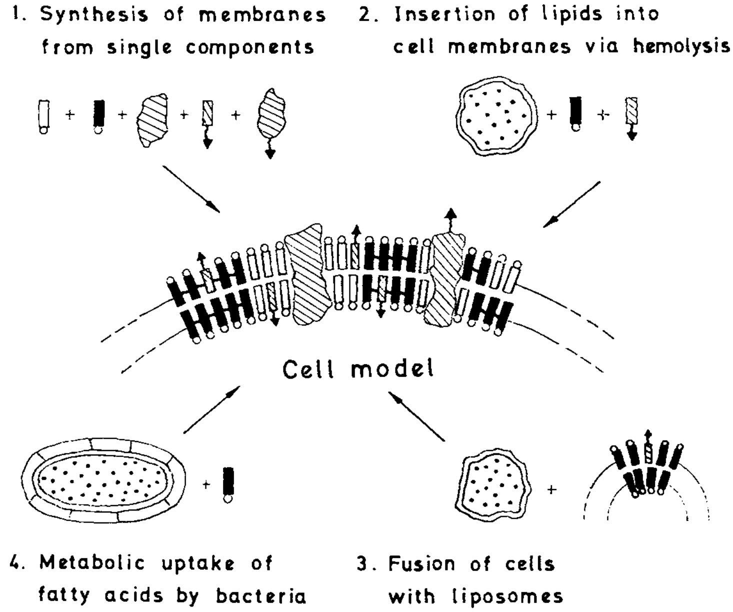

Fig. 32. Schematic representation of few possible ways to build up highly stable cell models by partial polymerization of the cell membrane. a) Natural or synthetic lipids; b) polymerizable lipids; c) proteins; d) protein or lipid bearing a recognition unit.

*First* of all, a mixture of synthetic or natural phospholipids, polymerizable lipids, and proteins can be converted into liposomes (by one of the methods described in Section 4.3.1.) and then be polymerized. First experiments with $F_0F_1$-ATPase (from *Rhodospirillum Rubrum*) show that complex proteins can be incorporated into such liposomes; the activity of the ATPase is retained[179]. Activity depends on time of polymerization, *i. e.* on the amount of polymerized lipid in the membrane. ATPase activity in a monomeric liposome (from compound *(23)*) is lower than in a liposome consisting of natural phospholipids. With increasing polymerization time, however, activity of the enzyme entrapped in liposomes formed by *(23)* increases and reaches the value found for lecithin liposomes. In contrast to the latter ATPase-containing polymer liposomes are more stable over a longer period.

A *second* possibility is the introduction of polymerizable lipids into, *e. g.*, erythrocyte ghost cells by controlled hemolysis and subsequent polymerization (UV). While osmotic hemolysis[153] has several decisive disadvantages, electric hemolysis as described by *Zimmermann et al.* allows the convenient variation of ghost cell membranes. This technique is based on a reversible dielectric breakdown of the cell membrane[106c, 180].

Dielectric breakdown also provides a *third* possible path to the production of cell models: *Zimmermann et al.* could show that under certain conditions cells can be fused with other cells or with liposomes[181]. Thus lipids from artificial liposomes can be incorporated into a cell membrane.

A *fourth* approach has been published by *Chapman et al.*[131]: bacterial cells incorporate polymerizable diacetylene fatty acids into their membrane lipids. The diacetylene units can be UV-polymerized *in vivo*.

The four paths to cell models sketched in Figure 32 may provide useful approaches to stabilized cell models for the investigation and characterization of cell properties and for the simulation of biological interactions.

## 5. Concluding Remarks

In the present paper we have attempted to report on the possible contributions of polymer science to the development of new antitumor agents. We have done so from a polymer chemist's point of view—which is necessarily a limited one.

The aim of our considerations was to point out some solved and unsolved problems and to speculate on possible further solutions. We are aware of the fact that the joint treatment of two entirely different fields (namely the development of polymeric antitumor agents on a molecular level and first attempts to build up stable cell models), may seem rather arbitrary to the reader. Indeed, development of the former has advanced to a point where first successes are seen—together with the corresponding difficulties. One can surely say that this field is a promising one, and needs further intensive research. In the case of cell models and hypothetical antitumor agents on a cellular level, only the very first steps have been undertaken and it remains to be seen whether this concept is a realistic one. Both approaches have one crucial point in common: targeting to tumor cells in the human body is still an unsolved problem: "The development of comparative biochemistry of various tissues and cells has lagged behind the ingenuity of the synthetic chemist, so that although in many cases the gun could be loaded with suitable ammunition, we lack information about the target"[182].

Considering this situation, one might object that it does not make sense to further load the gun before the target is exactly known. The cancer problem, however, is such an urgent one that we cannot give up empirical or rational search for antitumor agents. If this search is done in cooperation with chemists, pharmacologists, immunologists and molecular biologists, it should help in gaining more detailed information about tumor cells. Thus, development of antitumor agents can help to characterize and to treat tumors. The reader may consider that a great deal of the concepts presented here is speculative—he is right. We do feel, however, that this particular area of research merits stimulation and further collaborative investigation.

Macromolecular science can perhaps make modest contributions. In 1978 *C. C. Zubrod*, an expert in chemotherapy, compared minimal success in the chemotherapy of tumors with the triumph of antimicrobial therapy and added: "Remember, however, that with regard to infectious disease, quinine was discovered in the 17th century, and Salvarsan in 1910, and now, in 1978, we still lack curative agents for viral diseases. The only treatment for my grandchildren's chickenpox is watching TV. So the short list of cures of metastatic disease compiled in these 37 years should not be discouraging. I feel optimistic that wider success will follow in years or decades, rather than in centuries, as with chemotherapy of infection"[48].

Thus, neither uncritical optimism nor obstructive pessimism seems justified. As far as our "standpoint" is concerned, we feel that for the present attempt (as for all attempts to describe a field from an "elevated" perspective) the quote from *H. von Saalfeld* (Fig. 33) bears repetition: "You just can't do without the proper perspective these days!"

„Ohne den nötigen Überblick ist es heute einfach nicht mehr zu schaffen!"

*We are grateful to the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 41, Chemie and Physik der Makromoleküle, Mainz/Darmstadt), the Bundesministerium für Forschung und Technologie (Forschungsprogramm Arzneimittelentwicklung und -testung für die Krebstherapie) and the Fonds der Chemischen Industrie for support of our work.*

## Glossary

| | |
|---|---|
| Antibodies: | Proteins of the immunoglobulin type which specifically recognize antigens. They contain an antigen binding site which can bind to certain structural units of the antigen (antigenic determinants). |
| Antimetabolite: | Compound which blocks a metabolic pathway by competing with a normal metabolite (*e.g.* the substrate of an enzyme). Antimetabolites are also used as anticancer drugs (*e.g.* methotrexate). |
| Chronomers: | Bio-degradable polymers which release a drug in a controlled manner. |
| Endocytosis: | Process by which certain cells take up extracellular materials (see Fig. 3). Two types of endocytosis can be discriminated: phagocytosis (uptake of material visible in a normal light microscope) and pinocytosis (uptake of sub-microscopic material). |
| Hemolysis: | Loss of hemoglobin by lysed red blood cells (cell membrane lysis). Controlled hemolysis (induced osmotically or electrically) yields hemoglobin-free "erythrocyte ghosts". |
| Immunogen: | Antigen which induces an immune answer. |
| Immunostimulating: | Stimulating immune response, *e.g.* by stimulation of macrophages or antibody producing B-cells. |
| Immunosuppressive: | Suppressing immune response. |
| Interferons: | Proteins which are active against virus infections. |
| Liposome: | Closed, ball-shaped structure consisting of one or more double layers of lipid molecules with aqueous interior; often called vesicle. |
| Lyotropic phase: | Structure with high degree of orientation formed by amphiphilic molecules and a solvent (especially water) (*e.g.* lamellar or rod-like structures). |
| Monoclonal antibodies: | Chemically homogeneous antibodies which can be prepared by cloning a single antibody-producing cell [166a]. Naturally occurring antibodies specific for a given antigen are heterogeneous. |
| Phase transition temperature: | In membrane systems, temperature at which a solid-analogous state is converted to a liquid-analogous state. |
| Pyrogens: | Substances, which, 1—2 h after injection into higher animals or men, cause fever and shivers. |
| RES (reticulo-endothelial system): | Collective term for cells of different morphology and origin which are capable of endocytosis, mainly occurring in bone marrow, liver, spleen, and lymphatic tissue. |
| Solid tumor: | Tumor which is localized. |
| Trypanosome: | Parasitic protozoon which is transferred to vertebrates by insects. *T. cruzi* is found in South America and causes Chagas' syndrome: lymph node swelling, swelling of spleen, liver and thyroid gland, myocardial defects; chronic or fatal. |
| Vesicle: | See liposome. |

# Cells with Manipulated Functions: New Perspectives for Cell Biology, Medicine, and Technology

**By Ulrich Zimmermann, Peter Scheurich, Günter Pilwat, and Roland Benz**[*]

Exposure to electrical fields can reversibly increase the electrical conductivity and permeability of a cell membrane, which regulates and directs the exchange of materials and information between the cell and its environment. If cell membranes (or artificial lipid membranes) are exposed to a field pulse of high intensity and short duration (ns to μs), local electrical breakdown occurs in them. This electrical breakdown is associated with a large permeability change in the membrane, which is such that substances or particles (up to the size of genes) which cannot normally permeate through the membrane, are able to traverse the membrane into the cell. The original properties of the membrane are restored within μs to min, depending on the experimental conditions and the membrane properties.

Electrical breakdown in the zone of contact between the membranes of cells (or lipid vesicles), which have been made to adhere to each other by the action of weak inhomogeneous alternating electrical fields, leads to fusion of these cells with formation of a single cell having new functional characteristics. The electrical fusion method is very mild, and the yield of fused cells is high.

The electrically induced fusion and entrapment of membrane-impermeable substances and genes in cells provide a new tool for the production of a wide range of cells with manipulated functions, which could be used (or are being used) for the solution of a number of problems in cell biology, medicine and technology.

The application of electrical membrane breakdown to clinical diagnostics, the development of cellular carrier systems for the selective transport of drugs to a site of action within the organism and the potential applications of electrically induced fusion for breeding salt-tolerant crop plants, for converting solar energy into ethanol, for synthesizing natural materials and manipulating genes, are described.

## 1. Introduction

Both the increasing demand for high-grade natural substances and pharmaceuticals for medical and technical applications, and the pressing problems of providing sufficient food and energy for the world population have led to the search for new technologies involving the use of biological systems. This interdisciplinary area of research, which comprises the disciplines of chemistry, physics, biology and medicine, is known as biotechnology. The use of microorganisms in industry for the production of medically and technically useful substances and pharmaceuticals has already proved highly successful, although this area is still at an early stage[1].

During the course of evolution, plant cells developed the ability to photosynthesize, *i. e.* of being capable to convert solar energy into chemical energy with a high degree of efficiency. This energy can, in turn, be converted by other cells and organisms into osmotic, mechanical and electrical work. Technologically, we are still far from being able to convert solar energy on a large scale and with a sufficient degree of efficiency.

Many organisms, such as algae and bacteria, have solved the problem of an optimum existence in a saline environment, *i. e.* they are able to grow and multiply. The ability of crop plants to adapt to saline conditions, coupled with irrigation of the soil with salt or brackish water in the arid zones of the earth (which occupy more than 40% of the land mass) could thus make an important contribution to the solution of the world's food shortage[2].

An alternative approach to the solution of this problem is to breed crop plants that will give high yields even under un-

favorable conditions. Such high-yield varieties require a large amount of nitrogen fertilizer. Quite apart from the environmental problems caused by fertilization, the energy used world-wide for the production of mineral nitrogen fertilizers is, even today, quite considerable. A possible solution would be fixation of nitrogen by biological means, *i. e. via* cells of crop plants which have been manipulated in such a way that they are capable of binding and utilizing atmospheric nitrogen directly like some bacteria[3].

The technological application of biological systems for the amelioration of food and energy shortages, as well as for the production of medically valuable substances in general, thus requires the manipulation and modification of the spectrum of functions at the cellular level. The cell membrane, the plasmalemma, plays a central role in any considerations of this nature. This lipid-protein membrane, which is only 10 nm thick, regulates the exchange of substances between the cell and its environment. Its selectivity, its capacity to act as a filter and valve, as well as the presence of specific carrier systems for certain sugars, amino acids and ions, enables the cell to establish an intracellular environment which differs markedly from that of the external solution. In addition, intracellular compartmentalization with the aid of similarly constructed membranes (mitochondria, chloroplasts, nucleus *etc.*) fulfills the prerequisite of executing an enormous number of biochemical and biophysical reactions in a minimum of space[4,5].

In principle, it is possible to manipulate the spectrum of cellular functions, provided some means can be found of introducing genes or non-toxic substances through the plasma membrane, which is normally impermeable to these substances, without causing irreversible damage. Gene manipulation in microorganisms (procaryotes) has recently proved to be highly successful, although it has not been possible as yet to transfer the bacterial genes responsible for nitrogen fixation to higher plants[*].

Fusion of cells, organelles or cell nuclei with different properties and of different origin, which results in the formation of new cell systems, represents another type of gene manipulation which can be used to produce cells with the desired properties[6,7]. Even though there have been some quite remarkable results in this area using chemical and biological methods, we are certainly far from being able to satisfactorily manipulate cell function, particularly in more highly differentiated organisms (eucaryotes).

In this article a method is presented by means of which genes and substances which cannot normally permeate the membrane, appear in general able to cross the membrane of procaryotes and eucaryotes. In essence, this method entails subjecting the cell membranes, in which electrical fields of high intensity ($10^5$—$10^8$ V/cm) occur naturally, to a short external field pulse of comparable intensity[8]. Under these conditions, the membrane breaks down locally, so that it becomes permeable. This process is reversible, *i. e.* the membrane regenerates its original properties in time intervals which can be experimentally controlled.

The technique of electrical breakdown has been successfully employed for the entrapment of drugs in erythrocytes and lymphocytes[9-12]. Cells which have been modified in this manner can be used as carrier systems for organ- and tissue-specific transport of drugs or as storage systems in the blood stream, without eliciting any significant immunological reactions. With this type of carrier system (see also [12a]) it is possible to achieve an optimum concentration of the drug at the target site, while at the same time avoiding undesirable toxic side effects at other sites within the organism caused by high dosages and repeated administration.

In recent years it has been demonstrated that the technique of electrical breakdown can also be used for gene transfer and gene manipulation in eucaryotes. Furthermore, the fusion of cells by application of an electrical field puts a completely new perspective on the problems discussed above: problems which appear to be of a highly divergent nature[13]. In many areas we are still far removed from practical applications, but this article is designed to point out potential applications of this electrical method in medicine (therapeutics and diagnostics), gene technology, cell biology and plant physiology (crop science), by describing the processes which are induced in biological and artificial membranes in response to electrical fields, and by drawing attention to the current applications of manipulated cells.

## 2. Electrical Breakdown of Membranes

The currently accepted model of the biological membrane is depicted in Figure 1. Phospholipids are arranged in a planar bilayer into which peripheral or integral structural and carrier proteins are embedded in a mosaic-like fashion[4,5,14]. The lateral fluidity of the phospholipids is very high, while movement vertical to the membrane surface is severely limited. A 'flip-flop' movement of the lipids in this direction is therefore highly unlikely.

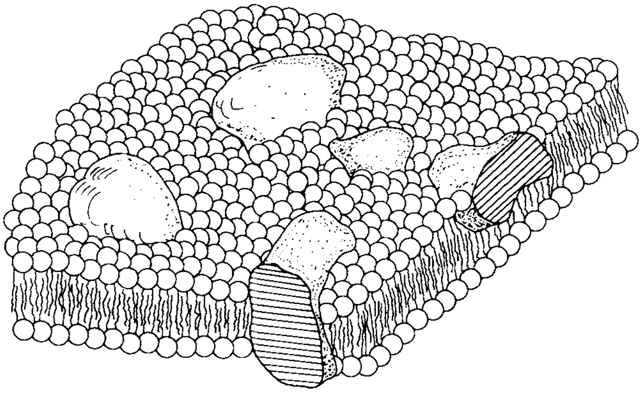

Fig. 1. Currently used model of cell membrane structure. Modified after [14].

In an equivalent electrical circuit, the membrane can be represented by a plate capacitor of specific capacitance $C_m$, and a resistor of specific resistance $R_m$, connected in parallel (Fig. 2). The aqueous external solution and the polar heads of the lipids represent the plates of the capacitor, while the membrane interior forms a dielectric with a relative dielectric constant of 2 to 3. The resistance of the aqueous external solution $R_E$ is in series with the membrane. The specific resistance of the cell membrane is in the order of $10^2$ to $10^4$ $\Omega$

---

[*] For a detailed discussion see Science *209*, 1317-1438 (1980).

$cm^2$, while that of artificial lipid bilayers is three to four orders of magnitude higher[15,16]. The specific capacitances of artificial and biological membranes, on the other hand, are comparable having values of 0.3 to 0.7 $\mu F\ cm^{-2}$ and 1 $\mu F\ cm^{-2}$, respectively[17,18].

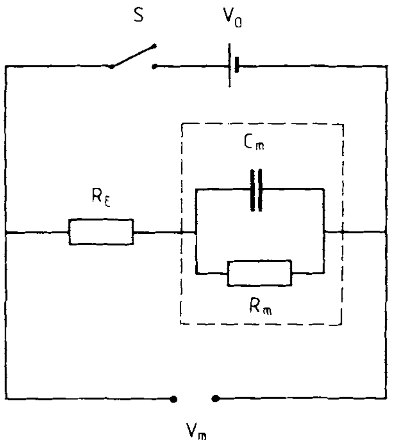

Fig. 2. Diagrammatic representation of the charge pulse technique and a model circuit diagram representing a biological or artificial membrane. The membrane can be regarded as a plate capacitor of specific capacitance, $C_m$, and a resistance connected in parallel (specific resistance, $R_m$). In charge pulse experiments the membrane capacitance, $C_m$, is connected to a voltage source ($V_0$ between 1 and 100 V) for ns to µs *via* a switch, S. After the pulse, the resistance of the outer circuit is increased, so that the charge on the membrane capacitance can only decay by ion transport through the membrane with a time constant of $\tau = R_m \cdot C_m$. The resolution is about 50 ns. See text and [28] for further details.

It is well known that capacitors can only be charged to a certain maximum voltage. Above this critical voltage level, which is dependent on the separation of the plates and on the dielectric, electrical (dielectric) breakdown is observed in the capacitor. Electrical breakdown is associated with an extreme increase in the electrical conductivity of the capacitor which is usually irreversible, *i.e.* the capacitor is destroyed. In "self-regenerating" capacitors, on the other hand, the original resistance and capacitance properties are restored. Under certain experimental conditions, biological membranes and artificial lipid bilayers behave in an analogous way to the electrical breakdown of the self-regenerating capacitors described above[8,19]. A prerequisite for reversible electrical breakdown in cell membranes is that the critical membrane voltage is reached in a matter of ns to µs. Reversible electrical breakdown is observed at membrane voltages ranging between 0.5 and 2.0 V, depending on temperature and charging time[12,20]. The increase in the electrical conductivity of the membrane and the associated increase in the permeability can be quite substantial. Proteins, deoxyribonucleic acids and even latex particles (diameter 0.2 µm) have been shown to permeate the membrane barrier of human red blood cells after field application[21-23]. If the polarization times of the membrane are relatively short, the electrically induced changes in membrane structure and permeability are reversible. The kinetics of the resealing process is a function of the temperature[24]. At high temperatures (37 °C) the resealing processes are completed within a few seconds or minutes, while at lower temperatures (4 °C) the permeability of the membrane remains high for many minutes to hours[12]. The degree of reversibility of the membrane breakdown phenomenon is largely dependent on the duration of the electrical field pulse. As far as biological membranes are concerned, the cells usually undergo irreversible changes if the field is applied for longer than 20 to 100 µs. When supercritical field pulses are applied, *i.e.* pulses whose intensity is 4—6 times higher than the intensity required to reach the breakdown voltage, the membrane and the cellular functions are irreversibly damaged, even after shorter application times[12]. Cells in which the volume of the nucleus occupies about 70 to 80% of the total cell volume (*e.g.* lymphocytes) are particularly sensitive to prolonged electrical field pulses of high intensity. In artificial planar lipid bilayer membranes, an irreversible mechanical destruction of the membrane is observed at pulse durations as short as 10 µs[25,26]. The latter phenomenon, which has been well known for artificial lipid bilayer membranes for more than 20 years, has been termed irreversible mechanical breakdown by *Benz* and *Zimmermann* (cf. [27]) in order to distinguish clearly the electrical and mechanical phenomenon in this pulse length range from that of reversible electrical breakdown.

### 2.1. Artificial Lipid Bilayer Membranes

Over the past two years, electrical charge pulse experiments on artificial lipid bilayer membranes have provided important insights into the processes involved in electrical and mechanical breakdown. These studies, which will be discussed in more detail, have paved the way both to the successful fusion of cells by using field pulses and to the entrapment of substances in cells to which the cell membrane is normally impermeable.

The schematic circuit diagram of the experimental set-up is shown in Figure 2[28]. The membrane is charged to a voltage, $V_m$, at a low resistance in a short time (ns to µs) using an external voltage source of high output voltage $V_0$. After application of the pulse, the outer circuit has a high resistance and the charge on the membrane capacitance (or the induced voltage $V_m$) can only decay by ion movement within the membrane.

From the exponentially decaying voltage it is possible to determine the relaxation time $\tau = R_m \cdot C_m$ of the membrane. Since the specific capacitance of the lipid bilayer membrane can be measured experimentally (see above), it is possible to determine the membrane resistance. The resolution of this charge pulse technique is in the order of 40 to 100 ns, if the planar lipid bilayer membranes are in contact with a 1 M KCl solution on both sides[27,28]. Figure 3 shows a charge pulse experiment on a planar lipid bilayer consisting of oxidized cholesterol/*n*-decane. This membrane was polarized to a voltage of 100 mV (relaxation 1) with a charge pulse of approximately 500 ns duration. Because of the high specific resistance, $10^7$—$10^8\ \Omega\ cm^2$, of the unmodified lipid bilayer, the membrane discharges within seconds. The same membrane was subsequently charged to 400 mV. At this voltage, mechanical breakdown of the membrane is observed, *i.e.* the membrane is irreversibly destroyed. Within about 300—400 µs, the membrane voltage drops to zero because of a widening hole (increasing permeability) (relaxation 2). *Chizmadzhev et al.*[29] have developed a theory for the mechanism of

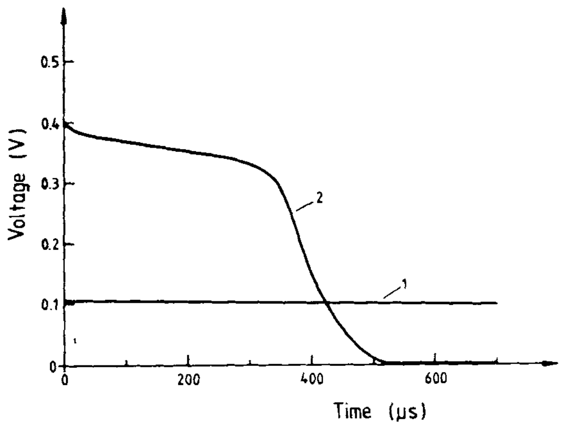

Fig. 3. Mechanical breakdown of artificial planar lipid bilayer membranes consisting of oxidized cholesterol (dissolved in *n*-decane). In the first charge pulse experiment (1) the membrane was charged to a voltage of 100 mV (pulse not shown; pulse duration 500 ns). Because of the long *RC*-time of the membrane the discharging process is very slow (almost parallel to the axis representing time). In the second experiment (2) the membrane was charged to 400 mV with a charge pulse of higher amplitude. After *ca.* 300 to 400 µs, the voltage declines to zero because of an irreversible mechanical breakdown [27]. Experimental conditions: solution 1 M KCl, temperature 17 °C.

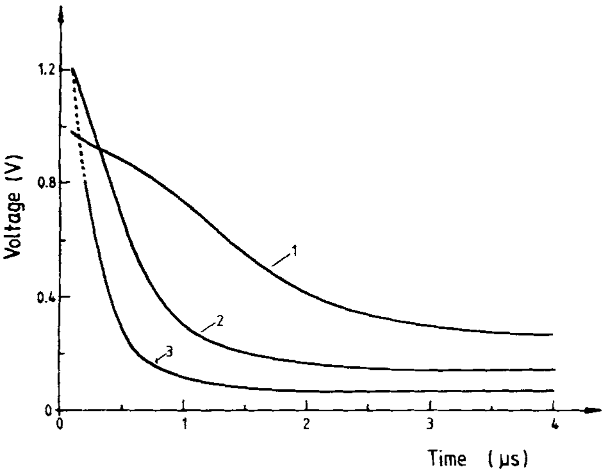

Fig. 4. Electrical (dielectric) breakdown of an artificial planar lipid bilayer membrane of oxidized cholesterol. The membrane was charged to 900 mV and 1.2 V with a charge pulse of high amplitude (pulse duration 500 ns) (experiment 1 and experiment 2, respectively). The rapid relaxation of the voltage after the end of the pulse is attributable to a large increase in the membrane conductance caused by reversible electrical breakdown. The voltage of about 1.2 V cannot be exceeded even if the amplitude of the charge pulse is increased (experiment 3). With supercritical charge pulses, electrical breakdown already occurs during the charging process, so that the initial voltage is apparently lower due to the limited time resolution between pulse application and the voltage measurement. The residual voltage across the membrane which remains after the electrical breakdown experiment, [1—3] is too low to induce mechanical, irreversible breakdown of the membrane. Experimental conditions: solution 1 M KCl, temperature 17 °C.

the mechanical breakdown in lipid bilayers based on pore fluctuation.

Figure 4 illustrates charge pulse experiments on an artificial lipid membrane in which the membrane was charged to substantially higher voltages within 500 ns. In the first experiment (relaxation 1) the membrane was polarized to about 900 mV. The charging process was followed by a very rapid discharge of the membrane, which was attributable to its electrical (dielectric) breakdown. Since electrical breakdown is reversible, the membrane remains mechanically stable, so that it can be recharged. In the second experiment (relaxation 2) the membrane was polarized to a voltage of about 1.2 V. The subsequent relaxation of the membrane voltage is considerably faster than that observed under the conditions of the first experiment. The rapid discharging of the membrane, as a result of electrical breakdown, is attributable to a transient resistance change in the membrane, which may be eight orders of magnitude (from $10^7$—$10^8$ Ω cm$^2$ to 0.1 Ω cm$^2$).

Because of the electrical breakdown of the membrane, the voltage level of about 1 V cannot be exceeded, not even when the amplitude of the charge pulse is raised several fold[25-27]. Rather, the use of supercritical charge pulses results in electrical breakdown during the charging process, so that the initial voltage drops as a result of the high conductivity of the membrane (relaxation 3). By extrapolating the relaxation curve to the end of the charge pulse, it is possible to estimate from this and similar experiments that reversible electrical breakdown occurs within 10 ns. Since breakdown is a very rapid event, longer charging times lead to current flow through the membrane which, in turn, can lead to secondary reactions. This result provides an explanation for the observation (see above) that, with longer pulse applications or higher field intensities, electrical breakdown causes increasingly irreversible changes in the cell and membrane. Studies on artificial lipid bilayers have shown that the currents flowing through the membrane can take on quite substantial values[27].

The electrical breakdown of the membrane can be explained in terms of local electro-mechanical compression. It can be shown theoretically[25-27] that the membrane becomes locally unstable above a certain level of compression and that it then breaks down, possibly resulting in the formation of pores filled with electrolyte. This concept of electrical breakdown in lipid membranes has been supported by extensive studies on cell membranes[19,20,30]. It has been shown that pressure gradients across the membrane or hydrostatic pressure can lead to transient conductivity phenomena equivalent to those observed during electrical field pulse applications[30-32].

The number of pores created during electrical breakdown in lipid bilayer membranes is estimated to be about $10^7$/cm$^2$, and the pore radius is calculated to be 4 nm[33]. During irreversible mechanical breakdown, on the other hand, the bilayer begins to tear from one point.

Compared to lipid protein membranes, the regeneration of lipid bilayer membranes is a very rapid process and is complete within a few µs. The regeneration of lipid bilayer membranes after electrical breakdown was examined in detail using a double-pulse method[33]. A current pulse of low amplitude is applied simultaneously with the pulse which is responsible for eliciting electrical breakdown. By measuring the current and voltage, it is possible to monitor the closure of the electrically induced pores as a function of time (Fig. 5). The reduction of the specific conductivity (reciprocal of the specific resistance) follows an exponential curve (cf. Fig. 6). At room temperature the time constants for the regenerative process are in the order of 2 µs, while at lower temperatures they increase to 10 µs[33].

Under certain assumptions it is possible to calculate the lateral diffusion coefficients of the lipid molecules within the

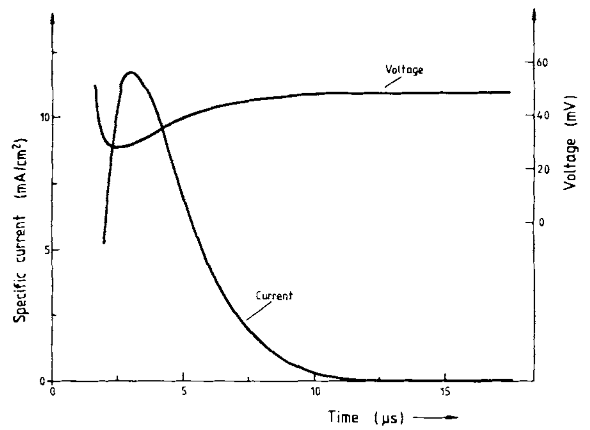

Fig. 5. Kinetics of the resealing process, after electrical breakdown, of an artificial lipid membrane consisting of oxidized cholesterol. Electrical breakdown is induced with a charge pulse of high amplitude and a duration of 500 ns (pulse not shown); a voltage pulse of low amplitude (48 mV) is simultaneously superimposed. The upper trace shows the course of the membrane voltage, the lower one the course of the current through the membrane during the process of regeneration [33]. During the resealing process the voltage increases to 48 mV while the current decreases correspondingly. Experimental conditions: solution 1 M KCl, temperature 20 °C.

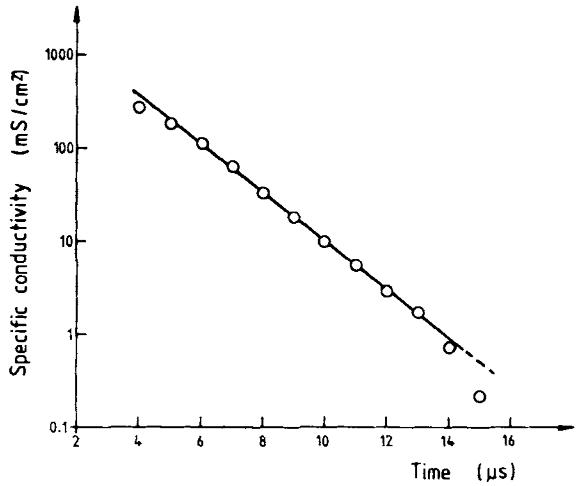

Fig. 6. Semi-logarithmic plot of the membrane conductivity during the resealing process, as a function of time. The corresponding current and voltage values are taken from Figure 5. The time constant of the exponential decline in conductivity with time is about 2 µs; the initial conductivity was about 4 S cm$^{-2}$.

membrane from the decline of the conductivity with time after electrical breakdown. The calculated value ($10^{-8}$ cm$^2$/s) is in the same range as that determined by optical means[33]. The time constants for the resealing processes in artificial lipid bilayer membranes are considerably lower than those normally calculated for cell membranes (s to min, see above)[12]. One can thus conclude that the reversal of field-induced changes in the proteins is much slower. In addition, enzymatic processes seem to play some part in the regeneration of the membrane.

Studies of cross-linked polymeric phospholipid membranes, such as those carried out by *Ringsdorf et al.*[34,35], can be expected to elucidate the mechanism of electrical breakdown and the subsequent resealing processes. The numerous variation possibilities in the production of such artificial membrane systems represent a fascinating future area of research.

## 2.2. Cell Membranes

In cells, which are large enough for the introduction of microelectrodes[2], electrical breakdown can be measured by determining the current-voltage characteristics or by charge pulse techniques, by analogy with the experiments on the planar lipid bilayers. Extensive studies of breakdown have been carried out in large algal cells, in eggs of *Fucus serratus* and, more recently, in the squid giant axon[36-39]. In marine algae, such as *Valonia utricularis* and *Halicystis parvula*, which can reach a cell diameter of up to 1 cm, the breakdown voltage exhibits the same dependence on pulse length[26,38], within a certain range, as in the planar lipid bilayers (Figs. 7 and 8). It is interesting to note that the range in which the breakdown voltage becomes dependent on the pulse length seems to be species-specific, an observation which is of great significance in the search for optimum conditions for electrically induced fusion and for the entrapment of impermeable substances in the cell.

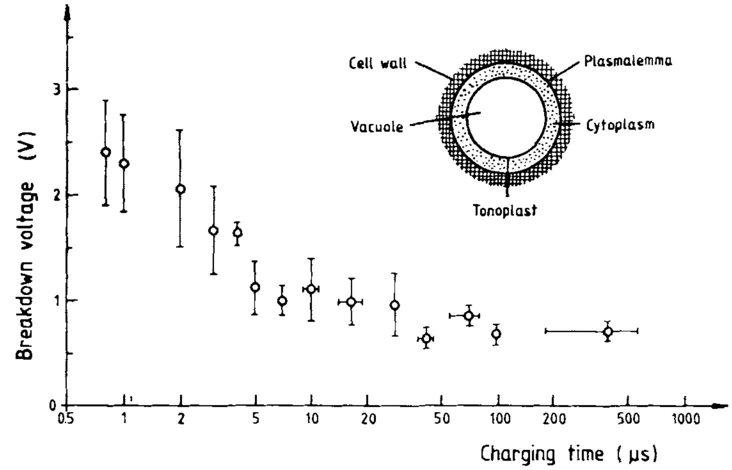

Fig. 7. Dependence of the electrical membrane breakdown voltage, $V_c$, on the charging time, t, for a cell of the giant alga *Valonia utricularis* (mean diameter: 0.5 cm). The electrical breakdown voltage is defined as the voltage which cannot be exceeded for a given charging time (pulse length). It should be noted that the dependence of the breakdown voltage on the pulse length over the range of 0.8—10 µs is different to that of *Halicystis parvula* (Fig. 8a). The inset shows the structure of a plant cell. Taking into account that there are two membranes in series in plant cells (tonoplast and plasmalemma membrane), the values for the electrical breakdown voltages are the same for very short and very long charging times, just as those measured in artificial lipid membranes (Fig. 8b); temperature 18 °C [38].

In plant cells, there are two membranes in series; the tonoplast and the plasmalemma (see Fig. 7). The tonoplast membrane separates the vacuole, a salt-containing compartment, from the cytoplasm, while the plasmalemma membrane protects the cytoplasm from the environment, as it does in animal cells. In addition, plant cells are stabilized by a cell wall which consists of cellulose, hemicellulose and pectin. This means that osmotic processes can set up a high hydrostatic pressure difference between the cell interior and environment under stationary conditions. The hydrostatic pressure difference is termed turgor pressure, and can assume values ranging between 1 and 40 bar[2,30]. If the plausible assumption that both membranes exhibit approximately the same breakdown voltage and *RC*-behavior is made, then the values for the electrical breakdown voltage, determined for very

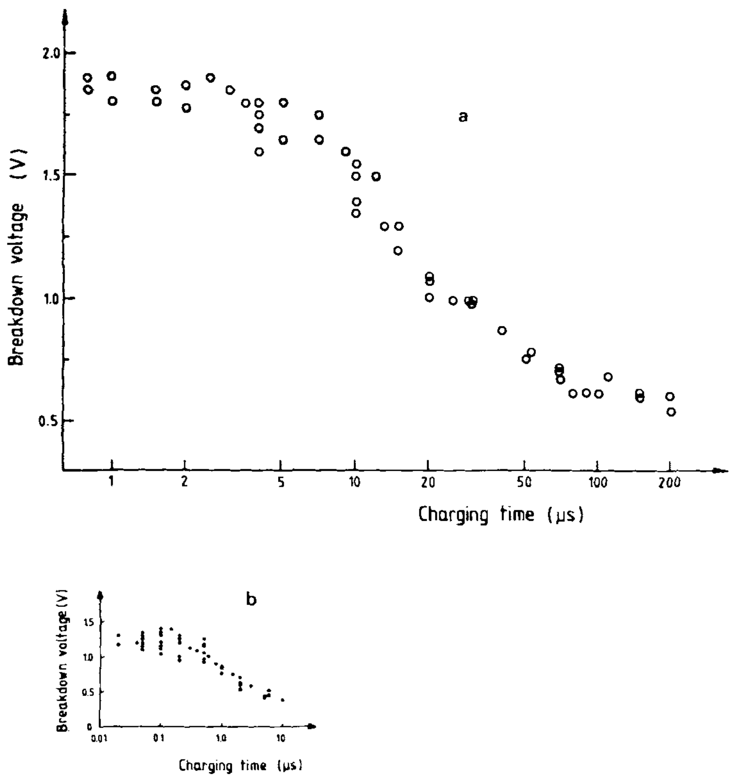

Fig. 8. Dependence of the breakdown voltage of the membrane on the charging time a) for a cell of the giant alga *Halicystis parvula* (mean diameter: 0.5 cm) and b) for artificial planar lipid membranes of oxidized cholesterol. In contrast to artificial lipid membranes and *Valonia utricularis*, the dependence of the breakdown voltage on the pulse duration in *H. parvula* is observed over the range 5 to 100 μs. Temperature 17 °C [25].

short or very long pulse durations, agree very well with those measured in artificial lipid bilayer membranes (Figs. 7 and 8).

For small cells, such as erythrocytes, lymphocytes, bacteria and plant cells (algae) it is necessary to demonstrate that reversible electrical breakdown has occurred by other means, since microelectrodes can no longer be used intracellularly without inflicting irreversible damage to the membrane. In general, the procedure with small cells is to either subject a cell suspension to an electrical field pulse of suitable intensity and duration or to move cells through a locally limited electrical field. Due to an external electrical field the membrane is polarized to a voltage, $V_m$, which is defined by the following equation (calculated for stationary conditions)[40]:

$$V_m = f \cdot a \cdot E \cdot \cos\theta, \qquad (1)$$

where $a$ is the radius of the spherical cell (or the semi-axis parallel to the direction of the field, in the case of elliptical cells) and $E$ is the field intensity. $\theta$ is the angle between the normal to the membrane surface and the field direction, *i.e.* with increasing field strength the breakdown voltage of the membrane is first reached at the poles (that is, in the direction of the field ($\cos 0° = 1$)) before other areas of the membrane break down: f is the shape factor which takes into account any distortions in the field brought about by the geometry of the cell. For spherical cells, $f = 1.5$, and for infinitely long cylinders, $f = 1$[41].

The breakdown of the membranes of suspended cells can be demonstrated, either by studying the exchange of substances across the membrane, or by measuring the resistance change in a particle analyzer, the latter being the more sensitive method.

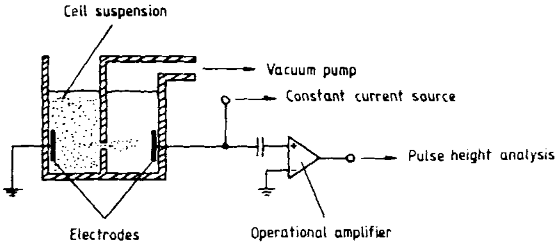

Fig. 9a. Diagrammatic representation of a particle volume analyzer. See text for further details [8].

The principle of the particle analyzer is illustrated in Figure 9a[42]. Two chambers, separated from each other by an electrically insulating wall, are filled with electrolyte. A small orifice in this wall forms a conducting connection between the two chambers, each of which contains an electrode. Because of the high conductivity of the electrolyte solution the voltage between the two electrodes drops almost completely across the measuring orifice. The field intensity in the orifice is thus in the range of $10^3$ to $10^4$ V/cm. The diameter of the orifice depends on the diameter of the cells to be investigated. It is usually 20 μm for bacteria and 40—60 μm for human red blood cells, tumor and other cells. The length of the orifice usually corresponds to the diameter. By creating a pressure difference across the measuring orifice, the cells, which are suspended in the electrolyte solution of one of the chambers, are drawn through the orifice. The nonconducting cells cause an increase in the electrical resistance of the orifice, which can be converted into a current or voltage signal by an operational amplifier.

The electrical field in the orifice is not homogeneous across its entire area. Furthermore, non-spherical cells may pass through the orifice with different orientations. The resistance change induced by a non-conducting particle (*e.g.* a cell surrounded by a membrane with a high electrical resistance) in the orifice, is thus not only dependent on the size of the particle in question but also on its orientation and path through the electrical field. After electrical amplification, the resistance change is analyzed by a pulse height analyzer. By calibrating the instrument with particles of known diameter, it is possible to determine the size distribution of the cells drawn through the orifice. Latex particles are normally used for calibration, since they exhibit a very distinct size distribution and because their diameter is known accurately.

Because of the field inhomogeneity and the random orientation during passage through the orifice, the size distribution of human red blood cells[*] is skewed to the right[43], even though it is known from other experiments (see below) that the distribution of these cells is normal. Particle analyzers of this sort, which are still in general use in clinics, are quite unsuitable for studies of electrical breakdown.

---

[*] Human red blood cells are biconcave and are deformed into ellipsoids because of the hydrodynamic focussing conditions in the orifice [44].

The inhomogeneity and the random orientation of cells passing through the orifice can be avoided if the cells are guided through the centre of the orifice by hydrodynamic focussing (Fig. 9b)[8]. This is achieved using a jet capillary whose diameter corresponds to that of the measuring orifice and whose tip is directed towards the orifice. The distance of the capillary tip from the latter is of the same order as the diameter of the orifice (see Fig. 9b).

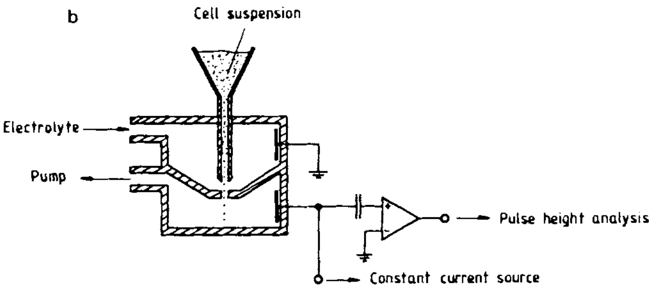

Fig. 9b. Diagrammatic representation of a particle volume analyzer with hydrodynamic focussing of the cells. Because of the focussing, the cells pass through the centre of the measuring orifice with the same orientations, an overestimation of the volume caused by peripheral disturbances (inhomogeneous field), such as occur in the apparatus illustrated in Figure 9a, can be avoided.

The hydrodynamic forces in the capillary tip (Bernoulli principle) force the cells to pass through the inhomogeneous field along the same pathway (*i.e.* along the central axis of the orifice). At the same time, non-spherical cells or cells which have been deformed by hydrodynamic forces are forced to enter the orifice under the same orientation, whereby the longitudinal axis of the particles is parallel to the central axis of the orifice. The cell-free electrolyte, which is drawn through the orifice along with the cell suspension, simultaneously cools the orifice. Under these conditions, the temperature increase in the capillary is less than 1 °C, and hence thermal effects on the cell membranes can be ruled out. The voltage signal induced by the passage of a cell through the orifice is dependent only on the resistance change caused by the cell and is therefore governed by the size of the cell. The volume of the cell can thus be accurately determined, provided that the deformation of the cells caused by the hydrodynamic focussing conditions in the orifice and, in turn, the shape factor have previously been determined by optical means[45].

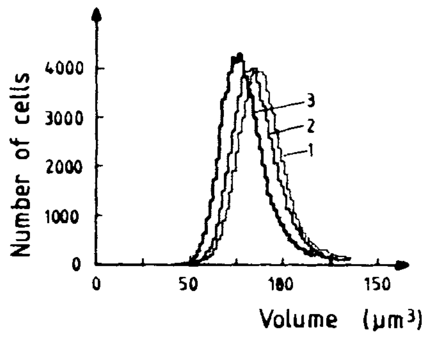

Fig. 9c. Volume distributions of human erythrocytes measured at different field intensities in the measuring arifice. The volume distribution (curve 1) was determined at subcritical field strength (0.6 kV/cm). The distribution is normal and exhibits a mean volume of 83 $\mu m^3$. Curves 2 and 3 show the increasing underestimation with increasing field strength in the orifice (2.5 or 3.5 kV/cm) due to electrical breakdown of the erythrocyte membrane [19].

Figure 9c shows a typical volume distribution for human red blood cells measured using this type of equipment[19]. Measurements were carried out at a field strength of 0.6 kV/cm in the orifice (curve 1). The distribution is normal and yields a mean volume of 83 $\mu m^3$. If the field strength in the orifice is raised (by a corresponding increase in the voltage between the two electrodes) a size distribution is obtained which, up to a certain critical value for the field strength (approximately 2.1 kV/cm), is identical with the distribution measured at low field strengths (provided that conditions of compensation gain were used[21]).

Above the critical field strength, which leads to the electrical breakdown of the cell membrane, the volumes are underestimated, resulting in an apparent shift of the volume distribution towards lower values (curves 2 and 3). The critical field strength at which underestimation occurs can usually only be accurately determined if the size distribution is not skewed at low field strengths (see above). The reason for this apparent underestimation of the volume at field strengths high enough to induce electrical breakdown is that the current (or field) lines partly pass through the cell interior which is considerably more conductive than the intact cell with its electrically insulating membrane. The change of resistance in the cell is correspondingly smaller and the volume of the cell apparently reduced. The underestimation of the cell volume is dependent on the field strength, on the one hand (Fig. 9c), and on the intracellular conductivity on the other. The more conductive the cell interior, the larger the underestimation (for a more detailed analysis see [40]). The intracellular conductivity of a cell is determined by the conductivity of the cytoplasm and the number and size of the compartments (organelles) in the cell. These compartments are also surrounded by an insulating membrane. Because of the smaller dimensions, the membranes of the compartments only break down at substantially higher field strengths [see eq. (1)]. In principle, the field strength can be raised to the level where the organelle membranes will also break down, so that the conductivity in these compartments and their breakdown voltage can be determined separately. Such studies yield information on the biochemical activity of the cell, since this is generally reflected by a change in the cell's conductivity spectrum.

The method described here for measuring the volume, the breakdown voltage and the internal conductivity of cells, has a few disadvantages. The number of cells to be studied must be relatively high ($10^5$ for each distribution), and measurement of the distribution as a function of the field strength is time-consuming and requires considerable effort. Furthermore, the values for the breakdown voltage and the internal conductivity cannot be assigned to the volume of an individual cell. It is therefore impossible, for example, to pick out cells with altered membrane or metabolic properties in the presence of a large number of cells with different properties. This is however, a prerequisite for broad diagnostic use in the laboratory.

In the procedure developed by *Pilwat* and *Zimmermann* (see *e.g.* [46–49]) these disadvantages have been elimated by modifying the experimental set-up (Fig. 9d). In this newly developed particle analyzer, the volume of the cell is measured as it enters the orifice. The cell is then subjected to a linearly increasing field during its passage along the central axis of the orifice. The level of the field strength is such that electrical breakdown of the membrane occurs when the cell is half-way through the orifice (Fig. 9d).

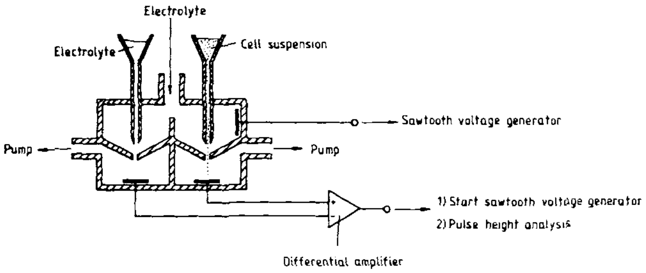

Fig. 9d. Multiparameter particle analyzer for electrical breakdown experiments on individual cells. During its passage through the orifice, every cell is first exposed to a constant field and then to a linearly increasing field. The increase in the field strength is chosen such that the membrane of the cell breaks down electrically about half-way through the orifice. This means that the cell volume, breakdown voltage of the membrane and the conductivity of the cell interior can be determined in one step. The increase in the field intensity in the measuring orifice induces an interference signal which is superimposed on the signal of the cell. The interference signal can be eliminated using a reference orifice in combination with a differential amplifier. See [46—49].

The increase in the field intensity is achieved by applying a saw-tooth voltage (range 10—40 V) to the orifice: the signal of the cell, which is of the order of 10 to 30 mV, is superimposed on the saw-tooth voltage. It is thus necessary to develop a method of registering this small signal. This can be achieved by arranging a second, geometrically almost identical orifice in parallel with the measuring orifice through which the cells are drawn. Cell-free electrolyte is drawn through this reference orifice, but the time-dependent field distribution in the reference orifice is the same as in the measuring orifice. By subtracting the voltage signals from the two orifices, using a differential amplifier, the voltage signal of the particle is obtained and is then amplified and analyzed electrically. Since it is technically not possible to produce orifices with exactly the same dimensions, the electric currents and resulting temperatures (however insignificantly small) are not identical in both. A temperature difference of only 0.01 °C can induce a voltage signal of the same order of magnitude as the voltage signal induced by the cell. This problem can be completely eliminated using the appropriate electric circuitry and experimental conditions (for a more detailed account see [46,47]).

Fig. 10 shows a typical measurement on a Friend cell. Friend cells are mouse erythroblasts which have been transformed by the Friend virus[50]. These cells represent a permanent cell line in which synthesis of hemoglobin can be induced by treatment with dimethyl sulfoxide. The first section of the Figure 10 corresponds to the constant field range where the signal height is proportional to the size of the cell. With increasing field strength the voltage signal of the cell increases linearly (Ohm's law), provided that the resistance of the cell membrane remains constant, and then continues to rise at a slower rate when breakdown of the membrane has occurred. From the ratio of the slope before breakdown to that after breakdown it is possible to calculate the degree of underestimation and, in principle, to determine the conductivity of the cell interior.

The histogram in Figure 11 summarizes more than 500 individual measurements described in Figure 10. The breakdown voltage varies between 0.7 and 1.25 V, with a peak value at 0.8 V. The range of volume of the cells, which was taken from the stationary growth phase, was between 500 and 1500 $\mu m^3$. In the stationary phase, one often observes (as in other permanent cell lines) a second, considerably smaller peak at a higher breakdown voltage, usually 1.1 V (see Fig. 11). The underestimation of the cell volumes after electrical breakdown of the membrane exhibits a distribution similar to that of the breakdown voltage. The main peak, with a breakdown voltage of 0.8 V, is correlated with an underestimation of 45%, while the subsidiary peak is correlated with an underestimation of only 30%.

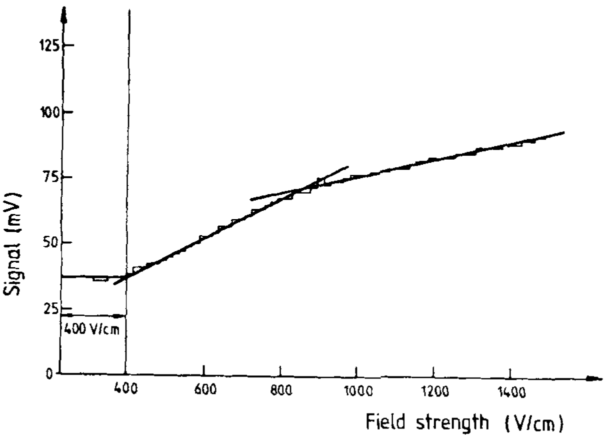

Fig. 10. The voltage signal of a Friend cell in the electrical field of the multi-parameter analyzer shown in Fig. 9d. When the cell enters the measuring orifice the voltage signal is first determined in a constant external field strength range (400 V/cm). In this range the signal of the cell is proportional to the volume and can thus be used for volume determinations. During its continuing passage through the orifice the cell is exposed to a linearly increasing field (see Fig. 9d). According to Ohm's law the signal of the cells thus initially increases linearly, because the membrane resistance and hence the resistance of the cell do not change in this field range. The volume can also be determined from the slope of this increase and used as a control. The membrane breakdown voltage is reached above a field strength of about 850 V/cm. Since the resistance of the cell decreases, the signal of the cell continues to rise at a slower rate after breakdown, with increasing external field intensity, than it did before breakdown of the membrane. From the ratio of the slope before and after breakdown conclusions about the intracellular conductivity of the cell can be drawn [46—49].

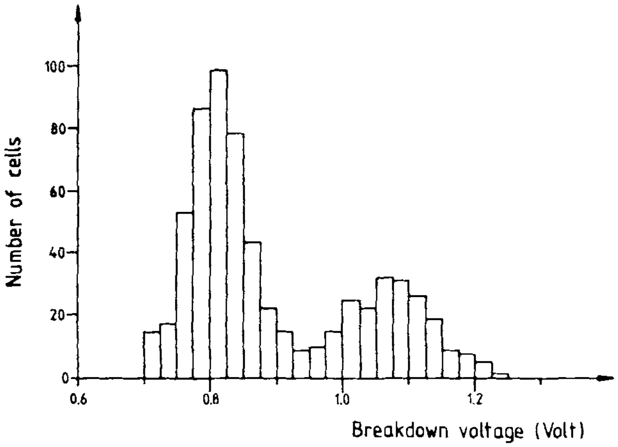

Fig. 11. Distribution of the electrical breakdown voltage in a population of Friend cells. The height of the second smaller maximum can vary considerably according to the culture conditions. The histogram represents 518 individual measurements as shown in Figure 10.

Studies of the sort, illustrated in Figures 10 and 11, provide information on the yield of electrically induced fusion of cells. To achieve an optimum yield in the fusion of cells by means of the electrical breakdown technique (see Section 4), the cells need to have a well-defined distribution for the breakdown voltage and volume. Under these conditions practically all the cells present in the field will fuse. Otherwise, only a proportion of cells exposed to the electrical field will normally fuse, because the membranes are not simultaneously polarized to the electrical breakdown voltage. A homogeneous distribution of the breakdown voltage for the whole population can be achieved by first subjecting the cells, in a discharge chamber, to a field pulse[19,51], the intensity of which is so high that some of the cells (about 20—40%) are irreversibly damaged. Irreversible damage occurs particularly in those cells which either have a low breakdown voltage or a large diameter, so that breakdown voltage is reached at very low field strengths [see equation (1)]. Those cells whose membranes have resealed can be separated by centrifugation. It is also advisable to remove large cells before application of a field pulse. This can be achieved by filtering the cell suspension using a filter of appropriate pore size. The discharge chamber[19,51] also permits the experimental study of solute exchange across the cell membrane induced by electrical breakdown and the entrapment of otherwise membrane-impermeable substances in the cells.

## 3. Electrically Induced Permeability Changes in the Membrane

Figure 12 shows a diagrammatic representation of the discharge chamber. Two electrodes, which are connected to a high-voltage capacitor *via* a high voltage switch, are submerged in a cell suspension. The capacitor is charged to the desired voltage by a high voltage source. The discharging process follows an exponential curve and the duration of the applied field pulse can thus be characterized by the *RC*-time, *i. e.* by the resistance of the solution and by the capacitance of the capacitor. Since the resistance of the solution can usually only be varied within certain small limits, the pulse duration must be varied by changing the capacitance of the capacitor. Pulse durations between 200 ns and 100 μs, which would be adequate for reversible electrical breakdown experiments, can thus be generated in this fashion.

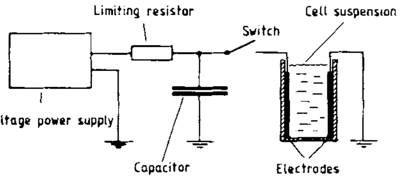

Fig. 12. Experimental set-up for the pulse apparatus and the discharge chamber. The capacitor is charged to the desired voltage by a high voltage source *via* a limiting resistance. By closing the switch the charge on the capacitor is discharged into the cell suspension *via* two platinum electrodes. The discharging of the capacitor follows an exponential course.

Figure 13 shows the results of experiments in which Friend cells (suspended in electrolyte solution buffered with phosphate buffer) were exposed to field pulses of varying intensity and duration at 4 °C. Following the application of the field, the cells were transferred to a nutrient medium and their growth followed at 37 °C. It is evident from Figure 13 that there is no observable influence on the growth of those cells exposed to an electrical field up to a pulse length of 1 μs and field intensity of *ca.* 10 kV/cm. On the other hand, above a pulse duration of 5 μs, or at higher field intensities, irreversible destruction of some cells (see above) and thus a reduced growth rate, or no growth at all occurs.

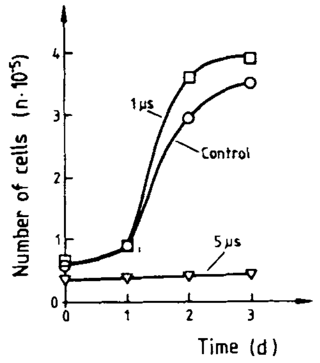

Fig. 13. The growth of Friend cells after pulse application in a discharge chamber (Fig. 12). The field intensity was 10 kV/cm. Up to a pulse length of 1 μs no influence on growth relative to the control is observed, whereas above a pulse length of 5 μs at the given field strength no growth at all occurs. For further details see text (*G. Pilwat, U. Rdest, W. Goebel* and *U. Zimmermann*, unpublished results).

Cells without a nucleus, such as human red blood cells, are considerably less sensitive to high field intensities and long application times. These cells can be exposed to field intensities of 12 kV/cm and pulse durations of 40 μs, without any observable effects on the resealing processes of the membrane at 37 °C[12].

With a pulse duration of 40 μs and a field strength of 2 kV/cm, a reversible $K^+/Na^+$ exchange is observed between the erythrocytes and the medium. This field intensity corresponds to a voltage of 1 V across the erythrocyte membrane, so that it may be concluded that reversible electrical breakdown is associated with an increase in the transport of ions across the membrane. At higher field intensities, incipient hemolysis is observed in the erythrocytes. The rate of hemolysis, *i. e.* the rate at which hemoglobin is lost from the cells, depends not only on the applied field intensity and the pulse duration, but also on the composition of the isotonic external medium. In isotonic electrolyte solutions hemolysis sets in at field intensities of 3—4 kV/cm (pulse duration 40 μs). To a first approximation, the kinetics of hemolysis follow an exponential course (first-order reaction), with a time constant of 1 minute. In isotonic solutions containing increasing concentrations of sucrose, hemolysis is correspondingly slower. At a concentration of 40 mM sucrose, for example, the time constant is about 2—3 h (see Fig. 14). In a theoretical study[51a] based on the phenomenological equations of the thermodynamics of irreversible processes[52], it has been possible to draw conclusions from these experiments about the diameter of the pores generated by the electric field.

These theoretical considerations are based on the assumption that the electrically induced permeability changes in the cell membrane are followed by osmotic processes. In the absence of an electric field there is an inwardly directed stationary concentration gradient for sodium ions across the intact erythrocyte membrane (20 mM intracellular, 85 mM extra-

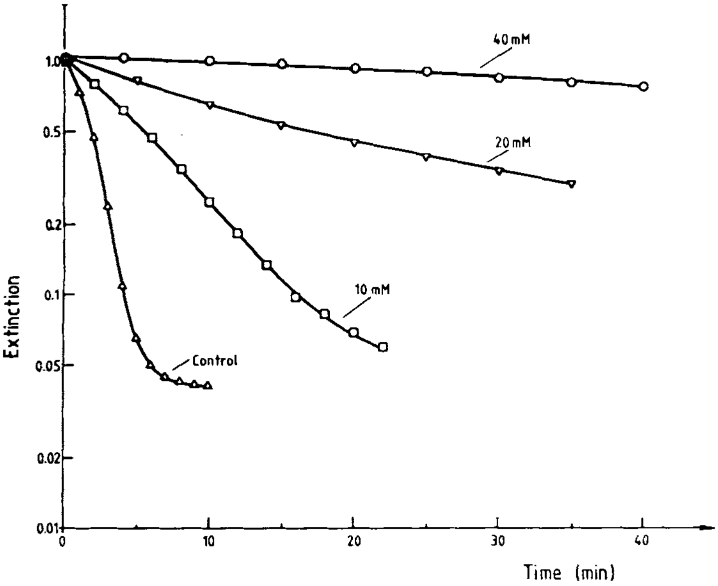

Fig. 14. Hemolysis of human erythrocytes after a field pulse application (field strength 8 kV/cm, pulse length 40 μs) in isotonic solutions containing different amounts of sucrose. After the pulse application in the discharge chamber at 4 °C, the rate of hemolysis was monitored by recording the decrease in intact cells by photometric measurement of the extinction at 700 nm. Hemolysis proceeds according to a first-order reaction and slows down with rising sucrose concentration.

cellular), which is osmotically compensated by an outwardly directed concentration gradient for potassium ions (95 mM or 40 mM respectively). Normally the membrane exhibits a certain permeability towards potassium and sodium ions, *i.e.* a passive transport (corresponding to the difference in the electrochemical potential of the ions concerned) is observed. The passive transport processes are compensated by active (dependent on the metabolism) transport processes in the opposite direction. A Donnan distribution is established for the main anion, the chloride ion, because the membrane is permeable to chloride ions[53]. The intact membrane is impermeable to sucrose. Under stationary conditions, the osmotic balance can thus be described by equations (2a) and (2b):

$$\sigma_{\text{Hb}}\pi_{\text{Hb}} + \sigma_{\text{KCl}}\Delta\pi_{\text{KCl}} + \sigma_{\text{NaCl}}\Delta\pi_{\text{NaCl}} = 0 \tag{2a}$$

for isotonic electrolyte solutions, and

$$\sigma_{\text{Hb}}\pi_{\text{Hb}} + \sigma_{\text{KCl}}\Delta\pi_{\text{KCl}} + \sigma_{\text{NaCl}}\Delta\pi_{\text{NaCl}} + \sigma_{\text{Sa}}\pi_{\text{Sa}} = 0 \tag{2b}$$

for isotonic electrolyte solutions with sucrose

where $\Delta\pi$ is the corresponding osmotic pressure difference for potassium and sodium ions, $\pi_{\text{Hb}}$ and $\pi_{\text{Sa}}$ the osmotic pressure of hemoglobin and sucrose respectively, and $\sigma$ the respective reflection coefficient which gives a measure of the permeability of the substance in question[52]. If $\sigma = 1$, the membrane is impermeable to that particular solute (ion). If the membrane becomes (or is) permeable to a given solute, the reflection coefficient decreases, as does the effective osmotic pressure, $\sigma\pi$, exerted on the membrane by the substance. $\sigma = 0$ means that the membrane has become completely permeable, so that the solute no longer contributes to the osmotic pressure balance[52]. $\sigma$ is a function of the field intensity and the pulse duration[24], *i.e.* a function of the field-induced permeability changes in the membrane. The decrease in $\sigma$ for a given solute with increasing permeability of the membrane is dependent on the size and charge of that particular solute. For monovalent ions (such as potassium and sodium ions) $\sigma$ becomes almost zero, even at electrical field intensities which are just sufficiently high to bring about electrical breakdown of the membrane. In the case of divalent ions (*e.g.* sulfate, hydrogen phosphate *etc.*) and non-electrolytes with a large radius (sucrose, 0.4 nm; inulin, 1.2 nm; and hemoglobin, 3.0 nm molecular radius)[54], considerably larger permeability changes have to be induced for the reflection coefficients to decrease significantly. The permeability of the membrane is markedly raised by electrical breakdown. The selectivity of the membrane, *i.e.* it's ability to discriminate between sodium and potassium ions is lost and the membrane becomes permeable to sucrose. The equilibration of potassium and sodium ions between the cell and the medium (Donnan equilibrium) thus proceeds very rapidly. According to equation (2a) the osmotic pressure of the hemoglobin can thus no longer be compensated for, and the cells hemolyze within a very short time. In the presence of sucrose hemolysis is retarded, because sucrose takes much longer to diffuse into the cell due to its larger molecular diameter and correspondingly higher reflection coefficient: this indicates, according to equation (2b), that the onset of hemolysis is reached considerably later. The amount of hemoglobin per cell is independent of age, while the volume decreases with age. Thus the hemoglobin exerts different osmotic pressures in the cells of the population of erythrocytes[55]. This is why not all cells reach the hemolytic point simultaneously, and hence hemolysis of the population as a whole extends over a longer time interval (see Fig. 14).

In principle, these considerations can be applied to other non-electrolytes or to electrolytes in the external solution.

From the slower rate of hemolysis, which is a function of the molecular diameter of the solute present in the external medium, it is thus possible to draw conclusions about the radius of the electrically induced pores[51a]. The radius of the pores was estimated to be 3 nm under these conditions, which is in excellent agreement with those estimated for artificial lipid membranes (see above).

At low temperatures the field induced permeability of the membrane remains high for prolonged periods of time, so that macromolecules are also able to equilibrate, provided that the appropriate field intensity and pulse length have been applied. If the temperature is raised to 37 °C, the original properties of the erythrocyte membrane are fully restored, including the active transport processes. Above 16 kV/cm (at pulse lengths of 40 μs), on the other hand, irreversible changes in the membrane are increasingly apparent. These may already have been observed at considerably lower field intensities under certain experimental conditions (*e.g.* isotonic sucrose solutions)[56]. As described above, the hemoglobin content of the resulting ghost cells can be varied to match the required experimental purpose. This is achieved by varying the field intensity and pulse length in combination with various compositions of the media[12,20,21,49].

Since the electrical field application is carried out in isotonic solutions, the described procedures can also be used en-trap membrane-impermeable substance into other cells. An example of this shown in Figure 15 for mouse lymphocytes[12]. Eosin, a dye which is irreversibly bound in the cytoplasm and which cannot normally permeate the intact membrane, was used as an indicator for electrically induced uptake across the membrane: it was added to the external solution at 4 °C before the pulse application. The pulse length was reduced to 500 ns, because the volume of the nucleus occupies 70% of the total volume in the lymphocytes, and hence irreversible secondary reactions in the cytoplasm, particularly in the nucleus after breakdown can occur (see above). It is evident from Figure 15 that the number of lymphocytes taking up eosin increases steadily with increasing field intensity. The reaction is reversible and this can be demonstrated by adding eosin at 37 °C just after the end of the resealing process in the membrane. Under these conditions, no uptake of dye is observed in the field-exposed and resealed cells up to field intensities of 16 kV/cm. It was possible to conclude from these experiments that the restoration of the cell membrane properties was complete in all cells within about 3 minutes[12].

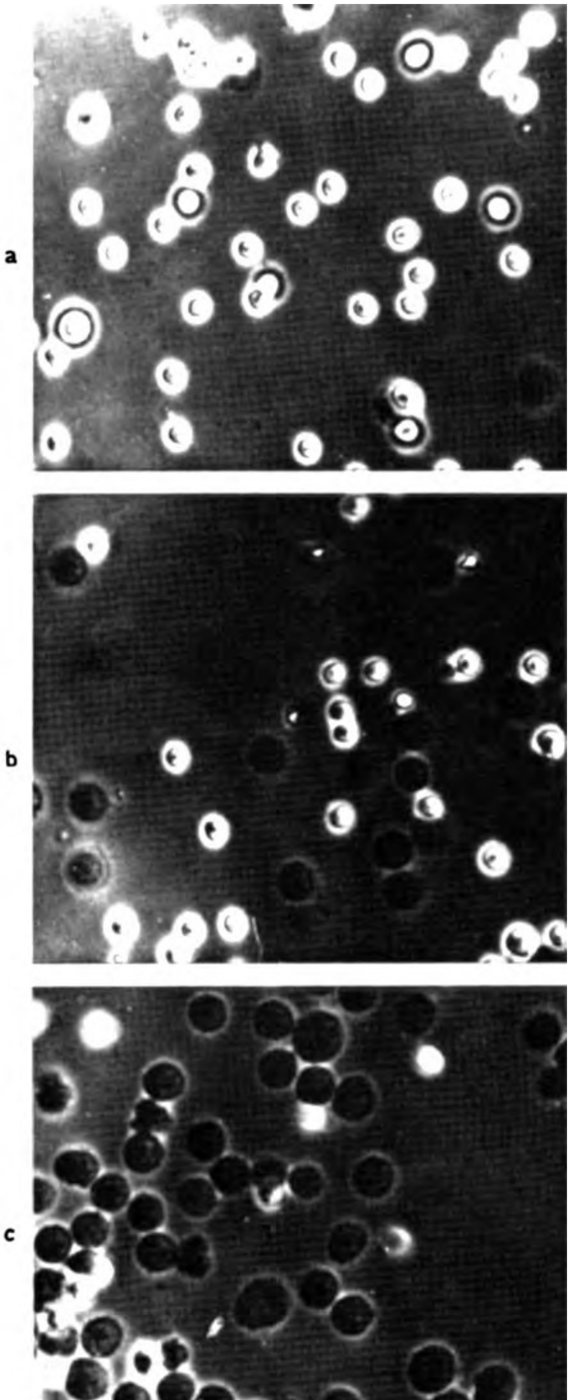

Fig. 15. The entrapment of eosin into mouse lymphocytes after the application of electrical field pulses (a, b or c resp. 6, 12 or 18 kV/cm, pulse duration 0.5 μs) at 4 °C. The dye was added to the isotonic solution before pulse application. The phase contrast pictures show that the number of lymphocytes taking up eosin steadily increases with increasing field strength [12].

## 4. Electrically Induced Fusion

The reversible electrical breakdown of the cell membrane leads to perturbation of the membrane structure, which permits an exchange of materials between the cell and its environment. In this section we shall consider field effects in two cells adhering to each other and orientated in the field direction (Fig. 16). In this case, electrical breakdown occurs at the poles of the cells and in the zone of contact between the two cells. As indicated diagrammatically, both an exchange of substances between the cells and their environment and an *intracellular* mass transport are possible under these conditions. If the membranes are in close enough contact (1—2 nm distance, say), it is also possible for lipid molecules (and possibly also protein molecules) to diffuse from one membrane into the other (Fig. 17). During the resealing process, lipid bridges may thus form between the membranes of the two cells; in other words, the two membranes do not reseal separately in the zone of contact. The bridges formed in this manner and illustrated in Figure 17, lead to very small radii of curvature and, in turn, to high surface tensions. The next step, *i. e.* the fusion of the cells into a sphere, is therefore energetically favored.

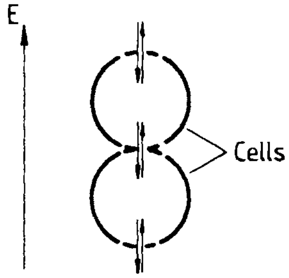

Fig. 16. Diagrammatic representation of electrical breakdown in two cells adhering to each other in the direction of the electrical field. Electrical breakdown occurs in the membrane areas in the zone of contact, which are orientated vertically with respect to the field lines [see arrows and equation (1)]. Under the given conditions electrical breakdown does not only induce exchange of substances between the cells and their medium but also intracellular exchange.

These qualitative considerations demonstrate that, in principle, electrical breakdown of the cell membranes can lead to fusion, provided that the membranes of two cells are in contact with each other and that the two cells are in the correct geometrical orientation. It has recently been observed that if

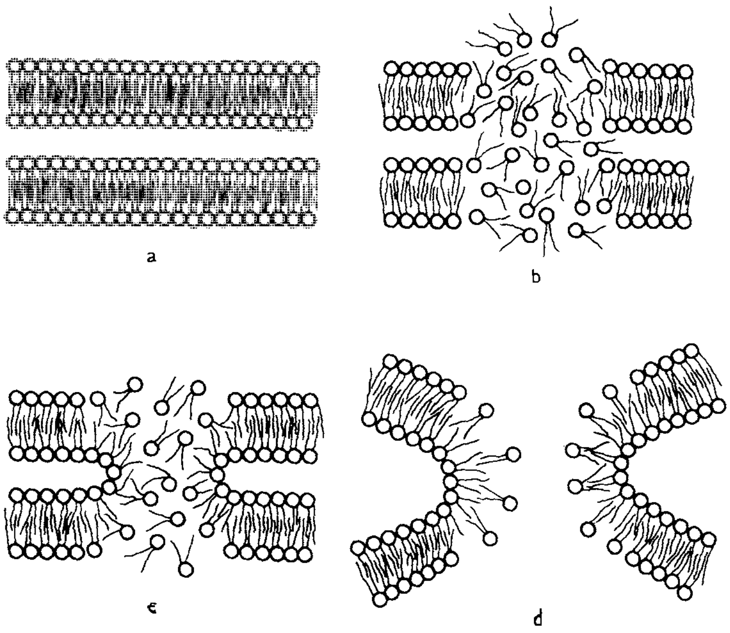

Fig. 17. Model of the molecular processes which are thought to occur during electrically induced fusion. The lipid bilayers of the two membranes are in close contact vertical to the field lines (a), whereby it is assumed that protein-free areas are formed by lateral diffusion of proteins. Electrical breakdown leads to a disruption of the membrane structure (b), so that bridges may be formed between the lipid bilayers of the two membranes during the reorganisation of the lipid molecules (c). The radius of curvature of the pores formed in this way is very small, so that formation of spherical "two-celled aggregates" is energetically favored (d).

an erythrocyte cell suspension of high density is subjected to field pulses by discharging a high voltage capacitor[57], some fused cells are formed. However, the yield was very low, since the necessary formation of two-celled aggregates is normally a rather improbable event. Brownian motion, the negative surface charge of the cell membranes, and the associated repellent forces prevent the necessary contact between membranes. This is also the reason why cells usually exhibit only a weak tendency towards spontaneous fusion under natural conditions. The current fusion methods are thus based on the use of "fusogenic" chemical substances or inactivated viruses having the same properties[6,7,58,59]. Fusogenic chemicals or viruses bring about "agglutination" of the cells and simultaneously disturb the membrane structure so that fusion is induced. However, as a rule, the cell suspensions have to be subjected to unphysiologically high or low pH-values or high calcium concentrations in order to bring about a sufficiently severe disturbance of the membrane[6,7,58,59]. The best-known and most effective fusogenic substance is polyethylene glycol (molecular weight about 6000). This substance has been used with great success for the fusion of protoplasts. For the fusion of mammalian cells, on the other hand, the *Sendai* viruses, which have a strongly agglutinative action, have proved to be particularly effective. The viruses are inactivated by UV irradiation before use, so that their effect is not associated with an infection of the cell[6,7]. Viruses whose fusogenic action depends on their replication in the cell, have not achieved any importance for the *in vitro* fusion of cells.

A number of disadvantages have to be accepted with these classic fusion methods. The unphysiological conditions influence the viability of the fused cells. The fusogenic substances or viruses can also elicit irreversible changes in the membranes, because they interact with the entire membrane surface for prolonged periods of time. Fusion is not synchronous and the yield is usually very low. Furthermore, the fusion methods are not understood mechanistically. They vary from one cell type to another and have to be optimized by trial and error. More recent fusion techniques suffer from similar disadvantages[60,61]. In this case, the cells are made to adhere to each other by chemical or viral means and the disturbance of the membrane necessary for the initiation of fusion is brought about by a field pulse exceeding the breakdown voltage of the membrane. Under these conditions, the yield is slightly higher, as demonstrated by *Berg et al.*[60] and *Neumann et al.*[61]. These studies demonstrate that fusion can be achieved by means of the electrical breakdown of the cell membranes. This conclusion is also supported by the observations of *Senda et al.*[62], who were able to show that two protoplasts held together with microcapillaries will fuse after the application of a field pulse. They, however, used dextran in the solution, which may have properties similar to polyethylene glycol. It is doubtful whether this method will find much practical application since the yield is *a priori* very low.

A generally applicable method with which different types of cells (or lipid vesicles) can be made to fuse with each other or with lipid vesicles has recently been developed by *Zimmermann* and *Scheurich*[13,63-66] (Fig. 18). The electrically induced fusion is based on the exclusive use of physical techniques and, in principle, consists of two stages. In the first stage, the membranes of the cells to be fused are brought into close contact by dielectrophoresis. In the second stage, fusion is induced in the resulting cell aggregates by electrical breakdown.

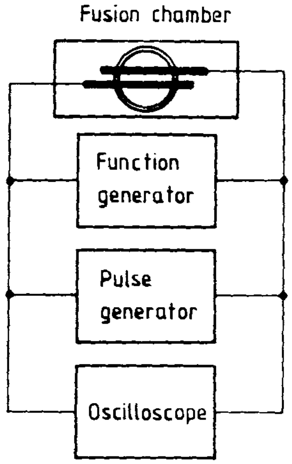

Fig. 18. Diagrammatic representation of the experimental set-up used for electrically induced fusion. Two electrodes, which can be observed under a microscope, are glued to a slide in parallel to each other. The frequency and amplitude of the dielectrophoretic voltage (see text) are controlled by a function generator; a pulse generator is connected in parallel and is used to elicit the breakdown pulse. The applied voltages are recorded on an oscilloscope. For further details see [13].

Dielectrophoresis, which was first applied to living cells by *Pohl* and *Crane*[67,68] has been known for a long time. It is used to render the distribution of the field lines in an electrostatic field visible with *e.g.* the aid of semolina particles suspended in oil. These particles orientate themselves along the field lines due to dielectric polarization.

In principle, the same applies to a cell present in an electrical field (Figs. 18 and 19). In a homogeneous electrical field (Fig. 19a) a force is exerted on the cells because of their net surface charge, and they begin to migrate towards the oppositely charged electrode. This phenomenon is known as electrophoresis. Since the surface charge is usually negative, the cells migrate towards the anode. In addition, a dipole moment is induced in the cells because of charge separation or because of orientation of dipoles in the membrane. However, this does not contribute to the movement of the cells since the field intensity in a homogeneous field acting on the generated dipole is equal on both sides of the cell; in other words, a neutral particle will not migrate in a homogeneous field (Fig. 19b). In an inhomogeneous electrical field, on the other hand, electrophoresis is observed as before, but the neutral particles are also seen to migrate, usually in the direction of greater field intensity (Fig. 19c). The reason for this migration is that the field intensities are different on the two sides of the dipole induced in the cell. The result is a net force which pulls the particle in the direction of greater field intensity. This effect is known as dielectrophoresis[67]. The direction of the net force exerted on a neutral particle in an inhomogeneous field does not change (cf. Fig. 19d) when the direction of the field is reversed by inverting the external voltage. The electrophoretic migration of a cell, on the other hand, which is determined only by its surface charge, proceeds in the opposite direction. In an inhomogeneous alternating electrical field, cells are no longer able to migrate because of their net charge. Instead, the cells oscillate around a certain position in the field and the surface charge is "masked". Only dielectrophoretically induced migration can occur, whereby the cells migrate towards the greater field intensity along the electrical field lines. The force exerted on the cell under dielectrophoretic conditions, is dependent on the square of the field intensity, on the field gradient, the particle volume, the difference between the dielectric constants of the cell and its environment (as well as the corresponding difference between their conductivities). As a rule, these differences are positive, so that cells are observed to migrate to the region of greater field intensity. Under certain conditions, however, the difference between the dielectric constants can become negative, so that negative dielectrophoresis is observed, *i.e.* migration into the region of lower field intensity. The reason for this is that the dielectric constant of a cell (or membrane) is a function of the frequency, since the membrane structure (including the boundary layers in contact with the solutions) is inhomogeneous[67,69]. The boundary layers become polarized, which is reflected macroscopically by a change in the dielectric constant (Maxwell-Wagner dispersion)[69]. At certain frequencies the dielectric constant of the cell may thus become smaller than that of the surrounding solution so that negative dielectrophoresis results. As a rule, positive dielectrophoresis is observed in the frequency range between 1 kHz and 10 MHz (for exceptions see [67]).

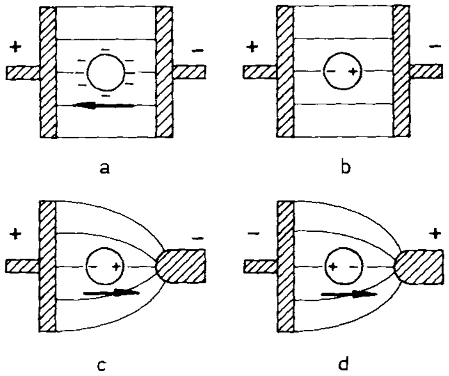

Fig. 19. Diagrammatic representation of electro- and dielectrophoresis. Because of the net charge on the outer surface of the membrane, cells or charged particles migrate in the direction of an electrode (electrophoresis) in a homogeneous electrical field (plate capacitor) (a). The direction of migration depends on the sign of the charge and on the direction of the external voltage. In general, cells have a negative surface charge. In addition, a dipole is induced in a dielectric particle or in a cell (regardless of whether these particles carry a net charge or not) (b). Since the electrical field intensity is equal on both sides of the particle or cell (b), this induced charge does not contribute to movement. Uncharged particles are thus unable to migrate in a homogeneous field. In an inhomogeneous electrical field, on the other hand, uncharged particles are also able to migrate, because the electrical field exerts a net force on the electrically induced dipole (c); the field intensity is not equal on both sides of the particle, resulting in a net force acting on the particle. This effect is known as dielectrophoresis. In contrast to the direction of migration during electrophoresis, the direction of the dielectrophoretic migration of the particles and cells is not reversed when the external electrical voltage between the two electrodes is reversed (d) (see [13, 67]).

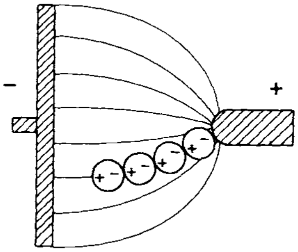

Fig. 20. Diagrammatic representation of the formation of cell chains during dielectrophoresis. The cells adhere to each other and form chains at the electrodes along the electrical field lines, because the dipoles induced in the cells attract each other.

When cells approach each other during their migration along the field lines towards regions of greater field intensity, they attract each other because of their dipole moments (Fig. 20) so that they move towards the electrode in the form of two-, three- or four-celled chains (depending on the suspension density), where they arrange themselves like "strings of pearls" along the field lines.

This configuration remains stable as long as the alternating external field is applied. If the field is removed, the chains break up, since the cells repel each other due to their net charge and Brownian motion. Dielectrophoresis is thus a reversible process (provided that the field intensity is not too high, see below), which allows membranes to come into close contact.

A limiting factor in the dielectrophoretic aggregation of cells is the electrical conductivity of the medium. If this is too high, too much current flows in the solution leading to heat production and associated turbulences which prevent the formation of chains. It is thus necessary to use non-ionic solutions if possible (specific conductivity $<10^{-4}$ S cm$^{-1}$). The osmolarity[*] of the solution must be established by addi-

---

Under light conditions chloroplasts are present, under dark conditions etioplasts, which are the precursors of the chloroplasts.

tion of non-electrolyte. Animal and plant cells have been shown to survive for long periods of time in solutions of mannitol, sucrose, glucose or neutral amino acids without any detectable irreversible deterioration of cell or membrane function[13,63–66].

In cells with high specific densities (*e.g.* mammalian cells with nuclei occupying up to 80% of the cell volume), the density of the external medium must be raised with Percoll, because otherwise the aggregated cells displace each other as a result of gravitational effects during and after the application of the electrical breakdown pulse.

Theory and experiment[13,63–66] have shown that the field intensity for the breakdown of the membranes of the dielectrophoretically aligned cells must be exceeded in order to induce fusion. The duration of the electrical field pulse, which leads to an optimum fusion of cells or cell organelles and lipid vesicles, depends on the properties of the respective biological system to be fused. It is evident from Table 1 that the optimum range for the pulse length is between 15 and 50 μs for plant protoplasts and isolated vacuoles, whereas for mammalian cells (*e.g.* Friend cells and human erythrocytes) the optimum range is between 1 and 4 μs. Outside these given ranges, fusion is observed only in a few cases or not at all. A possible explanation for this observation may be a cell- or membrane-specific dependence of the breakdown voltage on the pulse length (see Figs. 7 and 8). In the optimum range for the pulse length nearly all cells, both plant and animal, which have been exposed to the dielectric breakdown voltage, will fuse. Electrically induced fusion is shown in Figure 21 for mesophyll cell protoplasts of *Avena sativa* (oats), in Figure 22 for a vacuole and a mesophyll protoplast of *Kalanchoe daigremontiana*, in Figure 23 for Friend cells and in Fig-

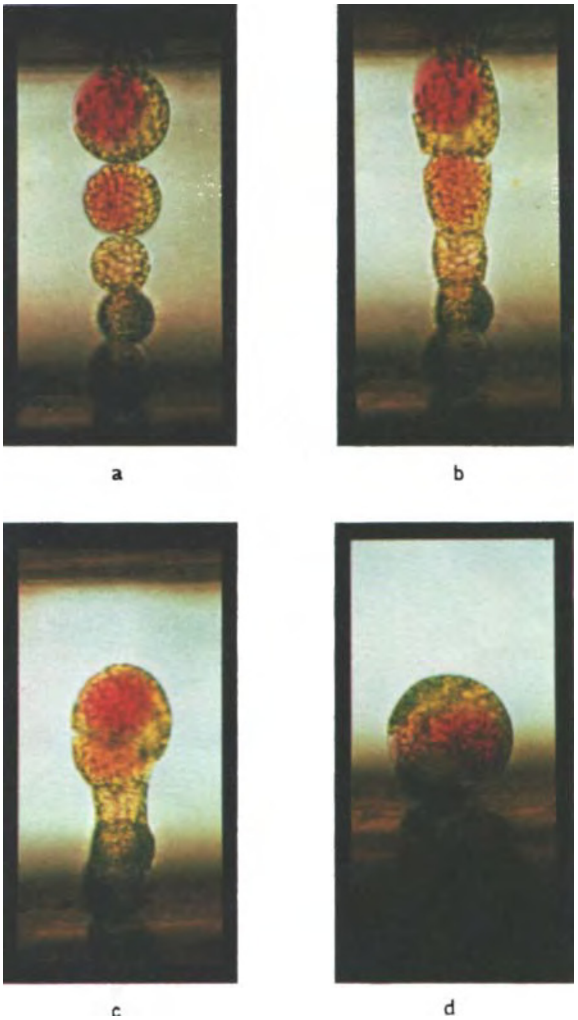

Fig. 21. Electrically induced cell fusion of mesophyll cell protoplasts of *Avena sativa*, some of which have been stained with neutral red, a vital dye which accumulates in the vacuole. The cells were suspended in a 0.5 M mannitol solution and collected by dielectrophoresis at the electrodes of the fusion chamber (a). Fusion was induced by an electrical field pulse of 20 μs duration, the intensity of which was so high that electrical breakdown occurred in the contact zone of the membranes. The photographs show the fusion process 10 s (b), 300 s (c) and 600 s (d) after the breakdown pulse [63]. 1 cm = 50 μm.

ure 24 for human erythrocytes. The relevant experimental conditions are given in Table 1. The time required for fusion following application of the pulse varies from seconds to 60 minutes (Table 1). The reason for this is not known but is probably related to different membrane fluidities in the various cell types and to different properties of the cytoskeleton (fibrillar system) within the cells. A determining factor for the duration of the fusion process is the extent to which the cell wall in plant cell protoplasts and the glycocalix layer on the outer membrane surface of animal cells has been enzymatically removed. The importance of the removal of these layers becomes apparent when erythrocytes, for example, are exposed to a critical alternating electrical field of long duration (a few seconds), after dielectrophoretic alignment[70]. Under these conditions, irreversible membrane fusion is observed with the formation of long tubes (corresponding to the length of the cell chain). Actual cell fusion, *i. e.* the formation of a single spherical cell, does not take place. It is not known whether intracellular transport of materials occurs in these erythrocyte tubes which can reach lengths of up to 200 μm or more and actually form bridges between the two electrodes.

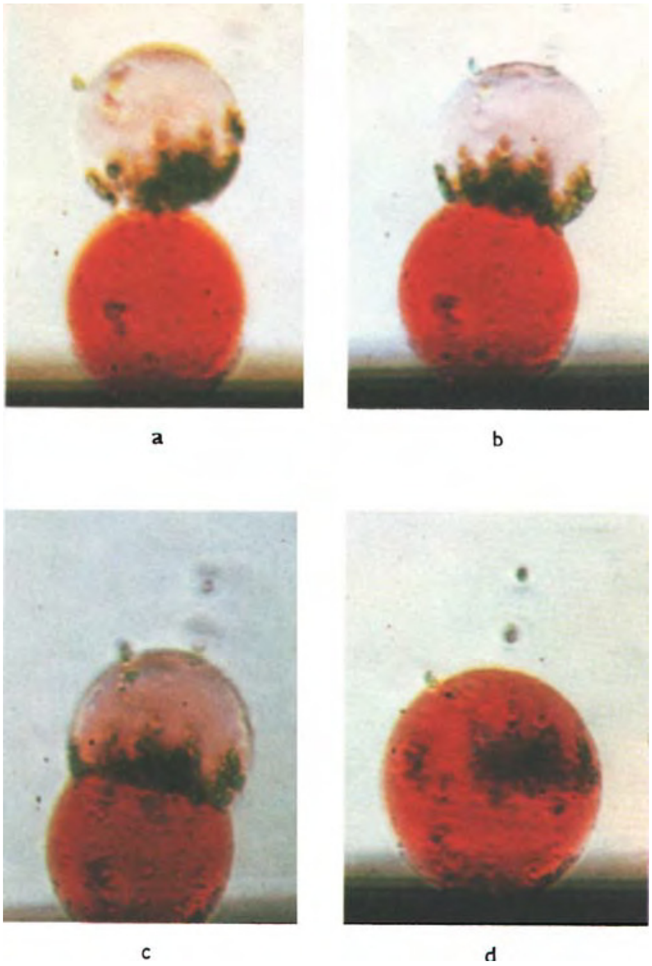

Fig. 22. Electrically induced fusion between a vacuole and a mesophyll cell protoplast of *Kalanchoe daigremontiana* (for conditions see Fig. 21). (a) Before the breakdown pulse, (b) 12 s, (c) 15 s and (d) 30 s after the breakdown pulse. For further details see text and Table 1. 1 cm = 35 μm [65].

For larger cells such as protoplasts and Friend cells it can be shown that the volume of the fused cells corresponds to the sum of the individual cell volumes, independent of the number of fused cells (see Figs. 21a, d and 22a, d). It has been observed that the tonoplast membranes, which surround the vacuoles, also fuse after fusion of the plasmalemma membranes. The fusion of the vacuoles was rendered visible with neutral red, a vital dye which does not lead to any irreversible changes and is exclusively accumulated in the vacuole.

The fusion of human erythrocytes offers particularly fascinating applications if it is carried out under the conditions described in Table 1. At high suspension densities, a large number of cell chains are obtained in which the cells are in very close contact (Fig. 24a). The breakdown pulse leads to the formation of a giant erythrocyte (Fig. 24b) which may have a diameter of up to 200 μm (the normal diameter is 7—8 μm). After fusion is complete, the glucose solution is replaced by an electrolyte solution and the individual giant erythrocytes may be isolated by a special technique using a pressure probe[2,30] and subsequently examined. At first sight, the formation of giant erythrocytes seems to contradict the mod-

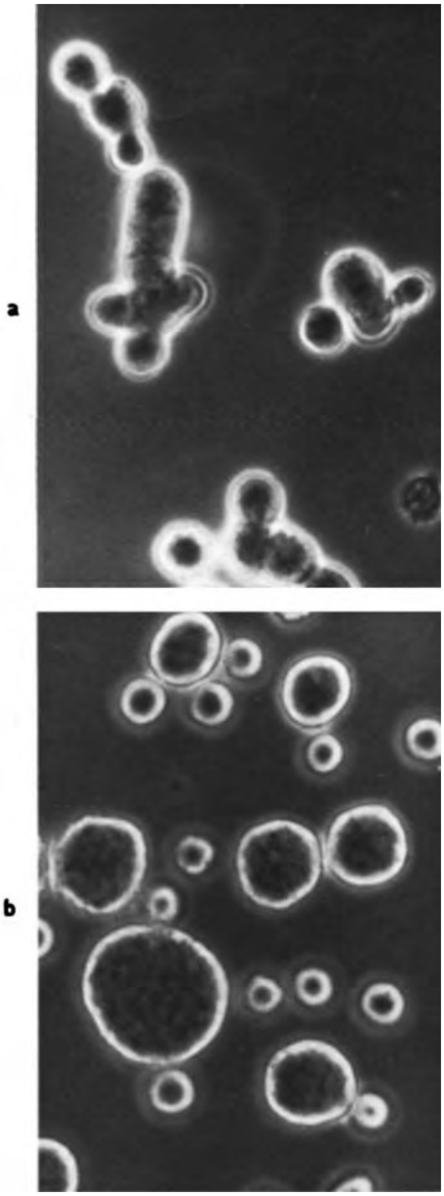

Fig. 23. Phase contrast photographs of electrically fused Friend cells. After brief pretreatment with pronase P (37 °C, 1 mg/cm$^3$, 5 min) designed to remove the glycocalix, the cells were suspended in the fusion chamber in a 0.3 M glucose solution and orientated dielectrophoretically. 1 min after application of the breakdown pulse (duration 2 μs), the cells were removed from the chamber with a specially constructed micropipette. The photograph (a) was taken 2 min after induction of electrical fusion. It also shows, in addition to fused aggregates individual cells which were not exposed to the field pulse (a). When the cells are transferred to a nutrient medium, the fusion aggregates become spherical within 10 min (b). 1 cm = 20 μm.

el developed for electrically induced fusion in Figure 17. According to the theory, breakdown should only occur in the polar regions, *i. e.* in the membrane areas in the zone of contact along the field lines. However, since electrical breakdown is an event lasting only 10 ns, as demonstrated by experiments on artificial lipid membranes, it does not seem improbable that the breakdown voltage is also reached in those membrane areas vertical to the electrodes given that the field lines pass through the cells and that the electrical field is distorted by the high suspension density of the cells.

It is interesting to note that in permanent cell lines, such as the Friend cells shown in Figure 23, the cells become more rapidly spherical after the fusion process when transferred from the glucose solution to a nutrient medium.

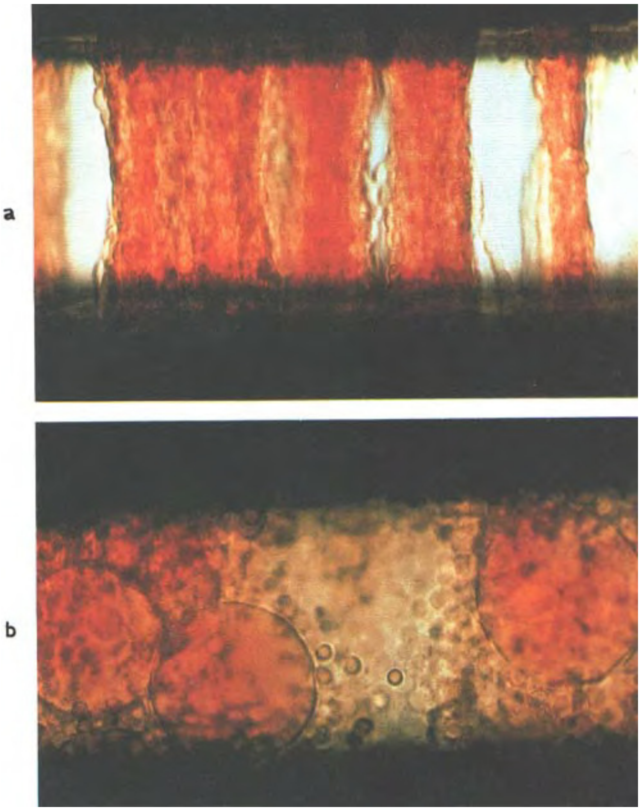

Fig. 24. Electrically induced fusion of human erythrocytes. The glycocalix layer was removed by treating the cells with neuramidase (37 °C, 4 μg/cm$^3$, 10 min). The cells were then suspended in 0.3 M glucose solution and collected dielectrophoretically between the electrodes (a). The suspension density chosen was high, so that many erythrocyte chains with membrane contact were formed in parallel to one another. Application of two breakdown pulses (duration 4 μs) leads to the formation of giant erythrocytes (diameter up to 100 μm) (b). There is no significant hemolysis during formation of giant erythrocytes. Under phase contrast they appear optically homogeneous [66]. 1 cm = 30 μm.

Furthermore, it is worth pointing out that it is also possible to fuse organelles, such as chloroplasts (the site of photosynthesis) and mitochondria (the site of energy production) by electrical means, even though these organelles have two membrane envelopes arranged in series. Artificial lipid vesicles can also be fused by electrical breakdown into giant vesicles with diameters exceeding 100 μm.

Fusion between cells of different types and between lipid vesicles and cells have also been demonstrated (see Table 1), so that one can conclude that electrical fusion is a generally applicable procedure for fusing different types of cells. Apart from the advantage of a high yield, fusion proceeds synchronously because it is triggered by a pulse. In future it should thus be possible to examine the molecular intermediate stages (still unknown), which occur during the process of fusion, by electron microscopy. It is quite conceivable that changes in the field in the membrane may also be important, even when the cells are fused by chemical or viral means.

Since the electrically induced fusion method causes only the minimum of damage (only small membrane zones are influenced for a very short time), the viability of the cells should be satisfactory. It has indeed been possible to demonstrate, for Friend cells, that growth continues after fusion and that hemoglobin synthesis can be induced by adding dimethyl sulfoxide to the suspension of fused cells[50]. There have been extensive studies on plant cell protoplasts of *Petu-*

*nia inflata*, and various authors[3] were able to show that individual mesophyll cell protoplasts of this species exhibit "totipotency": with this plant it is thus possible to observe formation of cell walls and subsequent cell division (and associated differentiation)[3] resulting in the development of a whole plant. Fusion experiments on protoplasts derived from this species are thus particularly tempting, since the viability of the fusion aggregates can be tested relatively quickly. Optimum conditions for the formation of cell walls and cell division can be achieved by immobilizing the fused protoplasts. It was first demonstrated in our laboratory[71-73] that plant protoplasts and animal cells can be immobilized in a cross-linked alginate matrix maintained in the appropriate nutrient medium. The alginate matrix is cross-linked by calcium ions. With the aid of this technique it has been possible to show that electrically fused protoplasts of *P. inflata* are capable of forming both cell walls and dividing. The immobilized cells can be released from the alginate matrix by adding a chelating agent (*e.g.* citrate) and then used for further breeding experiments. With citrate, nearly all the cells can be recovered without damage[71-73]. Experiments on sea urchin eggs (performed in collaboration with *H.-P. Richter*, Max-Planck-Institut für Biophysik, Frankfurt am Main) have revealed that fused eggs can still be fertilized by sperm.

## 5. Potential Applications of Electrical Membrane Breakdown

From the cell biological and medical point of view the breakdown voltage for the membrane can itself be used as a criterion for changes in membrane structure or composition. The variation in breakdown voltage during the growth cycle of a cell population (Fig. 11) indicates that there are changes in the electromechanical properties of the cell membrane during cell growth, which are reflected in changes in the breakdown voltage. *Escherichia coli* cells also exhibit an increase in the average breakdown voltage during the transition from logarithmic to stationary growth phase, as demonstrated in earlier studies with the particle analyzer as shown in Figure 9b[19]. These observations may indicate that specific growth phases can be characterized by the electrical breakdown voltage, a result which is very attractive from the medical and cell biological points of view, because the various stages of growth have until now normally only been identified by staining the cells with fluorescent dyes and by examination with an impulse cytophotometer[74]. Changes in the breakdown voltage as a result of processes of differentiation are also known. *Pilwat et al.*[75] were able to show that the breakdown voltage decreases significantly during the development of *Avena sativa* (oats) chloroplasts from the etioplast stage. The development of chloroplasts is induced within 48 hours by illuminating plants that have been grown in darkness. The decrease in the breakdown voltage as a function of the illumination time was interpreted in terms of an increase in the number of transport proteins incorporated into the membranes of the chloroplasts. The fact that certain local anaesthetics can change the electrical breakdown voltage of erythrocyte membranes may also be of clinical relevance. Increasing concentrations of benzyl alcohol decrease the breakdown voltage by more than 50%[76,77]. However, it should be pointed out that the breakdown voltage of planar artificial lipid membranes is apparently hardly influenced by the addition of various agents. Extensive studies, taking into account the recent finding that the breakdown voltage is dependent on the pulse length, will certainly be necessary to arrive at a more clear-cut statement. Furthermore, it is possible that the breakdown properties of the membranes are more sensitive to chemical changes in artificial lipid vesicles than in planar membranes. The interpretation of electrical breakdown in terms of local electromechanical compression with the formation of pores, indicates that elastic and mechanical forces in the membrane play a role (see above). The small radius of curvature of both lipid vesicles and cells and the tension forces in the membrane could considerably influence the value of the breakdown voltage, if the mechanical and elastic parameters of the membrane were influenced by the addition of certain substances. The development of a particle analyzer capable of making measurements on individual cells (Fig. 9d) will enable detailed studies of this nature to be carried out on phospholipid vesicles of varying chemical composition, different charge and degree of cross-linkage (see also [12a])[34,35,78-80].

In general, the present trend in medical technology is towards the development of multi-parameter analyzers, *i.e.* devices which enable measurements of a number of characteristic membrane and cell parameters in individual cells to be made simultaneously[81-83]. In the procedure described here (Fig. 9d), it is possible to measure the volume, breakdown voltage of the membrane and apparent underestimation of the cell volume after breakdown in individual cells, without any additional manipulation (*e.g.* staining *etc.*). As discussed above, the apparent underestimation of the cell volume is a direct measure of the intracellular conductivity pattern. The underestimation reflects the ratio of non-conducting to conducting space in the cell. This ratio depends, on the one hand, on the size and properties of the intracellular compartments within the cell, and, on the other hand, on the conductivity of the cytoplasm which itself is sensitively regulated by the biochemical activity in the cell. Measurements on human erythrocytes, which had been loaded with non-electrolytes or electrolytes by electrical breakdown in the discharge chamber, have shown that the degree of equilibration between the cell interior and the external solution can be monitored directly in the particle analyzer by measuring the apparent underestimation of the cell[10]. With appropriate calibration it is also possible to estimate the protein content of the cells. Studies of this type, which are of great clinical interest, are particularly simple to perform on human erythrocytes, since they have no nuclei or other intracellular compartments. *Pilwat* and *Zimmermann* (see *e.g.* [48]) were able to corroborate reports in the literature by showing that the hemoglobin content of erythrocytes of various ages, which were separated in a density gradient (Percoll), is independent of volume and hence age. With the aid of the new particle analyzer (Fig. 9d) it should be possible, in the future, to routinely detect early stages of pathological changes in the hemoglobin content of individual cells in an erythrocyte population (caused by anaemia, for example).

Field induced entrapment of membrane-impermeable substances in the cell interior and the associated possibility of manipulating the spectrum of cellular functions, offer a number of interesting prospects from the cell biological point of view. Two possible applications, both of which are at this moment being explored in different laboratories, will be mentioned in order to emphasize this aspect:

Specific reaction sites in carrier systems within the membrane or intermediate stages in biochemical and biophysical reaction chains, which are asymmetrically arranged in the membrane, can be located and identified by the entrapment of appropriate substances with a specific action (*e.g.* inhibitors). Since proteins and enzymes can be reversibly entrapped in cells by electrical breakdown[21], experiments in which the luciferin-luciferase system can be entrapped in cells to determine the ATP turnover in the cell, have become realizable. As a rule, since the turnover of ATP is determined using inhibitors and uncoupling agents, it is not always possible to exclude with any certainty side effects and non-specific interactions with the plasma membrane.

Cells whose functions have been manipulated, offer fascinating possibilities for clinical diagnostics and therapeutics. With a few exceptions, drugs (hormones, antibiotics, enzymes, radionuclides *etc.*) do not act in a cell-, tissue- or organ-specific way. The development of carrier systems which direct drugs to specific target sites and release them in a controlled manner, or which circulate in the blood for long periods of time acting as drug reservoirs, represents a very topical area of research in biomedical technology (see [10,79,84-87]).

So far, all work has concentrated on the development of artificial carrier systems (*e.g.* liposomes, microcapsules, binding to polymers, *etc.*). In spite of encouraging results, we are still far removed from the ultimate goal of clinical application. Compatibility with the organism, immunological reactions, lack of selectivity, and limitations in the life span of the carrier systems used at present are only some of the many problems which have still to be solved satisfactorily[10,79,84-86]. Cellular carrier systems have a number of intrinsic advantages, in particular, the lack of significant immunological reactions.

Experiments on mice, using erythrocytes which had been electrically loaded with a cytostaticum or other clinically relevant substances, confirm the satisfactory properties of the cellular carrier system[9,10,12,49,84]. A high percentage of the erythrocytes, which are loaded under the appropriate field conditions without any significant loss of hemoglobin and other cellular components, will circulate in the bloodstream after intravenous injection[10,88]. The life-span of these manipulated cells is of the same order as that of intact mouse erythrocytes. If, on the other hand, field conditions are chosen such that the hemoglobin content is very low after the resealing process (ghost cells) and the mean cell volume differs from that of the intact cells, the entrapped drug (*e.g.* methotrexate, a cytostatic agent which blocks an important step in the synthesis of purine) is targeted specifically to the liver[9,12,84]. Under these conditions, the manipulated erythrocytes are recognized as foreign bodies by the spleen and liver and degraded accordingly, so that the drug is specifically released in these organs. By the simultaneous field-induced entrapment of a drug and small magnetic particles (diameter about 10 nm) in erythrocytes, it is, in principle, possible to develop cellular carrier systems with other organ-specific properties. By external magnetic guidance, such "magnetic" erythrocytes can be directed to many specific sites within the organism. Experiments with mice have shown[10] that this procedure works in principle and that the magnetic particles can be eliminated by the body without any toxic reactions[10,89].

The fusion of cells by electric breakdown opens up a whole new range of possibilities for the development of drug carrier systems. Ghost cells loaded with a drug can be fused with intact erythrocytes, lymphocytes and other cells of an organism. Since there is apparently no significant loss of intracellular components, carrier systems with a long life span in the body and possibly with completely new organ-specific properties can be developed.

Carrier systems consisting of fused erythrocytes and liposomes could be of particularly interest, since liposomes can be loaded with proteins or DNA (genes) by simple chemical methods[85]. By incorporating liposomes into the erythrocyte membrane it should be possible to modify the membrane properties of the erythrocyte locally, depending on the chemical composition of the liposome membrane, so that the erythrocyte could release the entrapped substance in a controlled manner in space and time. The use of phospholipids, which can be polymerized under UV irradiation after the event of membrane fusion, is another promising tool for the development of an optimum drug carrier system[34,35,90].

Electrically induced fusion in general offers new possibilities for applications in other fields, since contrary to traditional methods it is universally applicable to all cells and artificial lipid vesicles. Both the lack of damage to the cells and the high yield indicate that fused cell systems are highly viable.

Nevertheless, we are still very much at the beginning of this development, but given our present knowledge, we can point out a number of potential applications for this fusion method.

Fusing plant protoplasts of different origins to produce crop plants with new properties such as improved yield or better salt tolerance is quite conceivable. Salt-tolerant mutants of the soya bean are well-known[91]. Several laboratories are thus attempting to fuse protoplasts of this mutant with protoplasts of other crop plants in order to produce a viable cell hybrid which can be used to breed plants having the combined properties of both.

The transfer of the gene responsible for nitrogen fixation from bacteria to plant protoplasts, with the aid of the electrical fusion method, is also coming into the realms of possibility. The fusion of protoplasts from yeast cells with plant cells is another fascinating area which could find technological application. Yeast cells are able to convert sugar into alcohol. By immobilizing yeast cells in cross-linked polymer matrices it is possible to produce alcohol in a continuous process [see [92-95]. Plant protoplasts on the other hand, are able to convert solar energy into sugar (and starch). A hybrid cell with the properties of both cells should thus be capable of converting solar energy directly into alcohol. If it were possible to operate such a cell system on a large scale, the implications for the solution of our current energy problems would be enormous. Undoubtedly the difficulties that would need to be overcome to achieve these goals technologically, are immense. In particular, it would be necessary to examine the compatibility of the cytoplasmic properties, the genetic material and other cellular factors when cells of different origins are fused. Even in the event of failure of the supposed technological applications, studies of this nature should at least provide fresh impetus for cell biology and for research into membrane structure and function, which may well result in the discovery of other applications which are not immediately obvious at present.

*The results reviewed here were partly supported by grants from the Bundesministerium für Forschung und Technologie and from the Deutsche Forschungsgemeinschaft. We are very grateful to Prof. Dr. Göbel, University of Würzburg, for supplying us with Friend cells, and to Mrs. S. Alexowsky for typewriting the manuscript.*

# Half a Century of Polystyrene—A Survey of the Chemistry and Physics of a Pioneering Material

**By Adolf Echte, Franz Haaf, and Jürgen Hambrecht**[*]

*Hermann Staudinger,* the founder of polymer chemistry, would have been 100 years old this year. One of the key materials with which he elucidated the structure of high polymers was polystyrene.—Polystyrene, one of the most important thermoplastics, has now been manufactured industrially for some 50 years. Not only has it simplified our daily lives in a variety of ways, it has also been a model substance for the development and expansion of polymer chemistry and polymer physics, and it was the pioneering material for handling polymer solutions and melts. This article surveys the development and present state of knowledge of the polymerization of styrene and of the relationships between structure and properties.

## 1. Introduction

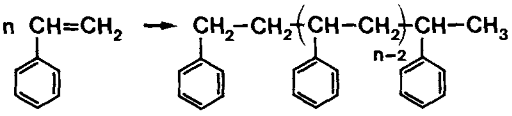
This year *Hermann Staudinger* would have celebrated his 100th birthday. It was *Staudinger* who founded polymer chemistry as a discipline; it was he who elucidated the structure of high molecular weight compounds and began to investigate their properties systematically[1]. For this fundamental work he was awarded the Nobel Prize for Chemistry in 1953.

*Staudinger*'s anniversary almost coincides with another milestone in the history of macromolecular chemistry: polystyrene had its 50th birthday in 1980. The pioneering material of high polymers was first manufactured on an industrial scale in 1930. In the autumn of 1930 I.G. Farbenindustrie AG's Ludwigshafen works—today BASF AG—became the first in the world to manufacture polystyrene industrially. Using this substance, *Staudinger* demonstrated that polymers are made up of fundamental units, the monomers, linked by primary valences.

### 1.1. Scientific Development

Polystyrene was first described by the Berlin pharmacist *E. Simon* in 1839[2]. In 1945, *J. Blyth* and *A. W. Hofmann* recognized that the polymerization of styrene was not accompanied by any change in chemical composition, and they called their glassy reaction product "Metastyrol", *i.e.* "metastyrene"[3]. This was followed by a period in which polystyrene only occasionally featured in the literature, as in a paper by *Berthelot*[4] and, later, *Stobbe* and *Posnjak*[5].

In 1920 *Staudinger* showed in his pioneering publication "Über Polymerisation"[6], that polystyrene is a high molecular weight substance, in which monomer units *(1)* are linked by covalent bonds to form macromolecular chains *(2)*. *Staudinger* also used polystyrene as a model substance in elucidating the radical chain mechanism of polymerization[7], and he resolved the long-standing controversy over the mechanism of formation of high polymers in favor of the radical chain concept, by hydrogenating polystyrene to polyvinylcyclohexane without changing its molecular weight[8]. This disproved[11] the low molecular weight synthesis principle of *Hess*[9] and the micelle theory of *K. H. Meyer*[10].



*(1)* *(2)*

Macromolecular substances require special techniques of investigation, because the methods suitable for low molecular weight substances are frequently inapplicable. As early as 1930, *Staudinger* first put forward a relationship between the viscosity of a polymer solution and the molecular weight of the polymer[12], and this was subsequently refined by *Mark et al.* and *Houwink*[13,14] and put on a theoretical basis by *W. Kuhn*[15]. Styrene also served as the principal compound in elucidating the reaction kinetics of radical chain polymerization. *Chalmers*[16], *Flory*[17], and *Breitenbach*[18] established

relationships between the rate of polymerization and the degree of polymerization, and finally *G. V. Schulz*[19] and *Flory*[20] also succeeded in providing a kinetic explanation of the molecular weight distribution.

In 1934, *Ziegler*[21] discovered that the polymerization of styrene could also be initiated by ions. His investigations on the effect of alkali metal-organic compounds on the polymerization of vinyl monomers followed earlier experiments by *Heumann et al.*[22] and *Schlenk et al.*[23], who in part envisaged a radical mechanism[23]. The first stereospecific polymerization of styrene was achieved by *Natta* in 1955, using Ziegler catalysts[24].

### 1.2. Technological Development

In 1911, *F. E. Matthews*[25] first described polystyrene as a construction material. However, it took until 1930 to develop the basic technology required for the industrial manufacture of polystyrene. After an unsuccessful attempt in the USA at the end of the 1920's, BASF set up a continuous manufacturing process, which also included manufacture of the monomer[26,27], and which, to this day, has remained the fundamental process in polystyrene manufacture.

The first polystyrene (PS) was a crystal-clear brittle material: crystal polystyrene[28]. 1934 saw the first attempt to produce polystyrene foam[29], but only in 1950 did this become an industrial reality[30]. The first copolymer (SAN) of styrene and acrylonitrile was produced industrially in 1936[31]. This was soon followed by the first rubber-modified polystyrene[32], which however only made a vital break-through in 1950 as a result of the development of a process for the continuous mass polymerization of styrene in the presence of rubber[33]. Styrene-butadiene (SBR) copolymer was first used as rubber component but this has now generally been replaced by polybutadiene.

It was a stroke of luck, and an essential factor in polystyrene development, that at the same time as the manufacturing process, a molding method was also developed to an industrially usable stage of perfection. This was injection molding, a joint achievement by Dynamit Nobel AG and IG Farbenindustrie AG, Ludwigshafen, again dating back to 1930[34]. This method first ensured the successful sales of polystyrene.

### 1.3. Commercial Development

After a modest start, polystyrene developed rapidly. In 1930, monthly production was only 6 tonnes; in 1936 the rate had risen to 500 tonnes per annum. Industrial production of polystyrene began in the USA in 1938[35] and Great Britain followed soon after. In 1939, polystyrene production was in excess of 6000 tonnes per annum[36]. The second world war interrupted this development, since styrene was needed for the manufacture of synthetic rubber. For this purpose, styrene monomer production capacity was greatly increased—in 1945, the USA alone had a styrene capacity of 270000 tonnes per annum—and this in turn stimulated rapid development of polystyrene in the post-war years. In 1950, the annual production of polystyrene had already reached 270000 tonnes. With the change in basic raw material in the 1950's—petroleum replacing coal—a substantial reduction in the price of styrene and hence also of polystyrene became possible. New fields of use were developed; in 1970, more than 2.1 million tonnes of polystyrene were used, and in 1980 the figure exceeded six million tonnes.

## 2. Synthesis

### 2.1. Polymerization Mechanisms

Polystyrene is one of the few polymers which can be produced by free radical, cationic, anionic, and coordinative polymerization. This behavior is due, not only to the extraordinary resonance stabilization of the reactive polystyryl species in the transition state, which lowers the activation barrier for the propagation reaction, but also to the low polarity of the styrene molecule, which facilitates attack by radicals and metal complexes and the addition of differently charged ions. Furthermore, side reactions similar to those occurring in the ionic polymerization of monomers with functional groups are excluded.

In industry, the free radical polymerization of styrene predominates by far[28]. Anionic polymerization is only employed for the production of block copolymers[37], whilst cationic and coordinative polymerization are not used on an industrial scale.

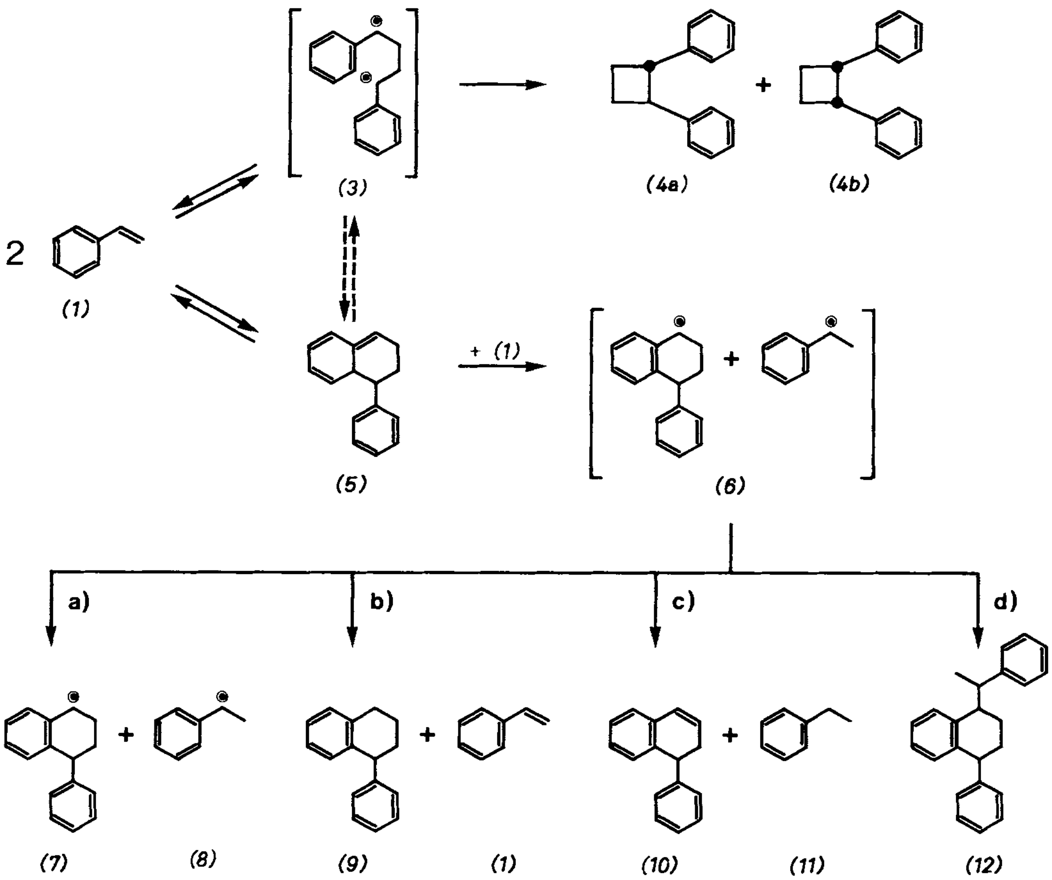
#### 2.1.1. Free Radical Polymerization

The *free radical* polymerization of polystyrene is one of the most extensively investigated reactions in polymer chemistry. It is started by free radicals (initiation), to which numerous monomer molecules then add successively (propagation). This produces a polymer radical which grows progressively until the process of growth is terminated. The polystyrene radical can also abstract a proton from a neutral molecule and thereby become saturated; this however produces a new radical, which in turn starts a new polymer chain (transfer). Finally, the polymer radical can react with another radical, by recombination or disproportionation, so that the existence of both radicals ceases (termination).

In styrene, the reaction chain can be initiated thermally or by addition of free radical initiators (peroxides or azo compounds). The mechanism of free radical-initiated polymerization was elucidated a number of years ago (see [38-41]). The mechanism of the initiation reaction in thermal polymerization of styrene is less well established (Scheme 1).

It is assumed that the Diels-Alder adduct *(5)*[42,43] eliminates the angular H atom and forms, with a further styrene molecule, a solvent cage *(6)* of two radicals[44]. These become stabilized either by recombination (route d) or disproportionation (routes b and c). The diffusion of the radicals from the cage (route a), which leads to initiation of the polymerization, is in fact only a side-reaction of oligomerization[17,45,46]. The extent to which the diradical *(3)*[47] participates in the initiation mechanism is unclear[48,49]. An analogous process has been proposed for the initiation of styrene-acrylonitrile copolymerization[50].

Chain termination was for many years thought to occur exclusively by recombination[51-53]. Investigations by *Olaj*[54] and by *Berger* and *Meyerhoff*[55,56] later indicated a contribution of disproportionation of 10—40%, which increases with



Scheme 1. a—d see text.

temperature. Studies on model radicals confirm these results[57,58].

Up to high conversions, the rate of polymerization can be satisfactorily represented as a 1st-order reaction[59]. Where more accuracy is required, the rate can be calculated from models given by *Hamielec et al.*[60,61] and *Bengough et al.*[49]. Though these models start from different initiation steps, they permit satisfactory predictions of the molecular weight and the polymolecularity index (Fig. 1).

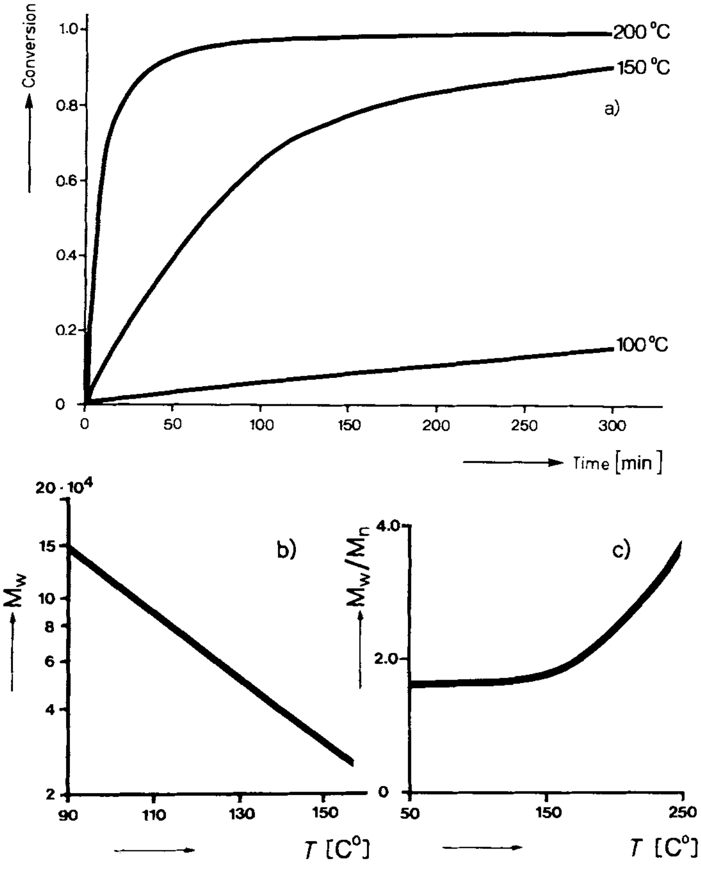


Fig. 1. a) Time-conversion curve for styrene polymerization at different temperatures [61]; b) dependence of molecular weight on polymerization temperature [28d] and c) polymolecularity index $M_w/M_n$ as a function of polymerization temperature [49].

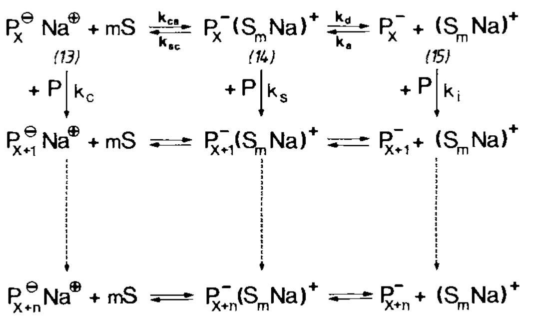
### 2.1.2. Ionic Polymerization

The mechanism and kinetics of the *cationic* polymerization of styrene are inadequately known; the extremely rapid reaction makes a thorough investigation difficult (for our present state of knowledge see [62,63]). Hitherto, the cationic polymerization of styrene has not been utilized industrially, since the process can only be operated in a controlled manner under exotic conditions. The simultaneous use of Friedel-Crafts catalysts for the polymerization and for electrophilic substitution at the aromatic ring provides a starting point[64,65].

In contrast to the cationic polymerization, the *anionic* polymerization of styrene has been investigated comprehensively. The kinetics and reaction mechanism have been substantially clarified. Intermediate situations between a multi-route mechanism and a single-route mechanism are obtained, depending on the polarity of the solvent employed[66]. The multi-route mechanism of the extremely rapid polymerization in polar media has been elucidated, in particular, by the schools of *M. Szwarc*[67] and of *G. V. Schulz*[68] (see Scheme 2).



Scheme 2. $P_x$ = polymer, P = monomer, S = solvent.

Three forms of active carbanionic groups, namely the contact ion pair *(13)*, the solvate-separated ion pair *(14)*, and the free ions *(15)* are involved in the polymerization, thus explaining the great influence of solvent and of the temperature (Fig. 2[68]). The rate constants of the propagation reaction differ substantially and decrease in the sequence $k_i > k_s > k_c$[69,70].
